Behçet's disease that has manifestations other than mucocutaneous involvement may be treated with systemic corticosteroids, although such treatment may not control severe ocular, neurological or non-vasculitic vascular disease [10–14]. Immunosuppressive agents such as azathioprine, methotrexate or ciclosporin may be used in the treatment of patients with severe Behçet's disease [10,15]. There is a potential concern that ciclosporin can cause neurotoxicity that appears very similar to neuro-Behçet's disease (some feel that it actually provokes neuro-Behçet's disease), so, although useful for treating uveitis, a degree of caution is warranted. Cytokines such as interferon-α are useful (alone or with azathioprine) [5,16], and thalidomide can be effective [1,17] but requires careful monitoring for neurological toxicity. Anecdotal reports suggest use of intravenous immunoglobulin (IVIG) with aspirin, and granulocyte and monocyte adsorption apheresis.

Increasingly, anti-TNF agents such as infliximab or etanercept have been documented to be effective [5,16], especially for uveitis or for severe oral aphthae (although dapsone is a more effective inhibitor of the pathergic response than is etanercept). Novel treatments under investigation for Behçet's disease include induction of tolerance using oral administration of the 336–351 sequence of HSP60 linked to recombinant cholera B-toxin B-subunit [16]. Surgical treatments for large-vessel disease are outside the remit of dermatologists but are summarized in [18].

There is an increasing case for early and aggressive treatment of Behçet's disease, especially in those with, or at risk of, severe symptoms. The highest risk of serious ocular, pulmonary artery or neurological involvement is in males, especially those with disease onset below age 40 years [19]. In general, the risk of complications gradually decreases with increasing age.

Neutrophilic dermatoses

Introduction

The spectrum of disorders currently considered as 'neutrophilic dermatoses' has widened hugely over the last two decades [1–6]. The common features in most of these entities can be summarized as follows:

1 the histological features are dominated by a neutrophilic vascular reaction that typically (although variably) falls short of vasculitis
2 within any diagnostic entity a significant proportion of cases can be demonstrated to have a reactive cause or systemic association (mainly haematological or gastrointestinal diseases, or drug-induced aetiology)
3 many of these disorders may coexist or occur in sequence in an affected individual, and
4 the neutrophilic process itself may in some cases cause systemic disease.

Epidermal neutrophilic dermatoses are not discussed here, other than where they are part of a disease overlap spectrum or where they share a common aetiology with neutrophilic dermatoses affecting the dermis or subcutaneous fat.

The following sections define and discuss the history, aetiology, pathogenesis, histopathology, clinical features, diagnosis and treatment of the major neutrophilic dermatoses, as well as briefly addressing histopathological overlaps, internal (systemic) neutrophilic dermatoses, and identifying areas of controversy. The conditions discussed are characterized by a neutrophilic infiltrate and blood vessel damage, probably as a result of immune complex deposition as well as involving neutrophil-induced injury. Increasingly, different types of infiltrate (lymphocytic, or early myeloid cells), and the presence of at least some features of vasculitis, are being accepted within the spectrum of neutrophilic dermatoses, although in some instances these variations may be secondary and reflect the timing of obtaining histopathology specimens. Some mechanisms of involvement of neutrophils in this group of dermatoses, and of their chemoattraction to tissues, have been discussed in [7–10].

Classification

A suggested classification of neutrophilic dermatoses is shown in Table 50.16. It should be noted that frank vasculitides, neutrophilic vascular reactions secondary to primary microvascular occlusion (Chapter 49), and infective causes of neutrophilic vasculopathy are not normally included in such classifications.

We have not included, or have listed but will not discuss, additional disorders in which the neutrophilic infiltrate is primarily epidermal such as *subcorneal pustular dermatosis*, *pustular psoriasis*, *Reiter's syndrome*, *intraepidermal neutrophilic IgA dermatosis*, *infantile acropustulosis* and *drug-induced pustular eruptions*, although one might also term these neutrophilic in type of infiltrate. Some authors have also suggested the inclusion of *Rosai–Dorfman disease with neutrophilic predominance* and of *congenital erosive and vesicular dermatosis with reticulated supple scarring*, based on histopathological similarity, but these conditions do not share the disease associations or behaviour of more accepted dermal neutrophilic dermatoses. All of these are discussed in other chapters.

There remain some areas of overlap or uncertainty. Some disorders, notably *Behçet's disease*, have features of vasculitis, pustular vasculitis and thrombosis, and therefore exhibit overlap between neutrophilic dermatosis and vasculitis, as discussed earlier (p. 50.56). *Erythema elevatum diutinum* (EED) is variably classified as a vasculitis or as a neutrophilic dermatosis; we have elected to discuss it as a vasculitis (p. 50.25). *Neutrophilic eccrine hidradenitis* (NEH) appears to have different aetiologies (physical/cold in children, often related to cytotoxic or other drugs and/or haematological malignancies in adults) and is neutrophilic but not primarily vascular; it is also discussed in Chapter 44. *Subcorneal pustular dermatosis* is not a vascular reaction but does share aetiological factors (notably monoclonal gammopathy) with disorders such as pyoderma gangrenosum and EED, and may coexist with them (especially in patients with myelodysplastic disorders), so is included in the classification but is discussed in Chapter 40. Some histological issues that influence classification (e.g. early lymphocytic rather than neutrophilic infiltrates) are discussed in relation to specific conditions below.

Neutrophilic sebaceous adenitis [1,2] is very rare, and how to classify it is unclear. Clinically it presents as annular plaques and papules, spreading from the face to the body and having some resemblance to Sweet's syndrome; histologically it is characterized by a sterile, neutrophilic and sometimes suppurative infiltrate around sebaceous lobules (although cases with a myelomonocytic [3] or granulomatous infiltrate are also reported [2]). It usually has a short, self-limiting course or responds to topical corticosteroids. An autoimmune aetiology has been proposed but it is tempting to suggest that this could be a sebaceous equivalent of neutrophilic eccrine hidradenitis (NEH), as the distribution, morphology, duration and neutrophilic infiltrate, in the presence of necrotic sebocytes without infection, would parallel several aspects of NEH. We have therefore very tentatively suggested that it may belong

Table 50.16 Neutrophilic dermatoses: an aetiological classification.

'Classical' neutrophilic dermatoses
- Pyoderma gangrenosum (various subtypes)
- Sweet's syndrome/acute febrile neutrophilic dermatosis (and possible variants: neutrophilic dermatosis of the dorsal hands; chronic recurrent [annular] neutrophilic dermatosis)

Overlap with vasculitis
- Behçet's disease
- Erythema elevatum diutinum

Specific link with gastrointestinal disease*
- Neutrophilic vascular reaction in bowel-associated dermatosis arthritis syndrome (BADAS)
- Pustular vasculitis/neutrophilic pustulosis (many cases represent pustular pyoderma gangrenosum)
- Aseptic abscesses in Crohn's disease
- Pyodermatitis–pyostomatitis vegetans (?)
- Peristomal pyoderma gangrenosum

Associated with acne or pustulosis†
- Synovitis, acne, pustulosis, hyperostosis, osteomyelitis (SAPHO)
- Pyogenic arthritis, pyoderma gangrenosum, acne (PAPA)

Associated with connective tissue disease or immune complex disease
- Rheumatoid neutrophilic dermatitis/dermatosis
- Palisaded neutrophilic and granulomatous dermatitis
- Relapsing polychondritis
- Sweet's syndrome-like, erythema gyratum repens-like, and figurate neutrophilic infiltrate, in systemic lupus erythematosus

Paraneoplastic or typically chemotherapy-associated
- Paraneoplastic neutrophilic figurate erythema
- Neutrophilic eccrine hidradenitis

Systemic neutrophilic dermatoses
- Neuro-Sweet's syndrome
- Other internal sites: myositis, pulmonary, pericarditis, osteitis (deep to pyoderma gangrenosum, or distant), lymph nodes, other sites of aseptic neutrophilic abscesses (often splenic or visceral), etc.

Other extra-cutaneous neutrophilic disease
- Peripheral ulcerative keratitis
- Neutrophilic panniculitis

Autoinflammatory diseases‡
- Familial Mediterranean fever
- Hyper-IgD syndrome

Non-vessel centred and miscellaneous
- Subcorneal pustular dermatosis (Sneddon–Wilkinson disease)
- Intraepidermal neutrophilic IgA dermatosis
- Neutrophilic urticaria
- Neutrophilic spongiosis?
- Neutrophilic sebaceous adenitis?

* Many of the neutrophilic dermatoses have a strong association with gastrointestinal disease, but this link is especially strong in the disorders listed.

† Pustules are also a feature in many of the other patterns listed, such as Behçet's disease, Sweet's syndrome, BADAS and others.

‡ Autoinflammatory diseases are increasingly classified on the basis of genetic findings, but Sweet's syndrome-like lesions and aseptic pustules, with leukocytosis, are often described.

in the neutrophilic dermatosis spectrum. *Neutrophilic spongiosis*, a disorder of uncertain classification, is discussed in the section on neutrophilic pustular disorders.

Aseptic and TORCH-screen negative pustular eruptions in children, with some features reminiscent of Sweet's syndrome, should be viewed with some suspicion. Paediatric Sweet's syndrome and PG may both occur, but a perforating neutrophilic and granulomatous dermatitis of the newborn was described in two children with immunodeficiency [4], and children with Down's syndrome are prone to transient myeloproliferative disorders, leukaemoid reactions and leukaemia cutis; the lesions may contain immature blast-like immature haemopoietic cells and, like neutrophilic dermatoses, may exhibit pathergy [5,6].

Lupus erythematosus has also been linked with Sweet's syndrome or other neutrophilic dermatoses; earlier reports were those in which hydralazine was implicated [7], but there are other reports where this was not the case [8] and there are increasing reports of neutrophilic dermatoses as the presenting feature of lupus erythematosus [9,10]. Sweet's syndrome, PG (8 years before lupus erythematosus [11]), and figurate and erythema gyratum repens-like patterns [12] of neutrophilic dermatosis have all been reported, as well as other potentially related conditions such as neutrophilic urticaria/urticarial erythema with neutrophilic infiltration [13,14], neutrophilic eccrine hidradenitis (after cyclophosphamide treatment [15]) and palisaded neutrophilic and granulomatous dermatitis. It has been recommended that lupus erythematosus should be considered in the differential diagnosis of neutrophilic dermatoses [10].

Pyoderma gangrenosum

Definition. Pyoderma gangrenosum (PG) is a rare, non-infectious neutrophilic dermatosis commonly associated with underlying systemic disease. Diagnosis is based on typical clinical features and exclusion of other cutaneous ulcerating diseases, as described in several reviews [1–10].

History and nomenclature. Brocq first described PG in 1916 [11]. It was later described in 1930 by Brunsting *et al*. [12]. The prevalence of PG in inflammatory bowel disease (IBD) was discussed by Greenstein *et al*. in 1976 [13]. Several clinical variants of PG have been described (Table 50.17), diagnostic criteria have been published [3], and PG at unusual sites or with specific triggers, such as pathergy, have also been reviewed [4]. The significance of the different variants described is unclear. There is some evidence that the pustular type may be mainly associated with IBD, the bullous type with haematological malignancies, and that the vegetative type is usually not associated with underlying disease [2,3]. Others describe lesions on the hands, arms and face as being associated with haematological diseases (and thus potentially overlapping with Sweet's syndrome, and with neutrophilic dermatosis of the dorsal hands) [8]. The peristomal pattern, unsurprisingly, is mainly but not exclusively associated with IBD. However, different morphologies may coexist with each other or with other neutrophilic dermatoses or pustular vasculitis [14] (although the vegetative pattern of PG is usually not accompanied by other lesions), or may evolve from one form to another [15], and none of the morphologies is consistently or exclusively associated with any specific cause; such classifications are, however, convenient for discussion and for initiation of the potentially most rewarding investigations. The different patterns are discussed in more detail below. As a guide, about 50–70% of patients will have an underlying disease, approximately equally divided between IBD, arthritides and haematological causes; conversely, about 2% of patients with IBD will develop PG.

Table 50.17 The main variants of pyoderma gangrenosum in selected reviews.

Authors (reference)	Main variants
Powell *et al*. [2,3] Wollina [9] De Moragas & Pujol [16]	Ulcerative Pustular Bullous Vegetative (= superficial granulomatous pyoderma)
Callen [4]	Typical (classical) Atypical (more superficial) Pustular eruption of ulcerative colitis Peristomal Vulvar Pyostomatitis vegetans Malignant pyoderma Bullous
Ahmadi & Powell [6]	*Main classification*: Ulcerative Pustular Bullous Vegetative *Unusual presentations*: Pathergic Peristomal Dorsal hand Head and neck (malignant pyoderma) Multisystem Paraneoplastic
Callen & Jackson [8,10]	Classic (usually on the legs) Atypical (hands, arms, face) Peristomal Other sites not specifically viewed as distinct (vulva, penis and oropharynx [pyostomatitis vegetans])
Present text (an arbitrary division according to morphology and/or site, where these factors influence diagnostic aspects, likely disease associations or therapy)	Classic/ulcerative Atypical forms: Pustular Bullous Upper limbs/trunk Superficial (vegetative) Peristomal Other specific sites that influence diagnostic aspects, disease associations or therapy (face/scalp, breast, genital, mucosal, etc) Pyostomatitis vegetans (?) Neutrophilic dermatosis of dorsal hands (? Sweet's syndrome or pyoderma gangrenosum)

Table 50.18 Diseases associated with pyoderma gangrenosum.

Category	Examples*
Gastrointestinal	Ulcerative colitis, Crohn's disease, collagenous colitis, gastritis, gastroduodenal ulcers, intestinal polyps
Arthritides	Rheumatoid arthritis, seronegative arthritis (sometimes with IBD), osteoarthritis
Haematological	Leukaemias (especially myelogenous, hairy cell), myelofibrosis, myelodysplastic syndromes/polycythaemia vera, paraproteinaemia including (usually IgA) monoclonal gammopathy, Waldenström's macroglobulinaemia, paroxysmal nocturnal haemoglobinuria, splenomegaly, T-cell lymphomas (less commonly)
Hepatic	Chronic active hepatitis, primary biliary cirrhosis, sclerosing cholangitis
Other vasculitides, collagen vascular and related disorders	Wegener's granulomatosis, Takayasu's arteritis, Behçet's disease, systemic lupus erythematosus, systemic sclerosis
Acne and related disorders	Acne conglobata, acne fulminans, hidradenitis suppurativa, PAPA (recurrent familial arthritis)
Other dermatoses	Many other neutrophilic dermatoses, relapsing polychondritis, pustular vasculitis (this chapter) Psoriasis
Autoimmune	Thyroid disease, diabetes mellitus
Drugs	Colony-stimulating factors† (several), gefinib (epidermal growth factor receptor inhibitor), interferon†, propylthiouracil, isotretinoin, several others (with apparently unrelated structures/activities)
Solid organ tumours	Colon, pancreas, breast, bronchus, carcinoid
Miscellaneous	Sarcoidosis Infections, including HIV, hepatitis C Chronic lung disease Immunological: congenital hypergammaglobulinaemia, autoimmune neutropenia in infancy, immunosuppression, complement deficiencies (C2, C4, C7 deficiency all described) Familial

PAPA: pyogenic arthritis, pyoderma gangrenosum, acne.

* It is not certain that all conditions listed represent true or causal associations.

† Have also been used therapeutically.

Aetiology and pathogenesis. Although the pathogenesis of PG is not fully understood, an immune-mediated process is thought to have an important role. Rather more than 50% of patients with PG have an associated systemic disease [1–3]. Common associations include IBD (in about 15–20% of cases with an associated disease), arthritis of several types, haematological malignancies and monoclonal gammopathies (Table 50.18). The strength of the different associations shows some variation with clinical pattern (see Clinical features section), but some associations may have pathogenetic importance (discussed below).

Both humoral and cell-mediated abnormalities have been associated with PG. Humoral defects reported include autoantibodies against skin and bowel, a dermonecrotic factor present in the serum that produces necrosis when injected into the subject's own skin, and a serum factor present in patients with PG that produces PG-like lesions when injected into guinea pigs [4,5]. Other studies have suggested the mechanism underlying PG is consistent with the Arthus and Schwartzmann reactions in which circulating immune complexes are deposited in vessels leading to activation of the classical and alternative complement pathways [4,6,7]. Direct immunofluorescence staining studies to detect immunoglobulins, complement and fibrin deposits in post-capillary venules have yielded inconsistent results [8,9]. The possibility of cross-reactivity between bacterial and cutaneous antigens has been suspected for many years [10], and treatment to decrease bowel bacteria has shown some benefit in therapy of PG [11], with *Escherichia coli* particularly implicated. Recent support for this possibility was documented in a study in which heat-killed *E. coli* were injected subcutaneously into clinically normal skin; in normal volunteers inflammation peaks at 24 h and fades by 48 h, but in some patients with ulcerative colitis (although in none with Crohn's disease) the inflammation persists; one patient went on to develop PG-like bullous lesions with very high IL-8 levels [12,13] (IL-8 being a very potent neutrophil chemoattractant, discussed further below). The patient had had a previous florid response to an infected wound on the foot, but did not have pathergy at needle injury sites. The authors suggest that this represents an abnormal reaction to bacteria, rather than being a form of pathergy, and suggest a local failure to terminate IL-8 production, resulting in

marked neutrophilic infiltration. However, a study of Crohn's disease lesions found intracellular consensus bacterial 16S rRNA in most bowel biopsies but in no lesions of PG, neutrophilic folliculitis and other skin lesions, including skin lesions from three patients with Crohn's disease and associated skin lesions [14]. The role of bacterial antigens warrants further study.

Cell-mediated defects found include cutaneous anergy to *Candida*, streptokinase and purified protein derivative, as well as altered production of macrophage inhibition factor by lymphocytes [15]. The association with inflammatory bowel disease and various arthritides, in which T cells play a part in the pathogenesis, prompted investigation of clonal T-cell responses in patients with PG. In five patients (three with classical and two with peristomal PG), all patients had evidence of expanded T-cell clones in peripheral blood, and four of them also had clonality identified in the skin at the leading edge of the PG lesions, some of the clones in each of these cases being shared between the skin and the blood (including one patient without underlying IBD) [16]. These results were interpreted as confirming an oligoclonal T-cell response due to an antigenic stimulus, and trafficking between the skin and blood (and, therefore, potentially to other organs also). Clonal gamma and beta T-cell receptor rearrangements have also been demonstrated in PG associated with haematological disease (including splenomegaly) [17], but a recent study (including patients with Sweet's syndrome or PG) found that clonal restriction of neutrophils was present not only in over half of patients with myeloid disorders but also in a rather higher proportion of controls (one of whom later developed myelodysplasia) [18]. Thus, clonality of both T cells and of neutrophils has been demonstrated in different studies, and neither appears to be specifically related to any particular associated disease entity.

Additional reports have described decreased neutrophil chemotaxis and impaired monocyte phagocytosis in association with PG [19]. These leukocyte abnormalities may contribute to the pathergic phenomenon that occurs in up to 50% of PG patients, whereby new lesions can be induced at sites of minor skin trauma including venepuncture, vaccination and surgical procedures [1–3], and also for occurrence of the Koebner reaction in some patients with PG [20]. Various studies support the importance of IL-8 as a neutrophil chemoattractant involved in the pathogenesis of PG. Overexpression of IL-8 induced in immunodeficient mice bearing human skin xenografts caused PG-like ulceration [21], high IL-8 levels in blood have been documented in PG [22], and high IL-8 levels have been demonstrated in fibroblasts from PG ulcers [21,22]; in cultured PG ulcer fibroblasts from one patient, the initially elevated IL-8 production fell over a few weeks to the same undetectable levels as demonstrated throughout the culture period in fibroblasts from normal skin in the same patient [22]. Thus the IL-8 production (which also occurs in IBD) is induced rather than constitutive, suggesting a potential role for cytokines that stimulate its production, such as IL-1 or TNF-α.

Early reports of PG emphasized the association with ulcerative colitis (UC) but, although UC remains more commonly associated with PG than is Crohn's disease, the latter became increasingly recognized as having an association with PG; both classic and peristomal PG have been reported with UC, Crohn's disease and collagenous colitis. Three areas of interest regarding the association of IBD with PG are the different immunopathogenesis of the UC (a Th2-type enteritis) and Crohn's disease (Th1-type), the role of cigarette smoking, and the role of bacteria, especially *E. coli* (discussed above). The possible protective role of smoking in UC has been uncertain, but a recent meta-analysis documented that smoking is protective against UC, is associated with less complications once UC has developed and with disease flares if smoking is discontinued, whereas the opposite (for all these aspects) applies to Crohn's disease [23]. A possible mechanism for the benefit of smoking on UC is that nicotine upregulates the lamina propria nicotinic acetylcholine receptor and could alter the bowel mucosal immune balance towards a Th1 pattern [24]. However, smoking is a significant factor favouring development of extraintestinal manifestations of UC, including PG and erythema nodosum [25]. Combined with the fact that PG may develop up to a decade after panproctocolectomy for UC [26], this dissociation of effect of smoking on the bowel and skin lesions suggests that the UC phenotype may be more important than the presence of colonic mucosa.

PG is not usually associated with vasculitis, but cases with positive tests for either C-ANCA or P-ANCA are occasionally reported (some in the context of drug-induced PG, typically with thiouracils). Patients with PG and other ANCA specificities are of some interest with regard to possible disease mechanisms. A patient who clinically had bullous and ulcerative PG on the legs, with polyarthritis, was found to have lung cysts and a novel ANCA to azurocidin [26]; the patient later developed a lesion on the ankle resembling blastomycosis-like pyoderma that was associated with autoantibodies to BPI. Azurocidin and BPI are antimicrobial components of neutrophil azurophilic granules (see discussion of ANCA in vasculitis, p. 50.8); antibodies to these proteins could potentially interfere with their antibacterial activity, thereby reducing innate immunity. Autoantibodies to azurocidin have also been associated with systemic and cutaneous vasculitis as well as with hydralazine-induced vasculitis [27]. More recently, a patient with PG and C-ANCA specific for h-lamp-2 has been reported [28].

Despite the evidence for cellular and cytokine responses being induced (presumably by antigenic stimuli), some cases may have a constitutive component. Several families with inherited PG have been described [29,30]; although cases have presented at any age in some kindreds, this should be noted as a possible explanation for neonatal PG which is generally rare [31]. There is also a predisposition to PG in patients with a mutation in caspase recruitment domain 15, leading to the autosomal dominant autoinflammatory syndrome of pyogenic arthritis, pyoderma gangrenosum and acne (PAPA); the relevant mutations affect CD2-binding protein 1 (CD2BP1, also known as PSTPIP1), a protein that is involved in cytoskeletal organization and that also reacts with pyrin, mutations in PAPA being predominantly expressed in granulocytes [32]. Other mutations in the same gene are the cause of some of the autoinflammatory (periodic fever) syndromes, some cases of Crohn's disease, familial granulomatous arthritis, and others [33,34].

Histopathology. Although the histopathological findings of PG are often variable and non-specific, they can be useful in excluding other possible aetiologies. Several variables must be considered when evaluating the histopathology, including the type of lesion, the site of the lesion from which the biopsy is obtained, the site within the lesion (biopsy of the edge reduces potentially misleading features that may occur in any chronic ulcerating lesions), the stage of evolution of the lesion, and therapy [1]. Typical findings include central necrosis and ulceration of the epidermis and dermis surrounded by an intense, acute inflammatory cell infiltrate, with a more peripheral mixed to chronic inflammatory cell infiltrate [2–4]. Each clinical variant has additional, more specific, histopathological findings. In the ulcerative variant of PG, there is massive dermal–epidermal neutrophilic infiltrate with suppuration/abscess formation; in pustular PG, a perifollicular neutrophilic infiltrate with subcorneal pustule formation; the bullous variant shows a neutrophilic infiltrate with intraepidermal vesicle formation; and in vegetative PG, there is a granulomatous reaction with peripheral palisading histiocytes and giant cells [4,5]. Otherwise, the presence of giant cells appears to be linked with IBD, especially Crohn's disease (and thus with peristomal PG, but distinct from stomal involvement by Crohn's disease) [6]. Although of different importance between countries, and depending on immune status/associated haematological malignancy, culture and staining of biopsy tissue for fungi, mycobacteria and other organisms is advisable—especially if any granulomas are present in the absence of IBD.

The presence of vasculitis in PG is an area of debate. Many investigators have reported findings consistent with a neutrophilic vascular reaction or leukocytoclastic vasculitis, fibrinoid necrosis, segmental necrotizing vasculitis, granulomatous vasculitis and lymphocytic vasculitis [2–4,7–10], although this is not supported by all studies [11]. True vasculitides and infective causes should be carefully excluded if vasculitis is evident.

Clinical features. PG can have a variety of clinical presentations. Extracutaneous involvement is discussed separately later. Diagnostic criteria have been proposed for the cutaneous lesions of classic ulcerative PG [1], with various amendments suggested [2,8], and, although not formally validated, can be summarized as:

Major criteria (both required)

1 Rapid (usually >1 cm/day) progression of painful, necrolytic ulceration with an irregular, undermined, violaceous border—usually with a preceding papule, pustule or bulla, and pain out of proportion to the size of the ulcerated area
2 Exclusion of other causes of ulceration.

Minor criteria (at least two required)

1 (a) history of pathergy, or (b) presence of cribriform scarring
2 Presence of a disease known to be associated with PG (usually listed as IBD, polyarthritis, myelodysplasia or leukaemia, but monoclonal gammopathy should be added to this list; overall about 50% have an associated systemic disease)
3 Appropriate histopathological findings (again, specifically excluding infective causes)
4 Rapid response to oral corticosteroid therapy (usually interpreted as at least 50% reduction in size using 1–2 mg/kg/day).

As described above, for pragmatic reasons of diagnosis, disease association or therapy (below) we have divided the types of PG as follows:

Classic/ulcerative PG [2–9]. This is the commonest and best recognized variant of PG, presenting with small, tender, red–blue papules, plaques or pustules that evolve into painful ulcers with characteristic violaceous undermined edges (Fig. 50.37). There may be granulation tissue, necrosis or purulent exudate at the ulcer base. Lesions may be solitary or multiple, and occur most commonly on the legs (in 70%), but may affect any body site. Pathergy occurs in 25% (usually defined as following minor injuries such as venesection, but numerous reports of PG at operation sites, especially after breast surgery, are also reported, and other forms of skin injury such as scalds or varicella may also act as a pathergic trigger). Healing usually occurs with an atrophic cribriform scar. Associated symptoms include fever, malaise, myalgia and arthralgia. Frequent disease associations include IBD, arthritis, monoclonal gammopathy or internal malignancy; over 70% have one of these [4]. Genital and mucosal involvement (other than pyostomatitis vegetans) are generally considered to be within this category, but are discussed separately below as they raise additional diagnostic issues.

Fig. 50.37 Pyoderma gangrenosum. Classic type, showing a deep ulcer with inflammatory border.

Atypical forms. The term 'atypical PG' has been used in several rather different contexts, and it may be useful to subdivide them. At one time bullous PG, possibly overlapping with bullous Sweet's disease (and being strongly linked with haematological malignancy), was the main 'atypical' form. It is now more common for atypical PG to mean a pattern that is relatively superficial, may be pustular and Sweet's syndrome-like or may be ulcerated, tends to occur on hands, arms and face or upper trunk, and is linked with myeloproliferative disorders and gammopathies (usually IgA) [2,8]; it overlaps with neutrophilic dermatosis of the dorsal hands, discussed separately later. However, others view peristomal or genital PG as also being 'atypical'—to bridge this gap between terminologies, and to help explain the patterns, we have subdivided the 'atypical' forms of PG into three morphological types and some site-specific variants.

Atypical form: (a) pustular PG. Pustular PG is a variant, noted two decades ago [4], that often occurs during acute exacerbations of IBD. Discrete painful pustules, with a surrounding halo of erythema, develop on normal skin [4,9]. These pustules commonly arise with a scattered distribution on the extensor aspects of the limbs. Nomenclature for these lesions varies somewhat, including pustular vasculitis and neutrophilic pustules, as well as pustular PG. This diagnostic area is discussed later with some other pustular neutrophilic dermatoses. Pustular PG lesions often resolve with control of IBD (in some cases using treatments appropriate for both PG and for IBD, discussed later) but some may evolve to form ulcerated classic PG.

Atypical form: (b) bullous PG. This pattern has also traditionally been termed 'atypical' PG. It presents with rapidly arising, superficial, haemorrhagic bullae, often located on the arms [4,6].

Fig. 50.38 Pyoderma gangrenosum. Superficial granulomatous type; the breast is a common site.

Fig 50.39 Pyoderma gangrenosum. Peristomal type, with additional pathergic involvement of surgical wounds. Systemic therapy was contraindicated by pelvic sepsis but the lesion healed with very potent topical corticosteroid treatment. Opiate analgesia and nitrous oxide for severe local pain was able to be discontinued by using topical instillation of amethocaine-prilocaine cream for an hour before dressing changes.

It shares clinical and histopathological findings with Sweet's syndrome, but typically ulcerates and heals with scarring. Bullous PG is especially associated with myeloproliferative disorders [1,4,7,9,10]; if it occurs with IBD it is usually in patients with a significant disease flare.

Atypical form: (c) upper limbs/trunk/face. The pattern of PG that is now often simply referred to as 'atypical PG' [2,8] is a more superficial variant than classic PG. It can occur at any site but most commonly on the arms or face. It can be bullous, and it may be difficult to differentiate from Sweet's syndrome. It is viewed as including neutrophilic dermatosis of the dorsal hands (discussed separately below to explain nomenclature and histological features in more detail; p. 50.80 and Fig. 50.42). The importance of this pattern is that the strongest link with internal disease is with myelogenous leukaemias, myeloproliferative disorders or IgA gammopathies.

Superficial (vegetative) PG (synonym superficial granulomatous pyoderma) presents as a superficial ulcer, usually on the trunk (Fig. 50.38) or sometimes the face, although it can occur at other sites. It has a non-purulent base and generally lacks the violaceous, undermined border of classic PG [4,9,11]. It is often a solitary, slowly progressing, relatively non-painful, variant that resolves with less aggressive treatment [12] and is not usually associated with any systemic disease [13]. Infections are the commonest differential diagnosis. The confusingly similarly-named, morphologically similar, but pathogenetically quite different disorder pyoderma vegetans is discussed on p. 50.89.

Peristomal PG [2,7–9,14] is currently a relatively common pattern of PG, perhaps accounting for about 15% of cases, and sometimes coexisting with pustular vasculitis or PG at other sites (Fig. 50.39). It has several notable features: it is almost always associated with IBD, biopsy may show giant cells or bacteria (the latter mainly due to contamination/colonization of ulcerated skin), there is a significant risk of the area being treated as an infected or broken-down surgical wound, and therapy may be very difficult (see later). Other associations of peristomal PG include diverticular disease, bowel carcinoma, perforated bowel and neurogenic bladder in one series [14], as well as recent reports of collagenous colitis [15] and systemic sclerosis [16].

Other specific sites of PG that influence diagnostic aspects, disease associations or therapy

(a) **PG of the face, lips, orbital adnexae or upper trunk** has already been discussed as these are sites that should give rise to suspicion of associated myeloproliferative disease. However, PG at these areas also causes differential diagnostic problems that may be a lesser consideration at other sites; orbital cellulitis, destructive lymphomas and factitious disease (discussed later) cause particular problems. Ulcerated neoplasms that have been concealed also need to be considered. Another difficult differential diagnosis is a condition termed malignant pyoderma (MP), first described by Perry *et al*. in 1968 [17] as a rapidly progressive ulcerative disease localized to the head, neck and upper trunk. Controversy exists as to whether MP represents a head and neck variant of PG or a cutaneous manifestation of WG. PG and WG may have similar clinical and histopathological findings, and both have been the reported cause of MP in some cases [18–22]. Interestingly, two of the original three reported cases of MP are now believed to represent WG. The presence of C-ANCA, which is highly specific for WG, should mean that it is now easier to distinguish PG from WG. However, some patients with WG may have negative C-ANCA test results, and thus close follow-up is war-

ranted for possible pulmonary or renal lesions that may develop in WG [21–23]. Because of the uncertainty regarding the nosology of MP, it has been suggested that this term should not be used as a final diagnosis [21].

(b) **PG of the genitalia** includes both penile [24] and vulval involvement. There is no reason to suppose that these sites of involvement represent a different form of PG (except perhaps in children, as perianal and genital involvement appears to be over-represented in the first decade of life [25]), or have specific disease associations, but differential diagnosis (below) may be difficult and PG may not be suspected.

(c) **PG of the breast** is also not a specific entity—most cases are either vegetative PG, or the breast is affected with the face or arms in the haematological disease-associated atypical variety. However, there are again specific differential diagnosis issues, one that has caused some problems in recent publications being that of factitial disease (discussed below). PG after breast surgery has been reported on many occasions [26,27].

(d) **PG of oral, pharyngeal, laryngeal, nasal, respiratory tract and ocular mucosae** [28–34] does have some reasons to be discussed separately. Diagnosis and treatment may be difficult, and respiratory involvement may have a predilection for children [33,34]. Ocular lesions are documented in Table 50.18, the most specific being peripheral ulcerative keratitis [28] and possibly nodular episcleritis. Pyostomatitis vegetans is an oral mucosal disease that in some instances appears to be related to PG, having a very strong link with IBD, but is less certain in other instances—it is briefly discussed separately below. Other oral lesions may be aphthous, pustular, frank extensive PG [29,30] or occur within the spectrum of Behçet's disease [31]. Nasal mucosal involvement may occur [29,32], even septal perforation [32], as well as tracheal [33] or respiratory tract involvement [34], either of these having a differential diagnosis of WG as discussed above for 'malignant pyoderma'.

(e) Systemic disease (affecting lung, bone, etc.) is discussed separately on p. 50.81.

Pyostomatitis vegetans [35–38] is nosologically an enigmatic disorder. It is a disorder in which there is oral mucosal thickening with multiple pustules and 'snail track' ulcers on an erythematous base (at any site, although the tongue is less affected). The oral lesions have a very strong link with IBD, especially active ulcerative colitis; this, combined with the presence of Sweet's syndrome-like or PG-like skin lesions in some cases, has led several reviewers to consider this disorder as a manifestation of PG. However, several factors argue against this. Although deeper tissues have a mixed infiltrate including neutrophils, early and superficial lesions have a preponderance of eosinophils and often associated peripheral blood eosinophilia. The skin lesions (perhaps best termed pyodermatitis vegetans, and discussed later in the differential diagnosis of pustular eruptions, p. 50.89) are often flexural and (although clearly distinguished by histology and direct immunofluorescence) are clinically more suggestive of pemphigus vegetans. The various terminologies are used interchangeably, which does not enhance understanding. On present evidence, it is probably best to view this as a predominantly IBD-associated eruption but not as a form of PG.

Diagnosis. There are two facets to diagnosis in PG; one is distinguishing PG from several possible alternatives, and the other is evaluation for underlying causes (of which arthritis and IBD are generally apparent, but haematological causes may not be). PG is often a diagnosis of exclusion as laboratory and histopathological findings are variable and non-specific; some of the more important differential diagnoses are enumerated in Table 50.19 [7–9,39,40]. Patient evaluation should include a detailed history, physical examination and skin biopsies for histopathology and culture (including unusual fungi, atypical mycobacteria and opportunistic infections, in the majority of cases), as well as appropriate laboratory tests to help rule out other possible aetiologies. Sweet's syndrome can often be distinguished by its rather sudden onset of non-ulcerating lesions that generally heal without scarring, although both share some aetiologies, both may coexist, and (especially associated with haematological malignancy) a clinical picture with features of both may occur (typically bullous, and variably termed atypical Sweet's syndrome or atypical PG). Syndromes with vasculitis such as WG, Behçet's disease and SLE can also be confused with PG; however, leukocytoclastic vasculitis is not a feature of PG.

There are examples of both factitious disease or other causes of ulceration being erroneously diagnosed as PG [40,41], and PG has also been misdiagnosed as factitial [42]; both situations are hugely important due to the extensive tissue destruction that may occur, so, provided infection is excluded, a trial of corticosteroid therapy is appropriate as PG is likely to respond. However, this should be limited in duration and other diagnoses considered if response is poor. In one study of 95 patients with ulcers resembling PG, 64 had been treated on this basis for 3–180 (median 10) months, 23 (36%) without response and eight (12%) with deterioration; final diagnoses included vascular occlusion, venous disease, vasculitis, neoplasia, various forms of tissue injury (five had factitial disease) and other inflammatory disorders [40].

In evaluation of associated diseases, it should be noted that the course of PG does not necessarily parallel that of IBD, but that PG in haematological disorders (unless provoked by a neutrophil-increasing therapy, such as colony-stimulating factors) may be an indicator of transformation to a higher grade malignancy [43–45]. Thus careful re-evaluation is appropriate. It is also worth considering re-evaluation of patients with ulcerative colitis who develop peristomal PG, as some will prove to have Crohn's disease.

Table 50.19 Some differential diagnoses of pyoderma gangrenosum.

Category	Examples	Comment
Infection	Bacterial: ecthyma, mycobacteria, syphilis, tropical ulcer, necrotizing fasciitis; folliculitis, gonococcaemia and other pustular infections may also mimic pustular PG Fungi: blastomycosis, sporotrichosis, cryptococcosis, zygomycoses, alternaria, *Penicillium marneffei* Viral: herpes simplex Other: amoebiasis	Consider infections especially in instances where 'pathergy' may have actually represented inoculation, and in immunosuppressed subjects (including therapeutic immunosuppression for IBD or arthritis, haematology disease-related immune compromise)
Vascular disease	Arterial disease, venous disease Occlusive angiopathic disorders (cryogelling, livedoid vasculopathy, antiphospholipid syndrome, calcific uraemic arteriolopathy, etc. (Chapter 49) Others: sickle cell disease, thalassaemia/haemoglobinopathies	
Vasculitis	Wegener's granulomatosis (WG), leukocytoclastic vasculitis, polyarteritis nodosa, mixed cryoglobulinaemia, Takayasu's arteritis	The differential diagnosis of WG may be difficult at head and neck sites, or if there is internal neutrophilic dermatosis
Neoplasia	Lymphoma (especially aggressive angiocentric T-cell lymphomas, anaplastic large cell lymphoma, bullous mycosis fungoides) Leukaemia cutis Langerhans' cell histiocytosis	Both a differential diagnosis and a possible cause of PG
Drugs	Halides: e.g. bromoderma Ulceration due to hydroxycarbamide Drug-induced lupus erythematosus	Check ANCA, often positive in thiouracil-induced PG or vasculitis; note that drugs may cause true PG rather than simulators Ulceration due to hydroxycarbamide particularly needs to be considered in patients being treated with this for a known haematological disorder
Other tissue injury	Necrotic bite reations: spiders, others Factitious injury (including panniculitis due to infective or toxic agents); intravenous drug abuse (± secondary infection); cocaine ulceration	Beware of cases without a response to corticosteroids
Medical disorders	Amyloidosis (especially bullous) Ulcerative sarcoidosis Cutaneous (metastatic) Crohn's disease Other neutrophilic disorders Necrobiosis lipoidica Pyodermatitis–pyostomatitis vegetans (see text)	Many of these have also been described as causes of PG

Treatment. Many effective treatment strategies have been reported, and have been the subject of extensive review articles [1–6], some evidence-based from literature on large numbers of patients [5], some giving doses and hints for use [4] and others addressing specific patterns of PG [6].

Choice of treatment generally depends on disease severity as well as on the presence of associated disease. For early or mild lesions, topical therapy may be sufficient [1]. This includes wet compresses, hydrophilic occlusive dressings, antimicrobial agents and topical corticosteroids. Topical tacrolimus is also useful for treatment of early PG lesions [7], and intralesional corticosteroids are another therapeutic option of reported benefit [8]. Indeed there may be situations, for example if there is a post-surgical infection which precludes use of systemic immunosuppressive therapy, where analgesia and topical treatment of PG is the most appropriate option (Fig. 50.39). Other topical agents, such as benzoyl peroxide, 5-aminosalicylic acid, nitrogen mustard (20% aqueous), cromoglycate preparations, platelet-derived growth factor, and intralesional therapy with ciclosporin, all have only anecdotal or small series data [5]. Topical nicotine cream was not considered in [5], but a recent (two patient) report supported previous suggestions of efficacy [9].

For more severe disease, or for PG resistant to topical therapy, oral corticosteroids have been the mainstay of therapy. Pulsed intravenous corticosteroid therapy has been reported to be effective in some cases refractory to oral corticosteroids; it has been recommended in PG refractory to other forms of treatment [10]. Evidence for benefit from sulphones and other antimicrobials such as dapsone, clofazimine and minocycline, which may have anti-inflammatory effects or modulate neutrophil function, is anecdotal [5]; however, these are widely used alone or with corticosteroids. Dapsone is probably most frequently used, although low-dose colchicine was recently advocated in a report of two patients [11]. Various immunosuppressant agents (Table 50.20) have been found to be useful in corticosteroid-unresponsive PG, either alone or as corticosteroid-sparing agents. Assessing their individual benefit is difficult as many have been used with other therapy, such as corticosteroids; because of the risk of severe adverse effects such as bone marrow suppression, use of these agents has usually been limited to severe or refractory PG. Ciclosporin was widely used due to rapid action [2] and several case series were published [5], but is not ideal long term. Cyclophosphamide, chlorambucil, intravenous tacrolimus, mycophenolate mofetil and thalidomide have all been effective in a limited number of patients reported [1–6,12–20]; although not providing high-quality evidence, use of these agents has often been in patients refractory to less complex therapies. Ideally, it is best to choose a treatment that will also address any underlying disease, such as melphalan in the case of patients with paraproteinaemia [21], or methotrexate in those with underlying arthritis or IBD [22]. In peristomal PG [6], there are two main issues that are slightly different from treatment of PG at other sites; one of these is that topical therapies (typically corticosteroids or tacrolimus) need to be formulated in a way that neither irritates unduly nor interferes with adhesion of appliances, the other is that, because of the strong link with IBD, there may be a lower threshold to consider systemic therapies (especially those that may be beneficial for both the PG and the bowel disease). Intralesional corticosteroids may avoid some of these problems. Achieving analgesia at this site, where activity of the stoma and need for adhesive appliances in close proximity to the PG both potentially add to discomfort, may be difficult.

In many of these situations, biologically engineered TNF-α inhibitors are now being used in preference to older agents, especially where there is associated IBD or inflammatory arthritis which is also likely to respond; there are several reports of benefit to etanercept, adalimumab and infliximab [23–29]. These reports include one randomized, controlled trial of infliximab (with benefit unrelated to underlying disease) [25], a report of benefit from adalimumab after failure of etanercept [24], reports of benefit of infliximab in vegetative PG [26] and in PG as part of PAPA syndrome [27], and a report of use of infliximab and adalimumab in systemic PG (aseptic abscesses of psoas muscle and spleen) [28]. However, these agents are expensive, and are contraindicated in the presence of malignancy or infection, but may be the most appropriate choice for severe PG with associated active IBD [29].

Other treatments that have been effective in small studies include plasmapheresis [14], leukocytapheresis/granulocytapheresis [30,31] and intravenous immunoglobulin (IVIG) [32–34]. In a retrospective review of ten therapy-resistant patients treated with IVIG, seven cleared, six maintaining benefit with ongoing

Table 50.20 Therapeutic ladder for pyoderma gangrenosum.

Topical:
Topical or intralesional corticosteroids (2)
Tacrolimus (2)
Nicotine (3)
Cromolyn sodium/disodium cromoglycate (3)
Platelet-derived growth factor (3)
Systemic:
Prednisolone (oral or pulsed intravenous) (2)
Dapsone (2), sulphapyridine (3), sulphamethoxypyridazine (3)
Minocycline (3)
Clofazimine (2)
Colchicine (3)
Potassium iodide (3)
Sulfasalazine (2)
Infliximab (1)
Etanercept (3)
Adalimumab (3)
Thalidomide (3)
Methotrexate (weekly pulse) (3)
Ciclosporin (2)
Azathioprine (3)
Cyclophosphamide (3)
Mycophenolate mofetil (3)
Intravenous immunoglobulins (2)
Colony-stimulating factors (perilesional injection) (3)
Interferon-α (3; a patient with hepatitis C)
Other (physical and non-drug therapies):
Skin grafting, flap repairs etc. (3)
Bioengineered skin equivalents, cultured keratinocyte sheets and other keratinocyte delivery systems (3)
Hyperbaric oxygen (3)
Low pressure dressings (3)
Leukocytapheresis/granulocytapheresis (3)
Radiotherapy (3; probably not beneficial)

1, double-blind studies; 2, case series (> just 2 or 3 cases); 3, case reports.

intermittent infusions [33]; one study reported rapid relief of pain after IVIG [34]. Aggressive surgical debridement is contraindicated because of possible exacerbation of PG by the pathergic response. However, split-skin grafts and cultured keratinocyte autografting have been demonstrated to be effective if performed while the pathergic response is minimized using prolonged courses of immunosuppressants, and a variety of bioengineered dressings or keratinocyte delivery systems have been tried [5,35–37]. Low-pressure dressings, and hyperbaric oxygen therapy, have been reported as beneficial in single cases. Gradient support hosiery is probably beneficial for leg lesions.

Therapy decisions depend on an assessment of the degree of active inflammation as opposed to simple wound healing requirements in refractory ulcers. Treatment of PG is usually discontinued after complete healing of lesions. Recurrences may occur but are unpredictable and therefore do not justify prolonged maintenance therapy [2]. A summary of therapeutic options for PG is depicted in Table 50.20; in general, initial treatment for localized disease comprises topical or intralesional corticosteroid or topical tacrolimus, for resistant localized or more widespread PG comprises systemic corticosteroids with possible addition of one of the less toxic steroid-sparing agents (usually dapsone, mycophenolate mofetil, medium-term ciclosporin), and for more severe disease, or where there is an associated disease requiring concurrent therapy, an appropriate systemic agent (increasingly, an anti-TNF monoclonal agent).

Sweet's syndrome

Synonyms
- Acute febrile neutrophilic dermatosis
- Gomm–Button disease

Definition. Sweet's syndrome is characterized by fever, peripheral neutrophil leukocytosis, acute onset of painful, erythematous papules, plaques or nodules and histological findings of a dense neutrophilic infiltrate without evidence of primary vasculitis [1]. Sweet's syndrome can be subdivided into three groups, depending on the clinical setting:

1 classical or idiopathic (classical may be the better term, as upper respiratory and other infections, IBD and pregnancy are all well documented triggers; thus the condition is not really idiopathic in such cases)
2 malignancy-associated
3 drug-induced [2].

Diagnostic criteria have been proposed for Sweet's syndrome [3,4] and also specifically for drug-induced cases [5]. The subject has been reviewed on many occasions, including two recent and comprehensive reviews [6,7]. It is also now acknowledged to have systemic manifestations, discussed separately (p. 50.81).

History and nomenclature. Sweet first described eight women with a 'distinctive and fairly severe illness' in 1964 [1]. The name Gomm–Button disease referred to initial patients with the condition. In retrospect, a patient described by Costello [8] probably had the same condition and was thus the first malignancy-associated case, having acute myelogenous leukaemia [8]. Sweet's syndrome is now considered the prototype of the wider spectrum of neutrophilic dermatoses discussed earlier.

Aetiology and pathogenesis. Sweet's syndrome is associated with underlying disease in approximately 50% of cases (Table 50.21) [1–6].

Classical or idiopathic Sweet's syndrome typically affects women in the third to fifth decade and has been associated with infection (streptococcal upper respiratory infections and yersinial gastrointestinal infections), IBD (ulcerative colitis and Crohn's disease) [1–6] and pregnancy [7].

Malignancy-associated Sweet's syndrome is estimated to comprise 20–25% [1,3,4,8–10]; in this situation, men and women are equally affected [3,10]. Most tumours are haematological malignancies, especially acute myelogenous leukaemia. However, solid tumours, most commonly of genitourinary organs, breast and gastrointestinal tract, are present in about 15% [8,9]. Sweet's syndrome may be the initial manifestation of malignancy or may precede the diagnosis by months to years, making close follow-up essential. In addition, recurrent episodes of Sweet's syndrome may be an indication of cancer recurrence [2,10].

Drug-induced Sweet's syndrome most commonly occurs in patients receiving granulocyte colony-stimulating factor (G-CSF) therapy [11,12], including recent pegylated types and other newer preparations [13,14]. Additional drugs implicated include all-*trans*-retinoic acid [15,16], minocycline [17,18], trimethoprim–sulfamethoxazole [19], carbamazepine [5] and oral contraceptives [20]; other drug associations (some possibly being coincidental) are listed in [3,21].

Other conditions reported in association with Sweet's syndrome include Behçet's disease [22], erythema nodosum [23], sarcoidosis [24–26], rheumatoid arthritis [4,27] and thyroid disease [28]; again, some reports may represent coincidental occurrences rather than true disease associations. The most reported, or most logical, are listed in Table 50.21. Triggering by various different types of trauma, although possibly only relevant if there is an existing systemic stimulus, are discussed in the section on clinical features. There may be some familial tendency; sibling cases have been described [29] and an association with HLA-type Bw54 (discussed

Table 50.21 Conditions that have been associated with Sweet's syndrome/neutrophilic dermatosis.

Category	Examples	Comment
Infections	Streptococcal and upper respiratory tract Gastrointestinal (especially *Salmonella*, *Yersinia*) Mycobacterial infections (including vaccinations) Many others	Upper respiratory tract infections; *Salmonella* and *Yersinia* are well documented causes of 'classical' Sweet's syndrome See also text for discussion of human granulocytic anaplasmosis
Inflammatory bowel disease	Ulcerative colitis Crohn's disease	Well documented causes of 'classical' Sweet's syndrome
Endocrine	Pregnancy Autoimmune thyroid disease	Pregnancy and thyroid disease are relatively well documented
Immunological disorders	Collagen vascular disorders: lupus erythematosus, Sjögren's syndrome, others Others: autoimmune thrombocytopenic purpura, pemphigus	
Haematological malignancy and related conditions, immunodeficiencies	Acute myelogenous leukaemias Myelodysplastic conditions, polycythaemia Aplastic anaemia Fanconi's anaemia Monoclonal gammopathy Lymphomas (various, less common) Chronic granulomatous disease Congenital deficiencies: neutropenia, T-cell immunodeficiency, complement deficiency	Strong evidence linking leukaemias and myelodysplastic disorders Some series suggest a significant association with paraproteinaemias; chronic granulomatous disease, see text
Other malignancies	Genitourinary Breast Gastrointestinal Prostate Larynx Many others	No specific site-association apparent other than the haematological group
Other medical conditions	Sarcoidosis Rheumatoid arthritis Still's disease SAPHO	Many reports of sarcoidosis
Medications	Numerous; the most consistently associated agents are: • Colony-stimulating factors (including recent pegylated types) • Neutrophil-maturation drugs (all-*trans* retinoic acid) • Other haematological treatments (imatinib mesylate, bortezomib) • contraceptives • propylthiouracil Physical treatments for haematological malignancy have also been implicated, in a patient having splenic irradiation	Although most colony-stimulating factor-related Sweet's syndrome has been reported in patients with haematological malignancy, there are also several reports of the same phenomenon in other contexts (e.g. congenital immunodeficiencies) As with vasculitis, there may be positive ANCA with thiouracils
Other neutrophilic dermatoses and related conditions	Pyoderma gangrenosum Neutrophilic dermatosis of the dorsal hands Erythema elevatum diutinum Relapsing polychondritis Neutrophilic eccrine hidradenitis Subcorneal pustular dermatosis Erythema nodosum Behçet's disease Vasculitis (various)	In some cases, several are associated either concurrently or sequentially
Mucosal manifestations of Sweet's syndrome	Oral or genital mucosa ulceration Ocular inflammation especially conjunctivitis, also nodular episcleritis	Oral lesions especially in cases with haematological malignancy; conjunctivitis mainly in classical Sweet's syndrome
Systemic manifestations of neutrophilic dermatoses, and deeper variants	Bone, muscle, tendons, neuro-Sweet's, heart, lung, liver, intestine, spleen, kidney, subcutaneous (Sweet's panniculitis)	Summarized on p. 50.80
Unusual consequences of Sweet's syndrome	Acquired cutis laxa, mid-dermal elastolysis, elastophagocytosis	Several cases of acquired cutis laxa

SAPHO: synovitis, acne, pustulosis, hyperostosis, osteomyelitis.

in more detail in the differentiation between neuro-Sweet's syndrome and neuro-Behçet's disease, p. 50.82).

As with the other neutrophilic dermatoses, the pathogenesis of Sweet's syndrome is unknown, but it is thought to be related to altered immunological reactivity. A hypersensitivity reaction to bacterial, viral, drug or tumour antigens has been suggested as a possible aetiology. This hypothesis is supported by the frequent association of Sweet's syndrome with infection, drugs or malignancy, along with the clinical improvement of symptoms and lesions with corticosteroid treatment. Circulating autoantibodies [30], immune complexes [31] and cytokines have also been proposed to play a part in the pathogenesis of Sweet's syndrome. Atypical ANCA have been found in a few cases of Sweet's syndrome but not in others [30]; in ten patients with Sweet's syndrome, two had C-ANCA of IgA class (both with BPI specificity) but these could only be demonstrated on ethanol-fixed neutrophils, and formaldehyde fixation gave uniformly negative results [32]. Interleukin IL-1 has been suspected of playing a role for some years [33], but IL-3, IL-6, IL-8 and colony stimulating factors are also probably relevant [4]. Cytokine dysregulation has been a favoured theory in the pathogenesis of Sweet's syndrome, an imbalance of cytokine secretion from helper T cells (Th) being implicated. Th1 cytokines (IL-2 and IFN-γ) rather than Th2 cytokines (IL-4) are the proposed mediators, which in turn may stimulate the cytokine cascade leading to activation of neutrophils and release of toxic metabolites [34]; however, an integral role for colony-stimulating factors would appear to have more support.

Elevated serum levels of granulocyte colony-stimulating factor were demonstrated in patients with active Sweet's syndrome, and were associated with reduced neutrophil apoptosis; furthermore, incubation of autologous neutrophils with patient serum caused reduced apoptosis [35], and would account for accumulation of neutrophils which are the hallmark of this condition. Increased superoxide anion generation, a potential consequence of tissue neutrophilia (and for which prednisolone is a potent inhibitor), has been documented in leukaemia- and myelodysplasia-associated Sweet's syndrome [36], and various diverse tumours produce granulocyte colony-stimulating factor [4,37].

There are some issues of interest in relation to the involvement of neutrophils in Sweet's syndrome, that extend the recognized fact that neutrophilic dermatoses can occur during granulocytopenia [38]. The occurrence of other cell types is discussed in the section on histology. First, Sweet's syndrome has been reported in a patient with *chronic granulomatous disease*, a condition in which defects in NADPH-oxidase lead to failure of neutrophil intracellular oxidative killing; thus, this mechanism does not have to be functional in order to develop Sweet's syndrome [39]. Second, there is an interesting case of Sweet's syndrome in a patient with *human granulocytic anaplasmosis* (formerly human granulocytotropic ehrlichiosis) [40]. The causative organism, *Anaplasma phagocytophilum*, is an intracellular infection that infects, multiplies in and disrupts neutrophil function. Whether this means that human granulocytic anaplasmosis is a true cause of Sweet's syndrome is uncertain but, again, it documents that Sweet's syndrome can occur when there is impairment of normal neutrophil function. Third, a patient with congenital neutropenia developed Sweet's syndrome when he was treated with *pegfilgrastim*, a pegylated granulocyte colony-stimulating factor, despite many uneventful treatments both before and subsequently with standard granulocyte colony-stimulating factor [14]. The observation was made that pegfilgrastim has a half-life of 33 h in comparison with 3.4 h for the parent drug, filgrastim; furthermore, filgrastim is largely renally-excreted whereas pegfilgrastim is too large to be eliminated in this fashion, and it is actually removed from the circulation by neutrophil receptor-mediated clearance (binding to the neutrophil G-CSF receptor ligand) and therefore stimulating production of (potentially abnormally functional) neutrophils. Finally, there are reported cases of Sweet's syndrome associated with specific (6:9) translocations in myelodysplastic syndromes [41,42]; it has been suggested that these patients may have clonal neutrophils that could perhaps be more susceptible to the stimuli such as colony-stimulating factors, or exhibit an enhanced skin tropism to account for associated Sweet's syndrome.

Other aspects relating to pathogenesis that have been examined include immunohistochemical studies to detect immune complex deposition in blood vessels. These have yielded inconsistent results, some investigators reporting immunoglobulins and complement within vessel walls [43–45] but others not confirming this [1,46]. Additional studies have found perivascular IgG, IgM, C3 and fibrin, thought to represent non-specific leakage from damaged vessels [47].

Histopathology. The diagnostic histopathological features of Sweet's syndrome include a dense, predominantly neutrophilic, infiltrate located in the superficial dermis, and prominent papillary dermal oedema which may occasionally lead to subepidermal vesiculation [1–4]. Lymphocytes, eosinophils and 'histiocytes' may be present (discussed below). The infiltrate often occurs in a diffuse pattern, but may be perivascular or have an upper dermal band-like distribution [5]. Neutrophil karyorrhexis (fragmented neutrophil nuclei; nuclear dust) is a common finding [2]. The epidermis is often normal, but spongiosis may be present, and rarely neutrophils may extend into the epidermis to form subcorneal pustules [6]. There are two major histopathological controversies in Sweet's syndrome, one being the role of different cell types in the infiltrate, and the other being whether or not vasculitis occurs; these will be briefly discussed.

In most instances, the main cell type present is the neutrophil. Several studies suggest that there may be an admixture of lymphocytes and/or eosinophils, either of which can be prominent in some cases [2,3]. Several small case series have documented a lymphocytic infiltrate over many months, typically in patients who then develop a haematological malignancy [7,8]. There has been debate about whether frankly malignant myeloid cells might be present in some cases, but it seems unreasonable that a skin infiltrate in a patient with circulating leukaemic cells might not have some abnormal myeloid series cells present [9–11], as documented in some reports [9] prior to the claimed 'first' demonstration of this feature [10]. It has also now been clearly documented that 'histiocytoid' cells in the infiltrate actually represent myeloblast-like immature neutrophil granulocytes [12]; although the histiocytoid cells in 41 patients stained positively with monocyte-histiocyte markers, they also stained strongly with myeloperoxidase, and a variety of measures, including fluorescent *in situ* hybridization studies in 14 patients to exclude *bcr/abl* gene fusion, confirmed that these cells did not represent a leukaemic infiltrate.

Historically, the presence of vasculitis excluded the diagnosis of Sweet's syndrome, but recent studies have reported histopathological features consistent with leukocytoclastic vasculitis. These findings include fibrinoid necrosis along with the presence of inflammatory cells within vessel walls. Additional evidence of vessel wall damage includes extravasated erythrocytes and intraluminal thrombi. However, multiple immunofluorescence studies have failed to consistently demonstrate immune complex-mediated injury, further supporting the theory of secondary vessel damage rather than a primary vasculitis. It has been proposed that toxic metabolites released by activated neutrophils may have a

role in the secondary vessel wall injury [1–3,5,13,14]. In a recent study, 74% of biopsies showed all criteria for a diagnosis of leukocytoclastic vasculitis (vessel disruption by neutrophils, leukocytoclasis and fibrin in or around vessels walls [2]), and nearly two-thirds also had erythrocyte extravasation.

Clinical features. The clinical presentation of Sweet's syndrome is usually distinctive. The patient typically appears ill, with a persistent high fever, neutrophilia and an elevated ESR. The cutaneous manifestations consist of erythematous to violaceous tender papules or nodules that often coalesce to form irregular plaques (Figs 50.40 & 50.41) [1–6]. The lesions typically involve the arms, face and neck, but may occur anywhere, and are usually multiple but may be solitary. Later lesions may appear pseudovesicular because of the prominent dermal oedema [1,2,7], and may be studded with tiny pustules resulting from neutrophil migration into the epidermis; in some cases frank bullae develop [8]. The plaques may develop central yellowish discoloration, producing a targetoid appearance [1]. The distribution may be localized, particularly on the face [1–6], or widespread, as may occur in malignancy-associated cases [9]. Several unusual body site distributions have been reported, including localization to recent wounds (Koebner response) [10], localization to old scars [11], localization to an area of lymphoedema (in a patient receiving colony-stimulating factor) [12] and localization to an area of radiotherapy [13]. Photoaggravated and photoinduced Sweet's syndrome have also been reported [14]. Healing usually occurs without scarring, although this can occur, particularly on the hands where it may have a reticulated appearance (see Fig. 50.43).

Fig. 50.40 Sweet's syndrome. The face is often affected.

Fig. 50.41 Sweet's syndrome. Multiple, large erythematous lesions on the legs.

Associated features typically, but not always, include fever and malaise; fever is the most common but may be absent, especially in malignancy-associated Sweet's syndrome [9]. Ocular manifestations are often found, most commonly conjunctivitis or episcleritis. Oral lesions are uncommon in the classical pattern but are more strongly linked with underlying haematological disorders [9]; genital lesions also occur. Subungual erythema has been reported [15]. A variety of systemic manifestations can occur, arthralgia, myalgia and arthritis also occurring frequently. Systemic manifestations of neutrophilic dermatoses are discussed on p. 50.80.

Diagnosis. The proposed diagnostic criteria for Sweet's syndrome state that patients must meet both of the two major criteria and two of the four minor criteria for the diagnosis [16,17].

Major criteria:

1 Acute onset of typical skin lesions

2 Histopathological findings consistent with Sweet's syndrome

Minor criteria:

1 Fever >38°C or general malaise

2 Association with malignancy, inflammatory disorder or pregnancy, or antecedent respiratory or gastrointestinal infection

3 Excellent response to systemic corticosteroids or potassium iodide (KI)

4 Abnormal laboratory values at presentation (three of four required: ESR >20 mm; leukocytes >8000; neutrophils >70%; positive C-reactive protein).

For drug-induced Sweet's syndrome, both major criteria and fever >38°C are required, together with two proposed additional criteria: (i) a temporal relationship between drug administration and clinical presentation; and (ii) a temporal relationship between drug withdrawal and disease resolution [18].

Otherwise, the differential diagnosis is wide. It includes infections (cellulitis/erysipelas, herpes virus infections, viral and bacterial exanthems), inflammatory dermatoses (erythema multiforme, urticaria, erythema nodosum, rosacea, pyoderma faciale, lupus erythematosus, drug eruptions, halogenodermas), tumours (especially leukaemia cutis), and other neutrophilic dermatoses and vasculitides.

Treatment. Treatments used in Sweet's syndrome have been summarized in [1–3]; further comprehensive details of the therapies discussed below are provided. Therapies for Sweet's syndrome are depicted in Table 50.22.

Systemic corticosteroids are a standard and effective therapy for Sweet's syndrome. A 4- to 6-week course of prednisone is generally sufficient to resolve cutaneous and systemic symptoms and signs, but occasionally prolonged low-dosage treatment may be required to prevent recurrences. In addition, topical and intralesional corticosteroids may be used alone or as adjuvant therapy for localized lesions [4].

Many corticosteroid-sparing agents have been reported to be effective in the treatment of Sweet's syndrome. Oral therapy with potassium iodide and colchicine has led to rapid regression of lesions and symptoms. These agents may be reasonable first-line therapy in patients with milder disease [5–9]. Indometacin and clofazimine have been used with success but appear to be less effective than corticosteroids, potassium iodide and colchicine [1–3,10]. Dapsone and ciclosporin have also been reported to be effective therapeutic agents, but require laboratory monitoring because of their potentially serious adverse effects [1–3,11–15].

Table 50.22 Treatment of Sweet's syndrome.

Corticosteroids
Systemic for 4–6 weeks
Adjuvant therapy for localized lesions
Topical
Intralesional
Corticosteroid-sparing agents
Potassium iodide
Colchicine
Dapsone
Indometacin
Clofazimine
Ciclosporin
Cyclophosphamide
Acitretin
Thalidomide
Intravenous immunoglobulin
Interferon-α

Small studies have reported clinical improvement in Sweet's syndrome using etretinate or IFN-γ [4,16,17]. Thalidomide [18], cyclophosphamide [19] and intravenous immunoglobulins [20] have also been used; more toxic agents obviously have a greater place if treatment of an underlying haematological disorder is needed. In one patient, with Sweet's syndrome due to myelodysplasia, and refractory to numerous therapies (including several of the above, plus azathioprine, mycophenolate mofetil and plasmapheresis), use of rabbit-antithymocyte-globulin caused remission of the myelodysplasia and the associated skin lesions. Looking forward, it will be interesting to see the effect of repertaxin, which inhibits chemokine receptors CXCR1 and CXCR2 [21], thereby inhibiting responses of IL-8 (CXCL8) which is a major activator of neutrophils; such approaches may be particularly valuable in those with systemic neutrophilic dermatoses. Other avenues of exploration include development of further inhibitors of IL-8 activated neutrophil chemotaxis, such as thapsigargin [22].

Neutrophilic dermatosis of the (dorsal) hands

Synonyms
- Pustular vasculitis of the (dorsal) hands
- Acral Sweet's syndrome
- Atypical pyoderma gangrenosum

Several case series [1–5] and individual reports have helped to define this disorder (Figs 50.42 & 50.43). An early case series described lesions that morphologically and histologically resembled Sweet's syndrome, but had additional histological features of vessel wall necrosis and deposition of fibrin around vessels, thereby constituting a vasculitis [1]. The presence of vasculitic change in this pattern of disease has varied in subsequent reports [2,6], but most reports do not suggest a primarily angiocentric angiodestructive process [7] and, as in Sweet's syndrome [8], the presence of vasculitis in neutrophilic dermatosis of the dorsal hands is probably a consequence of intense inflammation [9].

Thus, although it has been suggested that this entity might be a vasculitic process in the spectrum of EED [10], a site-variant of Sweet's syndrome, or a, usually superficial, variant of pyoderma gangrenosum, maintaining the term 'neutrophilic dermatosis of the dorsal hands' acknowledges the disease spectrum in a way that pustular vasculitis does not. Reviewing the disease associations of this entity reveals a very similar list to that of Sweet's syndrome, including streptococcal infections/pharyngitis [5], gastroenteritis [5], monoclonal gammopathy [5], IBD [4], myelodysplasia [3], lymphoma [4] or solid organ cancers [3,4]. Additional causes include other infections [11], sarcoidosis [11], medications [12] and SAPHO [13], all associated with Sweet's

Fig. 50.42 Neutrophilic dermatosis of the dorsal hands.

Fig. 50.43 Healing of neutrophilic dermatosis of the dorsal hands (without any associated disease) with reticulated scarring.

syndrome. Additionally, nearly 50% have lesions of Sweet's syndrome at other body sites [9], fever and leukocytosis occur in about 50% [1,2], the disorder can occur as an isolated event [5] or as a recurrent process [2], and treatments with corticosteroids or dapsone are usually effective [9].

In the review of Weenig *et al.* in 2004 [3], 25% of reported cases had had a myelodysplastic syndrome or leukaemia, supporting the view that this is an important association with neutrophilic dermatosis/atypical PG of the dorsal hands [7,14] (and often only becoming apparent after the cutaneous eruption). Indeed, review of dorsal hand lesions published earlier as either Sweet's syndrome or PG [15–18] reveals, for example, cases of newly diagnosed polycythaemia as a result of the dorsal hand lesion (termed PG) [15], of worsening myelofibrosis requiring splenectomy (PG) [16], of postpolycythaemic myeloid metaplasia progressing to leukaemia (Sweet's syndrome) [17] and of leukaemia diagnosed due to the hand lesions (Case 2; neutrophilic dermatosis) [18]. The term neutrophilic dermatosis of the dorsal hands thus lies closest to Sweet's syndrome nosologically, but includes lesions indistinguishable from PG, and has a stronger link with haematological malignancy than does 'ordinary' Sweet's syndrome, justifying retention of this terminology.

Streptococcal infection [19], other infections, neutrophilic eccrine hidradenitis, EED and other differential diagnoses for Sweet's syndrome are all in the clinical differential diagnosis; treatment is as for Sweet's syndrome or as determined by an underlying disorder.

Extracutaneous neutrophilic dermatoses

A number of extracutaneous internal manifestations of neutrophilic dermatoses have been described, separate from internal features of an underlying cause (haematological, inflammatory bowel disease, etc.). These are different from the systemic features (fever, malaise, myalgia, arthralgia, conjunctivitis, scleritis, etc.) that commonly occur in patients with Sweet's syndrome, in that they affect a small minority of patients. Inevitably, they all cause diagnostic problems; most will require involvement of other relevant disciplines for investigation. The main patterns of involvement are listed in Table 50.23 and reviewed in [1,2]. In most instances, 'internal' neutrophilic dermatoses are most common with Sweet's syndrome but several reports also include PG [3–7].

Lung lesions have been described in many reports [1,2]; they have been associated with PG, Sweet's syndrome, subcorneal pustular dermatosis and EED. Clinical features include fever, cough, dyspnoea and pleuritis. About half of the patients reported have had an associated underlying cause, most commonly haematological malignancies, and about a quarter have died despite treatment with corticosteroids as well as specific therapy for the underlying cause. Infection (including fungal infection, in the context of haematological malignancies) must be excluded; bronchial biopsies show sterile, densely neutrophilic and sometimes suppurative masses.

Table 50.23 Some examples of systemic disease associated with neutrophilic dermatoses.

Body system	Clinical features
Lung	Bronchial inflammation/pustules, infiltrates (patchy, lobar or diffuse interstitial), bronchiolitis obliterans organizing pneumonia, effusion, localized (sometimes cavitating) masses
Heart	Aortitis ± stenosis or dilatation, cardiac infiltrate, pericarditis, cardiomegaly, coronary artery occlusion
Bowel	Neutrophilic infiltrate (diffuse, ileal, pan-colitis); visceral abscesses
Liver	Hepatomegaly, elevated transaminases
Spleen	Splenomegaly, aseptic abscesses
Kidney and genitourinary tract	Mesangiocapillary glomerulonephritis, proteinuria, haematuria Prostatic PG with infarction of the urinary sphincter Sterile pyosalpinx
Muscle and tendon	Myalgia, myositis, fasciitis, tendonitis (usually symptomatic in Sweet's syndrome, may be due to exposed tendons in PG)
Bone and joint	Arthralgia, osteitis (may underlie pyoderma gangrenosum, or affect distant scattered sites), chronic recurrent multifocal osteomyelitis, SAPHO, sterile arthritis
Neurological	Neuro-Sweet's syndrome (mainly menigoencephalitis), headache, consciousness disturbance, convulsions, pareses, psychiatric symptoms, brainstem disease, Guillain–Barré disease, bilateral progressive deafness, polyneuropathy, retinal vasculitis
Ocular	Conjunctivitis, scleritis, iritis, uveitis (all non-specific); nodular episcleritis, peripheral ulcerative keratitis
Subcutaneous	Neutrophilic panniculitis, subcutaneous Sweet's disease (see p. 50.90)

SAPHO, synovitis, acne, pustulosis, hyperostosis, osteomyelitis.

Joint disease includes monoarthritis, seronegative polyarthritis and a destructive axial and peripheral polyarthritis. Bone disease is most common in children, as a chronic multifocal osteomyelitis. However, bone involvement may occur underlying ulcerative pyoderma gangrenosum. In one case, retrosternal cavitation due to pyoderma gangrenosum was successfully treated with local infusion of corticosteroids [7]. Myalgia in Sweet's syndrome is a non-specific finding, but rare cases of true myositis have been reported [1,8]; this seems to be particularly associated with use of all-*trans*-retinoic acid for acute promyelocytic leukaemia [8] (a drug also reported to cause cutaneous Sweet's syndrome [9]).

Neurological involvement is uncommon, but causes particular diagnostic problems due to the range of symptoms that can occur (Table 50.23) [1,2,10,11]. Encephalitis and meningitis are the most common patterns. One of the most difficult differential diagnoses is from neuro-Behçet's disease; the presence of HLA-Cw1 (and HLA-B54 in Japanese patients) rather than HLA-B51 is helpful, as is the absence of other features of Behçet's disease (p. 50.56). In the cerebrospinal fluid, neutrophil counts correlate well with levels of the chemoattractant IL-8 [12]. A prompt response to corticosteroids is expected [11], although recurrences may occur; indometacin, dapsone, colchicine and potassium iodide have also been used, especially in recurrent disease. Diagnostic criteria are listed in [11].

Aseptic neutrophilic abscesses are viewed as part of the spectrum of neutrophilic disorders. They may be solitary, but are usually multifocal [1,2,13]. The most common sites of involvement are the spleen, intra-abdominal lymph nodes, around abdominal viscera, liver, lung, pancreas and others. In some cases the skin or subcutaneous tissues may also be involved [1,14,15]. Most cases are associated with inflammatory bowel disease [13,14]; associated neutrophilic dermatoses include Sweet's syndrome (most frequently), PG, relapsing polychondritis, subcorneal pustular dermatosis and intraepidermal IgA pustulosis.

Erythema nodosum

Synonyms
- Erythema nodosum migrans
- Subacute nodular migratory panniculitis
- Chronic erythema nodosum

Definition. Erythema nodosum (EN) is characterized by painful erythematous, and sometimes ecchymotic, nodules on the anterior surface of the legs. The condition may be idiopathic or secondary to various internal diseases or treatments. The incidence of EN is 1–5 in 100 000 population per year, with women accounting for

about 80% of cases, and mainly affecting subjects aged 15 to 40 years [1–5].

History and nomenclature. EN was initially described by Willan in 1798 [6] and was further discussed by Wilson in 1842, who believed it to be a type of erythema multiforme. In 1860, Hebra further described the clinical manifestations of the condition, and suggested 'dermatitis contusiformis' as a name for the disorder [7]. A more chronic variant was described almost a century later, and has been termed 'erythema nodosum migrans', 'chronic erythema nodosum' or 'subacute nodular migratory panniculitis' [8–10].

Aetiology and pathogenesis. EN is thought to be a hypersensitivity reaction that may be triggered by antigens usually associated with infections, typically group A β-haemolytic *Streptococcus*. There are several large patient series [1–9], and some smaller series in paediatric patients [10,11], as well as detailed reviews [12,13], that document presumed aetiological triggers and coexisting diseases. A list of drugs that have been implicated is provided in [14]. The most frequent underlying causes vary somewhat depending on the country, age group, and specialty of the authors. In children, infections predominate as the trigger—typically upper respiratory tract (mainly streptococcal), but *Yersinia* and tuberculosis can be found [10,11]. In adults, streptococcal infection usually accounts for about 10–30% of cases, other infections for 5–10%, sarcoidosis for 10–35%, rheumatological and autoimmune diseases for about 5%, inflammatory bowel diseases for 2–3%, medications for about 5–15% (including oral contraceptives), pregnancy for 2% and malignancies rarely [1–9,12,13]; streptococcal infections, and especially tuberculosis, are less prominent in more recent studies, in which sarcoidosis tends to be a more important trigger. EN is also common in sarcoidosis; in a series of patients with respiratory sarcoidosis who had skin lesions, 20% had EN [15]. In about a third (25–50%) of patients with EN, the cause is unknown.

Triggers of the chronic EN variant are generally unknown, although pregnancy and oral contraceptives have been implicated [9,12,13,16,17]; overall, about a third of cases of EN have no cause identified, and nearly a third of these have lesions that continue for over 6 months [5]. In one study with long-term follow-up, over 62% of patients with idiopathic EN had annual recurrences, but such a course was only seen in one patient with a known cause (Behçet's disease) [7]. Another study reported 56 of 438 patients (12%) to have a chronic form; nearly all were women, half had no obvious trigger (pregnancy was implicated in 40% with a possible identifiable cause) and mean duration was 4.5 months [9]. In some cases of chronic EN, the prolonged course may be determined by the course of an underlying condition, a feature particularly noted with non-Hodgkin's lymphoma [5]. In one case, chronic erythema nodosum in a child resolved when she was found to have coeliac disease and was treated with a gluten-free diet [18]. In some cases the course of erythema nodosum is marked by episodic exacerbations rather than by constant lesions, as in a patient who developed EN in the first half of each of four pregnancies and whenever she used oral contraceptives [17].

The exact pathogenesis of EN is not understood, although it is thought that it may be the result of deposition of immune complexes in the venules of the septae of subcutaneous fat, causing a neutrophilic panniculitis. A study of ten patients with EN showed that they had a fourfold higher percentage of 'primed' neutrophils, assessed by production of reactive oxygen intermediates, in comparison with healthy controls [19]; there was also a correlation with disease activity, but it is not clear whether this is a cause or an effect. There may also be a genetic predisposition to EN; in a study that examined genetic polymorphisms associated with high TNF-α production in a group of patients with EN, with or without sarcoidosis, there was a strong correlation of sarcoidosis-associated EN with TNF AII allele [20]. Erythema nodosum was a frequent finding in a series of patients with fever, arthralgia, mucosal ulcers, erythema multiforme-like and Sweet's syndrome-like lesions, in whom a form of superantigen-induced id reaction was proposed as the mechanism [21]; implicated infections included streptococcus, parvovirus B19, cytomegalovirus, mycoplasma, *Klebsiella* and *Borrelia burgdorferi*. A more detailed list of causes, especially of infectious aetiologies, is provided in Table 50.24 [1–17,21–64].

Drug-induced erythema nodosum is well recorded [1–9,12–14]. In the case of antibiotics, it may be difficult to separate infection-induced from drug-induced EN, but penicillins and sulphonamides have been implicated in several series of patients with EN. Oral contraceptives are a fairly convincing cause; in one series, use of oral contraceptives was 2.5-fold the expected level compared with overall national sales figures [9]. Hepatitis B vaccine has been implicated as a cause in several reports [56,57]. Isotretinoin is of some interest as patients with EN have often had acne fulminans, and some have had immune complexes demonstrated [58,59]; this does create some uncertainty about whether antigens due to inflammatory acne, or *Propionibacterium acnes* itself [60], is actually the cause. Acne fulminans has also been documented as a cause of erythema nodosum migrans [61]. Glatiramer acetate-induced EN is also of interest in having a likely immunological explanation; this drug is a polymer that mimics major basic protein (MBP) and is used to treat multiple sclerosis, in which situation it is known to generate polyclonal antibodies that cross-react with MBP epitopes and that have been implicated in anaphylaxis,

Table 50.24 Causes of erythema nodosum [1–18,21–64].

Idiopathic [1–12]

Medical causes, excluding infections

- Sarcoidosis [1–9,12,13,15] and other granulomatous disease (granulomatous mastitis [20])
- Inflammatory bowel disease (see also Chapter 62) [1–9,11–13,23,24] and diverticulitis [13]
- Rheumatological and autoimmune disease, including lupus erythematosus, Reiter's syndrome, Sjögren's syndrome, Behçet's disease, coeliac disease, autoimmune hepatitis [1–9,12,13,18]
- Malignancy (uncommon, mainly haematological but others are recorded including lung, pancreas, renal, stomach, colon, uterus, cervix and others) [1–9,11–13,25–28]
- Haematological stem cell transplantation [29]
- Pregnancy [1–9,12,13]
- Acne fulminans (sometimes with isotretinoin) [58–61]

Infections [1–13,21]

1 Bacterial

- Group A β-haemolytic *Streptococcus* [1–13,21], uncommonly Group C streptococci
- Other bacterial upper respiratory infections, e.g. *Moraxella* [30], meningococcus
- *Staphylococcus aureus* (uncommon) [1–3]; also breast abscesses, probably staphylococcal [31]
- Tuberculosis (uncommon but over 10% in some geographical areas) [1–9,11–13]
- Leprosy (see Chapter 32) [32]; erythema nodosum leprosum may be chronic [33]
- Atypical mycobacterial infection [12]
- *Yersinia* (up to 15% in children) [10,34]
- Gastrointestinal infections: *Salmonella* [35], *Shigella* [36], *Klebsiella* [21], *Campylobacter* [37,38]
- *Escherichia coli* [2]
- Brucellosis [39,40]
- Cat scratch fever [41]
- *Borrelia burgdorferi* [21]
- Mycoplasma [1, 21]
- Genitourinary: syphilis, gonorrhoea, lymphogranuloma venereum, chancroid [13]
- Others: Q fever, tularaemia, *Pasteurella pseudotuberculosis*, leptospirosis, rickettsiae [12,13]

2 Other infections

- Unspecified upper respiratory infections
- *Chlamydia* (including psittacosis) [40–44]
- Coccidioidomycosis [45]
- Histoplasmosis [46]
- Blastomycosis [47]
- Dermatophytes [48]
- Hepatitis B [1,49] and C [50]
- Parvovirus B19 [13,21,51]

- Toxoplasmosis [8,52]
- Visceral larva migrans [53]
- Others: amoebiasis/giardiasis (both in the same individual), herpes simplex, varicella-zoster, HIV, infectious mononucleosis, measles, aspergillosis, trichomonas, ascariasis [12,13]

Medications

- Sulphonamides, penicillins [1–9,14]
- Halides [1–9,14]
- Oral contraceptive pill [1–9,12,13,17]
- Hepatitis B vaccine [56,57]
- Isotretinoin [58,59]
- Imatinib mesylate [64]
- Others (see text and [12–14])

livedo-like dermatitis and lymphocytic infiltration [62]. Amongst more recently-introduced drugs causing EN, selective serotonin reuptake inhibitors should be noted as they are so widely used [63]. Imatinib mesylate, a now standard drug in treatment of chronic myeloid leukaemia, causes many skin reactions, but amongst these are several neutrophilic dermatoses including Sweet's syndrome, neutrophilic eccrine hidradenitis and EN [64]. Dermatologists also need to be aware of azathioprine as a possible cause of EN, which may cause diagnostic difficulty as it is also used to treat EN in EN leprosum or in inflammatory bowel disease [65].

Histopathology. The histopathology of EN is quite varied and more than one biopsy may be required if there is diagnostic uncertainty. The classical picture is of a septal panniculitis without vasculitis [1–4]. Early lesions of EN demonstrate septal oedema and a lymphohistiocytic infiltrate, with an admixture of neutrophils and eosinophils. The inflammation is typically concentrated at the periphery of the septae and spreads into surrounding fat lobules between adipocytes. Miescher's radial granulomata, which are clusters of macrophages around small vessels or a slit-like space, are also seen in these lesions [1–6]; although characteristic of EN, they are also seen in other disorders that might clinically resemble EN, such as erythema induratum, nodular lesions in systemic fibrosing dermopathy, Sweet's syndrome and Behçet's disease. Finally, there may be oedema and lymphocytic infiltration of the walls of veins, although the amount of vascular involvement is variable [1–4]. Pathologists are divided on whether vasculitis within EN is consistent with the diagnosis; some would say that vasculitis does not occur [2], whereas others describe small vessel vasculitis, and even medium vessel arteritis, in at least some vessels [4]. It is probably reasonable to accept the possibility of some vasculitis at sites of severe inflammation where it may be secondary; in contrast, the erythema nodosum-like lesions of Behçet's disease may have foci of leukocytoclastic vasculitis, lymphocytic vasculitis, arteritis or venulitis scattered throughout lesions [7]. Ulceration should suggest that the diagnosis is not one of ordinary EN.

Many of the varied features of EN pathologically are explained by the chronology of lesions [8]. Older lesions of EN demonstrate widened septae with peripheral fibrosis, and inflammation extending into peripheral regions of fat lobules. There are fewer vascular changes and a shift from a primarily neutrophilic infiltrate to one of primarily lipid-rich macrophages with a 'foam-cell' appearance; in some cases, this lymphohistiocytic lobular infiltrate may predominate [4]. Macrophages without phagocytosed lipid surround multinucleated giant cells, forming granulomas. Histologically, chronic EN has similar features to the later findings in lesions of acute EN. However, vascular proliferation is accompanied by endothelial thickening and extravasation of red blood cells [9],

along with more marked formation of granulomas and lipogranulomas.

Histopathologically, the differential diagnosis includes other causes of septal panniculitis [1–4], although many are distinguished by longer duration (lipodermatosclerosis, localized morphoea), a different clinical picture (eosinophilic fasciitis), or associated features (Behçet's disease). Early lesions of erythema induratum have a greater vasculitic component. Infective causes of panniculitis may be difficult to distinguish. Subcutaneous variants of neutrophilic dermatoses, such as Sweet's disease, cause particular difficulty, especially as some of the aetiologies of these disorders are the same as for EN (and, indeed, the two conditions occasionally coexist [10]); a septal neutrophilic infiltrate in some cases of Sweet's syndrome, and even the presence of Miescher's radial granulomas [11], make the histopathological differential diagnosis difficult.

Fig. 50.44 Erythema nodosum. Note the location of the plaques on the anterior aspect of the lower leg.

Clinical features [1–3]. EN is typically manifest by the sudden onset of painful, erythematous, warm nodules and plaques, typically on the shins, knees and ankles. Lesions may occur at any body site, even the face, but are less common than on the lower legs. The lesions are often more easily palpated than visualized, and are typically bilateral and symmetrical, ranging between 1 and 5 cm in diameter. The nodules may coalesce to form plaques (Fig. 50.44). After several days, the erythematous nodules often flatten and become ecchymotic in colour, finally taking on a yellow-green appearance (similar to an old ecchymosis), sometimes referred to as 'erythema contusiformis'. This transformation is characteristic of EN, making retrospective diagnosis possible. Lesions of EN never ulcerate, atrophy or scar. Lesions erupt and are usually present for 3–6 weeks. In addition to cutaneous manifestations of EN, constitutional signs and symptoms may also be present. Fever, fatigue, malaise, gastrointestinal upset, headache and arthralgia may accompany the characteristic lesions of EN, as may ocular manifestations such as conjunctivitis; laboratory markers of inflammation such as ESR and CRP may be elevated. All of these factors should raise suspicion of secondary rather than primary (idiopathic) EN [4]. A relapsing course appears to be most common in idiopathic cases or those associated with upper respiratory infections.

In the chronic EN variant, lesions may be solitary or few, usually on the lateral part of the lower leg. They are initially nodular but become broader and flatter, vaguely circular or arciform in shape, and often last several months.

Diagnosis. The diagnosis of EN is clinical, although histopathological evaluation may sometimes be necessary to support the diagnosis. Other forms of panniculitis are the main diagnostic consideration on the legs, and primary infective processes must be considered at any body site. In atypical cases of suspected EN (such as the absence of lesions on the legs, persistence or ulceration of the lesions), a deep elliptical biopsy of an active lesion should be performed. A medication history should be considered and a search should be performed for an underlying cause. A chest X-ray, tuberculin skin test and antistreptolysin (ASO) titre may be obtained in such instances to exclude causes such as sarcoidosis, tuberculosis or streptococcal infection.

Treatment. If there is a treatable, or removable (e.g. medication), cause then this should be addressed, as rapid resolution is anticipated. Even without specific therapy for a causative condition, EN typically resolves without treatment, therefore symptomatic support may be all that is necessary for the majority of patients. NSAIDs may also be used [1,2,5], as may potassium iodide 360–900 mg/day [6–9]. The concept that potassium iodide causes release of heparin from mast cells, and that this suppresses delayed hypersensitivity reactions, suggested the use of topical heparinoids [1]. Dapsone can be effective in some cases, as can colchicine. Hydroxychloroquine has been used in chronic erythema

nodosum. Systemic corticosteroids are infrequently required for the treatment of EN and may worsen underlying disease such as tuberculosis; intralesional steroids may be beneficial. Recent reports include use of anti-TNF biological agents [10,11], but these are contraindicated in the presence of infections (in particular, in the context of EN, tuberculosis must be excluded); they may have a place in cases due to inflammatory bowel disease as they could treat this and EN together [11]. A therapeutic ladder for EN is depicted in Table 50.25.

Bowel-associated dermatosis–arthritis syndrome
(see also Chapter 62)

Definition. Bowel-associated dermatosis–arthritis syndrome (BADAS) is defined by the presence of pustular vasculitic lesions associated with blind loops of bowel or other causes of stasis of bowel content.

History and nomenclature. BADAS was first described in 1971 as pustular vasculitis, cutaneous lesions and serum sickness-like reactions in patients who had undergone jejunoileal bypass surgery for morbid obesity [1–4]. The term has been extended to include the same syndrome in patients with IBD, those who have had creation of a blind loop following surgery for peptic ulcer disease [5,6], or with other causes of stasis of bowel content, such as in achalasia or related to a defunctioning colostomy.

Aetiology and pathogenesis. Blood vessel damage secondary to bowel flora antigen-associated circulating immune complexes is thought to be the pathogenesis of the cutaneous lesions. In these patients, peptidoglycans from gastrointestinal flora may be the antigenic trigger for immune complex-mediated vessel damage [4]. Therapeutic response to antimicrobials in some cases supports this concept, and immune complexes have been demonstrated [5,7]. The various underlying conditions can be divided into two main categories:

1 Related to surgery: jejunoileal bypass [1–4,8], gastric resection [5], blind loops (Bilroth II or Roux-en-Y [5,6]), defunctioning ileoanal pouch procedures [9], biliopancreatic diversion [10] and others
2 Related to bowel disease: ulcerative colitis [5,11], Crohn's disease [5,12], diverticulitis of colon [13], jejunal diverticula [14], appendicitis [15] and achalasia of the cardia [16].

In some cases there are combined causes (e.g. surgery for inflammatory bowel disease). In most instances related to surgery, the loop of bypassed bowel, or a blind loop, is in continuity with the intestine, but may be separated as a defunctioning bowel segment [9].

Histopathology. The changes noted in dermal blood vessels from early lesions of pustular vasculitis in patients with BADAS are similar to those in biopsies from patients with Sweet's syndrome [4–8] and Behçet's disease. Several cases have both clinical and pathological overlap with other neutrophilic dermatoses.

Clinical features. The cutaneous manifestations of BADAS begin as small macular lesions that progress into papules and later pustules on a purpuric base, most often on the arms and other areas of the upper body (Fig. 50.45). These pustules measure 0.5–1.5 cm in diameter and typically occur in crops, with each crop lasting up to 2 weeks, and recurring at intervals of several months [4,5,8].

Fig. 50.45 Bowel-associated dermatosis–arthritis syndrome, showing a papule on an erythematous base.

Larger, erythema nodosum-like, lesions also occur, and sometimes larger pyoderma gangrenosum-like pustular lesions. Like Behçet's disease and pyoderma gangrenosum, pathergy seems to have a role in the distribution of the lesions. The cutaneous lesions may be preceded by constitutional signs and symptoms such as fever, flu-like symptoms or myalgia, or by gastrointestinal upset. Arthralgia or non-erosive polyarthritis affecting hands, wrists and other peripheral joints are common; ocular symptoms such as episcleritis [12], and haematuria or proteinuria [8,15] may also occur. Rarely, severe skin lesions and marked systemic manifestations may occur [17].

Diagnosis. It is important to distinguish between BADAS and Behçet's disease, as both may include oral aphthosis and lesions of pustular vasculitis. In order to distinguish between these two disease processes, an evaluation of the bowel, which may include barium studies as well as endoscopy, should follow a thorough patient history and physical examination. Clinicopathological evaluation of skin lesions is required but does not exclude lesions of Behçet's disease or early lesions of either PG or Sweet's syndrome; some patients appear to exhibit a spectrum of neutrophilic dermatoses [12], and a patient with previous pyoderma gangrenosum developed BADAS due to a defunctioning bowel segment after surgery for her ulcerative colitis [9]. Sweet's syndrome is associated with inflammatory bowel disease (p. 50.74) but has also been described with diverticular disease [18], supporting an overlap of diseases.

It is advisable to perform urinalysis in patients with BADAS as, unlike classical Sweet's syndrome, there may be haematuria or proteinuria, possibly representing an immune complex-initiated glomerulonephritis [8].

Treatment. For patients with BADAS following bowel bypass surgery, surgical correction of bowel anatomy often eliminates the signs and symptoms. In other cases, such as patients with blind loops (whether surgically created or due to bowel disease), surgical correction may be difficult and resolution of symptoms is therefore less likely. Manifestations of BADAS may be effectively controlled by the use of systemic tetracycline, metronidazole, ciprofloxacin or erythromycin [4,5,10,19]. Systemic corticosteroids are typically unnecessary for the treatment of BADAS but may be justified either depending on the degree of skin, joint or systemic symptoms, or to concurrently treat inflammatory bowel disease. Other treatments outlined for patients with cutaneous small vessel vasculitis, especially oral colchicine, dapsone or thalidomide have been used (Table 50.26); systemic drugs with an immunosuppressive action may need to be combined with an appropriate antibiotic.

Table 50.26 Treatment of bowel-associated dermatosis–arthritis syndrome.

Surgical correction of bowel anatomy if possible (may not eliminate symptoms if following blind loop)
Symptoms not secondary to or correctable by surgery, or temporary treatment prior to surgical correction
Systemic tetracycline
Systemic metronidazole
Systemic erythromycin
Other systemic treatments that may be used depending on severity of symptoms and associated bowel condition
Corticosteroids
Colchicine
Dapsone
Mycophenolate mofetil
Thalidomide

Pustular neutrophilic dermatoses

This is not a specific entity, but aims to draw together some overlapping disorders and to consider their differential diagnoses. It should be accepted that some of these are probably synonymous terms (Table 50.27) although whether they are viewed as part of Sweet's syndrome, pustular PG [1,2] or simply viewed as

Table 50.27 Nomenclature of some pustular eruptions in the spectrum of neutrophilic dermatoses.

Term	Comment
Pustular PG	Discussed above
Pustular vasculitis/neutrophilic pustulosis	In Behçet's disease, bowel-associated dermatosis-arthritis syndrome; less commonly in systemic lupus erythematosus, primary biliary cirrhosis
Diffuse pustular eruption of ulcerative colitis Vesicopustular eruption of ulcerative colitis Neutrophilic pustulosis in ulcerative colitis [3–7]	Synonymous disorders, appearances vary from Sweet's syndrome to pustular PG Often associated with disease flare, pyrexia, malaise
Vesicopustular eruption associated with hepatobiliary disease [8]	Also viewed as pustular PG Lesions are often necrotizing, although some lesions resemble Sweet's syndrome Associated diseases include autoimmune hepatitis, sclerosing cholangitis, primary biliary cirrhosis and others [8]
Disseminated pustular dermatosis of polycythaemia rubra vera (PRV) [9]	Sweet's syndrome variant with response to dapsone Scattered pustules but also semiconfluent acral grouping and facial plaques, with pustular glossitis, stomatitis and nail dystrophy
Palmar, plantar or vulval pustulosis in Sweet's syndrome [10,11]	May be a presenting feature; distinct from the dorsal hand eruption
Neutrophilic spongiosis (synonym granulocytic spongiotic papulovesiculosis) [12,13]	Intermittent eruption of neutrophilic vesicles, mainly facial and mucosal (see text)
Pyostomatitis vegetans	Oral lesions, 50% with skin involvement: oral lesions may be IBD-associated variant of pustular PG, discussed earlier

unspecified neutrophilic dermatoses is less relevant than recognizing the occurrence of pustular lesions within this spectrum.

Pustular eruptions that are likely to enter the differential diagnosis of the above conditions are numerous. Localized infections such as mycobacterial or fungal infections have been discussed in the differential diagnosis of localized PG. Infections (e.g. streptococcal), folliculitis (sterile or infective), pustular psoriasis, impetigo herpetiformis and acute generalized eruptive pustulosis (AGEP) are all generalized eruptions that may be considered. Non-spongiform pustules have been described due to chronic internal infection, and related to tobacco smoking. At acral sites in infants, scabies and infantile acropustulosis are considerations, and in adults Reiter's syndrome, acropustulosis of Hallopeau or idiopathic acral pustulosis. Both generalized and palmoplantar pustular lesions have been reported in Kawasaki disease [14,15]. Other disorders that fall into the vasculitis or neutrophilic dermatosis spectrum may resemble or coexist with lesions listed in Table 50.27, including intraepidermal neutrophilic IgA dermatosis, subcorneal pustular dermatosis and CSVV.

Some disorders require special consideration as differential diagnoses, either because of close clinical similarity to neutrophilic dermatoses or because their systemic disease associations may require interpretation.

Pyoderma vegetans/blastomycosis-like pyoderma (has also been termed mycosis-like pyoderma, pyostomatitis vegetans and pyodermatitis-pyostomatitis vegetans) [16–19]. This may resemble PG, especially of vegetans type, as a verrucous plaque studded with pustules, and having pseudoepitheliomatous hyperplasia and neutrophilic microabscesses on histology. To further mimic PG, it may occur at sites of injection or tattooing (resembling a pathergic reaction), and, although not exclusively, most patients are immunosuppressed, malnourished or have diseases that have been associated with PG (including IBD (especially ulcerative colitis), leukaemias, lymphoma, diabetes, acne conglobata, hidradenitis suppurativa and dissecting cellulitis of the scalp). However, it can occur in young and fit patients. Oral lesions (which may be the only feature) may occur, especially in those with IBD (the nosology of this 'pyostomatitis vegetans' pattern, and its relationship to PG is discussed on p. 50.70); dorsal hand lesions that are morphologically very similar to neutrophilic dermatosis of the dorsal hands [19] also occur, and a rash very reminiscent of Sweet's syndrome [20]. Various bacteria (not fungi) have been reported as a cause, and the disorder may represent an abnormal response to such organisms. Antimicrobials, rather than corticosteroids or antineutrophil therapies, are indicated if the cause is uncertain, although they do not always eradicate it; the oral disease may respond to topical corticosteroids or tacrolimus, and Crohn's disease-associated cases have been treated with methotrexate and infliximab. Possible diagnostic clues include some cases with raised IgE level, and eosinophilia which is present in 50–90%.

Erosive pustular dermatitis of the leg. Although likely to be suspected when it occurs on the scalp, the commonest site, erosive pustular dermatitis of the leg is a rare condition and may resemble PG. Skin atrophy is typical and may suggest this diagnosis rather than PG; additionally, most patients are aged over 65 years, whereas most PG occurs in younger subjects, but this is not reliable. Several cases (reviewed in [21]) have had bowel problems, some with ostomies, further raising the possibility of PG (although

the underlying condition in such cases has been mainly diverticular disease), and the histology shows neutrophilic spongiosis and an upper dermal neutrophilic or mixed neutrophilic and lymphocytic infiltrate. Reported responses to oral or topical corticosteroids, topical tacrolimus and colchicine, and recurrence around skin grafts as an attempted treatment, also suggest the possibility of PG. As occurs in *amicrobial pustulosis* (below), zinc deficiency, and therapeutic response to zinc, may be a feature [22].

Amicrobial pustulosis associated with autoimmune diseases (APAD; also termed amicrobial pustulosis, follicular impetigo or pyodermatitis vegetans associated with lupus erythematosus or other autoimmune diseases). This is a condition of rapidly evolving, small, semi-confluent pustules that predominantly affects the face, scalp (causing alopecia) and flexures, reviewed in [23]. There is neutrophilic epidermal and ostial exocytosis and spongiform pustules; positive direct immunofluorescence for IgM, C3 and less often IgG is variable and may be vascular or a lupus band. Most cases are in patients with systemic lupus erythematosus, but coeliac disease and other autoimmune conditions occur; corticosteroids or dapsone may be effective, and oral zinc was effective in two cases [23].

Localized reaction to granulocyte colony-stimulating factor (GCF). Colony-stimulating factors are a well-documented triggering factor for neutrophilic dermatoses of different types [24]. A localized form at injection sites may be less recognized. Histology may be Sweet's syndrome-like, a necrotizing vasculitis or predominantly eosinophilic [25].

Neutrophilic spongiosis [12] (originally described as granulocytic spongiotic papulovesiculosis [13]). This was described two decades ago but never fully explained. The cases described had intermittent outbreaks of myriad, semi-confluent, small vesicopustules, predominantly on the face, neck or upper trunk but sometimes at other sites such as axillae. In one case, severe mucosal involvement occurred with significant malaise. One case had dermoepidermal IgA (distinguishing it from intraepidermal neutrophilic IgA dermatosis, which is usually flexural, with annular lesions, no mucosal disease, and intercellular IgA), the other had negative immunofluorescence but did have an admixture of eosinophils in the infiltrate. Neither case had a consistent relationship with medications, making acute, generalized, exanthematous pustulosis unlikely, and neither had any evolution suggesting early spongiotic changes of pemphigus. The illustrated morphology, epidermal neutrophilic disease and extent of mucosal disease were not typical for Sweet's disease, but this might be considered.

Other neutrophilic dermatoses and overlapping or associated variants

Subcutaneous Sweet's syndrome and neutrophilic panniculitis

These relatively rare disorders represent a further part of the spectrum of neutrophilic dermatoses that histologically resemble Sweet's syndrome. Terminology varies between authors. Sutra-Loubet and colleagues reviewed these conditions and suggested a classification of neutrophilic dermatoses, in which 'neutrophilic panniculitis' was distinguished by affecting the fat lobules, whereas 'Sweet's syndrome with subcutaneous involvement' was the term applied if there was involvement of the septae [1]. Lesions that extend more deeply from the fat, or that are non-cutaneous, were termed aseptic neutrophilic abscesses (p. 50.82). However, Cohen [2] preferred to use 'subcutaneous Sweet's syndrome' to describe any variant in which there is neutrophilic panniculitis affecting the lobules, septae or both, with or without associated

dermal involvement, suggesting that neutrophilic lobular panniculitis is best viewed as a descriptive term of which subcutaneous Sweet's syndrome is one cause. Whichever term is preferred, the typical pathological pattern, as in Sweet's syndrome, is dominated by neutrophils, without vasculitis, and the involvement of fat is primary rather than simply deep extension of a dermal lesion [1–4]. Immature myeloid cells may be predominant [5]; the septal variant may be granulomatous [6].

Subcutaneous involvement can occur in patients with Sweet's syndrome or pyoderma gangrenosum, but is increasingly recognized in isolation; dermal/subcutaneous aseptic abscesses can occur in conjunction with abscesses at other sites, or combined with various neutrophilic dermatoses. Subcutaneous Sweet's syndrome is predominantly associated with myelodysplasia [1–4]; as in standard Sweet's syndrome, provocation by all-*trans*-retinoic acid [7] and by colony-stimulating factors [8] have been reported, although in one case it is likely that disease progression rather than granulocyte colony-stimulating factor (used uneventfully for the preceding year) was the cause of subcutaneous Sweet's syndrome [9]. A case related to breast carcinoma has also been reported, and some cases have had preceding viral infections.

Clinically, lesions present as subcutaneous nodules, infiltrated plaques or erythema nodosum-like lesions, at any body site, with or without more typical Sweet's syndrome lesions or occasionally pustules [10]. Fever, malaise, arthralgia, and peripheral blood eosinophilia are all common.

Important differential diagnoses, clinically and/or pathologically, include infections (especially in patients with myelodysplasia), α-1-antitrypsin deficiency, and hepatitis C infection [11]; neutrophilic lobular panniculitis also occurs in rheumatoid disease [12].

Relapsing polychondritis

Relapsing polychondritis is an inflammatory condition associated with antibodies against type II collagen, which is predominant in cartilage. The nose, ears, larynx, trachea, bronchi, joints and eyes are the most obvious sites affected, often with general malaise or fever during episodes of inflammation. Neurological (headache, nerve palsies, hemiplegia and others), cardiovascular (valvular regurgitation, aortic aneurysm, myocarditis, pericarditis, conduction defects and myocardial infarction) and renal (various forms of nephritis) features are also a consequence [1]. Issues regarding the pathogenesis and effects of the disease, and its treatment, are discussed in Chapter 51. However, features that link it with vasculitides and neutrophilic dermatoses are discussed here; in particular, it both occurs with, and has many disease associations in common with, paraneoplastic vasculitis and with neutrophilic dermatoses, and may appropriately be classified as a neutrophilic dermatosis [2], particularly given the view that neutrophilic dermatoses are a continuum of disease with vasculitides.

Some of the diseases that are associated with relapsing polychondritis as well as with vasculitis or neutrophilic dermatoses are listed in Table 50.28; vasculitides and neutrophilic dermatoses that have been reported in association with relapsing polychondritis are listed in Table 50.29. Myelodysplastic syndromes are an important association [1,3–5], possibly associated in a quarter of cases [4] although others suggest around 10% [6,7]; both Hodgkin's and non-Hodgkin's lymphomas are also reported [1,3], as well as a patient who developed paraneoplastic relapsing polychondritis associated with chemotherapy-induced erythroleukaemia after treatment for Hodgkin's disease [8]. Patients

Table 50.28 Diseases that are associated with both relapsing polychondritis and with vasculitis or neutrophilic dermatoses [1,5,7].

Disease category	Examples
Haematological malignancies	Myelodysplastic syndromes (most) Leukaemia Aplastic anaemia Lymphoma Multiple myeloma (usually IgA)
Collagen vascular disorders and autoimmune	Rheumatoid disease Systemic lupus erythematosus Dermatomyositis Sjögren's syndrome Still's disease Crohn's disease Autoimmune thyroid disease
Infections	Hepatitis C virus infection HIV infection
Other neoplasms [5]	Carcinomas of bladder (in a patient with Sweet's syndrome), breast, pancreas, lung/bronchus, colon/rectum, larynx; sarcomas (rarely)

Table 50.29 Vasculitides, neutrophilic dermatoses and associated clinical cutaneous findings that have been associated with relapsing polychondritis.

Disease category	Examples
Vasculitis	Wegener's granulomatosis Churg–Strauss syndrome Takayasu's arteritis Erythema elevatum diutinum Behçet's disease Temporal arteritis Leukocytoclastic vasculitis Lymphocytic vasculitis Pustular vasculitis
Neutrophilic dermatoses	Sweet's syndrome Erythema nodosum Neutrophilic panniculitis
Clinical findings	Oral and genital aphthae Non-follicular sterile pustules Thrombophlebitis Purpura Livedo reticularis Digital infarcts and necrosis Acral erythema nodosum-like nodules Subcutaneous nodules (representing thromboses and various panniculitides)

with an underlying myelodysplastic syndrome were statistically more likely to be male, older and to have additional skin findings in a large case series [7]. Cutaneous features other than those directly related to underlying inflammation of cartilage (e.g. auricular inflammation sparing the lobe, nasal inflammation and saddle nose) are documented in reviews and large case series [1,5,7], and are listed in Table 50.29. In one large series, over a third had dermatological findings in addition to those directly due to associated disorders (such as haematological or collagen vascular disorders); these features occurred with or separate from episodes of chondritis in approximately equal numbers (each about 10%), and 10% had cutaneous vasculitis (90% leukocytoclastic) [7].

Of the associated neutrophilic dermatoses, Sweet's syndrome has particularly been reported [9–11]; erythema nodosum, acral erythema nodosum-like nodules, neutrophilic panniculitis, non-follicular sterile pustules, and oral and genital aphthae occur and are part of the same spectrum [1,5,7]. Other neutrophilic disorders reported with relapsing polychondritis include pyoderma gangrenosum [12,13], aseptic abscesses [14], and erythema elevatum diutinum [15] (which we would classify as a vasculitis rather than a neutrophilic dermatosis, but which is viewed by some authors as a neutrophilic dermatosis [2]).

Rheumatoid neutrophilic dermatosis [1–6]

Rheumatoid neutrophilic dermatosis was described by Ackerman in 1978 [3], and a number of cases have been described subsequently, although it is an uncommon disorder. It is thought likely to be immune complex-mediated, and tends to occur in patients with severe, active rheumatoid disease. A significantly elevated rheumatoid factor may be found, but several patients with seronegative disease have been reported [4,7], including patients with rheumatoid nodules and rheumatoid papules [8]. Lesions occur at any site, mainly the limbs and face, and may consist of papules, nodules or plaques, sometimes with an annular morphology (Fig. 50.46). Urticated, vesicular, crusted and ulcerated lesions may all occur. Rarely, lesions may be bullous [9]. Sweet's syndrome may be difficult to distinguish, and coexistence of the two entities has been reported [7,10], as well as rheumatoid neutrophilic dermatosis associated with pyoderma gangrenosum [11].

Histologically, there is a dense neutrophilic infiltrate that may extend into the epidermis or deeply into the subcutaneous fat; papillary microabscesses may be present [1]. Vasculitis is not seen but leukocytoclasis may occur. The picture is similar to that of Sweet's syndrome, but the latter usually has more prominent dermal oedema and less admixture with other cell types (some eosinophils, plasma cells and lymphocytes may be present in rheumatoid neutrophilic dermatosis) [4].

Fig. 50.46 Rheumatoid neutrophilic dermatosis affecting the hands.

Lesions may resolve spontaneously or as a result of treatment of the rheumatoid disease with immunosuppressive agents. Some plaques may be chronic over a period of months [6]. Topical or oral corticosteroids, dapsone and hydroxychloroquine have all been used with benefit.

A disorder termed 'neutrophilic lobular panniculitis associated with rheumatoid arthritis' is of uncertain aetiology, and has been classified as a lobular panniculitis with vasculitis. Histologically, it is in the differential diagnosis of subcutaneous Sweet's syndrome, discussed above. The few cases reported had a perivascular neutrophilic infiltrate and leukocytoclasis without fibrinoid change or definite vasculitis, although one had associated leukocytoclastic vasculitis in the upper dermis [12].

Neutrophilic eccrine hidradenitis

Neutrophilic eccrine hidradenitis (NEH) has been reviewed in detail in [1,2]. It is characterized by a neutrophilic infiltrate that is centred on and extends into the eccrine coils. Typically, the eccrine apparatus shows vacuolar degeneration or necrosis, and there may be mucinous degeneration around eccrine glands and squamous metaplasia of eccrine ducts. There is usually, but not always, a neutrophilic infiltrate that surrounds the eccrine coil and ducts, forms focal dermal abscesses and may surround vessels, without vasculitis. Oedema and/or haemorrhage may be present [2].

Early reports [3,4] implicated chemotherapeutic agents as the cause, and approximately 90% of cases still occur in the setting of leukaemia (usually acute myeloid type) undergoing induction chemotherapy with cytarabine and anthracyclines. However, other causes have subsequently been recorded, and in some of the patients with leukaemia the eruption precedes the diagnosis or treatment. Most cases occur in the setting of neutropenia; in neutropenia associated with acute myelogenous leukaemia (AML), 2–3% of patients may develop a neutrophilic dermatosis [5]. NEH may occur more frequently in AML subtypes FAB 4 and 5 in which leukaemia cutis and skin tropism of blast cells is more common [6]. In some cases, NEH recurs during successive cycles of chemotherapy, and it can also occur recurrently during chemotherapy for relapses of leukaemia, but not in association with consolidation chemotherapy to maintain remission; it is unclear whether this represents altered type or dose of drug therapy, or an altered drug–disease interaction. Thus, NEH represents a reaction pattern with several causes. Nevertheless, cytotoxicity of drugs on the eccrine coil remains the likely explanation for this dermatosis in most cases. The causes can be summarized into a few main groups (Table 50.30).

Clinically, lesions may resemble those of Sweet's syndrome. They may affect predominantly the head (especially the periorbital regions), neck and upper trunk; in some cases they may be generalized, but in others they are limited (for example, to the limbs, face or ears, or, in one case, around the breasts). The palms or dorsa of the hands are occasionally affected, and lesions have been reported at injection sites as a pathergic phenomenon [5]. If recurrent, they may affect similar sites to those previously affected. Lesions may be plaques, papules, nodules, erythema multiforme-like, or urticated, and may be grouped. Annular lesions have been reported on the dorsa of the hands [7]. Pustules, vesicles and occasionally purpura may be present. The lesions may be painful or tender, but can be asymptomatic, and associated fever is common. Most chemotherapy-related cases occur about 2 weeks after starting treatment, and resolve spontaneously after 2–3 weeks. Associated neutrophilic abscess formation occurred in a patient whose cultures grew 'slight' *Staphylococcus aureus* but in whom the lesions all responded to corticosteroids and not to antibiotics [8].

Treatment options, if required, include topical or systemic corticosteroids and non-steroidal anti-inflammatory agents [1]. Dapsone was used to prevent recurrent episodes in a patient receiving lomustine; it was started 2 days before the chemotherapy and

Table 50.30 Causes of neutrophilic eccrine hidradenitis [see also 1,2]*.

Type of process	Specific group	Examples
Malignant disease	Haematological malignancy	Leukaemias (especially acute myelogenous; also acute myelomonocytic, acute lymphoblastic, chronic lymphocytic, others)
		Hodgkin's lymphoma
		Non-Hodgkin's lymphoma
	Other malignant disease	Testicular carcinoma
		Osteosarcoma
		Wilm's tumour
		Breast carcinoma
		Lung carcinoma
Drugs	Chemotherapy agents	Cytosine arabinoside
		Anthracyclines (daunorubicin, doxorubicin)
		Vincristine, vinblastine
		Bleomycin
		Lomustine
		Mitoxantrone
		Cisplatin
		Dacarbazine
		Etoposide
		6-Thioguanine
		Cyclophosphamide
		Chlorambucil
		Methotrexate
		5-Fluorouracil
		Topotecan
		Imatinib mesylate
	Other drugs	Paracetamol (acetaminophen)
		Zidovudine
		Granulocyte colony-stimulating factor
		Amoxycillin
		Minocycline
Other diseases	Infections	*Serratia marcescens*
		Enterobacter cloacae
		Staphylococcus aureus
		Streptococcal endocarditis
		HIV infection (includes untreated cases)
		Hepatitis C
		Nocardiasis
	Other	Idiopathic neutropenia
		Behçet's disease
		Actinic reticuloid (methotrexate treatment)
No apparent disease association		Rare

*It should be noted that many cases have occurred in the setting of haematological malignancy and multiple-drug schedules, so interpretation of a specific cause is difficult in some instances.

continued for 14 days [9]. It was also successful in a patient with chronic NEH associated with Behçet's disease [10]. Colchicine was effective in a patient with apparently idiopathic, persistent, NEH [11].

A paediatric variant of neutrophilic hidradenitis, variously termed 'idiopathic plantar hidradenitis' or 'recurrent palmoplantar hidradenitis' [1], is discussed in Chapter 44. These disorders are not discussed further here as they are primarily neutrophilic eccrine rather than neutrophilic vascular reactions.

Subcorneal pustular dermatosis and neutrophilic bullous disorders

Subcorneal pustular dermatosis is a rare neutrophilic dermatosis that is associated with monoclonal gammopathy, multiple myeloma, lymphomas, pyoderma gangrenosum, connective tissue disease and IBD [1,2]. Intraepidermal (neutrophilic) IgA pustulosis has some similarities, and has also been linked with monoclonal gammopathy (in 20% of cases) and with lymphomas. These disorders are bullous and are not discussed further here as they do not include a neutrophilic vascular reaction.

Introduction

Many single diseases can produce pathology in one or multiple organ systems. However, not all of the conditions that can affect multiple organ systems are related to each other, so what is it that determines the classification of diseases as 'connective tissue diseases'? We recognize that there are certain features common to all of them—the existence of autoimmunity in the form of autoantibody production or disordered cell-mediated immunity, vascular abnormalities characterized by Raynaud's phenomenon, occlusive vascular disease and vasculitis (although the pathology is not entirely a result of vascular inflammation), arthritis or arthralgia, and skin disease. However, dependence on clinical patterning is unreliable because similar patterns of disease may be seen with widely different pathologies. For instance, the primary vasculitides such as Wegener's granulomatosis or polyarteritis nodosa may share many systemic features of the connective tissue disorders, but so may sarcoidosis with a granulomatous pathology but without autoantibody production.

Despite this problem, it is still true that those disorders contained within the umbrella of the 'connective tissue diseases' share many clinical and pathological features. Indeed, it was this pathological similarity that first suggested that abnormalities of the connective tissue might be the common factor linking these conditions. In 1933, Klinge [1] was the first to propose that rheumatic fever and rheumatoid arthritis were disorders of the entire connective tissue. The changes in the intercellular components of the connective tissue, the presence of fibrinoid necrosis in collagenous tissue and the myxomatous swelling of ground substance were similar to those seen in experimental animals made hypersensitive to foreign protein, and for these reasons he concluded that the rheumatic diseases were caused by hypersensitivity. He included other conditions in which fibrinoid necrosis was a feature, such as polyarteritis nodosa, dermatomyositis and malignant hypertension. The presence of widespread fibrinoid change in the vessels led to the inclusion of systemic sclerosis by Masugi and Yä-Shu [2], and also of systemic lupus erythematosus. However, Klemperer *et al.* [3], with whose work the term 'collagen disease' is associated, struck a note of caution by pointing out that fibrinoid necrosis could be seen in the absence of hypersensitivity mechanisms, for example, in the base of peptic ulcers. It has been stated [4] that the presence of fibrinoid degeneration does not warrant the grouping of the conditions showing this change, nor does it imply an allergic mechanism. It is now recognized that there are various types of fibrinoid with somewhat similar staining properties. They have multiple origins from the degeneration of collagen, from ground substance, muscle, fibrin and other plasma proteins.

In 1950, Klemperer [5] stated: 'The term diffuse collagen disease was originally applied to acute and chronic maladies which are characterized anatomically by generalized alterations of the connective tissue, particularly by abnormalities of its extracellular components. In this case the term can include rheumatic fever, rheumatoid arthritis, polyarteritis nodosa, acute lupus erythematosus, generalized scleroderma and dermatomyositis'. Klemperer disliked the widespread indiscriminate use of the term 'collagen

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

disease' for disorders with unusual clinical or pathological features. He confirmed that his sole intention was to put forward the concept that, 'in certain diseases anatomical investigations reveal conspicuous alterations in the intermediary substances of the connective tissue in a systemic manner'. It is now realized that the connective tissue is not the only tissue involved in these disorders.

It has been customary to consider that systemic and discoid lupus erythematosus (SLE and DLE), systemic sclerosis, localized and generalized morphoea, dermatomyositis, rheumatoid arthritis and Sjögren's syndrome should be grouped together, and this has been supported by evidence of clinical, pathological and immunological overlap. The primary vasculitides, such as polyarteritis nodosa, Wegener's granulomatosis and giant cell arteritis, are sufficiently distinct to be considered separately, although there is much clinical overlap with these diseases too. However, these groupings may not be justified and may even hamper our understanding of these diseases. On the other hand, certain patients with evidence of clinical overlap can be distinguished by characteristic immunological abnormalities, associated with differences in outcome and response to therapy. With the passage of time, other conditions, sometimes newly described, such as eosinophilic fasciitis [6], may have to be added to the group.

When adequate criteria and modern investigative techniques are used, it is apparent that each disorder can usually be distinguished as a separate entity. For example, evidence has been produced that DLE is a separate disorder and not a benign variant of SLE [7–9]. Often, subsets can be distinguished clinically, pathologically or immunologically. Immunological subgroupings are becoming more numerous and complex with the identification of new antigens and the reacting autoantibodies. Specific antibodies may be strongly associated with particular disease patterns, such as the antibody to extractable nuclear antigen found in mixed connective disease or anti-Ro or anti-La antibodies in a clinically distinctive type of lupus erythematosus called subacute cutaneous lupus erythematosus (SCLE; see p. 51.22). Moreover, certain diseases that appear clinically homogeneous may be genetically heterogeneous. The separate genotypes in DLE related to age of onset [8,9], the clinical subsets in SLE and the severity of disease in systemic sclerosis related to HLA-B8 [10] are good examples.

Despite these improvements in investigational techniques, diagnosis of these disorders is sometimes far from easy. Results have to be interpreted in the context of the clinical presentation. Patients are not helped by a diagnosis of 'collagen vascular disease' or 'collagenosis' when suffering from an illness with obscure symptoms and signs, possibly associated with an elevated plasma viscosity, and a weakly positive antinuclear antibody. There is, however, often an early stage in the history of a patient's illness when the full pattern has not evolved. These patients may be said to have an 'undifferentiated connective tissue disease', but the disease usually reveals itself and it is usually ultimately possible to make a precise diagnosis. This is very important for the patient and critical for research, both epidemiological and therapeutic. It is more than an academic exercise as, in the future, specific therapy may well depend on the precision of diagnosis.

Accurate naming of diseases is important for patients, but is also relevant to this chapter. Is the term 'the connective tissue diseases' [11] the most appropriate title for this contribution? We believe that it is because there seems to be no better alternative. Some authorities prefer the older term, 'collagen disease'; others [12] apply it to all inherited or acquired disorders of the connective tissue system. 'Collagen disease' is incorrect because there is no evidence that collagen is primarily at fault. 'Collagen vascular disease' conveys a little more detail, but is still incorrect. The increasing emphasis on immunological abnormalities in these conditions has brought the terms 'autoimmune disease' [13] and 'immunological disease' [14] some popularity, but both are over-inclusive. To avoid the premature coining of a confusing new term we have preferred to continue to refer to 'connective tissue disease' wherever the use of a collective term is unavoidable.

Lupus erythematosus [1,2]

Lupus erythematosus (LE) is usually divided into two main types: DLE and SLE (defined on pp. 51.4 and 51.27 respectively). Although some authors [3] would prefer the term cutaneous LE to DLE, we are continuing to use the term DLE in view of the long usage and to avoid confusion with SCLE. Others [4] suggest classifying LE into three groups—cutaneous LE, intermediate LE and SLE, but this is still controversial. DLE can be subdivided into a localized form in which lesions are confined to the face above the chin, the scalp and the ears, and a disseminated form in which lesions also occur elsewhere on the body [5,6]. Although haematological and serological abnormalities occur slightly more frequently in the disseminated form, the natural history of the two subgroups is similar, and it is likely that they are subsets of the same disorder. SCLE has been described as a subset intermediate between DLE and SLE [7].

Table 51.1 Comparison of data on a series of patients with discoid and systemic lupus erythematosus seen by the authors.

	Discoid lupus erythematosus (*n* 120) (%)	Systemic lupus erythematosus (*n* 40) (%)
Rash	100	80
Joint pains	23	70
Fever	0	40
Raynaud's phenomenon	14	35
Chilblains	22	22
Poor peripheral circulation	26	32
ESR > 20 mm/h	20	85
Serum globulin >3 g (%)	29	76
LE cells	1.7	83
Antinuclear factor(s)	35	87
Homogeneous	24	74
Speckled	11	26
Nucleolar	0	5.4
Precipitating autoantibodies	4	42
WR positive	5	22
Rheumatoid factor positive	15	37
Direct Coombs' test positive	2.5	15
Leukopenia	12.5	37
Thrombocytopenia	5	21

ESR, erythrocyte sedimentation rate; LE, lupus erythematosus; WR, Wassermann reaction.

The more controversial point is whether DLE and SLE are variants of the same disease. The evidence in favour of this may be summarized as follows:

1 The cutaneous lesions of SLE and DLE may be clinically and histologically indistinguishable.
2 Certain clinical features are found in both conditions (Table 51.1).
3 Similar haematological, biochemical and immunohistochemical abnormalities can be demonstrated in both conditions (Table 51.1), although the incidence of abnormalities is lower in DLE.
4 Patients with DLE occasionally develop evidence of overt SLE.
5 Patients with SLE may develop typical lesions of DLE in the chronic phase of their disease [8].
6 Conditions such as lupus panniculitis, a recognizable clinical and pathological entity, occur in both DLE and SLE.

This seems to be formidable evidence, but the following observations require explanation.

1 The risk of a patient with DLE developing overt SLE is small. It varies from 1.3% [9] to about 6.5% [2,10]. The risk is higher in patients with disseminated DLE (22%) than in DLE confined to the head and neck (1.2%) [10]. In some series [11], such conversion was not encountered despite follow-up for nearly 30 years. A retrospective study [12] of 127 patients with SLE showed that eight patients had had discoid lesions from 2 to 29 years.
2 The presence of laboratory abnormalities in DLE does not in itself appear to predispose to the development of SLE [13], although they are common in disseminated DLE [10,14]. The same prognosis was found in a subgroup intermediate between discoid and SLE as in patients with uncomplicated LE [11].
3 Immunoglobulins and complement are present in uninvolved skin of patients with SLE and absent in patients with DLE [15].
4 Most patients with DLE exposed to UV radiation, stress, trauma, etc., do not develop the systemic disease.
5 The age and sex distribution of SLE [16] is strikingly different from that of DLE [17]. It has been proposed [2,18] that both SLE and DLE are initiated by the occurrence of somatic mutations in lymphocytic stem cells of predisposed individuals, and that they are genetically distinct. There are at least three genotypes related to age of onset in DLE [19] and the female/male ratios found in each disease suggest that there is only one X-linked allele involved in genotype 2 and two in genotype 3. On the simplest interpretation, three 'forbidden clones' [20] of lymphocytes synthesizing cellular autoantibodies develop in SLE, whereas only one 'forbidden clone' is involved in DLE. Autosomal predisposing alleles are probably also present in all the genotypes in both SLE and DLE. The nature of these somatic mutations and the predisposing alleles remain unknown, but almost certainly include polymorphisms of genes determining the production of inflammatory cytokines [21].
6 Further evidence that DLE and SLE are genetically different disorders is now available from studies of histocompatibility antigens in the two diseases [22]. There is a significant difference in the incidence of HLA-B8 in female patients developing each disease between the ages of 15 and 39 years. It is considered that patients may have the predisposition to SLE, DLE or both. Those patients who 'convert' from DLE to SLE, and those patients with SLE who have discoid skin lesions, must be genetically predisposed to both conditions. Those patients with only a genotype for DLE will never convert, even when subjected to environmental factors, such as drugs, bacterial or viral infections, UV radiation and stress. More recent molecular genetic data give further support to this concept [23].

At present, it is not possible to determine the genetic pattern of individual patients or to predict accurately the small proportion of patients with DLE-like lesions who will develop SLE, although the link with HLA-B8 has already been discussed [22]. Humoral autoantibodies are not the primary pathogen in these diseases [24], but they probably reflect the underlying cell-bound autoimmunity that causes the disease. Nevertheless, they may enhance tissue damage [25], and specific antibodies may be responsible for certain features such as the risk of neonatal LE (anti-Ro) and for thrombosis (the lupus anticoagulant). The ability to synthesize particular antinuclear antibodies may depend on additional genetic factors, and this could account for the absence of such antibodies in certain patients with active disease. If the possession of a serological abnormality in DLE implies a predisposition to transformation into systemic disease, we would expect the sex ratio of this group to be similar to that for SLE. This is not the case. The sex ratio in patients with DLE and laboratory abnormalities is not significantly different from the sex ratio in patients without abnormalities.

From consideration of the clinical features, the natural history, the age and sex distribution, and studies of histocompatibility antigens, it is concluded that patients with DLE and haematological and serological abnormalities are not cases of SLE in disguise, but are cases of DLE, which is a separate entity from SLE, and has a different genetic background. Each of these entities, however, consists of several subsets, also genetically determined.

Discoid lupus erythematosus

Synonyms
- Cutaneous lupus erythematosus
- Chronic discoid lupus erythematosus

Definition. DLE is a benign disorder of the skin, most frequently involving the face, and characterized by well-defined, red scaly patches of variable size, which heal with atrophy, scarring and pigmentary changes. The histology is characteristic. There are haematological and serological changes in approximately half of patients, and these changes, with other evidence, suggest an autoimmune aetiology.

Aetiology. This disorder has a characteristic age and sex pattern. The disease affects twice as many females as males, with a peak age of onset in the fourth decade in females and slightly later in males, although it can occur at any age. In a series of 1045 cases, 3% began under 15 years of age and 2.5% at over 70 years [1].

Genetic factors. Familial cases of DLE do occur. A family history was found in 4% of one series [2]. Steagall *et al.* [3] reported the condition in identical twin sisters, and listed 25 families with two or more members who had DLE or SLE. Studies also indicated a striking relationship between polymorphic light eruption and DLE, first in twins [4] and then in a large cohort of patients and their relatives, suggesting a common genetic background for these disorders [5]. Differences in the incidence of histocompatibility antigens [6–8] have supported the concept of multiple genotypes. Positive associations with HLA-B7, -B8, -Cw7, -DR2, -DR3 and -DQw1 are reported [9], but not always confirmed. The relative risk is increased with certain combinations of antigens—HLA-Cw7, -DR3 and -DQw1 and for HLA-B7, -Cw7 and -DR3. The extended haplotype—HLA*01, B*08, DRB1*0301—is associated with both SCLE and DLE, and the A*03, B*07, DRB1*15 haplotype has been associated with DLE alone [9]. Patients of both sexes developing lesions between the ages of 15 and 39 years have an increased incidence of HLA-B7, and females over the age of 40 years of HLA-B8, compared with controls [7].

Before the modern understanding of lymphocyte function [10], it was proposed that genetic factors, including somatic mutations, are implicated in the pathogenesis of the disease [11,12]. These studies suggested that there are at least three. The initiation of the disease may result from the occurrence of random events, either related to somatic mutation or to environmental factors. The model suggests that: (i) three mutations affecting autosomal genes; (ii) four mutations (one of which affects an X-linked gene); or (iii) five mutations (one involving an X-linked gene) could explain the three genotypes. The mutations interfere with control of lymphocytes; after a latent period of approximately 4 years in females and 2 years in males, clinical signs of the disease become manifest. Normally, an endogenous defence mechanism would control lymphocyte function and prevent self-harm. Environmental factors, by interfering with this defence mechanism, can precipitate or exacerbate the disease (Table 51.2). Supporting this view, DLE-like lesions have occurred after allogeneic bone marrow transplantation [13].

Table 51.2 Environmental factors associated with the onset or exacerbation of discoid lupus erythematosus [14–24].

Environmental factors	Frequency
Trauma (including X rays, diathermy, chemical burns)	11%
Stress	12%
Ultraviolet exposure (including PUVA and laser light)	5%
Infection (including herpes zoster and old smallpox vaccination)	3%
Drugs (including isoniazid, penicillamine, griseofulvin, dapsone)	Unknown
Seasonal exacerbation	Winter 10% Summer 50%
Cold exposure	2% (17% disease exacerbation)
Pregnancy	1% (onset)
Pre-menstrual	13% (disease flare)
Hormone replacement therapy	Unknown

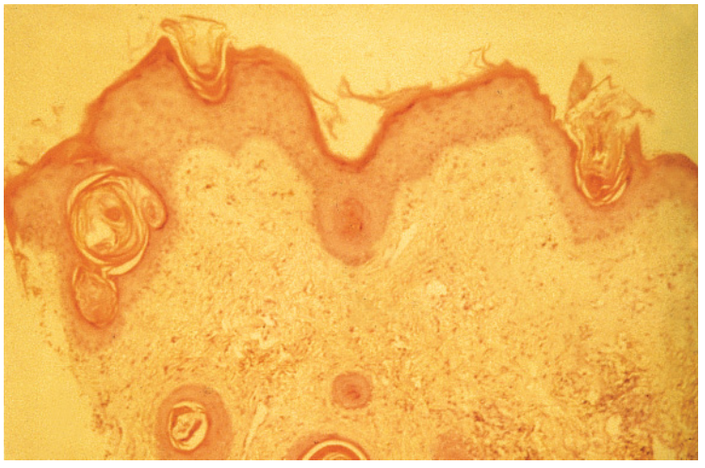

Fig. 51.1 Discoid lupus erythematosus: there is atrophy of the epidermis, keratotic plugging, liquefaction degeneration of the basal layer, oedema and hyalinization of the connective tissue below the epidermis and a marked inflammatory infiltrate.

Ultraviolet light and disease exacerbation [25]. In 120 patients at Leeds, UK a history of exacerbations with sunlight was found in 68%. In those with photo-aggravated disease, both wavelengths shorter than 329 nm and the whole range through UVB, UVA and visible light can produce lesions under experimental conditions. Skin lesions clinically and histologically compatible with lupus erythematosus (LE) were induced by UVB and UVA radiation in 42% of patients with DLE, 64% of patients with SCLE and 25% of patients with SLE.

Viruses. The finding of antibodies to reovirus RNA in 42% of patients suggests that viruses may have a role in DLE [20].

Pathology [1]. The various clinical types of LE show an essentially similar histological picture (Figs 51.1 & 51.2), and the subsets of LE cannot be easily distinguished histologically [2]. The salient features are as follows:

1 Liquefaction degeneration of the basal cell layer of the epidermis
2 Degenerative changes in the connective tissue, consisting of hyalinization, oedema and fibrinoid change, most marked immediately below the epidermis

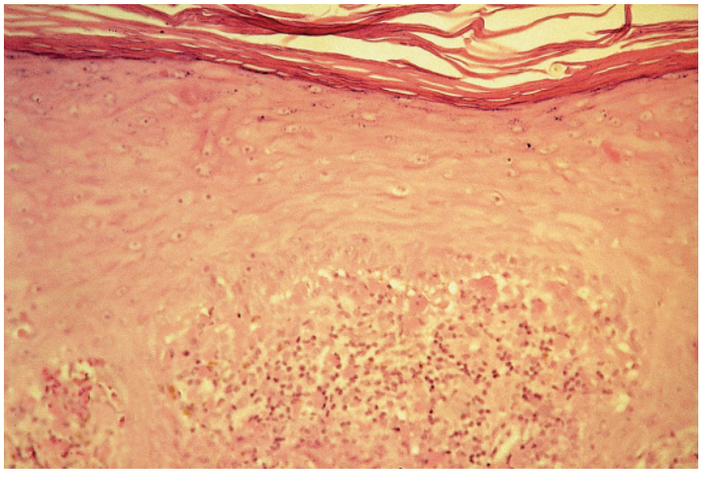

Fig. 51.2 Discoid lupus erythematosus: the degeneration of the basal layer and predominantly lymphocytic infiltration are well shown.

3 A patchy dermal lymphocytic infiltrate with a few plasma cells and histiocytes, particularly around the appendages, which may be atrophic.

The presence of at least two of these is essential to the histological diagnosis of LE. The following changes may also be found, but are less important:

1 Epidermal atrophy with relative hyperkeratosis and plugging of the follicular mouths, associated with pilosebaceous atrophy
2 Thickening of the basement membrane of the epidermis and sometimes of small vessels
3 Premature elastotic degeneration of collagen in light-exposed areas.

In more acute forms there is less hyperkeratosis and dermal infiltration, but more dermal oedema, liquefaction necrosis and atrophy. Disruption of the elastic lamina and, rarely, endothelial proliferation and thrombosis of the deeper vessels of the dermis have been reported [3]. Biopsy material from lesions on the palms stained for alkaline phosphatase activity shows irregular capillary loops with branching, 'dead end' spurs and coiling [4]. In SLE, similar changes are found in involved and uninvolved skin. In tumid lesions the dermal infiltrate can be very dense, and sometimes almost granulomatous. Dermal deposits of mucin occur [5], which may be diffuse or localized, and form nodular lesions. Deposits may be very gross [6]. Occasionally, irregular hyperplasia of the epidermis occurs, and there may be clefts, or even bullae, between the dermis and epidermis. Although keratotic plugs are usually found in the openings of the hair follicles, they may also block the sweat ducts or occur independently of either structure. Sometimes, the hair follicles contain concentric layers of keratin instead of hairs. Atrophy of the prickle cell layer occurs to a variable extent, and sometimes there may be acanthosis. Melanin may be found in the upper dermis as the result of pigmentary incontinence. Blood vessels are dilated and the upper dermis is oedematous.

Immunopathology. Immunohistology [7] shows the presence of immunoglobulins IgG, IgA, IgM and complement at the dermal–epidermal junction, in skin lesions present for 6 weeks or more, in approximately 80% of patients [8]. Homogeneous, granular or thready patterns occur, but the deposition is usually homogeneous in older lesions. They are more frequent on the face and in untreated lesions, but are rare on the trunk [9], and decrease after treatment with topical corticosteroids. They do not occur in uninvolved skin, unlike the majority of cases of SLE. For the diagnosis of DLE lesions, light microscopy is most valuable and should be carried out before direct immunofluorescence [10]. Immunoreactants are also found in oral mucosa and the conjunctiva [11]. C1q deposits are found in 29% of patients with immunofluorescent-positive DLE, compared with 90% in SLE, and the presence of such deposits implies an increased risk of eventual systemic disease [12]. Deposits at the dermal–epidermal junction are not specific to LE and have been found in many other circumstances (Table 51.3). However, in these diseases the deposits are less prominent at the dermal–epidermal junction and are more striking in the blood vessel walls. In LE, the deposits are heavy and contain several immunoglobulin classes, whereas in the other diseases only a single immunoglobulin class is usually present. In scarring alopecia caused by LE, the deposits occur around hair follicles, a feature not seen in other types of scarring alopecia [13].

Properdin, indicating complement activation, has been demonstrated at the dermal–epidermal junction in 70% of lesions, usually in association with deposition of immunoglobulin, C3 and C4 [14]. It may also be found in non-lesional skin. Serum properdin levels are raised in DLE and SLE [14].

Table 51.3 Diseases associated with the presence of immunoreactants at the dermal–epidermal junction that may be confused with lupus erythematosus.

Mixed connective tissue disease
Systemic sclerosis
Dermatomyositis
Sjögren's syndrome
Myasthenia gravis
Porphyrias
Granuloma annulare
Necrobiosis lipoidica
Amyloidosis
Graft-versus-host disease
Psoriasis
Pyoderma gangrenosum
Sarcoidosis
Leprosy
Erythema multiforme
Pityriasis lichenoides acuta
Granuloma faciale
Keratoacanthoma
Scabies
Facial telangiectases
Bullous pemphigoid

Immunocytochemistry. The majority of infiltrating lymphocytes are T lymphocytes and express Ia-like antigens, as well as the γδ T-cell receptor. There is some evidence of clonal selection of T-cell receptors, suggesting an antigen driven response in the skin. Infiltrating cells are a mixture of $CD4^+$, $CD8^+$ and HLA-DR^+ cells in all types of cutaneous LE, with $CD4^+$ cells slightly predominating [1]. There are also populations of mainly $CD45RO^+$ memory cells, with few activated $CD45RA^+$ differentiated effector cells [2]. In addition, there is evidence of vascular activation with up-regulation of ICAM-1, vascular adhesion molecule-1, E-selectin and P-selectin [3].

The description of the presence of skin-homing cytotoxic lymphocytes, expressing granzyme B, in association with a Th1 pattern of cytokine expression, and targeting the epidermal adnexal structures, is an important step in our understanding of the process of inflammation and scarring in cutaneous LE [4]. Although the pattern of cytokine expression may be variable, with interleukins 2 (IL-2) and -4 absent, and IL-5 and IL-10 variably present, the expression of predominantly type 1 interferons is likely to induce auto-reactive cytotoxic lymphocytes as indicated by Wenzel *et al.* [5].

Identification of the target antigen that drives this response is urgently needed to understand the pathogenesis of the discoid pattern of cutaneous lupus. Information on the interplay of the genetic control of cytokine profiles also gives important clues to the pathogenesis of the various sub-types of cutaneous lupus, particularly the role of TNF-α and IL-10 and their balance [6].

Histopathological differential diagnosis. Chronic DLE must be differentiated from other conditions in which lymphocytic infiltrations of the dermis occur.

1 In Jessner's lymphocytic infiltration [1], the dermis shows large circumscribed aggregations of lymphocytes, often concentrated round the dermal appendages and blood vessels, with a normal epidermis. Sometimes, the infiltrate may extend into the fat of the subcutaneous tissues. Immunohistochemical studies show that the cells are predominantly T lymphocytes [2], as they are in DLE and SLE [3]. Monoclonal antibody studies show an increase in natural killer (NK) cells and activated cytotoxic T lymphocytes in Jessner's lymphocytic infiltration [4].

2 In polymorphic light eruption (PLE), the infiltrate is less prominent and more likely to occur around blood vessels than cutaneous appendages. Liquefaction degeneration is infrequent but, if present, it may be difficult to distinguish from that of DLE. There may be spongiotic changes in the epidermis and parakeratosis (the histology has some features of eczema, but the dermal infiltrate is usually denser). Lever and Schaumburg-Lever [5] believe that most cases of Jessner's lymphocytic infiltration and the plaque-type of PLE represent variants of chronic DLE, but immunoglobulin does not occur at the dermal–epidermal junction in either of the first two conditions [6,7].

3 Scattered patches of lymphocytes occur in the dermis in lymphocytic lymphoma, but there are no epidermal changes.

4 The infiltrate in lymphocytoma cutis (Spiegler–Fendt sarcoid; see Chapter 57) is usually separated from the normal epidermis by a band of normal collagen, and consists of lymphocytes and a few histiocytes. Sometimes, a follicular arrangement is present, with lymphocytes surrounding islands of histiocytes resembling lymph node follicles.

5 In benign lymphocytic infiltration, polyclonal T and B cells form aggregates in the dermis.

Sometimes, patients show clinical, histopathological and immunofluorescence overlap between DLE and lichen planus. In such cases, a definite diagnosis cannot always be made, and it is likely that such patients have both diseases [8].

Incidence. Because the condition is persistent, DLE appears to be more common than it really is. The incidence among new patients in the Department of Dermatology at Leeds is approximately 4 or 5 in 1000. It is said that it is only half as frequent in black people [1], although the distribution is worldwide.

Clinical features

Symptoms. The patient usually presents with a rash, but on questioning a history of Raynaud's phenomenon, chilblains or poor peripheral circulation is often obtained. In 120 patients at Leeds, 14% had Raynaud's phenomenon and 22% had chilblains; a poor peripheral circulation, without a definite story of Raynaud's phenomenon, was noted in a further 26% of patients. Joint pains are complained of by approximately one-quarter of patients, but this is similar to the incidence in controls [1]. Most patients have no symptoms of systemic upset, even with widespread cutaneous disease, although fatigue is not uncommon in those with severe disease.

Most patients have disease limited to the head and neck (localized DLE), but a few have much more extensive disease, potentially affecting any area of the skin (disseminated DLE).

