Toxic epidermal necrolysis [1–10]

SJS should be differentiated from TEN, in which typically sheet-like erosions involve more than 30% of the body surface with widespread purpuric macules or flat atypical target lesions, and in which there is severe involvement of conjunctival, corneal, irideal, buccal, labial and genital mucous membranes [1–3]. SJS may, however, evolve into TEN.

Clinically, TEN presents with a prodromal period with flu-like symptoms (malaise, fever, rhinitis and conjunctivitis), sometimes accompanied by difficulty in urination, which usually lasts 2–3 days; however, it may last from 1 day to 3 weeks before signs of skin involvement develop. The acute phase of TEN is characterized by persistent fever, severe mucous membrane involvement and generalized epidermal sloughing to leave large, raw, painful areas, and lasts from 8 to 12 days. There may be an initial 'burning' maculopapular, urticarial or erythema multiforme-like eruption. This may start on the face and on the upper part of the body and rapidly extends. Most frequently, the initial individual skin lesions form poorly defined macules with darker purpuric or blistering centres, progressively merging on the chin, upper parts of chest and back. Less frequently, the initial manifestation may be a more confluent erythema. Sometimes the lesions are predominantly in photoexposed areas.

There is rapid progression to areas of confluent erythema, often starting in the axillae and groins, followed by blistering and sloughing of large areas of skin (Fig. 76.6). Nikolsky's sign, the ability to extend the area of superficial sloughing by gentle lateral pressure on the surface of the skin at an apparently unaffected site, may be positive. Detachment of the full thickness of the epidermis at sites of pressure or trauma, such as the back, shoulders or buttocks, leaves a dark red oozing dermis. In other areas, the pale necrotic epidermis remains *in situ*, with a wrinkled appearance. Blisters on the palms and soles may remain intact. However, the entire skin surface may be involved, with up to 100% of the epidermis sloughing off. Only the hairy portion of the scalp is never affected. The process tends to occur in waves, over a 3- to 5-day period (sometimes a week), but involvement of the whole of the body surface occurs within 24 h in approximately 10% of cases.

Fig. 76.6 Toxic epidermal necrolysis showing dusky erythema and stripping off of necrotic epidermis.

Mucous membranes (particularly the buccal, and less commonly the conjunctival, genital, perianal, nasal, tracheal, bronchial, pharyngeal and oesophageal membranes) are involved in nearly all patients (85–95%). Widespread painful erosions cause crusted lips and increased salivation, and redness and soreness of the eyes is conspicuous, with photophobia. Mucous membrane lesions may precede the skin lesions by up to 3 days in one-third of cases [3]. Urethritis develops in up to two-thirds of patients, and may lead to urinary retention. Stomatitis and mucositis lead to impaired oral intake with consequent malnutrition and dehydration. Intestinal involvement has been documented [5]. Healing occurs by re-epithelialization; this may occur within a few days on the anterior thorax, but is slower on the back and at intertriginous areas. Most patients' skin lesions are completely healed in about 3–4 weeks, but mucosal lesions take longer and the glans penis may take up to 2 months to heal over.

Investigations. Approximately 50% of patients have a slight increase in serum aminotransferases, and approximately 10% have overt hepatitis. A rise in serum amylase is often present during the first few days, probably secondary to involvement of salivary glands. Anaemia is constant after a few days, and lymphopenia is usual, with a selective and transient depletion of $CD4^+$ T lymphocytes. Neutropenia is observed in approximately 30% of patients, and thrombocytopenia in 15%; eosinophilia is very unusual. Hypophosphataemia is nearly constant, and hyperglycaemia is frequent, as are increased urea and creatinine levels. Subclinical interstitial oedema is often noted on early chest X-rays.

Complications (Table 76.4). Acute complications are similar to those of extensive burns. The total daily fluid loss averages 3–4 L in adult patients with TEN affecting 50% of body surface area. It induces a reduction of intravascular volume and functional renal failure. If not corrected, hypovolaemia may lead to haemodynamic alterations and organic renal failure. Pneumonia or pneumonitis occurs in up to 30% of patients, contributed to by sloughing of the tracheobronchial tree [11]. Adult respiratory distress syndrome (ARDS) is one of the main complications. Anaemia or leukopenia, caused by selective depletion of $CD4^+$ helper T cells, is moderately common [9]. Oesophageal and intestinal erosions, with an endoscopic appearance reminiscent of ulcerative or pseudomembranous colitis, are recorded [12]; strictures may result. Disseminated intravascular coagulation is documented. Septicaemia, primarily the result of *Staphylococcus aureus* or *Pseudomonas* but on occasion caused by Gram-negative organisms or *Candida*, may result from infection of the skin, lungs, urinary tract catheters

Table 76.4 Complications of toxic epidermal necrolysis.

Acute	Chronic
Similar to burns: depends on extent	*Ocular complications* (up to 35%)
Massive fluid and electrolyte loss (3–4 L/day)	Conjunctivitis, ectropion or entropion, corneal scarring
Prerenal renal failure	Symblepharon, Sjögren-like sicca syndrome
Bacterial infection and septicaemia	*Other mucous membrane involvement*
Hypercatabolism: insulin resistance	Oesophageal stricture
Diffuse interstitial pneumonitis	Phimosis
Mucous membrane involvement	Vaginal synechiae
	Orogenital ulcers
	Miscellaneous
	Wound infection
	Pigmentary changes
	Nail dystrophy
	Hypohidrosis
	Scarring alopecia
	Contractures
	Development of melanocytic naevi

and intravenous (especially central) lines. Patients are usually febrile and shivering, even in the absence of infection. Hypothermia is infrequent and usually a marker of severe infection and irreversible septic shock. Protein loss, from skin lesions and increased catabolism, may reach 150–200 g/day. Inhibition of insulin secretion and/or insulin resistance in peripheral tissues is frequent, resulting in elevated plasma glucose levels and glycosuria.

Mucocutaneous complications of TEN [13,14] include wound infections, pigmentary changes (either hyper- or hypopigmentation) which may or may not resolve with time, nail shedding or dystrophy, hypohidrosis or hyperhidrosis, scarring alopecia and hypertrophic scarring which may lead to contractures. Development of melanocytic naevi has been reported [15]. Mucosal involvement may lead to chronic xerostomia, oesophageal strictures, phimosis, and chronic orogenital erosions or vulvovaginal stenosis [16]. Appearances may resemble scarring from cicatricial pemphigoid or lichen planus.

Ocular complications occur in 40–50% of survivors [9], and include conjunctivitis, watery eyes because of tear duct obstruction, pseudomembrane formation, photophobia, ectropion, entropion with trichiasis, symblepharon and corneal vascularization, corneal opacities, and corneal ulceration and scarring [12]. Blindness may result. Lacrimal duct destruction may result in xerophthalmia. A Sjögren-like sicca syndrome may be seen [17]. A 'post-SJS/TEN' ocular syndrome with punctuate keratitis and formation of a corneal pannus may result in photophobia, burning eyes and visual impairment. Ankylosymblepharon (fusion of eyelids to each other and to the globe) may follow secondary infection.

Prognosis

There is an appreciable mortality as a result of TEN, increasing from 5% in SJS, to 10–15% in transitional SJS–TEN and 30–40% in TEN. ARDS and multiple organ failure are the usual causes of death [1]. They are often precipitated by sepsis with septicaemia, mainly resulting from *Staphylococcus aureus* and *Pseudomonas aeruginosa* [2]. Other causes of death are pulmonary embolism and gastrointestinal bleeding. A recent study of 64 patients with TEN recorded that 28% did not survive the acute episode, and another 23% died following discharge from hospital; the remaining longer-term survivors continued to suffer from ocular (54%), skin (81%) and renal (23%) problems. Of the patients with ocular involvement in the acute phase of TEN 79% had long-term ocular complications, and 73% of patients with mucosal involvement had persistent mucosal lesions [3].

Early withdrawal of the causative drug improves the prognosis, and drugs with a long half-life are associated with an increased risk of death [4,5]. Increased age in most [6] but not all [1] studies, extensive TEN, delay (more than 3–4 days) in referral to a regional centre [7], early thrombocytopenia and early empirical antibiotic treatment elsewhere are associated with a worse prognosis. It has been claimed that severe granulocytopenia is a poor prognostic indicator [8], although this has been disputed on the basis that lymphopenia is more usually found in severe TEN [9]. A specific severity-of illness score to determine prognosis for cases of TEN (SCORTEN) based on seven independent risk factors for death as

Table 76.5 SCORTEN prognosis score [10].

*Parameter**
Age > 40 years
Presence of a malignancy
Epidermal detachment > 30%
Heart rate > 120/min
Bicarbonate < 20 mmol/L
Urea > 10 mmol/L
Glycaemia > 14 mmol/L

1 point awarded for each parameter; SCORTEN derived by totalling scores

SCORTEN	Probability of death (%)
0–1	3
2	12
3	35
4	58
≥5	90

* Worst recorded value in the 24 h after admission.

assessed on the first day of hospitalization has been judged helpful (Table 76.5) [10–12]; others have pointed out that it does not take account of respiratory involvement in TEN, which may portend a poor prognosis [13].

Diagnosis

Toxic shock syndrome, which usually occurs in menstruating women, may cause widespread erythema and desquamation, but skin tenderness and bullae are absent. Similarly, SSSS can generally be differentiated on clinical appearances and on the basis of histology. Linear IgA bullous dermatosis, whether idiopathic or drug-induced (e.g. vancomycin), may mimic SJS or TEN clinically [1–3], as may a widespread bullous fixed drug eruption [4,5]. The subcorneal aseptic pustules of acute generalized exanthematous pustulosis (AGEP) or acute pustular psoriasis (von Zumbusch) are usually distinctive but may coalesce to produce extensive superficial detachment mimicking TEN. Paraneoplastic pemphigus may closely resemble SJS, but direct immunofluorescence is positive.

Identification of the responsible drug is often difficult, because patients frequently take more than one medication [6,7] (an average of 4.4 in one series). A helpful guideline is that most drugs that cause TEN have been given first between 1 and 3 weeks previously [8–10]; another very suggestive guide is that of recurrence within 48 h on administration of a drug previously recorded as having caused a similar reaction. A given drug is unlikely to be responsible for TEN if it was first given 24 h previously, or if the duration of treatment exceeds 3 weeks [6,9]. In case–control analyses, the risk of SJS/TEN with drugs normally used on a long-term basis, such as phenytoin, phenobarbital, carbamazepine and lamotrigine, was largely restricted to the first 8 weeks, that is the risk is with short-term rather than in the long-term therapy [10,11]. In another study, more than 90% of SJS and TEN cases related to introduction of antiepileptic drugs occurred in the first 63 days [12]. Phenytoin-induced TEN may occur any time between 2 and 8 weeks after initiation of therapy, and may progress despite discontinuation of phenytoin days or weeks earlier [13].

Skin testing is unfortunately unreliable. Relevant positive patch tests were found in only 9% of 22 patients with SJS/TEN, compared with 50% of 14 patients with AGEP [14]. The *in vitro* lymphocyte transformation test is of no great value [15]. In summary, there is no reliable test to confirm the aetiological role of a given drug in an individual case [8]. Re-exposure to drugs suspected of causing a reaction has resulted in fatality, and should not be carried out for diagnostic purposes [16].

Treatment [1–10]

The management of TEN is summarized in Table 76.6, and is perhaps best carried out on a dermatology intensive care unit or a burns unit. Clearly, presumptive causative drugs should be stopped as soon as possible. It should be remembered that HIV-1 infected patients with TEN are an occupational risk for health-care workers [11]. The main principles of symptomatic therapy are the same as for major burns and include analgesia, fluid replacement, anti-infectious therapy, aggressive nutritional support, warming of environmental temperature and skin care with appropriate dressings. The extent of the detachment of the epidermis should be evaluated daily as a major prognostic factor. It is expressed as a percentage of body surface area (BSA), using burn tables or the simple rule that one hand (palm and fingers) corresponds to 1% of the BSA. Hyperventilation and mild hypoxaemia on blood gas analysis indicate a high risk of progression to ARDS.

Table 76.6 Management of toxic epidermal necrolysis.

Intensive therapy or burns unit
Air-fluidized bed
Analgesia
Maintain fluid and electrolyte balance (replace up to 5 L/day)
Maintain body temperature
Maintain nutrition; oral hygiene
Frequent ophthalmological assessment
Antiseptic/antibiotic eye drops 2-hourly
Disrupt synechiae frequently
Limitation of infection
Neutropenia: reverse barrier nursing
Frequent cultures of erosions, and blood cultures
Culture tips of Foley catheters and intravenous lines
Prophylactic broad-spectrum systemic antibiotics (controversial)
Topical cleansing/antibacterial agents
0.5% silver nitrate solution on gauze *or* 10% chlorhexidine gluconate washes *or* saline washes *or* polymixin/bacitracin *or* 2% mupirocin
Avoid silver sulfadiazine
Wound care
Remove necrotic epidermis (controversial)
Paraffin gauze or hydrogel dressings
Biological dressings (xenografts, allografts, skin substitutes)

There is a significant incidence of disabling long-term complications in survivors, especially in relation to ocular and other mucous membranes. It is therefore particularly important to be aware of these and to take preventative measures. Physical contact with patients during nursing procedures may produce loss of large sheets of skin, and the use of a turning frame or a ripple or air-fluidized bed will lessen discomfort and facilitate nursing care. Trauma, as with adhesive dressings or ECG electrode attachment pads, should be minimized. Eyelids and conjunctivae should be lubricated with soft paraffin, and gently separated to prevent the formation of adhesions. Ophthalmological advice should be sought [12,13]. Use of gas-permeable scleral contact lenses resulted in improved quality of life in 90% of patients by reducing photophobia and discomfort, and also improved visual acuity and healed corneal epithelial defects in 50% of patients [14]. Amniotic membrane has been used as a dressing for eye lesions in TEN [13,15]. Autologous germinal cells taken from the limbus and grafted on a support of amniotic membrane may be beneficial in the most severe cases [16]. Skin or other infection must be treated promptly. Good mouth care is important in preventing parotitis. Vaginal examination should be repeated in women and appropriate dressings used to avoid synechiae if erosions are seen. The issue of whether necrotic tissue should be removed has been controversial; most authorities feel that this impairs healing. Eroded areas may be treated with biological [17] or synthetic [18] dressings. Use of silver nitrate impregnated dressings [19–21] has been advocated.

There is no consensus on the merits of therapy with moderately high-dose corticosteroids for TEN. Some authorities maintain that high-dose steroid therapy promotes or masks the signs of infection, delays healing, precipitates gastrointestinal bleeding, prolongs hospitalization and increases mortality [1,2,22–24]. However, others favour steroid therapy on the basis that it may reduce inflammation and keratinocyte necrosis [25]. It is generally agreed that if steroids, or any other immunosuppressive agent, are to be given, then they should be administered as early as possible in the evolution of the disease. There have been anecdotal reports on the beneficial use of plasmapheresis [26–28], but this has been questioned [29]. Both cyclophosphamide [30] and ciclosporin A [31–33] have produced improvement in anecdotal cases. Thalidomide therapy for TEN was associated with increased mortality [34,35]. *N*-acetyl cysteine was documented to be useful in a few patients [36], perhaps because it enhances drug metabolism. On the basis that potential *Fas* (CD95)-mediated keratinocyte death in TEN might be blocked by naturally occurring *Fas*-blocking antibodies included in human immunoglobulin preparations, there have been several reports, mostly favourable, on human intravenous immunoglobulin (IVIG) therapy for TEN [37–50]. In particular, early infusion of high-dose (1–2 g/kg/day for 3–4 days in adults) IVIG has been reported in a majority of studies to be beneficial in terms of improved survival and appears safe and well tolerated [47–50]; variations in the efficacy of different batches of IVIG have been recorded [41]. However, other studies failed to show any significant effect from either IVIG therapy or systemic corticosteroids on mortality in comparison with supportive care only [43,51], and there is currently no consensus on the best management for TEN [52,53]. There have been single case reports on the efficacy of treatment with anti-TNF-α antibodies [54–58]. Because of the

rarity of the condition, controlled trials assessing these different treatment approaches are very difficult to carry out. Intense pulsed light treatment had been used for persistent facial hypermelanosis following drug-induced TEN [59].

Prevention and future use of drugs

Cases should be notified to regulatory agencies. Patients should be advised to avoid re-exposure to the suspect drug(s). Published cases of recurrences have all been attributed to the same generic drug or to compounds chemically closely related (e.g. aromatic anticonvulsants). Therefore, there is no rationale for restricting the use of all classes of 'high-risk drugs'. Because familial cases have been reported, first-degree relatives should be alerted to their elevated risk of reaction to the same drug(s). Following realization of the importance of pharmacogenetics in the aetiology of SJS/TEN, it is recommended that genotyping be undertaken as a screening measure for the HLA allele B*1502 in all Asians prior to prescription of carbamazepine [1], and for the HLA-B*5701 allele in the case of prospective recipients of abacavir [2–5]. In predominantly Caucasian populations, 94% of patients do not carry the HLA-B*5701 allele and are at low risk for hypersensitivity reaction to abacavir [5].

Introduction

The acquisition of basic dermatological surgery skills is an important component of dermatological training. This chapter covers simple excisional surgery and provides an introduction to more advanced techniques. In addition, there are descriptions of Mohs micrographic surgery and several other surgical procedures. The reader is also referred to the specialist journal *Dermatologic Surgery*, and introductory [1–3] and intermediate textbooks [4–6]. Other books deal more specifically with cosmetic dermatological surgery [7,8] or general aspects of plastic surgery [9–11].

Critical anatomical areas

It is essential to have a working knowledge of the important clinical anatomy of each operation site. The following is only a brief introduction to some of the critical anatomical details with which the operator must be familiar. Excisions down to superficial fat will rarely result in exposure of or potential damage to functionally important structures, except in a very thin subject. Incisions to deep fat or fascia and the removal of large cysts or lipomas may result in exposure of important structures. On the head and neck, division of larger arteries and veins will not cause vascular complications because of the extensive collateral circulation. However, it is important to be aware of the position of large arteries and veins in order to be prepared to deal with bleeding from these

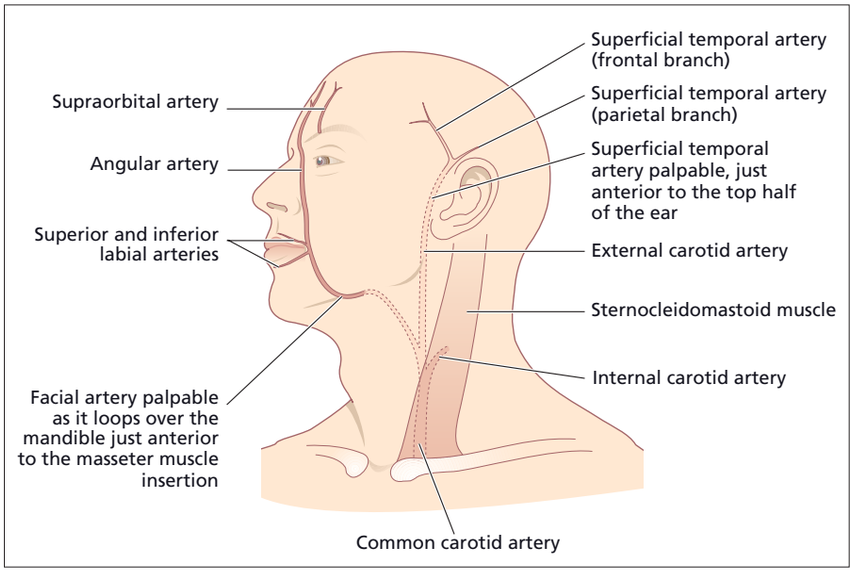

Fig. 77.1 Arteries of the head and neck encountered in skin surgery. The labial artery lies on the inside (mucosal) surface of the lip approximately 5 mm from the visible vermilion border. (---) Arteries rarely encountered; (—) arteries frequently identified during superficial skin surgery on the face.

vessels. Division of sensory nerves may produce annoying sensory loss, but this will have little functional impact on the head and neck. Knowledge of the anatomy of the supraorbital, infraorbital and mental sensory nerves is important, as these are commonly used in peripheral nerve blocks. Division of motor nerves is potentially disabling and thus it is essential to know the anatomy of the vulnerable superficial cranial and peripheral motor nerves.

Skin tension lines and the orientation of scars

Incisions should be designed to follow the wrinkles or relaxed skin tension lines (synonym stress lines; favourable skin tension lines; maximal skin tension lines) as the resulting scars will be stronger and less likely to stretch [1]. Relaxed skin tension lines run perpendicular to the direction of contraction of the underlying muscles and parallel to the dermal collagen bundles [2]; cutting transversely across these weakens the skin much more than a cut running parallel to the collagen bundles [3]. In the absence of wrinkles, relaxed skin tension lines can be identified by asking the patient to grimace or by skin manipulation. Langer's lines [4] (synonym resting stress lines) were mapped on cadaver skin, and differ from relaxed skin tension lines on the limbs and trunk [3]; they should not be used for identifying the elective direction of excision.

Head and neck

Cosmetic units

Cosmetic results of surgery are better if all the incisions remain within a cosmetic unit [5]. These are areas of skin that share similar characteristics (e.g. the nose, cheek and periorbital skin). The junction lines separating these areas are also important because scars placed in junction lines are usually unobtrusive whereas scars that cross a junction line (bridge two cosmetic units) are very obvious. It is thus important to try to design a repair so that the scars follow relaxed skin tension lines and remain within the same cosmetic unit, or run in the junction lines between two adjacent cosmetic units.

Blood vessels and lymphatic supply of face

Larger vessels, particularly the temporal artery, can be avoided by hydrodissection (see p. 77.34). The facial artery (Fig. 77.1) at the nasolabial fold, and its continuation into the angular artery at the medial canthus, are frequently divided when excising tumours at these sites. The external jugular vein runs under the platysma muscle but on top of the sternocleidomastoid muscle, and may be easily damaged during superficial incisions on the neck at this site (Fig. 77.2a). Emissary veins, connecting the intracranial and extracranial venous circulation, run across the subgaleal space towards the back of the scalp (parietal emissary vein) and just above the forehead (frontal emissary vein) [6]. These veins may be damaged when undermining the subgaleal space at these sites. Lymphatic drainage sites should be examined for metastases during follow-up of patients treated for squamous cell carcinoma or melanoma [7]. Division of skin lymphatics during incisions under the eye may result in temporary but unavoidable lower eyelid lymphoedema. Postoperative lymphatic leakage sometimes occurs after lower limb or axillary excision. This resolves spontaneously with conservative management.

Sensory nerves of face

Nerve blocks. Sensation to the face is supplied by the trigeminal (Vth) cranial nerve. The three branches readily blocked in skin surgical procedures on the head and neck include the supraorbital, infraorbital and mental nerves (Fig. 77.3). These emerge from the skull via palpable foramina, which all lie in the same plane, just medial to a vertical line running through the pupil [8]. Block-

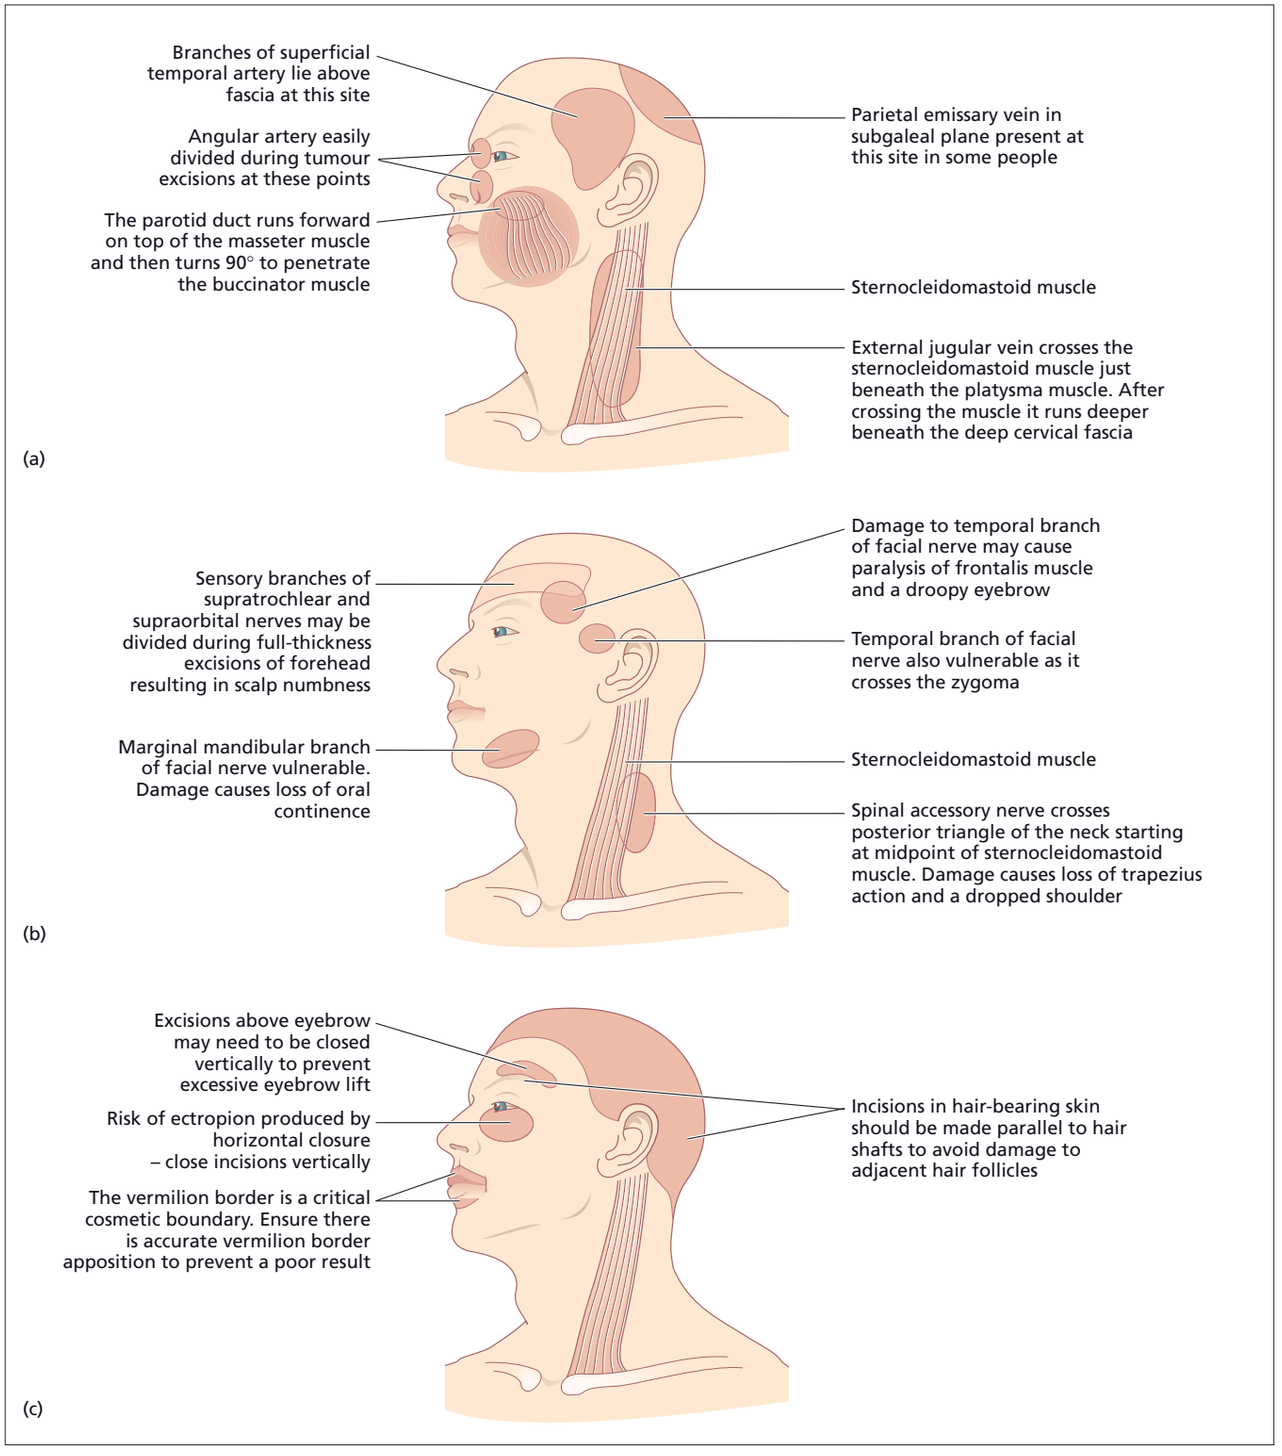

Fig. 77.2 Potential surgical hazard sites during skin surgery on the head. (a) Potential blood vessel and duct, (b) nerve and (c) cosmetic hazards on the head and neck. (From Lawrence [9].)

ing the great auricular, transverse cervical and lesser occipital nerves as they emerge, approximately 10–20 mm above and below Erb's point, from the posterior border of the middle third of the sternocleidomastoid muscle [10] produces anaesthesia of a large portion of the scalp, neck and ear. Erb's point is identified by dropping a plumb line from the mid-point of a line drawn between the mastoid process and the angle of the jaw. Where this line meets the posterior border of the sternocleidomastoid muscle is Erb's point. At this site, the spinal accessory (XIth) cranial nerve also emerges from behind the sternocleidomastoid muscle. This motor

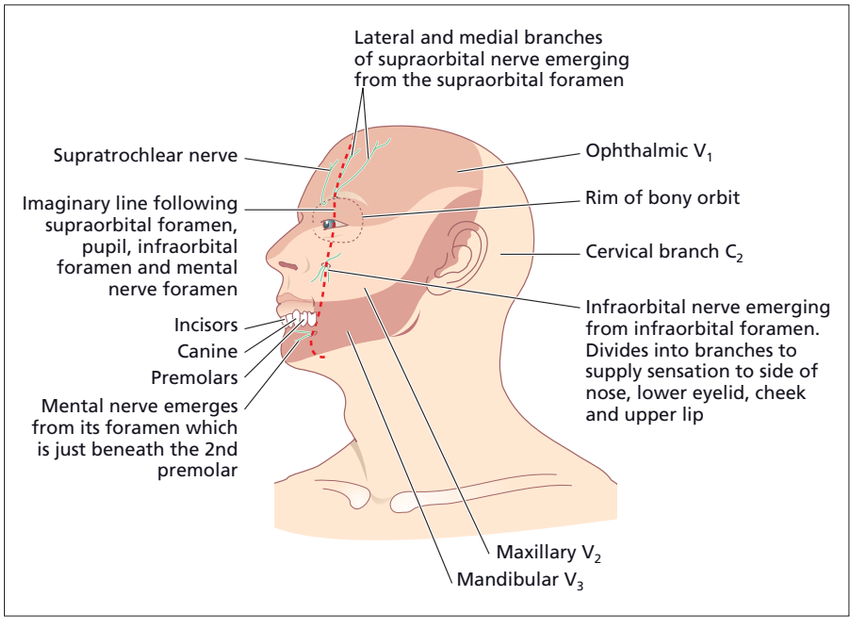

Fig. 77.3 Sensory nerves on the face used in nerve-block anaesthesia. Sensation on the face is served by the three main divisions of the trigeminal nerve: the ophthalmic, maxillary and mandibular divisions. Three important branches of these nerves—the supraorbital, infraorbital and mental nerves—emerge in the same plane along a vertical line running through the pupil.

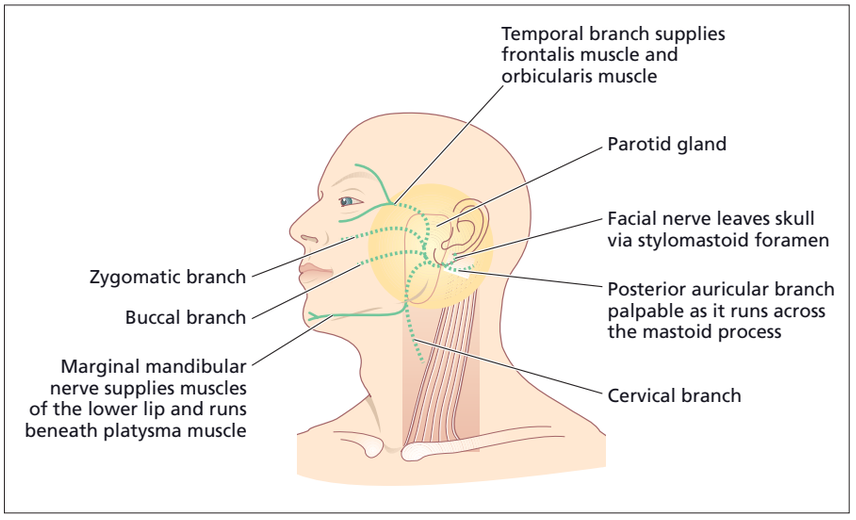

Fig. 77.4 Motor branches of the facial nerve vulnerable in skin surgery. (---) Nerves rarely encountered; (—) nerves at risk during superficial skin surgery on the face.

nerve is rarely affected by the local anaesthesia, as it lies deeper, on the floor of the posterior triangle, whereas the three named sensory branches of the cervical plexus curl round to lie on top of the sternocleidomastoid muscle [11].

Division of small sensory nerves. This is of little consequence, with the possible exception of scalp numbness following incisions on the forehead. Improvement in sensory loss can be expected for up to 1 year.

Motor nerves

Two branches of the facial (VIIth) cranial nerve, the marginal mandibular branch and the temporal branch, are vulnerable during skin surgery (Fig. 77.4). The temporal branch of the facial nerve supplies the frontalis and orbicularis muscles. Damage to the nerve supplying frontalis muscle results in difficulty raising the eyebrow, and the forehead furrows disappear. This can easily occur during excision of large tumours on the temple, lateral to the frontalis muscle, and as the nerve crosses the zygomatic arch.

Table 77.1 Undermining levels.

Site	Undermining level
Face	Mid-fat
Nose	Just above the periosteum and perichondrium
Forehead	Beneath the deep frontalis fascia (equivalent to the subgaleal plane)
Scalp	Subgaleal plane
Trunk and limb	
Small excisions	Deep fat
Large excisions	Just above the deep fascia

At both sites there is little tissue between the skin and periosteum (Fig. 77.2b). The marginal mandibular branch innervates muscles that move the lower lip. Damage can be devastating because it results in weakness of the lips, with dribbling when eating and drinking. The nerve is superficial and vulnerable as it emerges from under the parotid gland at the angle of the jaw, behind the point where the facial artery can be palpated as it crosses the mandible. More anteriorly, the nerve runs beneath the platysma muscle [12]. Variations in nerve position with age and neck position must also be considered. The remaining branches of the facial nerve are less vulnerable because they share several cross-connections and lie deeper. The other important motor cranial nerve is the accessory (XIth) nerve, which supplies the trapezius and sternocleidomastoid muscles. This may be damaged during dissection in the posterior triangle of the neck, causing weakness of the trapezius muscle and producing a dropped shoulder.

Undermining levels

When undermining to increase skin mobility, different levels are appropriate at different sites (Table 77.1).

Specific facial sites

If an incision runs across the vermilion of the *lip*, the vermilion border must be carefully marked before anaesthetic injection to avoid a poor cosmetic result (Fig. 77.2c). In older patients with poor lid elasticity, operations around the *lower eyelid* may result in ectropion if any downwards tension is applied to the lower eyelid. In a patient with poor lid elasticity, the procedure should be designed to increase rather than reduce eyelid tension; this usually means closing the wound vertically rather than horizontally. If an incision goes across the *hair line*, ensure that the scalp margin is reconstructed so that a smooth contour remains. Because hairs grow obliquely through the skin, any incision through *hair-bearing skin* should be made parallel to the hair shafts rather than vertically through the scalp so that fewer follicles are damaged.

Limbs

The only superficial motor nerve on the limbs is on the lateral aspect of the knee, where the common peroneal nerve (lateral popliteal) can be palpated against the bone as it winds round the neck of the fibula. Injury to the nerve at this site will produce a foot drop resulting from paralysis of foot dorsiflexors and elevators.

Equipment and sterilization [1–5]

Although most dermatological surgical procedures can be safely performed in well-lit, dedicated outpatient units using relatively simple equipment and surgical instruments [1–3], the absence of a need for either expensive equipment or a completely sterile environment does not justify the use of inadequate facilities or inappropriate equipment.

As dermatological surgery ranges from superficial tissue destruction and removal to surgical excision and complex wound repair, a range of basic surgical instruments should be available to the dermatological surgeon depending upon the procedure to be performed. The basic equipment, with optional items that should be available for more specialized procedures, is shown in Table 77.2. Advanced skin surgery (e.g. the excision and complex repair of difficult tumours and Mohs micrographic surgery) requires both dedicated facilities and specialized surgical instruments to achieve the best results.

Wound infection, an uncommon complication of dermatological surgery, is more commonly related to surgical technique than poor operator cleanliness or instrument sterilization. However, correct hand washing techniques are vital to the prevention of cross-infection [4]. The tradition of protracted 'scrubbing up' is not essential prior to most dermatological surgical procedures—two washes in warm running water using 4% chlorhexidine or 10% povidine–iodine solution are sufficient.

Hand hygiene in UK NHS hospitals has been the subject of much publicity and concern. The routine use of alcohol-based hand rubs [5] has been recommended to help prevent the spread of hospital acquired infections, particularly MRSA (methicillin

Table 77.2 Essential and optional equipment. (From Burge *et al*. [1].)

Essential	Optional
The room	
An examination couch with adjustable backrest	Theatre table
A stool for the surgeon	
Good lighting: Anglepoise lights	Overhead theatre lights
Equipment—preoperative preparation	
Autoclave for steam sterilization or electric oven for dry heat sterilization	
Skin preparation	
Chlorhexidine solution	
Chlorhexidine detergent (Hibiscrub®)	
Surgical gloves	
Sterile paper towels	Re-usable drapes
A window can be cut in the centre and the towel placed over the lesion	
Skin markers	Sterile pen and Indian ink
Gentian violet and pointed orange stick	
Skin marker pen	
Indelible felt-tip pen	
Anaesthetic	
Disposable syringes 2 mL, 5 mL fine needles	Dental syringe and fine needles
	Dental syringe vials
Lidocaine (lignocaine)	
1% and 2% plain and with epinephrine (adrenaline) 1 : 100 000 or 1 : 200 000	
Instruments	
Scalpel blades	
No. 15 for excision	
No. 22 for shave biopsy	
Scalpel handle	
Forceps	
Fine-toothed (e.g. Adson–Brown)	
Non-toothed	
Skin hook	
Can easily be constructed by pushing a sterile needle onto a sterile moistened cotton wool bud on an orange stick. Bend the needle into a curve	
Scissors	
Curved pointed iris scissors	
Blunt straight scissors	
Needle holders	
Small artery clamps	
Various sizes of absorbable and non-absorbable sutures attached to needles	Skin punch for biopsies, 3 mm and 4 mm
	Sharp ring curettes in various sizes
Haemostasis	
Gauze swabs	Hyfrecator

resistant *Staphylococcus aureus*). Hand disinfection using such alcohol-based hand rubs is associated with less skin irritation [6] and less skin barrier disruption [7] than hand washing using soap or detergent-based products.

During surgery the use of either clean, non-sterile or sterile surgical gloves is mandatory, and the wearing of eye protection is strongly recommended.

The sterilization of non-disposable medical and surgical instruments is an important factor in reducing the risk of infection. Three levels of importance have been described in this area [8]; firstly, non-critical items (e.g. dermatoscopes, which normally only come into contact with intact skin) require only low-level disinfection between patients; secondly, semi-critical items (e.g. endoscopes, which contact mucous membranes) require high-level disinfection between patients; and, finally, critical items (e.g. surgical instruments, which come into contact with sterile tissues) require sterilization between patients. Both high-level disinfection and sterilization should be preceded by manual or ultrasonic cleaning in order to remove any dried tissue, pus or blood [8–10]. Older methods of sterilization, for example boiling in water at atmospheric pressure and the use of various chemical agents (e.g. glutaraldehyde, phenolic agents), are no longer recommended [3]. The new variant Creutzfeldt–Jakob disease (vCJD) prion cannot be destroyed by sterilization, and equipment suspected of being contaminated must be quarantined. If contact is confirmed the equipment must be destroyed.

Safety aspects

Certain basic safety measures and protocols are essential within a dermatological surgery unit in order to minimize the risks of infection and accidental injury to both patients and staff [1].

The routine use of aseptic technique minimizes the risk of bacterial colonization at the operation site, and prevents contamination from adjacent sites. Antisepsis and sterilization are discussed elsewhere (see p. 77.5). Control of blood-borne infections, especially human immunodeficiency virus (HIV) and hepatitis viruses, has two main components: prevention of transmission from patient to patient, and protection of the surgical team [2]. It is now mandatory for all British medical and nursing staff to be adequately vaccinated against hepatitis B, and for hospitals to have both dedicated infection control staff and protocols to ensure instrument sterility. One approach suggested by the US Centers for Disease Control and Prevention (CDC) is to treat *all* patients as if they were infected with HIV, hepatitis B or other blood-borne pathogens and to adopt 'universal precautions' [3].

Needle-stick injuries and other sharp instrument cuts are particularly important, and all members of the surgical team should take extreme care with the use and disposal of 'sharps'. It is extremely dangerous to either leave uncapped needles on the instrument tray or to attempt needle recapping by the two-handed method. Ideally, the surgeon should make a habit of both disposing of used needles and syringes *immediately* after use and removing all sharp disposable instruments (e.g. needles, scalpel blades) from the tray after the operation, placing these directly into 'sharps disposal' boxes. All relatives and those theatre personnel not directly concerned with the procedure should be excluded from the operating room. Clothing should be specific for surgery—apart from potentially introducing a variety of organisms to the procedure room, clothes may become contaminated.

At the preoperative consultation, a careful history may identify certain potential problems (e.g. diabetes, epilepsy) and the presence of cardiac pacemakers [4]. A full drug history is important—aspirin and anticoagulants promote bleeding and non-selective β-blockers (e.g. propranolol) may rarely interact with epinephrine (adrenaline) in local anaesthetics, resulting in malignant hypertension. On direct questioning, some people may admit to a tendency to faint very easily, and some patients with epilepsy may have a history of fits triggered by surgery or dental procedures. As there is always a risk of patient collapse in operating rooms, there must be adequate space available for an emergency resuscitation to be performed. Resuscitation drugs and equipment, together with both suction and an oxygen supply, should be readily available [5]. All theatre personnel should be trained in advanced resuscitation techniques, including emergency electrocardiography and cardiac defibrillation [6].

Table 77.3 Complications in wound healing.

Complications	Predisposing factors	Prevention
Infection	Infected lesions Poor sterility Steroids Adjacent infectious source Occlusive dressings Poor blood supply Fat, haematoma and foreign material Sutures Poor technique Excessive devitalized tissue from careless handling or electrocoagulation	Careful preoperative and operative techniques Sutureless closure Antibiotic sprays Prophylactic antibiotics for infected or potentially infected wounds
Delay in closure	Poor blood supply Excess movement Infection Tension Steroids Debilitated patient Poor nutritional status	Layered closure Gentle tissue handling Minimize devitalization of tissues Care in decision to operate Warmth Careful postoperative dressings
'Gaping scar'	Inadequate apposition Dermal instability Excess movement Infection Tension	Careful apposition Subcutaneous or subcuticular sutures Adequate postoperative support (e.g. antitension dressings)
Painful scars	Feet and fingers especially	Avoid pressure sites if possible Dressings to reduce subsequent pressure and/or movement Careful apposition
Hypertrophic scars	Site Tension Reaction to embedded material Trauma Individual susceptibility	Avoid 'cape' area if possible Good surgical technique including undermining of edges where necessary
Keloids	Previous history Black skin Upper half of body Tension	Avoid surgery where possible Antitension measures for 3 weeks Watch and prepare to treat
'Railroad tracks'	Skin sutures under too much tension	Good suture technique Use of 'non-reactive' suture material
Stitch marks 'abscess'	Sutures left in too long	Early suture removal
Wound edge inversion	Poor technique	Good surgical technique Occlusive or semi-occlusive dressings
Bleeding and/or haematoma formation	Bleeding tendency Aspirin Clopidogrel Ticlopidine Eptifibatide Tirofiban	Preoperative screening Good haemostasis Use of epinephrine (adrenaline) in local anaesthetic

Complications [1]

All dermatological surgical procedures may result in complications [1], most commonly bleeding, infection and poor wound healing (Table 77.3). Although complications will always occur, most can be prevented by a combination of thorough preoperative preparation and good surgical technique.

