Recent advances in the understanding of these diseases have come from investigations of the humoral mediators of inflammation in the tears, and analysis of the cellular components by immunostaining and *in situ* hybridization. These techniques have shown that seasonal allergic conjunctivitis (SAC) and perennial allergic conjunctivitis (PAC) are primarily typical type 1 hypersensitivity diseases, whereas the others show varying degrees of a coexisting type 4 hypersensitivity response. SAC and PAC show mast cells and eosinophils in the conjunctival mucosa and submucosa, with high levels of locally produced IgE to specific allergens being present in the tears. The diseases can be mimicked by topical instillation of antigen; this reaction is blocked by drugs that are active against mast cells. AKC and VKC show both the cellular components present in SAC and VKC but also connective tissue hyperplasia, $CD4^+$ T lymphocytes and plasma cells, together with different subsets of mast cells. The T cells are probably important inducers of the cellular inflammatory response in these diseases. Differences in AKC and VKC phenotypes may be explained by differences in the predominance of T-helper subsets; the Th1 subset, predominant in delayed type hypersensitivity responses and inactivated by ciclosporin, is more predominant in AKC than in VKC, in which the Th2 subset, with a B-cell-helper role, may be more important. Mast cells and eosinophils are found in larger numbers in VKC than in AKC and functional heterogeneity in their populations may also be determinants of disease phenotype.

These effector cell types are known to cause atopic eye diseases by the following mechanisms. Mast cells release preformed mediators by exocytosis when they degranulate in response to binding of IgE with allergen. The important mediators released are histamine, resulting in hyperaemia, oedema and mucus production, and prostaglandins. Histamine has been detected in the tears in these diseases. Eosinophils release cationic proteins including major basic protein, which is epitheliotoxic and has been identified in the tears in VKC. It is probably a major factor responsible for the development of corneal epithelial erosions and macroerosion. The presence of the latter, with the mucus and debris present in an acute exacerbation of keratopathy, accounts for the formation of plaque. B cells produce IgE locally in atopic conjunctivitis; locally produced IgE is an important factor in the pathogenesis of SAC, PAC and some cases of VKC, but less so in AKC and ABC.

Management [10–15]

The management of VKC and AKC requires specialized ophthalmological care, as these diseases are uncommon, and some of the management strategies are outside the remit of the general ophthalmologist. Topical cromones (sodium cromoglycate 2–4%, or the more recently introduced nedocromil or lodoxamide) are the first-line treatment, given one to four times daily depending on symptoms. Topical olapatadine and Ketotifen combine the effects of a cromone with that of an antihistamine and are probably currently used more widely than cromones as first line drugs. Addition of a potent topical antihistamine (levocabastine or emedastine) or a systemic antihistamine may help relieve itch. These treatments are very safe and do not require ophthalmological supervision but are only effective for very mild disease. Cromones are often not tolerated until the inflammation is brought under control with high-dose topical corticosteroids, such as dexamethasone 0.1% or prednisolone acetate 1%. These will precipitate glaucoma

in 10% of patients as well as contributing to cataract; as soon as the disease is brought under control, a 'safe' corticosteroid with a lower risk of precipitating glaucoma (about 1% risk) should be substituted (fluoromethalone, rimexolone or clobetasone). Cromones are used topically, whenever possible, as corticosteroid-sparing drugs.

Topical ciclosporin is not yet available as a licensed preparation for any ocular indication in Europe, although a preparation designed for use in dry eye is available in the USA (Restasis®, Allergan, USA). However, a veterinary preparation is available (Optimmune®, Schering) in addition to preparations made up in hospital pharmacies (through the NHS Medicines Manufacturing Service). Topical ciclosporin has shown promise in two randomized trials for AKC, and in both randomized trials and in case series for VKC, and is used by the authors for these indications. Adverse effects, apart from stinging, are infrequent and introduction of the drug as a corticosteroid sparing agent, for patients requiring high doses of topical corticosteroids, has allowed reduction or complete withdrawal of corticosteroids in many cases. Topical ciclosporin is most successfully tolerated if introduced during remissions.

Systemic immunosuppression is needed in severe exacerbations of disease; a 3–4 week course of systemic corticosteroids, starting at a prednisolone dose of 60 mg daily, may be necessary to bring the disease under control while topical therapy is introduced. Systemic steroids also carry a risk of glaucoma. Patients with a previous history of labial or ocular herpes simplex (HSV), or with serological evidence of previous exposure to HSV, should be aware that they may develop herpetic keratitis while on systemic or topical corticosteroids. Patients who have had previous episodes of ocular HSV should receive prophylaxis with oral aciclovir 400 mg twice daily (or valaciclovir 500 mg once daily); topical prophylaxis is unnecessary and may complicate the clinical signs in patients with a complex keratoconjunctivitis. Patients with AKC are predisposed to bilateral herpes keratitis and prophylactic antivirals are advisable when they are using corticosteroids.

For a small number of patients, systemic ciclosporin (usually starting at 5 mg/kg) can be very helpful. Patients who need systemic ciclosporin for management of their atopic eczema will usually obtain substantial collateral ocular benefits.

Severe staphylococcal blepharitis often accompanies AKC and ABC and can be treated with a course of azithromycin followed by local therapy with an antibiotic ointment to which the skin flora is sensitive, usually chloramphenicol, together with a topical ophthalmic corticosteroid ointment such as hydrocortisone 0.5% or 1.0%. Combined preparations often contain aminoglycosides, which frequently cause toxicity or allergy and should be avoided.

The management of the corneal complications that often accompany these conditions (vernal plaque, bacterial keratitis and herpes keratitis) is beyond the scope of this summary but presents challenging management problems in the context of these conditions.

Practice points for dermatologists are that the dermatologist should be aware that any sudden deterioration in vision may herald one of the blinding complications of these diseases and should be treated as an emergency. Good control of the underlying condition aims to reduce the frequency with which the blinding corneal complications develop, whilst minimizing the potentially serious side effects of corticosteroid treatment.

The interaction of drugs used for the management of atopic eye disease and atopic dermatitis

Most cases of atopic eye disease are managed with topical ocular therapy which has no effect on the dermatological aspects of the disorder. However, treatment with courses of systemic corticosteroid and/or ciclosporin, when needed either for the dermatological or ophthalmological aspects of atopy, are beneficial to the management of both. The risk of glaucoma from systemic corticosteroids, while occurring, is very low whereas topical application of corticosteroid around the eyelids probably constitutes a higher risk; patients who chronically use corticosteroid cream around the eyes should have glaucoma screening.

Cicatrizing conjunctivitis and the immunobullous disorders

Description and epidemiology [1–4]

Cicatrizing conjunctivitis, although uncommon, is one of the most difficult management problems in ophthalmology because of the widespread effects on the ocular surface, leading to corneal blind-

Table 67.7 Immunobullous diseases (those associated with conjunctivitis are shown in italics).

ness in many victims. The classification of the conjunctival disorders follows the dermatological classification although not all of the dermatological disorders are associated with conjunctivitis (Table 67.7).

The severity of the conjunctival involvement varies but is mild, without scarring, in pemphigus vulgaris, and with variable degrees of scarring and severity in the remainder.

Mucous membrane pemphigoid (MMP) [5–11]

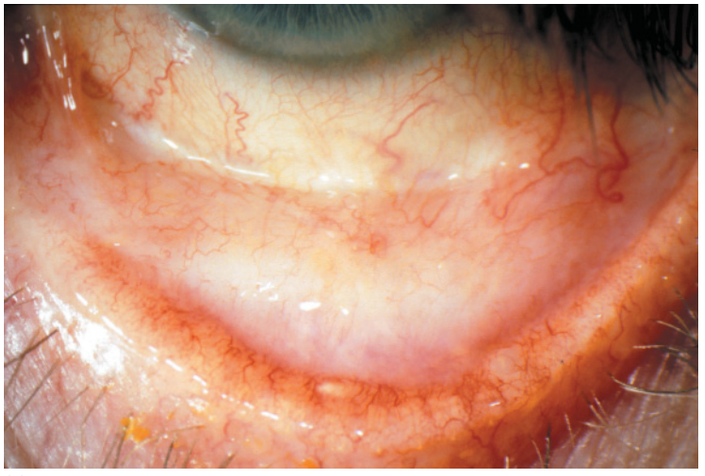
Synonym
- Cicatricial pemphigoid (CP)

MMP is the commonest of these uncommon disorders. It has also been termed cicatricial pemphigoid (CP) and benign MMP (but its effects on the eye are sight-threatening, so 'benign' has been dropped). It is a systemic disease that may be localized to one site or may affect multiple sites. The proportion of patients with ocular involvement alone has varied in recent series from 18 to 50%; these differences are likely to reflect differences in the referral base for each series. About 60% of patients presenting to a dermatology clinic will have conjunctival involvement, in addition to skin disease.

Epidemiology of MMP

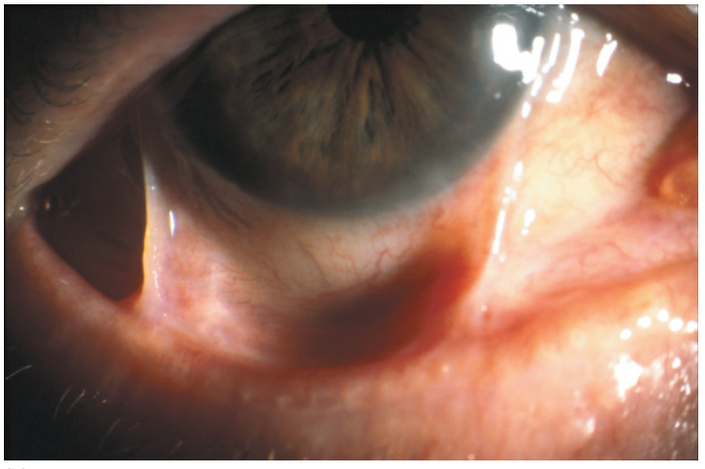
Unambiguous data on the epidemiology of the disease is difficult to obtain because studies have been based on the site of involvement. However, the incidence of dermatological disease is about 1/million/year. This is likely to be an underestimate of the disease as a whole because mucosal presentations are more common. In ophthalmology centres, MMP affects between 1:8000 and 1:46 000 patients. The male:female ratio is 1:3 and the age range is 30–90 years with peak onset in the seventh decade, although patients may rarely present in childhood and in extreme old age. At presentation, between 25 and 38% of patients with ocular disease have significant visual loss and about 30% become legally blind. Treatment has been shown to slow disease progression. A genetic predisposition has been found in an association with the *DQw7* gene and expression of the HLA-DR4 antigen.

Clinical features [12]



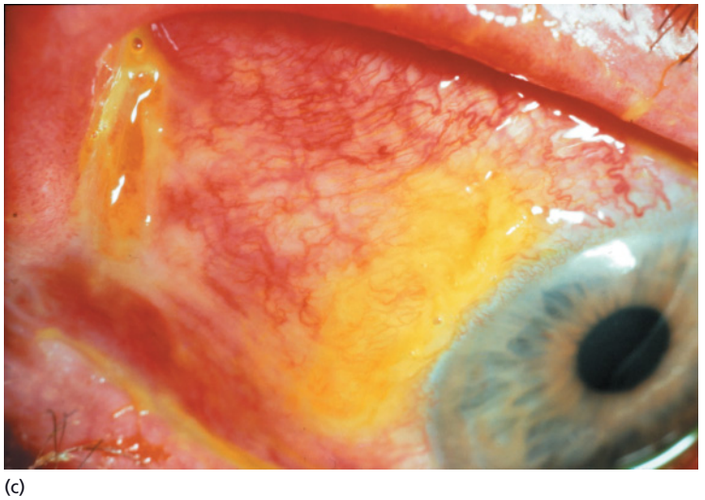
Most patients with ocular MMP (ocMMP) have progressive disease. However, early-presenting disease is usually milder and progresses more slowly than late-presenting disease. Current aggressive treatment regimens, with systemic immunosuppression, have been shown to reduce the rate of progression by about 50%. Because patients can occasionally progress to blindness within months from the onset, both early diagnosis and effective treatment are critical in improving the prognosis.

In most patients the onset is insidious, with non-specific conjunctival symptoms including irritation, hyperaemia and discharge. Dry eye and mucous deficiency are late signs. Acute disease occurs in about 20% of new patients with severe inflammation and conjunctival ulceration; this presentation may follow lid surgery for entropion on undiagnosed cases.



Signs, in order of progression, often start at the medial canthus with loss of the plica and later of the caruncle (Fig. 67.8f), subepithelial reticular fibrosis of tarsal conjunctiva (Fig. 67.8a), conjunctival infiltrate due to increased cellularity and collagen formation (Fig. 67.8c,d), hyperaemia, shortening of the fornices (Fig. 67.8a), symblepharon (Fig. 67.8b), blepharitis, trichiasis and entropion, punctate keratopathy, limbitis, conjunctival and corneal keratinization, and corneal surface failure (Fig. 67.8e). Late disease results in fusion of the lids and globe (Fig. 67.8f), and may obscure the cornea completely. Persistent epithelial defect, microbial keratitis and corneal perforation are common and, with the corneal surface failure, account for the management challenges posed by the disease. Mucous membrane pemphigoid is associated with the autoimmune diseases rheumatoid arthritis, systemic lupus erythematosus and polyarteritis nodosa.

Diagnostic problems in predominantly ocular MMP [9,10,13–18]



The diagnosis of predominantly ocular MMP (ocMMP) has been complicated by the definition of MMP used by the first International Consensus Statement on mucous membrane pemphigoid in which the disease is defined as 'a group of putative autoimmune, chronic inflammatory, subepithelial blistering diseases predominantly affecting mucous membranes that is characterized by linear deposition of IgG, IgA or C3 along the epithelial basement membrane zone (BMZ)'. Whilst it has done much to harmonize the various definitions of MMP in terms of the clinical and diagnostic characteristics, and also to encourage both careful clinical phenotyping and the application of diagnostic immunopathology tests, the necessity of positive direct immunofluorescence (DIF) raises important issues for ocMMP. It is well recognized that DIF is invariably positive from at least one site when MMP affects the oropharynx and skin as well as the eyes; compliance with a definition that requires positive DIF is therefore usually straightforward in such cases with multiple sites affected. However, from the perspective of clinicians caring for patients with MMP affecting the eyes alone, the Consensus Statement has resulted in a substantial proportion of patients (from 14 to 40% having negative DIF) failing to meet these immunopathological criteria for diagnosis. As a

(c) Acute exacerbation of conjunctival MMP showing conjunctival ulceration. This occurs in only 10% of patients presenting with MMP affecting the eye. (d) Severe conjunctival inflammation and limbitis. This leads rapidly to the ocular surface failure and corneal blindness shown in (e) unless it is promptly controlled with adequate immunosuppressive therapy. (e) Ocular surface failure and keratinization (the white area) in advanced pemphigoid. This eye is blind. (f) Advanced ocular pemphigoid showing loss of the medial canthal structures (plica and caruncle) with a reduced interpalpebral aperture secondary to shortening of the fornices (as in (a)) and fusion of the tarsal and bulbar conjunctivae.

result, despite having a typical MMP phenotype and response to treatment, they fall outside the Consensus Statement diagnostic criteria. Subsequent to the publication of the Consensus Statement, peer reviewers of studies on ocMMP have suggested that this group of patients be omitted from studies on MMP; extending this to clinical settings, the resulting uncertainty about the diagnosis has meant that immunosuppressive therapy has been delayed or deferred in some patients.

Sensitivity and specificity of direct immunofluorescence for MMP

However, DIF is not a specific test for MMP and a positive result does not exclude other immunobullous disorders as is made clear in the Consensus Statement.

In effect, a positive DIF test is used as a surrogate to provide evidence for an autoimmune pathogenesis. For DIF to be integral to a diagnosis of ocMMP, the test should ideally be both highly sensitive and specific. Not only is DIF of low sensitivity in ocMMP, it is also of low specificity. Conjunctival biopsies may have a positive DIF test in a range of disorders, including bullous pemphigoid, skin-dominated linear IgA bullous dermatosis, skin-dominated epidermolysis bullosa acquisita, drug-induced pemphigoid, Stevens–Johnson syndrome, rosacea and ulcerative colitis; most of these are immunobullous disorders with an autoimmune basis, but not all. Furthermore, some must be differentiated from each other by the clinical phenotype or may require more sophisticated tests to reliably distinguish them from each other (indirect immunofluorescence studies on salt-split skin, immunoblotting, immunoelectron microscopy, etc.; see Chapter 40). In addition, DIF may not be consistently positive and may change with time. With regard to the low sensitivity of DIF, studies have shown that there is a well-recognized DIF-negative subgroup comprising up to 14–40% of patients with ocMMP, these subjects having scarring conjunctival inflammation that is phenotypically indistinguishable from MMP, and which responds identically to immunosuppressive therapy.

Indirect immunofluorescence in MMP

Indirect immunofluorescence (IIF) was not included amongst the criteria for MMP in the Consensus Statement because this investigation is often negative in MMP. However, positive IIF also provides evidence for an underlying autoimmune pathology and may be positive in ocMMP when DIF is negative.

Recommended criteria for the diagnosis of predominantly ocular MMP

More workable, and clinically useful, criteria for ocMMP used in our clinical service are as follows:

Predominantly ocular MMP (ocMMP). This is a term that we use for those cases without any evidence of MMP affecting other systems. The term 'predominantly' is used to recognize the fact that, even with the most careful phenotyping, it is not possible to exclude asymptomatic involvement of, for example, the oesophagus.

Criteria for the diagnosis of ocMMP. Patients with positive conjunctival DIF or positive DIF from another uninvolved site meet currently agreed criteria for the diagnosis of MMP and can be reported as such. Patients with negative DIF from any site and positive IIF can be diagnosed as having MMP. Patients with negative immunopathology can be diagnosed as ocMMP providing that they have a typical phenotype of progressive conjunctival scarring and providing that other diseases that may cause this same phenotype have been excluded (Sjögren's syndrome, ocular rosacea, Stevens–Johnson syndrome, atopic keratoconjunctvitis, ectodermal dysplasia, sarcoidosis, scleroderma and drug-induced pseudopemphigoid). When ocular cases are reported in studies we believe that the detailed immunopathology findings should be recorded for each case so that the diagnosis can be interpreted in the light of future modifications to diagnostic criteria.

In ocMMP patients (without extraocular disease) the laboratory investigations are outside the scope of many ophthalmology services and ideally such patients should be referred to specialist corneal and external eye disease departments. However, many patients are elderly, for whom distant referral is unwelcome. For such cases a diagnosis, based on a history of progressive conjunctival scarring, the presence of the typical clinical signs and exclusion of other ocular causes, is adequate for clinical purposes.

Taking conjunctival biopsies for DIF

Conjunctival biopsies for DIF should be taken from the bulbar conjunctiva and the presence of IgA, IgG, and the C3 component of complement confirm the diagnosis of MMP when positive. Fornix biopsies should be avoided as biopsying this site may cause exacerbations of disease. The biopsy can be taken using topical anaesthesia with tetracaine, the conjunctiva can be tented up and a piece about 2 mm in diameter cut off with spring scissors. This can be done in the outpatient department using magnification from the slit lamp microscope. Routine histopathology of conjunctival biopsies is of little value in the diagnosis because the conjunctiva is fragile and detection of basement membrane zone cleavage is unreliable. However, it should be done to exclude surface neoplasia, particularly in unilateral disease, as this can present with scarring and inflammation. Squamous metaplasia of the conjunctival epithelium and a reduction in goblet cells are non-specific findings, as is an increased inflammatory cell infiltrate. In acute disease there is a neutrophil-rich infiltrate.

Differential diagnosis

The conjunctival signs in MMP may be identical to those produced by the other immunobullous disorders that are summarized in Table 67.7. However, in these conditions the skin disease precedes the ocular disease so that there is rarely any confusion. In erythema multiforme major, exacerbations of conjunctival inflammation can occur many years after the acute disease, leading to a condition indistinguishable from MMP both in terms of the clinical signs and immunopathology. The principal problems in differential diagnosis relate to diseases other than the immunobullous disorders that may also cause cicatrizing conjunctivitis (Table 67.8). Patients with conjunctival cicatrization secondary to infective causes are sometimes referred for investigation of what has been longstanding conjunctival scarring, following a long-forgotten episode of infection, in whom the absence of a recent history of inflammation, or of progressive symptoms, usually

Table 67.8 Causes of non-autoimmune cicatrizing conjunctivitis.

Ocular rosacea
Staphylococcal blepharoconjunctivitis

indicates static disease. Patients with sarcoidosis or systemic sclerosis normally have a well-established diagnosis by the time conjunctival scarring develops. Sjögren's syndrome may mimic early MMP but can usually be differentiated by the presence of Sjögren's specific antibodies and/or a positive labial biopsy. Atopic keratoconjunctivitis can occasionally be difficult to differentiate from slowly progressive MMP but the history and clinical signs of severe eczema, and a tarsal conjunctival biopsy (performed after withdrawal of topical corticosteroids for 2 weeks) that shows excessive numbers of mast cells and eosinophils can confirm the diagnosis. Iatrogenic conjunctivitis is non-progressive, except in the case of drug-induced MMP, which is indistinguishable from classical MMP. Awareness that conjunctival scarring can occur in ocular rosacea and in staphylococcal blepharoconjunctivitis (Fig. 67.5a) is usually enough to distinguish these conditions from MMP. Factitious conjunctival trauma is rare and usually more focal than classical MMP but can mimic MMP while the self-trauma is active.

Pathogenesis [19,20]

MMP is an autoimmune disease directed at components of the conjunctival basement membrane; progression occurs as a result of inflammatory disease and cicatrization, secondary ocular surface disease, infection and treatment toxicity. Drug-induced pemphigoid (pseudopemphigoid), and Stevens–Johnson syndrome, lead to an identical situation, suggesting that conjunctival damage may precipitate MMP, which may be the final common pathway following one type of conjunctival insult.

Inflammatory mechanisms in MMP are reasonably well understood and provide a rationale for immunosuppressive therapy. In chronic disease, macrophages and T cells are present, of which the Th1 subset is active, as demonstrated by the presence of the cytokines IL2 and interferon-γ, as opposed to the Th2 subset that is involved in B-cell activation. This, coupled with the low numbers of B cells but increased number of plasma cells, suggests that B-cell activation must be occurring in the extraocular tissues with homing of mature plasma cells to the conjunctiva. MHC Class II expression is increased, suggesting the potential for local antigen presentation to T helper cells. There is a slight increase in activated T cells, which are involved in the recruitment of fibroblasts and macrophages. In acute disease, neutrophils and antigen-presenting (dendritic) cells are also present, together with an increase in CD4 (helper) T cells, which probably reflects their role in recruiting other inflammatory cells.

Growth factors including FGF (fibroblast growth factor), PDGF (platelet-derived growth factor) and TGF-β (transforming growth factor-beta) are all present in MMP. PGDF upregulates the extracellular matrix component (ECM) thrombospondin, which is itself important in activating latent TGF-β. PDGF is a powerful chemoattractant for macrophages and fibroblasts and is probably pivotal to the scarring response. However, only TGF-β is capable of stimulating fibroblasts to produce collagen and ECM components. It also blocks matrix degradation by decreasing protease synthesis and increasing protease inhibition. In acute disease, TGF-β is significantly increased and is produced by macrophages and fibroblasts in ocMMP conjunctiva. Once macrophages and fibroblasts are present in large numbers and activated they may become self regulating; T-cell-deficient models have shown that T cells are not necessary for wound healing to occur, and fibroblasts from ocMMP conjunctiva display abnormal activity in cell culture after several passages.

Implications of immunopathological findings for therapy

Inflammation is important in acute disease; severe inflammation is associated clinically with rapid scarring and therefore demands effective immunosuppression to reduce scarring. Inflammation may also play a role in chronic disease although scarring often continues even in the presence of minimal inflammation, suggesting that growth factor production by macrophages and fibroblasts is relatively independent of the other inflammatory cells. Therefore, modulation of growth factor activity, collagen metabolism or fibroblast activity may be necessary to halt the disease process. Of these, growth factor activity can potentially be specifically blocked or inhibited, thus holding promise for new treatments.

Other subepithelial immunobullous disorders and conjunctivitis [21]

Other immunobullous disorders are much less frequently associated with conjunctival cicatrization. As a result, little is known about the pathogenesis of the conjunctival disease as opposed to the events in the skin. Bullous pemphigoid generally results in mild conjunctivitis although severe cicatrization has been reported. Epidermolysis bullosa aquisita, linear IgA disease, dermatitis herpetiformis and lichen planus may all be associated with progressive conjunctival scarring indistinguishable from that of MMP.

Erythema multiforme major and toxic epidermal necrolysis [22–26]

The ocular complications of these two conditions are identical (Table 67.9); about 70–80% of patients admitted for treatment of these diseases will develop eye disease. It is the eye disease which leads to the most profound, long-term morbidity in many such patients. In addition, the eye disease, unlike the lesions affecting the remaining mucosal surfaces, may progress years after the

Table 67.9 Ocular effects of Stevens–Johnson syndrome and toxic epidermal necrolysis.

Ocular effects	Resulting symptoms and signs
Loss of goblet cells	Disrupted tear film leading to poor vision and punctate keratopathy (Fig. 67.9b)
Loss of accessory lacrimal glands	
Scarring of meibomian gland orifices	
Metaplasia of meibomian gland epithelium with development of metaplastic lashes	Trichiasis secondary to metaplastic lashes (Fig. 67.9b)
Conjunctival scarring and obliteration of lacrimal gland ductules	Very dry eye with secondary conjunctival and corneal squamous metaplasia (Fig. 67.9b)
Keratinization due to squamous metaplasia	Exacerbates drying and discomfort
Conjunctival scarring with fornix shortening and symblepharon formation leading to lid shortening	May cause lagophthalmos and corneal exposure
Retroplacement of meibomian gland orifices	Disrupts tear film
Entropion of upper and lower lids with trichiasis of both metaplastic and normal lashes	Corneal punctate keratopathy and ulceration
Corneal epithelial failure secondary to limbal inflammation	Blindness

acute episode has resolved. Acute ocular complications usually occur concurrently with the skin disease but may sometimes precede it by several days. The conjunctivitis varies from a papillary reaction with watery discharge (Fig. 67.9a) to a membranous conjunctivitis with sloughing of the conjunctival epithelium. Corneal epithelial defects are common and may progress to corneal ulceration with or without bacterial superinfection. The morbidity of the disease may be due to the acute corneal complications but is more usually due to conjunctival scarring.

Chronic ocular complications are numerous. The severe conjunctival inflammation leads to loss of goblet cells and the accessory conjunctival lacrimal glands as well as disruption of the meibomian gland orifices leading to MGD. This results in a disrupted tear film and a secondary punctate keratopathy. In mildly affected patients this causes chronic mild discomfort, photophobia and slightly reduced vision. In more severely affected patients, the conjunctival inflammation leads to cicatrization of the lacrimal ductules, resulting in a severely dry eye accompanied by squamous metaplasia and keratinization of both the conjunctival and corneal components of the ocular surface, thereby causing more severe discomfort and loss of vision (Fig. 67.9b). In addition, the meibomian gland ductal epithelium undergoes metaplasia, resulting in the development of fine metaplastic lashes which are not a feature of MMP. The conjunctival shortening leads both to entropion, resulting in ocular surface abrasion by normal as well as by metaplastic lashes, and may also cause lid shortening, leading to reduced eye closure (lagophthalmos), which is easily overlooked. Lash abrasion and trichiasis lead to the development of corneal epithelial defects which, as a result of the poor tear film, may persist. Persistent epithelial defect predisposes to corneal stromal melts and perforation, which are often precipitated by infection. This evolution of changes is not the direct consequence of the acute disease but is secondary to the effects on the tear film and lids.