Localized disease. The face is most commonly affected, and the scalp, ears, nose, arms, legs and trunk to a lesser extent. The circumscribed or discoid type is the most frequent (Fig. 51.3), and occurs particularly on the cheeks, the bridge of the nose, the ears, the side of the neck and the scalp. Lesions may be bilateral, although not necessarily symmetrical, or unilateral. Alopecia occurs in the scalp lesions in approximately one-third of patients [2], and is usually permanent (Fig. 51.4). The eyebrows may be sparse, with erythema of the eyebrow skin. Usually, lesions occur as well-defined erythematous patches, varying in size from a few millimetres to 10–15 cm. There is adherent scale in many cases, and when this is removed its undersurface shows horny plugs which have occupied dilated pilosebaceous canals. This so-called 'tin-tack' sign can sometimes also be seen in localized pemphigus foliaceus [3]. When not obscured by scaling, these horny plugs can be seen on direct examination. The surface may present a dirty brownish yellow appearance that is rough to the touch, because of the follicular plugging. If hyperkeratosis is marked, a warty lesion with a red, slightly raised edge results. This warty type of LE is most commonly seen on the nose, temples, ears and scalp, but may also occur on the palms and soles and causes difficulty with walking (Fig. 51.5) [4].

Fig. 51.3 Discoid lupus erythematosus: the typical scaling is well shown.

Fig. 51.4 Discoid lupus erythematosus of the scalp: note the follicular plugging.

Non-itching hyperkeratotic papulonodular lesions on the arms and hands, resembling keratoacanthoma, hypertrophic lichen planus or nodular prurigo, also occur [5]. Sometimes, the appearance resembles psoriasis. In other cases, there may be very little hyperkeratosis. Lesions then present as reddish, well-defined, almost smooth plaques with little or no scaling. Sometimes, these plaques may show prominent flattening in the centre, giving rise to annular lesions. Over the course of some months, particularly

Fig. 51.6 Discoid lupus erythematosus: the pre-auricular type with pigmentation around the scarred area.

Fig. 51.8 Typical lesions in the ear.

if treated, lesions flatten and may clear completely without much scarring. More frequently, a thin white scarred area, often with a slightly raised, red border or zone of hyperpigmentation, remains (Fig. 51.6). Localized cribriform scarring occurs, particularly on the face (Fig. 51.7). Wide follicular pits, sometimes containing scale or blackheads, occur mainly in the concha or triangular fossa of the ear (Fig. 51.8). They occur in up to one-third of cases [6] of DLE but they also occur in SLE. In approximately 7.5% of patients, the lesions on the face resemble rosacea, and differentiation from true rosacea can be difficult, particularly as in approximately 15% of cases patients with true rosacea show exacerbation by sunlight. Low titre ANA also occurs in rosacea, complicating assessment, but has no clinical relevance [7]. LE of this rosaceous type presents with reddish nodular lesions on the nose, cheeks, forehead and sometimes chin, and is associated with a diffuse erythema of the face and easy flushing. Usually, unlike true rosacea, there are no pustules (Fig. 51.9) [8]. Biopsy is required to distinguish between LE and rosacea.

Fig. 51.9 Discoid lupus erythematosus: a rosaceous pattern seen in 7.5% of patients.

Fig. 51.10 Discoid lupus erythematosus: tumid lesions of the face.

Tumid lesions may occur, in which the tissues are swollen, brawny, warm and tense (Fig. 51.10). The surface shows a reddish, mottled appearance resulting from scarring. This type of lesion may be many centimetres in diameter and involve the whole of one cheek, or even the whole of a limb. Another clinical type of DLE results in annular atrophic plaques [8] on the face, neck and behind the ears. The centre of the plaques is depressed and sclerotic, and the lesions resemble morphoea, lichen sclerosus or 'annular atrophic plaques' [9]. Early lesions show IgG and complement at the dermal–epidermal junction [8], but repeated biopsies may be necessary to confirm the diagnosis.

Scarring. Pigmentary disturbances are common, especially in dark-skinned people, and there is some evidence that DLE is more severe in black people (Figs 51.11 & 51.12) [10]. Patches of leukoderma may be interspersed with hyperpigmented areas. If relapse occurs, it usually starts in the reddish zone surrounding the scar. Calcification may occur in the plaques [11]. Lesions on the ear lead to considerable atrophy and scarring (Fig. 51.13).

Disseminated DLE (DDLE). Characteristic lesions of DLE may occur in a widespread pattern on the trunk and limbs, or may be localized to other body sites. This occurs almost always in women, and they are usually cigarette smokers. The appearance may be indistinguishable from the papulosquamous type of SCLE (see p. 51.23), but scarring occurs in most patients. This variety tends to be persistent, resistant to therapy and associated with severe psychological upset. Lesions on the dorsa of the hands (Fig. 51.14),

Fig. 51.11 Discoid lupus erythematosus in a black person.

palms [4] or toes (Fig. 51.15) [12] occurred in 6% of patients at Leeds. Purplish plaques may occur on the front of the knees and on the back of the heels. Another disseminated variety results in a reticulate telangiectasia, usually seen on the arms, legs and the back of the calves. This type of telangiectasia is probably similar to 'lupus erythematosus telangiectoides', first described by Crocker [13]. The appearances are characterized by a persistent, blotchy, reticulate telangiectasia, which occurs on the face, neck, ears, dorsa of the hands, breasts, heels and on the sides of the feet (Fig. 51.16). Healing occurs with punctate atrophic scarring. The histology of this type of lesion shows an atrophic epidermis, with dilata-

Fig. 51.15 Discoid lupus erythematosus: characteristic redness and scaling of the toes.

tion of the superficial vessels of the skin and slight infiltration of the papillary part of the corium. A further, more annular variant has been called 'lupus erythematosus gyratus repens' and consists of a migratory gyrate annular erythema with the histological features of LE (Fig. 51.17), although the lupus band test is negative [14]. There may be an underlying carcinoma. A pruritic, chronic, discrete, umbilicated papular eruption may occur on the back, and results in acneiform hypertrophic follicular scars [15].

Occasionally, one or more fingers may show a curious atrophic spindling, sometimes with hyperextension of the terminal phalanges and dystrophy of the nails (Fig. 51.18). The fingers and toes may become markedly atrophic, with patchy erythema and tuft resorption on X-ray. Rarely, bullous lesions [16] may occur. Arteritic lesions resembling those of Degos' syndrome or disseminated atrophie blanche occasionally occur, and linear lesions following Blaschko's lines have been reported [17].

'Chilblain lupus' (Fig. 51.19) [18]. Approximately 6% of patients, predominantly female, develop chilblain-like lesions chiefly on the toes and fingers, but also on the heels, calves, knees, knuckles,

Fig. 51.16 Telangiectatic lupus erythematosus of the cheek.

Fig. 51.17 Gyrate erythema in lupus.

elbows, nose and ears. Usually, but not always, the chilblain lesions occur some years after the development of discoid lesions on the face. It can be precipitated by pregnancy [19]. When the discoid lesions remit with treatment, the chilblains persist. Less commonly, discoid and perniotic lesions start simultaneously, and sometimes perniotic lesions occur alone. Histology and immunohistology is that of DLE, and the non-lesional skin gives a negative fluorescent band test. Some patients may have cryofibrinogenaemia or cold agglutinins. Patients are usually Ro antibody-positive [20]. They are also either smokers, or have markedly abnormal peripheral circulation with low resting blood flow. Approximately 15% of patients develop SLE, and this occurs more frequently in those who develop both forms of cutaneous LE simultaneously and in those with the erythema multiforme syndrome.

Fig. 51.18 Unusual spindling of the fingers and hyperextension of the distal phalanges in discoid lupus erythematosus.

Fig. 51.19 'Chilblain' lesions in a patient with Ro-positive systemic lupus erythematosus.

Nail changes. Subungual hyperkeratosis is more common than the red-blue colouring of the nail plate with longitudinal striae and crumbling away of the nail [21]. The changes may respond to chloroquine.

Mucous membranes [22]. These are involved in approximately 24% of patients. Nasal mucosal lesions occur in 9% and hyperkeratotic lichen planus-like plaques on the buccal mucosa and palate in a similar number. The lips show slight thickening and roughness and redness, sometimes with superficial ulceration and crusting. Healing occurs with some scarring. Erythematous patches

Fig. 51.20 Discoid lupus erythematosus of the perianal area.

with a depressed centre and superficial ulceration occur on the inner cheeks, tongue and on the palate. Oral lesions may resemble leukoplakia [23]. Erythematous lesions occur on the vulva in 5%, or around the anus (Fig. 51.20) [24].

Eye lesions. Velvety oedema and marked redness of the conjunctiva may occur. Palpebral lesions have been reported without lesions elsewhere on the face [25]. The eyelids are red, especially peripherally, and are slightly infiltrated and always scaly. Lesions are most common on the lower eyelids, especially on the outer third. The free edge is rarely completely involved. Erythematous plaques on the lower eyelids occur in 6%, and may be associated with conjunctival scarring (Fig. 51.21), and symblepharon [26]. The lesions may itch, and are exacerbated by trauma and sunlight. Corneal involvement is rare. Superficial punctate keratopathy and stromal keratitis have been reported [27]. Acute mucinosis of the eyelids and periorbital skin can occur [28].

Fig. 51.23 Lupus erythematosus profundus.

Lupus erythematosus and erythema multiforme-like syndrome [1,2]

Synonym
- Rowell's syndrome

The distinctive syndrome of cutaneous LE, either discoid or systemic, occurring with lesions resembling erythema multiforme on the face, neck, hands, chest and in the mouth (Fig. 51.22) was first described by Rowell in 1963 in patients with discoid LE, but may be seen in both subacute and systemic disease. Characteristically, it lasts from a few days to over a month, but episodes may occur at intervals over a period of 20 years. No precipitating factor can be elicited. The lesions are at first papular, but later a ring forms and the edge becomes vesicular. Bullae, necrosis and ulceration may develop if the reaction is intense, although sometimes healing occurs without scarring. Patients with this syndrome also frequently have perniotic lesions [3]. They show a characteristic pattern of serological abnormality, in that the speckled type of antinuclear factor is associated with rheumatoid factor and the same precipitating antibody to saline extract of human tissues (anti-SjT). Anti-SjT is now thought to be identical to anti-La (SS-B). The syndrome has been reported in identical twin sisters, one of whom had DLE and the other SLE [4]. In patients with SLE, the homogeneous type of antinuclear antibody may also be present in the serum. When the syndrome occurs in DLE, the dermal–epidermal band test is positive in the discoid lesions and negative in the erythema multiforme lesions. If the LE is systemic, the bullous lesions show positive findings comparable with those seen in the uninvolved skin of patients with SLE [5]. The syndrome may be confused with patients showing coincidental LE and erythema multiforme [6]. In one case, anti-SS-B antibody and rheumatoid factor only developed after the erythema multiforme-like lesions appeared, suggesting that these factors are not just incidental findings but may have a role in the clinical presentation [7].

Childhood DLE [1]

DLE is uncommon in childhood. There appears to be no female preponderance, there is less photosensitivity and the frequency of progression to systemic disease is higher. The other clinical features are similar to those in adults.

Lupus erythematosus profundus (panniculitis) (Fig. 51.23) [1]

This is an unusual clinical variety of LE in which the cutaneous infiltrate occurs primarily (but not always exclusively) in deeper portions of the corium, with only microscopic epidermal changes, giving rise to firm, sharply defined nodules from one to several centimetres in diameter, lying beneath clinically normal skin [2]. The histopathology is sufficiently characteristic to establish the diagnosis in the absence of other cutaneous or systemic lesions of LE [1]. Clinical LE profundus occurred in 3–5% of patients with DLE [3,4], but histological disease may be found in up to 30% [5]. It can occur at any age and has been described in childhood [6].

The age and sex distribution of published cases is similar to that of DLE [7], and the disease may occur in childhood [8]. Familial cases have been reported [2,9].

Kaposi first described subcutaneous nodules in LE in 1883 [10], but Irgang [11] first used the term 'lupus erythematosus profundus' in 1940. Some authors [12] have considered the lesions to be sarcoid, but it is now usually accepted as a variant of LE [13], related more to DLE than SLE [14]. It was initially considered that it was different from 'lupus erythematosus hypertrophicus et profundus' described by Behçet [5], but the only difference is the involvement of the overlying skin in the version described by Behçet. Serological abnormalities occur when panniculitis is associated with SLE [15].

Histopathology. Microscopically [1], there may be epidermal atrophy, hydropic degeneration of the basal layer, follicular plugging and necrosis of the dermal collagen, suggesting LE. Collections of lymphocytes may occur around skin appendages and vessels in the mid-dermis. There is a striking lower dermal and subcutaneous necrobiosis, with some vasculitis and little cellular response. The collagen fibres in the lower dermis, in the septa and between the fat cells are swollen and poorly stained, and in some areas homogeneous masses and amorphous eosinophilic material replace the collagen. It is very important to exclude subcutaneous panniculitis-like T-cell lymphoma and this may require immunocytochemical investigation [16]. Immunofluorescence microscopy frequently shows linear staining at the basement-membrane zone [17]. Immune complexes can be demonstrated by direct fluorescence in small deep vessels in the dermis [18].

Clinical features. The nodular lesions are of varying size, but are usually one to several centimetres in diameter. They are usually firm, rubbery, sharply defined and persistent. The overlying skin usually appears normal, although histologically there are changes at the dermal–epidermal junction in two-thirds [1]. Typical lesions of DLE may be found elsewhere, most frequently on the cheeks. Healing usually leads to the development of depressed areas, and rarely to soft, slightly pink areas of anetoderma (Fig. 51.24) up to 4 cm in diameter. Cutis laxa followed one case [19]. Lupus profundus confined to the breast has been called lupus mastitis and may herald SLE. It may be confused with carcinoma [20]. LE profundus may affect the periorbital tissues and cause severe localized oedema [21]. It may occur with eyelid plaques [22]. Wherever it occurs, the nodules are persistent, and lesions in the cheeks may lead to marked disfigurement.

Fig. 51.24 Anetoderma secondary to lupus erythematosus profundus.

LE hypertrophicus et profundus starts as a violaceous, scaly, tender lesion, which rapidly enlarges, developing a warty hypertrophic surface with coarse adherent scales, which form a hard brown-black tar-like plaque [18]. Patients with LE hypertrophicus et profundus may have extensive serological abnormalities [18], and antibodies to extractable nuclear antigen (ENA) may sometimes be present [23]. On the legs, it may initially resemble thrombophlebitis [24]. Calcification can occur, and may be extensive, with the extrusion of thick, yellowish white material through ulcerated areas.

Associated diseases. LE profundus followed thrombocytopenic purpura in one case [15]. Lesions can occur after trauma or surgical biopsy [18], and have been precipitated by electromyography [25]. Monoclonal gammopathy has been reported in LE profundus [26].

Treatment. Clobetasol propionate cream (Dermovate) under a hydrocolloid occlusive dressing (Granuflex) is worth trying [27]. Antimalarial drugs are helpful [2,3,7], including in children [28]. Intralesional injections of triamcinolone (5 mg/mL) may be helpful [29]. Oral thalidomide has resolved resistant lesions, and this has been confirmed in a patient with associated partial C4 deficiency [30].

Associated features. Small telangiectases on the face occur in approximately 20% of patients. These dilated vessels may sometimes resemble spider naevi, but are usually small capillaries of irregular size and distribution, particularly on the cheeks. Dilated nail fold capillaries, similar to those seen in SLE and dermatomyositis, may be visible with the naked eye in 3%, and sometimes there may be erythema of the pulps of the fingers. More than half of patients state that they have a dry skin. Very occasionally, mild diffuse alopecia may occur, similar to that found in SLE, and alopecia areata has occurred in 10% of one series of DLE and mild SLE [1].

Bilateral enlargement of the parotids has been reported [2]. Histologically, there is lymphocytic infiltration of the parotid, which is said to be like that of LE profundus [2]. The parotid swelling may increase with exposure to sunlight and decrease during treatment with antimalarials and corticosteroids [2].

Livedo reticularis on the legs has been reported in DLE, and in one case cryoglobulins were intermittently demonstrated in the serum [3]. Table 51.4 lists the other conditions associated with DLE.

Table 51.4 Diseases reported in association with lupus erythematosus [4–14].

Porphyria
Cutanea tarda
Variegate
Acute intermittent
Erythropoietic protoporphyria
Pemphigus
Myasthenia gravis
Thymoma
Chronic lymphocytic leukaemia
Macroglobulinaemia
Benign monoclonal gammopathy
Multiple myeloma
Polychondritis
Thyroiditis
Carpal tunnel syndrome
Polymorphic light eruption
Sheehan's syndrome

Chronic granulomatous disease. Two siblings showing an autosomal form of chronic granulomatous disease with DLE-like lesions have been reported [1]. An illness resembling LE, especially of the discoid type, occurs in mothers of boys with X-linked chronic granulomatous disease. In these maternal carriers, a population of defective leukocytes can be demonstrated. Photosensitivity, chilblain LE of the fingers and toes, rosaceous lesions on the face, LE profundus and Jessner's lymphocytic infiltration-like lesions and stomatitis occur [2,3].

Complement abnormalities associated with DLE. Hereditary C2 deficiency occurs in association with skin lesions resembling the discoid lesion of SLE [1]. Homozygous C2 deficiency in females is the most common association, but DLE has also been reported in heterozygous C2 deficiency [2]. Low levels of C4 have been demonstrated in two sisters [3]. Hereditary deficiency of the third [4] and of the fifth component of complement has also been associated with a lupus-like syndrome [5]. DLE has also occurred with C1q deficiency [6]. Identical twin boys have been reported with DLE skin lesions, immunological abnormalities of SLE and hereditary angio-oedema with low C1-esterase inhibitor and C4 [7]. DLE is associated with classical hereditary angio-oedema with reduced levels of C1-esterase inhibitor [8]. Approximately 2% of patients with hereditary angio-oedema have LE-like disease [9].

Laboratory abnormalities in DLE. The incidence of laboratory abnormalities in 120 patients is shown in Table 51.5 [1]. Abnormalities were found in 55% of patients. T-cell counts are significantly lower than in controls, although B cells are not reduced [2]. Kidney biopsy has shown silent lupus nephritis in patients with hypocomplementaemia [3].

Table 51.5 Laboratory abnormalities in discoid lupus erythematosus.

Laboratory abnormalities	Frequency (%)
Anaemia, leukopenia or thrombocytopenia	30
Raised erythrocyte sedimentation rate (ESR)	20
Raised serum globulin	29
Positive Coombs' test	2.5
Positive cryoglobulins	<1
Positive cold agglutinins	<1
False-positive syphilis serology	26
Positive anticardiolipin antibodies (mainly IgM)	15
Positive LE cell test	1.7
Positive rheumatoid factor	17

Autoantibodies. Antinuclear antibodies are found in between 5 and 60% of cases depending on patient selection and laboratory techniques: the 'homogeneous' type of antinuclear factor being twice as frequent as the 'speckled' type. Antinuclear antibodies (ANA) are more common in older patients, in those who have had the disease for a long time and when there is extensive skin involvement. They are also more common in patients with chilblains, Raynaud's phenomenon and joint pains [4–7]. The incidence of anti-DNA antibodies varies from 0% [5,8] to 27% [9]. In the latter series, patients did not show any evidence of systemic involvement, and follow-up 3 years later showed no evidence of SLE [10], although progression has been reported [11]. Antibodies to single-stranded DNA (IgM in 20% [8]) occur in nearly one-fifth and may indicate widespread and progressive disease [12]. DNA antibody titres fall with chloroquine therapy. One-fifth of patients have IgM antibodies to single-stranded DNA [8]. Low-titre anti-Ro antibodies are found in 10% of patients with DLE, but are not related to photosensitivity and do not imply an increased risk of developing SCLE [13]. Antibody to extractable nuclear antigen is not found, but lymphocytotoxic antibodies have been demonstrated in 23% of patients in one series [14], but not found in another [5]. Precipitating autoantibodies are found in approximately 4% of patients. The SjT type of antibody (anti-La [SS-B]) is associated with 'speckled' antinuclear factor and rheumatoid factor in those patients with DLE and erythema multiforme [15]. Soluble IL-2 receptors may be found [16].

A high incidence of antithyroid antibodies has been found in DLE, particularly in females [17], and gastric parietal cell cytoplasmic antibodies occur in 13% of patients [17], but this incidence may not be higher than in controls.

Differential diagnosis. The relationship of DLE to SLE has been discussed elsewhere (see p. 51.2). The cutaneous lesions may be very similar, although patients with DLE of the face usually show more scaling, pigmentary disturbances, atrophy and scarring. In those with extensive DDLE, positive antibodies and mild systemic symptoms, it can be difficult to fit the patient into a precise diagnostic category, but patients may fulfil the ARA criteria for the diagnosis of SLE (see p. 51.27), so discussion of 'progression of disease' in these patients is often unhelpful.

The annular atrophic plaque variety of DLE may resemble morphoea or lichen sclerosus [1]. Jessner's lymphocytic infiltration may be confused with the more acute localized oedematous lesions of LE, but the marked histological lymphocytic infiltration in the former should help to distinguish it from the latter, and immunoglobulin deposition does not occur at the dermal–epidermal junction in Jessner's infiltration [2]. Evidence has been produced from a study of 100 patients that Jessner's lymphocytic infiltration is a distinct entity, which does not seem to proceed to DLE, PLE or lymphoma [3], and studies of lymphoid infiltrates using the monoclonal antibody Leu-8 tend to confirm the difference between DLE and Jessner's lymphocytic infiltrate [4]; however, there is still disagreement on the relationship between DLE and Jessner's infiltrate, and others believe the latter to be a precursor of classical cutaneous lupus [5]. Benign lymphocytic infiltration of the skin may be a further form of cutaneous LE as indicated by phototesting [6]. Reticular erythematous mucinosis (REM) syndrome (see Chapter 59), which can show clinical and histological features similar to DLE, may also be induced by ultraviolet radiation, but is a discrete clinical entity.

The history and the presence of lesions elsewhere should exclude contact eczema, seborrhoeic eczema and psoriasis. Lupus vulgaris may resemble DLE, but the lesions of the former usually occur at an early age, are rarely symmetrical, may be ulcerated and usually show characteristic 'apple-jelly nodules'. Necrobiosis lipoidica can give facial lesions like DLE. The rosaceous type of LE can usually be differentiated from true rosacea by the absence of pustules and the histology.

Chronic DLE has been found in 12% of patients diagnosed as having scarring alopecia of the pseudopelade type [7]. Lesions on the lips, tongue, scalp and buccal mucosa may be confused with lichen planus, and the skin of some patients may show clinical, histological and immunological features of both diseases [8,9]. Overlap cases, in addition to LE-like lesions, have lichenoid papules, verrucous lesions, anonychia, and oral and vulval lesions resembling lichen planus. Patients with lichen planus do not have features of LE immunopathologically or by HLA typing [10]. Overlap cases either have both diseases or are variants of LE. In favour of the latter, the verrucous lesions show immunofluorescent findings of LE, and electron microscopy reveals tubuloreticular inclusions in endothelial cells of dermal blood vessels—which are found in LE but not in lichen planus [11].

LE of the legs and feet may resemble chilblains. Plaques of sarcoidosis and lesions of eosinophilic granuloma may cause diagnostic difficulties that can only be resolved histologically. Occasionally, lesions resembling DLE are caused by dermatophytes [12].

The distinction from PLE may be difficult, but the absence of antinuclear factor from the serum [13] and of dermal–epidermal immunoglobulin deposits [14] in PLE may be helpful. PLE and DLE may coexist, or PLE may precede DLE by many years [15]. PLE is more common in the relatives of patients with LE; as many as 65% of patients with cutaneous LE have symptoms indistinguishable from those of PLE [16].

Infants may show sharply marginated, erythematous, finely scaling plaques on the cheeks and bridge of the nose, sometimes exacerbated by the sun [17], or a transitory rash with telangiectases on the face, particularly around the eyes, which clinically and histologically resembles LE [18]. These rashes probably are part of so-called neonatal LE (see p. 51.49). The annular erythemas of infancy have been reviewed [15].

An LE-like rash on the face with sun sensitivity occurs in Bloom's syndrome (see Chapter 15), which is thought to be caused by an autosomal recessive gene. A congenital telangiectatic erythema occurs in well-proportioned dwarfs, who look alike because of their bird-like facial appearance. The skin changes occur in infancy and may be associated with ectodermal and mesodermal defects.

Prognosis [1]. The untreated skin lesions of DLE tend to be persistent. With treatment, the more tumid lesions with little scaling may clear completely in the course of a month or two. Lesions of longer standing with much scaling and some scarring are slower to remit. Ultimately, scarring is found in 57%, with scarring alopecia in 35%; 35% also have pigmentary abnormalities [2]. Areas of activity at the edge of such scars may take years to settle. Twenty per cent of female patients notice a premenstrual flare, but there is no evidence of a deterioration of the condition on hormone replacement therapy [3]. Complete remission in the course of years can be expected in over 50% [1]. Long duration and lack of remission are related to Raynaud's phenomenon, scalp involvement and chilblain-like lesions [4]. Relapses occurring with sunlight, cold, trauma or mental stress after months or years of remission are not infrequent. In spite of the chronic and relapsing nature of the condition, the patient usually remains in good health.

Despite the fact that over half of patients have haematological and serological abnormalities, the risk of developing overt SLE is only approximately 6.5% [4,5]. The risk is higher in patients with disseminated DLE (22%) than in DLE confined to the head and neck (1.2%). Females developing DLE before the age of 40 years, with HLA-B8 in their histocompatibility type, have an increased risk of 'converting' to SLE [6]. Neither immunological nor biochemical abnormalities appear to alter the patient's progress [5,7]. Patients with active discoid skin lesions rarely have severe renal disease [8]. Patients with DLE showing signs of nephropathy, arthralgia and ANA titres of 1:320 or more should be carefully monitored [9].

Neoplastic change in DLE. Squamous cell and, less commonly, basal cell carcinomas occasionally occur in the scars of DLE, particularly on the scalp, ears, lips and nose. An incidence of 3.3% has been noted in a series of 120 white patients with DLE [1]. They are said to be more common in middle-aged males [2], but in either sex occur only in cases of 20 years' duration or more. Black people with DLE may also develop carcinoma [3,4], especially of the lip. Death may occur from multiple metastases [1,5]. Keratoacanthoma [6], malignant fibrous histiocytoma [7] and atypical fibroxanthoma [8] in lesions have been reported.

Treatment [1]. It is important to carry out a complete medical survey of the patient at the first attendance. Such a survey should establish a diagnosis of the sub-type of DLE, a likely prognosis and a baseline by which later progress may be judged. From the outset, general measures play a large part in successful management. Overwork, mental stress and fatigue are often factors in deteriorating disease, and patients with facial scarring often suffer severe psychological upset and depression [2]. Effective forms of camouflage by covering creams are available and help morale. Patients should be warned against excessive exposure to sunlight and they should be advised to wear a broad-brimmed hat, and avoid short-sleeved shirts and shorts. A sunscreen cream or lotion should be prescribed, and a preparation with a UVB protection factor of at least 15 is required; UVA protection is at least as important. Application should be frequent—probably every 2–3 h in bright sunlight. There are many suitable preparations, and patient acceptability is an important element in the choice of agent [3]. It is important that patients understand the preventative action of these preparations.

The management of cutaneous lupus has been well reviewed [1], as has that of 'resistant' disease [4]. Topical therapy can frequently control and sometimes clear lesions without systemic treatment. In one series [5], 43 out of 59 patients could be

Table 51.6 Oral agents useful in discoid lupus erythematosus.

Drug	Daily dosage	Response rate (%) (as first-line treatment)	Response rate (%) (as second-line treatment)	Side effects
Hydroxychloroquine	200–400 mg	60–75	20	See Table 51.7
Chloroquine	200–400 mg	60–75	20	See Table 51.7
Acitretin [21,22]	25–100 mg	50–75	15–20	Dry skin, hair loss, liver or lipid abnormalities, bony ankylosis
Auranofin [23]	3–9 mg	50	15–20	GI upset, haematological, renal or liver abnormality
Dapsone [24]	50–150 mg	25–50	10–20	Rash, haemolysis, dapsone syndrome
Methotrexate [25]	5–30 mg	–	25–50	GI upset, hepatitis, hepatic fibrosis, pulmonary fibrosis
Ciclosporin [26]	2.5–5 mg/kg	–	30–50	Hypertension, renal function abnormalities
Sulfasalazine [27]	1.5 g	–	5–15	
Isotretinoin [28,29]	20–80 mg	–	15–20	
Thalidomide [30–32]	50–150 mg	80–90	40–50	Drowsiness, constipation, teratogenicity, polyneuropathy
Clofazimine [33]	50–150 mg	40–60	5–15	
Phenytoin [34]	200–300 mg	–	–	
Azathioprine [35]	75–200 mg	–	20–30	
Cyclophosphamide [36]	50–200 mg	–	–	
Interferon α2a [37]		–		

controlled by applications of 0.025% fluocinolone cream, and 0.1% betamethasone 17-valerate cream alone was effective in 68 out of 78 patients without inducing epidermal atrophy [6]. There are few data supporting the use of one topical steroid over another, although more potent agents appear generally more effective. The efficacy in resistant cases may be enhanced by applications of steroid creams under plastic occlusion, using a self-adherent plastic dressing (e.g. Tegaderm [7]), or a moulded plastic prosthesis for more difficult anatomical areas such as the ears [8]. Fludroxycortide (Haelan) tape (in which steroid is impregnated onto the tacky side of polythene tape) can be cut to size and stuck on individual lesions.

Intralesional corticosteroid injections are helpful in resistant cases [9], even on lips, mouth and ears. Multiple and repeated injections may be required. Reversible, and occasionally irreversible, atrophy may result. Intralesional therapy is sometimes surprisingly effective in lesions on the nose and ears and it may also help resistant lesions on the palms and soles [10]. Intralesional chloroquine [11] has been tried with limited success. There can be considerable local pain and inflammation. Interferon-α (IFN-α) has also been used intralesionally with success [12]. Among other local measures, cryotherapy, surgical excision [13], painting small lesions with trichloracetic acid and local laser therapy may be helpful. The carbon dioxide laser, and both the pulsed-dye and argon lasers may be valuable for telangiectatic LE [14].

Oral therapy (Table 51.6). Most patients referred to hospital will need oral therapy in addition to local and general methods. In addition, vasodilator drugs, particularly calcium-channel blockers such as nifedipine, are helpful in those with Raynaud's phenomenon and chilblain lesions, and intravenous prostacyclin may be very helpful in winter, and used before intensive oral therapy in these patients.

For patients with severe, extensive or scarring disease, particularly affecting the scalp, oral prednisolone is often the most helpful initial treatment. A dosage of 0.5 mg/kg, rapidly tapered over 6 weeks, is quickly effective, minimizes scarring, and allows the slower acting agents such as antimalarials to work. Long-term therapy with oral steroids is best avoided because of side effects, but may be necessary in a small number of patients resistant to other maintenance therapy. In such circumstances, patients should also receive bone protection with bi-phosphonates or related drugs to avoid osteoporosis. Methylprednisolone 500–1000 mg/day for 2 or 3 days, given as intravenous pulse therapy, may help resistant lesions.

Table 51.7 Side effects of antimalarials.

Mild
Nausea, vomiting, abdominal pain
Severe
Corneal deposits
Retinopathy
Pigmentation of palate, nails and legs
Bleaching of hair
Exfoliative dermatitis
Lichenoid rashes
Myasthenia
Myopathy
Extrapyramidal involuntary movements
Neuropathy
Psychiatric syndromes

There is little doubt that in most cases first-line oral treatment should be with one of the antimalarials (see Chapter 74). Most would start therapy with hydroxychloroquine, initially at 200 mg twice daily, reducing to 200 mg/day once a response is achieved. Chloroquine sulphate is equally effective, usually at a dosage of 200 mg twice daily, but hydroxychloroquine is used first by most prescribers because side effects (Table 51.7), particularly eye toxicity, are less likely provided that the dosage limitations of 6.5 mg/kg lean body weight are adhered to [15]. The comparable safe daily dosage for chloroquine is unclear, but is probably around

2.5 mg/kg/day of chloroquine base. Cumulative toxicity is rarely a problem with hydroxychloroquine, although it can occur with chloroquine [16]. For this reason, courses of treatment lasting approximately 6 months are preferred, but this may not be possible in the most severely affected patients who will require ongoing therapy. Mepacrine is also useful, and is safe from an ophthalmological point of view [16], but it is often reserved for later use (because of skin pigmentation). It may be used alone, or as part of a combination of antimalarials, which may be more effective than the equivalent amount of each drug given individually [17].

The response to therapy varies; usually, the more tumid, less scaly lesions responding more rapidly than chronic, atrophic and scarring lesions. Most patients who are going to respond to antimalarials usually do so within 6 weeks.

The occurrence of side effects with one agent does not necessarily mean that they will occur with another antimalarial, so it is always worth trying an alternative drug. Taking an ophthalmological history and arranging for an examination by an optician before treatment in any patient with symptoms not corrected by spectacles may help in avoidance of the ocular manifestations. Monitoring during therapy should include taking an ophthalmic history, and testing reading ability with appropriate charts [15]. More elaborate tests, such as the electro-oculogram and electroretinogram, are no longer believed to be helpful [15].

Approximately 60–75% of all patients are helped by antimalarials. Cigarette smoking reduces the efficacy of treatment with antimalarials, probably by modifying metabolism [18]. Of those who respond, approximately 50% relapse within 6 months of stopping treatment, and repeated courses of therapy are usually required. Nevertheless, over the course of several years, most cases treated with intermittent oral antimalarials and topical corticosteroids tend to improve, and some clear completely. There is no evidence that the continuation of antimalarials after clearance prevents relapses. Hydroxychloroquine appears to be safe in pregnancy [19]. Responses to all other agents are very limited once topical therapy and antimalarials have failed [20].

For cases not responding to topical steroids, antimalarials and sunscreens, oral thalidomide has proved remarkably effective in suppressing lesions [30], and also in the treatment of chilblain LE. The originally employed dosages of 400 mg/day [31] are unnecessary, and 100 mg/day seems to be equally effective. If used as initial therapy, response rates of 80–90% may be achieved, but when used as second-line treatment the response rate is nearer 50% [20,32]. Short courses are preferable because of the risk of polyneuropathy and the teratogenic effects. The prescription of thalidomide is tightly regulated, with prescribers, dispensers and patients all having to be registered in a pregnancy prevention programme: patients are allowed only monthly amounts of drug, and all potentially fertile women should be using double contraception and require monthly pregnancy tests.

When all of the above have failed in patients with severe and persistent disease, other forms of systemic treatment may be used. Intravenous pulses of cyclophosphamide may be used, usually at a dosage of 10 mg/kg, at 3–4 weekly intervals. It is usually given in combination with intravenous methylprednisolone [36]. Most recently, the biological agents aimed at specific cytokine molecules have been used, with benefit following use of efalizumab [38].

Excision of oral lesions also may be practicable [39]. The carbon dioxide [40] and argon lasers [41] may produce improvement of disfiguring LE, although the latter may precipitate DLE [42]. Dermabrasion may help cribriform scarring of the face [43], as may carbon dioxide laser-brasion. Excision without grafting was successful in a case of verrucous LE following a burn [44].

Subacute cutaneous lupus erythematosus

Definition. Subacute cutaneous lupus erythematosus (SCLE) is a specific 'subset' of lupus first described by Sontheimer *et al.* in 1979 [1]. Patients exhibit mainly cutaneous disease and usually have a good prognosis. Antibodies to the Ro/SS-A antigen are closely associated with this subgroup.

Aetiology. Antibodies to the Ro/SS-A antigen are an almost universal finding in this subset of lupus. That these antibodies may be pathogenic was first suggested by LeFeber *et al.* [2], who demonstrated that sublethal doses of ultraviolet light (UVL) induced the synthesis of Ro/SS-A antigen by cultured human keratinocytes. In addition, they also showed that UVL promoted the expression of Ro/SS-A antigens on the surface of cultured human keratinocytes where they might bind antibodies. In 1988, Ro/SS-A antigen was identified in both adult and neonatal epidermis *in vivo* [3], and subsequent studies have confirmed that UVL increases Ro/SS-A antigen expression on the surface of keratinocytes [2,4,5] and that this is increased by oestrogen [6–8]. Thus, it has been postulated that in photosensitive lupus, UVL exposure leads to increased synthesis and subsequent expression of Ro/SS-A antigen on the surface of keratinocytes where it binds antibody and initiates disease [9,10]. Further support for this hypothesis comes from a study which showed that photosensitivity and the titre of Ro/SS-A antibodies correlated with the expression of Ro/SS-A in skin specimens of patients with LE [11].

Although attractive, this hypothesis does not explain why other patients with Ro/SS-A antibodies (e.g. patients with Sjögren's syndrome) do not exhibit photosensitivity and why in the clinical setting Ro/SS-A titres rarely reflect disease activity [12], although one study has suggested that titres of Ro/SS-A are higher in SCLE patients with systemic involvement than in those without [13].

HLA antigen status may have a role in disease susceptibility. The most common haplotype in SCLE is HLA-DR3 and B8, -DR3 being most commonly associated with the annular phenotype and the expression of Ro/SS-A antibodies [14]. A more recent study has suggested an association with HLA-A1, B8, DR3, DQ2, DRw2 and C4 null haplotype [15]. DR2 has been associated with an older age of disease onset and papulosquamous lesions [16]. Complement genes are located in the HLA region and patients with SCLE have been reported to have deficiencies in the 2nd [17], 3rd [18] and 4th components [19]. A single nucleotide polymorphism leading to decreased levels of C1q antigen has been reported in patients with SCLE, the only genetic association of SCLE that lies outside the HLA region [20]. In addition, the expression of the human leukocyte antigen-DR and CD25 on circulating T cells in cutaneous lupus has been reported to correlate with disease activity [21].

Two studies [22,23] have reported an association of SCLE with the tumour necrosis factor-α (TNF-α) 308A polymorphism, which may be pathogenic or act as a marker for the HLA A1, B8, DRB1*0301 haplotype associated with other autoimmune conditions. Studies of Ro60 exons to see whether sequence alterations might be associated with SCLE have not shown differences between patients with SCLE, DLE or controls [24].

Autoantibody status. SCLE was originally labelled ANA-negative lupus, as these patients often exhibited negative autoantibody screens. This was probably because of the use of test substrates that did not contain suitable antigens for the antibodies found in this group of patients. Using human cell lines as substrates, homogeneous antinuclear antibodies are found in approximately 60% and anti-Ro/SS-A antibodies in approximately 80% of patients [1], rising to higher levels in females [25]. Anticardiolipin antibodies occur in 16% [26].

Histopathology. Histopathologically, SCLE can be differentiated from DLE by the presence of more epidermal atrophy and less hyperkeratosis, basement-membrane thickening, follicular plugging and inflammatory infiltration [27,28]. Colloid bodies and epidermal necrosis are present in more than 50%, especially in those with Ro/SS-A antibodies [29]. Dust-like particles of inter- and intracellular IgG in the basement layers of the epidermis may be a specific feature [30]. It has been suggested that pilosebaceous atrophy is the only significant predictor of DLE versus SCLE

Fig. 51.25 Subacute cutaneous lupus erythematosus.

Fig. 51.26 Subacute cutaneous lupus erythematosus, showing annular polycyclic lesions.

[29,31]. Lesional subepidermal immunoglobulin is found in approximately 60%, and is more frequent in papulosquamous (88%) than annular lesions (29%) [1]. Recent studies have shown significant numbers of chemokine receptor CCR4 and cytotoxic T cells in the basal layers of the epidermis where keratinocytes showed apoptotic death [32] and strongly positive staining for TNF-α in involved skin [33].

Clinical features. This subset [1,34,35], which comprises approximately 10% of patients with LE, have either non-scarring papulosquamous (two-thirds) or annular polycyclic (one-third) lesions. The disease predominantly affects adults, although SCLE has been reported in a child [36,37]. Lesions usually occur above the waist and particularly around the neck, on the trunk and on the outer aspects of the arms (Figs. 51.25 & 51.26) and have been reported to occur along the lines of Blaschko [38]. The borders may show vesiculation and crusting and occasionally bullae [39,40] which may be associated with co-existent porphyria cutanea tarda [41]. Follicular plugging and hyperkeratosis are not prominent, and the lesions resolve leaving grey-white hypopigmentation and telangiectases. The pigmentary changes usually resolve completely. Diffuse non-scarring alopecia and photosensitivity occur in approximately half of patients, and other features include mouth ulceration (especially of the palate), reticular livedo, periungual telangiectasia and Raynaud's phenomenon. Presentation with pityriasiform lesions [2], erythroderma [42] and poikilodermatous lesions [43,44] has been described. Morphoea [45] and dystrophic calcinosis cutis [46] have followed SCLE. Some develop lesions related to mucin deposition [47].

Approximately half of patients fulfil the criteria for SLE of the American Rheumatism Association (ARA) [48], with arthritis the most frequent feature. Fever, malaise and central nervous system involvement occur, but renal disease is mild and infrequent, although a recent study suggested that the latter may occur in up to 16% of patients, a similar frequency to that seen in those with SLE in their series [49]. Urticarial vasculitis has been reported [50]. Chronic interstitial pneumonitis has been reported [51], as has hypokalaemic tetraparesis [52]. Occasionally, the annular lesions may resemble the lesions of Rowell's syndrome or the gyrate erythema secondary to occult malignancy [53]. Some patients also have Sjögren's syndrome [54], rheumatoid arthritis, Sweet's syndrome [55], Crohn's disease [56], lichen planus [57], psoriasis [58,59], hereditary angio-oedema [60,61], porphyria cutanea tarda [62], gluten-sensitive enteropathy [63], toxic epidermal necrolysis [64], inclusion body myositis [65] or calcifying lupus panniculitis [66] and Kikuchi's disease (necrotizing lymphadenitis) [67].

A number of drugs have been reported to precipitate or exacerbate SCLE and these are listed in Table 51.8.

SCLE may occur in the course of PUVA treatment of psoriasis [107], radiation therapy [108] and IFN-β1a therapy [109]. There have been occasional reports of associations with cancer, namely breast carcinoma [110], meningioma [111], hepatocellular carcinoma [112], Hodgkin's disease [113], lung cancer [114], prostate cancer [115] and squamous carcinoma of the head and neck [116]. Occasional patients develop overt SLE with severe visceral disease [117].

Treatment. The condition in most patients is controlled by sunscreens [118,119], topical or intralesional corticosteroids [120–122] or the macrolides pimecrolimus [123] and tacrolimus [124–128]. In those not responding to these agents, antimalarial drugs are often helpful [129]. These can be used as either hydroxychloroquine or chloroquine base, although the former is safer from the ophthalmological point of view and requires less ophthalmological monitoring [130]. The antimalarial mepacrine (quinacrine) does not have ocular side effects but does induce yellow discoloration of the skin. There is evidence that a combination of antimalarials may be more effective than either alone [131] and that they are less effective in smokers [132]. Patients not responding to antimalarials

Table 51.8 Drugs associated with subacute cutaneous lupus erythematosus.

Thiazide diuretics [68–72]
Griseofulvin [73]
Terbinafine [74–77]
Calcium channel blockers [78–81]
Tamoxifen [82]
Acebutalol [83]
Lansoprazole [84]
Statins [85]
ACE inhibitors [86–88]
Etanercept [89]
Efalizumab [90]
Infliximab [91]
Leflunomide [92–94]
Carbamazepine [95,96]
Cinnarizine [97]
Inhaled tiotropium bromide [98]
Bupropion [99,100]
Docetaxel (Taxotere) [101]
Ticlopidine [102]
Gold [103]
Naproxen [104]
Aldactone [105]
Fertilizer- and pesticide-containing hay [106]

may respond to oral corticosteroids or methylprednisolone [133], etretinate [134], acitretin [135], isotretinoin [136,137], dapsone [138], oral, intravenous and subcutaneous methotrexate [139–142], thalidomide [143–147], UVA [148], IFN-α [149], long-term cefuroxime axetil [150], mycophenolate mofetil [151], intravenous immunoglobulin [152,153], etanercept [154] and efalizumab [155].

Systemic lupus erythematosus [1,2]

Definition. A systemic disease characterized by multisystem organ inflammation, most commonly the skin, joints and vasculature, and associated immunological abnormalities. The main clinical features include fever, rashes and arthritis, but renal, pulmonary, cardiac and neurological involvement may occur, with increased mortality. For any individual patient, the ARA criteria may be used as an aid to diagnosis (Table 51.9).

Incidence. SLE is an uncommon disease [3–9], with incidence estimated at 1–12.5 in 100 000 per year at Leeds General Infirmary; for every case of SLE there are six cases of pernicious anaemia and 10 of leukaemia. The condition is universal, but is three times more common in black people than in white people [3]. Younger black American females are particularly predisposed to the disease [4], although it is rare in native Africans. It is also common in the Chinese and in New Zealand Polynesians [5]. The pattern of disease appears to be different in such ethnic subgroups, with black Americans and Hispanics having the highest rate of internal organ damage [6]. A study in Hawaii gave similar racial variation, with the prevalence in those of Chinese origin being 24.1 in 100 000, whereas that in whites was 5.8 in 100 000 [7]. The incidence of newly diagnosed cases in New York is 10–14 per million population [8]. The prevalence varies from less than 1 in 1000 for black females in New York [9] to approximately 1 in 2000 white females in San Francisco, and figures for England and Wales suggest a prevalence of 12.5 in 100 000 women, although this is an underestimate [10]. The observed annual incidence increased from 25 per million in 1955 to 50 per million in 1959 [11]. In Hong Kong, in 1987, the incidence was 2.4 in 100 000 [11], and in Baltimore, in 1985, it was 4.6 in 100 000, a twofold increase over the preceding 15 years. Self-reported physician-diagnosed SLE occurred in 124 in 100 000 in the USA [12]. This suggests that the disorder may be more common than it used to be, but it may also represent better awareness and earlier diagnosis. An epidemiological survey in New York showed that morbidity and mortality rates were highest among black people, followed in descending order by Puerto Ricans and then other white people. Racial differences were independent of housing, overcrowding and migration, but were associated with racial variation in normal gammaglobulin levels, which were higher in black people [6]. A more recent study from England confirms the increased risk of SLE in Afro-Caribbeans and Asians, irrespective of their place of birth [13]. Familial cases occur in approximately 10% [14,15]; relatives of patients with SLE also have an increased incidence of SLE and DLE, rheumatoid arthritis, rheumatic fever, polyarteritis nodosa, dermatomyositis and poikiloderma atrophicans vasculare [16].

The condition tends to occur in early adult life, and the peak age of onset of the first symptom or sign in females is approximately 38 years (35.5 in black women, and 40.7 in white women); it is 44.2 in men [17]. The incidence of the disease is the same in all age ranges, although serositis and Sjögren's syndrome are more common disease manifestations in the elderly [18]. Most authors agree that females outnumber males by a ratio of approximately 8:1, but the features in males are the same as in females [19].

Table 51.9 American Rheumatism Association criteria for diagnosis of systemic lupus erythematosus.

1	Malar rash
2	Discoid rash
3	Photosensitivity
4	Oral ulcers
5	Non-erosive arthritis
6	Serositis—pleurisy or pericarditis
7	Renal disorder—persistent proteinuria (>0.5 g/day) or cellular casts
8	Neurological disorder—seizures or psychosis
9	Haematological disorder—haemolytic anaemia or leukopenia (<4000/mm) or lymphopenia (<1500/mm) or thrombocytopenia (<100 000/mm)
10	Immunological disorder—LE cells or anti-DNA antibody or anti-Sm antibody or false-positive serology for syphilis (longer than 6 months)
11	Antinuclear antibodies

LE, lupus erythematosus.

Aetiology. The aetiology of SLE remains unknown. Aetiological theories must account for the known variations in the incidence of the disease, the marked immune dysfunction, known precipitating factors and the clear familial predisposition.

Genetic factors. There is considerable evidence to suggest that genetic factors play a part in the pathogenesis [1]. The condition has been reported in identical twins [2,3], with a concordance rate of 65% [2]. Of all cases, 4% are familial [4], with marked concordance of disease expression between parents and offspring. The onset of SLE in identical twins occurred within 2 years, compared with an interval of 9 years between siblings and 20 years between parents and offspring [5]. However, the onset of disease in siblings is temporally rather than age-related, indicating a possible environmental factor [6]. Occasionally, identical twins may be discordant for SLE. In this case, the non-affected twin does not have abnormalities of helper and suppressor T-cell numbers and activity, and has different cellular immune responses [7,8]. The incidence of SLE is probably higher in XXY males with Klinefelter's syndrome [9]. Relatives of patients with SLE have a higher incidence of connective tissue disease, hyperglobulinaemia and antinuclear factor than the relatives of matched controls [10,11]. They may also show increased incidence of anti-RNA and lymphocytotoxic antibodies, specific anti-DNA antibody idiotypes [12], anticardiolipin antibodies [13] and impaired suppressor T-lymphocyte function [14], although these are not related to disease expression [15].

Studies of histocompatibility antigens further support a genetic predisposition. White people with SLE have increased frequencies of HLA-B8 [16], -DR3, -A1 and -DR2 [17]. Similar associations have been confirmed in black people [18,19], as has an association with immunoglobulin allotypes Gm 1 and 17 [20]. HLA-DQ antigens may be even more closely related to the risk of developing the disease, and different alleles may be implicated in the risk of developing the disease from those that influence its expression [21]. There is evidence of linkage disequilibrium between B8-DR3 and alleles at the DQ locus, which is prevalent in patients who express anti-Ro antibodies [22].

Eighty per cent of patients (compared with 40% of controls) have null complement alleles [23], mainly at the C4A or B locus [24]. HLA-DR2 and the C4A null allele are independent and additive risk factors in SLE [25]. Deficiency of complement factors C5–9 is relatively common in familial cases of SLE. Genetic factors other than HLA and complement component deficiencies may also be involved [26]. The results of genome scanning of family pedigrees multiplex for SLE, including over 400 sib pairs and 175 affected relatives, suggest an epistatic interaction between chromosome 14p16–15.2 and chromosome 5p15 in European American families [27].

Autoantibodies [1,2]. Non-organ-specific humoral autoantibodies are the hallmark of SLE. A range of autoantibodies may be present in the disease, although some are more disease-specific (anti-double-stranded DNA and anti-Sm antibodies), and some are much more commonly found (antinuclear and anti-Ro antibodies). The disease could be produced by the development of such antibodies against tissue antigens to which tolerance has been lost by failure of homeostatic immunological mechanisms. This could occur either because of polyclonal B-cell activation or specific antigenic drive. There is evidence for both mechanisms of production of autoantibodies [3]. There is also considerable evidence that such non-organ-specific autoantibodies are not the primary pathogens: they are not specific to any disease, they are not present in all cases, their titres are independent of the activity of the disease, they are transmitted across the placenta without apparently harming the fetus [4] and they can be transfused into human volunteers without causing any apparent disease. In animal models, however, antinuclear antibodies can intensify experimental inflammatory lesions [5]; there is also evidence for involvement of immune complexes containing antinuclear antibody (either deposited or formed *in situ*) in the renal lesion of SLE as well as in tissue damage in other sites [6]. Recent evidence suggests that these antibodies may be formed against DNA-containing debris which is packaged into a vesicle after cells have undergone apoptosis, so-called 'apoptotic bodies' [7,8]. Anti-DNA antibodies bind the DNA receptor on white blood cells and block the binding and sequestration of free DNA by mononuclear cells [9]. These antibodies also produce the release of IFN-γ from mononuclear cells, enhancing immunological and inflammatory reactions [10]. Anti-Ro or closely related antibodies are implicated in the development of the rash and heart block found in neonatal LE (see p. 51.49), and possibly in other childhood SLE. The antiphospholipid antibodies, including the so-called lupus anticoagulant, are linked to thrombosis and abortion in patients with SLE (see p. 51.48). Conversely, neurofilament autoantibodies occur in 21% of patients with SLE, but do not correlate with neurological involvement [11]. Antiribosomal P proteins are highly specific for lupus psychosis [12]. Recent evidence suggests that there is switching of antibody types between the active and quiescent stages of the disease, with low-affinity IgM antibodies present when the disease is controlled, and high-affinity IgG, often directed against endothelial cells, being present when the disease is active [13]. Antiendothelial cell antibodies are associated with renal and vascular complications [14].

Idiotypes and anti-idiotypes [15]. Idiotypes are the antigenic determinants of immunoglobulin molecules and are found in the variable region of these molecules and the T-cell receptor. Antibodies to these antigens develop (anti-idiotype antibodies), and are themselves capable of stimulating anti-anti-idiotype antibodies. Thus, complicated networks of antibodies develop, which are involved in the mechanisms of autoimmunity and self-recognition. Anti-idiotype antibodies may have some of the capabilities of the original antigen, and may also cross-react with other self-antigens, interfering with the development of tolerance produced by the removal of self-reactive T cells. This interference would allow the development of the 'forbidden clones' originally predicted by Burch and Rowell [16]. Cross-reaction between self-antigens and those derived from extraneous sources such as infection or other environmental agents may provide the original source of anti-idiotype antibodies [17].

Other immune factors. Cell-mediated immunity is abnormal in SLE [1]. Lymphocyte transformation responses to common antigens [2] and decreased skin-test responses to purified protein derivative, candidin and streptokinase-dornase [3] are related to disease activity [4]. T-cell counts are diminished [5] and null cells are increased [6] in active disease. It would appear that there is an imbalance between T and B lymphocytes in the disease, with depressed cellular immunity and an overactive humoral antibody response, possibly related to a relative lack of suppressor and/or inducer T cells, although all T-cell types are reduced, and their function is impaired. IL-2 production by peripheral blood leukocytes is impaired, reducing the inhibitory effects of T cells on activated B cells [7].

There is a reduction in activated B cells, but hyperactive B cells are increased in SLE [8], and their differentiation abnormally stimulated by monocytes [9]. There is some evidence that in remission there is a return of immunological suppressor function despite a persisting impairment of T-lymphocyte reactivity [10]. Antibody-dependent cellular cytotoxicity may be another pathogenic factor, and antibodies directed against lymphocyte membranes are found in SLE. Serum-induced cytotoxicity occurs to T cells [11], and immune complexes may be implicated [12]. Circulating immune complexes occur in approximately half of patients, especially those with active and extensive disease [13]. Killer cell activity is increased [14], and complement activation occurs, and the anaphylatoxins C3a and C5a are increased during disease exacerbations, possibly contributing to the pathogenesis of the vascular lesions [15].

UV radiation. This may precipitate the onset or exacerbate the course of SLE in up to 60% of patients [1]. Phototesting to UVB and UVA [2] shows reduced minimal erythema doses and the development of skin lesions in patients with LE. The mechanism of action of UV radiation in SLE remains unknown, although antibodies to UV radiation-denatured DNA can be demonstrated. There is no defect of DNA repair in SLE [3], and the antibodies to denatured DNA have no clinical or immunological correlations [4]. The expression of Ro antibody can be induced on cultured keratinocytes by UV radiation [5], and this antibody is commonly found in photosensitive patients. However, there is no relationship between absolute levels of Ro and disease activity [6].

Environmental factors. Lupus-like disorders have been reported in association with a variety of environmental factors [1]. Although early reports suggested that silicone breast implants are more frequently associated with connective tissue diseases including lupus-like syndromes, scleroderma, fibrositis, inflammatory myopathy and autoimmune thyroid disease [2], later studies show that the incidence is no higher than in control populations [3]. Haemolytic anaemia with high titres of antinuclear and anti-dsDNA antibodies has followed the ingestion of sprouts, seeds and dietary supplements of alfalfa, which contains the amino acid L-canavanine [4]. Heavy metals including cadmium, mercury and gold have also been associated with autoimmunity [5]. Other industrial factors include silica [6,7] and trichlorethylene [8].

Infections, stress, hormonal factors. Other factors may precipitate the onset of SLE, and these include bacterial infection and mental or physical stress. A role for antigens derived from infecting organisms in the generation of anti-idiotype antigens [1] has been suggested, and microbial superantigens may stimulate abnormal T- and B-cell interactions, resulting in the state of autoimmunity found in SLE [2]. Infection is more common in SLE than in those not affected, and depressed generation of serum chemotactic factors may contribute to this increase [3]. Initial phagocytosis by polymorphonuclear neutrophils and macrophages is reduced [4].

As markedly more females than males are affected in early adult life, it has been suggested that endocrine factors may be involved [5]. In addition, 20% of female patients have premenstrual flares of skin disease, and a small number present after initiation of oestrogen-containing contraceptive therapy [6]. Levels of circulating androgens are reduced in women with SLE compared with normal controls [7], and men with SLE have reduced testosterone levels [8], indeed hypogonadism from whatever cause may be an aetiological factor in SLE [9]. Prolactin is an immunoregulator, and is secreted by immunologically active cells, suggesting an autocrine effect [10]. Normal humoral and cellular immune responses are greater in females than in males, but this may be a result of the influence of oestrogen on gene expression, rather than on immune responses [11]. A late menarche is associated with an increased risk of SLE in Japanese patients [12]. There is some evidence that neuroendocrine factors play a part in immunity, which could to some extent explain the influence of stress factors in the disease [13].

Viruses. An infective cause for SLE has long been postulated, and the role of acute viral infection has been reviewed recently [1]. The high incidence of antibodies to reovirus double-stranded RNA (70%) [2] and raised titres of antibody to measles and rubella antigens [3], suggest potential viral involvement, but this may be only an expression of T-cell suppression in this disease. There is no evidence of retrovirus infection in SLE [4], but endogenous retroviral DNA sequences are found [5].

Drugs. The precipitation of SLE by drugs [1,2], especially the antihypertensive hydralazine, is well known. However, there are features to suggest that drug-induced SLE differs from the spontaneous disease: it is uncommon in black people, it occurs in an older age group, renal and central nervous system involvement are infrequent, antihistone antibodies are frequent, anti-DNA antibodies are absent and serum complement is normal. Hydralazine is known to inhibit binding of complement component C4, and this action, with subsequent lack of control of complement activity, may explain the development of lupus-like syndromes.

Cutaneous involvement in drug-induced SLE may be vasculitic, bullous, erythema multiforme-like or resemble pyoderma gangrenosum. Cases have been reported of hydralazine-induced lupus with Sweet's syndrome [3]. It was thought that the clinical manifestations of drug-induced lupus resolved when the drug was withdrawn, but this is not necessarily so, and patients with hydralazine-induced syndromes may have hyperglobulinaemia and other abnormalities before the administration of hydralazine [4]. Patients who develop antinuclear antibodies during drug treatment need not have the drug stopped unless they have

Table 51.10 Drugs inducing systemic lupus erythematosus-like syndromes.

Acebutolol	Oral contraceptives, including:
Allopurinol	Chlormadinone
Aminoglutethimide	Ethinylestradiol
p-Aminosalicylic acid	Etynodiol diacetate
Atenolol	Medroxyprogesterone
Captopril	Mestranol
Carbamazepine	Norethindrone
Chlorpromazine	Norethisterone
Clobazam	Norethynodrel
Clofibrate	Oxyphenisatin
Co-trimoxazole	Oxprenolol
Diphenylhydantoin	Penicillamine
Ethosuximide	Penicillin
Gold salts	Phenothiazine
Griseofulvin	Phenylbutazone
Guanoxan	Phenytoin
Hydralazine	Pindolol
Hydrochlorothiazide	Piroxicam
Hydroxyurea (hydroxycarbamide)	Practolol
Ibuprofen	Primidone
Infliximab	Procainamide
Interferon	Propranolol
Isonicotinic acid hydrazide	Propylthiouracil
Isoquinazepon	Quinine
Labetalol	Recombinant interferon
Leuprolide acetate	Streptomycin
Lithium carbonate	Sulfasalazine
Methyldopa	Sulphonamides
Methylphenylethylhydantoin	Tertalol
Methylthiouracil	Tetracycline
Methysergide	Timolol eye drops
Minocycline	Trimethadione
Minoxidil	Valproate
Nitrofurantoin	Venocuran
	Vostatin/simvastatin

features of the lupus syndrome [5]. Twenty-four cases of lupus induced by minocycline [6] have been reported. It usually occurs after 2 years of therapy. Patients who require more than 1 year's therapy should have ANA and liver function tests monitored. Other drugs, particularly certain anticonvulsants, are known to precipitate SLE-like syndromes (Table 51.10). The biological agents targeting TNF-α are now well known to produce ANF, and occasionally clinical manifestations of lupus.

Drugs have been implicated in precipitating or activating SLE in 3–12% of cases [7]. There is an increased incidence of HLA-DR4 in drug-induced SLE [8] and the ratio of females to males is 4:1, indicating a possible genetic predisposition. It appears that individuals who are slow acetylators are more likely to develop drug-induced LE or LE-like syndromes [9]. The determination of acetylator type and DR typing may enable susceptible patients to be identified. In spontaneous SLE, however, there appears to be a preponderance of slow acetylators [10], although this is disputed [11].

Antihistone antibodies are not drug-specific, although different drugs do induce antibodies to different histone epitopes, and the antibodies are often present well before clinical manifestations occur [12]. Indeed, 50% of procainamide-treated patients develop immunological abnormalities, whereas only 20% develop clinical disease [13]. Of patients with drug-induced lupus syndromes, 82% have antihistone antibodies, compared with 32% of those with serological changes only [12].

Relationship of genetic and environmental factors and autoimmunity [1]. The relationship of genetic factors, possible virus infection and depression of cell-mediated immunity has led to the suggestion that genetic factors might allow virus replication in the thymus and in T cells, inducing damage to these cells and hence defective cellular immunity. The age pattern of the disease and its female predominance suggest that these abnormalities appear to affect only a specific susceptible genotype, involving three dominant X-linked alleles. Phenotypic expression then depends on accumulated randomly occurring changes in lymphoid stem cells, with three 'forbidden' clones of lymphocytes developing [2], and with hyperglobulinaemia and autoantibody formation from hyperactive B cells and the lack of T-cell suppression following. Normal defence mechanisms, which are more effective in females, prevent these changes persisting, but may be impaired by infections, drugs, UV radiation and stress, thus precipitating the disease. Organ involvement is determined by genetically controlled antigenic expression in target tissues. Such a concept would explain the sex differences, the occurrence of clinical and subclinical autoimmune disease and antibodies in the relatives of patients, the apparent spontaneous onset in many cases, and the precipitation and exacerbation of clinical manifestations by factors impairing the defence mechanisms.

Table 51.11 Pathological features of systemic lupus erythematosus.

Pathology (Table 51.11). The pathological changes of SLE have been well described. The primary lesions of SLE are fibrinoid necrosis, collagen sclerosis, necrosis and basophilic body formation, and vascular endothelial thickening. The basophilic (haematoxylin) bodies are aggregates of homogeneous material staining blue with haematoxylin and staining positively for DNA by the Feulgen technique. This material is similar to that of the homogeneous nuclear material of the LE cell.

Macroscopic appearances. Despite the widespread clinical manifestations and fatal outcome, it is often disappointing to find no macroscopic changes at autopsy. Sometimes, terminal changes and infection obscure the picture. Frequent macroscopic findings include pleurisy with adhesions and effusion, and pericarditis, especially if the patient has died with uraemia. The verrucose vegetations of Libman–Sacks endocarditis are diagnostic (Fig. 51.27) [1]. These are small firm warty deposits, up to 0.5 cm in diameter, adherent to the valves of both sides of the heart and adjacent endocardium of the ventricles, chordae tendinae and on the papillary muscles. Sometimes, lesions of subacute bacterial endocarditis may be superimposed on the warty lesions.

Microscopic appearances. Usually, pathological diagnosis requires histology, but in some cases histological changes can be demonstrated only by immunohistological techniques (Fig. 51.28) [2]. Immunohistology is also useful in diagnosing SLE in patients with a rash.

Skin. There is no single diagnostic pathological feature in the skin, but a combination of features aids diagnosis [3]. Some changes, such as hyperkeratosis without parakeratosis, and keratotic plugging of the hair follicles and glandular orifices, are similar to those found in chronic DLE. There may also be some atrophy or acanthosis of the prickle cell layer. Liquefaction degeneration of the basal cell layer is common. Epidermal necrolysis has been reported [4]. The dermal tissues may be oedematous, and sometimes vesicle formation occurs at the dermal–epidermal junction, with dilatation of the superficial vessels and perivascular lymphocytic infiltration. Occasionally, dermal mucinosis occurs, especially in papular lesions [5] and in areas of alopecia [6]. Pigment-containing chromatophores may occur in the infiltrate. Sometimes, the infiltrate is widely distributed in the upper portion of the dermis, being most pronounced in the more chronic type of lesions. Using monoclonal antibodies, the infiltrate is shown to consist of abundant T cells and Ia-positive cells, with rather fewer B cells and macrophages. Helper or inducer T cells and suppressor or cytotoxic T cells occur in equal numbers [7]. Fragmentation, splintering and oedema of the elastic tissue occur. Changes in the

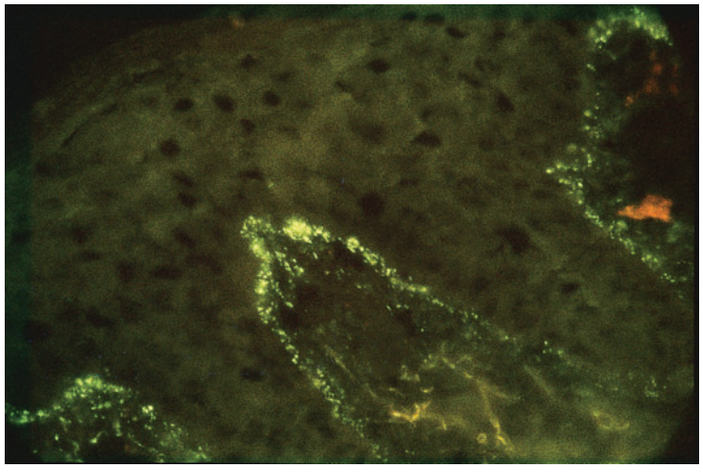

Fig. 51.28 Immunoglobulin at the dermal–epidermal junction in systemic lupus erythematosus.

walls of blood vessels are relatively infrequent, but hyaline changes and fibrinoid degeneration occur.

Immunohistology [8,9]. Immunoglobulins, predominantly IgG, but less frequently IgM and IgA, together with complement (C1, C3) can be demonstrated at the dermal–epidermal junction by immunofluorescence techniques [10,11]. They occur in more than 80% of skin lesions of DLE and SLE, and may be preceded by basement membrane abnormalities in erythematous and purpuric lesions [12]. Deposits occur more frequently in light-exposed areas and are invariably present in acute lesions, although in early and late stages the test may be negative. If IgG, IgM and IgA are all present, the diagnosis of SLE is likely, and the more common combination of IgG and IgM is also suggestive. Single immunoglobulins favour another diagnosis (see DLE). The basement-membrane phenomenon can also be demonstrated in the uninvolved skin in three-quarters of active cases of SLE if the biopsy specimens are taken from the exposed skin, preferably from the dorsum of the wrist or forearm. Biopsy specimens from the unexposed skin are positive in only approximately 50% of cases, which may or may not have more severe renal disease and decreased long-term survival [13,14]. Variability in the presence of immunoglobulins and complement in adjacent sites of both light-exposed and light-protected areas probably accounts for differences between series. Biopsy specimens taken from oedematous areas may be negative. The presence of IgG in unexposed normal skin rarely occurs without SLE, and indicates a poorer prognosis than the presence of IgM or the absence of deposits. An IgM band may be found in other diseases, and without other evidence is not sufficient to make a diagnosis of LE [15]. IgM can be found in 80% of lesion-free sun-exposed skin in patients with actinic keratoses [16]. Deposits also occur in patients without rashes or may be present before other features of LE develop. Positive tests may come and go depending on activity, and decrease after treatment or in remission. Deposits in uninvolved skin may occasionally occur in systemic sclerosis, mixed connective tissue disease, dermatomyositis, anaphylactoid purpura, hypocomplementaemic vasculitis, rheumatoid arthritis, pemphigoid and dermatitis herpetiformis. This basement-membrane phenomenon can also be demonstrated in the uninvolved skin in patients with the so-called transitory type of DLE [17]. This is a subgroup of DLE, described by Baart De La Faille-Kuyper [18], with cutaneous lesions of DLE and immunoglobulins at the dermal–epidermal junction in uninvolved skin, as in SLE, but no definite clinical or serological evidence of the latter. The basement-membrane phenomenon is negative in uninvolved skin in other cases of DLE. The staining may be homogeneous or granular, or there may be larger aggregates under the dermal–epidermal zone [19]. Burnham and Fine describe homogeneous, thready and stippled patterns [20], which are different from the 'tubular' band of bullous pemphigoid [21]. The stippled band occurs in uninvolved skin, thready bands in new lesions and homogeneous bands in older chronic lesions. The band type depends on the type of skin lesion and does not distinguish between DLE and SLE. The presence of complement at the dermal–epidermal junction in patients with widespread SLE without renal disease may be associated with a lowering of the serum complement [22]. Both fibrin and properdin have been demonstrated in the lesions of SLE [23]. Properdin deposition in normal skin appears to correlate with disease activity [24]. The presence of properdin suggests that the alternative pathway of complement activation is involved, but nevertheless the classical pathway is the primary complement pathway involved in SLE. In drug-induced SLE, deposits of IgG, IgM and C3 at the dermal–epidermal junction may disappear when clinical symptoms regress [25].

Epidermal nuclear deposits, usually giving a speckled IgG pattern, occur in the basal epidermal nuclei and cells of the lower epidermis in nearly one-third of patients [26]. Immunoglobulin (IgG, IgA and IgM), with or without complement, can be found in the walls of blood vessels in skin lesions and uninvolved skin. There may be homogeneous fluorescence of the subendothelial part of the vessel wall, or intramural or perivascular granular fluorescence, and these changes are present in discoid, transitory and systemic LE. Homogeneous staining occurs in the uninvolved skin of 20% of patients with DLE and over 80% of patients with transitory or systemic LE. Electron microscopy of involved and uninvolved skin has shown deposits of proteins on the dermal side of the dermal–epidermal junction and in small blood vessels, resembling morphologically those present in 'wire-loop' lesions in the kidney [27].

Internal organs. The characteristic microscopic features in the internal organs include haematoxylin bodies in the heart valves and elsewhere, periarterial fibrosis of the spleen, and the so-called 'wire-loop' lesions in the kidneys. In the heart, microscopic changes, including fibrinoid necrosis, may occur in normal-looking valves. The vegetations of Libman–Sacks endocarditis [1] occur in 50% of cases coming to autopsy [28], and arise from proliferation of ground substance and connective tissue cells [29], which raise the endothelium. Focal necrosis occurs in these areas, and basophilic bodies are frequently seen. Later, infiltration with inflammatory cells occurs, together with fibrosis. Focal atrophy and fibrosis occur in the myocardium, but myocarditis is unusual.

The lungs frequently show pulmonary oedema and infective changes, but specific abnormalities are uncommon. Pulmonary parenchymal lesions or pleuritis occurred in 18% of one series [30], and other findings included interstitial fibrosis, pulmonary vasculitis, haematoxylin bodies and pneumonitis. A mucinous basophilic oedema of the alveolar walls occurs, with a hyaline alveolar lining membrane similar to hyaline membrane disease of the newborn. Alveolar wall thickening and vascular changes similar to those of Hamman–Rich syndrome may be found.

The liver may show infiltration of the portal tracts with lymphocytes, histiocytes and plasma cells. The so-called 'onion skin' appearance in the spleen is caused by concentric periarterial fibrosis around central and penicilliary arteries.

The lymph-node enlargement is usually associated with retention of normal architecture, but sometimes necrosis and haematoxylin bodies may be found.

The so-called 'wire-loop' appearance in the kidneys is caused by thickening and hyalinization of the capillary basement membrane of the glomerular tufts. Although this change may be seen in other diseases such as systemic sclerosis, chronic glomerulone-

phritis and malignant nephrosclerosis, the changes in SLE are more likely to be localized to one part of the glomerulus. Thickening of the glomerular capillary basement membrane and alterations in reticular tissue in the media of arterioles are associated with deposits of IgG and C3 [31]. Lupus nephritis has been divided into three types [32]: focal proliferative (lupus glomerulitis) and membranous, which are relatively benign, and diffuse proliferative (lupus) glomerulonephritis, which has a poor prognosis. In focal proliferative nephritis, a mild proliferation is confined to parts of some of the glomeruli and electron microscopy shows no electron-dense material. In membranous lupus nephropathy, there is irregular thickening of the glomerular basement membrane with epimembranous deposition of electron-dense material. The most common renal disorder is diffuse proliferative nephritis, in which there is irregular endothelial cell proliferation, fibrinoid necrosis, hyaline thrombi and interstitial inflammatory changes. Electron-dense deposits are seen on electron microscopy in subendothelial, subepithelial and mesangial areas. Heavy proteinuria with large numbers of red and white cells and casts in the urine suggests glomerulonephritis [33]. Although most cases of the nephrotic syndrome and renal vein thrombosis show membranous glomerulonephritis, focal proliferative glomerulonephritis has also been reported [34].

Germinal centres in the thymus are frequently increased [35]. Abnormal epithelial hyperplasia in the thymus is said to occur in all cases of SLE, but the change is not specific [36].

There may be evidence of widespread vasculitis in other organs and in the central nervous system. Although the vasculitis in the nervous system is usually mild, it can be florid [37]. Gammaglobulin deposits and complement have been found in the choroid plexus when immunohistology of the cerebrum, cerebellum and brainstem has shown no abnormality [38]. This, together with the finding of low cerebrospinal fluid complement levels [39], suggests an immune-complex pathogenesis for the involvement of the central nervous system.

Lymphadenopathy	50
Pleurisy	40
Raynaud's phenomenon	35
Pericarditis	25
Hepatomegaly	25
Central nervous system involvement	25
Abdominal symptoms	20
Splenomegaly	15

Presenting symptoms. The disease may affect many systems of the body, and the presentation and course are by no means uniform. Large series of cases have been reported [1–8], including one from the Far East [9]. The subject has been reviewed [8,10]. Despite the female sex predominance, clinical gender differences are not found, although men may be more liable to fits and renal failure [11].

The initial manifestations vary. In one series of 200 cases, the first changes were articular in 58% and cutaneous in 13.5% [12]. Presentation with renal abnormalities, psychiatric disturbances, pericarditis, pleurisy, abdominal pain and pyrexia of uncertain origin are less common.

In fulminating cases, there is usually marked constitutional disturbance, with fever, loss of weight, anorexia, malaise and joint pains; the skin may be involved later, if at all. On the other hand, the evolution can be gradual, starting with localized skin lesions and systemic involvement developing later. Fatigue is a prominent symptom, both at presentation and subsequently [13]. The diagnosis in many cases is made only by considering the condition in a patient with an obscure illness. As most cases are females, sex is an important diagnostic point. Although weight loss is a feature in nearly 50% of the cases, some patients may gain weight, and 18% actually did so in the Leeds series, which included several patients with long histories. Menstruation is irregular in 18% and absent in 75%. The onset in 15% of females is after the menopause. Sometimes, there is a previous history of sensitivity to drugs such as penicillin, gold or sulphonamides. Raynaud's phenomenon occurs in the course of the illness in approximately 35% of patients, and others frequently have chilblains and a poor peripheral circulation. Approximately 2% of patients with Raynaud's phenomenon eventually develop SLE. Sometimes, there may be other apparent precipitating factors, such as exposure to the sun, stress, trauma and infection. Rarely, hypothermia may occur, often precipitated by therapy [14].

Skin. Approximately 80% of cases have a rash at some stage, and in up to 25% it is the presenting sign [1]. The prevalence varies between series. Findings from a typical UK population are shown in Table 51.13 [2].

The cutaneous changes may be broadly divided between: (i) those specific for LE, and showing the characteristic histopathological appearances of LE; and (ii) those that are less specific in their origin and not showing LE histological changes. Many of these are also seen in the other connective tissue diseases.

Specific changes. Cutaneous erythema is the most common feature, particularly on light-exposed areas (Fig. 51.29). A butterfly

Fig. 51.29 Systemic lupus erythematosus: typical symmetrical slightly scaling erythema of the face and neck.

Fig. 51.30 Systemic lupus erythematosus of the dorsa of hands and forearms. Identical changes may occur in discoid lupus erythematosus. Note the chloroquine pigmentation of the distal part of the nails.

blush or discrete maculopapular eruption with fine scaling on the butterfly area of the cheeks or elsewhere is also frequently found (Fig. 51.30). Photoaggravation occurs in approximately 33% of patients at Leeds, but up to 73% has been reported from America [3]. This may relate to the amount of sunlight. UV radiation such as that found in discos [4], fluorescent lighting [5] and UVA from photocopiers [6] may also cause exacerbations. Oedema, especially of the face, may resemble contact dermatitis, seborrhoeic eczema, dermatomyositis or erysipelas, and can follow tooth extraction [7]. Occasionally, more acute lesions with bullae may follow exposure to the sun (Fig. 51.31), and bullae may be haemorrhagic [8,9].

Epidermal necrosis may give an appearance resembling toxic epidermal necrolysis [10]. In other cases, lesions are like those of erythema multiforme (Rowell's syndrome; see p. 51.14). Very rarely, the skin may show centrifugal annular erythema like that of SCLE. Lesions resembling chronic discoid lesions are initial manifestations in approximately 10% of patients and occur in the course of the disease in approximately 33%; they may be more common in men [11].

Non-specific changes. Sometimes, lesions may be minimal. This is particularly so in the case of the reticulate telangiectatic erythema seen on the thenar and hypothenar eminences of the palms, on the pulps and dorsum of the fingers and, to a lesser extent, on the toes and over the lateral borders of the feet and heels. The lesions on the palms may be confused with the palmar erythema of liver disease. They are bluish red and may show small whitish areas of scarring. The changes occur particularly on the dorsa of the distal phalanges and between the joints, but sometimes there may be small vascular necroses on the tips of the fingers and alongside the nails (Fig. 51.32). The nail folds may show hyperkeratotic and ragged cuticles (Fig. 51.33). Splinter haemorrhages may sometimes be seen in the nails [1], and other changes include pitting, ridging, onycholysis, striate leukonychia [2] and red lunulae [3]. Nail changes occur in approximately 25% of patients [4]. Recurrent Osler's nodes may occur in the absence of infective endocarditis [5]. Clubbing has been reported [6]. Dilatation of the nail fold capillaries also occurs, but this is seen in other conditions. Biopsies from the nails and from areas of palmar erythema show marked dilatation of superficial capillaries [7].

Hair changes. Alopecia occurs in over 50% of patients, especially in the active phase of the disease. This takes the form of diffuse loss of hair with a reddish scalp or, less frequently, permanent scarring alopecia, similar to that found in DLE. The hair is usually coarse, dry and fragile, especially on the frontal margin. This leads to an unruly appearance with short, broken-off hair, the so-called 'lupus hair' (Fig. 51.34) [1]. This occurs in 30% of patients, predominantly females [2]. The hair recovers as the disease becomes inactive, but 'lupus hair' usually persists longer than alopecia. The shortened hairs are unbroken and are probably brought about by slowed anagen growth.

Urticarial lesions and vasculitis. Persistent non-itching urticaria-like weals are common, and may respond to dapsone if associated with C1q deficiency. Urticarial lesions occurred in 7% of one series, but in 20% of patients at Leeds, and were considered to be brought about by immune-complex deposition [1]. SLE may present as hypocomplementaemic urticarial vasculitis [2]. Widespread purpura, resulting from thrombocytopenia or cutaneous vasculitis, is a common finding. Leukocytoclastic vasculitis may lead to purpuric macules, up to 1 cm in diameter, and in certain cases

Fig. 51.34 Unruly 'lupus hair' with diffuse alopecia.

Fig. 51.35 Necrotic crusted leg ulcers in systemic lupus erythematosus.

purpuric urticarial lesions may be found. Purpura can also be a result of corticosteroid therapy. Livedo reticularis, a mottled or bluish red discoloration, which blanches on pressure and is not affected by temperature changes, may develop, especially on the outer aspects of the arms. It occurs most frequently in patients who later develop central nervous system lupus [3]. The appearance of livedo reticularis in association with flares of cerebral vasculitis has been noted [4]. Superficial ulceration can occur in areas of livedo. Atrophie blanche [5] and lesions similar to those of malignant atrophic papulosis (Degos' disease) [6] are other features of vasculitis. Patients with the perniotic lesions of 'chilblain lupus' (see p. 51.11) may go on to develop SLE. These lesions may ulcerate, as may the hyperkeratotic keratodermatous skin sometimes found. A subset has been described in which perniotic lesions on the dorsum of the knuckles and toes, fingers and the pulps and palmar and plantar surfaces is associated with anti-Ro antibody [7]. Chronic pyoderma gangrenosum occurs, and has been the presenting feature of hydralazine-induced SLE [8]. Follicular pyoderma resulting from infection has also been described [9].

Large vessel disease. Gangrene of the tips of the fingers and toes [1] may develop insidiously. At first the digits become blue and cold and may be painful. Radiography of the fingers in cases with peripheral ischaemia shows absorption of the distal part of the terminal phalanges, as in systemic sclerosis. Later, the phalanges may become exposed, and spontaneous separation of the tips of the fingers may occur. Amputation of digits may be required. Occlusion of large- and medium-sized arteries can occur suddenly and result in gangrene requiring amputation of a limb [2,3]. This may be the result of vasculitis or thrombosis. Patients with thrombosis frequently have antiphospholipid antibodies [3]. Major vessel occlusion can occur in childhood [4]. Leg ulcers (Fig. 51.35) occur in approximately 10% of patients, usually near the malleoli but sometimes on the feet and elsewhere, from breakdown in reticular livedo and in areas of cutaneous vasculitis. Erythromelalgia (pain in the feet aggravated by heat and dependence and relieved by cooling and elevation) may be a presenting feature [5].

Mucinosis. Although mucin deposition is a common and often prominent histological feature of cutaneous lupus, specific clinical patterns of mucinosis also occur. Papular or nodular lesions resulting from mucinous deposits in the dermis without microscopic features of LE have been reported [1], and form a distinct entity which may be the presenting feature of LE [2]. Multiple firm nontender dermal papules and nodules, between 5 and 15 mm in diameter, occur on the upper part of the body and extremities [3–6]. The overlying epidermis appeared normal. Hyperpigmented acral papular mucinosis has also occurred in one patient with total alopecia [6].

Connective tissue changes. Hardening, binding-down and pigmentation of the skin of the face and limbs may resemble systemic sclerosis, although the typical mat-like telangiectases of the latter are usually absent. Calcinosis is rare [1], but occasionally widespread and large palpable deposits may develop [2] or be found radiologically [3]. Subcutaneous nodules occur in approximately 5% of patients [4]. They resemble rheumatoid nodules, although there may be no evidence of arthritis. They occur mainly over the backs of the proximal phalangeal joints and wrists, but are also found on the elbows, knees, occiput and the flexor aspects of the fingers. They may respond to hydroxychloroquine [5]. Some are histologically identical with classic rheumatoid nodules [6], others are probably caused by vasculitis and thrombosis [7]. Panniculitis, similar to LE profundus, can occur in the course of the disease or can be the presenting sign [8–10]. Lesions may break down, resolve with oral corticosteroids or require surgery and grafting. Relapsing nasal and auricular chondritis have been described [11]. The nose and ears are tender, warm, swollen and red, but cartilage collapse does not occur as in polychondritis. Treatment with corticosteroids is effective.

Pigmentary changes. Pigmentary disturbances are not uncommon. Whole areas can show hypopigmentation. A bluish black pigmentation of the skin results from antimalarial therapy [1].

Other cutaneous changes. In the Chinese, hyperkeratotic follicular erythematous papules, sometimes becoming pigmented or confluent, occur on the trunk and limbs. Psoriasiform lesions and hyperkeratosis of the palms and soles are found [2,3]. Widespread ichthyosis and warty excrescences on knees and elbows may occur [4]. Eruptive dermatofibromas have been reported [5]. Acanthosis nigricans has been reported in lupoid hepatitis [6]. Herpes zoster is more frequent than expected in SLE [7], and scabies is more severe and may be of the crusted type [8].

Bullous SLE (Fig. 51.36) [1]. Blistering is uncommon in SLE. In the classic disease, separation of the epidermis and dermis occurs as a result of severe liquefaction degeneration of the basal layer and dermal oedema. A separate subset called bullous SLE has been defined, with distinct clinical and histopathological features, the

Fig. 51.36 Bullous lupus erythematosus of the face and neck.

latter resembling dermatitis herpetiformis [2]. Subepidermal vesicles contain neutrophils with microabscesses, and nuclear 'dust' and fibrin at the tips of dermal papillae. Immunohistology, however, shows linear deposition of IgA, IgG and IgM and, to a lesser extent, C3 at the basement membrane, resembling bullous pemphigoid and unlike the IgA seen in the dermal papillae in dermatitis herpetiformis. Electron microscopy shows the immunoreactants to be in the sublamina densa [3] and not in the lamina lucida as in pemphigoid, although the immunopathological changes are variable and may indicate that a number of basement-membrane antigens can act as targets [4]. This has subsequently been confirmed [5]. In particular, a form resembling epidermolysis bullosa acquisita (EBA) has been described [6]. The target antigen in some patients is type VII collagen, but other antigens may be involved in bulla formation [7].

Clinically, the bullous lesions are predominantly on the face, neck and upper trunk, but may be more widespread, and may heal with milia formation. One-third have mouth lesions. Photosensitivity may occur. The patient may initially present with lesions resembling erythema multiforme [8]. Glomerulonephritis is common, and associated with hypocomplementaemia and anti-DNA antibodies. Circulating antibasement-zone antibodies have many features of EBA antibodies. The demonstration of such antibodies may precede the development of SLE by many years [9]. It is not yet established whether patients with EBA antibodies are a unique subset of bullous LE or whether they represent the coexistence of two separate diseases, although it has been suggested that the spectrum of bullous LE should include all cases of bullous disease occurring in patients with SLE [1]. Rarely, drugs, including hydralazine [10] and IFN-α [11], may precipitate bullous SLE. Dapsone alone or in combination with prednisone is the treatment of choice. It is not always successful and may even exacerbate the disease [7]. The authors have used thalidomide successfully in these resistant cases.

Pemphigus erythematosus [1]. Erythematous, scaly, hyperkeratotic or crusted lesions, sometimes adversely affected by the sun, occur in a butterfly distribution on the cheeks and in a seborrhoeic distribution on the trunk of patients with Senear–Usher syndrome (see Chapter 40). This combines the immunological features of pemphigus and LE. Direct immunofluorescence shows immunoglobulin and complement in the intercellular substance and at the dermal–epidermal junction of perilesional and, to a lesser extent, of light-exposed and non-exposed skin. Circulating pemphigus-like antibodies and antinuclear factor occur in 80–100%, but anti-DNA and ENA antibodies are not found. Antidesmoglein antibodies have also been demonstrated [2]. The condition occurs spontaneously, but has been induced by penicillamine, propranolol, captopril, pyritinolol and thiopronine. Topical steroids alone may control the condition, but systemic steroids, immunosuppressives or dapsone may be required.

Mucous membrane lesions [1–3]. Mucous membrane lesions occur in 26% of cases, usually on the palate (82%) (Fig. 51.37),

Fig. 51.37 Systemic lupus erythematosus involving the palate.

buccal mucosa or gums, in active phases of the disease [3]. Lesions start as small erythematous or purpuric areas, which break down to form shallow and sometimes painful ulcers, with a dirty yellow base and surrounding reddish halo. There may be difficulty in swallowing. Histology and immunohistology show changes similar to those in the skin. Light microscopy can usually distinguish between LE and lichen planus [4]. Immunofluorescence is usually positive [5]. Repeated sore throats and oral ulceration may be presenting features [6]. The appearances can resemble a *Candida* infection, and sometimes *Candida* is present as a secondary infection. The lips may become cracked, oedematous and crusted in acute cases. Infarction of the tongue, with anticardiolipin antibodies, was the presenting feature in one case [7]. Cheilitis occurs in approximately 6%, the lips having a silvery appearance, with erythema, scaling and blurring of the vermilion border [1]. The larynx is occasionally involved. Ulceration of the mucosa of the nasal septum occurs in approximately 5%. Perforation of the nasal septum is a complication of exacerbations and presents with epistaxis [8]. Erythema of the vulva and perianal area occurs and vulval ulceration may develop, but is less common than oral ulcers. Patients may present with vulval and vaginal ulceration. Orogenital ulceration has been reported with hydralazine-induced lupus [9].

Table 51.14 Features distinguishing systemic lupus erythematosus (SLE) from rheumatoid arthritis (RA).

Distinguishing feature	SLE (%)	RA (%)
Deforming arthritis	25	Common
Subcutaneous nodules	5	25
Radiological erosions	Rare	Common
Involvement of kidneys	Common	Rare
Positive LE cell test	80	15
Positive ANA test	90	20
Rheumatoid factor present	40	80

ANA, antinuclear antibody; LE, lupus erythematosus.

Arthritis [1]. Involvement of the joints occurs at some time in approximately 90% of patients, arthralgia being more common than arthritis. A rheumatoid-like deformity is present in approximately 25% of cases, with marked soft-tissue swelling, especially of the dorsa of the fingers, hands and wrists, although joint erosions on X-ray are not a feature. The deformity is usually less, but the soft-tissue swelling is more marked than in rheumatoid arthritis [2]. Jaccoud's syndrome, severe deformity of the hands with ulnar deviation and swan-neck configuration, often with little pain and good function, occurred in 13% and fixed flexion contractures of the elbows in 11% in one series [3]. Arthritis mutilans of the distal interphalangeal joints of the hands can occur [4]. The elbows, shoulders, knees and feet may also be involved and soft-tissue nodules may occur, usually indicating calcinosis. Temporomandibular joint involvement may be indicated by locking or dislocation, tenderness and pain on mastication [5]. Features distinguishing SLE from rheumatoid arthritis are shown in Table 51.14. Migratory polyarthritis with inflammation, effusion and erythema occur less frequently. Sacroiliitis occurs in male patients [6]. SLE may rarely present with polymyalgia rheumatica [7]. *Salmonella* infections occur in patients with SLE, and may be associated with septic arthritis [8,9].

Heart. Cardiac involvement in SLE is common, and increases with the duration of the disease [1]. Pericarditis is the most frequent cardiac manifestation, but the incidence of 87% in one review [2] must have been the result of selection. Fibrinous pericarditis is frequently found, but sometimes a large effusion may occur and reabsorb on adequate corticosteroid therapy. Rarely, a large effusion can develop within hours, giving rise to cardiac tamponade [3] and requiring aspiration. The incidence of classic endocardial lesions (Libman–Sacks endocarditis) is difficult to estimate, but the diagnosis is rarely made clinically. Lesions were found at autopsy in only four out of 30 patients in one series [4] and in 50% of patients in another [5]. The valves on the left side of the heart are commonly involved. Both systolic and diastolic murmurs may be found depending upon the site of the lesion, and bacterial endocarditis can occur on the damaged heart valves. Aortic incompetence may occur without involvement of the mitral valve [6] at an early stage of the disease before steroids are used, or when the condition is well controlled. Tricuspid regurgitation has been reported [7]. Echocardiography is helpful in diagnosis [8], and valve replacement has been successful [9].

Coronary arteritis results in myocardial infarction [10]. Infarction may also result from atherosclerosis in young patients [11]. Antiphospholipid antibodies may be demonstrated in such patients [12]. The myocardium may also be affected and results in cardiac failure [13]. The diagnosis can be confirmed by endomyocardial biopsy [14]. Alterations in rhythm include atrial fibrillation and heart block of all types. This may be associated with both Ro and U_1-RNP antibodies [15].

Hypertension occurs in approximately 35% of patients. Alterations in the electrocardiogram (ECG) in the course of the illness may be helpful in diagnosing or in confirming the presence of cardiac involvement. There is some evidence that treatment with corticosteroids increases the incidence and degree of hypertension, coronary atherosclerosis and heart failure [5]. Reduced exercise tolerance occurs and may be caused by abnormal myocardial dynamics on exercise [16].

Lungs [1]. The incidence of involvement of the pulmonary system varies between series, and the radiological changes [2] depend on the stage of the disease. Transient pleurisy is the most common feature, and in approximately two-thirds of these cases some fluid develops, occasionally haemorrhagic. Pleural thickening can be shown radiographically. Involvement of the lungs is less frequent, and is shown mainly as transient infiltration, sometimes with mottling and reticulation (Fig. 51.38) [3]. Acute pneumonitis with severe dyspnoea and fever may be a presenting manifestation of SLE [4], and cases have been reported with disseminated intravascular coagulation [5]. There is a high incidence of anti-Ro antibodies in pneumonitis [6]. Diffuse fibrosis, like that occurring in systemic sclerosis, is not found [1]. Shrinking lung syndrome is probably caused by diaphragmatic fibrosis [7]. Pulmonary hypertension occurs [8], and pulmonary haemorrhage can be dangerous [9]. When dyspnoea, pleuritic pain and fever occur with linear shadows on radiography, recurrent pulmonary infarction may be simulated. Fibrosing alveolitis has been reported, as well as haemopneumothorax [10]. Hilar lymphadenopathy may cause confusion with other diseases [11]. Unlike those of systemic sclerosis, the pulmonary changes may resolve with steroid therapy.

Fig. 51.38 Pulmonary infiltration in systemic lupus erythematosus. This cleared in approximately 2 years on treatment with corticosteroids.

Impairment of pulmonary diffusion (transfer factor) occurred in 42–80% [12], and is more common than reduction in lung volumes [13]. Function of the diaphragm may also be deficient [12], and bilateral elevation of the diaphragm with linear shadows over the lower zones is characteristic of SLE. *Pneumocystis carinii* infections should be considered in all steroid-treated patients who present with respiratory distress and pulmonary infiltration [14]. Nocardial infection with lung abscesses [15] and Legionnaires' disease [16] have been reported. Laryngeal involvement is rare and indicated by stridor and hoarseness, and may be life-threatening. It can occur in inactive disease, and may be complicated by nocardiosis [17].

Renal changes. The renal changes [1] in SLE are very important in assessing the prognosis (see p. 51.60). Most patients will have renal involvement, as histological evidence of nephritis may occur without proteinuria or microscopic urinary abnormality and with normal renal function [2]. Sometimes, proteinuria and casts may occur transiently with febrile exacerbations. Renal disease in lupus accounts for 3% of end-stage renal failure, and is an important cause of mortality in SLE [3]. The need for regular screening by urinalysis, blood pressure monitoring, assessment of renal function and early renal biopsy is critical. Usually, renal exacerbations are associated with high titres of antinuclear factor, elevated DNA binding and low serum complement, but occasionally these features may revert to normal in severe relapse [4]. Impaired renal tubular potassium secretion can lead to persistent hyperkalaemia [5].

The course is variable, and albuminuria and casts may persist for years without marked deterioration in renal function. Kidney damage, if this is going to develop, usually appears early (within the first 3 years) and is more frequent and severe in younger patients [1]. However, renal involvement may appear as long as 34 years after diagnosis of SLE [6]. A relatively benign course is associated with membranous lupus nephropathy. This occurs in approximately 8% of patients with SLE. Clinically, proteinuria and microscopic haematuria occur some years after other evidence of the disease. Prednisone treatment does not seem to influence proteinuria or renal function in this type [7].

Some cases develop typical signs of the nephrotic syndrome, and renal vein thrombosis has been reported. The development of pleuritic pain in a patient with SLE and the nephrotic syndrome should alert the clinician to the possibility of renal vein thrombosis and pulmonary emboli [8]. Cystitis with reduction of bladder capacity and thickening of the bladder wall may be a primary manifestation of SLE [9]. A strong correlation between lupus cystitis and gastrointestinal involvement has been noted [10].

Gastrointestinal tract [1]. Anorexia, nausea and vomiting sometimes occur, and impairment of oesophageal motility has been reported [2], especially in patients with Raynaud's phenomenon. Motility studies show absent or impaired contractions in one-third of patients [3]. Abnormalities may occur in any part of the oesophagus but particularly in the upper third, and such dysfunction is not related to activity of the disease. Fewer patients complain of dysphagia or show radiological abnormalities. Pain, vomiting, diarrhoea, malabsorption [4,5], gluten-sensitive enteropathy [6] and protein-losing enteropathy [7], or evidence of obstruction or bleeding, result from intestinal involvement. Pneumatosis cystoides intestinalis and spontaneous pneumoperitoneum are rare [8],

but have been reported in a patient with antinuclear-negative SLE [9]. Patients with arteritis may present as an acute surgical emergency, and this complication may be fatal [10]. Small intestinal ulceration occurs in patients with antiphospholipid antibodies [11]. Mesenteric arteriography may be helpful in showing irregularities of the small intestinal arteries [12]. Pancreatitis [13] occurs in both children and adults and is often fatal. It can be associated with subcutaneous fat necrosis and calcinosis cutis [14]. Ulcerative colitis [15] and colonic perforation [16] also occur. Mesenteric lymphadenopathy may be associated with hilar lymphadenopathy [17].

Lymphangiographical changes can resemble those seen in early malignant lymphoma [18]. Painless ascites, in the absence of the nephrotic syndrome, congestive heart failure or hepatic cirrhosis, may be the presenting feature [19]. It is presumably a result of peritoneal serositis. Infarction of the tongue can be another presentation [20].

Hepatic lesions [1]. These may be more common than previously recognized. Liver disease is present in approximately one-third of patients, but it is usually mild and often asymptomatic. Histology usually shows steatosis or mild hepatitis. Lesions include granulomatous hepatitis, chronic active hepatitis, cirrhosis, death from liver failure and hepatic infarction. The role of hepatitis C infection has been reviewed [2]. Nodular regenerative hyperplasia occurs [3], and hepatic veno-occlusive disease has been reported [4]. Subclinical liver disease indicated by mild transaminase elevation occurs in approximately 10%. LE cells are sometimes found in hepatitis. The condition, inappropriately named 'lupoid hepatitis', involves mainly young females who have a benign cirrhosis and evidence of adrenal overactivity such as acne, hirsutism, pigmentation, amenorrhoea and abdominal striae. Other features include febrile upsets, polyarthritis, hyperglobulinaemia and other protein abnormalities. Smooth muscle and mitochondrial antibodies may be demonstrated. Patients with chronic active hepatitis may show extensive purplish telangiectasia [5].

Thyroid disease. Both hyperthyroidism and hypothyroidism occur in SLE, and there is a high frequency of abnormal thyroid function tests and thyroid autoantibodies in patients without diagnosed thyroid disease [6].

Nervous system [7,8]. Approximately 50% develop neuropsychiatric features from the disease itself [8]. There is no direct correlation between neurological and psychiatric disease and clinical or laboratory indices of disease activity. Livedoid vasculitis of the skin may be an important prodromal sign of central nervous system (CNS) lupus [9]. Anticardiolipin antibodies may or may not be present. Migraine can be a feature [10]. Epilepsy, resulting from small thromboses in cerebral vessels affected by vasculitis, can be the presenting manifestation of SLE, particularly in patients with high titres of anticardiolipin antibodies. The incidence of epilepsy is difficult to evaluate, owing to selection of cases in series from special clinics. Peripheral sensorimotor [11] and autonomic neuropathy occurs [12], brought about by vasculitis in the vasa nervorum. It is important to distinguish this from the neuropathy induced by chloroquine [13]. Trigeminal neuropathy, with numbness and pain in the face [14], deafness [15], transverse myelitis [16], optic neuritis [17], aseptic meningitis [18], Guillain–Barré syndrome, and a case presenting as disseminated encephalomyelitis, have been reported [19]. Patients may present with clinical features of multiple sclerosis, and in this variant there is a high incidence of chronic biological false-positive Wassermann reactions and mitochondrial antibodies [20]. Occasionally, a single cranial nerve may be involved. Sometimes, signs simulate an intracranial mass [21], and pseudotumour cerebri because of raised intracranial pressure occurs [22]. Subarachnoid haemorrhage [23] and massive spontaneous subdural haematoma have been reported [24]. Parkinsonism is rare [25]. The association of chorea with SLE has been reviewed [26]: two cases of chorea were reported in a series of 175 patients with SLE [27], and the authors have seen this association in two girls aged 3 and 16 years. Chorea

gravidarum also occurs [28]. SLE may also cause psychiatric symptoms, including anxiety, hypomania, emotional lability, memory defects and depression. Psychiatric symptoms are found in approximately 20–30% [29]. Patients may respond to the disease with hypochondriasis, depression and hysteria, and pseudocyesis has been reported [30].

The electroencephalogram (EEG), conventional CT scanning, MRI scanning and oxygen-15 brain scanning may be helpful in the diagnosis of cerebral LE, and abnormalities are related to clinical progress [31]. Cranial computed tomography (CT) may show focal areas of infarction and cerebral atrophy or calcification [31]. The former may be caused by steroid therapy rather than the disease. Autoantibodies to neuronal antigens can be demonstrated in approximately 20% of patients with SLE, especially in those with neuropsychiatric features [32,33]. Antiribosomal P protein antibodies seem to be associated with psychosis [34]. Patients with multiple strokes followed by dementia are likely to have antiphospholipid antibodies [35]. Depressed levels of C4 in the cerebrospinal fluid (CSF) are found in patients with CNS involvement, but not in patients with active SLE without CNS manifestations [36].

Toxoplasmosis of the brain may occur as an opportunistic infection in patients with SLE and the manifestations resemble cerebral lupus [37].

Involvement of the eyes. Eye changes in SLE are not uncommon [1]. They include lid oedema, conjunctivitis and subconjunctival haemorrhages, lacrimal hyposecretion, episcleritis, scleritis, anterior and posterior uveitis, retinal cytoid bodies, retinal haemorrhages and branch- and main-trunk arterial and venous occlusions. Optic neuritis is uncommon but may be the presenting feature, causing confusion with multiple sclerosis [2]. The retinal cytoid bodies—oval, whitish areas alongside arteries and veins—are not specific to SLE, and are thought to be brought about by damage to the endothelium of capillaries, which allows the passage of plasma and red cells into the nerve fibre layer. Depigmentation of the retina may be present. Retinal lesions rarely cause visual impairment, but blindness can occur [3]. Lupus retinopathy was found in approximately 8% in one large series and was associated with active disease and lupus cerebritis, and was a marker for poor prognosis [4]. Retinal changes can be demonstrated in nearly

one-third of patients by fluorescein angiography, and are associated with active disease [5]. Visual impairment may be the presenting symptom of SLE [6]. Symptoms of corneal involvement occur in more than half of patients, and 88% have corneal staining with fluorescein [7].

Involvement of the ears. Sudden bilateral loss of hearing, presumably because of vasculitis of the arteries of the cochlea, may be dramatic and permanent. One patient's hearing responded to plasma exchange [1].

Muscle changes. Muscle pain occurs in approximately 50% of patients, and this may be confused with the pain of arthritis. Muscle weakness is a less common feature. Electromyographic abnormalities correlate better with weakness than myalgia. The serum aldolase level is frequently raised but the serum creatine phosphokinase is usually normal [1]. A vacuolar myopathy is considered to be specific [2]. Calcinosis may occasionally occur [3]. Very rarely, there may be a myasthenic reaction and SLE can follow, or be associated with myasthenia gravis [4]. A thymoma may sometimes be found [5].

Involvement of tendons [1]. Tendon rupture is rare, and involves particularly the weight-bearing tendons such as the patellar, quadriceps and Achilles tendons, but it may occur in any tendon [2,3]. Tendinous laxity may precede rupture and be partly attributable to hyperparathyroidism secondary to chronic renal failure [4], although long-term corticosteroid therapy may be relevant. Abnormalities of the feet with clawing of the toes and flexion contractures have been designated 'lupus foot' [5].

Calcification. Calcification may occasionally occur. Nine patients in one series of 130 cases had calcification [1]. This is more frequent in the legs, and may be bilateral and diffuse in the skin or deeper soft tissues, or be unilateral and localized. Sometimes, there are large deposits or nodules in the subcutaneous tissues [2]. It can occur without preceding local inflammation or ulceration, and may antedate other manifestations of SLE by as long as 7 years [3]. Periarticular calcification in the hand has been reported [1]. Calcification of the arteries of the legs may occur in early adult life. The myopathy of SLE may result in calcification [4]. A case of SLE with hypercalcaemia has been reported [5]. The serum calcium returned to normal when the patient had responded to treatment with corticosteroids and intravenous pulse cyclophosphamide.

Bone changes. Avascular bone necrosis [1] occurs in 5–7% or more of patients and is considered to be part of the disease, although it may be exacerbated by corticosteroid treatment [2], especially in high doses. It may be more frequent in patients with the lupus anticoagulant [3]. It may occur in relatively mild cases of SLE [4], but the risk is increased in patients with Raynaud's phenomenon [5]. The femoral head or condyle is most frequently involved [6], but the condition also may involve the knees, ankles, humerus, metatarsals and the carpal bones causing wrist pain [7]. It is commonly bilateral, with involvement of multiple joints. It is rarely crippling, although it may proceed to destruction of the joint. X-rays may be normal, but the diagnosis is often clear on MRI [8]. The condition is thought to be associated with increased pressure in the bone marrow because of altered venous drainage, and core decompression may be successful [9]. Total hip replacement may be required if it fails, or in the late stages. There may be patchy sclerosis and cystic changes in the bones of the hands and feet, and metacarpophalangeal and metatarsophalangeal joints may rarely show subcondylar erosions and adjacent sclerosis [10]. Osteonecrosis, possibly resulting from infarction, has been found in as many as 13 joints during corticosteroid treatment [11].

Other manifestations of systemic involvement include lymphadenopathy, which occurs in more than 50% of cases, and splenomegaly. Swelling of the parotid, submaxillary and lacrimal glands sometimes develops. Some features of Sjögren's syndrome have been found in practically all cases of SLE on detailed investigation [12].

SLE in childhood [1]. The clinical picture, course and treatment are similar to the disorder in adults, but on the whole children have more severe disease [2]. The earliest age of onset reported is 3 months [3]. Bullous SLE may resemble chronic bullous disease of childhood [4]. In one series [5], 30% had CNS involvement and 87% had renal disease (diffuse proliferative lupus nephritis, 34%). Overall survival was 85% at 10 years and 77% at 15 years after onset. Children with CNS lupus did no worse than other patients, and this has been noted by others [6]. The prognosis of patients with renal disease is now better than earlier reports suggested. Enlargement of the liver, spleen and lymph nodes is more common in childhood cases. Pancreatitis associated with cutaneous panniculitis and calcinosis has been reported [7]. Prolonged therapy with high-dose steroids may increase disease-related damage; this may be avoided by judicious use of immunosuppressives [8]. Autologous stem cell transplantation has been used successfully [9].

SLE in the elderly [10]. The onset of disease over 60 years occurs in nearly 20% of patients and is often insidious. There is an increased incidence of lung disease and Sjögren's syndrome, and a lower incidence of renal disease and mesenteric vasculitis [11], and antibodies to Ro and La are frequent. There appears to be an association with HLA-DR3.

SLE in pregnancy [1,2]. Fertility is normal if renal function is good. Worsening of SLE is uncommon in pregnancy, especially in those on immunosuppressive therapy [3]. Clinical remission for 6 months before conception should indicate an uncomplicated pregnancy and a live birth [4]. The outcome with renal involvement is comparable with those whose kidneys are not affected [5]. There is a higher risk of premature delivery, fetal loss and perinatal mortality in all patients. Abortion occurred in 8% and perinatal mortality was 13% in one series [6]. The increased risk of fetal death may be because of immune complex deposition on the trophoblast basement membrane [7], or the transplacental passage of antiphospholipid antibodies. Anticardiolipin antibodies, especially of the IgG isotype [8] or the lupus anticoagulant, are associated with a markedly increased fetal loss in all stages of pregnancy, but the presence of these antibodies without a previous history of fetal loss or thrombosis is not an indication for treatment [1]. With a history of recurrent fetal loss, treatment with prednisone and aspirin may be effective [9]. With good obstetric care, close follow-up, and treatment with low-dose aspirin if antiphospholipid antibody is present, a success rate of 71% has been reported [10]. The authors have seen successful pregnancies following *in vitro* fertilization in patients with SLE and the lupus anticoagulant.

Therapeutic abortion is not indicated and only causes added stress, nor is caesarean section required. It is important to avoid excessive trauma, haemorrhage or shock. The dosage of corticosteroids should be temporarily increased at the time of delivery and postpartum. Corticosteroids do not appear to cause impairment of growth or malformation in the fetus, but high-dose steroids during early pregnancy can cause cleft palate. Babies of mothers with untreated SLE are usually smaller than expected, and corticosteroids may assist growth of the fetus *in utero* [5]. If the patient is on azathioprine, this should be continued as there is no evidence of an increase in the malformation rate [11].

Oestrogen-containing contraceptives, even at low dosage, should be avoided in women with SLE. If mechanical methods of contraception or intrauterine devices are not possible, pure progestogens may be an alternative [12]. Breastfeeding is probably safe if the patient is on aspirin or low-dose steroids, but should probably be avoided if other immunosuppressives are used.

Neonatal lupus erythematosus

Definition. Neonatal lupus erythematosus (NLE) is a disorder thought to be caused by the transplacental passage of maternal antibodies. The most frequent clinical manifestations are cutaneous lesions and congenital heart block (CHB).

Aetiology. Aylward [1] was the first to report CHB in the siblings of a mother with Mikulicz's disease (Sjögren's syndrome) in 1928. McCuiston and Schoch [2], however, were the first to suggest that the association of NLE and maternal systemic lupus may be related to the transplacental transfer of 'a transmittable aetiological agent' (maternal antibodies). This suggestion subsequently gained credence from the fact that the NLE skin lesions resolve as maternal antibodies are cleared from the infant's serum [3].

The first associated antibody described [4] and the serological marker most commonly associated with NLE is the Ro/SS-A antibody. This has been reported to be present in between 82% of infants and 92% of mothers [5] and 100% of NLE patients [6–8]. Two main Ro/SS-A proteins exist (52 and 60 kDa), and studies have suggested that the former is more frequently found in CHB [9,10], whereas the latter is more frequently associated with cutaneous disease [11], although this is by no means a universal finding [12]. It has been claimed that the aa200–239 (p200) locus on the 52-kDa Ro/SS-A protein is a more specific predictor of CHB [13], but a further study found this occurred with a similar frequency in children without CHB [14]. La/SS-B antibodies are less frequently found, one study detecting these in approximately 50% of NLE infants and 60% of mothers (usually in association with Ro/SS-A antibodies) [5]. A further study suggested that 50-kDa La/SS-B antibodies were associated with cutaneous disease [15], and another suggested that anti-idiotype antibodies to La/SS-B antibodies were protective against the development of NLE [16]. U_1-RNP antibodies are much less frequently found but have been reported as the only antibody in some patients with cutaneous NLE [17,18]. In this and subsequent reports, U_1-RNP antibodies have not been associated with CHB.

Evidence that these antibodies may be pathogenic comes from the studies of Lee *et al.* [19] who showed that purified Ro antibody bound to human skin grafted onto nude mice, in a pattern similar to that found in typical LE lesions. In addition, Ro/SS-A antigen is present in neonatal skin [20]. These antibodies have also been shown to bind to Ro/SS-A and La/SS-B antigen in human fetal cardiac conducting tissue [21–23] where they can cause conduction abnormalities [24,25]. A sequence of apoptosis, opsonization and fibrosis has been proposed [26].

It is unlikely that these antibodies represent the whole story, however, as they are non-specific for NLE, occurring in Sjögren's syndrome and SCLE. They are also found in approximately 0.5–2% of the normal population when assessed by immunodiffusion and in 5–11% when assessed by enzyme-linked immunoabsorbent assay (ELISA) [5]. Some studies have suggested that disease expression may be related to HLA status, the HLA-DR3 haplotype (especially when associated with DQA1 and DQB1) having been associated with the immune response to Ro/SS-A [27,28]. These, and a previous study [8], suggest that the HLA haplotype is important for antigen production in the mother but not necessarily relevant in the infants. Other workers argue that these antibodies are only indirectly related to disease, the disease process being caused by either: (i) the 52-kDa Ro/SS-A showing homology with the 5-HT_4 serotoninergic receptor, binding to which then mediates cardiac damage [10]; (ii) the presence of antibodies to a completely separate 57-kDa protein [29]; (iii) the prescience of the TNF-α 308A allele (associated with high TNF-α production), HLA-DRQB1*02, HLA DRB1*03 and TGF-β polymorphisms [30]; or (iv) via maternal microchimerisms [31,32]. A single case report has implicated α-interferon therapy in the aetiology of neonatal lupus [33].

Clinical features

Cutaneous. Approximately half of NLE infants manifest skin lesions [5], which may be present at birth or occur in the first few weeks of life. The most common finding is an erythematous, slightly scaly eruption on the face and periorbital skin (raccoon sign/owl-eye/eye mask) (Fig. 51.39), with the scalp, trunk, extremities, neck and intertriginous areas involved in decreasing order of frequency [34]. The eruption can be exacerbated by UV exposure and there are reports of the rash being precipitated by phototherapy for neonatal jaundice [35,36], although the rash is sometimes present at birth, which would make it difficult to implicate UV exposure in the aetiology [37]. Other manifestations include a vitiligo-like eruption in a black infant [38], morphoea-like lesions [39] and papules on the feet [40].

Fig. 51.39 Typical 'raccoon' eyelid lesions in neonatal lupus erythematosus.

The rash improves over the first few months of life and has usually resolved without scarring by 12 months of age. Occasional patients exhibit residual telangiectasiae [41], dyspigmentation or atrophy [34] and atrophic scarring [42].

Cardiac. Complete heart block occurs in approximately 60% of white patients [5], although it may be less common in Japanese patients [43]. Associated features may also include pericardial effusions, pleural effusions, ascites, intrauterine growth retardation and hydrops fetalis [44]. Up to 50% will require pacing in the neonatal period and others will require a pacemaker at a later date [45]. Dilated cardiomyopathy occurs in up to 20%, and has a significant mortality in the first year of life [45].

Haematological. Thrombocytopenia may occur in up to 20% of cases [41,46], is transient and does not usually require treatment, although it has been associated with petechial and purpuric lesions. Neutropenia, haemolytic anaemia and aplastic anaemia have also been reported [47,48].

Hepatic. Hepatomegaly and splenomegaly have been reported in NLE [49], with histological changes of 'neonatal hepatitis' and, on occasions, fibrosis. Cholestasis has been reported [49,50], as has cholestatic hepatitis [51,52]. A recent study showed hepatobiliary disease in 19 of 219 patients with NLE, and in three this was the only finding [53].

Miscellaneous. Case reports have associated NLE with pneumonitis [6], haemochromatosis [54], aseptic meningitis [55], myelopathy [56], transient myasthenia gravis [57], spastic paraparesis [41,58] and chondrodysplasia punctata [59]. One study demonstrated brain CT abnormalities in 10 of 11 infants with NLE although there was no clinical evidence of neurological disease, the authors emphasizing that it is important to be aware of these findings to avoid misdiagnosis of congenital viral infection in a newborn with multisystem NLE [60]. Hydrocephalus has been reported [61], affecting 8% of NLE infants in one study [62].

Treatment

Cutaneous lesions. Skin disease is often mild and requires no treatment. Sun avoidance should be advised and low-potency topical steroids may be of benefit [5,45]. Persistent telangiectasiae have been reported to respond to the tunable dye laser [63].

Cardiac. Up to 50% may require pacing in the newborn period, and others may require pacemaker insertion at a later date [44]. There is little information with regard to whether CHB and its consequences can be prevented or treated *in utero*. One study reviewed outcomes in pregnancies of mothers with Ro antibodies who had received systemic steroids during pregnancy [64]. When steroids had been given during the first 16 weeks of pregnancy, no conduction defects occurred, suggesting that they may have possibly suppressed disease initiation during this period of gestation. Corticosteroids administered after the first 16 weeks, however, were not beneficial and did not reverse established complete heart block. Another study compared outcome in fetuses whose mothers were treated with oral corticosteroids at various stages during pregnancy. Although there was no improvement in established complete heart block, the treated group showed less progression from first- to second-degree block to complete block and some improvement in pleural effusions, ascites and hydrops [43]. Anecdotally, a mother with the HLA-DR3 phenotype, high titres of Ro/SS-A and La/SS-B antibodies and an existing child with neonatal lupus, delivered a healthy infant after plasmapheresis three times weekly and systemic steroids during gestation [55].

The role of 'placenta crossing' steroids such as dexamethasone in at-risk infants is unclear at present, although a treatment algorithm has been suggested [26] and the results of a multicentre, prospective trial are awaited.

Haematological. Most resolve spontaneously without treatment, although prednisolone at a dose of 2 mg/kg/day for 14 days resulted in a dramatic improvement in thrombocytopenia in one patient [51].

Hepatic. Most resolve spontaneously without treatment.

Pregnancy. A pregnant patient who is known to have Ro/SS-A or La/SS-B antibodies should be made aware of the possible problems, and their obstetrician alerted. The risk of NLE in a Ro/SS-A positive mother without connective tissue disease or a previous history of NLE is probably low, perhaps about 2%. The risk may or may not be higher for symptomatic Ro/SS-A positive mothers, but for women who have already had a baby with NLE, the estimated risk of having another affected child ranges widely between studies, but is probably about 25% [65]. Perhaps in this latter group, the recommendation of serial fetal echocardiography by an experienced paediatric cardiologist [26] should be considered.

Although Ro/SS-A and La/SS-B antibodies have been demonstrated in human breast milk, a large study found no evidence to suggest that they had any pathological consequences. However, in the unusual circumstances of a worsening rash or developing cardiomyopathy, the authors suggested considering discontinuation of breastfeeding [66].

Prognosis

Infant. Although follow-up data are limited, some children have gone on to develop autoimmune disease, even in childhood [65], and one child developed a CNS vasculopathy at the age of 17 years [67]. Follow-up is therefore advised.

Mother. Although mothers are often asymptomatic at the time of the birth, long-term follow-up studies by several groups have shown that many develop signs and symptoms of autoimmune disease, especially Sjögren's syndrome, systemic lupus erythematosus and undifferentiated connective tissue disease [65]. Follow-up is therefore advised.

Laboratory investigations [1]. Laboratory investigations are frequently necessary to confirm the diagnosis, although even after extensive investigations it may be impossible to be entirely dogmatic, in view of the overlap of the manifestations of connective tissue diseases. Anaemia, of some degree, is found in approximately 75% of patients and is brought about by deficiency of iron, haemolysis or renal failure. The serum iron is usually low and may rise after corticosteroid therapy [2]. A positive Coombs' test can occur in the absence of haemolytic anaemia, and was present in 15% in a series of cases seen by the authors. Pure red cell aplasia has been reported [3]. Although leukopenia, specifically a lymphopenia, is a characteristic feature of the condition, and a white cell count of below 5000/mm^2 occurs in more than 33% of patients, leukocytosis may occasionally be found. The platelet count is reduced in approximately 20% of cases and is usually below 40 000/mm^2 in patients presenting with thrombocytopenic purpura. Thrombocytopenia may appear only during exacerbations or be a mild persisting feature [4]. Hyposplenism may occur [5]. The ESR is raised at some time in nearly 90% of patients; the C-reactive protein (CRP) is usually normal in the absence of infection, but some patients have a normal ESR throughout. The plasma viscosity may be raised, although initially thought unreliable, a more consistent assay is now being more widely used as an indicator of activity [6]. Serum globulins are frequently raised, with a rise in the gammaglobulin usually, although α_2-globulin may be elevated and the albumin decreased. IgE antibodies may be raised [7,8], particularly in patients with arthritis. False-positive serological tests for syphilis are found in approximately 25% of patients [9] and an atypical 'beaded' pattern of fluorescence of the *Treponema pallidum* antigen occurs when sera from certain patients are tested in the fluorescent treponemal antibody absorption (FTA-ABS) test [10]. Rheumatoid factor occurs in approximately 40%. Thrombosis occurs with the lupus anticoagulant (see p. 51.63), but occasionally haemorrhage results from other haematological abnormalities [11]. The lupus anticoagulant is one of a number of antiphospholipid antibodies that may be found in up to 50% of patients with SLE. As well as thrombosis, CNS disease is strongly related to the presence of these antibodies [12].

The LE cell phenomenon, first described by Hargraves *et al*. [13], is the basis for the LE cell test, which is positive in over 80% of patients. LE cells are polymorphonuclear leukocytes which have ingested nuclear material from degenerative white cells, in the presence of an antibody to deoxyribonucleoprotein (the LE cell factor) (Fig. 51.40). Sometimes, large masses of nuclear material are found extracellularly and, with surrounding leukocytes, form rosettes. LE cells, if present in large numbers, are highly suggestive of SLE, but the occasional LE cell is sometimes demonstrated in other conditions, including chronic DLE, systemic sclerosis and rheumatoid arthritis [14]. A positive LE cell test is a feature of drug-induced LE; LE cells were demonstrated in 60 out of 66

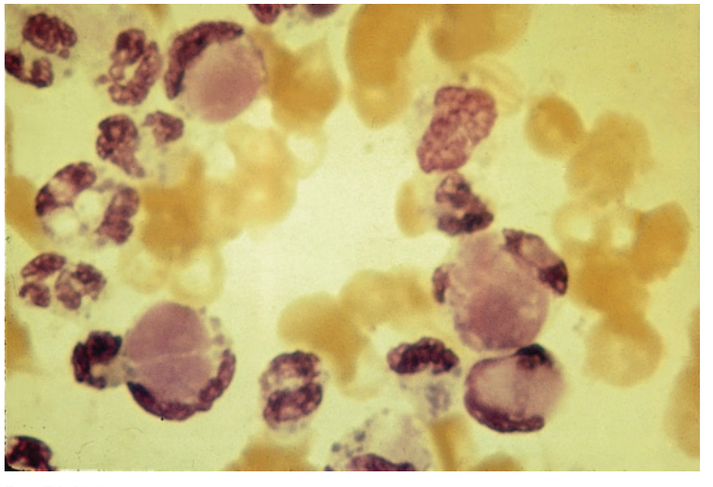

Fig. 51.40 Lupus erythematosus cells: the phagocytosed nuclear material is homogeneous and displaces the polymorph nucleus to one side.

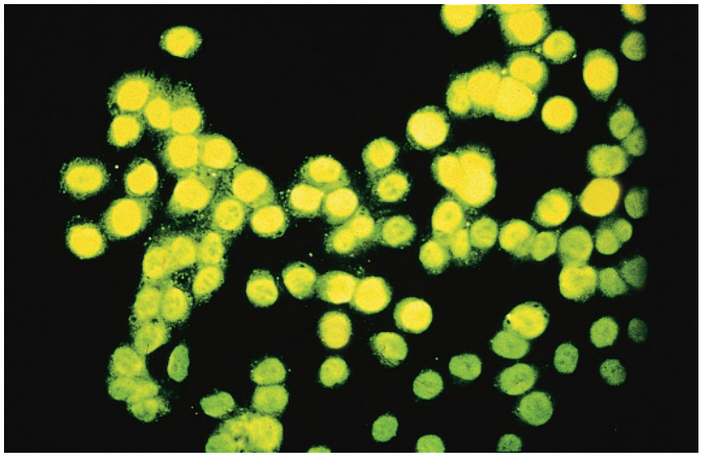

Fig. 51.41 Homogeneous type of antinuclear factor demonstrated on Hep-2 cells.

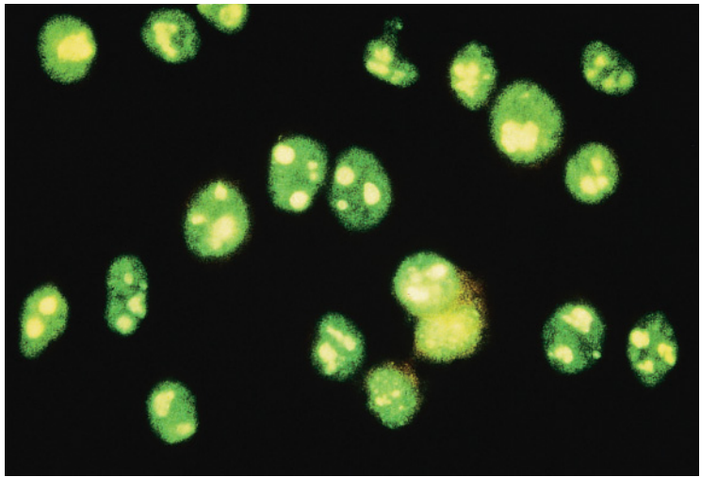

Fig. 51.44 Nucleolar type of antinuclear factor demonstrated on Hep-2 cells.

patients with procainamide-induced lupus [15]. The LE cell test has now been superseded by tests for antinuclear factors and anti-DNA antibodies.

One or more antinuclear antibodies can be detected by fluorescent antibody techniques in over 80% of cases. The incidence depends on the substrate used. Most British laboratories now use human cell lines for antibody testing, particularly Hep-2 cells derived from a human laryngeal cell line. This produces a reduction in the proportion of patients said to be antinuclear factor negative. Previously, the standard substrate was rat or mouse liver. Using rat liver, four staining patterns can be demonstrated [16], representing four systems of antinuclear antibodies (Figs 51.41–51.44).

1 In the *homogeneous pattern*, produced by antinucleohistone, the nuclei are stained all over.
2 The *speckled pattern* shows minute points of fluorescence scattered all over the nucleus, the antigens being saline-soluble proteins.
3 The *nucleolar pattern* shows uniform staining of each nucleolus.
4 Sera containing anti-DNA antibody give rise to the fourth *peripheral or membranous pattern* [16,17], in which staining occurs at the periphery of the nucleus.

These staining patterns are produced by separate antibodies, but more than one antibody may be present in a single serum, usually in different titres. No particular antibody is specific for any disease. Discrepancies in the incidence between series probably depend on differences in techniques and the substrate used.

Homogeneous antinuclear factor (which is the same factor as the LE cell factor, although the fluorescent antibody test is more sensitive than the LE cell test) is more than twice as common as the speckled factor, but antinucleolar antibody is only occasionally found. The peripheral factor is present in high titre in more than 50% in the active phase of the disease [18], and is infrequent in other diseases. The so-called shrunken peripheral pattern is thought to be associated with a poor prognosis and a high incidence of renal disease [19]. It may appear 10–15 days before an exacerbation of the disease and be associated with a fall in serum complement [20]. In a series of 63 cases of SLE seen by the authors, one or more antinuclear factors were demonstrated in 55 patients

(87%). Homogeneous staining was present in 46 cases, speckled staining in 18 and nucleolar staining in five. Titres up to 1:32 000 occur, but the titre frequently bears no relation to the activity, progress or duration of the disease. A high titre (over 1:64) of antinuclear factor(s), in a patient with symptoms and signs of a multiple system disorder, suggests the possibility of SLE or systemic sclerosis, and almost certainly excludes polyarteritis nodosa or cutaneous vasculitis. Any person in apparently good health found to have a high titre of antinuclear factor should be followed-up for years, as there is a considerable likelihood of developing LE or systemic sclerosis. A low titre (less than 1:16), in the absence of clinical symptoms and signs, can be ignored [21].

When Hep-2 cells are used as substrate, as well as being more sensitive to the presence of antinuclear antibody, further patterns can be identified [22]. These include centromere staining (see p. 51.103) associated with the CREST syndrome and in 6% of patients with SLE, homogeneous, peripheral (specific to SLE), fine and coarse speckles and a ground-glass appearance produced by Scl-70 antibody (see p. 51.103) found in systemic sclerosis. There are also several patterns of nucleolar staining: homogeneous, speckled and clumpy. The full clinical association of these antibodies has not been determined.

Circulating antibodies to DNA are almost always present in active disease [23,14] and may occur in the absence of antinuclear factors [24], although this is very uncommon using Hep-2 cells. Their demonstration by the Farr technique is the most specific aid to diagnosis, and levels often correlate with disease activity, although DNA antibodies should not be the only criterion [25]. Radiolabelled DNA is incubated with the test serum and any DNA–anti-DNA complexes formed are precipitated by 50% ammonium sulphate. Comparison of the radioactivity in the supernatant and precipitate gives the so-called DNA-binding activity. Values above 30% are abnormal. The level was raised in 83% of patients with SLE and in 100% of those with active disease. A rise in the index may precede an exacerbation of the disease, and levels fall with remission [26]. Normal values are found in drug-induced LE and in other disorders in which antinuclear antibodies occur. A high binding capacity is associated with poor prognosis and renal disorder [16]. The peripheral staining pattern of antinuclear antibody does not correlate with anti-DNA antibodies or with disease activity [27].

Several other antibodies occur in patients with SLE. Patients with antihistone antibodies have a lower incidence of renal and CNS disease, alopecia, anaemia and decreased complement [28]. Antibodies to soluble cellular antigens include anti-Sm antibody, which is found in 15–25% of patients and appears to be specific for the disease, occurring particularly in patients with renal disease, CNS disease and vasculitis. Anti-RNP antibodies occur in 25% of patients [29], but are characteristic of mixed connective tissue disease (see p. 51.111). It has been reported that titres correlate with disease activity [30].

Anti-Ro [31] antibody occurs in 30% of patients who have an increased tendency to photosensitivity [32,33], renal disease, Sjögren's syndrome and rheumatoid factor, as well as being a marker for neonatal lupus (see p. 51.49). It is also found in SCLE (see p. 51.22). Anti-Ro is an antibody to an RNP derived from RNA polymerase III-transcribed hY RNAs with a protein component that appears to be the main target. Two different proteins, one of 60 kDa and another of 52 kDa, react with most positive sera. The 60-kDa protein predominates in SLE, the 52-kDa in Sjögren's syndrome [34]. Patients with anti-Ro antibodies are more likely to have HLA-B8 and -DRw3 [35]. Anti-La, an antibody to another RNP product of RNA polymerase III, is present in 10–15% of patients, often with Sjögren's syndrome and with anti-Ro antibody. Although several different antibodies occur in the same patient, they fluctuate independently, and the antibody profile may alter over the years. The only characteristic pattern of antibody appears to occur in the LE–erythema multiforme syndrome [36], in which there is speckled type of antinuclear factor, a specific precipitating antibody (originally designated SjT but now thought to be anti-La) and rheumatoid factor. This syndrome is occasionally found in cases of systemic as well as DLE, in which it was originally described (see p. 51.14). In cases associated with SLE, homogeneous antinuclear factor is also usually present.

Cryoglobulins may be found in 11% of patients. Cryoglobulinaemia may precede the manifestations of SLE by many years [37]. Cold agglutinins occur in 6%. Serum complement is frequently low [38], especially in patients with active nephritis. A decrease in levels may precede clinical evidence of an exacerbation of disease, and return to normal with remission but, in general, estimations of CH50, C3, C4 and circulating immune complexes are rarely helpful in assessing disease activity [39]. Other possible indicators of disease activity include β_2-macroglobulin [40] and serum IFN [41]. Increased levels of plasma anaphylatoxins (C3a) may predict exacerbations [42]. The intracutaneous injection of DNA solution, which has been advocated as a skin test [43], is not specific. Occasionally, circulating anticoagulants may be demonstrated [44,45]. Factor II may be absent and return with steroid therapy [46].

Inherited deficiencies of the major complement components occur with SLE [47], usually as autosomal recessive traits [48]. These include C1 [49], C2 [50] and C4 [51], as well as C5–C9. The most common is homozygous C2 deficiency in which SLE occurs in one-third of patients. Clinically, the lupus-like syndrome in C2 deficiency shows a low incidence of renal disease, low incidence and low titres of anti-DNA antibodies, infrequent occurrence of immunoglobulin and complement deposits in the skin, and frequent anti-Ro antibodies [46]. Isolated C1q deficiency has also been reported [52], and there is an association between C1-esterase inhibitor deficiency and SLE [53]. Patients may be helped by danazol [54]. Hereditary angio-oedema and SLE were found in the mother of twin boys who had DLE and angio-oedema, and this was associated with low C1 inhibitor and C4 levels [55]. Antibodies to Australia antigen can be demonstrated in 25% of cases [56]. Serum CRP levels are usually normal or only slightly elevated. A level higher than 60 mg/L suggests the presence of superimposed infection [57]. A number of soluble cytokines or their receptors may be found in serum of patients with SLE, and may correlate with disease activity: intercellular adhesion molecule-1 (ICAM-1) [58], TNF receptor [59] and IL-10 [60]. There is differential overexpression of heat-shock proteins in patients with differing patterns of systemic involvement [61]. Urinary levels of neopterin [62], or of IL-6 [63], may also be useful to monitor disease activity.

Antinuclear antibody-negative SLE [1,2]. Patients originally described under this title have many similarities with patients suffering from SCLE (see p. 51.22). Because the cutaneous involvement is usually the predominant feature, many patients present initially to dermatologists. Clinically, a non-scarring malar flush, oral ulceration and photosensitivity, with papulosquamous or annular lesions on the face, trunk and arms, are prominent, but arthritis, serositis, renal disease and haematological involvement are less frequent than expected in SLE. In approximately 5–10% of patients with SLE, antinuclear factor cannot be demonstrated using standard substrates such as rat or mouse liver. This is a problem in less than 1% if Hep-2 cells are used. These patients frequently have anticytoplasmic antibodies. Over 60% of patients have anti-Ro antibodies and approximately one-third have anti-La antibody (anti-La rarely occurs without anti-Ro). Twenty-five per cent have antibodies to single-stranded DNA. There is no difference in the histology of the skin between antinuclear-negative and -positive cases. Immunoglobulins and complement are found at the dermal–epidermal junction in 70% of patients, but are rare in the non-light-exposed uninvolved skin. Topical steroid therapy may be helpful, but oral antimalarials and steroids may be required. Approximately 10% of patients eventually become antinuclear factor-positive, although the pattern of anticytoplasmic antibodies does not alter.

Assessment of disease activity. A number of attempts have been made to devise definitions of disease activity, accompanied by scoring systems using combinations of clinical and laboratory parameters to allow comparative and longitudinal studies. Global measures such as European Community Lupus Activity Measure (ECLAM) [1], Systemic Lupus Erythematosus Disease Activity Index (SLEDAI) [2] and the more detailed British Isles Lupus Activity Grading (BILAG) [3] are useful in the context of clinical trials in patients with active systemic disease. However, none is specifically designed for the assessment of patients who most concern dermatologists, and do not grade skin disease in any meaningful way. The CLASI has been described for assessment of cutaneous disease, but is not yet in routine clinical use [4].

Association with other diseases. SLE can occur concurrently with rheumatoid arthritis [1], and may present with polymyalgia in elderly patients [2]. Systemic sclerosis and SLE may occur in the same patient [3], and the demonstration of immunoglobulins at the dermal–epidermal junction may be helpful in confirming the presence of both diseases [4]. SLE occurs with lichen sclerosus and with 'en coup de sabre' morphoea [5], and linear and plaque morphoea [6]. Sjögren's syndrome and SLE occur together [7–9] but the former is usually mild, and is unlike secondary Sjögren's syndrome occurring with rheumatoid arthritis. Patients with hyperglobulinaemic purpura may have antinuclear factor; this condition may, in certain cases, have features of SLE [10]. The finding of LE cells in young females with liver disease has already been mentioned. SLE can follow primary biliary cirrhosis [11], and may occasionally occur in association with necrotizing angiitis [12] and giant cell arteritis [13]. Patients who have LE and psoriasis often have anti-Ro antibodies [14].

Myasthenia gravis may follow SLE [15], and SLE may follow thymectomy for myasthenia gravis [16] or be associated with a thymoma [17]. Myasthenia gravis, thymoma and pemphigus may occur together in patients with SLE [18], and heterozygous C2 deficiency associated with angio-oedema, myasthenia gravis and SLE also occurs [19]. Angio-oedema resulting from C1-esterase deficiency can be associated with SLE [20], and protein S deficiency can occur in these patients [21].

SLE has been reported with Hashimoto's thyroiditis and pernicious anaemia [22]. It was associated with seminoma of the ovary in one case. Removal of the tumour led to an apparent permanent cure of the LE [23]. Lymphatic leukaemia or Hodgkin's disease has followed SLE [24], and lymphoma has been reported [25]. Amyloidosis [26] can develop in SLE, and in one case this led to adrenal insufficiency and was followed by malignant lymphoma [27]. The presentation with haemolytic anaemia [28] or thrombocytopenic purpura [29] is well documented, and overt SLE may appear after splenectomy for 'idiopathic thrombocytopenic purpura'. If this occurs, it is likely that the thrombocytopenia is an early manifestation of SLE. It may also occur in association with thrombotic thrombocytopenic purpura [30], pernicious anaemia [31], von Willebrand's disease [32], myelofibrosis [33,34], selective IgA deficiency [35], erythroleukaemia [36], red cell aplasia [37], monoclonal gammopathy and multiple myeloma [38], biclonal gammopathy [39], myelofibrosis [39], hyperviscosity syndrome [40], Whipple's disease [41] and ulcerative colitis [42]. SLE also occurs with pemphigoid [43] and cicatricial pemphigoid [44], pemphigus [45], dermatitis herpetiformis [46], linear IgA disease [47], epidermolysis bullosa dystrophica [48], porphyria cutanea

tarda [49] (although the association has not been confirmed) [50], and occasionally with porphyria variegata or acute intermittent porphyria [51–53]. The disease has been reported in patients with Sweet's syndrome [54], Klinefelter's syndrome [55], hypoparathyroidism [56], partial lipodystrophy [57], relapsing polychondritis [58], pyoderma gangrenosum [59] and Kikuchi's disease [60]. In one case it has been associated with retroperitoneal fibrosis [61], and in another with eosinophilic fasciitis and retroperitoneal fibrosis [62]. It uncommonly occurs with gout [63] and sarcoidosis [64]. An unusual syndrome of breast hypertrophy, erythema annulare centrifugum, generalized melanoderma and immunodeficiency to viral warts has been associated with SLE [65]. Twelve per cent of patients with SLE have warts, which is a higher incidence than in a control population [66]. Senear–Usher syndrome (pemphigus and LE) has been associated with internal malignancy [67], but an overall increased incidence of malignancy in SLE is debatable. Malignancy occurred in 4.7% in one series [68]. Epidermodysplasia verruciformis occurs presumably as a result of immunodeficiency or prolonged treatment with corticosteroids [69]. Among other rare associations are Kaposi's sarcoma [70] and Kawasaki disease [71].

The relationship to DLE is discussed on p. 51.2. Patients with persistent false-positive serological tests for syphilis [72] may later develop SLE.

Kikuchi's disease and SLE. Histiocytic necrotizing lymphadenitis was first described independently by Kikuchi [1] and Fujimoto *et al.* [2] from Japan in 1972. Cases are predominantly female, but it can occur in males, and can occur at all ages. Usually, patients present with lymphadenopathy, frequently cervical, although other nodes can be involved. Fever, weight loss and night sweats are found in the more severely affected cases. There may be leukopenia and elevation of the ESR. Skin changes occur in 30% of patients [3]. They are all non-specific and include multiple, indurated, red papules on the back and arms [4], erythematous plaques resembling lymphoma, erythema and acneiform eruptions on the face (Fig. 51.45), and morbilliform, urticarial and rubella-like eruptions elsewhere. The oropharynx may be red or ulcerated.

Fig. 51.45 Erythematous facial plaques in Kikuchi's disease.

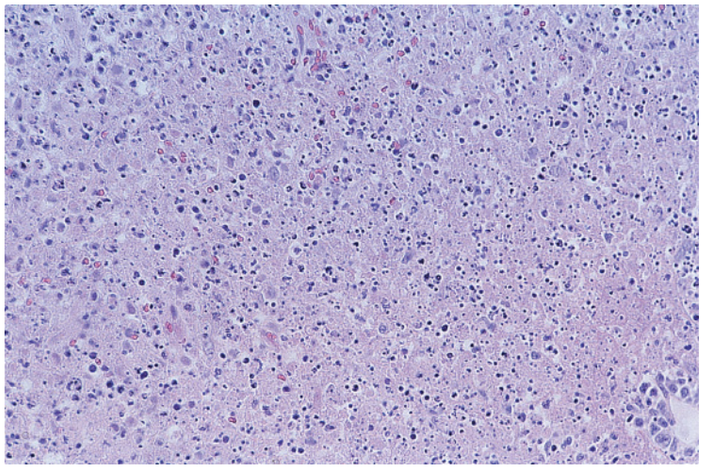

Fig. 51.46 Histiocytic necrotizing lymphadenitis (Kikuchi's disease). Lymph node. (Courtesy of Dr W. Merchant, Leeds General Infirmary, Leeds, UK.)

Histology of the skin shows oedema of the papillary dermis, with a patchy perivascular infiltrate in the dermis and subcutaneous fat. The infiltrate consists of histiocytes containing nuclear debris, and small lymphocytes. The nuclei of the histiocytes may be deformed. The lymph nodes show focal or complete loss of follicular architecture, with necrosis of cortical and paracortical areas (Fig. 51.46). The extensive infiltrate consists of small lymphocytes, immunoblasts, macrophages and so-called plasmacytoid T cells [5]. Neutrophils are rarely seen, a feature that may help to distinguish this condition from SLE. The natural history is for spontaneous healing in a few months but it can be fatal as a result of heart failure brought about by microscopic myocardial necrosis [6]. There was a 3.3% recurrence rate in one series [7]. In most cases, no treatment is required, but a course of prednisolone may speed resolution. Various triggers have been incriminated, including the human herpesvirus 6 [8], parvovirus B19 [9], Epstein–Barr virus [5], dengue virus [10] and infection by *Yersinia enterocolitica*, *Toxoplasma*, cytomegalovirus and human immunodeficiency virus (HIV) [11], and rupture of a silicone breast implant [12]. The condition is occasionally associated with SLE. It may precede SLE [13], may be the presenting feature of SLE [14] and, rarely, SLE may precede it [15]. The association was found in two of 108 patients with Kikuchi's disease studied by Dorfman [16], and two of eight patients studied by El-Ramaki *et al.* [17]. It has occurred with DLE

in a case encountered by the authors, and may be associated with other cutaneous manifestations of lupus [18]. Other associated conditions include Still's disease [19,20] and Sweet's syndrome [21]. In addition to SLE, the disorder can occur with lymphoma, tuberculous lymphadenitis, viral lymphadenitis, infectious mononucleosis and drug eruptions.

Differential diagnosis. The conditions mentioned in the above section must be differentiated from LE. Many patients suspected of having a connective tissue disease may, even after investigation, present problems of categorization. The criteria for SLE of the ARA (1982) are shown in Table 51.9 [1]. The presence of four or more of the 11 manifestations, serially or simultaneously, is compatible with SLE (96% sensitive, 96% specific).