The incidence of complications following both general dermatological surgery and Mohs micrographic surgery is generally low. In a prospective, multi-centre study published in 2005, 84 French

dermatologists performed 3788 outpatient dermatological surgical procedures under local anaesthesia. These included excision of benign and malignant tumours (excluding 'sebaceous' cysts and pyodermas) [2]. There were 236 recorded complications occurring in 213 (6%) procedures. Excessive bleeding (3%), vasovagal syncope (1.4%) and wound infection (2%) were the main complications. Infection was superficial in 92% of cases, with one case of systemic infection. Antibiotic therapy or further surgery was required in 1%, and haemorrhagic complications appeared to be independently associated with the risk of wound infection. In 2007, the same authors reported an almost identical study (73 dermatologists performed 3491 procedures) [3]. Overall, 67 (1.9%) patients developed wound infections, with a higher rate (4.3%) of infection following complex wound repair. Once again, haemorrhagic complications were independently associated with the risk of development of wound infection.

Mohs micrographic surgery is also a safe procedure associated with a low risk of complications. An overall infection rate of 2.3% was reported following 530 Mohs procedures and 517 non-Mohs excisions performed on outpatients [4]. One US Mohs unit reported its complication rate to be equal to or lower than the published complication rates from specialists in other surgical disciplines [5]. The common practice of using clean but non-sterile gloves during Mohs tumour excision stages appears to be both safe and cost-effective. A retrospective case note review of 1239 Mohs patients (1400 Mohs procedures) revealed 25 cases of wound infection, with no significant difference in infection rates seen between those treated with either sterile or non-sterile gloves in the Mohs excision stages [6].

Warfarin and other anticoagulants pose a significant risk of postoperative complications. In a prospective study of 102 patients undergoing minor plastic surgery (37 regularly taking aspirin, 21 taking warfarin and 44 on neither drug), 57% of the patients taking warfarin developed complications, significantly more than the control and aspirin-taking groups [7].

Similarly, antiplatelet drugs (e.g. aspirin, clopidogrel, ticlopidine) potentially increase the risks of bleeding complications. In one study of patients undergoing minor plastic surgery, no significant difference in bleeding complication rates was seen between aspirin-taking and control groups [7]. However, other reports have found a link between aspirin therapy and a small but significant increased risk of postoperative bleeding following excision of cutaneous head and neck lesions [8], the risk being particularly pronounced in patients undergoing local flap wound reconstruction. Consequently, opinion differs on whether or not to discontinue aspirin or anticoagulants prior to dermatological surgery, particularly in patients at high risk of potential cerebral and cardiovascular complications if therapy is temporarily interrupted. Some authors believe this is not routinely necessary [9,10], particularly for straightforward procedures, and others recommend caution in patients taking aspirin [8], and especially in patients receiving warfarin therapy [7].

In most instances, aspirin can be continued without resulting in a worse surgical outcome, although intraoperative bleeding may take longer to control. However, at some sites (e.g. around the eye) or in procedures involving extensive undermining or complex wound reconstruction, it may be appropriate to temporarily discontinue aspirin therapy. If aspirin is stopped this must be done at least 10 days before surgery to allow a sufficient number of new platelets with normal clotting responses to be produced. Non-steroidal anti-inflammatory drugs (NSAIDs) seem to present no significant problem and can probably be continued in all circumstances [11].

The use of epinephrine-containing local anaesthetics results in vasoconstriction and prolongs the duration of anaesthesia. Intraoperatively, bleeding can be controlled by a combination of electrosurgery, pressure and ligation. Postoperatively, the use of appropriate wound dressings is important—ranging from simple Band Aid dressings for superficial wounds to layered dressings with pressure pads for larger wounds where there is a significant risk of haematoma formation (e.g. following cyst or lipoma excision; widely undermined wounds). All patients should be given verbal and written information regarding wound care and how to contact the dermatology unit if problems arise. Haematoma formation may occur at various times after surgery and usually results in acute pain and swelling. The clinical appearances, together with the age and size of the haematoma, will dictate whether to open the wound, evacuate the haematoma and obtain haemostasis, or to manage the complication conservatively.

Wound infection is a major concern, but is fortunately relatively uncommon following skin surgery of all types [2–4]. If the risk of infection is higher than normal (e.g. following excision of an ulcerated tumour from a flexural site), prophylactic antibiotic therapy may be appropriate. Postoperative infection usually presents as erythema, pain and swelling in and around the wound, 4–8 days after the procedure. Depending upon the clinical appearances, management will range from wound care, topical and systemic antibiotics, through to incision and drainage of a frank wound abscess.

Other significant problems relate to both the cosmetic and functional results of surgery. The risks of scarring must be carefully explained prior to surgery, with special attention to the possibility of distortion of facial 'free margins' (e.g. vermilion, lower eyelid) and unsightly hypertrophic scars in high-risk body sites (e.g. upper arm, shoulders, chest). Altered pigmentation in and around the wound is an additional cosmetic risk in Asian and black patients. Nerve damage is a significant concern, as both sensory and motor nerves may be damaged during dermatological surgery, particularly at certain 'high-risk' anatomical sites (see pp. 77.3–77.5).

Local anaesthetics [1]

Principles and types

An ideal local anaesthetic agent would be non-toxic, painless on injection, rapid in onset, highly effective and carry a low risk of sensitization. The best compromise is found in 0.5–2% lignocaine hydrochloride (lidocaine), an amide-type local anaesthetic, which is the agent of choice for most dermatological surgery. Other amide-type local anaesthetic agents include mepivacaine, bupivacaine and ropivacaine, which have a slower onset but more sustained duration than lidocaine (lignocaine) [1]. Local anaesthetics in 'multiuse' bottles generally contain parabens preservative, but those supplied in glass ampoules are often preservative-free.

Ester-type local anaesthetics, for example procaine (ester of *p*-aminobenzoic acid), are seldom used by dermatologists.

Epinephrine 1:80 000 to 1:200 000, when added to local anaesthetic solutions, prolongs the duration of anaesthesia and produces local vasoconstriction. By reducing absorption, it may reduce the risk of systemic lidocaine toxicity.

Toxic reactions [1,2]

Toxic reactions to lidocaine are rare, and more likely to occur with the use of high volumes of high-concentration solutions or if accidental intravascular injection occurs. Lidocaine toxicity usually presents as a sensation of numbness or tingling. Systemic reactions include vasodilatation, cardiac or respiratory depression, or central nervous system manifestations such as dizziness, drowsiness, tinnitus, slurring of speech, muscle twitching and seizures. These side effects are, to some extent, reversible with diazepam (Valium) but full resuscitation measures may be required.

Ester-type local anaesthetics should be used with caution in patients with renal impairment. They also cross-react with a number of drugs of the *p*-aminobenzoic acid ester type (e.g. sulphonamides, paraphenylenediamine) [3,4]. Amide-type anaesthetics should be used with care in patients with hepatic impairment.

The maximum recommended dosage for lidocaine with epinephrine is 7 mg/kg or approximately 50 mL of a 1% lidocaine solution for an average adult. In practice, most dermatological procedures require substantially lower anaesthetic doses. In order to minimize the risk of accidental intravascular injection, it is a wise precaution to either aspirate prior to infiltration or, if using very fine (e.g. 30 gauge) needles, which will not aspirate blood, to keep moving the needle about in the skin while slowly infiltrating small volumes.

Systemic absorption of epinephrine may be associated with mild tachycardia and an excited state. More serious reactions are rare but, as with lidocaine toxicity, are more likely to occur with the use of high volume, high-concentration solutions or following accidental intravascular injection. The use of epinephrine in local anaesthetics should be avoided, or it should be used with caution, during pregnancy, in combination with inhalation anaesthesia or in patients suffering from severe glaucoma [5]. Interaction with non-selective β-blockers (e.g. propranolol) may rarely cause malignant hypertension [2], but this is not a risk with 'cardioselective' β-blockers (e.g. atenolol).

Patients should always be asked if they have had any untoward reactions to local anaesthetics (e.g. in dental procedures). These may have been nothing more than fainting, as vasovagal attacks are commonly associated with local anaesthesia, and should not be confused with serious toxic reactions. In cases of serious doubt, alternative methods of anaesthesia are necessary.

Methods

Local anaesthesia may be achieved *topically* using either tetracaine (amethocaine) cream (Ametop®) or a eutectic lidocaine–prilocaine cream (EMLA®) [4], or by *local infiltration*. Both EMLA® and Ametop® are applied under occlusion, 1–2 h before the procedure. Conjunctival anaesthesia is best achieved using proxymetacaine eye drops, which sting much less than tetracaine.

Other methods of anaesthesia include *field block* and *nerve block anaesthesia* [3,5], which produce temporary blockade of sensory nerve function in a given area. Field block involves infiltration of local anaesthetic at several points around surgical sites such as the nose and ear [2], and nerve block anaesthesia involves blockade of one or more major sensory nerves. The most useful facial nerve blocks in dermatological surgery involve branches of the trigeminal (Vth) cranial nerve (Fig. 77.3)—the supraorbital (forehead), supratrochlear (glabella), infraorbital (lower eyelid, nasal sidewall, upper lip) and mental (lower lip) nerves [4,5]. The choice of local anaesthetic method depends upon a number of factors, including the procedure itself, anatomical site and expected duration of the operation.

Controversy surrounds the use of epinephrine in digital nerve block ('ring block') anaesthesia because of a real or theoretical risk of digital ischaemia. Some believe it is absolutely contraindicated [6], whereas others describe routine use without incident [7,8].

In order to minimize discomfort when administering a local anaesthetic injection, consideration should be given to using a relatively fine needle, injecting slowly, and using both verbal and tactile distraction techniques. Injecting into the subcutaneous fat is less painful than intradermal infiltration, although it does take longer for the skin surface to become anaesthetic. Whenever possible, anaesthetic solutions should be at room temperature, and epinephrine avoided if not considered useful for the particular procedure. Pain on injection is less when lidocaine solutions are buffered with sodium bicarbonate immediately prior to use [9].

Other anaesthetic agents include the following:

1 *Ethyl chloride* and *liquid nitrogen* spray give short-lived periods of anaesthesia by skin refrigeration. This may be sufficient for quick superficial procedures such as the incision of small cysts and milia, abscesses or the curettage of multiple small warts.

2 The anaesthetic effect of *antihistamines* (e.g. 1% diphenhydramine hydrochloride solution) can be used when hypersensitivity to other agents is present or strongly suspected.
3 The intradermal injection of *normal saline* produces a brief anaesthetic effect [2].
4 *Hypnosis* and *acupuncture* may be useful when performed by an experienced practitioner and in a suitable subject.
5 *General anaesthesia* is rarely used in dermatological surgery. Patients requiring a general anaesthetic (e.g. children requiring treatment of large facial birthmarks) are best admitted to hospital either as a day case or overnight.

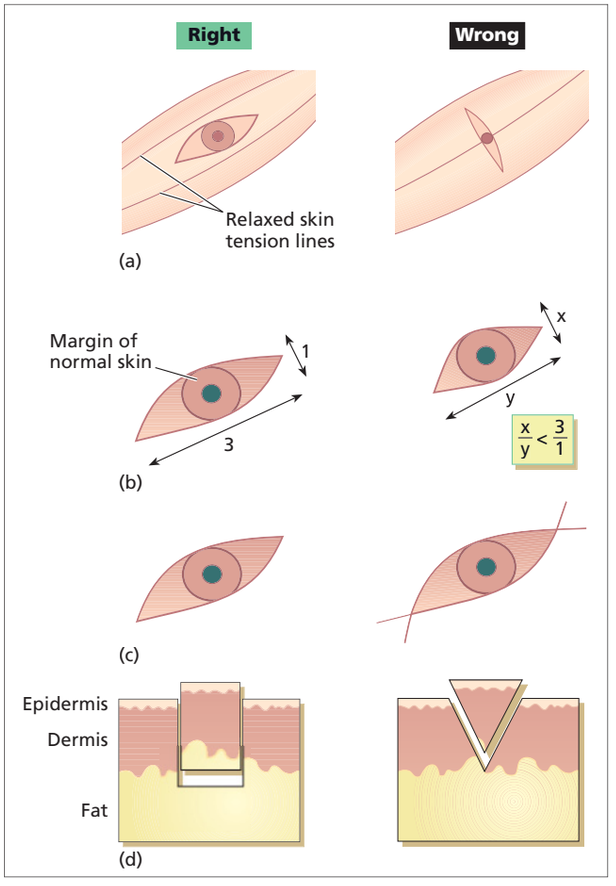

Fig. 77.5 Principles of elliptical excision. The ellipse is designed to follow skin-crease lines (a), and should be approximately three times as long as it is wide (b). Ensure that an appropriate margin of normal skin is also excised (b). At the ends of the ellipse, hold the blade vertically so that the incision lines do not cross over (c). The blade should be held at 90° to the skin when cutting the ellipse so that the wound has vertical sides down to fat. Do not bevel the blade towards the specimen as this makes the wound more difficult to close and may cut into the dermal component of the lesion (d). (From Lawrence [3].)

Biopsy techniques

Incisional and excisional elliptical biopsy

Elliptical excision biopsy is used for tumour or suspect mole removal. Incisional biopsy is used to take diagnostic biopsies of rashes and tumours before treatment is started. The technique has the advantage that the entire thickness of skin down to fat is excised. An appropriate margin can be selected if required and the incision line placed in the optimum direction [1].

For lesions on the face, orientate the ellipse so that the scar runs parallel to or within an existing skin crease (wrinkle line), or follows a boundary line between two adjacent cosmetic units. Excision direction is best assessed with the patient seated rather than lying flat, to allow for the effect of gravity on the skin crease lines. Wrinkle or smile lines can be exaggerated by asking the patient to grimace or smile, or by manipulating the skin [2]. In an excisional biopsy, measure the margin to be excised and mark the optimal line of closure before injecting the anaesthetic. When drawing on the skin, use a skin marker or Bonney's blue ink (a mixture of crystal violet and brilliant green), as other inks may tattoo the skin.

The ellipse length should be approximately three times the width, to produce an ellipse angle of approximately 30°, so that buckling does not occur when the wound is sutured (Fig. 77.5) [3]. A larger angle may suffice at some sites or in older people [4]. Make the incision as a single continuous sweep rather than a series of small nicks, and hold the blade at 90° to the skin, not angled inwards, so that the ellipse sides are vertical [5]. Ensure that the incision lines meet neatly without crossing over at the tip by starting and finishing each sweep with the blade held vertically. Incise down to fat. When the ellipse sides and tips are completely separate from the surrounding skin the ellipse should be sitting on a bed of fat. The fat under the ellipse should be cut through using scissors, while the ellipse is gently pulled away from the skin using a skin hook [6]. Undermine the edge at the appropriate level if there is any tension. Close the wound using both subcutaneous and surface sutures if necessary, using the correct suture technique.

Punch biopsy

Punch biopsy produces a core of skin down to fat. It is quick and easy to perform, and leaves only a small wound. The disadvantages

include the potential for sampling error and the difficulty in stopping bleeding if a small arteriole is punctured at the base of the wound. Punch biopsies can also be used to excise naevi on the back. At this site, wounds can be allowed to heal by second intention, with better cosmetic results than primary closure produces [7]. Subcutaneous tissue lesions can be sampled using a punch biopsy by pinching up a fold of skin to include the subcutaneous tissue before the biopsy is taken [8].

Disposable and reusable 2–8 mm diameter punches are available. When the skin is numb, drill the blade down to fat with gentle downward pressure [5]. To minimize the scar size, stretch the skin at right angles to the wrinkle lines while taking the biopsy so that, when the tension is relaxed, an oval rather than a round wound is produced, with its long axis parallel to the wrinkle lines [6]. The skin core may pop up when the surrounding skin is pressed down, or it can be hooked out using a needle. Cut through the fat at the base with scissors and remove carefully to avoid crushing the specimen. The wound can be sutured or allowed to granulate; the latter produces an acceptable small round or oval scar. If the wound is to be allowed to heal by second intention, stopping bleeding using a collagen matrix dressing results in a better cosmetic result than using Monsel's solution [9].

Shave

Shave excision is a simple, rapid and effective method of removing benign papular naevi. It can also be used to obtain a tissue diagnosis in protuberant nodular skin tumours. Shave biopsy of dermatoses affecting the epidermis or high dermis results in adequate tissue for diagnosis, and the subsequent re-epithelialization from follicular epithelium produces a good cosmetic result.

Naevi

Inject the local anaesthetic directly into the naevus, as this stiffens the tissue and makes it easier to slice off. Holding a No. 15 blade horizontally, shave off the naevus flush with the skin. Stop bleeding using cautery, electrodesiccation or a chemical haemostatic agent. Any remaining wound edge tissue fragments can be destroyed using cautery or electrodesiccation. The wound will take 2–3 weeks to heal. In approximately 45% of head and neck and 30% of trunk naevi, no visible scar remains (Fig. 77.6). In the remainder, the scar is smaller than the original naevus on head, neck and limb sites and a little larger than the naevus on trunk sites. Pigmentation at the scar edge or centre remains in approximately 25% of initially pigmented naevi after shave excision; non-pigmented naevi rarely, if ever, leave a pigmented scar [10]. Persistent pigmentation is even more common when aluminium chloride haemostasis is used rather than cautery [11]. Recurrent or retained pigment does not need to be excised. If a further specimen is sent, the pathologist must be given the full history in order to interpret the changes correctly. Hairs remain in 25% of initially hairy naevi; these can be destroyed by electrolysis if necessary. Shave excision using a safety razor or commercial equivalent (Dermablade) is also widely used [12].

Skin tumours

Shave biopsy of a solid tumour is faster and easier than an incisional biopsy, which needs to be sutured. A fragment can be

(a)

(b)

(c)

Fig. 77.6 Shave biopsy of benign papular naevi. (a) This patient had a benign tan-coloured naevus on the face (b) removed by shave excision followed by cautery, (c) resulting in a good cosmetic result 6 months later.

shaved off to confirm the diagnosis prior to definitive treatment. This type of biopsy will not help to distinguish a keratoacanthoma from a squamous cell carcinoma, and is unsuitable if histological examination of the deep margin or edge of a tumour is required to confirm the diagnosis. Bleeding can be stopped using silver nitrate stick coagulation, as the cosmetic outcome will be determined by the subsequent treatment. The fragile specimen should be mounted on paper before being placed in formalin.

Simple excision, suture technique and wound closure

Excision [1–3]

Skin biopsy specimens and cutaneous lesions can be removed using techniques other than elliptical excision, many of which (e.g. curettage, shave biopsy) do not result in a linear scar. Consequently, the decision to use formal surgical excision should balance the possible cosmetic advantages of other techniques (e.g. epidermal lesions and benign facial naevi) against the need to provide a full-thickness tissue specimen for histological examination (e.g. possible malignant melanoma).

Surgeon preparation

Dermatologists should be confident that they are competent to perform the proposed procedure and to manage any possible complications. If not, they should ask for a second opinion. The surgeon must be fully immunized against hepatitis B, and should observe safe practices with regard to handling sharps and tissue specimens. Surgical gloves should always be worn [4] and eye protection is strongly recommended.

Patient preparation

Patients should be fully aware of the significant risks, benefits and possible complications associated with the planned procedure. Informed consent [5] should be obtained, both verbally and in writing, for all invasive procedures. Usually, consent should be obtained from the parent or guardian in the case of minors, although some adolescents may be fully capable of both giving and withholding consent. Most patients about to undergo surgery are anxious and usually respond positively to appropriate reassurance as well as a calm and professional manner displayed by all members of the surgical team.

Examination and palpation of skin lesions will help to estimate their extent, depth and proximity to large blood vessels, nerves or other important structures. Langer's lines of skin tension [6] were previously used as a guide to incision, but the best cosmetic results are usually obtained by following the relaxed skin tension lines (RSTLs) [1,7], which tend to lie perpendicular to the major underlying muscles. Langer's lines and RSTLs often coincide, as on the neck. When they do not, as on the limbs, the choice depends on other factors. Excisions on the lower leg, for instance, close more easily along the long axis of the limb, rather than transversely. Testing for skin laxity by manipulating the skin usually clarifies the best direction in which to plan an excision. The size and type of excision made will also depend upon many factors, including the site and nature of the lesion to be excised and the nature of the planned skin closure.

The skin surface should be cleaned prior to operation with a detergent–antibacterial combination, most commonly containing either chlorhexidine [8] or povidone–iodine. This helps to reduce the risk of wound infection by removing pathogens and reducing the resident cutaneous bacterial flora [9].

Elliptical excision—general technique [2,3]

It can often be helpful to mark the planned lines of excision prior to cleaning the skin surface and infiltrating local anaesthetic. A reasonable period of time should be allowed for the anaesthetic to take full effect.

The small, round-ended Gillette No. 15 blade is most commonly used to make two hemi-elliptical incisions perpendicularly through the skin into the subcutaneous tissues. The length of the wound should be at least three times its breadth (the angles at the ends of the ellipse should not exceed 30°), taking care not to allow the incisions to cross each other ('fishtailing') at either end (Fig. 77.5). The skin ellipse is held firmly but gently with either fine-toothed forceps or a skin hook, and separated from its base. For both histological purposes and to facilitate wound closure, the excised specimen should contain subcutaneous fat.

For standard histological processing the specimen should be placed in a formaldehyde–saline specimen bottle, clearly labelled with the patient's details. To prevent curling of small biopsy or excision samples, these may be placed on small squares of filter paper and floated into the formalin solution. When histological confirmation of tumour clearance is required, it can sometimes be helpful to 'colour code' or place a suture at the '12 o'clock' position of the surgical specimen to facilitate orientation and examination in the pathology department. For immunofluorescence or frozen

section studies, specimens are placed on aluminium foil and immersed in liquid nitrogen.

Intraoperative bleeding is controlled by a combination of pressure, electrosurgery, clamping and ligation of vessels.

Depending upon the size of the defect and the body site, a variable degree of undermining of the wound edges will be necessary to facilitate the placing of subcutaneous absorbable sutures and to reduce wound tension. Finally, non-absorbable sutures are used to neatly appose and evert the wound edges [2,3].

The timing of suture removal depends upon the site and the amount of tension across the wound. With additional supporting surface tapes and buried sutures where appropriate, 4–5 days is usually sufficient for skin sutures on the face, 5–7 days for the scalp and neck and 10–14 days elsewhere.

Sutures [1–4]

An ideal suture would have high tensile strength, handle easily, provide good knot security and cause no tissue reaction. Skin sutures are of two main types: *absorbable* and *non-absorbable*.

Now that catgut is rarely used, popular synthetic *absorbable sutures* include Vicryl™ (polyglactin-910), Dexon™ (polyglycolic acid), PDS (polydioxane sulphate), Maxon™ (polyglyconate) and Monocryl™ (poliglecaprone), all of which cause very little tissue reaction and dissolve completely in 90–120 days. Absorbable sutures are usually placed either subcutaneously in the subcutaneous fat to close off potential dead space or as subcuticular intradermal sutures to close and evert wound edges.

Non-absorbable sutures include braided silk and synthetic monofilament sutures such as nylon (Ethilon™) and polypropylene (Prolene™). Most dermatological surgeons prefer the better tensile strength and low tissue reactivity of the synthetic monofilament sutures. Braided sutures such as silk and Dacron™ have better knot-tying properties but tend to drag through tissue, and their braided nature may increase the risk of wound infection. For wounds that are likely to remain under constant tension, such as those on the back or shoulders, a non-absorbable suture such as nylon can be used to close the deep subcutaneous layer. Alternatively, a running subcuticular Prolene suture can be left in place for long periods, leaving only two suture marks.

In general, skin suture needles are of the reverse cutting type (the sharp edge of the needle lies on the trailing rather than the leading edge). Suture sizes usually vary from 3/0 to 6/0, with suture selection depending on the wound size, anatomical site and surgeon preference.

Suture technique [2,3,5]

The ability to perform several different suture techniques is one of the skills needed in order to become proficient in dermatological surgery. The *simple interrupted suture* is the mainstay of final skin closure, although alternatives include a *running suture*, placed either as loops through the skin (*simple running suture*) or placed entirely within the dermis (*running subcuticular suture*). They are normally 4/0–6/0 gauge, and are placed close to the skin edge for fine approximation. If the wound tends to invert, then the deeper component of the suture can be placed more laterally to help evert the edges.

If there is tension across the wound, or a significant tendency to inversion, one or two *vertical mattress* sutures can be placed initially. A modification of this suture, the *half-buried mattress*, is also useful as a corner stitch when insetting the tips of skin flaps. The *horizontal mattress* suture (with or without bolsters) [6] can also be used to approximate long wounds or wounds under tension. Any wound tension must be managed by undermining and the use of buried sutures before the insertion of skin sutures. Failure to do this will increase the risks of infection and wound dehiscence, and often leaves permanent unsightly, papular or linear suture marks.

There are various forms of *buried suture*, which are used to close off 'dead space' in a deep wound. Normally, this is obliterated by the use of interrupted *deep subcutaneous* or buried absorbable dermal sutures [7], or by using a '*purse-string*' variant of the horizontal mattress suture. Running sutures, both cutaneous and subcutaneous, can be used to save time, but may be less secure than interrupted sutures and can be tricky to remove. The running subcuticular suture, although difficult to learn, is an elegant suture technique, and it can be left in place for long periods, leaving only two suture marks.

Tape closures (e.g. Steri-Strips™) may be used in conjunction with interrupted sutures or on their own if there is good approximation and adequate subcutaneous or subcuticular support. They provide additional wound support both while skin sutures are in place and for the immediate period following suture removal. Cyanoacrylate tissue glues may also be useful, especially in children [8], and for securing skin grafts [9].

Stainless steel staples are a rapid and effective way to close longer skin incisions. They are strong, incite very little tissue reaction, and can be useful for closing scalp wounds and skin graft donor sites [10].

Particular forms of excision

Variations in detail and technique apply to particular lesions and areas of the body.

Lesions on the shoulder and upper back

Surgical excision on the shoulders, upper back and deltoid areas frequently produces poor cosmetic results, with the formation of stretched and frequently hypertrophic scars. Although meticulous surgical technique, appropriate undermining and careful suture technique may minimize these problems, patients should be carefully counselled and only offered surgical excision in these areas when it is absolutely necessary. One suggested alternative to excision and repair in these areas is to excise the lesion with a narrow margin of normal skin and allow healing by secondary intention [1].

Benign naevi

Surgical excision, even by experts, leaves scars and consequently benign naevi are best either left alone or removed by shave excision when possible.

Non-melanoma skin cancer: basal cell and squamous cell carcinomas

Many different surgical and non-surgical techniques may be used to treat non-melanoma skin cancer [2,3]. The choice of treatment is based upon various factors relating to both the tumour [4] and the patient [5].

Small, primary well-defined lesions in areas of skin laxity are often best excised. An adequate margin should always be obtained, and prior skin marking following careful examination in good lighting is advisable [4]. Cure rates following surgical excision of such lesions can be excellent [6–8]. Some sites, such as the lips, ear, scalp and periocular and nasolabial areas, have a higher rate of recurrence, and (for squamous cell carcinoma) metastasis. Management of lesions in these sites, particularly if recurrent, poorly defined or showing infiltrative growth patterns, is best performed by a specialist dermatological surgeon [4,9].

Mucous membranes

Excision of lesions in the mouth and on the tongue, lips and genitalia can be difficult, with restricted access and often profuse bleeding. Consequently, only simple procedures should be attempted by non-specialists, and more complex cases referred to colleagues in oral surgery, urology and gynaecology as appropriate.

Keratoacanthoma

This is often difficult to differentiate, both clinically and histologically, from squamous cell carcinoma. Small lesions are often suitable for surgical excision, and larger lesions should be subjected to a transverse incisional biopsy passing from normal adjacent skin through the centre of the lesion and extending through the subcutaneous fat [10].

Pigmented lesions (see Chapter 54)

The diagnosis and management of pigmented lesions is a key component of clinical dermatology and forms an important part of the multidisciplinary treatment of malignant melanoma, also involving pathology, plastic surgery and clinical oncology.

Blue naevi, pigmented basal cell carcinomas, seborrhoeic keratoses and dermatofibromas are usually easily recognizable to the trained eye, although diagnostic difficulties occasionally occur. When diagnostic doubt exists, and especially when malignancy is suspected, the lesion should be excised and submitted for histopathological examination. When the lesion is too large to excise and repair directly, an incisional biopsy may be indicated (e.g. possible malignant change in a large congenital naevus or facial lentigo). In these cases, if malignant melanoma is proven on biopsy, a second procedure, possibly involving complex wound reconstruction, will often be necessary. In such cases, an initial incisional biopsy does not appear to influence the overall prognosis [11], although determination of key prognostic features (e.g. growth phase, depth of invasion, presence of vascular invasion) can only be made accurately from examination of the full excision specimen.

Hypertrophic scars

Although these may occur at any site, they are especially common in certain anatomical sites such as the upper back, shoulders and deltoid areas. Most will slowly resolve with time and regular gentle wound massage. Intralesional steroid injections can be helpful, but may cause skin and fat atrophy and should be used with caution. Hypertrophic scars may also be treated (and possibly prevented) by the use of Z-plasty techniques [12], with pressure dressings or devices [13], and silicone gel sheet dressings [14] and gel are claimed to be effective, although evidence is minimal [15].

Wound closure [1–3]

A significant part of dermatological surgical practice involves the repair of surgical defects. Wounds can be allowed to heal by secondary intention healing, closed primarily, or repaired using skin grafts or skin flaps. Experience and careful consideration of the various wound closure options are necessary in order to offer patients the best possible cosmetic and functional results.

The M-plasty [4]

This is occasionally useful if one end of an elliptical excision will cross an important anatomical or cosmetic line. In this situation, an M-plasty will help to reduce the overall length of excision required by bringing the apex of the excision back within the original area to be excised.

'Dog-ear' (synonym tricone) repairs [5]

'Dog-ears' (folds or humps of skin) tend to occur when the length to width ratio of an excision is insufficient to prevent the skin at the poles from bulging outwards when the opposing skin edges are brought together. They tend to occur more commonly when there is limited laxity or movement in the surrounding tissues. Excisions where the angle at the apex exceeds 30° are also liable to produce 'dog-ears'. 'Pseudo-dog-ears' occur if too much fat is left at the poles of an excision.

There are several ways in which this problem can be surmounted [3].

1 The excision can be extended and the redundant overlapping skin excised.
2 One side of the pucker can be cut back flush with the skin and the excess skin from the other side identified by drawing it across the wound; this can then be cut off.
3 The excess skin of the 'dog-ear' can be removed by converting it into a T-plasty or an M-plasty. This is a useful technique when the length of the wound cannot be extended [6].

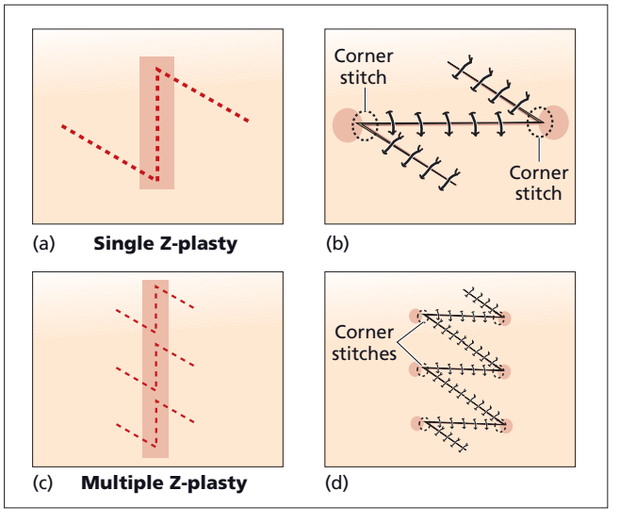

Fig. 77.8 Single and multiple Z-plasty. (a,b) Single Z-plasty. (c,d) Multiple Z-plasty. Note breaking up of zone of lateral tension (shaded areas) with multiple Z-plasty. (From Eedy *et al.* [7].)

Wound edges of unequal lengths

This problem can often be resolved by using a halving technique: a suture is placed across the centre of the wound and subsequent sutures used to divide the two resultant defects into ever smaller compartments. Because of local skin elasticity, the shorter side tends to stretch to match the longer. For more disproportionate edges, a wedge may have to be removed from the longer side in order to make the sides of the resultant ellipse more equal, or the wound can be sutured in the normal way and a 'dog-ear' repair performed to remove the excess skin from one side.

Z-plasty

This is a technique that is used to treat scar contractures, skin 'webbing' and to break up or alter the direction of linear scars to try to improve the cosmetic or functional result. The size of the angle used determines the increase in the length of the scar that will result (Figs 77.7 & 77.8).

Dressings

Wound dressings are not essential [1], although optimizing wound care by using an appropriate dressing probably produces a predictably better result. An ideal dressing should meet the following criteria:

1 Soaks up excess exudate from the wound surface, thereby reducing the risk of bacterial penetration.
2 Maintains a moist wound–dressing interface to encourage migration of epidermal cells over the granulating tissue. Covered split-thickness wounds heal faster than dry wounds [2]. A scab is a poor barrier against loss of moisture from the dermal surface because it allows the surface to dry out, thus forcing the epidermis to grow under the dry wound surface. As the epidermal cells migrate, they secrete a proteolytic enzyme which dissolves the base of the scab; migration ceases when cell–cell contact occurs [3].
3 Does not contain organisms or fibres that may contaminate the wound. Cellulose-derived dressings may shed fibre fragments into the wound [4], causing a foreign-body reaction and leading to increased risk of infection.
4 Is impermeable to bacteria.
5 Causes minimal injury to healing tissue when removed.

It is often claimed that a dressing that permits increased oxygen permeability aids wound healing. Such dressings do aid healing in split-thickness wounds [5]. However, in full-thickness wounds the same synthetic wound dressings create hypoxic conditions at the healing surface [6]. Paradoxically, tissue hypoxia in full-thickness wounds appears to stimulate rather than retard granulation tissue formation [7].

Basic dressing [8]

This includes contact, absorbent and outer layers [9]. The layer in contact with the wound is non-adherent, either because it contains a greasy ointment (e.g. tulle dressing) or because it is made from a specially designed, low-adherence material (e.g. polyethylene) [10]. The absorbent layer (e.g. cotton-wool, gauze) soaks up the excess wound exudate and cushions the wound. The outer layer (e.g. tubular bandage, elasticated tape) holds the other two layers in place and applies slight pressure. The basic dressing is left in place until suture removal, but needs to be changed if it becomes wet or is saturated with exudate [11], as this greatly increases bacterial penetration. Many proprietary dressings combine two or all three components (e.g. Melolin® contains a polyethylene non-adherent layer attached to an absorbent cellulose component). The hydrogel (e.g. Vigilon®), hydrocolloid (e.g. Granuflex®), xerogel (e.g. dextranomer starch polymer), alginate (e.g. Kaltostat®) and synthetic foam dressings are designed to provide all three components, and these can also be used on pressure sores [12,13], leg ulcers [14] and full-thickness surgical wounds [15].

Pressure dressings

These are placed over the basic dressing. Most commonly, and on suitable sites, a piece of compressible padded dressing (e.g. cotton-wool, sponge, eye pad) is pressed down onto the wound with an elasticated or *crepe bandage* for 48 h. Where bandage application is difficult, a *multitape dressing* can be used. Dental rolls are placed over and pressed down onto the dressing by using adhesive tape strips, and additional adhesive (e.g. collodion or tinct. benz. co.) is used to increase the tape adhesion. A *tie-over pressure dressing* is commonly applied over skin grafts, but can be used on any wound. Paired sutures are placed around the wound and tied together to hold down a three-layered contact, absorbent and compression dressing, so that the graft is held down onto the recipient site to prevent a haematoma forming beneath it. Aquaplast, a conforming thermoplastic material, is also used to tie over skin grafts [16].

Suggested dressing for wound types

Small full- or *partial-thickness wounds* (shave and curettage sites) require a simple low-adherent dressing or paraffin tulle held in place with a conforming adhesive tape. Unsutured punch biopsy sites do not appear to benefit from occlusive dressings, but heal better with a collagen matrix dressing than they do after simply applying Monsel's solution to stop bleeding [17]. *Sutured wounds* (side-to-side closures and flaps) require a greasy antiseptic ointment application and an absorbent-backed, low-adherent dressing held in place with a conforming adhesive tape. A pressure dressing may also be required. After suture removal, apply adhesive tape strips for 5 days. On a *full-thickness graft*, apply a simple contact dressing (e.g. greasy antiseptic ointment and paraffin tulle) and then a tie-over pressure dressing which includes a sponge or cotton-wool compressible pad. On *full-thickness wounds*, a variety of wound management methods are used. If acceptable to the patient, the wound can be left without a dressing and simply cleaned two or three times daily, and a sterile, white soft paraffin or Vaseline-based antiseptic ointment applied. Alternatively, the wound can be cleaned less frequently if a combination contact/absorbent dressing is applied. During the initial exudative stage (the first 4 days) the dressing will need to be changed at least once a day. Thereafter, the dressing should be changed if the wound surface starts to dry out or the dressing becomes saturated, wet or otherwise dirty. The wound should be cleaned with a simple antiseptic (e.g. aqueous chlorhexidine, 10 vol. hydrogen peroxide) before being re-dressed using a Vaseline-based antiseptic ointment (Polyfax®), and simple contact dressing (e.g. polyethylene/cellulose dressing; Melolin®) held in place with adhesive tape.

Alternatively, a semi-permeable adhesive polyurethane [18] or gel, or colloid dressing can be used and changed as necessary. *Split-skin graft donor sites* heal faster with a dressing that maintains a moist wound–dressing interface; for example, a calcium alginate [19] or semi-permeable adhesive polyurethane film [20]. A pressure bandage applied over the wound is also required, but bleeding will still occur. The exudate can either be allowed to drain through puncture wounds made in the lower portion of the polyurethane film, or can be removed by changing the dressing more frequently, although this may introduce infection and is painful.

Wound healing is delayed by topical steroid application [21], tobacco smoking [22] and possibly age [23] via a decrease in skin blood flow with increasing arteriosclerosis [24].

Secondary intention healing

Full-thickness wounds remaining after malignant [1,2] or benign [3] tumour excision can be left to heal by secondary intention. The cosmetic result depends on the wound site and the patient's age. The nasolabial fold, medial canthus, scalp and pre- and post-auricular skin produce particularly good results, although the technique can be used in many sites, including the fingers [4]. Almost half of the reduction in wound size occurs because of scar contraction [5] and subsequent stretching of surrounding tissues [6]. Therefore, if the wound is next to a mucocutaneous junction, such as the lip, ala nasa or eyelid, scar contraction may distort this free margin, producing poor cosmesis and function. Most other head and neck sites heal well, although in general the cosmetic results are best on concave rather than convex skin surfaces [7]. The older the patient the better the result, probably because wound contraction is aided by the availability of loose adjacent skin and because hypertrophic scarring is less common in older patients. The method can be used if there is doubt about the adequacy of excision, or closure of the defect requires a larger or more complex procedure, which the patient will not tolerate. In some situations, such as excision of naevi on the back [3] or the treatment of acne keloidalis nuchae [8] and hidradenitis [9], secondary intention healing is the preferred method as it results in a superior cosmetic result.

When a tumour is being excised, the specimen is orientated with a marking suture before complete removal, so that if further excision is required the affected margin can be identified. When bleeding is controlled, a contact dressing is applied, and this is covered by a pressure dressing for 24–48 h. Thereafter, the dressing can be changed at 2–4-day intervals, depending on the amount of exudate. At each dressing change, the wound is cleaned to remove crust or debris and a greasy antiseptic ointment (e.g. Polyfax®, Flamazine® or Betadine® ointment) and non-adherent dressing are applied. On average, a 25-mm diameter head and neck wound takes approximately 35 days to heal [10]. These wounds are surprisingly pain-free. Bacterial contamination may occur, but tissue infection is rare; when present the wound edge is tender, red and swollen. A yellow exudate is common in the first few days. Before granulation tissue appears, a yellowish fibrin clot covers the wound. Exposed periosteum and perichondrium must be kept moist and viable by using a saline-dampened alginate dressing. This encourages granulation tissue to migrate over the exposed area and also reduces the risk of bone or cartilage desiccation and necrosis [11]. If the periosteum has been stripped off, the exposed bone can be fenestrated or abraded to encourage the formation of granulation tissue and hence enhance re-epithelialization [12]. When the wound first heals, the scar often contains large looped vessels, which slowly disappear as the scar thickens. A slightly elevated, red, hypertrophic scar is then present, and the cosmetic result is not optimum until approximately 1 year (Figs 77.9 & 77.10).

Skin grafts

Skin of varying thickness can be used for skin grafting. A split-skin graft is not limited in size, because the donor site regenerates. Full-thickness and composite skin grafts potentially produce better cosmetic results than split skin grafts, but are limited in size by the amount of skin that can be harvested. Compared with flaps, grafts are technically easier to perform, but generally produce inferior cosmetic results because of the differences between the donor skin and recipient site.

Full-thickness grafts

A full-thickness graft is used, in preference to a split-skin graft, when the cosmetic result and strength of the repair are important. Any site with matching and spare skin is a potential donor site [1]. Common donor sites include the skin behind and in front of the ear, nasolabial fold [2], upper eyelid, inner aspect of the upper arm, lower abdomen and supraclavicular fossa. The donor and graft sites should match for skin thickness, adnexal structures, surface markings, weathering and texture. After carefully assessing the amount and shape of skin required, the donor skin is excised down to fat [3]. The fat is then trimmed off the under surface of the graft to aid new blood-vessel penetration. Edge sutures are used to prevent shearing forces dislodging the graft, and a pressure dressing, usually held in place using tie-over sutures, is employed to prevent a haematoma lifting the graft off the recipient site (Fig. 77.11). In most instances, the donor site is chosen because there are redundant folds of skin present and the skin edges can be sutured easily after donor skin excision. At some sites (e.g. behind the ear), the donor defect can be allowed to heal by second intention. Grafts take best on dermis and granulation tissue, perichondrium and periosteum, but will perish on exposed bone or cartilage and often fail on fat. Grafts fail because of infection or poor blood supply. The latter occurs because of faulty technique (e.g. incorrect haemostasis, suturing or wound care) or because the recipient site has an inadequate blood supply (e.g. previous radiotherapy or lower leg sites in people with compromised venous and/or arterial supply). All grafts contract, and near the lower eyelid this may lead to ectropion. Hence, at this and other critical sites, grafts should be 10–25% larger than the defect to compensate for this. Depressed graft scars may be elevated by injection of autograft fat under the graft [4]. Delayed grafting to allow the recipient site to produce granulation tissue increases the chance of graft survival and enables deeper defects to fill up prior to grafting, thus producing an improved contour [5].

Composite grafts

Composite grafts are defined as those comprising two or more germ layers. In dermatology, these are grafts containing skin and cartilage components. When used to repair full-thickness ala rim defects using skin taken from the helix rim, graft survival is unpredictable [6]. In contrast, composite grafts containing skin and perichondrium, or perichondrial cutaneous grafts, are claimed to be better than full-thickness grafts for nose, ear and periocular defects, as they contract less, induce new cartilage formation, and maintain their thickness and epidermal appendages [7].

Split-skin graft

Except in extreme circumstances (e.g. extensive burns) split-skin graft size is not limited by the amount of donor skin that can be harvested, because the donor skin site will re-epithelialize by regeneration from retained adnexal remnants. Split-skin grafts can therefore be used to cover very large wounds. Because the skin is thin and relatively transparent, split grafts are also sometimes used to cover tumour excision sites where the adequacy of excision is dubious, because recurrence is more easily identified through the thinner graft than it would be after full thickness or flap closure. The disadvantages of split-skin grafts compared with full-thickness grafts are the relatively poor cosmetic result and greater graft shrinkage [1]. When a split graft is taken, skin is sliced off through the dermis, leaving behind parts of the adnexal and follicular structures from which epidermis migrates to cover the donor site. Split-skin grafts can be taken using a hand-held knife or a mechanical dermatome (Fig. 77.12a). The latter is easier to use and produces a predictably good graft. *Meshing*, or cutting multiple parallel slits in the graft, allows it to expand rather like a fishnet stocking when stretched (Fig. 77.12b). The gaps are covered by epithelium migrating from the adjacent strips of the graft (Fig. 77.12c). A meshed graft will therefore cover a wider area, allow exudate to drain through the gaps (e.g. on the leg), and will conform to an uneven contour (e.g. ear). The common donor sites include the upper arm, upper thigh and abdominal wall. The donor site is best anaesthetized using EMLA® cream [8], and heals faster and painlessly with a dressing that maintains a moist wound–dressing interface (e.g. calcium alginate [9] and semi-permeable adhesive polyurethane film; Opsite®) [10].