(a)

(b)

Fig. 67.9 Ocular disease in Stevens–Johnson syndrome. (a) Acute conjunctivitis in a patient with mild Stevens–Johnson syndrome. The conjunctiva is hyperaemic with a papillary reaction and mucopurulent discharge. (b) The late ocular complications of Stevens–Johnson syndrome showing entropion, a dry eye with ocular surface failure (in this case an opaque keratinized epithelium).

The severe inflammation may also lead to blinding opacity of the corneal epithelium, not only as a result of squamous metaplasia, but also by loss of corneal epithelial progenitor cells (stem cells). Because of prolonged survival of transient amplifying cells, the progeny of stem cells, stem cell failure may not be manifest for 12 to 18 months after the onset of the disease.

An additional problem for patients with ocular complications of Stevens–Johnson syndrome is the development of severe conjunctival inflammation with progressive scarring that may be indistinguishable from MMP and may also be DIF-positive. This can occur as a continuation of the acute episode or may occur many years after the onset of disease. Other inflammatory complications are recurrent conjunctival inflammation following Stevens–Johnson syndrome and necrotizing sclerokeratitis. All of these severe inflammatory problems can precipitate stem cell failure and demand rapid control, usually requiring systemic immunosuppressive therapy. The cause of these late inflammatory complications is not understood.

Graft-versus-host disease [27–35]

Ocular complications are common in patients with graft-versus-host disease (GVHD) and result from involvement of both the conjunctiva and the lacrimal gland. In acute GVHD, conjunctivitis ranges from hyperaemia through chemosis to a pseudomembranous conjunctivitis, with or without corneal epithelial sloughing. Severe conjunctival involvement is a marker for the severity of acute GVHD and was found to occur in 12% of patients in one study; this subset had 90% mortality [26]. In chronic GVHD the same study found conjunctival involvement in 11% of patients for whom it was also associated with disease severity. Some of these patients develop a severe scarring response like that of MMP. Lacrimal gland involvement occurs in about 50% of patients with chronic GVHD who develop a Sjögren's syndrome-type picture of dry eyes. The pathogenesis of the conjunctival disease has been examined in a few cases and appears to be similar to that in the skin.

Although dry eye and cicatrizing conjunctivitis are the commonest ocular findings in GVHD, choroiditis, retinitis and scleritis may also occur.

Treatment of cicatrizing conjunctivitis and the ocular complications of the immunobullous disorders [11,36–47]

The same strategies can be used to treat the ocular aspects of all these disorders. The aim of treatment is the successful management of each of the three principal components that underlie the pathogenesis of these diseases: (i) the ocular surface disease, (ii) the treatment toxicity, and (iii) inflammation. These components of disease are present to variable degrees in different diseases. For example, in Stevens–Johnson syndrome, most patients have relatively little inflammation once the surface disease has been treated and any treatment toxicity eliminated, so that it is the minority of these patients, with recurrent inflammation or progressive cicatrization, who require suppression of inflammation with systemic therapy. On the other hand most, but not all, MMP patients require management of all three components of disease, with 80% of patients requiring systemic immunosuppressive therapy to control the inflammation that persists once the surface disease and toxicity has been controlled.

Successful management demands identification and treatment of all of the components of the disorder, including surface disease, treatment toxicity and inflammation related to activity of the underlying disease, as well as the early detection and treatment of secondary corneal infection.

Management of the ocular surface disease

The ocular surface disease is secondary to previous or current lid and conjunctival scarring and inflammation. The surface disease causes much of the damage to the cornea and is responsible for additional inflammation. Trichiasis and entropion, blepharitis, dry eye and filamentary keratitis, keratinization, persistent epithelial defect, microbial keratitis and corneal perforation may all result from a combination of a poor tear film, poor lid closure, and corneal damage secondary to trichiasis. These are treated as follows:

Trichiasis: epilate in the short term, use electrolysis or laser for odd lashes, cryotherapy for misdirected lashes and surgery for entropion (inferior retractor plication for lower lid and anterior lamellar reposition for upper lid).

Blepharitis: use oral tetracyclines and institute a lid hygiene regimen.

Dry eye and filaments: use non-preserved lubricants, topical acetylcysteine 5–10% as a mucolytic, and punctal occlusion to conserve tears (once any blepharitis has been controlled).

Keratinization: topical retinoic acid is effective in 30% but is only available in specialized centres.

Persistent corneal epithelial defect: exclude infection, treat ingrowing lashes, use non-preserved lubricants, therapeutic lenses (silicone hydrogel if the eyes are not too dry) and, if these measures are unsuccessful, close the eye with a botulinum toxin protective ptosis or with a temporary tarsorraphy. Other more specialized treatments may be needed.

Corneal perforation: temporize with therapeutic contact lenses and/or corneal glue, followed by keratoplasty only if absolutely necessary.

Eliminating or minimizing treatment toxicity

Treatment toxicity results principally from the preservative benzalkonium chloride, a component of most reusable bottles of eye drop preparations as well as of topical glaucoma medications and aminoglycoside eye drops.

Unnecessary topical treatment should therefore be avoided and unpreserved drops or saline used as far as possible. The effects of topical treatment toxicity are hard to distinguish from those of the ocular surface disease. After withdrawal of toxic topical therapy, the mean recovery period is 2 weeks but may extend to 3 months.

Suppressing inflammation/immunosuppressive therapy

Monitoring and side effects of the main immunosuppressive agents are discussed in Chapter 74 and are not repeated here.

In *mild disease* (*hyperaemia and oedema*), low-dose topical corticosteroid may be helpful, particularly in the alleviation of the symptoms of very dry eye. Topical ciclosporin preparations are being widely used for dry eye in the USA where there is a well-tolerated preparation (Restasis®, Allergan) that has been licensed for use in dry eye. This preparation is not licensed in Europe where less-well-tolerated preparations are available from hospital pharmacies. The role of topical ciclosporin for the severe dry eye associated with cicatrizing eye disease is currently uncertain but may provide benefits for this group of patients without the risks associated with topical steroid use. Comparative studies or randomized controlled trials comparing topical ciclosporin and steroids for dry eye are not available.

For *moderate disease* (*hyperaemia, intense infiltration*), sulphapyridine 500 mg daily for 2 weeks then 1 g daily (sulfasalazine 1–2 g daily is an alternative); 55% of patients respond in 1–2 months, but 15% develop an allergic reaction. If response is poor, dapsone 75 mg daily, increased each month by 25 mg daily to 125 mg,

can be used; there is a 70% response in 1–2 months, reducing to 50% after 1 year. Other agents that may be considered are azathioprine (1–2 mg/kg/day; effective in about 60%), methotrexate (7.5–25.0 mg once weekly) or mycophenolate mofetil (1–2 g daily) (each effective in about 80% depending on the severity of the disease).

For *severe disease* (*hyperaemia, limbitis, conjunctival ulceration*), start prednisolone 1 mg/kg/day, reduce the dose after 2 weeks and tail off after 2–4 months. This is ineffective at low doses in the long term and a steroid-sparing immunosuppressive agent is generally added for long-term disease control. The most effective currently is cyclophosphamide 1 mg/kg/day. The dose is adjusted until the lymphocyte count is between 0.5 and 1.0×10^9/L; other haematological parameters should remain normal. Cyclophosphamide therapy is usually discontinued after 1 year and substituted by sulphonamides or immunosuppressive agents as described above.

Most of this therapy is empirical and a sulphonamide (dapsone or sulphapyridine) is often used together with an alkylating agent (cyclophosphamide) or an antimetabolite (azathioprine, methotrexate or mycophenolate mofetil) to control inflammation. This immunosuppressive strategy is summarized in Fig. 67.10, and can be modified as necessary for all these disorders; generally any systemic therapy will benefit the underlying disease. This approach is summarized in a recent case series [11].

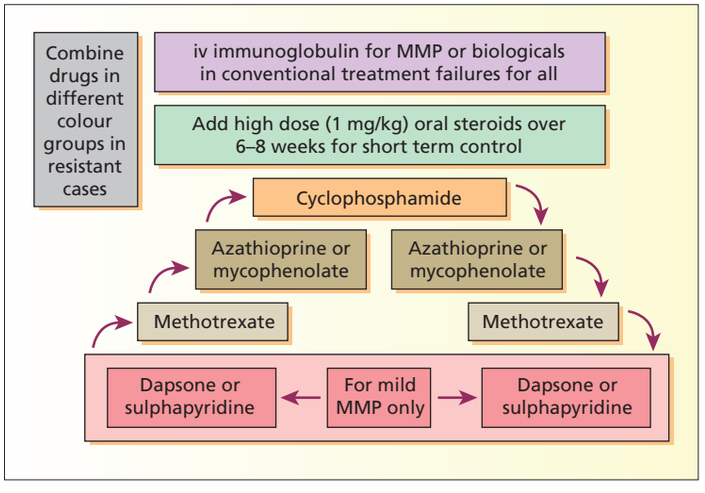

Fig. 67.10 Systemic immunosuppression stepladder for progressive conjunctival cicatrization. Immunosuppression can be carried out using a 'stepladder' approach for the introduction of systemic drugs. Dapsone or sulphapyridine (given as sulphasalazine) are only used in MMP and mild disease may respond well to these. If there is no response after 2–3 months, treatment is 'stepped up' to azathioprine or mycophenolate mofetil (methotrexate is an alternative, which the authors have little experience of using). If these drugs are not effective in another 2–3 months then cyclophosphamide is the drug of choice. For severe and rapidly progressive disease, cyclophosphamide is the drug of choice. Patients are started on this with a 2-month course of systemic steroids, which speeds up the control of inflammation, while the cyclophosphamide takes effect (2–3 months). When the disease has been controlled for several months, treatment can be 'stepped down' to a less toxic drug. Steroids, the sulphones (dapsone and sulphapyridine) and the bone marrow suppressive immunosuppressants (methotrexate, mycophenolate, azathioprine and mycophenolate) can be combined although neutrophil count, in particular, must be monitored. About 10% of patients with severe disease will not be fully controlled with cyclophosphamide. For these patients, intravenous immunoglobulin OR a biological agent (anti-TNF or anti-B cell) may be effective. Ciclosporin has been little used in cicatrizing conjunctivitis because of concern about potential fibrogenic side effects as well as likely renal toxicity in the elderly subset of patients.

Systemic diseases with skin and eye involvement

Some multisystem diseases affect both the skin and the eye [1–23]. It is not possible to catalogue every complication of all these diseases but the most frequent are summarized in Table 67.10.

Infections

A number of infections involve the eyelids, but the following are important to recognize because they are common or require urgent therapy or referral to an ophthalmologist [1].

Viral infections

Warts

These are common and are found on the eyelid margins, often as a long thin ('filiform') projection. Lesions in this site are best treated with careful cryotherapy and accurate application of liquid nitrogen to the tip of the lesion using a cotton wool bud rather than cryospray.

Molluscum contagiosum [2]

This condition mainly affects children and young adults. It is also prevalent in patients with acquired immune deficiency syndrome (AIDS), who may develop multiple lesions around the eyelids. Lesions may grow in the lash line as well as on the lid skin and, occasionally, on the mucocutaneous junction. Lesions can be easily overlooked or mistaken for a sebaceous cyst; this condition must

Table 67.10 Systemic diseases with skin and eye involvement.

Systemic disease	Eye disease
Sarcoidosis *Epidemiology*: ocular involvement the presenting feature in 10%; 20–30% of patients have eye disease at some stage [1–7]	*Lids and orbital findings*: clusters of granulomatous eyelid swellings. Proptosis from orbital granulomas. Dry eye from lacrimal gland involvement *Heerfordt's syndrome*: (uveo-parotid fever) consists of uveitis and parotid gland enlargement, fever and facial nerve palsy. *Lofgren's syndrome*: acute iritis, bilateral hilar lymphadenopathy, erythema nodosum and arthralgia. *Mikulicz's syndrome*: bilateral swelling of lacrimal and salivary glands *Anterior segment findings*: *conjunctivitis*: occasionally a granulomatous conjunctivitis mimicking a follicular conjunctivitis. *Uveitis*: usually, but not always, bilateral granulomatous anterior uveitis in 80% of patients with eye manifestations with redness, pain, photophobia and blurred vision with floaters *Posterior segment findings*: rare
Systemic lupus erythematosus [8–10]	*Anterior segment findings*: dry eye, peripheral corneal ulcers. Scleritis is rare. Episcleritis occurs in 10% causing a red eye *Posterior segment findings*: retinal vasculitis common during exacerbations of systemic disease with flame shaped haemorrhages and cotton wool spots. May be associated with severe central nervous system vasculitis or lupus nephritis
Sjögren's syndrome [11]	*Lids and orbital findings*: lacrimal gland inflammation causing dry eye *Anterior segment findings*: *symptoms*: often severe with chronic discomfort, foreign body sensation, dryness and blurred vision. *Conjunctiva*: conjunctivitis and scarring in some cases. *Cornea*: punctate keratopathy, persistent corneal epithelial defects leading to corneal ulceration and perforation or corneal infection
Reiter's syndrome *Epidemiology*: ocular involvement in about 30% of patients [1]	*Anterior segment findings*: *symptoms*: red irritable eyes resolving spontaneously within 7–10 days *Conjunctiva*: bilateral mucopurulent conjunctivitis is the most frequent manifestation affecting approximately 30% of patients; this usually follows a urethritis by about 2 weeks and precedes the onset of arthritis. *Cornea*: keratitis may occur in isolation and is rare. *Uveitis*: anterior uveitis (iritis) occurs in about 20% of patients either with the first attack of Reiter's syndrome or during a recurrence
Behçet's syndrome *Epidemiology*: ocular involvement in 60% to 70% of patients [12,13]	*Anterior segment findings*: *external eye diseases*: conjunctivitis, keratitis and episcleritis may occur but are not specific for the condition. *Uveitis*: is the commonest manifestation of the disease *Posterior segment findings*: visual impairment or blindness is a frequent complication of Behçet's syndrome as a result of the retinal ischaemia
Inflammatory bowel disease *Epidemiology*: ocular manifestations in about 5% of patients [14,15]	*Anterior segment findings*: *external eye diseases*: conjunctivitis, limbitis, peripheral corneal infiltrates and episcleritis may occur *Uveitis*: acute iritis in about 5% of patients which may occur at the same time as exacerbation of colitis
Acquired immune deficiency syndrome (AIDS) *Epidemiology*: ocular complications occur in about 75% of patients [16,19]	*Common features*: (i) opportunistic infections with viruses, mycobacteria and fungi; (ii) malignancies e.g. Kaposi's sarcoma; (iii) retinal microangiopathy; and (iv) neuro-ophthalmic lesions with intracranial infections and tumours *Anterior segment findings*: *external eye diseases*: *Molluscum contagiosum* is a common ocular finding in patients with AIDS, they tend to be large and when located on the lid margin can give rise to follicular conjunctivitis. The lesions can be complicated by epithelial keratitis with associated pannus formation. Kaposi's sarcoma may involve the lids and conjunctiva. *Herpes simplex* keratitis tends to be severe with more frequent relapses. The peripheral cornea is more often involved in contrast to central disease in immunocompetent patients. *Herpes zoster ophthalmicus* is common and may be a presenting feature of HIV infection, especially if severe disease presents in young patients *Posterior segment findings*: retinal microangiopathy is common and characterized by retinal haemorrhages, microaneurysms and cotton wool spots. *Cytomegalovirus* retinitis and *Pneumocystis carinii* choroiditis are serious ophthalmic complications signifying severe systemic involvement
Porphyria [20,21]	*Common feature*: ocular involvement results from either photosensitization and/or neurological dysfunction. Photosensitization can affect the eyelids, conjunctiva, cornea, sclera and possibly the retina *Lids and orbital findings*: inflammation can lead to vesicle and bulla formation, secondary infection scarring with ectropion and hyperpigmentation *Neuro-ophthalmic complications*: include optic neuritis, optic atrophy, ptosis and cranial nerve palsies
Wegener's granulomatosis [22]	Episcleritis is very common in active stages. Also retinal vasculitis, optic neuritis, orbital pseudotumour
Polyarteritis nodosa	Episcleritis, scleritis and keratitis

HIV, human immunodeficiency virus.

always be considered in the differential diagnosis of patients with unilateral or bilateral follicular conjunctivitis. There is associated conjunctival discharge and a variable, often severe, follicular conjunctival response (Fig. 67.11). A superficial epithelial keratitis may develop in longstanding cases, which can progress to pannus formation across the cornea. Treatment involves removal of the lesions by curettage. Cryotherapy is also effective, but these will cause depigmentation in pigmented skins. In a cooperative adult this can be done under local anaesthetic, but for children a general anaesthetic is required.

Herpes simplex virus [3–5]

Primary HSV infection is asymptomatic in many patients; in others it causes blepharoconjunctivitis. However, most of the ocular manifestations of HSV infection are due to reactivation of latent infection in the trigeminal ganglion. Both the primary infection,

Fig. 67.11 Molluscum contagiosum at medial aspect of the upper lid margin with an associated follicular conjunctivitis.

and reactivation of latent disease, may be particularly severe in patients with atopic dermatitis or with immunodeficiency. The blepharoconjunctivitis of HSV usually results in crops of small vesicles, which may be associated with mild oedema of the lids with or without associated conjunctivitis. As with HSV elsewhere, the vesicles dry to a crust and heal within a few days. The conjunctivitis can be treated with aciclovir ointment five times daily for 5 days or with oral aciclovir 400 mg three times daily. Neither the blepharitis nor conjunctivitis present a serious problem for most patients. The serious and sight-threatening ocular complications of HSV infection of the eye are due to recurrent keratitis or keratouveitis. Herpetic keratitis may affect the epithelium alone (dendritic keratitis), the stroma (in stromal herpetic keratitis, geographical corneal ulceration and metaherpetic keratitis), or the endothelium (disciform keratitis or herpetic endotheliitis). Dendritic keratitis is in itself a benign disease unless treated with topical corticosteroids when the disease will rapidly spread, resulting in geographical keratitis, which may cause destructive corneal disease. Most cases of corneal disease represent reactivation of latent HSV and patients may develop any of the corneal manifestations. Stromal and endothelial disease can progress to blinding corneal vascularization, scarring and ulceration. Fortunately the disease is normally unilateral, except in atopic individuals when it may often be bilateral. The management of the stromal and endothelial keratitis is beyond the scope of this review except to state that this involves the judicious use of topical corticosteroids with systemic or topical antivirals. Keratouveitis involves the endothelium and stroma and may also be associated with secondary glaucoma. Dendritic keratitis may occur during treatment with topical corticosteroids. Because of the difficulties of managing the ocular manifestations of this disease, patients with suspected HSV involvement of the eye should be referred for urgent ophthalmological assessment. Topical corticosteroids must not be used alone as these will mask the symptoms and signs, leading to spread of the ulcer and corneal perforation with catastrophic consequences for the patient's vision.

Herpes zoster [6–9]

Herpes zoster of the ophthalmic division (HZO) of the trigeminal nerve is an important condition to recognize. As occurs when it affects other sites, it often presents with a non-specific, flu-like illness with fever and malaise and symptoms of unilateral neuralgia. This develops over the distribution of the affected nerve and varies in severity from a mild tingling in the skin to a deep, severe pain. The characteristic lesions of herpes zoster may appear up to a week after the initial symptoms. Erythematous macules develop into clusters of papules and vesicles becoming pustular and haemorrhagic after 3–4 days. The lesions then scab and are dry by 7–14 days, separating to leave pitted scars. Involvement of the nasociliary nerve, which supplies the skin on the side of the nose, occurs in about 35% of patients and vesicles at this site (Hutchinson's sign) are associated with a high risk of ophthalmic complications. Ocular involvement may occur in the absence of nasociliary involvement but it is usually milder. Herpes zoster sine eruptione can cause ocular complications without the cutaneous eruption. It is rare but evidence of the infection can be found by polymerase chain reaction analysis of the aqueous fluid or sequential titres of HZO antibodies. Patients whose eyes cannot be examined due to persistent lid oedema, or those with ocular signs and symptoms, should be referred for urgent ophthalmological assessment. The disease can affect any part of the eye, including the orbit, extraocular muscles, optic nerve and cornea, and may give rise to long-term complications including severe relapsing keratitis, glaucoma and cataract. The commonest ocular complications are dendritiform keratopathy, stromal keratitis and uveitis.

Antiviral drugs reduce the duration and severity of acute herpes zoster but must be given within the first 3 days of the onset of the rash to be effective. Oral aciclovir has been the standard therapy at doses of 800 mg five times a day for 7–10 days. Valaciclovir (1000 mg three times per day) or famciclovir (500 mg three times per day for 7 days) are now preferred because of simpler dosing regimens and superior pharmacokinetics. Topical aciclovir is not indicated unhelpful. Topical corticosteroid therapy is needed to control the numerous corneal manifestations of the disease and may need to be continued for several years. Some of these complications may be delayed and occur months after the initial skin eruption.

Prolonged or severe post-herpetic neuralgia is a painful and unpleasant sequel to herpes zoster infection. It occurs in about half of elderly patients but is rare in children. There is some evidence that the use of amitriptyline in the early stages of infection is helpful in reducing the incidence and severity. Oral corticosteroids given concurrently with the antivirals may reduce the severity of post-herpetic neuralgia in some patients.

Bacterial infection

Staphylococcal infection

Impetigo

Impetigo is a common skin infection that mainly affects children. It can involve the eyelids, but usually as part of a general infection over the face. It presents as rapidly spreading erythematous macules, developing into flaccid vesicles that subsequently rupture to give rise to surface crusting. The lesions need to be swabbed for bacteriology and appropriate oral and topical antibiotics given.

Hordeolum

External hordeolum (stye) is caused by staphylococcal infection of an eyelash follicle and its associated glands. It presents with a

tender, red, inflamed swelling on the lid margin, which subsequently points anteriorly and discharges close to the lash roots. No treatment is usually required beyond the application of local soothing compresses and removal of the affected lash. If there is a local cellulitis then systemic antibiotics should be given. An internal hordeolum is a staphylococcal abscess of the meibomian glands and needs incision and drainage.

Streptococcal infection

Erysipelas [10]

This represents subcutaneous spreading cellulitis, usually caused by β-haemolytic *Streptococcus*. It usually presents with a rigor followed by a red, raised, erythematous plaque with a well-demarcated edge that spreads rapidly over the skin. Erysipelas is a serious skin infection that needs to be treated urgently with appropriate systemic antibiotics.

Necrotizing fasciitis [11]

This is a very rare condition, most commonly caused by *Streptococcus*, which mainly affects elderly or debilitated patients. A spreading purple discoloration of the eyelid rapidly progresses to gangrene. Unlike erysipelas, the periorbital tissue is not usually affected. Early recognition, immediate institution of intravenous antibiotics and referral to an ophthalmic plastic surgeon for debridement of the necrotic tissue are mandatory as the condition carries a high mortality.

Mycobacterial infection

Tuberculosis

There are no specific ocular findings in tuberculosis, and diagnosis is often based on indirect evidence such as intractable uveitis that is unresponsive to corticosteroid therapy, with negative findings for other causes of uveitis, and in the presence of tuberculosis at a distant body site. Chronic iridocyclitis, which is usually granulomatous, is the commonest feature. Choroiditis and retinal vasculitis may occur.

Leprosy [12,13]

Ocular complications of leprosy are common, most frequently madarosis, conjunctivitis, episcleritis or scleritis. Keratitis results from a combination of corneal anaesthesia, lagophthalmus, trichiasis and secondary infection. Iritis and its complications are the most common causes of blindness and leprosy. Lepromatous disease is more commonly associated with uveitis than is tuberculoid leprosy.

Treponemal infection

Syphilis [14]

Ocular syphilis is very rare and there are no pathognomonic signs. Eye involvement mainly occurs during the secondary and tertiary stages, though primary chancre of the conjunctiva may occur. External features include madarosis, scleritis and interstitial keratitis. Uveitis and chorioretinitis are rare but serious complications of syphilis and lead to blindness. Neuro-ophthalmic features include Argyll Robertson pupils, optic nerve lesions, and palsies of the third and sixth cranial nerves. Gummatous involvement of the brain can cause visual field defects.

Lyme disease [15,16]

Ocular manifestations of Lyme disease involve all parts of the eye. As with syphilis, the ocular manifestations vary according to the stage of the disease. In stage 1, a localized conjunctivitis with photophobia occurs in 10% of patients. This is mild and brief and ophthalmologists are rarely consulted. In stage 2, various ophthalmic complications have been described including cranial nerve palsies; these may occur within 1 month of the rash appearing. It is in the late stage 3 that most of the severe ocular complications are seen, including episcleritis, symblepharon, interstitial keratitis, uveitis, chorioretinitis and retinal vasculitis.

Parasitic infection

Phthiriasis (lice) [17,18]

An infestation of the eyelashes by the pubic louse, *Phthirus pubis*. It mainly affects children and causes chronic itching, irritation and rubbing of the lids. As with louse infection elsewhere, the adult lice can be difficult to see, though nits (eggs) and their shells are visible, adhering to the eyelashes (see Fig. 67.6c,d). The skin nearest to the base of the lashes may show small bluish spots due to the louse bites (maculae caeruleae). A number of measures have been used to treat louse infestation of the eyelids, including mechanical removal with forceps, epilation and trimming of infested lashes, and application of fluorescein, occlusive ointments (e.g. petrolatum) or aqueous malathion for 7 to 10 days.

Filariasis (onchocerciasis) [19]

Onchocerciasis or river blindness is caused by the filarial organism, *Onchocerca volvulus*. It is the second most common cause of preventable blindness in sub-Saharan Africa with an estimated prevalence of 500 000 cases with visual impairment and 270 000 with blindness. It appears that *Wolbachia endobacteria*, a bacterial symbiont, produces an endotoxin-like product which constitutes a major pro-inflammatory stimulus in the eye, causing corneal inflammation and sclerosing keratitis.

Protozoal infection

Ocular disease may complicate leishmaniasis. In *Leishmania donovani* infection, bilateral retinal haemorrhages may be a feature. In *L. tropica* and *L. braziliasis* infection, eyelid and corneal lesions occur, and subsequent destruction may lead to loss of the eye. In trypanosomiasis, unilateral oedema of the lids may occur.

Table 67.11 Inherited disorders affecting the skin and eyes.