Other features, such as cutaneous LE lesions of any type, diffuse alopecia, involvement of the scalp or mucous membranes, preferably confirmed by histopathology, or direct immunofluorescence, may be helpful.

Several practical points are important. The ESR need not be elevated. In patients at Leeds, 15% followed up for at least 5 years have never had an ESR above 20 mm in the first hour. Several of these have had high titres of antinuclear factor, raised levels of anti-DNA antibodies and lowered serum complement. Diagnosis thus depends upon the association of features rather than on any specific abnormality. The demonstration of a high titre of antinuclear factor is important. In the acute phase, the membranous types of antinuclear factor may be present as well as a raised level of anti-DNA antibody, anti-Sm antibody and a reduction in the serum complement. In the authors' experience, the presence of antinuclear factor in high titre almost certainly excludes polyarteritis nodosa and other arteritic disorders. When a raised ESR, raised serum globulin, leukopenia and evidence of renal disease are added, the diagnosis becomes highly probable. It is important to remember that antinuclear factor is not always present in SLE, and in such cases alopecia, Raynaud's phenomenon and oral ulceration commonly occur [2]. The demonstration of immunoglobulins in the dermal–epidermal junction of uninvolved as well as involved skin may be very helpful (see p. 51.34). The combination of IgG and IgM at the dermal–epidermal junction of involved and uninvolved skin, raised DNA binding, antinuclear antibody in a titre of more than 1:64 and decreased C3 or C4 is highly suggestive of SLE [3]. In drug-induced LE, anti-DNA antibodies are absent, serum complement is normal and globulin is not found in the uninvolved skin. Acute febrile neutrophilic dermatosis (Sweet's syndrome) may mimic SLE when a 'butterfly rash' is associated with fever, myalgia, arthralgia, hepatosplenomegaly, renal disease and hyperglobulinaemia [4].

Prognosis [1]. The course of SLE is very variable [2]. Acute fulminating cases are much less common than subacute cases, which smoulder on for many years. Mortality rates declined in both England and Wales in the 10-year period 1974–83 [3] and in the USA [4]. Although, in pre-steroid days, 52% of patients in one series [5] died within 2 years, in another series 54% of patients survived 11 years [6], compared with controls, of whom 97% survived a similar time. In 1977, an overall 5-year survival of 91% was reported [7], and 98% in another series in 1978 [8], although a 5-year survival of only 88% was reported from a rheumatological clinic in 1990 [9]. Approximately three-quarters will now survive

15 years [10]. Survival is related to organ involvement and to frequency of exacerbations [11]. Of those without renal involvement, 84% survive 15 years, compared with 57% whose kidneys are affected [10]. Spontaneous remissions, sometimes lasting 10–20 years, occurred in 35% of Dubois and Tuffanelli's [12] patients, the longest being 26 years. Serological as well as clinical remission occurred in 4% of 305 patients [13]. Exacerbations are more frequent in the first 5 years of the disease [14]. Pregnancy does not affect long-term survival. Prolonged survival is associated with an increased risk of atherosclerosis, avascular necrosis and neuropsychiatric dysfunction [15]. In elderly people the presentation is insidious and the clinical course is relatively benign. Renal disease and serological abnormalities are less frequent, and arthritis, with subcutaneous nodules, and pleuropericarditis are more prominent in elderly people [16].

The better prognosis of the more recent series is a result, not only of the administration of corticosteroids, but also of earlier diagnosis, the avoidance of stress and drugs such as sulphonamides, and the control of infections by antibiotics. The cause of death is frequently progressive renal failure, occasionally with anuria. Secondary infection, particularly bronchopneumonia, was a much more common cause of death in the pre-antibiotic era, although infection may still be more important than renal failure. The high infection rate is not caused solely by steroid [17] or antimetabolite therapy. Spontaneous peritonitis caused by Gram-positive bacteria is a complication of lupus nephritis treated with corticosteroids [18]. Unusual infections such as pneumococcal epiglottitis have been reported [19]. There is an increased risk of *Salmonella* bacteraemia [20] and rapidly fatal pneumococcal septicaemia [21]. Repeated skin infections may be a presenting feature. Cellulitis of the periorbital area caused by *Staphylococcus aureus* and group A haemolytic streptococci has been reported [22,23]. Neisserial infections may also occur [24]. Death may result from vasculitis of the CNS in patients presenting with convulsions, psychoses and paralysis. Patients with CNS lesions and psychosis have a poor prognosis. Deaths from CNS involvement become more important in the later stages of the disease [25]. Others may die from heart failure or the side effects of therapy [26].

A bimodal pattern of mortality has been described [27], but not confirmed, in black patients [28]. Patients who die early in the disease die from active LE, including renal involvement, receive large doses of steroids and have a high incidence of infection. Those who die later have relatively inactive disease, long duration of steroid therapy and a high incidence of atherosclerotic heart disease and myocardial infarction [11]. Nevertheless, it is the authors' experience that death from infection is common, even in long-standing cases. The maximum disease activity occurs early, and patients rarely develop new organ involvement after the first few years [8,14]. Late reactivation of SLE can occur [29].

Although the disease is much more common in females, the prognosis is worse in males [30–33]. Males are more likely to develop renal failure [34]. Although race and ethnic origin have been claimed not to influence prognosis [35], increased mortality has been noted in Asians [36] and black people [37], probably in part because of socioeconomic conditions. The degree of renal involvement is probably the most important factor in prognosis. Patients with nephrotic syndrome at the onset of nephritis do badly and may die within a few months, but development later in the disease does not have an adverse effect. Patients with albuminuria may survive on small doses of steroids for many years, and the overall prognosis of patients with renal involvement is not as bad as early studies suggested. Patients with cutaneous lesions of DLE and laboratory abnormalities have the same prognosis as uncomplicated cases of DLE [38]. Patients with arteritis, antiphospholipid syndrome, thrombocytopenia, haemolytic anaemia and CNS involvement have a poorer prognosis than those whose illness mainly involves the joints. There appears to be no increased risk of malignancy [39], although earlier reports suggested this might be so [40,41].

Genetic counselling. The clinical genetics of lupus has been reviewed [1]. Approximately 5% of first-degree relatives of patients may have or may develop lupus. The risk is doubled if there are two affected first-degree relatives, and this risk is even greater if further family members are affected. The risk for female relatives is greater than for males and may also be increased for those with hyperglobulinaemia or antinuclear antibodies. Mothers with anti-Ro and anti-La antibodies may have children with neonatal lupus and heart block. When a child has neonatal lupus or CHB, the risk of a subsequent child having heart block is approximately 25%.

Treatment [1]. The aim is to try to maintain optimal function with the minimum of therapy. SLE is an episodic disease, and treatment must be tailored to the patient's requirements and morale must be maintained. In acute cases, and during severe exacerbations, bed rest is required. Undue exposure to the sun should be avoided and patients should be advised to wear broad-brimmed hats, to cover the 'V' of the neck and the arms, and to use a sunscreen. Mental stress, physical overexertion and secondary infection should be avoided.

Hypertension must be treated aggressively and diuretics may be required for the nephrotic syndrome or cardiac failure, and anticonvulsants for epilepsy. Chlorpromazine is a good sedative for psychosis. Symptomatic therapy for joint pain using NSAIDs is valuable. Ischaemic necrosis of bone may be best treated early by core decompression [2].

Corticosteroids are required in acute cases, and should be given in adequate regimens. Prednisolone in doses up to 60 mg/day is the steroid of choice initially. It is rare for higher dosage to be needed. Once the condition appears to be under control, the dosage may be reduced gradually, until a maintenance dosage of approximately 5–15 mg/day is reached. A single dose daily, given in the morning [3], produces fewer side effects and does not impair the therapeutic response.

Not all patients require steroids, especially if there is no internal organ involvement [1]. It is important to assess the patient's progress by their general well-being and relief of symptoms, rather than by strict attention to laboratory abnormalities [4]. The ESR and DNA antibodies are variable and a poor guide to the adequacy of therapy; the titre of antinuclear antibodies often persists unchanged despite clinical remission. Anti-DNA antibody and serum complement levels may be helpful in predicting exacerbations [5]. Low C3 often indicates severe renal disease. There is some evidence that a return of serological abnormalities to normal is followed by a prolonged remission [6], but exceptions indicate that serological data alone cannot be used as a basis of therapy.

Some fulminating cases have been treated with massive doses of steroids but the advantages of such therapy rarely outweigh the risks, and complications such as steroid-induced psychosis can occur even in patients with CNS disease [7]. Prolonged high dosage of corticosteroids (e.g. prednisolone 60 mg/day for 6 months) is said to improve renal lesions more than small suppressive doses [8], but more aggressive immunosuppressive regimens are now preferred. Steroid myopathy can occur with high doses and is easily missed.

In mild cases, the administration of chloroquine or hydroxychloroquine may allow the dosage of steroids to be reduced, but the reduction may not be clinically meaningful [9]. Antimalarials are less useful than in DLE, but may have a place in patients with photosensitivity. Their use does not preclude pregnancy, as healthy live babies have been delivered by women on antimalarial therapy throughout pregnancy [10].

Immunosuppressive drugs have been used for patients not responding to corticosteroids, or to act as steroid-sparing agents [11]. The role of azathioprine is accepted, but at least some studies show that it adds nothing to high-dose prednisolone treatment in mild or moderate renal disease [12]. Another controlled trial, comparing azathioprine plus prednisolone with prednisolone alone, did not show any significant difference in the number of deaths, renal or extrarenal manifestations, serum complement levels, DNA antibodies, LE cells, antinuclear antibody titres, or Coombs' antibodies, or any evidence of a steroid-sparing effect [13]. Sudden withdrawal may be followed by relapse [14]. Cyclophosphamide is useful in SLE [15,16], although not all support routine use. Nevertheless, pulsed therapy with cyclophosphamide may be useful for renal disease and is as effective as pulsed methylprednisolone [17].

Chlorambucil has been used [18], but methotrexate is now a more widely accepted drug in SLE. Methotrexate 7.5 mg/week has improved steroid-resistant patients [19] and patients without renal or CNS involvement [20], and 10–20 mg/week is useful for mucocutaneous lesions [21].

The long-term risk of malignancy must be considered whenever immunosuppressive drugs are used. Cyclophosphamide has been associated with bladder cancer [22], acute non-lymphocytic leukaemia and solid tumours. Mesna may reduce urotoxic side effects, but 50% of patients develop rashes which may be confused with an exacerbation of SLE [23]. Reticulum cell sarcoma [24] and non-Hodgkin's lymphoma [25] are hazards of azathioprine therapy.

Ciclosporin has been used in resistant cases in a dosage of 3–5 mg/kg [26]. Pulse therapy with methylprednisolone 1 g given intravenously in 500 ml normal saline over 4 h on 3 successive days to in-patients may be helpful in individuals who are not controlled by oral prednisolone and immunosuppressives [27]. Given monthly it may prevent deterioration in renal function in patients with nephritis [28]. Mycophenolate mofetil has been used for non-renal SLE [29], and alternatives to cyclophosphamide as a modifier of B cell function have been found to be increasingly useful. Rituximab, an antibody targeting the CD20 marker antigen of B cell precursors, has been valuable for those in whom conventional therapy has failed [30].

Plasmapheresis of 2 L/day for 3–4 days each week over a period of 2–3 weeks may be helpful in a small number of patients with a high level of immune complexes, whose condition is deteriorating despite other therapy, but controlled trials have not been convincing [31]. Any benefit lasts only approximately 2–3 weeks. Plasmapheresis may be useful in managing life-threatening complications such as fulminating vasculitis or CNS disease [32]. Intravenous gammaglobulin 1 g/kg/day for 3 days improved four out of five patients. The effect lasts 4–6 weeks [33]. Provisional studies of extracorporeal photochemotherapy have shown improvement in a few patients, and treatment was not associated with any side effects [34]. Anticoagulants may be required for patients with lupus anticoagulant or anticardiolipin antibodies who have thrombotic episodes. Danazol 400–600 mg/day may help patients with premenstrual exacerbations [35], and sometimes has a marked effect on thrombocytopenia [36]. Oral levamisole, in a dosage of 150 mg three times daily has been found helpful by some [37], but not by others [38]. Antilymphocyte and antithymocyte antisera may help patients with nephritis not responding to either corticosteroids or azathioprine [39].

A new and surprising therapeutic approach is that although UV light can exacerbate SLE, it has been found in a controlled trial that exposure to UVA-1 (340–400 mm) at a dosage of 60 kJ/m^2 three times weekly reduced disease activity, reduced the need for medication and decreased antibody levels [40]. A low-fat, high marine oil diet (eicosapentaenoic acid: Maxepa 20 g/day) modified disease activity in 27 patients in a placebo-controlled trial over 3 months [41].

Some patients with cutaneous disease as their main form of disease expression will require specific treatment as for DLE. In these patients, dapsone may be helpful for urticarial lesions [42], bullous eruptions [43] and for thrombocytopenia [44].

The lupus anticoagulant, anticardiolipin antibodies and the antiphospholipid antibody syndrome [1]

The lupus anticoagulant was first described in SLE [2], but it also occurs in drug-induced SLE, other connective tissue diseases, polymyalgia rheumatica/giant cell arteritis (where 40–50% of patients may have antibodies [3]) and carcinoma and lymphoma [4]. It may be induced by infection, including that caused by Epstein–Barr virus [5] and varicella [6]. It also occurs as the causative abnormality of the primary antiphospholipid (Hughes') syndrome [7], although a small proportion of those classified as having the primary syndrome will progress to lupus or a lupus-like syndrome [8].

The lupus anticoagulant is only one of several antiphospholipid antibodies, which include the anticardiolipin antibody demonstrated by ELISA. IgG anticardiolipin antibody has been found in 23% of patients with SLE [9], and is associated with similar clinical features to those seen with the lupus anticoagulant [10]. The presence and titre seem to depend on disease activity and decrease with treatment, particularly when of IgM type. In a study of healthy blood donors, anticardiolipin antibodies and the lupus anticoagulant were found in 4–6% of 499 donors, mainly young females [11].

Table 51.15 Clinical features associated with the lupus anticoagulant.

Libman-Sacks endocarditis [15]
Chorea [16]
Labile hypertension
Epilepsy
Myelitis
Myocardial infarction
Valvular heart disease
Haemolytic anaemia
Retinopathy [17]
Addison's disease [18]
Avascular necrosis of bone [19]

The features associated with the lupus anticoagulant are caused by an acquired immunoglobulin (IgG or IgM), identified by prolonged activated partial thromboplastin and kaolin clotting times, which cannot be corrected by normal plasma. There may also be IgA antiphospholipid antibodies [12]. There are now a number of methods for detecting the abnormalities, and these have been reviewed [13]. The antibodies are directed against a range of phospholipids, including cardiolipin. The route by which thrombosis is induced remains unclear, but some antiphospholipid antibodies interact with a complex of phospholipid and β_2-glycoprotein-I to inhibit factor XII activation, platelet activation and prothrombinase activity [14].

Clinical features. The clinical features of the syndrome associated with the presence of the lupus anticoagulant are protean, and many are shown in Table 51.15. Rarely, patients develop vascular occlusions in multiple organs [20]. This catastrophic variety may be fatal. There is also a syndrome in which a severe reduction in clotting occurs because of a different set of antiphospholipid antibodies—the haemorrhagic lupus anticoagulant syndrome [21].

Cutaneous lesions [22] include thrombophlebitis, purpura and ecchymoses, livedo reticularis, leg ulcers, cutaneous necrosis, gangrene and subungual splinter haemorrhages. Histologically, non-inflammatory thrombosis of small dermal blood vessels can be demonstrated, but necrotizing vasculitis is not a feature [23]. Thromboses in the placenta lead to fetal death, and may recur in subsequent pregnancies. Thrombocytopenia also occurs. All women with SLE who have recurrent abortions and thrombotic episodes, or who are biological false-positive reactors, should be screened for the lupus anticoagulant, as treatment with prednisone 40–80 mg/day and aspirin 75 mg/day may result in successful pregnancy. One patient with repeated fetal loss was successfully treated with intravenous human gammaglobulin [24]. Full anticoagulation (international normalized ratio (INR) greater than 3), with or without aspirin, appears to be the most effective therapy in the non-pregnant patient [25]. The presence of the antibodies without clinical features is not an indication for either steroid therapy or anticoagulation.

Scleroderma [1]

Sclerosis of the skin occurs in a variety of conditions, such as dermatomyositis and LE, and invariably occurs as part of the cutaneous manifestations of systemic sclerosis, which is described elsewhere. However, the term 'scleroderma' should strictly be confined to sclerosis of the skin, either localized or generalized, occurring in patients as the only or prominent feature. In such circumstances it is better to use the term 'morphoea'. There has been much discussion and confusion about the relationship of morphoea to systemic sclerosis (see below), but the two conditions, despite certain similarities, are best considered as distinct entities.

Localized morphoea

Synonyms
- Localized scleroderma
- Circumscribed scleroderma

Definition. A disorder of unknown cause in which there is localized sclerosis of the skin. The condition has traditionally been subdivided clinically into the following types [1]:

1 Circumscribed plaques
2 Morphoea profundus/subcutaneous (deep)
3 Bullous morphoea
4 Linear morphoea
5 Frontoparietal lesions (en coup de sabre), with or without hemiatrophy of the face.

It is apparent, however, that there is sometimes overlap between these types, this occurring in up to 15% of cases in children [2]. Recently, a new classification for childhood localized scleroderma has been proposed, to include circumscribed morphoea (superficial and deep), linear scleroderma (trunk/limbs and head), generalized morphoea, pansclerotic morphoea and mixed morphoea [3].

Although some conditions, such as atrophoderma of Pasini and Pierini, eosinophilic fasciitis and lichen sclerosus, are sometimes included in the classification of morphoea, this is not widely accepted [2].

Aetiology. The cause of morphoea is unknown. A number of studies, however, have shown *in vitro* abnormalities in fibroblasts from patients with morphoea. These include fibroblast promotion of migration of mononuclear leukocytes across endothelial cell monolayers [1], increased platelet-derived growth factor and receptor expression [2], and increased transforming growth factor-β (TGF-β) receptor expression [3]. It is postulated that this may

lead to increased connective tissue growth factor (CTGF) gene expression and ultimately fibrosis [4,5]; possibly being mediated via activation of Smad and ERX1/2 [6] or integrin alphavbeta5 pathways [7]. That morphoea is an immunologically-mediated disease also gains support from studies that have found increased levels of circulating cytokines in patients with morphoea. These include IL-2 receptor [8,9], IL-6 receptor [10], IL-13 and TNF [11], soluble CD4 and CD8 [12], CD23 [13], CD30 [14], TNF-α [15], a B-cell activating factor belonging to the tumour necrosis factor family (BAFF) [16], soluble vascular cell adhesion molecule-1 (VCAM-1) and E-selectin [17], antiendothelial cell antibodies [18], and antibodies to fibrillin 1 [19] and superoxide dismutase [20]. That they may be involved in disease activity is supported by some studies, which have found increased levels of, for instance, soluble IL-2 receptor in active but not inactive disease [8,9], although such findings are by no means universal. Additional support for an autoimmune aetiology is the occurrence of scleroderma-like lesions in chronic graft-versus-host disease, and an association with idiopathic thrombocytopenic purpura [21]. A comprehensive review of chemokines and chemokine receptors in scleroderma has been published [22].

A number of studies have reported assays which may correlate with disease activity including levels of matrix metalloproteinase-13 [23], antiagalactosyl IgG antibodies [24] and manganese superoxide dismutase [25].

Experimental exchange of Thiersch grafts between normal and affected sites resulted in rapid transformation of the normal graft to morphoea and vice versa [26]. Trauma may be a triggering factor [27,28] and may precede the onset by many months. Immobilization has also been reported as a cause [29]. Morphoea has also occurred after bacille Calmette–Guérin (BCG) vaccination [30], following varicella [31], injections of vitamin K [32] and B12 [33], after antitetanus vaccination [34], after DTP and MMR vaccinations [35] and after herpes zoster [36]. There are several reports of morphoea occurring at the site of, and extending outside the field of, previous radiotherapy [37–41], and after fluoroscopy [42]. Surgical trauma has been reported as a stimulus for the development of lesions after arteriovenous fistula formation [43], rhinoplasty [44] and laparotomy [45], and recently mechanical compression from clothing has been suggested to trigger lesions [46]. A single case of linear morphoea occurring after linear lichen aureus has been reported [47]. Hormonal factors may influence the disease; morphoea may develop during, or be exacerbated by, pregnancy, but the influence of the menopause is less clear.

Infection with borrelial organisms has been implicated in the aetiology of morphoea, some central European studies suggesting a relationship between morphoea and acrodermatitis chronica atrophicans, a disease induced by infection with *Borrelia burgdorferi* [48–50]. These studies found raised levels of antibodies against this organism in patients with morphoea compared with controls, and described the presence of viable organisms in biopsies from morphoeic lesions. In addition, using the polymerase chain reaction, *Borrelia* DNA has been found in skin biopsies from patients with morphoea [51]. However, other studies [52–56] have shown no evidence of *Borrelia* antibodies or DNA in morphoea of patients from Scandinavia, Germany, Spain or America. A recent review [57] has suggested that the reason for these contradictory findings is that either *Borrelia* infection is not the cause of morphoea or that a subset of morphoea is caused by a special species of *Borrelia* present in some parts of Europe and Asia but not in the USA and other parts of Europe.

The genetic influence on morphoea is unclear. A familial incidence has been noticed [58], and localized and systemic scleroderma has been noted in monozygotic twins [59]. Some cases of the frontal type appear to have a genetic basis [60], but there are no significant HLA associations [61]. There is an increase in the incidence of organ-specific autoantibodies in patients and relatives [62]. Morphoea has been associated with phenylketonuria, and improvement has occurred with a low-phenylalanine diet, but excretion of phenylalanine and *o*-hydroxyphenylacetic acid in nine children with morphoea was normal [63].

Morphoea has been reported after therapy with a number of drugs. Morphoea-like plaques occurred in a patient on penicillamine therapy and remitted within a year of stopping treatment [64]. Cutaneous lesions have also been reported after therapy with bromocriptine [65], hydroxytryptophan and carbidopa [66,67], valproic acid [68], pentazocine [69,70], docetaxel [71] and the related drug paclitaxel [72], bleomycin [73,74] and after melphalan limb perfusion [75]. These localized lesions are in contrast with the systemic sclerosis-like reactions reported later in this chapter.

Although the clinical picture of morphoea is usually distinctive, and different from systemic sclerosis, the histology and histochemistry [76–78] of the skin are similar, and X-ray diffraction, historadiographical and electron microscope investigations [63,79–81] show no differences. Electron microscopy may show changes in the underlying muscle fibres in both conditions, but only in systemic sclerosis are endothelial changes found in the muscle capillaries [82]. Skin collagen may be increased in morphoeic plaques [83], possibly because of clonal overactivity of fibroblasts [84], but is decreased in the involved skin in systemic sclerosis [85]. The two disorders rarely occur together. Nail fold capillaroscopy may reveal abnormal capillaries in such patients [86].

Finally, the similarities between scleroderma and chronic graft-versus-host disease has led to studies which have shown the presence of microchimerisms in the peripheral blood mononuclear cells of patients with systemic sclerosis [87], and the presence of chimeric cells (including dendritic cells and B lymphocytes) in localized scleroderma lesions, suggesting a possible pathogenic role [88].

Pathology (Fig. 51.47). The epidermis may be normal, or flattened and atrophic with loss of the rete ridges. At first the dermis is oedematous, with swelling and degeneration of the collagen fibrils, which become homogeneous and eosinophilic. There may be a scanty perivascular lymphocytic infiltrate. Cellular infiltrates of lymphocytes, plasma cells and macrophages, either perivascular or diffuse, occurred in 84% in one series, and there is some evidence that the infiltrate may precede fibrosis [1,2]. Later, the dermis is markedly thickened, with dense collagen and relatively few recognizable fibroblasts. The elastic tissue is reduced. The dermal appendages and dermal and subcutaneous fat are progressively lost. Some sweat glands may survive, deep in the dense sclerotic mass. Small dermal blood vessels may show intimal thickening.

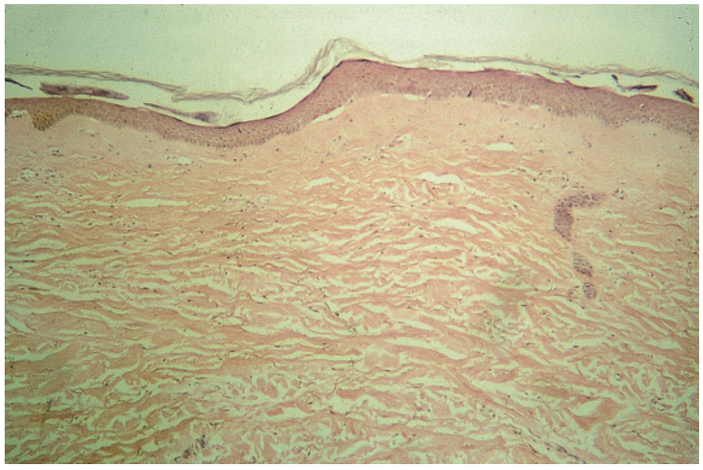

Fig. 51.47 Morphoea: slight atrophy of the epidermis with loss of dermal appendages and degeneration of dermal collagen.

Immunohistochemistry studies have shown that the main changes in morphoea consist of foci of intercollagenous staining for connective tissue antigens in the reticular layer of the dermis [3], and that there is a reduction in the size and number of dermal papillae, with increased angiogenesis in the early inflammatory stage and various numbers of enlarged vessels in inactive lesions [4]. A further study has reported an increase in dermal microvascular pericytes in the peripheral zones of active lesions, supporting the concept of a vascular pathogenesis of scleroderma [5]. IgM and C3 are found at the basement membrane and in dermal blood vessels, particularly in more extensive and deeper lesions, but there is no relation to systemic disease [6]. A study of glycosaminoglycans in normal and sclerodermatous skin has shown an increase in hyaluronic acid and altered dermatan sulphate in involved skin [7]. The histological features are similar to those seen in generalized morphoea and in the skin in systemic sclerosis.

Incidence. All ages are affected, the peak incidence occurring between 20 and 40 years of age, although 15% begin below the age of 10 years [1,2], in which age group the linear lesions predominate. The female to male ratio is around 3:1 in most studies. Most linear lesions (75%) occur before the age of 40 years, whereas 75% of localized plaques arise between the ages of 20 and 40 years [2]. In one series, localized plaques occurred in 60 patients, with linear lesions in 33 and guttate in 13 [3], but in another series [2] there were more patients with linear lesions than with plaques. A worldwide study of 750 children with juvenile localized scleroderma showed linear lesions in 65%, plaques lesions in 26%, generalized involvement in 12% and deep lesions in 2%, with 15% exhibiting a mixed subtype [4]. Six patients (0.8%) had linear lesions present at birth and were considered as having congenital scleroderma [5]. The condition is said to be rare in black people [3]. A recent epidemiological study of morphoea in the USA has found a female to male ratio of 2.5:1, an incidence of 2.7 in 10 000 and a prevalence at 80 years of age of 1 in 500 [6].

Clinical features

Plaque lesions. These occur as indurated areas of skin, which at first are faintly purplish or mauve in colour. After some weeks or months they lose their colour (Fig. 51.48), especially in the centre, and appear as thickened waxy areas, which are ivory in colour, with a characteristic lilac-coloured edge (Fig. 51.49). The surface is usually smooth and shiny but may be nodular [1]. The hairs are absent, and usually the area ceases to sweat. Vesicles, bullae [2] and haemorrhages may occasionally occur, and sometimes telangiectases may be seen. The plaque is attached to the deeper tissues and, if thick, may be hypoaesthetic. The lesions are round or oval, sometimes irregular, and vary in size from approximately 2 to 15 cm or more in diameter. They are usually multiple, and often bilateral, but asymmetrical. They occur on the trunk and limbs, face and genitalia. They are less commonly found in the axillae and perineum and around the nipples. Sometimes, plaques accompany linear lesions.

Fig. 51.48 Localized morphoea: plaque-like lesions on the abdomen.

Fig. 51.49 Localized morphoea on the foot: late stage but still showing lilac border.

Although the onset of lesions is usually insidious, they can occasionally occur rapidly, with erythema and oedema. Sometimes they may be preceded by pigmentation (Fig. 51.50). In subcutaneous morphoea, induration is indistinct and the lilac ring is

Fig. 51.50 Localized morphoea: pigmentation usually occurs as the lesion resolves but may occur at the onset.

absent. Deep involvement of underlying structures in morphoea of the trunk is unusual, but occurs occasionally and may be followed by deep atrophy [3]. Obscure abdominal pain and migraine were features in approximately 15% of patients in one series [4], but usually any pain is limited to the skin lesions. One study detected abnormalities of the vertebral column in 47% of those X-rayed, with spina bifida occulta occurring in 20 patients. These findings were most common in those with linear lesions, occurring in 26 of these 108 patients [4]. Other studies have not, however, reported such findings.

Recently, the term 'superficial morphoea' has been proposed for lesions with minimal induration [5]. Most cases occur in females although a single case in a male has been reported [6]. It has been suggested that atrophoderma of Pasini and Pierini may also be a primary abortive form of morphoea [7] in which induration fails to occur. Some authors argue that these two conditions are one and the same [8].

Guttate lesions. In true guttate morphoea, the lesions are similar to, but smaller and more numerous than, plaque lesions. Some cases may represent lichen sclerosus et atrophicus (white spot disease) rather than true morphoea. It has been suggested that these two diseases may have a similar pathogenesis [9] or coexist [10,11].

Bullous lesions. Peterson's classification [12], describes bullous morphoea as a distinct entity. However, blisters have been described in all types of morphoea and have been thought to result from lymphatic dilatation along with the release of major basic protein from eosinophils [13]. Others have suggested that, at least in some cases, the blisters represent the development of associated lichen sclerosus [14].

Subcutaneous morphoea/deep morphoea/morphoea profundus. Nodular [1], keloidal [15,16] or subcutaneous morphoea are variants of morphoea that exhibit differing amounts and depths of inflammatory changes and sclerosis. The term morphoea profundus was first suggested by Whittaker *et al.* [17], in 1989, to describe a solitary fibrotic plaque on the shoulder, back, neck or paraspinal area, which histologically showed fibrosis, hyalinization of collagen fibres and a deep dermal and subcutaneous inflammatory infiltrate. The overlying skin may be pigmented or hypopigmented. Osteoma cutis can develop within such lesions [18,19] and contracture of the flexor muscles of the finger has been reported in subcutaneous morphoea [20]. Most lesions of morphoea profundus are said to be non-progressive [21].

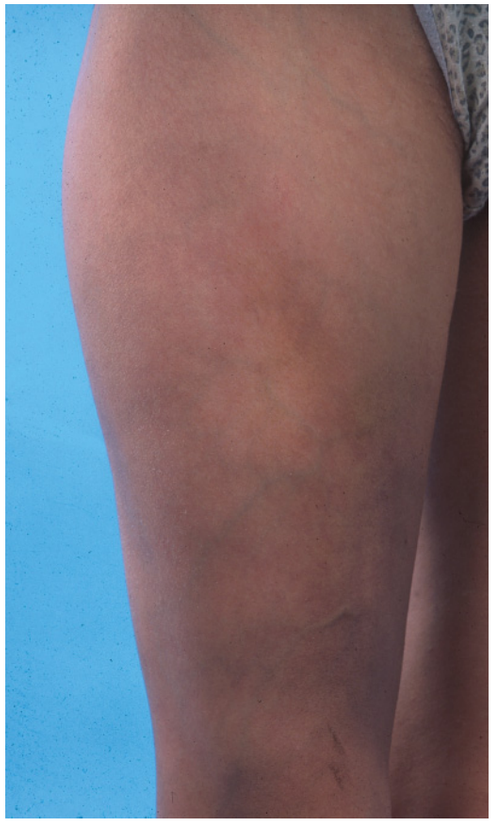

Fig. 51.51 Linear morphoea.

Linear lesions (Fig. 51.51). The essential features are similar to the plaque lesions, but the lilac ring is inconspicuous or only present at the advancing border. They are usually single and unilateral, although occasionally bilateral lesions occur. They can follow the lines of Blaschko [22–24]. The limbs are frequently affected, the legs more than the arms. They may also occur on the anterior aspect of the thorax, and sometimes the abdomen or buttocks are affected. Lesions involving one arm and one leg are usually homolateral. Rarely, half of the body (face, arm, trunk and leg) is involved [25]. Occasionally, a linear lesion on the leg is preceded by oedema of the limb. Lesions take the form of linear areas of induration, similar to those found in the plaques, but sometimes the condition may extend to involve the underlying muscles, or even bone, with resulting disturbances in growth in approximately 20% (Fig. 51.52) [26] and possibly severe flexion deformity [27,28]. The surface may show patchy hyperkeratosis. Usually, lesions occur along the length of the limb or around the trunk, but sometimes a band surrounds a limb or a finger, resembling ainhum [29,30]. The tissues

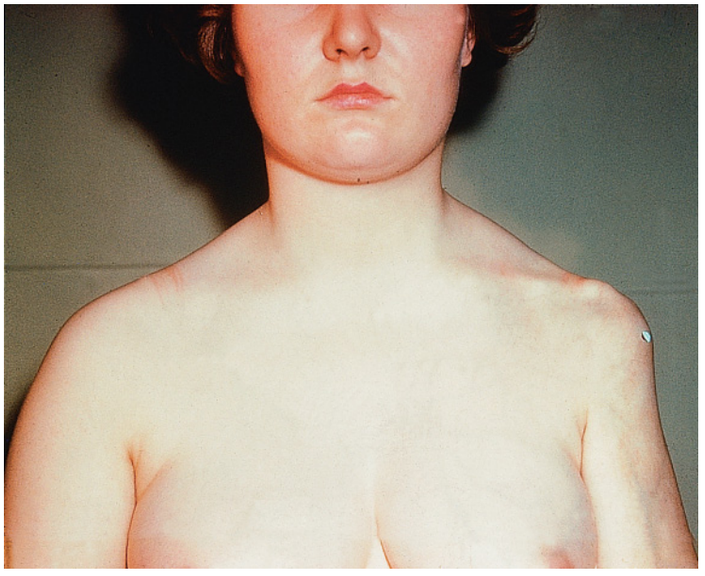

Fig. 51.52 Localized morphoea of the arm showing growth retardation.

Fig. 51.53 Frontoparietal morphoea ('en coup de sabre').

distal to such a band may be oedematous and depigmented [26]. The fibrosis may spare areas within an otherwise linear lesion, producing 'skip' lesions.

Linear scleroderma has been associated with hypertrichosis [31], melorheostosis [32–34], and ulcerated dystrophic calcinosis cutis [35]. Nodular morphoea has been reported in a linear pattern [36].

Frontoparietal lesions (Fig. 51.53) 'en coup de sabre' (from its resemblance to a sabre cut), with or without hemiatrophy. These lesions usually start with contraction and firmness of the skin over the affected area. Subsequently, an ivory irregular sclerotic plaque develops, sometimes with telangiectatic vessels coursing over it, together with hyperpigmentation at the edge. Eventually, a linear depressed groove appears on the frontoparietal region, extending into the scalp, producing a linear zone of alopecia, which may be preceded by bleaching of the hair. The groove may extend downwards into the cheek, nose and upper lip, and involve the mouth and gum. In severe cases, it extends as far as the chin and neck. The condition may affect the gingivae [37] and the jaw may also be involved, with alteration of the spacing and direction of the teeth [38]. The corresponding side of the tongue may be atrophic, although sometimes the lesion is in the midline of the tongue. Not infrequently, there is atrophy of the corresponding part of the face and cheek, with facial asymmetry, and this usually occurs within a year. The Parry–Romberg syndrome of hemifacial atrophy looks very similar, but there should be no cutaneous sclerosis at any stage [39]. Both problems may co-exist [40]. Rarely, frontoparietal lesions may be bilateral [41,42] or trilinear [43] and may follow Blaschko's lines [44]. Sometimes, there may be morphoeic plaques elsewhere on the body or evidence of linear morphoea on the extremities and trunk [45]. Facial atrophy without frontoparietal morphoea can be associated with morphoea elsewhere. Ipsilateral wasting of the upper limb occurs in less than 10% of cases [46]. Total hemiatrophy of one side of the body can occur.

Contralateral or bilateral atrophy is rare. The bones of the skull can be involved and the EEG may show evidence of dysrhythmia, maximal over the affected area. Neurological abnormalities have been reported [47–49]. A variety of ocular lesions occur [50], including enophthalmos, involvement of the lids, oculomotor muscles, iris and fundus, myopathy of the external eye muscles [51] and vasculitis [52]. Atrophy of the nasal part of the iris and loss of cilia on the upper eyelid followed exactly the line of the skin lesions in one case [53]. Heterochromia of the iris also occurs [54]. 'En coup de sabre' morphoea has presented as unilateral eyelid oedema [55]. Ossification occasionally occurs [56].

Localized scleroderma in childhood [1–3]. Childhood onset occurs in 2–3% of all cases of scleroderma. Most present with morphoea-type lesions (particularly linear) although systemic sclerosis does occur. The clinical features are similar to adult cases but localized trauma a few months before onset of morphoeic lesions has been reported to occur in one-quarter of childhood patients. A recent large series of 750 children from 70 European centres [4] showed linear scleroderma to be the commonest subtype (65%) followed by plaque morphoea (26%), generalized morphoea (7%) and deep morphoea (2%), and 15% had a mixed subtype. Twelve per cent had a positive family history for rheumatic or autoimmune diseases and 13% reported environmental events as a possible trigger. ANA was positive in 42%, rheumatoid factor in 16%, anticardiolipin antibody in 13%, anti-double-stranded DNA in 4%, Scl-70 in 3% and anticentromere antibody in 2%.

Disabling pansclerotic morphoea of children [5]. This is a rare, severe, mutilating form of morphoea involving the dermis, fat, fascia, muscle and even bone, usually starting before the age of 14 years, although adult-onset cases have been reported [6]. It may develop from linear morphoea. Superficial and deep cutaneous sclerosis involves the trunk and extremities, scalp and face, with sparing of the fingertips and toes (Fig. 51.54). There may be a claw deformity of the hands, and patients may walk on tiptoe because of contracture of the Achilles tendons (Fig. 51.55). Arthralgia and stiffness occur at the onset, and intense pain may be a problem,

Fig. 51.54 Disabling pansclerotic morphoea of the fingers.

Fig. 51.55 Disabling pansclerotic morphoea of the legs.

presumably because of involvement of cutaneous nerves [7]. Raynaud's phenomenon is not found, but a few cases have had oesophageal, pulmonary and periodontal changes. Flexion contractures, osteoporosis and other bone changes are frequent. The electromyogram and histology of muscle may be abnormal, but creatine phosphokinase is normal. Elevation of ESR, hypergammaglobulinaemia and eosinophilia are frequent. Treatment with PUVA [8], low-dosage UVA-1 [9] and ciclosporin [10] has been reported. The response is often poor, however, and in most patients the condition is progressive [11] and occasionally fatal [5].

Associated lesions. Arthralgia, sometimes localized to the sclerodermatous extremity, unilateral Raynaud's phenomenon, a history of migraine and intermittent recurrent colicky abdominal pain are sometimes found [1]. Abnormal radiological appearances of the spine occurred in 47% of patients in one series [1], particularly those with linear scleroderma. Spina bifida was found in 20 patients and was most common in patients with linear morphoea of the legs, lower abdomen and buttocks. Other abnormalities included sacralization of lumbar segments, the presence of six lumbar vertebrae, prolongation of transverse arches, scoliosis and kyphosis. Pain in the lumbar region, like that of a protruded lumbar intervertebral disc, was sometimes a feature. Rib abnormalities such as rudimentary or cervical ribs, torticollis, atrophic clavicle, absent pectoralis muscle, contracted pelvis, shortened ulna and deformities of the feet and toes have been reported [1], but other studies have not reported similar findings. Associated cutaneous abnormalities include warty, vascular or pigmented naevi, usually with linear morphoea on the same side, café-au-lait spots, alopecia areata, vitiligo [2], generalized ichthyosis or pigmentation, dystrophy of the nails, hirsutism and coarctation of the aorta [3]. Localized morphoea occurred in a pigmented area of Becker's melanosis [4]. A variant occurring later in life, in which morphoea confined to the face and anterior part of the scalp is associated with tissue calcification, hair loss and beaking of the nose, has been reported [5]. Sclerotic panatrophy, disseminated granuloma annulare and morphoea have occurred in the same patient [6].

Children may be intellectually precocious [1]. A recent review of 750 children with localized scleroderma from 70 European centres [7] showed that almost one-quarter had extracutaneous manifestations, including articular (47%), neurological (17%), vascular (9%), ocular (8%), gastrointestinal (6%), respiratory (3%), cardiac (1%) and renal (1%) abnormalities. Other autoimmune conditions were present in 7%.

Occasionally, morphoeic lesions may occur in association with lesions of lichen sclerosus et atrophicus. Localized patches of morphoea may occur in patients with systemic sclerosis [8] and

occasionally patients with localized patches of morphoea may later develop systemic sclerosis [1,9]. Although no systemic abnormalities were found in 27 autopsies on patients with localized morphoea [10], changes in the oesophagus, muscles and joints may occur in as many as 27% of cases [11]. The diagnosis of systemic sclerosis was confirmed at autopsy in a 71-year-old woman with two patches of localized morphoea on the front of the chest, who subsequently developed cardiac enlargement, pulmonary fibrosis and a dilated aperistaltic oesophagus [12]. Typical morphoeic patches on the skin and gastrointestinal radiological changes typical of systemic sclerosis were found in another patient [13].

Morphoea has occurred with DLE [14], mixed connective tissue disease [15] and eosinophilic fasciitis [16], and frontoparietal morphoea has been associated with SLE [17]. Morphoea has followed SCLE [18] and may also occur with dermatomyositis [19], carpal tunnel syndrome [20], nephritis [21], vitiligo [22], pemphigus [23], primary biliary cirrhosis [24] and myasthenia gravis [25]. The coexistence of morphoea, localized bullous pemphigoid and subcorneal pustulosis has been reported [26]. Elastosis perforans serpiginosa has also occurred with morphoea [27]. Localized scleroderma can follow augmentation mammoplasty [28], and linear oedema, nodularity and scarring, with hidebound skin, has been attributed to leaking of silicone into an arm [29].

There is no relationship between localized morphoea and internal malignancy [30], although systemic sclerosis has been associated with carcinoma of the lung, skin and liver [30,31]. The morphoea-like changes found in patients with carcinoid syndrome are thought to occur as a result of serotonin release by the tumour [31]. Squamous cell carcinoma has been reported in patients with long-standing pansclerotic morphoea [32] and in localized scleroderma in a patient treated with azathioprine [33].

Laboratory abnormalities. ESR and serum protein assays are usually normal, but eosinophilia may occur [1]. Anti-single-stranded DNA antibodies are more frequent in generalized morphoea (75%) and linear morphoea (53.3%) than in localized morphoea (27.3%) [2]. Antihistone antibodies have been detected in 32% of patients with linear morphoea and in 25% with localized morphoea in one study [3] and in 71% of children and 65% of adults with linear morphoea in another [4]. In the latter and one further study [5], it has been suggested that they mirror disease activity. Hereditary deficiency of complement factor C2 is reported [6]. Organ-specific autoantibodies are more commonly found than in controls [7]. Thrombocytopenia responding to corticosteroid therapy has been reported in two patients [8]. Approximately 40% of patients with linear morphoea have positive antinuclear antibodies, and the presence of these antibodies (with homogeneous and nucleolar patterns), antibodies to single-stranded DNA and the presence of eosinophilia may indicate disease activity [9] and the late development of systemic complications [10]. Serum procollagen type 1 carboxy-terminal propeptide has been reported to be raised in 30% of patients with localized morphoea, correlating

with the number of lesions. Levels are lower than in generalized morphoea and may be a useful indicator of disease activity [11]. Type 3 procollagen propeptide has also been reported to be raised [12]. However, others have not found these markers as useful.

Topoisomerase 1 (Scl-70) is unusual in localized scleroderma but a recent study has found autoantibodies to topoisomerase 11α in 70% of patients with localized scleroderma and 85% of patients with generalized morphoea [13]. IgM rheumatoid factor has been suggested to be a useful marker of disease severity [14], and IgM anticardiolipin antibodies have been reported as associated with a greater number of lesions [15]. In another study, antinucleosome antibodies were found to have a higher prevalence in localized scleroderma [16]. All the serological changes associated with localized scleroderma have been recently reviewed [17].

In children, in a recent large series from 70 European centres [18], ANA was positive in 42%, rheumatoid factor in 16%, anticardiolipin antibody in 13%, anti-double-stranded DNA in 4%, Scl-70 in 3% and anticentromere antibody in 2%.

Ultrasound scanning has been reported as being helpful in diagnosing morphoea [19], in differentiating morphoea from lichen sclerosus et atrophicus [20], and in monitoring the course of localized morphoea [21]. The dermatoscope has been reported as a useful tool for assessing nail fold capillary abnormalities [22].

Prognosis. Plaque-like lesions tend to improve with time. The induration lessens and the lesions blend in with the rest of the skin, leaving a brownish stain, which may persist for a long time. The duration of activity is usually between 3 and 5 years, but some lesions last up to 25 years. It is common to find fresh lesions developing on new sites as other lesions resolve. Residual pigmentation persists for a long time in approximately one-third of patients. Linear lesions tend to persist for longer than plaque lesions, but on the whole improve with time. Calcinosis occasionally occurs in linear lesions, and sometimes requires surgical removal. Contractures may limit movement of joints and give rise to clawing of the hand. Unilateral atrophy of one or more limbs may occur. Facial hemiatrophy is usually persistent, but frontoparietal scleroderma may clear, and may be accompanied by regrowth of hair. In 63 of 88 children with morphoea, lesions resolved with minimal cosmetic disability [23]. Very rarely, patients with localized morphoea may subsequently develop classical systemic sclerosis [23,24]. It has been suggested that the presence of anti-Ku antibody may be a prognostic indicator of such progression [24].

Differential diagnosis. The diagnosis is usually not difficult, the insidious development of indurated plaques and bands in the skin, with or without hemiatrophy, being unlikely to occur in other conditions. If there is a lilac-coloured border diagnosis is easier. Reticulate lilac lesions with minimal induration can resemble cutaneous polyarteritis nodosa. Morphoeic lesions occur in sarcoidosis [25]. Lesions can start as a vascular blush, and may be mistaken for a macular vascular naevus. In the acute phase, the condition must be distinguished from scleroedema of Buschke, but in this condition the onset is much more acute, and the lesions may follow an infectious episode. Fading pigmented lesions are sometimes very difficult to diagnose, but the previous history of some induration in the area is usually helpful. Atrophic pigmented lesions resembling lesions of the atrophy of Pierini and Pasini (see Chapter 45) [26] occurred in 47% of the patients in one series [27]. Abdominal lesions may be confused with so-called lipodystrophia centrifugalis abdominalis infantilis (see Chapter 46) [28,29]. Atrophic morphoeic plaques can result from intramuscular injections of vitamin K [30] or subcutaneous corticosteroid injections [31]. Conditions producing pseudoscleroderma (see p. 51.79) may have to be considered. Melorheostosis is a rare condition in which there are painful abnormalities of the skeleton and adjacent soft tissues, usually limited to a single limb. Linear endosteal bony densities of the long bones are seen on radiography, and resemble candle wax flowing along the affected bone. In children, the usual presentation is with asymmetrical contractures of a limb, occurring in association with thickening of the overlying skin and fascia, and distal vascular problems exacerbated by attempted surgical correction of the orthopaedic problem, including angiomas and arteriovenous malformations [32]. It is suggested that the distribution of these lesions represents the sclerotome, or the areas of the body supplied by a spinal sensory nerve, and that skin and muscle involvement occur in the relevant dermatome and myotome [33]. The cutaneous lesions are almost certainly a part of the developmental abnormality, rather than coexisting linear morphoea [34].

Treatment. As the expected natural history is towards spontaneous resolution, the condition may be allowed to take its natural course, if uncomplicated. If intervention is required, localized treatment with topical or intralesional steroids may be helpful [35]. More recently, calcipotriol has been shown to inhibit the growth of morphoea fibroblasts *in vitro* [36], and has proved beneficial when used topically *in vivo*, both alone [37,38] and in combination with UVA-1 in children [39]. Topical tacrolimus has been reported as being beneficial in seven patients [40] as has 5% imiquimod cream [41].

Numerous systemic agents have been reported to be helpful in morphoea (on the basis of case reports or small open studies), including phenytoin [42], *p*-aminobenzoate [43], griseofulvin [44], etretinate [45], vitamin E [46], chloroquine and hydroxychloroquine [47]. Tranilast was reported as helpful in a boy with linear morphoea and contractures [48], and plasmapheresis was helpful (in combination with systemic corticosteroids) in three patients with localized scleroderma and antinuclear antibodies [49]. Regression of plaques of morphoea after tamoxifen therapy has been reported in one patient [50], and a child with pansclerotic morphoea showed significant improvement after 3 months' therapy with the oral endothelin receptor antagonist bosentan [51]. Topical photodynamic therapy was reported as being helpful in five patients with localized disease [52].

Systemic corticosteroids have been found to be helpful in an open trial [53], although they are probably only beneficial in the inflammatory stage of the disease [35]. d-Penicillamine has been reported as helpful in open trials [54–56] in regimens of 2–5 mg/kg/day, with or without pyridoxine 20 mg/day. However, there is a risk of renal damage [54]. Ciclosporin was found to be helpful in open studies in localized morphoea [57,58] and in a single case of linear scleroderma in a child [59]. Oral calcitriol, in regimens of 0.5–0.75 μg/day, has been reported as helpful in a small study

[60], but a recent double-blind placebo controlled trial did not confirm this [61].

In recent years, UVA irradiation, both alone at low [62–65], medium [66] and high doses [67], as bath or oral photochemotherapy [68–71], and in combination with calcipotriol [39], has been reported as helpful. Two randomized controlled trials have both confirmed that low-dose broad-band UVA (UVA1) is as effective as medium- or high-dose UVA regimens or narrow-band UVB [72,73]. The effect is thought to result from increased production of collagenase and IFN-δ, and decreased TGF-β and collagen production [74]. A single case report has suggested that low-dose UVA was helpful in softening lesions in a case of pansclerotic morphoea in an 8-year-old girl [75]. The main therapeutic advance for morphoea, however, is the greater use of methotrexate. In low dose, this agent has proved useful in both widespread morphoea [76,77] and in localized morphoea in children when used in combination with systemic corticosteroids [78–82].

Physical therapy in the form of physiotherapy may be helpful in preventing joint deformities and contractures, and in maintaining joint movement and muscle strength. It may also help to prevent sclerosis secondary to lymphoedema in the limbs of patients with linear morphoea [35]. Surgical intervention for the relief of contractures [83], the lengthening of limbs and the correction of deformities may have to be carried out in certain cases. Various plastic surgery techniques can help patients with 'en coup de sabre' morphoea [84–95] and those with ossification [96]. Ulcers associated with bullous lesions have been treated with 'tissue-engineered' skin [97]. For those patients in whom the sclerotic processes have extended into the jaw to involve the teeth, dental treatment may be required.

Generalized morphoea

Synonym

- Generalized scleroderma

Fig. 51.56 Generalized morphoea showing diffuse tightness of the skin of the chest.

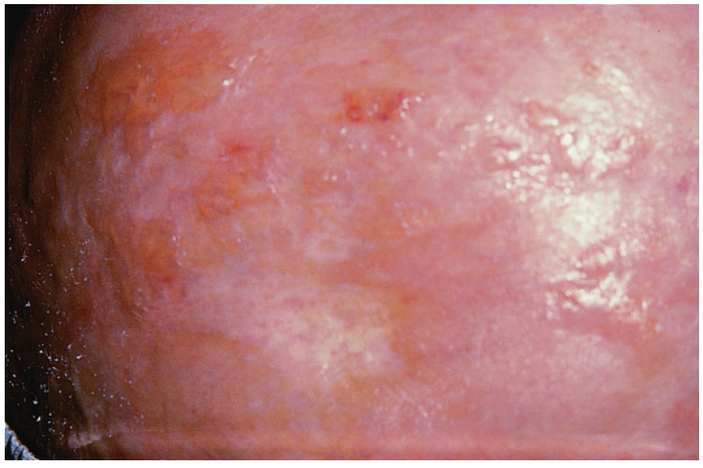

Fig. 51.57 Bullous lesions in generalized morphoea.

Definition. A rare condition in which idiopathic sclerosis of the skin occurs in a widespread manner. It usually starts on the trunk and is not associated with systemic disturbances.

Aetiology. The aetiology is unknown. The most frequent age of onset is between 30 and 40 years, and lesions start between the ages of 11 and 50 years in 80% of patients [1]. Approximately three females are affected for every male. The occurrence of generalized morphoea and localized morphoea in two sisters has been reported [2].

Pathology. This is identical to that of localized morphoea. It has been suggested that in the early stages an inflammatory infiltrate of lymphocytes, histiocytes and plasma cells is found, primarily in the subcutaneous tissue. Later, the subcutaneous tissue is replaced by hyalinized connective tissue and this is responsible for the induration of the skin. Direct immunofluorescence shows changes in approximately one-third of cases, with IgM in the basement membrane and IgM and C3 in the dermal blood vessels being the most frequent findings. Similar changes may occur less frequently in linear morphoea.

Clinical features (Fig. 51.56). The onset is usually insidious, and the patient notices the development of plaques resembling those of localized morphoea. A lilac-coloured border surrounding the indurated ivory-white shiny lesions is usually seen in the early stages. The plaques are commonly much larger than those seen in localized morphoea, being many centimetres in diameter. Usually, plaques start on the trunk and gradually increase in size, with the development of new plaques over the first year or two. The main areas involved are the upper trunk, breasts, abdomen and upper thighs. The arms may also be involved, and in some cases the hands resemble those seen in the tumid phase of systemic sclerosis, with spindling of the fingers, binding of the skin to the underlying tissues and semiflexion of the hands and fingers. The legs, face, neck and scalp may also be involved. Scarring alopecia can result from involvement of the scalp. In some cases, the whole of the body may be involved from the top of the head to the feet, although this occurred in only one out of 44 cases in one series [1]. Mechanical compression has been suggested as an aetiological factor [3]. If the chest wall is markedly involved there may be difficulty in breathing because of constriction of the thorax. The intercostal muscles may also be involved, and death may result from respiratory failure [4]. The face is expressionless, the skin being shiny, often brown, and indurated. Telangiectasia of the face is not a feature, and although mouth opening may be restricted, the radial furrowing of systemic sclerosis is not seen. Raynaud's phenomenon occurs occasionally but is not a characteristic feature. Sometimes, especially after trauma, the hands may develop whitlows, but there is no atrophy as seen in systemic sclerosis. The tissues of the trunk and limbs sometimes show a brawny non-pitting oedema and acute widespread oedema associated with hypoproteinaemia has been observed [5]. Bullae may develop in localized areas, particularly on the abdomen (Fig. 51.57). Nodular lesions may also occur [6], and multiple keloids may be the first manifestation of the disease [7]. Acral myofibromas have been reported [8]. If the condition is generalized, it may be impossible to see any area showing a lilac border. Pigmentation is common, and in some patients may be generalized. Amyloid deposition [9] and amyloidosis cutis dyschromica [10] have been reported. Keratoses and calcinosis can occur.

Contractures occur in limbs, which become thin and hard. Some patients complain of considerable soreness in the acute phase, especially of the trunk and breasts. Joint pains occur in approximately 50% of patients, particularly in the fingers, wrists, elbows and knees. Definite rheumatoid arthritis may be found. Very occasionally, severe contractures, atrophy and infection may be associated with intractable pain in the limbs, and amputation may be required. Squamous cell carcinoma may develop in lesions of over 20 years' duration [11,12].

Sometimes generalized morphoea may develop as an extension of localized morphoea or be associated with lesions of lichen sclerosus et atrophicus [13]. Subcutaneous morphoea [14] seems to be more inflammatory than generalized morphoea of the dermis, and may respond to anti-inflammatory agents. Such cases may be more likely to develop mild systemic involvement and have

eosinophilia. Generalized morphoea has been associated with polymyositis and the sick sinus syndrome [15], and necrotizing vasculitis [16], primary biliary cirrhosis [17] and fasciitis [18].

Laboratory investigations. Investigation for systemic disease is usually negative. Eosinophilia, elevated ESR and hypocomplementaemia occasionally occur. Anti-single-stranded DNA antibody occurs, but anti-double-stranded DNA antibody is rare. Serum procollagen type 1 carboxy-terminal propeptide may be a useful index of activity. Levels are higher than in localized morphoea [19]. Scl-70 antibodies are rarely found.

Differential diagnosis. The following points help to distinguish morphoea from systemic sclerosis. Raynaud's phenomenon is uncommon in generalized morphoea and is almost universal in systemic sclerosis. The distribution of the lesions also differs. In generalized morphoea, the trunk is more frequently involved, whereas the face, hands and, to a lesser extent, the feet, are most commonly involved in systemic sclerosis. Generalized morphoea usually slowly improves over the years. Scleroedema of Buschke is usually a more acute and less widespread disorder. Morphoea must also be distinguished from the various conditions described below under 'pseudoscleroderma'. Generalized morphoea may have to be distinguished from eosinophilic fasciitis (see p. 51.86).

Prognosis. Some improvement is usually seen in the course of 3–5 years, but the disease may last for many years and one patient still showed changes 33 years after diagnosis [1]. In most cases, the skin slowly softens and the pigmentation decreases. With time, the tendency to ulceration, with trauma and blistering, decreases. Although some patients may be severely disabled by the immobility associated with the sclerotic changes and contractures, others with widespread sclerosis may remain surprisingly active. Patients usually remain in good health although one patient died of bronchiolitis obliterans organizing pneumonia [20].

Treatment. The general measures outlined previously for the treatment of localized disease are just as important for patients with generalized disease.

A number of systemic agents may help generalized disease, including systemic steroids, penicillamine, antimalarials and low-dose methotrexate. In addition, individual case reports suggest a role for agents such as sulfasalazine [21], salazopyrin [22], grenz ray treatment [23] and extracorporeal photochemotherapy [24]. Initial reports suggested a role for oral calcitriol but a recent double-blind study has not confirmed this.

An increasing body of literature suggests that ciclosporin may be helpful for generalized morphoea either alone [25,26], or in combination with PUVA [27], although controlled studies are lacking. The last-mentioned case report also suggests a role for PUVA in combination with mycophenolate mofetil. Ciclosporin must be used with care, however, as side effects are common. Severe renal disease may result, although this is perhaps more likely in patients with active systemic disease [28,29]. As for localized disease, methotrexate in combination with steroids is emerging as a useful therapeutic regimen [30]. UVA phototherapy and photochemotherapy may be helpful.

Pseudoscleroderma

Sclerosis of the skin may be seen in several conditions other than morphoea or systemic sclerosis [1]. It comprises a major feature of eosinophilic fasciitis and may also be seen in dermatomyositis and SLE, and this is covered elsewhere in this chapter. Pseudoscleroderma-tous changes may also be seen in rheumatoid arthritis [2] and acrodermatitis atrophicans, a disease found in central and eastern Europe which resembles localized morphoea (see Chapter 45). Scleroderma-like changes may also be found in a number of other conditions, and these are set out below using the classification of a review article [1].

Metabolic disorders

Scleroderma-like changes are sometimes seen in porphyria cutanea tarda [1,2] and in phenylketonuria [3,4], when they usually appear in the first year of life. In the latter condition, irregular indurations appear first in the muscles and subcutis of the thighs and buttocks, and later the changes extend to the trunk and proximal parts of the limbs. Contractures, especially of the legs, are characteristic. Histology shows proliferation of histiocytes and fibroblasts in the connective tissue stroma, atrophy of the skin appendages and an inflammatory infiltrate. Improvement in the skin lesions occurs with exclusion of phenylalanine from the diet. In older children, the lesions and histology resemble morphoea. Two mentally retarded siblings with phenylketonuria had morphoea and atrophoderma of Pasini and Pierini, respectively [5], suggesting that these conditions may be related. Scleroderma-like lesions have been observed in cases of muscle glycogenosis with an undetermined enzyme defect [6], when induration and atrophy occur in the skin and muscles in the first few months of life. The proximal parts of the limbs are involved early and contractures occur, particularly in the legs, giving a characteristic bent-knee gait. Mental retardation may be a feature. Sclerosis of the legs may be found in patients with the carcinoid syndrome [7,8], and sclerosis of the skin occurs in the GEMSS syndrome (*g*laucoma, lens *e*ctopia, *m*icrospherophakia, *s*tiffness of the joints and *s*hortness due to increased production of normal collagen) [9]. The skin may be oedematous and indurated in hypothyroidism, and atrophic changes in the skin in postpartum hypopituitarism may resemble scleroderma. Pseudosclerodermatous changes may also be seen in patients with long-standing diabetes mellitus in which limited joint mobility, termed cheiroarthropathy, is associated with thickening of the skin. The changes are most marked on the hands [10].

A recent report linked the onset of scleroderma-like changes to the diagnosis of cancer, this being postulated to be due to elevated expression of basic fibroblast growth factor [11].

Deposition disorders

Scleroedema of Buschke is usually triggered by a febrile illness and comprises non-pitting induration of the face, neck, shoulders, arms and sometimes trunk. Scleromyxoedema also presents with thickening and tethering of the skin and is usually associated with a circulating paraprotein. The scleroderma-like lesions of primary systemic amyloidosis, with or without multiple myeloma, may be difficult to distinguish if not accompanied by nodular and papular lesions, particularly about the shoulders and neck, and by macroglossia. Primary localized cutaneous amyloidosis occurs in systemic sclerosis [1]. Pseudoscleroderma also occurs in multiple myeloma [2] and paraproteinaemia [3].

Genetic disorders

Atrophy of the acral parts occurs in Werner's syndrome and progeria; acrogeria and poikilodermatous epidermolysis bullosa [1] are other rare conditions in which scleroderma-like lesions occur. Sclerosis of the skin also occurs in the Moore–Federman syndrome (short stature, stiffness of joints, characteristic facies). The 'stiff skin syndrome' describes patients who from childhood develop stone-hard, subcutaneous indurations, which on MRI scan are seen to be derived from the fascia. The lesions are most pronounced on the buttocks, hips and knees, often leading to contractures. The children develop normally and no treatment other than physiotherapy is required [2,3].

Occupational causes

A number of chemicals have been reported to cause a scleroderma-like picture.

Vinyl chloride disease [1–4]

One to six per cent of polyvinyl chloride (PVC) workers, particularly reactor cleaners, develop coldness, stiffness, numbness, burning pain and discoloration of the fingers and hands, and to a lesser extent the feet, on exposure to cold. Other symptoms include loss of energy, loss of libido, impotence, dyspnoea and feeling light-headed, with irrational laughter and whistling. The skin of the hands, forearms, face and trunk may be thickened. The hands show mottled pink, purple or white areas. The terminal phalanges are shortened and bulbous, and the nails are curved. Telangiectases occur on the face, resembling those of systemic sclerosis, and there may be difficulty in opening the mouth, although radial furrowing and pigmentation are not features. Usually, it is possible to distinguish between classic systemic sclerosis and vinyl chloride disease [5]. Parotitis [6], hepatomegaly and splenomegaly occur. X-rays show erosion of the tufts of the terminal phalanges and thinning of the other phalanges of the fingers and toes. Erosions also occur in the metatarsals, pelvic bones, clavicles and bones of the arms and legs. Nail fold capillaroscopy shows changes similar to those seen in systemic sclerosis. Narrowing of digital arteries and hypervascularity of the digital tufts are seen on arteriography.

Histologically, there is thickening and separation of collagen fibres and fragmentation of elastic fibres in the dermis. Immunohistology reveals an immune-complex vasculitis with deposits of IgG, complement and fibrin in the media of small- and medium-sized arterioles [7]. Other immunological features include low levels of non-organ-specific autoantibodies, polyclonal hyperglobulinaemia, cryoglobulinaemia, cryofibrinogenaemia, *in vivo* complement activation and conversion, reduced T cells and moderate B-cell proliferation. Anticentromere or anti-Scl-70 antibodies cannot usually be demonstrated [8], although a patient who presented with 'pneumoconiosis' and systemic sclerosis features 10 years after exposure did have a positive ANA and Scl-70 antibodies [9]. Thrombocytopenia, abnormal platelet aggregation, abnormal liver function tests, raised serum creatine phosphokinase indicating muscle involvement, patchy defects of pulmonary ventilation and perfusion, hepatic fibrosis and oesophageal varices also occur.

The prognosis is unknown, and many men have not improved after removal from exposure. There is no effective treatment. Angiosarcoma of the liver is a serious complication. If the level of exposure to vinyl chloride monomer in PVC manufacturing plants is kept below five parts per million, further cases of vinyl chloride disease should not occur. A genetic susceptibility is shown by an increase in HLA-DR5 in all patients and of -B8 and -DR3 in those severely affected [8]. Acro-osteolysis has also been reported in a worker not exposed to vinyl chloride [10].

Scleroderma-like lesions resulting from perchlorethylene, trichlorethylene and organic solvents

A disorder, resembling vinyl chloride disease, has been reported after exposure to perchlorethylene, a solvent used in dry cleaning of clothes [11,12]. Acrocyanosis and acrosclerosis were associated with polymyopathy and hepatic damage. Some of the features, including the presence of speckled antinuclear factor and favourable response to prednisone, were suggestive of 'mixed connective tissue disease'. Exposure to trichlorethylene may be associated with scleroderma [13–16], possibly after even a single prolonged exposure. Of patients with systemic sclerosis in an eastern European series, 28% had suffered significant exposure to organic solvents [17]. Similarly, an Italian study has confirmed an aetiological role of exposure to solvents in scleroderma [18]. A man who used trichlorethylene for cleaning metal also had peripheral neuropathy, Raynaud's phenomenon, impotence, gynaecomastia, hepatomegaly, lymphadenopathy and pigmentation [16]. He was probably a case of Crow–Fukase (POEMS) syndrome. In a Japanese series, generalized morphoeic lesions, similar to those found in occupational scleroderma, were found in nine of 115 patients with systemic sclerosis. Seven had been exposed to organic solvents before the onset of Raynaud's phenomenon. Some had visceral changes of systemic sclerosis [19]. The same authors induced sclerotic skin changes in mice by the intraperitoneal injection of naphtha, *n*-hexane and hexachlorethane. A sclerodermatous syndrome consisting of cold sensitivity, restrictive lung defect, peripheral neuropathy, oesophageal dysfunction, labile hypertension and monoclonal paraproteinaemia has been reported in a man who had worked with many solvents. These included benzene, toluenes, toluidines, xylenes, xylidenes, aniline compounds, and ethanolamine and its derivatives [20]. Solvents recorded in other reports include isopropylalcohol, ethyl acetate, naphthalene, trimethylbenzene and terpene derivatives [21]. Systemic sclerosis occurred in two workers handling *meta*-phenylenediamine [22].

Scleroderma-like lesions resulting from pesticides

Sclerodermatous changes can occur in workers handling pesticides. Substances possibly incriminated include chlordane, heptochlor, malathion, parathion, DDT, sodium dinitro-orthocresolate and 7-chlorocyclohexane [2,23,24]. Raynaud's phenomenon occurs, but there is no evidence of involvement of internal organs. Hyperkeratosis of palms and soles with sclerodactyly of the fingers and toes has been reported in a weed sprayer with chloracne [25].

Scleroderma-like lesions resulting from epoxy resin

Six Japanese men exposed to the vapour of epoxy resins in the production of transformers for television sets developed scleroderma-like skin changes and erythema, with fatigue, loss of weight, myalgia and arthralgia [26]. The histological changes were those of scleroderma, but there was no definite evidence of systemic involvement. A hardener—1,1'-*bis*(3-methyl)-4-amino(cyclohexyl)methane—was thought to be the cause.

Improvement occurred when the men stopped work, and the disorder resolved completely within 5 years without any internal organ involvement developing [27]. One patient developed systemic sclerosis sine scleroderma after exposure to epoxy resin [28].

Silicosis and scleroderma

The association of silicosis and scleroderma has been reported in Italy [18], in South African coal mines [29] and in coal mines in other countries where silica is present [30–33]. Men in other occupations, such as sandblasters and quarrymen, may be affected. Because of the occupational risk, the condition occurs predominantly in men, particularly those suffering from silicosis. In East Germany, 93 of 120 male patients with systemic sclerosis had suffered long-term silica exposure, and 49 had coexisting silicosis [34]. The lung changes frequently precede the scleroderma. Visceral manifestations resembling those of systemic sclerosis occur in approximately half of cases, and antinuclear factor can be demonstrated in one-third. In these cases, the clinical and immunological changes are indistinguishable from those found in systemic sclerosis without any environmental exposure [35]. Systemic sclerosis-like syndromes may follow exposure to urea formaldehyde foam insulation [36].

Exogenous/iatrogenic scleroderma

Scleroderma-like changes resulting from bleomycin [1,2]

Cutaneous fibrosis with acrocyanosis, acrosclerosis, pigmentation, hair loss, flexion contractures and ulceration occurs in patients treated with the antitumour agent bleomycin. Pulmonary fibrosis is a prominent feature. Remission occurs some months after withdrawal of the drug. Cisplatin can cause similar changes.

Scleroderma resulting from other drugs

Carbidopa [3], pentazocine [4], cocaine [5] and appetite suppressants [6] have all been implicated in the development of sclerodermatous disease.

Scleroderma induced by silicone or paraffin implants (human adjuvant disease) [7]

Skin sclerosis, sometimes resembling morphoea, occurs at the site of injection of silicone for cosmetic breast surgery. It may act by the release of silica. Sometimes, more widespread connective tissue disease resembling systemic sclerosis [8], mixed connective tissue disease, SLE, rheumatoid arthritis, primary biliary cirrhosis, Sjögren's syndrome [9] or eosinophilic fasciitis [10] occurs. Paraffin injections may be a more important factor than silica in causing systemic sclerosis-like disease [11]. A causal link between silicone breast implants and autoimmune diseases seems to have been discounted [12].

'Toxic oil' epidemic syndrome [1,2]

In 1981, in certain areas of Spain, the ingestion of rapeseed oil denatured with aniline caused a multisystem disease affecting 18000 people. The most prominent pathological feature was a widespread non-necrotizing intimal vasculitis in practically every organ [3]. The early phase, lasting 2–3 months, consisted of atypical pneumonia, gastrointestinal and neurological symptoms and a pruritic rash. The rash involved the limbs, abdomen and trunk, and resembled a viral exanthem lasting approximately 5–20 days. Occasionally, palpable purpura or erythema multiforme occurred. Eosinophilia was always present, antinuclear antibodies were frequently found, and elevation of IgE and abnormal liver function tests could be demonstrated in one-third of cases. Histology showed dilatation of blood vessels, and an inflammatory exudate including eosinophils in the dermis. Three to four months after the onset, 10% of patients developed a transitory eruption consisting of multiple yellowish or brownish papules of all areas except palms and soles. Five to six months after the onset, patients, mainly women, developed a neuromyopathy, and either localized or generalized morphoea or a disorder resembling systemic sclerosis, with dysphagia, oesophageal changes and occasionally renal involvement. Sicca syndrome and pulmonary hypertension were prominent features in some cases. Histology of the skin showed dermal infiltration and sclerosis with interfibrillar mucin deposits, but immunology was negative.

Most patients recovered to some extent, although 50% had persistent symptoms when reviewed in 1984 [4]. The cause is unknown. An immune reaction to an unknown antigen seems likely. HLA typing showed an increased incidence of HLA-DR3 and -DR4 in females with chronic disease [5].

Nephrogenic systemic fibrosis (NSF)

Synonym
- Nephrogenic fibrosing dermopathy (NFD)

Nephrogenic systemic fibrosis is a relatively recently described scleroderma-like fibrosing disorder first reported in 2000 [1]. By 2003, over 100 US cases had been reported to the NFD registry established at Yale University. The lesions of NFD are skin coloured to erythematous papules that coalesce into erythematous/brawny plaques with a peau d'orange appearance. Nodules have been described. The involved skin becomes thickened and 'woody', resembling the skin lesions seen in eosinophilic fasciitis. Joint contractures may develop rapidly, with patients becoming wheelchair-bound within days to weeks. The lesions are typically symmetrical and develop on the limbs (often between the ankles and mid-thighs and between the wrists and mid-upper arms) and trunk. Plantar flexion of the feet may make walking impossible. Patients often experience pain and pruritis, but arthritis, fever and myalgia are uncommon [2]. Some patients, however, exhibit systemic features, with involvement of the striated muscles, pleura, pericardium and myocardium. The disease has been reported in both adults and children [3].

No single test is pathognomonic but a deep skin biopsy of involved skin will show fibrosis extending into the subcutaneous fat and sometimes fascia.

All reported patients have had renal disease and initially it was thought that the condition might be triggered by surgery, coexistent hepatic or pulmonary disease, a coexistent hypercoagulable state or following erythropoietin therapy in these patients.

Recently, however, it has become clear that the triggering factor is the use of gadolinium-based contrast agents in patients with renal disease, transmetallation of gadolinium chelates possibly leading to the precipitation of free gadolinium in the dermis or other organs [4]. Surgery and erythropoietin may be also be con-

tributory factors [5]. Alternative imaging should be considered in these patients.

Treatment is unsatisfactory, although some success has been reported with intravenous immunoglobulin, topical and systemic steroids, calcipotriol ointment, d-penicillamine, ciclosporin, cyclophosphamide, thalidomide, interferon-α, UVA-1, extracorporeal photophoresis and photodynamic therapy [3].

Graft-versus-host disease [1–3]

Definition. Graft-versus-host disease (GVHD) occurs when immunocompetent T cells from a donor recognize and react against 'foreign' tissue antigens in an immunocompromised host. Originally reported following bone marrow transplantation (regularly used in the management of leukaemias, lymphoma, immunodeficiency and inborn errors of metabolism), GVHD is now recognized to occur following transfusion of non-irradiated blood, after maternofetal transfer of lymphoid cells, and following peripheral blood stem cell transfer [4]. Post-transfusion-related GVHD is an uncommon but potentially fatal complication of transfusing blood between immunologically related individuals. It appears that transfused white blood cells are not recognized as foreign, and react against host tissue. The reaction seems to depend on heterozygosity of class I antigens. The two recognized forms of the disease are acute and chronic.

Incidence. Even using prophylactic therapy to prevent its occurrence, GVHD occurs in approximately 50% of patients receiving successful marrow allografts for various disorders, including immunodeficiency diseases, aplastic anaemia, acute leukaemia and radiation exposure, despite careful histocompatibility matching [3]. The frequency is the same in those receiving peripheral blood stem cell grafts [5]. It is clear that the typical acute form of the syndrome can also occur after syngeneic (identical twin) or autologous bone marrow grafting, in which genetically identical material is transplanted, and may occur in approximately 10% of such cases [7].

Aetiology [3]. Billingham described the original criteria for the development of a graft-versus-host reaction in 1966:

1 Genetically determined histocompatibility differences between donor and recipient

2 Immunocompetent cells in the grafted tissue able to recognize foreign histocompatibility antigens in the host and to react against them

3 Inability of the host to recognize and react against the grafted tissue.

It is clear from animal experiments [7], as well as the occurrence of typical GVHD in human syngeneic transplants, that criterion **1** is no longer an essential prerequisite for the development of the acute form of the syndrome. GVHD in this situation occurs because of MHC class II differences. It usually only occurs after the withdrawal of immunosuppression [8].

A similar syndrome occurs in recipients of IL-2 treatment and lymphocytes activated by this stimulating lymphokine given as treatment for widespread malignancy. Cells activated by this technique are non-specifically cytotoxic, capable of self-reactivity and may have the features of NK cells. In animal models, and in humans, HLA-DR-bearing Langerhans' cells are reduced in the acute form of the disease, and T cells directed against these cells are found. In addition, IFN production by activated T cells induces HLA-DR expression on keratinocytes, making them targets for a similar reaction [9,10]. The risk of developing GVHD may be related to cytokine gene polymorphisms [11]. T-cell depletion reduces GVHD in mouse models [12] but the effect on human GVHD is no different from conventional prophylactic regimens [13].

A possible hypothesis is suggested by Ferrara [14]; immunologically competent donor T lymphocytes are not destroyed in the host because they are not recognized as foreign. Activated T cells release IL-2, IFN and probably other lymphokines. IL-2 activates cytotoxic cells (probably NK cells), and HLA-DR-bearing epidermal cells and Langerhans' cells may be specifically attacked, giving rise to acute GVHD. The same, or similar, cells recognize any persisting malignant cells in the host, and it is suggested that graft-versus-leukaemia reactions explain the lowered incidence of recurrence of the original malignancy in patients with GVHD. However, there are some criticisms of the theory of T-cell-mediated cutaneous pathogenesis, mainly that early graft-versus-host reactions do not show T-cell infiltration of the skin [15]. There are also stimulatory antibodies to PDGF and its receptor [16], as well as high levels of B cell activating factors [12], suggesting a role for B cells in the pathogenesis. In addition, successful treatment of GVHD is accompanied by the induction of apoptosis in T cells and some epidermal cells. This suggests that a failure of programmed cell death may be a feature of pathogenesis [17]. Nevertheless, the use of T-cell-depleted marrow for grafting reduces the incidence of GVHD and prevents HLA-DR expression on keratinocytes, but unfortunately the failure rate of the transplant is markedly increased.

Pathology [18]. For acute GVHD, the cutaneous histological changes have been graded for severity.

Grade I Basal cell vacuolation with or without mononuclear cell infiltration

Grade II Solitary epidermal cell necrosis, surrounded by mononuclear cells

Grade III Regional epidermal cell necrosis with bullae

Grade IV Toxic epidermal necrolysis.

Less severe histological grades may be impossible to differentiate from drug-induced reactions. At an immunocytochemical level, the earliest (preclinical) changes are an increase in dermal

macrophages expressing α_1-antichymotrypsin. In grade I disease, there is keratinocyte HLA-DR and ICAM-1 expression, and in the later stages, CD25 T cells, L1 antigen-positive keratinocytes, and VCAM-1 macrophages are increased [19].

In chronic GVHD, histological changes are lichenoid, or resemble scleroderma. IgM may occur at the dermal–epidermal junction, with granular deposits of IgM, IgA and C3 in the walls of dermal vessels. There is associated microvascular disease mediated by cytotoxic T cells [20].

Fig. 51.58 Localized eroded sclerotic graft-versus-host disease.

Clinical features [1,2]. Acute GVHD usually occurs within 60 days of a bone marrow transplant, and most often after 7–12 days, when it is termed hyperacute. Mild fever is followed by a faint red maculopapular rash on the hands, feet, face and forehead. This spreads to the trunk and limbs, becoming deeper in colour. Desquamation or even toxic epidermal necrolysis follows. Bullous and ulcerated forms are described, and a follicular pattern may indicate more severe disease [3]. Hepatitis (indicated by raised bilirubin and alkaline phosphatase) and bloody diarrhoea resulting from enteritis are other features and, in severe cases, death occurs by the 21st day. In the original cases, it was rare to have liver and gut involvement without cutaneous pathology, and skin biopsy was the simplest reliable test for diagnosis. However, the introduction of T-cell depletion as a prophylactic measure has changed the pattern of disease so that skin disease may be mild, while liver and bowel disease may be severe. Clinical stagings for each organ system, and grading for the overall clinical picture, have been proposed [2].

Chronic GVHD may be localized (Fig. 51.58) or generalized, and principally involves the skin and the liver. The former occurs in 10% of patients as hyperpigmented nodular areas, which may be guttate, and eventually soften and atrophy. The early phase of generalized GVHD generally appears up to the 100th post-transplant day and usually, but not always, follows acute GVHD. Initially, a slowly progressive erythematous rash on the face, palms and soles becomes lichenoid, with changes resembling lichen planus in many sites. Lichenoid changes may be limited to the nails [4]. Later, scleroderma-like changes occur, which are sometimes widespread and disabling. The condition resembles systemic sclerosis, with tightening of the skin of the face, hands and

feet. Autoantibody changes similar to those found in systemic sclerosis may occur [5]. Disease may be localized to the extremities and associated with a polyneuropathy [6]. There may also be eczematoid changes [7].

Oesophageal changes and subcutaneous calcification may occur. Morphoea-like changes have been reported [8]. Eruptive violaceous vascular tumours on the legs may occur [9]. Reticulate patchy hyperpigmentation and, less commonly, hypopigmentation, poikiloderma, vitiligo (which may be total [10]), erythema, atrophy, alopecia, multiple follicular papules, deep ulcerations of the buttocks and legs, and dystrophic nail changes are other features [11]. Panniculitis may occur [12]. Gastrointestinal symptoms, a Sjögren-like syndrome [13], polymyositis [14], abnormal liver function tests, primary biliary cirrhosis [15] and other organ changes occur [14].

That there may be some interaction between viral infections and minor histocompatibility differences in the pathogenesis of chronic GVHD is suggested by the development of scleroderma-like skin changes in areas affected by measles in a patient 8 months after bone marrow transplantation [16]. Similarly, pathogen-free transplanted animals do not develop GVHD until given bacteria or endotoxin, and patients nursed in laminar flow isolation remain disease-free until they are removed from this environment [17].

Treatment [1]. Prophylactic use of ciclosporin, methotrexate and prednisolone and, in particular, combinations of these agents, has reduced the incidence of acute GVHD. None of these regimens has produced a definite reduction in the incidence of chronic GVHD, and recent studies indicate no benefit in 24-month rather than 6-month ciclosporin therapy in this situation [2]. T-cell depletion by using anti-T-cell receptor antibodies is successful in reducing the frequency of acute GVHD when used with post-transplant ciclosporin [3]. Combination therapy appears to be better at preventing GVHD than monotherapy, but overall survival is unchanged in younger patients because of higher leukaemic relapse. Older patients survive longer on combination therapy (methotrexate with ciclosporin or T-cell depletion) [4]. Granulocyte colony-stimulating factor, used to enhance engraftment, may reduce the incidence of GVHD [5].

Once the disease is established, treatment with high-dose corticosteroids or ciclosporin is of value symptomatically, and antilymphocyte globulin may be of additional benefit [6], particularly if combined with tacrolimus [7]. Treatment with prednisone and azathioprine for at least 9–12 months helps generalized chronic GVHD in one-third of patients [8], but complications are common, and survival may be reduced by the addition of azathioprine. Thalidomide, used in both low dosage (100 mg/day) and high dosage (400 mg/day), has been of value, but may result in severe cutaneous ulceration [9,10]. PUVA therapy [11], UVB [12], UVA-1 [13] and extracorporeal photophoresis may be of benefit, even in severe disease [14]. Biological therapies [15], including etanercept [16] and particularly rituximab [17], may be helpful for steroid-resistant disease.

Prognosis. Forty to fifty per cent of patients with chronic GVHD are dead within 10 years of developing the disease. Mortality is caused both by the disease itself, and by severe superinfection, related, at least in part, to the immunosuppressive effects of treatment. Recurrence of the original disease is also a problem. Patients who develop chronic GVHD after the acute form, those with the lichenoid type of eruption, and those with significant liver disease have a worse prognosis, with 80% mortality at 10 years [18].

Eosinophilic fasciitis [1,2]

Synonym
- Shulman's syndrome

This scleroderma-like syndrome appears to be a distinct entity, although some have suggested that it is an early variant of systemic sclerosis [3] or linear scleroderma [4], or that it may occur in conjunction with other connective tissue disease [5]. It occurs in children and adults, more commonly in males than females. In children, persistent sclerosis may occur [6]. The clinical features are the acute onset of pain, swelling and tenderness of the distal part of the limbs, which become indurated. There is limitation of movement of the feet and hands. Occasionally, the face or abdomen can be affected, and there may be superficial blistering and haemorrhage. A relationship to strenuous exertion or trauma has been suggested. Twenty-nine per cent of 52 patients showed lesions of localized morphoea at some stage [7]. Raynaud's phenomenon is rare, there is limited evidence of involvement of internal organs such as occurs in systemic sclerosis, and no history of a previous infection to suggest scleroedema. Blood eosinophilia up to 30% is a striking feature, occurring in approximately 70% of cases [7]; it is associated with elevation of the ESR and hyperglobulinaemia, but these are not present in all cases. Rarely, aplastic anaemia and thrombocytopenia occur [8].

Histologically, there is dermal sclerosis, with inflammation and fibrosis of the fat and deep fascia. The fascia is thickened and infiltrated with lymphocytes, plasma cells, histiocytes and eosinophils. IgG and C3 deposits can be demonstrated in the deep fascia. The inflammatory infiltrate consists of macrophages and predominantly $CD8^+$ T cells with eosinophils [9]. MHC class 1 antigens are over expressed [8]. Cytokine production is enhanced with a mixed Th1/Th2 profile [10]. Antinuclear antibodies cannot be demonstrated and serum complement levels are normal.

Table 51.16 Factors associated with onset of eosinophilic fasciiis.

Neoplasia [18]
Atorvastatin [19]
Autoimmune thyroiditis [20]
Eosinophilic colitis [21]
Hypercalcaemia [22]
Amegakaryocytic thrombocytopenic purpura [23]

An eosinophilic fasciitis-like syndrome occurs after recent ingestion of L-tryptophan [11]. In addition to the usual features of fasciitis, there is muscle weakness and elevated muscle enzyme levels. This may be demonstrated by nuclear magnetic resonance imaging [12]. Enhanced type I procollagen gene expression in the skin has been demonstrated [13]. Myalgia, eosinophilia, dyspnoea, oedema, arthralgia, neuropathy and rashes occur in the eosinophilia–myalgia syndrome [14] which can also be precipitated by tryptophan. Cutaneous manifestations include localized and generalized morphoeic lesions and urticarial and papular lesions [14].

Clinical improvement and disappearance of eosinophilia follow corticosteroid therapy, but spontaneous remission has been reported. Methotrexate may be useful [15]. Phototherapy [16], ciclosporin [17] and other cytotoxic agents may rarely be necessary.

Other factors associated with disease onset are shown in Table 51.16.

Connective tissue panniculitis (see Chapter 46)

This term has been used [1] for focal nodular or atrophic linear or plaque-like lesions on the face, upper trunk or extremities, which histologically show lymphocytic panniculitis with caseation necrosis. The lesions may respond to chloroquine.

Reference

1 Winkelmann R, Padilha-Goncalves A. Connective tissue panniculitis. *Arch Dermatol* 1980; **116**: 291–4.

Relapsing eosinophilic perimyositis [1]

This rare disorder is in the spectrum of eosinophilic myositis, and is characterized by inflammation within the perimysium (and often epimysium) without necrosis, as opposed to polymyositis and eosinophilic myositis in which necrosis and inflammation occur in the endomysium.

Clinically, patients may present with episodic swelling of the muscles, fatigue and fever. Skin lesions include blotchy erythema over the swollen muscles and erythematous papular lesions of the palms. There is peripheral blood eosinophilia and hyperglobulinaemia, but the muscle enzyme levels are normal or only slightly elevated. Histologically, there are perimysial eosinophilic infiltrates.

The aetiology is unknown. The prognosis is good, although the patient should be followed up in case of the development of lymphoproliferative disease. Most patients respond to moderate doses of steroids or indometacin.

Systemic sclerosis [1,2]

Synonyms
- Progressive systemic sclerosis
- Systemic scleroderma
- Acrosclerosis

Definition. Systemic sclerosis is a multisystem disorder characterized by vascular abnormalities, connective tissue sclerosis and atrophy, and autoantibodies (see p. 51.91 for diagnostic criteria) [2].

The name progressive systemic sclerosis was coined by Goetz in 1945; however, the term 'progressive' is now omitted by most authors because of the variable course of the disease [2–5].

Incidence. Systemic sclerosis is a rare disorder, with an incidence between 2.3 and 10 per million population [6–8]. The prevalence rates in a British study were 13 per million males and 48 per million females, although these figures may represent the minimum [9]; there may be considerable regional variations, possibly as a result of environmental factors [10]. Estimates of prevalence from South Carolina are much higher (67–265 in 100 000) [11]. The ratio of females to males is between 3 and 6 : 1 depending on the source [8,9,12]. The peak onset is in the fourth decade in females and usually later in males; however, overall, 85% of patients present between the ages of 20 and 60 years [8]. In men, the condition has a number of occupational associations, especially miners and stonemasons, and it has been suggested that pneumoconiosis and silicosis are predisposing factors [13]. It occurs in all races, but appears to be less frequent in Asians [14]. There is evidence that African American women with systemic sclerosis are more likely to develop diffuse disease at a younger age and have decreased survival compared with Caucasians [15].

Aetiology [1]. The aetiology of systemic sclerosis is unknown. The presence of vascular symptoms in virtually all patients, and the fact that these may predate the development of classic fibrotic change, and the presence of markers of vascular damage (e.g. elevated circulating von Willebrand factor antigen and endothelial adhesion molecules [2,3]), suggest the endothelial cell is either an initial target or the primary dysfunctional cell in this disease. Vascular abnormalities are not limited to the clinically abnormal skin [4]. Damage to the endothelial cell may initiate the fibrotic process, either through ischaemia/reperfusion or via growth factors released from platelets and inflammatory cells. However, the pathological changes in the internal organs do not always seem to be directly related to changes in the small blood vessels of the same area.

There is now clear evidence of endothelial injury and death [5], in addition to myofibroblast dysfunction, and the primary pathology in vascular endothelium appears to be a fibromucinous change [6]. Serum from patients with the disease is cytotoxic to endothelial cells, either directly [7] or by antibody-dependent cellular cytotoxicity [8] and, although patients' serum has no effect on unstimulated release of prostacyclin [9], stimulated release may be impaired [10]. The influence of sera from affected patients on angiogenesis varies with the phase and type of disease, being stimulatory in early limited disease, but inhibitory in chronic diffuse disease [11]. Damage to endothelium is followed by vascular occlusion resulting from thrombus formation, and tissue ischaemia follows. Abnormalities in various blood components contribute to this tissue anoxia: red cell deformability is reduced [12], platelet aggregation to collagen may be specifically enhanced [13] and *in vivo* markers of platelet activation are increased [14]. Levels of fibrinogen, von Willebrand factor antigen (possibly indicating the degree of vascular damage) [15] and other plasma proteins are also raised, contributing to increased plasma viscosity, further reducing microvascular blood flow. Anticardiolipin antibodies may be present and responsible for increased endothelial cell damage and risk of thrombosis [16].

The associated fibrosis in systemic sclerosis is caused by the increased production of collagen in the subcutaneous tissue. Scleroderma fibroblasts synthesize more collagen than those from normal controls [17,18], and collagenase activity is normal [19]. The deposited collagen is similar in composition to that deposited in other fibrotic disorders, with a normal ratio of type I to type III collagen [19]. The cause of this excessive production is unknown; both intrinsic overactivity and excessive stimulation of fibroblasts may occur. Fibroblast function is modified by endothelial cell products released in a cell culture system [20]. Small collagen fibres are increased, and the response of systemic sclerosis fibroblasts to most mitogens is normal, or reduced, indicating overstimulation [21]. Raised levels of growth factors, both platelet-derived [22] and non-platelet-derived [23], support this suggestion. In addition, glycosaminoglycan synthesis is increased in fibroblasts from patients with the disease, and is stimulated by a mononuclear cell product (possibly IL-1) [24], although other mononuclear cell products can inhibit collagen overproduction [25]. Other connective tissue proteins, including tenascin, are increased [26]. However, there is evidence for an expanded clone of overactive fibroblasts in systemic sclerosis [27], possibly derived from fibroblasts from the deeper dermis [28,29]. There is also an excessive response of fibroblasts to connective-tissue growth factor (CTGF) [30], TGF-β [31], to platelet growth factors [32] and to serum from patients with the disease [33]. TGF-β may have a role both in fibroblast stimulation and in endothelial inhibition [21]. There is a failure of the inhibitory feedback of the aminopropeptide of type I collagen on the fibroblasts [34]. Soluble cytokine receptors [35] and levels of adhesion molecules [36] are often raised in the serum of patients, reflecting disease activity. Circulating anticollagen antibodies to collagen types I and IV occur in patients with systemic sclerosis [37], but these appear to be inversely related to the severity of the disease. They occur in approximately half of British patients and in at least one relative in over 80% of their families. It has been suggested that serotonin hypersensitivity may be a factor in both the vascular and fibrous changes of the disease [38]. Abnormal metabolism of, and responses to, serotonin and tryptophan may contribute to both fibrosis and vascular abnormalities [39]. Raised numbers of mast cells in affected skin may similarly contribute.

Autoimmunity. The presence of antinuclear antibodies in over 80% of patients and specific autoantibodies—anti-isotopomerase (22%) and anticentromere (up to 30%)—suggests an autoimmune response. However, it is not clear if this is a primary abnormality or results from cellular damage. A role for immune factors in endothelial injury is also suggested by the presence of antiendothelial cell antibodies in 30% of patients [1,2], the ability of endothelial cells to act as a modulator of immune responses [3] and the finding of an IgM vasculopathy in acute-onset systemic sclerosis. Furthermore, circulating immune complexes occur in over 50% of cases [4], but their significance is unknown.

There is evidence of abnormal cellular immunity in patients with systemic sclerosis, with leukocyte migration inhibition to a variety of autologous, homologous and heterologous antigens [5]. However, the development of delayed cutaneous hypersensitivity is normal [6]. Patients have a deficiency of circulating T lymphocytes [7] and impaired lymphocyte transformation in response to phytohaemagglutinin (PHA) [8]. Both these features are related to the severity of the disease and the degree of visceral involvement, and also to an increased incidence of HLA-B8 [9]. The haplotype B8/DR3 is associated with decreased cellular immunity [10]. Helper cells [11], T cells possibly activated by raised levels of IL-2 [12] and NK cells are increased [13], whereas suppressor T cells are decreased [14]. These T-cell changes are more marked in the later stages of generalized disease. Patients with extensive disease have reduced antibody-dependent cytotoxicity, PHA-induced T-cell cytotoxicity [15] and NK-cell cytotoxicity to Chang liver cells [16], although others have found enhanced NK activity [17]. Some patients with systemic sclerosis develop a delayed cutaneous reaction to autologous leukocytes [18]. Scleroderma-like changes have been reported after allogeneic bone marrow transplantation, suggesting a graft-versus-host response (see p. 51.83).

Genetic factors. Despite the rarity of familial cases of systemic sclerosis [1–4], abnormalities of the serum immunoglobulins [5] and the high incidence of antinuclear factor in first-degree relatives of patients with systemic sclerosis [6], together with an increased incidence of HLA-B8 in the more severe cases [7], suggest that genetic factors play a part in the aetiology. Clinical and immunological subsets may be genetically determined, but to date there appears to be no clear relationship between HLA, autoantibodies and clinical manifestations [8]. Chromosomal abnormalities have been described in patients with the disease [9,10] and in their relatives, and a serum factor may be responsible for this abnormality. HLA-DR typing shows an increase in DR2, DR3 and DR5 [11]. There is an association between the B8-DR3-DR52-DQB2 haplotype and the development of pulmonary fibrosis [12]. Patients with mild disease have raised DR2 and DR5 and anticentromere antibodies. No relationship between HLA type and Scl-70 antibodies has yet been demonstrated. In identical twins discordant for the disease, autoantibodies [13], T-cell abnormalities and abnormal fibroblast response to mononuclear cell stimulation were found only in the affected twin [14].

An intriguing hypothesis suggests that transfer of fetal cells to the mother or vice versa during pregnancy may result in microchimerism, which has been demonstrated in higher frequency in systemic sclerosis [15]; this may then stimulate a unique immune response.

The age distribution of the disease suggests that the susceptible genotype is probably characterized by a single inherited dominant allele on the X chromosome, explaining the female predominance, together with autosomal factors. Initiation would depend on the occurrence of specific random events believed to be somatic mutations in lymphoid stem cells [16], producing 'forbidden' clones of lymphocytes. These synthesize cellular autoantibodies that are pathogenic, damaging endothelial cells. After a variable latent period, damage to tissue occurs. Antinuclear factors are the result of the disease. Normal defence mechanisms (more efficient in females) may be inhibited by precipitating factors such as silica or other environmental hazards. The pattern of organ involvement may be related to particular forbidden clones that are active, or to local tissue differences.

Other factors. There is no evidence of a chemical cause, although cocaine has been suggested as a trigger in some cases [1]. The role of silicone gel prostheses used for breast augmentation has been much discussed, but there is now agreement that there is no relationship between this procedure and the development of systemic sclerosis [2,3] (see Chapter 70). Physical trauma appears to precipitate the disease in genetically predisposed individuals [4], who may have the allele HLA-DR52 [5]. Virus-like particles have been observed by electron microscopy in striated muscle [6], and acid-fast bacilli, closely allied to mycobacteria, have been found in skin biopsies [7] in systemic sclerosis, but their significance is not known. Glucose-tolerance curves may suggest latent diabetes [8]. A prolongation of sensory chronaxia has been found in both normal and abnormal skin [9], and it has been suggested that the condition is a primary abnormality of the central autonomic nervous system. Reciprocal skin grafting has shown that if sclerodermatous skin is placed in a normal bed, it remains sclerodermatous, and if clinically normal skin is placed in a sclerodermatous area it becomes sclerodermatous [10]. Thus, in systemic sclerosis, the skin involvement is generalized or irreversible, in contrast with morphoea, in which the disorder is localized and reversible.

Diagnosis. The criteria for diagnosis have been established by the Subcommittee for Scleroderma Criteria of the ARA [1] and are generally accepted. Patients should have either:

1 Scleroderma proximal to the digits, affecting limbs, face, neck or trunk—this is the single major criterion; or
2 At least two minor criteria, consisting of:
(a) sclerodactyly
(b) digital pitted scarring
(c) bilateral basal pulmonary fibrosis.

These criteria have 97% sensitivity and 98% specificity, and difficulty arises principally in males who have a sclerodermatous condition brought about by occupational exposure to, for example, silica or vinyl chloride. These patients often fulfil two minor criteria, and indeed share many characteristics, both clinical and immunological, with true systemic sclerosis [2].

Classification of systemic sclerosis. There have been many attempts to classify the disease [3–6]. Most recently, a simplified classification has been proposed [7]. In this system, patients are classified as having diffuse cutaneous systemic sclerosis (dSSc), or limited cutaneous systemic sclerosis (lSSc). The distinction is made principally on the basis of the extent of cutaneous involvement, but also includes certain other clinical and immunological features (Table 51.17). This system appears satisfactory because systemic involvement, which determines the prognosis of the disease, is less frequent in patients with limited cutaneous disease.

Table 51.17 Classification of systemic sclerosis.

Diffuse cutaneous systemic sclerosis
Short interval (<1 year) between the onset of Raynaud's phenomenon and the development of skin changes
Truncal and peripheral skin involvement
Tendon friction rubs
Pulmonary fibrosis, renal failure, gastrointestinal disease, myocardial involvement
Capillary drop-out visible in nail folds
Scl-70 antibody-positive
Anticentromere antibody-negative
Limited cutaneous systemic sclerosis
Long history of Raynaud's phenomenon
Limited skin involvement (peripheral only)
Calcification, telangiectasia, late onset of pulmonary hypertension
Capillary dilatation visible in nail folds
Anticentromere antibody-positive

Pathology [1]. It is important to realize that this widespread disease does not involve all organs in any patient; in certain cases it may be limited to one or two organs. Even when changes are present in an organ, the distribution of these changes is by no means uniform. Although a striking abnormality in systemic sclerosis is the sclerotic change in tissues such as the heart, lungs, submucosa and muscularis of the gastrointestinal tract, widespread vascular lesions may be a prominent feature of certain cases. The digital arteries may be severely involved, and changes of endarteritis may be seen in the lungs, heart, gastrointestinal tract, muscle and kidney. Infiltrations of inflammatory cells, particularly lymphocytes, may occur in the joints, mucosa and submucosa of the gastrointestinal tract, and in striated muscle.

In the skin, the dermis shows hyalinization of the collagen, often with associated abnormalities of elastic tissue and reticulin. The changes may be slight and difficult to detect unless the histological technique is excellent. In particular, standard fixatives must be used if hyalinization of the collagen is to be assessed. In severely involved skin, the epidermis and its appendages are usually atrophic, with loss of the rete ridges. Sometimes, there is hyperkeratosis, and the dermis shows variable degrees of homogenization of the collagen, and occasionally a light dermal lymphocytic infiltrate. In the tumid or 'inflammatory' phase in the fingers, the dermis may show a striking infiltrate, with lymphocytes predominating. Cellular infiltrates of lymphocytes, plasma cells, fibroblastic-type cells and macrophages, either perivascular or diffuse, occurred in 49% of patients of one series [2], but there was no correlation with serum serological abnormalities. Electron microscopy has shown that both T and B lymphocytes are present in the infiltrates [3], although most are activated helper T cells. Hyalinization and intimal thickening of the blood vessels may occur, but fibrinoid change is uncommon. Evidence from electron microscopy [4] and the normal distribution of cutaneous enzymes, acid mucopolysaccharides and other ground substances, together with the absence of any abnormal gammaglobulin, fibrinogen or albumin, using fluorescent antibody techniques, suggests that the

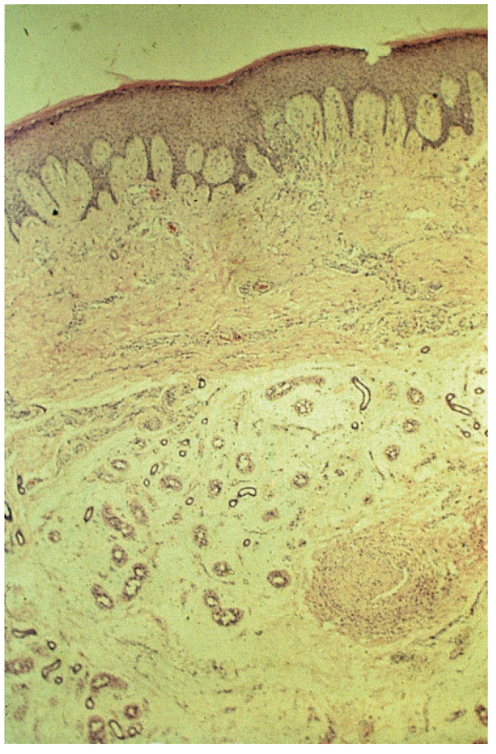

Fig. 51.59 Systemic sclerosis: section of finger showing thickened dermis with hyalinization of the collagen and almost complete occlusion of a digital vessel.

Fig. 51.60 Pearly white plaques in the oesophagus in systemic sclerosis, giving a cobblestone appearance.

alterations in dermal collagen are the result of a simple increase in the number of fibrils. Quantitatively increased fibrillogenesis, with an increased proportion of thin fibrils of type III collagen [5] in the dermis, has led some authors [6] to conclude that qualitative and quantitative disturbances in mesenchymal ground substances may play an important part in the increased formation of qualitatively normal collagen fibrils in scleroderma [7]. Further evidence that the ground substance is the tissue mainly involved has been provided by the finding of a normal concentration of water and hydroxyproline in the dermis [8]. Some authors believe that the main alterations in the skin in systemic sclerosis take place in the subcutaneous tissue and not in the dermis [9]. It is suggested that the replacement of subcutaneous tissue by connective tissue is the cause of the induration of the skin.

Histology, histochemistry, immunopathology and electron microscopy of depigmented areas of skin show changes similar to those found in vitiligo [10]. The digital vessels frequently show intimal and medial thickening, which may be so gross as to almost occlude the vessel (Fig. 51.59); this accounts in certain cases for gangrene of the fingers. Occasionally, fresh thromboses may be seen. Similar but less marked changes are found in the digital arteries of the toes, and the vessels of the leg may also show intimal thickening, which results in ischaemia and gangrene. The intimal thickening is very similar to that seen in the peripheral vascular obstruction that occurs in rheumatoid arthritis. Thromboses of major arteries can also occur [11], and reduction of local tissue fibrinolytic activity can be demonstrated in the involved vessels. Giant cell granulomatous necrosis of the intima of vessels and fat in nodular lesions of the skin has been described [12].

Immunoglobulins and complement may be demonstrated by fluorescent antibody techniques at the dermal–epidermal junction in telangiectases, but not in the indurated skin without telangiectasia [13]. Biopsies should not be taken from telangiectatic areas. The main immunohistological changes in the skin in systemic sclerosis consist of foci of intercollagenous staining for connective tissue antigens in the reticular layer of the dermis [14]. The absence of immunoglobulin and complement from the dermal–epidermal junction may be useful in distinguishing systemic sclerosis from SLE, in which the major changes are at the dermal–epidermal junction. Patients who have both systemic sclerosis and SLE have deposits of immunoglobulin and complement at the dermal–epidermal junction in involved and uninvolved skin as well as changes in the dermal collagen. Patients with scleroderma as part of 'mixed connective tissue disease' have positive immunofluorescence at the dermal–epidermal junction [15].

The gastrointestinal tract is frequently involved. The oesophagus may show areas of epithelium looking like pearly white plaques, giving a cobblestone appearance (Fig. 51.60). Microscopically, subepithelial fibrosis is the most common finding, but fibrosis may also occur in areas of muscular atrophy. The smaller arteries may show endarteritis, and some cellular infiltration also occurs. In the duodenum, jejunum, ileum and colon there is a patchy disappearance of muscle, especially of the circular layer, with replacement by fibrous tissue. The subserosal and submucosal tissues may also be thickened and fibrosed. Vessels in these areas may show sclerosis and intimal fibrosis.

Pathological changes in the lungs may be seen, even in the absence of symptoms or radiological signs of pulmonary involvement and even in the presence of normal pulmonary function.

Progressive diffuse alveolar fibrosis occurs with obliteration of capillaries and alveolar spaces, but is preceded by an inflammatory alveolitis [16,17]. In other cases, hyaline degeneration and fibrosis of alveolar walls result in the disappearance of the alveolar parenchyma and of the capillaries. Rupture of the thinned alveolar walls gives rise to cysts that are lined by cuboidal or columnar epithelium, which may be ciliated. Electron microscopy [18] may show thickening of the alveolar–capillary basement membrane. Arterial lesions in the lungs take the form of concentric thickening of the intima by loose myxomatous tissue and, later, sclerosis. In certain cases, the vessels may be almost completely occluded. Neoplastic change is a rare complication of the pulmonary abnormalities in systemic sclerosis. Various types of neoplasm have been reported [19,20], including malignant pulmonary adenomatosis, alveolar cell carcinoma, adenocarcinoma, oat cell carcinoma and squamous cell carcinoma.

The heart may show no change macroscopically, although showing widespread histological changes. The major coronary arteries are usually patent. Pericarditis, sometimes with effusion, is not uncommon, and sometimes the myocardium shows considerable streaky or focal fibrosis. Occasionally, the mitral or tricuspid valve is involved [21], and Libman–Sacks type of non-bacterial endocarditis has been reported [22]. Histologically, the myocardium may show focal or diffuse fibrosis, associated with degeneration or atrophy of some of the muscle fibres. Occasionally, smaller arteries and arterioles show thickening of the walls. Sometimes, an aneurysm of the myocardial wall develops, and the aorta may show adventitial fibrosis with a focal necrotizing panaortitis and valvulitis.

Involvement of the kidneys used to be the most common cause of serious morbidity and mortality, but this is now uncommon, probably because of the early and improved control of hypertension. In one of the first pathological studies, renal lesions were found in 74% of patients at autopsy [23], and in 90% in another series [24]. It has been suggested [25] that a triad of intimal proliferation of the small intralobular arteries and arterioles, fibrinoid necrosis of the walls of the afferent arterioles and sometimes the glomerular loops, together with cortical infarction characterizes renal lesions in systemic sclerosis. Vascular luminal occlusion may occur, particularly in patients with renal crisis [26]. These changes are not always found, and there are probably no absolutely specific features. Other changes include a mucoid appearance of the intimal thickening of the proximal part of the intralobular arteries. Hypercellularity of the glomeruli and fibrinoid necrosis of the basement membrane of the glomerular tufts may be found. The tubules may be atrophic and surrounded by increased connective tissue, or be dilated and full of hyaline eosinophilic material. A hyaline droplet nephrosis may occur. In the more chronic cases, glomerular hyalinization and interstitial fibrosis predominate. Immunohistological techniques show thickening of the glomerular capillary basement membrane and alteration in the reticular tissue of arterioles associated with deposits of fibrin and very occasionally with the presence of IgG and C3 [27].

The liver is usually normal in systemic sclerosis, although mild fibrosis of the portal tracts and around the bile ducts can occur. The gall bladder may be fibrosed. The spleen may show fibrinoid necrosis of arterioles and endarteritis obliterans, and endarteritis is also found in the adrenals, mammary glands, pancreas, uterus and ovaries.

Histological changes in the muscles are similar to, if not identical with, those of dermatomyositis. Muscle fibres show varying degrees of degeneration, such as loss of cross-striations, hyalinization of bundles, vacuolation and splitting, with interstitial and focal infiltration of lymphocytes. Later, sclerosis develops and the vessel walls may be thickened. There may also be some thickening of the endomysium and perimysium. The thyroid [28] and parathyroid [29] glands may be involved in the fibrotic process, and the thymus may show cortical atrophy [30].

Widening of, and vascular changes in the periodontal membrane of the teeth occur.

The CNS is rarely involved, but occasionally there may be thickening of the walls of vessels in the white matter, and meningeal lymphocytic or granulomatous infiltrates. Peripheral neurological involvement is characterized by increased collagen deposition in the epi- and perineuria, and intimal thickening of the vasa nervorum [31].

Natural history. In the majority of patients, the onset is with Raynaud's phenomenon, although this may have been present for many years, and the cutaneous changes occur after an interval. This is much shorter in males—in whom it is usually under a year—than in females, in whom it is usually approximately 5 years, but may be as long as 30 years [1]. Occasionally, Raynaud's phenomenon and cutaneous sclerosis are noticed at the same time, and sometimes Raynaud's phenomenon may follow the onset of cutaneous or other manifestations, or be absent. The risk of anyone with Raynaud's phenomenon developing systemic sclerosis is relatively small, although it seems to be greater in males than in females [2]. Sclerodactyly may be found in approximately 10% of patients with Raynaud's disease, but systemic sclerosis occurs in approximately 4% of patients with this combination [3]. The differentiation between severe Raynaud's disease and early systemic sclerosis is difficult, but may be aided by nail fold capillaroscopy and the presence or absence of autoantibody [2]. The main cause of mortality used to be renal disease, but recent studies show a preponderance of cardiovascular problems, with coronary and cerebrovascular events [4]. In addition to the microvascular changes described, it is now apparent that large vessel changes similar to atherosclerosis are also increased in systemic sclerosis [5].

Fig. 51.61 Systemic sclerosis: typical beaked nose, telangiectasia and radial furrowing round the mouth.

Clinical features. The earliest feature is usually, but not invariably, Raynaud's phenomenon. Other early presenting symptoms and signs include swelling of the hands in approximately 15% of patients, swelling of joints, ulceration of the fingers, whitlows and even gangrene. Occasionally, the diagnosis may be made in a patient presenting with leg ulcers or calcinosis cutis. With the increased availability of laser treatments, some patients' first presentation is for treatment of telangiectasia. Less common early symptoms include gastro-oesophageal reflux and dysphagia; constipation, diarrhoea and abdominal pain are usually late features.

Cutaneous changes. The hands and face are the most frequently involved, but the changes may extend proximally to involve the forearms and upper arms, usually but not always in a continuous fashion. The fingers may be oedematous and swollen, and the skin feels tight and has a shiny appearance. With increasing severity, the skin becomes immovable or hidebound. The clinical impression of thickness and toughness of the skin is enhanced because of binding down of the skin to deeper structures. The collagen content is decreased but the density is normal [1]. Sometimes, the chest becomes tight, shiny and pigmented. The facial appearance in a well-developed case is characteristic. The forehead is smooth and shiny, the skin is bound down and hard, the lines of expression are smoothed out and the nose becomes small and pinched (Fig. 51.61). The mouth opening is constricted and radial furrows appear, giving a pursed appearance (Fig. 51.62). The lower eyelids cannot be depressed by the fingers to show the conjunctivae, because of atrophy of the tissues. Very rarely, periorbital oedema

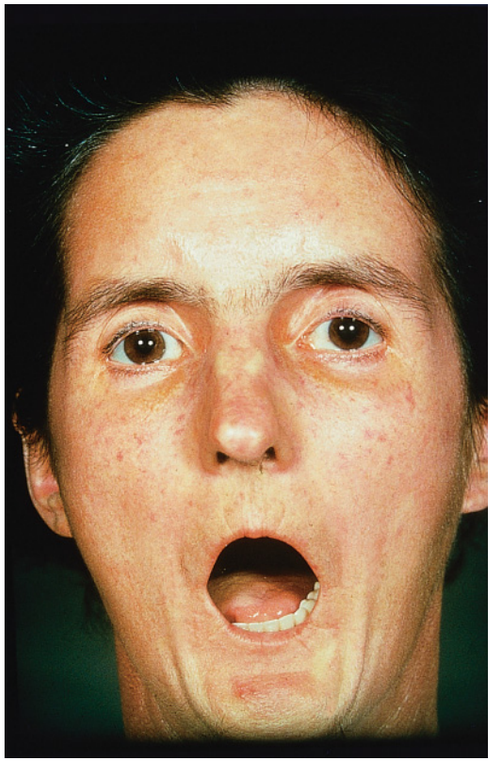

Fig. 51.62 Systemic sclerosis: restricted mouth opening.

Fig. 51.63 Systemic sclerosis: mandibular atrophy. (Courtesy of Dr J. Cotterill, Leeds, UK.)

can occur [2]. Small mat-like telangiectases are frequently found on the face. Sometimes, the changes on the face are minimal and detected only by an astute observer after the diagnosis has been suspected because of other changes. Mandibular atrophy can occur (Fig. 51.63). Chondrodermatitis nodularis helicis was found in three of 21 patients with limited cutaneous disease [3].

Just as the face may be involved to a greater or lesser extent, the hands may also show great variability in their appearance (Fig. 51.64). Sometimes, in the early stages, only a little atrophy can be seen. Occasionally, the fingers and hands are swollen and rather tumid, and there is difficulty obtaining full extension. The terminal phalanges may be bulbous. Later, however, the changes are easily recognized. Atrophy occurs first in the pulps of the fingers, and small painful ulcers are formed, which heal leaving depressed scars (Fig. 51.65). Pitted scars occur in over one-third of patients, not only on the tips of the fingers but also in a linear distribution on the ulnar border of the thumb and radial borders of the index and middle fingers, as well as the dorsa of the fingers over the joints [4]. Later, sclerosis of the overlying skin of the fingers develops, giving the fingers a smooth shiny tapered appearance, with the nails curving over the atrophic phalanges. Later still, the nails become very small and the whole of the distal part of the finger atrophies. The nail folds may show ragged cuticles. Pterygium inversum unguis-like changes are sometimes found [5]. Slow-healing whitlows and paronychia are common, and ulcers may also occur over the knuckles. Later, the atrophy and sclerosis extends to involve the whole hand, which is held in semi-flexion, full extension of the fingers and metacarpal joints being impossible. Gangrene of the fingers is not uncommon, and may occur surprisingly early in the disease. It does not necessarily indicate a poor prognosis. Digital arteriography confirms narrowing of the digital arteries [6].

Fig. 51.64 The hands in systemic sclerosis: oedematous phase.

Telangiectases are often found on the palms and on the rest of the hands. Calcium deposits occur in the skin of the fingers and hands, and may break down to discharge chalky material. Calcinosis may also be found around the elbow, where the olecranon bursa may be involved. Erythema may be seen on the thenar and hypothenar eminences. Hyperkeratotic plaques over the phalan-

Fig. 51.65 Systemic sclerosis: healed ulceration of the fingertips.

Fig. 51.66 Systemic sclerosis: 'cobblestone' appearance on the dorsum of the hand.

ges may indicate amyloid material deposited in the dermal papillae [7]. Multiple small papules of lymphangiectasia may occur in 'hidebound' skin because of obstruction of lymphatic channels by the sclerosing process (Fig. 51.66) [8]. Ivory-coloured subcutaneous nodules 3–20 mm in diameter occur rarely on the trunk and limbs. Histology shows fibromatous changes [9] or fibrinoid necrosis [10].

Similar, although less severe changes occur on the feet, and not infrequently the tips of the toes become black with incipient gangrene. The feet become encased in tight, firm skin with mottled patches of pigmentation and atrophy. These changes may extend up the legs and be present on the thighs.

In a series of patients at Leeds, changes on the hands occurred in 95% of cases, on the face in 90%, beneath the clavicles in 30% and on the feet in 15%. The changes on the face, hands and feet tend to be progressive, but changes on the trunk have been seen to regress over the years. Dilated nail fold capillaries visible without a lens occur in approximately 10% of patients and, occasionally, heliotrope cyanosis around the eye suggests a diagnosis of dermatomyositis. There is some evidence that the degree of nail fold capillary dilatation correlates with the severity of organ involvement [11], but this has not been confirmed [12]. Nail fold capillary abnormalities have been correlated with Raynaud's phenomenon, digital pitted scars and low finger temperature [13]. Using wide-field microscopy, the capillaries are enlarged and distorted. There is loss of capillaries with disruption of the capillary bed in approximately 90% of patients. These features may indicate those patients with Raynaud's phenomenon who will go on to develop systemic sclerosis [14,15], but do not distinguish between different connective tissue diseases [16]. Transient nodules resembling erythema nodosum occasionally occur; the histology of these shows panniculitis and endarteritis.

Fig. 51.67 Systemic sclerosis: pigmentation of the abdomen.

Telangiectases varying from 2 to 20 mm in diameter, blanching on pressure and refilling from several different foci, occur in 75% of patients. They are found mainly on the face, lips, mouth, upper trunk and hands, but may extend as far as the upper thighs. These mat-like telangiectases are not absolutely diagnostic of systemic sclerosis. Pigmentation occurs in approximately 50% of the patients, most frequently on the face, and to a lesser extent on the legs, thighs, lower abdomen (Fig. 51.67), axillary folds and dorsa of the hands. Occasionally, the pigmentation is so gross as to lead to a suspicion of Addison's disease [17], and sometimes gives a mottled appearance. Dense warty pigmentation in the axillae can resemble acanthosis nigricans [18]. Leg ulcers occur in 40% of patients and are difficult to heal. Livedo reticularis [19] and small white areas of atrophie blanche develop around the ankles, even without ulceration. These features can occur in patients without hypertension. A case has been reported of large soft cystic lesions over the interphalangeal joints of both hands. Aspiration revealed mucoid material, and the histology suggested focal mucinosis [20]. Rarely, papular and nodular mucinosis may occur and may be a presenting feature [21]. Lesions resembling acrokeratoelastoidosis have been described [22].

Systemic sclerosis without skin involvement [1–4]. Although skin lesions and Raynaud's phenomenon usually precede systemic changes, there is no doubt that occasionally the situation is reversed. In these cases, diagnosis may be difficult until the disease has progressed further to give characteristic changes in other organs.

Calcinosis. Weber [1] described calcinosis in scleroderma long before Thibierge and Weissenbach [2], whose names are usually associated with the syndrome. Calcification in systemic sclerosis occurs most commonly (25%) in the fingers, especially on the palmar aspects of the terminal phalanges. It is less common than absorption of the phalanges, but sometimes occurs in the absence of any radiological bone change. Digital calcification is approximately 10 times as common in females as in males. Calcification also occurs in the soft tissues around the iliac crests, alongside the spine between the vertebrae, around the knees, on the dorsa of the feet and around the elbows. Occasionally, ulceration of superficial nodules occurs, with discharge of chalky material. Deposits tend to be of considerable size and less diffuse than the calcification seen in the muscles of healed dermatomyositis. Calcification may occur in the internal organs. A suggestion that warfarin may inhibit and reverse calcification requires confirmation [3].

Bone changes. Absorption of the terminal phalanges is a feature of both systemic sclerosis and Raynaud's phenomenon, but systemic sclerosis is the only condition in which phalangeal absorption is associated with calcinosis (Fig. 51.68) [1]. Approximately 70% of patients show absorption, which may be minimal and only involve one terminal phalanx, or be gross and involve several phalanges, including the middle or even proximal phalanges. An erosive arthropathy, with 'pestle and mortar' deformity of the distal interphalangeal joints, resembles that seen in psoriatic arthropathy [2]. It must also be distinguished from gouty arthritis [3]. Pain in the temporomandibular area and a grinding sensation on chewing may be associated with bone resorption of the angle of the mandible [4] and zygomatic arches [5]. Other bone changes in systemic sclerosis include an increased intraosseous deposition

Fig. 51.68 Systemic sclerosis: terminal absorption of the phalanges and calcinosis.

of calcium [6,7] and osteopoikilosis, a rare condition in which multiple small islands of dense bone occur at the epiphyses and metaphyses [8–10]. Osteolysis also occurs in the distal end of the radius and ulna, humerus [11], acromioclavicular joint, ribs and cervical spine [12]. Avascular necrosis of the head of the femur, presumably resulting from vasculitis, has been described [13,14].

Pulmonary involvement. Lung involvment predominantly represents diffuse pulmonary fibrosis associated with diffuse disease or pulmonary hypertension, which is more associated with limited disease or CREST syndrome [1]. Symptoms may only develop some time after the lung disease, so they are a poor predictor of lung involvement. Dyspnoea on exertion is usually the first symptom, and this may progress until the patient is distressed even at rest. Cough, usually without sputum, is also a common symptom, and may be troublesome at night, suggesting aspiration; haemoptysis is rare. Cyanosis and occasionally finger clubbing may occur in patients with severe involvement, and these signs may indicate cor pulmonale. Recurrent episodes of pneumothorax, pleurisy, pulmonary effusion and pneumonia are less common features. Considerable loss of weight may also be a prominent feature at this stage. The earliest change consists of diffuse reticular shadowing extending from the cardiac borders to the peripheral and basal parts of the lungs, usually in the lower lung fields. Sometimes, nodular changes are seen, and occasionally the apices are involved (Fig. 51.69). Cystic changes are frequent. The cysts are usually small, but if extensive the appearances are those of 'honeycomb lung'. Pneumothorax may occur [2]. Pulmonary calcification has rarely been reported [3,4], as has telangiectasia [5].

Pulmonary function is frequently abnormal when radiology shows no abnormality [6]. A sensitive test of pulmonary function

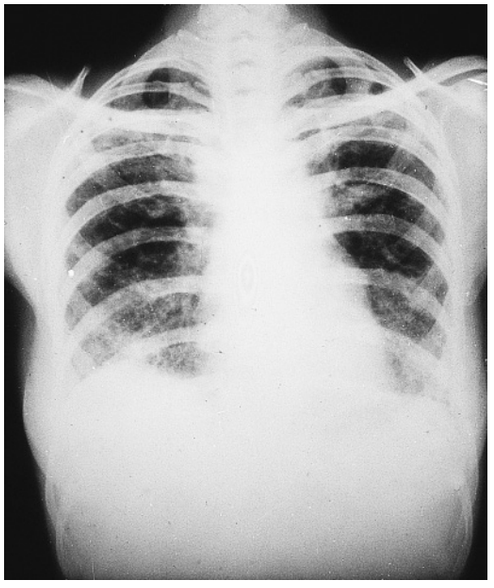

Fig. 51.69 Pulmonary involvement in systemic sclerosis: nodules are prominent, particularly in the upper zones, and there is some reticulation in the lower zones.

is the estimation of diffusing capacity (transfer factor); this test is impaired in 75% of patients. The DL_{co} may give an indication of survival; if it is less than 40% there is a 10% 5-year survival, compared with 75% if it is greater than 40%. Pulmonary involvement is more frequent in more severe and rapidly progressing disease, especially in males [7], but occurs in the CREST syndrome [8], and may precede cutaneous changes [9]. The presence of antihistone and antitopoisomerase (Scl-70) are associated with pulmonary fibrosis [10]. Small airway disease may precede measurable impairment of gas diffusion [11]. In severely affected cases, the vital capacity and maximum breathing capacity are both abnormal. Serial observations of pulmonary function may be helpful [12]. Pulmonary hypertension, sometimes severe, can occur, and does not necessarily correlate with tests of pulmonary function [1]. It is not yet possible to say whether impairment of pulmonary diffusion is caused by vascular changes or thickening of the alveolar wall and interstitial tissue. Pulmonary hypertension tends to be progressive and fatal, although new therapeutic options are available. Lung radiography may be normal in the face of symptoms and abnormal lung function, so the investigation of choice for pulmonary fibrosis is high-resolution CT scan, which is non-invasive. One series showed that high-resolution CT was 24% more accurate than radiography in demonstrating minimal evidence of fibrosing alveolitis [13]. The role of bronchoalveolar lavage is still debatable, but in expert centres it may provide additional information.

Involvement of the gastrointestinal tract [1]. Macroglossia may occur. The oesophagus is involved in approximately 75% of all patients and is the most frequent part of the gastrointestinal tract to be affected. Oesophageal manometry and radionuclide transit are better than radiography for showing motor abnormalities [2,3], although the changes are non-specific [4]. Although dysphagia is usually regarded as being the predominant symptom, this is not correct, as symptoms of oesophageal reflux are twice as common. The typical radiological appearance is that of an atonic dilated oesophagus, which contains air in the resting state (Fig. 51.70).

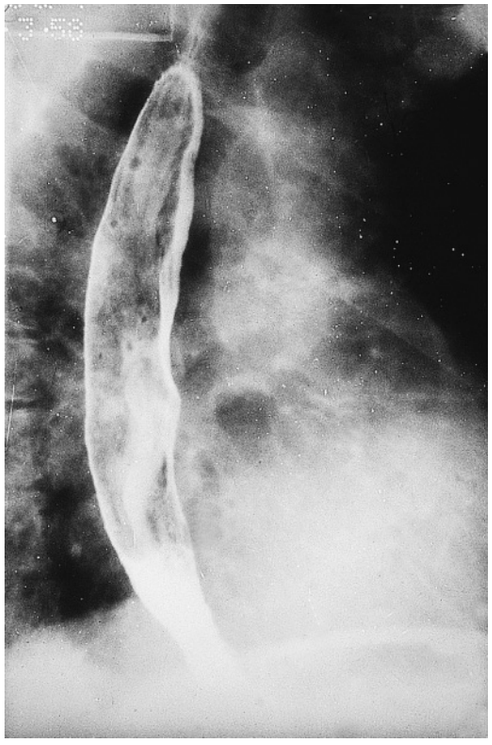

Fig. 51.70 The typical atonic, dilated, air-containing oesophagus in systemic sclerosis.

Oesophageal dilatation and abnormal peristalsis do not necessarily occur together. Stricture of the lower end of the oesophagus occurs in just over 10% of patients, is not necessarily related to gastro-oesophageal reflux or hernia, and can occur without any symptoms of dysphagia. Dysphagia is much more commonly the result of loss of propulsive activity in the oesophagus, and may occasionally be related to candidal overgrowth [5]. Hiatus hernia occurs in approximately 25% of patients. It is important to remember that approximately four out of every 10 patients with radiological changes have no symptoms. Carcinoma of the oesophagus has been reported [6,7]. Occasionally, dysphagia may be localized to the neck because of thickening of the pharyngo-oesophageal muscles [8].

Oesophageal aperistalsis has been reported in SLE and Raynaud's syndrome [9,10], but whenever aperistalsis is found systemic sclerosis must be suspected. Diffuse spasm may be detected by oesophageal manometry in approximately 5% of patients with systemic sclerosis [11].

The stomach shows dilatation and lack of peristalsis in approximately 6% of cases. Involvement of the stomach may be more common in Asians [12]. Carcinoma of the stomach has been reported [13]. Bleeding can occur from telangiectasia in all parts of the gastrointestinal tract, especially the stomach [14]. Systemic sclerosis is one cause of gastric antral vascular ectasia—the so-called 'watermelon stomach', because of the striped appearance on endoscopy. Gastric bleeding may occur at any time and may precede other signs of systemic sclerosis [15].

The duodenum shows changes of dilatation and lack of peristalsis in approximately one-third of patients. This does not appear to be a result of excess collagen deposition [16]. The changes are most pronounced in the second and third parts. Duodenal ulceration has been reported, but is probably not significant in comparison with its incidence in the normal population.

Intestinal involvement is infrequently noted in patients who have no relevant symptoms, but colicky abdominal pain and abdominal distension, with a pattern of distended loops visible through the abdominal wall, together with diarrhoea or, alternatively, constipation, may lead to a clinical diagnosis of obstruction, and death may follow from paralytic ileus. Volvulus of the small intestine may occur [17]. There may be bleeding from telangiectases. Radiological changes consist of dilated loops of bowel, with impairment of peristalsis and segments of normal or narrowed intestine. Strictures are rare. Jejunal sacculation has been reported [18,19]. Radiological changes occurred in approximately 10% of patients in the Leeds series, but others [20] found changes in 57%. Intestinal motility studies may be useful in determining changes in the small bowel [21]. If the abdomen is opened, distended loops of bowel may be seen showing a blue-grey serosal surface with numerous dilated lacteals. Small intestine involvement, determined by jejunal biopsy, small bowel radiology and tests for bacterial overgrowth and malabsorption, occurs in 55% of patients [18].

Steatorrhoea, malabsorption of glucose, calcium, vitamin B_{12} and folic acid may occasionally occur. It is important to remember that malabsorption of one or more of these substances may occur in the presence of normal fat absorption. Osteomalacia or skin changes have not been seen as the result of malabsorption.

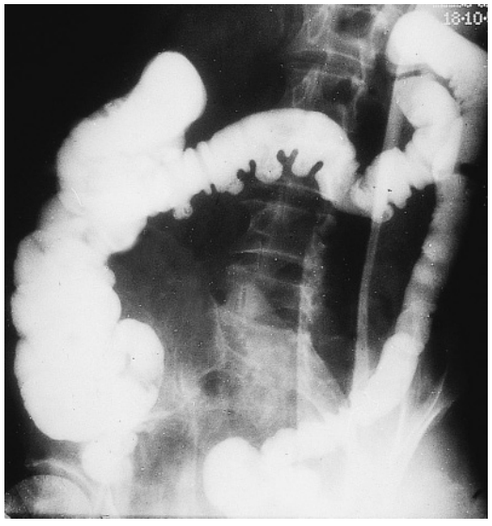

Fig. 51.71 Wide-mouthed diverticula of the colon in systemic sclerosis.

Excessive enteric loss of protein is sometimes a feature [22]. There is evidence [18] that bacterial overgrowth in the intestinal lumen as a result of stagnation because of abnormal peristalsis is a major cause of malabsorption in systemic sclerosis, and this may be corrected by therapy with tetracycline. Intestinal permeability is normal [23]. Pancreatic function is abnormal in 15% of cases [24], and death may occur from pancreatic necrosis [25].

Pneumatosis cystoides intestinalis may complicate small intestine involvement [26]. Patients present with recurrent acute or subacute intestinal obstruction [27] and rupture of cysts can cause pneumoperitoneum [28]. Treatment with respiration of high concentrations of oxygen has been successful [29].

The colon is frequently involved. In the Leeds series it occurred in 43% of cases. The patients may complain of constipation or diarrhoea. The most striking radiological change is the presence of wide-mouthed diverticula, best demonstrated on post-evacuation roentgenograms (Fig. 51.71). They usually occur on the inferior surface of the transverse colon and in the descending colon, which may be dilated and atonic; occasionally, the appearance may resemble that of ulcerative colitis [30]. Perforation of colonic diverticula may result in death from peritonitis [31]. Volvulus has been reported [32]. Colonic telangiectasia with consequent iron-deficiency anaemia may occur [33]. The mucosa of the colon has been described as being pale, dry and rather rigid on sigmoidoscopy [34], but this must be very uncommon. Anorectal pressure measurements show abnormal motility in 74% of patients [35]; symptoms are very much less common. Rectal prolapse and faecal incontinence may result. Primary exudative ascites has been reported [36].

Hepatic involvement. The liver is usually normal in systemic sclerosis, although cirrhosis and portal hypertension are occasionally found. It is by no means substantiated that such fibrosis is caused by systemic sclerosis. Bleeding from oesophageal varices may occur [1]. Systemic sclerosis has been reported in 17% of patients with primary biliary cirrhosis [2,3]. Ascites can occur without liver disease [4].

Cardiac involvement [1,2]**.** The resting ECG is abnormal in approximately 50% of cases, and cold-induced changes also occur [3]; however, the changes may be the result of other causes. Abnormalities of rhythm occur and these include paroxysmal atrial tachycardia, atrial fibrillation and flutter. Partial or complete heart block is not uncommon. In addition to abnormalities of rhythm, ECG may show bifid P waves and T-wave changes, indicating atrial or ventricular myocardial involvement. The conduction system seems to be relatively spared in systemic sclerosis and the high incidence of conduction disturbances may be the consequence of damage to the working myocardium [4]. Dyspnoea may be present but pain in the chest is not a prominent feature. Pericardial involvement occurs and is usually asymptomatic [5]. Mitral valve prolapse occurs more frequently in a number of connective tissue diseases, including systemic sclerosis, than in normal controls [6]. Other valvular abnormalities are rare [7]. Coronary reserve is reduced [8]. General enlargement of the heart, left-ventricular hypertrophy or a triangular outline are the most frequent radiological abnormalities. Radionuclide scanning [9], echocardiography [10], and 24-h ECG monitoring [11] are useful in the detection of abnormalities of the myocardium. More recently, studies using novel imaging technology including CT and magnetic resonance imaging (MRI) have demonstrated evidence of cardiac fibrosis [12].

Renal involvement. Pathological changes in the kidney used to lead frequently to serious clinical problems, but the management of hypertension, and in particular the introduction of modern drugs such as inhibitors of angiotensin-converting enzyme (ACE), have revolutionized this aspect of the disease. Slight proteinuria is considered to be the most common clinical feature, often early in the disease. Proteinuria occurred in 36%, hypertension in 24%, azotaemia in 19% and malignant hypertension in 7% of one series [1]. One or more markers were found in 45% of patients. Approximately 40% of patients show disturbances of creatinine clearance. Nephrotic syndrome is increasingly rare [2]. Approximately 8% of patients with renal involvement develop malignant hypertension [3]. This may develop rapidly in the course of a few weeks, with headaches, nausea, vomiting and deterioration of vision in a patient whose renal function has previously been normal. Prior to 1971, survival beyond 1 year was unusual, the usual survival being 1–3 months. The prognosis, even with renal crisis, has improved dramatically since the introduction of ACE inhibitors (see p. 51.108). Although renal involvement has an adverse effect on survival in systemic sclerosis, patients with mild impairment of renal function may live for years.

Muscle involvement [1,2]. Muscle weakness may occur, and differentiation from dermatomyositis may be difficult, especially if there is a heliotrope appearance and oedema of the eyelids, and dilatation of the nail fold capillaries. In one series [3], the two diseases could not be distinguished in 36 of 727 patients. Muscles of the forearms and hands are affected as well as the proximal muscles. Creatine phosphokinase elevation and excessive creatinuria correlate well with muscle weakness. Electromyography is abnormal in 50% of patients early in the disease and in 93% in late stages [4], and histological changes are present in approximately 40%. MRI and spectroscopy can be useful non-invasive monitors of disease activity [5]. There does not appear to be any evidence that systemic sclerosis occurs as a cutaneous marker of internal

malignancy, although carcinoma of the lung may develop in patients with pulmonary involvement [6].

Tendon involvement. Leathery, palpable and audible friction rubs occur over the limbs and tendons [7] in approximately 25% of cases. Rupture of the extensor tendons of the hand has been reported [8]. The tendon was infiltrated with amyloid.

Joint involvement [1–3]. Arthritic pain is not uncommon in the early stages of systemic sclerosis, and sometimes rheumatoid arthritis is the initial diagnosis made. Radiological changes indistinguishable from rheumatoid arthritis occur, especially in the hands, but there are no specific changes ascribable to systemic sclerosis. They include periarticular osteoporosis, joint-space narrowing, erosions and, rarely, avascular necrosis [4], erosions of long bones [5], bone ankylosis [6] and erosive osteoarthritis.

Dental changes (see Chapter 69) [1]. Widening of the periodontal membrane because of fibrosis, with thickening of the vessel walls, occurs in approximately 30% of cases (Fig. 51.72). Usually the whole root is involved. Anterior as well as posterior teeth are affected, and the lamina dura may or may not be abnormal. Thickening of the periodontal membrane is not related to the duration of Raynaud's phenomenon, calcinosis, involvement of internal organs, antinuclear factor or prognosis. Thickening of the periodontal membrane is not diagnostic of systemic sclerosis and is also found in periapical infection. Widening of the periodontal membrane in only one tooth is usually a result of such infection.

Fig. 51.72 Widening of the periodontal membrane in systemic sclerosis.

Osteolysis of the mandibular angle and coronoid process occurs with equal frequency [2], and these osteolytic areas may fracture [3]. A patient who had multiple external and internal root resorptions for which all the teeth were removed was successfully treated with osseointegrated implants [4].

Central nervous system [1,2]. The nervous system is involved in fewer than 10% of cases [3], although asymptomatic involvement may be more common [4], and others have found involvement in 40% of patients, which can be associated with ulceration of the skin [5]. Neuropathy has been reported [6,7]: autonomic neuropathy may not be uncommon [8,9]; trigeminal neuropathy presents with numbness and pain in the face [10], and occurs in 4% of patients [11]. Of 22 cases with chronic trigeminal sensory neuropathy, nine had systemic sclerosis [12]. It is unilateral at first but later becomes bilateral. Other cranial nerves may be involved [13]. Carpal tunnel syndrome and meralgia paraesthetica may occur. Local anaesthetics may have an abnormally prolonged action [1]. Subacute combined degeneration is the result of vitamin B_{12} deficiency caused by malabsorption secondary to involvement of the small intestine by systemic sclerosis [14]. Spinal cord compression may occur because of soft-tissue calcification [15]. The EEG is not specific. Sensory chronaxia is prolonged in both abnormal and normal skin. Such prolongation in normal skin does not occur in any other condition apart from tabes dorsalis [16]. Impotence has been reported as an initial manifestation of the disease [17,18].

Eye changes. Tightness of the lids, diminished tear secretion, keratoconjunctivitis sicca and shallow fornices are specific ophthalmic changes [1]. Sjögren's syndrome occurs in 15% of cases. Retinopathy, with haemorrhages, exudates and cytoid bodies may occur with a relatively low blood pressure, and has been attributed to direct vascular involvement by systemic sclerosis [2]. Fluorescein angiography shows vascular abnormalities in the choroid in 50% and in the retina in 10% of patients [3]. Central retinal vein occlusion has been reported [4].

Laboratory investigations. Anaemia may be found in patients with renal failure, gastrointestinal bleeding or malabsorption. The ESR is raised in approximately half of patients, as is the serum globulin level. Elevation of gammaglobulin occurs more frequently than elevation of α_2-globulin. Other acute-phase reactants are usually normal, although there are defects in the acute-phase response to some stimuli [1]. False-positive serology occurs in approximately 5%. Cold agglutinins may be found in 25% of cases. The Coombs' test is usually negative, although Coombs'-positive haemolytic anaemia and pancytopenia have been reported [2]. Circulating anticoagulant has been demonstrated in one case [3], but was not found in 24 patients at Leeds [4]. Anticardiolipin antibodies are found in 25% of cases overall, and occur more frequently in those severely affected [5]. Cryoglobulins are only rarely detected. Cryofibrinogenaemia has been held responsible for ulceration and gangrene of the fingers in some cases. Rheumatoid factor is present in approximately 30% of patients. Serum complement levels are usually normal. LE cells may be demonstrated in 8% of patients. Sometimes, SLE may occur in association with systemic sclerosis [6,7], but the presence of LE cells in systemic sclerosis does not necessarily imply coexistent SLE. Antinuclear antibodies have been demonstrated in 78% of patients using rat liver [8], and in 97% using Hep-2 cells [9] as substrate. Using Hep-2 cells, both speckled and homogeneous types occur, and nucleolar patterns—speckled, homogeneous and clumpy—are demonstrated more frequently than in other diseases. Centromere staining, resulting from an antibody that reacts with the kinetocore of metaphase chromosomes, occurs in 40–70% of milder (or CREST) cases [9,10] who have longer duration of disease and little renal involvement (Fig. 51.73). Anticentromere antibodies may be present in patients with Raynaud's phenomenon before the clinical features of systemic sclerosis appear. They seem to be indicative of a favourable prognosis [11]. They also occur in 6% of patients with SLE (including drug-induced lupus) [12], 6% of patients with mixed connective tissue disease, 17% of patients with primary biliary cirrhosis and systemic sclerosis [13], 11% of patients with primary biliary cirrhosis alone and 5% of patients with morphoea [14]. A diffuse 'frosted glass' staining of nuclei of Hep-2 cells is caused by Scl-70 antibody, a precipitating antibody to topoisomerase I, which is unique to systemic sclerosis and occurs in approximately 20% of patients, particularly those with lung involvement (Fig. 51.74) [10,15]. Higher frequencies are described, even in patients with acrosclerosis alone [16]. Scl-70 and anticentromere antibody occur together in 5% of cases [17], but

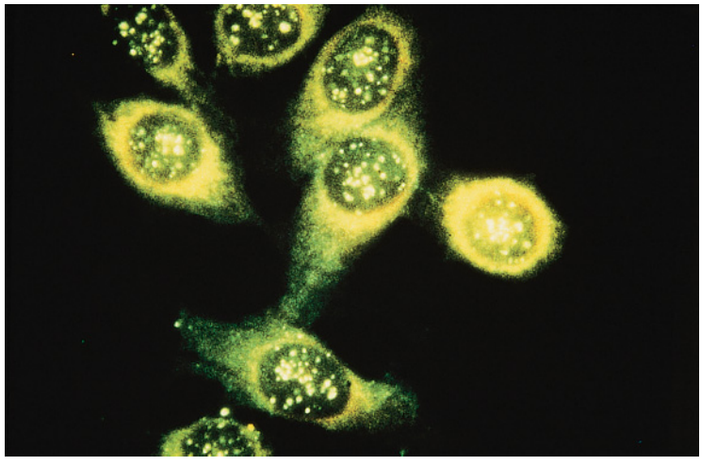

Fig. 51.73 Anticentromere antibody demonstrated on Hep-2 cells.