Pinch grafts

Pinch grafts are occasionally useful for wounds of the lower leg, although the donor site heals leaving unsightly scars. The technique is simple [11], but without careful aseptic technique success rates are low [12]. The skin is elevated on a needle tip, the apex sliced off, and when multiple skin shaves have been harvested the

(b)

(c)

(d)

Fig. 77.11 Full-thickness graft on the nose. This basal cell carcinoma on the tip of the nose (a) was excised (b). The defect size and shape was recorded using a sterile paper template (c); the template was placed on the donor skin site (d) and the appropriate-sized piece of skin excised. The fat was trimmed off the undersurface of the donor skin, and this was sutured into place on the wound (e). A tie-over dressing was applied (f). Seven days later the dressing was removed and the graft was pink and had clearly taken (g). The subsequent cosmetic result at 3 months was excellent (h).

grafts are placed at regular intervals on the clean granulating ulcer. As with all leg-ulcer skin grafting, if the causative factors are not eradicated before grafting, the ulcer will recur even if the graft is initially successful.

Grafting techniques used for vitiligo

Epidermal grafts containing viable melanocytes can be harvested using suction blisters [13], or very thin split-skin grafts [14]. Before grafting, the epidermis is removed from the hypopigmented skin by freezing to create a blister [13], or by dermabrasion [14]. Alternatively, *mini-grafts*, or tiny (1.2-mm diameter) full-thickness punch grafts of normally pigmented skin are grafted, at 2-mm intervals, into similar-sized punch wounds sited in the depigmented skin [15]. Because melanocytes migrate approximately 2 mm away from the graft site, there is no need to graft the whole area, and because the punch grafts are so small there is minimal cobblestone effect at the recipient site. In both techniques, a hidden donor site, such as the upper inner thigh or lower back, is used.

(e)

(f)

(g)

(h)

Fig. 77.11 *Continued*

Grafts of cultured, autologous melanocytes have also been tried [16].

Acne scar punch grafts

Ice-pick acne scars can be excised using a punch biopsy blade, and the wound filled with a slightly bigger punch biopsy-shaped piece of donor skin taken from a matching but unobtrusive site (e.g. behind the ear). Dermabrasion is usually subsequently required to reduce the cobblestone effect [17].

Flaps (Figs 77.13–77.17)

A flap is a full-thickness piece of skin moved to cover a defect where the proximal portion, or pedicle, remains attached to the original site while the distal portion is moved to cover the defect [1]. The blood supply of any flap is therefore, initially, provided by its pedicle. The pedicle is sometimes based on a portion of skin which remains attached to the origin and sometimes, as in an island pedicle flap, the skin is entirely detached and the blood supply comes from the underlying subcutaneous tissue or muscle.

Dermatologists almost exclusively use *local flaps* and have no use for *distant flaps* or *free flaps*. *Distant flaps* are tunnelled subcutaneously, with a long muscle pedicle attached over long distances; for example, from the anterior chest wall skin to the head and neck. *Free flaps* involve the harvesting of, for example, a piece of forearm skin with an attached artery and vein; these vessels must then be anastomosed onto named vessels at the recipient site before the skin can be used to repair the defect.

Similarly, dermatologists mostly use *random pattern flaps* where the blood supply is inherent in the skin being moved, as opposed to *axial pattern flaps* which obtain their blood supply from one named artery; a possible exception being the midline forehead flap [4], which is based on the supratrochlear artery.

Random pattern flaps are also sometimes subdivided into *reticular*, where the blood comes from the dermal blood supply (e.g. a bilobe flap), and *segmental*, where the blood supply comes from perforating vessels in the subdermal plexus (e.g. island pedicle flaps).

The more closely a flap resembles a graft (thin, defatted skin) the greater is the contribution to its blood supply from the

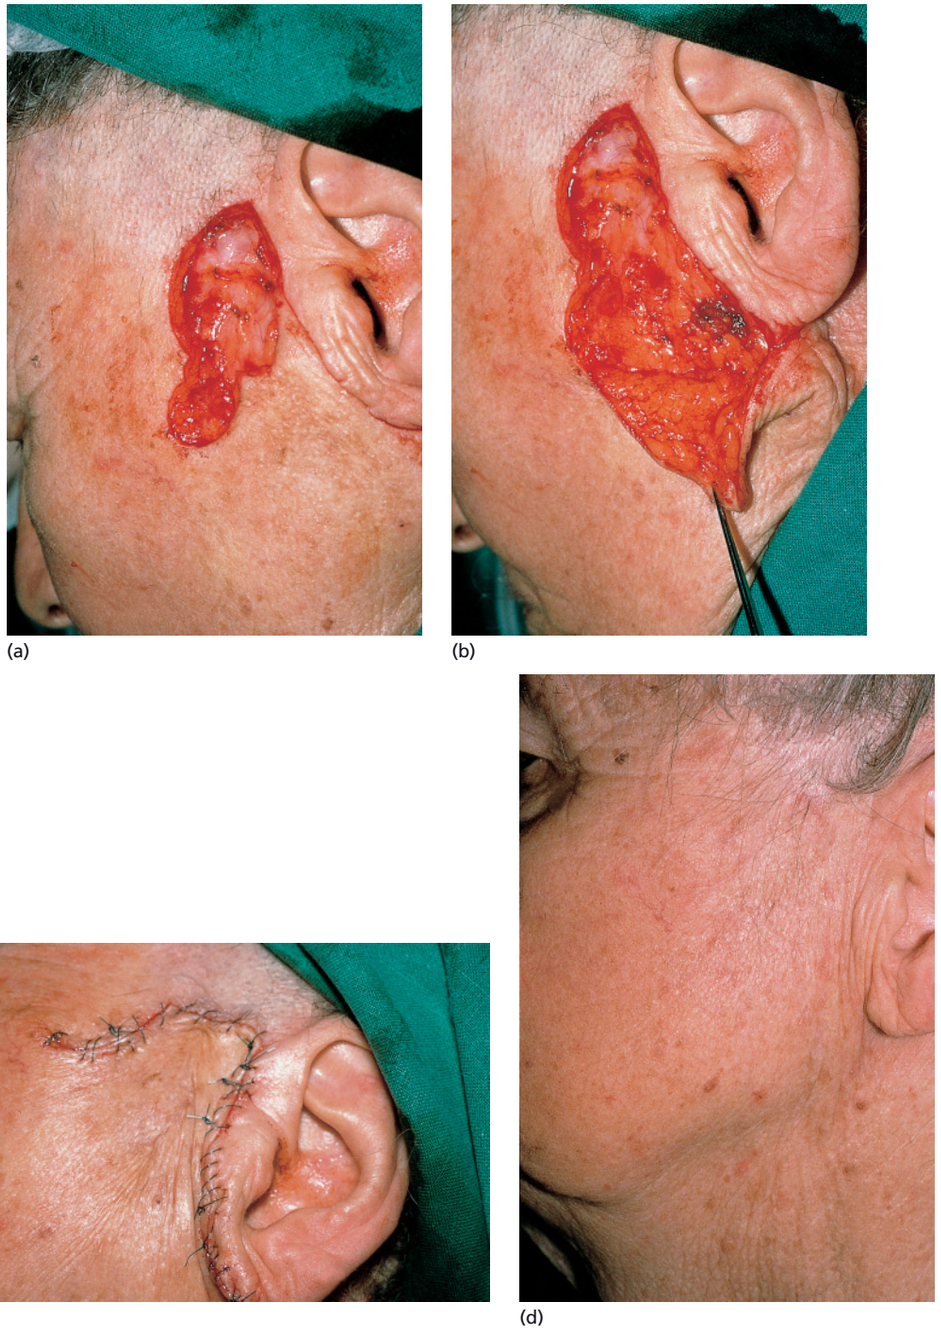

Fig. 77.13 Rotation flap on the pre-auricular skin. (a) This oddly shaped defect was closed (b) by rotating and advancing the loose skin under the chin up to cover the defect. (c) The incision line was placed in the skin crease at the anatomical boundary between the ear and the cheek, (d) and hence is inconspicuous 4 months later. The back cut was enhanced by Z-plasty under the ear (not shown).

recipient site rather than the flap pedicle. The thinner the flap, however, the greater the contraction, and this is particularly important when using thin skin around the eye. Different techniques can be used for many repairs [2], although some techniques [3] are inherently suited to the nose [4,5], chin [6], eyelid [7,8], ear [9,10], forehead [11], scalp [12], cheeks [13] and lip [14,15].

Flaps are variously categorized by the direction of movement, the name of the surgeon who first described the flap, the blood supply or the type of tissue moved. The most useful method relates to how the skin was moved to cover the defect—hence the description of advancement, rotation, transposition or pedicle flaps (Table 77.4). It is this classification that will be used here. As skin is moved to close the primary or original defect, a secondary defect is created which in turn also has to be covered. The essence of flap repair is to design the flap so that this secondary defect is created at a site where there is sufficient spare or loose skin to permit closure. On the face, loose skin is usually present in the middle of the forehead, the glabella region and bridge of the nose, the nasolabial fold, the front of the ear and the cheek. Hence, these areas of laxity will be exploited for most flaps.

Advancement flaps are used where skin must move in one direction from an area of laxity to cover the defect. Although simple to

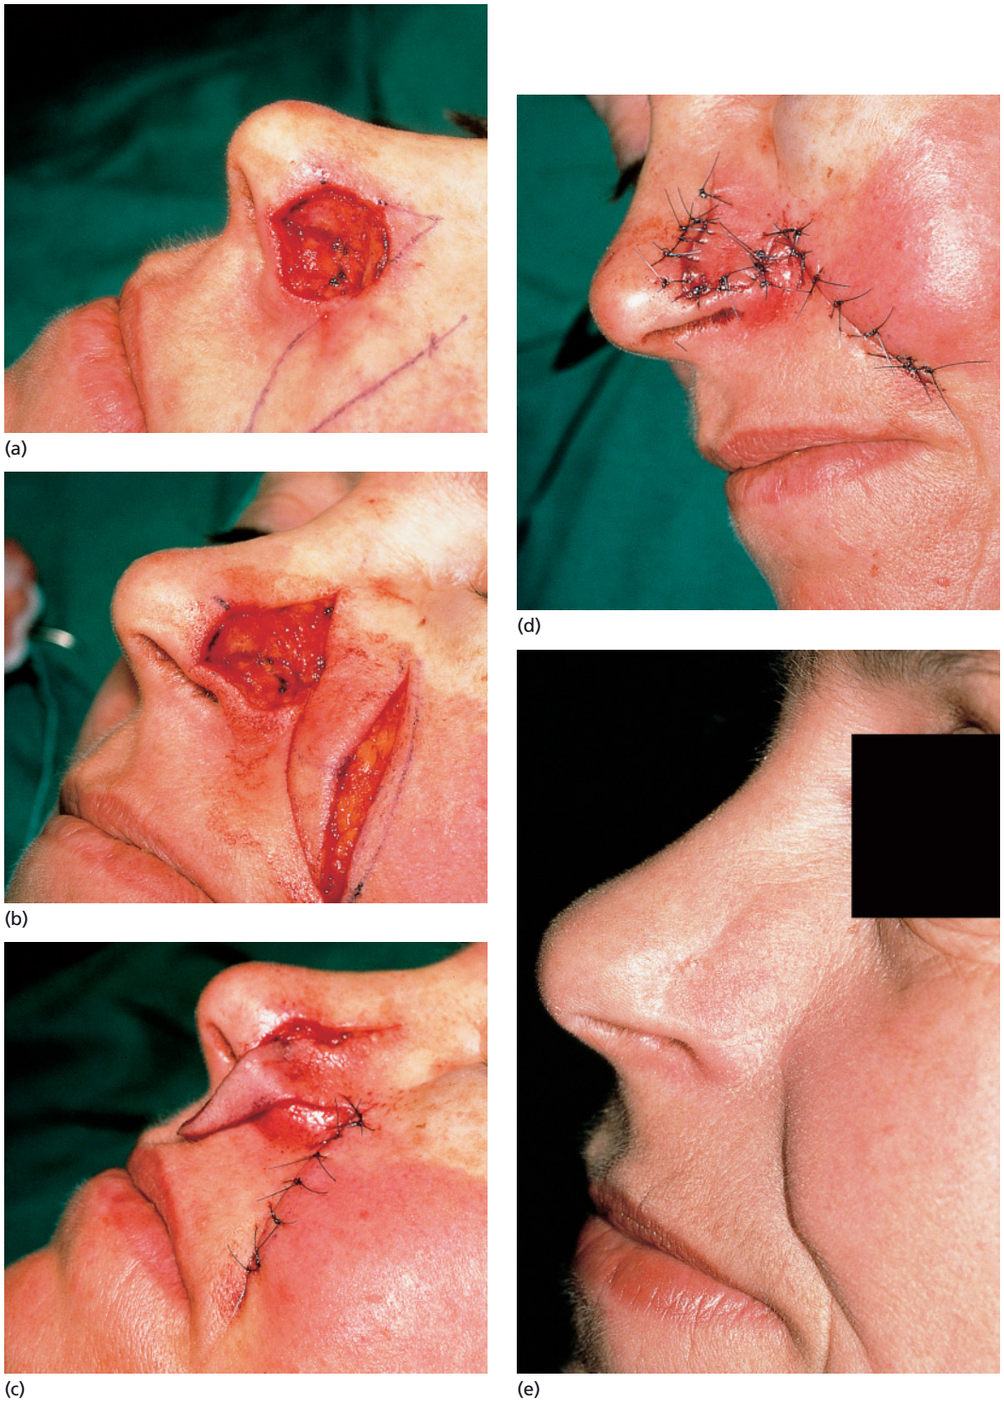

Fig. 77.14 Nasolabial fold flap. (a) This defect on the ala wall was covered by transposing a flap taken from the cheek skin (b). (c) The defect on the cheek was closed directly along the nasolabial fold, thus disguising the scar, and the flap of skin was then laid over the defect. (d) The flap was trimmed to shape and sutured into place. (e) The result 12 months later was good.

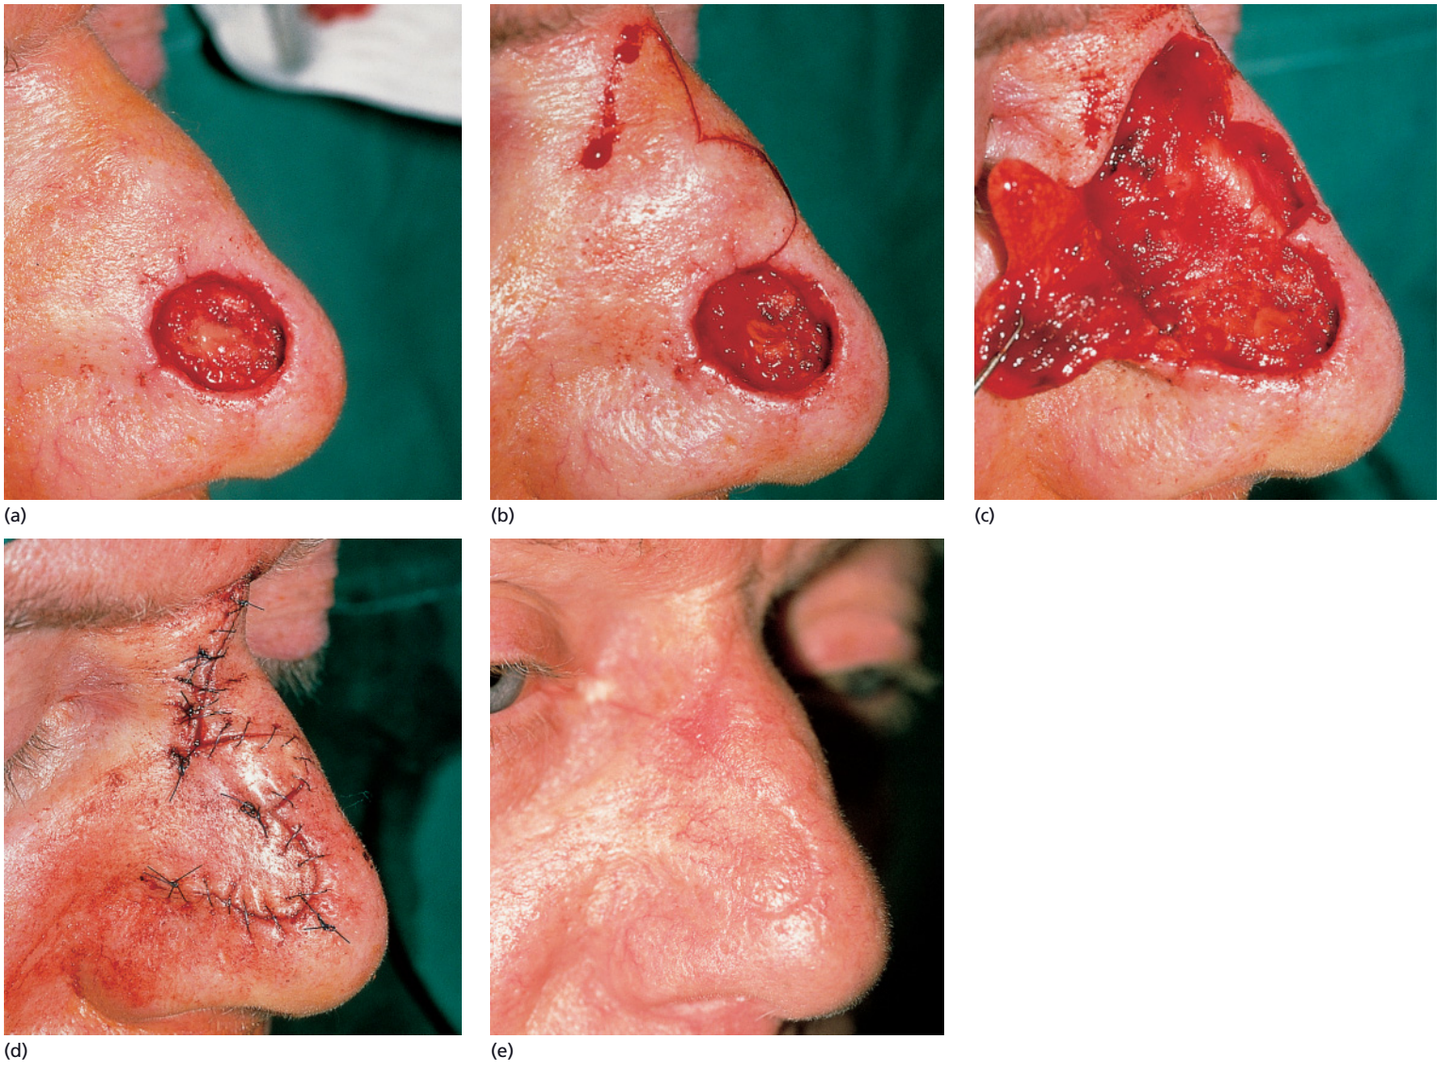
conceptualize they have limited use. The secondary defect is closed last, and the flaps have limited mobility. In many instances, defect coverage is only achieved by stretching the flap rather than transferring the tension to an area of lax skin. *Rotation flaps* usually require both advancement and rotation about a pivotal point on a broad pedicle (Fig. 77.13). Mobility is frequently limited, and long incisions and extensive undermining may be required to mobilize sufficient tissue; the secondary defect is closed last. *Transposition flaps* provide the greatest mobility, and the secondary defect is closed first (Fig. 77.14). As a result, the flap is pushed rather than dragged into the defect, so that if a transposition flap is designed properly virtually all the tension can be placed on the secondary defect rather than the flap, thus reducing the risk of ischaemic necrosis. These advantages make transposition flaps the most widely used (Fig. 77.15). A wide variety of flaps based on these three simple designs have been described, each with careful refinements for different sites (Table 77.4).



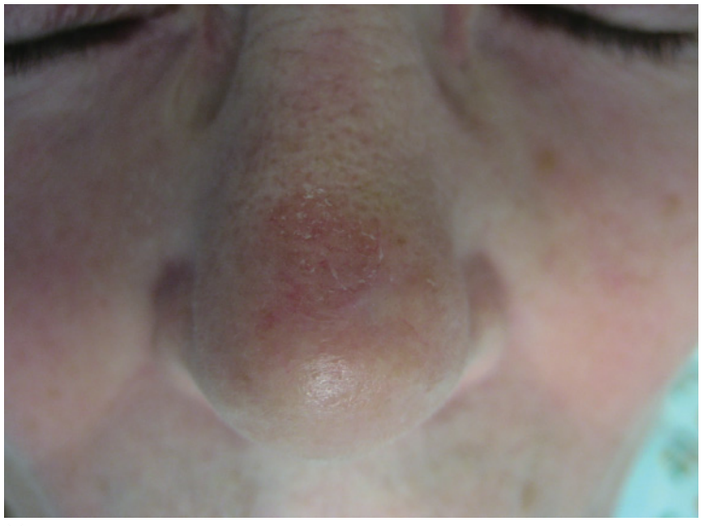


Fig. 77.15 Bilobed flap on the nose. (a) This defect near the tip of the nose was covered using a bilobed flap designed to cover the defect by exploiting the looser skin higher up on the side of the nose (b). (c) Both parts of the flap were raised together, and were transposed into the defect and the secondary defect; (d) the tertiary defect was closed directly. (e) The cosmetic result at 6 months was good.

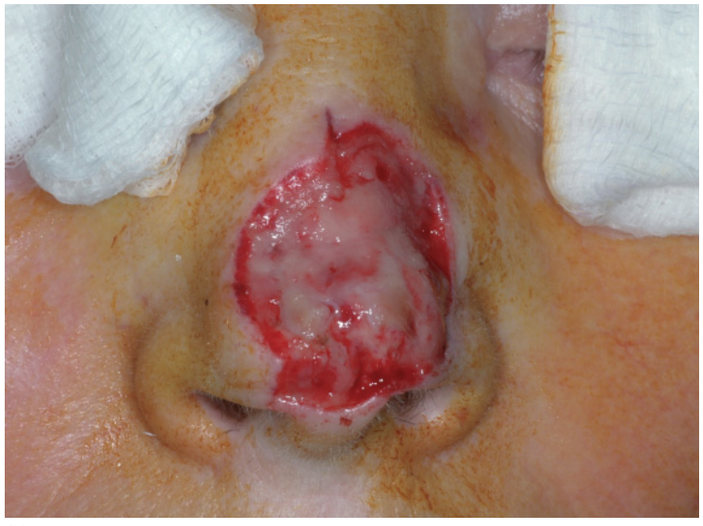

Pedicle flaps include island pedicle flaps and interpolation flaps. The island pedicle flap derives its nutritional support from the attached subcutaneous and muscle tissue, whereas the interpolation pedicle flap derives its vascular supply from a skin and subcutaneous tissue pedicle. The island pedicle flap is a one-stage procedure whereas the interpolation flap involves the creation of a bridge-like skin pedicle; this remains attached for 2–3 weeks at both the donor and defect site whilst the donor skin establishes another blood supply at the defect site. Interpolation flaps therefore always involve a second surgical stage when the pedicle has to be divided. Interpolation flaps are used when the nature, position or depth of the defect means that a simpler local flap or skin graft could not be used. Pedicle flaps still have to be moved into position by rotation, advancement or transposition, as described above, although the presence of the pedicle permits greater flexibility and less reliance on matching donor and recipient site.

Complications

Ischaemic necrosis of the flap usually occurs because of excessive tension resulting from poor design or mobility. Secondary infection is also more common if the flap has a poor blood supply [29]. On the head and neck, blood supply is excellent at all sites, but on the trunk, and especially on the lower limb, attempts at flap repair frequently result in failure because of relatively poor blood supply. Cigarette smokers are more likely to suffer from flap or graft necrosis than non-smokers (Fig. 77.17), although this can be reversed if smokers significantly reduce cigarette consumption 2 days before and 7 days after surgery [30]. If the flap scar is obtrusive, particularly on the nose, it can be revised by dermabrasion, which is best performed 6 weeks after surgery [31]. Manual dermabrasion [32] or scalpel sculpturing [33] may be less hazardous to the operator and equally effective.

(b)

(c)

(d)

Fig. 77.16 Interpolation flap. Midline forehead flap to cover a nasal tip defect. Excision of the ill-defined nasal tip BCC (a) resulted in a large and deep defect (b). Closure with a skin graft would have left a pronounced contour defect. The midline forehead flap was designed and sutured into place (c). Three weeks later the pedicle was divided. The final cosmetic result is good (d). The superior portion of the forehead donor skin was left to heal by second intention.

Fig. 77.17 Complications—flap necrosis in a cigarette smoker. Despite warnings, this patient continued to smoke before and after surgery. Possibly because of this, the rotation flap on her temple necrosed at 7 days.

Table 77.4 Flap types and uses.

Flap type	Random pattern flaps (synonym/s)	Uses	Comments
Advancement	Crescentic advancement flap [16]	Cheek/nose, cheek/upper lip closures	In effect side-to-side closure with special attention to cosmetic boundaries; a useful technique
	Single advancement (U-plasty)	Cheek, temple, forehead [6], upper lip [15]	If designed with a broad base can be very effective on the cheek
	Double advancement (H-plasty)	Forehead defects, eyebrow repairs	Little mobility, multiple scars, numb scalp; conceptually easy but difficult to get right
	O–T-plasty (A–T-plasty, V–T-plasty, Dieffenbach's winged V-plasty [17])	Lower eyelid, upper lip [15], forehead [6]	A bilateral advancement flap useful around the eye, lip, nose [3] and hair margin
	Single advancement (unilateral Burow's wedge flap) [3]	Upper lip, temple, cheek, forehead	A useful flap which is both advanced and rotated into position and the redundant skin removed using a Burow's triangle
Rotation	Single rotation with back-cut (hatchet flap)	Cheek, temple, medial canthus	A useful technique [1] (Fig. 77.13)
	Sliding glabella rotation flap (V–Y advancement)	Medial canthus, dorsal nose [18]	Exploits the redundant skin in the glabella area. Skin movement includes both advancement and rotation as do many rotation or advancement flaps
	Double rotation (O–Z-plasty)	Forehead, scalp, chin [6]	Large area of undermining required; only works on lax scalp
	Multiple rotation flaps (pinwheel design)	Scalp	Variant of O–Z-plasty
Transposition	Nasolabial flap [19]	Ala rim or side wall of the nose	Good results with careful attention to detail; pincushioning can be a problem (Fig. 77.14)
	Basic transposition/rhombic flap	Cheek, nose, chin, medial canthus, upper lip	Rarely if ever used as the true geometric rhomboid. Basic transposition flaps are very useful and generally exploit the natural elasticity of the skin so that the flap shape adapts to fit the defect [20]. A Z-plasty adaptation [21] may enhance flap mobility [22]. The glabella transposition flap (banner flap) [23] is a named variant.
	30° angle transposition flap [4] (Webster flap)	Dorsum of the nose	Not difficult; bilateral and single flaps can be used
	Bilobed [24]	Nose tip/side wall; medial canthus	Correct design important (Fig. 77.15)
Pedicle	*Interpolation flaps*		
	Median forehead pedicle flap (Fig. 77.16)	Full thickness ala wall defects; nose tip or lower third of nose	Variously described as an axial pattern flap and a random pattern flap. Two-stage procedure; the flap knuckle or pedicle has to be separated 2–3 weeks later
	Cheek interpolation flap	Nose tip or lower third of nose	In men the beard hair may be a problem at the recipient site
	Island pedicle flaps		
	Island pedicle flap [25] (kite flap of Dufourmentel)	Upper lip [14], trunk and limb	The blood supply comes from the subcutaneous tissue attached to the underside of the skin. A similar design is used in an axial flap employed for defects on the nose tip and ala. The pedicle is based on the branch of the angular artery that supplies the nasalis muscle [26]
	Bipedical advancement [27]	Forehead, nasal side wall, chin	
	Midline forehead island flap [28]	Medial canthus	The skin flap is tunnelled under the skin into the defect

Mohs micrographic surgery

Definition

Mohs micrographic surgery (MMS) is a specialized treatment for skin cancer which offers both extremely high cure rates and maximal preservation of healthy tissues. Repeated cycles of surgery and intraoperative microscopic examination of the entire surgical margin of the excised tissues allows accurate and dependable identification and removal of all residual invasive tumour. Mohs micrographic surgery is most often used to treat the most challenging forms of facial basal and cutaneous squamous carcinoma and can be used to treat less common forms of skin cancer.

History

The technique evolved from the pioneering work performed by Frederic E. Mohs while working as a cancer research assistant at the University of Wisconsin in the early 1930s. Initially called chemosurgery, the original technique involved the overnight application of a noxious zinc chloride paste, with subsequent excision of the devitalized, preserved tissues, and microscopic examination of histological tissue sections. Consequently, the wounds created had to be allowed to heal by secondary intention. Mohs introduced three features which remain fundamental to the success of the modern technique:

- the tissues were sectioned and examined in the *horizontal* plane
- a unique technique for marking and colour-coding excised specimens
- a mapping process to accurately identify the location of residual tumour which could then be excised with further cycles of treatment.

As experience of the technique grew, the combination of consistently high cure rates for large and extremely destructive tumours and the surprisingly acceptable results of wound healing by secondary intention [1], resulted in a gradual acceptance of the technique by the medical community.

Mohs, who was a formally trained general surgeon, first published his results in the general surgical literature [2], but as the main interest in his work was amongst dermatologists he subsequently began to publish in the dermatological literature [3]. Practical use of chemosurgery spread slowly amongst dermatologists, and nearly 30 years passed before there were enough 'chemosurgeons' to form a society; the original 23 members of the American College of Chemosurgery (ACC) first met in 1967 [4].

The evolution of chemosurgery into the technique that is now practised worldwide began at the 1970 meeting of the ACC when Tromovitch reported no recurrences in 99 (97%) of 102 patients following excision of basal cell carcinomas (BCC) using the Mohs technique but omitting the use of zinc chloride paste and simply excising living tissue under a local anaesthetic [5,6]. This 'fresh tissue' form of the technique had been first used by Mohs himself in 1953 and had become his preferred technique for the removal of periorbital tumours, a site where the use of zinc chloride paste led to particularly severe inflammation, swelling and morbidity [7].

As confidence in chemosurgery grew, it became increasingly clear that the success of the procedure was fundamentally linked to the comprehensive microscopic control of resection, rather than *in situ* tissue fixation. Consequently, there began a gradual move away from the use of chemosurgery and an increased adoption of the fresh tissue technique of Mohs surgery, most commonly using rapidly prepared frozen tissue sections. As a result, a painful, prolonged technique, producing sloughy, granulating wounds, was replaced by a procedure which could be performed comfortably under local anaesthesia, lasting hours rather than days, and resulting in defects which could be immediately reconstructed when necessary [8].

Treatment of skin cancer

Skin cancer can be treated with a variety of techniques including topical therapy, destructive procedures and radiation therapy. However, only surgical excision and MMS provide tissue suitable for histological examination of the surgical margins. The following are the fundamental differences between traditional surgical excision and MMS:

- Traditional surgical excision relies upon removing a predetermined margin of clinically normal skin from around and underneath the cancer, and generally wider and deeper margins are recommended for more advanced, difficult and recurrent tumours. Mohs micrographic surgery does not rely upon clinical estimation as the true extent of the cancer is revealed as the technique proceeds (Fig. 77.18a–f).

(a) Morphoeic eyebrow BCC, and defect (b) following MMS, showing extensive spread medially into the eyebrow; (c) poorly-defined BCC on the ear, and defect (d) following MMS, showing extensive spread and involvement of underlying cartilage; (e) morphoeic BBC left upper cheek, and Mohs defect (f).

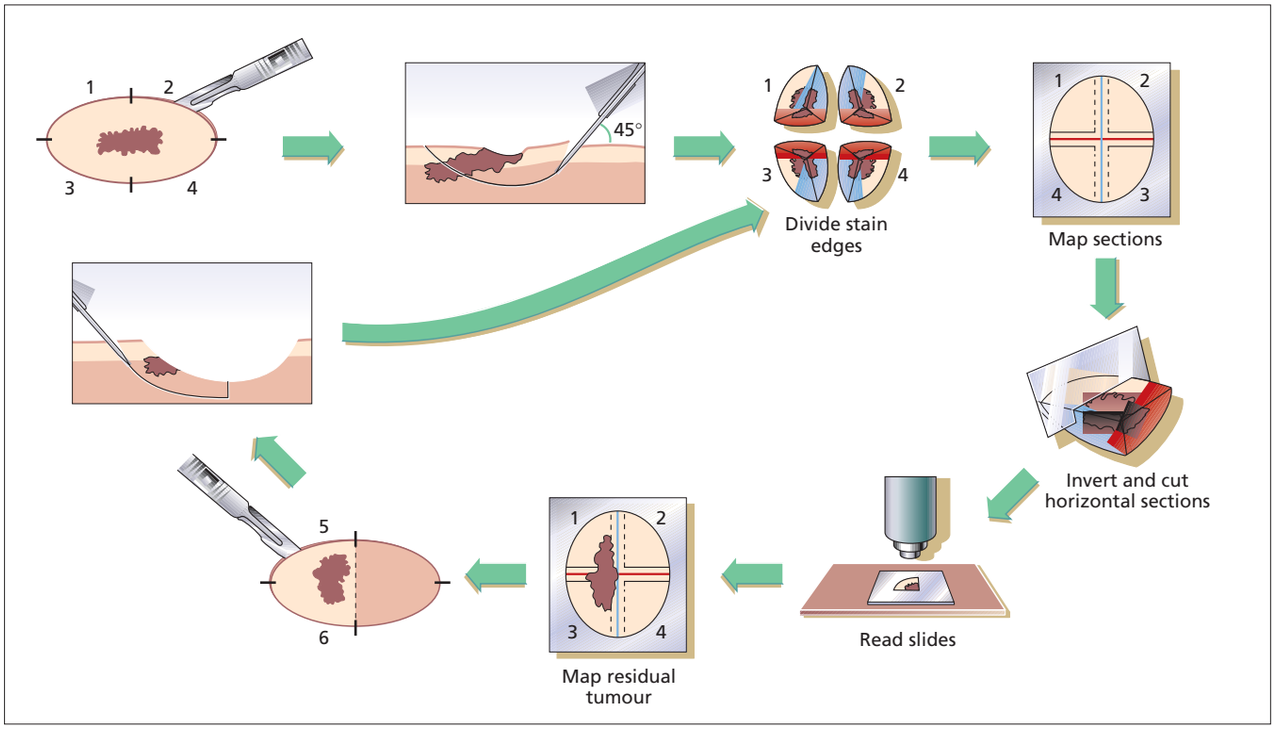

Fig. 77.19 The stages of Mohs micrographic surgery.

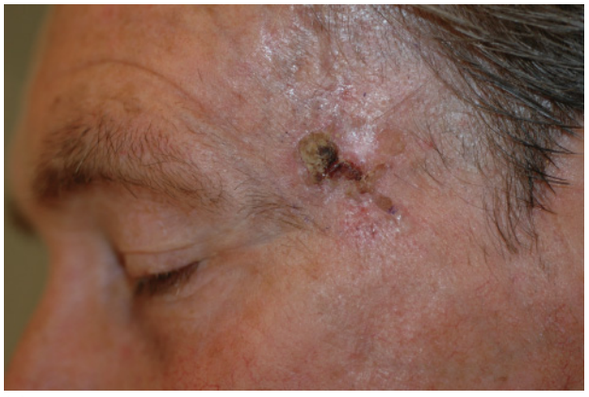

- Traditional surgical excision is generally followed by immediate reconstruction of the wound, with histological examination of the surgical margins occurring some days later. Mohs micrographic surgery uses intraoperative histological examination to establish complete tumour removal on the day of surgery. Consequently, traditional surgery may result in incomplete excision of the cancer, and difficult management decisions as the wound has already been repaired. In contrast, MMS confirms complete tumour resection *prior* to wound reconstruction.
- Traditional surgical excision generally relies upon histological evaluation of the surgical margins using vertically orientated tissue sections ('breadloafing') which has been estimated to have a sensitivity no greater than 44% [9]. In contrast, the horizontally-orientated tissue sections used in MMS are designed to allow microscopic examination of 100% of the surgical margin.
- Traditional surgical excision involves the surgeon, pathologist and possibly an anaesthetist. Mohs micrographic surgery is performed by the Mohs surgeon who also acts as anaesthetist, pathologist and reconstructive surgeon.

Procedure

The practical aspects of modern fresh-tissue MMS have been well described [8,10]. Essentially, the technique involves repeated cycles of local anaesthetic surgery and pathological investigation. Tissue is excised as a thin, flat layer with bevelled edges, which is accurately orientated, colour-coded, mapped, horizontally sectioned and examined microscopically (Fig. 77.19).

Any residual tumour identified at any part of the surgical margin is marked on the Mohs map, which accurately guides the Mohs surgeon in the re-excision of all residual tumour-involved areas (Fig. 77.20a,b). This methodical use of highly accurate, staged excisions underlies the high cure rates associated with the technique. In contrast, those areas of the wound that do not contain tumour are not excised further, which underlies the maximal tissue preservation associated with the technique. Each tissue layer is examined microscopically and, if there is still residual cancer, the process continues, layer by layer, until the cancer has been completely removed. Frozen-section histology is the preferred option for most experienced Mohs surgeons excising basal and squamous carcinoma [11], but permanent-section histology is used by some, and this means that the wounds cannot be repaired on the same day [12]. Mohs surgeons who routinely use frozen-section histology may occasionally use permanent-section histology when treating highly infiltrative or uncommon tumours [13].

In a feature unique to MMS, the final decision on the exact mode of wound repair is made only after the cancer has been completely removed, although likely wound repair options in a particular anatomical area can be discussed in advance. All wounds resulting from the old chemosurgical technique had to heal by secondary intention, but wounds following MMS are suitable for immediate reconstruction or secondary intention healing, whichever is most likely to result in the best cosmetic and functional outcome. In selected cases, other surgical specialists may perform reconstruction of the Mohs defect as part of a multidisciplinary approach to the management of aggressive facial skin cancer. In many major Mohs units, Mohs surgery is frequently performed in collaboration with plastic [14], maxillo-facial, otorhinolaryngeal (ENT) [15] and oculoplastic [16] colleagues.

(b) Intra-operative picture showing correlation between residual tumour (blue areas on Mohs map) and the Mohs defect.

Results

The results of MMS are impressive, with a 98–99% 5-year cure rate for BCC and a 94.4% 5-year cure rate for squamous cell carcinomas reported by Mohs himself [17]. There is considerable evidence supporting the use of MMS to treat the most difficult cases of BCC. A review of studies published since the mid-1940s suggested an overall 5-year cure rate of 99% following MMS for primary BCC [18] and 94.4% for recurrent disease [19]. Two prospective studies have been reported from Australia; in one, 5-year cure rates of 100% and 92.2% for primary and recurrent tumours were reported in 819 patients with periocular BCC [20], and in another study of 3370 BCCs on the head and neck treated with MMS there were 5-year cure rates of 98.6% for primary BCC and 96% for recurrent disease [21]. A retrospective review of 620 patients with 720 lesions gave estimated 5-year cure rates of 98.8% for primary BCC and 93.3% for recurrent disease [22].

Cutaneous squamous cell carcinoma (SCC) can also be successfully treated by MMS [17,23]. In an Australian multicentre study of 1263 cases (38.9% were recurrent lesions) treated over a 10-year period, there was an overall 5-year cure rate of 96.1% (97.4% for primary and 94.1% for recurrent disease) [24].

The comparative cost of MMS has been studied [25–27]. The procedure (to produce tumour-free margins) has a similar cost to traditional excision [25] but is less expensive than excision using intraoperative frozen-section control [26]. A study from the Netherlands found MMS was more expensive than traditional surgery [27], but as MMS is likely to produce much higher cure rates than standard excision it remains cost effective. The only study to date which tried to compare cure rates following standard excision and MMS [28] appeared to show little difference between the two treatment modalities. However, a failure to adhere to the study design (with 24 of 301 patients randomized to have standard surgical excision being moved into the MMS treatment group) raises concerns about the conclusions of this study [29].

Practical aspects and indications

Mohs micrographic surgery is a remarkably safe procedure when performed under local anaesthesia on a day-case basis [30,31].

The complete surgical margin control achieved by MMS lends itself ideally to the excision of tumours that grow in a contiguous (all parts of the tumour are directly connected to all other parts) fashion, and whereas the two most common tumours treated by MMS are BCC and SCC, many less common cutaneous tumours can be excised by experienced clinicians working in a multidisciplinary fashion and using either standard or modified forms of MMS. Such tumours include dermatofibrosarcoma protuberans (DFSP) [23,32], lentigo maligna [33], microcystic adnexal carcinoma [23,34], cutaneous sebaceous carcinoma [23], and extramammary Paget's disease [23]. The success of MMS has led to the development of other surgical/pathological techniques offering more comprehensive surgical margin control than is available using standard histology techniques. Techniques such as 'peripheral in-continuity tissue examination' [35] and 'three-dimensional histology' [36] all have their merits, but none has gained widespread popularity.

Many BCC and SCC lesions can often be adequately managed without the use of MMS, and the technique is generally reserved for 'high-risk lesions' [37,38], which can be defined by various criteria, including:

- Size (especially larger lesions) (Fig. 77.21a)
- Site (especially the perioral, periorbital, perinasal and periauricular areas where a combination of a high cure rate and maximal preservation of normal tissues and structures is vital) (Fig. 77.21b)
- Lesions with very poorly defined clinical borders (where it is difficult to accurately identify appropriate surgical resection margins)
- Clinically invasive tumours
- Failure of previous treatment (recurrent disease) (Fig. 77.21c)

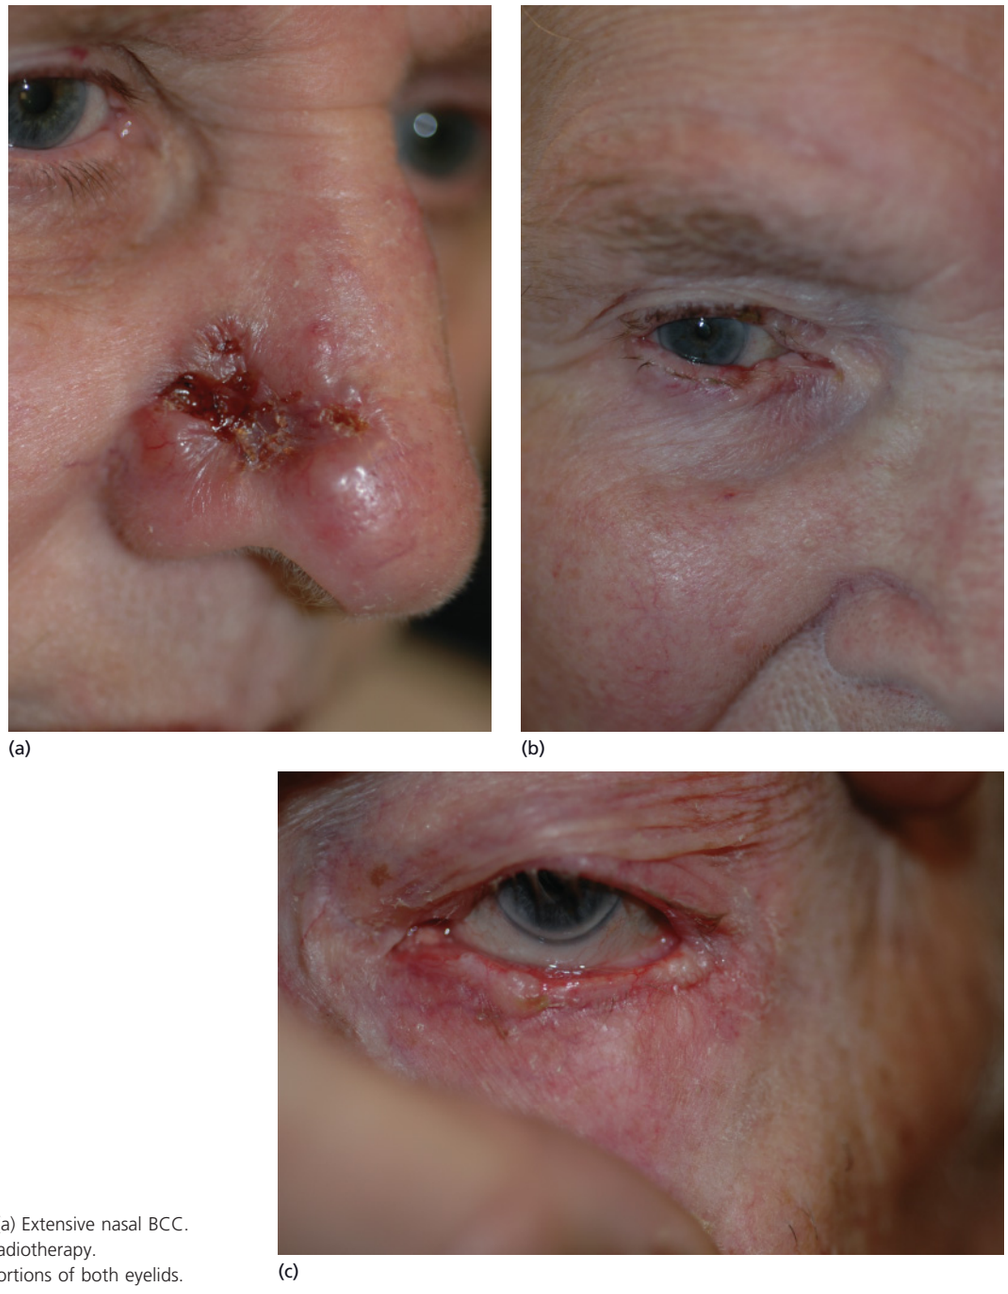

Fig. 77.21 'High risk' facial BCC suitable for MMS. (a) Extensive nasal BCC. (b) Extensive lower eyelid BCC, recurrent following radiotherapy. (c) Infiltrative medial canthal BCC involving medial portions of both eyelids.