Group	Condition	Inheritance	Ocular features
Bullous disorders	Acrodermatitis enteropathica [4]	AR (MIM #201100)	Loss of eyebrows and eyelashes, conjunctivitis, blepharitis, photophobia
Connective tissue disorder	Ehlers–Danlos syndrome [5]	Mainly AD (see MIM 130000)	Lax eyelid skin with redundant folds, epicanthal folds, hypertelorism, strabismus, blue sclera, corneal abnormalities including keratoconus, angioid streaks, ectopic lens. Retinal detachments occasionally occur
	Marfan's syndrome [6]	AD (MIM #154700)	Subluxation of lens—60–80% of patients in early childhood. Amblyopia, myopia, cataract, corneal abnormalities, glaucoma. Retinal detachment is most serious complication
	Pseudoxanthoma elasticum [7]	Types I & II AR (MIM #264800, 264810) Types III & IV AD (MIM #177850, 177860)	Angioid streaks (breaks in Bruch's membrane) in majority. Haemorrhagic maculopathy after trauma may cause visual loss
Dysplasias, hyperplasia, atrophies and aplasias	Ablepharon macrostomia [8] syndrome	Unknown (MIM 200110)	Absent eyelids and ectropion
	Aplasia cutis congenita [9]	AD (MIM #107600) AR (MIM 207700)	Congenital absence of skin leading to eyelid colobomas, corneal opacities, scleral dermoids and lamellar cataracts
	Blepharophimosis ptosis epicanthus inversus syndrome [10]	AD (MIM #110100)	Blepharophimosis, ptosis, epicanthus inversus, telecanthus. Amblyopia in 50% of patients
	Cockayne's syndrome [11]	AR (MIM *216400)	Corneal opacities, cataracts in 30%, retinitis pigmentosa, optic atrophy, strabismus, photophobia
	Dyskeratosis congenita [12]	XR (MIM #305000)	Obliteration of the lacrimal puncta in 80% of cases, conjunctivitis, blepharitis, ectropion, loss of eyelashes and eyebrows
	Ectodermal dysplasias—a complex group of disorders with various inheritance patterns and a variety of ocular findings [13]		
	Examples are given:		
	(i) Christ–Siemans–Touraine syndrome	XR (MIM #305100)	Photophobia, dry eye
	(ii) Fischer–Jacobson–Clouston syndrome	AD	Usually normal
	(iii) Ellis–van Cleveld syndrome	AR (MIM #225500)	Coloboma of iris, microphthalmia, occasional cataract
	Focal dermal hypoplasia (Goltz's syndrome) [14]	XD (MIM *305600)	40% have ocular abnormalities, the commonest being colobomas of iris, choroid, retina or optic nerve
	Fraser's syndrome [15]	AR (MIM *219000)	Bilateral or unilateral absence of palpebral fissure with loss of eyebrows, anophthalmia, microphthalmia
	Frydman's syndrome [16]	AR	Synophrys, blepharophimosis, weakness of extra-ocular and frontal muscles
	Hallerman–Streiff syndrome [17]	Unknown (MIM *264090)	Loss of hair of eyebrows and eyelashes, microphthalmos, cataracts, amblyopia and nystagmus
	MIDAS syndrome (MCOPS7) [18]	XD (MIM #309801)	Microphthalmia, sclerocorneal
	Pachyonychia congenita [19]	AD (PC1 MIM #167200 PC2 MIM #167210)	Cataract and corneal dyskeratosis
Hair disorders	Brachmann–Lang syndrome [20]	AR	Synophrys, long thick eyelashes, narrow palpebral fissure, myopia, nystagmus and strabismus
	Monilethrix [21]	AD (MIM #158000)	Loss of eyebrows and lashes
	Pili torti [22]	AR (MIM 261900)	Loss of eyebrows and lashes
	Chondrodysplasia punctata [23]	AD (MIM 215105) XR (MIM #302950)	Cataracts Ocular albinism, cataracts, microphthalmia
Keratinization disorders	The ichthyoses [24]		
	(i) Ichthyosis congenita gravis	AR (MIM *242500)	Severe ectropion
	(ii) Ichthyosiform erythroderma	AD (MIM 242100)	Early development of ectropion is characteristic
	(iii) Lamellar ichthyosis	AR (various types)	Cicatricial ectropion with exposure keratitis Direct conjunctival involvement may occur

(Continued)

Table 67.11 *Continued*

Group	Condition	Inheritance	Ocular features
	(iv) X-linked ichthyosis	XL (MIM *308100)	Deep corneal opacities
	KID syndrome [25]	XD (MIM #148210)	Keratitis
	Refsum's syndrome [26]	AR (MIM #266500)	Night blindness, posterior subcapsular cataracts develop in most cases
	Sjögren–Larson syndrome [27]	AR (MIM *270200)	Blepharitis, conjunctivitis, punctate corneal erosions and pigmentary degeneration of the retina
	Ulerythema ophryogenes [28]	AD	Erythema and perifollicular papules on eye to eyebrows spreading medially causing thinning of eyebrows (occurs in keratosis pilaris, Noonan syndrome, cardiofacialcutaneous syndrome)
Metabolic disorders	Alkaptonuria [29]	AR (MIM #203500)	Scleral pigmentation is early sign, eyelid pigmentation
	Angiokeratoma corporis diffusum [30]	XL (MIM *301500)	Angiokeratomas of conjunctiva, corneal opacities, posterior capsular cataracts
	Homocystinuria [31]	AR (MIM *236200)	Myopia, cataracts, subluxation of lens, secondary glaucoma, retinal detachment
	Hurler's syndrome [32]	AR (MIM *252800)	Early clouding of cornea
Neurocutaneous syndromes	Richner–Hanhart syndrome [33]	AR (MIM 276600)	Corneal lesions vary from erosions to deep ulcers Nystagmus and lens opacities
	Neurofibromatosis type I [34]	AD (MIM *162200)	Neurofibromas of eyelid, corneal clouding, Lisch nodules of iris, optic nerve glioma, palsies from cranial nerve involvement
	Neurofibromatosis type II	AD (MIM #101000)	Cataract fundus lesions, extraocular motility abnormalities
	Tuberous sclerosis [35]	AD (MIM #191100)	Tumours of the lids or nodules on conjunctiva and retina
Photosensitive disorders	Basal cell naevus syndrome [36]	AD (MIM #109400)	Basal cell carcinoma of eyelid and periorbital area, hypertelorism, strabismus, colobomas of the choroid, cataracts, glaucomas in 5–10%
	Bloom's syndrome [37]	AD (MIM #210900)	Telangiectasis on lower lids, blistering and scarring lower eyelids
	Rothmund–Thomson syndrome [38]	AR (MIM #268400)	Sparse eyebrows and eyelashes, degenerative changes in cornea, 50% of patients have bilateral cataracts which develop in childhood, strabismus
	Xeroderma pigmentosum [39]	AR (various types)	Angiomas, keratoses, papillomas, carcinomas develop on eyelids, sometimes extending on to conjunctiva and cornea, scarring and atrophy of lids with exposure keratitis leading to corneal ulceration symblepharon formation; ocular melanoma
	Chediak–Higashi syndrome [40]	AR (MIM #214500)	Oculocutaneous albinism, corneal opacities
Pigmentation disorders	Cross syndrome [41]	AR (MIM *257800)	Microphthalmia, small opaque cornea, coarse nystagmus
	Epidermal naevus syndrome [42]	Sporadic	Ocular melanocytic naevi, coloboma of the lids, iris and choroid; lipodermoid of conjunctiva or choroid
	Incontinentia pigmenti [43]	XD (MIM #308300)	35% of patients have eye abnormalities including strabismus, cataract and microphthalmia; retinal detachment may occur
	Hypomelanosis of Ito [44]	Sporadic (MIM *300337)	Hypertelorism, strabismus, myopia
	Oculocutaneous albinism [45]	AR (various types; Chapter 58)	Total loss of pigment in eyes, nystagmus, absence of binocular vision
	Piebaldism [46]	AD (MIM #172800)	Absent pigmentation medially of eyebrows, eyelids and eyelashes, heterochromia of iris
	Waardenberg's syndrome [47]	AD (MIM #193150)	Telecanthus, synophrys, partial albinism, heterochromia of iris
Vascular and haematological syndromes	Congenital telangiectatic cutis marmorata [48]	Unknown (MIM 219250)	Clouding of cornea, glaucoma
	Fanconi pancytopenia syndrome [49]	AR (MIM #227650)	Microphthalmia strabismus, nystagmus and colobomas
	Lymphoedema–distichiasis syndrome [50]	AD (MIM #153400)	Double row of eyelashes on upper and lower eyelids
	Sturge–Weber syndrome [51]	Sporadic (MIM 185300)	50% of patients have angiotomatous changes of the ipsilateral choroid causing glaucoma

AD, autosomal dominant; AR, autosomal recessive; XD, X-linked dominant; XL, X-linked; XR, X-linked recessive.

Ocular complications of dermatological therapy

A number of drugs used by dermatologists have significant side effects on the eye and require careful monitoring.

Corticosteroids [1–15]

The use of corticosteroids can cause significant side effects on the eye. Both systemic and topical corticosteroids are responsible, though the greatest risk is to those receiving prednisolone at a dose of 10–15 mg/day for over a year. Continuous therapy is more likely to cause side effects than intermittent therapy.

Posterior subcapsular cataracts are induced by long-term systemic corticosteroids in as many as 30% of patients. They rarely occur at doses less than 10 mg/day and for less than 1 year. Children are particularly vulnerable. Reversibility of cataracts is not common and progression of cataracts may occur in spite of reduction or discontinuation of corticosteroid therapy.

Patients also risk developing open angle glaucoma, particularly if genetically predisposed. The precise mechanism is unknown, though it is thought to be due to decreased aqueous outflow. Particular risk factors include type 1 diabetes, high myopia, connective tissue disorders and a family history of glaucoma. Topical corticosteroids induce a rise in intraocular pressure more quickly than systemic corticosteroids. Medium- or high-potency dermatological corticosteroids applied for long periods to, or near, the eyelids may spread over the lid margin and are absorbed through the cornea, reaching sufficient concentrations to elevate ocular pressures. Patients on long-term topical or systemic corticosteroids need to have their eye pressures monitored regularly at 1–6 monthly intervals depending on their degree of risk.

Topical corticosteroids predispose patients to cataract, glaucoma and secondary surface infection. Injudicious use in HSV infection masks the clinical signs of dendritic ulcer and risks perforation. Wearing a soft contact lens is a contraindication to topical ocular corticosteroid usage. Other ocular complications from corticosteroids include angioneurotic oedema, papilloedema from raised intracranial pressure and toxic amblyopia. Systemic treatment with corticosteroids may cause serous chorioretinopathy or diffuse retinal pigment epitheliopathy.

Oral retinoids [16–22]

Both isotretinoin and acitretin can cause ocular side effects. The most common is dry eye with associated conjunctivitis and blepharoconjunctivitis, giving rise to blurred vision. The blepharoconjunctivitis is frequently associated with staphylococcal infection. Exposure keratopathy and corneal ulceration rarely occur; asymptomatic corneal opacities may develop but resolve after 6–8 weeks. Patients should be warned that they may be unable to tolerate contact lenses whilst on retinoid therapy. Use of tear substitutes, humidification of the environment and lid hygiene measures help. Retinal abnormalities may also occur, with poor night vision and increased sensitivity to glare, and can be a significant problem in those who drive at night; pilots are not allowed to fly whilst taking isotretinoin due to the potential effects on night vision. The cause is unknown but may be due to competitive inhibition of ocular retinol dehydrogenase causing local vitamin A deficiency and reduction in rhodopsin formation. More serious side effects include papilloedema from raised intracranial pressure, optic atrophy and cataract. Although these are rare, a history of visual disturbance should be asked for when patients come for follow-up. Severe headache early in the course of treatment is significant. The ocular manifestations are dose-dependent and usually reversible, provided they are recognized and the treatment regimen adjusted. However, there have been reports of the dry eye syndrome and night blindness persisting after retinoids have been discontinued.

Antimalarials [23–27]

The most serious potential side effect of antimalarial drugs is retinopathy. The mechanism is uncertain but seems to depend on the ability of the drug to bind the retinal pigment epithelium. Ocular side effects from antimalarials are much less common now that hydroxychloroquine rather than chloroquine is the drug of choice. However, both drugs should be used with caution in patients with hepatic or renal impairment. The Royal College of Ophthalmologists and American Academy of Ophthalmologists have issued clear guidelines on screening protocols for use of chloroquine and hydroxychloroquine. Baseline ophthalmic assessment of patients, for whom these drugs are proposed, is carried out by the dermatologist and requires questioning the patient about any known visual impairment (uncorrected by spectacles) and the recording of near visual acuity using a test type. If visual impairment is reported or detected then referral to an optometrist is advised; the optometrist will refer any patient with abnormal findings to an ophthalmologist. Patients should not be treated with more than the maximum daily dosage (hydroxychloroquine at a maximum dosage of 6.5 mg/kg or chloroquine phosphate not exceeding 4 mg/kg daily) and should have this visual screening repeated annually and recorded in their notes. Referral to an ophthalmologist is appropriate if visual impairment is detected at baseline, if changes are detected on the annual screening or if the patient develops visual symptoms. The ophthalmologist will then carry out a range of tests, including visual acuity, colour vision, visual fields, Amsler fields, corneal and retinal examinations. If long-term treatment is required, for more than 5 years, the risks of ocular complications are increased; in this instance, individual arrangements for screening should be agreed with a local ophthalmologist. No screening is recommended for mepacrine as it is not associated with ophthalmological side effects.

Antibiotics for acne [28–32]

Oxytetracycline, minocycline and doxycycline can all cause raised intracranial pressure. The mechanism is unknown but is thought to be related to interference with energy-dependent absorption mechanism of cerebrospinal fluid, which is mediated by cyclic adenosine monophosphate (AMP) at the arachnoid granulations. Patients who complain of headache should be examined carefully

with fundoscopy through dilated pupils to look for papilloedema, and should have formal testing of visual acuity and of visual fields. The condition is far from benign; permanent visual field loss can occur if the condition is not recognized early and the drug stopped. Sometimes treatment with acetazolamide is required to reduce the pressure. Erythromycin or trimethoprim may cause erythema multiforme and associated ocular changes. Pigmentation due to minocycline can occur in the skin (Chapter 58) and has also been reported in the sclera.

Psoralens [33–46]

Psoralens have been shown to bind to the lens proteins, and some animal studies have shown induction of anterior cortical opacities though others have not. 8-Methoxypsoralen can be detected in the human lens 12 h after oral ingestion. There has been a longstanding concern about the risk of cataract in patients having psoralen and long-wave UV radiation (PUVA) therapy. Although PUVA has been used in treatment of skin diseases for 30 years, and clinical studies have not yet shown any convincing evidence of an increase in cataract as compared with the general population, it is still recommended that ultraviolet light A (UVA)-filtered spectacles are used for 12 h after ingestion of psoralens in case significant long-term sequelae eventually develop. Failure to do so may result in other signs of ocular toxicity such as conjunctival hyperaemia, decreased lacrimation and pinguecula formation, which represents elastotic degeneration of the cornea. Care must be taken to ensure that the spectacles are suitable for ultraviolet protection.

Botulinum toxin [47]

With the increased use of botulinum toxin for the treatment of facial wrinkling and eyebrow position dermatologists need to be aware of the potential side effects. These include haematoma, ptosis, ectropion, diplopia and eyelid drooping, and are often related to poor injection technique.

Tumours

Benign tumours of the eyelid

As would be expected of such complex tissue, the eyelid gives rise to a large number of skin tumours. Tumours can arise from the epidermis and dermis in addition to the adnexal structures, which include the meibomian and Zeis sebaceous glands, eccrine and Moll's apocrine sweat glands, and the specialized hair follicles of the eyelashes. They may also originate from lymphoid neural and vascular tissue found in the preseptal tissues of the eyelid. Although optimal treatment of the tumours begins with accurate diagnosis, many are rather non-specific in their appearance and are only diagnosed with certainty by histology.

Keratoses

Both seborrhoeic and actinic keratoses occur on the eyelid. They have similar clinical features to those elsewhere on the skin and are treated in the same way with local destructive measures, using carefully applied cryotherapy, curettage and cautery or laser ablation under local anaesthetic. Recurrent actinic keratosis should be biopsied and sent for histological examination to make sure it is not a deceptive manifestation of an early skin cancer.

Xanthelasma [1,2]

These present as yellowish cutaneous plaques, most commonly located on the medial part of the eyelids. They are usually bilateral and are much more common in elderly patients. About 60% of patients have an associated hypercholesterolaemia and lipid levels should be measured. Patients often request treatment for cosmetic reasons. Although 90% trichloroacetic acid applied with a cotton wool bud is used there is a significant risk of spillage into the eye. More effective treatment is by surgical excision or ablation with carbon dioxide laser. Necrobiotic xanthogranuloma may look similar to xanthelasma but they are thicker and more nodular. These lesions may involve the conjunctiva and sclera. On the rare occasions that they infiltrate the orbit they may cause proptosis.

Juvenile xanthogranuloma [3]

These lesions occasionally involve the eyelid, conjunctiva or uveal tract. They may be associated with glaucoma and threaten sight. Patients need screening by an ophthalmologist (Fig. 67.12).

Adnexal tumours [4]

Syringomas, milia, trichoepitheliomas and tricholemmomas present as small papules around the eyelids. They can be very difficult to distinguish from each other. Syringomas are the most common, but histology from a biopsy is the only way to make a definite diagnosis. Treatment is by local destruction of the lesions. Eccrine hidrocystomas can present in an eruptive fashion on the face and eyelids; they may respond to topical atropine.

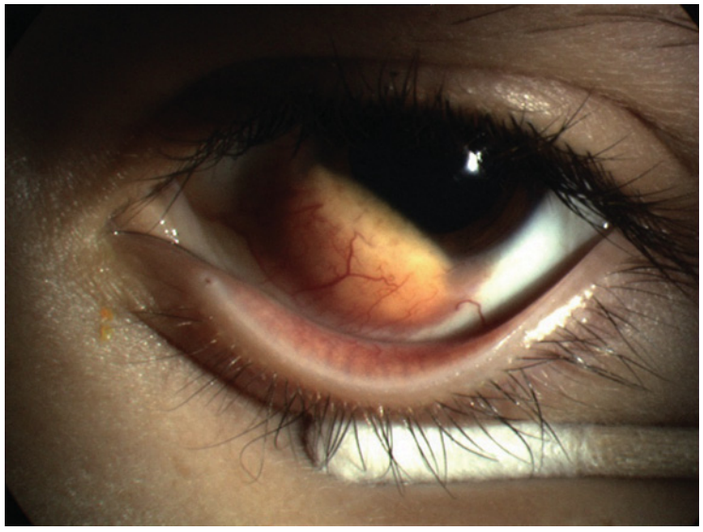

Fig. 67.12 Juvenile xanthogranuloma.

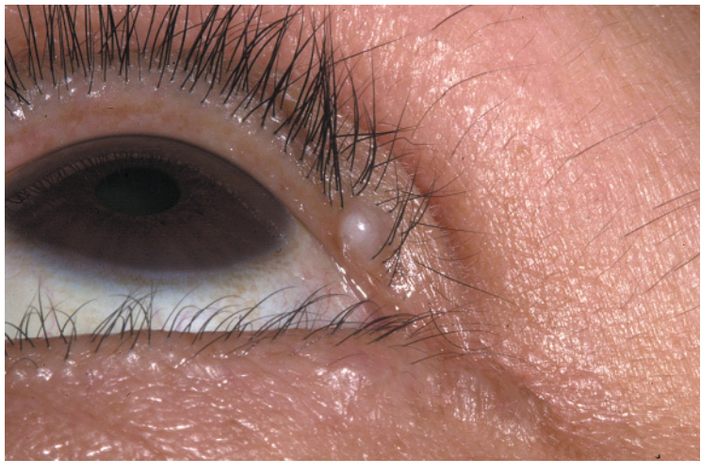

Fig. 67.13 Cyst of Moll. Small translucent cyst on anterior lid margin. (Courtesy of Mr N. Joshi, Chelsea & Westminster Hospital/Medical Illustration UK, London, UK.)

Benign cysts of the eyelid

Retention cysts may arise from either the glands of Moll or of Zeis. A cyst of Moll usually presents as a small translucent lesion on the anterior lid margin close to the lacrimal punctum (Fig. 67.13). Glands of Zeis are sebaceous glands and their retention cysts contain oily secretions and are more opaque than a cyst of Moll. An eccrine gland hidrocystoma is similar in appearance to a cyst of Moll but is not confined to the lid margin. These cysts are easily confused with a basal cell carcinoma clinically and are treated by excision and submission for histology.

Chalazion [5]

This lesion represents a chronic granulomatous inflammatory reaction around a blocked sebaceous gland. Patients with seborrhoeic dermatitis and rosacea are at increased risk of chalazion formation. A chalazion presents as a firm lump in the eyelid, which is clearly visible when the lid is everted; an association with chronic posterior blepharitis is common. Chalazia will usually resolve spontaneously but large and troublesome lesions can be treated by everting the lid with a special clamp, incising the cyst and curetting the contents through the tarsal plate. Patients who develop recurrent chalazion associated with seborrhoeic dermatitis and rosacea benefit from long-term antibiotic treatment using tetracyclines. Hot saline compresses reduce the inflammation.

Pigmented naevi [6,7]

The skin on the eyelid can develop pigmented naevi. Their appearance, classification and potential malignant change applies as elsewhere on the skin. Patients with dysplastic naevus syndrome should be referred to an ophthalmologist for ocular assessment. Melanocytic lesions of the conjunctiva extending onto the cornea or pigmented lesions of the conjunctiva, which change in character, should also be referred with a view to excision biopsy.

Naevus of Ota [8]

This lesion affects the eyelids, conjunctiva and sclera. Occasionally, the pigmentation is confined to the eye with no cutaneous involvement. Naevus of Ota carries an increased risk of ocular melanoma and glaucoma and patients need to be referred for ophthalmic examination and long-term review.

Melanoacanthoma [9]

These are small, shining, black papules situated along the line of the lashes and are a form of dermatosis papulosa nigricans.

Vascular naevi [10–13]

Strawberry naevus (capillary haemangioma) can affect the eyelids. It is more common on the upper lid and presents as a unilateral, red, raised lesion, which grows quickly during the first year of life (Fig. 67.14). Spontaneous involution occurs usually by age 9 years. Amblyopia is the main complication of larger periorbital lesions and results either from physical closure of the eye and occlusion of the pupil, giving rise to stimulus deprivation, or from refractive errors caused by corneal distortion due to lid pressure. Both systemic and intralesional corticosteroids can reduce the bulk of the haemangioma. Surgical resection or laser therapy is helpful in certain cases.

Port-wine stain

This is a rare, congenital, vascular lesion, which may affect the eyelids. It presents as a sharply demarcated red patch. Extensive lesions involving the periocular region have a high risk of central nervous involvement and of ipsilateral glaucoma (especially if the upper lid is involved), which may not develop until adult life.

Keratoacanthoma

Keratoacanthomas may develop on the eyelid. They present as a small papule, which grows rapidly developing a characteristic keratin-filled crater and may reach up to 3 cm in diameter (Fig. 67.15). The lesions then stop growing and remain static for 2 or 3 months before spontaneously involuting, which can lead to significant scarring of the eyelid. Because of this, the lesion should be excised at an early stage.

Malignant tumours of the eyelid [14–16]

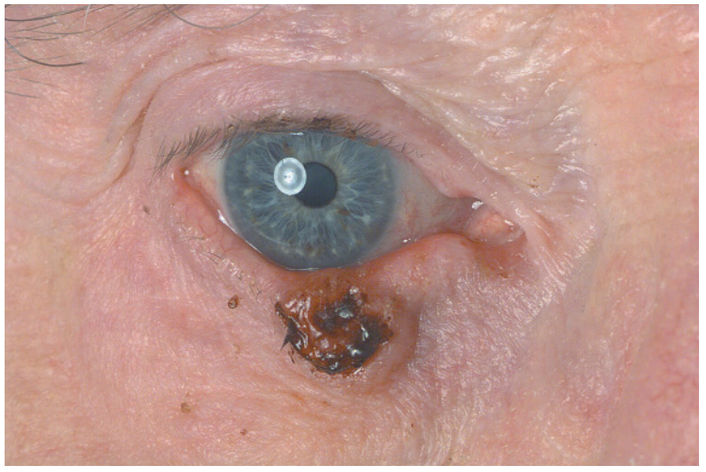
Basal cell carcinomas (BCCs), squamous cell carcinomas (SCCs) and malignant melanomas all occur on the eyelid as on other areas of the skin. The same rules for management apply on the eyelid as at any site, but the eyelid poses specific problems in preserving good cosmesis and residual function. Clinical examination is an unreliable way of determining the extent of many of these lesions, particularly sclerosing BCC. Early referral to an oculoplastic surgeon is advisable with a view to Mohs micrographic surgery if appropriate.

Basal cell carcinomas [17–19]

These are the most common skin malignancy and in most series account for 90% of malignant tumours. They rarely metastasize but cause problems by local tissue destruction and invasion of periorbital tissue. Over 70% arise on the lower eyelid, followed in order of frequency by the medial canthus, upper eyelid and lateral

canthus. Tumours located near to the medial canthus can invade the orbit and sinuses. They are more difficult to excise than those elsewhere, because of the high risk of damaging the tear duct. The majority of BCCs are solid or cystic and fairly straightforward to recognize (Fig. 67.16). Sclerosing or morphoeic BCCs are less common and can be difficult to diagnose as they infiltrate beneath the epidermis, forming a flat indurated plaque with indistinct margins, which may simulate a localized area of chronic dermatitis. The paucity of reticular dermis and subcutaneous fat to resist deep invasion presents a particular problem with the eye. Once the orbital septum is penetrated the BCC can rapidly invade, threatening the orbit. At the medial canthus the lacrimal sac and the rich anastomosis of blood vessels offers little barrier. Curettage and cautery is generally not advised for the treatment of eyelid lesions. The skin is thin and tears easily and the sensitivity of the curette is lost in the soft tissue. Successful initial treatment with surgery and accurate margin assessment to ensure complete excision is mandatory in management of these tumours. Mohs micrographic surgery is usually the treatment of choice where margins are in doubt. Radiotherapy damages and scars the eyelid tissues and lacrimal system and should be reserved for situations when surgery is otherwise inappropriate. Cryotherapy is best avoided due to the risk of leaving residual tumour.

Squamous cell carcinomas [20]

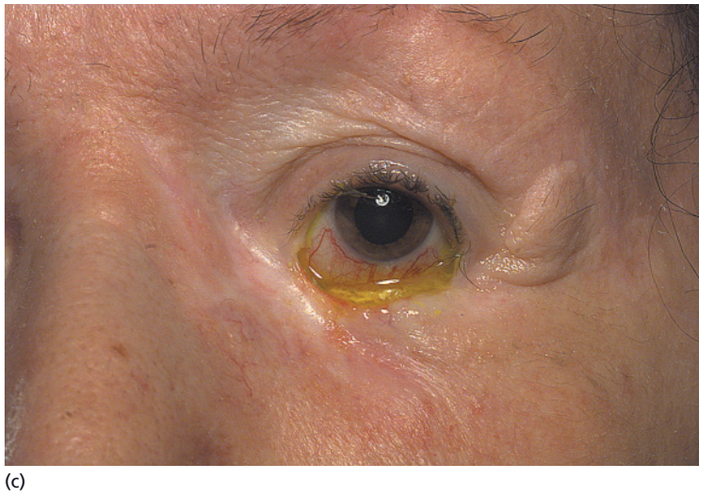


This is much less common than BCCs, accounting for between 5 and 10% of eyelid malignancies. SCCs occur on a background of marked actinic damage. They mainly affect the lower eyelid and lid margin, and may arise *de novo* or from pre-existing actinic keratoses. SCC of the eyelids may be nodular, plaque like or ulcerated (Fig. 67.17). Excision with adequate margins is the treatment of choice. Tumours greater than 2 cm in diameter and those with deep penetration have a higher risk of metastasis. Histological evidence of poor differentiation or of perineural invasion are also poor prognostic factors requiring more aggressive treatment. Mohs micrographic surgery is indicated where the initial margins are not free of tumour, and offers a good long-term prognosis. As with BCC, cryotherapy and radiotherapy are reserved for situations where surgery is inappropriate.

Malignant melanoma

This may occur on the eyelids or conjunctiva. As elsewhere, melanomas are characterized by a change in size, shape or colour of a pigmented lesion (Fig. 67.18). However, a significant proportion of lid melanomas are amelanotic and this may give rise to difficulties with clinical diagnosis.