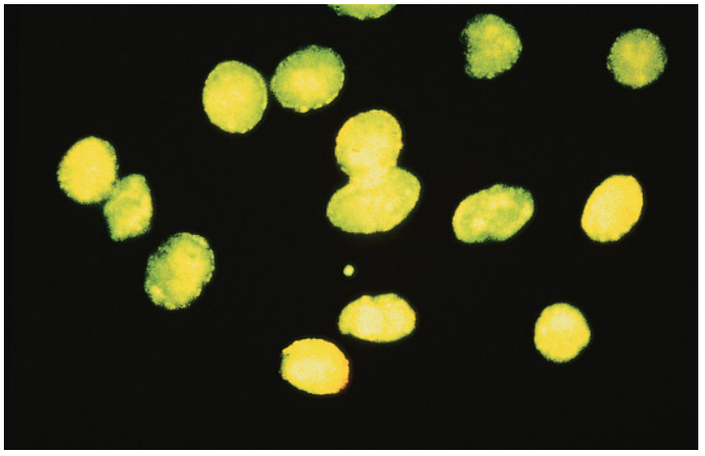

Fig. 51.74 Scl-70 antibody demonstrated on Hep-2 cells.

when occurring alone may define separate subsets of the disease. There is no relationship between Scl-70 and disease survival [18]. Scl-86 is a related antigen [19]. Other antibodies occur, presumably indicating immunological subsets, and include antibody to centriole [20,21], anti-Jo-1 [22] and anti-Ro/SS-A [23]. More intensive investigation of autoantibodies may reveal additional subsets of the disease [24]. Several patterns of nucleolar staining have been described [25]. A homogeneous pattern was associated with polymyositis/scleroderma overlap, a clumpy pattern with diffuse cutaneous systemic sclerosis and a speckled pattern with localized cutaneous systemic sclerosis. Anti-DNA antibodies are not found [26]. Anti-IgE antibodies occur [27]. Other precipitating antibodies to saline extracts of human tissue [8] may be found in 15% of patients. Anti-smooth-muscle and antiendothelial antibodies have been reported [28,29]. Antineutrophil cytoplasmic antibodies occur in 9% [30] and antihistone antibodies in 42% [31]. The latter was more frequent in patients with cardiac and renal involvement. Serum type III procollagen peptide concentrations are raised and reflect disease activity [32,33]. Urinary excretion of 5-hydroxyindole-acetic acid is normal, as is thyroid function.

Variations. Patients with calcinosis, Raynaud's phenomenon, sclerodactyly and telangiectasia may form a separate entity known as CRST syndrome [1], or CREST syndrome if oesophageal (esophageal) involvement is included. This is unlikely to be a separate syndrome, distinct from systemic sclerosis [2]. The variability of expression and course of the authors' series of patients with systemic sclerosis suggests that this type of case is only a subgroup of systemic sclerosis. This has been confirmed by other workers [3,4]. However, the delineation of this group of patients emphasizes that the diagnosis of systemic sclerosis does not

always imply such a poor prognosis as has hitherto been considered.

The suggestion that 'systemic scleroderma' should be divided into two groups—diffuse scleroderma and acrosclerosis—remains to be confirmed [5]. The former, a relatively small group, can be distinguished from acrosclerosis in that the sex distribution is equal, the age of onset is later, Raynaud's phenomenon is absent, cutaneous sclerosis is the usual presenting feature, the sclerosis of the skin is usually generalized rather than acral, and the course is more rapid and fulminating, with death in a few years. However, both types show similar visceral involvement and laboratory abnormalities, and some patients with acrosclerosis have a short course, and Raynaud's phenomenon is not invariable. Occasionally, acute diffuse scleroderma may be much more benign than expected [6]. These two groups are probably clinical variants of systemic sclerosis. A more recent attempt at subdivision of the disease into diffuse and localized forms has met with more agreement (see p. 51.91) [7].

Systemic sclerosis in childhood. Systemic sclerosis occurs in childhood, and the clinical features resemble those seen in adult cases. Raynaud's phenomenon is less frequent and renal disease is rare [1]. The course of systemic sclerosis in childhood is said to be slower, and the disability and visceral involvement less severe than in adults [2], but fatal cases have been reported [3]. The problem has been reviewed in depth [4].

Involvement of the genital tract [1]. Vaginal dryness, ulcerations and dyspareunia are significantly more frequent in patients with systemic sclerosis when compared with controls. Frequency of sexual intercourse and sexual satisfaction is decreased, and the menopause may be early.

Pregnancy [1]. Systemic sclerosis usually remains unchanged during pregnancy, but postpartum renal failure and peripheral gangrene have been described [2]. Severe renal, pulmonary or cardiac disease in the mother may be an indication for termination of the pregnancy [3], and such complications may occur late in pregnancy. ACE inhibitors may be of value for hypertension in pregnancy, although there are potential risks to the fetus [4]. There is conflicting evidence regarding the incidence of abortion and stillbirth [5,6]. Fertility may be impaired.

In some cases, pregnancy seems to precipitate the disease.

Associations. Sometimes, systemic sclerosis occurs in association with other conditions, particularly those considered to have some autoimmune features. Usually, it is possible to differentiate between the diseases, but occasionally there is clinical and immunological overlap. The relationship to SLE and dermatomyositis has already been mentioned. Immunohistology of involved and uninvolved skin is of value. Sjögren's syndrome, the most common features of which are dryness and atrophy of the conjunctiva, cornea and buccal mucosa, together with arthritis, occurs with systemic sclerosis in approximately 17–20% of patients [1,2], and resembles the primary form of Sjögren's syndrome [3]. Extensive investigation reveals at least one abnormal test of the sicca syndrome in all cases [4]. Salivary flow is normal, but deficient in IgA [5]. Antibodies to Ro and La are useful markers of the presence of Sjögren's syndrome in systemic sclerosis [6], occurring in 60% of cases [7]. Other muscle disorders that have been reported in association with systemic sclerosis include polymyositis [8], myasthenia gravis [9] and muscular dystrophy [10]. Pathological features of systemic sclerosis are sometimes found in patients with polyarteritis nodosa [11–13], but there is not the same clinical or immunological overlap as seen with SLE. Temporal arteritis has been reported [14,15], and the condition has also occurred with malignant atrophic papulosis (Degos' syndrome) [16], thrombophlebitis and cryofibrinogenaemia. The association with Hashimoto's thyroiditis is rare. Unsuspected hypothyroidism may occur [17]. Systemic sclerosis is one of the disorders that are sometimes associated with congenital agammaglobulinaemia and IgA deficiency [18]. It may occur with autoimmune haemolytic anaemia [19], autoimmune neutropenia [20], thrombocytopenic purpura [21], microangiopathic haemolytic anaemia [22], urticaria pigmentosa [23], pemphigus vulgaris [24], monoclonal gammopathy [25], primary biliary cirrhosis [26,27], nodular hyperplasia of the liver [28], coeliac disease [29], pseudoxanthoma elasticum [30], elastosis

perforans serpiginosa [31], lymphoma [32] and multiple sclerosis [33]. Reversible myasthenia gravis may occur on treatment with penicillamine [34].

Differential diagnosis. Well-developed cases of systemic sclerosis presenting with Raynaud's phenomenon and typical cutaneous changes on the face and hands are easy to recognize. Generalized morphoea may sometimes cause confusion. However, Raynaud's phenomenon is less common in the latter, and the distribution of the skin changes is different in so far as generalized morphoea involves the trunk, as well as the limbs. Systemic involvement is unusual, although not unknown, and the course is usually towards improvement over the years.

Localized morphoea should present little difficulty, although occasionally morphoeic patches may be seen in systemic sclerosis, and systemic lesions may occasionally be found in morphoea [1–3]. Sometimes, patients with localized morphoea may later develop systemic sclerosis. Morphoeic lesions were seen in 6.7% of Japanese patients with systemic sclerosis [4]. Patients with atrophoderma of Pasini and Pierini may progress to systemic sclerosis [5]. Acrosclerotic skin changes occasionally occur in SLE and dermatomyositis. Cold blue hands with inability to extend the fingers has been reported in bisalbuminaemia [6]. The pigmentation of systemic sclerosis may be confused with Addison's disease [7,8]. Cutaneous changes resembling systemic sclerosis have been reported in an unusual type of porphyria with features of erythropoietic protoporphyria and hepatic cutaneous porphyria [9]. A case of primary amyloidosis presenting as scleroderma has been described [10]. There is no Raynaud's phenomenon in familial sclerodactyly [11].

The stiff-skin syndrome [12], or congenital fascial dystrophy [13], is a rare condition presenting in childhood, in which stone-hard indurations of the fascia and dermal collagen occur. There is no systemic involvement, and the resulting disability is permanent. Patients with scleromyxoedema—a variant of lichen myxoedematosus—may resemble systemic sclerosis but there is no Raynaud's phenomenon or systemic involvement apart from the characteristic slow paraprotein in the serum. The POEMS (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M* protein, *s*kin changes) or Crow–Fukase syndrome also shows a monoclonal paraprotein among a large number of potential features, including diffuse hyperpigmentation, scleroderma, hypertrichosis and lymphadenopathy, as well as the features indicated by its acronym. Of these patients, 50% have multiple myeloma [14]. Differentiation from systemic sclerosis relies on the presence of neuropathy and gammopathy [15,16].

Raynaud's phenomenon, firmness of the skin of the fingers, radiological absorption of the terminal phalanges and thickening of the walls of dermal arteries occur in workers engaged in the polymerization of vinyl chloride (see p. 51.80). The cutaneous changes of systemic sclerosis may resemble acrogeria (see Chapter 45), but the latter dates from birth. The condition may have to be distinguished from leprosy if a peripheral neuropathy is present

[17]. Up to 40% of insulin-dependent juvenile diabetics have contractures at the proximal interphalangeal joints, with thickening of the skin of the fingers (diabetic cheiroarthropathy) [18,19].

Prognosis [1–3]. The prognosis for this disorder is variable. Some patients die within a year or two and others live for many years, even those whose course may initially have been rapid with gangrene of the extremities. Males have a poorer prognosis than females [2,3], although in a recent series [4] the reverse was true. Overall, there is a fourfold increase in mortality in patients with systemic sclerosis. Patients with extensive skin and visceral involvement have a poorer prognosis [5], as do approximately 20% with rapidly progressive disease [6]. Pulmonary involvement is permanent; patients with 60% or greater reduction in pulmonary diffusing capacity have a 5-year survival of less than 10% [7]. Renal involvement is also an adverse factor, although some patients live for years. Patients with telangiectases and calcinosis have the same prognosis as other patients. Those with changes confined to the hands have a good prognosis [8]. Five-year survival varies between series from 34 to 80%, the difference probably depending on the proportion of females. Cumulative survival rate in one series [9] was 80% at 2 years, 50% at 8.5 years and 30% at 12 years. There is no relation to the presence or type of antinuclear factor. Patients with depression of T cells and decreased cell-mediated immunity [10], and with histocompatibility type HLA-B8, appear to have extensive disease and a poor prognosis [11]. The usual causes of death are from intercurrent infection, respiratory failure, cardiac failure, renal failure sometimes with malignant hypertension, and perforation of the gastrointestinal tract. Occasionally, patients with pulmonary involvement develop carcinoma of the lung [12], but the association of isolated cases of carcinoma of the thyroid, ovary, cervix, brain, oesophagus, stomach, breast [13], lymphoma and leukaemia with systemic sclerosis may be fortuitous [14]. Occasionally, the two diseases occur simultaneously, and a rare improvement of systemic sclerosis with treatment of the malignancy has been observed [15]. Localized radiotherapy for solid malignant tumours in patients with systemic sclerosis has been noted to exaggerate the cutaneous and internal fibrotic reaction in the irradiated areas [16].

Treatment. Symptomatic management of the patient is very important. There is no specific treatment, and no therapy is known to alter the course of the disease. Corticosteroids in low dosage may give a feeling of increased well-being and reduction of articular symptoms, and in these cases maintenance on a low dosage of prednisolone, such as 5 mg once or twice daily, is justified. Larger dosage will be required for patients with associated LE. There is

no evidence that corticosteroids retard the progress of the disease in any way, nor is there any real evidence that corticosteroids induce the onset of renal failure. Dexamethasone pulse therapy has been claimed to improve some patients [1]. It is important to advise the patient to keep as warm as possible, particularly in the winter months, and suitable work may have to be found to allow this. A light job in a warm atmosphere is ideal, and it is important to avoid even minor trauma of the hands. Electrically heated gloves are helpful [2], except in patients with incipient gangrene. Smoking should be discouraged [3]. There is no specific therapy for the skin, but applications of 0.025–0.05% tretinoin (Retin-A) have decreased perioral and facial tightening and creases [4]. Areas affected by calcium deposits may break down and heal with difficulty. Occasionally, deposits may have to be excised [5]. These techniques may be superseded by treatment with the carbon dioxide laser [6]. Treatment of digital calcinosis was successful in approximately two-thirds of cases. The average healing time was 6 weeks. Reconstructive surgery for sclerodactyly has sometimes given satisfactory results [7].

Vasodilators, such as oral reserpine [8], guanethidine [9], and particularly nifedipine 10–20 mg four times daily [10,11] and diltiazem [12], may improve the blood flow in the fingers. Ketanserin 20 mg twice daily to 40 mg three times daily may [13] or may not [14] be useful. Nifedipine may worsen oesophageal symptoms [15]. Prazosin 1 mg orally three times daily reduces the frequency and severity of vasospasm [16]. Simply warming the hands in hot water for 5–10 min produces considerable improvement in peripheral blood flow [17], and regular use of such a technique reduces the number and severity of attacks of Raynaud's phenomenon [18]. Intra-arterial reserpine is ineffective, and may have serious side effects [19]. Prostacyclin [20,21] and the synthetic prostacyclin analogue iloprost [22] are potent vasodilators and inhibitors of platelet aggregation, and have been found to be effective in decreasing the frequency, duration and severity of Raynaud's phenomenon, warming the hands, relieving pain and healing ischaemic ulcers. Earlier reports of the effect of prostaglandin E_1 have not been confirmed [23]. Infusion of prostacyclin via a central venous catheter over 72 h at a rate of 2.5–10 ng/kg/min produces improvement for approximately 8 weeks. Side effects include hypertension, headache, facial flushing, abdominal colic, nausea, vomiting and diarrhoea, and pain at the angle of the jaw at the beginning of mastication, disappearing within minutes. Similar results have been obtained by 5-h intravenous infusions given weekly for 3 weeks through a peripheral vein [24], a procedure that can be carried out on outpatients. Iloprost is useful in cases of incipient gangrene and digital ulcers [25]. Transdermal applications of these agents may be beneficial [26].

The use of intravenous low-molecular-weight dextran (Rheomacrodex) has been advocated [27], but controlled trials [28] have shown no consistent benefit, although in occasional patients there is healing of ulcerated fingertips. Renal failure and oliguria have followed this treatment [29]. Intravenous pentoxifylline may be of benefit in acute ischaemic lesions [30]. Cervical or lumbar sympathectomy may produce some improvement in the cutaneous circulation for a year or two, but there is no lasting benefit.

Penicillamine in regimens of from 500 to 1500 mg/day (mean 750 mg) given over approximately 2 years may decrease skin thickness, reduce the rate of further visceral involvement and improve the prognosis of patients if given early in their disease [31,32], particularly those with pulmonary involvement [33]. Other authors have found no benefit or no improvement in vascular or systemic complications, even if there is limited skin improvement [34]. In particular, progression of oesophageal disease continues [35]. Penicillamine therapy is associated with troublesome side effects [36]. In one study [37], the skin of 32% of patients improved, but deterioration occurred in the same percentage. In patients known to be sensitive to penicillin, the risk of an immediate allergic reaction is low [38]. Colchicine (1 mg/day or higher for 6 days per week) has also been advocated [39], but found to be ineffective [33]. Isotretinoin in a dosage of 1 mg/kg may help cutaneous sclerosis [40], as may factor XIII given intravenously [41]. Plasmapheresis [42] and plasma exchange [43], combined with prednisone and cyclophosphamide, have been used for patients with severe systemic sclerosis [42], with some clinical improvement and reduction of endothelial cell cytotoxicity. Extracorporeal photochemotherapy is encouraging but expensive. It has been shown to be more effective than penicillamine in decreasing clinical skin involvement and also safer in patients with disease of less than 4 years' duration [44]. Patients were treated for two consecutive days every 4 weeks for 6 months. It may be insufficient to control severe progressive disease with systemic involvement [45], and its use is controversial [46]. Azathioprine in a dosage of 150 mg/day has been subjectively helpful in approximately one-third of cases. Chlorambucil by mouth does not halt the progression of systemic sclerosis [47,48]. Intravenous 5-fluorouracil, given intermittently for 6 months, improved cutaneous and systemic features in an uncontrolled trial [49].

Ciclosporin may be of benefit [50,51]. It may improve skin induration but not visceral manifestations; adverse reactions, particularly nephrototoxicity, are frequent [52]. IFN-γ influences fibroblast behaviour *in vitro* [53]. It has reduced the skin score and improved blood gas analyses without any adverse effects over 12 months' therapy, but other systemic involvement was unchanged [54]. Others have noticed no alteration in skin score or improvement in visceral involvement [55]. IFN-α2a has also failed to improve visceral involvement [56]. Antithymocyte globulin is ineffective [57].

Symptomatic treatment for cardiac, renal and gastrointestinal symptoms may be required. Antihypertensive drugs, including minoxidil, reduce the blood pressure in malignant hypertension [58,59], and captopril, an oral ACE inhibitor, is a considerable advance in its treatment [60,61], as in most cases there is elevation of plasma renin activity. It controls blood pressure in most, if not all patients and relieves encephalopathy. It can improve renal function and, if given early, prevents renal failure and death. Improvement in renal function over 2 years has been reported [62], but is not uniform [63]. There is little evidence for a more general improvement in the disease resulting from these agents [64]. Benefit must be weighed against side effects. Haemodialysis and renal transplantation have helped patients with renal failure, with surprising improvement in the renal function and cutaneous manifestations [65]. Recovery of renal function can occur after months of dialysis. In one case, renal biopsy 14 months after transplant showed no evidence of the original disease [66]. Cimetidine

or ranitidine are worth trying for the symptoms of oesophageal reflux. Gastrostomy may be required for short-term feeding difficulties if dysphagia is severe [67]. Stricture of the oesophagus may benefit from surgical intervention [68]. Although the diffusion defect in the lungs cannot be altered, patients benefit from breathing exercises, and chest infections must be treated energetically with antibiotics. Pulmonary hypertension is a serious complication that may be treated with endothelin inhibitors such as bosentan [69] or sitaxsentan [70].

Immunosuppressive agents such as cyclophosphamide have been reported as useful in the treatment of systemic aspects of disease including lung fibrosis in a number of small, open studies, and, more recently, in two randomized controlled clinical trials [71–74]. So far there are only two randomized controlled trials to evaluate such immunosuppressive drugs which have enrolled mainly patients with established or long-standing disease; therefore, the potential for these drugs early in the course of disease remains unclear.

Many other preparations, including relaxin, sulfasalazine, 3-hydroxy-2-phenylcinchoninic acid (HPC), antihistamines, dihydrotachysterol and nicotinic acid, potassium *p*-aminobenzoate [75,76], intravenous disodium edetate, topical dimethylsulfoxide [77], the combination of phenformin and ethylestrenol [78], and antiplatelet therapy [79] have not proved of benefit. Hyperbaric oxygen may occasionally produce some improvement [80]. Calcitriol 1.75 µg/day may be helpful [81]. Dietary essential fatty acids such as γ-linolenic acid do not improve the vascular or other features [82].

Migraine sometimes occurs with systemic sclerosis [83], and methysergide or drugs containing ergot should not be given to such patients.

Mixed connective tissue disease [1]

Overlap syndromes occur in the connective tissue diseases, and have recently been reviewed [1]. A number of attempts at defining diagnostic criteria, along the lines of those used for SLE, have been made [2]. Some associations are more frequent than others; for example, systemic sclerosis combined with dermatomyositis is more frequent than systemic sclerosis combined with SLE [3]. Some of these patients may have 'mixed connective tissue disease', an entity associated with a specific antibody to U_1-RNP, an ENA first described by Sharp and colleagues in 1972 [4]. These patients, predominantly female, show features of SLE, systemic sclerosis, dermatomyositis and polymyositis. Raynaud's phenomenon, arthritis and arthralgia, sausage-shaped fingers and swelling of the dorsa of the hands, abnormal oesophageal motility, impaired pulmonary diffusing capacity and myositis are frequent. More than half have the abnormal nail fold capillaries seen in systemic sclerosis. Angiography shows obstruction of small blood vessels in almost 90% of cases, and peripheral gangrene may occur (Fig. 51.75) [5]. The incidence of clinical renal disease is approximately 5%, but renal histology is abnormal in 20% [6]. Aseptic meningitis, trigeminal neuropathy, transverse myelitis and psychosis are prominent neurological features. Neuropsychiatric manifestations were noted in 15% of one series. Other, less frequent features have been reviewed [7], and include orogenital ulceration, pneumatosis intestinalis, protein-losing enteropathy, panniculitis and autonomic neuropathy. Enlarged

Fig. 51.75 Gangrene of the hands in mixed connective tissue disease.

nodes of Kikuchi's disease were the presenting feature in one case [8].

The response to treatment with corticosteroids is good, and other successful treatment options, including hydroxychloroquine and methotrexate, have been reviewed [9]. The characteristic antibody may be suppressed by treatment, and disappears in patients in remission [10].

Mixed connective tissue disease may be more severe in children, in whom cardiac and renal disease and arthritis are common, and thrombocytopenia may be marked, although the overall prognosis may be quite good [11]. Thrombocytopenia is also occasionally found in adult cases, and may occur with thrombotic thrombocytopenic purpura [12]. The role of silicone breast implants in the pathogenesis of the overlap syndromes is controversial, and there is probably no relationship [13]. Livedoid vasculitis [14], ankylosing spondylitis [15] and antineutrophil cytoplasmic antibody (ANCA)-related glomerulonephritis [16] are reported to occur with mixed connective tissue disease.

Immunology. All patients have the speckled type of antinuclear antibody together with a high titre of antibody to ENA, which is sensitive to digestion with ribonuclease (RNase), unlike the ENA antibodies often found in patients with SLE. Different molecular forms of U_1-RNP may be associated with different clinical variants [1]. Ro and La antibodies are also frequently found, usually in association with sicca symptoms [2]. Precipitating antibodies designated PM-1 [3] and Ku [4] occur in polymyositis/systemic sclerosis overlap, and SL-Ki in patients with SLE, scleroderma and the sicca syndrome [5]. Immune complexes occur in 90% of patients, and T cells are decreased. Complement levels are normal. Sometimes, anti-DNA antibody occurs in low titre, but this usually disappears with steroid therapy. Antiendothelial antibodies occur in approximately 50% of cases, and are associated with abnormal pulmonary, neurological and cardiac function, particularly pulmonary hypertension [6]. They are also related significantly to spontaneous abortion in female patients [7]. HLA-DR4 is found more commonly in patients with arthritis than in normal controls, and is associated with a young age of onset of the condition [8]. There are also reports of familial cases [9]. Differences in HLA antigens between patients with mixed connective tissue disease and SLE indicate that they are genetically separate disorders [10].

Immunohistology of uninvolved skin, where there is basement membrane staining with IgG or M, may be helpful in distinguishing MCTD from uncomplicated systemic sclerosis where staining is absent [11].

Direct immunofluorescence study of apparently normal skin reveals particulate ('speckled') epidermal nuclear staining, and this correlates with high titres of anti-RNP. Occasionally, epidermal nucleolar staining occurs. Patients with these features [12] show a high incidence of persistent, diffuse, non-scarring and focal alopecia, hyper- and hypopigmentation with follicular retention of pigment, swollen hands with sclerodactyly, and lesions of DLE.

Although the presence of anti-RNP is usually associated with a good prognosis, death occurs in approximately 4% from pulmonary hypertension, brought about by vascular changes similar to those seen in primary pulmonary hypertension [13], nephritis, myocarditis or widespread vasculitis. Approximately one-third develop into a characteristic connective tissue disease, usually SLE or SSc [14]. A few patients with HLA-DR4 developed rheumatoid arthritis. In patients whose disease differentiated into systemic

sclerosis, there was an association with HLA-DR5 [15]. The relatively good prognosis has been confirmed recently [16].

With time, more variants of the overlap syndromes are being described, both with and without U_1-RNP antibody. Hence, some authors now regard mixed connective tissue disease as one among many 'undifferentiated connective tissue diseases' or 'overlap syndromes'. Doubts about the concept of mixed connective tissue disease have been expressed, particularly in children [17]; nevertheless, it is important to recognize this group of patients because of the good prognosis and the response to steroid therapy. There may be an increased risk of malignancy, with cancer developing in 10% of cases [18].

Cold, flexed fingers (Fig. 51.76)

Several female patients have been seen with cold, flexed fingers, but no evidence of systemic abnormality, despite extensive investigations including pulmonary function tests. The presenting feature of inability to extend the fingers fully starts in the second to fourth decades. There may be difficulty in flexion of the fingers and in making a fist. All have thin, cold fingers, but there is no evidence of acrosclerosis, and Raynaud's phenomenon is not invariable. The condition remains unchanged for years and is not influenced by vasodilators or systemic corticosteroids.

Fig. 51.76 Cold flexed fingers: note the inability to extend the fingers fully.

Some patients may be early cases of systemic sclerosis. One patient has developed rheumatoid arthritis, with deformities of the hands.

The condition was first described in the first edition of this textbook in 1968 [1]. It appears to be similar to what has been termed 'bowed fingers' [2]. Some patients with bowed fingers had features of systemic sclerosis or mixed connective tissue disease.

Lichen sclerosus [1,2]

Synonyms

- Lichen sclerosus et atrophicus
- Guttate morphoea
- Guttate scleroderma
- White-spot disease

Definition. An uncommon disease of unknown aetiology in which characteristic, easily recognized, small, white, sclerotic areas occur at any site on the skin. This frequently involves the perineal skin in the female, and the penis and foreskin in the male. It may occur in genital and non-genital skin separately or together. Hallopeau [3] first described the condition in 1887, and Darier [4] reported the histological changes in 1892. They considered the disorder to be a type of lichen planus; others thought that the condition was

Table 51.18 Associations of lichen sclerosus.

Morphoea
Vitiligo
Alopecia areata (in males)
Pernicious anaemia (in females)
Limited cutaneous systemic sclerosis
Systemic lupus erythematosus
Lichen planus

related to localized scleroderma. Most people now regard lichen sclerosus as a separate entity, because of the distinct clinical signs and pathological changes. The term 'white-spot disease' is sometimes applied to the skin lesions on the trunk and limbs, although some authors refer to these lesions as 'guttate scleroderma'. It may be closely related to morphoea, as the two conditions can occur together and, rarely, morphoea can produce similar genital lesions [5] (Table 51.18).

Incidence [6]. The condition is an uncommon one. Females predominate and patients with lichen sclerosus make up nearly 2% of general gynaecologists' practice [7]. In Wallace's [8] series of 359 patients, females outnumbered males by 10:1. Approximately 20% of patients with lichen sclerosus of the vulva had lesions on the trunk [9]. Certainly, involvement of the vulva, perineum and perianal skin in females is more common than balanitis xerotica obliterans, which is the corresponding lesion in the adult male. The condition occurs particularly around and after the menopause, but also occurs in girls between the ages of approximately 1 and 13 years. The disease is not uncommon in boys with phimosis [9], and the incidence is probably underestimated. The mean age of onset in one series of cases [10] was 50 for females and 43 for males. The condition has been seen in mother and daughter, mother and son, brother and sister, and sisters and brothers, but not in father and son. It has occurred in monozygotic female twins [11] and in non-identical female twins [12].

Aetiology [1]. The aetiology is unknown, lesions usually appearing spontaneously without any precipitating factor. The predominance of females, the frequent onset around the menopause and the spontaneous improvement in girls after puberty suggest a hormonal factor, but no convincing causative factors have been identified.

The increased prevalence of organ-specific antibodies and of associated autoimmune diseases in both female patients and relatives suggest an autoimmune cause, but there is no difference in the natural history of those with or without antibodies [2]. The incidence of other autoimmune diseases in patients is highest when the onset is between the ages of 41 and 60 years, but is not related to the site or duration of lesions. Once the diagnosis of lichen sclerosus has been established, patients do not seem to be at continued excessive risk of developing autoimmune diseases [3]. Approximately 50% of female patients will have a personal or family history of autoimmune disease [4]. Male patients also have an increased prevalence of autoimmune disorders and autoantibodies [5]. Associations with HLA types have been inconsistent; HLA-A29 and -B44 were found to occur more frequently, both separately and together [6], but this was not confirmed [4]. The class II antigens DQ7, 8 or 9 were found to be present in 78% of patients [4], and in a large study HLA-DRB112 and its associated haplotype increased susceptibility to vulval disease, whereas DRB10301 conferred protection [7]. In men, HLA-DR11, -DR12 and -DQ7 were found to be positively associated with the development of the disease, and the association with autoimmune disease is less marked than in women [8].

A history of preceding vaginitis and, in the male, the limitation of genital involvement to the uncircumcised or very recently circumcised, who often give a history of chronic balanitis, suggests that infection may play a provocative or localizing part [9]. There may be geographical differences that explain the potential role of *Borrelia*, with evidence of infection found in Germany and Japan but not in the USA [10]. Vulval lesions are not related to parity. Trauma may act as a precipitating factor, and lichen sclerosus has been reported in a vaccination site [11], in the area of radiotherapy following mastectomy [12], after severe sunburn [13], in an old burn scar [14], as a result of welding sparks [15] and at the site of a strawberry naevus [16].

Pathology. The striking histological change in lichen sclerosus is a band of hyalinization of the dermal collagen below the epidermis. The hyalinized tissue appears structureless and oedematous, and contains sparse cells, but may show dilated capillaries. The epidermis shows variable thickening, hyperkeratosis and follicular plugging. Later, the epidermis becomes thinned. A band of lymphocytic infiltration may also be seen below the hyalinized area; in older lesions this may be more scanty and focal. The subepidermal elastic tissue tends to be depressed and separated from the epidermis by oedema. The infiltrate contains immunoregulatory lymphocytes [1] which may be self-recruiting [2]. T-cell-mediated inflammation and activation [3] is associated with basement membrane damage and laminin and collagen 4 and 7 over-expression [4]. There is also blood vessel proliferation [5], and over-deposition of dermal connective tissue, including hyaluronate [6], fibrillin, collagens I and III and elastin [7], with abnormal distributions of tenascin, fibronectin and fibrinogen [8]. Androgen receptors are reduced [9].

In vulval lesions, secondary infection and superficial erosion are common, and may mask the primary changes. In lesions with sclerotic change, the epidermis shows marked thickening, irregularity and hyperkeratosis. The dermal oedema tends to regress and sclerosis and dense chronic inflammation occupy the subepidermal zone. These changes are seen in over half of all biopsies of vulval lichen sclerosus, and in two-thirds when there is itching [10].

The condition must be distinguished from lichenification, in which the dermal papillae are prolonged and oedematous, with corresponding lengthening of the rete pegs. There is usually dermal oedema and epidermal spongiosis and parakeratosis. In primary atrophy of the vulva, the epidermis is thinned, the lower border is flattened and keratinization is normal or reduced. There is also a reduction in the elastic tissue, particularly in the superficial zone, but the collagen is unaltered. Immediately beneath the epidermis there is a band of chronic inflammatory cells. In dysplastic leukoplakia, there is some degree of hyperplasia of the epidermis, with considerable irregularity in the outline of the deeper border, together with some hyperkeratosis. An inflammatory infiltrate occurs near the deeper border of the epidermis. The collagen of the superficial part of the dermis shows hyaline changes and the elastic tissue is lost.

Electron microscopy has revealed striking changes in dermal collagen fibres and increased amounts of elastin [11]. Immunoglobulins (IgG, IgM, IgA), complement and fibrin may be demonstrated in the damaged skin. IgG autoantibodies to the basement membrane zone were found and may be relevant to pathogenesis [12].

Clinical features [1]

Non-genital lesions. The lesions on the skin are symptomless and occur on the trunk, particularly on the upper part and around the umbilicus, around the neck, in the axillae, on the flexor surfaces of the wrists (Fig. 51.77), around the eye and, very rarely, on the scalp, palms and soles [2]. They have also been described confined to the skin around the areolae [3]. Lesions can occur at sites of pressure (e.g. underneath bra straps or belts). The lesions are small, ivory or porcelain-white, shiny, round macules or papules,

Fig. 51.77 Lichen sclerosus of the front of the wrist.

Fig. 51.78 Lichen sclerosus of the vulva and adjacent skin. (Courtesy of Professor J.L. Burton, Bristol, UK.)

a few millimetres in diameter, but occasionally, they are semi-translucent and resemble mother-of-pearl. They may be very extensive, involving most of the trunk. Lesions may follow Blaschko's lines [4] even in the face [5]. They are slightly raised, or level with the surface of the skin, and typically their surface shows prominent dilated pilosebaceous or sweat duct orifices, which often contain yellow or brown horny plugs. If the plugging is marked, the surface may be rather warty. Lichenification may occur as a result of rubbing. Occasionally, bullae, which may be very extensive [6], telangiectases and purpura may occur, and resolve leaving milia [7]. In the later stages, atrophy occurs, and the surface of the lesions becomes wrinkled, and may actually be depressed. Usually, lesions are aggregated into plaques, which resemble morphoea, but the individual lesions of lichen sclerosus can nearly always still be identified. Scarring alopecia may occur, and nail disease is reported [8]. Involvement of the tendon sheath of the superior oblique muscle of the eye can give rise to diplopia [9].

Anogenital lesions in women (see Chapter 71) [1]. The condition most commonly starts between 45 and 60 years of age but is not uncommon in childhood. Lesions occur on the vulva and around the anus, and may extend to the skin of the inner side of the thighs. The ivory-coloured atrophic papules with follicular hyperkeratosis and plugging can often be identified on the vulva but, owing to friction and moisture, the lesions frequently break down to form a red raw surface, resembling macerated intertrigo (Fig. 51.78). Vesicles and bullae, sometimes haemorrhagic, may occur. In other sites, the tops of the papules become smooth and the area becomes flat and glistening. Small telangiectases and purpuric lesions sometimes occur, probably as a result of injury to the atrophic skin. Irritation may be marked, although sometimes—particularly in children—the condition is symptomless (Fig. 51.79). Patients often complain of soreness rather than pruritus, and dyspareunia may be considerable. Atrophy is a feature, and there may be gross shrinkage of the vulva, especially of the clitoris and labia minora. Labial fusion, clitoral burial and labial resorption can all occur. The vaginal introitus may become as small as 1 cm in diameter. Despite this, pregnancy and delivery are uninfluenced [2].

Mouth lesions. Occasionally, lesions are found in the mouth. They consist of bluish-white plaques, usually on the inner surface of the cheek or on the palate. There may be superficial ulceration. Sometimes, a reticulate appearance occurs and is difficult to distinguish clinically from the lesions of lichen planus [3]. The tongue can be involved. The presence of lesions of lichen sclerosus elsewhere is helpful, as biopsies from the mouth are sometimes difficult to interpret.

Fig. 51.79 Lichen sclerosus of the vulva in a young girl.

Fig. 51.80 Squamous carcinoma in an area of lichen sclerosus of the vulva.

Malignancy in lichen sclerosus. Premalignant and frankly malignant changes can occur in patients with lichen sclerosus, with squamous carcinoma occurring in 5% [4]. It usually arises in a sclerotic area, especially on the anterior part of the vulva (Fig. 51.80). The role of the human papilloma virus in this, as in other genital malignancies, has been discussed, and HPV of the strains associated with carcinogenesis has been found in pre-pubertal females with lichen sclerosus [5].

In a review of 83 cases of squamous cell carcinoma of the vulva [6], two patients with lichen sclerosus were found. Paget's disease may rarely occur in cases of lichen sclerosus of the vulva.

Lichen sclerosus in the male (balanitis xerotica obliterans) (Fig. 51.81) (see Chapter 71). Acquired phimosis or recurrent balanitis are the presenting features [7], together with itching and soreness, and erection may be painful. The prepuce becomes sclerotic and cannot be retracted. Ulceration of the foreskin can occur. The glans and undersurface of the prepuce are shining and bluish white, and there can be considerable telangiectasia. There may be back pressure affecting the urinary tract, demonstrated by urography, as a result of meatal closure. This may require surgical correction [8]. Urethral disease may occur, and lichen sclerosus was found in 14% of 925 patients with urethral stenosis [9]. The shaft of the penis is only occasionally involved. The condition is most common between the ages of 15 and 50 years. It can be overlooked in boys unless the prepuce is examined histologically in cases of circumcision for acquired phimosis. It was found in 40% of sections from boys, with the maximum frequency in those aged 9–11 [10]. In one series, the condition only occurred in patients not circumcised early in life [11]. Carcinoma may develop, and the condition may be associated with morphoea and vitiligo.

Fig. 51.81 Lichen sclerosus of the penis.

Very rarely, classical macular and papular lesions of lichen sclerosus occur on the glans and shaft of the penis and on the scrotum. The skin remains quite soft compared with the usual sclerotic skin of balanitis xerotica obliterans. Occasionally, classical lesions occur on the trunk.

Lichen sclerosus in female children [1]. The disorder is much less common in children than in adults. Published series show from 2% [2] to 15% [3] of cases begin before the age of 13 years. The earliest reported age of onset was at 6 months [4]. In Wallace's series [5], 28 of 50 started between the ages of 3 and 6 years. In this group, HLA associations are seen more frequently, although these may vary [6].

General health remains normal, and often the condition is symptomless. A vaginal discharge may precede the vulval lesions in approximately 20%, and pruritus vulvae occurs in approximately half of cases. Other presentations include pain on defecation and dysuria, resulting in constipation, nocturia and nocturnal enuresis as well as rectorrhagia [6]. Lesions have followed trauma (e.g. in operation scars and in scratch marks). The individual lesions are identical to those seen in the adult [1]. The vulva and anal region may be encircled in a figure-of-eight pattern, and shrinking of the labia and stenosis of the introitus may be marked. Follicular plugging and delling are usually absent from areas of the vulva with few or no hair follicles. Vesicles and excoriations occur. The condition may be misdiagnosed as sexual abuse [7], causing much anxiety [8], but there are suggestions that sexual abuse may precipitate the condition as a Koebner phenomenon [9]. Abnormal hirsutism may be seen on the inner side of the labia majora, disappearing with resolution of the lichen sclerosus [5]. In approximately 5% of cases, the lesions are solely outside the anogenital region, and in just over 10% lesions are found both in the anogenital region and elsewhere.

The prognosis through childhood has been studied [1]; symptoms improve, but abnormal signs persist in 75% and long-term follow-up is advised. Extragenital lesions usually clear before the menarche [5].

Laboratory investigations. Approximately three-quarters of female patients have one or more organ-specific autoantibodies [1,2], usually to thyroid microsomes, thyroglobulin, gastric parietal cells or intrinsic factor. The prevalence in males is approximately half that in females, and the antibodies are mainly to smooth muscle and gastric parietal cells [3].

Differential diagnosis. Lichen sclerosus of the trunk must be distinguished from plaques of morphoea, but this is rarely difficult in the presence of characteristic papules with follicular plugging. Lichen planus is distinguished by its raised, itchy, violaceous papules. The atrophic form of lichen planus may simulate lichen sclerosus quite closely [1]. Lesions of lichen sclerosus may sometimes occur in association with patches of morphoea and, in some patients, typical plaque morphoea may resolve to leave the white sclerotic features of lichen sclerosus. In patients with vulval lesions, a search should be made for lesions elsewhere on the trunk, but even if none is present, the margins of the affected area of the vulva or the perianal area usually show a few typical papules, sometimes forming a well-defined edge. The differential diagnosis of the genital lesions is discussed in Chapter 71. Vulval cicatricial pemphigoid may mimic lichen sclerosus [2]. The annular atrophic plaque type of DLE on the face may resemble lesions of lichen sclerosus [3].

Prognosis [1,2]. Lichen sclerosus is a chronic condition, but signs and symptoms may wax and wane. It is usually permanent but, occasionally, spontaneous resolution occurs. This is particularly likely in girls around the menarche. Resolution of cases

appearing after puberty is uncommon, and is probably restricted to extragenital lesions arising before the age of 30 years.

Treatment. The British Association of Dermatologists provide guidelines covering the management of lichen sclerosus [1]. There is no confirmed effective treatment for extragenital lesions. Calcipotriol may be helpful [2], and phototherapy, including narrowband UVB [3] and low-dose UVA-1 [4], has been reported to be of benefit. Mycophenolate mofetil was dramatically effective in one severe case seen by the authors.

For genital lesions, there is increasing evidence that the use of potent topical steroid preparations gives both symptomatic relief and prevents scarring, and may induce complete resolution of the problem, both histologically and immunohistologically [5]. Whether this is of long-term benefit remains to be seen [6]. Oestrogen- [7] or testosterone- [8] containing creams have given symptomatic benefit, but testosterone is less effective than topical steroid [9]. No report suggests histological resolution with their use. Topical tacrolimus [10] and pimecrolimus [11] may have a role, but there are anxieties about reactivation of wart virus infection [12]. Potassium *p*-aminobenzoate, 12 g/day in divided doses, is claimed to have helped symptoms and haemorrhagic bullae, and softened the skin in some cases [13]. Etretinate may have helped both adult [14] and juvenile cases [15] and ciclosporin may be of benefit [16]. Sulfasalazine has helped a solitary case [17]. Creams containing local anaesthetic preparations should not be prescribed because of the risk of sensitization. Superficial radiation or painting with thorium X are no longer used, and are potentially dangerous.

Vulvectomy is contraindicated for uncomplicated vulval lichen sclerosus, as recurrence occurs in approximately 80% of patients. Dysplastic change should at first be treated conservatively and observed regularly. Applications of liquid nitrogen may be useful, but treatment with a nitrous oxide cryoprobe has been found to be more satisfactory [18]. The carbon dioxide laser is also effective for genital lesions in both males and females [19]. Photodynamic therapy has been used to treat vulval disease [20]. Radical surgery is obviously required if a carcinoma develops. Surgery may also be required for severe narrowing of the introitus.

Topical corticosteroids, sometimes for short periods under a condom, or intralesional injections of triamcinolone may soften the sclerotic lesions of balanitis xerotica obliterans and reduce the phimosis. Circumcision may be helpful or even curative if the condition involves only the foreskin [21]. Meatal instillation of corticosteroid may help meatal narrowing. Attention to local hygiene and treatment of balanitis may be required.

Scleroedema

Synonyms

- Scleroedema adultorum
- Scleroedema of Buschke

Although the name of Buschke [1] is usually associated with this condition, it was originally described by Piffard in 1876. The older term, 'scleroedema adultorum', is incorrect, as the condition can occur in childhood: 29% of cases start before the age of 10 years, and a further 22% between the ages of 10 and 20 years [2].

Definition. A rare disorder of unknown cause in which areas of induration appear in the skin, frequently after an infection but also in diabetes, and spontaneously clear in months or years. There is an excess of acid mucopolysaccharides in the dermis.

Aetiology. The aetiology is unknown. Suggestions that have been considered include obstruction to lymphatic channels by inflammation, streptococcal hypersensitivity and neurohumoral disorders. Sera from patients with paraproteinaemia stimulate collagen production in dermal fibroblast cultures [3]. Some persistent cases are associated with moderate to severe diabetes mellitus [4], and both skin and diabetes are resistant to treatment. This persistent type, with no preceding infection and a strong association with diabetes, has been called scleroedema diutinum [5].

Histology. The epidermis is normal. The dermis may be three times its normal thickness. There is swelling and splitting of the dermal collagen bundles by an increase in ground substance. Clear unstained spaces, or fenestrations, occur between the bundles in severe cases. This process extends into the subcutaneous tissues, the fat of which is replaced by coarse collagen fibres. The ground substance stains metachromatically with cresyl violet or toluidine blue. Metachromasia in scleroedema is caused by the presence of hyaluronic acid [6], and is poorly seen in formalin-fixed sections as the hyaluronic acid is removed by the fixative, and in tissues treated by hyaluronidase. There is an excess of acid mucopolysaccharides, but neutral polysaccharides are normal. Mast cells may be increased [7]. Electron microscopy [8] shows an excess of interfibrillary material, and this is associated with clumping of the collagen fibrils. The voluntary muscle and heart may be affected. Deposition of IgG, IgM and C3 at the dermal–epidermal junction has been reported.

Clinical features. The condition is uncommon [1]. Occasional familial cases have been reported [2]. Females are more frequently affected than males in patients without diabetes, but scleroedema associated with diabetes occurs predominantly in males [3].

Although the condition may apparently start spontaneously, there is a history of an infectious episode, from a few days to 6 weeks prior to onset, in 65–90% [4] of cases. It is usually influenza, tonsillitis, pharyngitis, measles, mumps, scarlet fever, impetigo or cellulitis; prior streptococcal infections appear to be particularly common. Sometimes, there is a history of trauma. Prodromal symptoms of slight fever, malaise, muscle and joint pains occasionally occur between the infectious episode and the onset of induration. The latter is usually symmetrical and often starts on the back and sides of the neck or on the face. This loses its expression, and the patient notices difficulty in wrinkling the forehead and in smiling. There may be difficulty in opening the mouth. The tongue and pharynx may be involved, with difficulty in swallowing. Later, the shoulders, arms, hands and upper trunk become involved, but less frequently the abdomen and legs may be affected. The condition can be limited to the thighs [5]. The induration is non-pitting and hard, and there is no sharp demarcation between normal and abnormal skin. Wrinkling occurs when the skin is compressed between the thumb and index finger, indicating that the epidermis is spared. Brownish pigmentation can be widespread in the indurated areas [6]. The onset is more insidious in diabetics, and the skin induration may be preceded by erythema or pustules [7]. Sometimes, there is stiffness and restriction of movement of joints. Pleural and pericardial effusions sometimes occur, and the skeletal and cardiac muscles can be affected. Occasionally, there are ocular manifestations. The parotid glands may be involved [8].

8 Madison LL. Scleredema. *Am J Med* 1950; **9**: 707–13.

Laboratory investigations. The ESR may be moderately elevated, and the serum proteins usually show mild, non-specific abnormalities. IgG [1], usually IgG-kappa, and IgA paraproteinaemia [2,3], have been reported. Hyperlipoproteinaemia has been reported [4], and the antistreptolysin-O titre may be raised, especially in children.

Prognosis. The condition may completely disappear in the course of some months to a few years, but a few may persist for many years. One case [5] still had changes 38 years after the onset. A fatal case occurred following the development of IgA myeloma [4].

Differential diagnosis. The condition is usually easy to diagnose in view of the rapidity of the onset, especially if there has been a

Table 51.19 Conditions associated with scleroedema.

Malignant insulinoma [6]
Paraproteinaemia and multiple myeloma [7]
Waldenström's macroglobulinaemia [8]
Rheumatoid arthritis and Sjögren's syndrome [9]
Primary hyperparathyroidism [10]
Anaphylactoid purpura [11]

history of preceding infection. Localized and generalized morphoea are usually of much slower onset, and the ivory sclerotic areas, with a well-defined and, frequently, lilac-coloured border, are characteristic. Systemic sclerosis is usually preceded by Raynaud's phenomenon. Dermatomyositis may present more difficulty, as cutaneous oedema is a feature of both conditions. However, the presence of heliotrope cyanosis, particularly around the eyes, dilatation of nail fold capillaries and muscle weakness should distinguish the condition. Pseudoscleroderma (induration of the legs as a result of chronic oedema) and localized myxoedema should rarely cause confusion. Trichinosis may have to be considered. In the newborn, sclerema and subcutaneous fat necrosis differ in their mode of onset and course. For associated conditions see Table 51.19.

Treatment. No effective remedy is known, although multiple therapies have been tried, including systemic and intralesional corticosteroids. In a case associated with multiple myeloma, the skin softened with intravenous pulses of cyclophosphamide and oral prednisolone [12]. Improvement with ciclosporin [13] and electron beam therapy [14] have been reported, and PUVA using psoralen cream [15], UVA1 [16], extracorporeal photophoresis [17] and low-dose methotrexate are more recent suggestions [18].

Dermatomyositis [1]

Definition. A multisystem disorder mainly affecting skin, muscle and blood vessels in which characteristic erythematous and oedematous changes in the skin are usually associated with muscle weakness and inflammation. Calcinosis is frequent, especially in childhood, and is usually associated with a more favourable prognosis for life, but functional disability may be severe. In adults, the disease is commonly associated with an underlying carcinoma or lymphoma. A wide range of systemic involvement may occur.

Incidence. Dermatomyositis is rarer than SLE, polyarteritis nodosa or systemic sclerosis. It occurs at least twice as frequently in females as in males. The incidence in children under 16 years was estimated as 1.9 per million, with the median age at onset of 6.8 years, and occurring much more frequently in girls (ratio 5:1) [2]. It may occur in infancy [3]. In adult cases, onset is predominantly between the ages of 40 and 60 years. The mean age of onset is later in men than in women [4]. Dermatomyositis affects all races and there is no obvious geographical variation, although it appears to be approximately 10 times more common in the Bantu than in the white population of the Transvaal [5].

Aetiology. The cause is not known, but there is increasing evidence of early blood vessel damage, probably humorally mediated [6]. There may be significant titres of antiendothelial cell antibodies, particularly in those patients with pulmonary involvement [7]. However, a range of factors may be relevant (Table 51.20).

Genetic factors. Familial disease is unusual [8,9], but has been found in identical twins and in first cousins. A genetic factor is suggested by the increased incidence of HLA-B8 in childhood dermatomyositis in white people but not in black people [10], and -DR3 [11] and -B14 in adult patients [12]. Other HLA haplotypes

Table 51.20 Factors important in the aetiology of dermatomyositis.

Genetics
Infections
Autoimmunity
Malignancy
Others: drugs, trauma

Table 51.21 Infections associated with dermatomyositis.

Toxoplasmosis (raised IgM antibodies) [18]
Staphylococcal osteomyelitis and arthritis [19]
Streptococcal infection (antigenic homology) [20]
Parvovirus B19 [21]
Coxsackie B virus [22]

may be associated with pulmonary disease [13]. There are associations with other type I and type II major histocompatability antigens: DRB1*0301 is a risk factor for juvenile disease, but there are also protective alleles within the DQA 1 domain [14].

Dermatomyositis has been reported in a patient with recessively inherited absence of the second component of complement (C2) [15], and antinuclear antibodies occur in a significant percentage of first-degree relatives of patients with dermatomyositis and polymyositis [16].

Infection [17]. The disorder is not consistently caused by any one infection, vaccination, immunization or drugs, but occasional cases seem to follow such events [22,23]. The infections commonly associated with the onset of dermatomyositis are indicated in Table 51.21. For *Toxoplasma* and the staphylococcal infections, treatment of the infection may produce remission of the dermatomyositis. In childhood disease, the occurrence of symptoms of respiratory or gastrointestinal infection often precedes onset of the disease [17].

Immunological abnormalities. In childhood disease, dermatomyositis appears to be a true autoimmune disorder, whereas with increasing age there is a very significant relationship with malignancy, possibly as a result of an immunological response to the neoplasm. Granular deposits of IgG, IgM and C3, alone or in combination, have been described in the walls of skeletal muscle blood vessels, especially in childhood dermatomyositis [24], and cutaneous hypersensitivity to intradermal injections of tumour extracts, but not normal tissue, has been described [25]. In some patients, myopathy seems to have been mediated by an IgGκ paraprotein with antimuscle specificity [26]. It is not clear whether paraneoplastic dermatomyositis is the same entity as the condition occurring without an associated cancer.

Autoantibodies [27]. Several precipitating autoantibodies have been demonstrated, including PM-1, Jo-1, PL-12 and, in Japanese patients, KU. There are also antibodies directed against specific myositis-related antigens, for example p155 and p155/140. Jo-1 and PL-12 antibodies are directed against tRNA synthetase enzymes and are associated with interstitial pulmonary fibrosis, and the antibody may be detected before the appearance of the lung disease [28]. It has been suggested that Jo-1 production may be linked to HLA-DR3. Patients with Jo-1 antibodies tend to have an onset of symptoms between February and July; this is not the case for the other serological subgroups of the disease [29]. In those with malignancy, there may be complement-fixing antibodies to their own tumour [30], and circulating immune complexes have been demonstrated in 70% of patients [31].

Cell-mediated immunity. There is evidence that polymyositis may be caused by lymphocyte-mediated hypersensitivity. Large numbers of T lymphocytes can be demonstrated in the infiltrates in the muscle, and there is a marked decrease of suppressor/cytotoxic cells in the blood [32]. Lymphocytes from patients with dermatomyositis and polymyositis have shown an increased response to muscle antigen in lymphocyte-stimulation tests, and the index of response showed some correlation with clinical activity. Lymphocytes from patients with dermatomyositis were cytotoxic to muscle cultures, and this cytotoxic action could be prevented by antilymphocyte serum [33].

Cytokines. Soluble CD30 levels are increased, indicating activation of T lymphocytes [34], and soluble TNF receptors are found [35]. An increased frequency of the more inflammatory polymorphisms of the TNF-α gene is found [36]. Soluble IL-2 receptor is elevated in juvenile disease [37], and expression of interferon-inducible genes in blood reflects disease activity [38].

Relationship to malignancy. Several possible mechanisms to account for the relationship with malignancy can be envisaged, but these are mainly speculative at present. Tumours are known to differ antigenically from the tissues from which they are derived, and many myositis-related antigens are expressed by tumours, possibly triggering an autoimmune response directed against muscle [39].

The primary tumour most commonly occurs in the lung, breast, female genital tract, stomach, rectum, kidney or testis. The association with a range of tumours has been reviewed [39]. In the Chinese, nasopharyngeal carcinoma accounted for 75% of malignant disease [40]. Dermatomyositis precedes the neoplasm in 40%, both conditions may occur together (26%) or the neoplasm may occur first (34%) [41]. The incidence of carcinoma in association with dermatomyositis varies from 15 to 34%. Using strict criteria, 26% of adult patients with dermatomyositis were found to have a malignancy [42]. This figure may be higher in the elderly. Patients with dermatomyositis are more likely to have a malignancy than those with polymyositis, and usually do not fare so well. Neoplasia is not associated with childhood cases. Usually, dermatomyositis worsens in parallel with the progress of the neoplasm, but it may improve when the latter is treated. Neoplasia may be missed because of failure to reinvestigate relapse of previously stable dermatomyositis [43].

Other aetiological agents. Preceding heavy muscular exertion and stress have been suggested as triggering factors [6]. Polymyositis and dermatomyositis can occur with penicillamine therapy, and may be fatal as a result of cardiac involvement [44]. A possible relationship to tamoxifen therapy for carcinoma of the breast has been reported [45]. One patient developed dermatomyositis after taking oral progesterone for dysmenorrhoea.

Pathology [1]. Dermatomyositis mainly involves the skin and muscles, although other organs, particularly the lungs, may be affected. The histological appearance of the skin depends on the stage of the disease. In acute dermatomyositis, the changes resemble those of subacute LE, although the dermal oedema may be more extensive and involve all layers of the dermis. There is usually some lymphocytic infiltrate, either perivascular or in clumps. The majority of the cells are CD4 T cells and HLA-DR-expressing macrophages. Plasmacytoid dendritic cells are present [2], but B-lymphocytes are absent [3]. The infiltrate may also include histiocytes, plasma cells and, occasionally, eosinophils. Mucin deposits commonly occur in the dermis, and mucin in an otherwise non-specific skin biopsy, although not diagnostic, is suggestive of dermatomyositis [1]. Hyperkeratosis, acanthosis and mild papillomatosis are features seen in Gottron's papules [4]. In the later stages, the collagen of the dermis may show thickening, homogenization and sclerosis, with thickening of the walls of cutaneous blood vessels. The epidermis becomes atrophic, with flattening of the rete ridges, and the basal layer may show an increase in pigment. At this stage, the appearance can be similar to that of scleroderma [5]. On direct immunofluorescence, IgM, IgG and C3 may be found at the dermal–epidermal junction in 50% of cases. Those with IgM may also have cytoid bodies [6]. The subcutaneous fat may show mucoid degeneration and lymphocytic infiltration, or sclerosis and calcification, sometimes with membranocystic changes [7].

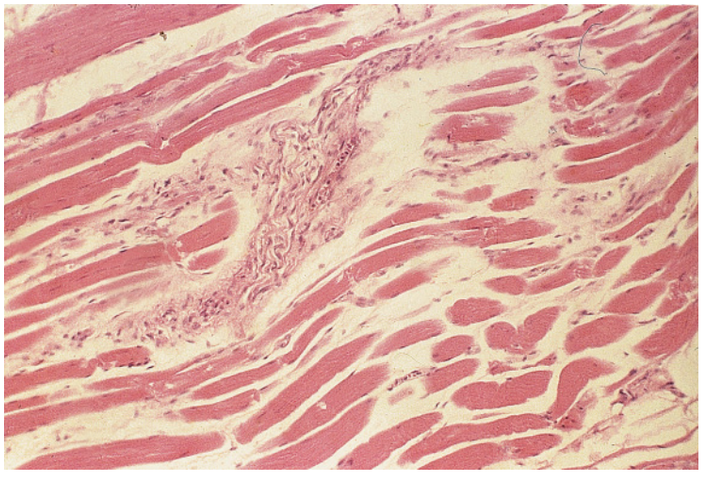

Fig. 51.82 Dermatomyositis: variable degeneration of the muscle bundles with oedema and inflammatory cells.

Fig. 51.83 Dermatomyositis: note the erythema and oedema of the eyelids.

The most frequently involved muscles are those of the limb girdles, the proximal parts of the limbs, the pharynx and the tongue. The muscle involvement [8] is not uniform, and histological examination of biopsy material may be negative. Biopsies should be taken from a muscle that is clinically weak, or that has been identified as abnormal on MRI scanning. The affected muscles may be pale, soft and flabby, or firm and fibrotic, depending on the stage of the disease. In patients with fibrosis, there may be calcification in the muscles and soft tissues. Histologically, in the early stages, the muscle fibres show loss of transverse striation, hyalinization of the sarcoplasm and an increase in sarcolemmal nuclei (Fig. 51.82). Later, the fibres fragment and show granular and vacuolar degeneration, and basophilic staining with histiocytic phagocytosis. There is variable cellular infiltration, mainly of lymphocytes, but also occasional plasma cells and macrophages. The blood vessels in the muscles may show eosinophilic intimal thickening, resembling the changes seen in malignant hypertension. Later still, the affected muscle fibres become atrophied and sclerosed, as in the muscles of patients with systemic sclerosis. No significant morphological differences have been found in the muscles in any of the diagnostic subgroups of polymyositis and dermatomyositis, and no consistent relationship between pathological changes in serial biopsies and clinical improvement in individual patients [9].

Intimal proliferation and thrombosis of arteries and arterioles of the skin, fat and alimentary tract [10] are sometimes seen, and the last accounts for the gastrointestinal ulceration and haemorrhage that occasionally occur. Changes resembling those seen in systemic sclerosis occur in the lungs or in the kidneys. The heart muscle may show changes similar to, but milder than, those in the voluntary muscles. Vasculitis of the cerebral and meningeal vessels has been reported, and in one case resulted in subarachnoid haemorrhage [11].

Clinical features. The clinical picture is variable. Some patients with typical features of muscle involvement show little or no evidence of skin involvement, and the condition is then known as polymyositis [1]. Sometimes, the rash occurs alone [2], a condition that has been called amyopathic dermatomyositis, and this may imply a good prognosis, although the outlook is not uniformly good. Severe calcinosis may occur even in this variety [3]. The rash may precede muscle weakness in around 50% of patients [4].

The rash in well-developed cases is diagnostic. A purplish-red or heliotrope erythema occurs on the face, especially involving the eyelids, the upper cheeks, forehead and temples (Fig. 51.83). Oedema of the eyelids and periorbital tissues is not uncommon [5]. The distribution may resemble that of seborrhoeic dermatitis [6]. Oedema of the hands and arms, and sometimes of much of the body, may also be found, and this is usually associated with erythema of the backs of the forearms, the upper back and, sometimes, elsewhere. This more generalized erythema may resemble the widespread eruption of systemic lupus. In other cases, the rash is more poikilodermatous.

Small erythematous or violaceous, flat papules (Gottron's papules [7]) and small plaques occur over the knuckles, on the dorsa of the finger joints and around the nail folds (Fig. 51.84). They also occur on the dorsa of the toes, on the front of the knees

Fig. 51.86 Hyperpigmented nail fold lesions in an Afro-Caribbean patient with dermatomyositis.

Fig. 51.85 The hands in dermatomyositis: note the linear erythema on the dorsa of the fingers.

Fig. 51.87 Dermatomyositis: dilated nail fold capillaries and hypertrophic ragged cuticle.

and on the backs of the elbows. Frequently, the rash of dermatomyositis on the dorsa of the hands occurs as linear streaking over the extensor tendon sheaths (Fig. 51.85). These may be hyperpigmented as the only cutaneous sign in Afro-Caribbeans (Fig. 51.86) [8]. As well as diffuse redness and shininess of the nail folds, the capillary loops of the nail folds may be dilated, irregular and tortuous, and easily visible with or without a lens, or by capillaroscopy. The capillary changes are more marked in patients with Raynaud's phenomenon, arthritis and pulmonary involvement, but are not related to active myositis or malignancy (Fig. 51.87) [9]. Thickening, roughness, hyperkeratosis and irregularity of the cuticles, with minimal or no redness or inflammation [10], is frequent. Ragged cuticles are also found in other connective tissue diseases such as systemic sclerosis and LE.

In the Chinese, hyperkeratotic follicular erythematous papules occur on the face, back of the neck, trunk, dorsa of the hands and feet, and palms and soles. On the dorsa of the hands and feet, the lesions occur in a linear fashion [11]. A variety of other cutaneous changes have been demonstrated (Table 51.22).

Panniculitis. In some patients, red, firm, tender areas of panniculitis develop (Fig. 51.88), and these may ulcerate or break down to form sinuses [18]. Some areas of panniculitis have their origin in vasculitis, and are often followed by severe calcification. They often occur on the buttocks and upper thighs.

Table 51.22 Less common physical signs associated with dermatomyositis [12–17].

Spreading erythema and fleeting or persistent oedema of the face and neck or of the limbs
Urticarial lesions, dermographism
Bullous lesions
Photosensitivity
Erythema nodosum, erythema multiforme
Follicular keratosis
Hypertrichosis, scalp erythema with hair loss
Hyperhidrosis
Psoriasiform eruptions and pitting of the fingernails
Gingival telangiectasia (childhood disease)
Linear, violaceous, itchy and oedematous streaks on the trunk (flagellate erythema)
Exfoliative dermatitis
Hyperpigmentation
Livedo reticularis, with ulceration

Fig. 51.88 Panniculitis with calcinosis in the thigh in dermatomyositis.

Mechanics' hands. Patients with antisynthetase antibodies may develop 'mechanics' hands'—hyperkeratosis, fissuring and linear hyperpigmentation of radial and palmar surfaces of the fingers. Histology shows hyperkeratosis, acanthosis, a mononuclear dermal infiltrate and liquefaction necrosis of the basal layer [19].

Muscle symptoms. Usually, the patient first notices aching and weakness of the muscles, which may be painful and tender, and later show some atrophy. Typical histories include difficulty in going up stairs or rising from a chair, or difficulty in raising the arms high enough to comb the hair. Usually, there is a feeling of malaise, and fever may occur. Raynaud's phenomenon occurs in approximately 10% of adults, but is very rare in children. Recurrent bursitis of shoulders and hips may precede myositis, and joint effusions occur [20].

In addition to the weakness of the limb muscles, which is mainly proximal, there may be difficulty with speech and swallowing (because of involvement of the muscles of the tongue, the pharynx and the upper third or distal part of the oesophagus [21]), diverticular out-pouching of the oesophagus [22], impaired muscular activity of the small intestine, pneumatosis intestinalis [23], sometimes with pneumoperitoneum [24], wide-mouthed diverticula of the colon, weakness of the ocular muscles and respiratory difficulty from involvement of the intercostal muscles and diaphragm which may lead to death because of respiratory infection or heart failure.

Other clinical features. Other clinical features include: interstitial pneumonitis [25], with non-productive cough, dyspnoea and hypoxaemia and radiological infiltrates or pulmonary fibrosis, may be the presenting manifestations or may occur in the course of the disease. Pulmonary hypertension, with cor pulmonale and fibrosing alveolitis, has been reported. Interstitial lung disease may be more frequent than suspected. Myocarditis, myocardial fibrosis, disorders of conduction and cardiac failure occur in approximately one-third of cases [26]. Renal lesions are uncommon [27]. Retinitis produces fluffy exudates around the papilla and along the veins; permanent visual loss occurs rarely [28]. A case of myoglobinuric acute renal failure has been reported [29].

A mild inflammatory arthritis may occur, but erosive arthritis is rare although a rheumatoid picture can occur. Patients with arthritis frequently have pulmonary involvement [30]. Trigeminal neuropathy has been reported [31].

Calcification. Calcification [32] occurs in the muscles or in areas of panniculitis in more than half of childhood cases, and approximately 15% of adults. The muscles mainly involved are those of the shoulder and pelvic girdles, and to a lesser extent those of the trunk and the limbs, especially around the elbows and hands. In adults, the distribution is less markedly around the pelvic and shoulder girdles than in childhood. Calcinosis increases over the course of months or years and, if extensive, can cause severe functional disability. Extrusion of calcium through the skin is associated with ulceration and cellulitis. Calcinosis is a good sign for survival, but functional recovery is less likely, although even severe calcinosis can resolve spontaneously. Sometimes, patients present with widespread calcification and apparently have not had a preceding myositic illness. In these cases, it is presumed—but not proved—that calcinosis is the result of old dermatomyositis. Sometimes, calcinosis developing in childhood decreases in adolescence; rarely, hypercalcaemia may occur [33].

Dermatomyositis in childhood. This has been well described and reviewed [1]. It is possible that microchimerism may be an aetiological factor [2]. The condition resembles that seen in adults, but malignancy is rarely associated with it and it is usually much more severe than in adults. The prognosis is variable. Calcification occurs more frequently than in adults and contractures develop in under 5%. Widespread vasculitis affecting small arteries, capillaries and veins of the skin, muscle, subcutaneous tissue and gastrointestinal tract is a prominent feature of the so-called Banker type [3]. It may take many years for the disease to burn out but, occasionally, a child recovers without any residual disability and late recurrences are rare. Psychological difficulties occur more frequently than might be expected [4]. A rare feature is hypertrichosis (Fig. 51.89) [5]. Juvenile dermatomyositis can be associated with partial lipodystrophy [6].

Fig. 51.89 Hypertrichosis in an area of erythema on the knee in childhood dermatomyositis.

Sclerodermatomyositis in childhood. This is an overlap syndrome in which cutaneous changes of systemic sclerosis and dermatomyositis are associated with myositis and the homogeneous nucleolar pattern of antinuclear antibody (anti-PM/Scl antibody). Serum muscle enzymes are normal or only slightly raised. The features of dermatomyositis are usually transient and respond to

non-steroidal anti-inflammatory drugs or corticosteroids, and aggressive treatment is not usually required. The systemic sclerosis features such as Raynaud's phenomenon, calcinosis and arthritis tend to grumble on over years, but visceral involvement is not marked. One case with 'mechanics' hands'—hyperkeratosis and fissuring on the tips and sides of the fingers resembling a labourer's dirty hands—has been reported [1].

Dermatomyositis in pregnancy [1]. Dermatomyositis can start in pregnancy. The overall fetal loss is over 50%, and half of pregnancies end prematurely. Pregnancy exacerbates the disease in approximately 50% and is associated with remission in 20%. Fertility is decreased in dermatomyositis [2]. Pregnancy should be planned at a time of remission and the patient monitored at least every month. If possible, treatment should be confined to oral steroids.

Differential diagnosis. The diagnosis depends upon the association of a typical rash with muscle weakness, and is confirmed by muscle biopsy, electromyography and certain laboratory investigations. The serum creatine phosphokinase (CPK), glutamic oxalacetic transaminase (SGOT) or aldolase are frequently, but not invariably raised [1,2], and in certain cases may reflect the activity of the disease and be helpful in regulating the dosage of steroids [3]. However, some patients continue to show considerable disease activity in the presence of normal serum enzymes, so serial estimations of the 24-h urinary creatine are helpful, if available [4]. Skin and muscle biopsy are helpful, but histological changes may be absent or minimal. Radiology of the muscles in the later stages may show calcinosis, a feature that may differentiate the condition from other connective tissue diseases [5]. In dermatomyositis, the calcium deposits are widely scattered throughout the muscles and soft tissues, whereas in systemic sclerosis the calcium deposits are found mainly in the hands and around the elbows and knees.

Table 51.24 Investigation of associated malignancy in dermatomyositis.

Clinical examination (including the breasts, pelvis and rectum),
Blood count and biochemistry
Radiography of the chest
Abdominal ultrasound
Examination of the stools for occult blood
Tumour specific markers including PSA, CEA etc.

Moreover, in the latter, the tips of the terminal phalanges often show some bone resorption. MRI scanning [6] and ultrasound give useful information for longitudinal studies and are non-invasive. In patients with little or no rash, muscular dystrophies may be closely simulated [7]; electromyography [8] is helpful in distinguishing myopathy from neuropathy. Dermatomyositis is of more rapid onset and remissions are frequent.

The ESR is moderately elevated in some, but not all patients in the active phase, and there may be some elevation of the serum globulin. It has been claimed that an elevated ESR and cutaneous necrosis are potential markers of malignancy [8]. Antinuclear factor, raised DNA binding and anti-RNP may occur, especially in overlap syndromes [9]. Antibodies to aminoacyl-tRNA synthetase are antibodies to soluble nuclear antigens and are associated with myositis [10]. The association of other antibodies with particular disease profiles has already been discussed. Antibodies to cytoplasmic antigens such as anti-SRP (signal recognition particle) occur, and antibodies to the nuclear antigen Mi-2 are strongly associated with dermatomyositis [11]. Occasionally, rheumatoid factor is found. The Wassermann reaction is negative. Anticardiolipin antibodies were found in three out of 14 patients with juvenile dermatomyositis, two of whom had vascular complications [12].

In all adult cases, a determined effort to exclude internal malignancy should be carried out [13], and although most of the neoplasms can be diagnosed by physical examination and simple investigation (Table 51.24), in a minority of patients, intensive investigation may be required.

Dermatomyositis can be confused with systemic sclerosis, and the two conditions can occur together. The muscle changes may be identical in the two disorders, but visceral changes are much more common in systemic sclerosis. From the clinical point of view, differentiation between the two diseases may be difficult, particularly in those cases showing sclerosis in the healing phase. Occasionally, patients with systemic sclerosis show heliotrope cyanosis of the eyelids, and dilatation of the nail fold capillaries. Sometimes, patients with dermatomyositis resemble patients with SLE but, in the latter, antinuclear factors and anti-DNA antibodies can usually be demonstrated. Myositis is a feature of so-called mixed connective tissue disease (see p. 51.110). Neuropathy is distinguished by the electromyographic changes and the presence of a raised CPK and urinary creatine excretion. The atrophic changes of the skin in the later stages may resemble morphoea, but the history should lead to the correct diagnosis. Polymyositis [14,15] is more common than dermatomyositis. It is usually found in adults in the third to the fifth decades. Females are three times more likely to develop the disease than males. Occasionally, sclero-edema may cause difficulty. It is important to exclude metabolic disorders in those patients with only muscle disease [16].

Prognosis [1,2]. The course is variable. The prognosis is said to be better in dermatomyositis than in polymyositis; however, some have found the reverse to be true [3]. Patients without muscle involvement may have a better prognosis and may not require steroids [4]. Approximately 50% of patients seem to be responsive to therapy; the remainder appear to be relatively resistant. The overall mortality is approximately one-quarter [5], and malignancy is a significant cause of death [1]. Adverse factors include acute pulmonary infiltrations, dysphagia, cutaneous necrosis and increasing age. Fulminating cases may deteriorate rapidly despite therapy, and in the past some 20% died within the first year; other cases settle slowly and burn out in time, usually over several years. Sometimes, patients complain of vague aching in the limbs when there does not appear to be any residual activity. Some are left with minimal cutaneous change and no residual weakness. Others, particularly children, have gross disability, with contractures of the limbs and calcinosis. Of the children followed up for 5–16 years, 75% survived [6]. Removal of an underlying carcinoma in adults can lead to regression of the dermatomyositis [7].

Calcinosis is a good prognostic feature. Out of 75 adults without calcification, 26 died, usually in approximately 2 years, whereas of 12 adults with calcinosis none died [8]. Seven out of 14 children without, and only one of 17 with, calcinosis died in a mean time of approximately 16 months. Calcification can decrease without treatment. In some patients, muscle disease settles with treatment, but cutaneous disease may be persistent and resistant to therapy.

Death usually occurs from respiratory infection, cardiac failure, malnutrition, weakness or debility because of difficulty in swallowing, carcinoma, or from the side effects of steroid therapy.

Treatment [1]. Rest is essential in the acute phase. In adults it is important to exclude an underlying carcinoma. Treatment with corticosteroids is required in almost all cases, the dosage depending upon the degree of activity. Initial dosage of as much as 60 mg/day prednisolone may be required [1]. This dosage should be gradually reduced as the patient clinically improves and the biochemical markers improve. However, a maintenance dosage of between 5 and 15 mg/day may be required for many months, or even years, and it is important to balance the maximum therapeutic effect against the presence of side effects. If the clinical signs and serum CPK level are not improving sufficiently quickly, bolus infusions of methylprednisolone (1 g on 2–3 successive days) may be tried and are often a good alternative to a high-dose oral regimen. Alternatively, an antimetabolite should be added. Oral azathioprine (1.5–3 mg/kg/day in divided doses) as a steroid-sparing agent [2], or oral methotrexate in a small weekly dosage (7.5–15 mg) may be used to suppress disease activity [3]. Patients not responding to prednisolone and immunosuppressives may be helped by the addition of ciclosporin 5 mg/kg/day [4]. Ciclosporin is also effective in childhood in a dosage of 2.5–7.5 mg/kg [5]. A number of studies have indicated a successful role for intravenous immunoglobulin in a regimen of 1 mg/kg for 2 days each month over 4–6 months [6,7]. Cyclophosphamide 100 mg/day [8], or as pulsed intravenous therapy, is used for pulmonary interstitial fibrosis, but may also be effective for muscle and skin disease and justified in severe cases. The advent of biological agents—monoclonal antibodies directed at specific cytokines—has provided a new set of therapeutic options, and both infliximab [9] (directed against tumour necrosis factor) and more usefully rituximab [10] (directed against the CD20 molecule on B lymphocyte precursors), have been used with success.

Children with minimal myopathy may remit with indometacin without steroids [11], and antimalarials may help the rash of dermatomyositis, which may persist when muscle activity settles [12]. Topical steroid or a topical calcineurin inhibitor may be of value [13]. Less commonly, levamisole (100 mg/week) [14] or plasma exchange [15] may help patients with severe disease not responding to steroids or immunosuppressives. Improvement may occur within 48 h of plasmapheresis [16]. Extracorporeal photochemotherapy may be useful in combination with other therapies [17]. Methandienone (30 mg/day) [18], dapsone [19] and pentoxifylline [20] have all produced apparent improvement in patients unresponsive to corticosteroids. Antiplatelet agents—aspirin (650 mg/day), dipyridamole (400 mg/day) and sulfinpyrazone (400 mg/day)—helped one patient with *in vivo* platelet thrombi formation causing digital and vascular ischaemia [21].

Therapy, with either prednisolone alone or in combination with an antimetabolite, may be required for some years, and the dosage is reduced very gradually until the disease is burnt out. Any recrudescence is treated with an increase in dosage. Early treatment with low-dose steroids in children is associated with fewer relapses and lower morbidity [22]. Occasionally, weakness may arise from corticosteroid myopathy, and may be difficult to distinguish from an exacerbation of the disease. Serum enzymes are normal, but the 24-h urinary creatine excretion is raised [23]. Recovery on reduction of dosage takes up to 4 months. Weakness in dermatomyositis may occur because of hypokalaemia, the result of corticosteroid therapy. Regular electrolyte estimations are required and potassium supplements should be given.

Gastrointestinal haemorrhage may occur as a result of the disease or corticosteroid therapy. Constipation can be a feature, and octreotide may increase gastrointestinal motility. Osteoporosis is a considerable risk because of immobility and corticosteroid therapy, and prophylactic treatment should be given to both female and male patients. Treatment of calcinosis is usually ineffective, although spontaneous improvement can occur. Aluminium oxide, by producing insoluble aluminium phosphate, decreases the intestinal absorption of phosphate and has been successfully used in calcinosis in a child. Aludrox 15 mL four times daily (2.4 g/day aluminium oxide) was given by mouth [24]. Diltiazem has also been used successfully [25].

Physiotherapy plays a considerable part in preventing the development of contractures, and careful splinting may also be required. Artificial ventilation may be required in reversible transitory ventilatory failure [26], as may intravenous feeding in patients with severe oesophageal involvement. If there is definite serological evidence of recent infection with *Toxoplasma gondii*, treatment with pyrimethamine and/or sulfadiazine may be indicated [27].

Dermatological manifestations of rheumatoid disease

Although it would be unusual for patients with rheumatoid arthritis to present initially with skin problems, cutaneous disease is not uncommon, both as an intrinsic part of the condition and increasingly as a consequence of therapy (Table 51.25). Some problems, such as rheumatoid nodules and vasculitis, are well recognized, but more recently other abnormalities, such as transparent skin, linear subcutaneous bands and neutrophilic dermatoses, have been described. The array of skin problems seen in patients with rheumatoid arthritis has been well reviewed [1].

A dermatologist may also be involved in deciding between rheumatoid disease and SLE as the primary diagnosis. A skin biopsy for immunofluorescence studies may be helpful in aiding diagnosis because in the skin of the former, fluorescence of the dermal–epidermal junction is not found, even in cases with a high titre of antinuclear factor [2].

Pseudosclerodermatous changes, particularly of the hands, occur in rheumatoid arthritis, and there are common instances of overlap syndromes, where features of a number of more specific connective tissue diseases occur together [3].

Table 51.25 Cutaneous problems occurring in rheumatoid arthritis.

Rheumatoid nodules
Rheumatoid vasculitis (RV)
Felty's syndrome
Pyoderma gangrenosum (PG)
Interstitial granulomatous dermatitis with arthritis
Palisaded neutrophilic and granulomatous dermatitis
Rheumatoid neutrophilic dermatitis
Juvenile rheumatoid arthritis (JRA)
Adult-onset Still's disease

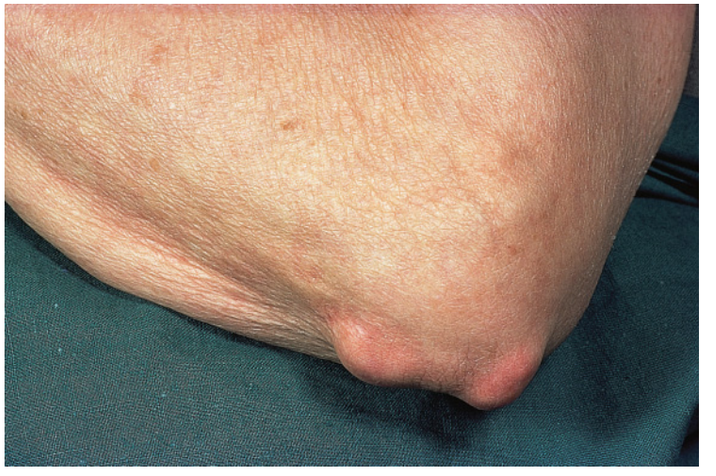

Fig. 51.90 Rheumatoid nodules on the elbow.

Rheumatoid nodules [4] (Fig. 51.90)

Palpable subcutaneous nodules occur in approximately 20% of patients with rheumatoid arthritis. The most common site is on the ulnar border of the forearm. Less commonly, they occur on the dorsa of the hands, on the knees, on the ears, over the scapulae and occasionally in other areas, especially those subject to pressure, such as the sacrum, buttocks or heels. They vary in size up to several centimetres in diameter, are firm in consistency and tend to ulcerate with trauma (Fig. 51.91), particularly on the sacrum. Secondary infection with staphylococci can result in staphylococcal septicaemia and septic arthritis. Subcutaneous nodules can erode the underlying bone [5]. Sometimes, there are numerous violaceous papules with centripetal scaling. A variant of rheumatoid disease, termed 'rheumatoid nodulosis' [6], has been described, and may precede rheumatoid disease. Multiple, small nodules occur on the hands and feet with palindromic rheumatism and little evidence of synovitis. Nodules may be found in other organ systems, particularly the lungs [4].

Fig. 51.91 Ulcerated rheumatoid nodule on the ear.

Nodules are almost invariably associated with more severe forms of the disease, and rheumatoid factor and antinuclear factors are frequently found in the serum. Occasionally, nodules may occur in mild rheumatoid arthritis and in anarthritic rheumatoid disease. Sometimes, they may precede rheumatoid arthritis by some years [4]. Rheumatoid nodules may rarely occur in the sclera (scleromalacia), which may perforate (scleromalacia perforans), leading to complete blindness. Severe nodulosis may be precipitated by therapies, including methotrexate and biological agents [7].

Histologically, rheumatoid nodules consist of fibrous tissue in which foci of fibrinoid necrosis are scattered, surrounded by a palisade of cells, mainly fibroblasts and histiocytes. A peripheral zone of lymphocytes and plasma cells occurs. Within the necrotic area are thin reticulum fibres, similar to those seen in young granulation tissue, amorphous material and some nuclear debris. Vasculitis can occur in rheumatoid nodules and papules. The histology has features in common with those of granuloma annulare (see Chapter 60).

The subcutaneous nodules of rheumatic fever [8] can be distinguished histologically from those of rheumatoid arthritis. There is much fibrinoid material, considerable oedema of the collagen, but relatively little infiltration with fibroblasts, histiocytes or lymphocytes. There is little attempt at zoning and fibrosis is minimal or absent. Large mononuclear cells, like those seen in Aschoff's nodes in the myocardium, may be found. Nodules from patients with Still's disease (juvenile rheumatoid arthritis) [8] resemble those seen in rheumatic fever. Another possible cause of nodulosis is the coexistence of erythema elevatum diutinum [9].

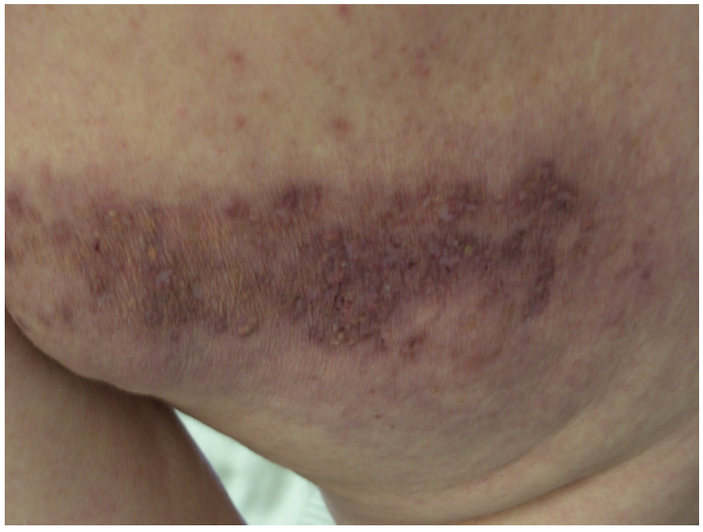

Fig. 51.92 Palisading and neutrophilic dermatosis in a patient with rheumatoid arthritis.

Linear subcutaneous bands and interstitial granulomatous dermatitis [10] (Fig. 51.92)

Elongated subcutaneous bands, 3–5 mm wide and 10 cm or more in length, have been described in patients with rheumatoid arthritis with nodules. Histologically, the bands show changes similar to the nodules, with interstitial granuloma formation, but no evidence of vasculitis. The bands, which are firm and non-tender, are adherent to the skin. They have so far been observed in the axilla, and extending from the axilla to the iliac crest. Similar histological appearances may be seen with a more papular clinical appearance.

Palisaded neutrophilic and granulomatous dermatitis

In addition, there are those who believe that another entity—palisaded neutrophilic and granulomatous dermatitis—may be part of a spectrum of cutaneous disease, with the degree of neutrophilic infiltration varying between patients. Others disagree, noting vasculitic histological change in those with more significant neutrophilic involvement [11]. Certainly, the two clinical patterns may occur together (Fig. 51.92).

Rheumatoid neutrophilic dermatosis. This may occur [12] in patients with severe arthritis as symmetrical erythematous nodules and 'urticaria-like' plaques on the dorsa of the hands and arms, extensor aspects of the joints, and the back of the neck and scalp and trunk. They are sometimes tender. Vertical symmetrical infiltrated linear cords on the median axillary line have been reported [11], as discussed above. Ulceration and vesiculation may occur. Histologically, there is a dense diffuse infiltrate of neutrophils in the dermis, papillary microabscesses and leukocytoclasia, but no vasculitis. The lunulae may be red [13]. Pyoderma gangrenosum may occur in association with neutrophilic dermatosis [14]. Dapsone, either alone or combined with colchicine, may help rheumatoid vasculitis and neutrophilic dermatosis [15].

Cutaneous changes due to steroid usage—purpura and paper-thin skin—are common.

Vascular lesions in rheumatoid arthritis [1,2]

The presence of vascular lesions in rheumatoid arthritis has been increasingly recognized in recent years. Raynaud's phenomenon is uncommon; it occurred in only 2.7% of one series [3]. However, there is now clear evidence of increased vascular pathology in RA, including the occurrence of large vessel atherosclerosis and cardiovascular disease [1,2].

The most characteristic lesions of arteritis in rheumatoid patients are small infarcts around the nails, sometimes at the apex of small cutaneous nodules. The lesions are usually transitory and may last only 2 or 3 days. Because they are usually painless, patients rarely complain about or even notice the lesions. Usually, a small brown spot persists a little longer, and sometimes scarring may occur. Occasionally, infarcts of the nail fold may result in grooving of the nail. Rarely, bullae may occur. The occurrence of digital necroses is closely correlated with the presence of rheumatoid factor and rheumatoid nodules [2]. Anticardiolipin antibodies can sometimes be demonstrated in patients with vasculitis, and are statistically significantly related to rheumatoid nodules but not to thrombotic events [4]. In addition to the infarcts around the nail folds, the pulps of the fingers may show small painful purpuric nodules (Bywaters' lesions). Histologically, these show leukocytoclastic vasculitis [5]. Palmar erythema is common.

In addition, the skin may show purpuric and necrotic arteritic lesions, which can be painful. The haemorrhagic areas appear without preceding trauma, and vary in size from small petechiae to areas of bruising and necrosis several centimetres in diameter. Sometimes, these areas develop black crusting, which may break down and ulcerate. The ulcers are well defined, with a surrounding bluish-red halo. Some of the ulcers are related to rheumatoid nodules. Healing occurs with scarring and may be slow. Arteritis occurs widely in rheumatoid disease, and involvement of the gastrointestinal tract [6] gives rise to abdominal pain, which may result from multiple ischaemic ulcers, gangrene of the bowel, intraperitoneal haemorrhage or splenic infarction.

Gangrene may result from changes in the digital vessels, and sometimes this may extend to involve a large part of the foot or hand, occasionally within a few days. Extensive pustular panniculitis, particularly on the legs, may occur as the result of breakdown of red, painful, nodular lesions. Treatment can be very difficult [7].

Leg ulcers. Leg ulcers are not uncommon in the rheumatoid population. Although vasculitis is an important cause, it was only considered to be a factor in 18% of rheumatoid patients in one recent series [8]. Venous insufficiency, complicated by immobility and postural factors, occurs in nearly half of cases, and trauma, pressure or arterial insufficiency are also major factors. Leg ulcers [9] may also be pyodermatous (Fig. 51.93). Arteritic ulcers are more common in males, particularly those with subcutaneous nodules and positive tests for rheumatoid factor. They are usually deep, punched out and slow healing. There is little discoloration of the legs and usually no sclerosis. Some of the ulcers may start as frankly purpuric or nodular lesions. Secondary infection is common, especially with *Staphylococcus aureus*. Response to treatment is slow and relapse frequent. Leg ulcers are more common in Felty's syndrome, in which arthritis is associated with splenomegaly and leukopenia.

Livedo reticularis [10] also occurs in rheumatoid arthritis, as does delayed pressure-induced vasculitis.

Peripheral sensory or motor neuropathy [11] is often associated with clinical evidence of arteritis elsewhere, and is caused by occlusion of the vasa nervorum by the arteritic process. These patients also have a high incidence of rheumatoid factor and nodule formation.

Fig. 51.93 Felty's syndrome: pyoderma gangrenosum of the perianal area.

A rash identical to that found in Still's disease (juvenile rheumatoid arthritis; see p. 51.133) occurs in adult rheumatoid arthritis, but is rare. It was found in only seven out of more than 500 patients [12].

Associations with other disorders. These have been comprehensively reviewed [13]. They include bullous pemphigoid, pemphigus vulgaris, pemphigus foliaceus, dermatitis herpetiformis, subcorneal pustular dermatosis [14], epidermolysis bullosa acquisita, yellow-nail syndrome, acquired cutis laxa [15], angioendotheliomatosis [16] and erosive pustular dermatosis of the scalp [17].

Fibroblastic rheumatism

This entity was originally described by Chaouat *et al.* [1] in 1980, and since then further cases have been described, mainly in France [2]. It occurs at all ages and affects both sexes equally. Clinically, it starts suddenly with symmetrical polyarthritis and cutaneous nodules. These are between 5 and 20 cm in diameter, and can occur before the onset of arthritis. Raynaud's phenomenon, sclerodactyly with inability to join palms, joint effusions and stiffness are frequent. The nodules occur on both surfaces of the hands, usually over the joints, and on the elbows, knees, ears and neck (Fig. 51.94). They are smooth, firm and usually skin-coloured. They resolve in 6 months to a few years. Histology shows a marked proliferation of spindle cells and dermal fibrosis. The hyperplastic cells have the phenotypic features of muscle, suggesting myofibroblastic differentiation [3]. There is a reduction of collagen and non-collagen protein synthesis by the fibroblasts from involved skin, which contrasts markedly with the increase in collagen synthesis in scleroderma.

Fig. 51.94 Nodules on the dorsa of the interphalangeal joints in fibroblastic rheumatism. (Courtesy of Dr M.H.A. Rustin, The Royal Free Hospital, London, UK.)

Systemic involvement does not usually occur—all laboratory tests are negative.

Spontaneous resolution of the nodules may be expected. Joint erosions may develop and changes tend to persist. There is little evidence indicating benefit from any treatment.

Still's disease

Synonym

- Juvenile rheumatoid arthritis

The characteristic rash [1] is seen in approximately 25% of patients with Still's disease. It occurs in boys (36%) more frequently than in girls (22%), the incidence decreasing with age. It consists of small, non-pruritic macules or papules up to 3 mm in diameter, with a slightly irregular margin. Larger lesions up to 5 cm show central pallor. The colour is bright salmon pink, often surrounded by a zone of pallor. The rash occurs most frequently on the limbs and trunk, but may occur on the face and neck, and lasts only a few hours, characteristically appearing at midday or in the evening with increased temperature of the patient or environment. It is more common in patients with fever, splenomegaly, lymphadenopathy and a raised ESR. It usually appears in the first 2 weeks of the disease but may precede other manifestations by up to 9 years. The rash may occur intermittently for many years and has no prognostic value [2].

Histologically, there is a scanty infiltrate, sometimes of neutrophils if the rash is marked, in the dermis. The rash fades as the disease settles; corticosteroids do not have a specific effect.

The rash can be distinguished from erythema marginatum by the smaller size of the lesions, their occurrence on the face and the fact that lesions are at their greatest size at the onset.

Subcutaneous nodules occur in Still's disease. The histology resembles that seen in the nodules of rheumatic fever rather than in those of rheumatoid arthritis [3]. Still's disease has been associated with Kikuchi's disease (see p. 51.58) [4,5].

Adult Still's disease [1]

In 1971, Bywaters [2] described 14 adults with arthritis and clinical features similar to those of juvenile rheumatoid arthritis. Features include a high spiking fever, sore throat, joint pain and arthritis, a transitory maculopapular rash, lymphadenopathy, hepatosplenomegaly and serositis. The white cell count is raised, and rheumatoid and antinuclear factors are usually absent. Both sexes are equally affected, and the onset is usually in the mid-twenties. The rash usually occurs in the evening, accompanied by fever in over 80% of patients, on the proximal limbs, trunk and face. Alopecia is another feature. Histologically, there is a perivascular dermal infiltrate of lymphocytes and histiocytes. Immunofluorescence is negative. The rash is an adverse prognostic indicator. Approximately one-third remit and another third become chronic; the remainder have an intermittent course. Aspirin and other non-steroidal anti-inflammatory drugs are the first line of treatment, but systemic steroids may be required. In the more chronic cases, intramuscular or oral gold may be helpful. Methotrexate has been of benefit in refractory cases [3].

Sjögren's syndrome [1]

Synonym

- Gougerot–Houwer–Sjögren syndrome

In 1933, Sjögren [2] drew attention to the syndrome that now bears his name. The first case was described in 1888, although earlier authors, including Mikulicz, had noted several of the manifestations. The disease is caused by an immune-mediated inflammation of exocrine glands, and involves salivary, lacrimal and sweat glands. It may be primary, in which case the exocrine dysfunction occurs alone, or as secondary Sjögren's syndrome in association with a connective tissue disease. The most common features of the condition are dryness and atrophy of the conjunctiva and cornea (keratoconjunctivitis sicca), and a dry mouth (xerostomia). The diagnostic criteria, including these features and objective demonstration of exocrine dysfunction, have been reviewed, and the consensus findings are shown in Table 51.26 [3]. In addition to the commonly involved areas, other glandular structures may be affected, and there is variable internal organ involvement, but 'sicca' symptoms alone occurred in 35% of one series [4]. Malignant lymphoma is associated with the primary form of the disease [5].

Table 51.26 Revised classification criteria for Sjögren's syndrome (SS).

1 Ocular symptoms: at least one of:
  1 Dry eyes for more than 3 months
  2 Sensation of sand or gravel in the eyes
  3 Need for tear substitutes more than 3 times a day
2 Oral symptoms: at least one of:
  1 Dry mouth for more than 3 months
  2 Recurrently or persistently swollen salivary glands as an adult
  3 Need liquids to swallow dry food
3 Ocular signs—at least one of the following two tests positive:
  1 Schirmer's test, performed without anaesthesia (≤5 mm in 5 min)
  2 Rose Bengal score or other ocular dye score
4 Histopathology: in minor salivary glands, focal lymphocytic sialoadenitis (focus score ≥1).
5 Salivary gland involvement: a positive result for at least one of the following diagnostic tests:
  1 Unstimulated whole salivary flow (≤1.5 ml in 15 min)
  2 Parotid sialography showing the presence of diffuse sialectasias (punctate, cavitary, or destructive pattern), without evidence of obstruction in the major ducts
  3 Salivary scintigraphy showing delayed uptake, reduced concentration and/or delayed excretion of tracer
6 Autoantibodies: presence in the serum of antibodies to Ro(SSA) or La(SSB) antigens, or both

For primary SS

In patients without any potentially associated disease, primary SS may be defined as follows:

a. The presence of any four of the six items is indicative of primary SS, as long as either item 4 (Histopathology) or 6 (Serology) is positive.
b. The presence of any three of the four objective criteria items (that is, items 3, 4, 5, 6)

For secondary SS

In patients with a potentially associated disease, the presence of item 1 or item 2 plus any two from among items 3, 4, and 5 may be considered as indicative of secondary SS

Aetiology. The onset occurs most frequently in the fourth, fifth and sixth decades, and 90% of the patients with the primary form are women. A genetic predisposition is indicated by the finding of

Table 51.27 Pathological changes in Sjögren's syndrome.

Lymphocyte and plasma cell infiltration
Connective tissue proliferation
Glandular cell apoptosis, followed by atrophy of glandular structures in affected tissues (salivary glands, sebaceous glands, sweat glands etc.)
Secondary changes e.g. oedema of conjunctiva

Table 51.28 Skin manifestations in Sjögren's syndrome.

Xeroderma, pruritus and scaling
SCLE-like rashes [4], annular erythema, including Sweet's-like lesions and papular erythema [5]
Raynaud's syndrome
Hyperglobulinaemic purpura and inflammatory vasculitis, including PAN-like lesions
Vitiligo
Abnormalities of sweating
Amyloid
Alopecia—diffuse and generalized

an increased incidence of HLA-B8 and -DR3 in patients with Sjögren's syndrome, although DR4 is more closely associated with the syndrome occurring with Raynaud's phenomenon [6]. Associations with the complement allele C4AQO [7] and HLA-DRw52 [8] in Japanese patients have been reported. Antibodies to the Ro antigen occur in excess in relatives of patients with Sjögren's syndrome, especially in association with DR2 and DR3 [9]. Further evidence of an autoimmune condition is provided by the infiltration of the tissues by lymphocytes and plasma cells, and, as with the majority of autoimmune diseases, it is suggested that glandular damage, induced by a number of exogenous stimuli, leads to the expression of antigens—in this case Ro—which stimulate autoantibody production. Dendritic cells accumulate, produce interferon, which stimulates lymphocyte activation and stimulation, and glandular cell apoptosis is induced [1].

Pathology [1]. The salient pathological changes are shown in Table 51.27.

Reference

1 Morgan AD, Raven RW. Sjögren's syndrome: a general disease. *Br J Surg* 1952–53; **40**: 154–62.

Clinical features [1]. The clinical picture is extremely variable. The consequences of reduced exocrine gland activity may be a minor manifestation of a serious systemic illness, or the presenting, and for many years the only, features. In a prospective study of patients presenting with dry eyes, 43% were found to have keratoconjunctivitis sicca with xerostomia, and 23% had associated connective tissue disease, particularly rheumatoid arthritis [2]. Oral symptoms may precede ocular, or both may occur late in the disease. Some cases present with generalized or anogenital pruritus, or with diffuse alopecia. Reduction in the appreciation of taste and smell has been observed [3]. Infections, including pneumonia, oral candidosis and bacterial conjunctivitis, are frequent.

Skin involvement occurs in around 50% of patients, and may be more common but not recognized (Table 51.28). Annular erythema in Japanese patients may differ from others. In Japan, annular erythema has been subdivided into three types clinically: Sweet's disease-like annular erythema with an elevated border; SCLE-like marginally scaled erythema; and papular erythema [5]. Annular erythema of Asian patients, which is recurrent and non-scarring, may occur in patients with LE, Sjögren's syndrome or both diseases [6]. These lesions are not photosensitive in origin. Ro antibody-positive patients tend to develop annular polycyclic lesions of SCLE as well as neuropsychiatric and pulmonary disease, and have a guarded prognosis [7]. Vascular responsiveness may also be impaired [8] and nail fold capillary abnormalities are found [9].

Non-thrombocytopenic purpura may occur as recurrent crops of round pink lesions in dependent areas (Fig. 51.95), and is associated with hyperglobulinaemia. It may be confused with vasculitis, and fades to leave brown-pigmented stains, but crops occur over many years. Biopsy shows perivascular mononuclear infiltration, but no active vasculitis. However, inflammatory and often necrotizing vasculitis can occur, including an arteritis like that seen in rheumatoid arthritis, lesions indistinguishable from polyarteritis nodosa and nail fold infarcts, splinter haemorrhages and gangrene of the fingers [10].

Mouth. The saliva is at first thick and mucoid, but later salivary volume decreases. The tongue is red, smooth and dry, and in severe cases there may be difficulty in swallowing dry food. Parotid duct narrowing and web formation may develop [11]. Dental caries is often severe and progressive. The lips are red, dry and scaly. There are frequently cracks at the corners of the mouth. Chronic oral candidiasis is frequent. Recurrent episodes of swelling of one or both parotid glands or, less often, the submaxillary and sublingual glands, may be due to autoimmune inflammation or infection, which is common. Impaired glandular function may

Fig. 51.95 Hyperglobulinaemic purpura in Sjögren's syndrome.

Table 51.29 Other manifestations of Sjögren's syndrome.

Joint symptoms—arthralgia and arthritis
Myalgia and myositis
ENT problems: sinusitis, hearing problems including deafness
Tracheal and oesophageal reflux
Interstitial pneumonitis, pulmonary fibrosis and pulmonary hypertension
Interstitial nephritis
Gastrointestinal conditions, including primary biliary cirrhosis
Neurological abnormalities: migraine, neuropathies, cerebral vasculitis

be due to both glandular destruction and functional changes due to altered responsiveness to neurological stimulus [12].

Other mucous membranes [11]. Atrophic changes in the mucous membranes of the upper respiratory tract lead to nasal crusting and dryness, recurrent episodes of infection, hoarseness or aphonia. Pulmonary infiltration, atelectasis or fibrosis may occur. Atrophic rhinitis can occur, and the sense of smell may be reduced. Digestive symptoms are attributable to atrophy of the gastric mucous membrane with achlorhydria. Similar changes in the vulva and vagina give rise to pruritus and vaginitis, and dryness of the anal and rectal mucous membrane leads to dyschezia and pruritus.

Other manifestations (Table 51.29) [1]. In patients without associated connective tissue disease, mild articular symptoms occur in 83%, with mild synovitis. Cervical or generalized lymphadenopathy and enlargement of the liver and spleen, which is sometimes considerable, may be found. The main renal abnormalities appear to be interstitial nephritis, renal tubular acidosis, impaired renal concentrating ability and generalized aminoaciduria [13]. Impaired renal function can occur without clinical manifestations [14]. A high prevalence of fetal loss has been recorded, but there was no correlation with anticardiolipin or anti-Ro antibodies [15].

Sjögren's syndrome in childhood. Primary Sjögren's syndrome is rare in childhood. Recurrent annular erythema similar to that seen in adults has been reported on the face, trunk and limbs [1]. Episodes, with or without fever and parotid swelling, occur over years and last a few months. Anti-Ro antibodies are positive but there is no evidence of SLE. Histology of the lesions shows a dermal lymphocytic infiltration but no vasculitis, and immunohistology reveals no immunoglobulins or complement at the dermal–epidermal junction or around blood vessels. The condition responds to oral steroids.

Laboratory abnormalities. Hypergammaglobulinaemia and rheumatoid factor are frequently demonstrated in the serum, even in patients without arthritis, and serum viscosity is usually raised [1]. Antinuclear antibodies are present in more than 50% of patients (homogeneous factor is more frequent than speckled, and nucleolar factor is only occasionally found). Anti-DNA antibody can occasionally be demonstrated, but anti-Sm and anti-RNP antibodies are never found in the sicca syndrome alone. Anti-Ro (also called SS-A) and anti-La (SS-B) are frequently found and are an important part of the diagnostic profile of the disease. Antibodies to Ro/La were found in 53% of patients with Sjögren's syndrome [2]. Anti-Ro antibodies are particularly associated with vasculitis,

purpura, lymphadenopathy, and haematological and serological abnormalities [3]. Recurrent annular erythema is associated with anti-La antibodies in Sjögren's syndrome [4,5] but not all anti-La-positive patients have a rash, and no disease-specific epitope has been demonstrated [6]. The epitope of anti-Ro antibody is similar in the annular erythema of Sjögren's syndrome and SCLE [7]. Antibody to salivary duct epithelium can be demonstrated in approximately 50% but is also found in uncomplicated rheumatoid arthritis [8]. Thyroglobulin antibodies are present in 25% of cases [9]. Leukopenia and eosinophilia are not infrequent. Immune complexes occur in 60%, but are not related to disease activity [10].

Diagnosis. So variable is the clinical picture that the diagnosis is easily overlooked, except in the more obvious cases presenting with ocular or oral symptoms.

It should also be suspected in the presence of anogenital pruritus in association with ocular and oral changes or with rheumatoid disease, and should be confirmed by specialist ophthalmological examination. Biopsy of labial salivary glands [1] or nasal mucosa [2] is useful, and the value of lip biopsy has been stressed, but a negative biopsy does not exclude the diagnosis [3]. The demonstration of anti-Ro (SS-A) and anti-La (SS-B) antibodies may be helpful in diagnosis, and anti-La may antedate clinical evidence of Sjögren's syndrome by months or even years [4]. Contrast sialography is useful [5], and sequential salivary scintigraphy [6] gives objective and sensitive estimation of salivary gland function. Once a diagnosis is made, every case requires detailed investigation to determine the extent and nature of the associated abnormalities.

Treatment. Symptomatic treatment for the dryness of the eyes is best accomplished by lubricating agents, such as 0.5% methylcellulose eye drops instilled into the eyes four or five times daily. Bromhexine 16 mg three times daily has been found to increase

the lacrimal secretion, but has no effect on salivary flow [7]. However, it does change the salivary composition towards normal [8]. Artificial saliva can be prescribed, and steam inhalations or an air humidifier may help dryness of the respiratory tract. Patients with Sjögren's syndrome associated with SLE seem to improve more than those with primary Sjögren's syndrome. Systemic corticosteroids are effective in reducing parotid swelling, but rarely increase parotid or lacrimal secretion. The immunological abnormalities in the serum are not markedly altered by corticosteroids. Chloroquine or hydroxychloroquine sulphate by mouth have been found useful by some authors [9] but not by others [10]. Ciclosporin improved subjective xerostomia and may reduce histopathological progression [11]. Nifedipine may help pulmonary Raynaud's phenomenon [12]. A patient with associated polymyositis improved with monthly intravenous pulse cyclophosphamide therapy [13]. The annular erythema in Japanese patients may be controlled by prednisolone 10–20 mg/day or by dapsone. There is no single therapy that helps hyperglobulinaemic purpura, although graduated compression hosiery may be significantly valuable. The role of biological therapies, particularly rituximab, is being evaluated [14].

Rheumatic fever

Erythema marginatum is the characteristic rash of rheumatic fever, and occurs in 25% of cases [1]. It appears as evanescent, asymptomatic, pinkish superficial semicircles and rings, which disappear without scaling or pigmentation in a few days. Histologically, there is a perivascular infiltration of neutrophils in the papillary dermis, and biopsy may help in the early diagnosis of rheumatic fever when the rash precedes arthritis and carditis [2]. Erythema multiforme, petechiae and urticaria may sometimes be seen in rheumatic fever. Livedo reticularis has been reported [3]. The overall clinical picture must be distinguished from post-streptococcal reactive arthritis [4].

Subcutaneous nodules occur, particularly on the occiput, wrist and the backs of the forearms, and are smaller and more transient than those seen in rheumatoid arthritis, from which they can be distinguished histologically [5]. Generalized eruptive histiocytomas [6] and erythema elevatum diutinum [7] have also occurred with rheumatic fever.

Introduction

The complexity of the cellular composition of the skin means that the range of tumours that can arise within it is very wide. This chapter deals chiefly with the benign and malignant tumours arising from epidermal keratinocytes. Non-melanoma skin cancers and related premalignant lesions are dealt with in a separate section in view of their clinical importance and the overlap in the epidemiology, pathogenesis and management of these tumours. Chapter 53 is devoted to appendage tumours, Chapter 54 to tumours arising from the melanocyte and Chapter 56 to soft-tissue tumours.

A *tumour* is an abnormal mass of tissue, the growth of which exceeds and is uncoordinated with that of normal tissues. Although most tumours retain a resemblance to the normal tissue from which they arise, they can show an extraordinary variation in their structure and it is this variation that causes difficulties in some cases in establishing a definitive pathological diagnosis. Most of the keratinocyte-derived tumours described in this chapter are *benign*, which is the term used to describe tumours where the cells remain at their site of origin, forming a single mass of tumour cells. *Hamartomas* are difficult to distinguish from true benign tumours clinically. They are not true tumours and best considered as a localized overproduction of one or more elements of a tissue but without the progressive growth characteristics of a tumour. *Malignant* tumours are composed of cells that have acquired the ability to invade through a basement membrane and this is associated with the capacity to metastasize to other organs via the lymphatics and blood vessels. In addition, malignant tumours frequently show more rapid growth and less differentiation than benign tumours, which is reflected histologically by higher mitotic

rates, cellular and nuclear pleomorphism and abnormal mitoses. Differentiation between benign and malignant tumours is one of the major responsibilities of a dermatopathologist. The distinction, however, can be difficult with small tissue samples and is not absolute, which means it is vital that there is good communication between the clinician and pathologist, particularly when the pathology report suggests biological behaviour not in keeping with the clinical impression [1,2].

Non-melanoma skin cancer and related premalignant lesions

Non-melanoma skin cancer (NMSC) is the most common human cancer. The term encompasses basal cell carcinoma (BCC) and squamous cell carcinoma (SCC) of the skin, which are both derived from epidermal keratinocytes. Although these tumours are clinically and pathologically distinctive, they share some characteristics and are frequently classified under the term NMSC for health care planning, cancer registry reporting and epidemiological purposes. In contrast to other common epithelial cancers, NMSCs rarely metastasize, which means that the case fatality rate for these cancers is low. This low mortality from NMSC has contributed to the widespread under-reporting of this cancer to disease registries in many countries which makes it challenging to quantify accurately the morbidity and health care costs associated with this disease. Nevertheless, given the high prevalence of NMSC and the frequent occurrence of multiple primary tumours in affected individuals, there is little disagreement amongst dermatologists that NMSC is an important and frequently underestimated public health problem.

Patients at risk for development of NMSC are also predisposed to the development of actinic keratoses (AK) and Bowen's disease, which are premalignant lesions that show some of the histological characteristics of SCC. The prevalence of AK and the multiplicity of lesions within individual subjects is considerably greater than that for NMSC. While there is some controversy about the premalignant potential of AK and Bowen's disease and their relationship to SCC, these lesions are, in themselves, an important clinical problem for three reasons. First, they need to be distinguished from SCC; secondly, they cause concern and anxiety in patients, particularly in those with a previous history of NMSC; and, thirdly, the scaling and inflammation associated with these lesions is an important contributor to the overall morbidity associated with photoageing.

Epidemiology and risk factors for non-melanoma skin cancer development

Epidemiological surveys have a key role in the generation of incidence and prevalence data for NMSC in populations, quantification of the clinical impression of increasing skin cancer incidence and identification of environmental and host factors important in NMSC development.

Incidence and mortality

Whilst the prevalence of NMSC is recognized as being high and represents a substantial economic burden to health providers, accurate figures for NMSC are unavailable in most geographical regions as these cancers are not reported in many national cancer registries. Giles *et al.* [1], in an Australian postal survey of 31 000 individuals, conducted in 1985, reported 652 BCCs and 160 SCCs and an increased incidence of SCCs from 166 to 250 per 100 000 over the 5-year period, and an 11% increase in the incidence of BCCs [2]. In the USA, a population-based study [3] quotes an incidence of 38 SCCs per 100 000 population, with a 3:1, male:female preponderance. Miller and Weinstock [4] have estimated that in 1994 there were 1 million new cases of NMSC in the USA. Mortality from NMSC in the USA is estimated at $0.44/10^5$ per year [5], with the main cause of death being metastases from SCC. There are a few recorded deaths from BCC, most of these being related to refusal of surgical treatment. The annual cost of treating NMSC in the USA has been estimated at over $500 million [6].

The incidence of NMSC has increased dramatically over the last 30–40 years in many populations worldwide. In addition to the study by Giles in Australia showing a 50% increase in the incidence of SCC and an 11% increase in the incidence of BCCs between 1985 and 1990 [2], Miller and Weinstock have reported a threefold increase in NMSC incidence in the USA over the past two decades with a continuing rise at a rate of 8% per year [4]. Increases in NMSC incidence have also been reported in Europe. In Wales, a population-based study has shown that the crude incidence for NMSC has increased from 173.5 to 265.4 per 100 000 population per annum between 1988 and 1998 [7]. Although differences in the methodologies between reported population-based studies make it difficult to directly compare NMSC incidence in different countries, comparison of age-specific incidence rates of BCCs in two studies from Sweden and Australia indicate that the rate in northern Europe is approximately three to four times less than that seen in the Australian population [1,7,8].

Most studies indicate that BCCs account for more than 70% of the cases of NMSC in areas with both high and low ambient sun exposure. Although a ratio of 4:1, BCC:SCC has been described as a relatively consistent finding in studies of NMSC incidence in non-immunosuppressed, white-skinned individuals, closer examination of the available information shows that this ratio differs between countries with low and high ambient sun exposure, which reflects a disproportionate increase in SCC relative to BCC with increasing sun exposure. In some groups such as white Maryland fisherman with very high occupational ultraviolet radiation (UVR) exposure, the ratio of BCC:SCC is almost 1:1 [9].

Environmental risk factors

Ultraviolet radiation

Ultraviolet radiation (UVR) is by far the most important and best understood risk factor for NMSC development. An association between sun exposure and NMSC was first suggested by Thiersch and Unna at the end of the 19th century and substantiated by the work of Hyde [1] and Dubreuilh independently at the beginning of the 20th century [2]. Since then, a large body of information from epidemiological, clinical and experimental observations has been generated to substantiate the proposed causal link between the sun and NMSC development. This evidence includes: the increased frequency of NMSC in areas of high ambient sun exposure; the latitude gradient in the annual age-adjusted incidence in the USA for cutaneous SCCs, with an increasing incidence the nearer one gets to the equator because of greater levels of the UVB component of terrestrial sunlight [3]; the increased incidence of NMSC in sun-sensitive people, which is dramatically highlighted by the differences in NMSC risk between albinos and non-albinos in countries such as Tanzania with high ambient sun exposure [4]; the association between NMSC and 'benign' sun-related conditions such as photoageing and solar telangiectasia; and the marked increase in NMSC incidence with increasing age resulting from cumulative sun exposure, which reflects both the intensity and duration of this exposure [3,5]. The strength of the evidence led the International Agency for Research on Cancer to conclude in 1992 that sun exposure is carcinogenic in humans and that it has a causal role in development of NMSC [6].

The rising incidence of NMSC over the last 30 years is largely the result of increased recreational sun exposure and there are many parallels between the changing epidemiology of NMSC with that other well-known 20th century epidemic, smoking-related lung cancer. Sunbathing, like cigarette smoking, became popular in the early half of the century with the popularization of the bronzed look by Coco Chanel in the 1930s. Although the development of sunbathing as a popular leisure pursuit has lagged behind cigarette smoking, changes in attitudes about the desirability of a tan, coupled with increased leisure time, the introduction of paid holidays and the development of cheap package holidays have seen a marked increase in the level of individual sun exposure in the latter half of the 20th century. In parallel with smoking-related lung cancer, the incidence rate for NMSC has lagged behind the changes in carcinogen exposure, which means that the current clinical impression of increasing NMSC incidence is likely to be a prelude to reporting on a more substantial scale over the next 30–40 years.

The relationship between exposure to UVR and skin cancer development is complex. Epidemiological studies have had an important role in the identification of differences between BCC and SCC with respect to age and pattern of sun exposure. Migrant studies have established that high sun exposure in childhood is especially important in determining NMSC risk and that there is a sharp change in relative risk of NMSC between arrival before and after 10 years of age [7]. Although the basis for this age effect is still unclear, an important consideration is the possibility that the skin is more susceptible to the carcinogenic effects of UVR in childhood. The concept that the response of the skin with respect to cancer susceptibility may be qualitatively different in early life is supported by the observation that susceptibility to melanocytic naevus formation is also greatest during this period [8]. Although the incidence of both BCC and SCC rises with increasing ambient sun exposure, there is a proportionately greater effect of increasing sun exposure on SCC risk [9]. Other observations suggest that the relationship between sun exposure is not the same for BCC and SCC. These observations include the greater preponderance of BCCs on intermittently sun-exposed areas, the plateauing of BCC but not SCC risk after moderate solar exposure, and the finding that for occupational sun exposure SCC but not BCC risk is related to hours of exposure, whereas BCC risk but not SCC risk is increased by sun exposure occurring during holidays [6,10].

UVR comprises a broad band of energy extending from 200 nm to visible light in the lower 400 nm range (see Chapter 29). The UV part of the solar electromagnetic spectrum is subdivided into three broad regions: UVA, UVB and UVC. Although UVB is the main wave band responsible for skin cancer induction, there is increasing interest in the carcinogenic potential of UVA. Exposure to UVA has increased considerably over the last 20 years for two reasons. First, UVB blocking sunscreens have allowed sunbathers to spend longer in the sun and, secondly, the desire to achieve a tan has led to the growth in popularity of UVA sunbeds. Experimental evidence suggests that UVA is carcinogenic [11] but it has been difficult to assess the risk of NMSC development from commercial tanning equipment, as people who tend to use sunbeds also tend to have greater levels of exposure to natural sunlight. Support for a role for UVA in NMSC induction in humans comes from recent reports of both precancerous lesions and NMSC in some individuals in areas of skin exposed almost exclusively to artificial UVA sources [12,13].

Photochemotherapy (PUVA) and UVB phototherapy

Photochemotherapy and UVB phototherapy are widely used by dermatologists and are recognized as highly effective treatments for a variety of skin diseases. On theoretical grounds, repeated exposure of the skin to artificial UVR or PUVA would be expected to result in cumulative actinic damage and an increased risk of NMSC. Demonstration of increased skin cancer risk and the relative risk of different types of phototherapy has, however, been challenging. This is supported by mathematical modelling approaches which demonstrate that the carcinogenic potential of UVB phototherapy can only be demonstrated with confidence in large multicentre audits with lengthy follow-up [1]. A meta-analysis has estimated an excess skin cancer incidence in patients treated with UVB phototherapy of between 0.6 and 2 extra skin cancers per 100 patients treated per year [2] which in itself is insufficient evidence to definitively establish that phototherapy for psoriasis and other dermatological problems increases skin cancer risk. Given the links between sun exposure and NMSC and the methodological challenges however, it is prudent to continue to ensure monitoring and accurate record keeping of cumulative doses of UV, particularly with the newer phototherapeutic modalities such as narrow-band UVB (TL01) and high-dose UVA1 regimens while this uncertainty remains.

In marked contrast to the lack of clinical evidence of carcinogenicity of UVB phototherapy, there is strong evidence that PUVA increases the risk of developing SCC. The carcinogenic potential of PUVA in humans was first described in 1979 [3] and there is now a substantial amount of information documenting the long-term clinical effects of PUVA [4,5]. NMSC risk in PUVA-treated patients is correlated with cumulative UVA dose and, although earlier data suggested that PUVA may increase susceptibility to both BCCs and SCCs, more recent studies indicate that the increased skin cancer risk is almost exclusively a result of increased SCC risk. Although at a population level it is clear that high-dose PUVA (defined as more than 200 treatments or 2000 J/cm^2) is associated with a 14-fold (95% CI 8.3–24.1) increase in NMSC incidence rate compared to low-dose patients [5], there is evidence that the risk is not uniformly distributed in high-exposure patients, which suggests that other factors may have an important role in modifying risk. High UVB exposure in PUVA patients has been shown to be associated with a small but significant increase in SCC risk [6]. Host factors may also be important as evidenced by the observations from a clinical review of patients exposed to more than 2000 J/cm^2 which revealed that only 50% of patients had SCCs or premalignant lesions [7]. Interestingly, none of the 13% of patients in this study without PUVA lentigines had dysplastic lesions, which suggests that the absence of lentigines may be helpful in the identification of patients at low risk of PUVA malignancy.

Chemical carcinogens

The importance of exogenous carcinogens in human skin carcinogenesis was first suggested by Sir Percival Potts, based on observations of an increased incidence of scrotal cancers in chimney sweeps [1]. This hypothesis was supported by observations made by Volkmann in 1874 of a high incidence of NMSC in workers exposed to tar and mineral oil. These observations, and the occurrence of NMSC in other occupational groups exposed to aromatic hydrocarbons at work, served as a stimulus for the large body of experimental studies with chemical carcinogens in animals, which have provided considerable insight into the biology of cancer. The epidemiology of skin cancers resulting from the occupational environment has been extensively reviewed [2]. Many aspects of occupational skin cancers parallel observations made in animal chemical carcinogenesis models. The prevalence of industrial skin cancer is determined by the potency of the carcinogens and by the thoroughness of the measures used to protect workers from them. The likelihood of an individual developing tumours is influenced by the duration of the exposure. An inverse relationship has been established between the age at first exposure and the length of the latent period following exposure to cutting oils and some other industrial carcinogens [3]. The long latent period between exposure and NMSC development and the observation that cancers can develop without a requirement for ongoing exposure means it is likely that many cases of occupational-induced skin cancers are not recognized. Therefore, and by implication, the published figures are likely to reflect a lowest approximation of the true incidence.

Arsenic is another important chemical carcinogen implicated in NMSC development. The association between arsenic administration and the subsequent development of both cutaneous and systemic malignancies was first recognized by Sir Jonathan Hutchinson in 1887. Unlike aromatic hydrocarbons where exposure was frequently occupationally related, arsenic exposure in the first half of the 20th century was more often caused by the ingestion of medical arsenic in the form of potassium arsenite (Fowler's solution) used to treat asthma and psoriasis [4]. Medicinal arsenic

exposure remains a problem in some regions where local medicines may still contain arsenic in asthma remedies (Asiatic pills), Chinese herbal medicines and traditional Indian medicines [5]. Most arsenic exposure today, however, results from its high levels in well water from either natural sources or as a result of contamination from mining waste [6]. In some provinces in China the burning of high arsenic coal in unventilated indoor stoves has recently been identified as an important cause of endemic arsenic exposure [7].

X-rays and thermal radiation

Physical agents other than solar radiation are less frequent causes of NMSC but are an important aetiological factor in some subject groups. The carcinogenic effects of X-rays on the skin were first recognized by Frieben in 1902. NMSCs resulting from X-rays still occur in some at-risk occupational groups such as dentists, radiographers, physicians and engineers. Other at-risk groups include patients treated with Grenz rays for other dermatological conditions such as scalp ringworm, and patients who have received radiotherapy for the treatment of ankylosing spondylitis [1], lymphomas and other malignancies. Exposure to X-rays in childhood appears to be an important risk factor for BCC development [2]. The long latent period between exposure to ionizing radiation and NMSC development means that cases of radiation-induced NMSC may be overlooked if a careful history is not taken, particularly if they occur on sun-exposed sites. Recent studies have highlighted the increased risk of NMSC in childhood cancer survivors with a 6.3 times increase in risk and a high frequency of multiple cancers in affected individuals. The high frequency of tumours (>90%) in irradiated fields supports the importance of ionizing radiation as a risk factor in this group [3]. Patients who develop large numbers of BCCs within an irradiated field should be examined for signs of the naevoid basal cell carcinoma syndrome (Gorlin's syndrome) as some patients with this syndrome show a marked increase in susceptibility to ionizing radiation-induced BCCs [4,5].

Chronic exposure to thermal radiation is also recognized as a risk factor for NMSC development. Most of the evidence comes from studies of different cultural groups where an increased incidence of NMSC has been linked to common practices within these groups. Examples include Kangri cancer in the people of the Kashmir, resulting from repeated contact of abdominal skin with an earthenware brazier containing burning charcoal [6]. Additional clinical signs implicating thermal radiation include erythema ab igne and/or thermal keratoses, which frequently co-localize with thermal-induced cutaneous SCCs [7,8].

Human papillomavirus

The association between human papillomavirus (HPV) and squamous cell neoplasia is best established for cervical and anogenital cancers, which have served as a useful paradigm for unravelling the complex relationship between HPV and cancer development. HPV infection of mucosal keratinocytes is common and the prevalence is increased in women at high risk of cervical cancer. Epidemiological HPV typing studies had a key role in defining two distinct groups of genital HPV types that show marked differences in their strength of association with cancer development. 'High-risk' types (HPV16, 18, 31, 33 and 35) were found to be strongly associated with cancer development while 'low-risk' types (HPV6, 11, 42, 43 and 44) were not [1]. HPV typing studies to date have not generated convincing evidence that implicates high-risk genital HPV types with the development of most cutaneous squamous cell neoplasms. HPV16 and other high-risk genital HPV types have, however, been linked to the clinically distinctive cutaneous squamous cell neoplasms, periungual SCC and palmoplantar Bowen's disease. It is likely in these tumours that the oncogenic effects are mediated by mechanisms similar to those operating in mucosal keratinocytes [2]. The observed association between the skin lesions and aggressive vulval and/or cervical carcinomas in some patients highlights the importance of ensuring that patients with these neoplasms are screened for genital malignancies [3].

Observational studies of patients with the rare inherited condition epidermodysplasia verruciformis (EV) highlighted an association between cutaneous viral warts and NMSC many years before the epidemiological studies linking HPV infection to cervical cancer [4]. Patients with EV develop extensive cutaneous plane and common warts at an early age and in later life frequently develop SCCs on sun-exposed areas. Although the genetic basis for EV is still unclear, HPV typing suggests that there may be an aetiological link between HPV and skin cancer development as over 90% of the EV-associated skin cancers contain HPV types 5 and 8. A high burden of persistent viral warts, keratotic skin lesions and skin cancers in organ-transplant recipients which

resembles the phenotype of patients with EV has led to speculation that HPV may also contribute to the increased risk of NMSC development in these patients [5]. This hypothesis is supported by the frequent detection of β-papillomaviruses, formerly called epidermodysplasia verruciformis (EV)-associated human papillomavirus types, in actinic keratoses and other keratotic skin lesions of organ-transplant recipients [6].

HPV DNA has been reported to be present in more than 80% of NMSC from immunosuppressed patients with a lower frequency (less than 40%) in NMSC from immunocompetent individuals [6]. HPV DNA can be detected in SCCs, BCCs and premalignant lesions in both immunocompetent and immunosuppressed patients and the most common HPV types are the β type. In a follow-up study using the same molecular strategy, HPV DNA was detected in 87% of normal skin samples from renal transplant recipients and 35% of samples from immune competent subjects. Although the prevalence and spectrum of HPV types in normal skin was not found to be impacted by sun exposure, multivariate analysis demonstrated that there was an association between the presence of β-HPV types in normal skin and skin cancer status (odds ratio of 6.41; 95% confidence interval 1.79–22.9) [7].

Host susceptibility factors

Familial cancer syndromes

Interindividual differences in the susceptibility to NMSC development have been recognized for many years and epidemiological studies have identified a number of phenotypic features, such as hair and skin colour, freckling tendency and ability to tan, which show a consistent correlation with NMSC risk. Genes that determine inherited susceptibility to NMSC development can be divided broadly into two main types. The first type are genes associated with rare, highly penetrant cancer predisposition syndromes and includes conditions such as the naevoid basal cell carcinoma syndrome (NBCCS), Gorlin's syndrome (MIM 109400), Bazex's syndrome (MIM 301845) and xeroderma pigmentosum. The second type are multiple low-penetrant genetic loci that may contribute to susceptibility in the general population. Evidence for the importance of these latter genes has come from quantitative trait loci mapping of other cancers in murine models. Although mapping of similar loci in humans is difficult, association studies provide some evidence to support a role for high-frequency, low-penetrant traits such as DNA damage repair capacity and xenobiotic metabolism in BCC susceptibility.

Naevoid basal cell carcinoma syndrome [1,2]

Synonyms

- Basal cell naevus syndrome
- Gorlin's syndrome

Definition. An autosomal dominant familial cancer syndrome in which affected individuals are predisposed to the development of multiple BCCs at an early age and a variable combination of other phenotypic abnormalities including a highly characteristic facies (with large forehead), bifid or otherwise misshapen ribs, vertebral and other skeletal anomalies, pits of the skin of the palms and soles, dysgenesis of the corpus callosum, calcification of the falx cerebri (at an earlier age than is seen in non-affected individuals) and macrocephaly.

Aetiology and incidence. Population-based studies suggest that the prevalence of this disorder in the UK is approximately 1 in 56 000 of the population [3]. The high rate of new mutations and the variable expressivity of the condition, however, makes full ascertainment difficult, particularly in mildly affected individuals where there is no family history of the condition. Although NBCCS differs from other autosomal dominant cancer syndromes in that many of the associated features are developmental abnormalities, the presence of multiple BCCs at an early age is consistent with the 'two hit model' for inherited cancers first proposed by Knudson. The NBCCS gene was mapped to chromosome 9q22.3–3.1 and, like other tumour suppressor genes, shows frequent deletion in both sporadic and familial BCCs [4]. The NBCCS gene was identified in 1996 with the identification of mutations in the *PATCHED* (*PTCH1*) gene in the germ line of NBCCS patients and in sporadic BCC tumour samples [5]. *PTCH1* is the human homologue of PTC, which was first identified as a key regulator of the evolutionarily conserved Hedgehog (Hh) signalling pathway in elegant genetic studies of embryonic segmentation and imaginal disc specification in *Drosophila*. This finding was the first reported example of a link between genes important in development and cancer, and provided a completely new insight into the molecular pathways important in the development of this common skin cancer. The importance of Hedgehog signalling during normal development explains many of the other phenotypic abnormalities seen in patients with NBCCS and these features are consistent with findings from studies of heterozygote *PTCH1* knock-out mice [6]. The *PTCH1* mutation rate in NBCCS in published studies appears to range between 40% and 80%. A variety of mutations have been described in these studies including nonsense mutations, in-frame deletion, frame shifts due to deletions and insertions and splice-site mutations [7]. In addition to point mutations a small number of patients have been described with larger

deletions detected by comparative genomic hybridization methodologies. These patients tend to present with additional clinical features which may be caused by codeletion of other genes in addition to *PTCH1* [8,9].

Clinical features [10]. The skin manifestations of the syndrome are varied and include BCCs, skin tags, palmoplantar pits, milia, epidermoid cysts and lesions that clinically resemble dermal naevi. Skin lesions including BCCs may be present at birth or develop in infancy but more frequently develop between puberty and 35 years of age. The number and type of skin lesions is very variable both within and between families and there is a marked difference between white people and African Americans in the number of BCCs [11]. It is not uncommon to find affected individuals with several hundred lesions. With the exception of the pits that are localized only on the palms and soles, skin lesions can occur in any region. The eyelids, nose, cheeks and forehead are the usual sites, but the neck, trunk and axillae are quite frequently involved. The scalp and limbs are usually spared.

The individual lesions are smooth surfaced, rounded, elevated papules, flesh-coloured or pigmented, varying in size from 1 to 15 mm in diameter. The lesions tend to increase in size and number up to late adolescence. There may be fine telangiectasia and milium-like bodies just below the surface. Tumours of the axillae, neck and eyelids tend to be pedunculated. Most lesions appear to behave in a relatively benign fashion with barely discernible growth and/or evidence of clinical progression. As is the case for patients with sporadic BCCs, some patients with NBCCS develop more aggressive tumours, which can be more difficult to treat and may cause significant morbidity or, rarely, death resulting from extensive invasion and/or recurrence following treatment. The proportion of NBCCS patients who develop very aggressive tumours and the risk factors for this have not been established. Aggressive tumours appear to occur more frequently on the eyelids or nose, and can cause gross destruction. In one study, four of five cases with aggressive BCCs in a series of 36 NBCCS patients received radiotherapy as the initial therapy, which suggests that radiotherapy may be a contributing factor to tumour aggressiveness in some NBCCS patients [12]. A variety of other skin manifestations have also been described, including multiple epidermoid cysts, milia and palmoplantar pits. The pits are a useful diagnostic feature that occur in about 65% of adults with NBCCS but are relatively rare in children. They are characterized by small, more or less circular pits, which may have an erythematous base and are usually 1–2 mm deep. In a recent study, re-examination of the skin phenotype in the context of data implicating Hh signalling in hair follicle biology led to the identification of discrete patches of unusually long, pigmented hair on the skin of three patients with NBCCS from two unrelated families with confirmed heterozygous mutations in the *PTCH* gene [13].

Other diagnostically useful phenotypic abnormalities in NBCCS patients include jaw cysts, a highly characteristic facies (broad nasal root, hypertelorism, frontal bossing), bifid or otherwise misshapen ribs, vertebral and other skeletal anomalies, dysgenesis of the corpus callosum, calcification of the falx cerebri (at an earlier age than is seen in non-NBCCS individuals) and macrocephaly [2]. The dental cysts are usually multiple, occurring in one or both jaws, and are odontogenic keratocysts [14]. Skeletal abnormalities include spina bifida occulta, bifid or splayed ribs, scoliosis or kyphosis, and occur with one-third of the frequency of the cysts or the basal cell naevi [15]. Less common associated anomalies include syndactyly, shortened metacarpals, cleft lip and palate, bicornuate uterus, hypogonadism in males, lymphatic cysts of the mesentery, ocular abnormalities including dystopia canthorum, cataracts and congenital blindness, and a variety of neurological disorders [16–21]. In addition to BCCs, the syndrome is associated with an increased susceptibility to other neoplasms including rhabdomyosarcoma, ovarian and cardiac fibromas and, in particular, medulloblastoma. Approximately 3% of NBCCS patients develop medulloblastomas, and approximately 3% of patients with medulloblastomas have NBCCS [22]. Atypical clinical features such as brachydactyly, pulmonary valve stenosis and mental retardation should prompt consideration of a contiguous gene deletion syndrome.

Pathology [23]. The histopathological appearance of BCCs from patients with NBCCS are indistinguishable from those seen in sporadic forms. The tumours induce a fibrous stroma as occurs with trichoepithelioma or nodular BCC, and the lesions may become papular or pedunculated. Deeper penetration, ulceration and invasion can occur, with lymphocytic infiltration. There may be pigmentation in and around the masses. The presence of calcification and the general architecture can resemble trichoepithelioma. Palmoplantar pits show focal absence of the stratum corneum with vacuolization of the spinous layer. At an ultrastructural level, pits show evidence of premature desquamation with a reduction in desmosomes and tonofibrils resulting from delay in maturation of the epidermal basal cells [24,25]. BCCs have developed in palmar pits [25–27].

Diagnosis. In many cases, the skin lesions resemble melanocytic naevi, von Recklinghausen's neurofibromatosis or skin tags rather than BCC, and their true nature may be suspected only because of associated features or family history. The correlation between the clinical and pathological features of the range of skin lesions seen in NBCCS patients is still poorly understood, which makes it difficult to draw firm conclusions about the natural history of the different skin lesions in these patients.

Treatment. The large number of lesions in patients with NBCCS means that primary excision of all lesions is not always practicable. Radiotherapy is contraindicated as many patients show an accelerated rate of development of new BCCs within an irradiated field, and where recurrences do occur they frequently are more aggressive and difficult to manage than the initial primary tumour. Surveillance of NBCCS patients who have developed BCCs can be useful for the early detection and treatment of new lesions. Although no controlled trials have established that reduced sun exposure can reduce the rate of BCC development in NBCCS patients, the reduced prevalence of BCCs in African Americans with this syndrome suggests that advice on reducing sun exposure is important [11].

Treatment of individual lesions should be guided by anatomical location, tumour size, clinical appearance and histology, with

primary excision the treatment of choice for BCCs on the central face near critical structures. For superficial BCC on the trunk, approaches such as curettage and cautery or cryotherapy are useful. While the recurrence rate is potentially greater with these therapies, they are an effective, convenient alternative for small or superficial BCCs distant from critical sites in patients with large numbers of lesions. Where the presence of large numbers of superficial lesions limits the acceptability of conventional therapies, then photodynamic therapy with a systemic or topical photosensitizer and an appropriate laser or non-laser light source can be a useful and effective treatment option. Other non-surgical approaches that can be useful in the management of superficial lesions at non-critical sites include topical 5-fluorouracil and imiquimod formulations. These approaches have been shown to induce histological clearing of some BCCs and can reduce but not replace the need for more conventional therapies in patients with large numbers of lesions [28,29]. The value of systemic chemoprevention strategies in the management of patients with NBCCS is still unclear. A few studies suggest that systemic retinoids (isotretinoin (>4 mg/kg) and etretinate (0.7–1 mg/kg)) may reduce the rate of development of new BCCs [30,31]. The clinical benefits, however, appear small relative to those seen in patients with multiple cutaneous SCCs.

Follicular atrophoderma and basal cell carcinoma

Synonym

- Bazex–Dupré–Christol syndrome

This syndrome is a rare genodermatosis that also predisposes affected individuals to multiple BCCs [1,2]. Additional clinical features that allow distinction from NBCCS include follicular atrophoderma, hypotrichosis and hypohidrosis. Follicular atrophoderma is present at birth or in early childhood, and shows as 'ice-pick marks', enlarged follicular ostia on the dorsa of hands, elbows, feet and face. The follicular changes are not caused by injury or inflammation but there may be facial eczema soon after birth. There may be anhidrosis of the face and head, and hypotrichosis. The BCCs appear on the face in the second or third decade and resemble cellular naevi [3].The absence of male–male transmission is suggestive of X-linked inheritance, and this has been confirmed by linkage analysis, which has mapped the gene to Xq24–q27 [4]. The association between BCCs and clinical abnormalities of the hair follicle is of interest as BCCs have the same cytokeratin profile as a subpopulation of follicular keratinocytes

[5]. The importance of the Hedgehog signalling pathway in BCC development in patients from affected families with this disorder is not yet known.

Rombo syndrome

Rombo syndrome is a very rare, autosomal dominant syndrome first described in 1981 (MIM 180730). Affected individuals develop vermiculate atrophoderma, milia, hypotrichosis, trichoepitheliomas and peripheral vasodilatation in addition to BCCs [1,2]. Although there are some similarities with Bazex's syndrome (follicular atrophoderma and milia), there are a number of distinctive features including cyanotic discoloration of the hands and lips in childhood, and telangiectasia. The genetic locus for Rombo syndrome has not yet been mapped.

Self-healing epitheliomas

Synonym

- Multiple self-healing epithelioma of Ferguson-Smith (MSHE)

This condition is an autosomal dominant condition first described by Ferguson-Smith in the 1930s, characterized by the intermittent development of spontaneously regressing skin tumours histologically identical to well-differentiated SCCs.

Incidence and aetiology. The incidence is unknown but the condition is very rare. Two large Scottish kindreds are well described in the literature [1–3], and accurate genetic pedigree analysis has suggested that the condition may have arisen in these two families from a single mutation around 1790. Recent haplotype analysis for polymorphic markers segregating with MSHE in non-Scottish and Scottish families has shown differences which suggest that MSHE may not be caused by a founder mutation and that the syndrome may be more common than originally thought [4]. The gene has been mapped to chromosome 9q22 in a region of less than 4 cm between the markers D9S197 and D9S1809 but has not yet been identified [5]. Other sporadic cases have been reported. The lesions develop most frequently on light-exposed skin and it is postulated that UVR is an important co-factor in the development of these tumours.

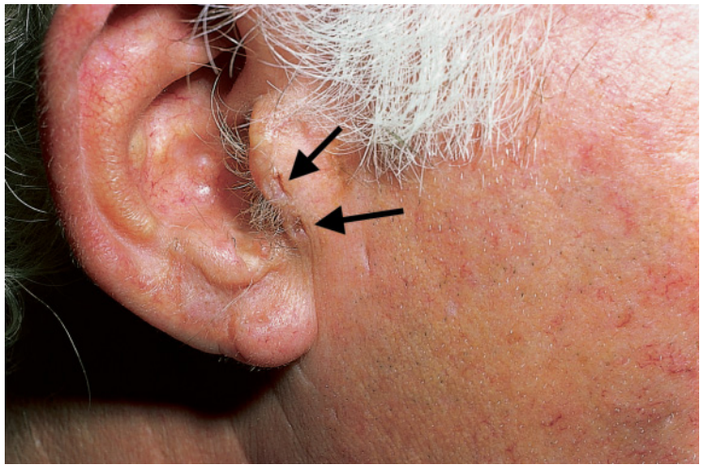

Fig. 52.1 Scarring seen in patient with multiple self-healing squamous epitheliomas of Ferguson-Smith.

Clinical features [6]. The first lesions usually appear in the second decade of life, and each patient tends to have a fairly specific pattern of development, duration and evolution. Knowledge of the 'normal' pattern for the patient is of great value in the management of individual lesions.

The lesions develop predominantly on exposed skin and may cluster around the nose or ears. In the majority of reported cases, one or more lesions have been present in the scalp, a site rarely affected by keratoacanthoma. A small, raised, red nodule is the first sign of a new lesion. This may grow over 2–4 weeks to a diameter of 2–3 cm and may become crusted or ulcerated. The lesion then may remain unchanged for 1–2 months, and then gradually shrink, leaving behind a very characteristic and unsightly, crenellated scar (Fig. 52.1). Lesions develop singly or in crops. In one case they were strikingly confined to half of the body [7].

Pathology. The lesions have features that are indistinguishable from invasive SCCs, but are quite distinct in most cases from multiple keratoacanthoma with which they should not be confused. The epidermis may be ulcerated, and demonstrates marked cellular atypia and loss of polarity. Invasive tongues of epithelial cells will be seen at the base of the lesion and isolated invasive clumps of cells may be seen detached from the main tumour mass, which is still adherent to the epidermis. There is no marked 'shouldering' of the lesion by normal keratinocytes as is seen in keratoacanthoma, and the leukocyte abscesses characteristic of the older keratoacanthoma are absent.

Management. Although spontaneous involution does occur, the resultant scar is unsightly and the end results of shaving or curetting the lesions at an early stage in their development are more acceptable. Cryotherapy of a lesion in the early stages produces an excellent result.

Xeroderma pigmentosum

This is a rare autosomal recessive disorder characterized by extreme sun sensitivity, associated with a marked increase in skin cancer susceptibility. Affected individuals develop multiple precancerous lesions and skin cancers at an early age (see Chapter 15). From a historical perspective, this condition is important as it is one of the key pieces of evidence that highlighted the carcinogenic potential of UVR and was the first model in humans that supported the somatic mutation theory of the initiation of cancer. Recent evidence from studies of other genetic sun-sensitive syndromes in humans has challenged the original assumption that the increased cancer susceptibility in xeroderma pigmentosum (XP) patients is exclusively the result of persistent DNA lesions caused by defective DNA repair following exposure to UVR. The new data have come from elegant studies of patients with trichothiodystrophy (TTD) who show photosensitivity and defective nucleotide excision repair that resembles that seen in XP patients [1]. In contrast to XP patients where there is a more than 2000-fold increase in skin cancer incidence, TTD does not appear to be associated with skin cancer. The basis for these differences in cancer susceptibility between XP and TTD, however, remains an enigma [2].