- Histologically incompletely excised lesions
- Histological features (aggressive growth patterns, perineural spread).

Historically, the growth in popularity of the technique was due in part to its excellent success rate, highly practical nature, and the challenge posed by the reconstructive surgery required following many procedures. As the use of MMS became widespread the ACC first changed its name to the American College of Mohs Micrographic Surgery and Cutaneous Oncology (ACMMSCO), and is now the American College of Mohs Surgery (ACMS), with over 850 members. For many years the College and its members have undertaken a long-term policy of improvement of the specialty, through scientific and technical development and through the formalization of training for new Mohs surgeons through minimum 12-month, College-approved fellowships. Successful graduates from fellowship training, and others trained outside the College training schemes, should not only be proficient in the technique, but also be experts in cutaneous oncology, and highly competent reconstructive surgeons. The continuing success and development of MMS as a recognized specialty is dependent upon a consistent demonstration of high cure rates, maximal tissue conservation and good aesthetic outcomes of the technique, which can only result from appropriate training and experience.

Miscellaneous surgical procedures

Techniques

Hydrodissection

The skin can be lifted away from underlying critical arteries and veins by hydrodissection. Approximately 20 mL of saline is injected into loose tissue beneath the lesion, thereby lifting the area to be excised off any underlying vital structures. The injection must be given after local anaesthesia, just before excision. The technique works best where there is a boundary that will delay the spread of the saline, for example on the temple and the ear [1].

Snip excision

Small tags can be snipped off with a pair of sharp scissors without the need for local anaesthetic [2]. The tag should be pulled away from the skin and snipped off at its base; bleeding usually stops spontaneously. Haemostasis may be a problem with larger polyps with a well-developed blood supply; hence, an anaesthetic will be required. The wounds can be left to heal by second intention, with excellent cosmetic results [3].

Relaxing incisions

Relaxing incisions are one of several techniques used to increase skin mobility. Multiple, small, full-thickness incisions are made parallel to the skin edge at the site of greatest wound tension [4]. These allow the skin to stretch like a meshed graft, resulting in small elliptical defects, which heal by second intention. The technique is particularly useful for excisions on the lower leg, where it produces surprisingly good cosmetic results with less morbidity than split- or full-thickness grafts. The technique can be used with

other ways of improving skin mobility [5]. Other types of relaxing incision include the V–Y-plasty [6], which should not be confused with the V–Y island pedicle advancement flap (Table 77.4).

Wedge excision—lip, eyelid and ear

On the eyelid, lip and ear, a tumour can be excised and the defect readily closed by removing a full-thickness wedge with an appropriate margin of uninvolved skin. The different layers at the defect edges are then sutured, and thus the technique varies with the site. The inherent tissue elasticity of the eyelid and lip allows considerable defects to be repaired by direct closure without distorting the free margins of these structures. On the lip, defects smaller than one-third of the lip length can be closed directly following a wedge excision [7], if necessary using a W-plasty correction on the lower lip to avoid excessive distortion [8]. On the eyelid, defects of up to 50% can be closed directly, provided the correct technique is used [9]. However, a wedge excision on the ear reduces its size considerably, and buckling of the ear may occur unless the technique is modified to avoid this [10]. In most instances this type of defect is not a problem, as spectacles can still be supported by the ear and differences in ear size are rarely noticed.

Lipoma removal

Simple skin incision and lipoma excision ensures complete removal but produces a large scar. Scar size can be minimized by breaking up the lipoma into smaller fragments using blunt-ended forceps or a needle-holder inserted via a 4–6-mm punch biopsy wound made over the centre of the lipoma. The fragmented contents can then be squeezed out through the small wound. The fat can also be removed using liposuction [11]. A further development of this technique involves emulsification of the lipoma using an ultrasonic suction scalpel and removal of the fragments under endoscopic control [12]. A subfrontalis lipoma (Fig. 77.22) must be distinguished from a forehead epidermoid cyst. This can be particularly difficult to remove because of its site beneath the frontalis muscle of the forehead [13].

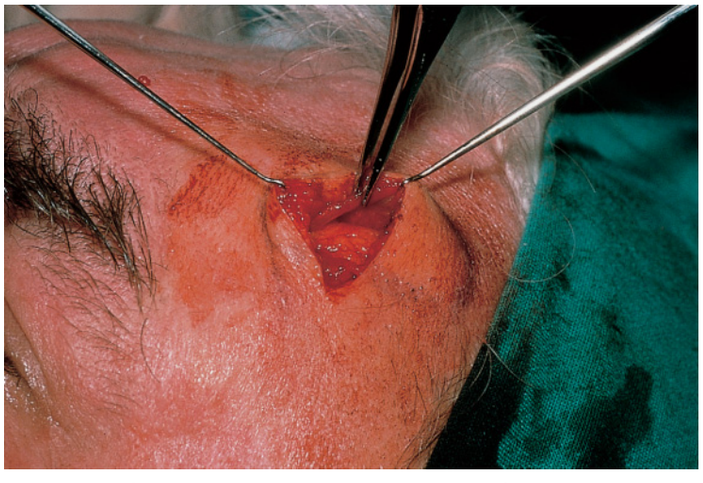

Fig. 77.22 Subfrontalis lipoma. This lipoma lies beneath the frontalis muscle. The muscle has been split vertically and is held back with forceps to reveal the lipoma.

Tissue expansion

Tissue expansion may be helpful if there is insufficient local skin laxity to allow immediate closure and a graft would produce a relatively poor cosmetic result. The skin needed to fill the defect can be stretched to the required size by steadily expanding saline-filled plastic bags placed under the skin adjacent to the proposed defect. For 8–12 weeks after insertion the bags are filled at intervals to produce a mound that stretches the overlying skin. When the defect is excised, the adjacent distended skin is then available to cover the resulting defect [14]. Because the skin used is almost identical to the piece excised, the cosmetic result is potentially excellent. Expansion does not simply stretch existing skin but actually appears to induce basal layer mitotic activity, an increase in dermal collagen, and development of an enhanced blood supply from the fibrous capsule around the implant. Atrophy of adjacent fat and muscle also occurs. In contrast, immediate tissue expansion or stretching the skin at the time of operation using skin hooks, Foley catheters [15] or sutures [16] increases available skin in the short term but appears to result in greater shrinkage and hence scar stretching.

Circumcision

This simple surgical procedure [17] may be indicated in the management of lichen sclerosus et atrophicus.

Specific diseases

Epidermoid cysts

Epidermoid cysts (sometimes incorrectly called sebaceous cysts) are lined by a keratinizing epithelium, which produces the cheesy, keratinous contents. They require excision if they are disfiguring or repeatedly infected. The inflamed tissue around an infected epidermoid cyst is friable, making it difficult to excise without fragmenting the cyst wall. An infected cyst should therefore be drained, and the patient treated with an appropriate antibiotic. When the inflammation settles the cyst can be excised. Cysts inflamed as a result of a foreign-body giant cell reaction to released keratin are best treated by triamcinolone injection followed by subsequent removal. Freely mobile cysts can be easily shelled out through the smooth tissue plane that separates the very thin cyst wall from the surrounding tissue, although at this plane the cyst wall is easily punctured and must be handled gently. In all cases the entire cyst wall and punctum should be removed, the latter at the centre of a small skin ellipse, which can also be used to manipulate the cyst during removal. If the cyst ruptures during extraction, every effort should be made to remove residual wall fragments to prevent recurrence. Irrigation of the wound prior to closure will help remove residual cyst contents which might otherwise cause a granulomatous tissue reaction. To avoid long scars, very large cysts can be decompressed via a 4-mm punch biopsy before excision [1]. The wound is either left to heal for 4–6 weeks before definitive removal of the shrunken cyst or an attempt can be made to pull the cyst inside out through the circular wound using artery forceps [2]. Immobile cysts are surrounded by extensive scar tissue and usually have to be excised with the surrounding fibrotic tissue and overlying skin. Excision of large skin cysts leaves subcutaneous dead space, which must be obliterated with deep sutures to minimize the risks of haematoma formation, infection and wound dehiscence.

Hidradenitis

If medical treatment of hidradenitis suppurativa has failed, involved areas can be excised and the defects covered with skin grafts or flaps. However, cure rates of less than 20% are reported [3] and secondary infection is a frequent problem [4]. Alternatives such as excision followed by healing by second intention are well tolerated by the patient and produce good results [5]. An even simpler procedure involves deroofing the fistula, leaving the floor of the track to re-epithelialize the wounded area. Excised tissue or suspect areas should be sent for histology because of the recognized complication of malignant change [6].

Vermilionectomy

This is sometimes called a mucosal advancement [7,8]. The vermilion, usually of the lower lip, is excised, principally because of actinic damage, and replaced by lip mucosa pulled forward and sutured at the vermilion–skin border.

Split ear lobe

Split ear lobes may be congenital, or occur as a result of trauma or wearing heavy earrings. Simply de-epithelializing the sides of the cleft and suturing the exposed edges usually results in a notch appearing at the lobe edge. A full thickness or single-sided Z-plasty correction of the cut edges, depending on lobe thickness [9], is advocated as the best way to ensure good cosmesis, although many other methods are described [10].

Partial or incomplete clefts can be repaired by excising and suturing the enlarged hole. However, if there is only a narrow band of skin separating the hole from the lower pole of the lobe, it is probably best to create a complete defect by cutting the small bridge of skin and closing the defect accordingly. Earrings can be worn again only in patients with thick lobes. Some repairs incorporate reconstruction of a new earring hole at the same time as repair of the defect [11].

Chondrodermatitis nodularis

Chondrodermatitis is a benign condition; the only indication for treatment is pain causing sleep disturbance. Conservative therapy includes a soft pillow, intralesional and topical steroids, and a pressure-relieving cushion is a good first choice alternative to surgery for antihelix lesions. Lesions on the helix are easier to treat surgically than antihelix lesions and give better cure results. Surgical excision of the affected cartilage without removal of skin (Fig. 77.23) will result in cure in over 90% of helix lesions and 70% of those on the antihelix [12]. Recurrences will occur if rough or protuberant edges of cartilage are left at operation, but can be treated using the same technique [13]. A novel 'punch and graft' technique has also been described [14].

Myxoid cysts

Myxoid cysts are ganglia arising as a result of joint fluid leakage from the distal interphalangeal joint into the surrounding tissues. The principle of treatment is that the connection between the cyst and the adjacent joint must be disrupted to prevent the cyst refilling. This is presumably what happens after successful cryotherapy [15], intralesional steroid therapy or curettage, although the cure rate of these procedures is relatively poor. The connection between the joint and the cyst can be identified by injection of dye into the joint [16]. Dye injection, however, is difficult and not essential. The joint fluid leakage site can be assumed to lie between the proximal portion of the cyst and the joint. A proximally based flap can be raised, to include the cyst and skin between the cyst and joint. The cyst is incised and drained. The flap is then resited (Fig. 77.24). The resulting scar presumably seals off the leak from the joint capsule [17].

Axillary hyperhidrosis

Axilla. If medical treatments fail (see Chapter 44), botulinum toxin can be used, and this blocks sweating for 4–6 months [18]. Axillary hyperhidrosis can also be treated by excision of the sweat-gland-bearing axillary skin [19]. The operation is not difficult, but wide excision scars invariably stretch, and infections are common. Shelley described the use of a transverse excision in the centre of the hair-bearing dome of the axilla approximately 4.5 × 1.5 cm wide [20]. The sweat glands can be visualized on the undersurface of the adjacent skin and many of these can be snipped off or destroyed by electrodesiccation when the skin edges are undermined and everted [21]. Methods that attempt removal of the

Fig. 77.23 Excision of chondrodermatitis nodularis helicis. (a) This helix nodule was treated by cartilage excision. An incision was made along the helix rim and the skin reflected to expose the cartilage. (b) A sliver of cartilage was taken to include the 3-mm punch biopsy of the skin nodule. Care was taken to ensure that the cartilage edges were smooth and gently shelving up to the uninvolved cartilage. (c) The skin edges were then sutured. (d) The result at 6 months was good.

sweat glands using subcutaneous curettage or liposuction [22], leaving the skin intact, are also described.

Palmar hyperhidrosis is difficult to treat. Endoscopic transthoracic sympathectomy [23] involves division of the sympathetic trunk running over the posterior wall of the chest cavity. However, side effects are significant, and over 80% of individuals develop compensatory sweating [24]. There is also a risk of Horner's syndrome and pneumothorax. In approximately 10% of cases [25], some recurrence of sweating occurs 1–2 years after surgery. The technique can also be useful in Raynaud's disease [26]. A similar approach can be used to reduce axillary sweating, when the second to sixth thoracic ganglia have to be destroyed. Access below the third thoracic ganglion is difficult, and this is believed to account for the poorer cure rate for axillary sweating [27]. Patients can also be successfully managed by repeated botulinum toxin injections into the palm. The effects last about 6 months. Injections are painful. Transient weakness of the small hand muscles occurs in 40% [28].

Cryosurgery

Various methods for freezing skin lesions have been described [1]. These achieve the following minimum temperatures: salt–ice mixture (–20°C), carbon dioxide snow (–79°C), dimethyl ether and propane (Histofreezer) (–50°C), nitrous oxide (–70°C) and liquid nitrogen (–196°C). Because of its very low temperature, liquid nitrogen works faster than other methods. It is also easy to use, inexpensive and readily available. Liquid nitrogen is therefore the most widely used cryotherapy agent. All significant studies of cryotherapy technique have used liquid nitrogen and it is the only agent discussed in this chapter. The effectiveness and freeze times of other cryogens have not been established.

Cryotherapy is believed to cause cell death in four ways.

1 Ice crystals formed in the cell damage cellular components [2]
2 Uneven intracellular ice formation during freezing leads to osmotic differences arising during thawing, which in turn causes cell disruption
3 Cold injury to small blood vessels results in ischaemic damage
4 Immunological stimulation produced by the release of antigenic components results in cell damage

The extent of injury is determined by the rate of freezing, the coldest temperature reached, the freeze time and the rate of thawing. Maximum damage is produced by rapid freezing and slow thawing. Repeating the freeze–thaw cycle produces much greater tissue damage than a single freeze because the greater conductivity of the previously frozen skin and the already impaired circulation both allow a greater and faster depth of cold penetration.

It is suggested that a temperature of –30°C is required to produce cell death. In practice tissue temperatures achieved during cryotherapy do not need to be measured because clinical studies have determined the duration of liquid nitrogen spray freeze times for common skin conditions.

Clinical methods

Liquid nitrogen is best stored in a pressurized container to reduce evaporative loss and the canister kept in a secure, ventilated, outside area. One litre of liquid nitrogen held in an unsealed vacuum flask will last approximately 6 hours. Liquid nitrogen can be applied using cotton-wool swabs dipped into the liquid. However, a liquid nitrogen spray can is easier to direct accurately, faster and more convenient.

Clinical uses

Liquid nitrogen cryotherapy has been used to treat a wide range of skin lesions (Table 77.5) [3]. The simplicity and speed of cryosurgery treatment is both a strength and a weakness. Cryotherapy can easily be done incorrectly and ineffectively. The correct technique and freeze times are required to produce results similar to those described in published studies [4].

Cryosurgical treatment of basal cell epitheliomas gives cure rates that compare favourably with other modes of therapy [5–7] provided the correct technique is used and the treatment limited to small (<20 mm), well-defined, previously untreated tumours, avoiding BCCs on the inner canthus of the eye, nasolabial and retro-auricular folds and the hair-bearing scalp. The temperature reached and the number of freeze–thaw cycles are also critical. Debulking the tumour using curettage or electrosurgery prior to cryotherapy is advocated by some authors [8,9]. However, lower leg Bowen's disease is best treated by curettage, which is superior to cryotherapy [10], which in turn is superior to radiotherapy [11].

Side effects [1]

Cryotherapy pain is significant but usually transient, and tissue swelling is common. Inflammation can be reduced with potent topical steroid applications [12]. Haemorrhagic blisters may occur but blister formation is not necessary for the cure of lesions such as viral warts. Sun-damaged and senile atrophic skin, and areas previously treated with topical steroids or X-irradiation, are more

likely to blister or become necrotic after freezing. Skin necrosis is a desirable part of the treatment of neoplastic and many preneoplastic lesions, and several weeks may elapse before healing is complete. Hypopigmentation is common after liquid nitrogen cryosurgery, is particularly noticeable in dark-skinned patients and may be permanent [2,13]. Temporary post-inflammatory hyperpigmentation is to be expected following less severe freezing. Nerve damage resulting in paraesthesiae, distal anaesthesia and motor paralysis occasionally occurs [14]. Similarly, deep freezing over the lacrimal ducts may, very rarely, lead to permanent ductal obstruction [1].

Curettage

Curettage is only possible when the curetted material is more fragile than normal skin (e.g. BCC), or there is a natural cleavage plane (e.g. seborrhoeic wart) between the lesion and the surrounding skin. On mobile or fragile skin areas, a starting point for curettage can be made by fulgurizing the rim using an electrosurgery machine. Stop bleeding using either a chemical haemostatic agent (e.g. aluminium chloride 30% in isopropyl alcohol), cautery or electrodesiccation. Do not use alcohol-based skin-cleansing solutions for the latter because of the fire risk. The resulting partial-thickness wound heals by re-epithelialization from the retained adnexal epithelium.

Benign lesions

Curettage of viral warts is sometimes effective. Treatment is painful and there is a risk of scarring and recurrence. Solitary warts on the face of adults can usually be removed by curettage, otherwise viral warts should only be curetted off when other methods have failed. Curettage is probably justifiable in painful plantar warts that have not responded to other therapies. Nerve block anaesthesia may be required [1] and there is a risk of painful scar formation. Peri- and subungual warts are difficult to curette off; the nail may have to be partially removed to allow adequate curettage. Genital or perianal warts that have not responded to cryotherapy, podophyllin or imiquimod can be curetted off. Seborrhoeic warts can be treated by cryotherapy or curetted off. In contrast, pyogenic granulomas (Fig. 77.25) and hypertrophic or solitary actinic keratoses (Fig. 77.26) are best treated using curettage, as this permits histological confirmation.

Non-melanoma skin cancers

The technique is the same for both BCC and SCC (Fig. 77.27). Tense the anaesthetized skin around the lesion and scrape off the bulk of the tumour using a small, sharp curette [2]. Beware of differences in technique required when using a disposable sharp curette rather than a reusable curette. The sharp side of a disposable curette is sharp enough to slice through the underlying dermis. A fragmented specimen should be mounted on a small piece of paper, where it is allowed to congeal, before being dropped

(a)

(b)

(c)

Fig. 77.25 (a–c) Curettage and electrodesiccation of a large pyogenic granuloma on the palmar aspect of the middle finger.

into formalin. In this way the pathologist receives a single sample rather than multiple small floating fragments. Cauterize, using a hot wire with a beaded tip, or electrodesiccate the wound surface. Repeat the curettage using a smaller curette to search for residual pockets of tumour. At this stage the curette will be scraping against the normal dermis and less material will be removed. Repeat the cautery or electrodesiccation. A third cycle of curettage and cautery is required if a large amount of material is removed at the second stage. The histological specimen only confirms the diagnosis; it provides no indication about the adequacy of treatment. Do not curette recurrent tumours because of the high recurrence rates [3]. If the curette penetrates the dermis and enters fat, curettage should be abandoned as it is impossible to distinguish between soft tumour tissue and the underlying fat; if this happens the curette site will need to be excised down to and including fat. Perforation of the dermis is particularly likely to occur if an incisional biopsy has been taken prior to treatment.

Basal cell carcinoma (BCC)

Curettage of BCCs depends on the tumour being easier to scrape off than the surrounding normal tissue. Thus, if strands of fibrous tissue separate clumps of tumour (as occurs in morphoeic, infiltrative, recurrent or invasive BCCs) or the adjacent skin tears easily, cannot be tensed or hair roots impede curettage, the results will be poor and curettage should be avoided. High recurrence rates occur after curettage of recurrent [3], morphoeic [4] or large tumours [4,5], or treatment by inexperienced operators [6] (Table 77.6). When small [4–8] (less than 20 mm diameter), non-recurrent tumours [3,9,10] on suitable sites (Table 77.7) are curetted by experts [6,11], the 5-year cure rate is 95% or better (Table 77.8). Cautery and electrodesiccation can be used interchangeably and their use improves cure rates [12]. Paradoxically, despite these high cure rates, histological examination after curettage and electrodesiccation shows that some residual tumour is present in almost 30% of cases [13,14]. Thus, cure must also depend on other factors, such as residual tumour cell mass, inflammatory reaction and healing responses.

Squamous cell carcinoma (SCC)

Experience shows [8,10,15] that well-differentiated, primary, slow-growing SCCs arising on sun-exposed sites can be cured by curettage and cautery (Table 77.9). However, SCCs with a higher risk of recurrence or metastasis should not be treated by curettage. These high-risk SCCs include lesions arising on scars, ears, lips, areas of radiation or thermal injury, chronic ulcers or sinuses, Bowen's disease and non-sun-exposed sites; and large (>20 mm), thick (>4 mm), poorly differentiated and recurrent SCCs or those arising in an immune compromised patient [16,17].

Intraepidermal carcinoma (Bowen's disease)

Intraepidermal carcinoma, especially on the lower leg, heals better after curettage than cryotherapy [18], presumably because the depth of tissue destruction is more easily determined by the operator. Radiotherapy, excision, topical 5-fluorouracil and imiquimod [19] are all alternatives.

Fig. 77.26 Curettage and cautery of an actinic keratosis. (a) After local anaesthetic injection, this hyperkeratotic actinic keratosis was (b) curetted off and (c) the wound cauterized. (d) At 4 months the wound had healed leaving a barely visible scar.

Electrosurgery

Electrosurgery includes electrodesiccation, electrofulguration, cutting diathermy (synonym electrosection, electroresection) and electrolysis [1,2]. Coagulation or tissue destruction is produced by the heat created as the electrical current passes through the tissue. Although not strictly an electrosurgical technique, electrocautery is usually also included because of its development from the age-old method of using heat in the form of hot oils, cautery irons, etc. to control bleeding.

Electrocautery

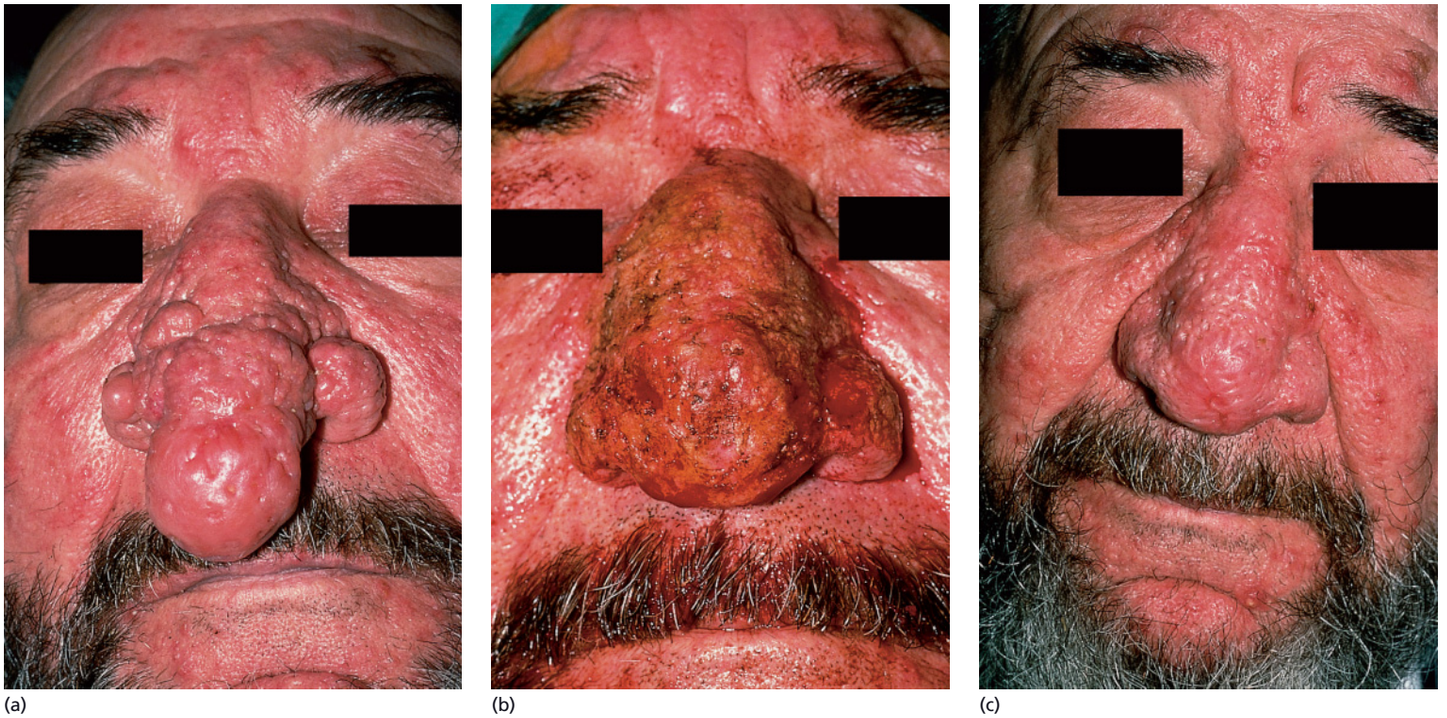
Synonyms
- Cautery
- Heat cautery
- Hot-wire cautery

The cautery machine power output should be controllable so that the tip temperature can be adjusted rather than being dependent on the battery power. A variety of tips are available. The beaded

(a) (b)

Fig. 77.28 (a) Electrodesiccation. Electrodesiccation occurs when the needle remains in contact with the skin and no spark occurs. The resulting tissue damage is deeper than that produced by electrofulgaration. (b) Electrofulguration. The needle tip is not in contact with the skin. As the spark jumps between the skin and the needle its energy is spread over a greater area, resulting in more superficial tissue damage.

tip is best for haemostasis after curettage and shave biopsy; this should be just hot enough to char a cotton swab, but not red hot as the platinum tip may melt. If the beaded tip drags on the tissue as it is drawn across the wound, the tip temperature is too low. After use, any remaining debris should be burnt off by briefly allowing the tip to glow red hot. The needle-like end of the cold point cautery tip is heated, by conduction, via a wire coil, and, before the advent of lasers, was used to treat spider naevi. The flat blade can be used for pedunculated lesions or shave excisions, but has to be glowing red hot to cut through tissue, producing a heating artefact on the excised material. Furthermore, the red-hot blade has to be quickly passed through the skin to avoid excessive heat damage at the wound site, so the direction and depth of the cut cannot be adjusted easily and the blade may accidentally cut or burn deeper into the tissue than required.



Electrosurgery

Synonyms
- Surgical diathermy
- Cold electrocautery

Waveform. Electrosurgical equipment converts domestic alternating current into high-frequency alternating current. When this passes through a high-resistance medium, such as the skin, heat is produced, resulting in tissue coagulation, desiccation or cutting, depending on the electrical waveform. A highly damped waveform (i.e. intermittent pulses of electrical discharge separated by intervals of zero voltage) results in electrodesiccation/fulguration. In contrast, a continuous waveform produces a cutting effect and a moderately damped or blended waveform (i.e. a mixture of continuous and highly damped waveforms) chiefly produces coagulation [3].

Unipolar/monoterminal/bipolar diathermy. Apart from the waveform produced, electrosurgery equipment also varies in the way the current is discharged and collected. Unipolar (monopolar) current is delivered via an active electrode, usually a needle or ball tip, resulting in a high concentration of current at the electrode tip. The current disperses through the patient's body and is collected via a dispersive (synonym indifferent, passive, return, earthing, ground) electrode with a large surface area. The current density falls with increasing distance from the active electrode and there is minimal risk of tissue damage as the current is collected over the large area of the dispersive electrode. If, due to faulty application or equipment, there is only a small area of skin/electrode contact, a burn may occur at the dispersive electrode. Also, if the current is channelled at narrow points along its path, for example the finger, an area of high-current density leading to tissue damage can occur. Bipolar electrodes avoid these hazards by producing and collecting the current using forceps so that current only travels in the tissue held between the tips. Monoterminal electrosurgical equipment (e.g. Birtcher Hyfrecator) produces a high-voltage, low-amperage current, and is designed to be used without a dispersive electrode. There is, however, a risk of a small but painful discharge occurring between the patient and the operator or other earthed point, for example the metal edge of an electrically insulated couch [4]. This can be prevented by maintaining a large area of skin contact between the operator and patient during use, or using a dispersive electrode.

Electrodesiccation/electrofulguration. These effects are produced using a monoterminal or unipolar electrode. Electrodesiccation (Fig. 77.28a) occurs when the needle remains in contact with the skin and no spark occurs. Because the current concentration is greater at the point of contact, the tissue damage is deeper compared with electrofulguration (Fig. 77.28b). During the latter,

(a) (b) (c)

Fig. 77.29 Shave excision and electrosurgery of a rhinophyma. (a) This disfiguring rhinophyma was reduced in size and (b) the nose shape recreated by shave excision and electrodesiccation of the bleeding surface under local anaesthetic, (c) resulting in an acceptable cosmetic result at 4 months.

the needle tip is not in contact with the skin and a spark jumps between the skin and the needle, but its energy is spread over a greater area. The resulting heat causes superficial damage to the tissues and is an effective way of stopping bleeding. Various needle tips have been developed for specific circumstances [5]. Because of the risk of virus transmission, a different, clean needle must be used for each patient [6].

Pacemakers and electrosurgery

There are reports of electrosurgery interfering with pacemaker function and causing temporary asystole if there is no underlying cardiac rhythm, or a demand pacemaker to switch to a fixed-rate mode [7]. The effect lasts only as long as the unit is being operated. When diathermy finishes, the pacemaker reverts to normal function. There are also anecdotal reports of the pacemaker failing shortly after electrosurgery [8]. Only pre-1990 pacemakers seem to be vulnerable, and modern pacemakers are considered to be resistant to these problems. All types of electrosurgical equipment, except cautery, can in theory cause problems, although bipolar diathermy is the least hazardous. When treating a patient with a pacemaker, short treatment bursts (less than 5 s) should be used, and diathermy should not be performed within 15 cm of the heart, the pacemaker or its leads. If considered necessary, the patient's heart rate can be monitored, and resuscitation equipment should be available. If monopolar diathermy has to be used, the path from the active electrode (diathermy tip) to the dispersive electrode should be at least 15 cm from the heart, the pacemaker and its leads.

Spider naevi

Spider naevi are probably best treated using a pulsed dye laser. They can also be destroyed using cold point cautery or electrodesiccation, but with greater risk of scarring.

Xanthelasma

Electrodesiccation and curettage of xanthelasma is relatively simple. The anaesthetized skin overlying the xanthelasma is fulgurized and disrupted. The underlying fatty deposits can be electrodesiccated, scraped off using a sharp curette, and left to heal by second intention. Trichloroacetic acid and ablative laser therapy can also be used.

Small seborrhoeic and plane warts

Eyelid seborrhoeic warts can be softened and removed by electrodesiccation provided the anaesthetized eyelid margin is pulled away to prevent conjunctival damage.

Surgical paring and electrofulguration of rhinophyma

Cutting diathermy (synonym electrosection) using a unipolar diathermy and dispersive plate is particularly useful for treatment of rhinophyma, where bleeding can be a problem [9]. Re-epithelialization takes place, with surprisingly little scarring, from the abundant pilosebaceous follicles which remain in the dermis (Fig. 77.29). Carbon dioxide laser resection is also effective.

Infrared coagulation [1–3]

The infrared coagulator produces non-coherent wavelengths in the visible and infrared spectrum of 400–2700 nm from a tungsten halogen bulb. The energy is transmitted along a quartz glass light guide, at the tip of which is a sapphire cap, which is placed in contact with the skin. The heat imparted causes thermal injury to a depth dependent on the duration of exposure, which can be set on an automatic timer and varied from 0 to 1.5 s, for example a 1-s exposure will remove tissue to a depth of approximately 0.75 mm.

The major characteristics are:

1 Non-laser radiation of maximum output 960 nm (near infrared)
2 Tungsten halogen bulb power source—15 V, 150 W
3 Pulsed energy
4 Solid quartz glass light guide
5 Diameter of treated area 2–10 mm, the larger diameters enabling more rapid treatment
6 Sapphire cap to light guide—sapphire is transparent to near infrared but rapidly conducts away heat generated in the upper dermis
7 Minimum optical hazard—the appearance of bright visible radiation causes aversion of the eyes if it is pointing in their direction, thus preventing infrared damage
8 It is portable, and relatively cheap.

It has been used mainly for tattoos [1], a variety of superficial vascular lesions [2], warts and myxoid cysts of the digit. Tattoos [1] can be treated with remarkably little morbidity. The area to be treated is mapped into overlapping circles similar in diameter to the sapphire tip, and each circle is treated with a pulsed exposure of approximately 1.25 s. An ice cube applied to the skin for 5 s before and after treatment is used to minimize conducted heat damage to surrounding skin. The immediate appearance of the coagulated tissue is white and slightly contracted; the eschar that develops over several days drops off in 2–3 weeks. Serous exudate, pain and swelling during the healing phase are generally insignificant.

Telangiectasia, port-wine stains and angioma serpiginosum have been treated using short exposure times, for example 0.75–0.875 s (also with ice). It is evidently less specific and probably less effective, with a greater risk of scarring, than an appropriate laser.

Caustics

In experienced hands, caustics provide a simple and readily available means of destroying many superficial skin lesions. The operator should be well acquainted with the action and degree of penetration of individual caustics, and the toxic effects that may result from absorption, especially if they are to be used on large areas, and particularly when applied to the face [1,2]. In treating individual lesions, caustics are usually applied by means of a cotton-bud applicator or a wool-tipped orange stick, pointed if necessary.

Aluminium chloride hexahydrate

A 20% solution (Drichlor; Anhydrol Forte), usually applied on a cotton-bud, is a very useful styptic for superficial wounds such as those following shave excision. Ferric subsulphate (Monsel's solution) is widely used, but may leave a pigmented scar.

Silver nitrate [3]

This is used in the form of a pencil or as a strong solution to suppress exuberant granulation. It is haemostatic and may be used to arrest bleeding after curettage. Repeated use tends to lead to unsightly staining of the skin.

Phenol (liquefied phenol)

This is a valuable superficial caustic, which should, however, be used cautiously. It should not be diluted as this increases its absorption and potency [4,5], and thus also its nephrotoxicity. Ochronosis may occur from prolonged absorption. It is not a haemostatic, and bleeding limits its effectiveness. When used as a treatment for ingrown toenails it is important that the phenol is applied to a 'dry' nailbed and that sufficient time is allowed for it to take effect [6].

Potential toxicity and cardiac arrhythmias remain a major concern, especially with more extensive use, and it should not be used during pregnancy. Phenol is also used in a soap/croton oil/water mix for chemical face peels (Chapter 80). A glycol-spirit solution can be used for neutralization if required.

Trichloroacetic acid

This is an effective haemostatic caustic, which has many uses. The 30–50% concentration can be used as a styptic, and is frequently employed in conjunction with superficial curettage in the treatment of solar keratoses, seborrhoeic warts, etc. The supersaturated solution can also be used on its own to treat many benign and

dysplastic skin lesions. Trichloroacetic acid 50% is similar to phenol in its destructive effect on the epidermis.

Trichloroacetic acid may be a useful treatment for xanthelasmata and solar lentigos. It must be applied with great care, however, especially around the eyes. Its action is rapid, and a white 'frosting' occurs within a few seconds of application. The caustic action can be partially neutralized by applying alcohol, water or sodium bicarbonate-soaked gauze, but this is unlikely to have any effect once the acid has penetrated the skin.

Excess sebum should first be removed using detergent, ether or acetone. Trichloroacetic acid should then be applied with an 'almost dry' cotton applicator. The concentration to be used will vary according to site, the condition to be treated and whether the trichloroacetic acid is being used as a styptic or a superficial skin caustic. Weaker solutions of trichloroacetic acid are sometimes used for treating wider areas of skin (Chapter 80). Because of deliquescence, trichloroacetic acid should be kept in a closed, coloured and corrosion-resistant bottle.

Dichloroacetic acid

This is also a powerful caustic and skin styptic.

Monochloroacetic acid

This should not be considered as a superficial caustic. It penetrates rapidly and may remove the whole epidermis by blister formation. It may be used for mosaic warts, and can also be used for resistant periungual warts.

Intralesional therapy

Intralesional triamcinolone [1]

Aqueous suspensions of triamcinolone acetonide (10 mg/mL [Adcortyl] and 40 mg/mL [Kenalog]) and the less soluble, potentially more therapeutically potent [2], hexacetonide salt (5 and 20 mg/mL [Lederspan]) are available. Both salts can be diluted with saline or lidocaine/lignocaine. Intralesional hydrocortisone acetate (25 mg/mL) can also be used. Triamcinolone acetonide 10 mg/mL is sufficient for all conditions except keloids. The amount injected ranges from 0.1 to 0.5 mL of 10 mg/mL solution, depending on the size and nature of the lesion. The injection should be given using a 27–30-gauge needle deep in the dermis when possible, to minimize the risk of collagen atrophy. The manufacturers recommend that no more than 30 mg of triamcinolone acetonide should be given in one session, with a maximum of 5 mg at any one site. (Steroid equivalence: 5 mg prednisolone = 4 mg triamcinolone = 20 mg hydrocortisone.) Plasma cortisol levels are suppressed for a few days by 20 mg of intralesional triamcinolone acetonide given into various sites; higher doses suppress cortisol levels for longer [3]. Cushing's syndrome has occurred 2–3 weeks after a single treatment with 40 mg triamcinolone acetonide injected into keloids [4]. Local side effects include collagen atrophy [5], hypopigmentation [6], skin necrosis [6], perilymphatic linear depigmented and atrophic streaks [7,8], and telangiectasia [9].

Needleless injection of steroids

Intralesional triamcinolone is also given using a needleless injector (Dermojet or Portojet). The injection is slightly less painful than using a needle, but is principally employed because the injections can be delegated and given quickly [10]. Beware of the risk of intraocular injection if this technique is used around the eye [11]. Dose-for-dose, needleless injection of steroid appears to be less effective than needle injection, probably because some steroid solution spills onto the skin.

Uses

Intralesional triamcinolone therapy is used for inflammatory acne cysts, lichen planus, lichen simplex, lupus erythematosus [12], chondrodermatitis [13], orofacial granulomatosis [14], granuloma annulare, psoriasis and nail psoriasis [15], alopecia areata and many other steroid-responsive conditions [16].

Intralesional therapies for skin malignancies

Intralesional methotrexate is reported to be a painless and effective method of treating keratoacanthoma, with faster than spontaneous resolution [1,2]. Intralesional 5-fluorouracil injections are very painful, but when used for 4–6 weeks destroy small, nodular BCCs [3] and some SCCs [4]. Intralesional interferon-α2b has been used to treat Bowenoid papulosis [5], melanoma [6], BCC [7,8] and SCC [9]. Up to 80% of small, solid or superficial BCCs injected using high-dose therapy appear to resolve, although adverse effects occur in 80% of patients at this dose. In contrast, only a minority of aggressive pattern, invasive BCCs respond [10]. Intralesional interleukin-2 in 1–4 weekly doses produced complete response in 8 of 12 BCC patients treated [11]. Intralesional bleomycin followed by electrical stimulation (electrochemotherapy) has been used for a range of skin tumours, including SCC [12].

Miscellaneous physical procedures

Keloid therapy

Keloids spread beyond the original wound and remain elevated, whereas hypertrophic scars are localized to the injured area and flatten spontaneously with time [1]. Both are commoner in young individuals, African-Caribbeans and at particular sites, especially the central chest, back and posterior neck, followed by the ears, deltoid areas, anterior chest, beard area and the rest of the neck [2,3]. Patients with one keloid, except those on the earlobe [4], are believed to be at risk of further keloids. Many treatments have been suggested, including excision, superficial X-ray therapy (although this may provoke malignant tumours [5]), cryotherapy [6,7], pressure [8,9], ultrasound, laser excision [10], intralesional steroids, interferon-α2b [11] and verapamil [12]. Most reports have claimed partial benefit, few have admitted failure. Despite systemic or local side effects [13], intralesional steroid, in the form of triamcinolone 10–40 mg/mL, injected into the scar every 2–3 weeks, is probably the most effective therapy, particularly for presternal and small keloids. High pressure is required to inject steroids into hard keloids, and a Luer-lock glass or hubless disposable syringe is advised [14].

Pedunculated or easily excised keloids, for example on the earlobe, are best treated by intramarginal excision and pre- and postoperative steroid injection [15]. On the earlobe, part of the skin covering the keloid can be salvaged to cover the defect created by removal of the latter [16]. Most authorities recommend a combination of surgery and triamcinolone injections. Some suggest that triamcinolone should be given before, during and after surgery [4], others use steroids during and after surgery [17], whereas others only use steroids postoperatively, to avoid the risk of wound dehiscence [18]. These authors excise and allow the wound to granulate after injecting the margins with triamcinolone. All agree that triamcinolone 40 mg/mL is usually required. On balance, it seems best to give steroids both intra- and postoperatively—approximately four times at 2- to 3-week intervals, starting 2–3 weeks after suture removal (which should be delayed for 10–14 days because of the risk of steroid-induced wound dehiscence). Freezing the keloid with liquid nitrogen before injection is also said to make triamcinolone injection easier [19]. This, however, may increase the risk of hypopigmentation. With repeated injections it becomes possible to inject more triamcinolone into the keloid, which can be felt to expand slightly as the steroid is injected. Remember that both cryotherapy and triamcinolone injections may produce skin depigmentation [4]. Alternative therapies include topical clobetasol propionate cream or flurandrenolone tape. The latter carries less risk of steroid atrophy of the adjacent skin because only the keloid is covered. Intralesional interferon-α2b appears to reduce keloid size and inhibit collagen production [11]. Intralesional verapamil is said to reduce keloid size [12] by inhibiting proline incorporation into collagen [20]. Silicone gel sheeting is advocated for larger keloids but the evidence that it is effective is not conclusive [21,22].