Sebaceous gland carcinoma and epithelioma [21,22]



These are very rare tumours, accounting for less than 1–5% of malignant tumours of the eyelid. Sebaceous gland carcinoma usually arises from the meibomian glands, occasionally from the glands of Zeis. In contrast to BCC or SCC, the majority of lesions affect the upper lid. Most lesions are nodular and look very much like a chalazion (see Figs 67.6a,b & 67.19), causing delay in diagnosis; a sebaceous tumour should always be suspected if a 'chalazion' lasts for more than 6 months, and a 'chalazion' that recurs should be viewed with great suspicion, excised and sent for histol-

(a)

(b)

(c)

ogy. Because of late diagnosis, sebaceous gland carcinoma carries a significant mortality. Wide local excision is the treatment of choice. The multicentric nature of the tumour may limit the use of Mohs surgery.

Eccrine carcinoma [23]

These are rare cancers of the eye and may present as an indurated thickening of the lid or with a signet-ring appearance. They are commonest in middle-aged or elderly men and recur after excision.

Merkel cell carcinoma

A very rare tumour. It can also mimic a chalazion in its early stages, with delay in diagnosis. It is highly malignant and has often metastasized by the time of excision.

Kaposi's sarcoma

A vascular malignancy. It presents as a purple lesion on the eyelid or conjunctiva and can be mistaken for a benign haemangioma. However, it grows rapidly and may ulcerate and bleed. When it presents on the eyelid it is associated with AIDS, of which it may be the sole manifestation at the time of presentation. These lesions are very radiosensitive, and this is the preferred mode of treatment once a biopsy has been taken to confirm the diagnosis.

Anatomy and physiology [1–3]

The external ear consists of the auricle, the external auditory canal and the outer layer of the tympanic membrane.

The auricle, or pinna (Fig. 68.1), is a convoluted, elastic and cartilaginous plate covered by skin which is continuous medially with the lining of the external auditory canal. Except on the non-cartilaginous lobe and at the back of the ear, the skin is bound firmly to the cartilage. The auricle is attached to the head by fibrous ligaments and three vestigial auricularis muscles. The size and general detail of the auricle can vary greatly between individuals, and may be characteristically affected in a number of congenital syndromes. In humans, the auricle is largely functionless and motionless.

The epidermis of the ear has a complex dermal–epidermal junction, a conspicuous stratum granulosum and a thick, compact stratum corneum [4]. The dermis contains abundant elastic tissue. Sebaceous glands are numerous, particularly on the tragus and lobe, and fine vellus or terminal hairs occur over the entire surface, but are especially prominent on the helix and tragus. Coarser terminal hair is seen in some men, possibly as a Y-linked and androgen-dependent inherited trait (OMIM 425500) (Fig. 68.2). Eccrine sweat glands are sparsely and irregularly distributed except in the external auditory canal, which has, instead, a large number of modified apocrine or ceruminous glands. The pinna has a variably thick fatty layer that extends between the perichondrium and the reticular dermis and that also forms the main fibrofatty core of the lobe of the ear.

The blood supply to the auricle is provided by anastomosing branches of the superficial temporal and posterior auricular arteries, which drain via posterior auricular and superficial temporal veins into the external jugular vein and via the superficial temporal, maxillary and facial veins into the internal jugular vein. Lymphatic drainage is to the superficial parotid, retroauricular and superficial cervical lymph nodes. Embryonic fusion planes and minute deficiencies in the cartilaginous portion of the external auditory canal provide potential pathways for the spread of infection and tumours.

There is a complex nerve supply to the ear involving elements of the Vth, VIIth, IXth and Xth cranial nerves as well as cervical branches of the greater and lesser auricular nerves. The back of the ear is supplied by the greater auricular nerve (C2,3), the concha by the auricular branch of the vagus (Xth) and the anterior part of the pinna and the external auditory canal by the auriculotemporal branch of the Vth cranial nerve. Intercommunicating branches of the VIIth, IXth and Xth supply the deeper parts of the ear. With this complicated nerve supply, otalgia is more commonly due to referred pain than to disease in the ear itself [4]. Within the dermis, the nerve supply is abundant, especially around hair follicles where there are complicated basket-like networks of acetylcholinesterase and butyrylcholinesterase nerve fibres [5]. Free nerve endings are also present, but there are no organized nerve endings as occur on glabrous skin elsewhere.

The external auditory canal extends upwards and backwards in an S-shaped curve from the concha to the tympanic membrane. The angle of curvature varies between races and individuals, being more marked in white people than in black people or Polynesians. This has a bearing on trauma, infection and the retention of moisture. The length of the canal is 2.5 cm as measured from the concha to drum. The outer third of the canal is cartilaginous and is lined by a thicker layer of skin than the inner portion within the temporal bone. Anteroinferiorly there are two horizontal fissures in the cartilaginous canal, the fissures of Santorini. These can allow infection or tumour to pass beyond the external auditory canal, for example to the parotid gland. Subcutaneous tissue is scanty, and the epithelium is firmly bound to the perichondrium. Sebaceous glands are plentiful, and open into the follicles of extremely fine vellus hairs. Occasionally, larger terminal hairs (tragi) arise in the canal or around the meatus and these, if they become matted with

Fig. 68.2 Coarse terminal hair on the auricle: a trait possibly associated with the Y chromosome.

wax or debris, may interfere with normal epidermal 'migration' and ventilation of the ear and hence may play a part in the development of 'hot-weather ear' (see p. 68.21).

Eccrine sweat glands are not present in the auditory canal but modified apocrine (ceruminous) glands are numerous. They increase in size and activity at puberty. There is great individual and racial variability, and although concentrated in the cartilaginous part of the canal, they may also occur, albeit sparsely, in the osseous portion.

The inner osseous part of the acoustic canal constitutes two-thirds of its total length. The skin is firmly bound to the periosteum, subcutaneous tissue being nearly absent and only 30–50 µm thick. The epidermis here is thin and easily traumatized, and rete ridges are absent [1]. The skin of the external auditory canal and tympanic membrane is unique in that there is no frictional loss of stratum corneum; cerumen (wax) and epithelial debris have therefore to be removed by a special 'migratory' property of the external ear canal epithelium [5]. A slight narrowing of the canal, the isthmus, occurs at or just medial to the junction of the two parts. When marked, it may impede the flow of cerumen to the exterior. Just medial to the isthmus, inferiorly and anteriorly, is the tympanic sulcus. Debris often collects here, especially in patients with chronic external otitis.

The surface pH of the auditory canal varies from 5.6–5.8 at the concha to 7.3–7.5 at 5–10 mm within the canal. With inflammation, the pH becomes slightly more acid.

Microbiology

The skin of the external auditory canal in most healthy individuals supports the growth of multiple bacterial species, especially *Staphylococcus epidermidis*, *Corynebacterium* spp., *Bacillus* spp. and less often *Staphylococcus aureus*. *Pseudomonas aeruginosa*, often relevant to external otitis, and fungi are not normally found [2]. The normal flora can include organisms such as *Turicella otidis*, which can cause otitis media [6].

Cerumen (wax) [7]

Cerumen is the combined product of sebaceous and apocrine glands. It contains both squalene and insoluble fatty acids. Analysis by flash pyrolysis–gas chromatography/mass spectrometry has shown numerous diterpenoids [8]. Its main function is to waterproof the external auditory canal. Extrusion is aided by mastication and by the peripheral movement and desquamation of the epithelial cells of the canal. It is impeded if the ear canal is too narrow or tortuous, or when inflammation interferes with the normal process of 'migration'.

There are genetically determined differences in cerumen composition and character: so-called 'dry' ear wax is light grey, dry and flaky; 'wet' ear wax is golden brown and sticky. The former is very common in Asians. Wax phenotype is determined by a single gene pair, the wet wax allele being dominant [7]. Cerumen darkens with exposure to air.

Although not bactericidal, cerumen does not encourage bacterial or fungal growth. It is likely that antimicrobial peptides play a role [9]; other possible reasons include the presence of lysozyme, immunoglobulins and polyunsaturated fatty acids.

Two populations have been shown to have excessive production and/or impaction of cerumen: individuals with mental retardation and the elderly [7]. An increased secretion of cerumen occurs in patients treated with aromatic retinoids [10,11].

If wax becomes impacted or adherent, it can cause various symptoms such as hearing loss, tinnitus, vertigo, pain and itching, and can be a contributory factor to external otitis. It may be removed by irrigation techniques or by suction under direct vision

[12,13]. A systematic review found no clear evidence that pharmaceutical agents have any proven value over irrigation with water [14]. It is possible that simple solutions such as 10% aqueous sodium bicarbonate or 2.5% aqueous acetic acid can be helpful in children [15]. Regular use of an emollient liquid may have a role in prevention of impaction [16]. Inflammation interferes with normal epidermal migration and tends therefore both to induce and to encourage the retention of scale. The pruritus associated with excess cerumen, and the low-grade inflammation that often accompanies this, frequently leads to a persistent form of low-grade neurodermatitis. Recently, 1% pimecrolimus has been shown to be effective when other measures have failed [17].

Contact dermatitis from medicaments or irritant cerumenolytics [18] is well recognized.

Examination [1]

As well as examining the pinna, the dermatologist may need to examine the ear canal. Equipment available should include a headlight or equivalent, otoscope, several sizes of ear speculae, ear curettes, metal applicators, bayonet forceps, ear irrigation apparatus and cotton.

General inspection of the auricles should take account of their symmetry, size, shape and position, and completeness of development.

The ear canal is best inspected when the auricle is pulled gently upwards, outwards and backwards, and the largest possible speculum is used. It is essential to avoid traumatizing the thin skin of the canal, particularly beyond the isthmus. If inspection reveals accumulation of cerumenous debris, this can sometimes be removed carefully using a curette or wire loop along the posterior wall. If the material is against the drum, gentle suction may be feasible. Irrigation should only be used if the drum is known to be intact.

Samples may need to be taken for bacteriology, mycology and histology. If a biopsy is required from the canal, this should be devolved to a surgeon with the necessary expertise.

Developmental defects

The auricle begins to develop at the end of the fifth week of embryonic life in the first branchial groove, contributed to by the first (mandibular) and second (hyoid) arches [1]. Six hillocks appear on these arches and later fuse to form the complex shape of the fully developed auricle. Inspection of the external ear at birth is important in the overall assessment of the neonate but interpretation can be complicated by the effects of birth trauma [2].

Developmental defects are considered in detail in Chapter 18. Only those defects of the ear sufficiently common to constitute a part of general dermatological practice are therefore considered here, together with some general principles relating to congenital ear abnormalities and their more important medical and otological associations [3–7]. Pinna abnormalities are associated sufficiently often with conductive hearing loss that screening tests should be carried out [8].

About 30% of infants with external ear anomalies have a renal anomaly identifiable by ultrasound examination, and this combination is a strong pointer towards a multiple congenital anomaly syndrome, in particular Townes–Brocks, CHARGE, branchio-oto-renal, Nager and diabetic embryopathy syndromes [9].

Many developmental defects are of unknown aetiology. Some, however, are associated with chromosomal abnormalities, for example those occurring in Down's syndrome, or are associated with syndromes that have well-recognized Mendelian inheritance patterns, for example the *e*ctrodactyly, *e*ctodermal dysplasia and *c*left lip–palate (EEC) syndrome. Environmental factors may be implicated as in fetal alcohol syndrome and fetal hydantoin syndrome, and maternal exposure to isotretinoin and thalidomide.

Congenital ear abnormalities exhibit great variability, even within syndromes or families, and any one aetiological factor may be associated with a variety of ear malformations. External ear malformations as part of a genetic syndrome account for less than 10% of all external ear abnormalities; isolated cases of ear malformation may either be non-genetic in origin or may have a genetic basis but with poor gene penetrance [10].

Microtia (small ears) [11]

Microtia designates a spectrum of underdevelopment of the pinna, from small ears to absence of an ear or ears. Small ears are often associated with hearing deficit and may be a feature of many syndromes. In addition to being small, the pinna may be rudimentary, resembling the hillocks from which it is embryologically derived. The more primitive the appearance, the greater the likelihood of hearing abnormalities, in most cases due to defects or atresia of the ossicles. There may also be a narrowing or atresia of the auditory canal [10–13] and various abnormalities of the middle ear [14] and inner ear [6]. A wide variety of non-aural abnormalities are associated with small ears, multiple malformations occurring in 56% in one large series [15]. Small ears are a feature of many syndromes, including Down's syndrome, Treacher Collins syndrome, Goldenhar's syndrome, Apert's syndrome, various first and second branchial arch and first branchial cleft syndromes, Mohr's orofaciodigital syndrome, Duane's retraction syndrome and thalidomide embryopathy [6,7,16].

Familial microtia inherited as an autosomal dominant trait has been described [17]. Microtia is one of the birth defects that occurs more on the right than the left side [18].

Macrotia (large ears)

Macrotia is a developmental variation in which the amount of tissue between the helix and antihelix is increased, causing the ears to wing out. The ear may also be diffusely enlarged, or elongated. Such changes are common in Turner's syndrome, and there may be associated sensorineural deafness. Large ears are well described in fragile X syndrome [19] and Kabuki's syndrome, although in the latter they may also be smaller than normal [20]. Generally enlarged ears are sometimes seen in patients with the XXXXY chromosome defect. The cartilaginous parts of the ears are enlarged and soft in Laband's syndrome [21,22]. In this rare disorder the ears are large and floppy, in association with a bulbous soft nose, gingival fibromatosis and a variety of other findings including absence or dysplasia of nails and/or of terminal phalanges, hyperextensibility of joints, hepatosplenomegaly, and rarely hypertrichosis and mental retardation.

Low-set ears

Normally, the top of the helix is at the same level as the eyebrow, the earlobe is above the angle of the mandible and the external auditory meatus is at the level of the ala nasi. Low-set ears may in addition be posteriorly rotated, and are often small. The condition is usually bilateral. Although it may be isolated, it is often associated with major middle-ear or systemic malformations, appearing for example in Turner's, Noonan's, Patau's and Crouzon's syndromes.

Periauricular anomalies

Pre-auricular pits, sinuses (Fig. 68.3) and tags are relatively common, with an incidence of approximately 1% [10,23]. Lesions on or near the tragus are probably best termed 'accessory tragus' [24]. The term 'accessory auricle' is sometimes used for this, and for similar firm elevations of skin and cartilage just near the ascending crus of the helix. They may be single or multiple, and may occur anywhere in a line from the tragus to the angle of the mouth. Accessory auricles, congenital fistulae and other external ear manifestations may occur alone or may be associated with more widespread first and second branchial arch abnormalities, for example Treacher Collins and Goldenhar's syndromes [4,5,9,23], or with developmental abnormalities of the genitourinary tract [9,23], as well as with isolated hearing defects. Because of the association with renal abnormalities, it has been recommended that a renal ultrasound scan should be performed if there is a pre-auricular pit or sinus associated with one or more of the following: another malformation or dysmorphic feature, a family history of deafness, auricular and/or renal malformations, or a maternal history of gestational diabetes [25].

Fig. 68.3 Pre-auricular sinus.

Variations in the shape of the pinna

Minor variations in size and shape are common and not usually associated with any other abnormality. These include *bat ear* or protruding ear, in which the antihelix lacks the usual bulge; *lop ear*, in which there is an unrolled helix, a poorly developed antihelix and scapha, and a large concha resulting in a somewhat floppy ear; and *prominent auricular* (*Darwin's*) *tubercle.* Variations in the contour of the helix and antihelix to produce a bulge of the anterosuperior part of the pinna account for so-called *Mozart's ear*, and in *Wildemuth's ear* the antihelix is prominent and the formation of the helix is poor. These minor ear anomalies can be a syndromic feature or can be associated with conductive and occasionally sensorineural hearing loss, but in most instances they are isolated. They may, however, be inherited, as in the Mozart family. A distinctive *railroad track abnormality* with marked prominence of the crus of the helix is said to occur in up to 30% of children with fetal

alcohol syndrome [12,16] and a protruding auricle may, rarely, be a sign of neuromuscular disease [26]. Various abnormalities of the configuration of the pinna have been described in the distinctive *lumpy scalp syndrome* [27], in which other features include absent or rudimentary nipples and dermal nodules on the scalp [28]. The lobule can show isolated abnormalities, for example pits and clefts. Absence of the lobule is, however, usually associated with a syndrome of a more serious nature [7]. Diagonal linear creases in the lobule are seen in Beckwith–Wiedemann syndrome, and in adult life in association with some degenerative diseases (see p. 68.6), although they are also a common finding in normal individuals.

Developmental anomalies of ear hair

Hypertrichosis of the pinnae (OMIM 425500) was originally described as a Y chromosome-linked trait [29]. An autosomal dominant genetic basis for hairy ears has also been noted in South Indians [30] and Maltese [31]. Acquired hairy ears have been described in infants born of diabetic mothers [32,33] and in association with human immunodeficiency virus (HIV) infection [34].

Management [11,35]

The infant with obvious malformation of the pinna that might have auditory system or other associations should be assessed by a paediatrician. The history may reveal exposure to a teratogen (e.g. isotretinoin) or family history of a syndrome and examination may show evidence of other anomalies. Investigations may include radiological evaluation [36], an auditory brainstem evoked response hearing test and a renal ultrasound. It may be appropriate for an ear, nose and throat (ENT) specialist and plastic surgeon [37,38] to become involved with correction of complications and the physical deformity, respectively.

Ageing changes

Many changes seen on the skin of the pinna attributed to ageing are a result of its exposure to environmental factors, especially UV radiation, cold (perniosis) and infrared radiation. The elderly exposed pinna often shows varying degrees of dermal and epidermal atrophy, solar keratoses and lentigines, solar elastosis, telangiectasia and venous lakes. If the pinna is at least partially

light-protected, as in many women, the skin may still appear somewhat thinned due to intrinsic ageing changes.

Ear length

It is recognized in Chinese culture that length of the ear in men is a predictor for longevity [1]. Two studies would appear to confirm this: one from Kent, UK [2], and one from Japan [3]. The increase in length of the male ear from the age of 30 years onwards may have a 7-year periodicity [4].

Earlobe creases

First described in 1973 [5], and now known as Frank's sign, a diagonal crease in the earlobes of adults has been associated in many studies with an increased risk for atherosclerotic coronary artery disease. A meta-analysis in 1983 gave a relative risk of 2.06 for heart disease if there are bilateral creases [6] and there is approximately double the risk for death from heart disease [7,8]. The crease can be graded in terms of length and depth, and deeper, longer creases have the strongest association. The ear crease appears to be separate from other risk factors for coronary artery disease, and is not simply a function of age [9]. A more recent case–control series suggested a relative risk of 1.37 for myocardial infarction [10]. The positive predictive value of the diagonal ear crease sign remains controversial: in one series of patients from London it was only 16% [11] whereas in another from Turkey it was 89% [12]. It is probably of greater significance in people under age 40 years [13].

Diagonal earlobe creases are seen in other contexts, for example Beckwith–Wiedemann syndrome [14] (Fig. 68.4), and do not seem to be associated with coronary artery disease in Hawaiians [15], native Americans [16] or Chinese [17].

Earlobe creases have also been associated with primary open-angle glaucoma [18].

Traumatic conditions

Contusion and haematoma

Bruises of the ear are usually due to blunt trauma and are common in contact sports, such as boxing, wrestling and rugby. In children, physical abuse may need to be excluded [1,2]. A distinctive condition known as *tin ear syndrome* has been considered pathognomonic of child abuse: a triad of isolated ear bruising, haemorrhagic retinopathy and a small, ipsilateral subdural haematoma [3].

Following trauma, blood and serum collects in the plane between perichondrium and cartilage, and will undergo fibrosis if not removed early. The patient should be carefully examined for concurrent auditory canal, middle ear, parotid and central nervous system trauma.

Repeated trauma may result in the distorted nodular deformity known as *cauliflower ear*, which is due to varying degrees of cartilage necrosis, fibrosis and dystrophic calcification.

Treatment. Subperichondrial haematomas must be treated promptly, with full aseptic technique to avoid secondary perichondritis. Small collections of fluid can sometimes be aspirated by syringe, but usually need to be drained through a small incision and a laterally placed pressure dressing applied to prevent reaccumulation [4,5]. Another useful technique is to use a through-and-through suture technique to maintain bolsters over the area where the haematoma has been evacuated [6]. Other approaches include a posterior incision and suction drainage [7], or fenestrations in the cartilage to promote adhesion of the opposing perichondrial layers [8]. Prophylactic antibiotics are sometimes given.

Improvement of cauliflower ear usually requires multiple corrective procedures.

Laceration and avulsion

Lacerations of the pinna vary from the trivial to amputation [1]. Because of the risk of cartilage infection, potentially dirty wounds should always be carefully cleaned and a course of prophylactic antibiotic given. It is probably best to avoid suturing the cartilage itself unless pieces overlap or are severely displaced [2]. Injuries that expose cartilage will need to be covered with a skin graft, for example taken from behind the ear or the upper eyelid. If the anterior perichondrium is destroyed, cartilage may need to be excised so that the graft can be placed on the posterior perichondrium. If the post-auricular area is not injured, a pedicled island flap of post-auricular skin may be pulled through the area of excised cartilage and sutured into place. If the helix or antihelix is exposed, it may be possible to cover it with an advancement or rotation flap from the posterior surface of the auricle. Large areas may need to be covered with a pedicled flap of temporoparietal fascia, which in turn is covered with a split-skin graft. The lobule of the ear can be repaired by direct closure, although a cosmetically superior result may be obtained by a broken line repair or Z-plasty [3]. Many techniques have been described for repair of major trauma, including even complete avulsion of the pinna [1,4,5], but these are likely to be beyond the scope of the dermatologist. Following total ear replantation there is lack of cutaneous sensation and this may explain the cold intolerance that can occur [6].

Dermatitis artefacta

The ear is occasionally the sole site for self-mutilation and there may be underlying psychodynamic reasons for this [1].

Ear piercing

Earrings have been worn by men and women since antiquity, and tend to follow the dictates of fashion. Current trends include using rings or studs in almost all parts of the body, the use of up to 10 or more in a single ear, and the piercing of cartilage. Body piercings other than earlobes represent a marker for risky behaviour [1–3].

Complications of ear piercing are very common, with rates of about 30% whether the procedure is carried out by medical personnel, friend or relative, or in a store; they are also independent of technique, there being little difference in frequency of complications from piercing by needle, staple gun or sharpened stud [4]. Minor infection is the most common adverse effect, with contact dermatitis, keloid and traumatic tear occurring less often [5]; other consequences occur occasionally. Although case series indicate that so-called 'high' ear piercing, that is through cartilage, has a significant risk for perichondritis [6,7] and chondritis [8], such events were not found in a population study of 1000 nurses [5]. Embedding of the earring seems to be a common problem in children [9].

The ear is also pierced in acupuncture as used in traditional medicine, and complications have been reported [10,11].

Complications. Various infections and reactions may occur after ear piercing.

Bacterial infection, usually with Gram-positive cocci, is common; predisposing factors include skin disease, such as atopic or contact dermatitis. Life-threatening septicaemia has been described [12]. Infants with unsuspected immunodeficiency and individuals with valvular heart disease may be at particular risk [13]. When cartilage is pierced the usual bacterial infection is with *Ps. aeruginosa*, which causes perichondritis [6] or chondritis [8], and for which the best treatment is ciprofloxacin [7]. Any purulent material should be cultured, since other pathogens have been described (e.g. *Lactobacillus* [14]). There is a report of pyogenic spondylitis [15]. Primary tuberculosis has been described [16].

Viral hepatitis may also be a hazard [17,18].

Oedema and haematoma [1,19] usually respond to cold compresses, pressure and removal of the earring. Haematoma may require incision and drainage [20].

Trauma can occur from pressure on the lobe and post-auricular skin, or from inaccurate insertion of the post of the earring. Heavy earrings can tear the earlobe, sometimes making it bifid. Repair of the latter is probably best by excision of the cleft and simple closure with eversion of the edges [21], although a staggered repair such as a Z-plasty may be appropriate in some cases.

Sensitization to nickel from earrings remains a major problem, and ear piercing is one explanation for the higher incidence of nickel allergy in females [22]. Even stainless steel studs and clasps, which can produce irritant as well as allergic effects, may release sufficient nickel to elicit contact dermatitis [23]. Gold sensitization, although less common [24], can be a protracted cause of dermatitis even after the earrings are removed [25]. Contact dermatitis from

other materials used in earrings, such as olive wood [26], copper [27], cobalt [28,29] and chromium [30], has been described, and may also occur from the use of topical antiseptics, antibiotics and dressings used to treat infection. When nickel in ear piercings has been banned, as in Denmark in 1992, there has been a substantial fall in nickel sensitization [31].

Granulomatous and lymphoid reactions. Reddish brown and purple papules and nodules at sites of ear piercing may denote a granulomatous response to gold [32,33] and a lymphocytoma cutis-like reaction has been described [34–36]. Similar reactions have been associated with palladium [37] and titanium [38]. Sarcoidosis has presented after ear piercing [39,40].

Embedded earrings. The spring-loaded gun method of ear piercing can result in the earring backing becoming embedded in the back of the ear [41]. The 'vanishing earring' [42] can resemble a keloid [43]. The embedded metal can usually be pulled out, or if necessary an incision can be made to locate it.

Epidermoid cyst formation. Implantation epidermoid cysts due to ear piercing often present as tender, chronic, inflammatory swellings, sometimes with drainage. There is usually an epithelial lined track as well as cysts, and all epithelial tissue must be removed, for example with a skin punch [44].

Keloids quite commonly follow ear piercing, especially in those ethnic groups with a predisposition (Fig. 68.5). Piercing before the age of 11 years is more likely to be followed by keloid than after that age [45]. The keloids seem to occur more on the back surface than the front of the earlobe [46]. As well as being unsightly, they can itch and be painful.

Treatment options include intralesional steroid, pressure [47], excision alone [48], with or without concurrent use of intralesional steroid [49] and radiotherapy (see Chapter 79) [50]. Combinations of these methods are often advocated [51,52]. Prospective, controlled trials are needed to assess these approaches. A relatively simple and safe method which has shown efficacy and acceptability is injection of intralesional steroid followed by Zimmer splints which can be decorated to look like earrings [53].

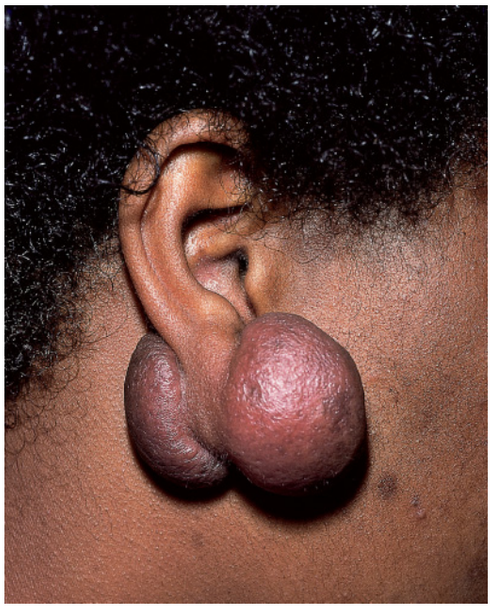

Fig. 68.5 Keloids following ear piercing.

Localized argyria. Bluish macules have been described on the posterior surface of the earlobe [54,55].

Frostbite has followed the use of ethyl chloride topical anaesthesia [56].

Systemic disease. A case of severe relapsing polychondritis following ear piercing has been reported [57].