Muir–Torre syndrome

Synonym

- Hereditary non-polyposis colorectal cancer

This autosomal dominant syndrome, originally described in 1967, is characterized by the presence of one or more sebaceous neoplasms in association with internal malignancies, most frequently carcinoma of the colon [1]. The clinical and pathological features overlap with hereditary non-polyposis colorectal cancer (HNPCC) syndromes. Mutations reported to cause Muir–Torre syndrome include the mismatch repair genes *MLH1* and *MSH2*, *MYH* and *MSH6* [2,3]. Tumours in patients with Muir–Torre syndrome are characterized by alterations in the length of DNA sequences called microsatellites. This microsatellite instability has been identified in sebaceous neoplasms from patients with Muir–Torre syndrome [4]. A number of other skin tumours, including SCC, BCC, keratoacanthoma and AK, have also been described in patients with this syndrome but the significance of these findings has been difficult to establish as the high frequency of undiagnosed NMSC in the population makes it hard to differentiate a real increase from an increase resulting from ascertainment bias. The identification of microsatellite instability in skin tumours other than sebaceous neoplasms indicates that the NMSC noted in previous clinical studies of Muir–Torre kindreds are also likely to reflect a true increased susceptibility and not simply a result of ascertainment bias [5,6]. Recent work suggests that immunosuppression may aggravate the Muir–Torre syndrome phenotype and it is interesting that switching from tacrolimus to a sirolimus-based regimen resulted in arrest of the disease [7,8].

Other cancer susceptibility modifying genes

In addition to the rare, highly penetrant skin cancer predisposition syndromes described above, there is increasing evidence that other genetic loci can contribute to sporadic NMSC risk. The importance of these so-called modifying genes has been highlighted in studies using mouse cancer models in which genes have been identified that markedly reduce the rate of cancer development in mice carrying germ-line mutations in known tumour-suppressor genes [1,2]. It is likely that similar, as yet unidentified genes in humans account for the marked variations in the susceptibility to BCC development seen both within and between families with NBCCS. At present, identification of these high-frequency low-penetrant genes in humans involves educated guesswork based on consideration of factors that might contribute to NMSC development. Epidemiological studies have already identified a number of complex phenotypic traits such as skin colour, ethnicity and freckling tendency, which are associated with an increased

risk of NMSC development [3]. In addition to the well-recognized importance of differences in skin pigmentation, variations in UVR, DNA repair capacity and xenobiotic metabolism have been implicated as important modifiers of sporadic NMSC risk [4]. The published information on DNA repair enzyme polymorphisms and NMSC susceptibility is difficult to interpret at present. This is because of contradictory findings which may be due to methodological differences and/or complex gene–environment interactions in different ethnic groups exposed to a range of exposure to environmental carcinogens [5,6].

Chronic injury and scarring

It has been recognized for many years that NMSC can arise at sites of chronic inflammation and/or scarring. Although there is a substantial literature on this subject, it is difficult to assess the risk as there are no prospective studies of patients with conditions recognized as being associated with NMSC development. Conditions linked to NMSC development include burns [1,2], discoid lupus erythematosus [3], necrobiosis lipoidica [4,5], lupus vulgaris and skin fistulae resulting from discharging sinuses. A particularly strong clinical association has been identified between patients with recessive dystrophic Epidemolysis bullosa (EB) and SCC development [6,7]. The basis for the association between deficiency in type VII collagen resulting from germ-line gene mutations and SCC risk in dystrophic EB patients is not known. In contrast to other forms of EB, fibroblast collagenase is increased in dystrophic EB and this has recently been shown to be associated with marked elevation of urinary excretion of basic fibroblast growth factor [8]. Further studies of SCC development in patients with dystrophic EBV may provide new insight into the long-recognized association between wounding and SCC development.

Immunosuppression

Immunosuppressed patients show a marked increase in susceptibility to NMSC development, with an earlier age of onset and a higher incidence of multiple primary tumours relative to immunocompetent patients. This marked increase in NMSC incidence in these patients is powerful evidence of the importance of the immune system in limiting NMSC development in humans. The cumulative incidence for NMSC uncorrected for age has been shown to vary between 27 and 40% after 20–25 years of immunosuppression in different populations within Europe [1,2]. In Australia, the cumulative incidence appears to be significantly higher after only 10 years of immunosuppression, highlighting the importance of UVR as a co-factor for cancer development in these patients [3]. The risk of NMSC development in renal transplant recipients, which is the best-studied group of immunosuppressed patients, is very variable between different centres as a result of differences between populations including the age distribution of the transplanted patients, the duration of transplantation and the ambient sun exposure of the country. In the UK, a 50-fold increase in the risk of developing SCCs and a fivefold increase in BCC risk has been described in renal allograft recipients [1]. Even greater increases in risk have been described in another European study with a 250-fold increase in SCC incidence and a 10-fold increase in the incidence of BCCs [4]. Epidemiological studies have established that in immunosuppressed patients there is a close association between the development of NMSC and premalignant lesions and the presence of viral warts [5]. The viral warts and skin cancers both preferentially co-localize to areas of sun-exposed skin, although there are some interesting differences between immunocompetent and immunosuppressed patients in SCC distribution with a greater proportion on the hands and forearms in immunosuppressed patients [6].

The molecular and cellular biology of non-melanoma skin cancer

NMSC is unique among human cancers in that the main aetiological factors have been identified and the accessibility of the skin has facilitated analysis of the clinical, pathological and molecular characteristics of these tumours. Advances in molecular and cell biology over the last 10 years have seen an enormous growth in the amount of descriptive data cataloguing changes at the DNA, RNA and protein level in NMSC [1]. While this information in itself has provided an insight into the basis for some of the clinicopathological differences between BCCs, SCCs and related premalignant lesions, a fuller understanding of the biology of NMSC will be critically dependent on approaches that integrate emerging molecular data with the clinical and epidemiological aspects of this important disease. This section outlines current concepts and summarizes some of the more important advances in the biology of NMSC, which have important clinical implications. Topics discussed include cancer genetics, multistage carcinogenesis, UV carcinogenesis and the role of HPV infection in NMSC development.

Cancer as a genetic disease

Cancers are, with few exceptions, clonal; they are derived from a single somatic cell and have accumulated a series of changes that lead to complex and persistent changes in gene expression and cell behaviour. Although it has long been thought that these phenotypic changes require the stepwise accumulation of growth-advantageous heritable changes, direct evidence of the importance of genetic alterations in tumorigenesis has only come within the last decade [2]. Genes important in cancer development can be broadly divided into three categories:

1. Proto-oncogenes that encode for proteins that regulate cellular proliferation and differentiation. These genes are inappropriately activated in cancer cells by point mutations, gene amplification or chromosome translocation.
2. Tumour suppressor genes that maintain a normal phenotype by limiting growth, invasiveness and other features of malignant cells. Mutations are recessive at the cellular level, which means that the effects of alterations in these genes are only seen when both copies are inactivated.
3. Mutator genes encode for proteins that play a critical part in maintaining genomic integrity. The importance of this class of genes in determining cancer susceptibility was first recognized in studies of patients with rare autosomal cancer susceptibility syndromes such as XP, Bloom's syndrome and ataxia telangiectasia where there are abnormalities in the recognition, response and/or repair of DNA damage [3]. Further evidence of the importance of 'mutator' genes has come with the demonstration of instability of dinucleotide repeats in a number of common cancers that are caused by either germ-line or somatic mutations in enzymes important in mismatch repair [4]. More recently, a number of groups have shown that genetic factors also influence genetic stability at a chromosome level and there is increasing evidence that the destabilizing of the genome by mutations in genes that normally maintain chromosomal stability plays an important part in the development of some cancers [5].

Molecular genetic analysis of human NMSC has to date focused on four main areas: the role of genes identified in other human cancers; the mapping of chromosome copy number changes; the mapping and positional cloning of familial NMSC susceptibility genes; and comparisons of genetic changes in SCCs with AK and Bowen's disease [1]. As has been the case for other epithelial cancers such as breast and colon cancer, most of the genes implicated to date in NMSC development are tumour-suppressor genes. DNA sequencing has identified mutations in the *p16* and *p53* tumour-suppressor genes. Comparison of the mutational spectra of these genes in NMSC and internal malignancies has confirmed the importance of UVR-induced mutagenesis in NMSC development [6]. Although the *p53* gene has been linked to genetic instability in other cancers, the mutation frequency in BCC and SCC appears broadly similar, which raises interesting questions about the functional effects of *p53* mutations in keratinocytes. Loss of heterozygosity (LOH) studies have revealed that BCCs and SCCs show marked differences in the pattern and extent of chromosome loss. BCCs differ from SCCs and other epithelial neoplasms in that chromosome losses are largely confined to the long arm of chromosome 9 where the *PATCHED1* tumour-suppressor gene that plays a key role in BCC development maps. Allelotype analysis of cutaneous SCCs has demonstrated more widespread allelic losses with frequent loss of 9p, 13q, 17p, 17q and 3p [1]. Similar findings have recently been described in BCCs and SCCs using single nucleotide polymorphism (SNP) microarray analysis [7,8]. The methods used in these studies have revealed that some LOH events in BCCs and SCCs reflect uniparental disomy (loss of one allele and gain of the remaining allele) and that non-random allelic gains occur in SCCs on 3q and 8q. Although the high frequency of copy number changes and imbalances on these chromosome arms suggests that these regions may contain one or more genes important in the development of cutaneous SCCs, with the exception of *p16* and the protein tyrosine phosphatase receptor type D (PTPRD) locus on 9p and *p53* on 17p chromosome, the identities of the candidate tumour-suppressor genes on these chromosome arms are unknown.

Multistage carcinogenesis in the murine skin model

Mouse skin has, for more than 50 years, played a critical role in the development of the concept of multistage carcinogenesis that has underpinned studies of the biology and molecular genetics of the carcinogenic process. While there are important differences between murine and human skin in the response to both chemical carcinogens and UVR, many of the basic concepts identified using this system have been shown to be generally applicable to many human cancers including NMSC. Observational studies of skin tumour induction by chemical carcinogens led to the concept of 'initiation', 'promotion' and 'progression', which represent different stages of the carcinogenic process [9]. 'Initiation' is characterized by the acquisition of an irreversible change in a cell that in the presence of appropriate growth selection pressures ('promotion') can clonally expand to form a benign tumour (papilloma). The probability of papilloma formation within a given mouse strain is dependent on the nature of the carcinogen, the dose applied and the time course over which the mouse is observed. In

the murine two-stage skin carcinogenesis model, 'initiation' is accompanied by mutations in the H-*ras* proto-oncogene and the position and type of mutation within this gene is carcinogen-specific. Dimethylbenzanthracene (DMBA)-induced skin tumours predominately have a mutation at the middle adenosine of Ha-*ras* codon 61 (CAA → CTA)s, whereas methylnitrosurea (MNU)-induced tumours have a G → A transition at codon 12 [10]. This concept of a 'signature' mutation in critical target genes identified in the murine model has underpinned the studies of mutation spectra in the *p53* tumour-suppressor gene and other genes in UVR-induced human NMSC.

The latency period for tumour formation following the application of an initiator is significantly reduced by the application of 'promoters' such as 12-*O*-tetradecanoyl-phorbol-13-acetate (TPA) and other phorbol esters. In contrast to an 'initiator', a 'promoter' generally has to be applied repeatedly and the frequent visible consequences of promoter application, such as hyperkeratosis and scaling of the skin, subside if the application is discontinued. The observation of latency has parallels with the recent observations in humans that clones of *p53* mutant keratinocyte exist within the normal sun-exposed epidermis many years before clinical lesions become detectable [11].

Initiation and promotion, for example using DMBA and TPA, result in the development of multiple papillomas, which rarely progress to invasive carcinoma. The rate of progression of papilloma to carcinoma can be increased by application of the initiator to a papilloma after it has developed or by repeated application of the initiator to 'normal' skin before promotion. Progression is distinct from promotion in that it is considered to reflect accumulation of additional genetic changes and is generally regarded as irreversible. Support for this concept comes from studies of mouse skin tumours, which have established that the transition from benign papilloma to carcinoma is accompanied by an increase in the number of genetic abnormalities in the tumours. This requirement to accumulate additional genetic changes to facilitate tumour progression can occur without further application of an initiator in tumour cells that show 'genetic instability' as this increases the probability of additional genetic changes, which allow histological progression, invasion and metastasis.

Differences between mouse strains and between species in both their susceptibility to cancer induction and the types of tumours induced by identical regimens highlight the importance of other genetic factors in determining cancer susceptibility. The well-defined mouse model system has allowed mapping of these 'modifier' genes and it has now been established that these genes frequently exert their effect by acting in combination and that the same allele can exert opposite effects in different strains of mice [12]. These observations highlight the difficulties in interpreting results from cancer gene association studies in humans.

Ultraviolet radiation mutagenesis and DNA repair

The overwhelming evidence from clinical and epidemiological studies implicating UVR as the most important skin carcinogen makes it easy for us to answer the question, 'Does the sun cause skin cancer?' Answering the question, 'How does the sun cause skin cancer?' is much more challenging and from the information available at present it is still unclear which one or combination of the multitude of effects that UVR has on the skin is critical for all of its carcinogenic properties.

The UV part of the solar electromagnetic spectrum is subdivided into three broad regions:

- UVC (200–280 nm)
- UVB (280–315 nm)
- UVA (315–400 nm).

UVC is widely used in *in vitro* studies of the effects of UVR but is not relevant to human skin cancer as it is efficiently attenuated by the Earth's atmosphere. Although it accounts for less than 10% of the spectral energy of sunlight, UVB is the main waveband responsible for sunburn and skin cancer induction. UVA differs from UVB in a number of ways. It is the main (more than 90%) component of terrestrial sunlight but is less biologically active than UVB. Both UVB and UVA are complete carcinogens in that they are both capable of inducing benign papillomas and SCCs in murine skin.

The effects of UVR on the skin are complex and it is likely that a number of these effects contribute to its initiating and promoting properties. Exposure to both UVB and UVA cause genetic changes in many biological systems [13]. Dose for dose, UVB is a much more efficient mutagen than UVA and the types of mutations induced by these different wavebands are distinct. The action spectra for DNA damage and skin cancer induction are very similar for UVB and closely coincide with the absorption spectra of DNA, which suggests that direct DNA damage by UVB is an important contributor to its carcinogenic effect. Cyclobutane or pyrimidine dimers and the 6–4 photoproduct are the predominant photolesions induced by UVB and these are the preferential sites for UVB-induced mutagenesis [14]. For UVA, the spectra for DNA damage diverges from that of DNA absorption and it has been inferred that DNA damage by wavelengths above 347 nm is not caused by direct absorption by DNA but is more probably a consequence of indirect effects caused by the generation of reactive oxygen species [15]. The types of DNA damage associated with exposure to UVA are DNA strand breaks and DNA protein cross-links.

The mutagenic effects of UVR on keratinocytes within the skin are dependent on the amount and wavelength of the exposure, cellular antioxidant defences [16], the effectiveness of DNA repair mechanisms and the characteristics of the target keratinocyte. Studies in *Escherichia coli* have demonstrated that UVB induces a characteristic spectrum of mutations that is sufficiently distinctive to serve as a molecular 'signature' or 'fingerprint' of DNA damage [17]. This 'fingerprint' is characterized by the presence of C → T transitions at dipyrimidine sites, either singly (C → T) or as a tandem double bases substitution (CC → TT). The identification of mutations that show this molecular fingerprint in human NMSC [6] and in mouse skin tumours induced by UV provides important evidence at the molecular level of the importance of UVB as a mutagen in skin carcinogenesis [18]. Considerably less is known about the characteristics of mutations induced by UVA. As the DNA damage with UVA is predominately indirect, it is more difficult to extrapolate findings from *in vitro* studies using bacteria or mammalian cells. *In vivo* studies using a transgenic mouse model have shown a predominance of GC → AT transitions at

non-pyrimidine dimer sites, which is consistent with the proposed involvement of oxidative DNA damage [19].

Mutations induced by UVR are a result of persistence of unrepaired photoproducts at the time of DNA replication. During DNA replication, the DNA polymerase complex misreads the photoproduct on the template strand and this leads to the insertion of a default adenine residue at this position. At subsequent cell divisions, this adenine pairs with thymine and the net result is the conversion of a cytosine base to a thymine base on the originally damaged strand. A number of studies have shown that there appears to be a close relationship between photoproduct formation and carcinogenesis in that enzymatic repair of photoproducts by endogenously activated photolysase [20] or by topical application of T_4 endonuclease in liposomes [21] reduces the incidence of tumour formation. Although these studies are consistent with the original XP paradigm, which directly links unrepaired DNA lesions, mutations and cancer, recent observations from studies of patients with TTD indicate that the marked increase in susceptibility to UV carcinogenesis seen in XP patients is a result of other effects and not simply a reflection of an increased mutation rate [22]. Detailed comparisons between XP and TTD cells have revealed a number of differences in the repair efficiency and mutational spectrum, but it is still unclear which of these underpin the differences in cancer susceptibility between these syndromes [23,24].

Immunological effects of ultraviolet radiation

The importance of the immune system in human skin carcinogenesis is dramatically illustrated by the marked increases in NMSC incidence in immunosuppressed patients. UVR, in addition to its mutagenic and other direct effects on keratinocytes, has been shown in murine models to exert an immunosuppressive effect that interferes with the ability of the immune system to eliminate UV-induced skin tumours. These observations and the importance of immunosuppressants as a risk factor for NMSC development in humans has led to speculation that UV-induced immunological injury may be an important contributor to the carcinogenic effects of UVR. In mice, skin tumours induced by UVR differ from chemical carcinogen-induced skin tumours in that they are highly immunogenic and are rejected when transplanted into genetically identical recipient mice. The importance of UV-induced immunosuppression in UV carcinogenesis was first recognized in the 1970s when Kripke [25] made the seminal observation that irradiation of recipient mice abolished the ability to reject the transplanted tumours. This work and subsequent studies established that immunosuppression could be transferred to unirradiated animals by adoptive transfer of splenic lymphocytes and that UVR exerted similar effects on the normal immunological reactions to sensitizing chemicals such as dinitrochlorobenzene in contact hypersensitivity reactions. Further investigation of the immunological effects of UVR using skin contact hypersensitivity has revealed that there are marked differences between mice strains in their susceptibility to UVR-induced immunosuppression. Genetic studies have demonstrated that the UV-susceptibility phenotype is dominantly inherited and two genetic loci have been identified that are thought to mediate this effect [26]. Recent studies using genetically modified mice suggest that deficiencies in IL-10 decrease and in IL-12 increase susceptibility to UV-induced immune suppression and accelerate UV-induced skin carcinogenesis [27,28].

The significance of UVR-induced immunosuppression in humans is still unclear. There are some similarities with the findings in mice in that UV irradiation decreases the ability to mount a delayed-type hypersensitivity response when the immunization occurs on exposed skin and there appears to be interindividual differences in the susceptibility to this effect [29–31]. One study suggests that the UV-susceptibility phenotype is more common in patients with NMSC and that 50% of such patients develop hapten-specific tolerance using this test system [32]. While these observations raise the possibility that exposure to UVR may interfere with the ability of the immune system to eliminate UV-induced skin tumours in humans, the clinical importance of this effect is unclear. The observation that pharmacological inhibition of the immune system has a profound clinical effect on NMSC development suggests that the impact of UVR-induced immunosuppression on NMSC development may not be as great as that seen in murine models. However, further work is required to better understand the impact and clinical significance of other, more subtle aspects of the effects of UVR on cutaneous immunity and the implications of these effects in determining NMSC susceptibility in humans.

Human papillomaviruses

The subdivision of HPV types, based on clinical biology and epidemiological studies of anogenital cancers, played a critical part in the dissection of the molecular mechanisms of HPV carcinogenesis. This allowed identification of the characteristics specifically associated with the carcinogenic properties of the high-risk HPV types [33]. Cell biology and molecular studies have shown a good correlation between high- and low-risk HPVs and their ability to transform primary human keratinocytes [34]. The major transforming proteins of the high-risk genital HPVs are the E6 and E7 proteins, which target and inactivate tumour-suppressor genes including *p53* and the retinoblastoma gene.

Clinical and epidemiological studies have also provided compelling evidence of a link between cutaneous viral warts and NMSC and recent molecular studies have allowed analysis of HPV types. Although the increased prevalence of HPV infection in NMSC from high-risk organ transplant recipients is less compelling compared to the information from studies of other HPV-associated cancers, there are some other pieces of evidence that point to a possible direct role for HPV in NMSC development. Genetic analysis of squamous cell neoplasms from immunocompetent and immunosuppressed patients has revealed that there are significant differences between these two patient groups, with significantly less chromosome loss in SCCs from immunosuppressed patients [35]. Further support for a causal role for HPV in NMSC development has come from recent molecular studies that have shown that the E6 protein from some cutaneous HPVs blocks the epidermal apoptotic response to UVR by targeting the pro-apoptotic Bak protein for proteolytic degradation [36]. This finding and the demonstration of an inverse correlation between Bak protein levels and HPV positivity in cutaneous SCCs suggests that cutaneous HPV may promote SCC development by blocking the normal epidermal apoptotic response to UVR [37].

General principles in the management of patients with non-melanoma skin cancer

Many aspects of the management of patients with BCC and SCC are common to both tumour types and these general principles are discussed in this section. Tumour-specific issues are discussed in the treatment section for the relevant tumour. Management of patients with NMSC requires early detection and accurate diagnosis, selection of the appropriate treatment modality based on the clinical and/or pathological findings, consideration of patient-specific risk factors and institution of preventative measures if appropriate.

Detection and diagnosis

Early detection of NMSC is critically dependent on a good awareness of risk factors and the characteristics of tumour development in at-risk groups. Although most patients with NMSC initially present with a lesion requiring a therapeutic intervention, the high prevalence of benign skin disease and the increasing use of medical screening examinations means that there are opportunities for identifying at-risk individuals sooner than they might present with an obvious clinical lesion. Superficial BCCs on the back, Bowen's disease on the leg and AK are not uncommonly either not noticed or dismissed as a normal consequence of ageing. Although early detection of such lesions may have little impact on the clinical prognosis of the identified tumour, the ability to identify at-risk individuals means that advice on preventative measures such as sun awareness and protection can be initiated much earlier than otherwise would have been the case.

Selection of appropriate therapeutic modality for tumour treatment

The aims of any treatment directed against an NMSC are the removal or destruction of the primary tumour mass and, in the

case of SCC, the prevention of metastasis. A broad range of therapeutic options are available to achieve these aims and while surgical excision is frequently the treatment of choice, there are patient-related factors which may influence treatment choices. These factors include the patient's general health, concomitant medication such as anticoagulants and antiplatelet agents, home circumstance and responsibilities due to employment or carer duties and previous experience of treatment for NMSC. Treatment selection is dependent on a good understanding of the clinical and/or pathological aspects of NMSC that affect prognosis and clinical experience of the pros and cons of the various therapeutic modalities.

The different modalities we may consider include: curettage and cautery, cryosurgery, radiotherapy, photodynamic therapy, topical imiquimod, laser surgery, conventional surgical excision and Mohs micrographic surgery (described in detail in Chapters 77 and 78).

Treatments can be broadly divided into destructive or excisional, the latter providing histologic evaluation of the diagnosis, adequacy of removal and information on the risk associated with that tumour. Destructive treatments may be based on a firm clinical diagnosis of basal cell carcinoma but diagnostic doubt should lead to histological confirmation of the diagnosis before treatment. In general, destructive treatments should be used for lower-risk tumours with the exception of radiotherapy, which will be dealt with in more detail later.

Cryosurgery. The application of liquid nitrogen to skin lesions aiming to cause destruction of the tissue and a margin of surrounding tissue requires the achievement of lesional temperatures of –50 to –60°C. This can be achieved by a number of techniques including single or double freeze–thaw cycles [1,2]. This modality has been recommended for the treatment of AK, Bowen's disease, superficial BCC, small nodular BCC and small well-differentiated SCC. While freezing with liquid nitrogen is a quick and relatively tolerable procedure that does not require local anaesthesia, it can be associated with significant morbidity, particularly when tumours selected for treatment require prolonged freeze times to ensure adequate treatment. Although hypopigmentation is a frequent consequence of cryosurgery for skin tumours, wounds tend to heal without significant tissue contraction and this can give rise to excellent cosmetic results for some patients [3,4]. This form of treatment is considered in more detail in Chapter 78.

Curettage and cautery. This modality can be used for the same spectrum of lesions as cryotherapy. Curettage with traditional Volkman spoon reusable curettes is critically dependent on the friable nature of the tumours, which leads to a selective removal of abnormal tissue. This differential effect on tumour tissue is an effective way of delineating the extent of some tumours and can be useful before standard or Mohs excision of some BCCs to define more accurately lateral tumour spread within the epidermis [5]. With the advent of disposable loop curettes, which have a much sharper edge, the technique has been modified to include a more gentle initial curettage to delineate the tumour followed by greater pressure after this point. When used therapeutically it is important that the stroma and surrounding dermis are charred with diathermy or cautery to a depth of 1 mm following initial curettage and that this is repeated on two further occasions with curetting of the charred tumour base. As the procedure does not divide the upper dermis connective tissue network, healing is usually predictable and occurs in most cases with mild scarring. However, hypopigmentation or hypertrophic scar formation may occur, the latter particularly when the upper trunk is treated.

Radiotherapy. Most NMSCs are sensitive to ionizing radiation. Radiotherapy offers the potential to treat large tumours and a surrounding area of normal skin with minimal tissue damage. The effectiveness and cosmetic end result of this therapy is critically dependent on the treatment regimen administered. This operator dependence, which makes comparison of published studies difficult, is also an important contributor to the misconceptions that some physicians have about the value of this approach. Radiotherapy can be an effective cosmetically acceptable treatment for NMSC including BCC, SCC and premalignant lesions such as Bowen's disease. Although it is often stated that radiotherapy is best suited for elderly patients, the inconvenience and practical difficulties of frequent outpatient appointments required for a full fractionated course need to be taken into account when it is considered as an alternative to conventional surgical approaches. In addition to a primary therapy, radiotherapy is also an important adjuvant following excisional surgery for the treatment of residual microscopic disease and as a prophylaxis against systemic metastases. Situations where radiotherapy is best avoided include NMSC on the lower limbs, ear and eyelid, recurrent tumours, lesions previously treated with radiotherapy, tumours with poorly defined clinical margins and patients with multiple NMSCs and severe actinic damage. The technical details of radiotherapy are discussed elsewhere.

Photodynamic therapy. The development of topically active photosensitizing agents 5-aminolevulinate (licensed as Levulan in the United States) and its methyl ester (licensed as Metvix in Europe) has led to studies on the role of photodynamic therapy (PDT) for the treatment of NMSC. These are pro-drugs which are naturally metabolized via the haem biosynthetic pathway to protoporphyrin IX, a powerful photosensitizer. It would appear that there is a relatively selective metabolism in tumour cells allowing the therapy to target premalignant and malignant skin lesions. This therapy appears particularly effective for AK of the face and scalp. Multicentre, randomized, controlled trials have shown greater than 80% clearance of superficial AKs on the face and scalp and similar figures for the treatment of Bowen's disease and superficial basal cell carcinoma. Recurrence rates of up to 20% at 5 years make this at least as effective as other destructive treatments but it may well have advantages over other therapies with respect to tolerability and cosmesis [6–8]. There are now several guidelines on the use of PDT including advice from the National Institute for Health and Clinical Excellence [6, 9–11]. So far, PDT for nodular basal cell carcinoma has been less successful than for superficial BCC but may have a place in selected patients [12]. Interestingly, PDT may have potential to delay the onset of skin tumours in at-risk groups as studies in a mouse model of BCC demonstrated an effect in terms of delayed onset of tumours [13].

Laser therapy. This therapy is rarely used to treat NMSC. Little evidence of its efficacy exists and there are no comparisons with other treatment modalities. One study utilizing the carbon dioxide ultrapulse laser in multiple, low-risk BCCs in the context of the naevoid basal cell naevus syndrome showed some efficacy [14].

Topical immune response modifiers. These are a new class of recently introduced topical therapies which stimulate innate and cell mediated immune responses by activating Toll signalling pathways and inducing cytokine production. Efficacy has been demonstrated in placebo-controlled, randomized clinical trials for imiquimod and it has been approved by regulatory authorities for the treatment of superficial BCCs and AKs in addition to its initial approval for the treatment of genital warts. Clearance of lesions is accompanied by a localized inflammation of variable severity in most subjects. Severe reactions occur in approximately 20% of subjects and may require either temporary treatment interruption or in rare cases discontinuation. Efficacy has also been observed in off-label studies of patients with Bowen's disease [15].

Conventional surgical excision. This is regarded by many as the treatment of choice for primary NMSC. Excision with primary closure, local rotational or advancement flaps or full-thickness graft to repair the defect, when carried out by a trained operator, usually produces a good cosmetic result and provides the pathologist with a specimen that allows confirmation of the completeness of excision and identification of histological factors associated with increased risk of local or systemic recurrence. Although under treatment because of lateral or deep tumour extension may be identified in conventionally processed surgical specimens, there is potential to miss cases of incomplete excision as only a small proportion of the tumour edge is examined using conventional histopathological techniques [16].

Mohs micrographic surgery. This technique combines excision with complete histological examination of the resection margins of skin tumours and has been shown to be very effective in removing NMSC [17,18] and preserves uninvolved tissues. It is only effective in tumours which extend in continuity and is particularly useful in high-risk or recurrent tumours or where tissue conservation is of importance such as the nasal tip and eyelids. Current guidance in the UK suggests that it is the treatment of choice for the highest risk BCCs and SCCs and may be particularly useful where there is evidence of perineural involvement of SCC [19,20]. The Mohs technique is described in detail in Chapter 77.

Selection of the optimal treatment modality

The selection of the most appropriate therapy for a patient is determined by three key factors: tumour size; tumour location; and the likely tumour characteristics based on clinical and, where available, pathological assessment. Low-risk NMSC and related premalignant lesions including AK, Bowen's disease and superficial BCC can usually be adequately dealt with using curettage and cautery, cryotherapy, PDT or topical imiquimod. Although the recurrence rate for these types of lesions with these modalities when used appropriately is slightly higher than that achieved with surgical excision, this needs to be balanced against the fact that these less invasive procedures are relatively simple to carry out, often associated with less short-term morbidity and more predictably give a good cosmetic result compared to excision. Excellent cure rates for curettage and cautery and/or cryotherapy have also been reported for small (less than 1 cm) nodular BCCs and well-differentiated slow-growing SCCs on sun-exposed skin [21,22]. For intermediate-risk NMSC (tumours less than 2 cm, well-defined clinical margins), the location of the tumour is an important determinant of treatment choice. A specific advantage of surgical excision over other destructive therapies is the provision of tissue for histological examination, which provides confirmation of the diagnosis, information on the adequacy of excision and may allow recognition of histological features associated with a high risk of local recurrence and risk of metastasis. For BCC, these features include location on the central face and a morphoeic histological pattern. For SCC, depth of invasion greater than 4 mm or extension into subcutaneous fat, poor differentiation and perineural involvement have all been associated with increased risk of local recurrence and metastatic disease [20]. For high-risk NMSC, the treatment of choice is Mohs surgery.

For the management of most NMSCs a treatment plan can be defined based on a clear understanding of the pros and cons of the different treatment modalities and a careful consideration of the tumour characteristics. In some cases, such as high-risk patients with multiple NMSCs, high-risk tumours, recurrent tumours or incompletely excised NMSC, optimal selection of therapy may be best achieved in the context of a multidisciplinary tumour clinic with input from dermatologists, plastic surgeons, oncologists and radiotherapists.

Chemoprevention and management of high-risk patients

The surgical treatment of high-risk NMSC differs from that of high-risk patients with many other common cancers such as colon, breast and bladder cancer in that it is not possible to completely remove the target organ. While excision or destruction of lesions is well suited for the management of small numbers of NMSCs or related premalignant lesions, these approaches become increasingly impractical and distressing for high-risk NMSC patients with multiple lesions. Examples of patient groups where this problem arises include patients with NBCCS, immunosuppressed organ transplant recipients, high-dose PUVA patients and patients with severe actinic damage. From our current understanding of the epidemiology and biology of NMSC, the number of high-risk patients is likely to increase considerably over the next 25 years as a result of the changing age structure of the population and increased recreational sun exposure. The management of patients with multiple NMSCs is a considerable therapeutic challenge, which is not helped by the limited number of treatment options available and the lack of controlled clinical studies.

Topical 5-fluorouracil is a valuable therapy for the treatment of Bowen's disease and for patients with multiple AK. For reasons that are still not understood, 5-fluorouracil acts on both clinically detectable lesions and subclinical lesions, which means that application to a contiguous area of skin may target a greater number of lesions than would be achieved using destructive therapies of visible clinical lesions. Although there is some evidence to suggest

that 5-fluorouracil may reduce the rate of development of new AK, there is no conclusive evidence at present favouring a role for 5-fluorouracil in the prevention of NMSC [23,24].

A number of systemic approaches have been investigated as chemopreventive agents for high-risk skin cancer patients (reviewed in [25,26]). Oral retinoids are used to treat patients with multiple SCCs where the rate of new SCC development makes management by surgical intervention difficult. Although oral retinoids show clinical efficacy and are the only agent proved to be chemopreventative, there are many unanswered questions on their mode of action and long-term effects as there are very few controlled trials on their use. Etretinate has been shown to be superior to placebo in the treatment of high-risk patients with AK, some of whom also had at least one NMSC [27].

Basal cell carcinoma [1–3]

Synonyms
- Basalioma
- Rodent ulcer

Definition. A malignant tumour that rarely metastasizes, composed of cells similar to those in the basal area of the epidermis and its appendages. The histology of the tumour and the surrounding stroma is characteristic.

Incidence and aetiology. BCC is the most common malignant tumour of the skin and the most common cancer in some countries, including the USA and Australia. Although the prevalence of this tumour increases within a population as exposure to sunlight increases, the distribution of the lesions does not correlate well with the area of maximum exposure to UVR in that BCCs are common on the eyelids, at the inner canthus and behind the ear, but uncommon on the back of the hand and forearm. The palm, sole and vermilion of the lips are rarely, if ever, involved. The basis for the different susceptibility of skin at different sites to BCC development is not known.

BCC is more common in males than females. A population-based incidence study in Minnesota gives annual incidence figures for males and females of 175 and 124 per 100 000, respectively [4], and an Australian survey gives an incidence in that country of 849 and 605 per 100 000 for males and females, respectively, in 1990 [5], while figures from Hawaii show an incidence of 576 per 100 000 for males and 298 in 100 000 for females [6].

A Canadian case–control study has identified outdoor occupations (particularly farming), freckling, and Scottish or Irish descent as particular risk factors [7]. The Australian case–control study by Kricker *et al*. [8,9] of 226 patients with BCC suggests that the tumour is more common in those born in Australia than in immigrants, that southern European ancestry is protective, and that poor tanners are more at risk than those who tan easily. The presence of large numbers of naevi, freckles and solar elastosis all add to the BCC risk, while a past history of acne is protective [8,9]. A large European study of 1549 southern European patients with BCC reports that those with fair or red hair, those who tan poorly and those who have a history of childhood sunburn are at greater risk, and that acute episodes of intense burning sun exposure are a greater risk factor than cumulative lifetime sun exposure [10,11].

Some clues on the potential importance of exposure to hazardous air pollutants, arsenic, ionizing radiations and burns have come from a recent European multicentre study which showed that the frequency of BCCs was highest in miners and quarrymen, railway engine drivers and firemen [12].

BCC is extremely uncommon in dark-skinned races, and less common in Chinese, Japanese and other oriental populations than in white populations [13,14]. Although it may occur at any age from childhood, more than three-quarters of patients are over 40 years old. It occurs earlier and multiple tumours are more common in those with a fair freckled complexion. On the lower leg, the incidence in women is three times as great as in men [13]. BCC appears to arise more frequently and at a younger age in patients who are immunosuppressed. These lesions are frequently aggressive [15]. It is occasionally seen adjacent to leg ulcers [16].

BCC may arise in skin damaged by sunlight and ionizing radiation. It may occur in burn scars [17] or vaccination scars [18,19]. Arsenic salts are also a proven cause [20]. BCC has been reported in identical twins [21]. The increased risk of BCC development in naevus sebaceus and other adnexal hamartomas is well recognized [22–24].

The identification of mutations in the *PTCH1* gene has provided important insights into the pathogenesis of this common skin cancer and points to a key role for the Hedgehog (Hh) signalling pathway in its pathogenesis (see above and [25,26]).

Histogenesis. Theories about the nature and origin of the cells of BCC have been put forward at intervals over the last 80 years or more. The histological variability does not accord with a derivation from any individual epithelial structure, and is now generally considered to stem from the pluripotentiality of immature cells of the epidermis. It is thus capable of maturing towards any of the epithelial structures, and its behaviour is governed, as is the normal immature cell, by the connective tissue in its proximity. Thus, the stroma dependence, the range of histological patterns and the way these merge with the more organized hamartomas are explained. It has been rightly emphasized that the stroma is an essential part of the neoplastic process and it must also be removed in treatment.

Clinical features [27]. The early tumours are commonly small, translucent or pearly, raised and rounded areas covered by thin epidermis through which a few dilated, superficial vessels show (Fig. 52.2). Tiny flecks of pigment may be seen with a hand lens. Other modes of presentation are a small, pearly, erythematous, lichenoid papule or plaque, as a keratotic and slightly indurated area, or as a small and superficial ulcer resembling an excoriation by a fingernail. It may occasionally be pedunculated and telangiectatic, resembling a pyogenic granuloma.

The more advanced tumours have as wide a variety of forms as the early lesions and tend to maintain the same pattern of growth throughout their course. One common type grows slowly as a well-marginated expanding nodule or thickened plaque. The thinned epidermis closely covers the tumour and may periodically scale or erode and crust. In this variety, ulceration occurs relatively late, and may re-epithelialize and break down several times before becoming permanent. The surface contour usually

Fig. 52.2 Typical early basal cell carcinoma on the nose.

becomes more irregular as the lesion grows. The degree of vascularity varies. There may be surface telangiectasia over a flesh-coloured mass or the tumour may be pink or red in colour. Pigment, when present, is usually unevenly distributed through the tumour. Some or all of the component nodules may have cystic centres, which add to the translucent appearance; the cystic parts may be more deeply pigmented than the peripheral parts.

Less commonly, the tumour spreads only superficially. It is bounded by a slightly raised thread-like margin, which is irregular in outline and may be deficient at part of the circumference. The epidermis covering the central zone is usually atrophic and may be scaly. This, combined with an increased vascularity, gives a resemblance to Paget's disease of the nipple. There may be a series of thickened papular islands of growth within the margin, and these may be crusted or eroded. Superficial tumours are often pigmented.

The atypical rodent ulcer has an indurated edge and base, but no thread-like margin. The edge is usually raised above the normal level but in some areas, particularly in the nasolabial furrows, it may be flush with the surface. The floor of the ulcer is depressed below the skin surface, fleshy in appearance and not very vascular. However, there is more or less inflammation around the tumour. Such an ulcerated lesion may have begun as a nodule, but more frequently it is crusted or eroded from an early stage of its evolution. If left, the tumour and its following ulcer may spread deeply and cause great destruction, especially around the eye, nose or ear (Fig. 52.3). There may be wide extension in the periorbital tissues; the bones of the face, the skull and even the meninges may be invaded, and advanced cases amply justify the title 'ulcus terebrans' (penetrating ulcer).

The morphoeic or sclerodermiform BCC is uncommon, and is so named because dense fibrosis of the stroma produces a thickened plaque rather than a tumour. The exact margin of the lesion is impossible to define, but palpation reveals a firm skin texture that extends irregularly beyond the visible changes (Fig. 52.4) [28].

Fig. 52.3 Extensive, ignored basal cell carcinoma on the back of the neck in an elderly man presenting to a British hospital in 1988.

Fig. 52.4 Recurrent basal cell carcinoma that has arisen on the basis of pre-existing morphoeic basal cell carcinoma which was incompletely excised.

The surface is smooth and may be slightly raised above, or sometimes slightly depressed below, the normal level. The colour is yellowish and has been compared with old ivory. Ulceration is uncommon and only very superficial when it does occur. Many patients, and doctors, may take little notice of this type of BCC until its slow extension produces a sizeable lesion.

The majority of BCCs arise on the head and neck, with a particular predilection for the upper central part of the face. The morphoeic type occurs almost exclusively on the face. The superficial type, however, is found mainly on the trunk. The palms and soles are rarely affected. BCCs may be multiple.

Post-irradiation tumours of the scalp [29] and those that occur in sun-damaged skin of the face may be multiple and show various stages of development. A few cases of genuine BCCs have been reported to arise from the epidermis over histiocytomas, but the not uncommon basaloid buds seen in sections of histiocytoma are of doubtful significance.

The typical BCC runs a slow progressive course of peripheral extension, which produces the thread-like margin, the nodule with a central depression or the expanding rodent ulcer. Some tumours grow at so slow a rate that they are, for all practical purposes, benign. This is true for many of the superficial lesions and some of the nodular cystic lesions also. There may be spontaneous fluctuation in size, and areas of scarring can be found within many superficial tumours. A patient who has had one BCC treated should always be followed up, not only for local recurrence but also to detect fresh tumours arising elsewhere. There is no recognized premalignant stage of BCC equivalent to solar keratoses or Bowen's disease for SCC.

Rapid growth is so uncommon as to throw doubt on the accuracy of the patient's history. Invasive rodent ulcers, if neglected, may cause death. This is preceded by prolonged mutilation of the face or scalp [30], with destruction of the nose or eye and exposure of the paranasal sinuses or the skull, dura or brain. A few giant exophytic tumours have occurred on the back [31].

In rare cases, the tumour may disseminate [32–37]. When the ulceration involves the airway, fragments of tumour cells and stroma may be inhaled and become implanted in the lungs [35]. Authentic cases of bloodstream metastasis are on record in which, for example, deposits in the viscera or spinal column have caused the presenting symptoms of the terminal illness. Other cases have spread via lymphatics to the regional lymph nodes before disseminating.

Pathology [38–40]. The tumour cells resemble those of the basal layer of the epidermis and the matrix cells of the appendages, in the relatively small amount of cytoplasm they possess and in their ability to interact with the dermis adjacent to them. Their nuclei are compact, rather darkly staining and closely set. Their cytoplasm stains poorly and the cell margins are rather indistinct. Adjacent cells are connected by bridges. The sparsity of keratin fibrils gives these connections a different appearance from the 'prickles' of the Malpighian layer, but the presence of desmosomes and tonofibrils has been shown by electron microscopy. The interaction with the dermis, which is one of the principal functions of the normal epidermal basal cell, produces the characteristic marginal palisade of tumour cells and the well-organized stroma that surrounds it. The dependence of the tumour on its stroma has been shown by transplantation experiments [41]. The cells within the palisade usually show little evidence of organization or differentiation. Mitotic figures may be frequent, and it is speculated that the combination of large numbers of mitoses and a slow growth rate result from a high rate of apoptosis. Data on cell kinetics indicate that a considerable proportion of cells in the tumour die fairly rapidly [42]. Bizarre and atypical cells occur commonly in arsenic-induced tumours [20]. In some tumours, the cells may become acantholytic and amyloid may be identified [38].

In early lesions, the tumour buds can be seen arising from the epidermis. In very small lesions, multiple buds have been seen. These very soon become confluent, and the three-dimensional examination of superficial BCC shows a coherent margin of tumour with a reticular pattern of growth along the interpapillary ridges and larger, more discrete masses centrally [39]. As the tumour progresses, the masses extend into the dermis, and may

separate from each other and from their point of origin. Growth in one area may be accompanied by involution of the tumour in nearby areas leaving an atrophic epidermis. A common site of origin in humans and in the experimental tumours of the rat is the junction between a pilosebaceous duct and the epidermis. From here the tumour may extend along the epidermis and down the duct. It is difficult to prove a purely adnexal origin for BCC, but some lesions behave as though this were so. In all considerations about the origin of the tumour, one must remember that the tumour can either sever its connection with epithelial structures or establish a secondary connection to structures to which it has grown close.

The variability of the natural history of BCCs is reflected in its pattern of growth. Most tumours are composed of rounded expansile islands. These throw out small buds that grow in the same way to produce multilobular masses with thin strands or septa of fibrous tissue penetrating them [39,40]. In some regions, a limited capacity to grow around and enclose adjacent connective tissue may be associated with a reticular or cystic pattern of growth. The capacity to invade in thin strands is often accompanied by an excessive and almost exclusive fibroblastic response, in contrast with the lymphocytic response around the expansile masses. Invasive strands may spread for long distances along nerve sheaths. BCC is truly invasive in only a small proportion of cases. In these, the tumours show no tendency to grow as rounded masses, have no palisade or organized stroma, and penetrate the dermis and deeper structures, destroying them as they go. Such tumours are almost always ulcerated, usually from an early stage. In the less invasive tumour, ulceration occurs when the epidermis is replaced by the tumour. An eroded, vegetating type of growth is rather uncommon.

Most BCCs provoke a round-cell inflammatory reaction of some degree. It increases in extent with ulceration and is often conspicuous in the papillary body, with superficial patterns of growth. Mast cells are often present in numbers among the fibroblasts of the stroma, and Langerhans' cells have been demonstrated within and near the tumour. This infiltrate has recently been correlated with the aggressive nature of the tumour [43].

The diversity of histological patterns of BCC is caused in part by features that have no direct bearing on the clinical course of the tumour. Not infrequently, melanocytes proliferate within the tumour. The melanin they produce causes the tumour to be pigmented, and numerous melanophages collect in the stroma, and sometimes in cystic cavities. Mucin is commonly found in the stroma, particularly at the margin of the tumour, and may be encysted within it. Cystic cavities also form when the centrally placed cells undergo necrosis. There is no evidence that such cavities represent glandular differentiation. Evidence of true sebaceous or sweat gland differentiation has been seen, but is very rare. Within some tumours there are strands of fusiform cells with more abundant eosinophilic cytoplasm, which may form whorls or keratinizing cysts, and which probably represent rudimentary differentiation towards hair roots. Citrulline can be demonstrated as a histochemical confirmation in such cases but does not help in the sometimes difficult separation from trichoepithelioma. Histochemical and electron microscopy investigations show little evidence of differentiation of the tumour cells. However, *in vitro* culture of tumour cells from nodular tumours produces evidence of keratinization after 30 days, suggesting that the cells possess the biochemical mechanisms for keratinization but that some factor, possibly dermal in origin, inhibits them.

Diagnosis. The common nodular type of tumour has a distinctive appearance when it is more than a few millimetres in diameter. In the initial stages it may be hard to separate from a melanocytic naevus (especially when pigmented), molluscum contagiosum or senile sebaceous hyperplasia without the aid of a biopsy. Naevi can be distinguished if hairs grow from the surface, and in molluscum contagiosum and sebaceous hyperplasia there is a central keratin-filled pit. Scaling or crusting on the surface can cause confusion with warts, keratoacanthoma, SCC or molluscum contagiosum. In all cases, the debris should be removed, and this is easily done in BCC. The friable, relatively avascular tissue beneath is characteristic, and if fragments are removed and smeared on a slide the diagnosis can be confirmed by cytology. Darkly pigmented, ulcerated tumours are occasionally confused with malignant melanoma. The margin of BCC is usually rolled, telangiectatic and multinodular, and there is no pigmented halo. The colour tends to be more definitely brown, in contrast with the dusky greyish brown of malignant melanoma.

Perhaps the most difficult problems (although least crucial from the patient's viewpoint) are found with superficial BCCs. Casual inspection may suggest that these are patches of eczema, psoriasis or Bowen's disease. When the scale is removed and the edge stretched, the thread-like margin will reveal the true diagnosis [44]. Careful inspection will almost always rule out eczema or psoriasis, which the patient's history will have also made unlikely. There are some cases, however, where distinction from Bowen's disease can be made only after biopsy. The consistency of a morphoeic BCC may resemble morphoea; the outline is usually less sharp and the evolution more gradual and relentless. A recently described elastotic nodule on the anterior crus of the antihelix of the ear in sun-damaged skin may resemble a nodular BCC on cursory examination.

Clinical diagnostic accuracy in the diagnosis of BCC, widely regarded by most dermatologists as being the easiest tumour to recognize, is surprisingly poor. One study reported a diagnostic accuracy rate of 70% for academic dermatologists, 65% for dermatologists in private practice and 64% for residents [45].

Treatment. As stated previously there are many factors that influence the treatment of BCC, these include: tumour characteristics; patient characteristics; experience of the clinician; and local facilities. In the case of BCC the factors that influence prognosis are shown in Table 52.1 and should be considered when choosing treatment options.

The aim of any therapy selected for BCC is to ensure complete removal or destruction of the primary tumour to prevent local recurrence and the need for further therapeutic intervention whilst exposing the patient to the least risk of complications and producing an acceptable cosmetic result. The wide range in natural history and biology of the different subtypes of BCC and the large number of treatment modalities available for the removal and destruction of skin tumours means it is difficult to draw up rigid

Table 52.1 Factors influencing prognosis in basal cell carcinoma.

Tumour characteristics	Risk
Tumour size	Increasing size increases risk, especially over 20 mm
Site of tumour	Risk increased with central face, periocular, nasal, ears and lips
Definition of margin	Lesions that are clinically poorly defined are of higher risk
Immunosuppressed patient	Possible higher risk
Recurrent disease	Increased risk
Histological subtype	Morphoeic/infiltrative, micronodular, basosquamous all increase risk
Aggressive histological features	Perineural or vascular invasion increased risk

guidelines for the management of this common cancer. Successful management of BCC requires a clear understanding of the clinicopathological factors that affect prognosis and a good theoretical and practical knowledge of the strengths and limitations of the many different treatments available. From published series on outcomes it is clear that successful treatment can be achieved by any one of the large range of therapies, subject to appropriate matching of the treatment to the tumour characteristics [46,47]. In most cases, treatment selection is usually based on a clinical assessment which considers a number of factors that are known to influence tumour prognosis. These factors include tumour size, location, clinical subtype and defined margin. In addition to the tumour characteristics, other factors such as the patient's age, adequacy and success of previous treatments and coexisting medical conditions that influence tumour biology or treatment tolerability need to be considered. For reasons that are still unclear, BCCs recurring following radiotherapy are particularly difficult to eradicate by conventional surgical excision and this needs to be taken into account when selecting the most appropriate therapy [48].

Destructive therapies used appropriately, mainly for low-risk tumours, can offer an effective alternative to surgical excision for small primary tumours at non-critical sites. A number of studies have shown that curettage and cautery of low-risk BCCs can give cure rates of up to 97% [49]. Similar high cure rates have also been reported for cryotherapy for low-risk BCCs [50,51]. Tumour size has an important effect on prognosis for BCCs and there is good evidence that the recurrence rate following curettage and cautery or cryotherapy increases significantly with increasing size [52,53]. In addition to risk of recurrence, it is also important to bear in mind that the morbidity associated with cryotherapy also increases with increasing size.

Conventional surgical excision with predetermined margins based on the clinical characteristics of the tumour is regarded by many as the most appropriate therapy for most nodular BCCs and provides a specimen for histological examination and assessment of the lateral and deep margins yielding <2% recurrence rate at 5 years post surgery [54,55]. Studies of Mohs surgical specimens have provided useful information about the probability of achieving complete excision in tumours with predetermined margins in different sized BCCs. For BCCs less than 2 cm in diameter with well-defined clinical margins, a 3-mm margin will clear the tumour in 85% of cases and a 4–5-mm margin in 95% of cases [56–58]. Although it has been estimated that careful inspection of the common nodular and plaque forms of the tumour with a loupe allows the margin to be determined to within 0.5 mm of the histologically proven border, inaccuracies in the clinical assessment of tumour margins are an important cause of incomplete excision of nodular BCCs. Small ulcerated nodular BCCs, which present as non-healing erosions, not infrequently extend several millimetres beyond the clinically defined margin. For these tumours and others where the margin is less clearly defined, curettage prior to excision is a useful technique for more accurately defining the true borders of the BCC [59,60]. Even in experienced hands there is a risk that nodular BCCs with apparently well-defined clinical margins may have infiltrated more extensively, leading to incomplete excision with residual tumour. In some cases, strands of cells extend along nerves for a considerable distance beyond the obvious clinical edge of the tumour [61,62]. The outlook is poor when cartilage, bone or the orbit have been invaded.

Studies of incompletely excised BCCs have demonstrated that not all incompletely excised tumours will recur but that between 21 and 41% will do so over a 2 to 5 year period [63–67]. Based on information generated over the years on residual tumour in re-excision specimens and recurrence rates of incompletely excised tumours, it may be reasonable in cases where there is incomplete excision of the lateral margin only, not to re-excise if the BCC is a primary tumour on a non-critical site with a non-aggressive histology. For all other cases and in those where the surgical defect has been repaired using a skin graft or local flaps, immediate re-excision with frozen section control or using Mohs micrographic surgery is the treatment of choice [47].

The management of morphoeic BCC, large BCCs (more than 2 cm in diameter), some smaller nodular BCCs with poorly defined clinical margins and recurrent BCCs needs to take into account the increased likelihood of subclinical extension. In the absence of either frozen section control or Mohs surgery, these tumours will require large predetermined margins; even a 5-mm margin will only give complete excision of 82% of morphoeic BCCs [56]. Management of recurrent BCCs is a difficult problem as cure rates are consistently poorer than those achieved for primary tumour. Mohs surgery is an important treatment option for the treatment of high-risk BCCs as it offers consistent high cure rates for even the most difficult BCCs. For primary BCCs and recurrent BCCs, treated with Mohs surgery, 5-year cure rates of 98.6% and 96% respectively have been reported [68]. The proportion of BCCs treated using Mohs surgery varies considerably between different countries as it is a relatively specialized technique and is more resource-intensive than simple surgical excision. Tumour characteristics that warrant consideration of Mohs surgery include BCCs at high-risk sites (nasolabial fold, periocular and nose), BCCs greater than 2 cm in diameter, morphoeic, infiltrative or micronodular BCCs and recurrent BCCs [46,47].

Basisquamous or metatypical basal cell carcinoma [69,70]

This term is used for tumours that on pathological study appear to have features of both BCC and SCC. The biological significance

is that this pathological pattern is associated with a significantly higher incidence of metastatic spread [71]. The pattern in these lesions is of small aggregates of cells lacking classic palisading and embedded in dense and profuse fibrous stroma. The cells are larger with a larger paler nucleus than in the classic BCC and have a more eosinophilic cytoplasm.

Squamous cell carcinoma

Definition. A malignant tumour arising from the keratinocytes of the epidermis.

Incidence and aetiology. The epidemiology and risk factors important for cutaneous squamous cell carcinoma (SCC) development have been described in detail in the previous sections on NMSC. SCC of the skin is a heterogeneous disease both aetiologically and clinically, with different risk factors implicated in its development in different populations. The epidemiology of the disease has changed over the last 50 years, with a decrease in the importance of occupational exposure to chemical carcinogens and an increase in the proportion of cases caused by recreational sun exposure. In addition, new diseases, such as HIV infection, and therapeutic advances, such as the introduction of effective immunosuppressive therapies to prevent rejection of transplanted organs and PUVA therapy, have resulted in the emergence of new populations that are highly susceptible to cutaneous SCC development [1,2].

Cutaneous SCC is predominately a disease of white populations and is especially prevalent in this group in areas of high ambient sun exposure [3,4]. Although the incidence is low in non-white populations, SCC is still the most common skin cancer in these populations but shows differences in the anatomical location of the tumours, recognized aetiological factors and prognosis [5]. Factors implicated in the pathogenesis of cutaneous malignancy in Africans and African Americans include trauma, albinism, burn scars, ionizing radiation, chronic inflammation and chronic discoid lupus erythematosus [5,6]. There is a high incidence of SCC in albinos in Tanzania but no evidence of an increased incidence in vitiliginous skin of black people [6,7]. Additional aetiological factors implicated in development of cutaneous SCC in some populations include chronic exposure to thermal radiation and scarring. Radiant heat from coal and peat fires may cause SCC in women who habitually sit with their legs close to the fire [8,9]. The preceding lesion is called erythema ab igne (Fig. 52.5). SCC is also an occasional complication of long-standing chronic granulomas such as venereal granulomas, syphilis, lupus vulgaris and leprosy and lupus erythematosus, chronic ulcers, osteomyelitis sinuses, old burn scars and hidradenitis suppurativa. It may complicate scarring dermatoses such as poikiloderma congenitale, dystrophic epidermolysis bullosa [10] and porokeratosis of Mibelli [11].

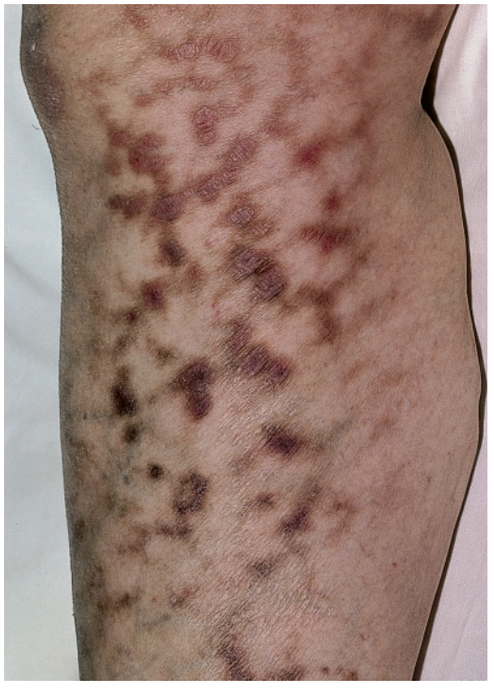

Fig. 52.5 Area of erythema ab igne on the lower leg of an elderly female.

Clinical features (Figs 52.6 & 52.7). SCC does not often arise from healthy-looking skin. Commonly, there are signs of photodamage: solar elastosis of the dermis, hyperkeratosis, irregular pigmentation and telangiectasia, or leukokeratosis and fissuring of the lip. The first clinical evidence of malignancy is induration. The area may be plaque-like, verrucous, tumid or ulcerated, but in all cases the lesion feels firm when pressed between the finger and thumb. The limits of the induration are not sharp and usually extend beyond the visible margin of the lesion. The resistance to pressure is much greater than that given by an inflammatory lesion or benign epithelial hyperplasia.

Fig. 52.6 Multiple invasive squamous cell carcinomas in a patient with a history of exposure to arsenic.

Fig. 52.7 Raised erythematous invasive squamous cell carcinoma in an elderly patient on a light-exposed site.

The tissue around the tumour is inflamed and the edge is an opaque yellowish red colour. The better-differentiated tumours are usually papillomatous and are capped by a keratotic crust in the earlier stages. This may be shed later to reveal an ulcer or eroded tumour with an indurated margin and a purulent, exuding surface that bleeds rather easily. The outline may be rounded, but is often irregular, and in premalignant lesions the induration and elevation is often asymmetrical at first. On mobile structures such as the lip or genitalia the presenting sign may be a fissure or small erosion or ulcer which fails to heal and bleeds recurrently.

The most common sites for SCC are those most exposed to the sun. They occur on the backs of the hands and forearms, the upper part of the face and, especially in males, on the lower lip and pinna.

The histological susceptibility of the scrotum in chimney sweeps, mule spinners and capstan-lathe operators was a result of the retention of the carcinogen on the skin surface. The relatively high incidence of lesions on the lower leg in the natives of tropical countries is related to the frequency of ulcers and scars. The nailbed is an uncommon site, which may be overlooked until the lesion is large enough to produce radiographical changes in the distal phalanx [12].

The evolution of SCC is usually faster than that of BCC, but is conspicuously slower than that of keratoacanthoma, which may attain the same size in as many weeks as SCC does in months or even years. Tumours arising in keratoses on the dorsum of the hand are particularly indolent and late in metastasizing. Early ulceration, and the absence of tumid outgrowth, are usually a result of an anaplastic lesion [13], and are more commonly seen on the lip and genital area than elsewhere. Regional nodes may become enlarged, either as a result of infection of the ulcer or from metastases. In the latter case, they feel harder, are more irregular and become fixed to the adjacent tissues. Spread by the bloodstream is uncommon [14].

Pathology [15–17]. SCC is a tumour that may arise in any epithelium, and its behaviour in the skin is essentially similar to its behaviour in the respiratory tract and elsewhere. Because of the accessibility of the skin, the precancerous changes that lead to the tumour are more easily observed and followed.

Potentially precancerous conditions include actinic keratoses, Bowen's disease and leukoplakia. Invasive SCC begins when atypical keratinocytes breach the dermal basement membrane and invade the dermis (Fig. 52.8). The distinction is thus architectural rather than cytological, and is based on the presence of descending strands of morphologically malignant keratinocytes, which can no longer be regarded as distorted interpapillary ridges. The distinction may be further complicated by the phenomenon of pseudoepitheliomatous hyperplasia [15], which may occur at an ulcer margin or over certain inflammatory or neoplastic states in the dermis (see below).

The cells of SCC vary from large, well-differentiated, polygonal cells with vesicular nuclei, prominent nucleoli and an abundant cytoplasm containing numerous tonofibrils and well-developed intercellular bridges, through to completely anaplastic cells with basophilic cytoplasm, which provide no cytological evidence of their origin. Some tumours have large bizarre cells, in others the cells may have a clear, almost vacuolated cytoplasm and in yet others the cells may be spindle-shaped. Well-differentiated tumours show areas of maturation that form parakeratotic horny pearls and individually keratinized cells, and also dyskeratosis, with lacunae and lumina that contain shed rounded, degenerating

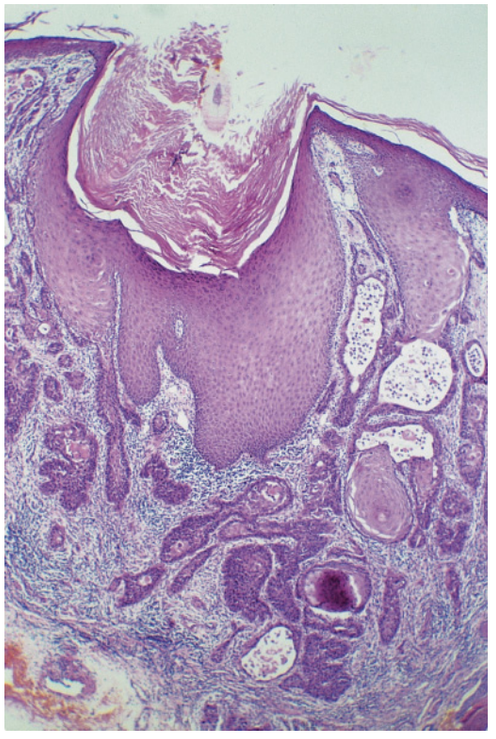

Fig. 52.8 Pathological features of well-differentiated, early invasive squamous cell carcinoma, showing differentiated keratinocytes invading the underlying dermis.

cells. The latter appearance is pseudoglandular, and is termed adenoid or acantholytic SCC [16,17].

Most tumours invade as coherent strands and columns, and reproduce the same pattern in their metastases. Many are composed of cells uniform in type and showing only moderate mitotic activity. They stimulate an inflammatory reaction in the dermis. The capillary pattern is abnormal and the number of vessels considerably increased [18]. Increasing anaplasia is associated with hyperchromatic nuclei, decreasing eosinophilia and tonofibril formation in the cytoplasm, and lessened intercellular adhesions. The cell outlines may be rounded or spindle-shaped. Mitotic figures become more frequent, and abnormal mitoses can be found. Even in extensively ulcerated tumours, the connection with the epidermis is usually maintained, and the origin can be traced to atypical epidermal cells, which may enable a distinction to be made from an anaplastic amelanotic melanoma. Its origin from an area of abnormal epidermis distinguishes it from keratoacanthoma. In rare instances, SCC may appear to arise in a keratinous cyst. Many reported instances of this occurrence, however, can now be considered as proliferating trichilemmal cysts.

Local extension of SCC may occur around nerves, sometimes for considerable distances, and may require extensive surgery [19]. Biological differences in the aggressiveness of SCCs arising in different locations and/or resulting from different aetiological factors are well recognized [20]. It is unusual for SCC originating in an AK on the hand or arm to show evidence of anaplasia or to metastasize until well advanced. In a Scandinavian series [21], fewer than 8% of tumours of the upper limb metastasized. Lesions of the vermilion of the lip, and to a lesser extent of the ear, metastasize much earlier even when they are relatively well differentiated. Those elsewhere on the face appear to be less aggressive. SCC of the external genitalia is also inclined to early invasion and metastasis. Spread is almost always by the lymphatic route.

Various ways of predicting the likelihood of metastasis from the histological features have been suggested. One that has been widely used is Broders' classification based on the proportion of differentiated to atypical tumour cells. From the practical point of view, this method needs to be supplemented by the depth of invasion. For tumours of the hand, for instance, metastasis is unlikely when the penetration does not extend deeper than the sweat coils [16]. At the two extremes of differentiation this criterion does not apply. A well-differentiated lesion such as 'epithelioma cuniculatum' may invade the soft tissues of the foot extensively without metastasis [22,23], while a completely undifferentiated tumour, of the lip for instance, may disseminate at an early stage.

Epithelioma cuniculatum [24] **and verrucous carcinoma** [25]. There are several uncommon tumours that are so well differentiated that the diagnosis may be in doubt if the unrelenting course is not taken into account. One such has been reported as the 'epithelioma cuniculatum' [22]. There is a soft bulbous mass with a squashy consistency on the distal part of the sole of the foot. Multiple sinuses open on the surface and, when pressed, greasy, rancid and foul-smelling material can be expressed. It is possible that the appearance of a vegetating pyoderma may at times be caused by the same process. In such cases, the distinction from pseudoepitheliomatous hyperplasia may be very difficult. A few examples of 'giant condyloma acuminatum' have eventually become low-grade SCC [26,27].

In both the oral cavity and on the genital mucosa [28], a strikingly verrucous lesion may develop [25,29]. These lesions, because of the site involved, may become massive, moist, cauliflower-like and often malodorous because of secondary infection. The clinically apparent relentless growth contrasts with the pathologically less aggressive appearance characterized by a lack of mitotic figures and a well-demarcated lower margin with no strands of cells becoming detached from the main bulk of the lesion.

At the other extreme, anaplastic SCC rarely may arise from skin not showing a premalignant lesion and in a form very difficult to recognize. The lesion is a red papule or nodule, relatively fast growing and looking inflammatory rather than neoplastic. It tends to ulcerate early. It may resemble a keratoacanthoma, but the central keratin core is usually absent. Induration is present, but may be less marked than in well-differentiated tumours. It can infiltrate deeply and metastasize quite early. It has been designated 'squamous cell carcinoma *de novo*' [30].

Squamous cell carcinoma following immunosuppression after organ transplantation. Recipients of organ transplants receiving immunosuppressive therapy have a much higher than expected incidence of SCC [1,31,32]. The development of carcinomas is directly related to time from transplantation, and appears to be independent of the immunosuppressive regimen used. The normal ratio of BCC:SCC is reversed, and SCC is more common. The lesions are most numerous on sun-exposed sites and are frequently multiple. They may clinically be deceptively banal, and resemble

either keratoacanthoma or actinic keratosis. All such lesions should be regarded with suspicion in transplant patients, and biopsied to establish their true nature. Female transplant recipients also have a much higher than expected incidence of genital premalignancy.

Careful, regular supervision of transplant patients by a dermatologist is required, and advice on sun avoidance should be part of the post-transplant care regimen.

Diagnosis. The indurated, well-differentiated SCC arising in skin damaged by sunlight presents no problems in diagnosis. The distinction from keratoacanthoma is usually easy, as the rate of growth and domed appearance of keratoacanthomas are characteristic. On occasions, however, a tumour develops like a typical keratoacanthoma, but proves by its progress to be an SCC [33]. In such cases, the histology of the early stage may not be conclusive one way or the other. The most important clinical distinction is between a poorly differentiated carcinoma arising *de novo* from normal skin, and an inflammatory ulcer or granuloma on the one hand, or an amelanotic melanoma or BCC on the other. The characteristic induration and opaque colour are the most important signs but any doubt is usually clarified by biopsy. Warty lesions such as viral warts or seborrhoeic keratoses are not indurated and are frequently multiple.

Treatment. The aims of any therapy selected for the treatment of cutaneous SCCs are to ensure complete removal and destruction of the primary tumour and to prevent metastasis. From published series on treatment outcomes it is clear that these aims can be achieved by any one of a range of therapies subject to appropriate matching of the therapy to the tumour characteristics [34]. There are a number of factors which influence the metastatic risk of cutaneous SCC, including clinical features such as size, site, rate of growth, aetiology and presence of immunosuppression. Histologic features influencing risk of metastases include tumour thickness, depth of invasion and degree of differentiation may or may not be available at the time of treatment planning but if available will aid in treatment decision making. Unfortunately, many of these factors are not routinely reported in the publications of outcomes of treatment in case series and there are few randomized trials comparing treatments to guide our decisions. Whilst published case series have provided insights into factors that impact metastases risk, the information is uncontrolled and does not take into account the impact of important factors such as differences between SCCs seen in office practice compared to secondary or tertiary care settings [20,34–42]. Treatment selection in clinical practice is based on an assessment of the clinical and, if available, pathologic tumour characteristics mentioned above that have been shown to be important in determining the level of therapy required and in identifying tumours with a poor prognosis. Identification of aggressive cutaneous SCCs is important as the overall 5-year rates of recurrence and metastasis for these tumours is 20–25% which is approximately three times greater than that for primary skin SCC (8%) [35].

Although there are considerable international differences in clinical practices, it is possible to make some generalizations. Destructive therapies used appropriately by experienced clinicians with careful tumour selection can offer an effective alternative to surgical excision for small (less than 1 cm in diameter), slow-growing, well-differentiated SCCs on sun-exposed sites [34,43]. For similar well-defined, low-risk tumours less than 2 cm in diameter, surgical excision with at least a 4-mm clinical margin is an appropriate starting point with anticipated complete excision rates of 95% [44]. Higher-risk tumours which are more than 2 cm, moderately or poorly differentiated, extending into the subcutis or on high-risk sites including the scalp, ears, nose, lip or eyelid require wider margins of more than 6 mm and may well benefit from histological examination of the margins with techniques such as Mohs surgery [44]. Tumour size has an important effect on the probability of both local recurrence and metastatic risk, with a doubling of local recurrence risk and a threefold increase in metastatic risk for SCCs greater than 2 cm in diameter. In addition to tumour size, other criteria used in the selection of appropriate therapy include the location of the tumour, the likely aetiological factor and histopathological characteristics [34,37,38]. UVR-associated SCCs on the ear, lip, scalp, eyelids and nose have a worse prognosis than UVR-associated SCCs at other sites. The basis for this difference has not been established but it is possible that some of the increased risk for cutaneous tumours may result from technical considerations at the time of surgery. SCCs on non-sun-exposed sites where aetiological factors other than UVR exposure are important are also associated with a worse prognosis. It has long been recognized that SCCs at sites of scarring, ulcers, chronic sinuses or previous thermal or ionizing radiation injury have a worse prognosis. SCCs arising in areas of Bowen's disease are also thought to have greater malignant potential. Although deaths resulting from metastatic cutaneous SCCs are more common in immunosuppressed patients, it is not clear if this increase is brought about by differences in the biology of SCCs in these patients or a reflection of the marked increase in the prevalence of SCCs in this group, which in itself could lead to more deaths from metastatic disease [45,46]. A further histopathological characteristic associated with a worse prognosis is the presence of perineural involvement [36,47,48]. SCCs extending into the subcutaneous fat or greater than 4 mm in depth are almost eight times (45.7% metastatic rate) more likely to recur than SCCs confined to the upper dermis (6.7% metastatic rate). Poorly differentiated tumours have a doubling in the incidence of local recurrence and a threefold increase in metastatic rate [34,49,50]. The worse prognosis and difficulties in managing recurrent SCCs highlight the importance of adequate initial treatment based on accurate clinical assessment and appropriate selection of therapy.

Radiotherapy is rarely the treatment of choice but may be indicated for some very large or rapidly enlarging tumours or in patients where aggressive surgical management may not be tolerated. It may also be better for certain sites where functional and cosmetic outcomes for surgery are less than ideal such as the lips, lower eyelid and occasionally the ear. Radiotherapy may also have a role as an adjuvant therapy in some high-risk SCCs where there are concerns about residual microscopic disease, for example in perineural involvement [51]. Mohs micrographic surgery offers advantages over conventional surgical excision and is widely regarded as the treatment of choice for high-risk SCCs as it reduces the risk of local recurrence and metastatic disease.

For patients with aggressive cutaneous SCCs, there are currently no recommended adjuvant chemotherapy regimes after definitive surgical or radiation treatment. A recent trial evaluating the effectiveness of adjuvant 13-*cis*-retinoic acid (13cRA) plus interferon alfa (IFN-α) failed to demonstrate benefit in the prevention of tumour recurrence or second primary tumour development [52].

The final results of any of the methods depend on the experience of the person using it rather than the technique itself. In experienced hands, all the techniques give 5-year cure rates of approximately 90% in a wide variety of SCCs at different sites. Patients with high-risk SCC and those who have evidence clinically of nodal disease are best managed with the help of a multidisciplinary team, which may comprise dermatologists, dermatopathologists, radiation oncologists, plastic surgeons, skin cancer specialist nurse and radiologist. In situations where treatment can at best be palliative, the involvement of the palliative care team may also be required [43].

Prevention. Patients presenting with SCCs or related premalignant lesions on sun-exposed skin should be advised about the importance of reducing exposure to solar radiation. In high-risk patients, regular follow-up and targeted treatment of small, low-risk tumours with cryotherapy and other destructive therapies may help reduce the frequency of tumours requiring surgical excision. Although intermittent 5-fluorouracil use may improve skin texture and reduce the rate of development of AK, there is no published evidence at present that this is associated with a decrease in the rate of development of invasive SCCs. In patients such as organ transplant recipients and patients with xeroderma pigmentosum, where the rate of new SCC development makes surgical management difficult, then it may be necessary to consider treatment with systemic retinoids to reduce the rate of development of new lesions and help target surgical excision to retinoid-unresponsive tumours. Etretinate and isotretinoin have both been shown to reduce the rate of development of new lesions in XP patients [53,54]. More recently, acitretin has been shown to reduce the rate of development of new SCCs [55,56]. In contrast to cytotoxic drugs, retinoids do not appear to eliminate neoplastic clones from the epidermis and discontinuation of therapy is associated with the rapid growth of numerous dysplastic lesions that were growth inhibited but not eliminated by retinoid therapy.

Premalignant epithelial lesions

Premalignant epithelial lesions are conditions that can be recognized clinically or histopathologically and are associated with an increased risk of cancer development. Although premalignant lesions frequently share many of the histopathological changes seen in invasive cancers, the ability to order lesions on the basis of severity does not in itself imply that the lesions identified represent consecutive changes in a neoplastic process [1]. The histopathological changes seen in premalignant lesions include nuclear pleomorphism, increased mitotic rate, abnormal mitotic figures and abnormal differentiation. In the skin, a number of premalignant epithelial lesions have been identified and there is convincing clinical and epidemiological evidence of an association between many of these lesions and an increased risk of NMSC. Some lesions, such as AK and leukoplakia of mucosal surfaces, may show relatively little evidence of cellular atypia, whereas others, including Bowen's disease and erythroplasia of Queyrat, can show marked dysplasia of the epidermis that is histologically indistinguishable from the changes seen in well-differentiated SCC. Premalignant lesions are distinguished from their invasive counterparts by the absence of histological invasion with the microscopical features of intraepidermal carcinoma confined above the dermal–epidermal junction. In addition to the epidermal changes, a common feature of many premalignant lesions is the presence of a chronic inflammatory cell infiltrate in the papillary dermis immediately beneath the abnormal epidermis [2]. The importance of premalignant lesions as indicators of increased NMSC risk is well illustrated by AK, Bowen's disease, tar keratoses, ionizing radiation keratoses and arsenical keratoses, which are frequently found in patients with NMSC or at high risk of developing this type of cancer. With the exception of arsenical keratoses, which are the result of systemic carcinogen exposure, all of the other premalignant lesions localize to areas of skin exposed to the carcinogen and these areas are the same as those at risk of NMSC development. Premalignant lesions frequently occur before the development of invasive cancers and can be useful in identifying individuals at high risk of NMSC development.

Conventional models of multistage carcinogenesis, such as the human colon cancer model and murine skin cancer models, are based on tumour systems that show an orderly progression through well-defined clinicopathological changes. In these models, cancer development is indirect, progressing through discrete clinicopathological changes and this is supported by molecular studies, which have shown that 'early' lesions have less genetic abnormalities than do 'late' lesions. Other tumours develop in the absence of any recognizable precursor lesions, that is they arise directly. Clinical observation suggests that most human cancers, including cutaneous SCCs, may not progress through intermediate stages and that progression of AK and Bowen's disease to invasive SCC may be the exception rather than the rule [1]. A full consideration of the natural history of most premalignant lesions, including AK and Bowen's disease, is difficult as therapeutic removal or destruction provides evidence of what the lesion looks like but destroys any chance of consideration of future behaviour. Notwithstanding these limitations, a number of longitudinal studies indicate that AKs frequently undergo spontaneous regression and have a low potential for developing into invasive SCCs [3,4]. Support for the hypothesis that most AKs are unlikely to progress into invasive SCCs comes from molecular studies. These studies have shown that AKs frequently show more extensive chromosome losses than do SCCs, in contrast to findings in the colon cancer model where indirect cancer development as part of a linear progression process is the norm [5,6]. These findings do not undermine the importance of regular skin examination of high-risk skin cancer patients and the treatment of lesions based on clinical need but they do not support the concept that aggressive treatment of some types of premalignant lesions such as AK will prevent cancer development in these patients.

Actinic keratosis [1–3]

Synonyms
- Solar keratosis
- Keratosis senilis

Definition. Hyperkeratotic lesions occurring on chronically light-exposed adult skin, which are focal areas of abnormal proliferation and differentiation that carry a low risk of progression to invasive SCC.

Aetiology and incidence. The great majority of actinic keratoses (AKs) occur on sun-exposed sites in fair-skinned people who have had excessive exposure to solar UVR [4]. Lesions with similar clinical and histological features may be induced by ionizing radiation or radiant heat and in workers exposed to pitch and other products of coal distillation.

The prevalence of these lesions is high in many countries and is influenced by the amount of ambient UV, the proportion of susceptible individuals in the population, the age structure of the population and the time spent in outdoor occupations and recreations. In the UK, a recent study has reported an overall prevalence of 15.4% in men and 5.9% in women over the age of 40 years and 34% and 18% in men and women, respectively, aged 70 years and over [5]. In areas with high ambient UVR levels such as Australia, a prevalence rate of 43% with 18% (of a population of 197) having more than 10 AKs is recorded [3]. Longitudinal studies in patients with AK have established, firstly, that there is a high probability of developing new lesions and, secondly, that many lesions undergo spontaneous resolution [6]. Although the rate of progression of an individual AK to invasive SCC has been estimated to be low (less than 0.1%), the presence of AK is an important biomarker of excessive UV exposure and increased NMSC risk [7].

Clinical features [8–10]. These lesions occur usually in middle-aged or elderly subjects on habitually sun-exposed areas such as the face, scalp and dorsa of the hands. The sides of the neck are involved in both sexes, but the ears predominantly in men. The vermilion of the lower lip but not often of the upper lip may also show keratosis, with a much higher incidence in men than women. Lesions are usually multiple and comprised of either macules or papules with a rough scaly surface resulting from disorganized keratinization and a variable degree of inflammation. Lesions vary in size from less than 1 mm to over 2 cm and are usually asymptomatic. In many individuals, the number of lesions can be better appreciated by skin palpation, which is a sensitive way of detecting the characteristic roughness associated with smaller lesions. Many of these small lesions may pass unnoticed by most patients, and the diagnostic changes often only appear later as a dry, rough, adherent and often yellow- or brown-coloured scale (Fig. 52.9).

Fig. 52.9 Multiple actinic keratoses on the dorsum of the hand of an outdoor worker.

Fig. 52.10 Pathological features of actinic keratoses showing alternating parakeratosis and hyperkeratosis.

The adherent scale can only be picked off with difficulty, revealing a hyperaemic base with punctate bleeding points. In some cases, scaling may be prominent and in time may become thick and horny. The edge of the keratosis is usually sharply demarcated and the reddening is usually closely confined to the area immediately below the area of abnormal scaling. The flat, atrophic or lichenoid variety is most commonly seen on the face.

Many patients give a history of relapsing and/or remitting lesions, which can often disappear either spontaneously or after sun avoidance and use of sunscreens.

Pathology. The boundary between unaffected and affected epidermis is a sharp line that slopes upwards and inwards, and there is a similar margin where the appendage ducts perforate the epidermis as funnel-shaped columns of orthokeratosis. The epidermal cells have a paler cytoplasm and mature through an absent or diminished granular layer to form a parakeratotic scale of varying thickness. There is usually some acanthosis, and the more dysplastic lesions show epidermal hypertrophy with hyperkeratosis and parakeratosis (Fig. 52.10). The interpapillary ridges may

be reduced in number and broader than normal. The affected zone tends to grow under the normal epidermis and around the ductal epithelium, and may separate from it by a cleft. The basement membrane is intact but basaloid cells may form multiple buds at the junction; the combination of clefting, budding and papillomatosis produces a Darier-like change. Within the epidermis there may be a simple dysplasia or a range of abnormalities up to a picture indistinguishable from Bowen's disease. These are the Bowenoid AK.

The papillary vessels are irregularly increased and there is a lymphoid infiltrate beneath the lesion. There is a variable degeneration of dermal collagen and deposition of material staining like elastin in the upper half of the dermis, except for a narrow band at the basement membrane; this change is more or less uniform, unlike the discontinuous keratosis.

The flat type of AK, most common on the face, may resemble discoid lupus erythematosus. The distinction is made by the altered epidermal cells, deficient granular layer and parakeratosis, the band-like rather than perivascular inflammatory reaction, and the absence of immunoglobulin in the basement membrane region. Occasionally, the appearance may appear pseudoepitheliomatous [8] or similar to lichen planus [9].

The occurrence of funnel-shaped columns of normal epidermis, derived from appendage ducts that appear to be trying to cover the diseased epidermis like an umbrella, suggests an effort at biological compensation [10]. It must be remembered, however, that in keratoses and Bowen's disease, sleeves of dysplastic cells growing down appendage ducts may survive damage by freezing or cytotoxic applications. The presence of an inflammatory response appears to be a warning sign of early malignant transformation [11].

Diagnosis. The diagnosis is usually based on clinical findings which take into account the morphology of individual lesions and the clinical setting. For lesions less than 3 mm, clinical discrimination from an early SCC may be difficult. This diagnostic uncertainty, particularly for small lesions, is one of the reasons why it is difficult to establish accurate rates of progression for AK to SCC. Clinical pointers favouring the diagnosis of an early invasive SCC include the presence of tenderness, induration or a raised shoulder that extends beyond the area of disorganized scaling. Other diagnoses that need to considered, particularly in patients with large confluent areas of erythema and scaling, include discoid lupus erythematosus. The brown colour of lichenoid AK, particularly when these lesions have only minimal scaling, can sometimes cause these to be mistaken for focal areas of lichen planus. When an AK is pigmented, it may resemble a superficial seborrhoeic keratosis, but can usually be distinguished from such lesions by the lack of organization of the hyperkeratosis. Bowen's disease on exposed areas usually has a more irregular contour and a more erythematous base.

Treatment. Management of patients with AK needs to begin with a thorough explanation of the nature, natural history and risks associated with the presence of these lesions. As AKs are a highly sensitive marker of levels of UV exposure capable of inducing premalignant and therefore malignant skin lesions, patients should be educated in the signs and symptoms of skin malignancy and given information in written and pictorial format to assist them in recognizing skin cancers when they occur. Having explained the above and discussed the treatment options, asymptomatic patients may decide that no treatment is required. Other patients may wish to simply use emollients. However, treatment decisions will be influenced by the symptoms the patient experiences, the confidence of the clinical diagnosis and patient anxiety about the potential for skin malignancy. Although AKs are frequently asymptomatic, the skin roughness may cause considerable distress and can be complicated by bleeding and pain because of low-grade skin trauma leading to detachment of the overlying scale. The presence of very large numbers of lesions can make it difficult for the patient or carers to see invasive malignancies at an early stage. The similarities between AK and SCC mean that there is always a small risk, particularly for small lesions less than 3 mm in diameter, that the lesion may not be an AK. Effective management of this risk requires a careful clinical assessment, a therapy plan and clear communication with the patient.

Once a decision that treatment aimed at clearing the AK has been made there are a number of options available [12]. Cryotherapy is effective for patients with a small number of lesions, and apart from hypopigmentation, generally gives excellent cosmetic results. This treatment does require a visit to a clinic and only deals with lesions within the treated area [13,14]. Other destructive therapies, such as curettage and cautery, can be useful for larger lesions and have the advantage of providing a specimen for histological assessment. However, a deep shave biopsy would provide better material for histological examination for evidence of invasion. Alternatively, small hyperkeratotic lesions treated by curettage and cautery with two or more cycles would have adequately treated a small, low-risk, well-differentiated SCC. Where there is significant diagnostic uncertainty, lesions are best excised for pathological examination of the base to be certain that the lesion is not an early invasive SCC.

In many patients, the number of lesions or the rate of development of new lesions makes management more difficult using approaches such as cryotherapy. For patients with extensive clinical lesions, a number of approaches are available that allow treatment of large areas of AK in severely photodamaged skin. Many of these treatments offer the added advantage that they also target early lesions, which means that a more sustained clinical effect may be achieved. These treatments can be subdivided into two broad groups based on their ease of use. The first group includes topical 5-fluorouracil, diclofenac in hyaluron gel and imiquimod which are effective therapies for AK [15–18]. Although 5-fluorouracil is an effective therapy, the marked local inflammation that commonly develops after 2–4 weeks of treatment may make it unacceptable to patients. Once-weekly application for 9 weeks with 5-fluorouracil has been shown, in a small study, to reduce the treatment-induced inflammation while maintaining efficacy [19]. A recent study has surprisingly reported greater efficacy and fewer side effects in patients treated with 0.5% fluorouracil cream compared with 5% fluorouracil cream [20]. The relative effectiveness and tolerability of 5-fluorouracil and diclofenac in hyaluron gel have not as yet been formally addressed in a clinical trial. A number of other approaches, including retinoids, are currently

being investigated as topical therapies for AK [21]. The second group of therapies involves procedures that are normally carried out in the office or clinic setting and includes PDT, dermabrasion and chemical peels. PDT with topical 6-aminolaevulinic acid has been shown to be an effective, well-tolerated therapy for patients with widespread photodamage and AK [22]. A recent comparison of PDT with cryotherapy has established that PDT is as effective as cryotherapy and superior to the latter in patient satisfaction and cosmetic result [23–25]. Dermabrasion and chemical peels have been widely used in some countries for the treatment of AK and severe photodamage. There is some evidence that this approach may provide more long-term, effective prophylaxis against AK [26].

The demonstration that regular sunscreen use reduces the rate of development of new AK indicates that continuing UVR exposure plays an important role in promoting the development of clinical lesions and highlights the importance of ensuring that patients with AK are provided with practical advice on sun-avoidance strategies [27].

Bowen's disease [1,2]

Definition. A form of intraepidermal SCC characterized by a persistent, non-elevated, red, scaly or crusted plaque with a small potential for invasive malignancy. Progressive growth is usual but spontaneous partial regression occurs occasionally.

Aetiology and incidence. Most cases of typical Bowen's disease in white populations are found on the lower legs of elderly women. The distribution in the context of differences between men and women in coverage of the lower leg by clothing and molecular epidemiological evidence of UVR-specific *p*53 mutations in typical Bowen's disease suggests that exposure to solar radiation is an important cause of these lesions [3]. Bowen's disease is uncommon in individuals with pigmented skin and, in these individuals, aetiological factors other than UVR exposure may be important [4].

In the past, arsenic exposure was also important [5]. Although fewer than 5% of a large series of patients with Bowen's disease gave a history of ingestion of arsenic containing medications, arsenic was found in a significantly higher proportion of the skin of patients than in that of the controls [6]. The possible sources of arsenic vary in different localities. Agricultural workers may be exposed to arsenic salts used as a fungicide, weedkiller, sheep dip or pesticide, and they frequently take inadequate precautions against accidental ingestion or inhalation. It may be a hazard in smelting and other industrial processes. In some countries, notably parts of Argentina, Bangladesh and Taiwan, the water supply has been contaminated [7].

Clinical features [8,9]. Although the lesions may occur anywhere on the skin surface or on mucosal surfaces, they are most frequently found on the lower legs of elderly women. The initial

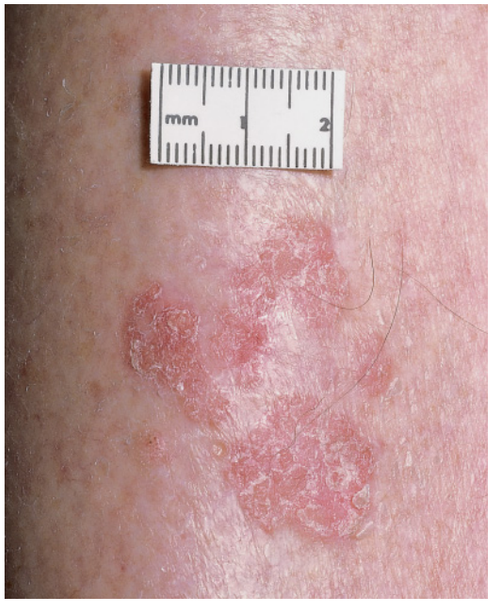

Fig. 52.11 Area of Bowen's disease on lower leg.

Fig. 52.12 Bowen's disease on the lower leg of a patient with a history of arsenic contact.

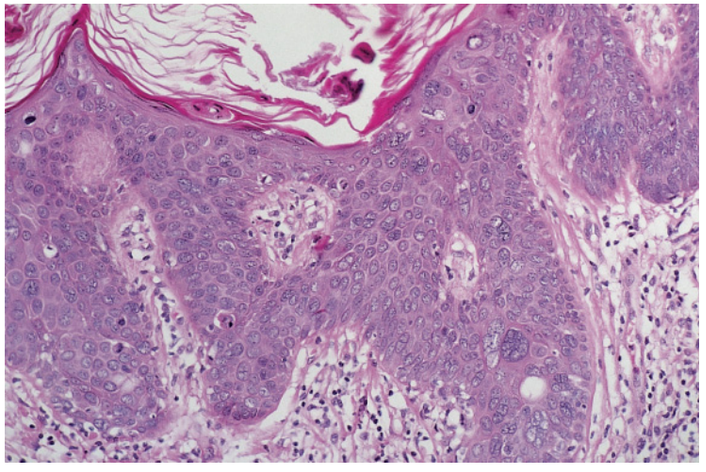

Fig. 52.13 Typical pathological features of Bowen's disease showing loss of polarity of the epidermis and the presence of atypical mitoses and giant cells.

change is a small, red and slightly scaly area, which is symptomless and gradually enlarges in a somewhat irregular fashion. The white or yellowish scale is detached without much difficulty to give a moist, reddened and at times granular surface, but without producing bleeding (Fig. 52.11). The margin is well-demarcated and the lesion slightly raised; the surface is usually flat, but may become hyperkeratotic or crusted. Ulceration is usually a sign of development of invasive carcinoma, and may be delayed for many years after the appearance of the intraepidermal change. Persistent superficial ulceration may, however, be the early clinical evidence of Bowen's disease of palmar skin without invasion. There may be several lesions, either widely spread or sometimes close together and becoming confluent with extension.

When there is good evidence of chronic arsenicalism (Fig. 52.12), either from the history or because of associated changes such as pigmentation or punctate palmoplantar keratoses, the possible evolution of a visceral malignancy, especially of the lung, should be borne in mind. Although studies in the 1950s suggested that there was a significant link between the presence of Bowen's disease on the skin and internal malignancy [10–14], more recent studies using carefully selected control populations have failed to confirm these results [15–19].

Pathology [20]. The normal epidermis is replaced by abnormal keratinocytes, which show disordered differentiation and loss of epithelial polarity. There is variable acanthosis, with increase in the length and thickness of the interpapillary ridges but retention of a distinct dermal–epidermal junction. The atypical cells have hyperchromatic nuclei, often larger than normal, giving an irregular appearance to the epidermis. Giant forms and multinucleate cells are seen and mitotic figures can be frequent (Fig. 52.13). There is a conspicuous disturbance of epidermal organization, and cells keratinize prematurely and lose their intercellular connections. The surface is formed by a thickened, loose, parakeratotic scale. The papillary body shows an inflammatory infiltrate that is often quite dense. In some cases, the proliferating cells may be surrounded by relatively normal epidermal cells to give a 'Borst–Jadassohn' appearance. The epidermis above the ducts of appendages may be normal, as in AK, but the cells of the lesion of Bowen's disease often grow down around the ducts like a collar. The condition can become invasive, and when it does it is always squamous cell in type. Arsenical Bowen's disease is said to be characterized by the presence of numerous vacuolated atypical cells. Electron microscope features have been described [21–24].

Diagnosis. The condition must be distinguished from lichen simplex, psoriasis and other papulosquamous dermatoses. If the diagnosis is uncertain on the first examination, the lack of improvement when steroids are applied is suggestive of Bowen's disease. The superficial ('pagetoid') type of BCC can produce a very similar appearance, but can usually be differentiated by the finely

elevated, 'thread-like' margin. Bowen's disease and superficial BCC can be seen in the same patient. Differentiation from the flat type of solar keratosis may be impossible.

Treatment [24]. There is a wide range of therapeutic options available for the treatment of Bowen's disease including: cryotherapy; curettage and cautery; PDT; laser destruction; excision; 5-fluorouracil cream; imiquimod cream; and radiotherapy. The preferred treatment option is based on a number of factors including size of lesion, site, previous treatment, experience of the various treatments and the number of lesions. Destructive therapies such as curettage and cautery, or cryotherapy are widely used in clinical practice. Comparison of the relative effectiveness of different therapies and regimens is difficult as published studies do not fully control for factors such as site and size and there are inconsistencies between treatment regimens used at different centres. Cryotherapy is an effective therapy with a recurrence rate when used optimally of less than 10% at 12 months. Regimens used include single freeze–thaw cycles, single freeze–thaw cycles repeated on more than one visit and multiple freeze–thaw cycles repeated at a single visit [25–27]. Prolonged single freeze cycles for larger lesions is painful and may be better performed under local anaesthesia. Slow healing can be a problem, particularly for lesions on the lower leg. Curettage and cautery is widely used in practice but poorly studied. Reported recurrence rates are higher than those described with cryotherapy but these findings are difficult to interpret as treatment regimens and equipment are poorly described. Surgical excision is a useful approach, particularly for small lesions in poor healing sites, perineal lesions and digital lesions.

Local cytotoxic agents such as 5-fluorouracil can be applied to good effect. Treatment regimens vary and include once daily application of a 5% cream for 4–8 weeks or more prolonged treatment using a once-weekly application. There is some evidence that occlusion may increase efficacy. Recurrences are common, and may come from extensions of the carcinoma *in situ* around appendage ducts that were unaffected by treatment. Current studies suggest that PDT, using a topical photosensitizer such as aminolaevulinic acid and a laser or non-laser light source may also be an effective method of treatment [24,27–29]. Imiquimod has been used in uncontrolled trials for the treatment of Bowen's disease and in one randomized controlled trial [30] which demonstrated good efficacy but with a suboptimal dosing schedule. Further work is required.

Arsenical keratosis

Definition. A corn-like, punctate keratosis caused by arsenic, characteristically affecting the palms and soles, which may progress to SCC.

Incidence. A considerable proportion of any population exposed to chronic arsenic intoxication develops keratoses, the frequency increasing with the degree of intoxication and its duration [1]. There is great individual variation in tolerance, and it is not

possible, on present data, to construct a precise dose–response curve. The problem is greatest in parts of Bangladesh, West Bengal and Taiwan resulting from well water contamination [2].

Clinical features. The keratoses usually begin on the palms or soles as small areas of hyperkeratosis resembling corns. These enlarge, thicken and increase in number. The fingers, backs of the hands and more proximal parts of the extremities may be involved. Induration, inflammation and ulceration occur when the lesion becomes malignant. There may be areas of Bowen's disease in other sites and multiple BCCs, mainly of the trunk, may occur in association.

Pathology. A range of changes may be seen from a benign-looking hyperplasia or dysplasia, through mild or moderate atypia, to frank Bowen's disease [3–5]. There is no microscopic feature that allows a positive diagnosis of arsenic as the cause. In most lesions there is no elastotic degeneration of the upper dermis.

Diagnosis. The palmar lesions have to be differentiated from the various types of punctate keratosis, such as disseminated punctate keratoderma (see Chapter 19), which usually appears in early life, and Darier's disease and lichen planus, which usually have characteristic lesions elsewhere. Plantar warts differ in being papillomatous.

Treatment. The multiplicity of the keratoses makes treatment difficult. Where it is necessary, the use of a keratolytic ointment and trimming down of the surface is helpful. Two recent case reports suggest that oral acetretin may be beneficial [6]. All affected patients should be examined periodically for evidence of malignant change and for signs of visceral malignancy.

Disseminated superficial 'actinic' porokeratosis

This disorder was first recognized in Texas [1,2], and is common in Australia [3]. It appears on sun-exposed areas of white-skinned individuals, becomes more prominent in summer and may improve in winter. New lesions have been provoked by exposure to a UV sun lamp [4]. The tendency to develop these lesions is inherited as an autosomal dominant [4]. The preponderance of females in reported cases has been attributed to their greater tendency to seek help for skin problems. The average age at which Texan patients first notice it is about 40 years, and its frequency in members of affected families increases with age. There are UK patients with multiple lesions who have never lived abroad, and the true role of the sun in the aetiology of the condition has been questioned, as has its degree of premalignant potential [5,6]. Genetic studies have mapped a gene, *DSAP1*, for this condition to chromosome 12q23.2–24.1 and a Chinese family with disseminated superficial 'actinic' porokeratosis (DSAP) has recently been reported with a second affected locus, *DSAP2*, on chromosome 15q25.1–26.1 [7].

Clinical features [2]. The lesion begins as a 1–3 mm conical papule, brownish red or brown in colour, and usually around a follicle containing a keratotic plug. It expands and a sharp, slightly raised, keratotic ring, a fraction of a millimetre thick, develops and spreads out to a diameter of 10 mm or more. The skin within the ring is somewhat atrophic and mildly reddened or hyperpigmented, but a hypopigmented ring may be seen just inside the ridge. The ridge itself is sometimes darkly pigmented. The central thickening usually disappears, but it may persist with an attached scale, follicular plug or central dell. Sweating is absent within the lesions. Sun exposure may cause them to itch. In sunny areas, lesions may be present in very large numbers and may change from a circular to a polycyclic outline. In less sunny climates, such as the UK, patients have fewer lesions, which tend to remain circular (Fig. 52.14). In a few cases, the centre of the area has become considerably inflamed and covered by thick hyperkeratosis, or has even ulcerated and crusted. The disorder affects areas exposed to sunlight, appearing mainly on the distal extremities and arising more frequently on the lower legs in women than men. The malar regions and the cheeks may be affected. It has not been seen on areas habitually covered by clothes, or on the palms or soles.

Fig. 52.14 Disseminated superficial actinic porokeratosis on the lower legs.

Pathology [8]. There is no microscopic feature that separates this disorder from porokeratosis of Mibelli (see Chapter 19), and both have been explained as the result of localized clones of abnormal epidermal cells [8], an idea supported by the successful autotransplantation of the disseminated superficial variety [4].

The distinctive pathological feature of porokeratosis is the cornoid lamella at the margin. This is a narrow column of altered or parakeratotic keratin, seated in a slight depression in the epidermis and directed obliquely inwards in some cases. It may involve the ostia of follicles and sweat ducts. The granular layer of the indented epidermis is usually missing and there may be dyskeratotic cells. The epidermis enclosed by the ridge is usually thinned, the interpapillary ridges and dermal papillae may be flattened, and the basal cells may show liquefaction degeneration. In addition to solar elastosis, decrease in collagen and telangiectasia, the upper dermis may have a non-specific inflammatory infiltrate with vascular proliferation, oedema and fibrosis. Malignant change has not been recorded.

Diagnosis. Porokeratosis is distinguished from other dermatoses by its sharp margin and history of outward expansion. The rim of DSAP is very much smaller than in Mibelli's porokeratosis and never contains a cleft. The onset of Mibelli's porokeratosis is often in childhood, and the lesions are usually solitary or few in number and do not necessarily affect exposed parts. Where the central keratosis and inflammation are prominent, the disseminated superficial variety may be mistaken for solar keratosis if the marginal ridge is not noticed.

Treatment. Lesions respond satisfactorily to cryotherapy with liquid nitrogen, but new lesions tend to develop [2,3].

Cutaneous horn [1]

This is a clinical diagnosis. Horny plugs or outgrowths may be caused by various epidermal changes, such as epidermal naevus, virus wart, molluscum contagiosum, keratoacanthoma, seborrhoeic keratosis, or marsupialized trichilemmal or epidermoid cyst (Fig. 52.15). In most of these cases, the primary diagnosis is suggested by the appearance and clinical course and, in most, the horn has a friable quality.

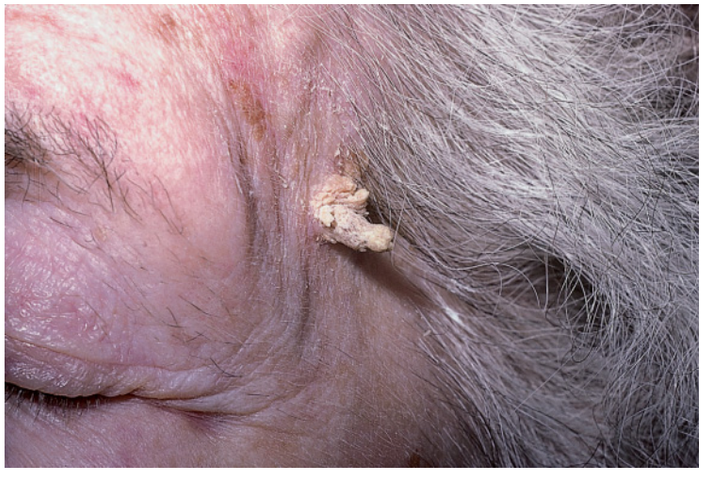

Fig. 52.15 Typical cutaneous horn. Underlying this lesion, a carcinoma *in situ* was identified after biopsy.

Clinical features. Clinical examination shows a hard, yellowish brown horn, often curved and having circumferential ridges, which is surrounded either by normal-looking epidermis or by an acanthotic collarette. Recurrent injury may cause the base to be inflamed; a combination of inflammation and induration beneath the horn is suggestive of malignant transformation. The lesions are most common on the exposed areas—particularly the upper part of the face and the ears. They are commonly single, but may be multiple; it is usual to find some more typical solar keratosis or other evidence of solar damage. Nodular AKs, which are largely confined to the dorsum of the hand and forearm and in which the histology may show an almost pseudoepitheliomatous picture, occupy a position midway between cutaneous horns and the more usual flat AKs.

Pathology. The gradual continuing development from relatively normal-looking skin to a hard keratotic protrusion resembling an animal horn in miniature is the result of dysplastic epidermal changes similar to those in a solar keratosis. Histologically, there is usually no atypicality or loss of polarity of the epidermal cells, but the granular layer is deficient or absent. In long-established lesions there may be budding from the basal layer, indicating early development of an SCC.

Erythroplasia of Queyrat [1–3]

This condition is described with the genital disorders (see Chapter 71). The histological appearance and natural history suggest that the lesion is Bowen's disease of the mucosa of the penis. However, its prevalence only in the uncircumcised indicates a different and locally acting cause.

Bowenoid papulosis of the genitalia [1]

This entity is fully discussed in Chapter 71. Bowenoid papulosis (BP) is characterized clinically by lesions with a benign appearance which show histological features suggestive of squamous cell neoplasia. Most of the lesions either regress spontaneously over time or undergo resolution after local treatment. BP is now generally viewed as a localized form of *in situ* SCC which develops as a consequence of infection by high-risk human papillomavirus, especially HPV 16 and HPV 18 (reviewed in [2]). In the older literature, cases which would today be classified as BP have been reported as Bowen's disease [3–5]. Treatment of BP traditionally has included locally destructive therapies such as excisional surgery, electrocoagulation, cryotherapy and 5-fluorouracil. A number of groups have recently reported successful clearance of Bowenoid papulosis using imiquimod cream 5% [6,7].

Intraepidermal carcinoma of the eyelid margin

This condition (see Chapter 67), which may resemble a banal warty lesion in its early stages, represented about 6% of all eyelid malignancies in one series [1]. Occupational exposure to oils and grease may be important. The dysplastic changes seen on biopsy may not be sufficiently severe to warn of the dangers of inadequate treatment. One clue is the way the intraepidermal carcinoma invades the deepest ciliary adnexae, causing loss of eyelashes and nodularity of the margin on clinical examination. SCC may supervene and complete excision is essential.

Leukokeratosis of the lips

Synonym

- Actinic cheilitis [1]

Actinic cheilitis is a pathologic condition which affects predominately the lower lip and is caused by chronic and excessive exposure of the lips to solar radiation. This disorder is described in more detail in Chapter 69. Patients are frequently male outdoor workers who usually give a history of recurrent sunburn of the lips. The lower lip often shows persistent dry scaling, a tendency to fissure and atrophic changes beneath and around the keratosis. The use of lipstick by women may be protective [2], especially in preventing dehydration. Actinic cheilitis is relatively common in renal transplant recipients [3]. A number of studies suggest that progression to SCC may be more common than previously recognized. In one series, 11 of 65 cases progressed to SCC [4]. Careful follow-up is important as it is also recognized that SCC of the lip metastasize four times as frequently as cutaneous ones [5].

Treatment. A number of treatments have been described including surgical excision, cryotherapy, carbon dioxide laser ablation, electrosurgery and the topical use of 5-fluorouracil. Successful treatment has also been described with newer modalities including PDT [6].

Post-ionizing radiation keratoses

These may occur in an area of scarring following radiotherapy or excessive fluoroscopy where there is obvious dermal damage. They may also be seen in radiologists, surgeons, dentists and others who have exposed their skin to frequent small doses of X-rays and where the dermis is less grossly changed, although such cases are now rare. The epidermal changes are similar to solar keratosis. Histologically, the dermis shows a much more extensive replacement of collagen by scar and elastotic material, obliterative changes in the vessels and, at times, the presence of abnormally large and irregular fibroblasts (Fig. 52.16).

Tar keratoses [1–4]

These are now very rare entities. In the past, they were seen in workers with tar and pitch. There were small keratotic plaques, not unlike plane warts, or flat seborrhoeic keratoses on the face and hands, which have the microscopic features of benign acanthomas. These usually disappeared when the exposure ceased. There were also lesions resembling solar keratoses, which persisted and a few became malignant. Other lesions with the appearance of keratoacanthomas were seen. Their course was usually more prolonged and, particularly on the scrotum, a relatively high proportion became malignant.

Benign epidermal tumours

Seborrhoeic keratosis

Synonyms
- Seborrhoeic wart
- Senile wart
- Basal cell papilloma

Definition. A benign tumour, frequently pigmented, more common in the elderly and composed of epidermal keratinocytes.

Aetiology and incidence. Seborrhoeic keratoses (SKs) are common skin lesions that occur with increasing age; usually appear in the fifth decade in a temperate climate but may develop earlier in tropical regions. There is little tendency to spontaneous disappearance and new lesions may continue to appear for many years. Males and females are equally affected.

Although extremely common, the epidemiology is not well characterized in most populations. In studies from Australia these lesions were identified in 30% of subjects under the age of 30 years increasing to 100% of subjects older than 50 years [1]. The overall prevalence in a UK population was slightly lower with lesions identified in approximately 75% of subjects over the age of 70 years [2]. The total number and size of SKs has also been shown to increase with age. Most lesions are found on the trunk with a smaller number on the limbs, head and neck; in the Australian population no correlation was found with traditional markers of skin sensitivity to ultraviolet radiation. The rapid development of large numbers of SKs can occur in patients with an inflammatory dermatosis [3] or in association with underlying malignancies where it is known as the sign of Leser–Trélat [4]. The neoplasms most commonly associated with this skin manifestation include stomach and colon cancer and in some patients it may be associated with the development of acanthosis nigricans. It has been recognized for some time that although SK and epidermal naevi have different natural histories they share some clinical and histological characteristics, including acanthosis, papillomatosis, and variable degrees of hyperkeratosis and hyperpigmentation. These similarities and the identification of mutations in the fibroblast growth factor 3 receptor in epidermal naevi [5] triggered analysis of SKs for *FGFR3* mutations. Mutations were identified in 39% of SKs and the genetic changes identified were identical to those found in patients with a rare dwarfing chondrodysplasia and thanatophoric dysplasia, which are both also associated with acanthosis nigricans [6]. More recently, additional molecular insights into SK aetiology have emerged with the identification of activating *PIK3CA* mutations in 16% of SKs examined [7].

Clinical features. Seborrhoeic keratoses occur on any body site. They are usually asymptomatic but may be itchy. They are most frequent on the face and the upper trunk. The first evidence is slight hyperpigmentation. On the hand and face, seborrhoeic keratoses may remain superficial for a long period, and can be mistaken for melanocytic lesions. It may be difficult to distinguish superficial seborrhoeic keratoses from lentigo maligna and pigmented AK. More florid examples may be pedunculated or acanthotic, smooth-surfaced, domed and heavily pigmented, but in contrast to melanocytic naevi do not reflect light and usually have plugged follicular orifices on the surface, giving an almost cerebriform appearance. Most seborrhoeic keratoses have fewer hairs than the skin they arise from. The most common appearance is that of a very superficial verrucous plaque which appears to be stuck on the epidermis, varying from dirty yellow to black in colour and having loosely adherent, greasy keratin on the surface (Fig. 52.17). The shape is round or oval and multiple lesions may

Fig. 52.18 Histology of classic seborrhoeic keratosis showing hyperkeratotic surface and numerous horn cysts.

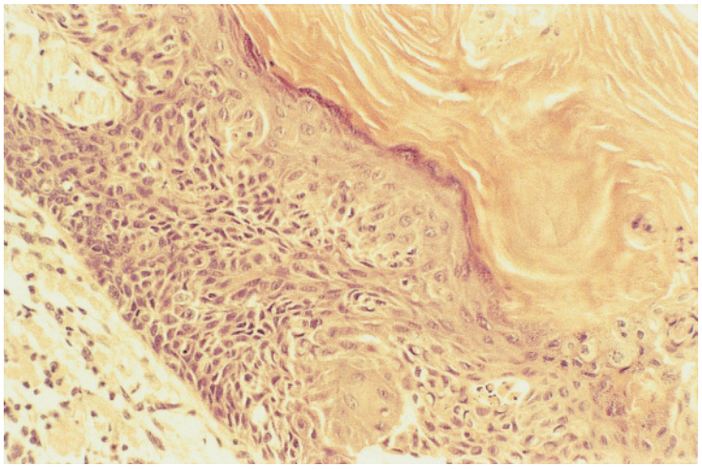

Fig. 52.19 Histology of irritated seborrhoeic keratosis. The squamous eddies are clearly seen in this illustration.

be aligned in the direction of the skin folds. The size varies from 1 mm to several centimetres. The smallest lesions occur around follicular orifices, particularly on the trunk. On the eyelids and major flexures, SKs may be pedunculated and less keratotic. Irritation or infection causes swelling, sometimes bleeding, oozing and crusting, and a deepening of the colour because of inflammation.

Pathology [8]. The essential change is an accumulation of normal keratinocytes between the basal layer and the keratinizing surface of the epidermis. Melanocytes may proliferate among these immature keratinocytes and transfer melanin to them. The dermal papillae may be elongated. Focal keratinization may occur within the mass of immature cells to produce horn cysts, which enlarge, may coalesce and can be carried to the surface by the tide of epidermal cells. If the formation and discharge of horn cysts is excessive, a verrucous surface will be formed. Marked papillomatosis will also cause an irregular 'church steeple' outer border which retains keratin. If, in contrast, the main mass of the lesion is composed of immature cells, the surface will be smooth and rounded, and the melanocyte population and degree of pigmentation will vary, so that the lesions may be deeply pigmented. The parenchymal cells are rather small and polygonal, possessing tonofibrils and intercellular bridges, and they are arranged in an orderly fashion.

The most common pathological type is the solid variant, in which a mass of immature keratinocytes is seen mainly above the level of the surrounding epidermis (Fig. 52.18). Occasional cystic areas containing fragments of stratum corneum are seen at these sites. A rarer variant is the hyperkeratotic variety, which may be clinically mistaken for an AK. The reticular form is a third variant, composed of strands of keratinocytes; this type is frequently seen as a flat lesion on the face.

If an SK becomes irritated, or develops a pattern of apparently inverted growth, frequently in association with a hair follicle opening, the pathological differential diagnosis may include an early invasive SCC. An irritated SK shows focal areas of whorls of keratinocytes in so-called squamous eddies, but mitotic figures are rare, and the base of the lesion shows a clear separation from dermal tissue, with no single-cell invasion (Fig. 52.19).

Diagnosis. The superficial type of SK has to be distinguished from simple and malignant lentigo (see Chapter 54) and from AK, especially on the face. The patterned fine fissures on the surface may be helpful. The pigmented domed variety may closely resemble a melanocytic naevus, but the surface is less lustrous and the follicular orifices are plugged. An inflamed keratosis may be confused with a malignant melanoma. If the lesion is treated with a topical antibiotic and occluded for 3–5 days the diagnosis may become obvious, but if clinical doubt persists an excision biopsy and pathological examination is indicated. Pigmented BCCs may also have to be considered in the differential diagnosis. They are usually rather irregular with a rolled edge, a thin shiny epidermis with telangiectases and a depressed or ulcerated centre.

Treatment. Removal with a small sharp curette leaves a flat surface that becomes covered by normal epidermis in a week. Cautery or diathermy should be used as little as possible to avoid scarring. Satisfactory results can be obtained by freezing briefly, a technique especially suitable for large superficial lesions, or by carefully painting the surface with pure trichloracetic acid and repeating if the full thickness is not removed on the first occasion. Seborrhoeic keratoses tend to recur, and it is often wise to encourage patients to accept them rather than to keep returning for further treatment.

Melanoacanthoma

This term has been used for a very rare lesion, originally described by Bloch as 'non-naevoid melanoepithelioma, type 1', and has been considered to be a benign neoplasm composed of epidermal keratinocytes and large dendritic melanocytes [9]. The current general view is that this is not a discrete entity. Some deeply pigmented acanthotic seborrhoeic keratoses contain, dispersed among the parenchymal cells, numerous dendritic melanocytes, which

are demonstrable by the dopa technique [10]. Normally, they transfer melanin to the surrounding immature keratinocytes. However, if irritation or inflammation caused the parenchymal cells to become more mature, the transfer of melanin would be impeded and pigment might be retained in the melanocytes, producing a microscopic appearance similar to that described as melanoacanthoma.

Stucco keratosis [11,12]

This title has been given to small, rough, whitish, keratotic plaques that are easily lifted off the skin with a fingernail and come away without causing bleeding. They are situated principally on the extremities, especially the ankle region, and occur in middle-aged or elderly persons. They have the same stuck-on appearance of SKs and a similar microscopic architecture. Basaloid cells and horn cysts are not seen and the histology is more that of a regular spiky papillomatosis, with loose lamellated hyperkeratosis capping the epidermis. If treatment is called for, curettage or cryotherapy are effective.

Dermatosis papulosa nigra

Definition. A pigmented papular eruption of the face and neck caused by a naevoid developmental defect of the pilosebaceous follicles, with histology resembling seborrhoeic keratoses. The condition is most common in black races.

Aetiology [1]. This lesion is probably genetically determined. The incidence in black people rises from about 5% in the first decade to over 40% by the third, and is rather higher in females than males.

Clinical features [1–3]. The individual lesions are black or dark brown, flattened or cupuliform papules 1–5 mm in diameter. They are rare under the age of 7 years, after which they increase steadily in frequency, number and size. They are most numerous in the malar regions and on the forehead. They are rare on the lower parts of the face and the chin, but in a few individuals may be found on the neck, chest and back [2].

Pathology [1,4]. The lesions, which are naevoid developmental defects of the pilosebaceous follicles, show irregular acanthosis and hyperkeratosis, and somewhat resemble seborrhoeic keratoses.

Treatment. Treatment is seldom requested. Removal with the diathermy or cautery is effective.

Skin tags

Synonyms
- Soft warts
- Achrochordon

Definition. A common, benign lesion composed of loose fibrous tissue and occurring mainly on the neck and major flexures as a small, soft, pedunculated protrusion.

Incidence and aetiology. These lesions are very common, particularly in women at the menopause or later. They are frequently found together with seborrhoeic keratoses.

Clinical features. The lesions are pedunculated and may have a long stalk. They vary in size and are about 2 mm in diameter on average. They are round, soft and inelastic. The colour may be unchanged, but they are frequently hyperpigmented. The most common site is on the sides of the neck, where they may be mixed with typical small, sessile, seborrhoeic keratoses. When more profuse, they can extend on to the face or down to the back and chest. Similar lesions may be found in and around the axillae and groins.

Pathology. The protruding mass is connected to the skin by a narrow pedicle. The bulk of the lesion is loose fibrous tissue, similar to that of the papillary dermis. The epidermis is thin, and the basal cell layer is flat and often hyperpigmented. Melanocytic proliferation and naevus cells are not usually seen and the majority of such lesions probably come within the seborrhoeic keratosis spectrum. However, there is an overlap with melanocytic naevi and neurofibromas. Some skin tags may be the last remnants of a pre-existing melanocytic naevus.

Diagnosis. The lesions are unmistakable. They are smaller than the average pedunculated melanocytic naevus or the lesions of neurofibromatosis.

Treatment. Both cautery and cryotherapy with liquid nitrogen are effective.

Haber's syndrome

Definition. A familial condition characterized by a persistent rosacea-like eruption, associated in some cases with keratotic plaques on the trunk and limbs.

Incidence. A family in which five members were affected was originally described [1]. Another case, with 15 affected relatives, has been described from Japan [2]. The rosacea-like eruption appears in childhood, and the keratotic lesions somewhat later. The mode of inheritance seems to be a simple autosomal dominant.

Clinical features. The cheeks, nose, forehead and chin are permanently flushed. The skin surface shows a combination of erythema and telangiectasia, prominent follicles, comedones, small papules, some of which are scaly, and tiny atrophic pitted areas. There is little fluctuation in the erythema, although sunlight may aggravate it. The warty lesions occur mainly on the trunk and thighs and are static, scaly or keratotic, flat and non-indurated plaques.

Pathology. The facial eruption shows perivascular inflammation leading to fibrosis, acanthosis and parakeratosis of the epidermis, distortion of pilosebaceous complexes with dilated follicular orifices, and proliferation of immature glands and basal cell strands. The warty lesions are produced by papillomatosis, acanthosis in the interpapillary ridges and dyskeratosis with areas of pale-staining cells giving a parakeratotic stratum corneum. Mitotic figures are present, but there is no evidence of malignancy.

Treatment. The facial eruption was controlled in the young patient in the first family and in the Japanese patients by steroid creams locally. The warty lesions respond to radiotherapy. Simple destructive measures are also effective.

Clear cell acanthoma [1–3]

Synonyms
- Degos' acanthoma
- Acanthome a 'cellules claires'

Definition. A scaly plaque or nodule that has a characteristic accumulation of clear glycogen-containing cells in the epidermis.

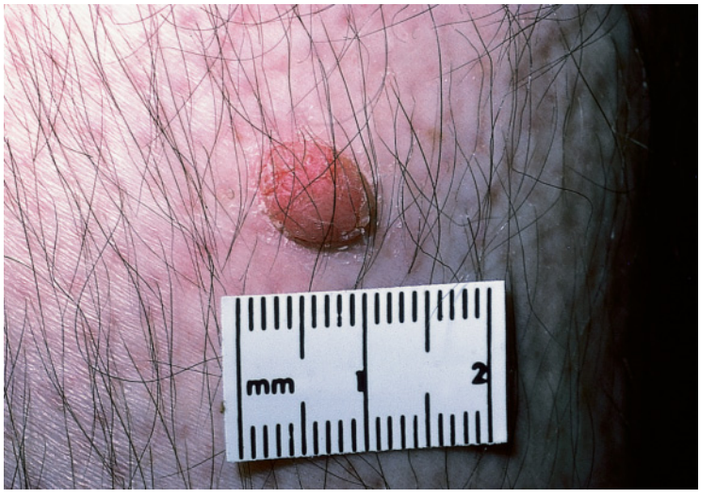

Fig. 52.20 Clear cell acanthoma.

Incidence and aetiology. Clear cell acanthoma is a relatively uncommon condition of adults. The sexes are equally affected [3]. The cause is unknown [4].

Clinical features (Fig. 52.20) [1,3,5]. The lesion is usually solitary. It is a slightly elevated to dome-shaped plaque or nodule with an abrupt margin and a wafer-like scale adherent at the periphery, which leaves a moist or bleeding surface when removed. The colour varies from pink to brown, but is most characteristically red with vascular puncta and it blanches on diascopy. It varies from 3 to 20 mm in diameter, and occurs most commonly on the lower limbs. The duration may be of many years, and there are usually no symptoms. The diagnosis can be suspected on the clinical evidence. The lesion may be mistaken for a histiocytoma, seborrhoeic keratosis or pyogenic granuloma.

Pathology [1,6,7]. The epidermis is thickened and papillomatous with sharply demarcated areas of light-coloured cells, which contrast with the normal basal cells below and Malpighian cells around them (Fig. 52.21). The cytoplasm of the clear cells contains an abundance of glycogen, which on electron microscopy is seen to displace tonofibrils [7,8]. The cells do not have the enzymes characteristic of eccrine sweat glands. There is intercellular oedema and an infiltrate often containing many polymorphonuclear leukocytes. The papillary body is oedematous and the superficial capillaries and veins are increased in number. There may be syringomatous sweat gland elements and evidence of sebaceous differentiation beneath the lesion [9].

Treatment. Excision is often needed to confirm the diagnosis [1].

Keratoacanthoma

Synonym
- Molluscum sebaceum

Definition. A rapidly evolving tumour of the skin, composed of keratinizing squamous cells originating in pilosebaceous follicles and resolving spontaneously if untreated.

Incidence. Keratoacanthoma is relatively common, and in white races tends to occur with about one-third of the frequency of SCC, whatever the environmental UV levels [1]. It is uncommon in dark-skinned races and in the Japanese [2]. Males are affected about three times more often than females. The adjusted age distribution shows that it is most frequent in middle-life and does not increase in incidence in old age, unlike BCC and SCC.

Aetiology. The epidemiological data suggest that the incidence of keratocanthoma is related to sun exposure, and the localization of the tumours mainly on the head and upper limb supports this. Contact with tar and mineral oil has also been shown to cause an increased incidence [3,4] and very similar lesions have been produced in animals by painting with carcinogenic hydrocarbons. In some cases, the lesion follows injury to the skin, which suggests that infection may play a part in its origin, a view supported by the occurrence of multiple keratoacanthomas in skin grafts of patients with the tumour in the recipient site [5], the donor site [6] or both [7]. Proof of a viral cause is lacking. Cases are reported of keratoacanthoma associated with carcinoma of the larynx [8], multiple internal malignancy [9], leukaemia [10], deficient cell-mediated immunity [11] and in transplant recipients [12]. Most recently, the solid tumour multikinase inhibitor Sorafenib has been reported to lead to the development of keratoacanthomas, which resolved or stopped developing when therapy was stopped; this may give us a new insight into the aetiology of the condition [13,14].

Clinical features [1,15,16]. The first evidence of keratoacanthoma is a firm, rounded, flesh-coloured or reddish papule, which may resemble molluscum contagiosum or, if keratotic, a virus wart. The patient rarely seeks advice at this stage. There is then a rapid growth phase and in a few weeks it may become 10–20 mm across. There is no infiltration at the base. The epidermis over the nodule is smooth and shiny; the lesion is skin-coloured to red with telangiectases just beneath the surface. The centre contains a horny plug or is covered by a crust which conceals a keratin-filled crater (Fig. 52.22). As the lesion matures, the accumulating keratin expands the outermost part making the edge overhang the base somewhat, but the radial symmetry is usually well preserved. The keratin may project like a horn or it may soften and break down. Spontaneous resolution is achieved by the epidermal covering receding towards the base and the horny core being shed. The base is revealed as irregular and puckered and the edge may remain as soft but thickened epidermis, either as a continuous rim or a series of tags. The process of spontaneous healing usually takes about 3 months.

A small proportion of keratoacanthomas grow to much larger dimensions—5 cm or more in diameter being not exceptional on the forearm. One lesion on the chest was more than 15 cm in diameter [17]. In some cases, the maximum size may be reached in a month or two; others may enlarge over many months. After growth ceases, involution may not occur for some months or may occur at part of the periphery while growth continues elsewhere. There may be recurrences after curettage or excision, more frequently in lesions on the lips and fingers and when treatment is carried out in the early stages [18]. Recurrence may happen after spontaneous resolution [19].

The most frequently affected area is the central part of the face, that is the nose, cheeks, eyelids and lips. The dorsum of the hand, wrist and forearm are commonly affected; the thigh, chest, shoulder and scalp less so; and the anogenital area uncommonly except in those exposed to occupational hazards. Lesions have occurred subungually [20,21], in the vermilion of the lips [18] and on the buccal mucosa.

In most cases, the tumour presents as a solitary lesion. Multiple or recurrent tumours are more likely to be present in several circumstances. Recurrent lesions occur in patients who have been exposed to pitch or tar [3] and in rare cases as a familial disorder, although there are reasons to keep this Ferguson-Smith type as a separate entity. There are a few cases of eruptive keratoacanthoma recorded. Multiple lesions have occurred with defective cell-

(a) (b)

Fig. 52.22 Typical keratoacanthomas, on the face, showing raised margin and central keratin-filled crater.

mediated immunity and also as part of Torre's syndrome, with multiple internal malignancies [9] and with sebaceous adenomas (see Chapter 53).

Pathology. The distinctive features are best seen when the fixed specimen is being cut before processing or in sections under low magnification. The tumour has a symmetrical, more-or-less globular form and is situated in the dermis, usually extending down no deeper than the sweat glands, although deep penetration has occasionally been recorded. The epidermis around the tumour is normal or slightly acanthotic, but becomes thinned as it rises over the tumour. A narrow spur of connective tissue separates the epidermis from the proliferating squamous cells, except where the two connect at the mouth of the keratin-filled crypt. Serial sections of an early lesion have shown connection of the masses of squamous cells with the upper part of a hyperplastic follicle [22].

The histological features vary with the stage of evolution. The early lesion is composed of a mass of rapidly multiplying squamous cells. These are large and rather pale with vesicular nuclei, prominent nucleoli and frequent mitoses. Hyperchromatic cells, atypical mitotic figures, individual cell keratinization and other evidence of loss of polarity may be found. The marginal cells invade the surrounding dermis aggressively, while those more centrally placed keratinize to form a branched core of keratin that communicates with the surface. The stroma is vascular and infiltrated with round cells and histiocytes.

Resolution occurs through maturation of the hyperplastic masses. The accumulating keratin dilates the central pore, the epidermal lips recede from the centre and the lesion opens like a flower bud. When the horn is finally shed, the irregular epithelium beneath it replicates the scalloped outline of the active mass. The cells take on the morphology of epidermis, and a scar is formed, which is depressed and may have papillomatous tags at the margin, the remnants of the epidermal lip. Older lesions frequently show clusters of leukocyte microabscesses at the base. Thus, the pathological features vary with the stage of evolution of the keratoacanthoma and, if an adequate specimen is not submitted, it may be impossible for the reporting pathologist to confidently rule out early invasive SCC. Keratoacanthomas may also rarely progress to SCC. In one case [23], it may have been precipitated by treatment with oral methotrexate for a recurrence. The conjunction of two independent lesions in sun-damaged skin may account for the finding of a BCC in the scar of keratoacanthoma in this and other cases.

Experimentally produced lesions differ in their form, depending on whether the hair follicles are in anagen or telogen when the proliferation begins [24,25]. Virus-like particles have been seen under electron microscopy [26].

Diagnosis. The most important differential diagnosis is to distinguish keratoacanthoma from SCC. In most cases, the more rapid evolution to a relatively large size, the regular crateriform shape and keratotic plug, the undamaged surrounding skin and the younger age of onset make a distinction relatively easy for the clinician. Spontaneous healing adds support to the diagnosis of keratoacanthoma. The problem is made more difficult in sunny areas where actinic damage and SCC are more common, and the most important single point is the history of rapid growth. The differential diagnosis includes cutaneous horn and hypertrophic AK, viral wart, molluscum contagiosum, pseudoepitheliomatous hyperplasia and granulomas of various types. Secondary deposits from non-cutaneous malignancies can also occasionally mimic keratoacanthoma.

Treatment. The end result of leaving the tumour to regress is usually a rather unsightly scar. Curettage and coagulation of the base, or excision and suture, produce a much more acceptable result. Excision is desirable if the diagnosis is in doubt, because curetted specimens yield poor sections. Radiotherapy shortens the course and improves the scar, and can be used in patients who

refuse surgery. A total of 2000 cGy in two closely spaced doses of adequate penetration can be given.

The application of 5-fluorouracil ointment twice daily may reduce the time taken for natural resolution and diminish scarring [27]. If there is real doubt about the diagnosis, surgical removal or radiotherapy should be carried out as for SCC, and the patient followed up.

Generalized eruptive keratoacanthoma [9,28]

A small number of cases of widely disseminated lesions, some of them typical keratoacanthomas, have been reported. Both sexes have been affected. The primary lesions are flesh-coloured to red, dome-shaped follicular papules, 1–3 mm in size and affecting particularly the face (where they may be confluent), the trunk and the roots of the limbs. Itching is a prominent symptom, and ectropion and narrowing of the mouth may be produced by the keratotic facial change. Scattered among the papules are larger, more typical keratoacanthomas, which resolve spontaneously. The palms and soles are spared, but the oral and laryngeal epithelium can be involved.

Pathology. Histological examination shows the papules to consist of a dilated and plugged follicle duct with acanthotic follicular epidermis around it; the mucosal lesions are irregular acanthosis; and the nodules are keratoacanthomas, but with no inflammatory changes.

Management. The nodular lesions heal in a few months. The papules are not influenced by cytotoxic drugs, but one case responded to topical retinol [25].

Pseudoepitheliomatous hyperplasia [1]

Aetiology. Epidermal hyperplasia is an early and essential feature in the healing of any breach of the skin surface. Ordinarily, this is coordinated with the repair of the dermis, and epidermal downgrowths eventually dissipate [2]. When the dermis is diseased, however, a persistent and much more extensive hyperplasia may occur. This is seen, for instance, at the margin of chronic leg ulcers, over chronic cutaneous granulomas such as lupus vulgaris, tuberculosis verrucosa cutis, insect-bite granulomas and halogen granulomas and, in a rather unusual form, over a small proportion of histiocytomas. It is also a component of some cases of lupus erythematosus and of lichen planus of the hypertrophic type. It may occur in association with tumours, particularly granular cell myoblastoma and malignant melanoma.

Clinical features. The appearance will vary with the primary disorder. Granulomas may be covered by a thickened, warty or heaped-up epidermis, perhaps best seen in chromomycosis. In chronic ulcers, the margin is heaped-up, often giving the appearance of being rolled, and has an irregular surface. The edge is not usually indurated to the extent that occurs in SCC. It is characteristic that the hyperplasia will subside as the ulcer is treated and heals. It is wise to remember that an ulcer whose margin has been affected by pseudoepitheliomatous hyperplasia in the past may eventually be the cause of metastasizing SCC.

Pathology. The nature of the primary disorder modifies the picture greatly. In simple ulcers and inflammatory lesions—by far the most common causes—there is disturbance of the upper part of the dermis, often with young fibroblasts and a rather myxoma-

tous connective tissue stroma replacing the normal dermal collagen. Columns of prickle cells grow down into the dermis in an irregular fashion. In some areas, there is maturation of the central parts of the columns to produce horny pearls. The general appearance is that of invasive proliferation of the epithelium. The individual cells, however, do not show the atypical features suggestive of malignancy. The columns may be penetrated by inflammatory cells, a feature that is not seen in malignant proliferations. In most instances, a weighing of dermal against epidermal changes suggests that the former are the cause and not the consequence of the latter.

Diagnosis. A good-sized biopsy from a representative area of the lesion is essential.

Cysts

Nomenclature. The term *sebaceous cyst* should be used only to describe steatocystoma multiplex, which contains oily sebum. Histological examination of all other cysts reveals the lining wall to be keratinous in nature. Keratinous cysts can be divided into two types, those with a lining identical in its stratification with epidermis and pilosebaceous duct, and those with a lining resembling the external root sheath of the follicle. The latter variety is less common, and is often familial, multiple and largely confined to the scalp [1]. This type is the trichilemmal cyst [2].

The cysts found in Gardner's syndrome are epidermoid in type [3] and are characterized by their appearance in childhood. There is no genetic overlap between trichilemmal cysts, cysts of Gardner's syndrome or steatocystoma multiplex, although all have an autosomal dominant mode of inheritance.

Histogenesis. Steatocystoma multiplex is most likely to be a genetically determined failure of canalization between the sebaceous lobules and the follicular pore. The common epidermoid cyst is the result of squamous metaplasia in a damaged sebaceous gland. Milia may result from either keratinization within the sebaceous anagen ('collars') of vellus hair follicles or cystic dilatation of an interrupted sweat duct. Trichilemmal cysts may be caused by survival of fragmented segments of the hair root during catagen.

The following cysts are described in this section or elsewhere in the book:

1 Keratinous cysts, both epidermoid and trichilemmal
2 Dermoid (see Chapters 69 and 71)
3 Milium
4 Steatocystoma multiplex
5 Eccrine hidrocystoma (see Chapter 53)
6 Apocrine hidrocystoma (see Chapter 53)
7 Bartholin's cyst (see Chapter 71)
8 Myxoid cyst of the skin (see Chapter 62)
9 Branchial cyst (see Chapter 18).

Epidermoid cyst

Synonym
- Epithelial cyst (sebaceous cyst is a misnomer)

Definition. A cyst containing keratin and its breakdown products, surrounded by an epidermoid wall.

Incidence and aetiology. Epidermoid cysts are common, most frequently affecting young and middle-aged adults. They are rare in childhood. Many are the result of inflammation around a pilosebaceous follicle, and are frequently seen following the more severe lesions of acne vulgaris. Some may result from deep implantation of a fragment of epidermis by a blunt penetrating injury. Those that occur as a part of Gardner's syndrome and of the NBCCS are probably caused by a developmental defect.

Clinical features. An epidermoid cyst is situated in the dermis and raises the epidermis to produce a firm, elastic, dome-shaped protuberance that is mobile over the deeper structures. It is tethered to the epidermis, and there may be a central keratin-filled punctum. The spherical form can be felt where the skin is sufficiently lax. Cysts near the surface, as in the ear lobe or scrotum, are yellowish or white. The size varies from a few millimetres to more than 5 cm in diameter. The common sites are the face, neck, shoulders and chest, which are areas favoured by acne vulgaris. Lesions may be solitary but are commonly multiple. They enlarge slowly and may become inflamed and tender. Suppuration may occur. Cysts that follow acne and have been subject to recurrent inflammation may be difficult to remove completely. Calcification of the contents of epidermoid cysts cannot usually be detected clinically; when it occurs in multiple cysts of the upper part of the trunk it can give a confusing picture on chest X-ray.

Traumatic inclusion cysts usually occur on the palmar or plantar surfaces, buttock or knee. A history of penetrating injury is not always obtained.

Pathology. An epidermoid cyst is unilocular and spherical, unless flattened by firm tissue beneath it. There may be an obvious connection with the surface by a keratin-filled duct, but this is probably less common than surgical texts would suggest. The cyst is situated within the dermis. The lining wall reproduces the layers of the epidermis, although attenuated in large cysts. The keratin is lamellated and birefringent. Cholesterol clefts may be seen. The basal layer may be flattened and surrounded by fibrosis, or may show papillary indentations similar to the epidermis. Some cysts have a chronic inflammatory or foreign-body type of reaction around them, at times producing (or caused by) partial disruption of the wall. Occasionally, a hair shaft may be found coiled within the cyst. These cysts probably result from inflammatory destruction of the sebaceous matrix cells and connective tissue investment of the gland and subsequent re-epithelialization of the abscess cavity, or from squamous metaplasia following impaction of a hair shaft within the sebaceous gland.

Fig. 52.23 Calcified cyst just below the eyelid margin.

Fig. 52.24 Inclusion cyst following trauma to the thumb.

Diagnosis. The uncomplicated cyst can usually be diagnosed with confidence. Other benign and rounded dermal tumours may be mistaken for epidermoid cysts, and inflammatory granulomas such as cutaneous leishmaniasis may mimic an inflamed cyst (Figs 52.23 & 52.24).

Treatment. A cyst that has not recently been inflamed can be dissected out. An inflamed cyst is better incised, drained and phenolized.

Trichilemmal cyst

Synonym
- Pilar cyst

Fig. 52.25 Clinical illustration of typical pilar cyst on the scalp.

Definition. A cyst containing keratin and its breakdown products, usually situated on the scalp, with a wall resembling external hair root sheath [4].

Incidence and aetiology. This is a fairly common condition, and accounts for about 5–10% of keratinous cysts seen by surgical pathology services. Women are affected more frequently than men. It is seen mainly in middle age [5] and is inherited as an autosomal dominant disorder [1,6].

Clinical features. The lesion occurs mainly on the scalp, and is a smooth, mobile, firm and rounded nodule (Fig. 52.25). Larger lesions may be lobular and multiple cysts are commonly found. Tenderness occurs with inflammation, and the surface may break down with infection. The cyst wall may fuse with the epidermis to form a crypt (marsupialized cyst), which can occasionally terminate by discharging its contents and healing spontaneously [6]. In contrast, the contents may protrude above the surface to form a soft cutaneous horn.

Pathology. Trichilemmal cysts differ from epidermoid cysts in the way the lining cells mature. They do not flatten and form a granular layer, and keratinization seems to occur mainly in the region of the cell membrane. The cells appear to disintegrate at the inner margin of the lining. The contents are not brightly birefringent lamellae, but may calcify (Fig. 52.26).

The wall of a trichilemmal cyst may become ruptured and the contents invaded by granulation tissue. The reaction is much less acute than in ruptured epidermoid cysts and produces proliferation rather than destruction of the wall. The proliferation may be progressive and simulate, clinically and histologically, a well-differentiated SCC [7]. Cases of proven malignant degeneration in scalp cysts are very rare.

Treatment. Uncomplicated cysts shell out of the dermis with remarkable ease. Proliferating cysts need to be excised with a margin because they will recur if tissue is left behind.

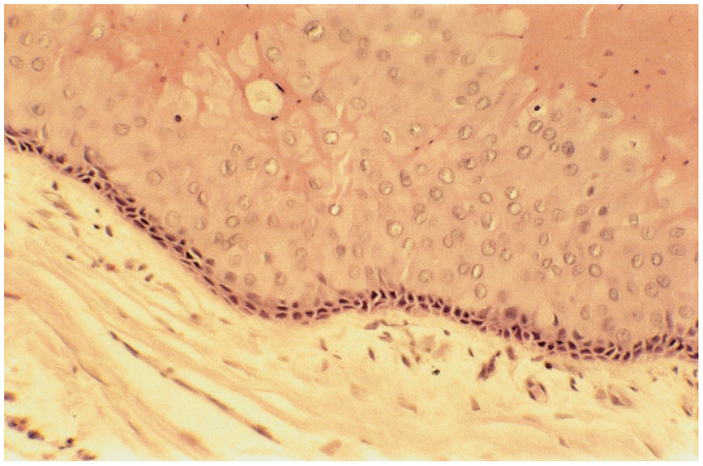

Fig. 52.26 Pilar cyst showing typical pathological features (see text).

Fig. 52.27 Clinical illustration of steatocystoma multiplex on the chest.

Steatocystoma multiplex

Synonyms
- Sebocystomatosis
- Hereditary epidermal polycystic disease

Definition. Multiple cysts in the dermis having sebaceous gland lobules in their wall and containing sebum.

Incidence and aetiology. It is a very uncommon condition, which usually begins in adolescence or early adult life [8]. It is inherited as an autosomal dominant condition in many cases [9,10]. The sexes are affected equally [11].

Clinical features. Multiple, smooth, compressible nodules are present within the dermis, varying in diameter from a few millimetres to 20 mm or more (Fig. 52.27). They usually first appear or become larger at puberty. The trunk and proximal part of the limbs are most commonly involved, particularly the presternal area. No punctum is usually apparent over the cyst, but there may be widespread comedones [12]. The more superficial lesions may have a yellowish colour. If pricked, an oily fluid can be expressed. Some lesions become inflamed, suppurate and heal with scarring.

Pathology. The cyst is situated in the mid-dermis. The wall is thin and composed of keratinizing epithelium. In some sections, lobules of sebaceous glands can be seen to form part of the wall or to empty by ducts into the cyst. The contents are oily, and are composed of the unsplit esters of sebum [13]. They may contain hairs. Hair roots and, occasionally, sweat glands may be found connected with the cyst, and the whole complex is joined to the epidermis by a short strand of undifferentiated cells [14].