Minor surgical procedures

Using an orange stick, small quantities of caustic agents can be precisely applied. When 90% liquid phenol is used to treat molluscum contagiosum or small cysts, the orange stick tip may need to be sharpened so that it just fits the cavity being treated. Remember that phenol melts some plastics.

Mollusca can be squeezed to express the cellular debris from the centre of the lesion before phenol application. The tip of the orange stick is dipped into the phenol, any excess wiped off, and the stick is then placed in the centre of the lesion and gently twisted. The solution does not need to be neutralized. After initial whitening, the molluscum becomes inflamed and then resolves 7–10 days later. Treatment is painful and not usually tolerated by small children.

Xanthelasma can be treated using the blunt end of an orange stick, dampened with trichloroacetic acid, dabbed onto the affected area. Multiple small facial epidermoid or acne cysts can be treated in a similar way. The cyst is incised, the contents expressed and phenol carefully applied to the cyst lining using an orange stick. No dressing is required, but a local anaesthetic is necessary.

Milia are tiny, keratin-filled, epithelial-lined cysts with no connection to the overlying skin. They can be removed via a small skin incision made with a sterile #21 or #19 venesection needle. No anaesthetic is required. Prick the needle tip into the skin and, by pulling the cutting edge upwards, incise the skin overlying the milium. Hook or squeeze out the cyst through the skin incision.

Comedones may be emptied using a comedone expressor—a small metal instrument with a cup-shaped end, which has a central hole.

Haemostasis

Bleeding from open wounds can be stopped readily using an absorbable haemostatic dressing such as Surgicel (glucosic copolymer), Kaltostat (calcium alginate), Oxycel (oxidized cellulose) or Gelfoam (porous gelatin matrix), although the mechanism of action of these agents is poorly understood. These materials may behave like a foreign body whilst dissolving in the wound, and increase the risk of infection; large pieces should be removed before wound closure.

Chemical haemostatic agents [1] are effective on oozing skin wounds, for example after curettage and shave excision, but are ineffective in the presence of arterial bleeding, and should not be used in sutured wounds as they cause cell death, which predisposes to infection. Application should be followed by pressure on the wound for 2–3 min to allow haemostasis to occur without the chemical being washed away. Ferric subsulphate (Monsel's) solution carries the risk of iron tattooing [2]. Silver nitrate sticks are effective but caustic, and may leave scars. Aluminium chloride, either 35% in isopropyl alcohol or 20% in ethyl alcohol, is effective; occasionally, it causes histiocytic reactions in treated skin [3].

Introduction

In the years preceding 1900, light had been postulated to consist of either particles or waves. Faraday had also demonstrated that it was related to electromagnetism. In 1901, Planck resolved what had been an experimental contradiction with the prevailing wave theory by postulating that electromagnetic radiation (including light) consisted of discrete packets of energy or quanta. Einstein's [1] subsequent study of the photoelectric effect ultimately formed the basis of the modern theory of light as a wave–particle duality and, indeed, for much of quantum mechanics.

The term 'laser', which is an acronym, seems to have been first used by Gould in 1959 in a lecture entitled 'The LASER, Light Amplification by Stimulated Emission of Radiation'. The first functional laser (ruby, 694 nm) was developed by Maiman [2] in 1960. Its clinical applications were described 3 years later by Goldman [3] in the first dermatological paper on the subject. The theory of selective photothermolysis was postulated by Anderson and Parrish in 1983 [4], since when there has been an explosion of new technology and its application to skin disorders and cosmetic surgery.

This chapter will focus largely on the treatment of skin disorders, whereas the cosmetic applications of light and related technologies will be described in Chapter 80.

Light and laser light

Atoms consist of a nucleus surrounded by electrons. In their resting state, electrons are usually at a low energy level and close to the nucleus. By absorbing energy in the form of a photon (i.e. a quantum of electromagnetic radiation or light), an electron will move to a higher energy orbit (Fig. 78.1). The probability of absorption is proportional to the radiation intensity of the light, and also to the number of atoms in the resting state. In its excited and unstable state, the tendency of the electron is to drop back to the ground state. During this process, termed *spontaneous emission* of radiation, a photon of energy is released.

Emission can also be stimulated, as in a laser. As stated above, 'laser' is an acronym for 'Light Amplification by Stimulated Emission of Radiation.' *Stimulated emission* occurs after an already excited atom is perturbed by a photon with a frequency (wavelength) corresponding to the energy gap between the excited and ground states. If this happens, the excited atom reverts to the resting state, releasing energy as a second photon of the same frequency as the incident photon. Because the incident photon is not absorbed, the atom emits two photons. Importantly, each of these has the same wavelength and phase, that is they are coherent. It is this property that allows *light amplification* and the production of a laser system. During the operation of a laser, all three of these light–matter interactions take place simultaneously (namely, the energizing of atoms as well as spontaneous and stimulated emission). The energy that is required to excite the atoms is provided to the laser by an external power source in a process called *pumping*. When most of the atoms are in an excited rather than in a lower energy state, they are described as having undergone *population inversion* (a condition in which stimulated emission is more likely).

Laser light differs from light emitted by a conventional light source in that it has the following characteristics:

1 **Monochromaticity**. The identity of the excited atom determines the wavelength of the radiation produced. In a laser, this is more precisely a narrow band in a Gaussian distribution around a characteristic wavelength. The argon laser is unusual in that it emits light of two wavelengths (488 and 514 nm), a consequence of there being intermediate orbits between the excited and resting states.

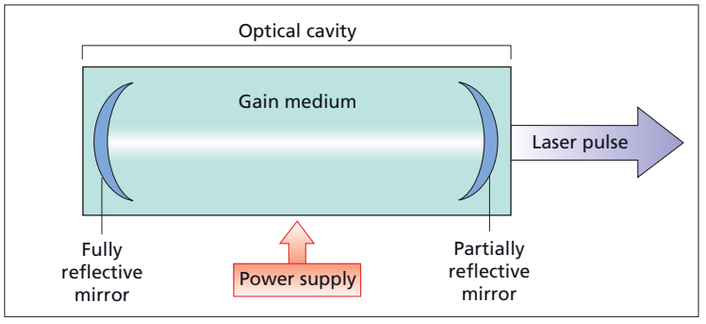

Fig. 78.2 Diagram of a laser showing the external power source, the active medium within the optical cavity and a system of fully and partially reflective mirrors.

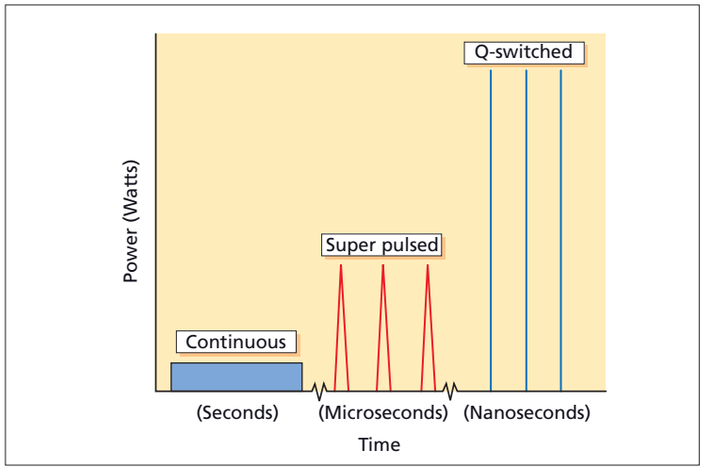

Fig. 78.3 Simplified representation of pulse types.

2 **Coherence**. Light can be likened to a sine wave. Laser light is both temporally and spatially coherent, that is the waves are in phase in time and space.
3 **Collimation**. This is a consequence of coherence and refers to its non-divergent and energy conserving properties. It means that the diameter of the beam changes only minimally over distance, unless it is focused by a lens. Both forms may be useful, such as in CO_2 laser surgery where a focused beam can be used for excision or where a collimated beam can be scanned for resurfacing.

Lasers and laser beams

Lasers are usually named after the constituents of the *gain medium*, which may be a gas, a liquid or a solid. The gain medium is contained within an *optical cavity* (Fig. 78.2). In its simplest form the optical cavity consists of two opposing mirrors, one of which is fully reflective and the other of which, the *output coupler*, is partly transparent. Photons moving parallel to the axis of the optical cavity are reflected between the two mirrors, in turn eliciting stimulated emission in the same axis. The energy required for the process of light amplification is supplied by an external source such as an electric current or light source (flashlamp or other laser). This supply of energy (pumping) amplifies the light until such time as it is emitted through the output coupler. It then enters a delivery system which transmits it to the operator handpiece. Delivery systems may take the form of fibreoptic cables or articulated arms through which light is reflected by mirrors. Fibreoptic cables are lighter and easier to operate and maintain, but they are also delicate and can break when bent or twisted beyond their tolerance. They are not sufficiently robust to transmit light emissions from systems such as CO_2, Er:YAG or the very short pulse Q-switched lasers, where articulated arms are required. Each delivery system ends in an operator handpiece through which light can be focused by a lens or transmitted as a collimated beam. Either beam type can be scanned to limit exposure time. Lasers are sometimes classified according to the pulse characteristics of the beam, which may be continuous, pulsed or quality switched (Q-switched) (Fig. 78.3). Continuous wave light consists of an uninterrupted beam of relatively low power, such as is emitted by the CO_2 laser. Light produced by lasers of this sort can be shuttered mechanically to interrupt the beam and may reduce accumulation of unwanted heat. Another modification, superpulsing, was developed so that the laser emits a rapid train of higher peak-power pulses of energy. One disadvantage of these so-called 'quasi-continuous' lasers is that the pulses are so close together that there is insufficient time for cooling. The tissue effect of this may therefore be very similar to a continuous wave laser beam.

It was only with the development of high peak-power lasers that clinically significant tissue effects could be achieved with

single pulses. Examples include the pulsed-dye laser, normal mode alexandrite and diode lasers, as well as CO_2 lasers with pulse durations in the millisecond or high microsecond range. *Q-switching* is a means of creating a very short pulse (5–100 nanoseconds) together with an extremely high peak power. This is achieved by means of an *electro-optical switch* which consists of two polarizers. Depending on their alignment, these will either transmit or block light. The pulse width is varied so that it approximates the thermal relaxation time (see below) of the target chromophore.

The beam diameter is identical to the so-called spot size and is usually Gaussian in profile. This necessitates a degree of spot size overlap during treatment in order to irradiate tissue more uniformly.

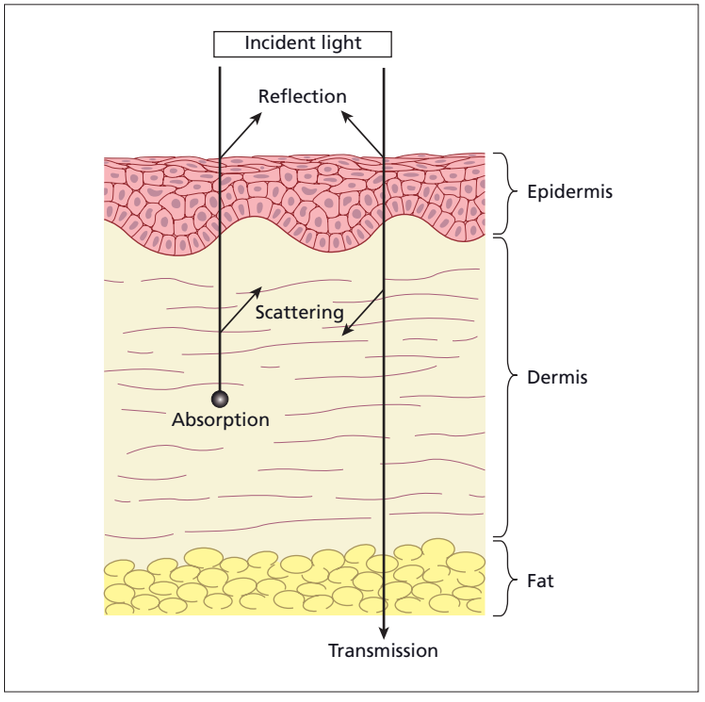

Fig. 78.4 Fate of incident light on skin.

Tissue optics

The fate of incident light on skin is as follows (Fig. 78.4):

1 **Reflection**. About 4–6% of light is reflected at the skin surface. Reflection increases with increased angle of incidence, that is it is lowest when the beam is perpendicular.

2 **Absorption**. This is governed by Beer's law, which relates the absorption of light to the properties of the substance through which the light is travelling. In essence, the law states that there is a logarithmic dependence between the transmission of light through a substance and the concentration of that substance, and also between transmission of light and its path length through the substance. Without absorption of light, there can be no effect on tissue. When a photon is absorbed by a target molecule or chromophore, all of its energy is transferred to that molecule. The basis for selective skin laser surgery is that light can be manipulated in terms of its wavelength, energy content and pulse duration so that a particular target chromophore absorbs light and is damaged or destroyed, whereas other chromophores are not.

   The endogenous chromophores of importance are melanin, haemoglobin, water and collagen (Fig. 78.5). Melanin is present in normal epidermis and hair follicles. Its principal function is to protect against sunlight and its absorption includes ultraviolet (UV) and visible light, with decreasing absorption into the near infrared spectrum. Haemoglobin has absorption peaks in the UVA, blue (400 nm), green (541 nm) and yellow (577 nm) wavelengths. Collagen absorbs in the visible and near infra-red spectra and water in the mid and far infrared regions. There are also a number of exogenous chromophores, such as tattoo ink.

3 **Scattering**. This refers to the deviation of light by non-uniformities in the medium through which it passes. In skin, this is largely due to collagen in the dermis. Because the collagen molecule is similar in size to the wavelength of visible and near

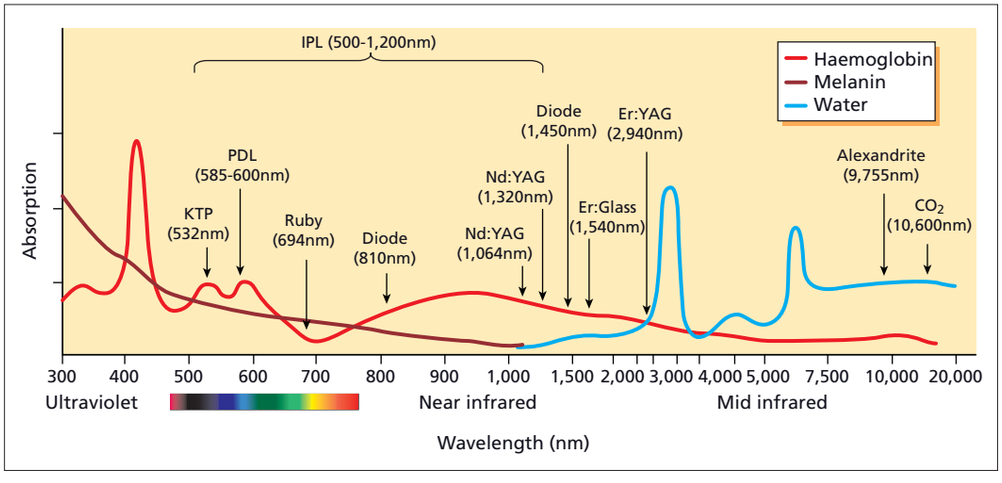

Fig. 78.5 Absorption spectra of principal tissue chromophores.

infrared light, scatter is mainly forward in direction. In certain situations, however, back scatter can be high enough to increase the energy density in the upper dermis to beyond that of the incident light. In relation to laser light, so-called coherent backscattering can be more than twice as much as if the incident light was incoherent.

Scattering is important in that it reduces the light energy available for absorption by the target chromophore and thereby decreases the clinical effect in tissue. Scattering in skin diminishes with longer wavelengths, allowing these to reach deep dermal structures such as hair follicles. Light between 600 and 1200 nm has been described as an optical window into the skin because it is subject to low scattering in addition to being well absorbed by endogenous chromophores. Longer wavelength light is absorbed by water and does not penetrate deeply.

4 **Transmission**. Light that is not reflected, absorbed or scattered passes to deeper tissue. This is dependent on wavelength, shorter wavelengths (300–400 nm) being scattered and penetrating less than 0.1 mm. Wavelengths in the 600–1200 nm range penetrate deeper because they are scattered less.

Light–tissue interaction (Table 78.1)

The wavelength of light determines its absorption by a tissue target or *chromophore.* In addition to being absorbed, light must have sufficient energy if it is to alter the target's structure. Energy is measured in Joules (J), although it is usually more useful to consider its *fluence* or energy density (J/cm^2). *Power* is the rate at which energy is delivered, and is measured in Watts (i.e. W or J/s). The term *irradiance* refers to the power density—the rate at which energy is delivered per unit area—and is measured in W/cm^2. Fluence and irradiance are therefore directly proportional and are inversely proportional to the square of the radius of the spot size. This means that doubling the spot size decreases the fluence and the irradiance by a factor of 4. On the other hand, increasing the spot size (up to a maximum of about 12 mm) reduces scatter.

Depending on these qualities, light may affect tissue as follows:

1 **Photostimulation**. There is equivocal evidence to suggest that low energy lasers expedite wound healing. The mechanism of this is unclear.

2 **Photodynamic change**. This forms the basis of photodynamic therapy (PDT) and usually involves the topical or systemic administration of a photosensitizer or precursor thereof. Subsequent irradiation with an appropriate light source elicits two types of photo-oxidative reaction and an immediate cytotoxic effect. PDT can also target endogenous chromophores (such as produced by *Propionibacterium acnes* and used in blue light treatment of acne vulgaris.)

3 **Photothermolytic and photomechanical reactions**. The theory of selective photothermolysis [4] has been used to target structures containing haemoglobin, melanin and collagen. It postulates that light can be used to selectively damage or destroy a chromophore if a wavelength is selected that offers as big a difference as possible between the absorption coefficient of the target and the surrounding tissue, if its energy is high enough to damage the target and if its pulse duration is less than or equal to the *thermal relaxation time* (TRT). The TRT is the time taken for the target to dissipate about 63% of the incident thermal energy. These are considered in more detail below:

i **Wavelength.** The absorption spectra of important tissue chromophores are shown in Fig. 78.5 in relation to the wavelengths of the lasers widely used in dermatology [5]. Haemoglobin has a number of different absorption peaks whereas absorption by melanin gradually diminishes with longer wavelengths of incident light. The depth of the target structure must also be considered because scattering of light in

the dermis is strongly influenced by wavelength. For this reason, long wavelength light which penetrates well but is poorly absorbed by a deep chromophore, may be more damaging to it than a shorter wavelength with the opposite characteristics. In some situations, particularly in relation to melanin, a single wavelength may not be necessary and it may even be preferable to use flashlamps because of their broad emission spectrum (500–1200 nm). These are cheaper to manufacture than lasers and can be used with light filters to allow a potentially wide range of applications. It is possible to vary their pulse durations from 0.5 to 88.5 ms and to introduce intervals between pulses of 1300 ms. At present they cannot substitute for lasers where focused, high energy beams are required.

ii **Energy fluence.** The energy contained within light is expressed in Joules (J) and its fluence or energy density per unit area in J/cm^2.

iii **Thermal relaxation time (TRT).** The TRT is related to the size of the target chromophore and varies from a few nanoseconds (tattoo particles) to several hundred milliseconds or more (leg venules).

Some tissue targets, notably the hair follicle, are not uniform in their absorption of light, and it is possible that light-assisted hair removal is better explained by an 'extended theory of selective photothermolysis' [6]. This distinguishes between an 'absorber' chromophore (in which heat is generated) and a distant 'target', to which heat is transmitted and which is damaged as a result. This may also apply to hair removal, melanin in the hair shaft and matrix cells acting as the absorber whereas the stem cells of the isthmus (and possibly the blood vessels in the papilla) represent the distant target. The time to achieve selective damage of the target is the *thermal damage time* (TDT). This is the time for the entire target, including the primary chromophore (e.g. melanin) and the surrounding target (e.g. hair follicle) to cool by about 63% and includes cooling of the primary chromophore as well as the entire target. The TDT is longer than the TRT as it allows for heat diffusion from the chromophore throughout the entire target.

A practical outcome of this theory has been termed 'thermokinetic selectivity' [7]. Because large structures cool slower than small structures, it is proposed that they reach higher and potentially damaging temperatures if the light source is manipulated appropriately. An example of this is light-assisted hair removal, where a pulse is used that is longer than the thermal damage time of the melanin-containing epidermis (1 ms) compared with the melanin-containing hair follicle (30–100 ms). Lasers or light sources with pulse durations of 5–50 ms can therefore allow energy to accumulate in, and thermally coagulate, the hair follicle. Even while the energy is being delivered, the epidermis is protected as it cools and its temperature is therefore kept below its thermal coagulation threshold.

Tissue cooling

Light in the 500–1200 nm spectrum is preferentially, but not specifically, absorbed by either haemoglobin or melanin, depending on the wavelengths employed. Epidermal melanin will therefore absorb both direct and back-scattered light from all such devices, whether or not it is the intended chromophore. Heat damage to the epidermis may result in blistering, dyspigmentation or scarring and is particularly likely in pigmented skin. To reduce this risk, the wavelength should be optimized with respect to the absorption characteristics and depth of the target chromophore. The use of long pulses [8] and cooling of the epidermis further enhances safety in these patients. The latter may be done before, during or after the light pulse or all three.

Cooling may take three forms:

1 **Cold air convection**. Air, chilled to temperatures as low as –30°C, is directed onto the area to be treated.
2 **Contact cooling**. This can involve simple application of ice-packs or more sophisticated systems in which cold water flows between colourless and transparent plates (usually sapphire as it is a more efficient conductor than glass). Although a good method of cooling, condensate which develops on the plates can obscure the skin and may require frequent removal.
3 **Cryogen spray (dynamic) cooling**. A frozen gas is sprayed onto the skin immediately before the laser pulse. Evaporative cooling has a high heat transfer coefficient and this is therefore the most efficient way of pre-cooling. With timed, automated control this method is also relatively predictable and reproducible.

One important benefit of epidermal cooling has been to allow treatments at higher energy fluences than would otherwise be considered safe, and in this way to reduce the number of treatments required. Cooling has also made it possible to safely treat patients with all except the most heavily pigmented skin types. Furthermore, cooling decreases the pain associated with treatment, thus reducing the need for topical or local anaesthetic. Cooling can cause cryogen injury if used inappropriately.

Lasers and flashlamps for vascular lesions

Light–tissue interaction

Oxyhaemoglobin has its main absorption peaks at 418, 542 and 577 nm. As an initial practical application of their theory of selective photothermolysis, Anderson and Parrish selected a flashlamp-pumped dye laser with a wavelength of 577 nm, a pulse duration of 0.3 ms and a fluence of $2\,J/cm^2$ [1]. In subsequent treatment of port-wine stains, this wavelength was replaced

with 585–600 nm light, which has the advantage of deeper dermal penetration (although with reduced oxyhaemoglobin absorption at the longer wavelengths [2]). A slightly longer pulse duration (0.45 ms) was used in the first generation of pulsed-dye lasers on the basis of a calculated TRT of <1 ms for vessel diameters of 10–50 μm. This may have been an underestimate, and the TRT was measured in a subsequent *in vivo* study as 1–10 ms for vessel diameters of 30–150 μm [3]. Pulsed-dye lasers are now manufactured with pulse durations of up to 40 ms although the short-pulse PDL is optimal for paediatric port-wine stains (PWS) because vessel diameters are relatively small [4]. Another laser useful for vascular anomalies (especially facial telangiectases) is the potassium titanyl phosphate (KTP) laser (532 nm), light from which does not penetrate beyond superficial vessels but which is well absorbed. The alexandrite (755 nm) and neodymium:yttrium–aluminium–garnet or Nd:YAG (1064 nm) lasers emit light with longer wavelengths and therefore relatively deep penetration. This is targeted at a low absorption peak at 900–1000 nm.

Devices in common use

The frequency doubled Nd:YAG or potassium titanyl phosphate (KTP) (532 nm) laser. Nd:YAG laser emissions can be passed through a KTP crystal to double the frequency to 532 nm. They may be flashlamp or diode pumped and are characterized by trains of short pulses which summate to give a wide pulse-like or 'quasi-continuous' effect that is not associated with purpura. Light produced by KTP lasers is highly absorbed by haemoglobin (and melanin) but its wavelength penetrates only superficially. They are widely used, with or without cooling devices, to treat small facial vessels.

Pulsed-dye lasers (585–600 nm) 4.5 and 1.5–40 ms. These contain a rhodamine dye which is excited by a xenon flashlamp to produce light at 585–600 nm in pulses of 0.45 ms (short-pulse PDL) or 1.5–40 ms (long-pulse PDL) through spot sizes of up to 12 mm diameter. Light penetrates the dermis to a depth of 1.2 mm [5] and photocoagulates vessels of up to 100 μm in diameter.

The alexandrite (755 nm) and neodymium:yttrium-aluminium-garnet (Nd:YAG) (1064 nm) lasers. These emit light with longer wavelengths and therefore relatively deep dermal penetration. The wavelengths are absorbed by a small haemoglobin absorption peak at 900–1000 nm. Used with long pulses (up to several hundred ms) and epidermal cooling systems, the Nd:YAG laser may have a role to play in treating relatively deep and large vessels, including those on the legs.

Intense pulsed light source (500–1200 nm). This device emits non-coherent light over a broad spectrum. Filters are used to eliminate wavelengths shorter than selected thresholds. There is contact cooling and its potential advantages are the large spot size and the reduced likelihood of patterning or over-correction when treating fine facial telangiectasiae.

Superficial vascular abnormalities

Anaesthesia

Topical anaesthesia is usually satisfactory for treating facial lesions in adults but local or regional anaesthesia may be required. Treatment at other anatomical sites can usually be tolerated with topical or no anaesthesia. Depending on the size and site of the lesion, children under 12 years of age may need treatment under general anaesthetic. Emollients and analgesics relieve postoperative pain, swelling and erythema. Some patients develop crusting of the treated area.

Haemangiomas

Haemangiomas appear at birth and are the commonest, benign tumours of infancy. They are characterized by endothelial hyperplasia and may proliferate for months. It is possible that they originate in maternal placenta, with which they share distinct tissue-specific markers [6]. Most regress, sometimes leaving redundant, atrophic skin. Intervention may be indicated if the site and/or size of the haemangioma are likely to cause functional impairment or abnormal psychological development. Haemangiomas have been reported to show improved colour and size when treated with the pulsed-dye [7] or Nd:YAG lasers [8]. Laser treatment may be particularly helpful in ulcerated, involuting haemangiomas [9] (Fig. 78.6), although ulceration is itself a rare complication of treatment [10]. In one uncontrolled study [11] of 548 children with 692 haemangiomas treated with a short-pulse PDL, further proliferation was halted in 96% of lesions. On the other hand, a randomized controlled study of 121 infants with early, uncomplicated haemangiomas showed no advantage of pulsed-dye laser treatment over observation at 1 year [12]. Patients with five or more separate lesions should be scanned for systemic involvement. Large haemangiomas may be life-threatening if there is organ infiltration, high-output cardiac failure or Kasabach–Merritt syndrome. In these patients, treatment should be attempted with systemic corticosteroids, and failing this with interferon-α, cyclophosphamide or vincristine [13].

Port-wine stains (PWS), or capillary malformations

Vascular malformations may be arterial, venous, capillary or lymphatic and may include elements of more than one type. 'Port-wine stains' (PWS) are capillary malformations in which the vessels are characterized by flat endothelium with normal turnover. Sturge–Weber syndrome features a PWS involving skin in the distribution of the ophthalmic branch of the trigeminal nerve, together with involvement of the ocular choroid and leptomeninges. Patients with periorbital PWS should also be tested for glaucoma.

The PDL is the intervention of choice for uncomplicated lesions, and six to eight treatments will achieve 'good results' in as many as 60% [14] (Fig. 78.7). In recent years, PDLs have been manufactured with longer wavelengths, bigger spot sizes and longer pulses, as well as with cooling devices which allow use of higher fluences. The 585-nm short-pulse PDL is probably optimal for treating paediatric PWS because vessel diameters are relatively small. More recently manufactured PDLs emit light with a wavelength of 595 nm, absorption of which by haemoglobin is lower by a factor of five than at 585 nm. However, used in conjunction with a longer pulse, this may be most suitable for the deeper, bigger vessels in resistant or adult PWS [15]. The use of spray cooling and higher fluences with both short [16] and long [17] pulse (1.5–4.0 ms) PDLs has considerably expedited treatment of

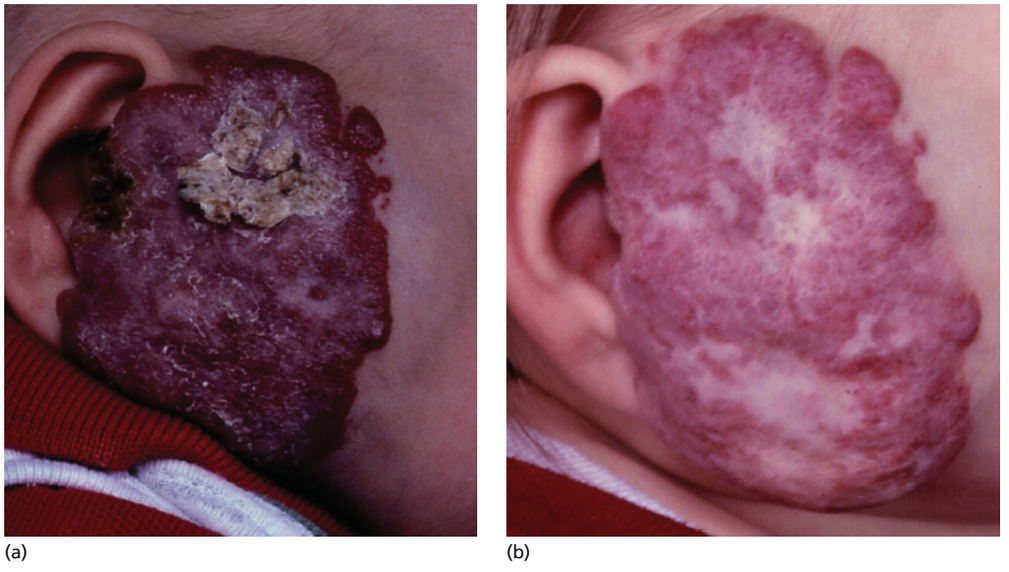

Fig. 78.6 Ulcerated haemangioma, (a) before and (b) after two pulsed-dye laser treatments.

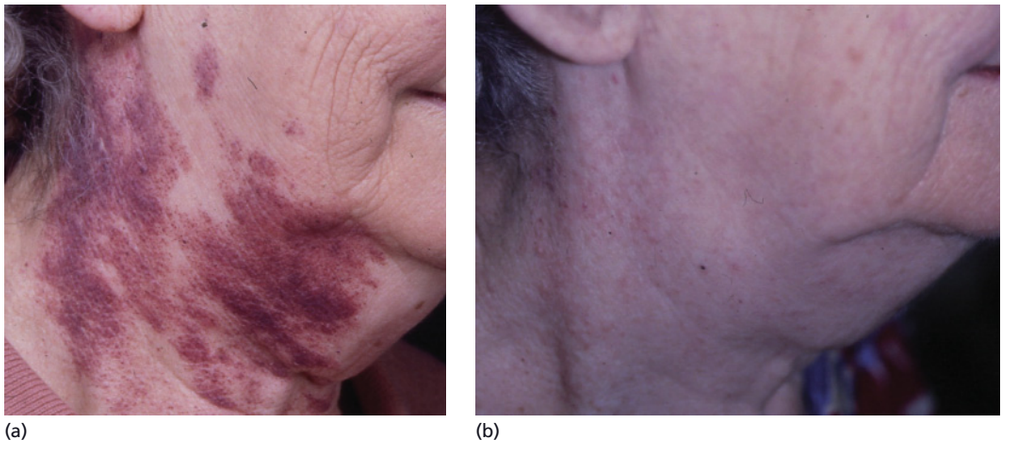

Fig. 78.7 Flat and superficial port-wine stain, (a) before and (b) after four pulsed-dye laser treatments (590 nm), showing an unusually good response.

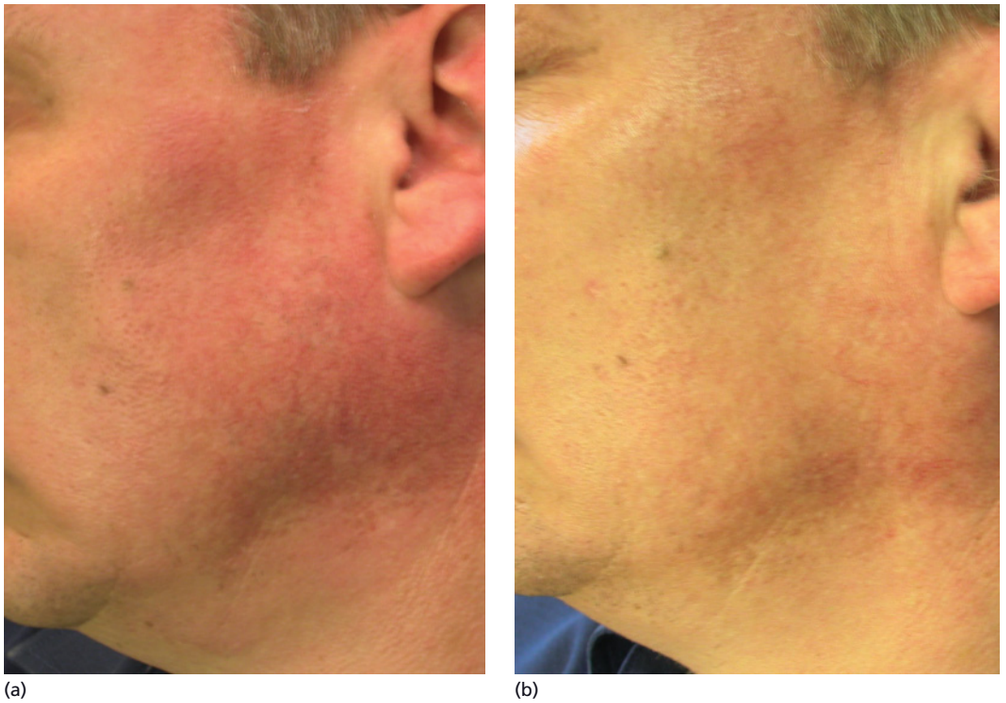

PWS. Lesions become purpuric if treated with both high fluences and pulse durations of 6 ms or less. Although reduced by both cooling and long pulsing, a degree of post-treatment purpura formation is thought to be necessary for effective treatment of lesions [18]. Factors favouring a good response to PDL treatment are youth, as well as flat and scarlet (as opposed to purple) PWS on the head and neck (excluding the cheeks or midline) [19]. Partial re-emergence (in up to 40% after 4 years) may occur after successful treatment [20].

Hypertrophic and PDL-resistant PWS have sometimes been treated with near-infrared lasers such as the alexandrite (755 nm) and Nd:YAG (1064 nm). Resistant lesions have also been treated with pulse-stacking using either short and long wavelength PDL (to treat superficial and deep vessels respectively) or combined pulsed-dye and Nd:YAG lasers [21]. Other possibilities under investigation include electro-optical synergy technology and vacuum-assisted laser treatment [22]. The mechanism of the former is supposedly that light technology can be used to preheat a tissue chromophore, the electrical resistance or impedance of which drops as a consequence and so renders it more sensitive to subsequent electrical damage. Adult patients in whom progressive vascular ectasia has resulted in very exophytic lesions are probably best treated with the CO_2 laser [23].

Flashlamps (500–900 nm) have larger spot sizes and have also been used to treat PWS, supposedly with good effect [24].

Telangiectases

These are acquired capillary malformations and usually occur as so-called spider angiomas or more diffusely as manifestations of either photodamage (including poikiloderma of Civatte) or rosacea. Spider angiomas consist of a central arteriole with a high filling pressure, and these lesions are probably best treated with the PDL. The superficial telangiectases which are commonly found in a mid-face distribution in middle-aged and elderly, fair-skinned patients respond safely and well to KTP lasers [25]. More diffuse, finer telangiectases or erythema will respond to short-pulse PDL treatment

(a) (b)

Fig. 78.8 Facial erythema, (a) before and (b) after one treatment with a flashlamp, showing minimal patterning and a near disappearance.

[26], not necessarily with associated purpura but with a risk of subsequent honeycomb patterning. The flashlamp is usually a non-bruising and probably better treatment modality [27] because it reduces erythema more gradually and is less likely to cause patterning (Fig. 78.8). However, this may be more painful than laser treatment, and several treatments may be required [28].

Leg veins

These vary in terms of size, depth and flow characteristics. In the absence of deep venous insufficiency, superficial dilated venules are best treated by sclerotherapy [27]. If this is contraindicated, these vessels should respond best to laser treatment with large spot sizes (3–4 mm), high fluences and long pulse durations, combined with effective cooling devices. Wavelength should be chosen according to the depth of the target vessel. Accordingly, long pulse (1.5–4.0 ms) PDLs were developed with wavelengths in the 585–600 nm range and, used with fluences of 7–9 J/cm², are sometimes useful for superficial vessels less than about 0.5 mm in diameter [29]. Longer wavelengths are used to target a different absorption peak of haemoglobin and achieve deeper penetration. The 3 ms alexandrite (755 nm) laser has been used with fluences of up to 80 J/cm² in treating leg vessels of up to 2 mm in diameter [30], and the Nd:YAG (1064 nm) laser [31] with fluences higher than 100 J/cm² and pulse durations of up to 1 s in treating even deeper and larger vessels. Complications are relatively common and include ulceration, dyspigmentation and scarring [27]. There are few data on the flashlamp in this context, but its emission spectrum and large applicator head would suggest a role in treating widespread, fine telangiectases.

Other cutaneous vascular lesions that respond to laser treatment, optimally with pulsed-dye laser, include angiomas and venous lakes [27]. Small, red angiofibromas may do well in young patients with tuberous sclerosus in whom ablative treatments are inappropriate. Angiokeratomas are likely to recur unless treatment elicits fibrosis. Pyogenic granulomas should probably be curetted.

Other applications of vascular lasers

Viral warts. PDLs have been used to treat viral warts [32], often at high fluences and without cooling. The rationale for this was originally that photocoagulation of the underlying dermal vessels compromised the viability of the abnormal epidermis. It seems more likely that it represents a non-specific injury to the infected epidermis. Treatment of cryotherapy-resistant warts on the nail folds and the soles of the feet is often only partly successful [33]. Here, CO_2 laser ablation may be more effective, despite the greater likelihood of pain, infection and scarring [34].

Hypertrophic scars. PDLs have been reported to improve the colour and contour of erythematous and hypertrophic (but not keloid) scars in studies which have sometimes been supported with objective measurements such as reflectance spectrometry and silicone profilometry [35]. The mechanism of action is unknown, although it is also possible that destruction of small vessels plays a part. In more raised scars, lasers may be most useful after lesions have first been substantially reduced in bulk by intralesional corticosteroids.

Psoriasis. Localized and resistant plaque psoriasis has been reported to respond to treatment with either the short- or long-pulse 585 nm PDL [36]. Although non-toxic, treatment is often painful, and can cause dyspigmentation and scarring.

Granuloma faciale. This condition is poorly understood, and it is not clear why the reddish-brown facial plaques should respond to pulsed-dye laser treatment, as has been reported [37]. Their colour is likely to be due to the inflammatory infiltrate rather than vascular dilatation.

Complications

These include dyspigmentation and both atrophic and hypertrophic scarring. They appear to be more common in pigmented skin and when treating leg vessels.

Lasers and flashlamps for treatment of tattoos and pigmentary disorders

Light–tissue interaction

Melanin absorbs light in the ultraviolet–1200 nm range (Fig. 78.5). At the shorter wavelengths, absorption is higher but penetration less deep than at the longer wavelengths.

The Q-switch is an electro-optical device that is used to produce pulses of only a few nanoseconds. These are designed to be within the estimated TRT of melanosomes (0.5–1 μs) [1] but longer than that of tattoo particles, which is in the low nanosecond domain. Flashlamps can pulse within the millisecond range, which is relatively long in this context. Pulses in the nanosecond range may fragment and disperse melanin and tattoo ink, thereby altering their optical properties. Most tattoo lightening is probably due to uptake and removal of the fragmented particles by activated macrophages through the lymphatic system. Some may also be removed by transepidermal elimination [2].

Devices in common use

Q-switched neodymium:yttrium-aluminium-garnet (1064 nm) and frequency-doubled (532 nm) Nd:YAG lasers. The Q-switched Nd:YAG laser emits light that penetrates 2–3 mm into the dermis and is therefore suitable for the removal of deeper dermal pigmentation [3]. By passing the beam through a KTP crystal the frequency is doubled and the wavelength halved

(a) (b)

Fig. 78.9 Freckles on sun-exposed skin, (a) before and (b) much improved after one treatment with a Q-switched ruby (694 nm) laser.

(532 nm). The shorter wavelength penetrates less deeply and is therefore more useful for the removal of epidermal pigment.

Q-switched alexandrite (755 nm) and diode (810 nm) lasers. These also emit red light at intermediate wavelengths, allowing somewhat deeper dermal penetration, although with some loss of absorption.

Intense pulsed light source (500–1200 nm). These emit non-coherent light over a broad spectrum, with potential advantages in terms of penetration and absorption. The relatively long pulse duration (0.5–88.5 ms) appears not to constitute a practical problem in treating pigment with TRT in the nanosecond domain.

Tattoos

Q-switched treatment of tattoos is cosmetically superior to older destructive modalities [4]. Black or blue tattoo pigments absorb across a broad range of wavelengths in the visible and near infrared spectrum. Green inks respond optimally to the Q-switched ruby (694 nm) [5] and Q-switched alexandrite (755 nm) lasers but often persist [6]. Conversely, red pigments respond best to the green light emitted by the frequency-doubled Nd:YAG (532 nm) [7]. The Nd:YAG laser is effective for blue/black tattoos but is relatively poorly absorbed by green pigments [8]. It has been used successfully to treat tattoos in pigmented skin [9]. Red, brown or flesh-toned inks may contain ferric oxide (Fe_2O_3) which can be reduced by laser treatment to ferrous oxide (FeO), which is black. Although test treatments are therefore important, this reaction is rare and usually responds to subsequent treatment with the appropriate wavelength. Yellow and pastel colours are difficult to treat and complete resolution is unusual. Amateur tattoos usually require fewer treatments than professional tattoos [10].

Benign pigmented lesions

Epidermal pigmentation. Ephelides and solar lentigines respond well to treatment with the Q-switched KTP (532 nm) and Q-switched ruby (694 nm) lasers (Fig. 78.9), although the former may bruise [11]. Each lesion has to be lasered individually, a sometimes tedious and hazardous task on the faces and chests of photodamaged patients in whom there is a mottled appearance of hyperpigmented lesions on a background of chronic 'bronzing' and guttate hypopigmentation. There are limited published data on the use of the flashlamp in this context and its pulse width is relatively long [12]. However, its large beam diameter allows treatment of the entire affected area and not just the pigmented lesions themselves.

Café-au-lait patches show a variable response to laser treatment [13], and repigmentation occurs in 50% [14]. Becker's melanosis consists of dermal melanophages as well as epidermal hyperpigmentation. Its response to Q-switched lasers or to flashlamps is unpredictable, particularly if there is hypertrichosis, and repigmentation may occur from the hair follicles. This has led some authors to suggest that ablative treatment with an Er:YAG laser may be preferable [15].

Seborrhoeic keratoses that resemble solar lentigines, in being flat and brown, will respond well to laser treatment. However, lesions that are warty or poorly pigmented are likely to respond better to destructive treatment modalities.

Lentigo maligna should not be treated with lasers [16].

Dermal pigmentation. Speckled and lentiginous naevus (naevus spilus) consists of a lentiginous patch speckled with compound naevi. A small, early study with both Q-switched ruby and Q-switched Nd:YAG (532 nm or 1064 nm) lasers suggested that the former was more effective. One out of six patients developed dyspigmentation and another showed focal recurrence [17]. In a larger, recent study of Japanese children, naevus spilus was noted to respond poorly to Q-switched alexandrite laser treatment [13]. The conclusions of this second study seem more plausible in view of generally disappointing experience with Q-switched laser treatment of both café-au-lait macules and compound naevi.

Naevus of Ota has been treated with the Q-switched ruby [18], alexandrite [19] and Nd:YAG lasers [20] (Fig. 78.10). The relatively deep dermal pigmentation responds optimally and with fewer complications to treatment with the Q-switched Nd:YAG laser [21]. Some patients repigment after treatment [22].