Measures to prevent complications [58]. Many of the complications of ear piercing are avoidable. The procedure is best not carried out on children, or in those with immunodeficiency, valvular heart disease or sarcoidosis, and there is clearly a risk if the individual has a tendency to keloid formation. For a dermatologist who wishes to pierce ears or instruct others, a simple method with a low likelihood of complications has been described [59]. The use of a surgical-grade, stainless steel, one-piece earring with an interlocking groove has been recommended. Gold-plated or gold-alloy earrings should be avoided for at least 6 weeks after the ear has been pierced. Sterile technique is important. Piercing of cartilage should be avoided. Only nickel-free earrings should be used. Large or heavy earrings should be removed prior to activities that may result in tearing the earlobes. A technique using a piece of intravenous catheter to avoid reactions in metal-sensitive individuals has been described [60].

Acanthoma fissuratum

This chronic response to friction and pressure from the spectacle frame can present with papules or nodules, sometimes with ulceration, in the supra-auricular or retro-auricular folds (Fig. 68.6); even when bilateral, basal cell carcinoma is a differential diagnosis. Acanthoma fissuratum is discussed in Chapter 28.

Fig. 68.6 Acanthoma fissuratum. Nodular thickening behind the pinna superficially resembling basal cell carcinoma.

Fig. 68.7 Perniosis. Purple discoloration, soft-tissue loss and crusting due to acute-on-chronic cold injury.

Fig. 68.8 Venous lakes on a sun-damaged pinna.

Cold injury

The ears are extremely susceptible to cold, and the pinna may be affected by chilblains in winter (Fig. 68.7). Extreme cold will cause frostbite (see Chapter 28). Similar changes have also been reported as a consequence of using excessive amounts of ethylchloride spray for ear piercing [1]. Frostbite may result in vesiculation, blisters and ischaemic necrosis of both skin and cartilage. Ears that have previously been damaged by cold may subsequently become calcified and even ossified [2–4].

Cold is also a provoking factor in many conditions that can affect the ear, for example chondrodermatitis nodularis, chilblain lupus erythematosus and cryoglobulinaemia.

The ear subjected to frostbite should be thawed rapidly by the application of wet, sterile cotton pledgets warmed to 38–42°C for about 20 min [5] with adequate analgesic cover.

Emollients have traditionally been thought to protect against frostbite [6], at least in Finland. However, those who use them experience more frostbite, probably through conferring a false sense of safety, and only thermal protection from clothing can be expected to have protective value [7].

Solar damage

The external ear is often exposed to solar radiation and is therefore liable to acute and chronic sequelae. A significant hazard from severe sunburn is the development of perichondritis (see below). Many photosensitivity disorders will present on the ear, for example polymorphic light eruption, juvenile spring eruption, lupus erythematosus and porphyria (see Chapter 29).

The full gamut of chronic solar damage is frequently seen on the ears, including erythema, telangiectasia, atrophy, blotchy pigmentation, solar keratoses and cutaneous malignancies. As on the lower lip, venous lakes may be seen (Fig. 68.8). Solar elastosis is often evident, and distinctive elastotic nodules may be seen particularly on the anterior crus of the antihelix [1–3]. These lesions are usually bilateral and asymptomatic, and present as pale papules or nodules. Occasionally, they can occur on the helix and be painful, simulating chondrodermatitis nodularis. They differ from 'weathering' nodules (Fig. 68.9), which, like chondrodermatitis nodularis, occur on the helix of the ear [4]. A distinctive combination of elastosis with vellous hair cysts on the pinna has been described [5].

For treatment of mild acute sunburn, cold compresses may be sufficient. More severe cases may benefit from a course of systemic corticosteroid, given for 5 days and then tapered. Preventive measures are discussed in Chapter 29.

Fig. 68.9 Several firm, white, 'weathering' nodules on the helical rim.

Altitude injury

A distinctive presentation of petechiae and haemorrhagic bullae in the skin of the external auditory canal and tympanic membrane has been described in air pilots descending from high altitudes or in pressure chambers while wearing well-sealed earplugs as noise protectors [1].

For treatment, a steroid–antibiotic ear drop has been advised, and if sizeable clots are present they can be gently dislodged by suction after the application of hydrogen peroxide. Preventive methods include the use of perforated earplugs on high-altitude descent.

Radiation injury

Therapeutic use of radiation may result in characteristic acute and chronic changes (see Chapter 79). The cartilage can be susceptible to destruction if inappropriate techniques are used. Post-radiation changes on the external auditory canal include thickening of the canal epithelium, subepithelial fibrosis and resorption of underlying bone, as well as ulceration of the epithelium and the development of cholesteatoma [1].

Foreign bodies

A variety of vegetable, animal and mineral substances may be encountered lodged in the external ear and external auditory canal, and are frequently unsuspected. Presenting symptoms include pain, hearing loss, inflammation and discharge.

Vegetable matter, such as beans, peas and cotton, tends to absorb water and swell, impacting in the ear canal. Arthropods are the commonest animal material. While alive, their motion within the ear can produce distinctive symptoms, even vertigo. Flies can deposit eggs in the external auditory canal and the resulting myiasis has produced severe complications [1]; larvae in the triangular fossa of the pinna can also cause marked inflammation [2]. Mineral materials include beads, sand and pebbles, fragments of plaster and metallic substances. Even batteries have been found lodged in the ear and can produce serious consequences [3–5]. Impacted cerumen can behave like a foreign body in the ear canal. Loose hairs in the ear canal have been reported as a cause of noise [6].

Retrieval of foreign bodies should only be undertaken if appropriate instrumentation and expertise is available. The outcome is generally better if the procedure is done by an otolaryngologist [7]. For children, with whom the problem is more common, general anaesthesia is required. Small foreign bodies can usually be extracted with a curette or alligator forceps. Live insects should first be killed by drowning, for example in 2% lidocaine (lignocaine) [8], ether, chloroform or spirit. If some vegetable materials have absorbed water and become impacted, it may be necessary to divide the foreign body *in situ* and remove the fragments. It may be necessary to control bleeding from the skin of the canal, for example with epinephrine (adrenaline)-soaked gauze, and the canal should then be packed with an antibiotic-impregnated dressing. In cases of a battery lodged in the ear canal, it is essential that an ENT surgeon is involved in the management, because of the likelihood of serious destructive change to the middle ear and beyond.

Chondrodermatitis nodularis

This painful condition usually involves the superior portion of the helix, but may appear on the antihelix, concha, tragus and antitragus.

Aetiology. The principal factors in its pathogenesis are pressure and a compromised local blood supply. It is much more common in patients who habitually sleep on one side at night but can be triggered off by other factors, including cold, and by other types of pressure (e.g. from headgear, earphones). Alteration of connective tissue by chronic sun exposure may also be a factor in some cases [1]. The age of onset is over 40 years in most cases and the condition is commoner in males than females. We have encountered chondrodermatitis nodularis (CDN) in juveniles, but only when there is an abnormality such as marked prominence of the antihelix or a history of injury (e.g. from contact sports). Paediatric CDN is reviewed by Grigoryants [2]. Chondrodermatitis nodularis has been reported in a series of patients with systemic sclerosis [3] and in childhood dermatomyositis [4].

Pathology [5,6]. A typical lesion of chondrodermatitis nodularis consists of a nodule of degenerate homogeneous collagen surrounded by vascular granulation tissue with an overlying acanthotic epidermis, and there may be a central ulcer through which the damaged collagen is extruded. In nearly all cases there is inflammation and fibrosis of the underlying perichondrium, and degenerative changes may be seen in the cartilage. Although many authors view the condition as an example of transepidermal elimination of altered connective tissue, it has been suggested that the infundibular portion of the hair follicle is primarily involved, with perforation of the follicular contents into the dermis [7,8]. There is an increased number of small nerves [9].

Clinical features. The patient, usually a middle-aged to elderly man, seeks advice on account of pain. The more stoical may postpone consultation until the lesion interferes with sleep. The pain, which is sometimes severe, is initiated by pressure and occasionally by cold. It may be brief but can persist and throb for an hour or more. Occasionally, and particularly in women, there is little discomfort. The lesion is a globular or oval nodule, about 0.5–2 cm in diameter, raised above the often hyperaemic surrounding skin (Fig. 68.10). The surface is frequently scaly or crusted, concealing a small ulcer.

In men, nearly 90% of nodules are situated on the helix, usually at the upper pole and more frequently on the right, but may occur on the antihelix [10], tragus, concha and antitragus, in order of decreasing frequency [11]. Occasionally, there are multiple nodules or lesions, and they may occur bilaterally [12]. In women, the left and right ears are affected equally and the proportion of lesions on the antihelix and tragus is greater [13]. The nodules attain a maximum size in a few months and then remain unchanged indefinitely.

Diagnosis. Although the associated pain and tenderness are characteristic, the lesion is often misdiagnosed. Differential diagnosis includes basal and squamous cell carcinomas, solar keratosis, calcification of the pinna, elastotic nodules and 'weathering nodules' [14].

Fig. 68.10 Chondrodermatitis nodularis of the helix. A superficially ulcerated, exquisitely tender nodule.

Treatment. For symptomatic CDN, treatment options include strategies to relieve pressure, intralesional steroid injection, surgical removal, cryotherapy, and laser destruction. There are no satisfactory comparative trials between these approaches. Removal of the abnormal cartilage leaving most or all of the overlying skin [15] has superseded wedge excision, giving higher cure rates, sustained over lengthy follow up, and a better cosmetic outcome than the older technique [16,17]. Removal of cartilage only can not only be used for lesions on the helix but also for other sites such as the antihelix [15,16] and tragus. If surgery is not considered suitable, a useful conservative approach is to strap a pressure-relieving sponge over the ear at night time for 4 weeks; this can heal CDN in the short term in a high proportion of cases [18]. A similar approach is to use a doughnut shaped pillow [19]. Other treatments include intralesional steroid therapy which can help about a third of cases [20], liquid nitrogen cryotherapy and carbon dioxide laser [21]. Whenever possible, efforts must be made to reduce pressure or trauma to the helix.

Fig. 68.11 Pseudocyst. Asymptomatic fluctuant swellings on the upper pinna.

Pseudocyst of the ear

Synonyms
- Endochondrial pseudocyst
- Idiopathic cystic chondromalacia

A non-inflammatory, fluid-filled cavity within the cartilage of the ear.

Aetiology. Although the cause is unknown in most cases, trauma is likely to be important at least in some, as in fracture in the ear cartilage [1], habit-twisting of the ears [2] and rubbing due to atopic eczema [3]. Most speculations about the pathogenesis include an underlying malformation of the cartilage [4] and degeneration due to release of lysosomal enzymes from chondrocytes. A role for cytokines has also been suggested [5].

Pathology. There is a cavity within the cartilage, the walls of which show the presence of eosinophilic amorphous material [6,7]. There may be focal fibrosis, especially in older lesions.

Clinical features. Most cases are young men, although the condition is seen over a wide age range [8] including infants [9]. Occasional cases have been recorded in females [4]. All races are affected [10]. There may be a predilection for Chinese, although this could be reporting bias [11,12]. The condition is usually unilateral and presents as an asymptomatic swelling, which is non-tender and fluctuant. Occasionally, there are signs of inflammation and some tenderness. The commonest location is on the upper half of the ear (Fig. 68.11), on the scapha, less commonly over the helix and antihelix. Sometimes, coalescent swellings are seen. Aspiration usually yields serous fluid, which soon reaccumulates.

Diagnosis. The differential diagnosis includes traumatic perichondritis, relapsing polychondritis (see Chapter 45), haematoma, dermoid cyst and epidermoid cyst, and various benign and malignant tumours; any of these can if necessary be excluded by histological examination.

Treatment. There are no adequate studies comparing various treatments that have been proposed. Aspiration followed by pressure is simple and can be effective, for example the use of a simple bandage, or perhaps better a thermoplastic material as used for mobilizing extremities can be used to provide the pressure [13,14]. After aspiration the introduction of a few drops of 1% tincture of iodine [10] or corticosteroid [15] and then application of a contour pressure bandage has been suggested but the value of such measures is unproven. A suture has also been recommended to prevent re-filling [16,17] as has a fibrin glue [18].

For recurrences, excision of the anterior wall of the cyst, suturing the skin flap back and use of a pressure dressing can produce a cosmetically satisfactory result in most cases [12].

Dermatoses and the external ear

Atopic dermatitis

A crusted eczematous fissure at the junction of the earlobe and the face is a common finding in atopics, and can be regarded as a reliable feature of atopy [1–3]. In the series of Tada *et al*. [3], 45 of their 46 patients with severe atopic dermatitis had infra-auricular fissures. In addition to involvement of the infra-auricular crease, the tragal notch and sometimes the whole of the pinna may be commonly involved. Treatment of eczema and the secondary infection that often accompanies it is discussed in Chapter 24.

Seborrhoeic dermatitis

In its mildest form, seborrhoeic dermatitis simply causes a little scaling and inflammation at the entrance to the external auditory meatus, in the concha or in the auricular folds. When severe, the whole pinna may be affected and there may be infective eczematoid dermatitis both in and around the ear or post-auricularly. The relationship between seborrhoeic dermatitis and otitis externa is discussed in Chapter 23.

Asteatotic eczema

The exposed position of the ear renders it vulnerable to the climatic changes that can induce asteatotic eczema (see Chapter 23). This common cause of a dry, itchy ear is mainly seen in the elderly. Aggravating factors include overzealous cleansing, cold, windy weather, low humidity indoors and air-conditioned air during the summer. There may be little to see other than slight scaling. Similar changes can occur in the ear canal, where additional factors include drying vehicles used in ear drops, for example alcohol and acetone. Management will include avoidance of provocative factors, and use of emollients.

Contact dermatitis

The external ear is commonly affected by both irritant and allergic contact dermatitis [4]. Causes of contact allergy may be grouped as follows.

1 Products used for the hair and scalp: hairspray, shampoos, hair dyes, hair nets, bathing caps.
2 Items worn or placed in or on the ear: jewellery, especially nickel alloys (see p. 68.23).
3 Plastic, rubber or metal ear appliances, for example hearing aids, spectacles, headphones, telephone receivers including cellular phones, earplugs, hair nets.
4 Objects used to clean or scratch the ear, for example hairpins, matches.
5 Cosmetics and toiletries: make-up, perfumes, soaps and creams.
6 Topical medicaments
7 Others (transferred to the ear by fingers), e.g. nail varnish, plant resins (e.g. poison ivy, oak or sumac).

The role of occult allergic contact dermatitis in patients with otitis externa is discussed on p. 68.23.

Psoriasis

Both guttate and plaque psoriasis involve the external ear. Sometimes this is by extension from the scalp, face or neck. Like seborrhoeic dermatitis, psoriasis often involves the concha and distal part of the external auditory canal, but usually its colour, the nature of the scaling and the presence of psoriasis elsewhere allow it to be differentiated. Sometimes both conditions appear to coexist.

Acne

Comedones frequently involve the concha, and are occasionally found on the helix, tragus or earlobe. Inflammatory cysts may be found on the lobe, at the entrance to the external auditory canal, or in both the pre- and post-auricular areas. Pressure from spectacle frames, telephone receivers or headsets can aggravate acne lesions.

Darier's disease

Occasionally, Darier's disease can present with involvement of the external ear as the principal affected site, with erythema, oedema and crusting mimicking an eczematous reaction [5].

Transepithelial elimination disorders

The ear may occasionally be the site for lesions of Kyrle's disease, elastosis perforans serpiginosa, perforating folliculitis and perforating papules of diabetic dialysis patients. These conditions are discussed in Chapter 45.

Lupus erythematosus (Fig. 68.12)

Although most parts of the pinna may be involved in lupus erythematosus (LE), pits and scarring in the concha are distinctive

Fig. 68.12 Cutaneous lupus erythematosus. Acute erythema and erosions following sun exposure.

Fig. 68.13 Angiolymphoid hyperplasia with eosinophilia. Firm red-brown nodules at the entrance to the external auditory canal.

features [6,7]. Atrophy often occurs, and even perforation of the pinna [8]. LE profundus can involve the lobe [9].

Lymphocytoma cutis

When the ear is involved, the lobe is characteristically affected, often with a large, single nodule. Possible causative factors include *Borrelia burgdorferi* infection [10] and gold earrings [11,12].

Lichen planus

There is a single case report of conductive deafness due to erosive lichen planus in both ear canals causing stenosis [13].

Jessner's benign lymphocytic infiltration

This condition occasionally involves the ear and post-auricular region, and sunlight may precipitate or worsen the eruption.

Granuloma annulare

Typical papular and annular dermal lesions of granuloma annulare may involve the pinna, sometimes in the absence of lesions elsewhere [14].

Primary cutaneous amyloidosis

Asymptomatic papules on the helix and concha of the ear have been described as the sole manifestation of cutaneous amyloidosis [15]; such lesions can also occur with more generalized papular amyloid [16] and with macular amyloid of the back [17].

Angiolymphoid hyperplasia with eosinophilia

Synonyms
- Pseudopyogenic granuloma
- Nodular angioblastic hyperplasia with eosinophilia

This is a reactive proliferative disorder of blood vessels with a variable component of inflammatory cells [18]. Opinions vary as to whether it is identical with Kimura's disease, a condition mainly found in Eastern Orientals (see Chapter 56). Angiolymphoid hyperplasia with eosinophilia occurs in both a dermal [19] and a subcutaneous [20] form, and is most commonly found on the head and neck. The two forms are regarded as variants of the same condition [21–23].

Aetiological factors include trauma, pregnancy and immunization procedures [24].

Histology. There are circumscribed collections of vessels whose endothelial cells are epithelioid, that is have abundant eosinophilic cytoplasm and large nuclei. These cells sometimes proliferate into the lumen, and may occur in solid clumps. The associated inflammatory infiltrate consists of lymphocytes, sometimes lymphoid follicles, and there are varying numbers of eosinophils. At least in some cases there may be an underlying associated arteriovenous malformation [25]. In typical Kimura's disease there is more prominent lymphoid hyperplasia.

Clinical features. The dermal form commonly affects the pinna, external auditory meatus (Fig. 68.13) and post-auricular area. The

lesions are red-brown papules or nodules. Occasionally, they itch and can be painful or pulsatile [24]. The condition mainly affects young to middle-aged adults, and in some series there is a female preponderance [26].

Kimura's disease has been reported as involving the ears [27,28] but more commonly produces subcutaneous, lymph node and salivary gland-related masses in the head and neck.

Differential diagnosis includes pyogenic granuloma (rare at this site), bacillary angiomatosis and angiosarcoma.

Treatment. The treatment of choice is surgical excision, although there is often recurrence. Intralesional corticosteroids, pulsed dye laser [29], radiotherapy or oral immunosuppressive agents have been used in some cases with benefit.

Skin reactions to osseo-integrated implants

Restoration of the pinna following traumatic loss or congenital absence may be achieved using an osseointegrated skin-penetrating titanium fixture. About 10% of such patients have skin reactions [30,31]. The reaction consists of erythema and crusting, sometimes with significant infection, which should be adequately treated.

Elephantiasis of the external ears

Chronically red swollen ears may occur for a number of reasons, including long-standing eczema, psoriasis [32] and chronic streptococcal infection. Long-standing head louse infection has also been reported as a cause [33].

Psychocutaneous disorders

Dermatitis artefacta and delusions of parasitosis (see Chapter 64) may occasionally result in self-induced lesions on the ears and even in the ear canals.

Granuloma faciale

The ear is an occasional site for this distinctive disorder [34].

Bullous diseases

Pemphigus, pemphigoid, dermatitis herpetiformis and epidermolysis bullosa aquisita may all involve the ear, and occasionally the auditory canal. Blistering of the pinna and stenosis of the canal can occur in dystrophic epidermolysis bullosa [35].

Verruciform xanthoma

This uncommon condition is typically found in the mouth but has been reported on the ear, where it can mimic squamous cell carcinoma [36].

Adult-onset xanthogranuloma

Symmetrical, yellow-red, nodular lesions with the same histology as juvenile xanthogranuloma have been described on the earlobes [37].

Mudi-chood

This distinctive dermatosis, which typically affects the nape of the neck and upper shoulders of girls and young women in the state of Kerala in South India, can occur on the ears. It is thought to be the result of the frictional and occlusive effects of moist, oily hair in a hot and humid environment. Individual lesions are hyperpigmented papules with a thin surrounding rim of scale, occurring on the posterolateral aspects of the pinnae [38,39].

Systemic disease and the external ear

Many conditions described more fully elsewhere will occasionally present on the external ear with lesions of diagnostic value.

Granulomatous disorders

These include sarcoidosis [1,2], especially the lupus pernio variety. Metastatic Crohn's disease may rarely involve the ear [3]. Atypical facial necrobiosis may involve the ear, as well as the more typical location on the face and scalp. Wegener's granulomatosis can present with serous or suppurative otitis and conductive or sensorineural deafness [4,5]. A similar allergic granulomatosis affected both ears in a young black South African who died from glomerulonephritis [6]. Infective granulomatous diseases involve the ear, notably leprosy, in which the earlobe is a valuable site for taking smears [7]. Lupus vulgaris, other manifestations of tuberculosis, atypical mycobacterial infection (e.g. *Mycobacterium marinum* from swimming-pool injuries), deep fungal infections and even syphilis [8] can involve the ear.

Collagen vascular diseases

As well as discoid lupus, subacute cutaneous lupus erythematosus and systemic lupus erythematosus may also involve the ears. Scleroderma can produce pallor and telangiectasia of the auditory canal. Rheumatoid disease is characterized by nodules, which can occur on the ear, where they may ulcerate due to pressure from the pillow or spectacles. Redness, tenderness and swelling of the ear, but sparing the lobe, is characteristic of relapsing polychondritis (see Chapter 45).

Pyoderma gangrenosum

The ear is an occasional presenting site [9] for this primary ulcerative disorder, discussed in Chapter 50. Vasculitis and factitial disease may be mimicked.

Metabolic disorders

Xanthomas occasionally occur on the ears, presenting as yellow nodules. Gouty tophi frequently involve the pinna (Fig. 68.14), and may antedate the onset of joint disease or appear decades after the initial attack. The helix and antihelix are typical sites. Histology is distinctive. Porphyria cutanea tarda (Fig. 68.15) may present with

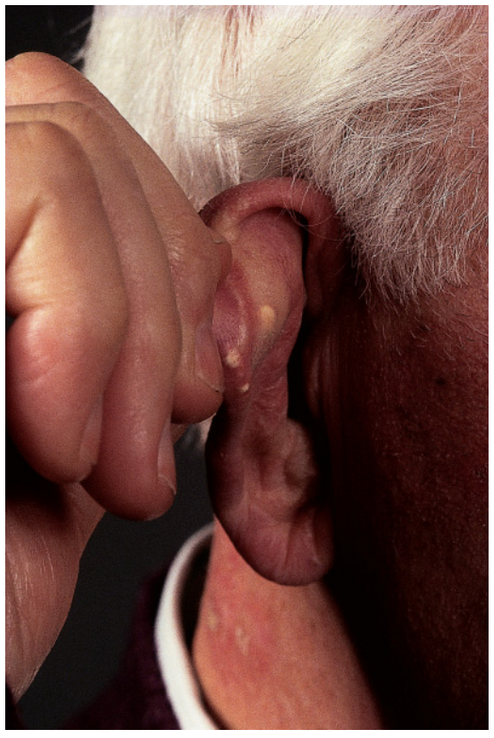

Fig. 68.14 Gouty tophi. Yellowish dermal nodules.

Fig. 68.15 Porphyria cutanea tarda. Firm, whitish, sclerodermoid changes at the site of repeated blistering.

vesicles and bullae, often on a background of scarring, hyperpigmentation, milia, sclerodermoid plaques and hypertrichosis. Pseudocysts of the auricle and perichondritis may be simulated [10].

Diseases of connective tissue

Cutis laxa may result in distinctive pendulous earlobes [11].

Alkaptonuria

Synonym
- Ochronosis

This is typically associated with a bluish discoloration of the auricular cartilage due to oxidation of bound homogentisic acid (Fig. 68.16). The cerumen in such patients may be very dark, a finding that can precede other clinical manifestations.

Calcium deposition

Calcium deposition may occur in many circumstances (see Chapter 59) and occasionally the ear is involved. The so-called petrified ear has been described in association with diabetes mellitus [12]. Usually, calcium deposits in the ear occur for local reasons, for example degenerative changes in the cartilage. In infants, congenital nodular calcification of Winer should be considered [13].

Endocrine disorders

In Addison's disease, the pigmentary changes may involve the ear, and ossification of the auricular cartilage may occur [14]. In acromegaly, there is usually enlargement of the auricular cartilage and coarsening of the overlying skin.

Paraneoplastic syndromes

Bazex's syndrome (acrokeratosis paraneoplastica) (see Chapter 62) commonly affects the ears and is an important marker for internal malignancy [15].

Fig. 68.16 Alkaptonuria. The auricular cartilage has a distinctive blue colour. (Courtesy of Dr P. Hollingworth, Southmead Hospital, Bristol, UK.)

Drug-related effects

Purpura of the ears has been described in a series of children receiving levamisole for nephritic syndrome [16]. Both vasculitis and thrombotic changes occurred, and there was an association with circulating autoantibodies.

Hypertrophy of the retro-auricular folds may be seen as a consequence of phenytoin therapy [17]. Hypertrichosis of the ear canal due to minoxidil therapy can be a predisposing factor for external otitis [18].

Lymphoma

Systemic lymphoma can occasionally present as an isolated lesion on the ear [19].

Infection

The anatomy of the ear, with its many folds and the semi-occluded nature of the external auditory canal, make it particularly susceptible to intertriginous infection, especially with Gram-negative organisms. The close anatomical relationship between the middle

and external ear means that infections can pass relatively easily from one to the other, and the eardrum should always be examined. The cartilaginous and bony structures close to the skin are particularly vulnerable to infection. Although chondritis and perichondritis may have other causes, they are included in this section.

Infections of the pinna

Staphylococcus aureus, alone or in association with group A β-haemolytic *Streptococcus*, may cause impetigo contagiosum of the ear. This is a relatively common site for infection in infants and young children. *Staphylococcus aureus* is also the most common causative organism of furuncles (boils) and carbuncles, which are more common in the external auditory canal than on the pinna. Cracks and fissures around the auricle are often the portal of entry for β-haemolytic streptococcal infection manifesting as erysipelas. This is more common in the elderly, the newborn and those suffering from malnutrition, disability, alcoholism, diabetes or immune deficiency states.

Erysipelas typically begins with high fever and constitutional upset, including malaise, vomiting and headache, and there is rapidly spreading erythema and oedema from the pinna on to the face. There is often lymphadenopathy. Recurrent attacks of cellulitis of the face may have the same predisposing factors as at other body sites. Recurrent attacks of cellulitis lead to fibrosis and lymphoedema. Treatment of erysipelas and cellulitis is discussed in Chapter 30.

Necrotizing fasciitis has rarely been described arising from an initial infection of the pinna [1].

The term *infective eczematoid dermatitis* is still sometimes used for an oozing, crusted, eczematous condition occurring on and often below the pinna in association with chronic discharge from the ear. Coagulase-positive staphylococci are the most frequently isolated bacteria. The ear canal is oedematous and erythematous, and purulent discharge may be seen coming from a perforated tympanic membrane. The condition should be differentiated from impetigo, secondarily infected contact dermatitis, seborrhoeic dermatitis and atopic dermatitis.

Treatment. Primary infection of the ear must be treated appropriately, usually with a systemic antibiotic; any associated chronic otitis media or mastoiditis is likely to be managed by an otologist. Involved skin can be cleansed with saline, 1 in 10 000 potassium permanganate or dilute aluminium acetate soaks and then treated with a topical steroid. Surgical intervention will be required for necrotizing fasciitis.