Treatment. The number of cysts makes excision impractical in most cases. There is no reason, apart from cosmetic, for treating them.

Milium

Definition. A small subepidermal keratin cyst.

Incidence and aetiology. Milia are quite common at all ages from infancy onwards. Many arise in undeveloped sebaceous glands. This may occur in young women as an eruptive phenomenon, and is sometimes a sequel to sunbathing. Others may arise in the proximal part of divided sweat ducts. The cause of the duct damage is usually avulsion accompanying an acute subepidermal bulla, particularly in second-degree burns, epidermolysis bullosa, porphyria cutanea tarda and bullous lichen planus. They may also follow dermabrasion and occur in areas of chronic topical corticosteroid-induced atrophy. Destruction of skin appendages by radiotherapy may result in a ring of milium-like lesions at the margin of an area treated with tumour doses. These, unlike other forms, can be expressed easily.

Clinical features. The lesions are firm, white or yellowish, rarely more than 1 or 2 mm in diameter and appear to be immediately beneath the epidermis. They are usually noticed only on the face, and occur in the areas of vellus hair follicles, on the cheeks and eyelids particularly. Those that follow blisters are scattered more or less at random in the affected area (Fig. 52.28).

Pathology. The lesion is so easily treated that specimens for histological examination are uncommon. However, the milia that follow blistering can often be traced to eccrine sweat ducts in serial sections. Those at the margin of an irradiated area are usually situated in the distorted remnant of the pilosebaceous duct. The much more common milia of the face are found within the undifferentiated sebaceous collar that encircles many vellus hair follicles. The white milium body is composed of lamellated keratin.

Diagnosis. Milia are recognized as groups of small uniform spherical white papules with a smooth non-umbilicated top. They are usually whiter and more translucent than syringomas, which appear clinically to be more deeply situated in the skin. Milia tend

Fig. 52.28 Multiple milia on the upper cheek area.

to occur in isolation and are not associated with papules, comedones and cysts such as may be seen in closed comedones associated with acne and chloracne. Trichoepithelioma may rarely cause confusion, but tend to be larger, more multi-lobulated structures even on clinical examination.

Treatment. Incision of the epidermis over the milium with a cutting edge needle or sharp-pointed scalpel and squeezing out the contents is usually effective. Recurrence is uncommon. Spontaneous disappearance occurs in many milia in infants.

Premalignant fibroepithelial tumour (of Pinkus)

Definition. A premalignant tumour composed of cells resembling those of BCC arranged in a thin honeycomb around a prominent, overgrown papillary stroma.

Incidence. Relatively uncommon. Several examples have arisen in areas treated by radiotherapy for ankylosing spondylitis [1,2]. The author has seen one case on the chest of a patient with multiple postarsenical BCC.

Clinical features. The tumour is sessile with a domed surface and is firm and flesh-coloured. Most of the recorded lesions have been found on the abdomen or loins. There may be seborrhoeic keratoses or BCCs, or both, elsewhere [3]. Increase in size, when it occurs, is slow. The tumour is most likely to be diagnosed as a fibroma.

Pathology. The outline is domed and the surface is formed of normal epidermis. The bulk of the tumour is composed of considerably enlarged dermal papillae, more cellular and fibrotic than normal, which are surrounded by strands of small dark cells that extend down from the underside of the epidermis. Small buds of cells may arise from the strands and enlarge to form BCC, replacing part or all of the tumour [4].

Treatment. The lesions should be surgically excised.

Introduction

The anatomical relationships of the epidermis and dermis are fully discussed in Chapter 3. The skin appendages are of particular interest in this respect, in that they clearly show a morphological and, in some instances, functional interrelationship. The appendageal tumours discussed in this chapter either differentiate towards or arise from the pilosebaceous apparatus (including the apocrine gland) and eccrine sweat gland [1–9].

The pilosebaceous apparatus can be divided into the hair follicle, the adjacent sebaceous gland and in some body sites the apocrine glands. Small strips of smooth muscle, the arrector pili muscle, are also found in association with these structures.

The pilosebaceous apparatus is concentrated in the head and neck area, with the pilar element predominant on the scalp and the sebaceous element on the face, chest and upper back. Thus, tumours arising from these structures are found predominantly at these anatomical sites.

The eccrine sweat glands are, in contrast, found on all body sites and comprise a double-layered, deeply situated secretory structure and a more superficial excretory duct winding through the dermis and spiralling through the epidermis to reach the surface of the skin.

The excretory (ductal) portions of the eccrine and apocrine glands are identical and cannot be differentiated on morphological grounds unless the apocrine duct can be identified entering the hair follicle. To complicate matters further, the apocrine duct rarely opens directly into the epidermis, and there are no histochemical or immunohistochemical stains that allow distinction

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

between eccrine and apocrine tumours. From this, it can be inferred that adnexal tumours showing ductal differentiation may be either eccrine or apocrine, and distinction is not possible unless there is concomitant follicular differentiation. It has therefore been proposed that the classification of adnexal tumours should follow a more logical approach that takes this into consideration [6]. It has become apparent that tumours traditionally considered to be of eccrine differentiation, such as cylindroma, spiradenoma and mixed tumour (so-called chondroid syringoma) may show either line of differentiation and this is probably most often apocrine. Even a classical eccrine tumour such as poroma has been described occasionally as differentiating towards the apocrine duct [7].

A wide range of cells make up the secretory and excretory components of the appendage ducts, the hair follicles and the sebaceous glands. As each cell type capable of dividing can give rise to a tumour as a result of inappropriate transfer of genetic material and cell division, it follows that an equal number of tumours are theoretically possible. The great majority of these appendage-derived tumours are relatively benign, with behaviour and prognosis similar to that seen in basal cell carcinoma. Thus, although local recurrence is well recorded, metastases are rare, with the exception of the malignant eccrine and apocrine gland-derived tumours and ocular sebaceous carcinoma. It is important to take into account that malignant adnexal tumours with metastasis are over-reported in the literature and that this has led to overestimation of their true malignant potential.

Appendage tumours are relatively rare, and their clinical appearance is commonly non-specific. The great majority are not diagnosed as such until after excision and pathological study. Classification systems for these lesions tend to be controversial, but in general the system groups lesions according to their morphological similarity to normal appendage structures.

Hair-follicle tumours

A large number of tumours are theoretically capable of arising from the hair follicle and matrix, depending on the exact type of cell and its situation within the dermis. A representative selection of these tumours will be described here. For a comprehensive list, the reader is referred to specialized publications [1,2]. Studies on the role of the sonic hedgehog gene and related proteins in basal cell carcinoma (see Chapter 52) have been extended to hair-follicle tumours [3]. The patched gene is located on chromosome 9q22.3, and loss of heterozygosity has been identified in sporadic trichoepitheliomas [4]. Overexpression of Gli-1, which is integral to this pathway, has been observed in trichoepitheliomas in mice [5].

β-Catenin plays a key role in signal transduction and subsequent tissue modelling, and mutations in the β-catenin gene have been recorded in pilomatricomas [6,7].

Inverted follicular keratosis [1–3]

Definition. A localized area of hyperkeratosis found in association with the pilosebaceous orifice. A number of these lesions arise as a result of infection of the infundibulum of the hair follicle by human papillomavirus (HPV). It is likely that a majority of these lesions may be regarded as the most superficial tumour of the follicular infundibulum (see below), arising as the result of irritation.

Clinical features. In common with many of the lesions described in this chapter, this lesion presents as a solitary papule on the head and neck area. It may reach a considerable size, and be inflamed and pruritic.

Pathology. The pathological features show an endophytic lesion connected to the infundibulum of the hair follicle. Irritated keratinocytes form whorls of cells, so-called 'squamous eddies', and keratin cysts. All of these features may give rise to problems with the differential diagnosis of squamous cell carcinoma, especially on small biopsies. This can be relatively easily distinguished on low-power examination, as there is no individual cell invasion into the dermis. At higher power, mitotic figures may be seen, but they are not abnormal mitoses. The appearances are identical to an irritated seborrhoeic keratosis, but the latter is exophytic.

Management. Local surgical excision is generally needed, for both diagnostic and therapeutic purposes. Occasionally, the lesions recur [3].

Dilated pore [1,2]

Synonyms
- Wiener's pore
- Infundibuloma

Definition. An area of expanded follicular infundibulum with a dilated poral opening extending down to subcutaneous fat [2].

Clinical features. The pore is a comedo-like lesion found mainly on the head and neck area of the elderly.

Pathology. There is a wide, crater-like cavity, from which acanthotic areas of follicular epithelium radiate. The follicle is lined by outer root-sheath epithelium, and there is little evidence of a sebaceous gland or a well-formed emerging hair. Rare lesions may be associated with trichoblastoma [3] and exceptionally with either basal cell carcinoma [4] or squamous cell carcinoma [5].

Tumour of the follicular infundibulum [1]

Definition. This lesion may be considered the hair-follicle equivalent of the eccrine dermal duct tumour (p. 53.24).

Clinical features. These lesions are usually found on facial skin and may be relatively large, irregular nodules. They are usually biopsied or excised to obtain a diagnosis, as the clinical appearance is not specific. It has been suggested that they can be divided into four main groups: solitary lesions; those in association with Cowden's disease; multiple eruptive tumours [2]; and follicular infundibulum-like changes in the epidermis [1].

Pathology [3–5]. The pathology is that of a large, horizontally orientated plate of small, dark cells situated in the superficial dermis, usually with multiple connections to the overlying epidermis. The cellular detail is focally similar to that seen in the trichilemmoma, with large numbers of small polygonal cells with clear cytoplasm contained within a palisaded border. Basaloid cells are often seen. The resemblance to basal cell carcinoma is striking, but the stromal element is lacking. Occasionally, sebaceous differentiation may be seen [6]. These lesions with sebaceous differentiation have been termed superficial epithelioma with sebaceous differentiation [7] and acanthomatous superficial sebaceous hamartoma [8].

Pilar sheath acanthoma [1]

Clinical features. These lesions are very rare and are most commonly seen on the upper lip area of the elderly [2,3].

Pathology. The pathology is that of an expanded area of the outer root-sheath epithelium within an irregularly branched cystic cavity, with large lobules of epithelial cells radiating outwards from this cavity area.

Trichoadenoma [1–5]

Definition. A rare benign tumour, with multiple cystic structures closely resembling the infundibular portion of the hair follicle. The keratin profile expression supports the theory that this tumour differentiates towards the follicular infundibulum and the follicular bulge region [6].

Clinical features. This lesion presents as a non-specific nodule, usually on the face, although there are some reports of lesions on the buttocks. An exceptional congenital case has been reported [7] and lesions may occur within a naevus sebaceus [8] or coexist with an intradermal naevus [9].

Pathology. The lesions are in the upper dermis, and on light-microscope scanning power give the impression of a cluster of cysts. On higher power, these cyst-like structures have an appearance similar to the infundibular portion of the hair follicle but turned through 90°; no recognizable hair shafts are seen.

Comedo naevus [1–3]

Definition. A rare abnormality of the follicular infundibulum presenting as a group of comedo-like lesions.

Clinical features. These lesions are rare and are seen mainly on the head and neck area. Cases may also occur at other sites including the palm and wrist [4]. The palm is not an area that contains hair follicles and the unusual presentation of nevus comedonicus in this location has led to the suggestion that these lesions may really represent variants of sweat duct naevus [5]. They may be present at birth or develop throughout adult life. They appear as a cluster of comedones or as a single giant lesion [3].

Pathology. A rudimentary pilosebaceous follicle is present, with a large overlying keratin-filled crater. The surface of the keratinous material oxidizes to give the comedone-like appearance. Rarely, lesions develop trichilemmal cysts [6].

External root-sheath tumours

Trichilemmal cyst

Definition. A cyst apparently arising from the external root sheath, containing keratin and breakdown products [1,2].

Clinical features. These lesions are mainly seen on the scalp and are relatively common. They may be familial, inherited by autosomal-dominant transmission [3]. Females are affected more often than males. They present clinically as firm nodules, which may become infected or inflamed after minor trauma. They are commonly multiple. Unusual locations include the extremities and even the pulp of a finger [4]. A case of Merkel cell carcinoma arising from a trichilemmal cyst has been reported [5]. A further case of multiple trichilemmal cysts following Blaschko's lines and associated with filiform hyperkeratosis and referred to as trichilemmal cyst naevus has also been published [6].

Pathology. These cysts are well circumscribed in the dermis and lined by two or three layers of small, dark keratinocytes. There is then an abrupt transition, towards the centre of the lesion, to large, pale cells with features of root-sheath cells. A granular cell layer is absent. The centre of the cyst contains keratin debris. Some lesions are hybrid and show focal changes of an epidermoid cyst, with formation of a granular cell layer [7]. Occasional lesions have a verrucous lining and in one of these lesions, human papillomavirus has been identified [8].

Management. These are commonly excised to obtain a diagnosis. Lesions that are shelled out may recur [9].

Proliferating trichilemmal tumour

Synonym
- Proliferating trichilemmal cyst

Clinical features. The tumour presents as a rapidly growing, large nodule, commonly on the head (scalp and less commonly the face) and neck area followed by the trunk of the elderly with predilection for females [1,2]. Some lesions are very large and may be more than 10 cm in diameter. The history of rapid expansion frequently gives rise to concern about malignancy. Malignant change has been rarely reported in these lesions (see below). Occasionally, tumours may develop within a pre-existing naevus sebaceus [3]. Multiple lesions are exceptional [4].

Pathology. These lesions may arise from pre-existing trichilemmal cysts, and remnants of a classic trichilemmal cyst may be present [1,2]. The architecture is lobular and expansile, without an infiltrative growth pattern. Tumour lobules are cystic and composed of pale squamous cells with mild atypia. However, tumour cells in the periphery of the lobules may display more prominent cytological atypia and mitotic activity. This is particularly true in early lesions that are actively growing. The surrounding stroma may be fibrotic with inflammation consisting of lymphocytes and plasma cells and a foreign body granulomatous reaction may be seen in areas where cystic structures have ruptured. Cholesterol clefts and areas of calcification may also be seen. Rarely sebaceous, apocrine and matrical differentiation may be present [5,6]. Exceptionally a malignant spindle cell component has been described [7,8]. If there is frank invasion into adjacent structures in association with tumour necrosis, cytological atypia and increased mitotic activity, the diagnosis of a malignant proliferating trichilemmal tumour should be made [9–11]. Such tumours are often characterized clinically by rapid growth and large size [11]. Metastases may occur, leading to death. The diagnosis is often very difficult in small samples of tissue, and ideally the whole tumour should be submitted for histological examination to avoid confusion with a squamous cell carcinoma. The increased expression of p53 by tumour cells similar to that seen in ordinary squamous cell carcinoma but much lower than that seen in trichilemmal cysts suggests that all these lesions may represent low-grade malignancies [12].

Management. Local recurrence takes place and complete excision is therefore necessary.

Trichilemmoma [1–3]

Definition. This lesion is classically considered to be a proliferation of the external root sheath of the hair follicle [4,5]. However, immunohistochemical studies with different molecular weight keratins normally expressed by different components of the hair follicle have not only confirmed the latter but suggest that the lesion also displays infundibular keratinization [6].

Clinical features. Clinically, these lesions are small, non-specific papules on facial skin; they present in young and middle-aged adults. Their importance lies in the fact that patients with Cowden's syndrome or multiple hamartoma and neoplasia syndrome [7–14]—which is associated with a very high incidence of breast, thyroid and gastrointestinal carcinomas—have large numbers of trichilemmomas. The diagnosis of multiple trichilemmomas should therefore stimulate a search for other evidence of Cowden's syndrome. This includes a characteristic 'cobblestone' appearance of the oral epithelium, multiple skin tags, squamous papillomas and sclerotic fibromas (storiform collagenomas). Mutations of the *PTEN* tumour suppressor gene on chromosome 10q23 are found in Cowden's syndrome [15,16]. The number of mutations identified is large and continues to increase [16]. It seems that the benign lesions in Cowden's syndrome occur without loss of the second *PTEN* allele while the malignant tumours require inactivation of both alleles and additional somatic mutations [17].

Pathology. These lesions are well-circumscribed, lobular tumours extending down from the epidermis and often connected to a hair follicle. Tumour cells display prominent clear cytoplasm secondary to the deposition of glycogen. The presence of glycogen can be confirmed with a positive periodic acid–Schiff (PAS) stain, which becomes negative after treatment with diastase. There is an irregular enclosing PAS-positive, diastase-resistant membrane. In a number of cases, there is prominent hyperplasia of the surface epithelium, with hypergranulosis, clumping of keratohyalin granules and hyperkeratosis. This suggests induction of some lesions by HPV. A viral aetiology has been confirmed by demonstration of HPV DNA by polymerase chain reaction in some [18] but not all cases of the tumour [19]. Trichilemmomas are often found within a naevus sebaceus.

A variant of trichilemmoma, described as desmoplastic trichilemmoma, has been reported [20]. The periphery of this lesion has histological features identical to those of ordinary trichilemmoma, but towards the centre there are strands of squamous cells embedded in a desmoplastic stroma. This stroma appears to contain type I collagen and tenascin but not laminin or type IV collagen [21]. This results in an infiltrative appearance that may be confused with a squamous cell carcinoma, particularly in small biopsy samples.

Trichilemmal carcinoma [1–4]

Definition. A very rare tumour with metastatic capacity, usually arising in sun-exposed skin of the elderly.

Clinical features. This lesion presents as a solitary, expanding, often ulcerating lesion on the face. Clinically it may be misdiagnosed as a basal cell carcinoma. Exceptionally, multiple tumours have been described [5]. Trichilemmal carcinoma may arise from a trichoblastoma and in the context of a naevus sebaceus [6]. It has also been described in the setting of solid organ transplantation [7,8].

Pathology. These lesions invade downwards from the epidermis or outer root-sheath areas in a multilobular and infiltrative fashion. They may have a surrounding PAS-positive membrane, and there is central trichilemmal keratinization. There is a high mitotic rate, with abnormal mitoses present. The diagnosis of trichilemmal carcinoma should only be made in the presence of clear evidence of trichilemmal differentiation. The presence of clear-cell change is not enough to make this diagnosis. Most malignant cutaneous tumours with clear-cell change are squamous cell carcinomas and often show at least focal evidence of keratinization. An exceptional case of trichilemmal carcinoma with neuroendocrine differentiation has been reported [9]. Immunohistochemical studies in a single case of trichiolemmal carcinoma, suggest that the tumour shows differentiation towards the follicular infundibulum rather than towards the outer root sheath as ordinary trichilemmomas usually do [10]. However, the latter also show infundibular follicular differentiation and it is possible that malignant counterparts lose the expression of markers of outer-sheath differentiation.

Management. Surgical excision with clear margins is the treatment of choice.

Hamartomas and hair germ tumours and cysts

Hair-follicle naevus [1,2]

Clinical features. These naevi are very rare and are recognized as plaque-like lesions with small tufts of hairs. They present in children and may be congenital. The so-called 'faun tail naevus' is a hair-follicle naevus on the sacral skin. Rare cases occur following Blaschko's lines [3]. A rare association with frontonasal dysplasia has been reported [4]. It is not clear whether some hair follicle naevi are variants of accessory tragi [5].

Pathology. The pathology of this entity consists of a group of normal vellus hair follicles clustered together.

Eruptive vellus cyst

Definition. Occlusion and cystic dilatation of vellus hair follicles.

Clinical features. These present as small red or brown papules on the chest, commonly in the second decade of life [1]. They are usually multiple, and family clusters have been reported with some lesions showing features of eruptive vellus hair cysts, other lesions showing features of steatocystoma and some displaying hybrid features [2,3]. Lesions may rarely be unilateral [4] or even generalized [5] and have been reported in chronic renal failure [6]. They are commoner than expected in patients who also have pachonychia congenita [7,8].

Pathology. Cysts are located in the mid-dermis, and are lined by squamous epithelium. They contain vellus hair and keratin debris. Biopsies from some lesions show features indistinguishable from steatocystoma, with absence of vellus hairs. This finding shows that there is an overlap with steatocystoma multiplex [9,10].

Management. If treatment is requested, the lesions may clear after application of topical retinoids [11]. Curettage and laser therapy may also be effective, but it is easy to cause scarring. Pulsed carbon dioxide laser is useful for facial lesions but this treatment may induce hypertrophic scarring if used for truncal lesions. Success has been reported at the latter site with erbium:YAG laser [12]. However, when this treatment is used on facial lesions, although initial results are good, there is tendency for local recurrence. This is due to the fact that the depth of ablation of facial lesions is superficial to avoid scarring and atrophy [13].

Trichofolliculoma [1]

Definition. This lesion is a hamartoma of the pilosebaceous follicle, which results in several hairs being formed within the follicular opening and all protruding onto the epidermal surface from the one pilosebaceous orifice [2–6].

Clinical features. Most cases occur in young adults with predilection for the head and neck, particularly the face. Occasionally, tumours present in the vulva [7]. Clinically, lesions can be recognized as small, raised nodules with two or three hairs protruding together in a small tuft (Fig. 53.1).

Pathology. The pathological appearance is that of a dilated and abnormally large pilosebaceous canal containing numerous, poorly formed hairs, with several pilosebaceous-like structures opening into the canal (Fig. 53.2). The components of the lesion undergo evolutionary changes similar to those of the normal hair follicle [8]. Malignant change has been suggested in a single case with perineural invasion [9]. The so-called folliculosebaceous cystic hamartoma is considered by some authors to be a variant of trichofolliculoma in a late stage of development [10]. This view, however, is not agreed upon by other authors [11].

Management. Simple surgical excision is the treatment of choice.

Trichoepithelioma [1]

Synonyms
- Epithelioma adenoides cysticum
- Brooke's tumour

Definition. A hamartoma of the hair germ composed of immature islands of basaloid cells with focal, primitive follicular differentiation and induction of a cellular stroma. Trichoepithelioma is regarded nowadays as part of the spectrum of trichoblastoma and it is increasingly described under the same heading in some textbooks.

Clinical features. The presentation of a solitary lesion is that of a smooth nodule, usually on the face, which clinically resembles a non-ulcerated basal cell carcinoma. Most affected patients are young adults. Multiple lesions, which are inherited by autosomal-dominant transmission, are seen as multiple, small, pearly lesions, mainly on centrofacial skin (Fig. 53.3). Malignant transformation of trichoepithelioma is extremely rare [2].

Pathology [3–5]. The pathology is identical for solitary or multiple lesions and consists of lobules of small, dark basaloid cells,

Fig. 53.3 Multiple trichoepitheliomas on the central face.

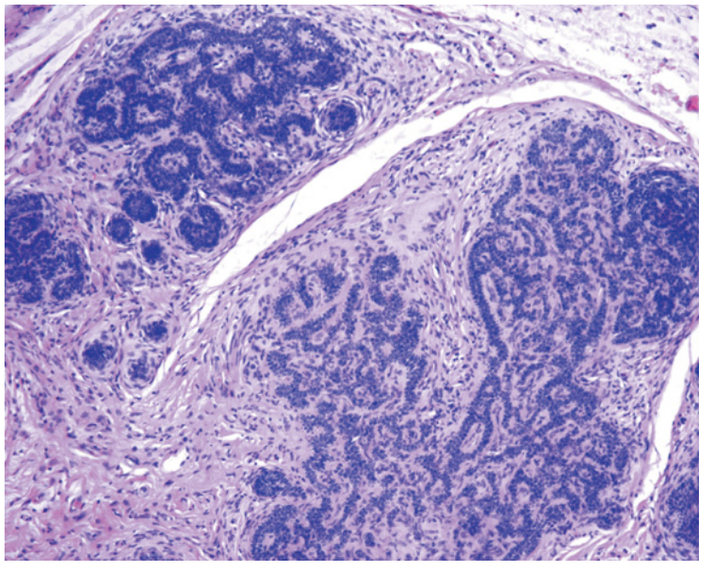

Fig. 53.4 Trichoepithelioma. A lobular basaloid tumour with induction of stroma and immature follicular differentiation.

often with a degree of peripheral palisading surrounding a central area of eosinophilic amorphous material (Fig. 53.4). Occasionally, hair shaft-like structures can be seen in these central areas. A fibrous cellular stroma is seen around the cellular lobules. There is frequently a strong resemblance to basal cell carcinoma, and at times differentiating between the two can be very difficult. However, the stroma in trichoepithelioma is distinctive in that it contains clefts, with an absence of retraction artefact between tumour cells and the surrounding stroma.

The gene for multiple trichoepitheliomas has been mapped to a locus on chromosome 9p21 [6]. The commoner sporadic cases of trichoepithelioma have, in a proportion of cases, deletions at chromosome 9q22.3, the site of the human homologue of the *Drosophila* patched gene [7]. Familial basal cell carcinomas and some cases of sporadic basal cell carcinomas also show this deletion. It has been proposed that in multiple trichoepitheliomas tumours develop

from undifferentiated germinative cells of the pilosebaceous–apocrine unit [8].This explains why in some cases tumours have features of spiradenoma and/or cylindroma, particularly in the Brooke–Spiegler syndrome. The Brooke–Spiegler syndrome inherited by autosomal dominant transmission consists of multiple trichoepitheliomas, cylindromas and spiradenomas and the gene for this syndrome has been mapped to chromosome 16q12–13 [9]. Mutations in the gene *CYLD*, a tumour suppressor gene, are responsible for the manifestations of the disease [9].

In multiple lesions, which are present in epithelioma adenoides cysticum [10–14], larger lesions may be yellow, pink, or sometimes bluish from pigmentation, and there may be dilated blood vessels over the surface. Individual tumours reach a limiting size, but the numbers may increase over the years.

Treatment. Any suspicion of malignant change calls for adequate excision and histological examination. The only other reason for treatment is cosmetic. Partial destruction is usually followed by regrowth. Many treatment modalities may be used including surgical excision, curettage, cryotherapy and dermabrasion. High energy pulsed carbon dioxide laser has also been advocated as a useful treatment [15,16].

Desmoplastic trichoepithelioma [1–3]

Synonym
- Sclerosing epithelial hamartoma

These two terms were introduced almost simultaneously. The US group of Brownstein and Shapiro used the term 'desmoplastic trichoepithelioma' [2], while MacDonald, Wilson Jones and Marks in the UK suggested the term 'sclerosing epithelial hamartoma' [3].

Definition. A slowly expanding plaque of tissue containing hair follicle-like structures.

Clinical features. Lesions are found mainly on the face of young patients and have a depressed centre and a raised, rolled edge in many cases, causing clinical confusion with basal cell carcinoma. To date, more females than males have been reported with the condition. Exceptionally, lesions may be familial [4] and a congenital case has been described [5].

Pathology. Tumours are symmetrical on scanning magnification. The three features that characterize this lesion are large numbers of small, keratin-filled cysts, strands and ribbons of small, dark, epithelioid cells, and a dense fibrous stroma surrounding the first two structures. Perineural invasion is not a feature.

The striking palisading of the basal cell carcinoma is absent. There is, however, a considerable similarity to the sclerosing (morphoeic) variant of basal cell carcinoma, although the number of cysts is very much greater in the desmoplastic trichoepithelioma. Distinction from microcystic adnexal carcinoma may be impossible in a small and superficial biopsy. The latter, however, shows a diffuse infiltrative pattern, with prominent perineural invasion. Merkel cells are present in desmoplastic trichoepithelioma and absent in microcystic adnexal carcinoma and in most cases of morphoeic basal cell carcinoma [6]. Immunostaining with cytokeratin 20, to identify Merkel cells, is therefore useful in the differential diagnosis of these neoplasms.

An electron microscopic and immunohistochemical study with different types of keratins has suggested that this tumour derives from basal cells in the outer root sheath of the hair follicle which can differentiate into various components of the folliculosebaceous and apocrine unit [7].

Occasional desmoplastic trichoepitheliomas are combined with a benign melanocytic naevus [8].

Treatment. Local excision is effective in the majority of cases.

Solitary giant trichoepithelioma [1,2]

Synonym
- Giant trichoblastoma

This is a rare variant of trichoblastoma with a dramatic clinical presentation that may cause concern about a rapidly growing malignancy. It has also been described under the name 'trichoblastic fibroma'. Trichoepithelioma and giant trichoepithelioma represent the more mature end of the spectrum of trichoblastoma. These tumours are described separately because they represent distinctive clinicopathological entities. However, it should be remembered that histological overlap is often seen.

Clinical features [3–5]. The clinical presentation is of a very large, polypoid lesion presenting on the lower trunk, frequently in the perianal area, with a history of recent rapid growth. The lesions may cause considerable discomfort because of their size. They affect both sexes equally.

Pathology. The pathology shows the features of the smaller, classical trichoepithelioma but the lesions are much larger, deeper and often located in the subcutaneous fat. An oedematous myxoid stroma is frequently seen and focally, various stages of follicular differentiation are identified. Mitotic figures are frequent, but abnormal mitoses are not seen.

Management. Excision is required, both to confirm the diagnosis and because of discomfort as local recurrence is exceptional [6]. Malignant change into basal cell carcinoma has been reported in a giant trichoepithelioma in a patient with multiple trichoepitheliomas [7].

Trichoblastoma [1–4]

Synonyms
- Trichogenic fibroma
- Trichoblastic fibroma

Definition. Tumours of the hair germ composed of follicular germinative cells.

Clinical features. These are deeply or superficially situated dermal and/or subcutaneous nodules [5], found—as is common with follicular tumours—on the head and neck. Often lesions are found within naevus sebaceus [6] and trichoblastoma is regarded as the most common neoplasm occurring in this hamartoma [7]. Tumours may be induced by low-dose X-ray depilatory treatment such as was used in the past to treat ringworm [8].

Pathology. Nests of basophilic basaloid cells with a lobular architecture and prominent induction of stroma are seen in the dermis and/or subcutaneous tissue. Focal evidence of follicular differentiation is seen, but this usually consists of less mature structures than those seen in trichoepithelioma. Characteristically, condensation of cellular stroma is seen around aggregates of basaloid cells but true follicular papillae are not formed as the stroma does not invaginate into the epithelial component. Mitotic figures vary and may be frequent. Usually, the tumour is not connected to the epidermis. According to the degree of follicular differentiation and the amount of stroma induced, lesions have been subclassified into different categories, including trichogenic and trichoblastic fibromas. However, all tumours in this category are best classified as variants of trichoblastoma. Some tumours display sebaceous and even ductal (apocrine) differentiation confirming the theory that they differentiate towards the folliculosebaceous and apocrine germ [9,10]. Melanin deposition is often seen, may be prominent and is not uncommonly associated with the presence of melanocytes [11] within the tumour as seen in normal hair follicles. In some cases, rows of tumours cells are arranged parallel to each other in a pattern that has been described as rippled trichoblastoma [12]. Occasional neoplasms consist mainly of clear cells, a change that indicates trichilemmal differentiation [13]. Histological overlap with trichoepithelioma is often seen and there is a tendency to regard all these tumours as part of the same spectrum. Distinction between nodular trichoblastoma and follicular basal cell carcinoma may be very difficult, particularly in small biopsies. Distinction is usually based on the presence of a deep infiltrative pattern in the latter [14]. The presence of Merkel cells in trichoblastoma identified by immunohistochemical markers (cytokeratin 20, chromogranin) is useful in the differentiation from basal cell carcinoma which lacks these cells [15]. Based on clinicopathological features and the presence of Merkel cells in the neoplasm it has been proposed that fibroepithelioma of Pinkus is a variant of trichoblastoma rather than a variant of basal cell carcinoma [16]. A further aid in the differential diagnosis between basal cell carcinoma and trichoblastoma is the immunohistochemical expression of androgen receptor. The latter is usually positive in basal cell carcinoma and negative in benign follicular neoplasms [17].

Management. Behaviour is usually benign but malignant transformation of the epithelial or even the mesenchymal component (trichoblastic carcinoma/sarcoma) may occasionally occur [18,19]. Complete excision is often desirable as exclusion of a basal cell carcinoma may be difficult in small biopsies.

Cutaneous lymphadenoma [1–7]

Synonym
- Adamantinoid trichoblastoma

Definition. This entity was first described in 1991 [1], and to date there are around 35 reported cases in the literature. Follicular, sebaceous and ductal differentiation has been demonstrated and therefore this tumour is regarded as a variant of trichoblastoma, a neoplasm differentiating towards the folliculosebaceous and apocrine germ [4,8].

Clinical features. The lesions are seen mainly on the head and neck area, and present as non-specific papules or nodules. Both sexes are affected equally. The preoperative clinical diagnosis is frequently either basal cell carcinoma or intradermal naevus.

Pathology. The tumour consists of nests and lobules of basaloid cells in the reticular dermis, with no connection to the epidermis.

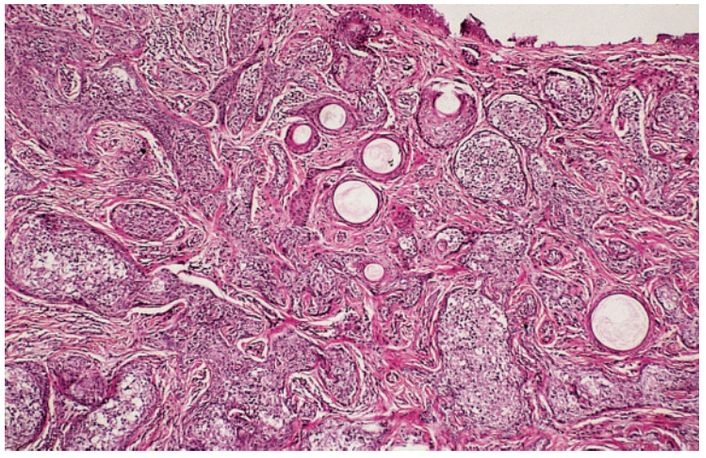

Fig. 53.5 Lymphadenoma. Nests and lobules of epithelial cells with prominent infiltration by lymphocytes.

These aggregates of cells are embedded in a fibrous stroma. Tumour cells are bland and display focal peripheral palisading. A striking feature is the presence of prominent infiltration of tumour lobules and nests by T lymphocytes and histiocytes (Fig. 53.5). These inflammatory cells are mainly located in the centre of the tumour lobules. No cellular atypia is seen, and mitotic figures are rare. Focal areas of keratinization are seen in some cases.

Treatment. Local excision is recommended. The behaviour is entirely benign.

Basaloid follicular hamartoma [1–4]

Definition. A hamartoma consisting of a proliferation of basaloid cells, with frequent involvement of hair follicles.

Clinical features. These lesions are usually small multiple papules that may become confluent to form a plaque. Involvement of the face is common but lesions may also present on the trunk. Presentation may be generalized or localized and the latter may be linear [4,5]. They may be present in isolation or inherited as an

autosomal-dominant trait [6,7]. Association with autoimmune diseases and alopecia has been described particularly in the generalized variant [8]. The autoimmune diseases include lupus erythematosus [9] and myasthenia gravis [5]. Other rare associations include cystic fibrosis [10], milia and hypohidrosis [11]. In exceptional cases, basal cell carcinomas may develop within the lesions [12].

Pathology. A multifocal proliferation of cords, strands and nests of basaloid cells is seen, with frequent connections to the epidermis. Basaloid cells focally replace neighbouring hair follicles. In addition, immature follicular bulbs may also be seen.

Hair matrix tumours

Pilomatricoma [1–4]

Synonyms
- Benign calcifying epithelioma of Malherbe
- Trichomatricoma
- Pilomatrixoma

Definition. A benign tumour considered to be a hamartoma of the hair matrix composed of cells resembling those of the hair matrix and cortex and inner root sheath. The cells usually undergo 'mummification'.

Incidence. This lesion makes up around 20% of all hair follicle-related tumours in most series and is therefore the commonest hair-follicle tumour. It may occur at any age from infancy and is frequently seen in children [5]. The majority of patients are under 20 years of age, and females are affected more often than males. A number of familial cases are recorded [6]. Association with myotonic dystrophy [6], Turner's syndrome [7] and Rubinstein–Taybi syndrome have been described [8]. *MYH*-associated polyposis is an autosomal recessive variant of familial adenomatous polyposis with susceptibility to colorectal carcinoma and association in some affected individuals with multiple pilomatricomas [9].

Fig. 53.6 Pilomatricoma. Small, red, firm papule.

Clinical features [10–16]. The lesion is usually a solitary, deep, dermal or subcutaneous tumour 3–30 mm in diameter situated on the head, neck or upper extremities (Fig. 53.6). Very large tumours occur occasionally [17]. The skin over the tumour is normal and the lesion has a firm to stone-hard consistency and a lobular shape on palpation. In adult life, there may be quite a short history [4] and there is usually no evidence of a preceding cyst. It may be subject to periodic inflammation and can present as a granulomatous swelling. Rarely, ulcerated lesions may show transepithelial elimination [18]. An unusual case associated with hypercalcaemia and high levels of parathyroid hormone has been described [19]. Malignant change is very rare (see below).

Pathology [20–27]. The tumour is situated in the dermis, and is composed of well-circumscribed, rounded islands giving a lobulated contour. The outer cells are small, and their rounded nuclei crowded together make this region deeply basophilic. Normal mitotic figures can usually be seen and are often numerous. The cytoplasm is scanty and the cell margins indistinct, but intercellular connections can be seen. Towards the centre of the mass, the cytoplasm becomes more abundant and eosinophilic. The nuclear outline persists, but the chromatin is sparse and clumped in dark granules; when all basophilic material disappears, a mummified 'ghost cell' remains (Fig. 53.7). The ultrastructural and histochemical characteristics of these cells mark them as hair-matrix cells maturing towards cortex or root sheath [3,26,27]. The central areas

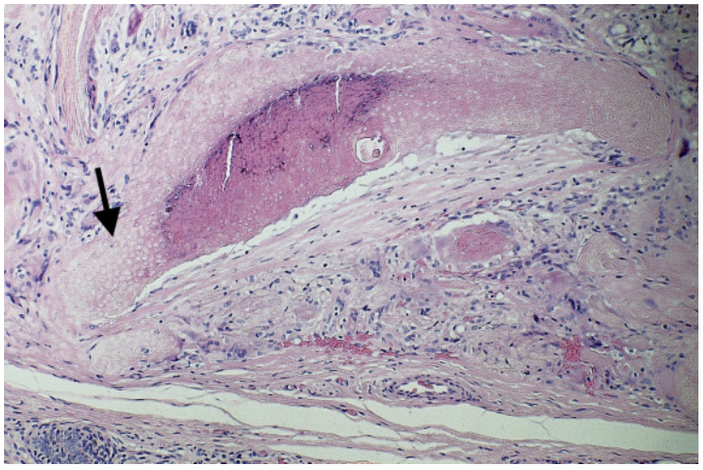

Fig. 53.7 Pilomatricoma. Lobules of basaloid cells intermixed with pale pink areas containing ghost cells.

often calcify, and calcium can be demonstrated in the basophilic areas of the tumour. In older lesions, the basophilic cells may be greatly reduced or disappear entirely. Melanin may be present, and dendritic melanocytes have been found between the tumour cells. The stroma that encapsulates the masses usually contains inflammatory and foreign-body giant cells, and occasionally ossifies. A rare variant of superficial pilomatricoma presenting clinically as a cutaneous horn and with an intraepidermal location has been reported [28]. A bullous appearance may occur consequent on lymphangiectasia [29], and anetoderma can occur in the dermis surrounding the tumour [30]. Occasional hybrid cysts may show areas of pilomatrical differentiation identical to pilomatricoma [31].

Studies have shown that 75% of pilomatricomas possess activating mutations of the β-catenin gene [32–34]. The sites of β-catenin expression within pilomatricomas suggest that this may affect cell–cell adhesion [35].

Diagnosis. The diagnosis can be suspected if a subcutaneous nodule feels hard and lobular. The presence of calcium salts may be apparent on radiographs, but these can also be deposited in other cysts and tumours of the skin. The microscopic picture is, however, diagnostic.

Malignant change is recorded in several cases, and appears to arise chiefly in large pilomatricomas that have been present for many years (see below).

Management. Local excision is required for benign lesions, as there is a tendency for local recurrence. Wider excision will be needed if malignancy is suspected.

Pilomatricarcinoma [1–4]

Definition. The malignant counterpart of the pilomatricoma, possessing metastatic potential.

Clinical features. A rapidly expanding firm nodule. Approximately 70 cases are reported in the literature, and the average age of the patients is 70 years. Males are more often affected than females. Most tumours develop on the head and neck followed much less frequently by the trunk [5].

Pathology. Many pilomatricarcinomas appear to arise on long-standing benign pilomatricomas. Definition of malignancy is usually very difficult on histological grounds. Malignant tumours usually have a very large predominant basaloid component, an infiltrative growth pattern and extensive necrosis. In addition, there are numerous abnormal mitotic figures, and both lymphatic and vascular invasion may be seen. There may be metastases to distant organs such as the lungs, bone and lymph nodes [6–9]. At least two cases have proved fatal.

As in pilomatricoma, mutations in β-catenin have been demonstrated in pilomatricarcinomas suggesting the activation of a common cellular pathway in both types of neoplasms despite the difference in clinical behaviour [10,11].

Management. Wide local excision is usually curative, but follow-up is required because of the possibility of metastatic spread.

Lesions of hair-follicle mesenchyme

Trichodiscoma [1]

Definition. This lesion is a hamartomatous proliferation of the mesodermal component of the *Haarscheibe* described by Pinkus [1]. The *Haarscheibe* is considered to be a slowly reacting mechanoreceptor associated with the hair follicle.

Clinical features. The clinical appearance of the trichodiscoma is that of multiple, discrete, flat-topped papules 2–3 mm in diameter. They occur mainly in the central area of the face. Familial cases are recorded [2,3]. Multiple trichodiscomas, trichofolliculomas and acrochordon-like lesions have been described as part of the Birt–Hogg–Dubé syndrome [4]. This syndrome is an autosomal dominant genodermatosis also associated with lung cysts, spontaneous pneumothorax and renal neoplasms (chromophobe renal carcinoma and oncocytoma) [5]. The causative gene, *FLCN*, has been mapped to chromosome 17p12q11. Interestingly, the acrochordon-like lesions display the histological features of either trichodiscomas or trichofolliculomas [6].

Pathology. A discrete but non-encapsulated area of myxoid, poorly cellular stroma with focal collagen deposition is seen in the dermis, associated with a proliferation of blood vessels, some of which are thick-walled. The proliferating cells are CD34 positive [7]. A variant with a cellular spindle-cell component has been described [8]. Pilosebaceous units are often seen on both sides of the myxoid stroma. Trichodiscomas and trichofolliculomas usually show histological overlap.

Perifollicular fibroma [1,2]

The clinical appearance of these lesions has not been well described. The pathology is that of a striking fibrous proliferation around a relatively normal pilosebaceous apparatus.

Fibrofolliculoma

Definition. Rare lesions of perifollicular connective tissue [1].

Clinical features. These lesions usually first appear in middle age and tend to affect the upper part of the body. Multiple lesions are seen in the Birt–Hogg–Dubé syndrome, which is an autosomal-dominant condition mapped to chromosome 17p11.2 [2–5]. In this syndrome, fibrofolliculomas are seen in association with trichodiscomas, acrochordon-like lesions, renal tumours most commonly chromophobe carcinoma and spontaneous pneumothorax [6,7]. Colonic neoplasms do not seem to be increased in this syndrome, as previously suggested [6].

Pathology. Histology shows multiple, small, poorly formed pilosebaceous follicles set in a very striking fibrous stroma. There is also an obvious proliferation of the outer root sheath similar to that seen in the perifollicular fibroma.

Sebaceous gland tumours [1]

The following tumours or tumour-like conditions of sebaceous glands are considered elsewhere in the book:

1 Naevus sebaceus (Chapter 18);
2 Senile sebaceous hyperplasia (Chapter 42);
3 'Sebaceous' cyst (Chapter 42);
4 Steatocystoma multiplex (Chapter 52).

The two main conditions discussed in this section are sebaceous adenomas and sebaceomas, and sebaceous carcinoma. The old term 'sebaceous epithelioma' is no longer used, as it causes confusion with the exceptionally rare basal cell carcinoma with sebaceous differentiation.

Sebaceous adenomas and sebaceomas [1–5]

Definition. Benign tumours composed of incompletely differentiated sebaceous cells of varying degrees of maturity. Sebaceous adenoma and sebaceoma are described together, as they do not have distinctive clinical features and, although histological separation is possible in most cases, there is also some degree of overlap.

Incidence and aetiology. These are fairly rare tumours [4]. The solitary type may occur in either sex, and most cases have occurred in the elderly. They may be associated with a cutaneous horn [6]. There is no evidence that actinic radiation or other recognized carcinogens are to blame.

Patients with multiple benign sebaceous tumours (other than sebaceous hyperplasia) should be suspected of having the Muir–Torre syndrome, associated with multiple visceral malignancies [7–18]. It is important to note, however, that a single sebaceous neoplasm and more uncommonly a sebaceous carcinoma particularly in an extraocular location may represent a marker of the syndrome [19]. It has also been demonstrated that a single sebaceous tumour outside the head and trunk is a strong indicator of the syndrome [20]. Muir–Torre syndrome is a rare subset of the hereditary non-polyposis colorectal carcinoma, representing 1–2% of cases of the latter [21,22]. It is characterized by cutaneous sebaceous tumours, gastrointestinal malignancies, especially colonic and, more rarely, renal, uterine and breast neoplasms [5]. The internal malignancies tend to be fairly low grade, and often patients develop them earlier in life than the equivalent neoplasm in the general population. Sebaceous neoplasms tend to develop later in life. Patients with Muir–Torre syndrome may also develop sebaceous keratoacanthomas [20], thus diagnosis of one of these tumours should raise the possibility of the syndrome. Microsatellite instability has been reported in the Muir–Torre syndrome [23,24], which results in the loss of a number of mismatch repair proteins particularly MLH1 and MSH2 and less commonly MSH6. Loss of expression of these proteins is a marker of patients who carry the syndrome and are therefore at risk of systemic malignancy [25,26]. The loss of expression of MLH1, MSH2 and MSH6 may be demonstrated by immunohistochemical methods [25]. In Muir–Torre syndrome, MSH2 is lost 10 times more frequently than MLH1 [21].

Clinical features. Tumours are usually rounded, raised and either sessile or somewhat pedunculated (Fig. 53.8). They are normally less than 10 mm in diameter, but older lesions may form plaques or ulcerate. Occasional tumours are more deeply located and appear cystic. The colour is fleshy or of a waxy, yellowish hue,

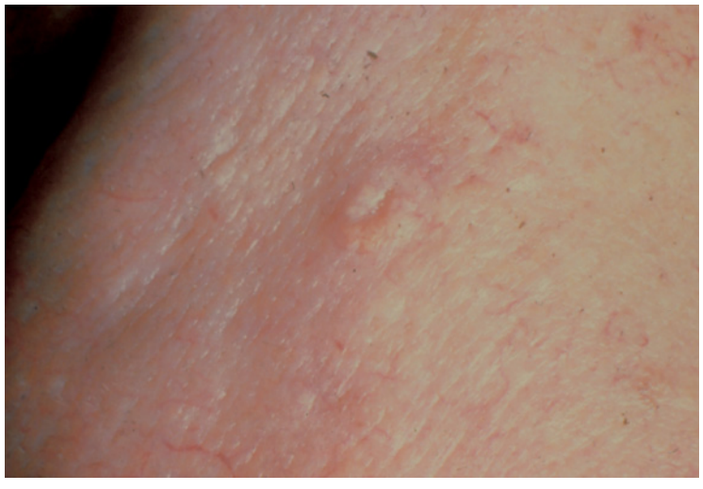

Fig. 53.8 Sebaceous adenoma. Small, yellowish papule.

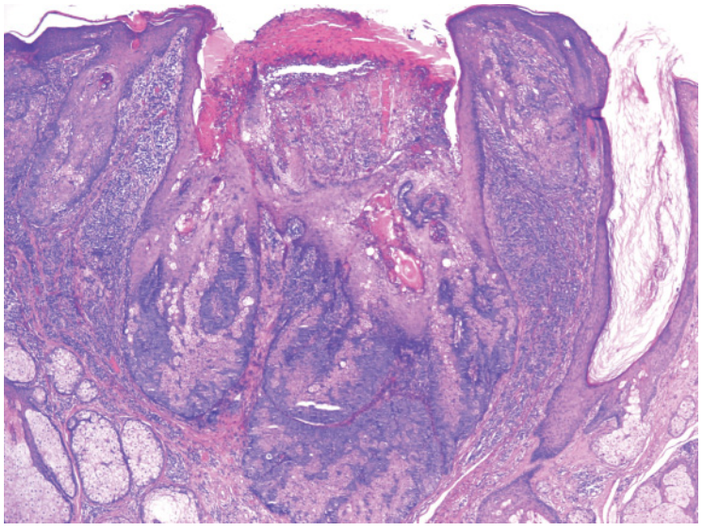

Fig. 53.9 Sebaceous adenoma. Lobular lesion with prominent maturation in the centre and immature cells in the periphery.

and the surface may be papilliferous. The common situation is the face or scalp, and it may occur on the eyelid. It usually grows slowly, but a sudden increase in growth rate can occur.

Diagnosis. A yellow-tinged facial nodule may be suggestive, but clinical differentiation from other epithelial tumours, especially basal cell carcinoma, may be impossible. The microscopic diagnosis is more certain when fat can be demonstrated, but sebaceous differentiation can usually be distinguished in ordinary sections.

Pathology [3,6,15,27]. The tumours are multilobular and usually connected to the epidermis. The lobules are well-defined, composed of variable numbers of small, basophilic, sebaceous matrix cells peripherally and larger cells—mature sebaceous cells—containing cytoplasmic fat globules. The proportion of immature, transitional and mature sebaceous cells may vary widely from one area to another. In sebaceous adenoma, mature sebaceous cells predominate in the centre of the lobules (Fig. 53.9), whilst in sebaceoma, immature basaloid sebaceous cells predominate, occupying large areas of the lobules. In both tumours, there may also be cystic spaces lined by a thin layer of eosinophilic material similar to the intraglandular sebaceous ducts. The outline of the tumour is less regular than normal sebaceous glands, and may be irregular. However, some sebaceous adenomas closely mimic the normal sebaceous gland, except for an increase in the number of immature sebaceous cells. Mitotic figures are frequent in the immature sebaceous cells, and this feature should not be regarded as evidence of malignancy. Larger and deeper tumours with cystic degeneration usually represent sebaceomas, but adenomas may also be seen. Some of these tumours have atypical histological features [28]. The cystic space contains abundant holocrine (sebaceous) material. It has been suggested that these cystic sebaceous tumours are a marker for the mismatch, repair-deficient subtype of Muir–Torre syndrome, which has a high risk of internal malignancies [28]. However, a more recent study although demonstrating that sebaceous keratoacanthomas are often associated with the syndrome failed to show the same correlation with cystic sebaceous neoplasms [20]. Glandular apocrine differentiation may occur rarely in some sebaceous neoplasms [29].

Treatment. The best treatment is surgical excision. Patients with tumours showing loss of expression of mismatch proteins should be screened for internal malignancy, particularly of the colon.

Superficial epithelioma with sebaceous differentiation [1–4]

This is a rare tumour that has no distinctive clinical features and presents as a solitary papule on the face or trunk of adults. Occasionally, lesions are multiple. Histological features consist of a multifocal, plate-like proliferation of basaloid cells with focal sebaceous differentiation and connections to the epidermis.

Sebaceous carcinoma [1–3]

Definition. A malignant tumour composed of cells showing differentiation toward sebaceous epithelium.

Incidence. The variable incidence reported for this tumour reflects the differing diagnostic criteria of different workers. It is, however, rare, comprising less than 1% of all skin malignancies. The tumour has been reported following radiodermatitis [4], and in a patient with multiple arsenical skin cancers. Lesions may rarely occur in naevus sebaceus [5]. It is likely that a number of sebaceomas with high mitotic activity have been reported in the past as sebaceous carcinomas.

Clinical features [6–14]. Most lesions occur in middle-aged and particularly old individuals. Exceptional cases have been reported in children [15]. The tumour is solitary, firm, sometimes translucent and covered with normal or slightly verrucose epidermis. The colour may be yellow or orange. The face and scalp [16] are the commonest sites, especially the eyelid (Fig. 53.10). The evolution may be very slow, and a size of 5 cm or more may be reached after many years without metastasis. Some tumours grow rapidly and invade early, but metastasis is uncommon [17,18]. In the absence of the yellow colour there is no feature to indicate the diagnosis clinically. Sebaceous carcinomas may occur in immunosuppressed organ-transplant patients, and these tumours are associated with microsatellite instability [19]. Sebaceous carcinoma may be associated with the Muir–Torre syndrome [20]. The latter association is mainly seen with extraocular carcinomas and those tumours occurring outside the head and neck area [21].

Fig. 53.10 Sebaceous carcinoma. Ulcerated, yellowish lesion of the eyelid.

Pathology. The same problem of terminology exists with sebaceous carcinoma as with the adenomas. Basal cell carcinoma with sebaceous differentiation is not included in the description of sebaceous carcinoma. It is uncommon for the lesion to be aggressively invasive on the skin, although it frequently is when situated on the eyelid [6–10]. There are, however, individual case reports of aggressive lesions with occasional metastatic spread [22,23].

The essential feature is cytological evidence of sebaceous differentiation. The proportion of cells showing fat globules and the degree of cytoplasmic vacuolation are variable. The undifferentiated cells are of moderate size, with round, centrally placed nuclei and rather basophilic cytoplasm, and they tend to group themselves in masses of a multilobular configuration. The differentiating cells tend to be more central. There are, in addition, cytological features of malignancy and evidence of an infiltrative growth pattern. Mitotic figures including atypical forms are frequent. Pagetoid infiltration of the epidermis is frequent, particularly in tumours arising around the eye [6].

Treatment. Complete surgical excision is required [12,24]. Reports of excellent results with Mohs surgery suggest that this may be the treatment of choice [25].

Apocrine gland tumours [1]

Apocrine hidrocystoma [2]

Synonym
- Apocrine cystadenoma

Definition. A lesion produced by cystic dilatation of apocrine secretory glands. Although the terms apocrine hidrocystoma and cystadenoma have been used as synonyms, and the clinical features of both lesions are identical, there are a number of histological findings that set them apart (see below).

Incidence. The lesion is not uncommon, but is most often seen in ophthalmological or surgical clinics. It occurs in adult life, in no particular age group. Males and females are equally affected.

Clinical features [3–6]. The lesions are solitary or occasionally multiple, well-defined, dome-shaped, translucent nodules [7]. The surface is smooth and the colour varies from a skin colour to greyish or blue-black; pigmentation may affect only part of the cyst. The commonest site is around the eye, particularly lateral to the outer canthus (Fig. 53.11). It has also been reported on the penis [1], fingers [8] and multiple lesions bilaterally in both axillae [9]. There are no symptoms. The cyst increases slowly in size, and may become 10 mm or more in diameter. Multiple lesions may be seen in Schöpf–Schulz–Passarge syndrome (a form of ectodermal dysplasia syndrome characterized by hypotrichosis, hypodontia, nail dystrophy, palmoplantar keratoderma and periocular apocrine hidrocystomas) [10].

Fig. 53.11 Apocrine hidrocystoma. Cystic, translucent papule on the right inner canthus.

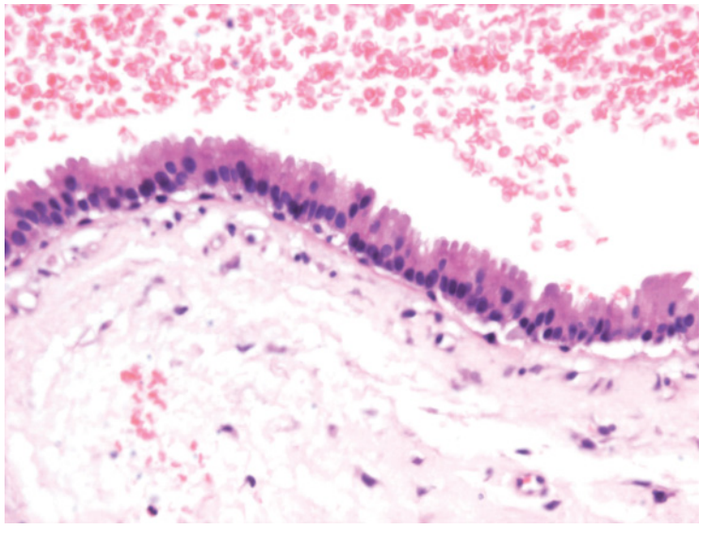

Fig. 53.12 Apocrine hidrocystoma. Cystic cavity lined by cuboidal cells with pink cytoplasm and decapitation secretion.

Pathology [11–13]. Large cystic cavities are found in the dermis if the lesion has been carefully dissected out. Commonly, the cyst is punctured and has collapsed before fixation. The cavities are lined by cuboidal or high-columnar apocrine secretory cells with decapitation secretion and a peripheral layer of myoepithelial cells (Fig. 53.12). Papillary projections or solid buds of secretory cells may break the smooth contour of the cyst lining. The secretory cells may contain pigment [5,6], which is neither melanin nor haemosiderin. The secretions in the cysts may be coagulated and

stained using the PAS technique. There is a well-organized fibrous stroma. Electron microscopy confirms the apocrine nature of the secretory epithelium [14]. Lesions designated as apocrine cystadenoma are regarded as proliferative lesions with true papillary projections (containing a fibrous core) and often display focal cytological atypia and mitotic activity. Based on these atypical features in cystadenoma, complete excision is suggested for tumours classified as such [15].

Diagnosis. Basal cell carcinoma is usually of a firmer consistency, less regular in its surface contour, and has surface telangiectases. The cystic nature of the lesion, which can often be shown by transillumination, separates it from blue naevi and malignant melanoma when pigment is present.

Treatment. The tumour is cured by surgical removal, which is commonly also needed for diagnosis. Other treatment modalities are the same as those used for eccrine hidrocystomas (see p. 53.22). Multiple lesions have been treated successfully with trichloroacetic acid [16].

Syringocystadenoma papilliferum [1,2]

Definition. An exuberant proliferating lesion, commonly seen on the scalp in association with an organoid naevus, and showing differentiation in an apocrine pattern [3].

Clinical features [4]. These lesions may be present at birth or in childhood [5], but the majority are seen on the face and scalp of young adults. There is frequently a history of papillomatous expansion of a small pre-existing lesion at or around puberty and lesions often occur in a pre-existing organoid naevus. The lesion is composed of multiple warty papules, some of which are translucent and pigmented (Fig. 53.13). Tumours may be seen in other locations including the vulva [6], external ear [7], lower leg [8], scrotum [9] and breast [10].

Fig. 53.13 Syringocystadenoma papilliferum. Papular lesion with superficial erosion.

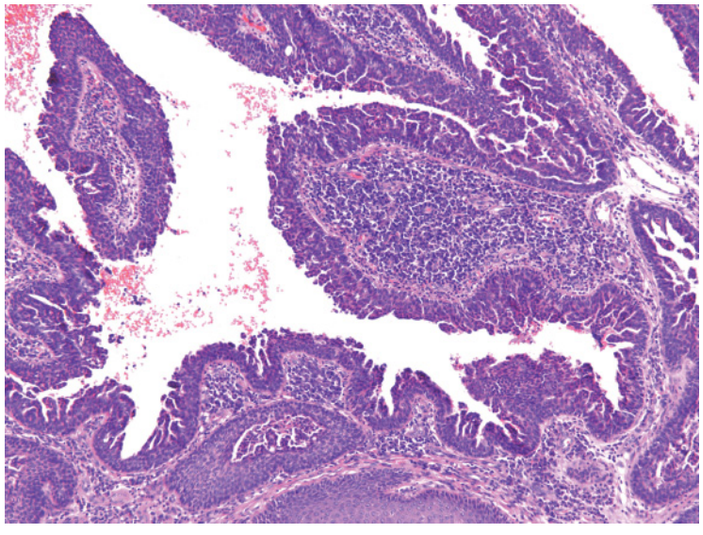

Fig. 53.14 Syringocystadenoma papilliferum. Papillary projections with a fibrovascular stroma.

Pathology [11–14]. The epidermal surface shows papillomatous expansion, and from these areas cystic invaginations are seen. The cystic structures are lined by papillae that have a lining of a double layer of columnar epithelium, which shows an apocrine pattern of secretion (Fig. 53.14) [15,16]. The underlying stroma is rich in plasma cells [17]. Sebaceous differentiation may occasionally be seen [18]. Occasionally, basal cell carcinoma, a squamous cell carcinoma (including verrucous carcinoma) [19] or a ductal carcinoma [20] develops on a pre-existing syringocystadenoma

papilliferum. *In-situ* carcinoma [21] and invasive apocrine carcinoma are exceptional. Molecular biological studies have identified loss of heterozygosity at chromosome 9q22, the locus of the patched gene [22]. Superficial lesions on apocrine tubular adenoma (see below) may overlap histologically with those of syringocystadenoma papilliferum [23].

Management. Surgical excision is recommended, both to confirm the diagnosis and for cosmetic reasons.

Hidradenoma papilliferum

Definition. A skin tumour of the anogenital area of adult females, composed of frond-like papillae lined by apocrine epithelium.

Incidence. This is an uncommon tumour, which occurs predominantly in women. In one large series, the subjects were exclusively white, and 75% were between the ages of 25 and 40 years. It occurs four times as commonly on the vulva as in the perianal area [1].

Clinical features [2–4]. The patients usually seek advice for a lump in the vulval or perianal area, which may be symptomless or, less frequently, may be tender or liable to bleed. The tumour is rounded, freely mobile, often elevated and may feel firm, soft or even cystic. It may range in size from 1 to 40 mm. The commonest site is the labium majus, but it may occur elsewhere on the vulva or perianal area and, exceptionally, in other sites such as the eyelid [4,5], nose [6], arm [7] and chest [8]. Coexistence with a naevus comedonicus has been described [9].

Occasionally, the epithelial surface will ulcerate and the tumour becomes everted to form a reddish-brown papillary mass, which may be suspected of being malignant [1]. Malignant transformation, however, has not been reported.

Pathology. The tumour is well-circumscribed and located just below the skin surface. It is usually spherical in shape and enclosed by compressed connective tissue stroma. Lesions are composed partly of slender fronds of connective tissue lined by one or two layers of epithelial cells, and partly of glandular structures (Fig. 53.15). The epithelial cells have histochemical characteristics in keeping with an apocrine origin [10,11]. Sebaceous differentiation is seen occasionally [5]. Mitotic figures vary and may be frequent. In the absence of other features indicative of malignancy, the mitotic count does not imply malignant behaviour [12]. Rare cases overlap with syringocystadenoma papilliferum [13].

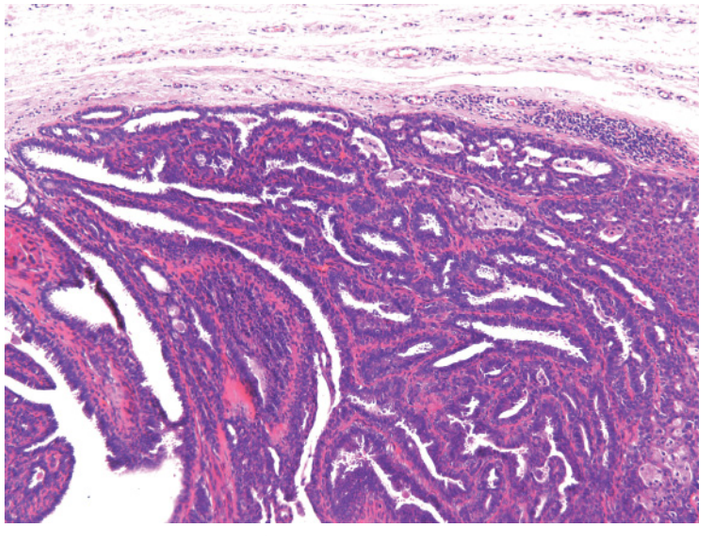

Fig. 53.15 Hidradenoma papilliferum. Well-circumscribed tumour with glands and papillary projections displaying apocrine differentiation.

Diagnosis. The tumour is usually mistaken for a cyst, polyp, angioma or haemorrhoid. A prolonged history and a firm, spherical form make the last three diagnoses unlikely.

Treatment. Simple excision is curative.

Apocrine tubular adenoma [1–3]

Definition. A rare tumour usually arising on the scalp.

Clinical features. These are usually large, slowly expanding lesions on the scalp. The lesion often arises in association with a naevus sebaceus.

Pathology. Clusters of tubular structures are seen in the dermis, with a lining of cells showing decapitation secretion. There is no surrounding inflammatory response. Cytological atypia and an infiltrative margin are absent. As with many adnexal tumours, often one finds histological overlap between tubular apocrine adenoma and papillary eccrine adenoma [3,4]. Overlapping features with syringocystadenoma papilliferum are also seen, especially in superficial tumours [5].

Apocrine carcinoma [1–3]

Definition. A malignant adnexal carcinoma showing clear evidence of apocrine differentiation—large cells with abundant pink cytoplasm and decapitation secretion.

Clinical features. This is a rare entity. Lesions have been reported mainly from the head and neck area, including the eyelid and external ear, anogenital skin and also the axilla [4]. It is not possible on morphological grounds or with the help of immunohistochemistry to separate a cutaneous axillary apocrine carcinoma from an apocrine breast carcinoma spreading or invading the skin by direct extension. It is therefore always important to rule out a primary breast tumour. Some tumours arise within a naevus sebaceus [5,6]. The tumour presents as a nodule, usually measuring more than 1 cm in diameter. Rare cases may be bilateral [7]. There is a slight predilection for females, and patients are middle-aged or elderly. Metastatic spread to regional lymph nodes and internal organs occurs in between 20 to 30% of the cases [6,8].

Pathology. Three histological patterns may be seen: tubular, tubulopapillary and solid (Fig. 53.16). The degree of differentiation varies, and the diagnosis is often difficult in poorly differentiated tumours. Mitotic figures, local invasion and nuclear pleomorphism all suggest a malignant lesion. The most specific pathological feature is the presence of decapitation secretion [1].

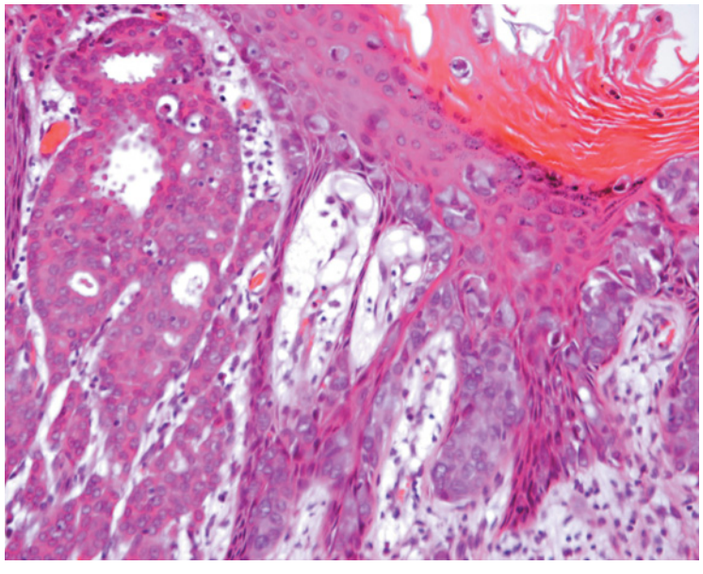

Fig. 53.16 Apocrine carcinoma. Prominent glands with decapitation secretion. Note the epidermotropism.

Some cases are associated with prominent pagetoid spread, particularly those presenting on genital skin [9]. Tumour cells are positive for gross cystic disease fluid protein-15 (GCDFP-15) [10], and they show positivity for oestrogen, progesterone and androgen receptors in up to a third of cases [6].

Treatment. It has been found that grading tumours according to the modified Bloom–Richardson method of grading breast carcinoma is very useful in establishing prognosis [6]. Patients with grade 3 tumours have a poor prognosis [6]. Wide excision and close follow-up are required. Based on the similarities between breast and apocrine carcinoma it may be of benefit to treat patients with high risk tumours and positivity for steroid receptors with medications such as tamoxifen [6].

Eccrine gland tumours [1]

Eccrine gland-derived lesions make up a large and relatively common group of appendage tumours. Hidroacanthoma simplex, dermal duct tumour and eccrine poromas form a fairly homogeneous family derived from eccrine duct and pore. However, there are clear examples of apocrine poroma. Eccrine syringofibradenoma probably also belongs in this subsection. Eccrine hidradenoma, although closely related, has features suggesting both secretory and ductal differentiation, which makes the term 'acrospiroma' misleading, thus is perhaps best kept in a separate category.

Malignant tumours of sweat glands are relatively rare, but important to recognize. Their morphology and behaviour are variable.

Eccrine hidrocystoma [1–7]

Definition. A tumour produced by mature, deformed eccrine sweat units, whose secretions dilate the ducts. Lesions are usually situated on the face and are often multiple.

Incidence and aetiology. This is a rare tumour that occurs mainly in middle-aged women. It was formerly reported as being more common in those who had to work exposed to heat, such as cooks. A report indicating that the lesion is usually solitary and situated close to the eyelid underlines the problem of differentiating eccrine from apocrine hidrocystomas [1].

Clinical features [1]. The lesions are largely confined to the cheeks and eyelids. They are cystic, often blue in colour and there is frequently a history of enlargement when the skin is exposed to heat and flattening of the lesion when the skin is exposed to cold. Administration of atropine also induces disappearance of the cyst [5]. The lesions may be multiple and pigmented [6]. Exceptionally, multiple eccrine hidrocystomas have been reported in Graves' disease with resolution after treatment of the condition [8].

Pathology [2–4]. The general features are those of a dermal cystic lesion uni- or multilocular lined by two layers of cells. The inner layer of cells is columnar and the outer layer consists of elongated myoepithelial cells. In cases with prominent dilatation, the epithelium appears flattened. Distinction from apocrine hidrocystoma is based on the presence of decapitation secretion in the cells of the inner layer.

Treatment. Treatment may consist of topical atropine or scopolamine but this is usually discontinued due to side effects [9]. Electrodesiccation, carbon dioxide laser and pulse dye laser have been used with good results [7,10]. Excision produces satisfactory results.

Hidroacanthoma simplex [1–4]

Definition. An intraepidermal tumour derived from the eccrine duct epithelium, which could be considered an intradermal eccrine poroma.

Clinical features. Hidroacanthoma simplex is a verrucous plaque or ring with a hyperkeratotic usually brown surface. It often mimics a flat seborrhoeic keratosis. Ulceration or elevation of the lesion suggests a dermal component. From the few reports available, it appears that the limbs are more likely to be involved than the head or trunk.

Pathology. Nests of clearly discrete, small, rounded cells are seen within the normal epidermal cells. They are smaller and more cuboidal than surrounding keratinocytes and are rich in glycogen and the glycolytic enzymes. These lesions may be confused with intraepidermal or clonal seborrhoeic keratoses, demonstrating what has in the past been called the 'Borst–Jadassohn phenomenon' [5]. The individual cells in these lesions are larger and less rich in glycogen. However, for the diagnosis to be made, ductal differentiation should be demonstrated.

Management. Excision is recommended both to confirm the diagnosis and for management. Malignant change has been reported in hidroacanthoma simplex including pigmented and clear cell variants [6–10]. If malignant change occurs, wider excision and follow-up is advisable.

Eccrine poroma [1,2]

Definition. A tumour arising from the eccrine duct epithelium in the epidermis (acrosyringium). Traditionally, all poromas have been regarded as eccrine. However, a number of lesions may show apocrine differentiation.

Clinical features [1–11]. This lesion is one of the easiest of the appendage tumours to recognize in the clinic. The great majority of these lesions are found on the palms and soles (Fig. 53.17), in contrast to other skin-appendage tumours which tend to be concentrated around the head and neck area. The anatomical distribution is, however, wide. There is no sex predilection. Most patients are adults, tumours rarely presenting in children [12]. They are moist, exophytic lesions, pink or red in colour, and may reach 1–2 cm in diameter. Occasional lesions are pigmented and look similar to pigmented basal cell carcinoma under dermatoscopy [13,14]. Exceptional examples of poroma have been reported in a naevus sebaceus [15], with rapid growth during pregnancy [16], after electron beam therapy for mycosis fungoides [10], after radiotherapy [10] and at the site of a burn [17]. Multiple poromas have been reported in a case of hidrotic ectodermal dysplasia [18].

Fig. 53.17 Poroma. Note the red, shiny surface, which often leads to misdiagnosis of a pyogenic granuloma.

Pathology [19–21]. These lesions are relatively easy to diagnose, with a clear margin between adjacent, normal epidermal keratinocytes and a population of smaller cuboidal cells, usually with darker nuclei protruding down into the underlying dermis (Fig. 53.18). The cells are strongly PAS-positive and are similar to those seen in the dermal duct tumour [22]. Reports, however, have stressed the fact that some poromas may show either sebaceous or apocrine differentiation [23–25]—highlighting the fact that adnexal tumours with ductal differentiation may be either eccrine or apocrine, as the ducts of both structures are identical.

Malignant change has been recorded on many occasions (see under porocarcinoma).

Management. Benign eccrine poromas are treated by surgical excision.

Eccrine dermal duct tumour [1,2]

Definition. A benign proliferation of the eccrine dermal duct situated in the papillary dermis.

Clinical features. The clinical picture is that of a dermal nodule, occasionally with verrucous change overlying it.

Pathology. The pathology is similar to that of the hidroacanthoma simplex, but the nests of tumour cells making up the lesion are located in the dermis. The cells are small, cuboidal, regular and stain strongly with PAS. Ductal structures are often seen. An intraepidermal component may be seen in some cases, confirming that this lesion is part of the spectrum of eccrine poroma. In some cases, there is prominent clear-cell change [3].

Poroid hidradenoma is regarded as a variant of poroma with overlapping features of hidradenoma (dermal solid and cystic nests) and poroma (poroid cells and ductal differentiation) [4]. This lesion more likely represents part of the spectrum of dermal duct tumour.

Management. Excision is required for diagnostic and therapeutic purposes.

Eccrine syringofibroadenoma [1]

Clinical features. This is a rare entity, and may present as a solitary, often warty nodule on the arms or legs, especially on distal sites. The lesion may be reactive, representing hyperplasia as a result of diverse stimuli, or may be neoplastic usually presenting as a single lesion. Unusual presentations include plaques and multiple lesions [2], occasionally with a linear distribution, may be seen [3]. Coexistence with a squamous cell carcinoma and porocarcinoma has rarely been described [4,5] and lesions may rarely present within naevus sebaceus [6]. Syringofibroadenomatous hyperplasia of sweat ducts is seen in the background of other tumours, a healing ulcer, stasis, a reparative process after bullous diseases, in skin affected by leprosy, in peristomal skin, in burn scars and in association with ectodermal dysplasia [7–13]. In small biopsies, this type of hyperplasia may be confused with a syringofibroadenoma.

Pathology. A network of epithelial cells extends down from the epidermis, forming a mesh-like structure in the underlying epidermis. These cords are composed of smaller cells than in the overlying epidermis, and may contain ductal structures. This mesh is surrounded by a fibrovascular stroma. Unlike basal cell

carcinoma, there is no palisading [14,15]. Clear cells may occasionally predominate [16].

Management. Simple excision is the treatment of choice.

Syringoma [1–3]

Synonyms
- Hidradenomes eruptifs
- Syringocystadenoma
- Syringocystoma

Definition. A benign skin tumour that is usually multiple. The histology is characteristic.

Incidence. It is a relatively uncommon lesion, occurring more commonly in females. It is most likely to appear at adolescence, and further lesions may develop during adult life. It does not appear to be hereditary.

Clinical features [4–11]. The individual small dermal papules [12] are skin-coloured, yellowish or mauve, but sometimes appear translucent and cystic. The surface may be rounded or flat-topped and the outline sometimes angular. Rarely, injury to the surface will allow a drop of clear, watery fluid to escape. They vary in size from 1 to 5 mm, but most are less than 3 mm. Some cases resemble milia and in these cases, the histology reveals a number of cystically dilated structures [13]. In most cases, there are multiple tumours, and they tend to have a bilateral symmetry in distribution. The front of the chest, face and neck are the chief areas affected. A few lesions are usually found on the eyelids when the cheeks are involved (Fig. 53.19). Eruptive syringomas have predilection for the neck, chest, abdomen, pubic area and more rarely on the buttocks [14,15]. They are more frequent in women and tend to occur in teenagers and young adults. Syringomas are seen more often than expected in patients with Down's syndrome [16,17] and may erupt dramatically (Fig. 53.20) [18]. Lesions may rarely occur on the vulva and are associated with pruritus [19,20]. Familial cases rarely occur [21]. A case of multiple syringomas probably sun-induced and in an acral location has been described [22]. Multiple syringomas have also been reported during radiotherapy for breast cancer [23]. The lesions regressed after cessation of radiotherapy.

Fig. 53.19 Multiple syringomas on the upper cheek area.

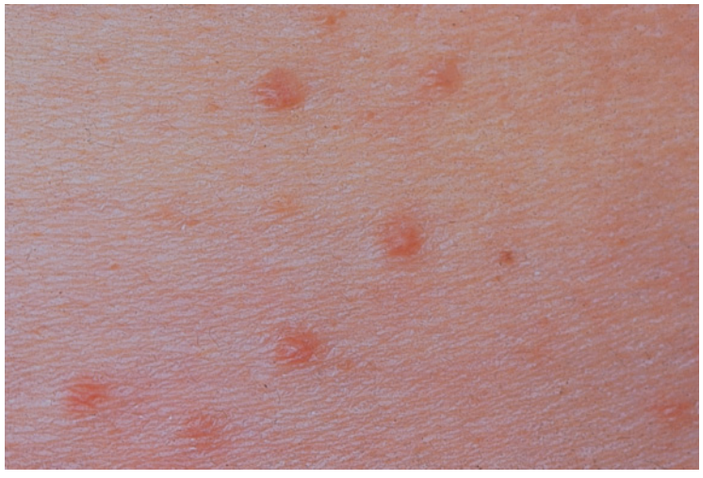

Fig. 53.20 Eruptive syringomas. Multiple, tiny, brownish or red lesions are often seen on trunk and limbs.

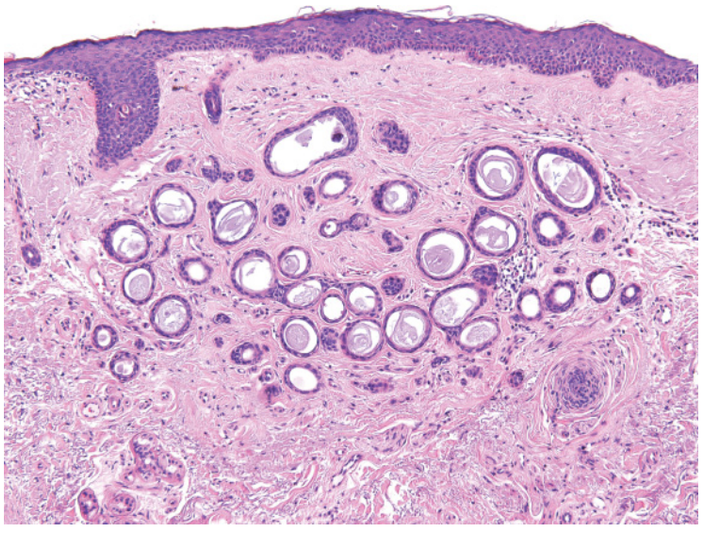

Fig. 53.21 Syringoma. Typical ductal structures with a tadpole appearance.

Pathology [24–26]. The lesion has a characteristic architectural pattern on light-microscope scanning power. Collections of convoluted and cystic ducts are seen in the upper half of the dermis. Most are lined by a double layer of cells similar to, but flatter than, those that line normal eccrine ducts. The lumina contain amorphous debris. A characteristic feature is the tail-like strand of cells projecting from one side of the duct into the stroma, giving a resemblance to a tadpole or comma (Fig. 53.21). The ducts may be enclosed in a fibrous stroma similar to the hair-follicle hamartomas, but in most cases it is narrower and less cellular. When the stroma is dense, it may be difficult to differentiate from the morphoeic basal cell carcinoma, in which, however, well-developed duct structures are not associated with cellular strands and there is a clear infiltrative margin with frequent perineurial invasion.

Diagnosis. Syringoma is most likely to be confused with trichoepithelioma on the face. The syringomas tend to be smaller, rather less superficial, more flat-topped and disposed more evenly over the cheeks and eyelids, rather than favouring the nasolabial creases. There is no family history. Lesions on the lids may be mistaken for xanthelasma, but lack the orange colour. Those erupting on the trunk may be mistaken for disseminated granuloma annulare.

Treatment. The main reason for treatment is cosmetic. Careful destruction with diathermy can produce good cosmetic results.

Papillary eccrine adenoma

Definition. This rare lesion was first described in 1977 [1]. A solitary nodule, usually on the limbs of darker-skinned individuals it is controversial whether papillary eccrine adenoma represents the same entity as tubular apocrine adenoma [2]. The issue has not been settled but it seems that most tumours are probably apocrine and this is confirmed by examples that display follicular and sebaceous differentiation [3]. True eccrine lesions are unusual and are those arising in areas where no apocrine glands are present normally, such as the limbs [4].

Clinical features. It presents in a non-diagnostic manner as a slowly growing nodule on the limbs [5].

Pathology. The lesion is in the papillary dermis and consists of ductal structures with papillary projections. These ductal structures may display either eccrine or apocrine differentiation (decapitation secretion). Dilated ducts form a complex honeycomb-like structure.

Eccrine or apocrine/follicular tumours

In recent years, it has become apparent that a number of adnexal tumours that were regarded as exclusively showing eccrine ductal differentiation often display ductal apocrine differentiation. Because of the close relationship between the apocrine and the pilosebaceous unit, these tumours may also show evidence of focal follicular and even sebaceous differentiation [1,2]. The list of tumours with potential to display apocrine ductal differentiation continues to expand and even includes rare examples of poromas showing apocrine differentiation (see p. 53.23).

Hidradenoma [1]

Synonyms
- Nodulocystic hidradenoma
- Clear-cell hidradenoma
- Acrospiroma

Definition. A relatively rare tumour of sweat gland origin. Although traditionally regarded as displaying eccrine differentiation, it is now accepted that tumours can show either eccrine or apocrine differentiation [2].

Clinical features [3]. This is an uncommon tumour, found mainly in adults, and is excised more commonly in women than in men. Lesions in children are very rare [4]. The tumours are firm dermal nodules, 5–30 mm in size, and may be attached to the overlying epidermis, which can be either thickened or ulcerated (Fig. 53.22). Growth is slow and there may be a history of serous discharge. The lesions are usually solitary and are most likely to be found on the scalp, face, anterior trunk and proximal limbs.

Pathology [5–8]. The tumour may connect with the epidermis. It forms lobulated, circumscribed masses and is composed of two cell types—polygonal cells, whose glycogen content may give the cytoplasm a clear appearance; and elongated, darker and smaller cells, which may occur at the periphery. Often, tumours do not contain cells with clear cytoplasm, and the name 'clear-cell hidradenoma' is therefore misleading. Cuboidal or columnar cells are seen lining duct-like spaces and clefts. In cases with a connection to the epidermis, the superficial component displays poromatous features. Focal squamous differentiation may be seen [9] and occasional mucinous cells are also present. The latter is often seen in lesions with apocrine differentiation.

Malignant transformation is very rare, and the diagnosis relies on identification of the pre-existing benign component [10–13].

Fig. 53.22 Hidradenoma. Red–brown irregular papule.

Diagnosis. When the tumour is attached to the epidermis, the diagnosis may be suspected on clinical grounds, especially if there is a history of discharge. Ulcerated lesions may resemble basal cell carcinoma. Dermal nodules are non-diagnostic by clinical inspection.

Treatment. Surgical excision will cure benign lesions. Local recurrences are rare [14]. Malignant eccrine hidradenoma may metastasize.

Cylindroma [1–5]

Synonyms
- Turban tumour
- Spiegler's tumour

Definition. A skin tumour of uncertain origin with a characteristic histology (see below) that usually manifests as nodules or tumours of the scalp.

Incidence. This is an uncommon tumour, affecting females more frequently than males. It is frequently familial and an autosomal-dominant gene determines its inheritance [6,7]. It has been reported to follow radiotherapy epilation of the scalp. The onset is usually in early adult life, but may be in childhood or adolescence.

Clinical features [8,9]. The tumours are frequently multiple, smooth, firm, pink to red in colour and often somewhat pedunculated (Fig. 53.23). The lesions may be familial and a suppressor gene (cylindromatosis gene, *CYLD*) has been identified on chromosome 16q12–13, loss of which is associated with cylindroma development [10–12]. Somatic mutations have also been identified in sporadic cases. The loss of this gene causes activation of NF-B which is a transcription factor with antiapoptotic activity [13]. Based on genetic studies and the identification of mutations in the same gene in the Brooke–Spiegler syndrome, multiple familial trichoepitheliomas and familial cylindromatosis it is suggested that the three diseases have the same genetic basis and are phenotypic expressions of the same disease [14,15]. The rate of growth of cylindroma is slow and often seems to cease when a certain size has been reached. Some tumours become 5 cm or more in diameter, but most are smaller. Pain is an occasional symptom. The commonest site is the scalp and adjacent skin. Tumours on the scalp may be almost hairless when pedunculated, but the smaller lesions form dermal nodules with little loss of overlying hair. Multiple tumours have attracted much attention in the literature, but solitary lesions are not uncommonly seen by surgical pathology services. A proportion of lesions occur on the face and neck away from the scalp margin; in fewer than 10% of cases, they are situated on the trunk and limbs. Rare lesions may occur in the breast sporadically or in association with Brooke–Spiegler syndrome [16]. When the lesions are multiple, new tumours arise over the years. In some patients, there may be an admixture with trichoepithelioma, either in separate tumours or sometimes in the same tumour. This is a clear confirmation of what can be inferred from the syndromes associated with cylindromas and follicular neoplasms which is that cylindromas are more likely to be related to the apocrine gland than to the eccrine gland.

Fig. 53.23 Cylindroma. Two large tumours on the head of an elderly woman.

Pathology [17–23]. The tumours have a rounded outline and are composed of closely set mosaic-like masses ('jigsaw-puzzle' appearance) and columns of cells that are invested by a hyaline basal membrane of variable thickness. Thin bands of stroma (Fig. 53.24) separate tumour lobules from one another. The cells are of two types—one large, with a moderate amount of cytoplasm and a vesicular nucleus; and the other small, with little cytoplasm and

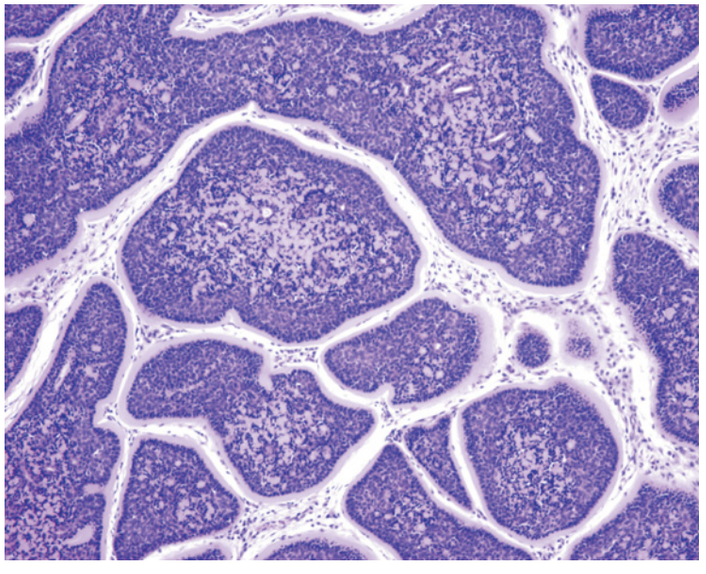

Fig. 53.24 Cylindroma. Classical jigsaw-puzzle architecture, with tumour lobules displaying a thick basal membrane.

a compact nucleus. The small cells tend to be peripheral; they also surround duct-like spaces or masses of hyaline material within the tumour lobule. There are strong immunohistochemical similarities between cylindromas and spiradenomas, and they may coexist in the same individual [24,25]. Malignant transformation is very rare and a sarcomatous component may exceptionally be seen [26–28].

Diagnosis. The multiple type on the scalp is most likely to be confused with tricholemmal cyst, which is, however, usually smoother, firmer and more mobile. Small tumours are difficult to diagnose, and must be distinguished from trichoepithelioma, steatocystoma, or basal cell carcinoma if solitary. Large, pedunculated and lobular tumours are almost unmistakable.

Treatment. Surgery is the treatment of choice. Extensive involvement of the scalp may require wide excision and replacement of the whole area by a graft. Topical salicylic acid has been used with some success in patients with multiple cylindromas [29].

Spiradenoma [1,2]

Synonym
- Eccrine spiradenoma

Definition. A benign tumour of sweat gland origin, which is usually solitary and is distinguished by its histology (see below).

Incidence. It is relatively uncommon, appears mainly in young adults, equally in both sexes and is rarely familial (see under cylindroma).

Clinical features [3,4]. The lesion is usually solitary and painful and consists of a firm, rounded, bluish, dermal nodule 3–50 mm in diameter [3]. The usual site is on the front of the trunk and proximal limbs. Rare sites include the vulva, breast and the external ear. Congenital tumours are exceptional, and in one case lesions followed Blaschko's lines on the face [5]. Multiple neoplasms in a linear or zosteriform distribution may also be seen [6,7] and tumours may rarely be seen in a naevus sebaceus [8]. Lesions with features of spiradenoma may be part of the Brooke–Spiegler syndrome [9]. Spiradenoma often overlaps with cylindroma and this gives support to the theory that they are part of the same spectrum (see under cylindroma) [10]. Furthermore, the coexistence of spiradenoma with follicular tumours confirms an apocrine line of differentiation at least in a percentage of these tumours.

Pathology [11,12]. The tumour is lobular, with two cell types in the islands (Fig. 53.25). Larger, paler cells may be grouped around lumina, and smaller, darker cells form the periphery. Small, tubular structures or cystic spaces may occur, and large, thin-walled, dilated vascular channels are also present [13,14]. The lobules are surrounded by condensed connective tissue, which may encroach on the islands as hyaline droplets. Degenerative changes in old tumours are often prominent. Haemorrhage and

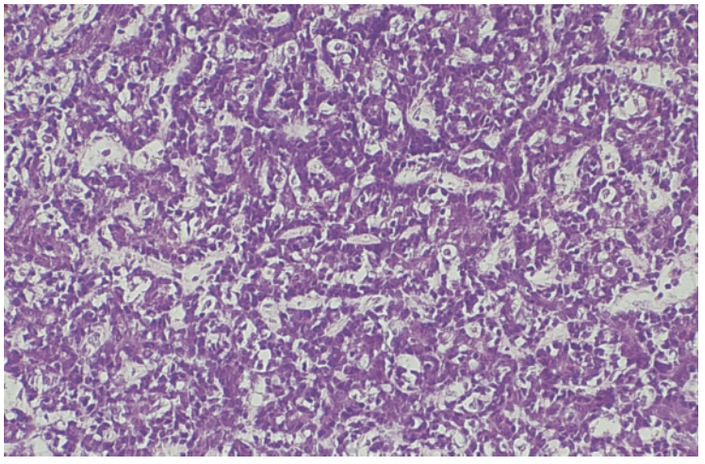

Fig. 53.25 Eccrine spiradenoma. Ductal structures and intermixed pale and dark cells.

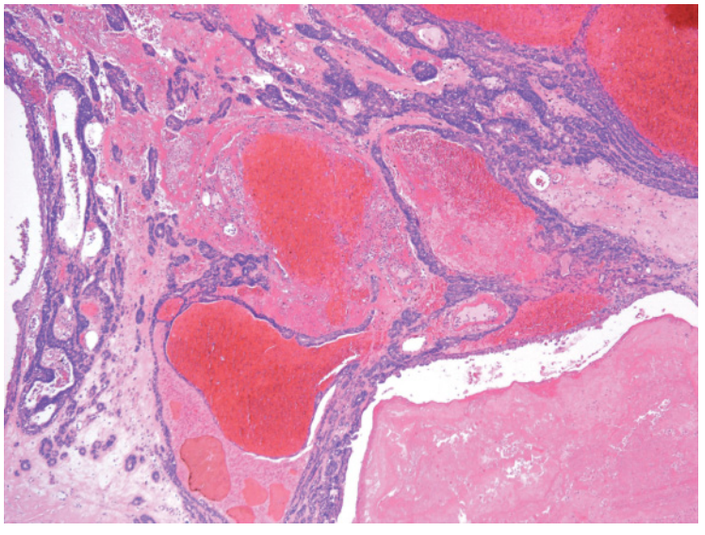

Fig. 53.26 Eccrine spiradenoma. Extensive haemorrhage with or without ischaemic necrosis may result in rapid clinical growth. Only small areas of residual spiradenoma remain.

ischaemic necrosis as a result of degeneration often obscure the histological features, and only focal areas display the typical features of a spiradenoma (Fig. 53.26). Old tumours with degenerative changes tend to be very large. Malignant transformation may occur and usually presents in long-standing tumours [15–20]; lesions may have features of cylindroma and spiradenoma [10]. The diagnosis of a malignant spiradenoma is often only made after a residual benign component is identified. Rare tumours have a sarcomatous component [21]. Malignant tumours may metastasize but it is difficult to be certain of how aggressive these neoplasms are because of their rarity and the bias to report mainly cases with aggressive behaviour.

Diagnosis. Clinical differentiation from other dermal tumours and cysts may be made if the tumour is firm, dark blue and domed.

Treatment. Surgical excision should be complete, as there may be recurrence.

Mixed tumour of the skin [1]

Synonym
- Chondroid syringoma

Definition. Although traditionally regarded as a tumour showing eccrine derivation, it has been demonstrated that a majority of lesions are folliculosebaceous-apocrine and only rare tumours are truly eccrine [2].

Clinical features [1,3–5]. This tumour is usually found on the head and neck, followed by the trunk and the extremities, as a solitary nodule. The lesions are frequently large and nodular,

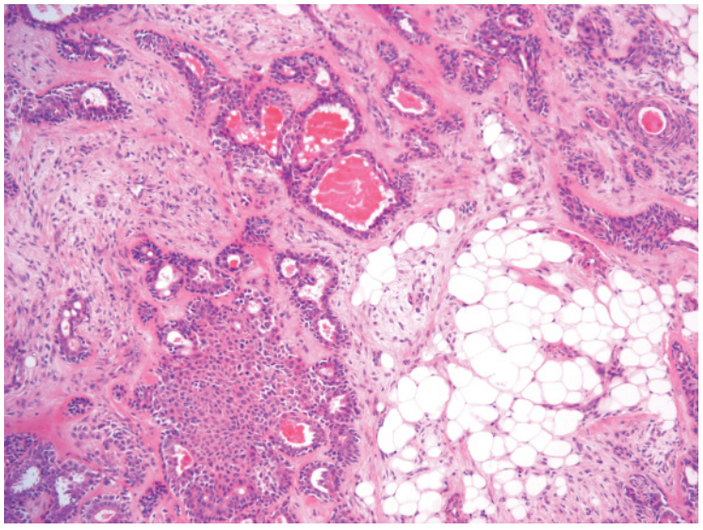

Fig. 53.27 Apocrine mixed tumour. Notice the apocrine glands with a surrounding myxoid/hyalinized stroma with fatty metaplasia.

sometimes with a diameter of 5–10 cm, and occur most commonly in middle-aged males. Lesions in children are rare [6]. Local recurrence is rarely seen.

Pathology [7–13]. This is usually a large, multilobulated tumour located in the dermis and/or subcutaneous tissue. Tumour lobules are separated by fibrous septa. A myxoid, hyalinized or chondroid stroma is variably seen in all tumours. The epithelial component consists of nests and strands of cells with pink cytoplasm and vesicular nuclei with a single, inconspicuous nucleolus. Cytological atypia is absent, and mitotic figures are sometimes seen. Tubular structures and ductal differentiation are frequently seen. Epithelial cells may show various types of metaplasia and differentiation including squamous and mucinous metaplasia and clear cell change and columnar and oxyphilic change [2]. Larger tumour cells with a plasmacytoid appearance are a frequent finding and suggest myoepithelial differentiation. Myoepithelial cells may also be spindle-shaped or display hyaline or clear cell change and collagenous spherulosis [2]. Ductal structures usually have a peripheral layer of flattened myoepithelial cells. Immunohistochemical studies reveal positivity for keratin and focal positivity for S100 and smooth muscle actin, confirming myoepithelial differentiation. Areas clearly indicative of apocrine (Fig. 53.27) and follicular differentiation are often identified [9,10,14,15]. Tumours with follicular differentiation often show numerous keratocysts indicating infundibular differentiation. Staining with cytokeratin 20 may be helpful to identify Merkel cells which, when present, confirms follicular differentiation [16]. The stroma stains positively with Alcian blue, indicating the presence of chondroitin sulphate and hyaluronic acid. Focal calcification, mature fat and bone formation may also be seen [2,17]. From this description, it is clear that all the different cellular elements in mixed tumours including the epithelial, myoepithelial and stromal components may show a wide spectrum of differentiation and metaplastic changes that may make histological interpretation difficult and a potential source of pitfalls [2]. Tumours composed exclusively of myoepithelial cells are regarded as myoepitheliomas [18]. In some cases of mixed tumours, focal architectural and cytological atypia may be seen but this does not seem to imply a more aggressive behaviour [19].

Malignant chondroid syringomas have been reported [20–27], including rare cases with metastasis [28,29].

Management. Local excision is recommended. If there is any suspicion of malignancy, wide excision and follow-up are required.

Sweat gland carcinomas, including ductal apocrine/follicular carcinomas

These lesions can be divided into two broad groups. The first group represents the situation in which malignant change develops in a pre-existing, apparently benign lesion, such as hidradenoma, mixed tumour, spiradenoma, cylindroma and eccrine poroma. The latter is the most commonly recorded example of such malignant progression [1,2]. In most adnexal tumours, with the exception of malignant eccrine poroma, the diagnosis usually requires identification of a benign component. Even when there is unmistakable cytological evidence of malignancy, the biological behaviour of malignant tumours of skin appendages is generally relatively benign, with local recurrence being much more common than cutaneous metastases.

The second group of carcinomas consists of lesions that develop as carcinomas *ab initio*. The primary eccrine carcinomas include microcystic adnexal carcinoma, eccrine epithelioma (regarded by many as part of the spectrum of microcystic adnexal carcinoma), aggressive digital papillary adenocarcinoma, mucinous carcinoma and adenoid cystic carcinoma. Lymphoepithelioma-like carcinoma of the skin is also included in this group.

A review of 60 sweat gland carcinomas reported 41 porocarcinomas, three syringomatous carcinomas, eight ductal carcinomas, five adenoid cystic carcinomas and three mucinous carcinomas [1]. The rarity of sweat gland carcinomas makes it difficult to say whether or not this distribution is the norm, but porocarcinoma does appear to be a relatively common lesion.

Eccrine gland carcinomas

Malignant eccrine poroma [1,2]

Synonym
- Porocarcinoma

Definition. A malignant tumour with metastatic potential arising from intraepidermal eccrine duct epithelium. In up to 18% of cases, tumours arise from a pre-existing benign eccrine poroma [3].

Clinical features [4–7]. These are relatively common malignancies (0.01–0.005% of all cutaneous tumours), arising most often on the lower limbs (44% of cases) in older patients, with an average age at presentation of 73 years. Females are more commonly affected than males. The lesion presents as an endoexophytic tumour, which is often ulcerated. Tumours may attain a very large size and are frequently long standing. Local recurrence is seen in 17% of cases. Regional lymph-node metastases and systemic metastases occur in 19% and 11% of patients, respectively [3]. A small number of patients present with multiple lesions, and it is not clear whether this represents epidermotropic metastasis or true multifocality [1,3,8]. An exceptional case has been reported arising in a scar [9], and a further metastatic lesion was associated with exposure to poison gas [10]. A neoplasm developed from a poroma in a child [11].

Pathology [3,12–14]. Tumours show multiple connections to the epidermis, and a pre-existing benign eccrine poroma may be present. *In-situ* lesions are seen occasionally [3,15]. The tumour infiltrates the dermis and the subcutaneous tissue in nests and lobules composed of relatively small cells that do not have a basaloid appearance. Peripheral palisading is absent. Ductal differentiation is necessary for the diagnosis to be made. This may be demonstrated by the use of immunohistochemical stains for carcinoembryonic antigen (CEA) and epithelial membrane antigen (EMA). A PAS stain may also be used, but this only highlights the ducts in very well-differentiated tumours forming ducts with a cuticle. Comedo necrosis is often present. Clear-cell change and squamous differentiation may be seen, and the latter may be prominent in some cases making it difficult to decide whether the tumour represents a squamous cell carcinoma with ductal differentiation or a porocarcinoma with squamous differentiation [16]. Sarcomatoid change may be seen in rare cases [17].

Poor prognostic factors are a large number of mitotic figures, lymphovascular invasion, tumour depth greater than 7 mm and an infiltrating rather than a pushing border [3].

Treatment. Wide excision and follow-up are required. Two series, including a total of 93 cases, suggest that these lesions may have less metastatic capacity than thought previously [3,18]. In a smaller series of 12 cases, half displayed metastases to regional lymph nodes [19]. Mohs micrographic surgery is useful in those cases with a prominent infiltrative growth pattern [20].

Aggressive digital papillary adenocarcinoma

Definition. A rare tumour found on the hands and feet, with a high risk both of local recurrence and metastasis. Prior publications have described both a benign, aggressive digital papillary adenoma and a carcinoma [1,2], but the lack of pathologically diagnostic or prognostic differentiating features suggests that all lesions in this category should be treated as carcinomas.

Clinical features. Both sexes are affected and although most patients are young adults, the age range is wide and an exceptional case in a teenager has been reported [3]. The lesion presents as a non-diagnostic, asymptomatic nodule on the fingers, toes, palms or soles. Delayed diagnosis is frequent [1,2,4,5]. Lesions may masquerade as either a fibrokeratoma [6] or paronychia [7].

Pathology [1,2,5]. The lesions are obviously cystic on low-power microscopic examination, and have papillary projections into the cystic cavities. Ductal and tubuloalveolar structures are also present. There may be focal necrosis and both nuclear hyperchromatism and a high mitotic count. In some cases, a tubular architecture tends to predominate and papillary projections may not be so prominent. Histological features do not allow accurate prediction of behaviour, as tumours with low-grade histology may metastasize [2].

Tumours may invade surrounding soft tissues and blood vessels and can destroy bone.

Treatment. Wide local excision including amputation of the affected digit and follow-up are recommended in view of the high recurrence rate, both locally and via metastatic spread [1,2,8,9]. It has been suggested that sentinel lymph-node biopsy is appropriate for these lesions [10].

Eccrine or apocrine/follicular carcinomas

Malignant cylindroma [1–7]

Definition. A rare tumour, which develops from a pre-existing benign dermal cylindroma.

Clinical features. These unusual tumours develop as expanding nodules, usually on the scalp or very rarely in the external ear [8]. They may be suspected by expansion of a previously static dermal cylindroma or turban tumour. They have been reported in familial cases of cylindromas [1,2].

Pathology. These lesions have the characteristic architecture of a dermal cylindroma, with deeply basophilic small cells surrounded by an eosinophilic basement membrane [3–6]. In addition, however, there is marked nuclear atypia, irregularity of cell size and an infiltrative growth pattern. Mitotic figures, both normal and abnormal, are present. Exceptionally, a sarcomatous component may be seen [9].

Treatment. Wide local excision and follow-up are required.

Malignant hidradenoma

Synonyms
- Hidradenocarcinoma
- Malignant acrospiroma

Definition. A malignant tumour traditionally regarded as displaying eccrine differentiation and arising from a pre-existing hidradenoma.

Clinical features. These lesions are most often recorded as red, ulcerated nodules on the face, hands or feet. They are commonest in older adults, but cases have been recorded in children [1–4]. They may be very aggressive and pulmonary metastases have occurred.

Pathology. Large clusters of glycogen-rich clear cells are present in some cases, but others may resemble basal cell carcinoma [5–9]. Focal necrosis may be present, and the range of mitoses is highly variable. Squamous differentiation may be prominent [10]. Tumour cells are usually positive for EMA, CEA, S-100, gross-cystic disease fluid protein-15, the keratin cocktail AE1/AE3 and cytokeratin 5/6 [11]. Tumours may be eccrine or apocrine. Amplification of the Her-2/neu gene has been demonstrated in a single case with lymph node metastases [12]; based on this finding the patient was treated with trastuzumab.

Treatment. Wide local excision is recommended. Mohs surgery has been used successfully for lesions on the foot [13]. Follow-up is essential, as the lesions may recur locally and/or metastasize [14]. Sentinel lymph node biopsy has been used exceptionally to demonstrate early metastatic disease [15].

Malignant spiradenoma

Synonym
- Spiradenocarcinoma

Definition. A rare tumour, which usually arises in a pre-existing spiradenoma.

Clinical features. Sudden expansion of a pre-existing nodule is the most likely presentation [1]. A study of 12 cases reports the commonest site as the trunk, with limbs, head and neck less frequently involved [2]. The sex distribution appears equal, and presentation is usually in the seventh decade.

Pathology [2–4]. These lesions usually show evidence of origin from a pre-existing benign spiradenoma. Necrosis, a high mitotic count, loss of the dual cell population and an infiltrative growth pattern are features that raise the possibility of malignant transformation.

Treatment. Excision and follow-up are required. Up to 20% of these tumours have been reported to metastasize [2–5].

Microcystic adnexal carcinoma

Synonyms
- Sclerosing/syringomatous sweat duct carcinoma
- Malignant syringoma

Clinical features. This tumour is relatively rare, has an equal sex incidence and a predilection for the central area of the face, often as an inconspicuous, elevated or depressed sclerotic plaque or nodule in the upper lip area [1–4]. The trunk is also rarely involved. The age range is very wide, but young and middle-aged patients are more frequently affected. If the lesion is not promptly treated, or if local recurrence occurs, the lesions may present with pain or a burning sensation because of perineural spread. Cases have been reported both in patients with generalized immunosuppression and in sites of previous radiotherapy [5–7]. It has also rarely been reported arising within a naevus sebaceus [8]. Multiple tumours are exceptional [9]. The rate of local recurrence is very high (up to 40%). Bone involvement is rarely seen [10].

Pathology [11,12]. The salient histological features are the presence of cords of cytologically banal epithelial cells with focal, variable ductal differentiation set in a very sclerotic desmoplastic stroma [2–4]. Horn cysts are seen in many cases and pilar and sebaceous differentiation may also occur (Fig. 53.28) [11–14]. Superficial areas show a resemblance to syringoma, desmoplastic trichoepithelioma and, in some cases, to infiltrative basal cell carcinoma. The diagnosis can therefore be impossible if only a small, superficial biopsy is evaluated, as clues to the correct diagnosis reside in an infiltrative growth pattern and prominent perineural invasion. Immunohistochemistry is of limited value as an aid in the histological diagnosis of microcystic adnexal carcinoma. Although it has been claimed that BerEP4 is consistently negative in microcystic adnexal carcinoma [15] and this may allow distinction from infiltrative basal cell carcinoma, which is consistently positive for this marker, this finding is contradicted by a more recent study in which 38% of microcystic adnexal carcinomas were positive for this marker [15]. Although desmoplastic trichoepithelioma and microcystic adnexal carcinoma may both show positivity for CK15 and BerEP4, it has been shown that CK15 tends to be negative in infiltrative basal cell carcinoma and this may be a useful marker in the histological differential diagnosis of both tumours [16]. Cytogenetic analysis of a case of microcystic adnexal carcinoma has shown a deletion on chromosome 6q (23–25) [17].

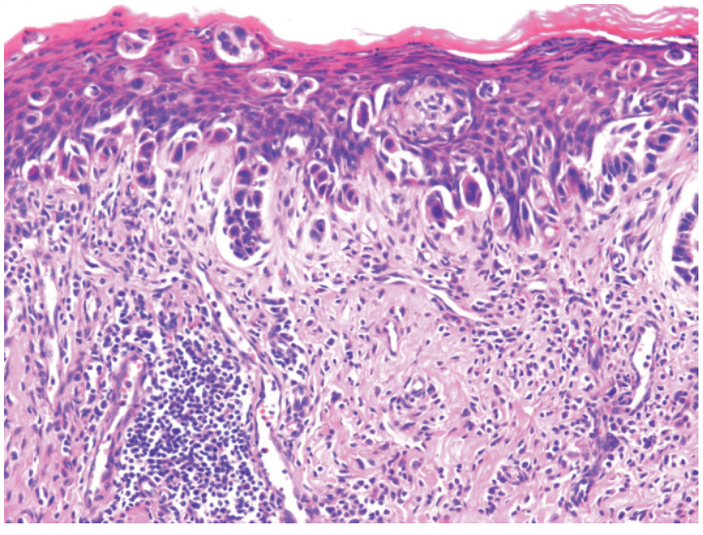

Fig. 53.28 Microcystic adnexal carcinoma. Strands and small nests of bland epithelial cells with an infiltrative growth pattern.

Management. The importance of this tumour is that perineural permeation is common, and for this reason microscopically controlled surgical excision is recommended. Mohs surgery has been recommended as the surgical approach of choice [18].

Metastatic spread is very rare [19,20], but extensive local recurrence can be a major problem. Tumours may rarely extend into the brain as a result of perineural invasion.

Eccrine epithelioma [1–4]

Synonyms
- Basal cell carcinoma with eccrine differentiation
- Syringoid eccrine carcinoma

Freeman and Winkelmann, who considered it to be a basal cell tumour with eccrine differentiation [1,2], first described this rare tumour in 1969. However, the tumour does not represent a basal cell carcinoma with eccrine differentiation [3]. Some authors have proposed that it is part of the spectrum of microcystic adnexal carcinoma. At least 12 cases are currently reported in the world literature. The lesion has some resemblance to both benign syringoma and to dermal cylindroma.

Clinical features. Two-thirds of the cases so far reported have occurred on the scalp as large, non-specific, sometimes ulcerated nodules. They may be painful, due to their position in the deep dermis.

Pathology. The tumour consists of cords and clusters of small, dark-staining, cuboidal basophilic cells set in a very dense stroma. The cells are cytologically abnormal, with a high nuclear/cytoplasmic ratio, and mitotic figures are seen. These features occur in the lower part of the dermis, extending into the subcutaneous fat. The islets of cells have a surrounding PAS-positive membrane.

Management. Wide local excision is required. Follow-up is essential, as repeated local recurrences are common. In one case, metastasis to a local lymph node was recorded.

Mucinous carcinoma

Definition. A rare, adnexal apocrine mucin-producing carcinoma arising on the head and neck area in more than 90% of the cases. This tumour is very similar to mucinous carcinoma of the breast [1].

Clinical features. The most frequently described clinical presentation is that of a grey nodule on the face of an elderly male, often in the periorbital area [2–6]. Occasional tumours present in younger patients [7]. Rarely tumours are bilateral [8]. An important clinical differential diagnosis is a cutaneous secondary deposit from a more common site for mucinous carcinoma such as the stomach and breast [9]. The distinction between a primary skin tumour and a metastasis is often very difficult and has to rely on some histological features (see below), clinicopathological correlation and additional studies to rule out an internal primary. In the case of a suspected metastatic mucinous breast carcinoma, staining for oestrogen and progesterone receptors is not useful, as primary cutaneous mucinous carcinomas are often positive for these markers [10].

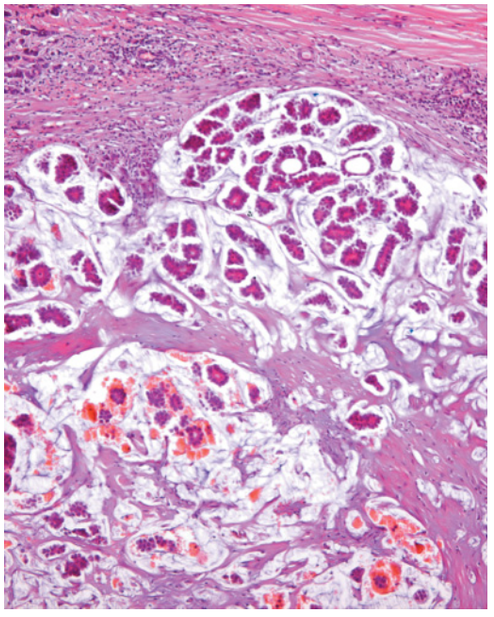

Fig. 53.29 Mucinous carcinoma. Nests of tumour cells surrounded by pools of mucin.

Pathology. These lesions are relatively deeply situated and consist of clusters of cells with pink cytoplasm and some degree of cytological atypia. The central cells are paler and surrounded by darker-staining cells arranged in a palisaded fashion. Broad, fibrous septa run between these cytologically malignant cells, and both cells and septa are separated by lakes of mucin (Fig. 53.29) [11,12]. The mucin stains with diastase-resistant PAS, and acid Alcian blue (pH 2.5). Distinction from metastatic breast of gastrointestinal mucinous carcinoma is difficult. In many cases of primary cutaneous mucinous carcinoma there is evidence of an *in situ* component in neighbouring glands and this confirms a tumour as primary arising in the skin [1,13]. Tumours presenting in the trunk often originate in the breast and those with dirty necrosis usually represent a metastasis from a gastrointestinal primary [1].

Management. Wide local excision, possibly with Mohs micrographic surgery, is recommended [14,15]. Extensive metastatic spread and invasion of bone is very rare [16,17]. Local recurrence is often seen and the risk of metastatic spread to regional lymph nodes increases after a recurrence.

Adenoid cystic carcinoma [1–3]

Synonym
- Primary cutaneous adenocystic carcinoma

This is a particularly rare variant of adnexal carcinoma, which has only been recognized as an entity since 1975. Adenoid cystic carcinomas arise relatively frequently from salivary glands, and direct spread or even metastasis from this site should be ruled out before the diagnosis of primary cutaneous adenoid cystic carcinoma is made [4]. Around 50 cases are presently recorded in the literature.

Clinical features [1,2]. These lesions are non-specific, sometimes painful, nodules on the head and neck area. The pain is attributed to perineural spread. Rarely, tumours develop elsewhere in the skin including the scrotum [3].

Pathology [5–8]. The pathology is that of large masses of cells with mild or no cytological atypia, arranged in a distinct adenoid or cribriform pattern. The cystic spaces are occupied by mucin, which stains with Alcian blue (pH 2.5). The lesion occupies the middle to deep dermis and may extend to the subcutaneous tissue. A more solid variant may be seen occasionally. Many of these tumours show at least focal evidence of myoepithelial differentiation.

Management. The management of these lesions is by wide local excision and Mohs surgery is a good treatment option [9]. Local recurrence is common and metastasis to the lung and regional lymph nodes has rarely been reported [6,10–13]. Metastatic spread to the lungs has also been reported, rarely many years after removal of the primary cutaneous tumour [14]. Erosion of bone at the primary site has also been recorded.

Miscellaneous tumours

Tumours of anogenital mammary-like glands

For many years it was assumed that a number of female genital tumours with features identical to those arising in the breast were derived from ectopic mammary gland tissue along the milk lines. Van der Putte, however, has proposed that this theory is not accurate as primordia of mammary glands do not extend beyond the axillary–pectoralis area [1]. His proposal is that there is a group of distinctive, mammary-like genital glands that share features with true mammary glands and eccrine and apocrine glands and from which most genital glandular neoplasms arise [1,2]. The latter include hidrocystoma, hidradenoma papilliferum, extramammary Paget's disease and tumours identical to those arising in breast tissue including fibroadenoma, cystosarcoma phylloides and adenocarcinoma [3–7].

Paget's disease of the nipple [1]

Definition. A progressive, marginated, scaling or crusting of the nipple and areola due to invasion of the epidermis by malignant cells, which are currently thought to originate in the intraduct carcinoma of the breast that frequently accompanies the condition.

There is a strong, current view that Paget's disease arises from apocrine duct-derived epithelial cells.

Incidence and aetiology [2]. Paget's disease of the nipple is an uncommon occurrence, considering the frequency of breast cancer [3,4]. In one series, it occurred in fewer than 3% of breast cancers. It occurs chiefly in women, although rare cases have been recorded in men [5] and is exceptionally bilateral [6]. It is rare before the fourth decade and is most frequent in the fifth and sixth. Published cases suggest that the disease is more common in Anglo-Saxon countries. The current view is that the majority of cases of Paget's disease arise from either invasive or *in-situ* ductal carcinoma in the deeper breast tissue. In a minority of cases no underlying *in-situ* or invasive carcinoma is found [7]. Although the incidence of breast cancer is increasing, the incidence of Paget's disease has decreased by 45% in the USA in the last decades [8]. Equally, the incidence of Paget's disease associated with underlying invasive cancer of ductal carcinoma *in situ* has also decreased [8].

Clinical features [9,10]. The early changes may be minimal, with a small, crusted and intermittently moist area on the nipple giving a brownish stain on clothing, or producing itching, pricking or burning sensations. Less often, there is a serous or blood-stained discharge from the nipple, or a lump may be noticed in the breast (Fig. 53.30). The surface changes persist and gradually spread to produce an eczematous appearance. The nipple, areola and, at a later stage, skin of the breast are erythematous and moist or crusted (Fig. 53.31). The change is sharply marginated and may spare a segment of the areola. The edge is slightly raised and irregular in outline. If the crusts are removed, a red, glazed, moist or vegetating surface is revealed. Itching may be a prominent symptom and excoriations may be found in the established lesion. Some areas may be ulcerated. The nipple itself may be retracted, and a subjacent mass or a lump deeper in the breast may be felt. The regional glands should be examined; they are rarely enlarged when a mass cannot be felt, but are enlarged in more than half the cases with a detectable tumour. The rate of spread of the skin changes is slow, and patients often wait a year or more before seeking advice. The change may occasionally involve not only the skin of the breast but also spread on to the chest wall. Poor prognosis is associated with invasive disease and the presence of a palpable mass [11]. An exceptional case has been recorded in which the patient presented with ipsilateral eruptive seborrhoeic keratoses of the nipple and areola (Leser-Trelat sign) [12].

Fig. 53.30 Paget's disease of the nipple. Distant clinical view, showing unilateral lesion.

Fig. 53.31 Paget's disease of the nipple. Close-up view, showing erythema and well-marked lateral edge of the lesion.

Pathology [13–15]. The epidermis is thickened, with papillomatosis, enlargement of the interpapillary ridges and hyperkeratosis or parakeratosis on the surface (Fig. 53.32). Within the epidermis, characteristic Paget's cells are dispersed between the prickle cells. They vary in number, and when profuse the Malpighian layers

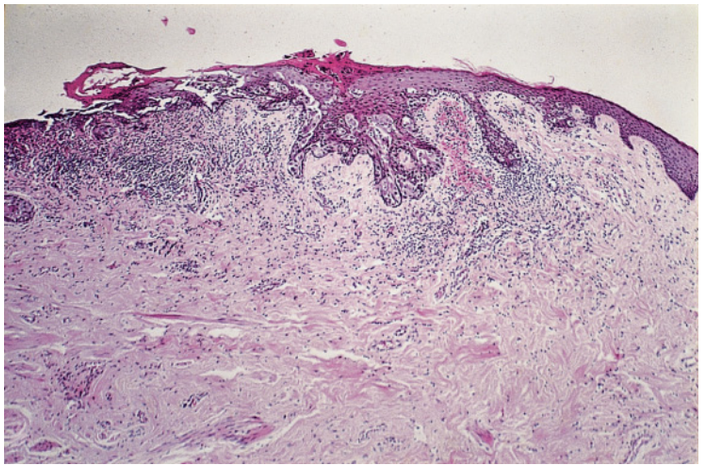

Fig. 53.32 Pathology of Paget's disease of the nipple, showing epidermal ulceration, colonization of the epidermis by large pale Paget's cells and an underlying brisk lymphocytic infiltrate.

may be disrupted and the surface covered by a crust. There is a chronic inflammatory reaction in the upper dermis. In the later stages, the epidermis may be atrophic or eroded. On scanning microscopy, the differential diagnosis may include superficial spreading malignant melanoma.

The Paget's cells have a clear, abundant cytoplasm and do not establish intercellular bridges with the adjacent normal keratinocytes. Both the cells and their nuclei are rounded; the nuclei are vesicular or hyperchromatic with a high nuclear/cytoplasmic ratio. The cytoplasm is PAS-positive and diastase-resistant [16], which indicates the presence of neutral polysaccharides and supports the glandular origin of the cells [17]. Staining with antibodies to CEA is also positive [18,19]. The cells are distributed singly among the prickle cells, or in clusters in a pattern similar to that seen in superficial spreading melanoma. The Paget's cells may also be seen in appendage ducts, so that it can be impossible to determine if these cells are migrating from these ducts to the epidermis, or invading downwards into the ducts from the epidermis.

An underlying breast carcinoma, if present, is not always seen on biopsy, as it may be deeply set. Careful examination of the amputated breast may show an intraduct carcinoma, sometimes of quite small dimensions, usually situated most distally, but sometimes in the terminal ducts, and often appearing to spread between the two layers of epithelial cells of the duct. The cells may accumulate within and distend the ducts and spread in both directions. A number of ducts are usually involved. At a later stage, the carcinoma becomes invasive and behaves like classic breast carcinoma.

Diagnosis. The principal differential diagnosis is eczema of the nipple. This is frequently bilateral and runs a more fluctuating course, improving in response to local treatment and spreading rapidly when irritated. Eczema lacks the sharp, raised and rounded margin and the superficial induration of Paget's disease. In doubtful cases, biopsy will be required. Bowen's disease and superficial basal cell carcinoma may also produce a similar clinical picture. They are both very uncommon on the nipple and can be differentiated histologically. Psoriasis and erosive adenomatosis of the nipple may also need to be considered in the clinical differential diagnosis, and again a biopsy to obtain pathology will clarify the situation. The chief pathological challenge is to distinguish Paget's disease from malignant melanoma, the latter exceptionally presenting in the nipple [20,21]. Paget's disease cells will be CEA-positive, EMA-positive and Cam 5.2-positive, while those of melanoma will be positive for Melan A mart melanoma antigens [18,19]. Positivity to antibody to S100 protein is not useful, as although it is positive in the great majority of melanomas, this is also the case in a proportion of cases of Paget's disease. The absence of melanophages and the presence of neutral mucopolysaccharides in the cells are also helpful.

Treatment [22]. All patients should have a mammogram or ultrasound to establish whether or not there is deeper pathology in the underlying breast, as this will help determine the extent of surgery required. Surgery should be carried out as for carcinoma of the breast. In patients with no evidence of an underlying breast carcinoma, conservation may be a realistic option [23,24]. A recent study has confirmed this, recommending breast conserving therapy with or without radiotherapy according to the presence or absence of an invasive component as the treatment of choice. Sentinel lymph node biopsy is performed in cases with an invasive component [7]. Surgery should always include the whole of the nipple–areolar complex [7].

Extramammary Paget's disease [1]

Definition. A marginated plaque resembling Paget's disease clinically and histologically, but occurring in sites rich in apocrine glands, such as the vulva, anogenital region and axilla.

There is currently controversy as to how often this condition arises on the background of an underlying carcinoma, and how often it arises primarily in the epidermis or apocrine ductal tissue of the affected area. This has given rise to the concept of primary and secondary extramammary Paget's disease [2].

Incidence and aetiology. This is a rare disease. It occurs more frequently in women and starts usually in the fifth decade or after. The current view is that in about 75% of cases, extramammary Paget's disease arises as a primary intraepidermal neoplasm, possibly from apocrine gland ductal cells or from keratinocyte stem cells. It has also been suggested that the disease may originate from Toker's cells [3]. In the remaining 25% of cases, an underlying primary adenocarcinoma is found. These cases are referred to as secondary Paget's disease.

Clinical features. The lesion has many features in common with Paget's disease of the nipple. The margin is sharp, rounded and slightly raised, and encloses an area that is pink or red. The surface may be scaly, and small, greyish crusts may cover erosions. Itching is a prominent feature and there may be excoriations or lichenification. Variable hyperpigmentation may be present, adding to the pathological confusion between extramammary Paget's disease and superficial spreading melanoma. In a proportion of cases, there may be leukoplakia.

The appearance varies somewhat according to the site. The commonest area involved is the vulva [4–6] (Fig. 53.33), followed by the perianal area, which is more frequently affected in men than women, the scrotum, penis and axilla [7,8]. The first symptom, especially in vulval lesions, is itching and burning, which may be persistent and spread. Quite often it is regarded as a dermatitis,

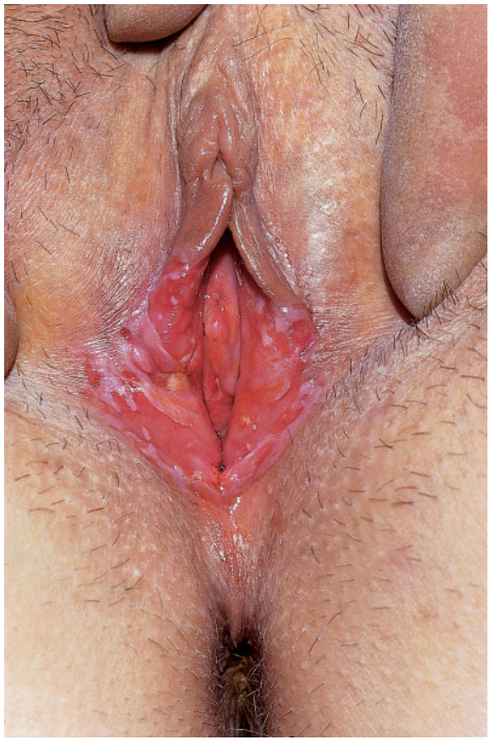

Fig. 53.33 Extramammary Paget's disease of the vulva showing inflamed eczematous presentation.

and may be irritated by topical therapy. The mucosal surfaces of the labia are frequently a rather more vivid red than the skin when both areas are involved, and the change may spread to the thighs, mons pubis and into the vaginal introitus. There may occasionally be a papillomatous surface. Perianal lesions may extend up into the anal canal. Lesions on the scrotum spread to the thigh or onto the shaft of the penis. Very occasionally, extramammary Paget's disease may be present on the eyelids or ears. Characteristic clinical features include the relentless progression, despite all local applications, and the sharp margin. Eventually, one area may become thickened and ulcerated as evidence of invasion downwards. Lymph node or distant metastases can occur.

Although most of the cases in which a primary carcinoma is found result from an underlying sweat gland adenocarcinoma, it is necessary to examine the patient for evidence of an adenocarcinoma elsewhere, particularly of the cervix and rectum.

Pathology. The changes in the epidermis are essentially similar to Paget's disease. The cells stain positively for acid as well as neutral mucopolysaccharides. They may contain melanin granules. Immunohistochemistry shows cells positive for CEA and Cam 5.2 and other low-molecular-weight keratins such as CK7 and CK8/18 [9]. GCDFP-15 is a marker of apocrine epithelium [10] and is frequently strongly expressed in primary vulval or perianal Paget's disease with no detectable underlying malignancy. Cytokeratin 20 is usually negative in primary cases and tends to be positive in lesions associated with an internal gastrointestinal tumour. Apomucin expression may be of help in establishing the origin of cases of extramammary Paget's disease [11]. Cases of

intraepidermal vulval and penile and scrotal extramammary Paget's disease usually have a phenotype that is MUC1 positive, MUC2 negative and MUC5AC positive. In contrast, mammary Paget's disease is usually negative for the latter marker and perianal lesions associated with underlying rectal adenocarcinoma are positive for MUC2 and only variably positive for MUC1 and MUC5AC. Vulval lesions with underlying apocrine carcinoma tend to be negative for MUC5AC.

Comparative genomic hybridization studies in cases of extramammary Paget's disease have shown that the most common change is amplification at chromosomes Xcent-q21 and 19 and losses at chromosome 10q24-qter [12].

Diagnosis. The differential diagnosis from eczema, intertrigo and pruritus vulvae is made by the steady spread, lack of response to topical anti-inflammatory agents and the sharp and extending margin. Bowen's disease is usually more raised and verrucous, and superficial basal cell carcinoma has a thread-like margin. It may be difficult to differentiate leukoplakia or Bowen's disease of the mucosal surfaces, and biopsy may be required. As with mammary Paget's disease, superficial spreading melanoma is an important pathological differential diagnosis.

Prognosis and treatment. Local recurrence is common, even in cases with a wider excision [13]. Poor prognosis is associated with depth of invasion and with elevated serum levels of CEA [14]. Adequate tissue sampling and other investigations are essential to establish whether or not there is an associated underlying malignancy requiring surgical excision. If an underlying malignancy is present, it should be excised together with all clinically abnormal epithelium. If no underlying malignancy is detected on careful examination, the entire affected area of epithelium should be excised. Mohs surgery with careful control of excision margins may be useful, as a common cause of recurrence is inadequate excision of the lesion [15–17].

Promising results are reported with photodynamic therapy, but larger series and longer periods of follow-up are required [18,19]. In cases with limited disease, the use of topical imiquimod has been advocated with good results [20]. However, reports are mainly anecdotal. Radiotherapy has been advocated either as an adjunct to surgical therapy [21] or as an alternative therapy for elderly patients in whom surgery may be difficult [22].

Lymphoepithelioma-like carcinoma

Lymphoepitheliomas are well-recognized tumours of the nasopharynx, and an entity with similar histological features has also been observed in the skin [1]. However, the latter is not associated with Epstein–Barr virus (EBV) infection and its behaviour appears to be less aggressive than that of upper respiratory tract lesions [2,3]. Association with other viruses including HPV and simian virus 40 has not been found either [4].

Clinical features. The clinical appearance is of non-specific nodules on the head and neck area of older patients. Occasional cases present on the eyelid [5] and the trunk and vulva [6] are also rarely involved.

Pathology. The pathological features are those of a very dense infiltrate of inflammatory mononuclear cells, including lymphocytes and histiocytes, with small strands and nests of atypical epithelial cells. Inflammatory cells extensively infiltrate nests and strands of tumour cells, and the epithelial nature of these cells is often not immediately apparent unless more or less intact nests of epithelial cells are found. Confusion with a lymphoma is therefore a possibility, and often immunostaining for keratin and lymphoid

cells is necessary to distinguish the two populations of cells. Cytological atypia is usually present, and mitotic figures are common. Focal evidence of adnexal differentiation and even neuroendocrine differentiation may be seen [7–12]. Some tumours appear to be arising from a squamous cell carcinoma. A sarcomatoid component may be seen [13]. It has therefore been suggested that this is not a distinctive entity but a morphological pattern in various cutaneous carcinomas [14].

Treatment. Surgery followed by radiotherapy is recommended. Some cases have been treated by Mohs surgery [15]. However, the lesions are aggressive, and both local recurrence and distant metastases, with one tumour-associated death, have been recorded [8,10,16].

Merkel cell carcinoma [1]

Synonyms
- Trabecular cell carcinoma of skin
- Primary neuroendocrine carcinoma of the skin

Definition. An aggressive and frequently lethal tumour thought to arise from the cutaneous Merkel cell, a neuroendocrine cell [2].

Incidence and aetiology. The first definitive report of Merkel cell tumour dates from 1978 [2], although there are reports in 1972 of 'trabecular cell carcinoma of skin' [1], which is synonymous. De Wolf-Peeters *et al.* [3] were the first to suggest the use of the term 'Merkel-cell tumour'. More than 2000 cases have been recorded to date. This is a rare tumour of the elderly presenting mainly in Caucasians (0.23 annual age adjusted incidence per 100 000) [4], with a high concentration of primary tumours on sun-exposed sites. There are also a high number of cases in association with immunosuppression [5], including not only transplant patients but also those with HIV infection [6]. Incidence in patients with chronic lymphocytic leukaemia is much higher than in the general population [5]. The general incidence seems to be rising [7]. Tumours very rarely occur in patients with dark skin. An unexpectedly high proportion of Merkel cell tumours arise in association with either squamous cell or basal cell carcinomas, or in patients who have a past history of such lesions [8]. These facts suggest that excessive ultraviolet exposure may play an aetiological role in the development of Merkel cell tumours. Recently, it has been suggested that a novel type of polyomavirus (named Merkel cell polyomavirus) may play a role in the aetiology of the neoplasm as clonal integration of the virus was demonstrated in eight out of 10 cases of Merkel cell carcinoma tested [9].

Clinical features [10]. The lesions appear to have few distinctive features, and are described as raised, reddish-blue nodules, which may develop on any body site, although the head and neck area is over-represented in terms of surface area. Tumours are asymptomatic in the majority of cases and grow rapidly with most lesions measuring between 0.5 and 2 cm. Spontaneous regression of Merkel cell carcinoma has occasionally been reported [11,12]. Partial regression has been reported as a result of withdrawal of azathioprine in an immunosuppressed patient [13], although rapid growth of a tumour was described after treatment with rituximab [14].

Pathology [15,16]. The cells making up the tumour may be either a solid mass or a more diffuse collection of cells, initially situated in the mid-dermis. They are intensely basophilic, with abundant mitotic figures and also many apoptotic cells (Fig. 53.34). Lymphatic and vascular invasion is frequently present. On light microscopy, they may resemble small lymphocytes or a poorly differentiated metastatic deposit, particularly of small cell carcinoma of lung or of naevoid melanoma. The cells are argyrophilic, with sparse cytoplasm, dispersed chromatin and inconspicuous nucleoli. There may be a dense lymphoid infiltrate [17]. Exceptional cases are restricted to the epidermis (*in situ*) [18].

Electron microscopy [19] may be used for positive identification of the multiple, round, secretory granules that pack the cytoplasm of these cells. However, cytomorphology of tumour cells and immunohistochemistry is enough to establish a diagnosis.

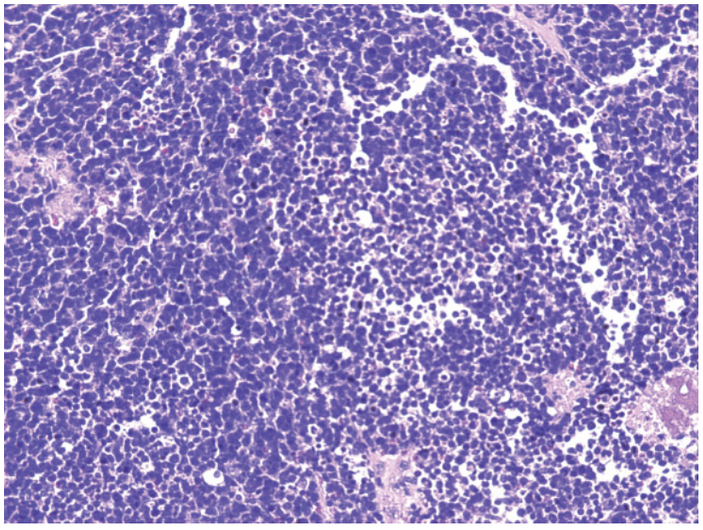

Fig. 53.34 Merkel cell carcinoma. Hyperchromatic medium-sized cells with scanty cytoplasm, prominent apoptosis and high mitotic activity.

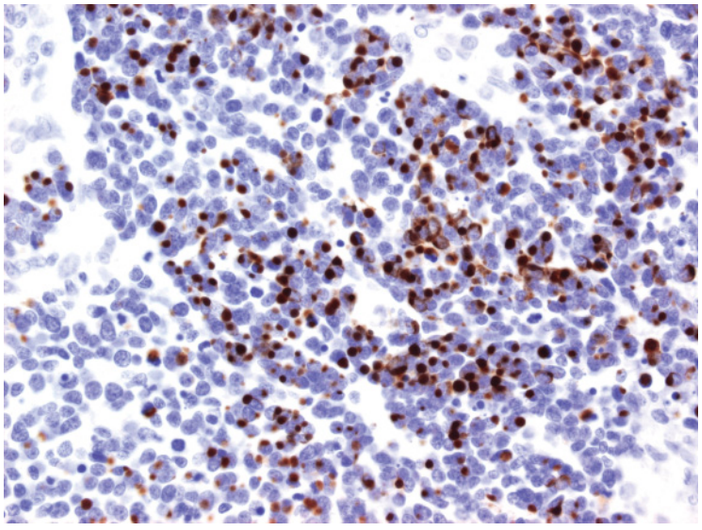

Fig. 53.35 Merkel cell carcinoma. Characteristic dot-like perinuclear positivity of cytokeratin 20.

Immunohistochemistry is useful in confirming the diagnosis. Merkel cells show a characteristic 'dot' positivity with antibodies to low-molecular-weight keratins such as cam 5.2 and CK20 (Fig. 53.35). CK20 is particularly useful in the differential diagnosis from metastatic neuroendocrine carcinomas arising in other organs. The latter except for neuroendocrine carcinoma of salivary glands tend to be negative for this marker [20]. They are also positive for neurone-specific enolase, CD56 and variably positive for chromogranin and synaptophysin. The latter is much more sensitive than chromogranin. A small subset of cases has been identified in which tumour cells are negative for cytokeratin 20 but positive for cytokeratin 7 [21]. These tumours are otherwise typical Merkel cell carcinomas.

Histological features associated with poor outcome include tumour size (≥5 mm), extension into the subcutaneous tissue, diffuse growth pattern and a heavy mononuclear inflammatory cell infiltrate [22]. A further study, however, has found that absence of lymphocytic infiltration adversely influences disease-free survival. In the same study a further important adverse variable was the presence of positivity of more than 50% of tumour cells for Ki-67 [23]. Expression of p63 by tumour cells has also been found to be an independent factor indicating poor prognosis [24]. Tumour thickness does not seem to influence prognosis [25].

Treatment. Surgical excision is required [26], but metastases occur early and 30–50% of patients may die from metastases. Arterial limb perfusion has been used for lesions on limbs and may be beneficial [27]. Merkel cell tumours are considered to be radiosensitive, and trials of postoperative radiotherapy suggest a survival advantage [28]. Sentinel lymph node biopsy is a useful procedure not only to demonstrate spread in patients that have been understaged by clinical and radiological (CT scan) examination but is also important in predicting prognosis and improving survival in patients with positive results who undergo lymph node dissection [29]. The detection of micrometastasis in sentinel lymph nodes is increased by the use of immunohistochemistry for cytokeratin 20 [30]. The preferred treatment at present is surgical excision with sentinel lymph node biopsy followed by lymph node dissection if the latter is positive. Postoperative radiotherapy is also given and this approach improves locoregional control and also improves disease-free survival [31,32]. Treatment of involved regional lymph nodes, with or without lymphadenectomy, has also been found to increase survival [33]. Chemotherapy is not routinely recommended as there is lack of evidence that it increases survival, there is important morbidity and mortality associated with this modality of treatment and resistance to chemotherapy quickly develops in many patients [34].

Introduction

Factors responsible for variation in skin pigmentation are discussed in Chapter 58. Melanin pigment is synthesized and distributed to adjacent cells by cutaneous melanocytes, which are found in normal skin in the basal layer of the epidermis. Melanocytes lie in continuity with adjacent keratinocytes into which they transfer melanosomes. Melanocytes and keratinocytes are therefore biologically interdependent and cells of both lineages may be involved in many of the entities discussed below. Melanin synthesis and distribution is accelerated by exposure to UV radiation. Cutaneous pathology attributable to the melanocyte may arise as a result of overproduction of melanin by a normal quota of melanocytes as in the simple freckle, by proliferation of benign melanocytes as in a melanocytic naevus, or as a result of malignant transformation of the melanocyte as in malignant melanoma (henceforth referred to as melanoma).

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

The freckle or ephelis

Definition. A pale-brown, macular lesion, usually less than 3 mm in diameter with a poorly defined lateral margin, which appears and darkens on light-exposed skin sites during periods of UV exposure.

Clinical features. At any age, simple freckles are commoner in individuals who are red- or fair-haired and fair-skinned (Fig. 54.1). They fade during the winter months.

The clinical distinction between a freckle and a lentigo is that the lentigo persists in the absence of UV stimulation, and histologically a lentigo has a linear increase of melanocytes at the dermal–epidermal junction, but the two entities coexist in the same individuals and the risk factors for both are generally the same.

Pathology. The simple freckle shows no anatomical abnormality on biopsy [1,2]. It arises as a result of temporary overproduction of melanin by a normal quota of melanocytes due to stimulation

by UV radiation. It has been claimed that the melanocortin 1 receptor gene (MCR1) is the major freckle gene, and that *MC1R* gene variants are required for the development of freckles [3], but it is still unclear what mechanism underlies this. Elder and Murphy have even speculated that the signal for increased transfer of pigment from the melanocyte might come from the keratinocyte [4].

Diagnosis. This is usually obvious with the presence of regular macular brown lesions on light-exposed skin. The freckles and café-au-lait spots of neurofibromatosis (Chapter 15) are distinguished as they are commonly on the trunk and axilla, and other features of neurofibromatosis may be present.

Management. No treatment is needed for these benign lesions, and their biological significance lies in the fact that they have been identified in case–control studies as an independent risk factor for skin cancer and in particular for melanoma: in a meta-analysis a high density of freckles was associated with a relative risk of melanoma of 2.10 (95% CI 1.80–2.45) [5].

Fig. 54.1 Freckles in a child with red hair: freckles are indicative of fair skin vulnerable to sunburn.

Lentigines (Table 54.1)

These are also macular hyperpigmented skin lesions, but they persist throughout the year, and on microscopy have an increase in the number of melanocytes at the dermal–epidermal junction compared to that expected for the body site in question. The proliferation of melanocytes occurs usually in response to sun exposure in fair-skinned people (common lentigines). Rarely, syndromal lentigines occur when melanocyte proliferation is determined by inherited genetic anomalies.

Common lentigines are usually seen in fair-skinned people, and represent proliferative responses of melanocytes to the sun. They are commonly subclassified, but excessive exposure to natural or artificial UV radiation is the major aetiological factor for all of the following: simple lentigines, actinic (or solar) lentigines, psoralen UVA (PUVA) lentigines and the ink-spot lentigo. To some extent, the distinction between these subtypes is artificial as they represent a continuum or variations on a theme. Their features are described below, and compared in Table 54.1.