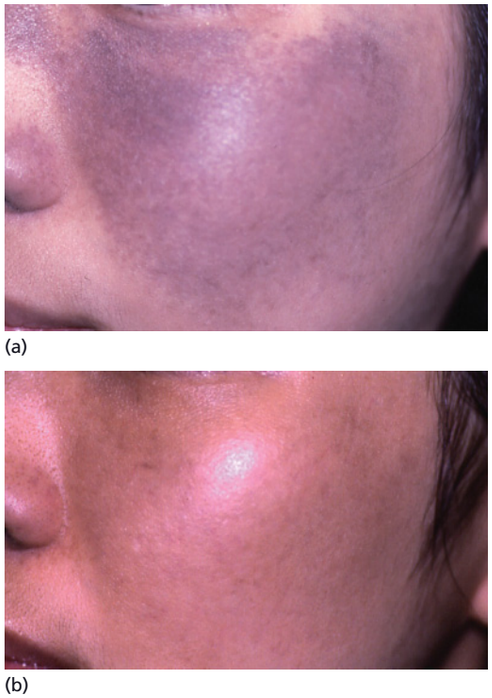

Fig. 78.10 Naevus of Ota, (a) before and (b) after two treatments with a Q-switched Nd:YAG (1064 nm) laser, showing reduction of abnormal pigment and minimal patterning.

Both congenital and acquired melanocytic naevi have been treated with Q-switched lasers [23], although this remains controversial. One reason is that the long-term effects of non-lethal laser irradiation of melanocytes are unknown. With the possible exception of flat, junctional naevi, moles tend to respond incompletely and many lesions repigment. In a study in which 31 congenital and acquired (including atypical) melanocytic naevi were treated with the Q-switched ruby laser, normal mode ruby laser or both, only 16 were visibly lighter 4 weeks after treatment [24].

Melasma can be epidermal, dermal or mixed in type, and usually responds unsatisfactorily to Q-switched laser therapy [25]. More recently, fractional photocoagulation, the 'microthermal treatment zones' of which have been claimed to function as a 'pigment escalator', has been reported to be effective in treating this condition [26]. Laser treatment of post-inflammatory hyperpigmentation, as with melasma, frequently aggravates the situation [27]. Haemosiderin seen in association with venous stasis will only occasionally respond to laser treatment. Hyperpigmentation secondary to administration of minocycline [28] and amiodarone [29] responds readily to treatment with the Q-switched ruby, alexandrite and Nd:YAG lasers.

Complications

These are most commonly dyspigmentation or scarring. They are more frequent in pigmented skin.

Lasers and flashlamps for removal of hair

Light–tissue interaction and devices in common use

The mechanism for light-assisted hair reduction remains incompletely understood. Light is probably absorbed by melanin in the hair shaft and matrix, but it is likely that heat is then transferred to the true target structures—stem cells (mainly in the bulge area of the outer root sheath) and possibly blood vessels in the papilla [1]. Follicles in early anagen are thought to be most susceptible to laser treatment because they are more superficial than in other phases. Follicular disruption is an immediate effect and is followed by conversion from the anagen to the telogen phase, with subsequent miniaturization of the hair follicle.

The normal mode ruby (694 nm), alexandrite (755 nm), diode (800 nm) [2] and Nd:YAG (1064 nm) [3] lasers have all been used for photoepilation. Cooling is required to protect the epidermis. The TRT of a 200–300 μm follicle is about 25–50 ms but much shorter pulse durations also seem to be effective. It has also been shown that considerably longer pulses (30–400 ms) are effective in damaging the stem cells and papillary vessels, neither of which contains melanin nor is in direct contact with the melanin-rich components of the follicle. This observation has been explained in terms of an 'extended theory of selective photothermolysis' [1]. By using long pulses and by limiting the power of the light source, the heat generated by an 'absorber' (here, melanin in the hair shaft) can be kept below levels that would alter its structural and optical properties and thus interfere with further absorption of light. On the other hand the heat generated may be high enough to diffuse to and denature a distant 'target' (here, the stem cells and papillary vessels). The delay between heating of the absorber chromophore and the distant target is referred to as the thermal damage time (TDT) and is significantly longer than the TRT.

Laser-assisted hair removal

A clinical end-point of mild peri-follicular erythema and oedema is often recommended by manufacturers. Multiple treatments (three to six) performed at 6- to 8-week intervals are necessary to achieve what has been defined as 'permanent' reduction of hair growth. In an early study of 13 individuals, follicular damage was demonstrated using a ruby laser with a pulse duration of only 270 μs. Six months later only four had <50% regrowth and five showed complete regrowth of hair [4]. These results were maintained at 2 years follow-up, suggesting that long-term loss of terminal hair is possible after one treatment with the normal-mode ruby laser, albeit in a minority of patients [5].

Lasers with longer wavelengths are likely to be safer and more effective. A study of patients treated at least three times at 4- to 6-week intervals with the 3-ms alexandrite laser showed a mean long-term hair reduction of 74% [6]. This was even higher in those patients with non-pigmented skin in whom higher fluences were used. Optimal results are obtained in patients with non-pigmented skin and with pigmented hair. Fair or white hair lacks melanin and is largely resistant to treatment.

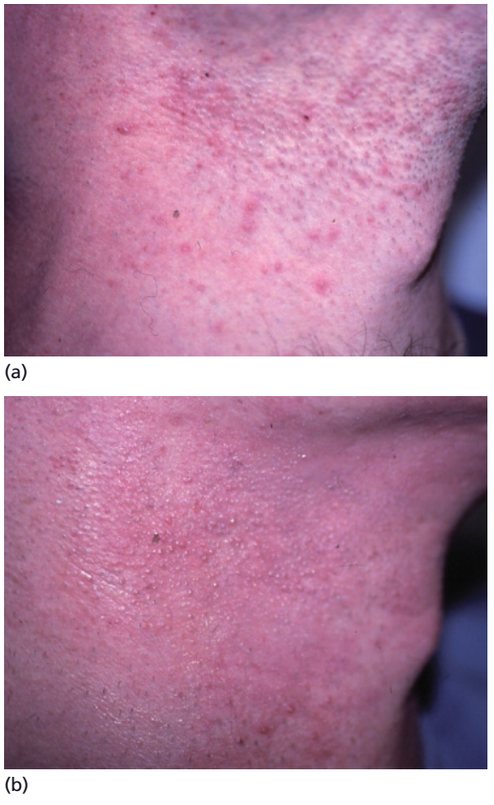

Fig. 78.11 Pseudofolliculitis barbae, (a) before and (b) after a treatment with a normal mode alexandrite (755 nm) laser. Residual hair is sparse and fine and there are no inflammatory lesions.

Flashlamps have been used to treat hypertrichosis [7] but it seems likely that subsequent blistering and dyspigmentation is more common than after laser treatment.

Skin and hair disorders in which laser-assisted hair removal may be beneficial include cosmetically poor hair grafts, pseudofolliculitis barbae (Fig. 78.11) and pilonidal sinuses [8].

Complications

There is a low incidence of usually self-limiting side effects (blistering, crusting, dyspigmentation and scarring) which depend on the laser used and on skin type [9]. The risk is highest with the ruby laser and drops with longer wavelengths. Similarly, risk is higher in patients with pigmented skin, in whom it can be reduced by two-thirds by use of the Nd:YAG laser (1064 nm). A paradoxical increase in hair growth occurs rarely [10].

Photothermal ablation in the treatment of skin disorders

Light–tissue interaction

Incisional with haemostasis. The carbon dioxide (CO_2) laser (10 600 nm) can be used as an incisional or resurfacing instrument. Tissue can be incised by using a high-power, focused beam which vaporizes the tissue in its immediate path. The power, diameter and pulse characteristics of the beam determine the thickness of a surrounding cuff of thermal damage which forms due to scatter and temperature diffusion. The main advantage of thermal damage, in this context, is haemostasis.

Ablative laser resurfacing. This was performed initially with pulsed or scanned CO_2 lasers, the immediate effect of which is ablation (or vaporization) of the epidermis and sometimes the superficial papillary dermis. There is also thermal damage to a band of underlying dermis, together with collagen denaturation and contraction. In the healing period, re-epithelialization occurs from surrounding epidermis and from adnexal structures. This is followed by the formation of a band of upper dermal fibrosis, often referred to in the cosmetic literature as 'collagen remodelling'.

The CO_2 laser emits light which is relatively poorly absorbed by water and which therefore has a relatively high penetration (30 μm). Unless the irradiance is high, this elicits relatively little ablation compared with thermal damage (up to 300 μm), or less than was initially thought desirable. Furthermore, with each subsequent pass there is less and less ablation and more and more thermal damage as the water content drops in the underlying dermis. These considerations led to the development of the erbium:yttrium-aluminium-garnet (Er:YAG) laser (2094 nm) which emits a wavelength that is highly absorbed by water and therefore has a low penetration (3 μm). This in turn is associated with more ablation (2–4 μm per J/cm^2) and less thermal damage (10–15 μm). It soon became apparent, however, that a degree of thermal damage was necessary for haemostasis. In addition, the thermal damage that underlies CO_2 laser-treated sites may influence the thickness of subsequent fibrosis [1]. As a result, Er:YAG lasers were adapted to cause more rather than less thermal damage, in other words to make a wound more like that produced by a CO_2 laser. Attention eventually switched from ablative to non-ablative injury, the former having become undesirable on account of the morbidity of the burn wound.

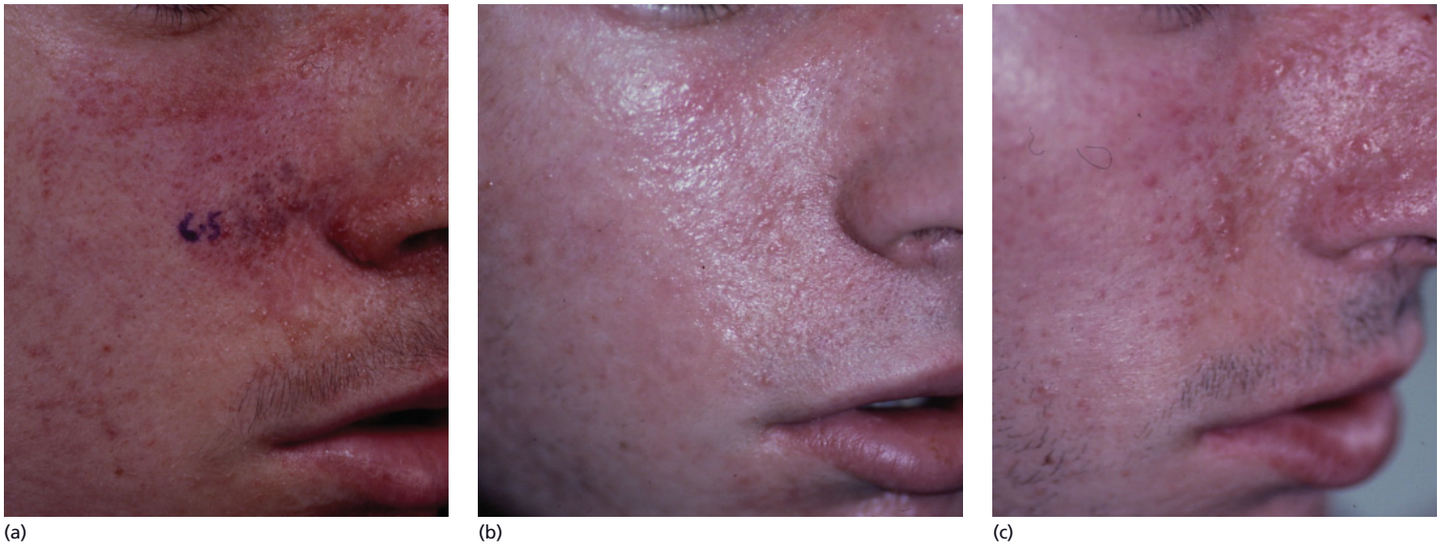
Non-ablative photocoagulation. This has largely been applied to the effacement of wrinkles and acne scars and as such will be explored in detail in Chapter 80.

The aim of treatment is to selectively wound the upper dermis in order to induce dermal fibrosis (or collagen remodelling). The epidermis is protected and retained to avoid the problems of the open wounds caused by ablative modalities. Prerequisites for this are therefore epidermal cooling systems and wavelengths that are sufficiently long to penetrate and injure the dermis. A variety of lasers and flashlamps have been studied, including some originally developed for other purposes.

Radiofrequency and infrared devices designed to cause deep, volumetric heating and subsequent skin tightening have only been used for cosmetic purposes and will be discussed in the relevant chapter.

Fractional photocoagulation. An erbium glass laser (1540 nm) emits light through a fibre with an optical deflection and focusing system. This causes microscopic treatment zones (MTZs) of non-ablative coagulative damage to the epidermis and upper dermis. The diameter of MTZs is about 100 μm, and their depth and density determine the clinical response. These heal with micro-epidermal necrotic debris (MENDs), which supposedly remove pigment, and with subsequent fibrosis [2].

This technology improves fine wrinkles and possibly melasma and is described in more detail in Chapter 80.



Fractional ablative resurfacing. At the time of writing, this is a clinical prototype, the development of which may be consequent upon the subtle clinical effects of fractional and other non-ablative photocoagulation. A CO_2 laser (10 600 nm) with a scanned 120 μm spot is used to create MTZs of ablative injury [3]. It is likely to occupy a place between fractional photocoagulation and ablative resurfacing in terms of increased efficacy (and increased morbidity) in cosmetic applications.

Devices in common use

Ablative

Carbon dioxide (CO_2) (10 600 nm) laser. The CO_2 laser produces light (10 600 nm) that is relatively poorly absorbed by the chromophore, water, and which therefore penetrates relatively deeply (30 μm). The beam can be operated in continuous wave or can be pulsed or Q-switched using a rotating mirror or electro-optical switch. Incisional surgery is achieved using a focused beam, whereas ablative resurfacing is effected by the scanning of either focused or high-power, wide-diameter beams. For ablation, the fluence should exceed the vaporization threshold of skin (5 J/cm^2) [4] and the pulse duration (or its laser equivalent, the 'dwell time') should be shorter than the TRT of 700–950 μs [5]. These lasers have recently been modified to perform fractional ablative resurfacing.

Erbium:yttrium aluminium garnet (ER:YAG) (2940 nm) laser. This laser emits light with a higher absorption coefficient for water and a lower optical penetration depth than the CO_2 laser. These lasers are used for ablative resurfacing and more recently have been modified for fractional procedures.

(a) (b) (c)

Fig. 78.12 Angiofibromas, (a) before, (b) 6 months after and (c) 24 months after CO_2 laser resurfacing, showing gradual recurrence of lesions over time.

Non-ablative

Neodymium:yttrium-aluminium-garnet (Nd:YAG) (1064 and 1320 nm), diode (1450 nm) and erbium:glass (1540 nm) lasers. These all produce infrared light which is absorbed by melanin or by water in collagen.

Skin disorders treated with photothermal excision and ablation

CO_2 laser incisional surgery may confer an advantage over conventional scalpel incisions because of associated haemostasis due to thermal damage around the beam. A potential disadvantage is that thermal damage of the apposed wound edges may result in slower healing and a more obvious scar. This technique may be most useful in making surgical wounds that are to heal by second intention. One example is the dissection of head and neck keloids below the hair follicles through the subcutaneous fat. Results have varied [6] but are probably better on the head than at other sites, particularly if augmented with intralesional corticosteroids before and after re-epithelialization. A difficulty in performing or assessing studies on keloids is defining what is meant by cure.

Ablative modalities remain the most effective means of resurfacing wrinkles and some acne scars, although with increased morbidity. This is explored in more detail in Chapter 80.

Epidermal dysplasia and neoplasia

CO_2 laser ablation is a useful option in treating actinic cheilitis as well as Bowen's disease on periungual folds and on the glans penis. Superficial basal cell carcinomas have also been managed with laser ablation, although this is unlikely to be the treatment of choice.

Appendigeal tumours and hyperplasia

Familial trichoepitheliomas and angiofibromas can be flattened with lasers, but lesions recur over time in some patients. It is possible that this can be prevented by making a deeper wound and preventing recurrence by eliciting more fibrosis [7].

Peri-orbital syringomas and xanthelasmas can be managed with any of a number of destructive modalities, including CO_2 laser ablation. In peri-orbital skin, the dermis is thin and it may be difficult to ablate to a depth where the procedure is not followed by either recurrence of the lesions (Fig. 78.12) or by colour and texture change. Newer, non-ablative modalities may be preferable for these conditions and for sebaceous hyperplasia. Rhinophyma can be recontoured for cosmetic purposes and in order to relieve nasal obstruction, when present.

Dermal inflammatory infiltrates

Granuloma faciale and cutaneous facial sarcoid usually present with flat, violaceous lesions which have been reported to respond to pulsed-dye laser treatment, although it seems likely that their colour owes more to the infiltrate than ectatic vessels. Plaques of granuloma faciale can be flattened with a CO_2 laser and will reform slowly, if at all. Likewise, plaques and nodules of facial sarcoid can be usefully and often indefinitely debulked if the disease is stable [8].

Miscellaneous

A number of other, unrelated conditions have been treated with CO_2 laser ablation, including periungual and plantar warts, axillary Hailey–Hailey disease and vulval lymphangiectasia/lymphangioma [9].

Skin disorders treated with non-ablative photocoagulation

These modalities are widely used for cosmetic purposes and are described elsewhere. They may have a role in treating xanthelasmas and sebaceous hyperplasia.

Complications of photothermal ablation

The risk is dependent on the depth of photothermal ablation. Before re-epithelialization, the major complication is infection and this occurs in about 4% of patients after full-face resurfacing. It is

usually due to staphylococci, although infections with *Candida* species and herpes simplex have also been implicated, and all may cause scarring. Complications after the third week include acneiform folliculitis and milia formation, contact reactions, dyspigmentation and scarring. Post-operative erythema occurs in all patients and its duration is mainly a reflection of wound depth [10]. Hypopigmentation is not usually apparent until 6 months postoperatively and may be caused by loss of epidermal melanin or by underlying fibrosis. This is now quoted as one of the reasons for the swing from ablative to non-ablative resurfacing.

Low-power lasers

There is anecdotal and conflicting evidence relating to the use of low-power lasers and light emitting diodes for expediting wound healing [1] and for treating aphthous ulcers [2]. Increases in collagen synthesis and stimulation of immune pathways have been proposed as mechanisms of action [3].

Photodynamic therapy

Photodynamic therapy (PDT) using a topical photosensitizer has become a popular treatment for some forms of epidermal dysplasia and superficial neoplasia, as well as for some benign skin disorders.

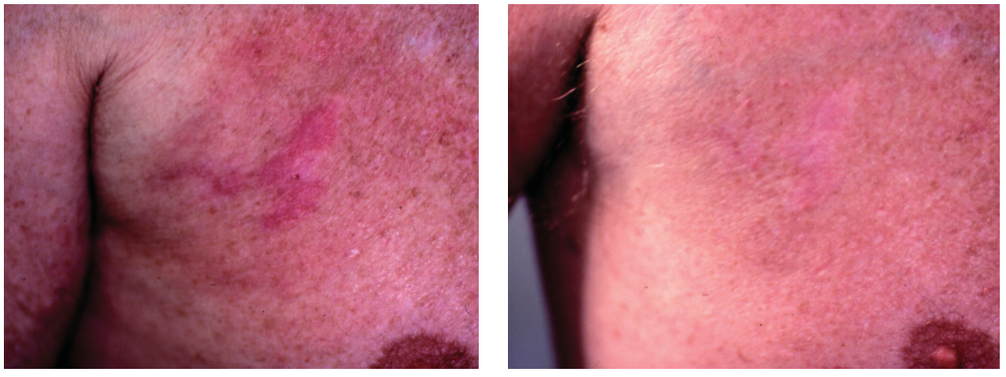
The photodynamic reaction requires a sensitizer, light and oxygen. The main groups of exogenous photosensitizers are the porphyrin and chlorin derivatives and the phthalocyanines. Alternatively, the haem biosynthetic pathway can be used to generate the endogenous photosensitizer protoporphyrin IX (PpIX) from 5-aminolaevulinic acid (5-ALA) or its derivatives. It is possible to achieve preferential accumulation of PpIX in target tissue, which is then irradiated with a laser or non-coherent light source. This excites the PpIX molecule, which is necessary for the formation of free radicals and singlet oxygen, which in turn damage intracellular organelles [1].

Challenges in the development of this treatment modality are the optimal formulation, delivery and duration of application of the photosensitizer as well as the irradiance, wavelength and total dose of light [2].

Light–tissue interaction

5-aminolaevulinic acid (ALA)

PDT with topical 5-ALA has become popular in dermatology since its introduction by Kennedy *et al*. in 1990 [3]. Exogenous administration of 5-ALA bypasses the feedback control mechanism and causes increased intracellular concentrations of PpIX. This in turn is metabolized within 48 h, avoiding prolonged photosensitivity. ALA is hydrophilic and most studies [2] have used a 20% concentration as an oil-in-water emulsion which is applied for 3–6 h under a light-occlusive dressing. Penetration is improved if the epidermis overlying a lesion is abnormal, and can be enhanced through use of lipophilic methyl and other esters of ALA (e.g. methyl aminolaevulinate). Of more questionable benefit are iontopheresis and the penetration enhancer, dimethylsulphoxide. Preferential accumulation within tumours may be influenced by differences in haem synthesis and iron availability [4].



Other topical photosensitizers have also been used but data concerning these are still limited.

Light sources and doses

The absorption spectrum of porphyrins is maximal in the Soret band (centred around 410 nm), with smaller peaks between 500 and 635 nm (Q bands) [5]. In practice, lesions are irradiated with light at 630–635 nm. This corresponds to the lowest absorption peak but has better tissue penetration. Light of 630–670 nm may activate photoproducts of PpIX but probably has little clinical relevance [6]. Polychromatic light sources are as effective as lasers [7] but are cheaper and can irradiate larger skin areas with sufficiently high fluence rates (i.e. irradiance, W/cm^2) to keep treatment times within practical limits. In clinical studies, light dosage is usually estimated from the fluence (J/cm^2) alone. The limitation of this is that it does not account for variables relating to ALA, its pharmacodynamics, the wavelength or irradiance of the light or, indeed, to the tissue optics. Fluence rates higher than 50 W/cm^2 may affect oxygen availability, and if higher than 150 W/cm^2 may result in thermal injury [8].

Mechanism of action

The absorption of light excites the photosensitizer, which fluoresces as it reverts to the resting state. The excited molecule initiates two types of photo-oxidative reaction, one of which results in generation of singlet oxygen. Subsequent cell death is probably

(a) (b)

Fig. 78.13 A large superficial basal cell carcinoma on the chest, (a) before and (b) after one episode of photodynamic therapy.

mediated by apoptosis [9] and an inflammatory response secondary to direct cytotoxicity [10].

Topical PDT and skin disorders

As noted previously, clinical studies of PDT differ widely with respect to the formulation, delivery and duration of the photosensitizer (or its precursor). There is also variation in terms of the irradiance, wavelength and dose of the light and also in the light sources used. Furthermore, there are few controlled studies. It is therefore difficult to compare studies, and many reviews have had to resort to individual summaries of each and every one of them.

It is possible, however, to make the following broad observations [11]:

Actinic keratoses

Most studies have used a 20% formulation of ALA applied for 3–6 h. It seems likely that methyl 5-ALA shows preferential accumulation in actinic keratoses. Green, blue or red light seem equally efficacious. Lesions that are not hyperkeratotic show an improvement of about 70% if on the face and about half of this if on the limbs. PDT is similar in efficacy to 5-fluorouracil (5-FU) or to cryotherapy, and may be better cosmetically.

Bowen's disease/SCC in situ

Methodology has been similar to that used for actinic keratoses. Clinical cure rates are about 80%, although a proportion relapse. The consensus seems to be that PDT is more effective than 5-FU or cryotherapy and associated with fewer adverse events.

Basal cell carcinoma (BCC)

Long-term, complete clearance rates of superficial (<2 mm thick) BCCs are 80–90% if treated once or twice (Fig. 78.13). This falls to about 50% in nodular BCCs, unless they are first curetted. Cure rates are even lower with infiltrative tumours.

Other indications

PDT has been applied to a wide range of unrelated, benign skin disorders. It may be effective in treating warts, although probably only if the warts are pared and if treatment is repeated. Low-dose single treatment of patients with acne has been attempted using red or blue light, sometimes using endogenous porphyrins, and reportedly to the benefit of some patients. Claims have been made for a role in photorejuvenation.

Associated morbidity

Topical PDT is painful, the degree of discomfort sometimes seeming to be disproportionate to the superficial nature of the lesions treated. Treatment is usually followed by erythema, oedema and crusting, often responsive to emollients or topical steroids. Local photosensitivity can occur, but is short-lived. Topical PDT is usually followed by a good cosmetic result, but may be complicated by dyspigmentation.

Introduction

The clinical effects of ionizing radiation on the skin have been known since the discovery of X-rays in 1895 [1,2]. Initially both benign and malignant skin conditions were irradiated, and dose and clinical indications were chosen empirically with little knowledge of the late effects of radiation on skin and subcutaneous tissue. Indications for treating benign disease by irradiation have declined since the advent of topical steroids.

It is in the best interest of patients suffering from skin tumours to be seen in a clinic where the expertise of specialists in radiotherapy and oncology, plastic surgery and micrographic surgery as well as dermatology are present, and this is being achieved with the mandatory development of multidisciplinary team meetings and clinics in the UK, as described in the *Improving Outcomes* guidance [3].

Ionizing radiation in the treatment of skin cancer

X-ray photon beams: megavoltage and kilovoltage X-ray therapy

X-rays are part of the electromagnetic spectrum, of shorter wavelength and more energetic than UV light. The most commonly used form of therapeutic radiation is now megavoltage radiotherapy, using energies of greater than one million electron volts (>1 MeV) delivered by linear accelerators, in the treatment of deep-seated tumours. However, these beams are usually not suitable for the treatment of skin cancers because of their greater penetration and skin sparing properties. X-rays in the kilovoltage range (50–140 kV) are very suitable for treating skin cancer as their maximum energy is deposited on the surface. Fall off subsequently is exponential (Fig. 79.1), and some radiation dose reaches underlying subcutaneous structures. Higher voltage beams can be used for thicker tumours.

Electron beams

Beta rays are electrons and can be derived from radioactive isotopes, such as ^{90}Strontium, or produced by a linear accelerator. An electron beam differs from a superficial X-ray beam or other photon beams as the energy does not fall off exponentially as the beam goes through tissue but builds up to a peak and then falls off rapidly (Fig. 79.2). The depth of penetration is proportional to the energy of the beam. A useful treatment depth in centimetres is approximately one-third of the energy of the beam, so a 4.5-MeV

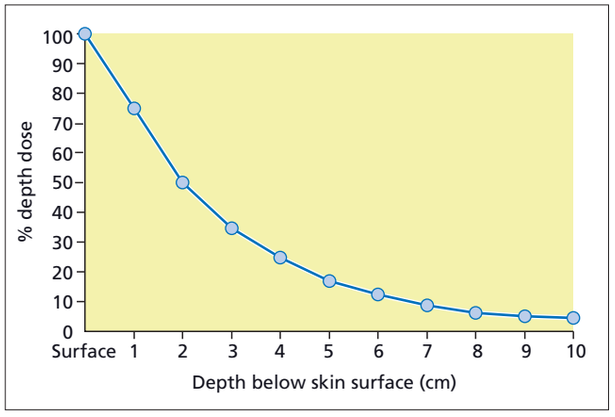

Fig. 79.1 Approximate per cent depth dose values for 90 kV superficial X-ray beam.

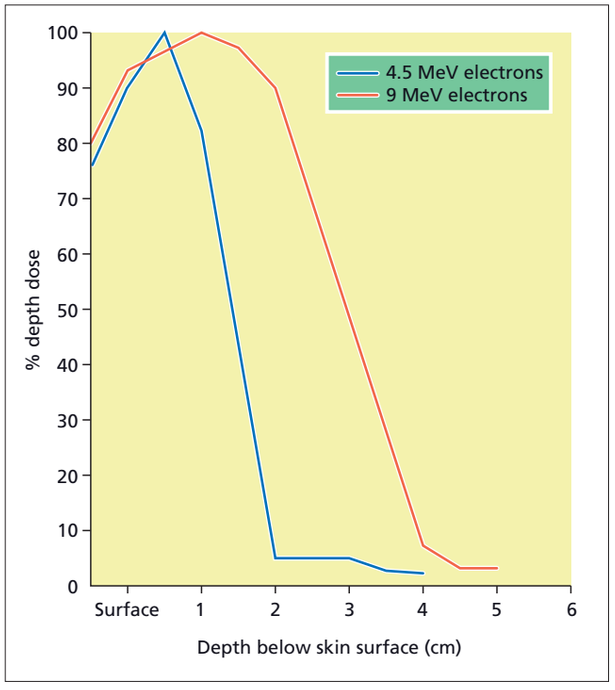

Fig. 79.2 Approximate per cent depth dose curves for 4.5 and 9 MeV electron beams.

electron beam will be useful for treating to a depth of 1.5 cm, and a 12-MeV beam to 4 cm. The width at the peak of the beam also increases with electron energy, giving more of the plateau at the peak at higher energies, as shown by the representation of the 9-MeV beam shape in Fig. 79.2. This can be useful when trying to enclose all of a thick tumour within the highest energy part of the beam. To avoid skin sparing, tissue equivalent material such as wax or paraffin gauze is applied over the tumour so that energy is deposited in this 'build-up' material, moving the beam peak left towards the skin surface in Fig. 79.2.

Superficial X-ray therapy is indicated for the majority of skin cancer treatments. However, there is a slightly higher risk of late bone and cartilage necrosis with this modality, as X-rays are absorbed proportionally more in high-molecular-weight tissues than in soft tissue. Electrons are absorbed similarly in all tissues, and have the advantage of sparing sensitive underlying tissues. This may be the modality of choice for tumours on the pinna, scalp, dorsum of the hand and tibia. Superficial X-rays have been used successfully in the past in these sites [1], but electrons are preferred nowadays [2].

Unfortunately, in practice, electrons have limited use in the treatment of common skin cancers. As an electron beam is produced by a linear accelerator, which is much larger than a superficial X-ray machine, the treatment applicator is unwieldy and the minimum applicator size on the skin is 4 cm^2 for a reliable dose calculation. Air cavities can give unacceptable dose non-homogeneity with electrons, and eye shielding is not possible for the treatment of periorbital tumours. Setting up electron treatment fields is often more time-consuming than with superficial X-ray therapy.

It is possible to irradiate the whole skin area with an electron beam [3–8]. The minimal depth–dose characteristics that may be achieved avoid the irradiation of subcutaneous structures, which would occur if X-ray therapy was used as it is absorbed exponentially. This technique is used in the treatment of mycosis fungoides [4]. Multiple radiation fields are combined to give a homogeneous dose to the whole skin down to a depth of approximately 1 cm.

Moulds and implants [1,2]

Other treatment modalities available for the irradiation of skin cancer, but in much less common use nowadays, are a 'mould', which is a cast loaded with radioactive material applied to the surface of the tumour and secured in place for the required treatment time, or interstitial brachytherapy (described below), as in the treatment of keloid. Use of these techniques has declined in recent years, because although cosmetic results are good there is a need for hospital admission for radiation protection reasons, and the results depend on local expertise.

Radiotherapy treatment technique

The superficial X-ray tube is manoeuvrable and the patient can be made comfortable on a treatment couch with an applicator resting on the skin to be treated (Fig. 79.3). The tumour and a margin of normal tissue is treated with a standard applicator. If the tumour is an irregular shape in two dimensions, a piece of lead shielding 1.5 mm thick can be 'cut out' in the shape of the skin to be treated, and the applicator placed on this (Fig. 79.4). The individual surface area for treatment is measured and the treatment time adjusted by calculation, giving the number of machine units which have to be delivered for each treatment.

Once the applicator is in position, the radiographer leaves the treatment room. Treatments last for a few minutes on each occasion, and the patient is watched throughout using a remote camera system or special glass window.

Radiosensitivity

All radiation is destructive. The basis of radiotherapy is that abnormal cells repair radiation damage less well than normal cells. This inability to repair is reflected in death at mitosis. Anaplastic cells and those with a high mitotic index are more radioresponsive than differentiated cells. Radio-responsiveness and radio-curability are dissimilar and are functions of differences in cell population kinetics, so a rapidly resolving cancer may recur and a slowly resolving tumour may be completely cured. Radiotherapy is usually given as a fractionated course, as the intervals between doses allow for the recovery of normal cells. The effect of a dose of radiation is reduced by increasing the number of fractions in which it is given or by lengthening the total overall treatment time. The effect of irradiation can be modified by anoxia, infection, oedema, trauma and any inborn genetic susceptibility. The face tolerates irradiation well and radical dosages may be accompanied by good cosmetic results [1].

When irradiating benign conditions, the minimum dose and the lowest voltage appropriate to achieve the desired effect should be chosen. The threat of radiation carcinogenesis must clearly be seen in the context of the clinical indication for treatment. There is a threshold for somatic radiation changes which need not be breached in the treatment of benign conditions. The late radiation sequelae of treatment given many years ago are inexcusable with modern standards of dosimetry and equipment, and should not be seen in the treatment of benign diseases [2].

Indications for radiotherapy: benign skin disease

Some of the misconceptions about the role of radiotherapy have arisen because of its widespread use in the past for the treatment of benign conditions. X-ray production was discovered in 1895, and soon afterwards it was noted that the antiproliferative effect of low energy X-rays was advantageous in the short term in a variety of visible tumours and benign dermatoses, and sometimes multiple retreatments were offered. There was, however, no dose measurement apart from the biological effect of 'skin erythema', no radiation protection for workers or patients, and no appreciation of the late effects of radiodermatitis, leukaemia and other malignancies, and of skin cancer induction after a very long latent period.

Radiation epilation for tinea capitis, a treatment offered widely in Europe, well demonstrates radiation carcinogenesis. In a series of 2200 who received X-ray epilation treatment for scalp ringworm during the 1940s and 50s, and who were subsequently followed by mail questionnaire for an average of 26 years, 41 had one or more BCCs of scalp or face (80 lesions in 41 cases), whereas there were only three BCCs in a comparable group of 1400 treated without X-ray [1]. Skin cancers induced by this treatment have a very long latent period, often over 30 years, and cases treated in the 1930s and 40s have been seen until recently in cancer treatment centres in the UK (Fig. 79.5). For a fascinating and well illustrated discussion of these early treatments and their consequences, see [2].

Radiotherapy is used much less now in the management of benign skin conditions than formerly and then usually only after other treatment modalities have failed or are contraindicated. In some conditions, such as psoriasis and eczema, there is a response to radiotherapy, but often only temporary [3–7]. This, coupled with the risk of late radiation-induced malignancy, has led to the decline in its use in all but the most refractory of cases. It is also still used occasionally in the management of keratoacanthoma where the differentiation from squamous cell carcinoma cannot be made with complete confidence [8–9]. Other rare uses are in Darier's disease, familial benign chronic pemphigus and acrodermatitis of Hallopeau [5–7].

Recent UK National Institute for Health and Clinical Excellence (NICE) guidance on the use of Grenz rays, which are very low kV X-rays absorbed chiefly in the epidermis, advises that the evidence for their safety and efficiency is very limited, and that their use in inflammatory skin conditions be limited to carefully selected patients, who are refractory to other treatments, and preferably under trial conditions, or at least with national data collections [3,7,10].

Keloids

This is the most common benign condition now treated with radiotherapy. Intractable keloids resistant to intralesional steroids or other conventional treatment may respond well to radiation. Excision of the keloid with early irradiation of the scar and stitch marks is more successful, but in some sites, for example tip of shoulder and upper middle chest, where surgery is inadvisable, good response of pain, itch and redness can be achieved with some regression of the keloid itself. Relatively high doses are necessary; these will cause temporary pigmentation, which will remain for many months in pigmented skin. Doornbos *et al*. [1] noted that 17 of 18 unexcised keloids that were less than a year old regressed with 1500 cGy given in three treatments over 6 days at 120 kV. Older keloids respond less well to irradiation. The most satisfactory management of keloids is postexcision irradiation, where a dose–response relationship can be seen. Total doses less than 900 cGy, irrespective of fractionation and postsurgical interval, did not prevent recurrence. Three doses of 400 cGy were reported by Kovalic and Perez [2], to give a 73% success rate. Using the commonly employed dose of 900 cGy, Lo *et al*. [3]

described an 85% success rate and Borok *et al*. [4] a 96% response rate. No late sequelae or carcinogenesis was described by any of the previously quoted authors, with follow-up in excess of 30 years.

As well as using superficial X-rays, or electron beam radiotherapy [5], treatment can be given using a radioactive iridium wire implant. With the latter technique, at the time of excision, a small plastic tube is inserted below the incision, with both ends of the tube exposed. The patient is then transferred to the radiotherapy department within 24 h, and the tube is loaded with iridium wire, and the scar irradiated to a dose of 20 Gy at 2 mm from the wire over 2 days [6]. Escarmant *et al.* [7] describe the results of treating 783 keloid scars in 544 patients with interstitial iridium implants.

Indications for radiotherapy: malignant skin disease

For most small basal cell carcinomas (BCCs) or squamous cell carcinomas (SCCs) without nodal involvement, surgical excision or radiotherapy will give excellent cure rates [1–4]. Superficial radiotherapy has a long history in the successful treatment of BCCs and SCCs of the skin—1695 such patients received treatment in 1945 at the Queensland Radium Institute [5]. A number of series have been reported, from 1947 onwards [6], showing cure rates of 90% or greater.

Choice of treatment

If cure is the intention, then surgery or radiotherapy are the treatment options, although a variety of other modalities, including cryotherapy, curettage and topical therapies, may provide temporary control [7,8].

The decision as to which is the most appropriate modality will depend on several factors. These include the size and location of the tumour, any involvement of underlying tissues and the likely functional and cosmetic outcome of either treatment. For small BCCs, simple excision with clear margins is ideal; it is within the remit of suitably trained practitioners and leads to good cosmesis with low recurrence rates. For larger BCCs and SCCs in critical sites, particularly around the eyes, ears and nose, plastic surgery and radiotherapy should be considered as treatment options.

The patient's overall condition is important, as is the complexity of any surgery required; even the distance from the patient's home to the radiotherapy centre may play a role in determining the choice of treatment. Social factors such as working patterns, transport availability and patient preference, where there may be a wish to avoid either surgery or multiple hospital visits for radiotherapy, have also to be taken into consideration. The decision as to which treatment modality is used should not be made solely on the basis of the patient's age. The advantages and disadvantages of each treatment modality should be explained to the patient in order to enable an informed, shared decision to be made.

If the lesion cannot be cured, again a compromise is reached. Some patients with multiple tumours elect to have treated only those that are causing symptoms. Some very large tumours will not be cured by any modality but might respond for a worthwhile period to palliative radiotherapy (Fig. 79.6).

Radiotherapy has a role to play in the treatment of almost all malignant skin conditions. Its use has been variable for several reasons. In some areas, traditional referral patterns have curtailed its use, and the siting of radiotherapy departments in the larger conurbations has not enabled universal access for all patients. Specialists have not always been aware of what various treatment modalities can offer [7]. Radiation damage, with skin atrophy, telangiectasia and necrosis and ulceration, occurred in the past, but this is now rare as a result of better dosimetry, a wider range of radiotherapy modalities [9] and more careful fractionation. Multidisciplinary team working will be strengthened in future, and with appropriate cooperation and communication between colleagues it is likely that all modalities will find their proper place, and the patient will receive optimal advice. This is in contrast with previous practice where only 2% of patients with BCC were referred to joint clinics [10], or a radiotherapeutic option was needlessly dismissed [11]. New UK national guidance [12] recommends that all health professionals treating skin cancer should be members of either a local hospital or a specialist skin cancer multidisciplinary team, and should work to locally approved protocols based upon nationally accepted guidelines, such as those of the British Association of Dermatologists [13]. The implementation of this guidance by the Cancer Networks, and the peer review process in prospect, can only improve the likelihood that the patient will receive optimum advice for their particular situation. A similar approach has been recommended in American guidelines [14].

It is not disputed that surgery offers a better cosmetic result, with the passage of time, nor that radiotherapy is able to preserve existing structure and function, although it is not of course able to replace tissue destroyed by tumour.

Few trials have been reported that compared surgery directly with radiotherapy. Avril *et al.* [15] showed that in 347 patients with facial tumours less than 4 cm in diameter, the recurrence rate within 3 to 5 years was 1/174 in the surgery group compared with 11/173 for radiotherapy. The cosmetic results were better with surgery. However, the radiotherapy regimens were heterogeneous, and the surgical results exceptionally good, better even than for Mohs surgery, where one large series had a 30-month recurrence

(a)

(b)

Fig. 79.6 (a) SCC too large to expect long-term cure. (b) Satisfactory control at 6 months.

of 3/160 tumours, compared with 5/171 for conventional surgery [16].

Published studies of radiotherapy for skin cancer do, however, report consistently high long-term control rates. Olschewski *et al.* [17] reviewed five studies treating over 5000 BCCs between 1984 and 2002, with a cure rate of over 93%, and similar results in 1267 cases treated in 1988–1992 were reported by Schulte *et al.* [18]. It is important in practice for the oncologist and plastic surgeon to be cooperative colleagues rather than rivals, each knowing what the other can offer.

(a)

(b)

Fig. 79.7 (a) SCC unsuitable for radiotherapy on the back. (b) SCC unsuitable for radiotherapy on the buttock.

Surgery preferred as primary treatment

Surgery is usually preferred to radiotherapy in a younger patient, where the cosmetic appearance of excision with or without grafting can be expected to become superior with the passage of time. Multiple lesions may also be conveniently treated at the same 'sitting'. There is evidence that radiotherapy is contraindicated in Gorlin's syndrome [12]. Bulky tumours and those requiring a field size of over 6 cm are best excised, as they are unlikely to be cured with radiotherapy. If the tumour has eroded bone or cartilage, both cure and re-epithelialization are unlikely with radiotherapy, and surgical reconstruction is preferred.

Certain anatomical sites also tolerate radiotherapy treatment less well, with more painful acute reactions and proneness to infection and slow healing; the trunk and perineum fall into this category (Fig. 79.7). Carcinomas below the knee are also better excised, as radiotherapy tends to be associated with slower healing and a risk of persistent ulceration [19].

Radiotherapy preferred as primary treatment

Radiotherapy is particularly suitable as a treatment modality for tumours of the face, especially the nose, lips, ears and around the orbit, where surgical removal may result in a poor cosmetic result or loss of function [20], or where complex surgical reconstruction would otherwise be required. Elderly patients on warfarin or with significant co-morbidity can usually tolerate treatment well, and are spared an invasive procedure and an anaesthetic. Treatment is delivered as an outpatient, and can often be accessed without a waiting list. Although the capital cost of the equipment is quite high, once installed it is a relatively cheap modality to run, and radiographer staffing can be provided efficiently from the radiographer pool if the machine is operating on certain limited days or times during the week.

There is little difference in outcome between external beam radiotherapy with either superficial X-rays or an electron beam [21]. Locally placed moulds or applicators have also been used for malignant skin tumours, placing a radioactive source over the tumour and leaving this in position for a predetermined period [9,10], or implanting radioactive wire into the tumour-bearing tissue.

The areas that have traditionally been considered as not suitable for radiotherapy, such as pinna, dorsum of the hand or anterior lower leg, can be treated if careful consideration is given to the volume treated, the total dose and the fractionation. It is also important to consider the general fitness of the patient and the condition of the skin in the site to be treated [22–25].

There are some patients who, for practical reasons, cannot have radiotherapy; for example, if they are unable to lie still because of confusion or neurological disease it can be impossible to deliver radiotherapy effectively and safely.