Perichondritis and chondritis

Inflammation of the cartilage itself (chondritis), or more commonly the vascularized lining (perichondritis), can be indistinguishable from infection of these structures, and infection is a common complication whatever the cause [2,3].

Aetiology. There are many causes, including physical trauma (Fig. 68.17), thermal and chemical burns, frostbite, pressure (e.g. from tight headphones and head-dresses [4]) and ear piercing, especially so called high piercing (i.e. through the cartilage; see p. 68.7). Acupuncture is also a risk factor [5,6]. Perichondritis may occasionally follow superficial infections of the ear such as furunculosis or otitis externa. The most common infecting organism is *Ps. aeruginosa*, although other Gram-negative organisms or staphylococci may at times be responsible.

Fig. 68.17 Pressure ulcer exposing cartilage, a potential cause of chondritis.

Clinical features. Chondritis and perichondritis are typically painful. The pinna becomes hot, painful and swollen, with loss of normal contour due to oedema, and there may be accumulation of pus in the subperichondrial layer. Constitutional symptoms are common. The inflammation can spread back to the adjoining face. The destruction of cartilage results in deformity of the ear, which may be severe. Necrotizing fasciitis can follow perichondritis of the pinna [1], and if suspected must be treated by urgent debridement.

Diagnosis. Perichondritis may be difficult to distinguish from cellulitis, although perichondritis is usually more painful and does not involve the lobule of the ear, which lacks cartilage. Relapsing polychondritis (see Chapter 45) usually also involves cartilage at other body sites, and is often recurrent.

Treatment. Treatment should be instituted promptly. If an abscess has developed, early drainage is necessary. Surgery is necessary if perichondritis is secondary to malignant external otitis [7]. Ciprofloxacin or other quinolones are probably the treatment of choice [8,9]. Necrotic cartilage may subsequently need to be excised, and fluid collections aspirated.

Other bacterial infections of the pinna

Mycobacterial infection can rarely involve the external ear. Lupus vulgaris can produce extensive destruction [1] and may mimic other conditions [2]. Secondary involvement from underlying lymph node disease (scrofuloderma) can present with hearing loss, tinnitus and periauricular lymphadenopathy, with only minimal secretion in the ear canal [3].

Atypical mycobacteria that may involve the ear include *M. marinum* acquired from swimming-pool injuries.

In leprosy, the ear is almost always involved in the lepromatous type, and there may be evident infiltration of the skin. The earlobe is often used for taking smears [4].

Syphilis may occasionally involve the ear, usually in the secondary stage [5].

Viral infections

Herpes simplex occasionally involves the ear. It is often transmitted during contact sports such as rugby and wrestling. Herpes zoster may present as an isolated herpetiform eruption of the external ear or may be associated with ipsilateral facial palsy and auditory symptoms (Ramsay–Hunt syndrome; geniculate herpes). The condition usually begins with pain and may initially be mistaken for erysipelas. Vesicles usually appear on about the fifth day and involve the pinna, the external auditory meatus and, rarely, the tympanic membrane. There is usually malaise, pyrexia and lymphadenopathy. Facial palsy, when it occurs, is usually transient, but more severe and persistent cases do occur. Taste and lacrimation may also be affected. Compression damage to the VIIIth cranial nerve may lead to tinnitus, vertigo, nystagmus, nausea and deafness. Management of herpes zoster is discussed in Chapter 33. Orf affecting the ear has been described, presenting as an inflammatory nodule on the tragus [1].

Superficial and deep mycoses

Dermatophyte fungi may rarely involve the ear, and when present can simulate granulomatous disease [1,2] and chondritis [3].

Pityriasis versicolor may involve the ears, but is usually easy to diagnose.

In cases of ulcerative granulomatous disease of the ear, deep fungal infections, for example sporotrichosis [4], should be considered. Biopsy, examination of smears, cultures and serological studies should enable accurate diagnosis. Deep fungal infection may prompt an enquiry for underlying immune deficiency.

Otomycosis is discussed below (Otitis externa).

Infections of the external auditory canal and meatus

External otitis

Synonym
- Otitis externa

Otitis externa [1] is a loose term that embraces more than one disease process. Aetiologically, it is rarely unifactorial [2]; constitutional, traumatic, environmental and microbial factors usually coexist. The condition is characterized by inflammation of the canal epithelium and by varying degrees of pain, itch, deafness and discharge. It may be acute, usually lasting less than 6 weeks, or chronic if lasting more than 3 months. The term 'external otitis' sometimes includes furunculosis of the ear canal, and is then subclassified as acute localized external otitis; furunculosis is described separately below. Invasive (necrotizing) external otitis, which involves the temporal bone, is described later (p. 68.25).

Incidence. Tha annual incidence of acute otitis externa is probably between 1:100 and 1:250 of the general population, with regional variations depending on age and geographical factors [3].

Pathogenesis. Otitis externa can be divided, for convenience, into two main groups [4]: (i) a *reactive* group consisting of patients suffering from eczema, psoriasis or seborrhoeic dermatitis; and (ii) a predominantly *infective* group in which either bacteria or fungi are involved. However, the two components often coexist. The cause in many cases is not apparent [5] but the following predisposing factors appear to be important.

Genetic and constitutional. There are significant racial and individual differences in susceptibility to otitis externa. This may be due to anatomical differences in the curvature of the external auditory canal or narrowing of the isthmus—natives of New Guinea with wide, straight canals only rarely suffer from external otitis [6]—or, possibly, to differences in the type, amount or composition

of cerumen, whose waxy consistency and low pH are protective against bacteria. Lack of ear wax is associated with external otitis. An alkaline pH is associated with chronicity [7]. *Pseudomonas aeruginosa*, the commonest bacterial pathogen in external otitis, binds to cells by a lectin-mediated process, and binding occurs more in individuals expressing blood group A on their epithelial cells [8]. Increased levels of proteases may also be associated with chronicity [9].

Abundant tragal hair or plugs of wax and debris increase the relative humidity and reduce ventilation of the external auditory canal so that the canal epithelium becomes macerated and more susceptible to infection. Hypertrichosis of the canal due to minoxidil has been associated with external otitis [10]. Dental abnormalities and poor mastication [11] may also retard expulsion of wax and epithelial squames.

The atopic and seborrhoeic states predispose to external otitis not only by interfering with the integrity of the auricular epithelium but also by encouraging scratching and secondary infection. Both too much and too little cerumen and alterations in skin pH have at times been held responsible [12].

Environmental. Heat, humidity and moisture are undoubtedly important in 'hot-weather ear' or 'swimmer's ear' [13]. This condition is common, especially among white people in tropical and subtropical regions. High temperature, high relative humidity and swimming [14] all encourage maceration and secondary bacterial or fungal infections of the canal epithelium. Freshwater swimming appears to be a particular risk factor [15]. Failure to dry the ears completely after swimming, shampooing or showering may also be a factor in some cases [5].

Traumatic. Trauma, in the opinion of many investigators [2,14,16,17], is one of the prime factors in both the initiation and the persistence of many cases. In one series of 113 patients, 58 admitted using wool-tipped matches, two admitted using bare matches and seven used hairgrips to relieve itching [2]. Patients suffering from eczema or those with neurodermatitis tend to scratch, rub or 'fiddle' with their ears; other patients appear obsessed about cleaning their ears and by doing so excessively they interfere with the normal homeostatic and self-cleaning properties [18]. Impacted cerumen may cause irritation, which is often increased by inexpert attempts to remove it. Pressure from hearing aids and in-the-ear auditory equipment may also cause irritation and, especially with the 'internal' hearing aid, a combination of pressure and occlusion often leads to the development of external otitis.

Bacterial and mycotic infection. The epidermis of the external auditory canal is normally fairly resistant to infection. The bacterial flora, although varying with race, geography and season, tends to resemble that of the skin but with a higher likelihood of finding *Ps. aeruginosa* [19]. In hot humid environments, however, and particularly among swimmers, whose ears are habitually wet, the incidence of *Ps. aeruginosa* and other Gram-negative infections rises substantially [20,21] as does the frequency with which *Aspergillus* or *Candida* species are isolated [16]. An outbreak of *Pseudomonas* otitis has been reported in association with contaminated pool water [22] but a source has rarely been found in other series, and it is assumed that *Pseudomonas* infections are of endogenous origin. Some strains may be more pathogenic [23].

In more temperate climates, *S. aureus* is often isolated. This may be associated with evidence of skin disease elsewhere or with staphylococcal carriage. Methicillin-resistant *S. aureus* (MRSA) infections are becoming more common, especially when the patient has recently had hospital exposure [24]. Certainly, patients with recurrent staphylococcal otitis externa should have nasal and perianal swabs sent for bacterial culture; occasionally it may be necessary to swab and 'de-Staph' the whole family. In other cases, there may be an underlying tympanic perforation or coexistent otitis media. The eardrums should therefore always be examined, especially in patients with unilateral or recurrent disease. Occasionally, infection spreads out from the ear canal and causes impetigo or infective eczema of the auricle and surrounding skin.

In the tropics, mycotic infections of the external ear canal are relatively common [25,26]. *Aspergillus*, *Candida*, *Penicillium* and *Mucor* spp. are the organisms most often incriminated, most cases being due to either *Aspergillus niger* or *Candida albicans*. There is some debate, however, as to whether these fungi are pathogenic, opportunistic, saprophytic or simply commensal [26–29].

Histopathology. In most cases of external otitis, there is acanthosis, elongation of the rete ridges and an increase in orthokeratosis and parakeratosis. Spongiosis occurs in eczematous and seborrhoeic forms. The nature of the dermal infiltrate varies with both cause and chronicity. The histopathology is seldom diagnostic except when fungal mycelia are seen.

Clinical features. The condition can be acute, subacute or chronic. In patients seen at hospital, it tends to be severe, chronic or chronic relapsing, but in the community it is less severe and recalcitrant [1,2].

Mild attacks may present with pain or itching without discharge and with a minimally congested or swollen meatus. The degree of irritation or discomfort is often out of all proportion to the appearance. This stage probably represents early damage to the meatal skin [3]. Most cases of this type will resolve with simple therapeutic measures, but a minority, perhaps due to trauma, secondary infection or failure to keep the ear dry and clean, progress to more severe disease.

Fully developed, acute external otitis (diffuse otitis externa) is characterized by a sudden onset of ear pain, itching, a sense of fullness or stuffiness if there is significant oedema, and a variable degree of hearing loss. The otalgia is often exacerbated by jaw movements. With progression, there is usually drainage of malodorous pus, which tends to be bluish-green in colour if *Ps. aeruginosa* is the dominant infecting organism. Examination shows erythema and swelling, which may spread from the external auditory meatus to involve the concha or beyond. The external auditory canal shows erythema and oedema, and there is macerated debris and perhaps greenish pus present. In severe cases, inflammation can extend to involve the tympanic membrane. Hearing loss is due to oedema of the canal, and this may be sufficient to obscure vision of its full length. Traction on the pinna to examine the canal and pressure over the tragus characteristically elicit pain. There may be associated fever, malaise and regional lymphadenopathy. *Pseudomonas* is the commonest cause of acute external otitis [4].

It is important to gently remove debris in the process of a full examination, and to try to determine whether the disease is secondary to otitis media and whether or not the tympanic membrane is intact.

Bullous external otitis [5] is an uncommon variant in which there is a sudden onset of severe pain followed by discharge of blood from the ear canal. Bluish-red haemorrhagic bullae are visible on the osseous canal walls.

In granular external otitis the lining of the meatus and canal is replaced in part or whole by granulation tissue, which can project inwards as pedunculated masses. These are usually found near the tympanic membrane, arising from the osseous end of the canal. Granular external otitis is associated with a severe or neglected course [6,7].

The term 'chronic external otitis' is sometimes used for cases that have had persistent symptoms for more than 2 months [8]. Microbiological assessment demonstrated a significant organism in 82% of cases in one series [9]: *S. aureus* in one-third, *Pseudomonas* in one-third and various other Gram-negative and Gram-positive organisms in the remainder; in addition, 17 of the 99 patients had fungal disease alone. There is often a dry canal due to lack of cerumen. It is likely that in most cases of chronic otitis externa, particularly when treatment has been used for the acute attack and symptoms have continued, concurrent dermatological disorders are present (Fig. 68.18). In patients in whom the disorder behaves in a recalcitrant manner it is important to consider the possibility that they may have an underlying systemic disease, such as acquired immune deficiency syndrome (AIDS), malnutrition or

Fig. 68.18 Chronic otitis externa. There is longstanding eczematous change, in part due to contact allergic reactions to ear drops, and induration causing narrowing of the canal.

uncontrolled diabetes mellitus; a poor therapeutic response is also seen in patients treated with high-dose steroids or chemotherapeutic agents [10].

Seborrhoeic dermatitis, atopic dermatitis and psoriasis usually occur only at the meatus but may sometimes extend further into the canal. Seborrhoeic otitis externa is extremely common and has been regarded by some dermatologists as the basis for most cases of otitis externa. The symptoms and signs, however, are normally mild unless complicated by secondary factors and usually consist of no more than superficial scaling and a little discomfort or itching. Signs of pityriasis capitis or seborrhoeic dermatitis elsewhere are usually present. The condition may deteriorate at times of stress or fatigue. Secondary bacterial infection is common. In this 'reactive' group the appearance is often that of a dermatitis spreading into the ear, in contrast with those cases with a primarily 'infective' aetiology where infection and/or inflammation often appears to be spreading out from the ear and where the entire length of the canal is often affected. The clinical appearance, however, is often non-diagnostic.

In infective eczema there is usually intense pruritus associated with exudate. The condition may complicate both otitis media and otitis externa and is usually associated with some degree of otorrhoea. In others, it appears to develop from seborrhoeic dermatitis that has become secondarily infected. The condition may affect the meatus, concha, lobe and periauricular skin and often spreads widely. The post-auricular fold is commonly affected. The symptoms and signs are those of eczema with an accompanying or preceding aural discharge. In seborrhoeic individuals, other areas may be involved at the same time. Fissures and cellulitis are common complications.

Contact dermatitis is often occult [11] and easily overlooked. It is both a complication (see below) and a contributory factor to chronicity. Sensitivity to topically applied medicaments is common in chronic external otitis. Neomycin and the related aminoglycosides are likely to be the commonest sensitizers [12–14]. As well as drops, medicated gauze should be considered [15]. Occlusion, the recurrent nature of the disease and frequent use of antibiotics on an already damaged skin probably account for the high incidence of contact dermatitis at this site. Other sensitivities include nickel from hair pins, metal implements, chromate and phosphorus sesquisulphide in matches, and nail varnish. It is characteristic that the degree of itching and burning is often markedly out of proportion to the amount of erythema and oedema present. Contact dermatitis may also rarely occur with ear moulds [16]. Clinically, it is often difficult to differentiate neurodermatitis from contact dermatitis.

Lichen simplex (neurodermatitis) may be localized to one area of the meatus or may occur more diffusely over the tragus, triangular fossa and adjoining skin. The condition is usually diagnosed by the history rather than the signs. Itching is intense, but often intermittent. The need to scratch or rub is compulsive, although often denied. Signs of inflammation are often minimal, but some degree of oedema and scaling is common. Complications from trauma, infection and sensitization are frequent. Intermittent itching of the external auditory canal (non-specific external otitis) can also occur, irregularly and over a long period, without any obvious cause and with minimal signs of disease.

Whatever the primary aetiology, with the passage of time chronic external otitis becomes an increasingly complex diagnostic and therapeutic problem.

Differential diagnosis. The part played by trauma, environment, infection, sensitization and altered physiology and anatomy must be assessed and evaluated as accurately as possible. Difficulties often arise in the interpretation of bacteriological and mycological findings. 'Hearing-aid dermatitis' is more often due to traumatic and physical factors than to allergic sensitivity. Sensitivity to topical antibiotics may be occult, especially when they are prescribed in combination with corticosteroids, and are one cause of chronicity. Contact hypersensitivity to aural treatments (see below) may produce eczema that extends onto facial skin anterior to, or below, the ear. The importance of perineal and nasal transfer of infection should not be underestimated, and mechanical interference with the external auditory canal in patients with otitis externa tends to be the rule rather than the exception.

External otitis is unlikely to be confused with any other condition except perhaps psoriasis and eczema, and these, of course, may coexist. Middle-ear disease, past and present, should always be excluded.

Swabs should be taken for bacteriological culture and epithelial debris examined and sent for mycological culture. Potassium hydroxide preparations showing evidence of epithelial invasion with hyphae are probably more important in this respect than a positive culture, which may simply indicate commensal or saprophytic infection.

In any long-standing or resistant case, patch testing with a special 'ear battery' [1] should be undertaken to rule out unsuspected contact dermatitis. If there is excess granulation, middle-ear disease should be ruled out, and if the patient is diabetic, debilitated, very young, elderly or immunosuppressed, malignant otitis externa must also be excluded.

Another condition that may need to be considered is *bullous myringitis*, an uncommon condition probably due to upper respiratory tract viral infection (e.g. influenza), which presents with single or multiple bullae on the tympanic membrane and adjacent canal wall. It can resemble bullous external otitis, which is usually due to *Pseudomonas*. Sudden, severe pain is a feature, but this resolves rapidly after rupture of the bullae. Furuncles of the external auditory canal are described below. Other bacteria may be a rare cause, for example gonococcal otitis externa [2].

Complications. Recurrent otitis externa may also develop into hypertrophic otitis externa or localized elephantiasis nostra [3] of the ears as a result of the effects of chronic lymphatic obstruction. The resultant narrowing of the external acoustic canal coupled with the underlying lymphoedema makes recurrent and repeated infections even more likely.

Secondary trauma. Once an irritable focus occurs in the canal, energetic attempts to remove wax or debris or to satisfy the urge to rub or scratch the infected area often intensify the inflammation. Cotton buds, although frequently regarded as safe, are a common cause of tympanic perforation [4].

Secondary sensitization. This is usually a consequence of treatment or a reaction to objects placed in the ear to alleviate itching. Therapeutic agents may therefore enhance and perpetuate the condition for which they were prescribed. The commonest causes are neomycin, framycetin (Soframycin®) and gentamicin, with quinoline mix, which includes iodoform, and the caine mix giving a much lower level of positive reactions in a recent series [1]; allergy to topical corticosteroids used in the ear may also occur [5]. Allergy to topical medicaments is found in as many as 40% of patients with chronic or treatment-resistant otitis externa [6]. In only about 20% of cases is there improvement after discontinuing topical agents to which patients have been shown to be allergic [5].

Sensitivity to nail varnish may be misconstrued as lichen simplex and, in women who are nickel sensitive, otitis externa may be aggravated by using metal objects to alleviate itching or to clear the ear. Otoscopes themselves may release nickel. Another source of contact dermatitis is chromate [7] or phosphorus sesquisulphide in match heads, which some people use to scratch their ears.

Benign non-necrotizing otitis externa. This usually presents as chronic, non-painful otorrhoea with an ulcer present in the floor of the external canal. Surgery may be a better alternative than long-term medical management [8].

Allergic and 'ide' reactions [9,10]. A few well-documented cases have been reported in which recurrent pruritus, oedema and scaling of the ear canal have occurred in response to fungal infection at a distant body site, or associated with food or drug allergies. Some such cases also have an 'ide' reaction affecting the hands or other areas.

Treatment [1–4]. The general principles of treatment of otitis externa are to relieve pain [4], reduce itching, prevent trauma and avoid known sensitizers. Significant infective organisms should be identified and treated appropriately, although in practice treatment will be initiated before results are available.

Many mild cases of otitis externa will respond to simple aural toilet, optimally with careful suction and under direct vision, followed by the use of an acidifying and drying agent. Flushing of the ear canal should not be attempted unless the tympanic membrane has been clearly visualized. Moderately severe cases are likely to require topical treatment as outlined below. Systemic antibiotics are not usually needed [4].

When there is coexistent eczema, combined steroid–antiseptic or steroid–antibiotic drops or wicks can be used. In chronic cases, a great variety of treatments will already have been given and medicament contact dermatitis will therefore be more likely. Because this is often occult, patch testing should be done in all patients with chronic disease.

Pain is often severe, especially with acute staphylococcal infections, and strong analgesics may be required. Local heat also often helps. Bed rest and daily wicks or dressing may be needed in the more severe case.

If there is significant pyrexia (>38.3°C), lymphadenopathy, concurrent otitis media or failure to improve with topical therapy, an oral antibiotic should be used, for example a cephalosporin or fluoroquinolone. If pain is very severe, granulations are present in the canal or the patient is diabetic or immunocompromised, there should be suspicion for invasive (necrotizing) otitis (see p. 68.25).

Topical treatment. This is the essential part of therapy and the most difficult to carry out satisfactorily. Ear drops are of less value than regular cleaning of the ear, and this initially needs to be done daily by a doctor or an experienced nurse. Less severe cases may be treated once a week. Having cleaned the ear of debris and wax,

preferably by suction under direct vision, a wick may be inserted or the patient instructed to apply ear drops regularly. When the cartilaginous portion of the canal alone is involved, the patient can be shown how to apply the prescribed medicament by holding a loose wool-tipped orange stick 2.5 cm from its end and inserting this until the fingers touch the tragus.

If wax is impacted, this can be softened with oil, glycerine or sodium bicarbonate eardrops and then removed either manually or by syringing, as long as the drum can be visualized and there is no perforation. Obstinate cases should be referred to an otologist. Some proprietary cerumenolytics are irritant and should be left in the ear for only 15–30 min before syringing.

In most chronic or complicated cases, treatment must be continued regularly for some weeks after apparent cure. Care must be taken to prevent cross-infection from other body sites, especially from the anterior vestibule of the nose or the perineum, and the ear should be kept as dry and as clean as possible.

A very large number of medicaments have been used in the treatment of uncomplicated, acute otitis externa and there is a dearth of good quality, randomized controlled trials (RCTs) on which to base a choice of treatment [3,4]. Simple antiseptics have an important role, aluminium acetate solution being especially useful against the expected pathogens [5,6] and as effective as hydrocortisone/neomycin/polymyxin drops [7]. Other antiseptics used include 70–85% isopropyl alcohol, 1–2% acetic acid, and 2% salicylic acid in 60% spirit. If acidic ear drops cause a burning sensation, ophthalmic hydrogen peroxide drops are a practical substitute. Wicks with 8–13% aluminium acetate, 0.25–0.5% silver nitrate, or glycerine and ichthyol are used to treat hypertrophic otitis externa. Corticosteroids with or without antimicrobials are commonly used as first line treatment. Only one RCT has shown a topical steroid to be better than placebo [8], and interestingly hydrocortisone, a weak steroid, may be as effective as hydrocortisone butyrate, classed as potent [9]. Topical steroids are more commonly used with antibiotics, usually neomycin, framycetin (Soframycin®), gentamicin, polymyxin or a quinolone such as ofloxacin. The combination of neomycin and polymyxin will cover both *S. aureus* and *Ps. aeruginosa*. Topical ofloxacin is as effective and only has to be used twice daily [10]. There is probably no difference in efficacy between these many preparations [3,11], except with regard to the risk of sensitization and cross-sensitization, the quinolones probably representing less risk. Long term continuous use is therefore best avoided. For patients with chronic or chronic relapsing otitis externa, an antiseptic such as iodochlorhydroxyquinoline (Vioform®, chinoform) can be used alone or in combination with corticosteroids and aluminium acetate has the advantage of a lack of sensitizing potential.

The role of antifungals is not clear [3], but if fungi are thought to be contributory the imidazoles have largely replaced nystatin and amphotericin as they are active against *Aspergillus* as well as against *Candida*, although acetic acid, boric acid and 25% *m*-cresyl acetate may still at times be useful; 2% salicylic acid in spirit is useful for prophylaxis.

Several ear-drops, for example the aminoglycosides, chlorhexidine, polymyxin and chloramphenicol, are potentially ototoxic [12,13] and should be avoided in the presence of tympanic perforation.

In all cases of external otitis, treatment should be prolonged beyond the time of apparent recovery and patients should be advised how best to avoid recurrence and about the dangers of indiscriminate or prolonged self-medication.

Surgical treatments. Occasionally, chronic otitis externa is due to narrowing of the external auditory meatus. Surgical enlargement of the meatus can then bring about resolution [14–16].

Invasive external otitis [1,2]

Synonyms
- Malignant external otitis
- Necrotizing external otitis

This is an infection of the skin of the external ear canal that spreads to deeper structures and causes necrosis.

Aetiology. In most cases, the infecting organism is *Ps. aeruginosa*, although occasionally other organisms have been involved: *S. aureus* [3], *S. epidermidis* [4], *Klebsiella oxytoca* [5], and fungi such as mucormycosis [6], *Candida glabrata* [7], *Aspergillus* [8,9], *Malassezia sympodialis* [10], *Scedosporium apiospermum* [11] and *Actinomycetes.* The condition characteristically occurs in elderly diabetics [12,13] but is also seen with some frequency in the immunocompromised,

including patients with HIV infection [1,13,14]; it has also been reported in association with diabetes insipidus [15]. Cases have been reported in children [16–18] in whom chronic illness or immunosuppression is usually present. In diabetics, microangiopathy may be important in the pathogenesis [1]. It is possible that abnormalities of cellular immunity and polymorphonuclear function are important in some cases [19,20], but in many instances the pathogenesis is poorly understood.

Pathology. In most cases, there is evidence of osteomyelitis [5]. An early event is acellular necrosis of cartilage [21].

Clinical features. Quite often there is a preceding history of irrigation of the ear. The commonest presenting symptom is pain, which is usually very severe and persistent. It may spread from the region of the ear to the vertex, temporal or occipital areas, and there may be temporomandibular joint pain. Pain progresses more quickly in children than adults. The second most common symptom is discharge from the ear. In up to 50% there is some degree of hearing loss. Systemic symptoms, including fever, are uncommon [1]. There may be symptoms due to involvement of cranial nerves, particularly dysphagia.

On examination the external auditory canal is always abnormal, with varying degrees of oedema and erythema, and extensive granulation tissue formation is evident. This is particularly seen on the posterior and inferior aspect of the wall and at the junction between the bony and cartilaginous segments of the canal. There may be swelling of the soft tissues around the ear. The tympanic membrane is frequently necrotic in children but characteristically spared in adults [18]. Cranial neuropathies may be found in up to 40% of patients [1,14]. Facial palsy is the most common finding but involvement of cranial nerves IV, VI, VIII, IX, X and XII may be variably present. When such nerve involvement is found, the disease is more extensive.

Investigations usually show elevation of the erythrocyte sedimentation rate, but the white-cell count is often normal.

Diagnosis. Invasive external otitis is usually diagnosed on clinical suspicion. It is essential to obtain material for culture to determine the infective cause, and samples should be taken from the ear canal, granulations, soft tissue and bone, depending on the case. Blood cultures may also be valuable.

Imaging techniques can be helpful, particularly in diagnosing bony involvement and following progress of the disease, and should enable granular external otitis to be distinguished from the much more serious invasive external otitis. Plain films, computed tomography (CT), bone scans, magnetic resonance imaging (MRI) and single-photon emission tomography (SPECT) have all been used. MRI with or without gadolinium enhancement is probably the best technique for imaging soft-tissue involvement, and for evaluation of the meninges and changes within the osseous medullary cavity, although CT is preferred for the initial diagnosis and recognition of cortical bone erosion [22,23]. When available, SPECT is probably the best method for initial diagnosis of the distinctive bony changes, and gallium scintigraphy most useful for assessing response to treatment [24].