Rare forms of lentiginoses are also seen as characteristic features of a number of rare but potentially serious hereditary multisystem syndromes associated with an increased risk of tumours (Fig. 54.2; Chapter 15).

Very rarely, segmental lentiginoses may be seen; these emerge during childhood and are presumed to represent mosaicism of an unidentified gene [6]. Usually there are no other congenital anom-

Table 54.1 Comparison of freckles, lentigines and related disorders.

Lesion	Distribution	Melanocyte number	Significance
Freckle	Sun-exposed skin	Not increased	Risk factor for skin cancer and sunburn
Simple lentigo	Sun-exposed skin	Increased	Risk factor for skin cancer and sunburn
Solar lentigo	Sun-exposed skin	Increased and accompanied by pathological evidence of solar damage	Risk factor for skin cancer and sunburn
PUVA lentigo	Anywhere	Increased	Risk factor for skin cancer
Ink-spot lentigo	Anywhere but commonly shoulders	Increased and accompanied by pigment in the epidermis and dermis	Probably a risk factor for skin cancer and sunburn but no data are available
Hereditary lentiginoses	Generalized and not preferentially sun-exposed skin. Mucosal surfaces also often involved	Increased	Marker of risk of hamartomas and cancer
Genital melanosis	Genital skin	Debated: no (or extremely subtle) increase in number	None: if *in situ* melanoma excluded by biopsy
Labial melanotic macule	Lower lip generally	Debated: no (or extremely subtle) increase in number	Sun protection required

Fig. 54.2 Multiple lentigos in a patient with hereditary lentiginosis and cardiac anomalies.

Fig. 54.3 A systematized lentiginosis in which a superficial spreading melanoma developed on the knee.

alies and the differential diagnosis includes neurofibromatosis type 1. Melanoma may occur in patients with segmental or generalized lentiginosis (Figs 54.3 & 54.4).

Simple lentigo

Definition. A brown macule, arising as a result of an increased number of melanocytes at the dermoepidermal junction, without evidence of proliferation of these melanocytes downwards into the dermis.

Aetiology and incidence. Multiple, benign lentigines occurring as an isolated phenomenon are very common, particularly in those with red hair and fair skin with melanocytes which produce a high phaeomelanin/eumelanin ratio.

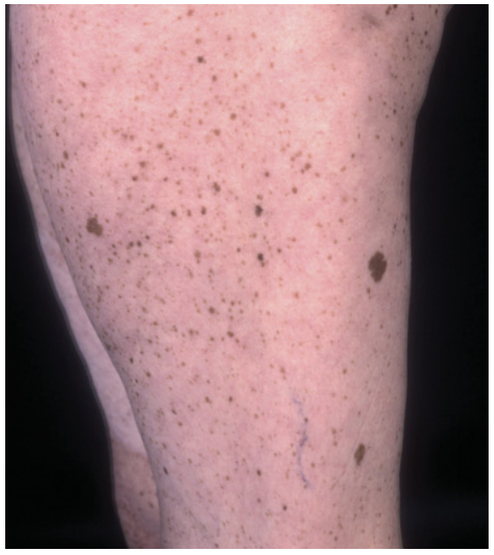

Fig. 54.4 Generalized lentiginosis in a patient who developed cutaneous melanoma in her 50s.

Clinical features. A lentigo is a macular area of brown or brown-black pigmentation, usually circular or oval, although several individual lentigines may coalesce. There may be slight scaling of the surface, but the skin markings are unaltered. The pigmentation is usually light brown and fairly uniform. Lentigines usually start to appear in childhood and increase in number in the second and third decades. Rarely, they may erupt in large numbers [7], sometimes after inflammation, or related to use of immunosuppressive agents [8,9]. The majority of lentigines remain static in adult life. Most commonly, lentigos occur on sun exposed skin as they are part of the spectrum of lesions (ephiledes, simple lentigos, solar lentigos) which occur in fair-skinned people exposed to excessive amounts of sun exposure for their phenotype.

Whilst a lentigo, by definition, is characterized by an increased number of melanocytes, there is a clinical and even a pathological overlap with lesions in which there is an increased number of melanocytes but in which there is also a proliferation of keratinocytes; these are often referred to as 'flat seborrhoeic keratoses' or, on the back of the hands, as 'liver spots'. In practice, this overlap is of little clinical importance; all are markers of fair skin, excessive sun exposure and some risk of skin cancer. All are to be distinguished from lentigo maligna, which is usually relatively easy.

There are a number of hereditary disorders, however, in which multiple lentigines are markers of syndromes characterized by hyperplasias, hamartomas and neoplasia [10], and in these people the lentigos develop much earlier in life and are not restricted in site to sun-exposed skin. In some of these, the causal genetic mutations specifically affect tissues sharing a common origin in the neural crest [11,12] such as melanocytes and cardiac tissues. The familial lentigines include Peutz–Jeghers syndrome [13], the LEOPARD syndrome (*l*entigines, *e*lectrocardiogram anomalies, *o*cular anomalies, *p*ulmonary stenosis, *a*bnormal genitalia, *r*etardation of growth and *d*eafness), in which mutations in the *PTEN* gene have been described [14], the Carney complex and

the closely related NAME and LAMB syndromes. The genetic origin of these syndromes appears to involve diverse pathways which are supposed to converge in embryogenesis and the development of systems including the neural crest [10]. Rarely, lentiginoses may develop in childhood in the absence of multisystem disease [15].

Even more rarely, multiple lentigines may be seen in patients with an evident increased susceptibility to melanoma (Fig. 54.4). A single case report of a patient with lentiginoses and gastrointestinal stromal tumours in the presence of a hereditary *c-kit* mutation suggests that this may represent a further, extremely rare, new subtype [16].

Pathology. There is a linear increase in the number of melanocytes along the dermal–epidermal junction. There is more melanin than normal in the adjacent epidermis and stratum corneum, and melanophages are abundant in the papillary body. The papillae and interpapillary ridges may be elongated—hence the overlap with pigmented seborrhoeic keratoses.

Diagnosis. Lentigines are distinguished from freckles by their darker colour, comparative sparseness and scattered distribution, and by the fact that they do not darken or increase in number on sun exposure, and do not disappear during the winter months. It is often impossible to distinguish lentigines from flat junctional or compound naevi on clinical grounds.

Treatment. As common lentigines are usually multiple, and have no pre-malignant potential, the patient should be reassured. They are however a marker of fair skin, as are freckles. For treatment, see Solar or actinic lentigo, below. Patients with lentiginoses presenting in childhood or early adult life, on non-sun-exposed sites, should be examined for multisystem disease. Extremely rare patients who present with systematized or generalized lentiginoses may be at increased risk of melanoma, and so should be educated about avoidance of sunburn and about self-examination.

Solar or actinic lentigo

Definition. A macular area of brown pigmentation appearing after either acute or chronic sun exposure.

Clinical features. In younger patients, solar lentigines are most commonly seen on sun-exposed sites, such as the face in both sexes and the shoulders in males. They are macular, tan coloured and may be very large, with a striking irregular border. There is frequently a history of acute sunburn, followed by the sudden appearance of large numbers of these irregular macular lesions [17,18]. In the UK, they are rare before the age of 12 years but in sunnier countries they may appear at a very young age.

Solar lentigines are also seen on older fair-skinned patients who have had excessive sun exposure [19]. The backs of the hands and the face are common sites. Once again the lesions are large and macular, have an irregular edge and are usually a uniform shade of brown. They are situated in an area of obviously sun-damaged epidermis and as above there is a clinical and pathological overlap with flat seborrhoeic keratoses.

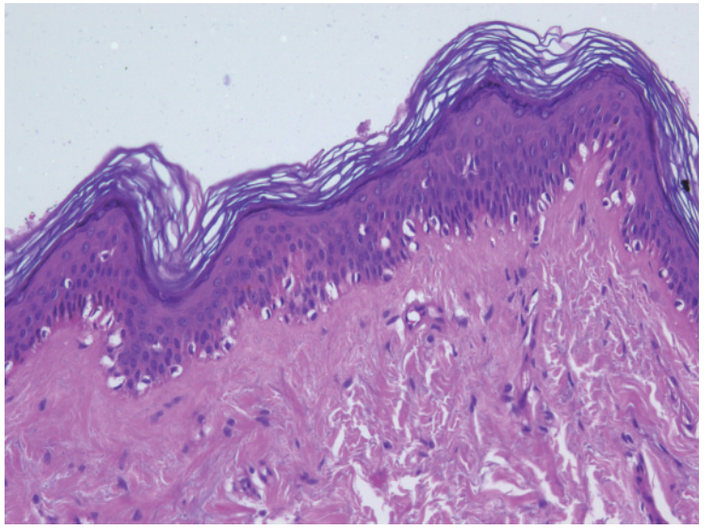

Fig. 54.5 An increased number of melanocytes is seen in this solar lentigo. The dermis also shows elastosis as evidence of sun damage. (Courtesy of Dr S. Edward, Leeds Teaching Hospitals Trust, Leeds, UK.)

Pathology. The pathological features of a solar lentigo are a continuum of those seen in the smaller simple lentigines. There is a linear increase of melanocytes at the dermal–epidermal junction, but no cytological atypia of these melanocytes, and no budding down of these cells into the underlying dermis. There is frequently associated actinic damage to the adjacent dermal collagen (Fig. 54.5).

Treatment. Because of the large size and unsightly appearance of some actinic lentigines, patients frequently request treatment. Prevention of further UV-induced damage should be encouraged by sun avoidance and the use of a high sun-protection factor, broad-spectrum sunscreen. With these measures, there is often some spontaneous resolution of existing lesions. A consensus supported the use of cryotherapy as first line therapy, where cosmesis is required [20]. There is, however, an extensive literature on the cosmetic treatment of lentigines using a variety of additional treatments including intense pulsed light [21,22], laser therapy and topical agents such as retinoids [23]. A review suggested that superficial pigmented lesions of this type respond well to the high-energy QS red and infrared lasers [24].

The majority of solar lentigos progress little over time. A small proportion, however, do slowly progress to become lentigo malignas over many years (Fig. 54.6). A well-defined, large solar lentigo on the face of a younger patient should therefore probably be treated although there are no data to support this advice.

Photochemotherapy (PUVA) lentigo

Lentigines are a well-recognized complication of long-term use of PUVA therapy [25]. They were reported in 20% of a small series of 198 patients given a mean cumulative dose of UVA of 169.5 J/cm^2 [26], and PUVA lentigines of any degree (slight, moderate or extensive) were noted on the buttocks of 53% of 1380 psoriatic patients an average of 5.7 years after starting PUVA [27]. They are

Fig. 54.6 This lentigo maligna developed from a tiny lentigo over a period of 30 years.

relatively large, macular, pigmented lesions, which develop on the skin of patients receiving photochemotherapy. The number of melanocytes in the relevant body site is increased, and ultrastructural examination reveals morphological abnormalities of the melanosomes [28]. Follow-up of PUVA-treated patients in the USA has indicated that PUVA lentigines are a marker of patients at increased risk of non-melanoma skin cancer [29]. The association of risk of melanoma with PUVA treatment generally is less clear, as although an increased risk was seen in a series from the USA [30] this was not seen in a series from Scandinavia [31].

Ink-spot lentigo

Definition. A small (less than 5 mm in diameter), densely black, irregular macule, usually on sun-exposed skin (such as the upper back in a very fair-skinned person who has had a good deal of sun exposure), which resembles an ink spot (Fig. 54.7) [32].

Clinical features. These lesions commonly cause concern because they are so black and irregular in shape. The clinical diagnosis is obvious, however, when the dermoscope is used (Fig. 54.8).

Pathology. The pathology of the lesion is that of a lentigo, with a linear increase in melanocytes in the basal layer of the epidermis, and an associated increase in melanin pigmentation both in the basal cells of the epidermis and also lying free in the underlying epidermis. The melanocytes are normal, and there is no evidence of cellular atypia.

Management. These lesions do not require treatment.

Mucosal melanotic lesions

Pigmented melanotic macules (mucosal melanosis/genital lentiginosis)

Some macular pigmentation of the mucosa in the mouth or on the genitalia is normal; the pigmentation may be increased at sites of trauma and is generally subtle. In the mouth, smoking is thought to induce melanosis and post-inflammatory pigmentation occurs. Lentines may also occur in familial lentiginoses discussed above.

More discrete, more deeply pigmented macules are also common on the vulva and sometimes on the glans penis, when they are usually referred to as genital melanotic macules, or mucosal melanosis. These macules result from local excessive pigment production with normal numbers of melanocytes [1]. There is confusion around aetiology and nomenclature so that some authors refer to melanoses, others to lentiginoses, but the entities probably overlap.

Fig. 54.9 Genital melanosis; a benign condition of unknown aetiology which none-the-less can cause considerable clinical concern.

Rarely, these melanotic macules may expand to several centimetres in size, they may be patchy in distribution and may develop irregular deep pigmentation, which resembles melanoma and causes concern. Melanoma must be excluded by biopsy as melanoma in the genital area may begin with a protracted *in situ* phase, but normally the histological appearance of such lesions is banal, although it has been suggested that the majority have a subtle increase in melanocyte number [2]. The aetiology of genital melanosis is unclear; the presence of pruritus has led to suggestions of a precursor inflammation but none has been clearly identified [1].

The presence of pigmented patches in the genital skin of women affected by lichen sclerosus et atrophicus has been reported [3]. Biopsy of these lesions has shown the lesions to be atypical melanocytic naevi. There is no obvious explanation for the development of these naevi in lichen sclerosus et atrophicus, but it is important to be aware of this association, as clinically the lesions may suggest melanoma.

Clinical features. These lesions are relatively large macular areas of uniform brown, black or grey pigmentation (Fig. 54.9). They may have slowly expanded to reach a large diameter over several years. The differential diagnosis in the mouth is that of oral melanoma which is a rare tumour, representing 0.5% of oral cancers [4]. Oral melanomas may be subtle in appearance (see Fig. 54.64 below) and are described as a smooth swelling which might be evenly hyperpigmented or irregularly pigmented.

Pathology. The pathology of mucosal melanosis is usually much less dramatic than their clinical appearance. There is a clear increase of melanin pigment in the basal layer keratinocytes with some overspill into the dermis, resulting in pigment-laden macro-

phages. The melanocyte count is relatively normal with only a slight linear increase and no junctional activity.

Treatment. No treatment is required if an incisional biopsy of appropriate area(s) has confidently excluded a significant lentiginosis or melanoma. The often dramatically intense pigmentation, however, usually leads to persistent concern and it is therefore reasonable to keep under review, although the issue is actually only one of excluding *in situ* melanoma; mucosal melanosis without the proliferation of atypical melanocytes is held not to be pre-malignant. A change in appearance would merit another biopsy, as the differential diagnosis is *in situ* melanoma.

If there is a significantly increased number of melanocytes, particularly if there is confluent proliferation resembling lentigo maligna, then treatment is required. The treatment options are limited in these circumstances. In the presence of clear *in situ* change, then surgery would be the normal treatment choice. The mutilating effect of this surgery, however, is such that a therapeutic trial of topical imiquimod might be justified with biopsy after treatment [5], although patients may find it difficult to tolerate in this site.

Labial melanotic macules [6,7]

Definition. Flat areas of benign, non-progressive melanin pigmentation on the lips, which may be best viewed as a type of freckle or a lesion akin to a simple lentigo [8].

Clinical features. Labial melanotic macules usually affect the lower lip in the central third. More females than males seek treatment for these lesions. The site suggests that excessive exposure to natural UV radiation may be an aetiological factor. The natural history is of the relatively rapid appearance of a brown to black macule on the lower lip in a young adult. The macules rarely become larger than 0.5 cm in diameter, and are usually single lesions (Fig. 54.10). The differential diagnosis includes an amalgam tattoo.

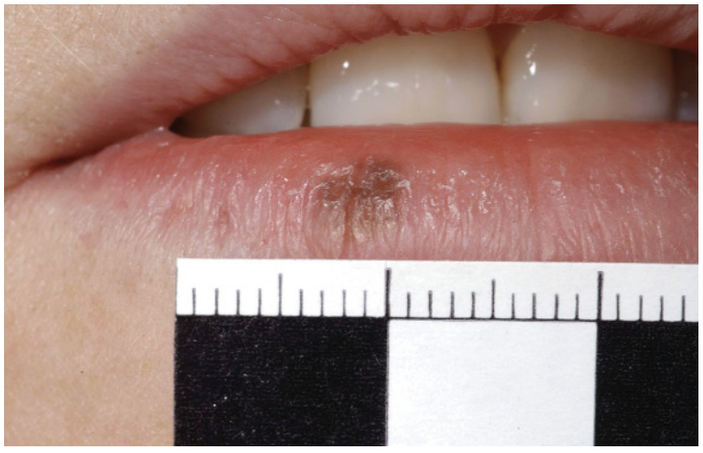

Fig. 54.10 A labial melanotic macule. This is a benign lesion seen in fair-skinned people, which is thought to be related to sun damage.

Pathology. The pathology is that of linear increase in melanin pigment in the basal cells. There may be a very modest increase in the number of melanocytes [8]. Malignant transformation has not been reported in these lesions.

Treatment. Reassurance is all that is needed on medical grounds. If removal is requested for cosmetic reasons, cryotherapy, use of the infrared coagulator or laser therapy [9] may all be effective.

Dermal melanocytic lesions [1]

Common acquired melanocytic naevi described later in this chapter are believed, on the basis of biopsies from multiple lesions in patients at varying ages, to develop from epidermal melanocytes that completed their migration from the neural crest to the dermal–epidermal junction in fetal life, proliferated and then senesced (i.e. ceased proliferation). By contrast, the dermal lesions described here differ in that they are believed to arise from dermal melanocytes that have become arrested in the dermis during fetal life and tissue modelling and have not reached their normal site in the basal layer of the epidermis. Many mammals have a population of dermal melanocytes normally but these are not commonly observed in human dermis, with the possible exception of the Mongolian spot.

Mongolian spot

Definition. Macular blue-grey pigmentation present at birth on the sacral area in normal infants.

Incidence. The incidence of Mongolian spot varies with skin colour. They are rare in white-skinned European infants (the highest prevalence in Europe being in the Mediterranean region). By comparison, the majority of babies born to families from the Far East have a Mongolian spot. The incidence in other populations lies between these extremes. It has been found in some 26% of Turkish babies [2] and 71% of Iranian babies [3]. The relationship with skin colour raises the possibility that such lesions are

Fig. 54.11 A Mongolian spot which was evident on the limbs as well as in the lumbosacral area.

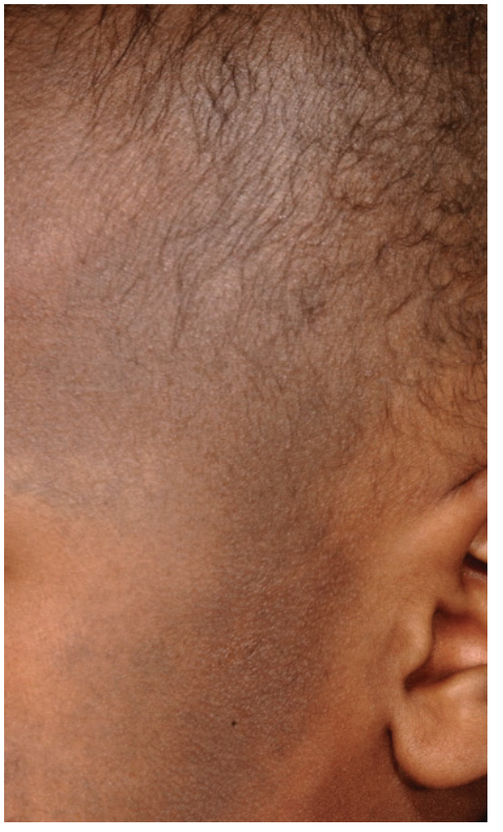

Fig. 54.12 A naevus of Ota visible in a young child.

merely more obvious in the skin where the patient has melanocytes producing a good deal of pigment.

Clinical features. The pigmentation is macular, diffuse and more or less uniform, slate blue to grey and usually relatively faint. The patches are usually rounded or oval in shape, up to 10 cm or so in diameter, and usually single but occasionally multiple. The lumbosacral region is the common site, and the buttocks, flanks or even shoulders and lower legs (Fig. 54.11) may be affected in extensive lesions. The pigmentation develops in fetal life, increases in depth for a period after birth and then diminishes. It usually disappears during the first decade, but has occasionally persisted into adult life.

Pathology. Melanocytes are dispersed in a ribbon-like pattern between the collagen fibres and around the neurovascular bundles of the dermis. They run parallel to the skin surface and contain very fine granules of melanin. There is no disturbance of the pattern of collagen and elastic fibres. Melanophages are not found. The last two characteristics enable it to be differentiated from blue naevus.

Management. No treatment is needed.

Naevus of Ota

Synonym
- Naevus fuscocaeruleus ophthalmomaxillaris

Definition. An extensive, blue, patch-like area of dermal melanocytic pigmentation of the sclera and the skin adjacent to the eye due to the presence of dermal melanocytes. The melanocytes may also extend into the uveal tract, dura and nasopharynx.

Incidence. This disorder is most common in Asian people (but still seen in less than 1%) [4] but is very rare in other groups. Unlike the Mongolian spot, it is not usually visible at birth, but becomes progressively darker in childhood (Fig. 54.12) and persists in adult life. There are published cases in which these lesions are acquired in adult life (Fig. 54.13) [5].

Clinical features. The pigmentation is often speckled and is composed of deeper bluish and more superficial brownish elements, which do not always coincide. The two colours are perhaps best seen in the eye, where the affected sclera is blue and the conjunctiva brown. The brown pigmentation is patchy and may be patterned in a reticular or geographical way; the blue pigmentation is more diffuse. The areas involved are the eyelids, the bulbar and palpebral conjunctiva and the sclera, and the cheeks, forehead, scalp, alae nasi and ears. The mucosa of the palate and cheeks may also be affected. The distribution is usually restricted to the first and second divisions of the trigeminal nerve, but rarely patches may occur on the trunk.

The pigmented spots usually appear in childhood and increase in number and extent to become confluent in some areas. There is one report of the onset following trauma, and in another the ocular

Fig. 54.13 This patient acquired a naevus of Ota in adult life and then developed a meningeal melanoma in relation to this blue naevus.

pigmentation became much more pronounced after an attack of conjunctivitis. The distribution is usually, but not always, unilateral.

Benign intracerebral proliferations, known as melanocytomas, are described as complications of these lesions [6]. In very rare instances malignant melanoma has developed in naevus of Ota, and this may also occur within the meninges, as in the patient seen in Fig. 54.13, or in the choroid [7,8]. Survival after excision of meningeal melanoma in these circumstances may have a surprisingly good prognosis [9].

Pathology. The features are the same as those of Mongolian spot. A variety is described called Naevus fusco-caeruleus zygomaticus [10] in which speckled naevi are seen on the upper cheek, and microscopy shows bipolar pigment-bearing cells in the upper dermis only, in contrast to the naevus of Ota in which pigment-bearing cells are seen throughout the dermis.

Treatment. Laser therapy may be of value [11], although post-treatment hypopigmentation may result [12], and cosmetic camouflage may also be useful.

Naevus of Ito

This type of dermal melanocytosis involves the acromioclavicular region and the upper chest and, like the naevus of Ota, is largely confined to the Japanese (Fig. 54.14).

Fig. 54.14 Naevus of Ito, showing typical distribution over the shoulder area.

Melanocytic naevi

Epidemiology. Melanocytic naevi are normal, benign proliferations of melanocytes. Although the risk of a naevus evolving into a melanoma is extremely small, melanocytic naevi are both risk factors for melanoma and precursors of melanoma.

The prevalence of pigmented lesions present at birth varies considerably between published series; this is principally because of the ethnic mix of the patients examined, as congenital melanocytic naevi may be more common in black or Asian children [1], but they are generally considered to be present in between 1 and 2% of newborns [2]. Most congenital naevi are deeply pigmented at birth but it may be difficult to differentiate congenital naevi from café-au-lait spots clinically. There is very limited sequential information about the eruption of acquired naevi in the period immediately after birth, but it is thought that naevi clinically and

Table 54.2 Terms commonly used in the description of melanocytic naevi.

Melanocyte	A pigment-producing cell characterized by its ability to synthesize melanosomes. Contains the enzyme 3,4-dihydroxyphenylalanine (DOPA)
Theque	A group of melanocytes (generally four or more) in contact with the basal layer of the epidermis but budding downwards into the dermis
Freckle	An area of increased melanin pigmentation The only histological abnormality is an excess of melanin pigment; the lesion would therefore appear to be the result of functionally overactive melanocyte/keratinocyte units These lesions are stimulated by UV irradiation
Lentigo	An area of increased melanin pigmentation, which shows histologically a linear replacement of keratinocytes in the basal layer of the epidermis by melanocytes This replacement does not reach the level of theque formation; if this were the case, the term junctional naevus would be appropriate
Junctional activity	The presence at the dermal–epidermal junction of theques of melanocytes
Junctional naevus	A pigmented melanocytic naevus in which the main histological feature is that of junctional activity A few naevus cells are usually observed scattered in the underlying dermis
Compound naevus	A pigmented melanocytic naevus in which the histological features include both junctional activity and the presence of naevus cells in the dermis Such naevi usually contain melanin
Intradermal naevus	A melanocytic naevus in which there is little or no abnormality of melanocytes in the epidermis The main feature is the presence of packets of naevus cells in the dermis Melanin pigmentation is often absent and such naevi may be clinically non-pigmented The deepest dermal cells tend to neural or fibroblastic differentiation

histologically similar to the congenital type may erupt within the first year of life. In adults, it has been reported that around 2% of individuals have congenital naevus-like lesions [3]. In the only sequential study reported to date of acquired naevi in the same cohort of children [4], 0.5% of 1012 babies examined at birth had melanocytic naevi compared with 35% at the age of 1 year.

Terminology commonly used in describing melanocytic naevi is included in Table 54.2.

Congenital melanocytic naevi

Congenital melanocytic naevi have been arbitrarily divided into three size ranges in order to develop consistent approaches to prognosis and management. Of those melanomas that have evolved from or within congenital naevi, the majority have occurred in large naevi; because of this, great distinction has been drawn between congenital naevi less than 10 cm in diameter and larger ones. Most authors use the American National Institutes of Health (NIH) consensus definition to categorize these naevi according to size. In this document, small congenital naevi are defined as under 1.5 cm in diameter, large as having a diameter between 1.5 and 20 cm and giant naevi as having a diameter of 20 cm or more [1] (Table 54.3). The great majority of congenital

Table 54.3 Overview of congenital melanocytic naevi.

Naevus type	Subtype	Characteristic pathology	Significance	Treatment
Congenital melanocytic naevus, evident at birth	Small (<1.5 cm) May appear in the first 2 years of life	Deeper naevus cells exhibiting a tendency to extend deeply in relation to skin appendages	Very small risk of melanoma	None, other than self-examination Consider excision in sites where review is difficult such as the scalp
	Large (1.5 to 20 cm)	Deeper naevus cells exhibiting a tendency to extend deeply in relation to skin appendages	Increased risk of melanoma	Excise if technically feasible with good cosmetic result
	Giant (>20 cm)	Deeper naevus cells exhibiting a tendency to extend deeply in relation to skin appendages May be associated with benign but atypical proliferations such as hamartomas	Increased risk of melanoma especially if over the trunk and associated with many satellite naevi Lifetime risk is poorly quantified but is likely to be less than 14%	Removal of risk not possible because such lesions cannot be fully excised Surgical decisions should be based upon the cosmetic likelihood of success and should be deferred to assess spontaneous improvement in the first few years of life
Naevi thought to be variants of congenital naevi but which appear in childhood	Speckled naevus	Banal naevi arising in a macular lentigo with subtle increase in melanocyte number	Uncommon cases of melanoma described arising in such naevi	Education about self-examination
	Agminate Spitz naevus	Spitzoid proliferations arising in a macular area of pigmentation	Similar to a speckled naevus but with spitzoid elements	Review at intervals and excise changing elements within

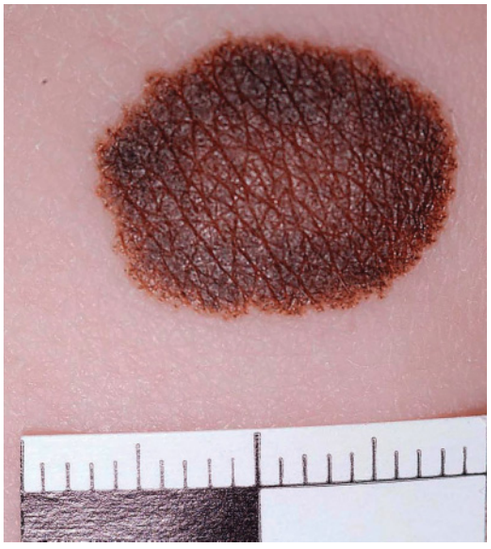

Fig. 54.15 A small congenital melanocytic naevus in a child.

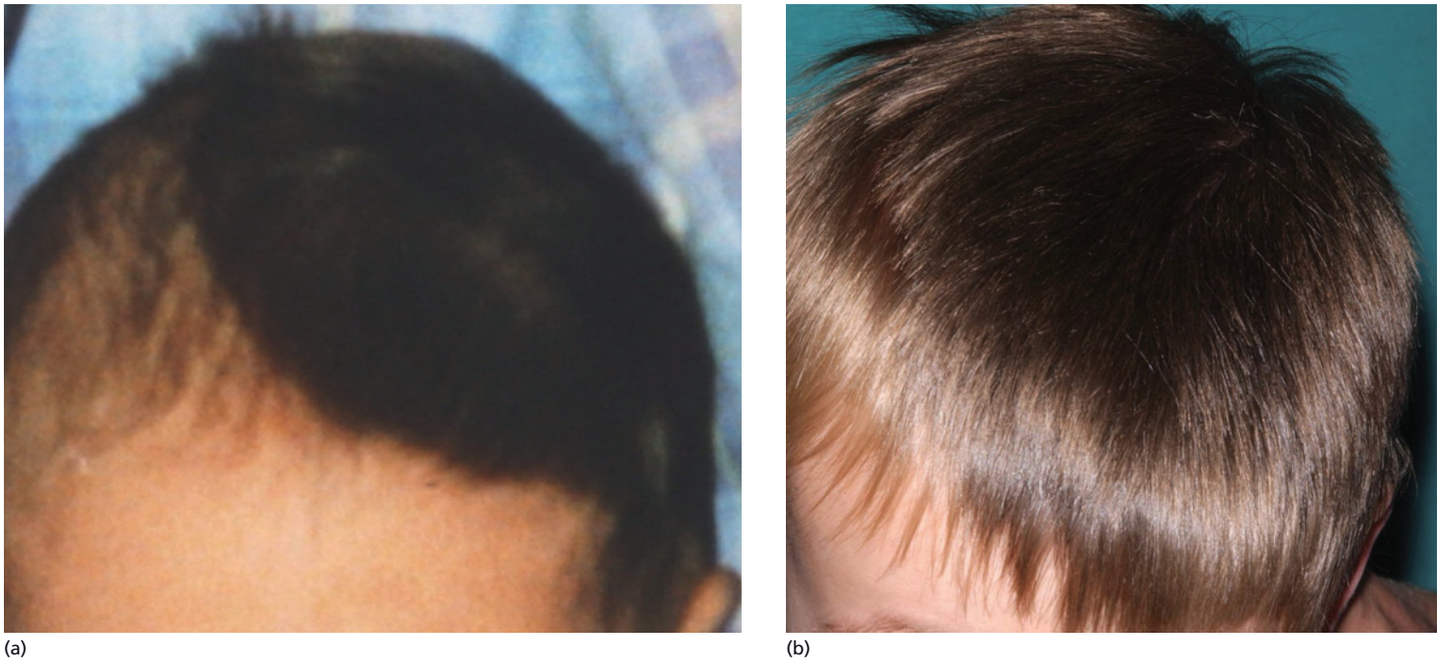
Fig. 54.16 A large congenital melanocytic naevus with junctional and compound elements.

naevi are small, although the published studies in the literature, particularly in relation to the malignant potential of congenital naevi, mainly relate to the giant, or garment, type. The giant type is rare; Castilla *et al*. described a study of 500 000 infants in South America in which one naevus at least 10 cm in diameter was identified per 20 445 subjects [2].

Clinical features. Congenital naevi are usually obvious and deeply pigmented at birth, although occasional naevi may be initially obscured by vernix and a proportion appear in the months after birth (Figs 54.15 & 54.16). The majority are macular at birth.

As the child grows the naevus usually grows in proportion. At some sites, such as the scalp, there is commonly a considerable increase in terminal hair (which is often darker than normal hair and more wiry), soon after birth, which causes alarm. In other sites, an increase in terminal hair tends to occur more subtly over time and may be accompanied by the development of rugosity. A significant proportion of naevi become paler in the first 1 to 2 years of life, and at sites such as the scalp may fade to cosmetic insignificance [3] (Fig. 54.17). There is, therefore, much to be said for deferring treatment decisions until after this period if surgery is being considered for cosmetic reasons, as, in a good proportion, the cosmetic appearance of the naevus will have considerably improved and this may influence decisions regarding the need for surgery.



The giant, garment or bathing-trunk naevus is very rare but is a considerable cosmetic problem for children and their families. The common site is the lower back and thigh area and a very large proportion of the infant's surface area may be involved (Fig. 54.18). There may also be large numbers of smaller congenital naevi present elsewhere on the infant's skin; increased numbers of these will develop over time. Such so-called satellite naevi (Fig. 54.19) were reported in 74% of one series [4]. In the same series, 31% of the patients also had naevi on mucous membranes.

As the infant grows, the surface of the naevus may become rugose or warty and nodules can develop within a large naevus (Fig. 54.20). The hairy component, which occurs in 95% of lesions, tends to become more prominent in late childhood, but at this stage the naevus itself ceases to thicken and may become paler. The hair growth pattern may have a 'vortex' distribution, often centred on the midline in giant naevi of the back. Some lesions involve both the opposed surfaces of the upper and lower eyelid so that when the eyes are shut the naevus takes its normal rounded shape. This shows that the site of the naevus was determined during the period when the lids were fused, that is between the second and sixth month of fetal life.

Neurocutaneous melanosis may produce raised intracranial pressure, hydrocephalus or space-occupying spinal lesions; this is a very rare complication. In a series of 80 Mexican patients with giant naevi only one case of hydrocephalus was reported [4]. There may be associated abnormalities such as meningeal involvement, spina bifida or meningocoele when the naevus is over the vertebral column, or club-foot and hypertrophy or atrophy of the deeper structures of a limb. Absence of subcutaneous fat is the most common associated anomaly and may be symptomatic in sites such as over the sacrum.

Congenital melanocytic naevi are said to occur in the epidermal naevus syndrome [5]. There is also a less well-substantiated association with neurofibromatosis [6].

Pathology. The majority of congenital naevi are dermal or compound melanocytic naevi with naevus cells typically extending more deeply into the dermis (within appendages and even into striated muscle and fat) than those of acquired naevi [7]. It was suggested, on the basis of histological studies, that congenital

(a) (b)

Fig. 54.17 (a) A large congenital melanocytic naevus of the scalp, which faded dramatically (b) until there was nothing visible on the skin in the first few years of life.

Fig. 54.18 Giant or garment congenital naevus on the lower back area of a child.

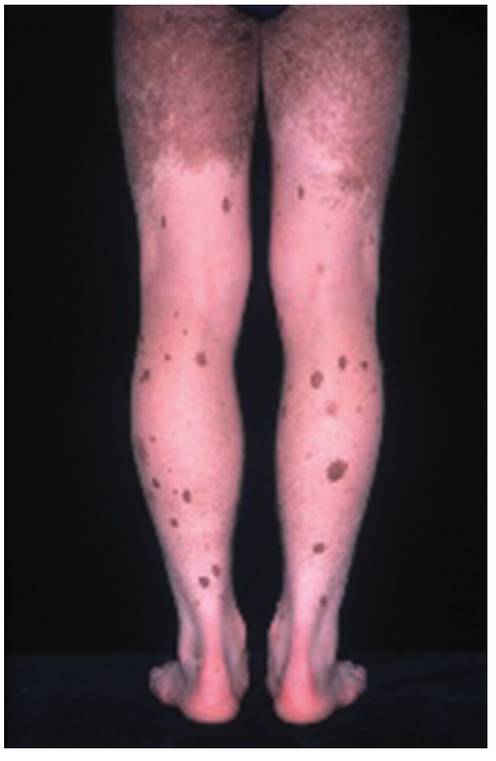


Fig. 54.19 Multiple satellite naevi in an adult with a giant congenital melanocytic naevus. These naevi usually emerge in children with giant congenital naevi, in the first 2 years of life.

naevi evolve within the first few months of life from junctional to deep lesions and it was thought that this transition offered the possibility of early treatment having an effect on long-term distribution of naevus cells, giving potential for early treatment by dermabrasion [8–10]. The current view, however, is that variation in depth of melanocytes reflects variation between individuals rather than being time-dependent.

There are a variety of proliferative neoplasms that may develop in congenital melanocytic naevi, which cause great consternation

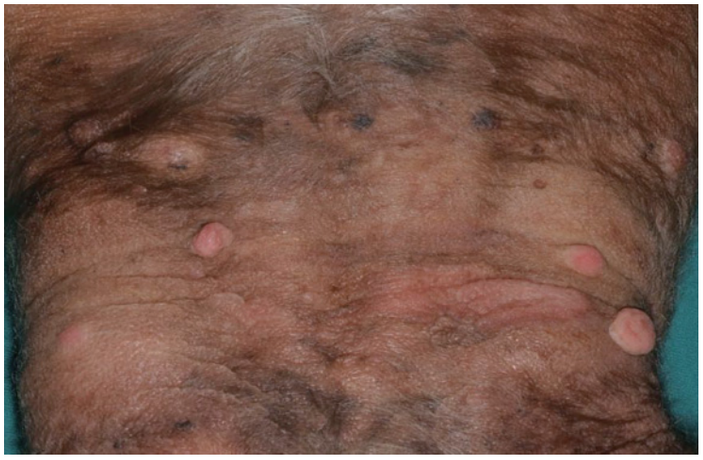

Fig. 54.20 Hypertrichosis and benign hamartomatous proliferations in a toddler with a particularly troublesome giant congenital melanocytic naevus.

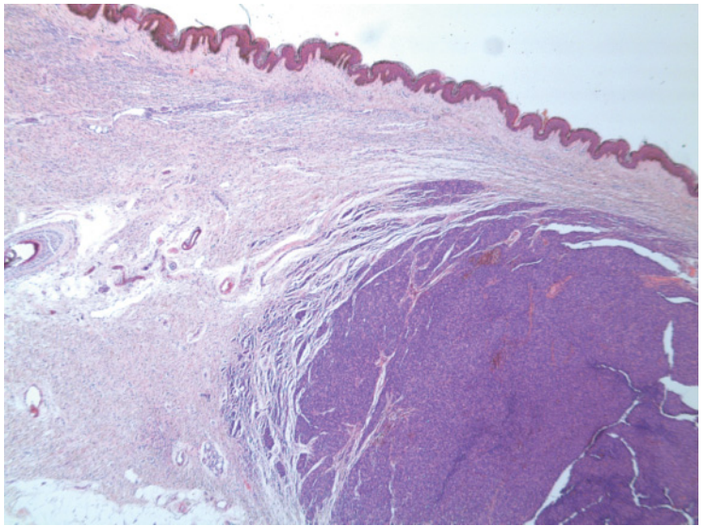

Fig. 54.21 The histological appearance of a benign proliferative nodule which arose in a giant congenital pigmented naevus in a child aged 12 years. (Courtesy of Dr S. Edward, Leeds Teaching Hospitals Trust, Leeds, UK.)

and confusion (Fig. 54.21). Certainly, malignant melanoma may arise [11]. In addition, a rapidly growing, ulcerative tumour called nodular proliferative neurocristic hamartoma has been described at birth [12]. This fetal hamartoma consists of diverse tissues of neuroectodermal and ectomesenchymal origin. The greatest diagnostic difficulty occurs when simulants of melanoma occur, characterized by the proliferation of epithelioid melanocytes.

Genetic counselling. Congenital naevi are essentially considered to be developmental abnormalities of the skin, with a very low risk of recurrence in subsequent pregnancies, which is particularly important when reassuring parents who have a child with a giant melanocytic naevus [13]. However, there are extremely rare instances of families in which more than one case has occurred, raising the possibility that, at least in these families, there may be an inherited tendency to develop giant congenital naevi. Such risks, however, are very low.

Prognosis and complications. Superficial spreading melanoma is the most significant complication of congenital naevi but the level of that risk remains the most controversial, mainly because most of the reported series come from large referral centres and may therefore suffer from ascertainment bias.

There seems to be no doubt that there is an increased risk of melanoma in patients with very large naevi. In the series reported by Swerdlow *et al*. [14], two melanomas, both fatal, occurred in 265 patients with melanoma covering at least 5% of their body area. The melanomas occurred at the ages of 18 and 20 years. In a second series of 80 patients, three melanomas occurred [4], including two in children under the age of 3 years. In giant naevi there therefore appears to be a definite risk, with the age of onset of the melanoma being very much earlier than in the general population. In contrast to the normal development pattern of melanomas, those occurring within congenital naevi may arise from below the dermoepidermal junction, which may delay diagnosis [15]. There have been several attempts to estimate lifetime risk, giving values between 4.6 and 14% [16]. Krengel *et al.* performed a useful review of a total of 6571 patients with congenital melanocytic naevi, followed up for a mean of 3.4–23.7 years, and 46 patients (0.7%) developed 49 melanomas [17]. The mean age at diagnosis of melanoma was 15.5 years (median 7 years). Primary melanomas arose inside the naevi in 33 of 49 cases (67%). In seven cases (14%), metastatic melanoma with unknown primary was encountered; in four cases (8%) the melanoma developed at an extracutaneous site. The risk of developing melanoma and the rate of fatal courses were highest by far in congenital melanocytic naevi 40 cm or greater in diameter.

There are numerous case reports of melanoma arising in smaller congenital naevi [18] but such naevi are relatively common and it is very difficult from studies reported so far to compare, for example, the relative risk of melanoma arising from a small congenital naevus with that of a melanoma arising in an acquired naevus. It seems likely, as congenital naevi tend to be bigger, that the risk might be greater at least in proportion to the melanocyte mass. Various estimates of risk have been made. Rhodes and coworkers have estimated a lifetime risk of between 2.6 and 4.9% [18,19] in naevi less than 4.5 cm in diameter. However, Swerdlow *et al*. [14] failed to demonstrate any increased risk for naevi smaller than those covering 5% of the body surface. It seems unlikely that the true risk from a small congenital naevus will ever be established accurately because of the impossibility of gathering a sufficiently large cohort of patients whose congenital naevi are left *in situ*.

Rarely, intracerebral primary melanoma may complicate leptomeningeal melanocytosis [20].

Treatment. An MRI scan should be considered in babies with naevi over the cranium or spine to exclude significant leptomeningeal melanocytosis. However, although MRI anomalies are common, occurring in around 30% [21], symptomatic neurocutaneous melanosis is rare, so the value of scanning seems

questionable in the absence of neurological signs. Regular neurological examination, however, is clearly important.

The aims of treatment are to improve the cosmetic effect of naevi and to reduce the risk of malignant transformation. To date, there is no proof that any treatment regimen fulfils the second aim for giant naevi in which there is no possibility of complete excision of the naevus, because of the surface area of skin involved and the depth of the naevus within the skin and subcutis. There is perhaps a stronger argument for prophylactic excision of large naevi where complete excision of the naevus is technically possible with reasonable cosmetic result. The most common treatment is surgical, using a variety of plastic surgical techniques such as multistep surgery, the use of tissue expanders and grafting. Tissue expansion is usually used for the head and neck, but in other sites excision and grafting are more usual, with consequently poorer cosmetic results. The cosmetic results of surgery for giant naevi on the trunk are generally poor and there have been attempts to improve results, mainly by treatment within the first few weeks of life by dermabrasion or curettage [22]. The rationale for this is that there may be a natural plane of cleavage within the upper dermis very early in life which may be exploited by the curette to reduce the risk of subsequent scarring [23]. It is difficult from the literature to assess the long-term cosmetic results of the approach of curettage but those from dermabrasion seem disappointing. A review of 215 patients treated in Germany reported hypertrophic scars in 15% (particularly on the lower back) but there was good, permanent reduction in pigmentation in 34% (which was more likely when treatment was carried out early) [24]. A smaller series of 12 neonates treated by dermabrasion reported good results in 10, although six went on to have surgery later [25]. The long-term cosmetic results of surgery may therefore be disappointing, although children in one study reported a preference for a surgical scar rather than the naevus [26]. Other ablative techniques have been tried such as cryotherapy and, more recently, the Q-switched ruby laser. This laser emits light at 694 nm, which is relatively selectively taken up by melanin, but its value remains unclear.

Overall, the choice about intervention in children born with large or giant naevi is made on the basis of balancing a risk of melanoma (which is poorly quantified), and the cosmetic deficit of the naevus, against the risks of surgery. The psychological impact of giant congenital naevi is great and the risk of melanoma established, so that there is a need to establish better approaches for removal. Currently available methods leave much to be desired and it is eminently possible to operate on children to little overall benefit indeed, even do harm. The decision as to whether to proceed to surgery or not may be very difficult for families.

Parents of children with congenital naevi left *in situ* should be advised to keep the naevus under review and to seek advice if it changes in shape, size or colour. As such naevi do change through life in an entirely benign way, education about the nature of changes which would cause concern is essential. Photographs of the child's naevus and images of melanomas are useful for the family to take home. It would seem reasonable to prophylactically excise small naevi that are difficult to keep under review, such as those in the scalp or in the middle of the back, particularly if they have any atypical features such as intense or irregular pigmentation which persists beyond infancy.

Fig. 54.22 Speckled and lentiginous naevus. Note the variation in colour of this lesion.

Speckled and lentiginous naevus

This term is recommended in preference to the term naevus spilus. Such naevi may be viewed as a type of congenital melanocytic lesion which is lentiginous in early childhood and which might develop palpable components at puberty in a 'speckled' distribution.

Clinical features. Speckled and lentiginous naevus is a relatively uncommon entity. It is comprised of a flat, macular component, subtly darker shade than the surrounding skin, resembling a café-au-lait spot. Within this pale background there are lentigo-like lesions and also elevated darker-brown naevi (Fig. 54.22). It may also coexist with other types of melanocytic naevus such as a blue [27] or Spitz naevus, indeed there is a clinical overlap with the agminate Spitz naevus described below (see also Table 54.3).

Pathology. Pathological examination shows, as the clinical appearance suggests, a background macular lesion with a very subtle increase in melanocytes, and lentigos with superimposed individual compound naevi.

Management. There have been reports of malignant change in these lesions [27,28]. There are no data however on which to estimate the risk of such a change and it is likely that the risk is very low. Patients should generally, therefore, be counselled as to self examination as is done for patients with congenital melanocytic naevi. There are very rare patients in which the naevus develops atypical melanocytic proliferations at puberty and in these patients excision should be considered if technically feasible.

Acquired melanocytic naevi

Synonyms
- Cellular naevus
- Naevocytic naevus
- Mole

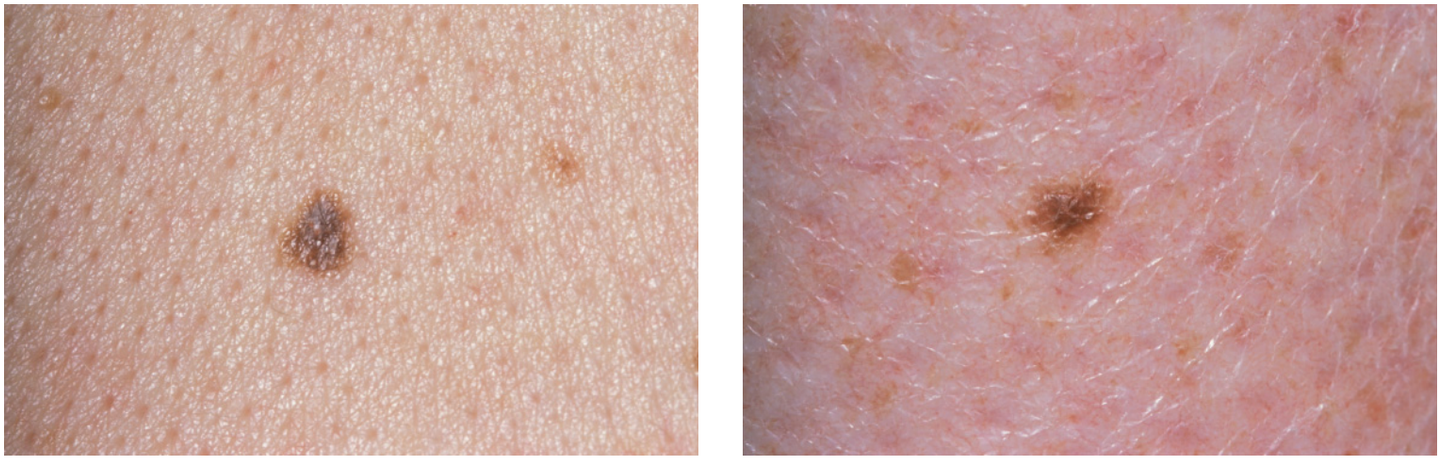
Definition. A benign cluster of melanocytic naevus cells arising as a result of proliferation of melanocytes at the dermal–epidermal junction. These may all remain in contact with the basal layer of the epidermis, giving rise to the junctional naevus. In other naevi, some of the naevus cells may migrate into the dermis over time, giving rise to the compound naevus. The end stage of this process is when there are no naevus cells attached to the epidermis and all are lying free in the dermis. This pattern is that of the mature intradermal naevus. A melanocytic naevus is therefore a benign tumour of melanocytes, in which the melanocytes (naevus cells) proliferate for some time but then cease proliferation and differentiate (or senesce) and come to resemble cells of neural or fibroblast lineage. Different types are summarized in Table 54.4.

Aetiology and incidence. Melanocytic naevi are almost universal. They develop through childhood and twin studies provide good evidence that naevus number is predominantly genetically determined [1] with a smaller effect of sun exposure [2]. There are a number of studies from Europe and Australia, which suggest that naevus number is higher in children exposed to more sun, particularly intermittent sun exposure as on sunny holidays [3–6].

Naevi continue to erupt in adult life so that the mean number bigger than 2 mm in diameter in 754 healthy women between the ages of 18 and 46 in the UK was 57 [7]. After this age naevi then involute so that the elderly usually have very few. In a UK study, 30% of 20 to 34 year olds had 50 or more moles compared with 4% of patients between 65 and 75 years old [8]. This natural history of naevi means, therefore, that new naevi developing in later life should be viewed with more suspicion than naevi of similar appearance in younger individuals.

The number of melanocytic naevi is the strongest phenotypic risk factor for melanoma [9] and the genes that control naevus number are therefore candidate melanoma susceptibility genes.

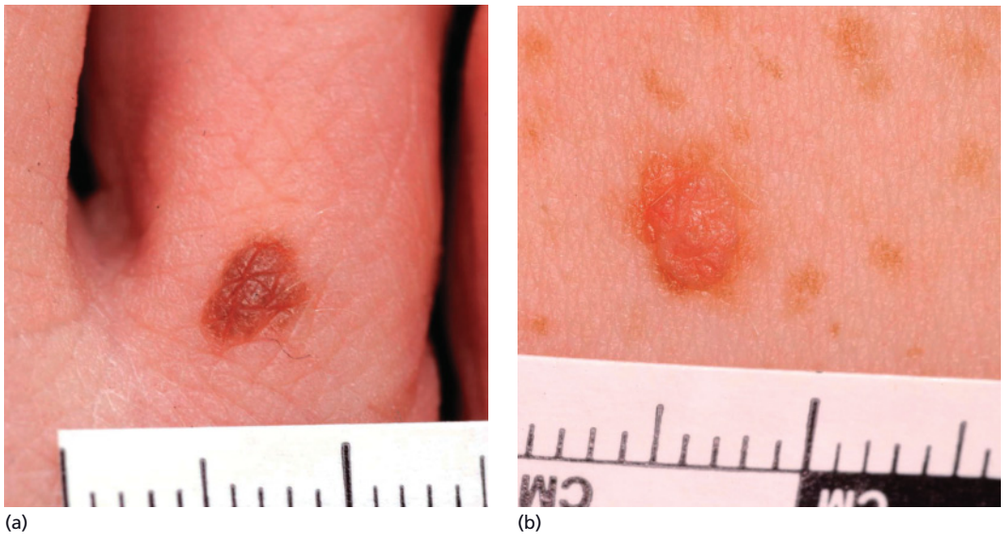
There is some, as yet unexplained, variation in naevus number. Patients with atopic dermatitis may have significantly lower naevus counts than age-matched controls [10] and individuals with Turner's syndrome have larger than average numbers of naevi, although there is no evidence that they have an increased risk of melanoma [11]. Children who have been treated for leukaemia [12] and recipients of renal transplants [13] also have increased numbers of naevi, which is postulated to be a consequence of immune suppression. There is some evidence that survivors of childhood cancer do appear to be at increased risk of melanoma [14] although, as melanoma was not increased as a second malignancy after haematological malignancies, other than possibly after Hodgkin lymphoma [15], it is not clear whether that increased risk is treatment related or genetic.



Clinical features. The new naevus is a junctional naevus and is a macular brown lesion, which may show pigment lying along the normal skin markings. It may have a slightly irregular lateral margin because of this, and may have a large diameter of up to 10 mm. The pigmentation tends to be uniform and regular (Fig. 54.23). In some body sites, such as the limbs, junctional naevi may

Table 54.4 Overview of acquired melanocytic naevi.

Naevus type	Subtype	Pathological characteristics	Significance	Treatment
Common acquired melanocytic naevus	Junctional	Benign proliferations of melanocytes in the epidermis	Normal finding but increased numbers of naevi are a risk factor for melanoma	None
	Compound	Benign proliferations of melanocytes in the epidermis, showing evidence of migration of cells into the dermis and 'maturation' of those cells within the deeper dermis	Normal finding but increased numbers of naevi are a risk factor for melanoma	None
	Dermal	Benign tumours of melanocytes in which there is no longer epidermal proliferation; the naevus cells have migrated into the dermis and matured there	Normal finding but increased numbers of naevi are a risk factor for melanoma	None
	Balloon cell naevus	Compound naevus with balloon cells (the melanocyte cytoplasm is foamy)	None	None
	Naevi of unusual sites such as the nail bed, palms and soles and genitalia	More likely to have more atypical junctional proliferation of melanocytes. However, the criteria used for the diagnosis of melanoma in these sites remain the same	None usually	Excise if there are atypical clinical features as for any naevus elsewhere
	Halo naevus	Dense lymphocytic infiltrate in the early phase and subsequent removal of naevus cells	None	None in the absence of atypical features clinically
	Meyerson's naevus	Benign naevus with overlying spongiosis of the epidermis	None	The eczematous component should be treated and the naevus re-examined
	Naevus en cockarde	None	None: unusual rosette-like variant of no significance	None
Spitz naevus	Classical type	See text	Differentiation from melanoma is the key	Excision except for very bland lesions in young children
	Pigmented spindle cell naevus of Reed	See text	Differentiation from melanoma is the key	Excision to exclude melanoma
	Atypical spitzoid tumour of unknown malignant potential (STUMP)	See text	Should be managed as for melanoma	Treat as for melanoma
Blue naevus	Common	Spindle or dendritic melanocytes within the dermis, containing pigment even deeply in the dermis (which naevus cells in acquired naevi do not do)	None save differentiation from a melanoma	None
	Cellular blue naevus	As for the common blue naevus except that the dermal naevus cells are more numerous and extend deeply even up to the fat	None save differentiation from a melanoma	
	Combined blue and acquired naevus	Histological features of both blue and acquired naevi	None	None
	Deep penetrating naevus	Larger than most naevi with extension of naevus cells deep into the dermis with a wedge shape (base abutting onto the epidermis)	None save distinction from melanoma	Excision to exclude melanoma is usual because the appearance of the naevus may be unusual
Atypical or dysplastic naevus	Junctional or compound	Characteristic architectural and cytological atypical (see text)	Precursors, and marker, of risk for melanoma although the vast majority behave in an entirely benign way	Excise only to exclude melanoma



remain unchanged through much of adult life, but the majority do 'mature' with age, becoming first a 'compound naevus' and then an 'intradermal naevus'.

The compound naevus usually slowly becomes raised above the epidermal surface and may be round or oval (Fig. 54.24). The colour varies with the natural pigmentation of the patient and may be very dark, but the majority become paler with age. There is usually little if any pigment on the flat surrounding epidermis. It is important to recognize that slow elevation and the transformation of a macular melanocytic naevus to a palpable symmetrical,

(a) (b)

Fig. 54.23 Two junctional naevi: macular brown lesions which are composed of a proliferation of melanocytes at the dermoepidermal junction.

(a) (b)

Fig. 54.24 Two compound melanocytic naevi in which junctional melanocytes persist but senescence of melanocytes has also occurred and those cells lie within the dermis.

evenly pigmented symmetrical papule over time, is not a sign of malignant change but a normal maturation pattern of these naevi.

Intradermal naevi are frequently raised, dome-shaped, non-pigmented nodules, most commonly seen on the face (Figs 54.25 & 54.26). There are often some overlying telangiectatic vessels (leading to diagnostic confusion with basal cell carcinomas) and outgrowth of one or two coarse terminal hairs is common. A proportion in some body sites, such as the flexures, may become skin tags with time.

Inflammation within intradermal naevi may occur, as a result of bacterial infection in hair follicles or granulomatous inflammation. These changes often cause alarm for patients and their family doctors, but the symptoms associated develop 'overnight' and it is useful to reassure those concerned that acute changes like this are rarely indicative of malignant change. Fragments of hair shaft can often be demonstrated histologically. The inflammation may recur and leave a fibrous nodule, or one that goes on to calcification or even ossification.

The balloon cell naevus is a subtype of compound melanocytic naevus, which has a predominant population of cells with a high volume of foamy cytoplasm [16]. These are called balloon cell naevi because of their pathological appearance. The pathological picture is striking, but there is no known biological significance. There is also a malignant counterpart of balloon cell melanoma, but the balloon cell naevus is not a precursor to balloon cell melanoma.

Naevi in unusual sites

Naevi on the palms and soles may cause concern because they are relatively infrequent and because public education has in the past suggested that they are easily confused with acral lentiginous melanoma. It is also recognized that histologically naevi in these sites show more architectural and mild cytological atypia [17]. In fact, naevi in these sites are not so rare and as they behave as do junctional naevi in other sites, they can be distinguished from melanoma. The incidence of pigmented naevi on the palms, soles

(a) (b)

Fig. 54.25 Two mature dermal naevi, one of which has prominent vessels which can cause confusion with basal cell carcinomas. In these naevi, junctional proliferation of melanocytes has ceased and all the melanocytes are senesced and lie in the dermis.

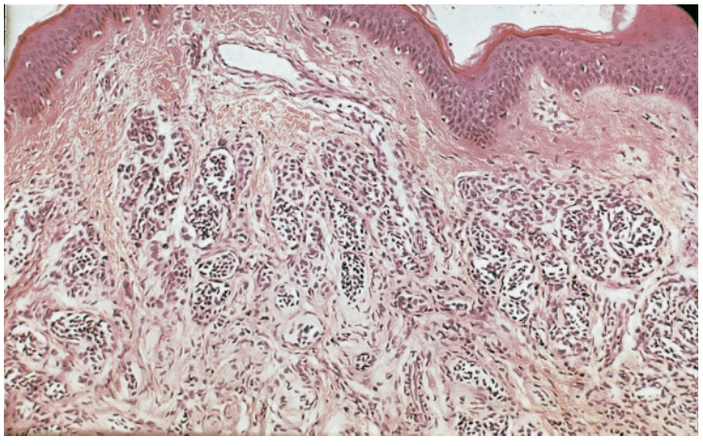


Fig. 54.26 Histology of intradermal naevus. Note the normal overlying epidermis and the maturation of dermal naevus cells, with neural appearance at lower levels.

and genitalia has been studied in a large series of normal young men [18], and more than 10% of the sample were found to have one or more. They should therefore be managed as junctional naevi elsewhere.

Conjunctival naevi are similar in their behaviour and histology to cellular naevi of the skin; and the same clinical changes would evoke the same concern.

Naevi of the nail matrix or bed may present as a longitudinal brown stripe on the underside of the nail plate (Chapter 65). There may be difficulty in distinguishing such lesions from early subungual melanoma. Benign naevi and melanoma both originate in the nail matrix and therefore typically produce a linear band of pigmentation along the length of the nail. However, as applies to melanoma at other sites, subungual melanoma has a disorganized irregular appearance, so that the pigmented band of a melanoma appears later in life than those due to naevi, tends to widen progressively and shows variable colour. Due to rapid growth, the proximal diameter is wider than the distal so the pigmented band appears funnel-shaped (see Fig. 54.63 below). Dermoscopy can be used to improve the clinical diagnosis of such lesions, demonstrating irregular pigmentation [19,20].

Pathology. The pattern of evolution of pigmented naevi has been deduced by pathological examination of a large number of lesions removed at different ages. Elder and Murphy describe how normal melanocytes are rarely seen in contact with each other, being normally surrounded by keratinocytes even in lentigos, but in naevi proliferative groups of contiguous cells are seen [21]. In childhood, over 90% of naevi are *junctional* and show melanocyte proliferation at the dermoepidermal junction to form small clusters of cells that indent both the overlying epidermis and the underlying papillae. The cells have abundant cytoplasm containing melanin granules. The majority of naevi on the palms and soles, and also on the vulva, appear to be junctional naevi.

The next stage occurs when some of these melanocytes migrate into the dermis, where they form nests and columns of cells. In the *compound* naevus both junctional proliferation and dermal cells are present. The dermal cells accumulate in the papillary body and extend more deeply around appendages and neurovascular bundles. The more superficial cells (type A) remain recognizable as naevus cells, continuing to form melanin, which is taken up by melanophages in the stroma. The deeper cells (type B) are smaller and usually contain no melanin. The more superficial cells may throw the epidermis into a series of folds by expanding dermal papillae (so that the naevus is clinically warty in appearance). The deeper cells are arranged as a band (type B) or as arborizing columns in the deeper dermis, when the cells become spindle shaped (type C) and more closely resemble cells of neural or fibroblast lineage. Thus, as cells migrate into the dermis they are at first similar to junctional naevus cells, but over time lose the characteristics of melanocytes.

When the junctional melanocytes stop proliferating, and the overlying epidermis returns to normal, the naevus becomes *intradermal*. Many intradermal naevi have neuroid cells in their deeper parts, and some are composed of little else. These neural areas in

the deeper areas of intradermal naevi are sometimes referred to as Masson's naevic corpuscles, after Pierre Masson who first evolved the theory of evolution of melanocytic naevi [22]. The stroma around the dermal naevus cells is loose and fibrillar, the nests of cells are often enclosed by flattened cells that resemble endothelium and may give an erroneous impression of naevus cells in vessels. Multinucleated naevus cells are commonly seen, but mitotic figures are rare and occur only in the type A cells. The end stage of a melanocytic naevus is a flesh-coloured, pedunculated skin tag in which very few naevus cells are observed. Pigment is sparse and fat cells may be present. The evolution of neural like cells with age has led some to suggest that melanocytic naevi are hamartomas, but they are more likely to be proliferative lesions [23] and that as the cells cease proliferation and senesce, they have a more 'neural' phenotype. Understanding why melanocytes proliferate and then senesce is crucial to understanding tumourigenesis [24].

Diagnosis. In older adults, there may be difficulty in clinical differentiation between seborrhoeic keratoses (Chapter 52) and larger papillomatous compound naevi. The seborrhoeic keratosis usually has a 'stuck-on' appearance with its bulk above the normal skin contour, and the colour is usually more grey-brown than the typical melanocytic naevus. In addition, the surface is usually dull and pitted, with a tendency to crumble, and does not reflect light in the same way as naevi.

The most important clinical differential diagnosis is from early malignant melanoma. A history of very rapid growth, over days rather than weeks, and tenderness suggests the development of an underlying infection/granuloma rather than malignant change. Features suggestive of an early malignant melanoma either developing *ab initio* or in a pre-existing naevus are progressive change in size (surface area), shape and colour. Typically, melanomas develop irregularity of outline and the presence in the lesion of several shades of brown, red, blue or black. Melanomas do sometimes itch or produce at least a changed sensation, but itch poorly differentiates between melanoma and benign naevi.

The techniques of dermoscopy and of computerized diagnosis are discussed in the section on malignant melanoma (p. 54.38). Several groups have produced useful atlases of the clinical dermatoscopic appearances of melanocytic naevi and the differences between these naevi and malignant melanoma. Dermoscopy is an essential technique used to distinguish benign from malignant, and must be learnt by all dermatologists.

Management. The management of naevi is essentially that of differentiating benign maturing naevi from those that are behaving atypically, and which therefore might either be melanomas or naevi having the potential to develop into melanomas (such as severely atypical or dysplastic naevi). The keys to the diagnosis are the history of the lesion, and its appearance to the naked eye and the dermoscopic appearance. Thus a pigmented lesion, which arises in childhood and grows progressively in size in the following months is likely to be benign, but a similar story in a 50 year old should be viewed as suspicious. Normal junctional naevi may show minor variations in shape and colour but are essentially symmetrical and the variation in colour is usually limited to shades of brown. Severely atypical naevi and melanomas tend to be asymmetrical and the colours tend to be mixtures of browns, grey/blues, reds and blacks (see Figs 54.42–54.45 below). Dermoscopy is essential in order to examine the pigment pattern for irregularity, as described below.

If a melanocytic naevus is excised for whatever reason, it should always be sent for pathological examination. Partial removal must be avoided, both because this may lead to sampling error and the wrong diagnosis, and in order to avoid failure to completely remove the deeper dermal cells. When this occurs, residual naevus cells may proliferate soon after excision and give rise to a pathological picture very like an early melanoma. This picture has been termed 'pseudomelanoma' or, more appropriately, a traumatically activated naevus. This can give rise to needless anxiety and is avoidable. Elder and Murphy suggest that the observation of pigment beyond the original scar suggests recurrent melanoma rather than the benign simulant [21].

Halo naevus

Synonym
- Sutton's naevus

Definition. A melanocytic naevus surrounded by a depigmented halo of otherwise normal skin.

Incidence and epidemiology. Halo naevi are relatively common, particularly in older children and young teenagers. They are frequently multiple. They are thought to result from immunologically mediated host responses to a naevus: there is some laboratory evidence for local and circulating immunological T-cell activation in affected patients [25].

Clinical features. These lesions have a characteristic appearance and progression. A halo of depigmentation appears around a pre-existing melanocytic naevus, and on white skin this will usually be seen during the summer months when the rest of the epidermis has acquired a tan, showing the non-tanned halo in sharp contrast to the normal skin (Fig. 54.27). The back is the commonest site and several naevi may develop haloes simultaneously, while other adjacent naevi remain unchanged. Over the next few months, the central naevus will gradually disappear leaving a macular area of non-pigmented skin. This depigmented area may persist for years and may never, or only gradually, return to a normal colour. On biopsy, all traces of the original naevus will be found to have disappeared.

Pathology. These lesions are variants of compound melanocytic naevi, and at the time of appearance of the halo they show a very striking lymphocytic infiltrate admixed with the intradermal naevus cells. The use of DOPA stains will reveal a loss of epidermal melanocytes in the halo area.

Management. Reassurance rather than excision is recommended in young people, particularly if the lesions are multiple. The patient should be warned that the depigmented areas will burn in

sunlight because of the reduced numbers of melanocytes and should be advised to use a sunscreen.

In older patients, the differential diagnosis may include an early superficial spreading melanoma with surrounding depigmentation. In this case the surrounding area of depigmentation is usually irregular, and the central pigmented area may also be irregular in both shape and pigmentation. The central area has dermoscopic appearances suggestive of melanoma [26] whereas the dermoscopic appearance of a halo naevus is bland. If there is any clinical doubt, excision biopsy and pathological confirmation must be obtained.

Meyerson's naevus [27]

This name is used to describe a melanocytic naevus that has developed an associated inflammatory reaction, which looks like eczema. Meyerson's naevus is a similar lesion to the halo naevus and they may coexist although in Meyerson's naevus the central naevus does not usually subsequently disappear [28], although it may do so [29].

Fig. 54.27 Clinical appearance of a halo naevus.

Clinical features. These lesions present as melanocytic naevi with associated epidermal scaling and a halo of inflammation. The original report was of multiple naevi developing this associated inflammatory reaction simultaneously. The naevus may be pruritic, and there may be overlying scaling and the appearance is of a naevus with superimposed discoid eczema.

Pathology. The pathology is usually that of a banal, usually compound, naevus with associated spongiotic dermatitis in the overlying dermis.

Treatment. These are benign naevi and it is reasonable in the first instance to treat for 1–2 weeks with a moderately potent topical steroid before re-examination. Normally, the secondary eczematous reaction will settle and examination with dermoscopy can be carried out to ensure that the underlying naevus is benign (Fig. 54.28).

Cockade naevus

Synonyms
- Kokardennaevus
- Naevus en cocarde

This rare variant of the pigmented naevus was first described by Mehregan and King in 1972 [30]. The lesion is named because of its resemblance to a rosette. All cases so far reported are in young patients with multiple, target-like naevi showing concentric circles of increased melanin pigmentation. The central lesion in all cases would appear to be a junctional naevus (Fig. 54.29).

(a)

(b)

Fig. 54.28 (a) Meyerson's naevus in which an eczematous response to the naevus occurred, which cleared with 2 weeks' treatment with topical steroids (b). This allowed dermoscopic examination of the naevus, which then looked banal.

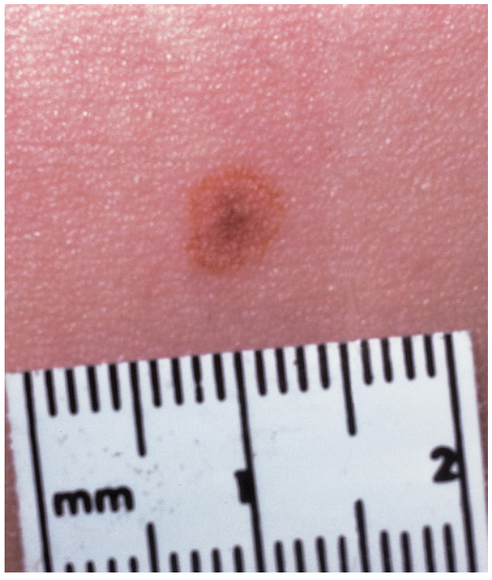

Fig. 54.29 Cockade naevus (naevus en cocarde). Note the darker outline to this lesion.

Spitz naevus

Synonyms
- Spindle and epithelioid cell naevus
- Spitz tumour
- Juvenile melanoma

Definition. An uncommon type of melanocytic lesion, seen most commonly in children but also in adults, which has distinctive pathological features first described by Sophie Spitz as an unusual type of melanoma [1], but subsequently called benign. The entity has been controversial ever since. Whilst a characteristic clinical and histological appearance of a benign lesion usually called a Spitz naevus is recognized, there are three types of lesion that are often difficult to distinguish from each other: Spitz naevus, spitzoid melanoma and an entity that has become increasingly diagnosed an 'atypical spitzoid tumour of unknown malignant potential', reflecting the difficulties of pathological interpretation of spitzoid lesions. Much controversy still surrounds the pathology of spitzoid lesions, as reviewed [2,3], and it is clear that we have much yet to learn.

Incidence. Spitz naevi are most common under the age of 14 years; indeed 50% are thought to occur under this age, around 25% between the ages of 14 and 30 and 25% over the age of 30 years [4].

Clinical features. The classic Spitz naevus usually appears in early childhood as a firm, rounded or dome shaped, red or reddish-brown symmetrical nodule. The red colour is due to increased

(a)

(b)

Fig. 54.30 Two classical Spitz naevi in children. The differential diagnosis is often that of a haemangioma.

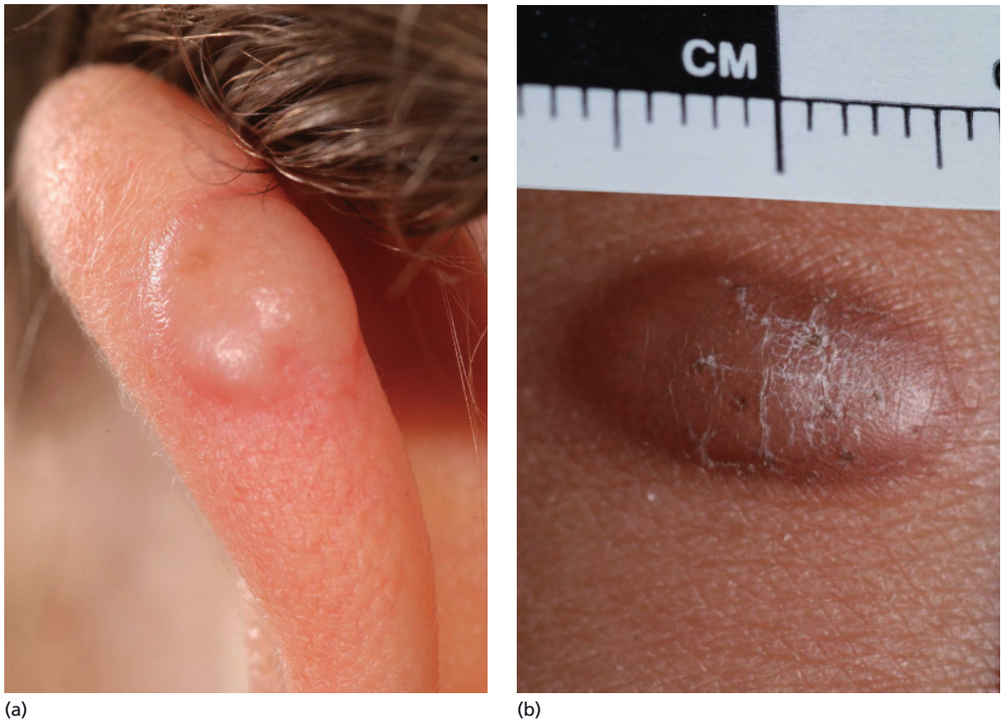
vascularity and the naevus can usually be bleached by firm pressure or diascopy to show the residual degree of true melanin pigmentation (Figs 54.30 & 54.31).

The lesions usually grow rapidly over a period of 3–6 months and may reach diameters of 1–2 cm. The surface can remain smooth, with a thin, fragile, overlying epidermis. This may cause bleeding and crusting after minor injury, causing diagnostic confusion with haemangiomas or pyogenic granulomas. The commonest sites for Spitz naevi are the face, particularly the cheeks, and the legs (in young adults), but other areas may be affected. After rapid initial growth they may remain static for years. Spitz naevi may be more pigmented in some patients, particularly adults.

The spindle cell naevus of Reed is a more deeply pigmented variant, which was first described in 1975 [5]. The majority of patients reported with such lesions are young females, and they are most commonly seen on the thighs. They are densely pigmented, irregularly shaped dark-brown or black nodules and are usually isolated (Fig. 54.32a).

Spitz naevi may have a characteristic dermoscopic appearance, the most common being a 'starburst' pattern (Fig. 54.32b) [4]. Some have a more globular pattern however, and others a multicomponent pattern.

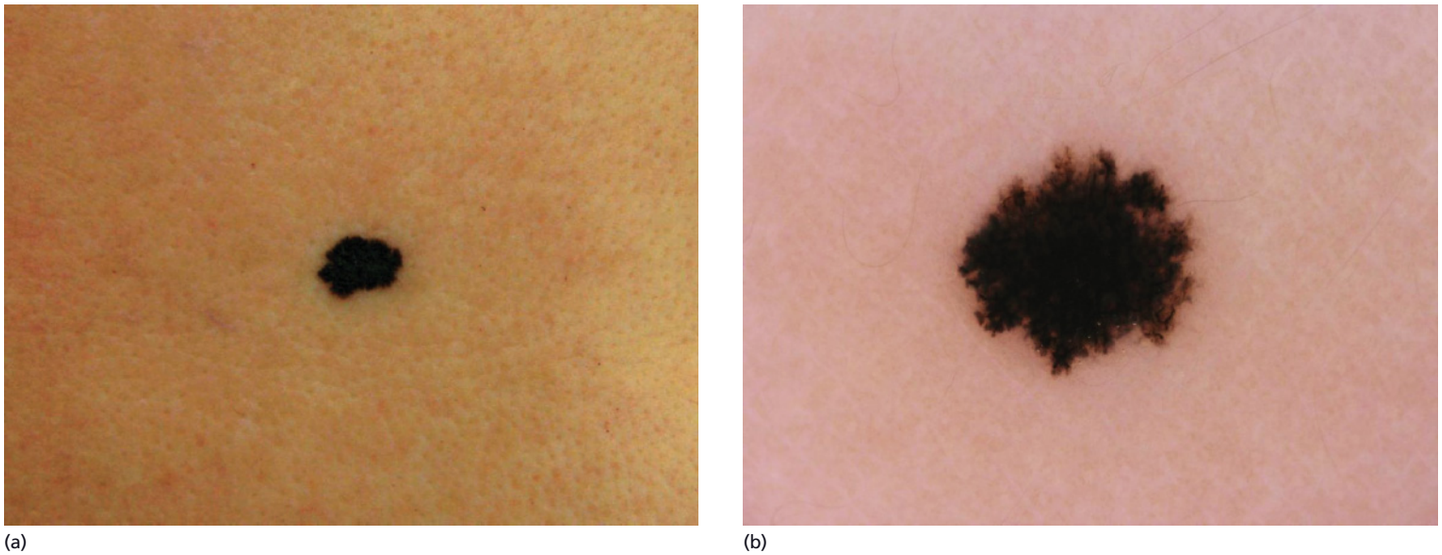
A striking and unusual variant is that of *multiple Spitz naevi*. In these very rare cases multiple Spitz naevi erupt over a period of time [6]. The aetiology is unknown although authors have suggested that they may develop in relation to triggers [7] such as sunburn. An important differential diagnosis in these cases is epidermotropic metastatic melanoma.



Agminate Spitz naevi are lesions seen in childhood where a group of Spitz naevi develop on skin which looks normal other than for the presence of a macular pigmentary background. The individual Spitz naevi develop rapidly and thereafter remain relatively static. In some ways these lesions resemble speckled naevi and it is likely that all are subtypes of congenital pigmented naevus.

A rare subtype of the Spitz naevus is a *desmoplastic naevus* (desmoplastic Spitz naevus), seen most commonly in adults [8]. These are usually firm and may show little or no clinically visible melanocytic pigmentation, to appear as pink or red, firm, raised nodules. The lesions may be woody hard, and the clinical differential may include a keloid, although there is no history of injury (Fig. 54.33).

Some authors have developed the concept of a metastasizing Spitz as being different to melanoma. It seems unlikely, however, that there is a fundamental difference between a spitzoid lesion, which spreads to a regional node, and melanoma, although it is possible that spitzoid melanoma may have a better prognosis. This remains an area of unresolved controversy, which requires long-term investigation.



Pathology. The 'classic' Spitz naevus typically is a symmetrical and well-defined compound naevus. There is a degree of epidermal acanthosis overlying the naevus cells, in the absence of any upward epidermal invasion by naevus cells. The melanocytes at the dermal–epidermal junction are often separated from the underlying dermis by a cleft, and may be associated with amorphous pink globules. These globules are thought to be degenerating keratinocytes and are called *Kamino bodies*. They are frequently seen in Spitz naevi, but their presence is neither totally sensitive nor specific for Spitz naevi, as they may also be present in early melanoma.

The Spitz naevus cells may be either spindle-shaped, and stream into the dermis in interlacing bundles, or epithelioid, and arranged in clusters with giant and multinucleated naevus cells among them. Mitotic figures may occur but abnormal mitoses are not seen. Mitotic figures are rarer in the deeper naevus cells, and their presence should alert the observer to the possibility that the lesion is, in fact, a spitzoid melanoma. The deepest naevus cells show some degree of maturation and are usually smaller than those seen at the dermal–epidermal junction. The dermal vessels are usually dilated, and the stroma may be oedematous and infiltrated with lymphocytes. Melanin is rarely abundant, and may often be absent.

(a) (b)

Fig. 54.31 Two Spitz naevi showing less typical appearances: both were excised.

(a) (b)

Fig. 54.32 (a) The naked-eye appearance of a typical pigmented spindle cell naevus of Reed in a child and (b) the corresponding dermoscopic appearance. (Courtesy of Dr S. Puig, Hospital Clinic Barcelona, IDIBAPS.)

In the variety known as a pigmented spindle cell naevus of Reed, there is well-demarcated junctional melanocytic activity with large quantities of melanin pigment. Spindle-shaped melanocytes proliferate downwards towards the dermis, but there is no upward movement of naevus cells through the epidermis, and usually very little, if any, intradermal component. Some naevus cells may be seen in the papillary dermis, but these naevi do not involve the reticular dermis. A sparse lymphocytic infiltrate is seen at the base of the naevus cells, but the lesion is relatively small and circumscribed. As with 'classical' Spitz naevi, symmetry is an important feature.

The problem is that many lesions with clinical and histological characteristics of Spitz naevi have some atypical features, which cause concern (Fig. 54.34), so that the most important and difficult pathological differential diagnosis is the separation of true benign Spitz naevi from spitzoid malignant melanoma. Two useful studies have tried to identify pathological factors that may help in this situation. Crotty and colleagues [9] have identified symmetry of

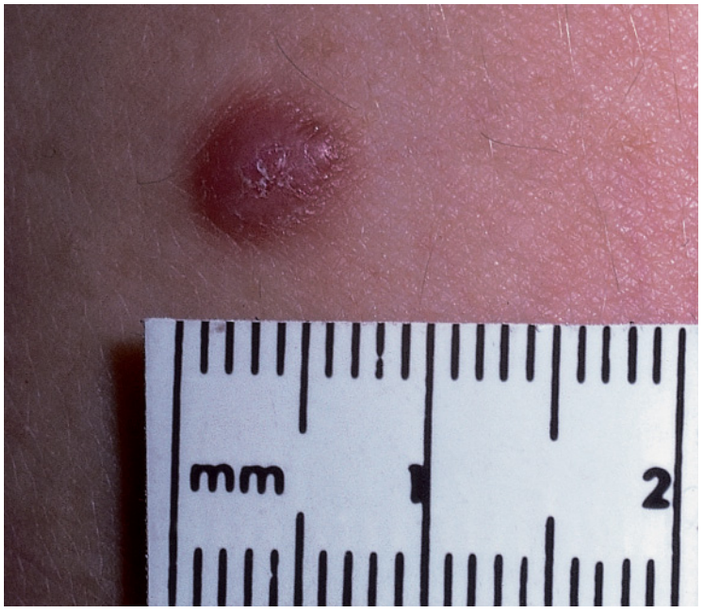


Fig. 54.33 Desmoplastic Spitz naevus.

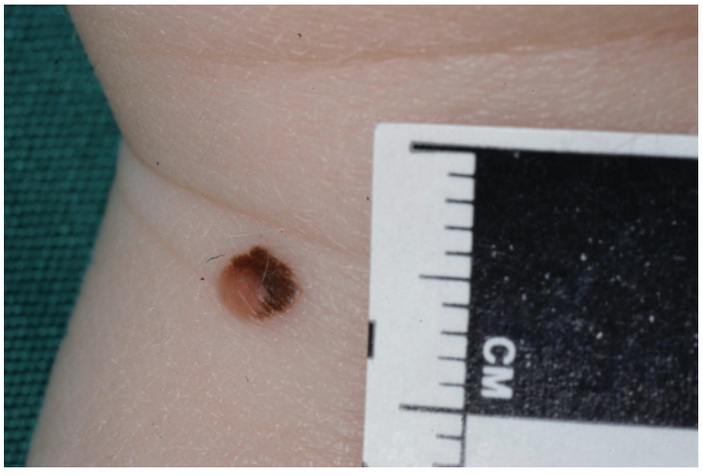

Fig. 54.34 This child developed a pigmented lesion on the wrist at the age of 1 year. At 2 and a half years the lesion was asymmetrical and showed variation in colour. Although clinically likely to be a benign Spitz nevus, prompt excision was necessary.

the lesion from side to side, the presence of Kamino bodies and the uniformity of cell nests or sheets in the dermis as features of benign Spitz naevi. In contrast, they identify abnormal mitoses, mitotic counts of over 2/mm^2 and deep mitoses as suggestive of spitzoid melanoma. Spatz *et al*. [10] have identified age over 10 years, diameter over 10 mm, ulceration, invasion to subcutaneous fat and mitotic activity of over 6/mm^2 as suggestive of spitzoid melanoma rather than Spitz naevi. Whilst these approaches are helpful, even between expert pathologists interobserver variation for spitzoid lesions is significant [11], and metastases have been reported from lesions categorized as 'low risk' [10]. Any atypical features should therefore be regarded with suspicion.

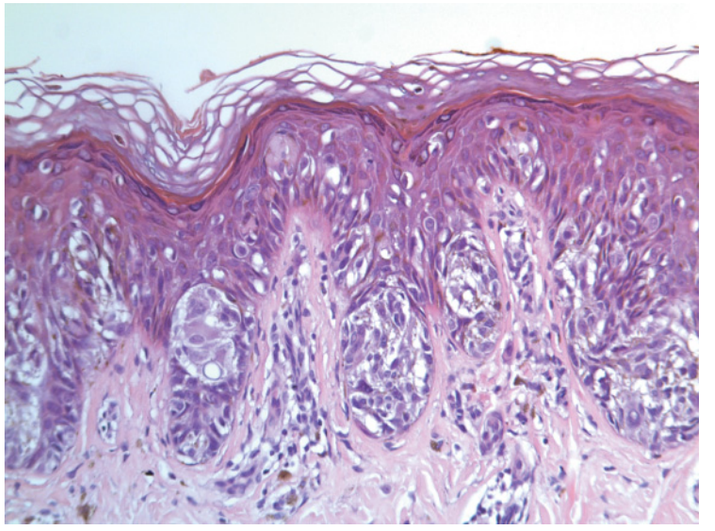

Fig. 54.35 The histological appearance of a classical Spitz naevus, with epitheliod cells and Kamino bodies. (Courtesy of Dr S. Edward, Leeds Teaching Hospitals Trust, Leeds, UK.)

In clinical practice, therefore, it is increasingly common for pathologists to report atypical Spitz naevi as 'atypical spitzoid tumours of unknown malignant potential', or STUMPs [3]. In this case, the norm is to manage the patient as if they had had a melanoma, but to reassure the patient that the lesion may, in fact, be benign although it is preferable to take a cautious view. Given the pathological difficulties around diagnosis, this seems a sensible approach to management.

Molecular biology may ultimately allow better characterization of spitzoid tumours. Comparative genomic hybridization (CGH) has been used, for example, to show differences between Spitz naevi and melanoma [12].

The pathology of the desmoplastic Spitz was well described by Barr *et al.* in 1980 [13] and it has a very striking and characteristic pathological appearance. The lesions are predominantly intradermal, and a relatively small number of naevus cells will be found embedded in thick collagen fibres. The naevus cells are usually distributed singly through the stroma rather than in clumps, and may be very large and bizarre, with copious cytoplasm, which may contain inclusions. The nuclei look unusual but not frankly malignant, and mitotic figures are rare (Fig. 54.35).

Diagnosis. Most Spitz naevi in children are red rather than brown, and may be confused clinically with vascular tumours, pyogenic granuloma, histiocytoma, juvenile xanthogranuloma or granulomas. Pigmented Spitz naevi may resemble compound melanocytic naevi or spindle cell naevi of Reed, but often cause diagnostic confusion with superficial spreading melanomas. Dermoscopy may improve the accuracy of the clinical diagnosis, especially if the lesion has the typical starburst appearance (Fig. 54.32b).

In young children, a lesion typical of a Spitz naevus, being symmetrical and red-brown in appearance, is very unlikely to be a melanoma and would normally not be excised, although review in clinic at 2 to 3 months is essential to ensure that the lesion is not developing any atypical features. In older individuals, or in

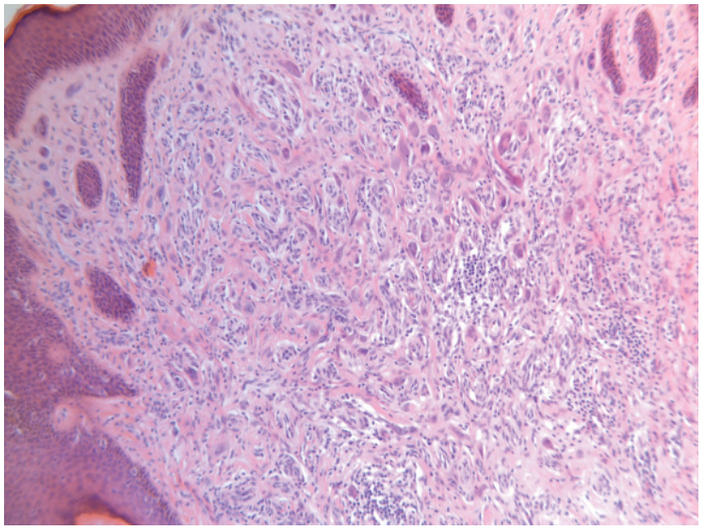

Fig. 54.36 The histological appearance of an atypical spitzoid tumour, showing relative lack of symmetry. (Courtesy of Dr S. Edward, Leeds Teaching Hospitals Trust, Leeds, UK.)

all patients (regardless of age) in which the lesion is asymmetrical or irregular in colour, excision should be carried out to exclude a 'spitzoid' melanoma (atypical spitzoid lesion) (Fig. 54.36). It is said that Spitz naevi are more common in adults on the thigh but rare on the trunk and therefore spitzoid lesions on the trunk of adults [14] would be viewed with particular suspicion. Complete excisions must be carried out, never incisional or punch biopsy. Because of the clinical and histological overlap between Spitz naevi and melanoma, some authors suggest that all spitzoid lesions should be excised [2] and Elder and Murphy suggest that a consensus is emerging towards excision of all [15]. In summary then, it seems reasonable not to remove very typical Spitz naevi in young children unable to tolerate local anaesthetic, but a 3-month review would be sensible. All other clinically spitzoid lesions should be removed in their entirety.

Treatment. Local excision with a narrow margin of 1–2 mm of normal skin is usually required to confirm the clinical diagnosis. Local recurrence has been recorded in both isolated and agminate lesions [16]. In the presence of atypical features (either clinically or histologically), or where the diagnosis of a STUMP is made, the margin of excision should be as for melanoma: 1 cm for tumours of less than 2 mm in thickness; 2 cm or more where the thickness is 2 mm or greater.

There are small reported series of sentinel node biopsies in patients with atypical spitzoid tumours that demonstrate positivity in a proportion [17], supporting the view that such lesions may be melanomas in terms of how they behave. The use of sentinel node biopsy in such patients is subject to the same limitations as for melanoma. In particular there is a no survival benefit.

Blue naevus and cellular blue naevus

Definition. A blue or blue-black melanocytic naevus comprised of aberrant collections of pigment-producing but benign melanocytes, in the dermis rather than at the dermoepidermal junction (as in common acquired naevi).

Incidence and aetiology. Blue naevi are relatively common. Their aetiology and pathogenesis is unclear. Some authors view these as equivalents of dermal melanocytic proliferations seen in animals [1]. Uncommon lesions have mixed 'blue' and 'acquired' characteristics (combined naevus, below) and this might suggest that others are variants of common acquired melanocytic naevi. Multiple epithelioid blue naevi may be associated with the Carney complex (Chapter 62).

Clinical features. There is an area of diffuse blue pigmentation, usually slightly raised and smooth surfaced. Blue naevi may be found on any site but patients with facial naevi most often request excision for cosmetic reasons. The cellular blue naevus is seen most often on the extremities, particularly the dorsa of the hands and feet (Fig. 54.37), the buttocks and the face. The onset may be before birth, but lesions frequently first appear around puberty. The blue naevus is usually very symmetrical, and has an

Fig. 54.37 A cellular blue naevus.

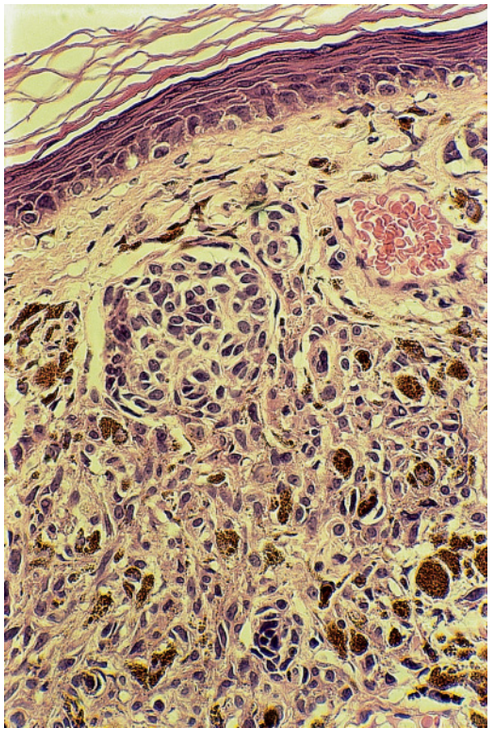

Fig. 54.38 Histology of a blue naevus. Note the normal overlying epidermis with spindle cells and dense pigmentation in underlying dermis.

amorphous, structureless pigment pattern on dermoscopy which may be blue, white or darker in colour [2].

The combined naevus is a rare variant in which there are elements of a blue naevus and a common acquired melanocytic naevus. They may cause concern clinically because of their unusual appearance and are therefore commonly removed.

The deep penetrating naevus is a further rare variant said to be more common on the head and neck [3]. Clinically, it may be a deep blue or black colour with a diffuse, irregular lateral margin. The clinical differential diagnosis is therefore frequently melanoma. The blue appearance is attributed to the 'Tyndall effect', which states that red light penetrating the skin is diffused by the dermis allowing blue light to be reflected by deep pigment.

Progressive growth in blue naevi is rare and would cause concern, although malignant transformation is very rare indeed (below). There is a view that the term malignant blue naevus is confusing and that lesions dubbed 'malignant blue naevi' are just melanomas which resemble blue naevi, or that these are very rare instances of malignant transformation in a blue naevus [4].

Pathology. In the common or classic variety, bipolar and dendritic melanocytes lie singly or in masses in the dermis (Fig. 54.38). The melanocytes tend to be profuse in the lower dermis and are often concentrated around appendages or in the perivascular and perineural areas. Deeper tissues may be involved. The melanocytes are relatively inconspicuous, containing fine granules of melanin dispersed through their cytoplasm. There are varying numbers of melanophages in which the melanin granules are coarse and more closely clumped.

The cellular blue naevus is composed of the same elements as the common blue naevus, but in addition possesses islands of larger cells arranged in a neuroid ('pigmented neurofibroma') or sarcomatoid fashion. The appearance may raise suspicions of malignant melanoma, but the lack of mitotic activity, vascularity or inflammatory reaction, the regularity of the cells and the absence of junctional proliferation in continuity with the cellular masses enable the distinction to be made [5,6].

The compound blue naevus is a more recently described entity [7], with additional dendritic cells in the overlying epidermis. This lesion may clinically be very similar to early malignant melanoma.

The deep penetrating naevus may be considered as a distinct entity [3] or as a variant which frequently has features of both a compound and a blue naevus or Spitz naevus, making it a variant of the so-called combined naevus but with minimal junctional activity. They are larger than most naevi, with extension of naevus cells deep into the dermis in a wedge shape, the base abutting onto the epidermis. The diagnostic feature is the presence of clusters of widely separated but deep naevus cells throughout the dermis. Frequently these clusters are around the skin appendages. The cytology is of a spindle cell population and mitotic figures are rare [8].

Malignant blue naevus is discussed below.

Diagnosis. The blue naevus is characterized by its colour and symmetrical shape and must be differentiated from other dermal melanoses. It is a relatively static, non-progressive lesion.

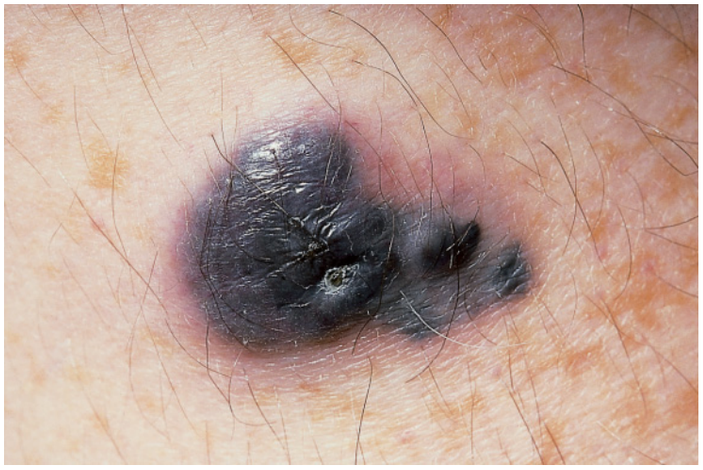

Fig. 54.39 Malignant blue naevus which has arisen in a previous cellular blue naevus. This lesion subsequently metastasized to lymph nodes.

Treatment. None is needed save for distinction from melanoma.

Malignant blue naevus

Definition. A very rare malignancy often confused with melanoma although it is argued that the difference is semantic [4]; in some cases it is not possible to differentiate between classic malignant melanoma and malignant change within a blue naevus.

Pathology. Malignant cells of melanocytic origin are seen in the deeper dermis with no overlying abnormality of epidermal melanocytes. Pathologically there is a sheet-like growth pattern. Necrosis and atypical mitotic figures are diagnostic features which will distinguish these lesions from benign classic or cellular blue naevi [9]. Mitotic figures are rare [10], but the presence of any at all should suggest the diagnosis of melanoma rather than a blue naevus.

Clinical features. Malignant blue naevus usually arises in a cellular blue naevus, and the scalp is the commonest site (Fig. 54.39). Expansion of a previously identified blue naevus should suggest the diagnosis. Metastases do occur [9].

Treatment. Wide surgical excision is required as for other types of melanoma.

Clinically atypical naevi

Synonym
- Dysplastic naevus

Definition/pathogenesis. A melanocytic naevus, which is 5 mm or larger in diameter, with an irregular or diffuse edge and variable or mottled pigmentation (Fig. 54.40). Although there are histological correlates, the diagnosis is a clinical one.

Natural history. The natural history of acquired benign naevi is of proliferation of melanocytes until the naevus reaches up to

5 mm in diameter, and the proliferation at the dermoepidermal junction then ceases. The naevus cells migrate down into the dermis but subsequent cellular senescence occurs, resulting in the development of a compound and then a dermal cellular naevus. In an atypical naevus, the melanocyte proliferation continues so that the naevus continues to grow in size beyond the 'usual' size, and the junctional proliferative component may show some features reminiscent of an early melanoma, resulting in some irregularity of shape and colour clinically. Although in the majority of such naevi the melanocytes eventually cease proliferation, resulting in 'maturation' of the naevus as a compound and then a dermal naevus, a proportion of such naevi continue to grow and may evolve into radial growth phase melanoma. Thus, although the majority of atypical naevi behave in a benign manner, they are viewed as lesions exhibiting a more proliferative phenotype than common acquired naevi, and are therefore both markers of risk of melanoma and precursor lesions for melanoma.

Incidence and epidemiology. The term 'dysplastic naevus' was first used by Elder [1] as a pathological description of a sporadically occurring melanocytic naevus, which was clinically larger and more irregular, and showed a constellation of pathological features that also distinguished it from common or banal naevi. Earlier, Clark *et al*. [2] and Frichot *et al*. [3] had separately, but almost simultaneously, described families in which multiple primary melanomas were much more common than expected and who also had large numbers of unusual naevi—the BK mole syndrome or FAMMM syndrome (*f*amilial *a*typical *m*ultiple *m*ole *m*elanoma syndrome) [4]. The naevi seen in these syndromes have come to be recognized as 'atypical naevi'. Technically, atypical is a clinical description and dysplasia is determined histologically; although a clinically atypical naevus may not exhibit histological dysplasia, and vice versa, the terms have often been used interchangeably.

Atypical (or dysplastic) naevi are common in white-skinned peoples. In studies reported from Sweden, 18% of the population were reported to have at least one clinically diagnosed atypical naevus [5], as had 37% of young men in an Italian study [6]. In other populations the prevalence is lower, so that in a German study 5% of adults were reported to have at least one [7]. The prevalence is therefore variable and some of this variation is explained by differences in skin type, age of people studied and probably differences in clinical definitions or interobserver variability. There is no doubt, however, that they are common, although most individuals who do have some atypical naevi only have small numbers—one or two generally.

Atypical naevi are undoubtedly precursors of melanoma, although progression to melanoma is uncommon. They are also markers of risk of melanoma; in a meta-analysis the melanoma relative risk associated with the number of atypical naevi was 6.36 (95% CI 3.80–10.33) for five versus none [8]. Twin studies have provided evidence that benign naevi in general are genetically determined [9] and it is supposed that atypical naevi are also genetically determined at least in part, although with evidence that sunburn is also important [10].

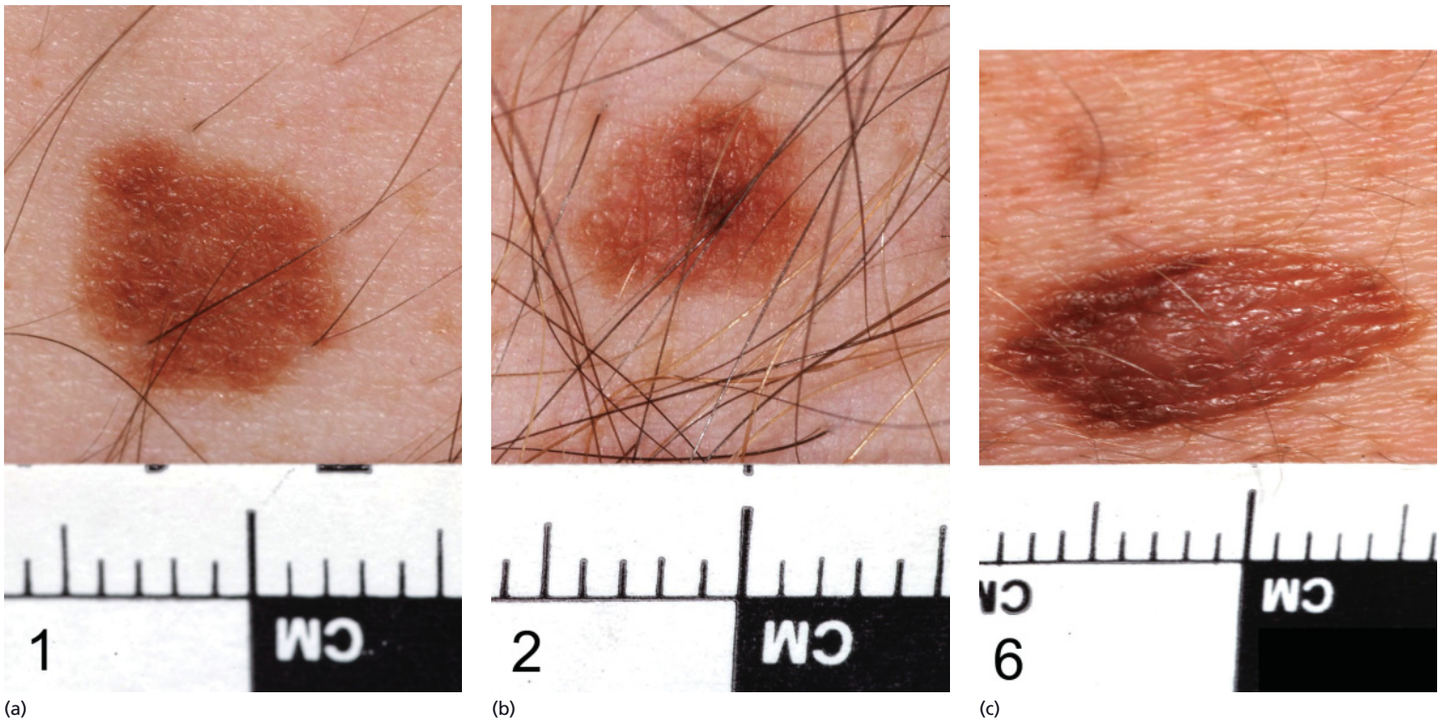

Fig. 54.41 The atypical mole syndrome is characterized by the presence of an increased number of naevi and clinically atypical naevi. This is the strongest phenotypic risk factor for melanoma.

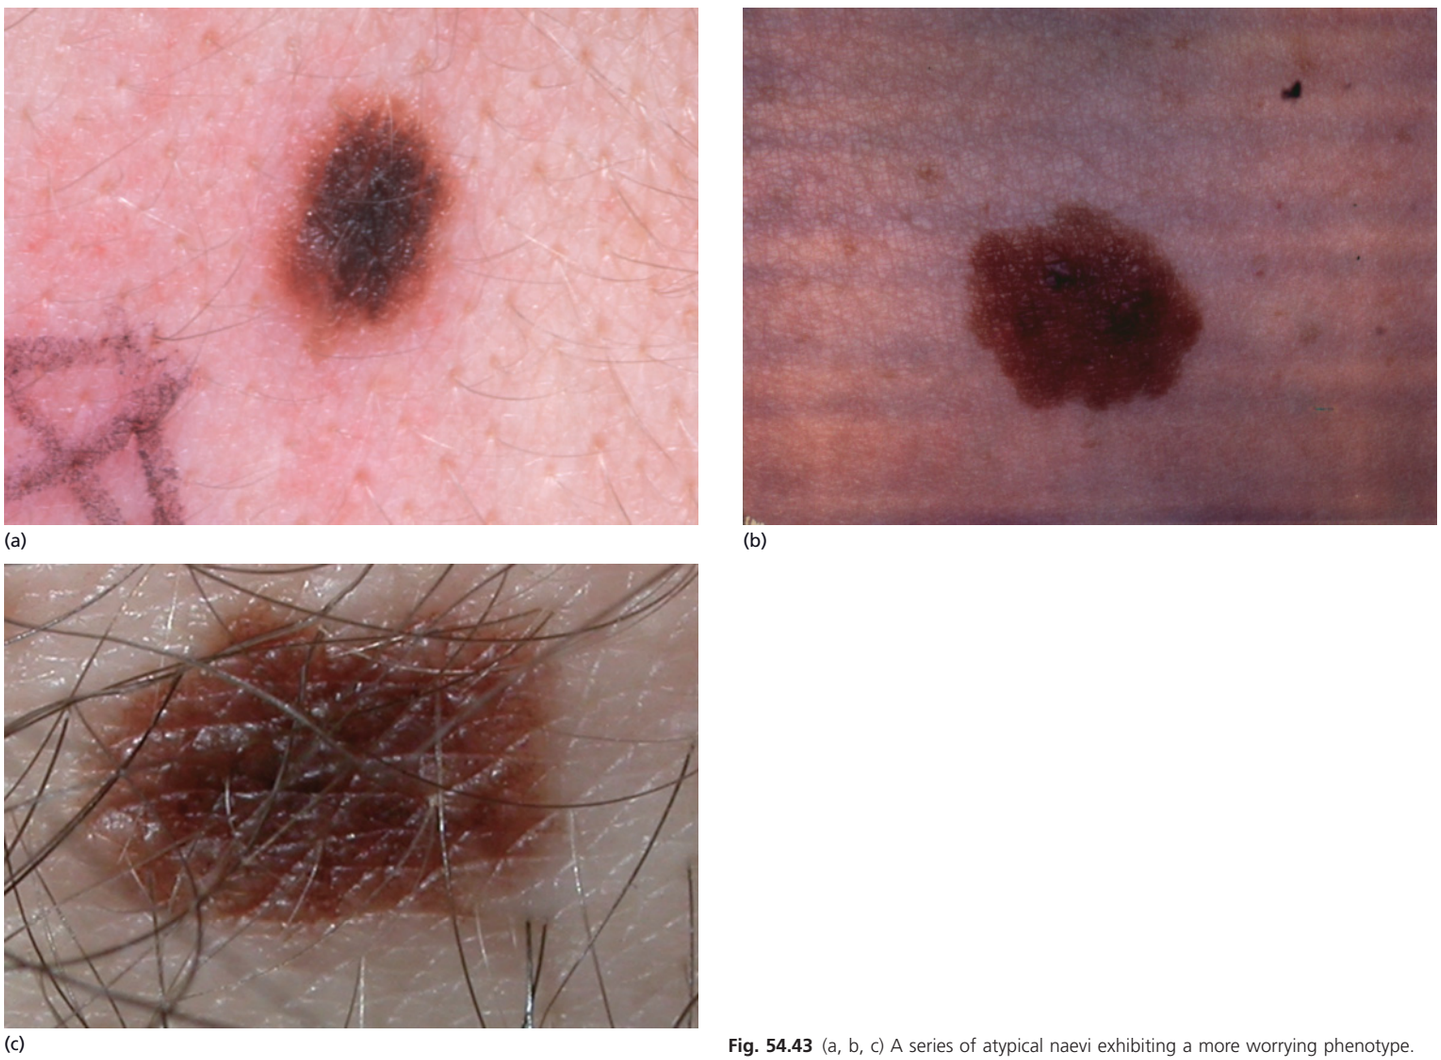
Although small numbers of atypical naevi are common in most fair-skinned populations, as documented above, and although they are both a precursor and an associate of melanoma, the majority of people with some atypical naevi have neither a personal nor a family history of melanoma. However, many such individuals will also have increased numbers of small benign naevi (Fig. 54.41) and are recognized to be at increased risk of melanoma. The atypical mole syndrome is my preferred term to describe patients with this phenotype, but others use the 'dysplastic naevus syndrome' or the FAMMM syndrome phenotype. Their relative risk of melanoma is something around 6 to 10 times that of people with very few naevi [8,11]. The identification of this 'at risk' group, which accounts for around 2% of the UK population [12], is therefore important in terms of prevention and for education around early detection.

Clinical features. The original description of dysplastic naevi indicated that these were lesions larger than 5 mm with an irregular edge, irregular pigmentation and a degree of inflammation. Although there is a recognizable histological pattern associated with such naevi, the correlation between clinical and pathological features is poor. This, in some respects, is not a problem. The diagnosis of an atypical naevus is a clinical one. The importance of this diagnosis is only in terms of educating the patient about risk and what to look for when self-examining.



The clinical imperative is to distinguish the atypical naevus from *in situ* or early radial growth phase melanoma. In practice, the clinical features of atypical naevi are in continuum with those of *in situ* melanoma, and the clinician must have a sufficiently low threshold for excision to avoid missing the latter whilst avoiding the excision of excessive numbers of benign naevi (Figs 54.42–45).

Pathology. The great majority of atypical naevi are variants of acquired compound melanocytic naevi, although features described in atypical lesions may be seen in junctional naevi, in some congenital naevi and, occasionally, in Spitz naevi and variants.

(c)

Fig. 54.44 (a, b, c) A series of *in situ* melanomas to illustrate the continuum of clinical change that is the progression from atypical naevi to melanoma.

The specific pathological features described in atypical naevi can be divided into architectural features, cytological features and features indicative of a host response to the naevus cells. The architectural features are lentiginous melanocytic hyperplasia, fusion of individual nests of naevomelanocytes and associated elongation of epidermal rete ridges (Fig. 54.46). The cytological abnormalities are the increase in the nuclear to cytoplasmic ratio of individual melanocytes, an increase in nuclear staining and occasional normal mitotic figures in melanocytes. Elder and Murphy describe random, slight to moderate atypia, occasional macronuclei, scattered epithelioid naevus cells and scattered cells with dusky pigment [13]. Most groups would not make the diagnosis on architectural features alone but consider melanocyte cytological atypia an essential feature for the diagnosis. It is preferable to report the presence of architectural and cytological atypia specifically. The three pathological features indicating a host response

are the presence of a lymphocytic infiltrate, a degree of fibroplasia of the collagen of the papillary dermis and a relative increase in the vascularity of the underlying dermis (Fig. 54.47). The presence of these changes in an atypical naevus that has evolved into a melanoma may cause confusion with the possible presence of regression.

Treatment. Atypical naevi are in the majority of cases benign, stable lesions, which are bland in appearance, clinically and using dermoscopy. They can be left in place although the patient must be educated about monitoring the appearance of such naevi over time. Photographs of early melanomas are essential for this purpose, as leaflets or on line [14]. A picture of the naevus given to the patient may also be helpful.

Where the naevus is sufficiently atypical (and particularly when a single naevus is present) then it should be removed in its entirety with a 2-mm clinical margin and subjected to pathological examination, to exclude *in situ* melanoma. Such naevi should NEVER be punch biopsied or an incisional biopsy taken, as sampling error may cause an early melanoma to be missed.

Two per cent of the UK population [12] have the atypical mole syndrome in which there are multiple naevi, many of which may be clinically atypical, although this is variable. The majority have no family history of melanoma. In these patients the phenotype is

a marker of risk and that risk cannot be removed by removal of the naevi. Such patients must be counselled about avoidance of sunburn for themselves and their children. They should be taught how to self examine with the aid of images [14] and a short period of follow-up is sensible, to ensure that the naevi are stable and that the patient is confident about self examination. Advice for follow-up of those with a family history of melanoma is discussed below.

Malignant melanoma of the skin (melanoma): background

Definition. A malignant tumour arising from the epidermal melanocyte.

Incidence and mortality [1]

There has been a steady rise in the incidence of melanoma of the skin in many areas of Australia, New Zealand, North America and Europe since the 1950s. The most recent incidence figures are available on line from the Globocan 2002 project at the Cancer Mondial Statistical Information website through the International Agency for Research on Cancer [2]. The highest incidence is seen in Australia and New Zealand. There has been a levelling off in incidence in many areas of Western Europe in recent years, but in Eastern and Southern Europe levels are still increasing [3]. In the UK, there is some evidence for a levelling off in some areas [4,5] but not in all [6]. In the USA, the SEER programme reported that the incidence of melanoma continued to rise at least till 1995, with a trebling of melanoma incidence in males aged 45–64 years over the 30-year period 1969–99, from 13.5 to 40.0 per 100 000 population per annum, and a fivefold increase in older males aged over 65 years, from 18.8 to 91.9 per 100 000 population per annum. Incidence rates for females aged 45–64 years and for those aged over 65 years have also risen but less steeply than for males, while the incidence of melanoma in younger adults of both sexes aged under 45 years has only risen slightly over a 40-year period [7]. In Australia, age-standardized incidence is continuing to increase despite long-standing prevention campaigns. However, a study has provided evidence for stabilization of incidence rates in those younger than 35 years and the proportionate increase for both *in situ* and invasive lesions appears to be lower for the most recent period compared with previous periods, providing hope of a reversal in years to come [8].

Despite the increase in incidence in the north of the UK recently, mortality seems to be levelling off [6]. In Australia, melanoma mortality seems to have peaked in the 1980s [9]; statistically significant decreases in mortality rates for both men and women younger than 55 years have occurred in recent years, for 55–79 year olds, rates are now stable for both men and women whereas previously the rates were increasing. For both men and women 80 years or older, rates have continued an increase of 3–4% per year [10]. Similarly, in the USA, mortality appears to be stabilizing in women, but still rising slightly in men [7].

Overall then, melanoma is most common in white-skinned peoples living at lower latitudes such as Australia, and the incidence continues to increase in many countries but has levelled off in others. The mortality seems to have levelled off or have reduced in most areas, however, suggesting that early diagnosis may have been effective in reducing mortality. Some authors have contested this, suggesting that increased numbers of melanocytic lesions may be being removed which would not necessarily have progressed to invasive melanoma [11]. Certainly, in many areas of the world the absolute numbers of thick tumours appear to be relatively constant over time [12] suggesting persistent difficulties in early diagnosis. Thicker tumours occur particularly in older patients [6,12], and, in many series, males had a higher proportion of thicker tumours than did females [7,12]. Furthermore, in Europe generally, mortality has continued to increase in older men [13]. In terms of prevention, therefore, an important target group for early detection are older patients, particularly males.

Aetiology

Melanoma is predominantly a cancer of white-skinned peoples, which gave the first clue that sun exposure is causal. The variation in incidence amongst such populations with latitude of residence (as described above) is further evidence, the highest incidence being in Australasia where susceptible, fair-skinned peoples live in sunny climes. The aetiological factors for melanoma are therefore both genetic (related to cutaneous responses to the sun such as skin type) and environmental.

The precise type of sun exposure that is causal has been controversial but the data are now strong that the dominant cause is

intermittent sun exposure. Holidays in the sun, associated with sunburn, have been identified in numerous case–control studies, and results have been subjected to meta-analysis [14]. Chronic sun exposure does not seem to be causal, at least in many areas of the world; there was even some evidence for a protective role for occupational sun exposure in the same meta-analysis [14]. In Australasia, however, solar keratoses appear to be risk factors for melanoma and it has been suggested that there are two routes to melanoma [15,16]: one associated with short sharp exposures to excessive sun exposure and sunburn and another related to chronic sun exposure which might be responsible for a greater proportion of cases in hot countries. These hypotheses are still being explored.

There is some evidence that sunbed usage is also causal for melanoma: in a meta-analysis based on 19 informative studies [17], use of sunbeds ever was positively associated with melanoma (summary relative risk 1.15; 95% CI 1.00–1.31), although there was no consistent evidence of a dose–response relationship. First exposure to sunbeds before 35 years of age significantly increased the risk of melanoma, based on seven informative studies (summary relative risk 1.75; 95% CI 1.35–2.26). It is difficult to separate the effects of sunbed use from those of sunbathing, however, and sunbed usage is likely to explain a relatively small proportion of melanoma cases.

Whether the continued increase in incidence is an artefact of the removal of increased numbers of lesions which might have progressed or not, the relationship between melanoma and intermittent sun exposure and increased mobility of fair-skinned peoples to hot countries is a cause for concern.

Phenotypic risk factors for melanoma

The strongest phenotypic risk factor for melanoma is the presence of increased numbers of melanocytic naevi. In a meta-analysis of 46 studies, 101–120 common naevi compared with less than 15 was associated with a significantly increased risk of melanoma (pooled relative risk (RR) = 6.89; 95% CI 4.63–10.25) as was the number of atypical naevi (RR = 6.36; 95% CI 3.80–10.33, for 5 versus 0) [18]. Twin studies have provided strong evidence that naevus number is predominantly genetically determined [19], with a smaller effect of environmental factors, particularly sun exposure [20]. It is theorized, therefore, that the genes that determine naevus number are also common melanoma susceptibility genes. The first evidence for inherited genes that are both naevus and melanoma susceptibility genes was published in 2009 [21].

Weaker phenotypic risk factors relate to the presence of skin that burns easily in the sun such as: skin type (I vs. IV: RR = 2.09, 95% CI 1.67–2.58), high density of freckles (RR = 2.10, 95% CI 1.80–2.45), skin colour (fair vs. dark: RR = 2.06, 95% CI 1.68–2.52), eye colour (blue vs. dark: RR = 1.47, 95% CI 1.28–1.69) and hair colour (red vs. dark: RR = 3.64, 95% CI 2.56–5.37) [22]. These phenotypes are also genetically determined; a key gene, *MC1R,* codes for the melanocortin receptor receptor, which, at least in part, determines the presence of both red hair [23] and freckles [24]. The gene mediates these effects by modulation of the ratio between the pheomelanin and eumelanin produced by the melanocyte.

Skin changes indicative of sun damage are also shown to be risk factors at meta-analysis [22], such as pre-malignant and skin cancer lesions (RR = 4.28, 95% CI 2.80–6.55) and actinic damage indicators (RR = 2.02, 95% CI 1.24–3.29).

Familial melanoma

Any family history increases the risk of melanoma. A study from the Swedish Cancer Registry estimated the standardized incidence ratio for melanoma to be 2.40 (95% CI 2.10–2.72) for offspring if one parent had a melanoma, 2.98 (95% CI 2.54–3.47) for an affected sibling and 8.92 (95% CI 4.25–15.31) if a parent and a sibling were both affected. The highest ratio was for offspring when a parent had multiple melanomas [25].

A strong family history is rare, but families with multiple cases are reported from around the world. In these families, inheritance of melanoma is consistent with inheritance of an autosomal dominant gene with incomplete penetrance (Fig. 54.48). Inheritance of mutations in the *CDKN2A* gene on chromosome 9 [26] (which codes for the cell cycle inhibitor protein, p16) explains a proportion of these families, but not all. The importance of p16 in the pathogenesis of melanoma was emphasized by the identification of germline mutations of *CDK4* as the second highest penetrance melanoma susceptibility gene [27,28], as mutations in this gene, found at chromosome 12q13, occur at the p16 binding site. Families with mutations in *CDK4* are excessively rare. Many of the reported *CDKN2A* mutations have been shown to be founder mutations, such as Gly101Trp [29], which is common in mainland Europe (France and Italy), the so-called Leiden mutation, which is an exon 2 19-bp deletion [30], and Met53Ile [31], which may be of Scottish origin. 113insArg is a Swedish founder mutation [32] and a common founder for Val126Arp has been shown by haplotype studies in North American families [33]. To date, only one mutation seems to appear repeatedly at a hotspot, a 24-bp duplication at the N-terminus [31]. An on-line database of locus specific variants, named eMelanoBase, is maintained by the Leiden Medical Center group of GenoMEL [34]. The proportion of families with identifiable mutations is higher with larger numbers of affected family members, early age of onset and if there are cases with multiple primaries, and if family members have pancreatic cancer [33], although there is variation by continent so that the association with pancreatic cancer, for example, is much less clear in Australia than it is in many parts of Europe and the USA. The majority of families appear to be predisposed to melanoma alone, if risk is assessed by pedigree examination. The gene penetrance has been estimated by GenoMEL, the Melanoma Genetics Consortium [35]. Overall, *CDKN2A* mutation penetrance was estimated to be 0.30 (95% CI 0.12–0.62), meaning that on average 30% of mutation carriers develop a melanoma by the age of 50 years and 0.67 (95% CI 0.31–0.96) by age 80 years, in 80 families pooled from the US, Australia and Europe. Not surprisingly, penetrance was higher in families living in Australia where sun exposure is more intense. A lower penetrance was reported in a population based study [36].

A significant proportion of families do not have identifiable *CDKN2A* or *CDK4* mutations and there are, therefore, other high-risk genes yet to be identified. Two possible sites are at 1p36 [37] and 1p22 [38].

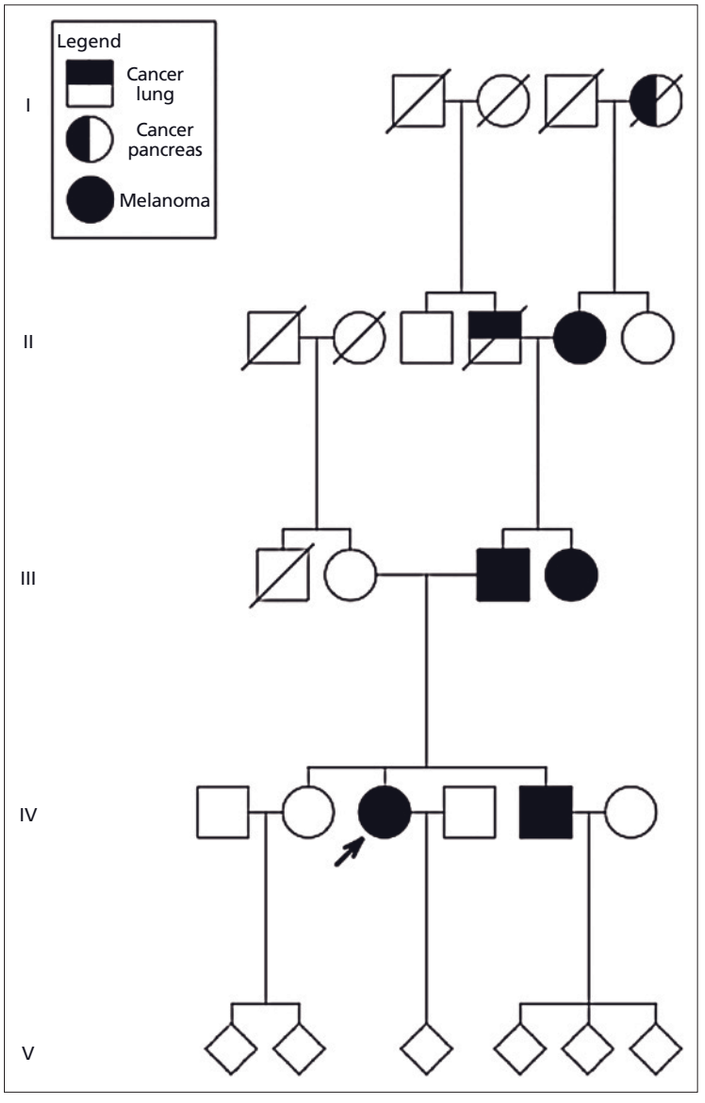

Fig. 54.48 A family tree from a family with a hereditary mutation in the *CDKN2A* gene, which is a high-risk gene for melanoma. The black circles represent melanoma cases in women, the squares, cases in men. There was a single case of pancreatic cancer.

Families with multiple cases of melanoma should be referred to specialist units for screening, education about early detection and prevention and counselling about risk. Although testing for mutations in the *CDKN2A* gene does take place in some countries, the value of the test is currently unclear and GenoMEL has taken the view that it is as yet premature [39]. GenoMEL is working to establish the information necessary to inform this counselling process in the future. The increased risk of pancreatic cancer in some countries but not in others remains confusing and may be due to variation between mutations or environmental factors. As pancreatic cancer is associated with smoking and alcohol-induced pancreatitis [40,41], it is important to advise members of melanoma families to avoid smoking and moderate alcohol intake. Screening for pancreatic cancer remains a difficult issue but there are trials currently taking place to establish the role of radiographic screening.

Identification of 'at risk' patients

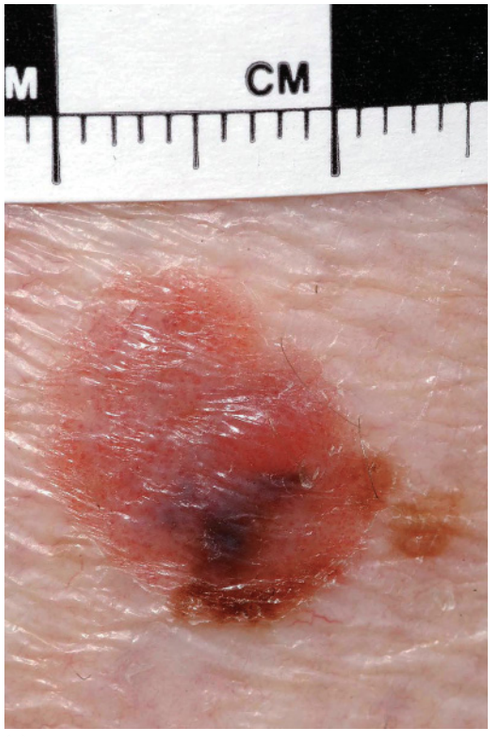
The strongest risk of melanoma to an individual is that associated with familial melanoma where there are multiple cases. Within such families, all first-degree relatives are considered at risk regardless of naevus phenotype, although the presence of increased numbers of naevi increases the likelihood that the family member is a *CDKN2A* mutation carrier [42].

Patients with the atypical mole syndrome are at increased risk irrespective of family history and those with red hair and freckles are also at increased risk, although at a lower level. Algorithms have been, or are being, developed in order to estimate risk [43,44].

Prevention

The continued increase in incidence of melanoma in most white-skinned populations, and the very strong evidence that intermittent sun exposure is causal, suggests that sun exposure on holidays in sunny places is the most important behaviour to be addressed. As air fares are currently much lower than they were, there is a concern that this will prove even more difficult to modify in the next few years. It might be that directing the advice to those at increased risk will be more effective, stressing freckles, naevi and family history as risk factors for the cancer. For such people, protection using avoidance and clothing is optimal but less popular than the use of sunscreens. The wavelength of light that is causal for melanoma is still not known and therefore sunscreens should be broad-spectrum types, providing protection across both UVB and UVA ranges. Advice should be to use sunscreens that are water proof, and are applied regularly and in sufficient quantities.

Sun exposure for vitamin D synthesis is critical to human health. 1,25-dihydroxyvitamin D_3 is synthesized in the skin as a result of exposure to sunlight and is present in a few foods and dietary supplements. It has become apparent that suboptimal vitamin D levels are widespread [45], and increasing epidemiological evidence has emerged for a role for vitamin D deficiency in a number of cancers [46,47]. Most European peoples rely upon cutaneous synthesis as a result of sun exposure and the UV action spectrum for vitamin D synthesis and non-melanoma skin cancer carcinogenesis is the same [48], so that the balance between benefit and risk is close. There are, therefore, concerns that we should not give blanket advice to all to reduce their sun exposure. It seems sensible to direct advice to those at particular risk and to give the following advice:



- That people who burn in the sun, who have freckles, red hair or a larger number of melanocytic naevi, and those with a family history of skin cancer should be careful in the sun
- That these people should in particular avoid any sunburn
- That those who burn readily in the sun should probably avoid direct exposure to the sun and compensate for this avoidance by taking vitamin D supplements sufficient to maintain normal levels of vitamin D in the serum
- That dark-skinned peoples who have a low risk of skin cancer should avoid sunburn but, to avoid vitamin D depletion, which would be detrimental to their health overall, should not practise too much sun avoidance.

Clinicopathological variants and growth phases of primary melanoma

In 1969, Clark *et al*. suggested that, using a combination of clinical and pathological features, malignant melanoma could be divided into three main subsets [1]; the superficial spreading melanoma, the nodular melanoma and the lentigo maligna melanoma. In 1975, Reed *et al*. added a fourth group, the acral lentiginous or palmoplantar malignant melanoma [2]. There is some controversy as to whether or not these subsets are completely discrete entities, and it has been established that the clinicopathological variant is not an independent determinant of prognosis [3]. However, the four subtypes have distinct clinical features and possibly some biological distinctions, which are useful in clinical practice and each will be discussed in more detail later. The growth phases of melanoma also have clinical importance and are discussed here.

(a)

(b)

Fig. 54.49 (a, b) Two superficial spreading melanomas showing typical variation in colour and shape.

In situ disease

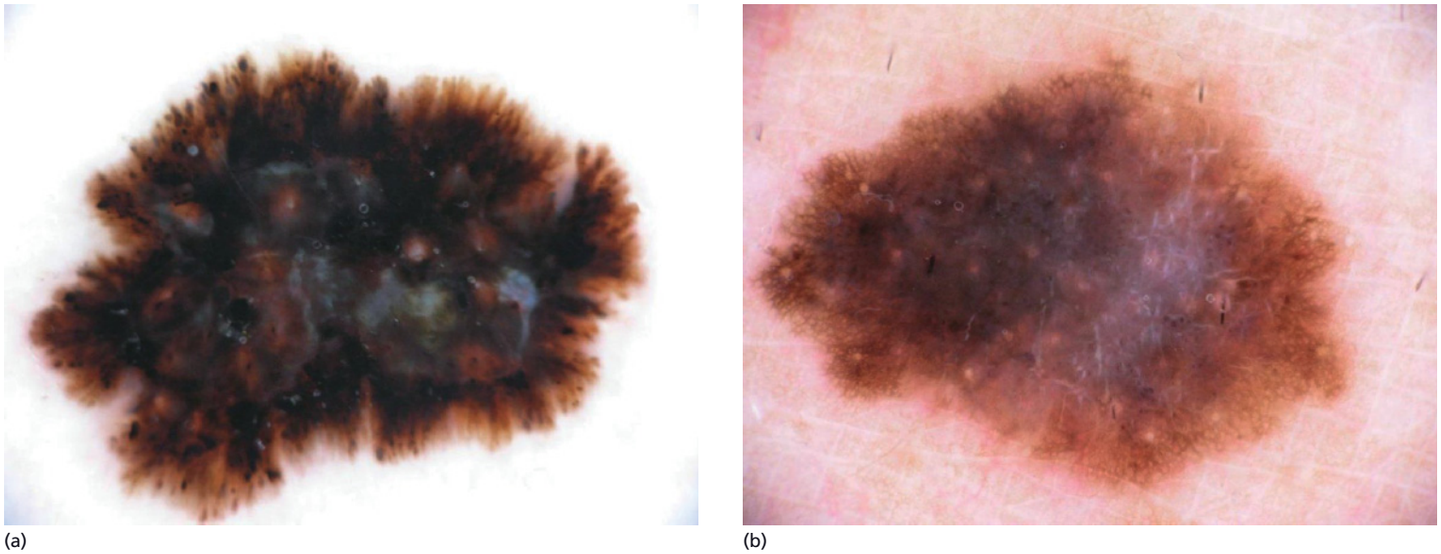
Melanomas arise from melanocytes within the epidermis generally. In the majority of cases, the proliferation of melanocytes is limited to the epidermis for some time, before the cells acquire the capacity for survival and growth in the dermis. This phase is known as '*in situ*' disease, which may last for a period of years.

The commonest type of melanoma, the superficial spreading melanoma (SSM), for example, may evolve from an atypical naevus, through a borderline *in situ* lesion, to an SSM (Figs 54.49–54.51). In some subtypes of melanoma, such as lentigo maligna melanoma, acral lentiginous melanoma and genital melanoma, the *in situ* phase is particularly protracted. The *in situ* component in these rarer subtypes may, furthermore, be widespread and ill-defined and this is often known as the 'field effect'. Although ill-defined *in situ* disease typifies the subtypes of melanoma listed above, it may rarely occur on other sites, such as chronically sun-exposed skin of the arm or leg, in the skin around an SSM.

Fig. 54.50 A superficial spreading melanoma which has developed into a vertical growth phase tumour. Variable colours are seen with prominent vasculature and variable pigment. Even without a dermoscope large pigment dots can be seen.

So-called nodular melanomas are the only type in which the malignant melanoma cells appear to have the capacity for invasive growth into the dermis and beyond from the beginning, without an *in situ* phase, and these tumours therefore develop much more rapidly and are much more difficult to diagnose at an early, curable stage.

Radial growth phase melanoma



The concept of evolution from *in situ* disease to invasive disease which is still unlikely to metastasize, called the 'radial growth phase', was developed by Clark and Elder [4]. Radial growth phase melanoma is strictly defined histologically. There is epidermal melanocyte proliferation and there may be some dermal cells provided that they are single or in small clusters, falling short of a dermal tumour nodule. A tumour nodule in the dermis is one which exceeds the diameter of any nest of cells along the dermo-epidermal junction [5]. The concept of radial growth phase melanoma as a lesion that should not recur means that these authors estimate a 100% expectation of survival for patients from whom such a lesion is removed.

Vertical growth phase melanoma

Melanoma in vertical growth phase is a tumour in which growth of malignant cells occurs within the dermis. These tumours have acquired the capacity for growth and, to a variable degree, the capacity for invasion of vessels and growth in other tissues. Variation in the characteristics of vertical growth phase melanoma histologically and immunohistochemically mirrors biological differences between tumours having prognostic significance, considered below.

Clinical diagnostic aids

The clinical diagnosis of melanoma is based upon recognition of a progressively changing melanocytic lesion, which is growing and becoming irregular in shape and colour.

There are two diagnostic systems, which are intended to aid recognition by non-experts and the general public. Both apply mainly to the superficial spreading variant of malignant melanoma, which is the commonest subtype and generally has a relatively slow growth rate, at least in its early radial growth phase. These are the American ABCD categories and the Glasgow seven-point check-list. The American ABCD mnemonic is A = asymmetry, B = irregular border, C = irregular colour and D = diameter over 1 cm. The Glasgow seven-point check-list is divided into three major and four minor features. These are:

Major features:
1 Change in size
2 Change in shape
3 Change in colour

Minor features:
4 Diameter more than 5 mm
5 Inflammation
6 Oozing or bleeding
7 Mild itch or altered sensation.

It is suggested that any lesion with one major feature in an adult be considered for removal, and that the presence of additional minor features should add to clinical suspicion. For experts and possibly even for non-experts, however, assessment of lesions appears to be made using a 'global' assessment and it may be that widespread availability of images of melanomas may be the most effective means to promote recognition [1]. Images on the Internet may be particularly helpful here.

A number of computer-based systems are in clinical trial to aid in the diagnostic process, but these remain of unclear value.

Melanoma: specific histogenetic types, sites and variants

Superficial spreading melanoma

This is by far the most frequent type of melanoma. The commonest sites are the female leg and the male back, but any body site may be involved. An evolving, superficial spreading melanoma has the appearance of a flat, pigmented lesion, which becomes increasingly irregular in shape and colour over time. Shades of brown, black, red and grey or white may be present (Figs 54.49–54.51). The red colour usually indicates a degree of inflammation/vascular neogenesis and the resultant 'juicy' appearance should cause concern. White–grey areas may be indicative of a degree of regression. The lesion may still be very small, only 4–5 mm in diameter, but there may be a history of growth or change, and of subtle altered sensation, often described as a new awareness of the lesion or a tickling sensation. At this stage, the lesion will almost certainly be in the early radial growth phase, but as growth continues the lesion will become palpable, indicating that the lesion is progressing to the vertical growth phase. If the melanoma is developing in a pre-existing naevus, which occurs in approximately 50% of lesions, the irregular appearance of the growing melanoma may contrast strikingly with the more regularly pigmented and outlined residual naevus component.

Differential diagnosis. Benign naevi are usually smaller than melanoma, have a regular oval or circular outline, and are a uniform shade of brown. Seborrhoeic keratoses are dull, non-reflective lesions, which have a hyperkeratotic surface and a tendency to crumble. The main differential diagnosis in practice is between an early melanoma and a benign but atypical melanocytic naevus. A history of growth or change strongly suggests early melanoma, as does a size of 6 mm or greater, but the clinical features may be very similar in atypical naevi and early melanomas, and an excision biopsy may be needed.

Dermoscopy is an essential diagnostic aid for early melanoma. The most widely used dermoscope allows a 10-fold magnification. Fluid placed on the lesion (oil, water or even antiseptic gel) eliminates surface reflection and renders the cornified layer translucent, thus allowing a better visualization of pigmented structures within the epidermis, the dermoepidermal junction and the superficial dermis. The size and shape of vessels of the superficial vascular plexus can also be inspected. The technique of dermoscopy requires training; there are tutorials on the Internet [1–3] but it is desirable to attend a course. Benign naevi typically have an even pigment pattern on dermoscopy, which might be reticulate or globular. Melanomas typically have a disordered pigment pattern with variation in size of the pigment network, variably sized dots and often blue-grey or blue-white areas (Fig. 54.51).

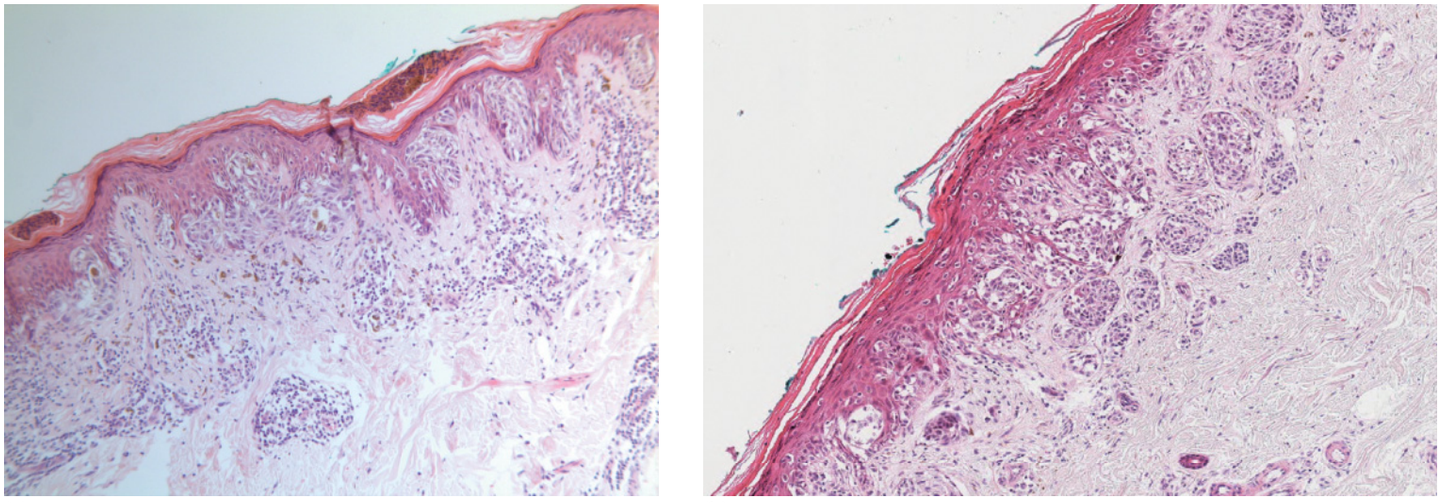
There are also currently a number of computerized image analysis systems in development to aid preoperative diagnosis of malignant melanoma. These include the Mole Max system™ and spectrophotometric intracutaneous analysis using the Siascope. The absolute value of these machines in increasing both sensitivity and specificity of preoperative diagnosis of melanomas, thus reducing the number of unnecessary removals of benign naevi in routine practice, is not yet established.

Biopsy. All patients with suspected malignant melanoma should have an excision biopsy of the lesion carried out with a margin of 1–2 mm of clinically normal skin. This will enable the pathologist both to confirm the diagnosis and also to measure the thickness of the melanoma, which is an essential guide to further management. In rare situations when an excisional biopsy is not practical, such as a large possible melanoma on the face, an incisional biopsy from the area of the lesion which appears to be most invasive is acceptable, provided any necessary definitive surgery follows promptly. This procedure should probably be carried out by specialists.

Incisional or punch biopsies should not be performed in suspected melanoma because of sampling error, because an inaccurate tumour thickness may be obtained due to biopsy trauma, and also because the overall shape and symmetry of the whole lesion is important to the diagnosis of melanocytic lesions. There is a theoretical risk of displacing melanoma cells deeper into the dermis, although there is no evidence for this.