Postoperative radiotherapy treatment

Although ideally the patient should receive a single curative modality of treatment, sometimes in individuals who have had a macroscopic excision of a SCC or a BCC histology indicates extension beyond the excision margins. For squamous carcinoma, because of the consequences of recurrence and nodal spread, it is sensible to offer 'postoperative' radiotherapy to the scar and tumour bed, using the normal dose and fractionation regimens. With a well-healed scar or skin graft, the radiation reaction is often very mild. Adjuvant radiotherapy has been advocated by some authors [26–28] where there has been inadequate excision and further surgery is either not possible or not recommended, or if the tumour shows prognostic indicators of poor outcome such as positive lymph nodes, especially with extra-capsular spread, a large primary SCC or in higher-risk primary tumours of the head and neck. Adjuvant radiotherapy may improve outcome even after Mohs surgery [28], and there is some evidence that delaying radiotherapy may result in early tumour recurrence [29].

The situation is different for BCC. Liu *et al*. [30] reported a series of 187 incompletely excised BCCs; 119 had immediate postoperative radiotherapy, one was excised and 67 were managed expectantly. The 5-year probability of remaining relapse-free in the group immediately treated was 91% versus 61% if managed expectantly. Once relapse occurred in the group of lesions treated expectantly, 85% of the relapses were salvaged by radiation or surgery. The 10-year actuarial probability of local control for the lesions immediately treated and observed were similar—92% and 90%, respectively. Not all patients therefore require radiotherapy, and it can be reasonable to wait and see, particularly in the elderly where a 'lifetime' cure may be anticipated. To wait for recurrence also allows an appropriate treatment field to be determined. The patient will often have a preference for one particular course of action.

Table 79.1 Commonly used superficial radiotherapy dosage regimens for skin BCC and SCC.

Total dose	No. of fractions	Fractionation interval
18 Gy	1	—
28 Gy	2	7 weeks apart
35 Gy	5	Daily (for tumours less than 4 cm in diameter)
45 Gy	10	Daily (for tumours more than 4 cm in diameter)

These fractionation regimens are only examples. Many centres will have other similar but locally derived dose fraction regimens.

Radiotherapy dose fractionation and treatment regimens

Radiotherapy doses have evolved empirically over a long period of time and there is a wide range in use. As a rule, the greater the fractionation employed, that is the more the total dose is broken down into smaller fractions, the better the cosmetic effect. This is obviously very important to some patients, but others are content to accept a poorer cosmetic effect if it allows fewer visits to hospital (Table 79.1).

Dose and radiotherapy prescription

The SI unit of absorbed dose is called the Gray (Gy), and is 1 Joule/kilogram. This unit has replaced the rad. Note that 100 rad = 1 J/kg = 1 Gy; 1 rad = 1 cGy (centiGray). The dose prescription is defined by the total dose given, the energy of the beam, the number of fractions given, the total number of days over which treatment is given and the volume or area treated. For example, a typical prescription for the treatment of a small basal cell carcinoma might be '35 Gy using 90 kV superficial X-ray beam given in five fractions over 5 days to a 3-cm diameter circular area'. This time–dose relationship is crucial to understanding the biological effect.

It is often possible to see the patient as a new case and start treatment on the same day. A clinically obvious BCC is commonly treated without a tissue biopsy but it is prudent to obtain biopsy confirmation if the lesion could be a SCC, as wider treatment margins are usually advisable, and the follow-up for recurrence and lymph node metastasis differs.

The field size must be adequate to cover the extent of the tumour, with a margin of at least 5 mm, and the correct energy chosen for clearance at depth. Stretching the skin and use of a bright light will often show the extent of subepidermal infiltration of tumour. The morphoeic BCC has the reputation of a high 'recurrence rate', but regrowth of tumour is often because of a 'geographical miss'

at the edge of the field, and a failure to apply adequate margins. The oncologist marks the field to be treated directly on the patient's skin with a felt-tipped pen. The radiographer is responsible for the necessary calculations, and for delivering the dose as prescribed to this exact area of skin. For a thin BCC, 80 Kv X-rays are perfectly adequate, but if deeper penetration is suspected, or there is possibility of spread through underlying tissue planes, as for example in the nasolabial fold, a higher Kv energy can be chosen, and the radiographer instructed to apply the applicator very firmly to flatten the tissues.

Dose and fractionation

Dose and fractionation regimens are similar for BCC and SCC. There is a small therapeutic ratio between tumour cure and normal tissue necrosis, and even a slight alteration of dose or fractionation can be critical; in a retrospective study of 1005 BCCs and SCCs treated by superficial X-rays in 1976 at the Christie Hospital, Manchester, Chan *et al*. [31] found that for a field size of 3 cm^2 or less, a single fraction of 20 Gy gave a 10-year disease free rate of over 90%, with a late necrosis rate of 6%. An increase of dose to 22.5 Gy did not improve tumour control rates, but did significantly increase late necrosis, although of 60 patients with necrosis, spontaneous healing was common, and only 10 proceeded to surgical excision.

Fractionated radiotherapy is usually offered for larger tumours, as it is more likely to produce tumour control and a better long-term cosmetic result [6,32,33]. In addition, the brisker the primary treatment, the more painful the acute reaction, as there is less repair of sublethal damage in normal tissue between treatment fractions.

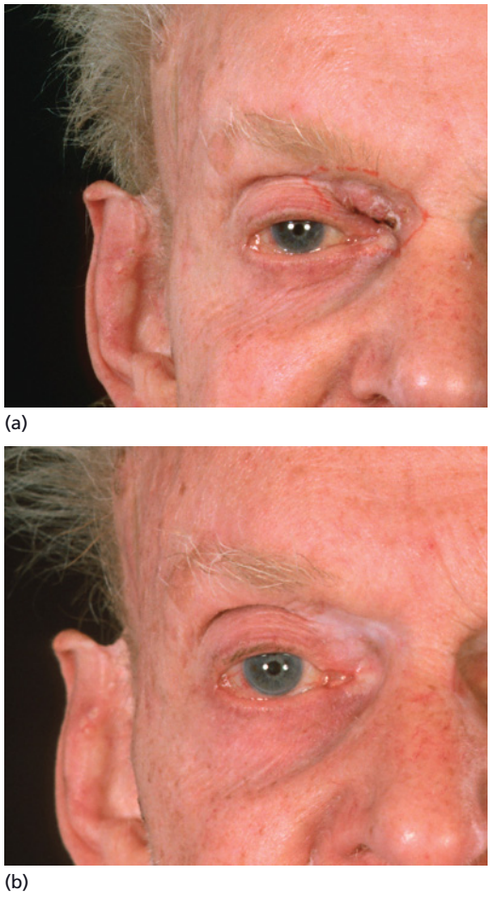
Radiotherapy for particular skin sites: basal cell carcinoma and squamous cell carcinoma



Eyelid (Fig. 79.8)

The upper eyelid, a rare site for skin cancer, is best treated surgically, as keratinization of the conjunctiva of the inner upper lid leads to traumatic damage subsequently. Tumours of the lower eyelid, however, are often suitable for superficial X-rays.

(a) (b)

Fig. 79.8 (a) BCC lower eyelid. (b) The same patient, 6 months after superficial X-ray treatment.

(a) (b)

Fig. 79.9 (a) BCC upper inner canthus. (b) The same patient, 5 years after superficial X-ray treatment.

A protective metal internal eyeshield is placed like a large contact lens over the globe of the eye, after the insertion of local anaesthetic eye drops, with an applicator resting on this and on the lower lid tumour (including an appropriate margin). Even the whole lower eyelid can be successfully treated in this manner.

Inner canthus (Fig. 79.9)

These tumours, close to the orbit, have a high cure rate if there is meticulous attention to dose calculation. An individual, thin lead mask is made for the patient by the 'mould room' technicians, with the treatment area cut out. This provides a seating for the applicator, avoids the possibility of trauma on the treated side, and protects the contralateral eye from the exit beam. If the nasolacrimal duct has been damaged by tumour and the patient has epiphora for this reason, then radiotherapy is not likely to reverse this symptom. However, it is uncommon for radiation *per se* to cause a new stenosis of the ductal system. Different authors advocate either radiotherapy or Mohs micrographic surgery depending on the size of tumour, potential for disfigurement or loss of function [1,2].

Ear (Figs 79.10 & 79.11)

Because tumours of the pinna and outer ear canal have close proximity to cartilage, electrons are preferred for treatment (see above), although in a study of 62 patients treated by kilovoltage techniques [3] of six apparent necroses, five healed spontaneously and only one required resection, with 97% local tumour control. A large Canadian study [4] showed that a persistent ulceration rate of 3% did not relate to beam energy, but to dose and fractionation, with control of cancer at 10 years of 93%. However, electron treatment does give very good results for tumours covered by a 4- or 5-cm diameter applicator [5] and most departments nowadays will offer electrons, unless for any reason the patient is unable to tolerate the linear accelerator procedures. The visible tumour is delineated, with a margin of up to 1 cm to account for the depth–dose characteristics of the electron beam, and the fact that the smallest reliable treatment applicator size is 4 cm diameter. The patient lies on the treatment couch with the ear for treatment uppermost, and wax or paraffin gauze is applied to make a level treatment surface. A lead shield protects the scalp. Once this 'sandwich' is in place, the applicator is brought down firmly on the surface, and treatment is delivered using 5 or 6 Mev electrons.

(a)

(b)

Fig. 79.10 (a) BCC upper pinna. (b) The same patient, 6 weeks after electron beam therapy.

(a)

(b)

Fig. 79.11 (a) BCC posterior aspect of the ear. (b) The same patient, 6 months after electron beam treatment.

Nose

Although skin cancers are here very closely applied to cartilage, in practice superficial X-rays give excellent control rates, and often a better cosmetic result than tumours irradiated at other sites. A lead plug is inserted inside the nostril to protect the nasal mucosa from the exit beam. At the nasolabial fold, the depth to be treated needs careful consideration.

Lip (Fig. 79.12)

Squamous cell carcinoma of the lip has a high local cure rate with radiotherapy using either electrons or kilovoltage X-rays [6]. Treatment margins should be generous, because of the tendency to spread mucosally (usually at least 1 cm of apparently normal tissue). The whole thickness of the lip is treated, choosing appropriate electron energy and build-up wax, or higher energy kilovoltage X-rays (300 Kv). A wax-coated lead gum shield protects the inner mouth from the exit beam, but a patch of sore mucositis inside the lip is inevitable, and will interfere with normal eating and drinking for a few days after treatment.

The patient is usually able to tolerate treatment to most of the upper or lower lip at a time, but not both areas simultaneously. The final cosmetic result is usually excellent.

Other areas of the face (Fig. 79.13)

Even large BCCs can do well with radiotherapy.

Parotid and cervical lymph node involvement from cutaneous squamous cell carcinoma

A subset of patients who develop cutaneous squamous cell carcinoma of the skin of the head and neck risk developing regional disease within parotid or cervical nodes, with worse outcomes [7]. Several studies have now shown that adjuvant radiotherapy gives higher rates of local control in this patient group than if they were treated with surgery alone [7–10], for both parotid and cervical node involvement [11].

(a)

(b)

Fig. 79.12 (a) SCC lip. (b) The same patient, 8 years after higher energy kilovoltage treatment.

(a)

(b)

Fig. 79.13 (a) Large BCC pre-auricular skin. (b) The same patient, 6 months after superficial X-ray treatment.

Parotid node involvement, if considered separately from cervical nodal disease, has been shown to act as an independent prognostic factor for survival, and patients with both parotid and neck node involvement do worse than those with either parotid or neck node involvement alone [12].

Radiotherapy for particular skin tumours

Basal cell carcinoma. Radiotherapy is useful for the primary treatment of small basal cell carcinomas or larger lesions where surgery will leave a poor functional or cosmetic result. Radiotherapy also has a role to play after primary surgery if the margins are ambiguous and further surgery is thought not to be appropriate for the patient. It should not be used for re-treating BCCs which have recurred after previous radiotherapy. The morphoeic BCC subtype or the presence of underlying bone or cartilage involvement are relative contraindications for the use of radiation treatment, but even in the latter situation, radiotherapy can be given safely and effectively [1].

Squamous cell carcinoma of the skin. As with BCC, radiotherapy can be used as either the primary modality of treatment or as adjuvant treatment after surgery if there is a narrow surgical margin of clearance, the margin often being determined by the particular anatomical site of the tumour. The technique and dose are the same as for treating a basal cell cancer, but a wider margin is taken around the tumour and the patient is subjected to a more frequent and longer follow-up, as suggested in the British Association of Dermatology guidelines [2]. If the SCC has developed on the face, it is mandatory to check for cervical lymphadenopathy. Radiotherapy may be especially useful for squamous cell carcinoma on or around the nose, where resection may be incomplete or the potential for reconstruction suboptimal [3]. Adjuvant radiotherapy may reduce the development of nodal disease in higher risk cutaneous squamous cell carcinoma, as described by Veness [4].

Radiotherapy can also be useful in palliation of advanced skin tumours, and in some patients gives long-term survival [5].

Bowen's disease. Radiotherapy can be effective for Bowen's disease [3], but it is not a commonly used treatment for this condition. Lesions on the leg have to be treated with more caution [6,7] as there is a danger of ulceration and very slow healing if large areas are treated. A recent retrospective review of 44 cases by VanderSpek *et al.* [8], where radiotherapy was used as a primary treatment or for managing residual disease, showed a crude local control rate of 93%. This condition can also be treated with a local mould, although this would be a relatively uncommon treatment modality nowadays.

Malignant melanoma. Malignant melanoma cells are not insensitive to radiotherapy as is sometimes stated (Fig. 79.14), but they do require higher dose per fraction regimens to overcome their ability to sustain more sublethal damage than other cell lines. Treatments may be hypofractionated, with patients receiving larger single doses in fewer fractions—for example treatment being given three times rather than five times per week—although this may lead to a greater risk of postradiotherapy morbidity [9]. Radiotherapy is also useful for palliation of both cutaneous and visceral metastases from melanoma [10].

There have not been any published prospective, randomized, controlled trials comparing surgery in melanoma with surgery and adjuvant radiotherapy, but there have been studies suggesting improved local control if postoperative radiotherapy is given

(a)

(b)

Fig. 79.14 (a) Malignant melanoma, pre-radiotherapy. (b) Malignant melanoma, post-radiotherapy.

[11,12]. Burmeister *et al*. [13] have reported the Trans Tasman Radiation Oncology Group (TROG) trials, where adjuvant radiotherapy was given to nodal drainage areas in the neck, axilla and groin. Grade 3 lymphoedema developed in 40% of the patients having radiotherapy to the groin, in 8% of those patients having axillary radiation, and in none of those given neck irradiation. The increasing use of sentinel node biopsy may allow better patient selection and targeting of patient subgroups who may benefit from adjuvant radiotherapy. The impact of adjuvant radiotherapy on survival is unknown, but may be minimal, even if local control is improved [14].

Lentigo maligna and lentigo maligna melanoma. Radiotherapy has been used very successfully in both of these conditions. In one German study, there was no recurrence in any of 42 patients with lentigo maligna, with a mean follow-up of 15 months, and only

two patients with lentigo maligna melanoma out of 22 showed local recurrence. Cosmetic results were also reported as good or excellent in the majority of patients [15]. Similar complete responses for lentigo maligna were seen in studies from Australia [16] and Canada [17], again with good cosmetic results.

Merkel cell carcinoma. These tumours of neuroendocrine origin are most common on the head and neck, but can occur elsewhere on the skin. They have a tendency to recur locally after surgical removal and improved local control has now been shown, in a large number of studies, with a combination of wide excision and adjuvant postoperative radiotherapy to the primary tumour site and local nodal drainage [18–28], with some studies also showing improved survival. Mojica *et al.* [22] in a recent, large, retrospective study looking at 1665 cases from the NCI SEER survey data, have shown a survival benefit from the use of adjuvant radiotherapy. Adjuvant radiotherapy may not add any benefit in terms of improved local control or survival after Mohs surgery if complete excision has been achieved [29]. These are radiosensitive tumours and radiotherapy has been used as a primary treatment [30,31].

Chemotherapy using regimens for small cell lung cancer, to which these tumours are related, is used for metastatic disease. It is not known what role chemotherapy has to play in improving survival when added to adjuvant radiotherapy. The prospective Australian study by Poulsen *et al.*, using historical controls, found no effect on survival but was not powered to detect a small increase in survival [32].

Cutaneous T-cell lymphoma. Radiotherapy can be used as both a localized treatment for isolated patches or plaques and for treating all of the skin by whole-body electron beam therapy [33–35]. With the latter, the patient takes up standard predetermined poses for a number of fields, allowing maximum cutaneous exposure to the beam. If treated early in the course of the disease, the patient can remain well and disease-free for a considerable period of time, but there is still doubt as to whether patients can be cured with this technique [36]. The eyes are shielded and the patient is made aware that they will lose their nails with this technique. Despite its drawbacks, radiotherapy is the most effective modality in achieving a complete response to treatment in cutaneous lymphomas. The UK National Institute for Health and Clinical Excellence has given guidance on treatment of these uncommon tumours [37].

Cutaneous Kaposi's sarcoma. It is well known that these tumours are sensitive to low-dose radiotherapy. Either superficial X-rays or electron beams can be used depending on the thickness of the lesion(s) and consequently the depth of treatment required. Treatment is used cautiously as patients are prone to develop severe local reactions and mucositis. Radiotherapy is also used to palliate systemic disease, such as pulmonary masses [38,39].

Dermatofibrosarcoma protuberans. This low-grade sarcomatous tumour has a propensity to recur after surgery alone, and local control is improved by giving adjuvant radiotherapy [40,41].

Carcinoma metastatic to the skin from other primaries. Skin metastases tend to originate from the most common parenchymal tumours such as breast, colon and lung but, occasionally, isolated skin metastasis occurs from tumours originating in the thyroid or urinary system. The latter two sites should be borne in mind if a patient presents with a single bizarre metastasis with no obvious evidence of previous primary tumour.

Squamous cell and basal cell carcinoma in transplant patients. Skin tumours developing after organ transplant are known to have more aggressive characteristics and carry a poorer prognosis [42]. These patients develop more SCCs than BCCs, reversing the normal ratio, and can develop multiple skin cancers and at an earlier age than the non-transplant population. There is no contraindication to using radiotherapy in this group, but most patients will undergo surgery as their primary treatment, especially if they have multiple primary skin tumours. Radiotherapy may play a greater adjuvant role in this group of patients with more aggressive tumours [43]. The guidance on *Improving Outcomes for People with Skin Tumours* [37] recommends that cancer networks make special provision for surveillance for cancer in these patients.

Acute radiation reaction (acute radiodermatitis) (Figs 79.15 & 79.16)

Radiation works by damaging clonogenic cells, both benign and malignant, and the damage is expressed at the next cell division, when the cell either dies or repairs sublethal damage. Tissues with a rapid turnover, such as the epidermis and mucosal endothelium, therefore show radiation damage soon after treatment, and this is the 'acute reaction'. For the treatment to result in cure, the basal or squamous carcinoma must be unable to repair this damage [1,2].

In acute radiodermatitis, histopathology shows oedema and sparseness of connective tissue beneath the epidermis. There may be flattening and loss of epidermal rete ridges with separation of the elastic tissue from the basal layer. Capillary endothelium may be hypertrophic and congested capillaries a feature. Haemorrhage and thrombosis are often observed. Special stains may show subtle changes in the DNA–RNA structure of epithelial cells as early as the third day [1,2]. During the healing phase, the patchiness of the pathology is a striking feature. Atrophy may be bordered by epidermal hyperplasia, pigmentation is very irregular, and blood vessels are of variable size and shape; deeper vessels may be fibrosed.

Normal tissue repair occurs when normal clonogenic cells on the basement membrane, which have either not received damage or have repaired sublethal damage, repopulate the basement membrane, and re-cover the epithelium [3].

In a commonly used regimen, where the patient attends at daily intervals for five doses of treatment, the irradiated skin starts to redden 5–7 days after the first treatment, because of increased vascularity and inflammation associated with cell damage. Subsequent doses add to the reaction, which proceeds through dry and sometimes moist desquamation and scabbing, usually reaching a height of discomfort at 3–4 weeks after treatment finishes, and settling over the next 2–3 weeks with re-epithelialization, which begins in the perifollicular areas, and proceeds as cell colonies coalesce to cover the denuded surface.

The acute reaction is more painful if there is ulceration and scabbing before treatment commences. The larger the surface area of the tumour and therefore the treatment field, the longer the healing takes, but even so, commonly at 6 weeks after the end of the course healing is virtually complete. The brisker the treatment, that is the larger the dose given in the shorter the time, the more marked the acute reaction is likely to be, as there is less opportunity for normal tissue repair between treatments.

However, if the skin is previously unbroken, or the tumour nodular, treatment may be followed by a very mild erythematous reaction only, with little discomfort for the patient.

Individual skin reactions vary, and those who burn in the sun tend to have a brisker reaction to X-ray treatment. Occasionally,

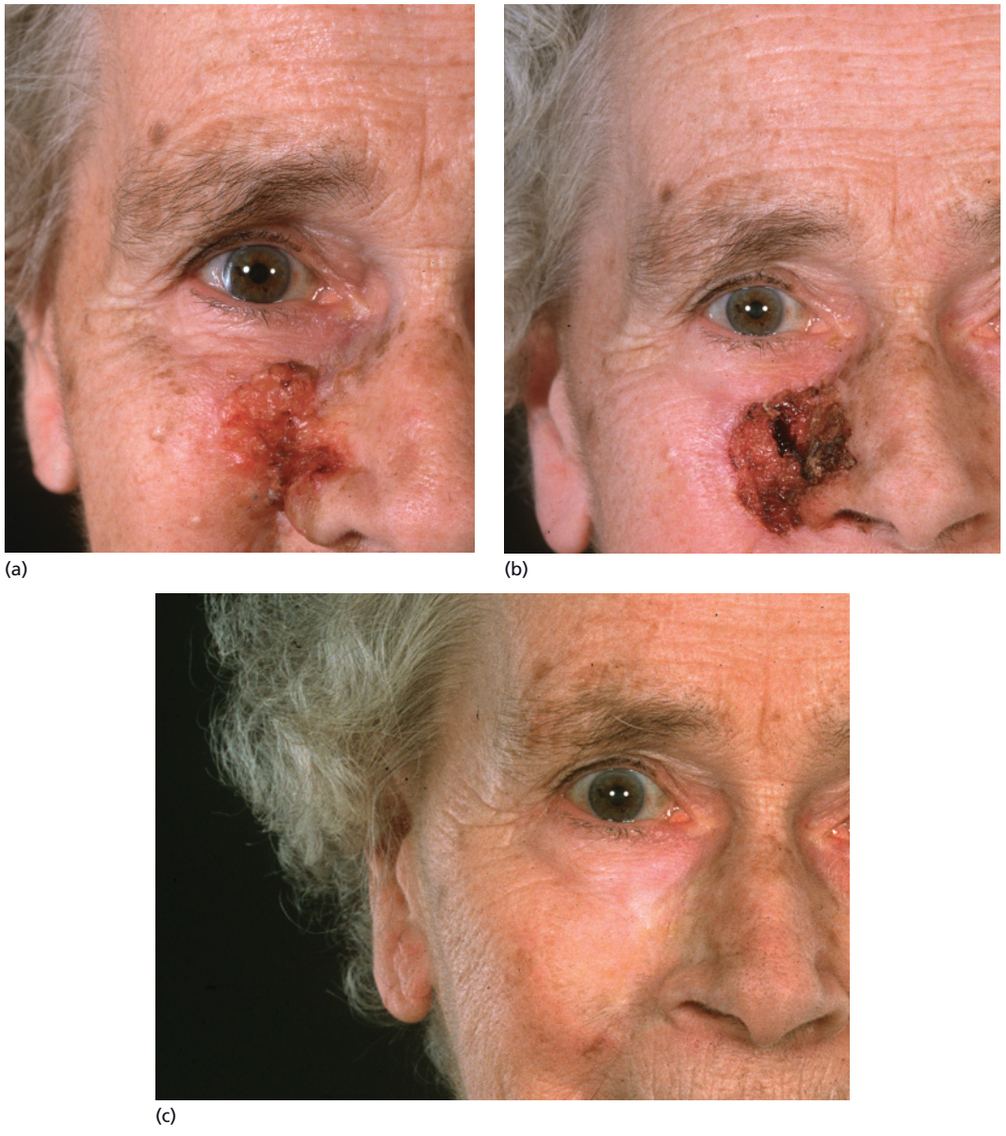

Fig. 79.15 (a) Large BCC cheek. (b) The same patient, showing acute radiation reaction 6 weeks after superficial X-ray treatment. (c) The same patient, showing settled reaction 6 months after superficial X-ray treatment.

especially on the face, infection occurs, usually with *Staphylococcus aureus,* and antibiotics are indicated.

If the exit beam passes through mucosa, a patch of mucositis will develop, of similar size to the treatment field. This reaction usually occurs earlier, and is of much shorter duration than the skin reaction, and heals completely without long-term sequelae. The nasal mucosa may swell and occasionally bleed, with the feeling of a blocked nose; in the mouth a sore patch may make eating uncomfortable for a few days. Although lead can be used to protect structures beyond the inner mucosa, such as the gums and the nasal septum, the mucosa just beneath the cancer cannot be protected.

Management of acute radiation reaction

The natural history of the acute reaction cannot be modified, but the patient can avoid making the reaction worse. They are advised to leave the area open to the air as far as possible, and to avoid trauma, extremes of heat or cold, irritation with chemical ointments and physical rubbing, which displaces regenerating clonogenic cells. Steroid creams are also best avoided. Patients are warned to report to the doctor if there is redness and soreness spreading outside the treated area, or a purulent discharge. Friction and infection may cause ulceration, as such skin cannot readily repair damage. Vigorous and repeated washing should be avoided in the acute stage. Once the treated area is dry and scabbed, normal washing can resume. It can be emphasized that only the area of skin that has been treated needs to be managed with caution—the remainder of the hair and face can be washed normally. The mucosal reaction must be endured, although application of Vaseline is sometimes soothing to the nasal mucosa, and some patients find a simple mouthwash helpful.

(a) (b) (c)

Fig. 79.16 (a) Large BCC jaw. (b) The same patient, showing acute radiation reaction 4 weeks after superficial X-ray treatment. (c) The same patient, showing settled radiation reaction 6 months after superficial X-ray treatment.

Although the reaction is described as 'like a sunburn effect' it is wrong to refer to the normal radiation reaction as a 'radiation burn', with the implication of 'overdose' or 'something going wrong'. The reaction can be predicted and explained in advance, and the patient who is well warned can usually take this in their stride, and be pleasantly surprised if the reaction is less troublesome than expected.

Late radiation reaction (chronic radiodermatitis) (Figs 79.17 & 79.18)

Tissues with a slow rate of cell division, such as subcutaneous fat, fibrous tissue and small blood vessels, will show radiation effects months or years after treatment, and this is the late reaction. At the 6-month review, the treated skin often looks slightly paler or pinker than the adjacent untreated skin; with the passage of time sequelae usually appear, with late appearances established at 5–10 years. The irradiated skin may show pallor or increased pigmentation, with lack of adnexae, and a degree of atrophy. Telangiectasiae are the main cosmetic nuisance. In time, the vascularity of the centre of the previous tumour-bearing area may show compromise and ulceration may develop, either spontaneously or after trauma; such ulcers often heal spontaneously [4].

The fundamental histopathology of chronic radiodermatitis is fibrosis of the vessels, with occlusion and varying degrees of homogenization of the connective tissue. Residual vessels may be enormously dilated. Bizarre, large, stellate fibroblasts may be seen in the dermal connective tissue in some cases. Fibrosis of the deep dermis and subcutaneous tissue may occasionally occur after megavoltage radiotherapy [5].

The changes in the epidermis vary from simple atrophy to acanthosis and extreme dyskeratosis. There is usually loss of adnexae such as hair follicles.

The late cosmetic result varies with the individual, and may reflect the underlying damage caused initially by the tumour, as well as the patient's skin type. In one study of 339 patients, occurrence of telangiectasiae, pigmentation and fibrosis were directly related to increasing size of field needed for treatment rather than the treatment regimen used [6]. The late cosmetic result is also less good if the patient has had multiple treatments with cryotherapy to the area beforehand (personal observation) or a biopsy which has left a scar. However, as radiotherapy is usually offered to the older population, often with sundamaged skin, and certainly not unblemished, patients are usually satisfied with the cosmetic result, even though imperfect, and even when warned of this in advance are quite prepared to go ahead with treatment.

Tissues which do not divide, such as neurones, may accumulate damage, but not express it; treatment will not cause numbness or pain, although persistent erosive tumour may do so.

Chronic radiation change may be confused with a recurrence of a malignant lesion. The effects of normal ageing and sun exposure may combine with the effects of ionizing radiation, and produce accelerated changes. This may also be seen when psoralens and UVA (PUVA) is used on irradiated skin.

Late radiation changes leading to ischaemic necrosis should rarely be seen when modern techniques of fractionation to a radical dose for skin malignancies are used. Radionecrosis

Fig. 79.17 (a) Extensive erosive BCC of the ear. (b) The same patient, 2 years after superficial X-ray treatment.

Fig. 79.18 Telangiectasiae after treatment for a small BCC of the nose.

typically occurs approximately 1 year following complete healing of the skin after radiotherapy, and is often precipitated by trauma or infection. Excision and grafting may provide the only satisfactory treatment of extensive radionecrosis, although small areas may slowly heal with conservative management [4].

Many thousands of patients have been treated with curative radiotherapy for BCC and SCC both in reported series and in busy radiotherapy departments. Second malignancy within the irradiated fields is very rare indeed, as would be expected from the high average age of the patient receiving radiotherapy for skin cancers.

Tumour recurrence after radiotherapy

BCC and SCC can reoccur after radiotherapy [1–3] and especially if the patient has undergone multiple treatment modalities [2]. Tumour healing has invariably occurred at 6 months, and persistent ulceration usually means persistent tumour. Some authors suggest that one reason for avoiding primary radiotherapy is that surgical salvage is more difficult after treatment failure, but if the patient is referred on at an early stage, excision of the irradiated skin and grafting is usually possible. Mohs surgery may give the best results in these cases but there can even be recurrence after

this meticulous form of treatment [2]. As with surgical treatment, radiotherapy for recurrent BCC has a higher relapse rate [4], and recurrence after radiotherapy may be related to a decreased HLA G expression [5].

Retreatment with radiation is not usually offered, because the primary is by definition relatively radioresistant and the normal tissues may have already received a 'tolerance dose', thus to repeat treatment might produce radionecrosis. However, in practice, radiotherapy has been given successfully in these circumstances with acceptable cosmetic results, especially if there has been sufficient time interval between the two radiotherapy treatments [6]. Occasionally, it is reasonable to offer treatment to persistent tumour at the edge of a previous radiotherapy field, when a small degree of overlap may be acceptable; although the risk of a small area of necrosis will be higher, this strategy is often acceptable to the patient, and successful.

Radiation-induced tumours

Both BCCs and SCCs can occur in areas of skin previously irradiated for other conditions, such as Hodgkin's disease or post-mastectomy, with some evidence that radiation-induced BCCs are more common [1], but this is very rarely seen in modern radiotherapy practice.

The type of tumour induced by radiation depends on both the cellular structure and the anatomical location of the damaged tissues. Basal cell epitheliomas occur following radiation to the face, scalp and trunk, whereas on the hands squamous cell tumours may occur. These are much more rarely seen since the development of more sophisticated radiotherapy machinery and a greater knowledge of radiobiology. It has not been possible to demonstrate any precise quantitative relationship between the development of cutaneous epitheliomas and the amount of radiation received on the skin surface, nor is it known what total dose or fractionation regimen would be most carcinogenic. It has long been known that carcinomas occur more profusely in areas subjected to many small doses administered at intervals over a long period. Multiple basal cell epitheliomas on the skin over the spine following radiotherapy to the lumbar spine for ankylosing spondylitis have been reported [2]. Some may show the histological appearances of the pre-malignant fibroepithelioma of Pinkus. Radiation-induced basal cell epitheliomas of the scalp may be seen 20–50 years following X-ray epilation for ringworm infection. Late radiation changes are not always visible on the scalps of these patients, and hair growth may be relatively normal.

The doses of radiation used to treat benign dermatological conditions should never produce late radiation damage of even mild type [3]. In general, radiation-induced cancers have occurred after inappropriate doses, often of many thousands of centiGray, given over a long period, frequently by lay therapists for conditions such as hirsutism or greasy skin and large pores [4], which are not indications for treatment by radiotherapy today. Shielding of structures especially sensitive to irradiation, for example the adolescent thyroid [5], was not routinely carried out. Although a greater knowledge of the limitations and effectiveness of radiation should prevent the occurrence of late radiation damage including carcinogenicity, the long latent period often demonstrated in those cases warns against early complacency [4,6].

As the numbers of childhood cancer survivors increase there is some evidence of an increased incidence of basal cell carcinoma developing within irradiated skin sites [7], but this is not confirmed by all studies [8]. As most of these children will also have had treatment with chemotherapy, the aetiological factors causing their second malignancy are not all known.

Treatment. Most radiation-induced tumours should be excised. However, where there is no radiation damage evident on the skin, a subsequent radical dose of radiotherapy can be tolerated, if planned carefully [9].

Rare tumours associated with previous irradiation

Atypical fibroxanthoma

Synonym
- Pseudosarcoma of the skin

This tumour, seen particularly in fair-skinned males who have suffered actinic damage, may also follow radiation damage [10–12]. It usually occurs on the face, but occasionally on the trunk or limbs. The clinical course is benign, despite the highly anaplastic histological appearance. Twenty-one tumours initially labelled as spindle-cell squamous carcinomas were found by Hudson and Winkelmann [10] to be atypical fibroxanthoma.

Fibrosarcoma

Sarcoma appears to arise in irradiated skin much less frequently than carcinoma, and many of the tumours are low grade, showing no tendency to produce distant metastases [13]. At least some of the reported sarcomas are in reality spindle-cell carcinomas [14]; this may be shown by the attachment of the tumour to the epidermis or by the presence of horny pearls. Radiation fibromatosis [15] is a diffuse proliferation in which bizarre and sometimes monstrous fibroblasts appear in the dermal connective tissue; the appearance can easily be mistaken for fibrosarcoma. Only exceptionally does fibromatosis undergo malignant change. It does appear that irradiation of an already chronically inflamed skin is more likely to be followed by a fibrosarcoma than irradiation of normal skin.

The fibrosarcomas, like the carcinomas following radiation, appear usually after repeated exposures to kilovoltage X-rays, and rarely from megavoltage radiation. The latent period in one series [16] averaged 26 years.

Introduction

Over the last century there has been a dramatic increase in the ageing population in most developed countries. For example, it is expected that one in five Americans will be aged 65 years or older by the year 2030 (source 2000 USA census), a trend similar to that in most developed countries. Increased social pressure to look younger has led to great demand for effective cosmetic treatments for skin and facial rejuvenation. In particular, there has been an increase in what have been termed non-invasive and minimally-invasive cosmetic treatments, that is treatments that avoid surgery and involve surface skin treatment such as lasers or peels, or a variety of injections [1].

Currently, most of those seeking these treatments are women, but an increasing number of men are considering rejuvenation treatments, and it is important for the practising dermatologist to be aware of the treatment options.

Types of skin ageing

Skin ageing has historically been divided into intrinsic ageing [2], which will occur in all skin, whether or not exposed to external ageing factors, and extrinsic ageing, which is accelerated skin ageing due to external influences such as smoking and sun exposure [3].

Intrinsic ageing

There are numerous factors that contribute to intrinsic ageing, including oxidative phosphorylation that generates destructive 'superoxides', which are thought to damage mitochondrial DNA and lead to progressive cell and tissue senescence [2]. Other factors that can prematurely age skin intrinsically are inflammatory skin diseases, for example inflammatory acne which can lead to dermal injury and subsequent scarring.

Collagen comprises up to 80% of the dry weight of ageing skin, and it is type 1 collagen, which comprises 70% of the total collagen content, whose larger diameter fibres provide the mechanical and stretch integrity of the skin. Type 3 collagen, which has narrow fibres, is also important. The quality and functionality of collagen substantially decreases with time [4].

The dermis is a connective tissue matrix of collagen housed in an elastin network. As part of the intrinsic ageing process there is a reduction of fibroblast activity in the dermis, and a decline in the ability of these cells to synthesize collagen and elastin contributes to loss of elasticity and wrinkles. In combination with the decline in collagen synthesis there is altered expression of matrix metalloproteinases (MMP), which mediate collagen breakdown. As a result, intrinsic ageing and dermal thinning occurs; dermal collagen, elastin and glycosaminoglycans are all altered during the ageing process [5].

Skin collagen fibres do not appear to shrink with age, but the balance of their intermolecular cross-links changes, with an increase in cross-linking resulting in a stiffening of the skin. Ageing is also associated with a decrease in proteoglycan content, resulting in a reduction of the tensile strength of the skin. The elastic fibres show a progressive change, and there is evidence that elastin gene expression declines with age [5].

Accompanying these changes is a reduction of skin microvasculature, a reduction in activity but not in numbers of sebaceous glands, and a reduction of subdermal fat leading to skin laxity and change of facial profile (Fig. 80.1).

Hyaluronic acid and other glycosaminoglycans decline during the intrinsic ageing process; a 50-year-old is estimated to have half the hyaluronic acid level of a youth. As an accompaniment to the dermal changes of intrinsic ageing, the epidermis becomes thinner, with a reduction in thickness of 10 to 50% between the ages of 30

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

Fig. 80.1 Signs of intrinsic ageing—the patient shows brow ptosis, loss of cheek volume and malar ptosis, hollowness in the lower face, atrophic lips and marionette lines.

and 80. Mitotic activity of keratinocytes is reduced, and the epidermal transit time is increased. The orderly maturation of the epidermis becomes irregular. The corneocytes become less adherent and this produces a clinical appearance of roughness and scale. There is a flattening of the dermal–epidermal interface by as much as 35%, with increased skin fragility [4].

Table 80.1 summarizes some of the changes of intrinsic ageing.

Extrinsic ageing

Extrinsic ageing, whose principal cause is ultraviolet radiation, results in changes in areas exposed to the environment such as the face, neck and dorsal hands. UVB (290–320 nm) penetrates to the lower epidermis, whereas UVA (320–400 nm) penetrates into the dermis and may be more responsible for some of the clinical changes associated with photoageing. Other factors that contribute to facial and skin ageing include repetitive facial expressions, leading to dynamic lines and rhytides. Gravity accelerates facial skin ageing, and this factor becomes more evident in the 30s when skin elasticity starts to decline [1].

Cigarette smoking also contributes to some of the characteristic changes of skin 'coarseness' and colour, or sallowness, which can be recognized in many who smoke 10 cigarettes or more daily for 10 years [6].

Signs of extrinsically aged skin include fine and coarse rhytides, macular and diffuse pigmentation, solar lentigines, increase in surface roughness, telangiectasiae, sallowness, loss of skin tone

Table 80.1 Some features of intrinsic skin ageing.

Component	Function	Change with age
Fibroblasts	Synthesis and degradation of extracellular matrix (ECM)	Decrease in number Decline in growth factor response
Collagen	ECM component Dermal support	Reduced synthesis of 'new' and decreased degradation of existing collagen
Elastin	ECM component Elasticity of skin	Reduced microfibril content Elastin fragmentation
Keratinocytes	UV protection—barrier and mechanical protection Cell signalling Melanin carrier	Less proliferation and differentiation Reduced barrier function
Melanocytes	Melanogenesis for UV radiation protection Endogenous free radical 'quencher'	Decline in melanocyte number and life span
Langerhans' cells	Antigen presentation	Reduction in number and morphological abnormalities

and solar keratoses, basal and squamous cell carcinomas, and melanoma—particularly superficial variants such as lentigo maligna.

Structural changes that occur during extrinsic ageing include deficiency of collagen types 1, 3 and 7, which include the anchoring fibres and fibrillin in the papillary dermis. Fibrillin is thought to be one of the key structural support components. There is usually a decline in connective tissue support for dermal blood vessels, leading to vascular dilatation and the clinical appearance of telangiectasia [6].

A primary cause of UVA skin damage is oxidative damage mediated by a variety of reactive oxygen species [7]. It has been estimated that 50% of UV-induced damage results from the generation of these reactive oxygen species. Unlike intrinsic skin ageing, where collagen production declines, collagen synthesis is increased during UV radiation. There is a decrease in pro-collagen, which is absent 24 hours after exposure to sunlight. Increased production of matrix metalloproteinases, such as collagenase and gelatinase, results in collagen and dermal extracellular matrix degradation. The total collagen content of chronically sun-damaged skin is reported to be 20% less than non-solar exposed skin.

Ultraviolet exposure also leads to changes in the structural organization and function of elastic tissues. Photodamage results in abnormally thickened, tangled and disintegrated elastic fibres, which form an amorphous mass [6].

It has been shown that small fluences of repetitive UVA radiation can produce abnormal pigment and vascular damage after 12 weeks of twice-weekly radiation [8]. UV radiation creates a favourable environment for angiogenesis and dermal blood vessel fragility. UVA radiation also damages DNA, cell membranes and proteins, leading to cell ageing and an increased risk of skin cancer.

The changes of facial ageing are summarized in Table 80.2 and shown in Figs 80.1 & 80.2.

Table 80.2 Some clinical effects of intrinsic and extrinsic facial ageing (see also Figs 80.1 and 80.2).

Greater visibility of bony landmarks
Increased rhytides
Hollowing of the cheek and perioral area
Deepening nasolabial folds
Descent of facial fat pads
Brow ptosis
Upper eyelid laxity
Infraorbital laxity and fat herniation
Atrophy of lips
Descent of the corners of the mouth
Ptosis of the nasal tip
Lower face and neck sagging and laxity
Surface photodamage—lentigo, telangiectasia, solar comedones, rhytides
Solar keratoses and skin cancers

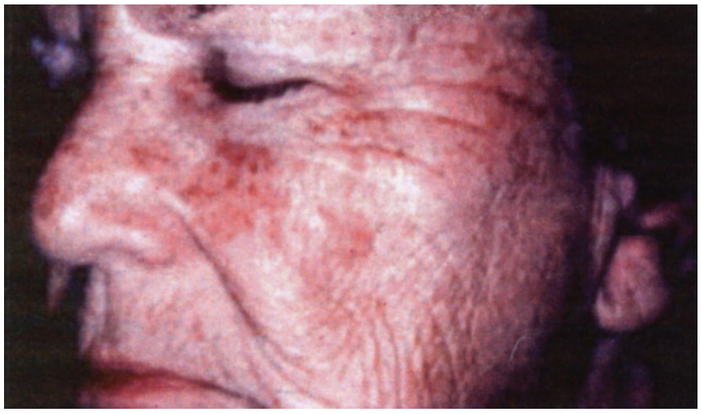

Fig. 80.2 Signs of extrinsic ageing—surface photodamage, loss of volume, lentigo, sagging, dynamic rhytid, atrophy of lips and solar elastosis.

Prevention of skin and facial ageing

Topical protection is the primary means of prevention of photodamage and should be a part of routine skin care. The first sunscreen was developed in 1928, and combined benzylsalicylate and benzylcinnamate [1]. Details of sunscreens and photoprotection are discussed in Chapter 29. In order to be effective a sunscreen must be both a UVB and UVA filter or reflector. The concept of sun protection factor (SPF) as an assay for protection is well established [2,3].

The methods of evaluating protection by sunscreens against UVA continue to be debated, but guidelines have been established in the UK using an *in vitro* UVA assay [4].

Topical treatments

Photoprotection and topical treatments should be a key part of any antiageing programme. Tretinoin has been shown to be effective for improvement of both photodamaged and intrinsically aged skin [5]. It is a non-selective retinoic acid that increases epidermal thickness, promotes dermal collagen production and reduces its degradation, and inhibits UV-induced matrix metalloproteinases [6]. Other retinoids shown to produce objective clinical and histological changes include retinal, retinaldehyde and retinyl esters [7]. An important part of any topical retinoid treatment protocol is to control retinoid-induced skin irritancy while maintaining retinoid-induced skin rejuvenation. Choice of frequency of treatment and adequate skin moisturization are key variables. A range of non-prescription topical products have been claimed to possess some activity against skin ageing changes. These agents have been called cosmeceuticals, as they are not regulated as medicines by the Food and Drug Administration (FDA) in the USA, or the Medicines and Healthcare Products Regulatory Agency (MHRA) in the UK. Accurate assessment of their efficacy is often difficult because of limited available data.

A recent study of the effects of retinol on intrinsically aged forearm skin has been presented as further evidence of the rejuvenation potential of topical retinoids for ageing skin, increased dermal matrix protein synthesis and glycosaminoglycan induction being noted in this study [8].