Complications. Spread of the disease can produce parotitis, mastoiditis or osteomyelitis of the base of the skull and thence spread to the contralateral side. Meningitis can occur, and is an important cause of death. Cranial nerve paralysis may result in aspiration pneumonia. A rare complication is destructive osteomyelitis of the temporomandibular joint [25]. Overall, there is a mortality of 10–20%; in the presence of cranial neuropathies the mortality has been high [1,14] but with prolonged courses of appropriate antibiotics is less nowadays [26]. Facial nerve palsy is less likely to recover than that of other cranial nerves [26].

Treatment. Because of the range of possible infections, it is essential to base treatment on the result of culture. For *Pseudomonas*, the traditional approach has been to use an extended-spectrum antipseudomonal penicillin for 4–8 weeks and an aminoglycoside for 4–6 weeks [1]. Ciprofloxacin [27,28] can be successful if used early in the course of disease but drug resistance is increasing [29]. When there is evidence of extensive bone destruction, removal of necrotic material is necessary. Some cases fail to respond to antibiotic therapy and, if the facility is available, hyperbaric oxygen can improve the outlook [30]. Ascorbic acid has also been recorded as an adjuvant therapy [19].

When the infective cause is bacteria other than *Pseudomonas* or is a fungus, advice on the choice of antimicrobial agent should be taken from a microbiologist.

Furunculosis

Synonym
- Acute localized external otitis

A furuncle is a staphylococcal infection of a hair follicle [1]. A common site is between the junction of the tragus and the anterior crus of the helix. Furuncles also may occur in the skin of the external auditory canal at the junction with the concha. Coalescence of adjacent infected follicles results in a carbuncle.

The patient presents with pain, which can be aggravated by chewing if there is involvement of the anterior wall of the canal. There may be sufficient swelling to obstruct the entrance to the canal. There is often regional lymphadenopathy and sometimes fever.

Furunculosis can usually be distinguished from external otitis by the normal appearance of the canal epithelium and an absence of discharge; the two conditions can, however, coexist. If possible the tympanic membrane should be examined, in order to exclude otitis media and mastoiditis.

Localized lesions associated with mild swelling usually respond to an oral antistaphylococcal antibiotic [1]. If an abscess or carbuncle is present, incision and drainage is usually necessary. The latter can be achieved with a wick. Any draining material should be sent for culture and antibacterial sensitivities.

Otomycosis

Otomycosis is an inflammatory process due to a variety of yeast and fungal organisms as the primary aetiological agent. The same range of fungi may be found in patients with multifactorial or bacterial external otitis (see above).

Aetiology. The species of fungus and yeast involved vary somewhat depending on ambient climate. In most tropical regions of the world *Aspergillus* species account for the majority of isolates, whereas in temperate areas *Candida albicans* is the most frequent [1]. Others include phycomycetes, *Rhizopus*, *Actinomyces* and *Penicillium*. The fact that these organisms can be pathogenic as well as saprophytic has been confirmed in a number of studies [2–5].

The factors that convert organisms that are normally saprophytic into pathogens are similar to those that apply to bacterial external otitis. Local trauma, heat and humidity are foremost, and account for the frequency of otomycosis in the tropics and in those using hearing aids or occlusive ear moulds. Diabetes mellitus, immunosuppression, systemic and topical antibiotics, and steroids are also important.

Clinical features. The principal symptom is usually itching, which can have a quality of being deep inside the ear. This is often accompanied by a sensation of fullness. Pain is uncommon, in contrast to bacterial external otitis. Discharge, if any, is usually slight. There may be hearing loss of a conductive type. Because of the irritation, patients are liable to traumatize the canal and may then initiate the symptoms and signs of bacterial external otitis. The most important complication is perforation of the eardrum [6].

On examination the dominant feature is the presence of wispy filamentous masses, which may be isolated or diffusely present in the canal. These masses are white, grey or stippled black if *Aspergillus* is present. Inflammation of the canal epithelium is usually mild. There may be some epithelial debris, which may be either moist or dry.

Diagnosis. The clinical appearance is usually distinctive. As always with external canal disorders it is important to check for other pathology. Material can be taken for mycological examination and culture.

Treatment [7]. Careful cleaning followed by drying is a prerequisite to successful management. The canal can then be wiped out, for example with *m*-cresyl acetate or 1% thymol in 70% alcohol, and the specific treatment applied on a wick. Treatment should be changed daily until a satisfactory result has been achieved. Many agents have been advocated for otomycosis, but there is little evidence to promote one above the others. They include aluminium acetate, acetic acid, *m*-cresyl acetate, thiomersal, gentian violet, clioquinol, nystatin, amphotericin and the imidazoles.

In rare situations, usually in immunosuppressed patients, there may be cellulitis of the surrounding soft tissues directly due to fungal infection. In such cases, itraconazole is likely to be the treatment of choice. Oral terbinafine has also been used when other treatments have failed [8].

HIV, AIDS and the external ear

The consequences of HIV infection will at times be seen on the pinna and in the external auditory canal [1,2]. The ear is a relatively common site for manifestation of Kaposi's sarcoma. Florid seborrhoeic dermatitis is often a presenting feature of AIDS. The occurrence of molluscum contagiosum lesions in an adult should prompt a suspicion of immunodeficiency; on the ear the lesions can resemble basal cell carcinoma. Bacillary angiomatosis may produce vascular papules and nodules on the ear. Herpes simplex and zoster can be more florid in patients with AIDS. Polyps in the external auditory canal due to *Pneumocystis carinii* have been described [3,4] and can invade the middle ear and middle cranial fossa [5]. Invasive external otitis (see p. 68.25) is a well-recognized consequence of HIV-related immunosuppression [6]. Cryptococcosis of the external ear can be a presenting sign of AIDS [7]. Excessive growth of ear hair has been noted [8].

Tumours of the pinna and external auditory canal [1]

Benign tumours

On the pinna, these will present as papules or nodules, sometimes with distinctive morphology. In the external auditory canal, benign tumours tend to present with hearing loss and may predispose to infection [2].

Fig. 68.19 Seborrhoeic keratosis (basal cell papilloma) of the pinna.

Fig. 68.20 Lobulated capillary haemangioma (pyogenic granuloma). A bright-red nodule with a surrounding collarette of keratin.

Benign tumours found on the pinna include melanocytic naevus, seborrhoeic keratosis (Fig. 68.19), squamous cell papilloma, pilomatrixoma [3,4], trichoepithelioma [5], trichofolliculoma [6,7], Winer's dilated pore [8], myoma, chondroma, osteoma, fibroma [9], neurofibroma [10], neurilemmoma [11], granular cell tumour, haemangioma (Fig. 68.20) and lymphangioma [12]. Benign glandular tumours may occur on the pinna, but are more common in the canal, especially sebaceous adenoma. Occasional unique lesions have been described [13].

Benign mass lesions in the canal include exostosis and osteoma, fibrous dysplasia both monostotic and polyostotic (Albright's syndrome), eosinophilic granuloma, cholesteatoma and keratosis obturans (see p. 68.35), benign ceruminous gland tumours

(see below), cartilaginous choristomas [14] and temporomandibular joint herniation [15].

Papillomatosis of the external auditory canal presents with multiple rounded papules; it has been associated with human papillomavirus (HPV) 6 [16].

Extra-adrenal paraganglioma (glomus jugulare tumour) of the temporal bone can manifest in the external ear canal as a friable haemorrhagic neoplasm and can cause conductive hearing loss [1]. This tumour can be locally aggressive, and there are rare instances of metastasis.

Various conditions can mimic benign tumours. On the pinna, these include cysts of various types, viral warts and molluscum contagiosum, chondrodermatitis, elastotic and weathering nodules, keloids, congenital malformations such as accessory tragi, nodular calcinosis, gouty tophi, deposits of amyloid, angiolymphoid hyperplasia with eosinophilia and 'pseudolymphoma', inflammatory polyps, hamartomas [17], choristomas [18] and congenital cysts of branchial arch origin in the external auditory canal. Cholesteatoma (see p. 68.35) may also occur in the external canal.

Exostosis and osteoma

Exostoses of the external auditory canal are usually bilateral, symmetrical, multiple, diffuse, broadly based growths of bone arising from the tympanic bone in the external auditory canal [1,2]. Frequent exposure to cold water is an aetiological factor in nearly all cases [3]. Exostoses are very common in surfers, risk factors including years spent surfing and exposure to cold water [4–7]. A male who has been surfing more than 20 years has a 1 in 2 chance of having exostoses that impair hearing [7].

Osteomas can usually be differentiated by their solitary and unilateral distribution, although they may be similar to exostoses histologically [8]. They are often attached by a narrow pedicle to the tympanosquamous or tympanomastoid suture line [1].

Occasionally other fibro-osseous lesions are found which are neither exostosis nor osteoma [9,10].

Osteomas and exostoses are normally asymptomatic unless they enlarge sufficiently to block the external auditory canal [11]. Surgical removal may be indicated [12–15].

Glandular tumours

Tumours of the ceruminous glands are rare. It is often difficult to distinguish between adenoma and carcinoma on histological grounds [1,2]. The tumours comprise benign and pleomorphic adenomas, adenocarcinomas, adenoid cystic carcinomas and perhaps others including mucoepidermoid carcinomas. The glandular tissue of a ceruminous adenoma has myoepithelial basal cells which are positive for CK5/6, S100 and p63 and luminal ceruminous cells which stain for CK7 [3]. Tumours of the cerumen glands have been reported in association with other sweat gland tumours elsewhere [4].

Isolated cases of syringocystadenoma papilliferum, apocrine cystadenoma, benign eccrine cylindroma, hidradenoma papilliferum and carcinomas of eccrine and sebaceous origin have also been reported [5,6].

Extramammary Paget's disease of the external ear and/or canal resembles Bowen's disease or a dermatosis [7].

Benign tumours produce symptoms of obstruction and hearing loss. Pain is the usual presenting feature of the more malignant tumours. They are usually seen as polypoid masses in the canal. Other symptoms include bleeding, otorrhoea and, with spread of the neoplasm, nerve palsies.

Treatment is the province of the otorhinolaryngologist. Because of the potential for malignant behaviour, all ceruminous gland tumours should be fully excised with an adequate margin of normal tissue [8].

Premalignant epithelial neoplasms of the auricle

Because of its high level of exposure to UV radiation [1], especially in men, the auricle is a common site for premalignant and malignant lesions of epidermal origin. Other predisposing factors include prior ionizing radiation, a chronic dermatosis such as lupus vulgaris, and genetic factors such as xeroderma pigmentosum and Gorlin's syndrome.

The commonest premalignant lesion is the solar keratosis, which can occur on all sun-exposed aspects of the auricle, but is especially common on the upper surface of the helix [2,3]. The clinical presentations include an erythematous telangiectatic patch, a focal area of scaling or hyperkeratosis, or a cutaneous horn. Solar keratoses on the auricle are often multiple. Solar elastosis may be evident in the surrounding skin. On the auricle, progression to squamous carcinoma from solar keratosis may occur more readily than at other sites [4].

Other premalignant lesions include Bowen's disease, radiation and tar keratoses and, rarely, keratoacanthoma [5,6].

Treatment. Several forms of treatment can eradicate premalignant lesions from the auricle, but there are no adequate data to compare them. They include excision, curettage, electrosurgery, cryotherapy, 5-fluorouracil and photodynamic therapy. The choice will depend on a number of factors, including the need for a tissue diagnosis, size and location of the lesion, likely cosmetic outcome and the available facilities. Follow-up is important for detection of recurrences and the appearance of new lesions. Lesions closely resembling squamous carcinoma, such as keratoacanthoma, should probably be totally excised to ensure accurate diagnosis [6].

Squamous cell carcinoma of the auricle

Although the ratio of basal cell carcinoma (BCC) to squamous cell carcinoma (SCC) is about 4:1 on the head and neck generally, on the ear SCC is relatively more common (BCC:SCC, 1.3 : 1) [1].

In most instances, SCC evolves from a premalignant lesion, usually a solar keratosis, and occurs predominantly in elderly white men, although at a younger age in the immunosuppressed. The most common site is the helix [2]. Early SCC may be suspected when there is induration of the base of a scaly papule, nodule or cutaneous horn. With progression, SCC usually ulcerates and with invasion of cartilage can become grossly destructive (Fig. 68.21). Local spread along perichondrial, periosteal and neurovascular planes can make SCC of the auricle very difficult to control. With the exception of the lip, auricular SCC is more likely to metastasize

Fig. 68.21 Squamous carcinoma of the auricle. An advanced tumour with extensive destruction of the ear cartilage. (Courtesy of Mr D. Baldwin, Southmead Hospital, Bristol, UK.)

than is SCC at any other sun-exposed site (11% compared with 2%) [3]. There is a small but significant mortality [2,4,5]. Adverse prognostic factors for both local recurrence and metastasis of SCC include size (>2 cm), depth of invasion (>4 mm, Clark levels 4 and 5), perineural involvement and poor differentiation of the tumour [6,7]. The pre-auricular site may also confer a poor prognosis [8]. It is not clear, however, to what extent these are independent variables; shallow lesions with large surface area (i.e. >2 cm diameter) do not seem to have a poor prognosis. There is an increased risk for a poor prognosis for SCC of the ear in renal transplant recipients [9–11]. If SCC recurs after primary treatment, there is a much greater risk for further recurrence and metastasis [6].

Treatment. It is important to achieve control of the disease with the initial treatment for SCC. For small, minimally invasive lesions, simple excision, cryotherapy or curettage with cautery/electrodesiccation may be adequate. Excellent results have been reported from the combination of curettage and cryotherapy for carefully selected cases [12]. For larger lesions, and especially for those with adverse prognostic factors, the choice is likely to be between wide margin excision, Mohs' micrographic surgery and radiation therapy.

The surgical procedure used will depend on the location and extent of the tumour. Smaller lesions can often be removed by wedge excision with primary repair by advancement flaps. Larger and ill-defined lesions are best closed by temporary grafts pending a histopathological assessment of the margins before definitive repair is carried out [13]. Partial or total amputation may be needed for large tumours. If there is spread beyond the pinna, resection of the parotid, temporal bone, temporomandibular joint or mandibular ramus may be required, with appropriate repair.

Several authors have recommended minimal resection margins, for example 1 cm [14], 6 mm with frozen section control [15], 8 mm for 1-cm-diameter tumours and 1.5 cm for 3-cm-diameter tumours [16], all with removal of the underlying cartilage. Overall, there is an incidence of 18.7% recurrence during follow-up for 5 years or more with non-Mohs' modalities compared with 5.3% for Mohs' micrographic surgery, suggesting that the latter is the treatment of choice [6,17].

SCCs in the tragal and pretragal location appear to have a greater tendency to spread along embryonic fusion planes and may only be curable by radical surgery, for example parotidectomy in association with removal of the tumour [8,18].

Various techniques are needed to reconstruct the ear after curative surgery [19–26].

Radiotherapy can be successful as a primary treatment for SCC of the auricle, megavoltage electron-beam therapy having therapeutic and cosmetic advantages over conventional orthovoltage X-ray treatment [27]. There may, however, be a higher recurrence rate [28] compared with surgery, particularly for large tumours [2,29,30]. Radiation therapy can be complicated by damage to the cartilage and associated chronic infection; deformity of the pinna is another long-term consequence. Radiotherapy may improve the outlook for cases with extensive local spread requiring radical surgery.

In renal transplant recipients, reducing the degree of immunosuppression can improve survival in poor prognosis SCC without necessarily jeopardizing the transplant [31].

The management of SCC with metastasis to regional lymph nodes and beyond is outside the scope of the dermatologist.

Basal cell carcinoma of the auricle

BCC of the auricle is somewhat less common than SCC (Fig. 68.22). It is also mainly due to the effects of solar radiation, but is much less liable to metastasize [1,2]. Presentation is generally as for BCC elsewhere, although could be missed when resembling a cleft earlobe [3].

The approach to treatment is essentially similar to that outlined for SCC. Mohs' micrographic surgery is the most likely modality to achieve cure with lesions that are extensive, deeply invasive or recurrent, or which have a morphoeic growth pattern.

Squamous and basal cell carcinoma of the external auditory canal

Non-glandular carcinomas of the external auditory canal are uncommon. Most are squamous in type (Fig. 68.23). They affect a younger age group (50–65 years) and, in contrast to SCC of the auricle, there is much less of a male preponderance. A preceding history of chronic otitis is common [1,2]. Pseudoepitheliomatous hyperplasia secondary to chronic infection or inflammation can sometimes be difficult to distinguish from SCC [3]. *In situ* squamous carcinoma has been described [4]. Rarely, the tumour is bilateral [5].

Most squamous carcinoma of the canal has an infiltrative growth pattern. It tends to grow along the canal, escaping anteriorly through Santorini's fissures in the cartilaginous segment and Huschke's foramen in the bony portion, into the temporomandibular joint and parotid. Spread also occurs posteriorly into the mastoid, and through the tympanic membrane into the middle ear and thence to the carotid canal, apex of the petrous temple bone, the internal auditory canal, base of the skull and the dura. Metastasis to lymph nodes and distantly is common.

Overall, there is a much poorer prognosis than for SCC of the pinna, with 5-year survival rates of about 65% [6,7] but the proportion surviving depends on tumour staging—see below. Adverse factors are a large lesion, invasion of cartilage or bone, facial nerve palsy, spread to the middle ear and beyond, and lymph node metastasis. The extent of the disease can be determined accurately by CT [8]. The University of Pittsburgh staging using clinical and

imaging data [8,9] is important for assessing prognosis [10] and the likelihood of benefit from adjuvant radiotherapy; patients with more advanced stages are unlikely to be cured [11].

Verrucous carcinoma of the external auditory canal is an uncommon variant that can appear cytologically banal but nevertheless invade bone, by a pushing rather than an infiltrative growth pattern [12,13]. Mucoepidermoid carcinoma is also encountered rarely [14].

BCC of the external auditory canal can be locally destructive (Fig. 68.24) and can be difficult to fully remove surgically [15], but does not metastasize and usually has a better prognosis than SCC [16].

The most common symptoms of invasive SCC of the canal are purulent and bloody discharge from the ear, followed by pain, hearing loss and facial paralysis. Examination reveals a friable tumour, partially or completely obstructing the external auditory canal.

Treatment. Surgery has been regarded as the treatment of choice, the extent determined by an assessment of the limits of tumour growth. However, radiotherapy alone may be as effective if the disease is limited to the site of origin, that is there is no evidence of nerve or bone involvement [17,18]. Post-operative radiotherapy improves the outlook [6,7,19–22], but for lesions that have spread deeply or have metastasized cure is most unlikely.

Malignant melanoma

Malignant melanoma of the external ear is relatively uncommon, constituting about 1% of all cutaneous melanomas [1,2]. It accounted for 4.8% of all auricular malignancies in one series [3] and represented 7% of all melanomas in another series [4]. Melanomas at this site are about three times more common in males than females [4,5]. Melanoma is found in a similar frequency distribution on the ear as SCC and its precursors, that is about half occur on the helix and one-quarter on the antihelix [4], but they are rarely found in the external auditory canal [6,7]. Most melanomas on the ear are of superficial spreading or nodular type, the latter being relatively more common than at other head and neck sites [8,9]. The major determinant for prognosis is Breslow thickness [5,10].

Treatment is in principle no different from malignant melanoma elsewhere (see Chapter 54), and relatively conservative excision followed by reconstruction can be safe [2,10,11]. Sentinel lymph

node mapping may be valuable for accurate staging, particularly for melanoma of the ear, since its lymphatic drainage is notoriously unpredictable [12,13], but whether prognosis will be altered is uncertain.

Other malignant tumours

Other malignant tumours involving the external ear or the external auditory canal are all rare. The pathology is reviewed in Friedman and Arnold's monograph [1]. The dermatologist may encounter sebaceous carcinoma [2], atypical fibroxanthoma (Fig. 68.25), trichilemmal carcinoma [3], Merkel cell tumour [4], carcinosarcoma [5], Kaposi's sarcoma [6,7] or rhabdomyosarcoma (mainly in children) [8–10]. Angiosarcoma of the pinna has the same gloomy outlook as it does on the scalp [11]. Other sarcomas have been recorded but are exceptionally rare. Lymphomas may occur on the external ear [12], particularly mycosis fungoides [13]. Perichondritis can be mimicked by non-Hodgkin's lymphoma [14,15], and both lymphoma [16,17] and myeloma [18] can present with an external auditory canal tumour. The ear may be involved by direct extension from tumours nearby, for example the parotid, and also by metastases from distant sites [19].

Miscellaneous conditions

Petrified ear

This is a rare clinical entity in which the cartilage of the ear is replaced by ectopic calcification or ossification [1]. The clinical presentation is of a partially or wholly rigid auricle, which may be uncomfortable with pressure over it. One or both ears may be involved. Causes include frostbite, trauma, including radiation therapy, and several systemic diseases. Addison's disease seems the commonest; others include diabetes mellitus, hypopituitarism acromegaly and hypothyroidism.

Cholesteatoma of the external auditory canal

Cholesteatoma of the middle ear space is accumulation of keratinous debris within a sac-like squamous epithelial lining. It can grow at the expense of normal structures and if it ruptures, the associated foreign body-type inflammatory reaction can produce serious damage.

A similar condition occurs rarely in the external auditory canal, although its status as a true cholesteatoma is disputed [1,2]. The accumulation of stratum corneum occurs within a cyst-like penetration of the bony portion of the canal wall by the epithelial lining. There is localized ulceration of the skin of the floor of the canal, with underlying osteitis and sometimes necrosis of bone. A necrotic sequestrum may become incorporated into the cholesteatoma. The cause is unknown, although trauma, for example from hard wax and manipulation of the canal, seems important in some cases [3].

Cholesteatoma usually occurs in patients over the age of 40 years. Symptoms are a dull pain in one ear and otorrhoea. Examination shows a white cystic mass protruding into the canal. The main differential diagnosis is from neoplasms and keratosis obturans [4,5]. External auditory canal cholesteatoma can occasionally behave aggressively, and may erode into the mastoid cavity, middle ear, temporomandibular joint and adjacent soft tissue. CT can be useful to assess the extent of the disease. Treatment is within the province of the otorhinolaryngologist.

Keratosis obturans

In this uncommon condition there is a localized accumulation of desquamated keratin in the ear canal. It may be due to a defect in the normal epithelial migration [6]. It is usually bilateral and typically occurs in younger patients than those presenting with external auditory canal cholesteatoma, which it can resemble. There is conductive hearing loss, sometimes with otalgia. Keratosis obturans can be associated with paranasal sinus disease and bronchitis; it has also been described in association with the yellow nail syndrome [7]. Treatment consists of careful removal of the accumulated keratin. Irrigation with water should be avoided [4,5].

Referred pain [1]

Due to the complicated nerve supply to the ear, referred pain is commoner than pain due to lesions in the ear itself [2]. Non-otological causes of such pain include the otomandibular syndrome [3] due to dysfunction of the temporomandibular joint, cervical arthritis with involvement of the cervical nerves, tonsillitis and carcinoma of the pharynx. Hair in the ear canal is an occasional cause [4]. Psychogenic otalgia has also been reported [5].

Introduction

Oral lesions are usually the result of local disease but may be the early signs of systemic disease, including dermatological disorders, and in some instances may cause the main symptoms. This chapter mainly discusses disorders of the dental, periodontal and mucosal tissues that may be related to skin disease and that may present at a dermatology clinic. It should be borne in mind that the professionals most competent in diagnosing and treating oral diseases are dentally qualified; few without this formal training and education are in a position to understand the full complexities of the region.

The chapter is an overview only and is divided into a brief discussion of the biology of the mouth, an overview of the more common signs and symptoms affecting specific oral tissues, discussion of the disorders of the oral mucosa of most relevance to dermatology and a tabulated review of oral manifestations of systemic diseases. Diseases affecting the salivary glands, or jaws or temporomandibular joints are not discussed in any depth.

Only the more classic oral lesions are illustrated. About 20 of the colour illustrations are from the *Colour Atlas of Oral and Maxillofacial Diseases*, 2004 (reproduced by kind permission of C. Scully, S. Flint, S.R. Porter and K. Moos, and publishers Taylor and Francis, London). More detail of histology is available elsewhere [1].

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

Biology of the mouth

Oral epithelium

The oral epithelium consists of a *functional compartment*—the progenitor cells (basal and parabasal cells)—which is the site of cell division; a *maturation compartment* (spinous and granular cells) where the cells become more terminally differentiated; and a superficial *cornified compartment* of squames and areas of keratinization, either orthokeratotic or parakeratotic. In the non-keratinized regions such as the buccal (cheek) and floor-of-mouth mucosae, overt keratinization and granular cells are absent and the surface cells are flattened, with elongated nuclei [2].

Lips

The lips extend from the lower end of the nose to the upper end of the chin. They mainly consist of bundles of striated muscle, particularly the *orbicularis oris* muscle, with skin on the external surface and mucous membrane on the inner surface, which has a profusion of minor salivary glands.

The vermilion zone, the transitional zone between the glabrous skin and the mucous membrane, is found only in humans. The vermilion zone contains no hair or sweat glands but does contain

sebaceous glands (Fordyce spots, see below). The epithelium of the vermilion is distinctive, with a prominent stratum lucidum and a very thin stratum corneum. The dermal papillae are numerous at this site, with a rich capillary supply, which produces the reddish-pink colour of the lips in white people. Melanocytes are abundant in the basal layer of the vermilion of pigmented skin, but are infrequent in white skin.

The *oral commissures* are the angles where the upper and lower lip meet. The upper lip includes the *philtrum*, a midline depression, extending from the columella of the nose to the superior edge of the vermilion zone [3].

Oral mucosa

The mucosa is divided into masticatory, lining and specialized types. *Masticatory mucosa* (hard palate, gingiva) is adapted to the forces of pressure and friction and is keratinized, with numerous tall rete ridges and connective tissue papillae and little submucosa. *Lining mucosa* (buccal, labial and alveolar mucosa, floor of mouth, ventral surface of tongue, soft palate, lips) is non-keratinized, with broad rete ridges and connective tissue papillae and abundant elastic fibres in the lamina propria [4,5].

Specialized mucosa on the dorsum of the tongue, adapted for taste and mastication, is keratinized, with numerous rete ridges and connective tissue papillae, abundant elastic and collagen fibres in the lamina propria and no submucosa. The tongue is divided by a V-shaped groove, the *sulcus terminalis*, into an anterior two-thirds and a posterior third. Various papillae on the dorsum include the *filiform papillae*, which cover the entire anterior surface and form an abrasive surface to control the food bolus as it is pressed against the palate, and the *fungiform papillae*. The latter are mushroom-shaped, red structures covered by non-keratinized epithelium. They are scattered between the filiform papillae and have taste buds on their surface. Adjacent and anterior to the sulcus terminalis are eight to twelve large *circumvallate papillae*, each surrounded by a deep groove into which open the ducts of serous minor salivary glands. The lateral walls of these papillae contain taste buds.

The *foliate papillae* consist of four to eleven parallel ridges, alternating with deep grooves in the mucosa, on the lateral margins on the posterior part of the tongue. There are taste buds on their lateral walls. The *lingual tonsils* are round or oval prominences with intervening lingual crypts lined by non-keratinized epithelium. They are part of *Waldeyer's oropharyngeal ring* of lymphoid tissue. The lingual tonsil is a mass of lymphoid tissue in the posterior third of the tongue, between the epiglottis posteriorly and the circumvallate papillae anteriorly. It is usually divided in the midline by a ligament.