The surgeon should measure accurately the clinical excision margins, as biopsy samples shrink by 20–30% during fixation in formalin and the pathologist may report a narrower margin than was excised. It is the clinical rather than the pathologically measured excision margins that should be used in decisions concerning further surgery.

Pathology. The specimen should be examined by the pathologist in total. Features required in the biopsy report are the diagnosis, the tumour thickness, histogenetic type, growth phase, presence (and probably width) of ulceration, presence of regression, presence of tumour infiltrating lymphocytes (and whether they are brisk or non-brisk) [4], an estimate of the number of mitoses in the tumour, and whether there is evidence of vascular invasion. The presence of regression, if observed, may influence decisions on the width of definitive excision. Clark levels add little prognostic information for thicker primary melanomas, but should also be included, particularly for melanomas less than 1 mm in thickness, as Clark level 4 lesions in this thickness range appear to have a worse prognosis than level 3 lesions. In about 40% of cases [5] there will be pathological evidence of a pre-existing, benign melanocytic naevus on which the melanoma has developed. In these cases the pathologist may feel it necessary to give two tumour thicknesses, one measuring the entire thickness of the lesion and one measuring only to the deepest obvious tumour cell, ignoring any deeper apparent naevus cells. The presence of desmoplasia or neurotropism should be recorded.



The margin of excision should be recorded—both the minimum lateral margin and the deep margin in mm.

The essential pathological features of superficial spreading melanoma are the presence of a focus of malignant melanoma cells invading the dermis with areas of *in situ* malignant change in the adjacent epidermis. This consists of the presence of cytologically atypical melanocytes in the suprabasal layers of the epidermis, both singly and in clumps (Fig. 54.52). On H&E sections, the pattern may be very similar to that seen in extramammary Paget's disease, and the term pagetoid melanoma may therefore also be used to describe this lesion.

The verrucous variant. These are melanomas simulating benign warts that are easy to miss. They are characterized by gross hyperkeratosis and also epidermal hyperplasia. The significance of this lesion is the fact that it is not usually recognized clinically because of the hyperkeratosis, and it may be confused with both benign and malignant lesions derived from the keratinocyte, such as a seborrhoeic keratosis or a squamous cell carcinoma.

Pathological differential diagnosis. There are two quite distinct problems in pathological differential diagnosis of primary malignant melanoma. The first is distinguishing it from benign melanocytic naevus, the second is distinguishing non-melanocytic but malignant tumours, either primary or secondary. These are more often a problem when a clinically indeterminate, large nodule is excised.

The differentiation between benign and malignant melanocytic lesions rests on both the pattern of involvement and the cytological features of individual cells. The association of cytologically atypical melanocytic cells in the upper layers of the epidermis with apparent proliferation at the dermoepidermal junction and invasion of the underlying dermis by atypical melanocytic cells is a malignant pattern. The cells in the deeper areas of the dermis

(a) (b)

Fig. 54.52 (a) The histological appearance of an *in situ* melanoma with atypical melanocytes within the epidermis. There are dermal inflammatory cells but no tumour cells. (b) A superficial spreading melanoma showing more proliferation of tumour cells in the epidermis (known as pagetoid spread). Dermal nests of tumour cells indicate that the tumour is in vertical growth phase.

will show no maturation such as is seen in a benign naevus with dermal involvement. The cytological characteristics of malignancy are a high nuclear to cytoplasmic ratio, intense nuclear staining, size variation between adjacent cells and the presence of abnormal mitotic figures.

Two of the more difficult pathological differential diagnoses of melanoma are the halo naevus and the Spitz naevus. It is unusual for a melanoma to elicit as intense a lymphocytic response as in the halo naevus, but a careful search should be made through the lymphocytic infiltrate in a putative halo naevus for cytologically malignant cells, particularly if the clinical information suggests an unusual history, such as presence in an elderly individual.

The differentiation between malignant melanoma and Spitz naevus can be extremely difficult, as discussed above. Features suggesting that the lesion is a melanoma and not a Spitz naevus are asymmetry with a poorly defined lateral margin, the presence of abnormal (or deep) mitoses in the melanocytic cells, lack of any maturation or differentiation in the deeper naevus cells, nuclear pleomorphism, and an epithelioid cell pattern with striking lack of adhesion of one cell to the other. These features are not absolute, and there are times when it may be necessary to state that a firm diagnosis cannot be made on pathological grounds when the term STUMP is used, as discussed above. In such cases the lesion should be managed as if it was a melanoma.

A range of antibodies are currently in routine diagnostic use. They will confirm the melanocytic nature of the lesion, but cannot differentiate between benign and malignant melanocytic lesions. S100, gp100/HMB-45, typrosinase, MART-1/Melan-A and HMW_MAA are melanocyte differentiation markers. S100 is less specific than the other three, but highly sensitive and therefore is usually used in combination with at least one of the others [6].

Definitive surgical treatment to the primary site. Once the diagnosis of primary malignant melanoma is established, and the thickness of the melanoma has been measured, the definitive excision can be planned. The extent of this excision will relate to the tumour thickness. At present, if the diagnosis is of a level 1 or *in situ* melanoma, a margin of only 2–5 mm of surrounding normal skin is considered adequate [7]. This may have been included in the diagnostic biopsy and therefore no further surgery may be necessary. There are no data, however, to support this margin, and the rare occurrence of a 'field effect' of atypical melanocytes around primary melanoma means that the patient and his doctor often elect to remove up to 1 cm of normal skin, especially if a second operation is required.

Invasive melanomas up to 2 mm thick may be safely treated with a minimal excision margin of 1 cm based upon the WHO trial [8]. Patients with thicker tumours are more likely to develop lymph node recurrence if a 1-cm margin is used [9], and therefore the recommended excision margin is 2 to 3 cm [7] where anatomically possible. Margins of this size are most difficult to achieve on the face.

In some centres, sentinel node biopsy (see p. 54.51) is offered to patients as a staging tool. Sentinel node biopsy can only be carried out at the time of wide local excision of the primary and therefore patients should be counselled about this option prior to definitive excision.

Nodular melanoma

This variety presents most commonly in the fifth or sixth decade and occurs more frequently in males than in females. The trunk is a common site. These lesions grow rapidly and are therefore more likely to present as thicker tumours and they tend, therefore, to have a poor prognosis. Thicker tumours are more common in the elderly and diagnostic delay may be associated with living alone and lack of knowledge [1].

Nodular melanomas develop as an elevated, dome-shaped polypoid or even pedunculated structure (Fig. 54.53). Melanin pigment may be sparse in these lesions and a raised, red central area, with only a peripheral brown ring of melanin, is a common clinical pattern; in others the more typically variable pigmentation may be seen. Ulceration and bleeding from the lesion occur frequently. This variety of malignant melanoma is misdiagnosed prior to surgery more frequently than either a superficial spreading melanoma or a lentigo maligna melanoma, as they may be symmetrical and have a relative lack of melanin pigment. Thus they are not readily identified using the ABCD rule, for example.

Lesions to consider in the differential diagnosis are angioma or pigmented basal cell carcinoma. Histiocytoma or sclerosing angioma may also cause clinical confusion. Dermoscopy is very helpful in distinguishing melanoma from these benign lesions.

Pathology. The nodular melanoma has the pathological features of a focus of invasive melanoma cells in the dermis with direct contact with the immediately overlying epidermis, but no morphological abnormality apparent in the adjacent epidermis on either side of the invasive nodule (Fig. 54.54). This is, therefore, a primary melanoma with no recognizable adjacent *in situ* or radial growth phase. There is a tendency to use the term nodular melanoma inappropriately for any primary melanoma that has a visible nodule. This is incorrect usage, as superficial spreading, acral and lentigo maligna melanomas can all develop elevated nodular areas in the course of later growth.

Management. The management of nodular melanoma is the same as for superficial spreading melanoma, described above.

Lentigo maligna melanoma

In this histogenetic variant the preceding horizontal or *in situ* growth phase is known as a lentigo maligna (Hutchinson's melanotic freckle; melanosis circumscripta precancerosa of Dubreuilh). By comparison with the radial growth phase of the superficial spreading melanoma, lentigo maligna represents a much more prolonged period of lateral extension. Most occur on the face, commonly on the upper cheek, temple or forehead: the facial skin most exposed to the sun through life. A small proportion of lentigo malignas are observed on extrafacial exposed sites such as the arm, hand or leg.

Occasionally, periocular lentigo maligna extends into the conjunctiva. Sometimes the *in situ* component may even arise in the conjunctiva as a condition known as 'primary acquired melanosis'

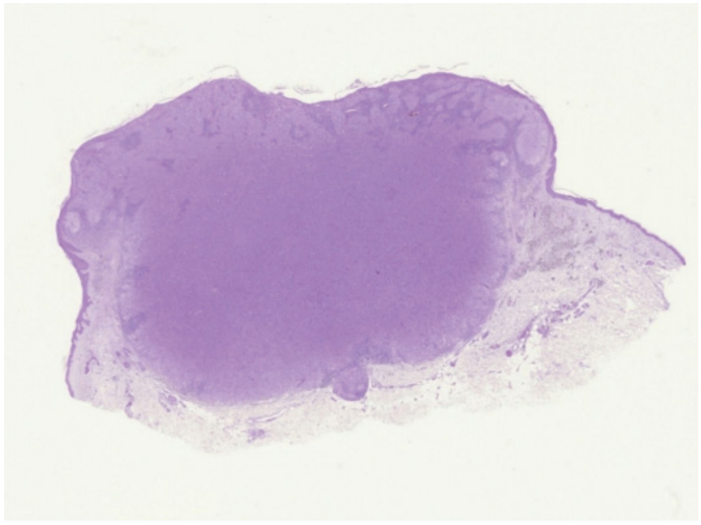

Fig. 54.54 A low power image of nodular melanoma pathology. (Courtesy of Dr S. Edward, Leeds Teaching Hospitals Trust, Leeds, UK.)

Fig. 54.55 Primary acquired melanosis of the eye, which can be likened to a continuum between an atypical naevus and *in situ* melanoma.

(PAM) [1]. PAM typically presents as irregular pigmentation at the limbus of the eye (Fig. 54.55). The pigmentation may progress very slowly over many years and then, generally, ophthalmic surgeons tend merely to observe, but a proportion do go on to invasive melanoma and melanoma may develop within the conjunctiva and in the adjacent skin. The histology of PAM has been subdivided into PAM with and without atypia, but PAM which progressed into melanoma is said to be architecturally more irregular and the melanocytes are more likely to be epithelioid in nature [1]. PAM bears some clinical and histological similarities to atypical naevi and indeed has been reported in patients with the atypical mole syndrome [2]. PAM may therefore be considered to be a continuum in the conjunctiva equivalent to the atypical naevus/*in situ* melanoma spectrum.

The *in situ* component of lentigo maligna may be extremely slow growing and probably evolves from solar lentigos (although the vast majority of solar lentigos clearly do not progress). Progression from a solar lentigo to a lentigo maligna is usually characterized by darkening, enlargement and the development of a more defined edge (Fig. 54.56). A difficulty of management is that atypical melanocytes often extend out from the edge of the lentigo for considerable distances, even involving 'skip' lesions. This is often known as the 'field effect'. Treatment may therefore initially appear to be successful, yet there may commonly be recurrence at the edge after treatment.

A proportion of lentigo malignas will evolve into invasive melanoma, developing as discrete colour change or nodules within the lentigo (Fig. 54.56). Rarely, the melanoma may be desmoplastic in type, in which case the lesion may present as a central, firm thickening, within a macular pigmented area, which may be quite subtle. These melanomas are very easy to misdiagnose; it is particularly important to write the differential diagnosis of desmoplastic melanoma on the histopathology form if there is any suspicion at all of this diagnosis, so that the pathologist will carry out an S100 stain.

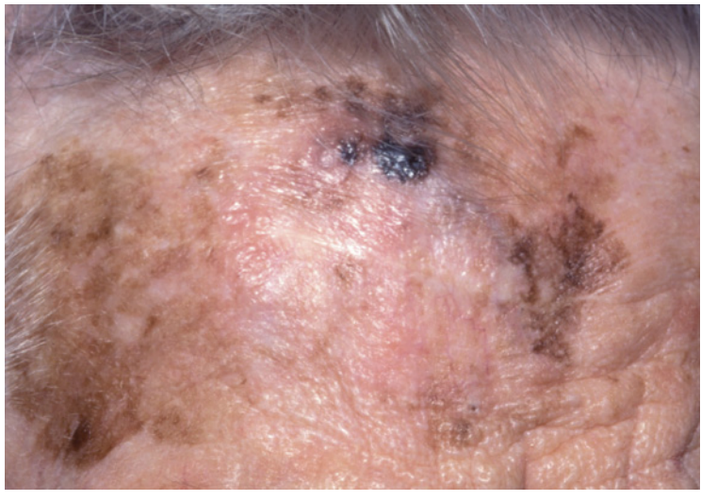

Fig. 54.56 A very extensive lentigo maligna melanoma in which a nodular element developed at the hair line.

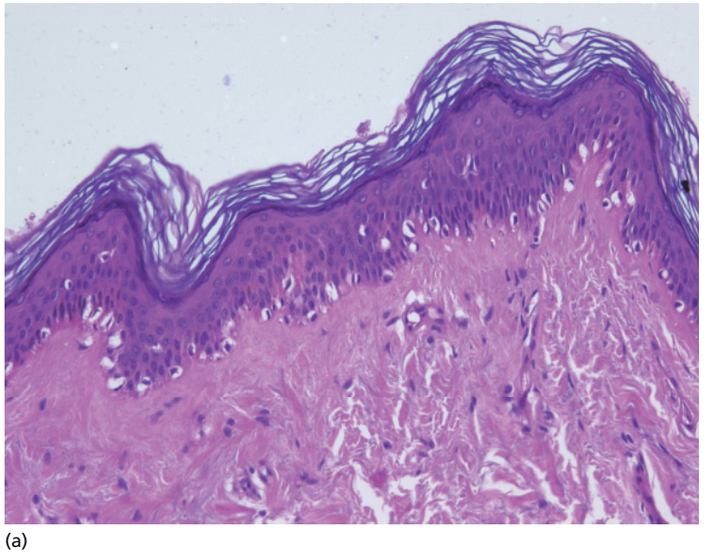
Patients tend to be older than those presenting with the other types of melanoma. Many of the identified risk factors suggest that the aetiology of this variety of melanoma has a greater similarity to squamous cell carcinoma than to the other melanoma variants. Affected patients have evident solar damage both clinically and pathologically.

Initially the lentigo maligna is a flat, brown or black, irregularly shaped lesion. These lesions will grow very slowly, over months or years, and there may be central regression while the peripheral margin continues to extend. In time, a raised central nodule will develop, indicating transition to the vertical growth phase.

In clinic, referral of macular pigmented facial lesions is common and the differential diagnosis of very early lentigo maligna includes solar lentigo, and pigmented actinic keratoses and the

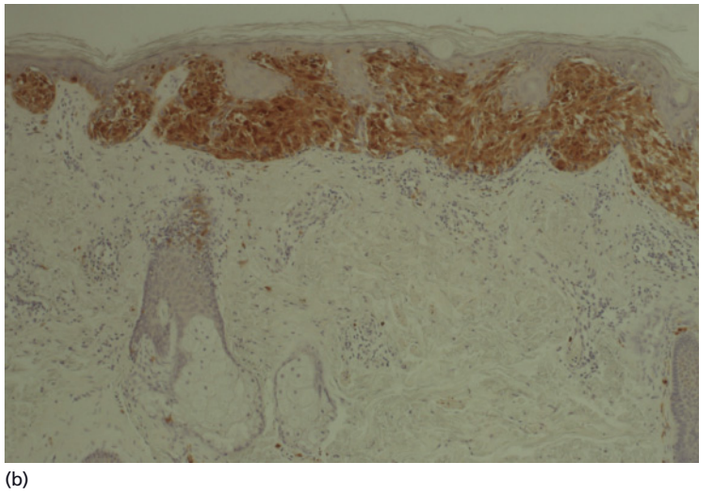
flatter variant of seborrhoeic keratoses. Both of the latter tend to have more surface scaling, lack a visible melanin pigment network and have a dull, non-reflective surface. Size, depth of colour and irregularity of pigment are pointers to the diagnosis of lentigo maligna.

Pathology. This variant of melanoma is the most distinct histologically. It has a long pre-invasive or radial growth phase, during which there is striking lentiginous replacement of the basal keratinocytes by atypical melanocytes but no downward invasion into the underlying dermis, which will show actinic damage of the dermal collagen. During this phase, the names *lentigo maligna* or Hutchinson's melanotic freckle are appropriate. There is also often extensive colonization of the hair-follicle epithelium by atypical melanocytes. After a variable period of time, invasion into the underlying dermis will take place. The site of such early invasion in its earliest stages may be marked by a lymphocytic infiltrate. Once obvious dermal invasion is present, the name *lentigo maligna melanoma* is appropriate (Fig. 54.57).



Desmoplastic, neurotropic and myxoid variants. The very rare desmoplastic variant of malignant melanoma may be seen in association with chronically sun-damaged skin and overlying lentigo maligna in the epidermis. The clinical appearance may be very subtle and has few easily recognizable features. In desmoplastic melanoma arising from lentigo maligna then, the lesion may present as a subtle area of thickening associated with macular pigmentation. In other sites it may resemble a pink scar-like nodule (Fig. 54.58) and there may be an inflammatory component.

As the name suggests, this lesion represents a combination of malignant melanocytes in association with extremely dense desmoplastic change of the dermis. The stromal change in the dermis is usually much more obvious than the malignant melanocytes, which may be few in number. If an S100 stain is not carried out it may be extremely difficult to recognize the lesion as a melanoma, as the spindly dermal cells extend singly between the more obvious stromal cells.



The clinical importance of this variant is that it can be difficult to be absolutely certain that excision is complete, and local recurrence is a common problem.

In a review of published studies of desmoplastic melanoma [3], a total of 856 patients with this diagnosis were evaluated in the 17 included studies. There were 539 males (63.0%) and 317 females (37.0%). The mean age of patients varied from 55.6 to 71.3 years across the included studies, while the age range was from 4 to 99 years. The lesions were most commonly located on the head and neck (53.2%), followed by the extremities (20.6%) and the trunk (26.2%). Desmoplastic melanoma is associated with a high local recurrence rate, a lower nodal recurrence rate but systemic metastatic rates not dissimilar from melanoma as a whole [3]. Overall survival in 16 published studies ranged from 67.1 to 100%. Disease free survival in 14 studies at the end of follow-up ranged from 52 to 100%.

A pathological variant sometimes coexisting with the desmoplastic pattern is the neurotropic melanoma. In this variant, the pattern of metastatic spread is along the cutaneous nerve trunks.

(a)

(b)

Fig. 54.57 The range of pathologies described as lentigo maligna. (a) Very early lentiginous proliferation. (b) Confluent proliferation at atypical melanocytes in a lentigo maligna melanoma; the slide has been stained with S100. (Courtesy of Dr S. Edward, Leeds Teaching Hospitals Trust, Leeds, UK.)

This is seen particularly in lesions on the head and neck area, and may cause severe, relentless pain. In a review of desmoplastic melanoma, the percentage of desmoplastic melanomas with neurotropism ranged from 16.7 to 77.8% among included studies [3]. As with the desmoplastic variant, completeness of excision can be difficult to determine. Myxoid melanoma is a rare variant in which there is a striking myxoid stroma in the dermis surrounding malignant spindle cells. The morphology has some features in common with desmoplastic melanoma.

Treatment of lentigo maligna. The diagnosis of lentigo maligna is made clinically and confirmed histologically. It is one of the very few instances where incisional biopsy of a melanocytic lesion is justifiable, where a suspicious but large macular lesion is present in a cosmetically sensitive area such as the face. The site for incisional biopsy is chosen based upon clinical examination and

dermoscopy, choosing the most irregular or darkest area of pigmentation and/or any palpable or thickened areas. More than one site may be necessary. The concern is both to make the diagnosis of lentigo maligna and to determine the presence of invasion; however, exclusion of the presence of any invasive disease requires examination of the whole lesion.

If the diagnosis of lentigo maligna is confirmed, then the treatment is usually surgical excision. However, there are few clinical trial data to inform that choice. Standard excision with 5-mm margins proves to be insufficient in 50% of cases. The recurrence rate with standard excision ranges from 8 to 20%. Mohs' micrographic surgery and staged excision may offer better margin control and lower recurrence rates (0–5%) [4,5]. Estimates of recurrence rates following non-surgical therapies such as cryosurgery, radiotherapy, electrodesiccation and curettage, laser surgery, and topical medications range from 20 to 100% at 5 years [4]. The most pressing argument for surgical excision is the consequent ability to review the whole specimen for invasive disease, which occurs in 5 to 16% of lentigo malignas excised [6,7].

Topical imiquimod is an encouraging new therapeutic option but the data so far are few, and randomized clinical trials are needed. It may cause significant inflammation or ulceration at the site (Fig. 54.59) or, when treating the face, on the lip (Fig. 54.60). A review summarized 11 case reports and four open-label studies, with a total of 67 patients. There was significant variability in treatment schedules and regimens. Eight patients failed to respond, with lentigo maligna melanoma developing in two of these. In certain cases there were discrepancies between clinical and histological response with some patients clearing clinically but not histologically, and vice versa. Follow-up periods were short, exceeding 12 months in only five cases [8]. Some centres are using surgery as the primary treatment with imiquimod as an adjuvant but this needs to be formally evaluated. The development of lentigo maligna melanoma within lentigo maligna incompletely eradicated by imiquimod is a concern.

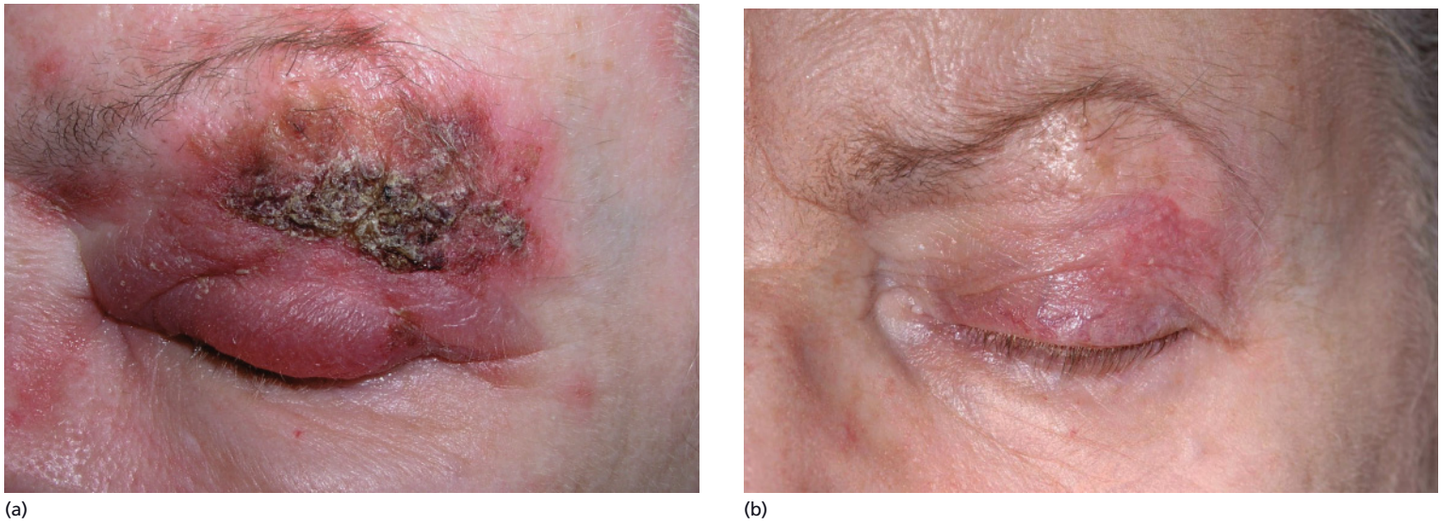


Fig. 54.58 An ill-defined, ulcerated lesion which proved to be a desmoplastic melanoma. Desmoplastic melanoma can be very difficult to diagnose clinically, being commonly sparsely pigmented but indurated to the touch.

Treatment of lentigo maligna melanoma. The treatment of the melanoma is as for other sites in that the margin of excision for tumours thinner than 2 mm is 1 cm minimum and for thicker tumours should be 2 to 3 cm. It is recognized, however, that on the face these margins may not be attainable without unacceptable cosmetic deficit. The surgery is also subject to the same constraints as described above for lentigo maligna, in that there is a high local recurrence rate of the *in situ* component.

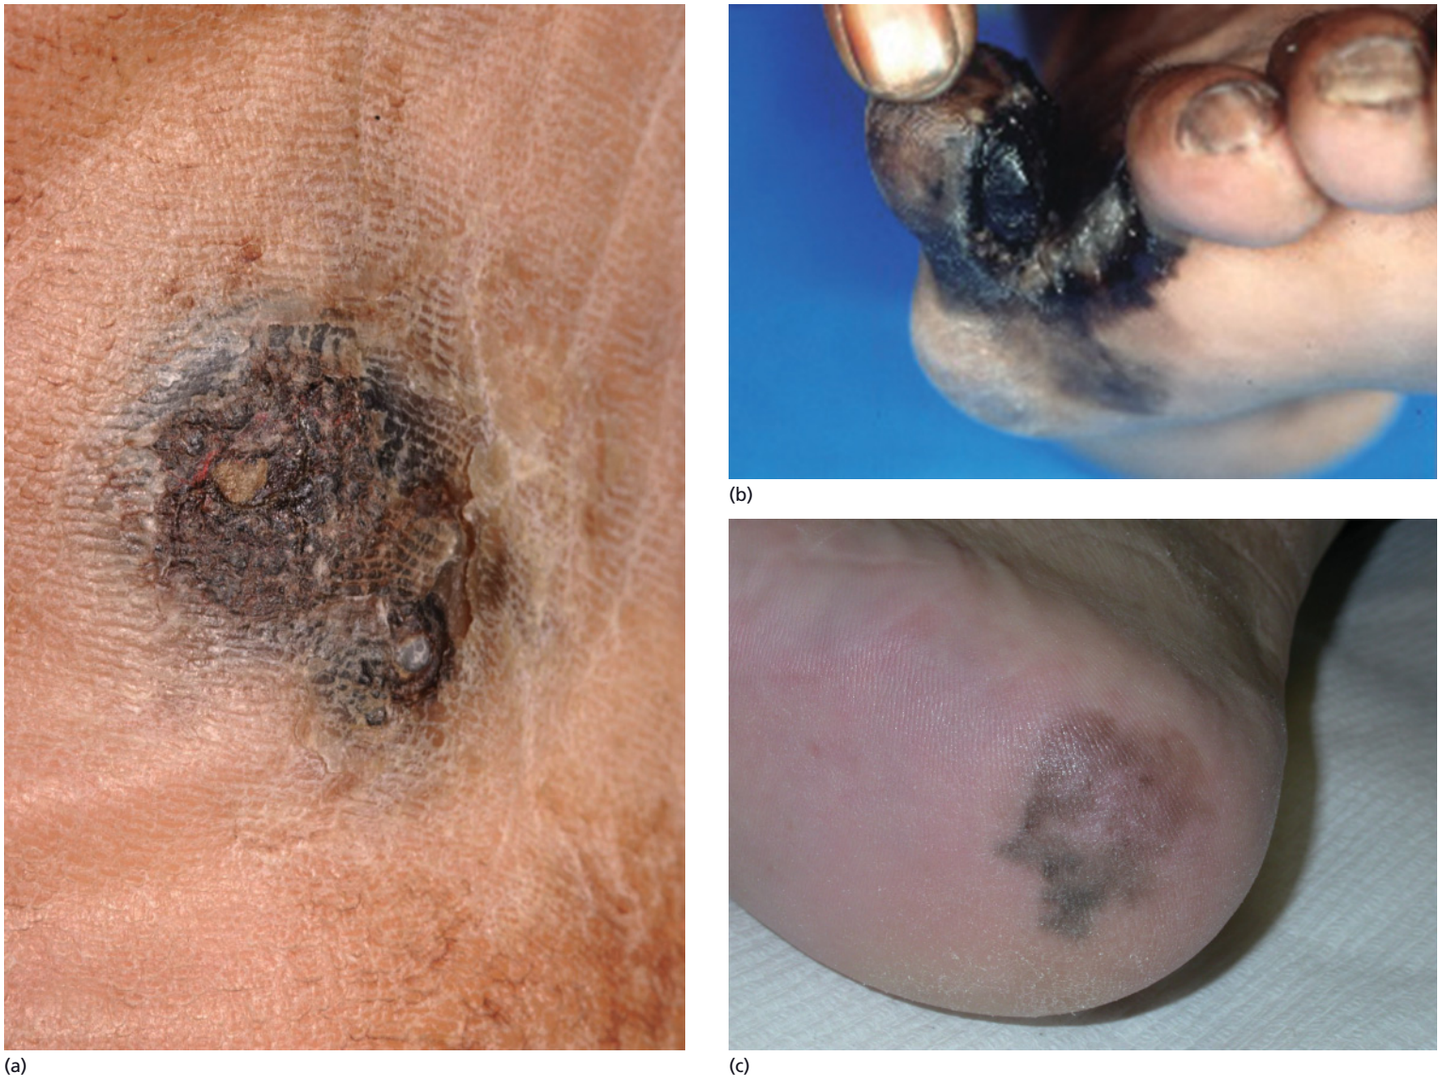
Acral lentiginous melanoma (palmoplantar malignant melanoma)

This type of melanoma comprises around 10% of all melanomas on white skin but over 50% of all melanomas on darker-skinned peoples. It is the commonest type of melanoma, for example, in Japan. The recorded incidence in different ethnic groups is around 1 to 2 per million per annum [1]. The lesions are found mainly on the sole of the foot but also on the palm of the hand, and are characterized, as their name would suggest, by a large, macular, lentiginous pigmented area around an invasive, raised tumour. Approximately 50% of all melanomas on the foot are of this type (Fig. 54.61).

This precursor *in situ* component is in many ways similar to lentigo maligna in that its growth rate may be very slow, it may be very extensive, and it shows a tendency to recur because of failure to excise sufficient normal skin laterally (Fig. 54.62).

The clinical differential diagnosis may include a plantar wart, which is a common cause of delayed diagnosis, and black heel (talon noir) (Chapter 28), due to haemorrhage into the superficial layers of the epidermis. Any tender, growing nodule, or an 'ulcer' that won't heal, on the sole of the foot, should give rise to concern that the lesion is a melanoma and biopsy should be considered. The risks of missing the diagnosis are higher in circumstances where delayed healing of an ulcer is expected, such as in a diabetic ulcer.

Pathology. The essential pathological features are the presence of an extensive area of lentiginous change in the epidermis around the focus of invasive primary melanoma. In early disease, the lentiginous component may be large, but the invasive focus is small and difficult to find, requiring cutting of many sections. The basal keratinocytes are replaced by cytologically malignant melanocytes, and there is often an associated inflammatory flare of lymphoid cells in the underlying dermis. An important feature is the presence of skip areas, with foci of relatively normal epidermis in areas of gross lentiginous change, as in lentigo maligna. This feature makes it particularly important to examine the excision specimen thoroughly to determine whether or not the lesion has been completely excised.



Treatment. As for lentigo maligna, the management of acral lentiginous melanoma is one of the few occasions where incisional biopsy may be acceptable in order to plan treatment. The area chosen is that showing the most pigmentary irregularity or the most palpable nodular area.

The margins of excision are as for melanomas in other sites, 1 cm for tumours thinner than 2 mm and 2 to 3 cm for thicker tumours. As for other melanomas characterized by extensive *in situ* disease, however, there is also a need to resect adjacent precursor lentiginous hyperplasia so that the clinical margin should be measured from the most distal area of macular pigmentation. It can be easier to see this margin if emollient is applied to the sole before examination. If the patient has elected to proceed to sentinel node biopsy, this would be carried out at the time of definitive surgery. The margins used in practice are subject to the functional implications of the surgery. Acral lentiginous melanoma is commonly on the weight-bearing sole and the implications of the surgery must be discussed with the patient and in practice a compromise may be reached between margin and function.

Subungual melanoma

Subungual melanomas are rare. Like acral lentiginous (palmoplantar) melanomas they occur in people of all skin types and their aetiology is unknown. They are most common on the thumb or the great toe. It has been suggested that this indicates that trauma may play a role in their aetiology, but this localization may simply reflect the relative surface area (and therefore the number of melanocytes) of the nail matrix from which all subungual melanomas are thought to arise.

Because they arise from the nail matrix, subungual melanomas usually produce an abnormal nail and a variable degree of pigmentation of the nail itself. The classical presentation is of a new, linear, pigmented band along the length of the nail, which starts to widen progressively, especially at the base, so that the pigmented band tends to be funnel shaped. Over time, proliferation of the melanoma cells within the nail matrix then additionally

(a) (b) (c)

Fig. 54.61 (a, b, c) Three acral lentiginous melanomas arising on the sole of the foot in a black, asian and white-skinned person, respectively. This is the only form of melanoma to have a similar prevalence in all ethnic groups.

interferes with nail formation and a progressively dystrophic nail results (Fig. 54.63). Eventually, pigment may spread to the surrounding normal skin as 'Hutchinson's sign'.

A sizeable proportion of subungual melanomas, however, are either amelanotic or produce little pigment so that the 'classical' linear pigmented band is actually uncommon. In these tumours, therefore, the lesions present as a progressively abnormal nail, such as a fissured nail or destruction of the nail beginning proximally.

Subungual melanoma is commonly diagnosed at a late stage in development because of earlier confusion with a benign melanocytic lesion, a traumatic haemorrhage under the nail, pyogenic granuloma, persistent paronychia, a fungal infection or even a subungual wart. A high degree of suspicion is required if subungual melanoma is not to be missed. Dermoscopy may help; a band of brown to black pigment comprised of thin irregular bands which are not parallel may be seen in melanoma [2] and origin from the nail matrix may be confirmed. Subungual pigmentation due to causes other than melanoma, which must be considered as differential diagnoses, is usually distal rather than arising from the nail matrix.

Diagnosis. The diagnosis of early lesions usually requires biopsy of the nail matrix. The proximal nail plate may be reflected and the matrix biopsied. Pigment bands less than 3 mm in diameter may be biopsied using a punch biopsy, which may produce minimal damage if the lesion proves to be benign. Wider bands require elliptical biopsy, which is likely to damage the nail permanently [2]. Confirmed melanomas, or clinically obvious more advanced subungual melanomas, should be managed by expert multidisciplinary teams, as they are sufficiently rare and surgically difficult to merit pooling of experience.

Fig. 54.62 Two skin grafts used to treat multifocal acral lentiginous melanoma. Residual *in situ* or lentiginous disease is seen between the two grafts. The whole of the area was subsequently excised. Subtle precursor lentiginous disease is common.

Treatment. The treatment of subungual melanoma is surgical. The affected digit is usually the thumb or great toe and preservation of function is therefore highly desirable. Early lesions may therefore be managed, if possible, using excision and grafting. *In situ* disease, however, is very common in the skin around the nail and therefore it is rare to achieve adequate clearance without at least partial amputation. For more advanced disease partial amputation is the norm, through either the distal interphalangeal or proximal interphalangeal joints. The choice of surgical option should be made in discussion with the patient depending on the functional implications for the patient and the thickness of the tumour. Transplantation of a toe to the thumb stump may be possible to restore function. If the patient has elected to proceed to sentinel node biopsy this must be done at the time of definitive surgery.

Mucosal melanoma

Mucosal melanomas are rare, but can be seen in the oral cavity, on the genital mucosa and in the perianal area. The most common presenting feature of mucosal melanoma is the presence of extensive, irregular macular pigmentation. This may be extensive but

(a) (b) (c)

Fig. 54.64 A melanoma arising on the buccal mucosa. In this site the appearance may be subtle.

spotty and may extend laterally for years before becoming elevated. Such lesions should be biopsied without delay, although clinically they may look deceptively benign (Fig. 54.64).

Genital melanomas are also discussed on p. 54.6. They are rare variants of melanoma, which unfortunately usually still present late as a mass or with vaginal bleeding. The average age at presentation is in the seventh decade, significantly older than for cutaneous melanomas. On biopsy the majority of the tumours are in vertical growth phase and unfortunately many are thick and have a poor prognosis (Fig. 54.65).

Fig. 54.65 Vulvar melanoma. This lesion is obviously deeply invasive and has a poor prognosis.

Pathology. Primary melanomas arising on the mucosal surface of the oral cavity, the vulvovaginal and the rectal areas have some features in common with acral lentiginous melanomas, and the term palmoplantar mucosal melanoma is sometimes used to describe the entire group. Extensive lentiginous change is frequently visible, both clinically and pathologically, and the focus of invasion may be very difficult to find in early tumours, even in the presence of obvious metastases.

Treatment. Wide local excision of the melanoma is necessary. The extensive surrounding *in situ* disease makes this difficult in practice in many patients, partly because of the anatomical constraints and partly because it is very difficult clinically to distinguish involved tissue from normal. It may be necessary to do multiple biopsies prior to surgery to determine the extent of disease, and radical excision is unfortunately often necessary. Where the margins of excision are by necessity suboptimal, topical imiquimod may be used to try and remove *in situ* disease, although the treatment may be difficult to tolerate and there are insufficient data to support its use.

Secondary melanoma from an occult primary site

About 8% of melanomas present as metastatic disease from an unknown primary. The commonest site of the metastasis is regional lymph nodes but very rarely the patient may present with stage IV disease. In the majority of such patients, there is evidence of a regressed primary, presenting typically as an area of depigmentation, or a history of a lesion, which spontaneously cleared. Rare primary sites should, however, be inspected, such as the mucosae (including the anus). In a proportion, however, no origin for the metastasis can be found. As naevus cells may be seen not uncommonly in the subcapsular area of lymph glands it seems possible that melanoma may arise *de novo* in a lymph gland.

Where no origin for the melanoma can be found, the disease should be treated as usual; lymph node metastases should be treated by block dissection after imaging has been carried out.

Multiple primary malignant melanomas

At present around 5% of patients who have already had one melanoma diagnosed will develop a second and possibly a third or further primary melanoma. This is more common in patients with the atypical mole syndrome. These primaries are not infrequently in the same anatomical area, such as on one leg of a woman. This often causes concern that the second and later tumours might represent metastatic disease. It is important that the pathologist consider this as a possibility.

For patients who have had a thin melanoma diagnosed, the risk of a second primary melanoma is greater than the risk of the first melanoma metastasizing. Complete skin examination is therefore important in follow up of melanoma patients.

Treatment. Each primary should be treated by wide local excision. An important part of the management, however, is to take a family history, as the development of multiple primaries is indicative of genetic predisposition to melanoma. Patients who have a family history of melanoma comprise a proportion of those who

develop multiple primary melanomas, and a small number will have mutations in the *CDKN2A* gene. In the presence of a family history of melanoma or pancreatic cancer, referral to a specialist familial melanoma clinic or clinical geneticist is appropriate.

It is supposed that the majority of those who do not have a family history have lower risk susceptibility genes and have had extensive sun exposure, although a proportion will carry high-risk genes. Patients should be advised to moderate their sun exposure and taught how to self examine. Whilst all melanoma patients should also be advised to protect the skin of their families without becoming vitamin D deficient, this is particularly appropriate in the presence of multiple primaries and a family history.

Rare histological subtypes of melanoma

Naevoid melanoma (minimal deviation melanoma, small cell melanoma). A further pathological variant is the so-called naevoid, minimal deviation or small cell melanoma. These lesions lack epidermal involvement, are fairly well defined at their lateral margins, and the small naevoid cells in the dermis, which make up the bulk of the tumour, show partial differentiation. However, careful examination will reveal the presence of abnormal mitoses in naevomelanocytes. These lesions may be confused with compound naevi.

Animal-type melanoma. This is a rare pathological variant of melanoma, which, as the name suggests, has some morphological similarities to melanoma found in grey horses. Blue-black nodules are the clinical presenting feature, and the pathology shows heavy dermal melanin pigmentation with sheets of atypical spindle cells, which may be difficult to visualize without bleaching because of the quantity of pigment present. The epidermis is usually, but not always, involved, and mitotic figures may be difficult to find. Metastases to both regional nodes and to distant organs may occur.

Melanoma of the soft parts (clear cell sarcoma). This is a further rare pathological variant of malignant melanoma. The tumours usually arise on the tendons and aponeuroses. The ankle appears to be a relatively common site, and the tumours generally appear in young people. There appears to be no epidermal component, which gives rise to diagnostic confusion with various types of sarcoma, but the malignant cells contain premelanosomes and melanosomes. Plump, pale spindle cells with clear cytoplasm are seen in the tendons (Fig. 54.66). They may be deceptively bland on microscopy as mitotic figures are difficult to find, but both local recurrence and distant metastases are relatively common.

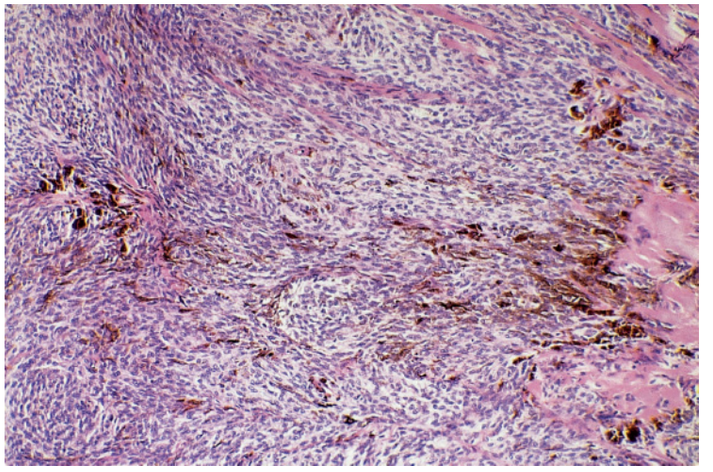

Fig. 54.66 Pathology of melanoma of the soft parts. Note the eosinophilic cytoplasm and also the pigmentation.

Childhood melanomas

Incidence. Metastasizing melanoma is fortunately extremely rare in children. The true incidence of cutaneous melanoma is unknown, not least because of the difficulties of histological diagnosis of melanoma in children and, in particular, its differentiation from the Spitz naevus, but pre-pubertal melanoma is thought to be rare [1].

After puberty the incidence of melanoma starts to rise slowly [2]; melanoma is unusual amongst solid tumours in that the incidence is proportionately greater in young adults. In Europe the age-standardized incidence rates for girls range from 0.2 new cases per million in Bulgaria to 3.8 in Norway [3]. Incidence is higher (as it is in adults) in Queensland, where the age-standardized incidence is 0.1/100 000 per annum in 0 to 4 year olds and 3/100 000 per annum in 10 to 14 year olds [4,5].

This section refers to melanoma in children both before and after puberty.

Aetiology. Childhood melanoma may occur in the normal host but there are three known predispositions: congenital naevi (see above), the atypical mole syndrome (AMS) (see above), familial melanoma and other cancer family syndromes such as retinoblastoma and xeroderma pigmentosum (XP) [6–8]. Melanoma accounts for 7% of second malignancies in familial retinoblastoma [8]. Many of these have developed within the field of irradiation. The role of chemotherapy in the induction of melanoma as a second malignancy is unclear. Xeroderma pigmentosum occurs as a rare autosomal recessive condition. There are a variety of subtypes with very different degrees of severity. In the severe types there is extreme photosensitivity, with freckling of the skin and the occurrence of multiple skin cancers, including melanoma. Most melanomas appear to occur in the teens [9]. In the mildest types the phenotype is similar but much less marked and there are patients described who appear to overlap clinically with Cockayne's syndrome or who do not yet fit into any well-defined entity [10].

There are several small series of childhood melanomas in the literature [1,4,11,12] and the relative importance of these predisposing conditions varies, as would be expected in such inevitably selected series. In a series of 15 cases in children under the age of 12 years from the MD Anderson Cancer Centre [2], four occurred in children with either giant congenital naevi or meningeal melanocytosis. In a review article, Williams and Pennella concluded that only 3% of reported childhood tumours occurred in giant congenital naevi [13] but 19% of the reported cases had been thought to have developed in small congenital

naevi. In a series from New South Wales, none of 52 cases were associated with giant congenital naevi or xeroderma pigmentosum [4].

Although the single most common predisposition to childhood melanoma appears to be congenital naevi, the majority of childhood cases occur in patients with no obvious increased susceptibility. A case–control study from Australia of adolescent melanoma identified the same risk factors for melanoma as are seen in the adult population: family history (23/201 cases compared with 6/205 controls), red hair and an abnormal naevus phenotype; 2/147 had germline *CDKN2A* mutations [14].

Rarely, transplacental transmission of melanoma has been recorded [9,15].

Melanoma: prognosis and management

The estimation of prognosis for patients with melanoma

A large number of pathological features have been suggested as offering prognostic information. Tumour thickness was established by Alexander Breslow as the most valuable prognostic guide [1]. Blocks are cut from the apparently thickest area of the primary melanoma by the pathologist and the slides cut from this block are examined using an ocular micrometer to measure the distance between the overlying epidermal granular layer and the deepest invasive area of the primary lesion (Fig. 54.67). This figure in millimetres is the Breslow or tumour-thickness measurement and should be included in all pathology reports of primary melanoma. The thickness is indicative of the likelihood of vertical growth phase, tumour volume and correlates with biological markers of tumour progression.

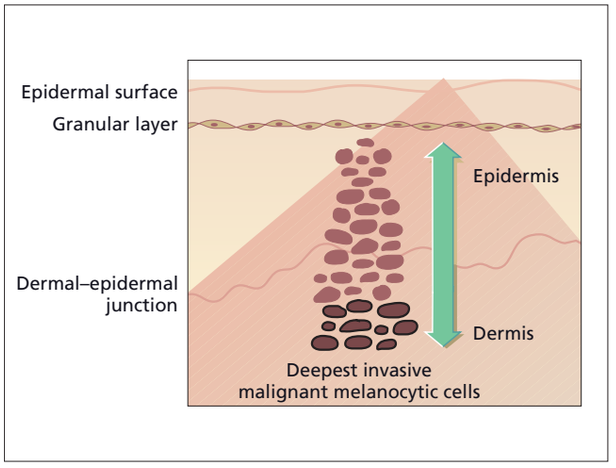

Fig. 54.67 Malignant melanoma thickness measurement (Breslow). The pathologist measures in millimetres the distance between the granular layer in the epidermis and the deepest invasive melanoma cell.

Subsequently, additional histological measures predictive of survival have been established, which have been used to develop the AJCC staging system [2] (Table 54.5). In this system the key roles of thickness and ulceration of the primary in determining outcome are recognized as are the number of lymph nodes involved in metastatic disease.

With respect to primary disease, the AJCC system benefits from very large data sets and it has been validated in population-based data sets (although with a somewhat better survival in the population based SEER data set [3]). The AJCC system is still being improved and a further revision will follow soon. Attempts, however, have been made in the interim to improve the estimates by other groups, particularly the Melanoma Programme at the University of Pennsylvania. Patient sex, mitotic rate, growth phase [4] and tumour site are important determinants of survival, which are not as yet taken into account by the AJCC system; a number of algorithms have been developed that take these additional factors into consideration.

Factors associated with a higher risk of recurrence in those diagnosed with thin primaries have been identified using prognostic trees [5]. In this system the acknowledged effects of sex, site and tumour growth phase are taken into account, so that, for example, females with level II, thin, non-ulcerated tumours had 100% 10-year survival rates compared with males with level III and IV tumours and a 'mitogenic' histological subtype who had an 83.4% 10-year survival. Ultimately, additional information may come from immunohistochemistry (using dermal Ki67 expression, for example [6]), and it seems entirely preferable that this will be incorporated into web-based risk algorithm tools.

Table 54.5 The AJCC staging system [2].

Stage	Primary tumour (pT)	Lymph node (N)	Distant metastases (M)
0	*In situ* tumours	No nodes	None
IA	<1.0 mm no ulceration	No nodes	None
IB	<1.0 mm with ulceration	No nodes	None
	1.01–2.0 mm no ulceration	No nodes	None
IIA	1.01–2.0 mm with ulceration	No nodes	None
	2.01–4.0 mm no ulceration	No nodes	None
IIB	2.01–4.0 mm with ulceration	No nodes	None
	>4.0 mm no ulceration	No nodes	None
IIC	>4.0 mm with ulceration	No nodes	None
IIIA	Any Breslow no ulceration	Micrometastases in nodes	None
IIIB	Any Breslow with ulceration	Micrometastases in nodes	None
	Any Breslow no ulceration	Up to 3 palpable nodes	None
	Any Breslow ± ulceration	No nodes but *in transit* Metastases or satellite lesions	None
IIIC	Any Breslow with ulceration	Up to 3 palpable nodes	None
	Any Breslow ± ulceration	4 or more palpable nodes Or matted nodes Or *in transit* metastases with nodes	None
IVM1			Skin, subcutaneous or distant lymph nodes
IVM2			Lung
IVM3			All other sites or any site with raised LDH

Prognostic tables published by Elder and Murphy [7] are useful aids to management of patients in the clinic, although caution must be exercised as these are not population specific and must be judged as estimates only.

The most recent TNM staging system for melanoma published by the AJCC is outlined in Table 54.5, based upon validation in 17 000 subjects. The staging system reflects the dominant effects of Breslow thickness and the presence of ulceration on outcome for primary disease but for the first time allows risk stratification by the results of sentinel node biopsy (SLNB), a positive SLNB being Stage IIIa. The staging system also reflects the poorer prognosis associated with multiple nodes, matted nodes or *in transit* disease in Stage III melanoma, and the observation that outcome for Stage IV patients is poorer with visceral metastases rather than soft tissue disease, and poorer still when lactic dehydrogenase (LDH) levels are raised. This staging system was validated in 41 417 patients in the SEER registry [3], although the survival was generally higher so that the authors suggest that population-specific figures would be preferable (although very difficult to achieve). The 10-year survival rates of the SEER registry patients are compared with the AJCC figures in Table 54.6.

Management of cutaneous malignant melanoma after excision of the primary

UK guidelines are available for the management of all stages of melanoma [1] and similar guidelines have been published by other national groups [2,3].

Staging

The only form of staging normally offered to the majority of patients presenting with primary melanoma is sentinel node biopsy. Some centres perform base-line chest X-ray and blood tests, including LDH, although there are no data supporting their use [4]. The likely yield of true positives on chest X-ray here is likely to be around 0%.

Staging imaging is necessary at relapse. The most typical first relapse is detected as enlarged regional lymph nodes and it would be usual to perform a CT scan prior to surgery, on the basis that the patient might choose to decline surgery if they had metastatic disease elsewhere. In practice, however, it is a very rare event to find true positive scans, and if waiting for a scan would delay surgery this may be carried out after surgery. A post-surgery scan may also be needed for trials of adjuvant therapies. For melanomas on the arm metastatic to the axilla or supraclavicular nodes,

Table 54.6 Prognosis of melanoma according to disease stage. Adapted from [2] and [3].

Substage	Characteristics of the primary such as depth and ulceration, presence of nodal or distant metastases, see Table 54.5	AJCC 10-year survival (% ± S.E.) [2]	SEER 10 year survival (% ± S.E) [3]
IA	≤1 mm	87.9 ± 1.0	97.4 ± 0.35
IB	≤1 mm with ulceration	83.1 ± 1.5	90.2 ± 1.8
	1.01–2.0 mm, no ulceration	79.2 ± 1.1	84.1 ± 1.4
IIA	1.01–2.0 mm, with ulceration	64.4 ± 2.2	65.2 ± 7.7
	2.01–4.0 mm, no ulceration	63.8 ± 1.7	67.3 ± 2.6
IIB	2.01–4.0 mm, with ulceration	50.8 ± 1.7	62.1 ± 5.9
	> 4 mm, no ulceration	53.9 ± 3.3	56.3 ± 4.4
IIC	> 4 mm, with ulceration	32.3 ± 2.1	47.5 ± 7.1
IIIA	1 micrometastases in node	62.0 ± 4.4	
	2–3 nodes	56.9 ± 6.8	
IIIB	Micrometastases and ulcerated primary	37.8 ± 4.8	
	1 palpable node	35.9 ± 7.2	49.7 ± 7.6
	2–3 nodes	47.7 ± 5.8	43.6 ± 10.6
	Satellites, no nodes	39.2 ± 5.8	59.2 ± 7.1
IIIC	1 node and ulcerated primary	24.4 ± 5.3	36.6 ± 15.7
	2–3 nodes and ulcerated primary	15.0 ± 3.9	32.9 ± 16.3
	≥4 nodes	18.4 ± 2.5	22.4 ± 6.7
IV	Overall		14.1 ± 3.2
	Skin and SC	15.7 ± 2.9	
	Lung	2.5 ± 1.5	
	Other visceral	6.0 ± 0.9	

then a scan with contrast of the chest and abdomen is the norm. For melanomas on the head and neck or upper trunk, a scan with contrast of the thorax and abdomen is usual. For melanomas on the lower leg and lower trunk including the genitalia, a scan with contrast should be performed of the thorax, abdomen and pelvis. A chest X-ray and bloods, including liver function tests and LDH, are also justified, but only as a baseline. Although LDH is commonly measured it is a poor biomarker of relapse (see below).

Patients who present with clinical signs and symptoms of Stage IV disease would normally have a CT scan with contrast of the abdomen, thorax and pelvis. As melanoma commonly metastasizes to the brain, a CT scan of the brain is also appropriate. A chest X-ray and bloods, including LDH, as a baseline are also helpful.

There is no widely used biomarker with which to monitor high-risk melanoma patients. Circulating levels of protein S100beta, melanoma-inhibitory activity (MIA), LDH, alkaline phosphatase (AP), and tyrosinase/MART-1 reverse transcription-polymerase chain reaction (RT-PCR) are biomarkers that have been evaluated. In one study of 286 patients, protein S100beta and MIA demonstrated a higher sensitivity, specificity, and diagnostic accuracy in the diagnosis of newly occurring metastasis compared with the tumour markers AP, LDH and RT-PCR diagnostics [5]. The superior value of measuring S100 compared with LDH has been reported by other groups [6,7]. When there is an effective treatment for Stage IV disease, the clinical value of markers such as S100 will be higher and it is likely that their use will increase.

Sentinel node biopsy (SLNB)

SLNB grew out of a recognition that elective lymph node dissection (ELND) does not offer a survival advantage to melanoma patients and it is worth briefly considering this history. Three randomized controlled trials that evaluated the effectiveness of ELND on survival in melanoma patients were identified with sufficient data for a meta-analysis [8–10], the Intergroup Melanoma Trial and two WHO Melanoma Trials (No.1 and No.14). The total number of participants was 1533; 768 were assigned to have ELND and 765 to delayed lymphadenectomy or no treatment. A total of 416 deaths within 5 years of the primary tumour excision were recorded in the three trials. Death occurred in 197 patients who underwent ELND compared to 219 from control groups. The pooled odds ratio was 0.86 (95% CI 0.68–1.09), showing no evidence of any therapeutic effect [11]. Whilst these trials and the subsequent meta-analysis showed no significant effect, they did not exclude a small effect and because lymphatic draining in individuals may vary, Morton developed sentinel node biopsy as a means of ensuring that the node biopsied was the one most likely to be the first draining lymph node [12]. The technique was widely adopted although the first randomized clinical trial to evaluate it was only published in 2006 [13]. In SLNB, lymphoscintigraphy is used to identify the lymphatic drainage pattern from the site of the primary melanoma, by injecting radiolabelled colloid and/or blue dye at the site of the primary melanoma. The tracer/dye are concentrated in the so-called sentinel node and are detected using a hand-held gamma probe (neoprobe) and examination by naked eye for the blue stained node. Sometimes there is more than one sentinel node and sometimes these sentinel nodes are in different

lymph node basins. The node is removed, sectioned and subjected to detailed, time-consuming examination by specialist pathologists using immunohistochemistry (S100 and HMB-45). Protocols have been developed to ensure consistency between groups and the identification of small deposits in only one part of a node [14]. The Dewar classification was developed by Cook in the UK [15], to describe the anatomic metastatic deposits in the sentinel node; they were found to be subcapsular in 26.0% of patients. None of the patients with only subcapsular disease had any non-sentinel nodes involved on completion of lymphadenectomy. In the patients whose sentinel node metastases had a different microanatomic location (such as parenchymal or mixed subcapsular or parenchymal), the rate of non-sentinel node involvement was 22.2% overall. Thus it would appear that if melanoma patients have subcapsular deposits of melanoma only, they are less likely to have involvement of other glands. This finding, therefore, has prognostic importance but needs to be established in prospective trials.

The surgical technique must be learnt and false-negative results are more common in trainees, so that many centres require a training experience of around 30 cases. The pathological examination of the nodes is also a skilled procedure; naevus cells may be seen, for example, in the subcapsular area of the node and must be distinguished from melanoma cells. The technique is expensive of resources and expert time.

The likelihood of a positive SLNB result is correlated with Breslow thickness so that in a review of 4218 published cases only two were positive for patients with thickness less than 0.75 mm [16]. Patients with melanoma of Breslow thickness more than 1.0 mm and less than 1.5 mm have a low but definite risk of having micrometastases (around 8%). Use of SLNB to stage patients for trials of adjuvant therapies would appear reasonable but the patient should be aware that the risk of positivity is low. In patients with melanoma of Breslow thickness from 1.5 to 4.0 mm the risk of positive SLNBs is significantly higher at 23%. The value of SLNB in patients with tumours of Breslow thickness 4 mm or thicker is questionable (if the intent is therapeutic as well as being a staging tool) because the risk of haematogenous spread is so high. More recently, some authors have suggested that additional prognostic information does come from SLNB in these patients [17].

The first randomized clinical trial of SLNB in 1269 patients with an intermediate-thickness primary melanoma has been reported [13], and the prognostic value of SLNB was confirmed. The 5-year survival rate was 72.3 ± 4.6% among patients with tumour-positive sentinel nodes and 90.2 ± 1.3% among those with tumour-negative sentinel nodes (hazard ratio for death 2.48; 95% CI 1.54–3.98; $P < 0.001$). There was no overall survival benefit however of SLNB; the mean (±SE) estimated 5-year disease-free survival rate for the population was 78.3 ± 1.6% in the biopsy group and 73.1 ± 2.1% in the observation group (hazard ratio for death 0.74; 95% CI 0.59–0.93; $P = 0.009$). Five-year melanoma-specific survival rates were similar in the two groups (87.1 ± 1.3% and 86.6 ± 1.6%, respectively). The authors suggested that within patients with nodal metastases, there might be some benefit in that the 5-year survival rate was higher among those who underwent immediate lymphadenectomy than among those in whom lymphadenectomy was delayed (72.3 ± 4.6% vs. 52.4 ± 5.9%; hazard ratio for death 0.51; 95% CI 0.32–0.81; $P = 0.004$). This conclusion requires that an assumption is made that all patients with a positive SLNB will progress (which may not be true). The conclusion from the study may also be that SLNB could have a survival benefit for a small proportion of melanoma patients overall, but the study is as yet insufficiently powered to show this effect.

Lymphoscintigraphy for SLNB of the head and neck is technically more difficult than in other sites [18], as is the surgery [19], and is not therefore offered in all SLNB centres.

Thus, at present, SLNB is of proven staging value but of no established therapeutic value. Its use in identifying patients for adjuvant therapies means that it will continue to be used, but its role must be evaluated in the long term.

Follow-up after surgery for Stage I or II melanoma

Patients who have had surgery for primary melanoma with no evidence of spread beyond the primary site have traditionally undergone a period of hospital-based follow-up at varying intervals for a varying number of years. The three main purposes of this follow-up are to detect any local recurrence around the scar of the excised melanoma, to palpate the local draining nodes for any clinically detectable evidence of nodal spread and to examine the rest of the skin surface for a second primary melanoma. Regular ultrasound examination of draining nodes is carried out in some centres and there is some evidence that this leads to earlier detection of metastatic disease, although this must be operator dependent [1].

Accepted intervals and duration of follow-up are 3-monthly intervals for 3–5 years. As, however, there is no evidence that this routine follow-up examination advances the time of diagnosing metastatic spread, and the majority of recurrences are detected between such visits, these intervals can be interpreted according to the needs of individual patients and the geographical situation. Some patients benefit emotionally from follow-up in hospital, and some find it traumatic. All patients should be taught how to look for local recurrence, how to palpate the relevant area for enlarged nodes, and be made aware of the clinical features that would suggest a second primary melanoma. They should have information about an appropriate contact in case they detect possible recurrence between regular appointments. The opportunity should also be taken to educate the family about the risk of melanoma and the avoidance of behaviours thought to be causal.

Patients with only an *in situ* melanoma do not require to be placed on a follow-up regime but can be discharged after appropriate surgery and education about self examination and sun protection.

Management of melanoma metastatic to lymph glands

Patients with a positive SLNB would normally proceed to completion lymphadenectomy, although a randomized clinical trial is currently taking place to address its value after SLNB. Axillary surgery would normally be performed to levels I, II and III. For inguinal nodes, a superficial groin dissection would normally be carried out. An additional deep ilioinguinal dissection may also be performed if a pelvic node was seen on lymphoscintigraphy which was not retrieved at SLNB, if there were multiple positive sentinel nodes superficially in the groin (often four or more is suggested), if Cloquet's node (the first of the deep pelvic nodes, lying just below the inguinal ligament) was shown to be involved with melanoma [1], or if lymphatics were seen bypassing nodes superficially and entering the pelvis directly. There are no data to support these clinical practice guidelines.

Patients who present with palpable lymph glands in the drainage area of their primary melanoma should be examined, and, in the majority of such patients, the nodes feel sufficiently firm and large (usually greater than 1 cm in diameter) for a clinical diagnosis of presumptive metastatic melanoma to be made. Patients do commonly present concerned about palpable lesions which prove to be benign such as pea sized normal lymph glands, glands which have enlarged as a result of an insult such as a recent immunization or viral illness, and lipomas.

Where there is doubt about the diagnosis, fine needle aspiration cytology should be used to aspirate a sample under vacuum for pathological examination. A slide preparation can be made in clinic and cytological examination carried out immediately in order to expedite management. An additional cytospin preparation can be examined if insufficient sample is obtained. A negative result should not be taken to exclude metastatic disease if either there was insufficient sample, or in the presence of very suggestive clinical evidence.

The examination of lymph glands is easier in some anatomical locations (inguinal and neck) than in others. The axilla may be particularly difficult, especially in larger men. In these circumstances ultrasonic examination plus fine needle aspiration cytology may be helpful.

If the diagnosis of metastatic disease is clear either clinically or cytologically, then lymphadenectomy is carried out. Again for axillary nodes, levels I, II and III should be removed. A superficial ilioinguinal dissection is usual, extended to a deep dissection if there is evidence of a pelvic node clinically or on CT scan, involvement of Cloquet's node, extensive superficial nodal involvement or a node distal to the inguinal ligament is involved [1].

Melanoma metastatic to the neck should be operated on by surgeons specialized in head and neck surgery. A functional neck dissection is usually carried out for melanoma.

Biological therapies for melanoma

Melanoma is an immunogenic tumour; immune-mediated regression is common in primary tumours and immune-mediated vitiligo in Stage IV disease correlates with a higher chance of response to chemotherapy. Biological therapies have therefore been trialled extensively and the most widely used as an adjuvant is interferon. There have been numerous trials and much controversy but the conclusion now seems to be that interferon-alpha (IFN-α) appears to increase disease-free survival in some patients [1] but is associated with no significant overall survival benefit. Except for TNM stage, there are currently no well-recognized factors that predict outcome. There are some data however from Gogas *et al*., which might suggest that host variation in immune response predicts outcome [2]. In a study of 200 melanoma patients treated with high-dose IFN-α 2b, the median relapse-free survival was 28.0 months, and the median overall survival was 58.7 months. Autoantibodies and clinical manifestations of autoimmunity were detected in 52 patients (26%). The median relapse-free survival

was only 16.0 months among patients without autoimmunity (108 of 148 had a relapse) and more than 45 months (median not reached) in patients with autoimmunity (seven of 52 had a relapse). The median survival was 37.6 months in patients without autoimmunity (80 of 148 died) and was not reached in patients with autoimmunity (two of 52 died). The significance of this remains to be evaluated.

Of the newer biological therapies, the anti-CTLA-4 antibodies, ipilimumab and ticilumumab, intended to enhance immune response, and the antiangiogenic agent bevacizumab, are currently being investigated in clinical trials.

A series of different vaccines have been trialled, from single agents such as ganglioside vaccines to multivalent vaccines. Despite early enthusiasm however, unfortunately, as yet no adjuvant value has been established for these treatments. There is also some evidence of poorer [3] survival in patients receiving vaccine.

Interleukin 2 showed encouraging responses in conjunction with chemotherapy in Phase II clinical trials but not in Phase III trials [4]. A Cochrane review failed to show any evidence that the addition of biological therapies to chemotherapeutic regimes for melanoma increased survival [5].

Interest remains therefore in biological therapies for melanoma, but there are no established roles for these agents as yet. It is fair to say that, despite early optimism, biological therapies have proved disappointing.

Management of patients with Stage IV disease

The AJCC TNM staging revision has clearly indicated that patients with metastatic spread to certain tissues, including the lungs and soft tissue, have a better outlook than those patients with spread to the liver or central nervous system. Lung and soft tissue lesions tend to be more responsive to chemotherapy, but even for these patients such responses are rarely complete and tend to be of short duration.

Where patients have small volume disease, such as a single deposit in the liver or lung, then excision of this lesion should be considered. In these circumstances a PET scan might be used to ensure the absence of disease elsewhere.

No chemotherapeutic agent gives a high proportion of complete responses in melanoma. The current chemotherapeutic agent of choice is dacarbazine (DTIC). In large randomized trials, response rates with dacarbazine ranged from 6 to 15%. Almost all responses were partial, with a median response duration of only 7–8 months [6]. With modern antiemetics, DTIC is relatively non-toxic and can be given as an out-patient, usually at 3-week intervals. Patients should be assessed for response after four to six courses. There is no evidence that combination therapy of DTIC with other chemotherapeutic agents [2] or with biologicals [5] increases the response rate or the duration of response achieved by DTIC alone.

Temozolomide has demonstrated efficacy equal to that of dacarbazine in a randomized Phase III trial. However, unlike dacarbazine, temozolomide is a convenient oral treatment that penetrates the blood–brain barrier and that has shown activity against brain metastases. Although surgery is the preferred treatment modality for patients with solitary brain metastases from melanoma, temozolomide is the preferred chemotherapy for patients with brain metastases who require systemic treatment [6].

Management of recurrent disease in a limb

Recurrent disease is common in patients after resection of melanoma on a limb, particularly the leg. When recurrence occurs within 2 cm of the primary, convention is that this is called a 'local recurrence', but in fact the majority are *in transit* metastases.

More distant deposits in the skin or subcutaneous tissues are called '*in transit*' metastases. Occasionally, these may be present at diagnosis. Usually these are proximal, along the line of lymphatics, but rarely they may actually be distal to the primary tumour site. They are usually well under 1 cm in diameter at removal but larger deposits may occur. They may be pigmented or non-pigmented (Fig. 54.68). *In transit* disease is usually accompanied by regional lymph node metastases at some time or other, either simultaneously or years later. Sometimes, multiple *in transit* metastases may develop over years without spread elsewhere.

Treatment

The treatment of such lesions is essentially surgical. Tiny lesions may be removed by punch excision and if large numbers are present, these may be left to heal by secondary intention. Larger ones will require more extensive surgery, even skin grafting. The CO_2 laser may be a very useful means of removing large numbers of small lesions.

If it appears that the disease within the limb is becoming difficult to control surgically then isolated limb perfusion [7] should be considered. Isolated limb perfusion with the administration of cytotoxic drugs (primarily melphalan) has been successfully used to treat melanomas of the extremity since it was first introduced in 1958. The vessels are dissected at open surgery and cannulated. Blood transfusions, systemic drug leak, infection and damage to the blood vessels and nerves, even rare limb loss, are all potential hazards associated with this technique.

Isolated limb perfusion is used to palliate disease [8], although there is some weak evidence for an effect on survival; in a meta-analysis of four trials of 1038 patients, the analysis confirmed the reported increase in survival in two of the trials, but neither had sufficient power to detect significant benefit for perfusion [9]. There is a significant morbidity associated with the treatment and a 1% limb loss rate in most studies [10]. In order to increase the efficacy of treatment, tumour necrosis factor (TNF) may be added [11]. Perfusion with melphalan results in complete response rates of 54% (meta-analysis). The addition of TNF can improve these complete response rates (59–85%) and although no data from randomized controlled trials are available, it is said to be of value in large, bulky lesions or in patients with recurrent disease after previous isolated limb perfusion [12]. The addition of TNF adds to the toxicity. The treatment may be repeated if there is an initial good response but relapse occurs later [13]. Other cytotoxics used in isolated limb perfusion in some centres include dacarbazine and fotemustine [14].

As a result of the morbidity, an alternative, simpler technique termed isolated limb infusion (ILI), was developed by the Sydney Melanoma Unit [15]. ILI is a less invasive procedure involving the

(a) (b)

Fig. 54.68 *In transit* metastases in a limb are reasonably frequent. Some recur over long periods of time without distant relapse.

use of angiographically placed catheters inserted percutaneously through the femoral vessels, which does not require use of a heart–lung machine. It has been suggested (although based on single institution experiences) that there are fewer resultant morbidities but no compromise in patient outcomes. The overall reported response rate [16] in the treated limb of 135 patients was 85% (complete response [CR] rate 41%, partial response rate 44%). Median response duration response was 16 months (24 months for patients with CR). Median patient survival was 34 months. In those with a CR, the median survival was 42 months.

There is no value for isolated limb infusion as an adjuvant therapy [17].

The treatment of melanoma metastatic to the brain

Melanoma commonly metastasizes to the brain in Stage IV disease, presenting usually as headaches and/or fits. It can occasionally present as motor or sensory symptoms. In a series of 133 patients, 82 patients had involvement of only the cerebrum at the initial diagnosis, whereas in seven patients only the cerebellum and the brainstem were involved. Seizures (n = 29) were the single most often reported symptom. The overall median survival time was 24 weeks. Women had a significantly longer survival with 36 weeks (3–196) compared to 17 weeks (1–159) for men [18]. Although these survival figures are poor, there is a view that aggressive treatment does palliate symptoms and prolong survival [19]. The diagnosis is confirmed by CT scan, and the immediate treatment is with oral dexamethasone to control the secondary oedema.

A single (or few) brain metastasis might be amenable to surgery or stereotactic radiotherapy, and it is unclear which is most effective. Surgical resection is preferred when a pathologic diagnosis is needed, for tumours larger than 3.5 cm or when immediate tumour mass decompression is required. Stereotactic radiosurgery (SRS) is the use of highly collimated beams of radiation to deliver high-dose radiotherapy to defined areas with rapid fall off into surrounding tissues; it should be applied for single tumours less than 3.5 cm in surgically inaccessible areas and for patients who are not surgical candidates. Small tumours (i.e. <3.5 cm) that cause minimal oedema and are surgically accessible may be treated with either surgery or SRS [19]. Both surgery and SRS are normally followed by whole-brain radiotherapy, although it is not clear how much benefit this gives, and neurocognitive late effects are a side effect. There is a view that the whole-brain radiotherapy increases local control but has no effect on survival [20] and in some centres it is therefore avoided.

For unresectable lesions or multiple lesions the options are radiotherapy or chemotherapy, neither of which are very effective. Radiotherapy is usually given as whole-brain radiotherapy, but SRS may be used. In a series of 244 patients given SRS for the management of 754 metastatic tumours, the median survival was 5.3 months (mean 10 months; range, 0.2–114.3 months) [21]. Sustained local control was achieved in 86.2% of tumours. Multiple lesions and failure to provide systemic immunotherapy were predictors for the occurrence of new brain metastases, which developed in 41.7% of the patients. Symptomatic radiation changes occurred in 6.6% of the patients. Overall, 71.4% of the patients improved or remained clinically stable. Whole-brain radiotherapy is usually delivered as a short course over 1 to 2 weeks.

Temozolomide is an oral alternative to dacarbazine for the treatment of metastatic melanoma; it penetrates the blood–brain barrier and is therefore preferred treatment for brain metastases [6], although it is not yet approved in many countries. The response rates are, however, low.

Radiotherapy

Malignant melanoma is traditionally regarded as a radioresistant tumour but it does have a role, particularly in palliation, and there is a view that it is underused [1]. The view that melanoma is radioresistant originated from radiobiological experiments, but a modern view is that melanomas have a wide range of sensitivities and that some are radiosensitive [1]. It is usually held that melanoma responds better to hypofractionation (larger, more infrequent doses) but this remains contested.

Radiotherapy has little part to play in the management of primary tumours, although it has been recorded in the past that the lentigo maligna melanoma variant is relatively radiosensitive, and radiotherapy has been used (low-energy electron or X-ray beams with limited penetration). It may be particularly useful where extensive disease occurs in difficult sites such as at the eyelid margin. However, data are inadequate to compare treatment modalities for lentigo maligna.

Radiotherapy may have palliative value for locoregional disease, which is not amenable to surgery. Radiotherapy can also be of considerable value in the palliation of metastatic disease in relieving pain from bony metastases.

There has been a persistent interest in postoperative adjuvant radiotherapy for Stage III melanoma, particularly where there is extracapsular spread and therefore an increased risk of local recurrence. The data on efficacy are interesting but are not based upon sufficiently large randomized clinical trials [2]. Stevens and McKay, however, have compared nodal basin relapse rates after surgery alone with those after radiotherapy and local recurrence did seem to be much lower when adjuvant radiotherapy is used [1], although the morbidity in terms of lymphoedema, for example, is increased. Randomized clinical trials are needed, and one trial began in 2002 in Australia and New Zealand.

Melanoma, pregnancy and female sex hormones

Concern about the effect of pregnancy on outcome from melanoma began in 1951, when Pack and Scharnagel reviewed 32 cases of melanoma diagnosed during pregnancy reporting extremely poor prognosis due to the rapid development of metastases [1]. A number of studies subsequently, however, have not shown any adverse effect on outcome [2]. A large study based on a Swedish cancer registry of 185 women diagnosed with melanoma during pregnancy and 5348 women of the same childbearing age diagnosed with melanoma while not pregnant, showed no evidence of an adverse effect of pregnancy on survival, before or after diagnosis [3]. Clinicians often advise patients with thicker primaries to defer pregnancy after diagnosis, but this is social rather than medical, based upon waiting until the period during which metastasis is most likely has passed.

Placental and fetal metastasis of melanoma is a rare but well described phenomenon. In a review of published cases the risk of

fetal disease in the presence of placental metastases was estimated to be 22% [4], so that examination of the placenta at delivery in patients with poor prognosis disease is sensible.

There is no evidence that the contraceptive pill has any effect on causation of melanoma [5] and none that hormone replacement therapy should be avoided [6].

The histiocytoses are a heterogeneous group of diseases that are characterized by the accumulation of reactive or neoplastic histiocytes in various tissues. Many of the signs and symptoms of the histiocytoses may be the result of the functional activity of histiocytoses, and which may also be important in the pathogenesis of these diseases (Fig. 55.1).

Ontogeny of the histiocyte

Synonym
- Tissue macrophage

Histiocytes are derived from circulating monocytes and thus share a common bone marrow progenitor cell, the *neutrophil/macrophage colony-forming unit* (NM-CFU; Fig. 55.2). Promonocytes are actively dividing cells and their replication is controlled by a series of stimulatory glycoprotein hormones, colony-stimulating factor (CSF) and inhibitory prostaglandins. Colony-stimulating factor has a molecular mass of 20–50 kDa. Its main source is cells of the monocyte/macrophage lineage [1] but activated T cells [2], keratinocytes [3] and neoplastic monocytes and macrophages [4] are also capable of secreting CSF. Cell division is limited by a negative feedback mechanism involving the E prostaglandins, which are released by macrophages after stimulation by CSF.

Other factors have been shown to influence the maturation of monocyte precursors, including 1,25-dihydroxyvitamin D_3 [5], retinoic acid [6], interferon-γ (IFN-γ) [7] and phorbol esters [8]. The promonocyte matures into a monocyte, which is released into the circulation where it represents a replacement pool for tissue macrophages or histiocytes. The half-life of a circulating monocyte is about 71 h [9], after which the cells migrate into various tissues where they differentiate into histiocytes without further division. Most histiocytes do not actively divide, although in some tissues, such as the lung, they are capable of replication [10].

The Langerhans' cell is a histiocytic cell that represents a resident immigrant population in the epidermis. It is an archetypal member of a subpopulation of histiocytic cells, the dendritic cells, which play key roles in various aspects of immunity. As with all histiocytic cells, Langerhans' cells are of bone marrow origin [11] and are ultimately derived from the haemopoietic stem cell. Haemopoietic stem cells can differentiate into myeloid or lymphoid-committed precursors and Langerhans' cells can differentiate through both lineages [12]. The intermediate stages of Langerhans' cell development are unknown, but a possible intermediate cell in the bone marrow has been identified, which, in common with the Langerhans' cell, expresses the CD1 complex [13]. In the blood of healthy individuals, CD1a cells are found in very low numbers, but in cord blood [14] and blood from burns patients [15] high levels of CD1a cells are observed. It is speculated that these represent immature Langerhans' cells.

The factors that control the migration and development of Langerhans' cells in the skin are not fully understood. Langerhans' cell precursors express the cutaneous leukocyte antigen (CLA), a glycosylated form of p-selectin which acts as a homing molecule for the skin and express CCR6, the receptor for the chemokine CCL20 which is produced by epidermal keratinocytes [16]. Granulocyte/macrophage CSF (GM-CSF), interleukin (IL)-3 and tumour necrosis factor-α (TNF-α) all induce CD34 cells to

develop the phenotypic features of Langerhans' cells. Caux *et al.* [17] generated CD1a cells from CD34 bone marrow cells using GM-CSF and TNF-α. The cells demonstrated potent antigen-presenting function. However, further research has shown that the whole field of Langerhans' cells ontogeny is more complex. Studies have now shown that GM-CSF will induce expression of CD1a, CD1b and CD1c by blood monocytes [18]. *In vitro*, human monocytes can differentiate into dendritic cells with some characteristics of Langerhans' cells on culture with GM-CSF, IL4 and TGF-β [19]. $CD34^+$ bone marrow cells can be induced to differentiate into Langerhans' cells with GM-CSF and TNF-α [20], IL3 and TNF-α [21], or FMS-like tyrosine kinase-3 (FLT3) ligand and transforming growth factor-β (TGF-β) [22]. A possible immediate precursor of epidermal Langerhans' cell in the epidermis is the *indeterminate cell* [23], which bears a Langerhans' cell surface phenotype but lacks the characteristic Birbeck granule (see Chapter 3 and section on the phenotype of Langerhans' cells below).

Within the epidermis, Langerhans' cells are immature, able to process antigen but do not express the co-stimulatory molecules CD80 and CD86 unless activated and are poor antigen-presenting cells. Maturation and migration out of the epidermis can be stimulated by a wide variety of signals including TNF-α and IL1β, CD40 ligand, microbial products and ultraviolet radiation. Langerhans' cells down-regulate CD1a, express CD80 and CD86, lose CCR6 expression and express CCR7 which directs migration to the lymphatics and regional lymph nodes. The fate of Langerhans' cells after their development in the skin is speculative. Some authors maintain that Langerhans' cells migrate from the skin in the efferent lymphatics as *veiled cells* and eventually develop into *interdigitating reticulum cells* in the paracortical zone of the regional lymph nodes. If Langerhans' cells are cultured *in vitro*, they lose their characteristic phenotype and adopt an interdigitating reticulum cell phenotype [24]; this phenomenon has been proposed as evidence for their extraepidermal differentiation. However, the *in vitro* culture conditions are unphysiological, and it is more probable that Langerhans' cell, veil cell and interdigitating cell are related but differentiate separately from an early common progenitor cell series.

Dermal dendrocytes, first described by Headington in 1986 [25], are highly dendritic interstitial cells of the papillary and reticular dermis. They are positive for adenosine triphosphatase (ATPase), α-napthylbutyrate esterase, β-glucuronidase and acid phosphatase, indicating they are of monocyte/macrophage lineage. They are also phagocytic *in vivo*, showing melanin and haemosiderin phagocytosis. Dermal dendrocytes are of bone marrow origin and are thought to have a possible role in phagocytosis, antigen presentation or in homeostasis of macromolecules of the dermis [26]. Elegant computer-assisted three-dimensional reconstruction of dermal dendrocytes in adult human skin has shown that in those associated with superficial blood vessels, the dendrites are thin, membrane-bound flaps that enshroud the vessel wall. In subepidermal dermal dendrocytes, the flap-like dendrites are parallel to the dermal–epidermal junction. Twenty to 40% of perivascular and some subepidermal dermal dendrocytes are closely associated with mast cells, their membrane flaps enshrouding 50–90% of the surface of the mast cell [27].

Phenotype of Langerhans' cells

For many years after the original description of Langerhans' cells [28], this epidermal clear cell was considered to be an effete melanocyte. Significant interest was generated by the finding that Langerhans' cells express a number of surface molecules, which suggested immunological importance. These molecules include major histocompatibility complex (MHC) class II molecules (which are constitutively expressed by Langerhans' cells), FcIgG receptors and C3b receptor. Langerhans' cells also express the chemokine receptors CCR5 and CCR6. A full list of the phenotypic markers of Langerhans' cells is given in Table 55.1.

A major advance was the finding that epidermal Langerhans' cells expressed the CD1 complex [29], previously considered to be restricted to cortical thymocytes. CD1 is a group of non-polymorphic membrane glycoproteins that non-covalently bind to β_2-microglobulin. Five genes have been identified and cloned [30]. Four molecules have been described: CD1a, CD1b, CD1c and CD1d [31]. CD1a and CD1c are expressed by Langerhans' cells and may play a role in presenting lipid antigen to T cells [32]. Langerhans' cells have since been shown to express other molecules, identified by antibodies to CD4 and CD25, which were initially thought to be specific for lymphocytes.

The unique phenotypic feature of Langerhans' cells is the trilaminate cytoplasmic organelle, the *Birbeck granule* [33]. This organelle is only observed in Langerhans' cells, Langerhans' cell histiocytosis (LCH) cells (which are abnormal Langerhans' cells) and some hairy cell leukaemia cells. The granules are rod-shaped

structures with a central lamella. They are of uniform width (33 nm) and of variable length (200–360 nm). The granules often have terminal vesicular dilations, giving rise to the characteristic 'tennis racket' appearance. The Birbeck granule was initially thought to originate from the Golgi apparatus, but studies now suggest that it arises from the cytoplasmic membrane by receptor-specific endocytosis [34]. Lag is an antigen expressed on Birbeck granules and anti-Lag antibodies can be used to identify Langerhans' cells [35].

The phenotype of the Langerhans' cell changes with activation or with culture *in vitro*. Activation involves up-regulation of human leukocyte antigen (HLA)-DR and expression of CD4 and the co-stimulatory molecules CD80 and CD86 [36]. At the same time, Birbeck granules become sparser and CD1a is down-regulated (see Table 55.1).

Phenotype of the dermal dendrocyte

In addition to showing the enzyme histochemical features of the monocyte/macrophage lineage, a characteristic feature of dermal dendrocytes is expression of factor XIIIa. The cells are always negative for CD1a, which differentiates them from Langerhans' cells, and express HLA-DR, HLA-DQ, CD36, CD68, CD34, CD11a and CD11b but neither CD15, CD54 nor CD2. Thus, they show the immunophenotype of monocyte/macrophages and antigen-presenting cells, with no features of granulocytes or T cells [37]. Following stimulation with IFN-γ, the expression of HLA-DR increases and dermal dendrocytes express CD54. In atopic dermatitis and psoriasis, cells positive for factor XIIIa, HLA-DR and CD54 are observed in the upper dermis and foci of factor XIIIa-positive cells are seen in the epidermis [37].

Dermal dendrocytes have been shown to express S100A6 [38] and type XVI collagen [39]. CD14 peripheral blood monocytes stimulated with GM-CSF and IL-4 express factor XIIIa [40] and collagen XVI [39]. It is postulated that type XVI collagen forms an intermolecular cross-link through its non-collagenous domain, contributing to the integrity of factor XIIIa.

Dermal dendrocytes also express the von Willebrand factor receptor GPIbα. Expression of this factor *in vitro* is up-regulated by mast cell degranulation [41]. Expression of GPIbα on dermal dendrocytes suggests that these cells may have a role in skin remodelling and repair.

The fate of dermal dendrocytes is unknown. The factors that influence maturation of these cells include mast cell products, although *in vitro* studies using TNF-α have failed to demonstrate up-regulation of GPIbα on factor XIIIa-positive cells [42]. When skin is maintained in organ culture, dermal dendrocytes lose their dendritic morphology and become more rounded. This change is accentuated by mast cell degranulation, regardless of stimulus. These non-dendritic cells express variable amounts of factor XIIIa, CD34 and CD68.

Function of the histiocyte

Histiocytes can be broadly divided into two functionally separate cell populations: the 'professional' phagocyte; and the antigen-presenting cell.

Phagocytes include the majority of resident tissue macrophages and immature macrophages. Immature macrophages are cells that have migrated, as monocytes, from the blood but remain responsive to chemotactic stimuli and are attracted to sites of inflammation where they become inflammatory macrophages. Phagocytes take up foreign or altered material and digest it using a number of lysosomal enzymes, they also recognize material to be taken up by a variety of different cell-surface receptors. Important in this are the carbohydrate and lectin receptors, which are involved in the phagocytosis of bacteria and possibly tumour cells. The cells also express the specific complement component receptors CR1 and CR3, which bind to C3b and C3bi respectively, and FcIgG receptors, which bind to the Fc fragment of IgG. These receptors are important in the phagocytosis of material that has bound IgG and complement, which act as opsonins and augment phagocytosis.

Phagocytosis is important in the removal of particulate matter and destruction of bacteria and parasites. The phagocytosed particles are internalized and destroyed in phagolysosomes. Partially degraded antigen may subsequently become associated with MHC class II antigens and be re-expressed on the surface of a macrophage, where it can be presented to T-helper cells.

Phagocytes also possess some antigen-presenting capacity, although this is limited—cells express class II MHC molecules and can process and re-express antigen on their surface in association with these specific molecules, but only elicit responses in specific responder T-cell populations. In general, phagocytes present antigen to sensitized T cells but not to naïve or 'memory' T cells.

Antigen-presenting cells are histiocytic cells, or in some instances other cell types, that have specialized functional activity in presenting antigen to T cells. These cells are represented in humans by the blood dendritic cell, epidermal Langerhans' cell, interdigitating reticulum cell of the lymph node paracortex and veil cell of the efferent lymph. These cells have no phagocytic activity and, unlike professional phagocytes, are unable to adhere to surfaces. They are able to internalize antigen by endocytosis, process it by lysosomal digestion and re-express the antigen on their surface in association with MHC class II molecules. In addition, these cells are potent antigen-presenting cells and are able to present antigen not only to sensitized T cells but also to memory and naïve T cells, and are also able to present self antigen to allogeneic T cells to elicit an allogeneic or mixed-cell reaction [43].

Langerhans' cells are central to the regulation of contact allergic dermatitis, responsible for cutaneous immune surveillance and the target for skin graft rejection [44]. Epidermal Langerhans' cells are immature but, following stimulation, they migrate from epidermis to lymphatics and thus to the regional lymph nodes, and during this process undergo maturation. The signals that initiate and regulate the directed movement of Langerhans' cells from skin to regional lymph nodes include chemokines and cytokines. In cutaneous sensitization, TNF-α, GM-CSF, IL-1β and IL-18 are required, while IL-4 and IL-10 antagonize this process [45,46]. Maturation of Langerhans' cells is accompanied by specific phenotypic changes, with up-regulation of HLA-DR, down-regulation of CD1a, and expression of CD4 and CD25. There is a switch in chemokine receptor expression from CCR5 and CCR6 to CCR7 and CXCR4, which enables Langerhans' cells to exit the epidermis and follow a gradient of chemokines (CCL19, CCL21 and CXCL12) to the paracortical zone of the lymph nodes [47]. Langerhans' cells

also express other activation markers, including CD83 and CD40 and the T-cell co-stimulatory molecules CD80 and CD86 [48].

Classification of the histiocytoses

Understanding of the histiocytoses has been severely hampered by the lack of a universally accepted classification of these diseases and the widespread use of eponyms to describe them. For these

reasons, the Histiocyte Society published their classification of the histiocytoses for use as a standard in both diagnosis and management [1]. This classification has been generally accepted and is now widely used. In this chapter the original classification has been modified in the light of new insights into reactive histiocytoses of dermal dendrocyte phenotype. The histiocytoses are separated into four classes according to our current understanding of the biology of these diseases.

Class I: Langerhans' cell histiocytosis (LCH)

Class I histiocytoses are a diverse group of clinical diseases that are all reactive histiocytoses in which the predominant histiocyte is of Langerhans' cell phenotype. Patients with LCH can be further subdivided on the basis of the clinical organ involvement present. Bone disease and lung disease in adults appear to be significantly different in their biology from other single-system involvement and it is valid to separate them. The significance of organ involvement is discussed further in the section on LCH.

Class IIa: histiocytoses involving cells of the dermal dendrocyte lineage

Class IIa histiocytoses are reactive diseases in which cells with the phenotype of the dermal dendrocyte (positive for CD68 and factor XIIIa) accumulate in the skin and other tissues causing tissue damage. The typical histological change is a xanthogranulomatous reaction, although the histological changes reflect the cell type present. Juvenile xanthogranuloma is typical of this group of diseases, and some of the conditions described may not be specific disease entities but clinical variants of a single disease. These diseases are reactive with no clinical evidence of malignancy.

Class IIb: histiocytoses involving cells other than Langerhans' cells and dermal dendrocytes

Class IIb histiocytoses are reactive diseases in which histiocytes other than those bearing the Langerhans' cell or dermal dendrocyte phenotype accumulate in various tissues and may cause tissue damage. Within this heterogeneous group of diseases are included a number of rare and often poorly understood disorders. The major features of all these histiocytoses are that they are reactive, with no clinical or laboratory evidence of malignancy, and that Langerhans' cells and related cells are not involved.

Class III: malignant histiocytic disorders

Class III histiocytoses include all the malignant histiocytic diseases. These include monocytic leukaemias, malignant histiocytosis, which may be of the mononuclear phagocyte, dendritic cell or Langerhans' cell type, and the true histiocytic lymphoma, which once again may be of the mononuclear phagocyte, dendritic or Langerhans' cell type.

Definition. LCH is a reactive condition in which a clonal population of cells with the phenotype of the Langerhans' cell accumulate in various tissues and cause damage. Tissue damage appears to be due, in part, to cytokine production.

Aetiology. The aetiology of LCH is unknown but over the last century several possibilities have been considered, including tuberculosis [1] and a lipid abnormality [2,3]. The discovery of Birbeck granules in the cytoplasm of lesional cells using electron microscopy [4] led to the suggestion that these cytoplasmic bodies could be viral inclusion bodies and that LCH could be a virally mediated disease [5]. However, a large retrospective study on the fulminant form of LCH showed a random geographical distribution and little month-to-month variation in the incidence of the disease, which argued against it being due to a conventional virus [6]. A study of 56 LCH tissue samples using *in situ* hybridization and polymerase chain reaction (PCR) analysis failed to show any consistent evidence of adenovirus, cytomegalovirus, herpesvirus, parvovirus, human T-cell virus or human immunodeficiency virus infection [7].

The possibility of an immunological aetiology for LCH has been suggested by the occurrence of a number of immunological abnormalities in this disease. The fact that the lesional cell bears the phenotype of the Langerhans' cell, which is a key cell in the immune system, also suggests that the immune system is in some way involved in its pathogenesis. However, none of the immunological abnormalities have been a consistent feature, and most authors now consider them to be epiphenomena.

Serum immunoglobulins may be increased or decreased. The most common finding is that of reduced IgA and IgG levels, with normal IgE and IgM levels. In some reported cases, IgE and IgM levels were elevated [8].

In some patients, particularly those with aggressive disease, cutaneous anergy has been found on cutaneous testing, and *in vitro* studies have shown reduced T-cell responses to mitogens, recall antigens and alloantigens [9]. A reasonably consistent feature in three reported series of LCH [10–12] is a reduction of the CD8 T-cell subpopulation in the blood, with an associated normal or reduced total T-cell number. In one report [12], this reduction in the number of CD8 cells was associated with reduced suppressor T-cell activity *in vitro*.

Considering that Langerhans' cells are members of the monocyte/macrophage series of cells, very few abnormalities of this group of cells have been reported. Reduced monocyte-mediated, antibody-dependent cytotoxicity occurred in six patients with LCH, all of whom were in clinical remission [13]. This certainly warrants further study. LCH cells are unable to provide accessory cell function in a mitogen-driven T-cell response, and are inhibitory to T-cell proliferative responses [14]. Only one study has investigated the functional activity of LCH cells in depth [15]. In this report, LCH cells were shown to be functionally deficient in presenting alloantigen to T cells. It is possible that the defect in functional activity may be linked with the apparent arrest of these cells in an early stage of activation, leaving the cells immature so that they do not have the functional capacity of a normal Langerhans' cell.

Historically, LCH has been considered a malignant disease, and care of children with the disease has been in the hands of paediatric oncologists. The main reason for this is the clinical course and high mortality associated with the more fulminant forms of LCH. Flow cytometric studies have in general failed to identify aneuploidy in LCH [16,17]. In one report of an adult case with clinically and histologically confirmed LCH involving the skin, flow cytometry revealed an aneuploid peak [18]. Many features of this case were unusual and it is possible that the patient had the rare form of malignant histiocytosis of Langerhans' cell type.

Studies have demonstrated that lesional CD1a cells in LCH are clonal. Clonality studies in LCH have been difficult to perform because of the lack of cell-specific markers. Unlike the T-cell receptor in T cells and immunoglobulins in B cells, histiocytic cells have no markers that can be employed in such studies. The study of genes carried on the X chromosome have now allowed such studies in female patients with this disease. Of the gene loci examined, the human androgen receptor (*HUMARA*) is the most informative as there is a high degree of heterogeneity for this locus in the population. The underlying theory behind the assay is that the two alleles for *HUMARA* are acquired from maternal and paternal genes, each of which is a different size because of the presence of tandem repeats. Only one allele is activated, the other being inactivated by methylation, and the use of methylation-sensitive restriction enzymes in PCR allows the inactivated allele to be expanded and identified. In a normal population of cells, activation of the alleles is random so that 50% are derived from maternal and 50% from paternal genes, giving two bands on gel electrophoresis. In a clonal population of cells, all cells are derived from a single cell and therefore all these cells will have an inactivated allele, which is either maternal or paternal, giving a single band on gel electrophoresis. In a study of four female patients with LCH, purified lesional CD1a cells were shown to be clonal using this assay system [19]. Studies by Willman *et al.* [20] have confirmed these studies and shown that lesional cells are clonal regardless of the extent or severity of the disease. In isolated pulmonary LCH in adults, a study using X chromosome inactivation at the *HUMARA* locus has shown that 29% were clonal and 71% non-clonal. Discrete lung nodules from the same patient showed different allele inactivation [21]. Pulmonary LCH in adults is often an isolated disease that may remain restricted to the lungs and thus behaves in a different way biologically compared to other forms of LCH. It is possible that primary lung disease is a separate entity and only when it progresses to involve other organs does it become a clonal disease.

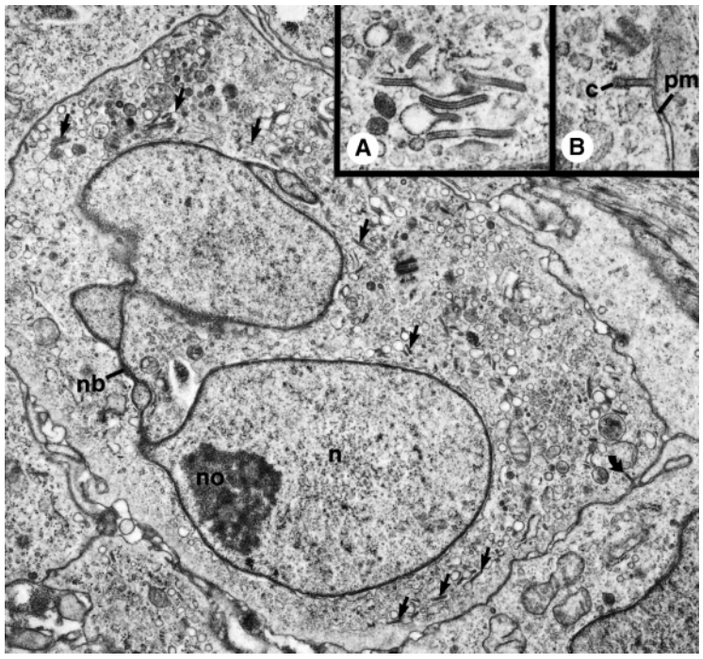

Fig. 55.3 Electron micrograph of a Langerhans' cell histiocytosis (LCH) cell in the epidermis of a patient with multisystem LCH. The cell shows a lobulated nucleus (n) with a prominent nucleolus (no) and attenuated nuclear bridge (nb). Numerous Birbeck granules (straight arrows) are evident in the cytoplasm. One granule (curved arrow) is seen projecting from the plasma membrane (× 13 000). (A) Birbeck granule in the cytoplasm. Some show characteristic vesiculation of the end, forming typical tennis-racket bodies. (B) Birbeck granules appear to be budding from the plasma membrane (pm) (× 39 000). (Courtesy of Professor R.A.J. Eady, St John's Dermatology Centre, London, UK.)

What clonality in LCH means is difficult to interpret. It certainly identifies the LCH cell as the primary cell in this disease but this does not mean that LCH is a malignancy. Many reactive diseases, for example lymphomatoid papulosis, have been shown to be clonal. Although of major interest, such studies have thus not altered our management of patients with this disease, nor have they identified the disease as malignant.

Pathology. The histological picture of LCH depends on the age of the lesion biopsied and the organ involved. The pathology of LCH was reviewed by the Histiocyte Society in 1987 [22], who recommended three levels of diagnostic confidence. A presumptive diagnosis is made when the histological appearance of the biopsy is consistent with the diagnosis of LCH. Diagnostic confidence increases if marker studies are performed and lesional cells are found to be positive for S100 protein, peanut agglutinin or α-D-mannosidase. If lesional cells are found to express the CD1 complex or to exhibit Birbeck granules on electron microscopy (Fig. 55.3), this constitutes a definitive diagnosis.

The characteristic histological appearance of LCH in the skin is of an upper dermal and junctional accumulation of large histiocytic cells with homogeneous pink cytoplasm. These cells have

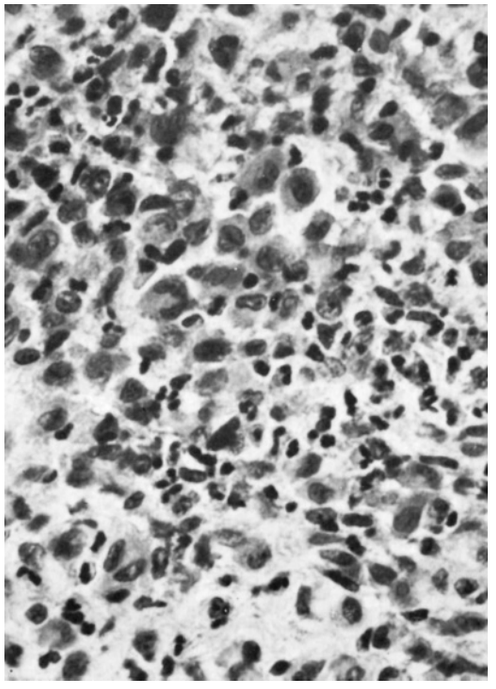

Fig. 55.4 Langerhans' cell histiocytosis cells in the dermis intermingled with polymorphs and eosinophils (H&E × 250). (Courtesy of Professor E. Wilson Jones, St John's Dermatology Centre, London, UK.)

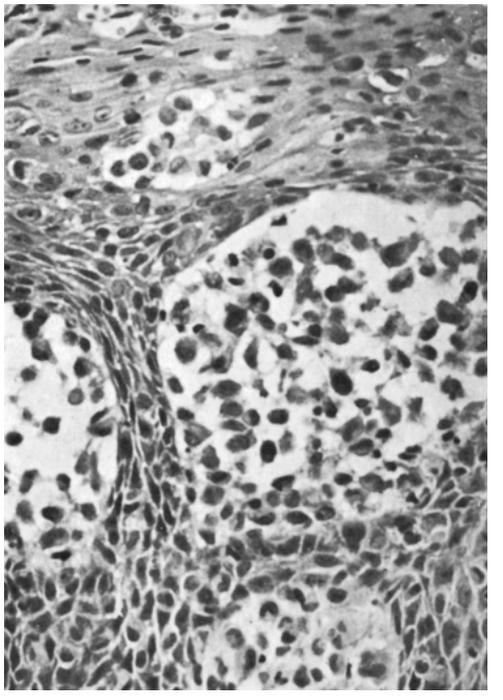

Fig. 55.5 Langerhans' cell histiocytosis (LCH). Details of a papillary tip containing LCH cells, with a small intraepidermal abscess overlying it (H&E × 250). (Courtesy of Professor E. Wilson Jones, St John's Dermatology Centre, London, UK.)

lobulated, bean-shaped or boat-shaped nuclei (Fig. 55.4). There is a variable lymphocytic infiltrate, deep to the aggregates of LCH cells. In some patients with LCH, large numbers of γ/δ T cells have been identified in the lymphocytic infiltrate [23]. Eosinophils are present in variable numbers, being rare in the more fulminant forms of LCH but present in high numbers in the less aggressive spectrum of LCH. Within the epidermis, LCH cells are often observed either singly or forming Pautrier-like microabscesses (Fig. 55.5).

With time, the histological picture changes, with fewer LCH cells present and the emergence of a more xanthomatous pattern, which is eventually followed by fibrosis. Several studies have shown no correlation between histology and extent of disease, morbidity or mortality [24–27].

In one clinical variant of LCH, described by Hashimoto and Pritzker [28], in which the disease is restricted to the skin and regresses spontaneously over a period of several months, the pathology in the skin is sufficiently different to warrant separate description. In this variant, the infiltrate is deep within the dermis, with sparing of papillary dermis and epidermis. Lesional cells are large histiocytic cells with copious glassy eosinophilic cytoplasm. Multinucleate giant cells are often observed. Up to 25% of these histiocytes contain Birbeck granules.

Immunocytochemistry. Immunohistochemical studies have demonstrated that LCH cells show many of the characteristics of the epidermal Langerhans' cell, particularly in its activated state (see Table 55.1) [29–31]. The labelling pattern with certain markers (C3b and C3bi receptors, CDW14, Ki-M1 and Ki-M6) has been shown to be variable. This does not correlate with the clinical course of the disease but probably reflects different phenotypic 'ages' of the Langerhans' cell [30].

Table 55.2 Diagnostic markers for Langerhans' cell histiocytosis (LCH) cell.

Marker	Tissue needed
S100	Paraffin-embedded
Peanut agglutinin	Paraffin-embedded
Placental alkaline phosphatase	Paraffin-embedded
α-D-Mannosidase	Fresh
CD1a	Fresh-frozen (paraffin-embedded with 010 monoclonal antibody)
Birbeck granules	Electron microscopy prepared

Three markers have now been shown to be expressed by LCH cells but not by normal epidermal Langerhans' cells. These are peanut agglutinin, an epitope shared with IFN-γ [32,33] and placental alkaline phosphatase [34]. Placental alkaline phosphatase is negative in normal Langerhans' cells and is not observed in reactive dermatoses where Langerhans' cells are present in the dermal infiltrate. However, *in vitro* studies have shown that placental alkaline phosphatase expression is an early and transient activation marker of Langerhans' cells [35]. These observations are of particular interest, as they show that LCH cells are not merely reactive Langerhans' cells but are arrested at a particular stage of their ontogeny.

Immunohistochemistry is important in confirming the diagnosis of LCH. For retrospective studies where only formalin-fixed and paraffin-embedded tissue is available (Table 55.2), three

markers are of value: S100 protein, peanut agglutinin and placental alkaline phosphatase. S100 protein staining is a consistent feature of LCH cells but is also present in normal Langerhans' cells and a variety of other skin cells and structures, including nerve tissue, melanocytes and naevus cells. In a study by Rowden *et al.* [36], the histiocytic cells and giant cells in juvenile xanthogranuloma, necrobiotic xanthogranuloma, papular xanthoma, eruptive histiocytoma and reticulohistiocytosis were all negative for S100 protein, but all LCH specimens were positive.

Peanut agglutinin shows characteristic labelling of LCH cells, with paranuclear and cell-surface deposition of reaction products. Peanut agglutinin labels other cell types in the same way, including interdigitating reticulum cells [37], but normal Langerhans' cells and other histiocytic cells show diffuse cytoplasmic labelling with this marker [32].

Placental alkaline phosphatase is normally found in placental tissue and in the female reproductive tract. It is also expressed in malignancies of the ovary and testis. In normal skin, placental alkaline phosphatase is negative and cells expressing this enzyme are absent in reactive disorders. It is perhaps the most informative marker that can be used in archival LCH material, where only the LCH cells express this enzyme [34].

Fascin is a 55-kDa actin bundling protein that is highly selective for dendritic cells of lymphoid tissue and blood. It is involved in the formation of dendritic processes in maturing epidermal Langerhans' cells and can be used to differentiate LCH from other histiocytoses. In a study of 34 samples of LCH from skin, bone, lymph node, thyroid, orbit and extradural cranial tissue, all samples stained positive for fascin, CD1a and S100. Normal epidermal Langerhans' cells were consistently negative for fascin [38].

To establish a definitive diagnosis by the criteria of the Histiocyte Society, the involved tissue must be examined for CD1a staining or for the presence of Birbeck granules (which requires fixation and processing for electron microscopy). Staining with monoclonal anti-CD1a antibodies may be carried out in paraffin-embedded tissue [39].

Incidence. The incidence of LCH is unknown because of the heterogeneity of clinical expression of the disease. In many patients, the disease is undiagnosed, with mild skin involvement being attributed to seborrhoeic dermatitis and isolated bone disease remaining undetected. Also, the diverse clinical presentation of the disease means that patients may be under the care of orthopaedic surgeons, ear, nose and throat surgeons, paediatricians, paediatric oncologists or dermatologists. In the UK, 15–20 cases are reported to the UK Children's Cancer Study Group Register each year. These represent only the more severe paediatric cases, and the real incidence in the general population is more likely to be at least four to six per million, with 50–70 new cases presenting annually.

Clinical features. LCH can affect many different organs and may cause fever, malaise and, in children, failure to thrive.

Of 58 patients with LCH seen at the Hospital for Sick Children, London, over a 7-year period, 14 had single-system disease (13 bone and one skin) and 44 had multisystem disease, of whom 50% had vital organ dysfunction [40]. At the Children's Hospital in Philadelphia, 64 patients were seen over a 14-year period of whom 33 had single-organ involvement in bone (27 patients) or skin (six patients), 22 had multifocal single-organ disease affecting bone (17 patients) or soft non-osseous tissue (five patients), and nine patients had disseminated disease with dysfunction of liver or lungs [41].

Fig. 55.6 Langerhans' cell histiocytosis of the scalp and ear of a child showing the characteristic seborrhoeic dermatitis-like eruption.

In a large series of 124 patients [42], bone, lymph node and skin lesions were the most frequently seen, but 50% of patients showed liver disease and 23% lung disease with frequent haematological changes.

Skin. The most characteristic presentation is with scalp involvement. The scalp is erythematous with greasy scales, looking very like seborrhoeic dermatitis (Fig. 55.6). On the trunk, the lesions are discrete, yellow-brown, scaly papules, often showing areas of purpura (Figs 55.7 & 55.8). Lesions may become nodular and crusted or eroded. Ulceration of the flexures, groin or perianal or vulval region is a common presentation in adult patients (Fig. 55.9).

In the Hashimoto–Pritzker variant of LCH, the eruption starts in the neonatal period with nodular lesions that resemble healing chickenpox. The eruption may involve any skin surface, including palms and soles, and is self-limiting over a few weeks. In a report of four cases of Hashimoto–Pritzker LCH, follow-up showed recurrence of disease in two children, with cutaneous relapse in one at 3 months of age and bony relapse requiring systemic therapy at 6 months in the other child. Follow-up of such children is therefore necessary [43].

Fig. 55.7 Langerhans' cell histiocytosis in a child. Scaly maculopapular eruption on the back with mild purpura.

Fig. 55.9 Langerhans' cell histiocytosis in an adult showing a characteristic erosive lesion in the groin.

Fig. 55.8 Langerhans' cell histiocytosis in an infant showing typical eruption on the abdomen and groins mimicking seborrhoeic dermatitis and napkin eruption.

In patients with peripheral lymph node involvement, chronic draining sinuses may develop over involved sites (Fig. 55.10).

Juvenile xanthogranuloma has been associated with LCH. In a report of three children with multisystem LCH, juvenile xanthogranulomas appeared 3–6 years after the initial presentation with LCH [44]. It is possible that the juvenile xanthogranulomas developed as a reaction to the inflammatory reaction in LCH.

Fig. 55.10 Langerhans' cell histiocytosis in an adult with multisystem involvement. Scarring is present at sites of previous fistulae from underlying involved lymph nodes. Active skin lesions are scattered over the chest. These are scaly, erythematous, maculopapular lesions. Marked striae are the result of high-dose steroids used in therapy.

Fig. 55.11 Langerhans' cell histiocytosis: involvement of nails in an adult patient showing nail-fold destruction. (Courtesy of Dr D.A.R. de Berker, Bristol Royal Infirmary, Bristol, UK.)

Fig. 55.12 Radiograph of the jaw of an adult with oral involvement in Langerhans' cell histiocytosis. The alveolar bone shows marked reabsorption and the teeth have become detached and appear to be floating.

Nails. Nail involvement in LCH is rare. Changes include paronychia, nail fold destruction, onycholysis and subungual expansion with nail plate loss (Fig. 55.11) [45].

Ears. Disease of the ears is common [46], with involvement of external and middle ear and mastoid. This may present with persistent aural discharge due to skin involvement or polypoid involvement of the external auditory canal. If the middle ear or mastoid is involved, deafness is common.

Oral. The commonest presentation in the mouth is with periodontal involvement, affecting particularly the lower molar areas [47]. There may be destruction of the alveolar ridge with infiltration of the gums with LCH cells resulting in the teeth floating free from their sockets (Fig. 55.12). Premature eruption of the teeth may be a presenting sign [48]. Mandible involvement is frequently observed in adults, with a palpable tender mass over the affected area. This is usually associated with oral involvement.

Bone marrow. Involvement may be occult or there may be pancytopenia. When bone marrow involvement is severe, splenomegaly is generally present. In bone marrow aspirates, LCH cells are often sparse and staining for CD1a is essential for assessment [49].

Lungs. Primary pulmonary LCH is rare and is usually seen in young or middle-aged adults. In adult patients, smoking is invariably associated with lung involvement, and in any adult smoker with LCH the lung should be examined for possible involvement. Computed tomography is usually more informative in such patients as it identifies lung disease at an earlier stage than chest X-ray. Abnormalities consist of nodular opacities representing aggregates of LCH cells which progressively show cystic central change, and cystic changes. Diagnosis is established by lung biopsy or bronchial lavage, as LCH of the lungs may be impossible to differentiate from other chronic interstitial lung diseases on clinical and radiographic findings.

Pulmonary signs and symptoms are non-specific and are rarely observed until there is frank dysfunction, with dyspnoea, tachypnoea and subcostal recession. Pain and sudden dyspnoea may indicate a pneumothorax due to rupture of a peripheral bulla. Pneumothoraces are common [50], but up to 23% may be asymptomatic.

Patients with multisystem LCH and lung involvement often have progressive lung disease and progressive dysfunction which may result in respiratory failure. Isolated pulmonary LCH may respond to cessation of smoking with regression of the nodular lesions. It is important in assessing patients with lung LCH to perform sequential lung function tests and to start treatment as soon as any fall in lung function is noted. Studies have demonstrated that lung function and gas exchange parameters correlate to cystic change but not to nodular lesions, which suggests that treatment should be directed to early nodular lesions before cystic changes lead to irreversible reduction in lung function [51].

Gastrointestinal tract. Liver involvement is very common as part of multisystem LCH, producing hepatomegaly or ascites. Cholestatic jaundice may be a late feature due to fibrotic obstruction of the biliary tree. Diarrhoea may be the result of infiltration of the lamina propria by LCH cells or may be caused by abnormal bile acid metabolism or infection within the gastrointestinal tract. Digestive tract involvement in LCH is very rare but in children even mild involvement of the gastrointestinal tract, which produces no overt symptoms of diarrhoea, may still cause failure to thrive due to mild malabsorption [52].

Central nervous system. Diabetes insipidus may be the presenting feature of LCH. Other focal lesions may occur, commonly affecting the cerebellum, temporal lobe and occipital lobe. Intracerebral disease is more frequently seen with bone involvement

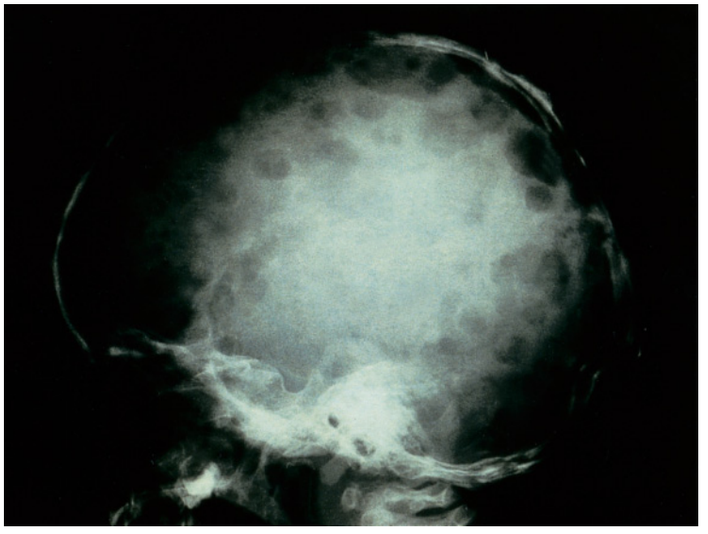

Fig. 55.13 Multiple osteolytic lesions in the skull of an infant with Langerhans' cell histiocytosis.

of the skull. A cerebellar syndrome with ataxia, dysarthria and choreoathetoid movements may be a late sequel of LCH. This is caused by progressive cerebellar atrophy. Biopsies of the cerebellum have so far failed to show infiltration with LCH cells only gliosis [53].

Bone. Solitary bone involvement with LCH is common but occasionally goes undiagnosed. The commonest sites are the bones of the calvarium, but femur, scapula, rib, mandible and vertebra are often affected [54]. Lesions may be asymptomatic or may present with swelling over the affected bone, pain or pathological fracture. Radiography is better than radionucleotide studies in detecting bone involvement in LCH [55]. Lesions appear as osteolytic areas that are sharply demarcated and may have a scalloped border (Fig. 55.13) [56]. When vertebrae are affected, the structural bone is lost and the vertebra may collapse. Spinal cord compression resulting from vertebral collapse has been reported with LCH [24]. Healing of bone lesions is usually seen as peripheral sclerosis of the lytic lesion. Radiographic changes may still be evident for long periods after the disease has been adequately treated or has undergone spontaneous remission.

Endocrine system. Diabetes insipidus is the commonest endocrine problem, the incidence in children with multisystem disease ranging from 22 to 50% [57–59]. Diabetes insipidus may result from pituitary involvement or hypothalamic involvement. Magnetic resonance imaging may show thickening of the pituitary stalk with recent-onset disease. Patients with multisystem disease and those with craniofacial bone involvement carry a significantly increased risk of developing diabetes insipidus [60]. Anterior pituitary dysfunction is always accompanied by diabetes insipidus and may develop slowly after the initial diagnosis of diabetes insipidus is made [61]. In the author's experience, men with LCH-related diabetes insipidus often develop hypoandrogenism and require testosterone replacement.

Short stature in children with LCH has been associated with growth hormone deficiency, which may be secondary to hypothalamic involvement [62]. Some of these children respond to treatment with growth hormone [58,62]. Hypogonadism with delayed puberty and thyroid involvement have also been reported [63,64].

Prognosis. Three important, independent, prognostic indices in LCH are the age of the patient, the extent of the disease and the presence of vital organ failure.

Children under the age of 2 years with multisystem disease have a much poorer prognosis than older children. In a study by Komp *et al.* [65], the mortality in children under the age of 2 years with disseminated LCH was 37% compared with 16% in the group aged over 2 years.

Lahey [66] found a positive relationship between increased mortality rate and widespread organ involvement, but Greenberger *et al.* [67] found that organ failure was a better prognostic indicator than organ involvement. Organ failure relates to lung, liver and bone marrow in children and lung and liver in adults. Studies have also suggested that survival in children is better if they respond to treatment in the first 6 weeks of therapy [68]. Both Lahey and Greenberger *et al.* [66,67] looked at prognosis in relation to mortality, but since LCH is a reactive rather than a malignant disease, prognosis should consider morbidity as well as mortality. The long-term sequelae of LCH can be related to both disease and treatment. Morbidity caused by the disease itself may be minor (e.g. skin lesions) or there may be major consequences if organs such as the liver, lungs and brain are damaged. Treatment with cytotoxic reagents may result in sterility and may cause leukaemias and other secondary malignancies. In a long-term follow-up of children with LCH over a 16-year period, only 33% of children with multisystem disease were alive and healthy without sequelae; 15% had diabetes insipidus, 10% had CNS complications and 11% had late-stage pulmonary disease [69].

Diagnosis. Pathological diagnosis is most important as many diseases can clinically mimic LCH, and S100 staining or even CD1a staining is insufficient to establish a diagnosis of LCH if the histological picture is not consistent. The differential diagnosis in cutaneous LCH includes seborrhoeic dermatitis, juvenile xanthogranuloma, xanthoma disseminatum and benign cephalic histiocytosis. In disseminated LCH there may be diagnostic problems with familial haemophagocytic lymphohistiocytosis, sinus histiocytosis with massive lymphadenopathy (SHML) and virus-associated haemophagocytic syndrome. Histological examination of tissue biopsy with specific marker studies is usually sufficient to differentiate LCH from these other conditions.

Investigation. LCH may present in various organs and it is important to investigate the patient for other sites of disease so that treatment can be properly planned. Patients may present with skin, bone, lymph node, pituitary, lung or liver disease as primary site but need to be fully investigated before a diagnosis of single-system disease can be made. Table 55.3 details investigations that should be conducted on all suspected cases and indication for more specialized investigations in some patients.

Table 55.3 Investigating the patient with LCH.

Investigations on all patients
Full blood count and ESR
Electrolytes, urea, liver function tests and CRP
Skeletal survey
Chest X-ray
Tests indicated in some patients
MRI of brain: lytic skull lesions, diabetes insipidus, symptoms suggestive of CNS involvement
Water deprivation test: polyuria, polydipsia
High resolution CT chest: adult smoker, respiratory symptoms
Lung function tests: lung involvement
Abdominal ultrasound, liver biopsy: abnormal liver function tests

In some patients with LCH, ESR and CRP are raised and these prove to be valuable markers of disease activity and response to treatment in these patients. A recent study has advocated the use of whole-body MRI to assess bony and extraosseous LCH, showing that it is superior to conventional X-rays and bone scintigraphy [70].

Treatment. Treatment depends on the extent and severity of disease. Patients with single-system bone or skin disease have a good prognosis and often require no or only limited treatment. In one study, McLelland *et al.* [40] showed that in 14 patients with single-system disease, eight required no treatment. In isolated bone disease, curettage to establish the diagnosis may be curative. In weight-bearing bones that are symptomatic, intralesional steroid injections are effective [9]. If vital structures are compromised, such as the optic nerve or spinal cord, low-dose radiotherapy (700–1000 cGy) can be given.

In single-system skin disease, topical treatment with 20% nitrogen mustard is effective [71]. Psoralen and UVA (PUVA) therapy may be useful for those patients who do not tolerate topical nitrogen mustard or fail to respond adequately. Reports have shown a good response of isolated skin disease to thalidomide [72], but poor responses in patients with multisystem disease [73].

Single-system bone disease may respond to simple curettage or intralesional steroid injections. Radiotherapy has been used in the past but is now generally restricted to use in single vertebral lesion or if there is a risk of pathological fracture in the greater trochanter [74].

In multisystem LCH where there is evidence of organ dysfunction, systemic chemotherapy is indicated. Treatment in children should initially be with prednisolone 2 mg/kg for a short course of about 2 months, with the dose adjusted to disease response [40]. Adults tend not to respond to systemic steroids and often suffer severe side effects from their use. In disease that is either unresponsive, aggressive or in adults, a number of chemotherapeutic agents have been tried, mainly the vinca alkaloids, especially vinblastine, but also methotrexate and 6-mercaptopurine in combination with prednisolone. Response rates of about 50–70% can be achieved using these agents. Evidence suggests that the epipodophyllotoxin etoposide as a single drug is better than other drugs tested [75], and ciclosporin and IFN-α have also been beneficial [76]. 2-Chlorodeoxyadenosine, a purine analogue with antiproliferative effects on histiocytes and lymphocytes, has been used in recurrent or high-risk LCH. Treatment is with 5–7 mg/m^2 daily for 5 days every 21–28 days. In a study of six children with LCH, five patients remained in clinical remission with a follow-up of 15 months [77]. 2-Chlorodeoxyadenosine also seems to be of particular value for patients with lung involvement but should ideally be used when patients have nodular involvement rather than late-stage cystic change [78].

Class IIa histiocytosis: histiocytoses involving cells of the dermal dendrocyte lineage

Class IIa histiocytoses are non-malignant diseases in which mononuclear phagocytic cells with the dermal dendrocyte phenotype

accumulate in various tissues where they may or may not cause symptoms.

In many of these diseases the histological features are of a xanthogranulomatous reaction in the skin. This pattern is seen in juvenile xanthogranuloma, benign cephalic histiocytosis, generalized eruptive histiocytosis, xanthoma disseminatum and necrobiotic xanthogranuloma. In some, such as progressive nodular histiocytosis, the cells have a more spindle-shaped appearance in a storiform pattern, particularly as the lesions progress.

Histopathological studies have suggested that benign cephalic histiocytosis represents a clinical variant of a xanthogranulomatous reaction rather than being a distinct entity in its own right. In one study [1], biopsies from benign cephalic histiocytosis, generalized eruptive histiocytosis, papular xanthoma and juvenile xanthogranuloma were examined in an observer blinded fashion. In all specimens examined, three distinct patterns of histiocyte proliferation were observed—papillary dermal, lichenoid and diffuse. Benign cephalic histiocytosis, generalized eruptive histiocytosis and early non-xanthomatous juvenile xanthogranuloma could not be specifically differentiated on histopathological grounds. This study certainly suggests that benign cephalic histiocytosis may be a localized form of generalized eruptive histiocytosis or an aborted phase of juvenile xanthogranuloma. In a further study, sequential biopsies were taken from a patient with solitary giant xanthogranuloma and from a patient with benign cephalic histiocytosis. In both cases, early stages of the disease showed infiltration with histiocytes positive for Ki-M1p, HAM56 and factor XIIIa. This was followed by a polymorphic infiltrate of mononuclear and multinuclear histiocytes, which were CD68 positive. This study suggests that both entities are variants of a xanthogranulomatous reaction [2]. In one case report, a 2-year-old girl with clinical, histopathological and ultrastructural benign cephalic histiocytosis developed a varicella-zoster infection with evolution of her skin disease both clinically and histologically to juvenile xanthogranuloma [3]. In a further report of a child with generalized eruptive histiocytosis, where the diagnosis was made on clinical, histological and ultrastructural grounds, the disease progressed with the growth of yellowish confluent papules and the development of diabetes insipidus. At this stage the diagnosis was changed to xanthoma disseminatum [4].

The dermal dendrocytes involved in these diseases show a spectrum of maturation of the cells. In juvenile xanthogranuloma and benign cephalic histiocytosis, the cells are morphologically the most immature and the disease has the shortest life span. Generalized eruptive histiocytosis and xanthoma disseminatum show increasing maturation of the cells and at the other end of the spectrum, progressive nodular histiocytosis shows mature spindle shaped cells with no tendency to spontaneous remission of the disease [5].

Dermatofibroma

This benign, nodular, dermal lesion is discussed in Chapter 56.

Juvenile xanthogranuloma

Synonyms

- Naevoxanthoendothelioma
- Xanthoma multiplex
- Juvenile xanthoma
- Multiple eruptive xanthoma in infancy
- Congenital xanthoma tuberosum
- Xanthoma naeviforme
- Juvenile giant-cell granuloma

Definition. Juvenile xanthogranulomas are benign tumours of histiocytic cells that occur predominantly in infancy and early childhood and spontaneously regress.

Aetiology. The aetiology of juvenile xanthogranuloma is unknown. The tumours represent accumulations of differentiated histiocytes. These cells express the phenotype of the dermal dendrocyte, although it has been suggested that the cell of origin could be the plasmacytoid monocyte [1]. The appearance of giant cells and foamy lipid-laden histiocytes occurs late, and they are almost certainly secondary events, possibly in response to cytokine production by the lesional histiocyte. Serum lipid levels are normal. Conflicting reports have suggested that juvenile xanthogranuloma can be associated with cytomegalovirus infection. A study by Vasconcelos *et al.* [2] has demonstrated early and late cytomegalovirus antigens in some histiocytes in a case of oral juvenile xanthogranuloma.

Pathology. An established lesion shows a mixed cellular dermal infiltrate with histiocytes, lymphocytes, eosinophils and occasional neutrophils and plasma cells. This extends from the epidermis into the subcutaneous fat but epidermal involvement is rare. A typical feature is the presence of giant cells with a wreath-like arrangement of nuclei (Touton giant cells).

In very early lesions, only spindle-shaped fibrohistiocytic cells are seen. In older lesions, foamy lipid-laden histiocytes appear, and resolution is marked by gradual replacement by fibrous tissue. A spindle cell variant of juvenile xanthogranuloma has been described [3]. In deep juvenile xanthogranuloma the lesions tend to be more cellular with fewer Touton giant cells [4].

Immunocytochemical examination in most cases shows that lesional cells are positive for lysozyme, α_1-antichymotrypsin, CD68, Ki-MIP [5], fascin, factor XIIIa and may express HLA-DR and CD4, but are negative for S100 protein [6]. However, Tahan *et al.* [7] found a small population of S100 dendritic cells in juvenile

xanthogranuloma, which they felt were important in pathogenesis, and Kraus *et al.* [1] have shown reactivity to polyclonal S100 in six of eight specimens they examined. Cells are always CD1a negative.

At the ultrastructural level, the lesional histiocytes do not exhibit Birbeck granules but do show complex interdigitation of the cytoplasmic membrane [8].

Incidence. Half of the cases of juvenile xanthogranuloma have been reported in infants less than 6 months of age. Lesions may occur in children over 3 years of age and cases have been reported in adults [9]. There is no sex association and no familial tendency. Juvenile xanthogranuloma is 10 times more frequent in white than in black people.

Clinical features. The characteristic clinical features of juvenile xanthogranuloma are its onset in infancy, sudden appearance of lesions and spontaneous regression. Most patients develop single lesions, but in others several lesions may develop and occasionally hundreds of lesions may be present. In one case report, a generalized lichenoid variant of xanthogranuloma was described. The eruption consisted of small, flat, shiny papules, which resolved spontaneously [10]. The lesions most commonly occur on the upper part of the body, particularly affecting the face, neck, scalp and upper trunk (Fig. 55.14). Lesions may occur in the oral mucosa with or without skin involvement [11]. They generally start as reddish-yellow papules, which may enlarge up to 1 cm in diameter and evolve into yellow–brown plaques and macules. The lesions are firm and rubbery and can develop surface telangiectasia. Larger lesions, up to 2–3 cm in size, have been reported [12] and ulceration and satellite lesions have been described [13]. Deep dermal lesions may occur which may infiltrate skeletal muscle. Such lesions may exhibit a more aggressive biological behaviour [4]. Resolution occurs spontaneously over a period of months or years, leaving small atrophic scars. There are no subjective symptoms.

Visceral involvement may occur in lung, liver, spleen, testes [14], pericardium, gastrointestinal tract, kidney [15,16], deeper soft tissues [17] and central nervous system. Eye involvement occurs in up to 10% of cases [18] and may lead to secondary glaucoma or may be mistaken for a malignant tumour, such as melanoma or neuroblastoma. The iris is most commonly affected, producing haemorrhage into the anterior chamber, which may result in secondary glaucoma. Infiltration of the orbit, iris, ciliary body and episclera may occur, with unilateral glaucoma, recurrent hyphaema, uveitis, heterochromia, iritis or severe and sudden proptosis [19]. Eye lesions may precede the appearance of skin lesions. Central nervous system involvement is rare but several reports have been published. Lesions may present as isolated or multiple tumours of the brain involving the cortex and cerebellum [20,21], and extensive involvement of cranial nerves has been reported [22]. Central nervous system involvement may occur with or without cutaneous involvement.

Juvenile xanthogranuloma has been associated with neurofibromatosis [23], Niemann–Pick disease [24], myelogenous leukaemia [25], lymphocytic leukaemia [26], urticaria pigmentosa [27] and LCH [28].

Fig. 55.14 Juvenile xanthogranuloma in an infant with typical lesions on the back.

Prognosis. Juvenile xanthogranuloma is a self-healing tumour and lesions generally resolve in 1–5 years. Disseminated neonatal juvenile xanthogranuloma may be more aggressive and fatalities in this group have been reported [29]. In addition, a recent case report describes juvenile xanthogranuloma diffusely involved the brain in an 11-year-old boy. Initial partial response was achieved with 2-cholorodeoxyadenosine but the patient then failed to respond to further chemotherapy, with dissemination of the disease to the peritoneum and bone marrow. Biopsy at this stage showed pleomorphic histiocytes with tetraploidy suggesting malignant transformation. Despite continued chemotherapy the patient died [30].

Diagnosis. Juvenile xanthogranuloma can be differentiated from xanthomas by the distribution of the lesions and the absence of lipid abnormalities. Papular urticaria can be distinguished by the symptomatic nature of the lesions and histology. The major difficulty in clinical diagnosis is with the nodular forms of LCH. Histology and immunocytochemistry will easily differentiate the two disorders.

Treatment. No treatment is necessary for the cutaneous lesions as they are self-healing. Where treatment is indicated in ocular, upper airways and central nervous system lesions, surgery or radiotherapy gives good results [31,32]. In patients with multiple cutaneous juvenile xanthogranulomas, carbon dioxide laser has been successfully used [33]. In patients with symptomatic visceral involvement, systemic steroids [16] with or without chemotherapy with vinca alkaloids have been used successfully [34]. Patients

with aggressive disease with vital organ involvement, that is lungs, liver and bone marrow, are generally treated with multiagent chemotherapy, including cytarabine, methotrexate, vincristine and prednisolone [29].

Benign cephalic histiocytosis

Synonym
- Papular histiocytosis of the head

This is a rare, self-limiting histiocytosis that typically starts in early childhood [1]. As stated before, many now feel that benign cephalic histiocytosis represents a clinical variant of juvenile xanthogranuloma [2] but the clinical features of the disease are distinct enough to maintain a separate nomenclature. Erythematous papules, nodules and macules develop on the cheeks and spread to the forehead, earlobes and neck. The lesions, which are asymptomatic, gradually become reddish-brown and may spread onto the trunk, upper limbs and rarely the buttocks. Mucous membrane involvement has not been described.

No sex predisposition has been reported. In a review of the literature, the average age of onset was 15 months (range 2 to 66 months). The disease is self-limiting, and in 39 cases the mean age at resolution was 50 months in 10 patients where this detail was recorded [3]. In one case report, a 5-year-old girl developed diabetes insipidus 1 year after presenting with typical benign cephalic histiocytosis. Imaging demonstrated infiltration of the pituitary stalk [4]. Histologically, the epidermis is thinned over a well-circumscribed histiocytic infiltrate in the superficial and mid-dermis. Histiocytic cells have oval to reniform nuclei and occasionally may be pleomorphic. In older lesions, a few giant cells may be present. The cells are S100 and CD1a negative [5] but stain positively for OKM1, Leu-3 and factor XIIIa [3]. Electron microscopy shows that 5–30% of the infiltrating cells have cytoplasm rich in comma-shaped bodies and coated vesicles [3]. Dense bodies may be present and worm-like bodies have been described [6]. Since the condition is self-limiting, no therapy is indicated.

Erdheim–Chester disease

Synonym
- Uber lipoidgranulomatose

This is a rare lipoid granulomatosis characterized by infiltration of viscera, bones, retroperitoneum and skin. It was first described by William Chester while working in the laboratory of Jakob Erdheim in 1930 [1] and the eponym was first used by Jaffe in 1972 [2].

Veyssier-Belot *et al.* [3] reviewed the literature on Erdheim–Chester disease in a comprehensive study of 59 patients. The age range was 7–84 years with a mean of 53 ± 14 years, and there was a male to female ratio of 33 : 26. The most common presentation is with chronic mild bone pain, particularly of the lower limbs. Radiography shows symmetrical sclerosis, typically affecting the long bones, with involvement of the diaphyseal and metaphyseal regions; 86% of reported cases have involvement of the long bones [4], with the distal femur, proximal tibia and fibula being most commonly affected [5]. Up to 30% of patients show lytic lesions of flat bones, which can cause problems in differentiating this disease from LCH.

Half of patients have extraosseous involvement of the retroperitoneal space, lungs, heart, kidneys, liver, pituitary, central nervous system, orbit and skin. Approximately 30% of patients have exophthalmos (Fig. 55.15), diabetes insipidus or retroperitoneal involvement. Retroperitoneal disease is often asymptomatic and may develop over many years. It may present with dysuria, abdominal pain, obstructive renal damage or renal artery stenosis [6]. Adrenal infiltration may occur and in a study of 22 patients with Erdheim–Chester disease, 31.8% showed CT evidence of adrenal involvement and one patient developed clinical adrenal insufficiency [7].

Fig. 55.15 Erdheim–Chester disease: a 47-year-old man presented with diplopia and unsteady gait. Clinically he had exophthalmos and MRI of brain showed retro-orbital masses and lesions in the mid-brain and temporal lobes. CT scan of the abdomen showed thickening of perirenal fascia and hydronephrosis demonstrating extensive disease in the retroperitoneal space.

Skin involvement is seen in about 20% of patients, usually presenting with xanthoma-like lesions, usually on the eyelids but occasionally on the trunk and submammary area. Two patients have been reported with cutaneous masses. Lung disease is seen in 35% of patients, with accumulation of histiocytes and fibrosis in a perilymphatic and subpleural pattern. It is generally asymptomatic and found on chest X-ray with diffuse interstitial fibrosis or infiltration. Advanced pulmonary involvement is associated with extensive fibrosis, which may result in cardiopulmonary failure. Prognosis tends to be poor despite treatment [8].

Cardiovascular involvement with Erdheim–Chester disease is relatively common. In a review of 72 patients with cardiovascular involvement, 55.6% had periaortic fibrosis, 44.4% had pericardial involvement and 30.6% had myocardial involvement. Six patients had a right atrial tumour and six had symptomatic valvular heart disease; 26.4% developed heart failure and 11 patients died of cardiovascular complications [9].

Central nervous system involvement is seen in 15% of patients, presenting with ataxia, paraparesis, hemiparesis or change in mental state. Imaging has shown thickening of the dura, with infiltration extending into the cerebellum. More rarely, intracerebral masses have been described. In a review of 66 patients with Erdheim–Chester disease and neurological involvement, cerebellar and pyramidal syndromes were the most common clinical manifestation, affecting 41% and 45% respectively. Seizures, headache, neuropsychiatric and cognitive problems, sensory disturbances and cranial nerve paralysis have been reported. Neurological involvement resulted in severe functional handicap in almost all of the reported patients and resulted in death in six of them. Three patterns of involvement have been demonstrated by imaging: infiltrative in 44% with widespread nodules or masses, meningeal in 37% with thickening of the dura or meningioma-like tumours, and composite in 19% with elements of both [10]. A case of slowly progressive cerebellar syndrome, similar to that seen in LCH, has been reported in a 50-year-old patient with Erdheim–Chester disease associated with unilateral exophthalmos, secondary hypogonadism and skin lesions [11].

Histological examination shows a xanthogranulomatous infiltration by lipid-laden histiocytes within a mesh and surrounded by fibrosis. Touton giant cells and eosinophils may be prominent. Cells are positive for CD68 and factor XIIIa [6] but negative for CD1a and S100 [12]. In one study of a 35-year-old woman with Erdheim–Chester disease, clonality studies based on the *HUMARA* assay in paraffin-embedded tissue showed only random distribution of allele activation and thus no evidence of clonality [13]. In a further male patient, balanced chromosomal translocation t(12; 15; 20)(q11; q24; p13.3) was identified amongst other chromosomal abnormalities, suggesting that Erdheim–Chester disease could be a clonal neoplastic disorder [14]. Further studies are needed to confirm this.

A variety of treatments have been used in Erdheim–Chester disease, including IFN-α [15,16], corticosteroids, radiotherapy, vinblastine, vincristine, cyclophosphamide [3] and 2-chlorodeoxyadenosine [17], with variable responses. There is no clear consensus as to the best therapeutic regimen. Overall mortality is 57%, with death resulting from pulmonary, cardiac or renal failure [3].

Fat-storing hamartoma of dermal dendrocytes

A single case report has described this entity [1]. The patient was a 30-year-old man who had a very large, circumscribed, red-brown plaque in the lumbosacral area. The plaque was composed of firm papules and nodules and was asymptomatic. The lesion had been present since birth and had slowly grown since that time.

Histology showed a slightly acanthotic epidermis and a Grenz zone, below which was a dense infiltrate of foamy histiocytes, which extended deep into the dermis. Occasional Touton giant cells were present. Lesional cells stained for factor XIIIa and vimentin and 40% of the cells labelled with Mac-387, a monoclonal antibody directed against monocyte-derived macrophages. S100 and CD1a staining were negative. Electron microscopy showed large histiocytic cells with convoluted nuclei filled with lipid droplets.

Generalized eruptive histiocytoma

This is a rare cutaneous histiocytosis that mainly affects adults [1], although children with the disease have been reported [2,3]. Clinically, the disease presents as multiple, symmetrical papules that occur on the face, trunk and proximal extremities. The papules are skin coloured, brownish or blue–red and tend to come up in crops, although they are not grouped. The number of lesions is variable but may reach hundreds. Mucosal lesions are rare. The lesions are asymptomatic and resolve spontaneously to leave a macular area of hyperpigmentation.

Histology shows a proliferation of monomorphic histiocytic cells in the upper and mid dermis. No giant cells or foam cells are present. Scattered lymphocytes may be present. Ultrastructural studies have shown that the histiocytic cells lack Birbeck granules but do have cytoplasmic laminated bodies [4]. These bodies are often clustered in the cytoplasm of the cells and each measure about 1.5 μm. They are not restricted to generalized histiocytoma but have been reported in congenital self-healing histiocytosis [5].

In one case report of a 4-year-old boy with generalized eruptive histiocytoma, diagnosed using clinical, histological and ultrastructural studies, the patient subsequently developed a new eruption of yellowish confluent papules with associated diabetes insipidus. Histology of the lesions and ultrastructure confirmed the diagnosis of xanthoma disseminatum. The authors suggest that generalized eruptive histiocytoma and xanthoma disseminatum are variants of a continuous spectrum of histiocytoses [3].

The disease is generally self-limiting and often does not require treatment. PUVA has been shown to be an effective treatment in one patient with widespread disease [6].

Papular xanthoma

This is a rare histiocytic disorder that was first described in adults [1] and subsequently reported in children [2]. Whether it represents a separate clinicopathological entity or a variant of other xanthogranulomatous conditions is open to debate. Clinically it

can resemble juvenile xanthogranuloma but has not been associated with systemic involvement or café-au-lait spots, and may resemble xanthoma disseminatum but papules do not coalesce and there is no predilection for flexures.

Clinically, papular xanthoma is characterized by 2–15 mm yellow or reddish-yellow papules affecting both skin and mucous membranes. The back and head are most commonly affected. There are marked clinical differences between papular xanthoma occurring in adults and children. Mucous membranes are affected in adults but this has not been reported in children. In adults progressive disease has been reported [3] but in children spontaneous resolution is the norm, with involution starting after weeks or months and being complete in 1–5 years, often leaving anetoderma-like scarring [4].

Histologically, there is an upper- and mid-dermal infiltrate of foamy histiocytes and giant cells. Few inflammatory cells are present. Histiocytic cells are positive for CD68 and factor XIIIa and negative for S100 and CD1a [2,4]. More recent studies, however, have shown that the foamy cells in this disease are factor XIIIa negative [5,6]. In such a rare condition, further studies are needed to confirm the dermal dendrocyte origin of lesional cells. Electron microscopy shows similar changes to those seen in mature juvenile xanthogranuloma, with myeloid bodies filling the cytoplasm of the histiocytes with associated lysosomal inclusions, laminate bodies and lipid droplets.

No treatment is needed in children while none has been shown to be effective in adults.

Progressive nodular histiocytosis

Synonyms
- Progressive nodular histiocytoma
- Spindle cell xanthogranuloma

This is a rare histiocytosis first described by Taunton *et al.* [1] in 1978. The eruption consists of two different types of lesions, superficial papules and deep nodules, both of which may number into hundreds [2,3]. Papules are 2–10 mm and yellow–orange (Fig. 55.16). Nodules are 1–5 cm in diameter and may be skin coloured or reddish-orange. Distribution is random with no predilection for the flexures. Lesions may occur in the oral cavity, larynx and conjunctival mucosa.

Over the years new lesions may develop and although patients remain in good general health, the eruption may be very disfiguring causing a marked reduction in quality of life.