A variety of antioxidants have been incorporated in the formulation of some topical products. There is evidence that they are capable of reducing some photodamage, with a reduction of erythema and other markers of UV damage such as sunburn cell accumulation. Some topical vitamin C analogues have been shown to regulate collagen and tissue inhibitors of matrix metalloproteinase [9]. Other antioxidants employed include botanical agents, such as extracts of grape seed, pomegranate, green tea and raspberry [10]. It appears that polyphenol and isoflavone are also ingredients that may be effective for photoprotection. Coenzyme Q-10, which is a component of a mitochondrial electron transport chain acting as an antioxidant in the skin, has also been used as a protective antioxidant in cosmeceutical topical products [11].

A variety of synthetic plant derivatives such as *N*6-furfuryladenine, and ferulic acid have also been employed in some cosmetic preparations because of their *in vitro* cell protective properties [12]. Further research is required to confirm the degree of *in vivo* human activity of these agents in different formulations for photoprotection and repair of ageing skin.

Oestrogen

Oral oestrogen use in females is associated with a statistically significant decline in the risk of skin wrinkling, but interestingly

not in atrophy [13]. These clinical changes are due to an increase in skin collagen content. Topical progesterone is associated with increased skin elasticity in pre- and postmenopausal women, suggesting a possible value for improving some aspects of ageing skin in women [14].

Skin rejuvenation procedures

There are now many non-invasive or minimally invasive treatments for skin rejuvenation. The remainder of this chapter will discuss some of the more commonly accepted options (Table 80.3).

Table 80.3 Some treatment options for facial rejuvenation.

Objective	Treatment options
Superficial rejuvenation	Topical antiageing creams
	Superficial peels
	Microdermabrasion
	Intense pulsed light
Dermal remodelling	Non-ablative facial rejuvenation (lasers)
	Laser and fractional resurfacing
Muscle relaxation	Botulinum toxin type A injections
Soft tissue augmentation	Fillers
Volume replacement	
Deeper rejuvenation	Fractional resurfacing—carbon dioxide Fraxel
	Carbon dioxide lasers
	Medium peels
	Deep peels

Volume replacement by fillers

Volume replacement using a variety of dermal fillers is designed to address the subcutaneous atrophy and facial hollows that often accompany ageing. A number of soft-tissue fillers are now employed, ranging from non-biodegradable, which may be permanent, to more transient, biodegradable fillers [1]. It is important to know that these fillers have different risks of adverse events [2], which are related to the skill of the injector and the intrinsic properties of the filler [2–4].

Categories of dermal fillers

Fillers can be categorized according to their source:

- Autogeneic, e.g. fat, autologous plasma, autologous collagen
- Allogeneic, e.g. human cadaver tissue, human fibroblast cell culture
- Xenogeneic, e.g. collagen, usually derived from bovine or porcine sources; hyaluronic acid products derived from animal sources or the results of bacterial fermentation
- Synthetic products, e.g. silicone, polymethyl methacrylate, hydroxyapatite, carboxy cellulose, poly-L-lactic acid, polyacrylamide.

Specific dermal fillers

Xenogeneic bovine collagen has been used for over 20 years, and results can last from 3 to 12 months, depending on the choice of bovine collagen [5]. The duration depends on the site and type of injection selected. Because of a risk of delayed cutaneous allergic reactions with bovine collagen it is advised that double skin testing is carried out, as it has been estimated that approximately 3% of injected patients will develop delayed nodular reactions [2,6], including necrotic reactions [7].

Products developed over the last 10 years include a variety of hyaluronic acid derivatives. In some parts of the world there is little regulatory requirement for testing of these new fillers before they are used on patients. The original hyaluronic acid filler was derived from rooster combs [7], but this has now been largely superseded by materials produced by bacterial fermentation and stabilization using proprietary processes [8].

The duration of benefits from hyaluronic acids fillers for correction of nasolabial folds is usually between 6 and 12 months, but it is less when used for lip augmentation [9] (Figs 80.3 & 80.4). The duration of benefit in an individual will depend on several factors, including formulation of the hyaluronic acid filler, depth of injection and laxity of skin injected.

Side effects include immediate oedema, haematoma, delayed allergic reactions, nodules, vascular occlusion and infections, including, rarely, atypical mycobacteria [2,3].

There are still occasional delayed reactions to these fillers, leading to inflammatory nodule formation, although their frequency has declined significantly over the past 5 years [2,10]. Other volume replacements that give immediate filling include calcium hydroxyapatite, which is useful as deep injections for

Fig. 80.3 Lip augmentation: before (a) and (b) after 1 cc of hyaluronic acid filler.

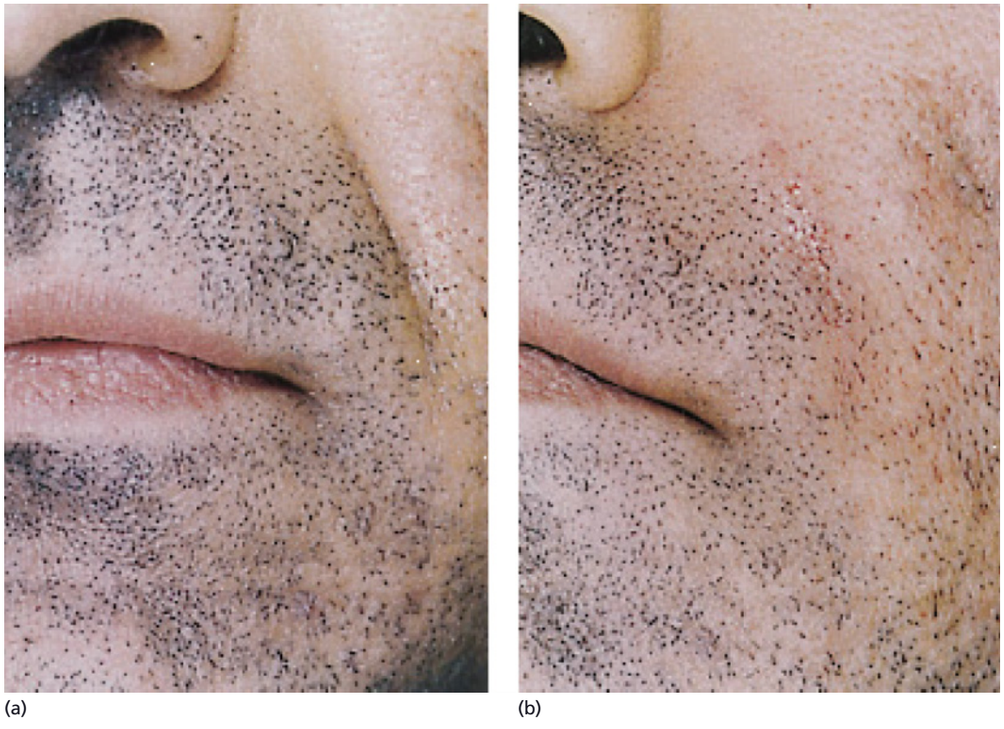

Fig. 80.4 Before (a) and (b) following 0.75 cc of hyaluronic acid filler to the nasolabial folds.

volume replacement of cheeks and deep nasolabial folds [11]. Another group of injectables that increase the collagen matrix, ground substance and dermal elastic formation by stimulating dermal fibroblast activity include poly-L-lactic acid (PLLA). This is injected as a dilute suspension which dissolves within the dermis and subcutaneous levels, inducing fibroplasia and increasing dermal and subcutaneous thickness. Originally, PLLA was used to improve the facial lipodystrophy often associated with earlier types of antiretroviral therapy [12]. It was subsequently shown to be effective for correcting facial volume loss in the ageing face and for atrophic scars. The main side effect is nodule formation, most commonly in perioral and periorbital areas, and these are therefore areas which should be avoided with PLLA [12]. It is most useful for nasolabial folds and mid-cheek sites [13]. PLLA has also been used for atrophic scar improvement [14].

Another recent approach has been to use allogeneic human-derived fibroblasts from a single source of neonatal tissue; this procedure is in the early stages of research and development [15]. Safety phase studies have shown increased dermal and epidermal thickness, and no toxicity. Further studies are proceeding.

An autologous filler that has been used for many years is fat, harvested from the patient and processed with filtration plus cleansing, or simply reinjected. A debate as to the efficacy of these different methods of fat replacement injections continues. One problem is variable duration of benefit, and it has been suggested that this is site specific, with the cheek area having the best retention of injectable fat [16]. Post-injection oedema and bruising is temporary but can last several weeks [16]. One study suggested that fresh autologous fat transfer has good viability compared with refrigerated or frozen fat storage and later injection [17].

Table 80.4 Adverse reactions to dermal fillers.

Early adverse events (occurring up to several days post-treatment)	Delayed adverse events (occurring from weeks to years post-treatment)
Injection site reactions:	Infection (e.g. atypical mycobacterial):
erythema	erythema
oedema	oedema
pain/tenderness	pain/tenderness
bruising	nodules
pruritus	systemic responses to infection
Infection:	Granulomatous inflammation:
erythema	varying from subclinical histological changes to disfiguring nodules
oedema	Migration of filler
pain/tenderness	Hypersensitivity:
pustules	aseptic abscess
nodules	Persistent hyperpigmentation
abscesses	Persistent scarring
Hypersensitivity:	
erythema	
oedema	
pain/tenderness	
Lumps caused by maldistribution	
Discoloration:	
erythema	
hypochromia	
hyperpigmentation	
Local tissue necrosis caused by vascular occlusion	

Fat is best used for deeper volume replacement of the face or localized areas of fat atrophy [16].

Adverse reactions (Table 80.4)

Adverse reactions to fillers can be described in terms of:

- Clinical seriousness
- Aesthetic relevance
- Immediate versus delayed onset
- Causality: expected procedure related events; events related to improper technique; reactions to the product.

Reactions can be attributed to the procedure itself, procedural technique and the agent injected. Some of these reactions are preventable, whereas others are inevitable; most are mild and transient. Improving product formulations, altering the concentration of product injected or changing injection technique can dramatically reduce the incidence of adverse reactions. Since its reformulation in mid-1999, the biologically engineered hyaluronic acid filler, Restylane, elicits less than one allergic reaction in 1600 treatments. There are over 85 different hyaluronic acid fillers currently available in Europe. Skin reactions with PLLA (New Fill/Sculptra) are considerably less likely if a greater dilution and deeper injection technique are employed.

Botulinum toxins—their use in controlling facial lines

The first medical use of botulinum neurotoxin was described by Dr Alan Scott during the 1970s when he used a botulinum toxin type A (BTX-A) for reducing over-activity of selected periocular muscles in patients with strabismus [1–3]. Following this observation botulinum neurotoxins have been increasingly studied for a wide variety of therapeutic and aesthetic uses. Double-blind controlled studies of BTX-A for reduction of upper facial lines in the USA have shown benefit of approximately 4 months' duration [4,5]. These initial observations were followed by double-blind, placebo-controlled studies of several hundred patients performed in the USA, which demonstrated that BTX-A was safe and effective for reducing the severity of glabellar lines (lower forehead vertical frown lines) [6,7]. Significant improvement was observed as early as a few days after treatment, and the mean duration of improvement was in excess of 4 months using appropriate doses of BTX-A, which were initially 20 units for lower forehead frown lines. Several other studies confirm that BTX-A is also effective for lateral periorbital lines, often known as 'crow's feet' [8] and also rhytides of the infraorbital area [9].

There are two main serotypes of botulinum toxins used clinically—the most commonly used being botulinum toxin type A (BTX-A) (Table 80.5). Type B botulinum toxin (BTX-B) has a much shorter duration of effect than BTX-A, but is occasionally used if therapeutic resistance is observed to BTX-A.

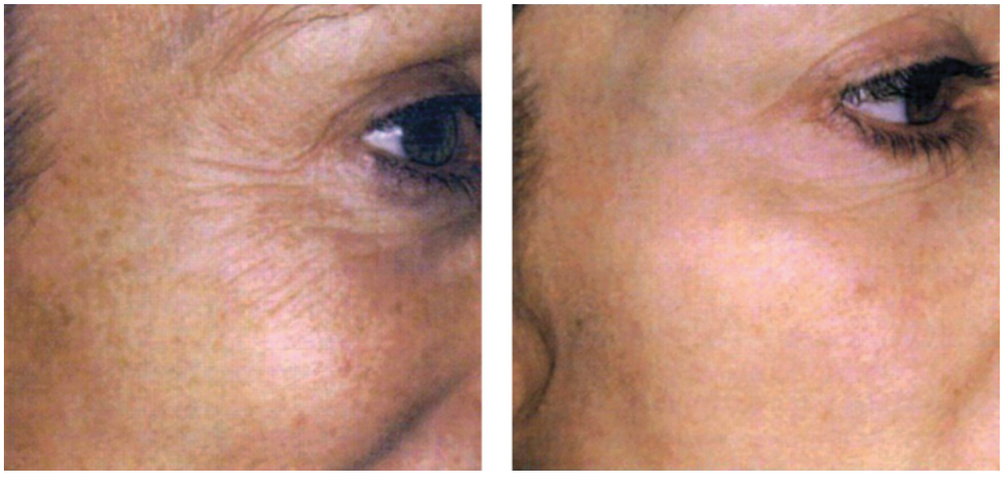
Other clinical studies have confirmed that both type A and type B botulinum toxins are effective at reducing facial lines [10], as well as excessive sweating in areas such as the axillae [11,12]. BTX-A treatment for axillary hyperhidrosis has been approved by the MHRA in the UK, and regulatory agencies in numerous other countries including the FDA in the USA.

The mode of action of BTX-A is by rapid inhibition of acetylcholine release at the neuromuscular junction. As a result, BTX-A causes localized, reversible muscle relaxation [1], and because some facial lines result from repetitive contraction of underlying muscles this produces a reduction of facial lines [4,5,7,8]. The mode of action against hyperhidrosis (which is covered in more detail in Chapter 44) is again the result of inhibition of release of acetylcholine, which is one of the neurotransmitters for emotional, non-thermoregulatory sweating [11,12].

The sites of injection used to improve facial lines, and therefore some signs of facial ageing, are most commonly: upper face—horizontal forehead lines, vertical forehead lines, supraorbital lines, periorbital (crow's feet) lines, infraorbital lines, paranasal lines; lower face—perioral lines, vertical rhytides above the upper lip and turning down of the angles of the mouth (melomental folds) [13]. Vertical neck bands produced by platysmal muscle activity can also be reduced by the use of BTX-A [14].

Two different commercial types of BTX-A have been available in Europe since the 1990s. They are produced by different bacteria, with differing fermentation and purification processes, and have different potency and diffusion. Dilution and dosing have been investigated, and estimated conversion ratios of one type of BTX-A to the other have been proposed [15,16].

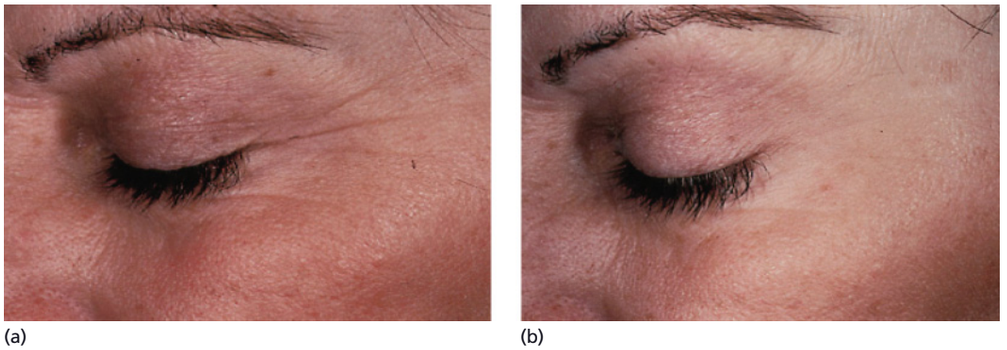
Side effects from BTX-A are local at doses used for aesthetic indications, for example bruising and brow and/or eyelid ptosis. They are usually the result of inexpert injection of BTX-A—for example, injection of too high a dose of BTX-A into the lower lateral forehead may result in both brow and upper eyelid ptosis. Injection too low in the infraorbital area may result in upper lip and lower facial weakness. Facial asymmetry may occur. These side effects are usually temporary, but can be of understandable concern to patients [17]. The physician injecting BTX-A should be trained to try to avoid these problems.



Other side effects are extremely uncommon. A rare problem is that of resistance to BTX-A, the mechanism of which is unknown, but may involve antibodies blocking the uptake or action of BTX-A.

Combination treatments with BTX-A

Combination treatments are selected for appropriate patients to rejuvenate the ageing face [17]. An example of a combination treatment is administration of BTX-A prior to use of either resurfacing lasers [18] (Fig. 80.5) or fractionated rejuvenation lasers (p. 80.11). The BTX-A is ideally delivered at least 1 week prior to the laser; this enables the hyperactive muscle action to be diminished thereby reducing the facial lines. In addition, as one theory of skin rejuvenation with these laser systems is the stimulation of neocollagenesis, it is likely that a less folded skin following BTX-A leads to more uniform neocollagenesis.



The effects of combined BTX-A injections and lasers have been confirmed as being superior to placebo injections and laser alone [18].

Another situation where combination treatments are useful is the use of BTX-A and dermal fillers in problems such as deep vertical lower forehead lines. Here, BTX-A alone will improve, but not clear, the deep furrows that are present in some patients. The

use of BTX-A plus temporary filler can give a more prolonged effect than using the filler alone [19]. In a similar mechanism, the use of BTX-A to the upper lip area together with filler in the upper lip can provide adjunctive benefit in the correction of upper lip lines. Dermal fillers and BTX-A can also be combined in lower facial areas, where the BTX-A is injected into areas such as depressor angulae oris and mentalis muscles and the filler is injected into melomental folds.

Figure 80.6 shows the effect of BTX-A injected in the periorbital area, thereby reducing the intensity of the periorbital rhytides.

Chemical peels for improvement of facial ageing

Chemical peels have been used for many years for skin surface rejuvenation, and treating irregular pigmentation and superficial scars [1].

A limiting factor is the depth of penetration of the different chemicals used for skin peeling. Another important factor is the toxicity of the chemical, for example phenol or 50% trichloroacetic acid are considerably more toxic to the skin than 50% buffered glycolic acid peels [2,3]. Even in expert hands there are some patients who will have undesirable results from chemical peels. These may include changes in pigmentation, for example hypopigmentation, which can be permanent, and hyperpigmentation, which can be long-lasting, and may be permanent and scarring.

More superficial peels, for example glycolic acid, lactic acid [3] and Jessner's peels, will accelerate epidermal shedding, but other more aggressive peels can chemically destroy epidermis and progressive layers of the dermis by protein coagulation and cell lysis. The main classification of peels is usually based on the expected depth and severity of the peel—a commonly used classification being superficial peels, medium-depth peels and deep peels [2–4]. Examples of the peeling agents leading to different severities of peel are listed in Table 80.6.

The nature of the chemical influences the depth of peel; for example, lactic acid is usually a very superficial peeling agent and 50% trichloroacetic acid (TCA) is a much deeper peeling agent [2,3]. Another factor that affects the peel is skin preparation with topical retinoids, which is felt to increase the uniformity of the peel. It alters the stratum corneum barrier, and enhances the penetration of some peeling agents by altering epidermal and stratum corneum morphology. It is possible to change a superficial-depth glycolic acid peel into a medium-depth peel by altering the percutaneous penetration characteristics of the skin with agents such as tretinoin and other peeling agents applied prior to the final peel [5,6].

Superficial peels include a combination of resorcinol, lactic acid and salicylic acid, known as Jessner's peel. This is useful for abnormal superficial pigment, fine rhytides and very superficial scars. It can be reapplied numerous times over the treatment session [7].

Every practitioner using peels in their practice should become trained and familiar with the particular peel they will be using.

Site dependence

The density of appendigeal structures, such as pilosebaceous glands, will also govern the safety and healing of the skin following deeper chemical peels. An area such as the face, which has a much higher density of pilosebaceous structures, generally responds in a more predictable way to chemical peels than the neck, chest and limbs. Superficial peels should only be used in areas where there are minimal sebaceous appendages, that is most areas other than the face. Medium-depth peels can be used on the face, but care should be exercised in using them on other parts of the body. Because of the relatively low density of skin appendigeal structures, impaired healing can occur in these non-facial areas, resulting in an increased risk of scarring and pigmentary changes.

Skin phototype and chemical peels

Skin phototype (Table 80.7) is of key importance in chemical peel selection. Because of the risks of facial pigmentation disorders following the peels it is important that skin phototypes III and above are treated with peels that are not likely to result in hypopigmentation [7]. Patients with skin phototype III and above will always have some hyperpigmentation following peels. This is usually transient, but often requires pre- and post-treatment therapy with tretinoin 0.25% or 0.5% creams for 6 weeks prior to the peel, often together with skin lightening preparations such as hydroquinone. Post-peel treatment with these agents is usually begun after complete re-epithelialization and stabilized erythema, several weeks after the peel. This post-peel treatment may reduce the degree of hyperpigmentation [4] (Fig. 80.7).

The superficial chemical peels remain valuable for treating milder skin ageing problems and as adjunctive treatments in diseases such as acne. The medium-depth and deeper chemical peels have now largely been replaced by laser skin rejuvenation, as described below in this chapter. There is some agreement that lasers lead to a more controlled impact on the skin and are not dependent on the vagaries of chemical peeling, for example variations of percutaneous penetration and toxicity that can lead to variable results. These problems are much less with modern lasers such as fractionated lasers (Lowe, N.J. personal observations).

Table 80.6 Different depths of chemical peels.

Level	Histology	Peel
Superficial	Destruction of epidermis alone	10–25% TCA Glycolic acid 50–70% Jessner's solution
Medium	Destruction of epidermis plus papillary dermis	TCA 35% Jessner's solution Glycolic acid + 35% TCA
Deep	Destruction of reticular dermis	Baker's phenol/TCA 50%

TCA, trichloroacetic acid.

Table 80.7 Fitzpatrick's classification of skin phototypes.

Skin type	Colour	Reaction to sun
I	Very white or freckled	Always burns
II	White	Usually burns
III	White to olive	Sometimes burns
IV	Brown	Rarely burns
V	Dark brown	Very rarely burns
VI	Black	Never burns

Intense pulsed light and laser treatment—selection for cosmetic indications

Selection of intense pulsed light (IPL) and lasers will depend on the nature of the clinical lesion to be treated. Table 80.8 summarizes some of the more frequent clinical lesions to be treated and the selection of the type of laser and light source to be used. The reader is also referred to Chapter 78 for further information on lasers and light sources.

Intense pulsed light system

Intense pulsed light (IPL) sources give a non-coherent emission rather than the coherent specific single wavelength of a laser [1]. Most IPL systems emit a spectrum between 500 and 1200 nm, with a variety of cut-off filters designed to reduce selectively lower visible wavelengths, for example below 515 nm or below 560 nm. This lower wavelength selectivity allows for selection of different treatment indications. For vascular problems, for example telangiectasia and haemangiomas [1], wavelengths down to 500 nm are used, whereas skin pigmentary problems such as lentigo will best respond to wavelengths down to 560 nm. Poikiloderma of Civatte has also been treated with IPL. Care has to be taken to obtain a uniform improvement [2].

Table 80.8 IPL and laser treatment of clinical problems.

Clinical problem	Type of laser
Vascular lesions	Pulsed-dye usually 585–595 nm
Telangiectasia	Copper bromide
Haemangiomas/port-wine stains	KTP
Cambell de Morgan angiomas	IPL
Benign pigmented lesions	Q-switched, ruby, alexandrite, neodynium:YAG,
Lentigo, melanosis, melasma	IPL
Tattoos	Q-switched
	Ruby, alexandrite
	Neodynium:YAG
Ageing skin, rhytides, laxity	Carbon dioxide lasers
Seborrhoeic keratoses	Erbium YAG lasers
	Fractional lasers
Hirsutes (pigmented hair)	Long pulsed ruby, alexandrite, neodynium:YAG, IPL

Skin surface cooling for cosmetic IPL and laser procedures

Surface skin cooling has provided significant safety advantages for some laser and IPL systems. The concept is that by cooling the skin surface it is possible to reduce undesirable thermal injury to the epidermis by the IPL or laser, thus diminishing the risk of hypopigmentation and scarring (see Chapter 78).

There are three main types of tissue cooling:

1 Cold air convection, which is directed on to the area prior to and during treatment
2 Contact cooling, where the laser or light tip itself is cooled and thereby cools the skin surface
3 Cryogen spray cooling, where a frozen gas is sprayed on to the skin just prior to, and with some lasers during, the delivery of the laser light [3].

Another benefit of the use of cooling is that higher laser and IPL fluences can be used, enabling otherwise more resistant lesions, for example high blood-flow telangiectasia or vascular haemangiomas, to respond. Cooling also has another important effect of reducing the discomfort associated with treatment. It is important, however, to avoid cold injury from the cooling device. Cryogen freeze injury has been seen (Lowe, N.J. personal observations), particularly in skin phototypes III and darker from cryogen-cooled hair removal lasers.

Lasers for skin ageing problems

These may be grouped into treatment of vascular, pigmented or skin surface irregularities, that is superficial rhytides, and deeper problems of skin laxity, deeper rhytides and scars.

Vascular changes associated with skin ageing

Telangiectasiae on the cheeks, nose and other light-exposed areas are vascular abnormalities commonly associated with skin ageing. In addition, poikiloderma of Civatte, particularly affecting the lateral face and neck, is a superficial abnormality that is probably the result of repetitive ultraviolet injury together with, in some patients, phototoxic or photoallergic reactions to fragrances.

Choice of lasers for these vascular problems includes vascular pulsed dye lasers (usually between 585 and 595 nm), alexandrite (755 nm), Nd:YAG lasers (1064 nm), copper bromide lasers and potassium titanyl phosphate (KTP) lasers. The initial development of these lasers resulted from knowledge of the action spectrum responsible for laser vascular injury [4].

Electrocautery is sometimes used for solitary telangiectasia. One of the problems with electrocautery is a higher risk of recurrence of the lesion and/or atrophic scarring compared with pulsed-dye lasers. However, electrocautery does not give the transient purpura associated with pulsed-dye lasers.

Intense pulsed light (IPL) sources with selective wavelength cut-offs down to 500 nm and 550 nm are also used with benefit in these vascular conditions [1,2].

An important guideline when treating a large area with any of these laser or light systems is to perform a test treatment on a small, preferably non-visible part of the skin, to ensure the correct choice of laser and laser parameters. This is particularly important before treating large areas of skin, for example poikiloderma on the neck or extensive telangiectasiae on the cheek. It is possible to get irregular 'patchy' improvement that requires numerous further treatment sessions to become more uniform and acceptable.

Some darker skin phototypes, for example phototype III and darker, may elicit long-term and occasionally permanent hyperpigmentation following light and laser therapy. If too aggressive an IPL or laser treatment is selected, skin blistering with subsequent scarring and hypopigmentation is possible [5].

Benign pigmented skin lesions associated with ageing

The most common type of benign pigmented skin lesion associated with photoageing is the solar lentigo. These usually respond well to a variety of lasers and pulsed light sources. The original observations on laser treatment by Goldman used a ruby laser for tattoos and pigmented lesions [6].

Naevus of Ota persists into old age and responds well to a variety of Q-switched pigment lasers [7].

Melasma shows an extremely variable response to all lights and laser treatments—indeed to most treatment intervention [7]. The reasons remain to be determined, but possibly involve continued endogenous or exogenous hormonal stimulation of melanogenesis [8].

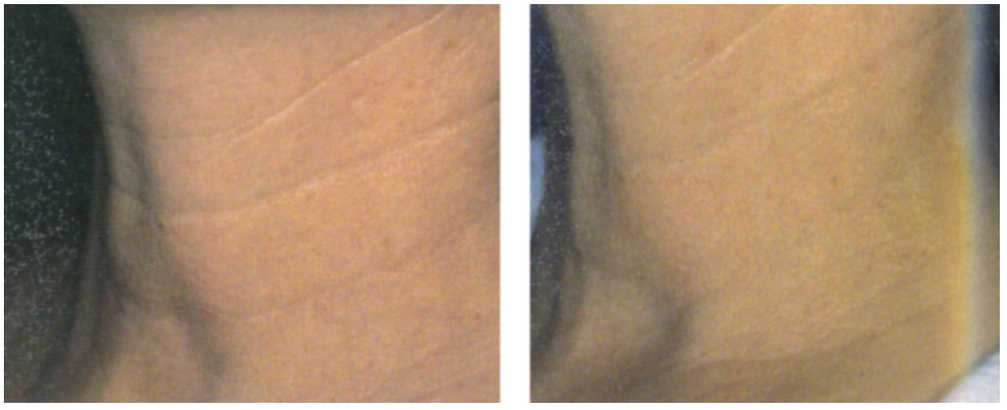
Lasers for benign pigmented lesions include Q-switched ruby (605 nm), alexandrite (755 nm), Nd:YAG (532 and 1064 nm) and Q-switched KTP (532 nm) [7–9].

Frequently, patients with photodamage will exhibit a combination of facial telangiectasia, plus lentigo and diffuse facial melanosis which can be treated with IPL sources. One advantage of an IPL system is that because of its broad spectrum of visible wavelengths both these types of photodamage may respond to the IPL [5,10].

Pigmented and non-pigmented seborrhoeic keratoses will respond well to laser ablation with either carbon dioxide or Er:YAG lasers. These can give a more accurate lesion vaporization than cryotherapy, and in some patients may be less likely to result in hypopigmented areas.

Lasers for surface skin changes

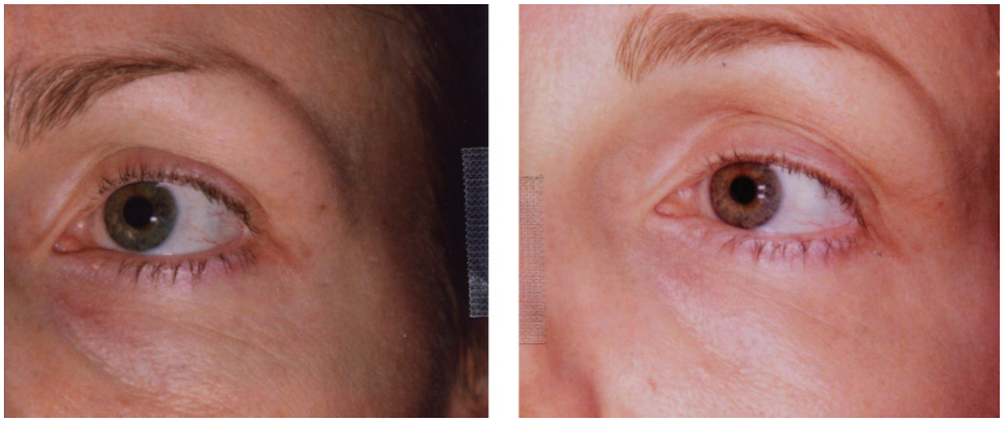
The first laser to be used successfully for photodamage treatment by 'skin resurfacing' was a pulsed carbon dioxide laser [11]. The carbon dioxide laser emits a wavelength of 10 600 nm and is absorbed by tissue water content. It penetrates up to 30 μm into previously non-treated skin; once absorbed, further penetration is limited by the reduced tissue water content.



Various other types of carbon dioxide laser have been developed, including scanned devices. The concept of ultrapulsing [12,13] is to give a uniform treatment area from the laser that produces skin surface vaporization but rapid re-epithelialization from undamaged hair follicles and other adnexal structures. There is a rejuvenation of the damaged skin surface. In addition, it has been shown that with ultrapulse carbon dioxide lasers there is a degree of dermal tightening which may continue for up to 1 year after treatment [14]. This tissue tightening may be the result of either a delayed wound healing response following the laser or neocollagenesis resulting from release of cytokines and other dermal growth factor stimuli [15–17]. Other carbon dioxide devices have used scanning systems rather than ultrapulsed systems to control skin injury [18].

Another skin resurfacing laser, which has greater affinity for water absorption compared with the carbon dioxide device, is the Er:YAG laser, emitting a wavelength of 2940 nm [19,20]. It is highly absorbed by skin water, but has a relatively low penetrance of 3 to 5 μm. Ultrapulse carbon dioxide lasers are more effective than conventional Er:YAG lasers [21]. In addition, because they do not produce as much haemostasis as the carbon dioxide laser there tends to be a greater degree of bleeding during treatment [21].

Some newer Er:YAG lasers have variable pulse duration so that they act in a manner similar to the carbon dioxide laser (Lowe, N.J. unpublished observations).



Fractional laser skin rejuvenation

Newer developments in skin rejuvenation by lasers have been the use of the fractional laser delivery systems [22]. Fractional

(a) (b)

Fig. 80.8 (a) Pre-treatment, showing mild ageing neck changes with horizontal lines and skin folding; (b) after three fractional laser treatments.

(a) (b)

Fig. 80.9 Periorbital ageing and skin laxity (a) before and (b) after five Fraxel laser treatments.

photothermolysis (FP) is a relatively new technology that creates microscopic zones or columns of thermal damage surrounded by healthy tissue, in contrast with layers of thermal vaporization from the ultrapulse carbon dioxide and Erbium:YAG lasers. The first FP laser device was introduced in 2003, as an erbium-doped fibre laser emitting at 1550 nm [22,23].

The microscopic thermal treatment zones vary in depth depending on the energy settings of the laser. As they are surrounded by an area of untreated skin this acts as a reservoir of keratinocytes for rapid repair of the treated areas of skin. Success has been reported with facial rhytides, photodamaged skin and scarring [23–25].

Initially, this system used a surface-applied blue dye to act as an optical activator of the laser [23]. The latest Fraxel laser system employs a motion detector whereby the laser is triggered by motion across the skin. This can be described as a 'rolling' FP laser system. The efficacy of FP with the 1550 nm laser, mentioned above, has been reported in a number of studies [23–25]. Results are encouraging for the improvement of surface photodamage, solar lentigo, diffuse facial melanosis, fine rhytides and atrophic facial scars (Figs 80.8–80.10). Another advantage of this laser is that it can be used (at appropriate settings) on areas other than the face, for example the neck, chest and limbs (Fig. 80.11). This is because with fractionated laser delivery, there are remaining areas of non-treated skin which lead to rapid re-epithelialization and reduced scar risk [22]. With previous lasers, for example ultrapulse carbon dioxide and Erbium:YAG, there was complete epidermal and dermal photothermolysis and a significant risk in non-facial areas of compromised, delayed healing with scarring risk due to the relative paucity of adnexal structures. A very recent development is a fractionated delivery carbon dioxide laser.

A variety of other 'pseudo-fractionated' and 'stamp' fractionated systems have been developed including systems using several wavelengths between 532 and 10 600 nm. These all have their own proponents, but as yet there is a lack of data to enable comparison with the rolling FP system.

Skin preparation and post-treatment care for laser rejuvenation

Pre-treatment preparation and post-treatment care of the skin are important, particularly in the management of pigmented and photodamaged skin. Pre-treatment with topical retinoids and, where pigmentation is a problem, additional depigmenting agents such as hydroquinone or combinations thereof, may help to enhance healing and reduce post-laser hyperpigmentation [14]. In addition, it is important to enquire about the occurrence of herpes simplex on the area to be treated, and prophylactic oral aciclovir 400 mg b.d. 1 day prior to and 7 days following laser treatment may be employed [26]. Post-laser care involves the use of topical emollients, as well as treatment of any possible post-laser acne relapses and folliculitis.

(a) (b)

Fig. 80.10 Forehead melasma, (a) before and (b) after four Fraxel laser treatments.

After initial healing—usually 1–2 weeks—the patient should be encouraged to use daily photoprotection with a sunscreen, topical antioxidants and, if necessary, depigmenting agents. Maintenance treatment can include topical retinoids, for example tretinoin 0.025% cream may be used nightly as tolerated.

Non-laser skin surface rejuvenation

A recent development is a 'plasma' skin rejuvenation system, using high surface energy generated with nitrogen gas released at high velocity. This 'plasma' system is currently being evaluated as an alternative to laser skin rejuvenation [27].

Radiofrequency

Radiofrequency has been developed as a treatment to promote skin and facial tightening. The results to date are mixed. Appropriate patient selection is critical, with early facial laxity subjects more likely to respond than older patients.

Monopolar radiofrequency skin tightening was first approved by the US FDA in 2002 as a facial treatment. More recently, it has gained approval for treatment of selected body areas [1,2]. The concept is that a controlled radiofrequency pulse selectively heats

(a) (b)

Fig. 80.11 Before (a) and after (b) combining Botulinum toxin A (upper face), deep volume filler (upper cheeks), hyaluronic acid filler (lips) and Fraxel CO_2 repair laser (whole face).

zones of the dermis and deeper tissue, while a proprietary cooling surface system protects against injury to the epidermis and upper dermis.

Initial investigations showed some degree of improvement in selected patients, but in general the first treatment algorithms were unpredictable. Subsequently, this monopolar radiofrequency system has become more consistent and the algorithm is now to use multiple passes over the same area, with moderate energy settings, to give greater consistency.

A recent retrospective study showed that 54% of patients observed skin tightening 6 months after treatment, and 26% showed an immediate tightening. This was with the original treatment algorithm. However, with the multiple pass moderate energy treatment algorithm 87% were reported as observing immediate tightening and 92% noted skin tightening 6 months after treatment [2].

In the author's opinion one of the most important factors in the use of monopolar radiofrequency is patient selection. Patients who are candidates for facelift surgery are clearly not candidates for radiofrequency facial skin tightening. Conversely, patients who have early laxity of forehead, as well as lower facial and neck skin, may be improved using these treatments.

Other forms of radiofrequency treatment include bipolar radiofrequency, which is sometimes combined in some instruments with intense pulsed light. One of the problems with these other systems is that there has been little consistent research.

Combination minimally invasive treatment

The idea of combining several different non- or minimally invasive treatments is a relatively recent concept for facial rejuvenation. See Figure 80.11 for an example of a combination of minimally invasive treatments. Examples of such combinations include:

1 Topical agents, e.g. sunscreens, tretinoin cream, glycolic acid peels and BTX-A
2 BTX-A to forehead and crow's feet; filler to mid and lower face; Fraxel laser to face and neck
3 Fraxel laser to neck plus BTX-A to platysmal band.

These combinations are selected for appropriate indications and patterns of ageing [3,4].

  in animals 2.16
  antimalarials in 74.25
  assessment 72.10
  cell factor, deoxyribonucleoprotein 51.52
  cell phenomenon 51.52
  cell test 51.52
  cold-induced injury 28.65
  cutaneous 74.19
  cutaneous atrophy 45.6
  differential diagnosis 29.12, 61.10
  discoid *see* discoid lupus erythematosus (DLE)
  drug-induced 29.21
  drug-induced syndrome resembling 75.20, 75.41–2
  ear involvement 68.14–15, 68.17
  erythema multiforme-like syndrome and 51.14
  exfoliative cutaneous, in dogs 2.16
  gyratus repens 51.11
  hypomelanosis in 58.52
  idiopathic thrombocytopenic purpura and 49.9
  immunopathology 10.18
  keratoderma produced by 19.117, 19.118
  leg ulceration and 47.55
  localization to tattoos 58.58
  matrix metalloproteinases (MMPs) and 12.52
  methotrexate in 74.19
  neonatal **17.16–18,** 51.49–51, 62.78, 62.109
    telangiectases in 47.14
  neutrophilic dermatoses and 50.63
  pigmentation changes 58.27
  post-inflammatory hypermelanosis after 58.31
  subacute cutaneous 51.22–7
  subcutaneous nodules 51.14–15
  systemic *see* systemic lupus erythematosus (SLE)
  treatment
    antimalarials 74.25
    methotrexate 74.19
lupus erythematosus gyratum repens 62.39
lupus erythematosus profundus 46.25–7, 51.14–16
  associated features 51.16
  breast involvement 46.25–6, 70.12
  clinical features 51.15
  histopathology 51.15
  hypertrophicus et profundus 51.14–15
  telangiectases 51.16
  treatment 51.15–16
lupus-like reaction, minocycline-induced 42.51
lupus mastitis 46.25–6, 70.12
lupus miliaris disseminatus faciei *see* acne agminata
lupus nephritis 51.35
lupus panniculitis *see* lupus erythematosus profundus
lupus pernio 61.1, 61.7, 61.9–10, *61.11*
  rosacea vs 43.5
  treatment 61.21
lupus vulgaris 31.10, **31.16–19**
  clinical features 31.16–17
  complications 31.17–18, *31.19*
  cutaneous atrophy 45.6
  definition 31.16
  diagnosis 31.18–19
  differential diagnosis 61.5, 61.13
  ear involvement 68.17, 68.20
  following BCG vaccination 31.29
  histopathology 31.9–10, 31.16
  incidence 31.16
  miliary 31.17
  papular and nodular forms 31.17
  pathogenesis 31.16
  plaque form 31.16, *31.17*
  prognosis 31.17–18
  treatment 31.19, 31.28
  tumour-like forms 31.17, *31.18*
  ulcerative and mutilating forms 31.16, *31.18*
  vegetating form 31.16–17, *31.18*
luteinizing hormone (LH) 8.4
  in adolescence 8.4
  LH:FSH ratio, acne aetiology and 42.22
  menopausal flushing and 8.20
  in menstrual cycle 8.8
  in polycystic ovary syndrome 66.82
lutidine test 27.8
Lutzomyia 37.33, 38.5
Lycopodium serratum 75.160
Lycosa 38.30
Lycosidae 38.32
Lyctocoris campestris 38.25
Lyell's syndrome *see* toxic epidermal necrolysis (TEN)
Lyme disease **30.64–6,** *69.118*
  arthralgia in 62.105
  erythema migrans 62.106–7
  late-phase 30.65, 45.9–11, 45.18
  ocular involvement 67.27
  race and 9.18
  syphilis serological cross-reactivity 34.21
  vectors 38.35
lymecycline
  in acne vulgaris 42.46, 42.47, 42.48
  in rosacea 43.6
lymph 13.8–9
  drainage 48.3
  drainage failure 48.7, 48.8
    causes *48.8*

activation 4.8, 13.10–11, 17.50, *24.13*
Langerhans' cell role 3.17, *3.18*
adverse drug reactions and 75.18–19
ageing effect 8.24
in allergic contact dermatitis 26.6
anergy 17.50
antigen presentation to 13.9–10, 17.50–1, 55.4
in atopic dermatitis 24.6–8, 24.11
blister formation 40.26
CD8+ class I pathway 12.13
clonal proliferation, cytophagic histiocytic panniculitis 46.23
cytokines released 35.4, 35.18, 35.22, 42.26
acne pathogenesis 42.26
cytotoxic (Tc/$CD8^+$) 12.13, 13.7
activation 4.8
commercially available antibodies to 10.25
development 13.8
in HIV infection 35.3–4
increased in pruritic papular eruption in HIV 35.19
increased in psoriasis in HIV infection 35.17
in lichen planus 41.1
reduced in Langerhans' cell histiocytosis 55.6
subtypes 13.11
Tc1 13.11
Tc2 13.11
in delayed-type hypersensitivity reactions 26.5
depression/anergy
in Langerhans' cell histiocytosis (LCH) 55.6, 55.7
in measles 33.75
in dermis 3.18–19
development 13.7, 13.8, 17.49–50
differentiation 35.4
EBV infection 33.31
in eczema 23.5
extrathymic generation 13.8
γδ 13.6
in Behçet's disease 50.56
in Langerhans' cell histiocytosis 55.8
in vasculitis 50.6
in granuloma annulare 60.4
helper (Th/$CD4^+$) 13.7, 64.9
acne scarring and 42.27
activation 4.8

in atopic dermatitis 24.6–7
autoreactive, antiphospholipid syndrome 49.41
commercially available antibodies to 10.25
defective in psoriasis in HIV infection 35.17
destruction in HIV infection 35.4, 35.5, 35.10
development 13.8
differentiation 24.13–14, 35.4
in HIV infection 35.4
in lichen planus 41.1
polymorphic light eruption 29.11
reconstitution by HAART 35.4
subtypes 13.11
in urticaria 22.3
in vasculitis 50.6
see also Th1 cells, Th2 cells, Th3 cells (below)
helper (Th/CD4$^+$) count
AIDS-defining complication 35.5
eosinophilic folliculitis in HIV infection 35.18
in HIV infection 35.5
immunogenotyping 10.30