Teeth

The teeth develop from neuroectoderm [6]. Tooth development begins in the fetus, at about 28 days *in utero*. Indeed, all the deciduous and some of the permanent dentition commence development in the fetus. At around the sixth week of intrauterine life the oral epithelium proliferates over the maxillary and mandibular ridge areas to form primary epithelial bands that project into the mesoderm, and produce a dental lamina in which discrete swellings appear—the enamel organs of developing teeth. Each enamel organ eventually produces tooth enamel, and the mesenchyme, which condenses beneath the enamel organ (actually neuroectoderm), forms a dental papilla that produces the dentine and pulp of the tooth. The enamel organ together with the dental papilla constitute the tooth germ, and this becomes surrounded by a mesenchymal dental follicle, from which the periodontium forms, ultimately to anchor the tooth in its bony socket. Mineralization of the primary dentition commences at about 14 weeks *in utero* and all primary teeth are mineralizing by birth. Permanent incisor and first molar teeth begin to mineralize at, or close to, the time of birth, mineralization of other permanent teeth starting later. Tooth eruption occurs after crown formation when mineralization is largely complete but before the roots are fully formed.

Teeth comprise a crown of insensitive enamel, surrounding sensitive dentine, and a root which has no enamel covering (Fig. 69.1). Teeth contain a vital pulp (nerve) and are supported by the periodontal ligament by which roots are attached into sockets in the alveolar process of the jaws (maxilla and mandible). The fibres of the periodontal ligament attach through cementum to the dentine surface. The alveolus is covered by the gingivae, or gums, which in health are pink, stippled and tightly bound down, and form a close-fitting cuff, with a small sulcus (gingival crevice), round the neck of each tooth.

The first or primary (deciduous or milk) dentition comprises two incisors, a canine and two molars in each of the four mouth quadrants (total 20 teeth). There are 10 deciduous (primary or milk) teeth in each jaw: all are fully erupted by the age of about 3 years (Fig. 69.2; Table 69.1). The secondary or permanent teeth begin to erupt at about the age of 6–7 years and the deciduous teeth are slowly lost by normal root resorption.

The normal permanent (adult) dentition comprises two incisors, a canine, two premolars and three molars in each quadrant (total 32 teeth). The full permanent dentition consists of 16 teeth in each jaw: normally most have erupted by about 12–14 years of age. However, some milk teeth may still be present at the age of 12–13 years. The last molars (third molars or wisdom teeth), if present, often erupt later or may impact and never appear in the mouth.

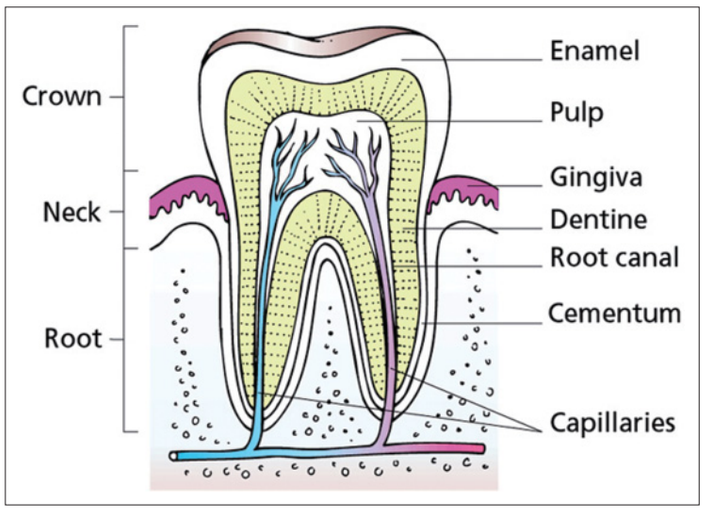

Fig. 69.1 Tooth structure.

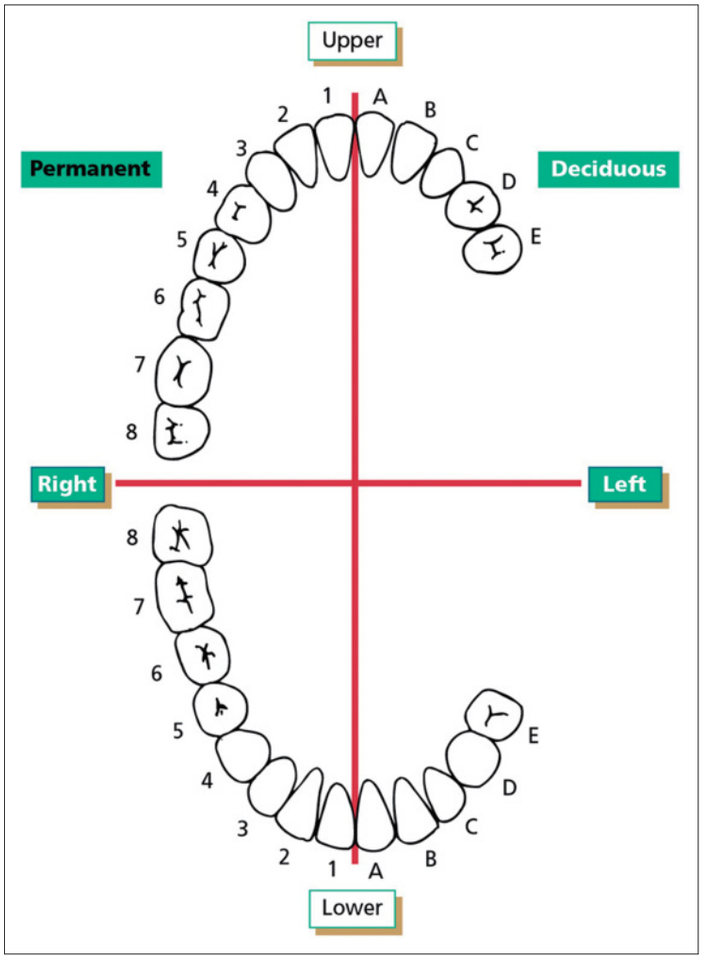

Fig. 69.2 Tooth notations.

Junction of the mucosa with the teeth

The dentogingival junction represents a unique anatomical feature concerned with the attachment of the gingival (gum) mucosa to the tooth. Non-keratinized gingival epithelium forms a cuff surrounding the tooth, and at its lowest point on the tooth is adherent to the enamel or cementum. This 'junctional' epithelium is unique in being bounded both on its tooth and lamina propria aspects by basement membranes. Above this is a shallow sulcus or crevice (up to 2 mm deep), the gingival sulcus or crevice. Neutrophils continually migrate into the gingival crevice, and there is also a slow exudate of plasma (crevicular fluid).

Immunity in the oral cavity

Movement of the soft tissues during speech and swallowing, and salivation, ensures that much foreign material is swallowed. The need for this cleaning mechanism is clearly apparent in patients with facial paralysis, or in those with xerostomia, in whom there is accumulation of oral debris and subsequent infection.

Saliva also aggregates bacteria and deters their attachment to surfaces. Salivary lysozyme, thiocyanate, peroxides and various mucins and other components may be antimicrobial and saliva is inhibitory to various microbial agents including, for example, human immunodeficiency virus (HIV).

Table 69.1 Tooth eruption timings (average timings; there is a wide range).

	Upper	Lower
Deciduous (primary) teeth		
A Central incisors	8–13 months	6–10 months
B Lateral incisors	8–13 months	10–16 months
C Canines (cuspids)	16–23 months	16–23 months
D First molars	13–19 months	13–19 months
E Second molars	25–33 months	23–31 months
Permanent teeth		
1 Central incisors	7–8 years	6–7 years
2 Lateral incisors	8–9 years	7–8 years
3 Canines (cuspids)	11–12 years	9–10 years
4 First premolars (bicuspids)	10–11 years	10–12 years
5 Second premolars (bicuspids)	10–12 years	11–12 years
6 First molars	6–7 years	6–7 years
7 Second molars	11–13 years	11–13 years
8 Third molars	17–21 years	17–21 years

Salivary tissue derives its B cells from the gut-associated lymphoid tissue (GALT) system [7]. Salivary acinar cells produce secretory component (transport piece) needed for transport of IgA into the saliva and its stability in the presence of salivary or gastric proteolytic enzymes. Although the exact contribution to oral defence made by salivary IgA antibodies is difficult to assess, some patients who have IgA deficiency suffer from oral infections, and in animals it is possible to induce protective salivary IgA antibodies to caries-producing organisms such as *Streptococcus mutans*.

Neutrophils and other leukocytes are particularly essential for oral health as shown by the fact that patients with HIV infection, neutropenia, agranulocytopenia, leukaemia or chronic granulomatous disease are predisposed to severe gingivitis and rapid periodontal breakdown, as well as mouth ulceration and infections.

Examination of the mouth and perioral region

Examination includes inspection and palpation of the lymph nodes, temporomandibular joints, jaws, salivary glands and oral cavity.

Lymph nodes (Table 69.2)

Lymph from the superficial tissue of the head and neck generally drains first to groups of superficially placed lymph nodes, then to the deep cervical lymph nodes.

- Systematically, each region needs to be examined lightly with the pulps of the fingers, trying to roll the lymph nodes against harder underlying structures.
- Parotid, mastoid and occipital lymph nodes can be palpated simultaneously using both hands.
- Superficial cervical lymph nodes are examined with lighter palpation as they can only be compressed against the softer sternomastoid muscle.
- Submental lymph nodes are examined by tipping the patient's head forward and rolling the lymph nodes against the inner aspect of the mandible.
- Submandibular lymph nodes are examined in the same way with the patient's head tipped to the side being examined. Differentiation needs to be made between the submandibular salivary gland and submandibular lymph glands. Bimanual examination with one finger in the floor of the mouth may help.
- The deep cervical lymph nodes, which project anterior or posterior to the sternomastoid muscle, can be palpated. The jugulodigastric lymph node should be specifically examined, as this is the most common lymph node involved in tonsillar infections.

Table 69.2 Drainage areas of cervical lymph nodes.

Area	Draining lymph nodes
Scalp, temporal region	Superficial parotid
Scalp, posterior	Occipital
Scalp, parietal region	Mastoid
Ear, external	Superficial cervical over upper part of sternomastoid muscle
Ear, middle	Parotid
Over angle of mandible	Superficial cervical over upper part of sternomastoid muscle
Medial part of frontal region, medial eyelids, skin of nose	Submandibular
Lateral part of frontal region and lateral part of eyelids	Parotid
Cheek	Submandibular
Upper lip	Submandibular
Lower lip	Submental
Lower lip, lateral part	Submandibular
Mandibular gingivae	Submandibular
Maxillary teeth	Deep cervical
Maxillary gingivae	Deep cervical
Tongue tip	Submental; remainder drains to submandibular nodes
Tongue, anterior two-thirds	Submandibular; some midline cross-over of lymphatic drainage
Tongue, posterior third	Deep cervical
Tongue, ventrum	Deep cervical
Floor of mouth	Submandibular
Palate, hard	Deep cervical
Palate, soft	Retropharyngeal and deep cervical
Tonsil	Jugulodigastric

- The supraclavicular region should be examined at the same time as the rest of the neck; lymph nodes here may extend up into the posterior triangle of the neck on the scalene muscles, behind the sternomastoid.
- Parapharyngeal and tracheal lymph nodes can be compressed lightly against the trachea.
- Some information can be gained by the texture and nature of the lymphadenopathy.
- Tenderness and swelling should be documented. Lymph nodes that are tender may be inflammatory (lymphadenitis). Consistency should be noted. Nodes that are increasing in size and are hard or fixed to adjacent tissues may be malignant.
- Both anterior and posterior cervical nodes should be examined as well as other nodes, liver and spleen if systemic disease is a possibility.

Temporomandibular joints and muscles of mastication

Although disorders that affect the temporomandibular joint often appear to be unilateral, the joint should not be viewed in isolation but always considered together with its opposite joint, as part of the stomatognathic system. The area should be examined as follows.

Inspection

- Facial symmetry
- Evidence of enlarged masseter muscles (masseteric hypertrophy) suggestive of clenching or bruxism
- Mandibular opening and closing paths
- Mandibular opening extent:
  (i) measure the interincisal distance at maximum mouth opening
  (ii) measure the amount of lateral excursions achievable
  (iii) listen for joint noises (a stethoscope placed over the joint can help).

Palpation

- Both condyles: via the external auditory meatus to detect tenderness posteriorly, and by using a single finger placed over the joints in front of the ears to detect pain, abnormal movements or clicking within the joint.
- Masticatory muscles on both sides.

Masseters: by intraoral/extraoral compression between finger and thumb. Palpate the masseter bimanually by placing a finger of one hand intraorally and the index and middle fingers of the other hand on the cheek over the masseter over the lower mandibular ramus.

Temporalis: by direct palpation of the temporal region. Palpate the temporal origin of the temporalis muscle by asking the patient to clench the teeth. Palpate the insertion of the temporalis tendon intraorally along the anterior border of the ascending mandibular ramus.

Lateral pterygoid (lower head): by placing a little finger up behind the maxillary tuberosity (the 'pterygoid sign'). Examine

the lateral pterygoid muscle, which cannot readily be palpated, indirectly by asking the patient to open the jaw against resistance and to move the jaw to one side while a gentle resistance force is applied.

Medial pterygoid muscle: intraorally lingually to the mandibular ramus.

Some palpate using a pressure algometer to standardize the force used, and undertake range-of-movement measurements.

- Examination of the dentition and occlusion: this may require monitoring of study models on a semi-adjustable or fully adjustable articulator. Note particularly missing premolars or molars, and attrition.
- Examination of the mucosa: note particularly occlusal lines and scalloping of the tongue margins, which may indicate bruxism and tongue pressure.

Jaws

There is wide normal individual variation in morphology of the face. Most individuals have facial asymmetry but of a degree that cannot be regarded as abnormal.

- Maxillary, mandibular or zygomatic deformities or lumps may be more reliably confirmed by inspection from above (maxillae/zygomas) or behind (mandible). The jaws should be palpated to detect swelling or tenderness.
- Maxillary air sinuses can be examined by palpation for tenderness over the maxillary antrum, which may indicate sinus infection. Transillumination or endoscopy can be helpful.

Salivary glands

Inspect and palpate the major salivary glands (parotid and submandibular) for:

- symmetry
- evidence of enlarged glands
- evidence of salivary flow from salivary ducts
- appearance of saliva.

Parotid glands. Palpate by placing fingers over the pre-auricular glands, to detect pain or swelling. Early enlargement of the parotid gland is characterized by outward deflection of the lower part of the earlobe, which is best observed by looking at the patient from behind. This simple sign may allow distinction from simple obesity. Swelling of the parotid sometimes causes trismus. Swellings may affect the whole or part of a gland or tenderness may be elicited. The parotid duct (Stensen's duct) is most readily palpated with the jaws clenched firmly since the duct turns medially at the front edge of masseter, pierces the buccinator muscle and opens at a papilla on the buccal mucosa opposite the upper molars.

Submandibular glands. Bimanually palpate using fingers inside the mouth and extraorally. The submandibular gland is best palpated with a finger of one hand in the floor of the mouth lingual to the lower molar teeth, and a finger of the other hand placed over the submandibular triangle. The submandibular duct (Wharton's duct) runs anteromedially across the floor of the mouth to open at the side of the lingual fraenum.

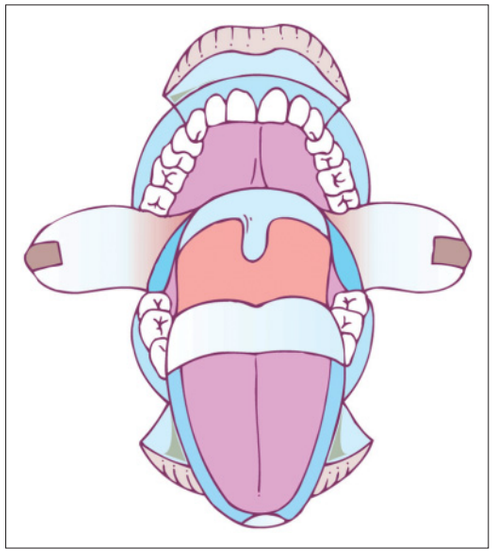

Fig. 69.3 Diagram of oral cavity.

Intraoral examination

The examination should be conducted in a systematic fashion to ensure that all areas are included. If the patient wears any removable prostheses or appliances, these should be removed in the first instance, although it may be necessary later to replace the appliance to assess fit, function and relationship to any lesion.

Complete visualization with a good source of light is essential. All mucosal surfaces should be examined, starting away from the location of any known lesions or the focus of complaint. The lips should be inspected first. The labial mucosa, buccal (cheek) mucosae, floor of mouth and ventrum of tongue, dorsal surface of the tongue, hard and soft palates, gingivae and teeth should then be examined in sequence and lesions noted on a diagram of the oral cavity (Fig. 69.3).

Lips. Features such as cyanosis are seen mainly in the lips in cardiac or respiratory disease; angular cheilitis (stomatitis) is seen mainly in oral candidosis or in iron, vitamin or immune deficiencies. Examination is facilitated if the mouth is gently closed at this stage, so that the lips can then be everted to examine the mucosa.

Labial mucosa. Normally appears moist with a fairly prominent vascular arcade. In the lower lip, the many minor salivary glands, which are often exuding mucus, are easily visible. The lips therefore feel slightly nodular and the labial arteries are readily felt. Many adults have a few yellowish, pinhead-sized papules in the vermilion border (particularly of the upper lip) and at the commissures; these are usually ectopic sebaceous glands (Fordyce spots), and may be numerous, especially as age advances.

Cheek (buccal) mucosa. This is readily inspected if the mouth is held half open. The vascular pattern and minor salivary glands so prominent in the labial mucosa are not obvious in the buccal mucosa but Fordyce spots may be conspicuous, particularly near the commissures and retromolar regions in adults. Place the surface of a dental mirror against the buccal mucosa. The mirror

should lift off easily; if it adheres to the mucosa, then xerostomia is present.

Floor of mouth and ventrum of tongue. These are best examined by asking the patient to push the tongue first into the palate then into each cheek in turn. This raises for inspection the floor of the mouth, an area where tumours may start (the 'coffin' or 'graveyard' area of the mouth). Its posterior part is the most difficult area to examine well and one where lesions are most easily missed. Lingual veins are prominent and, in the elderly, may be conspicuous (lingual varices). Bony lumps on the alveolar ridge lingual to the premolars are most often tori (torus mandibularis). During this part of the examination the quantity and consistency of saliva should be assessed. Examine for the normal pooling of saliva in the floor of the mouth; normally there is a pool of saliva in the floor of the mouth.

Dorsum of tongue. This is best inspected by protrusion, when it can be held with gauze.

This raises the floor of the mouth which aids inspection. The floor of mouth and posterolateral margin of the tongue is an area where tumours may start. The posterior aspect of the floor of the mouth is the most difficult area to examine well and one where lesions are most likely to be missed.

The anterior two-thirds of the tongue is embryologically and anatomically distinct from the posterior third, and separated by a dozen or so large circumvallate papillae. The anterior two-thirds is coated with many filiform, but relatively few fungiform, papillae. Behind the circumvallate papillae, the tongue contains several large lymphoid masses (lingual tonsil) and the foliate papillae lie on the lateral borders posteriorly. These are often mistaken for tumours. The tongue may be fissured (scrotal) but this is usually regarded as a developmental anomaly. A healthy child's tongue is rarely coated but a mild coating is not uncommon in healthy adults. The voluntary tongue movements and sense of taste should be formally tested. Abnormalities of tongue movement (neurological or muscular disease) may be obvious from dysarthria or involuntary movements and any fibrillation or wasting noted. Hypoglossal palsy may lead to deviation of the tongue towards the affected side on protrusion. Taste sensation can be tested by placing the tongue across the terminals of a pocket torch battery when a metallic taste may be obvious. Formal testing with salt, sweet, sour and bitter should be carried out by applying solutions of salt, sugar, dilute acetic acid and 5% citric acid to the tongue on a cotton swab or cotton bud.

Palate and fauces. These consist of an anterior hard and posterior soft palate, and the tonsillar area and oropharynx. The mucosa of the hard palate is firmly bound down as a mucoperiosteum (similar to the gingivae) and with no obvious vascular arcades. Rugae are present anteriorly on either side of the incisive papilla that overlies the incisive foramen. Bony lumps in the posterior centre of the vault of the hard palate are usually tori (torus palatinus). Patients may complain of lumps distal to the upper molars that they think are unerupted teeth but the pterygoid hamulus or tuberosity is usually responsible for this complaint. The soft palate and fauces may show a faint vascular arcade. In the soft palate, just posterior to the junction with the hard palate, is a conglomeration of minor salivary glands. This region is often also yellowish. The palate should be inspected and movements examined when the patient says 'Aah'. Using a mirror, this also permits inspection of the posterior tongue, tonsils, oropharynx, and can even offer a glimpse of the larynx. Glossopharyngeal palsy may lead to uvula deviation to the contralateral side.

Gingivae. In health they are firm, pale pink, with a stippled surface, and have sharp gingival papillae reaching up between the adjacent teeth to the tooth contact point. Look for gingival redness, swelling or bleeding on gently probing the gingival margin. The 'keratinized' attached gingivae (pale pink) are normally clearly demarcated from the non-keratinized alveolar mucosa (vascular) that runs into the vestibule or sulcus. Bands of tissue, which may contain muscle attachments, run centrally from the labial mucosa onto the alveolar mucosa and from the buccal mucosa in the premolar region onto the alveolar mucosa (fraena).

Teeth. The dentition should be checked to make sure that the expected complement of teeth is present for the patient's age. Extra teeth (supernumerary teeth) or deficiency of teeth (partial loss or hypodontia; oligodontia; complete loss or anodontia) can be features of many syndromes but teeth are far more frequently missing because they are unerupted, or lost as a result of caries or periodontal disease. The teeth should be fully examined for signs of disease, either malformations such as hypoplasia or abnormal shape or colour, or acquired disorders such as dental caries, erosion or abrasion, or superficial discoloration due to poor hygiene, habits, foods or drugs. The occlusion of the teeth should also be checked; it may show attrition or may be disturbed, as in some jaw fractures or dislocation of the mandibular condyles.

Anatomical variants

Patients sometimes become concerned after noticing various anatomical variants in the mouth. These include tori and exostoses [1–3], which are developmental bony lumps seen especially in Mongoloid and Negroid races. Most common is torus palatinus, a slow-growing, asymptomatic, benign, bony lump in the midline of the palate (Fig. 69.4). Tori mandibularis are bilateral, asymptomatic, benign, bony lumps lingual to the premolars.

Fig. 69.4 Torus palatinus.

The diagnosis is confirmed by radiography. Surgery is rarely indicated. These are excised or reduced only if causing severe difficulties with dentures.

Disorders affecting the teeth

Disorders of tooth eruption

Teething

'Teething' in infancy is a poorly understood condition and the soreness and fever is often due to infection such as herpes simplex stomatitis. Nevertheless, there may be a very minor degree of pyrexia around the time of tooth eruption [1,2].

References

2 Peretz B, Ram D, Hermida L, Otero MM. Systemic manifestations during eruption of primary teeth in infants. *J Dent Child (Chic)* 2003; **70**: 170–3.

Premature eruption of teeth [1–5]

Erupted teeth, particularly in the mandibular central incisor region, may be present at birth (natal teeth) or appear within the first few days or weeks of life (neonatal teeth). This rare event (about 0.1% of live births) occasionally has a familial basis or is associated with some other developmental anomaly. Such teeth occasionally cause ulceration of the infant's tongue or mother's nipple but usually they can be safely left *in situ*.

Delayed eruption of teeth

Congenital hypopituitarism, congenital hypothyroidism (cretinism), Down's syndrome, cleidocranial dysplasia, cytotoxic drugs and radiotherapy may cause delayed eruption of teeth, but most cases are of local aetiology (e.g. impactions).

Extra teeth

Extra (supernumerary or supplemental) teeth are uncommon and usually of an unknown cause. They are generally found in the premaxilla. Supernumerary teeth are common in cleidocranial dysplasia.

Missing teeth

It is important to remember that teeth may be apparently missing simply because they are unerupted but early loss or hypodontia may be responsible.

Dental aplasia

Synonyms
- Hypodontia
- Anodontia
- Oligodontia

Wisdom teeth (third molars), second premolars and upper lateral incisors are sometimes absent in otherwise normal individuals, probably because of some unidentified genetic trait. Up to 25% of white people lack a third molar. Absence of several teeth may indicate systemic disease such as cleidocranial dysplasia, incontinentia pigmenti or ectodermal dysplasia.

Hypodontia is often associated with microdontia and is often bilaterally symmetrical.

Loosening and early loss of teeth (Table 69.3)

Early loss of teeth is usually caused by trauma, dental caries or destructive periodontal disease, as discussed below [1–4]. Congenital disorders that may predispose to periodontal breakdown include Down's syndrome, Papillon–Lefèvre syndrome, neutropenia and other immune defects. Acquired disorders such as diabetes mellitus or immune defects also predispose to periodontal breakdown. Teeth are also lost early in other rare systemic disorders, for example eosinophilic granuloma or hypophosphatasia.

Table 69.3 Pathological causes of loosening and early loss of the teeth.

Local causes
Trauma
Periodontitis
Neoplasms
Systemic causes
Disorders with some immune deficit
Down's syndrome
Diabetes mellitus
Leukopenia or leukocyte defects
Human immunodeficiency virus disease
Juvenile periodontitis
Rapidly progressive periodontitis
Papillon–Lefèvre syndrome
Hypophosphatasia
Ehlers–Danlos syndrome (type VIII)
Others
Acrodynia
Neoplasms
Eosinophilic granuloma

Table 69.4 Causes of discoloration of teeth.

Extrinsic
Poor oral hygiene
Tobacco
Coffee, tea, other beverages/food
Drugs, e.g. iron, chlorhexidine, amoxicillin, sweetened medication
Stains, e.g. from betel chewing
Intrinsic
Trauma
Caries
Restorative materials, e.g. amalgam
Pink spot (internal resorption)
Drugs: mainly tetracyclines
Fluorosis
Dentinogenesis imperfecta
Amelogenesis imperfecta
Porphyria
Kernicterus (severe neonatal jaundice)

Fig. 69.5 A peg-shaped maxillary lateral incisor, a fairly common variant.

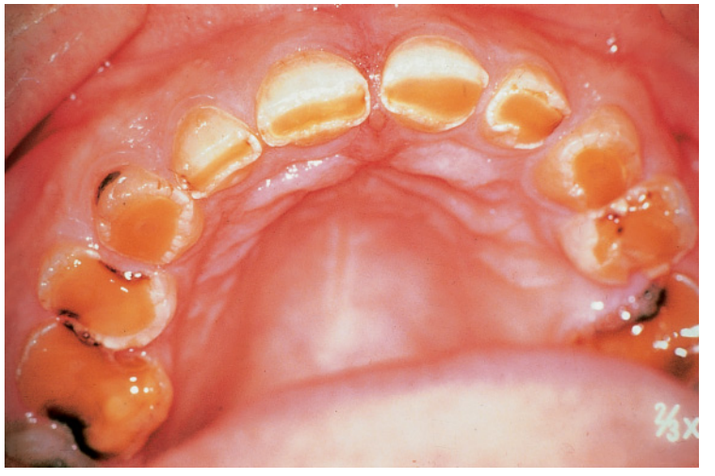

Fig. 69.6 Dentinogenesis imperfecta: staining and severe attrition.

Malformed and discoloured teeth (Table 69.4)

There is a wide range of normal variation in tooth morphology and colour, especially between races.

Most dental discoloration is caused by lifestyle habits such as smoking, betel, foods and beverages (such as tea), medicines such as iron or chlorhexidine, or poor oral hygiene [1]. The regular use of sweetened medication at night (e.g. trimeprazine syrup in a child with eczema) can cause discoloration due to dental caries. Erosion of teeth may occur because of the repeated use of acidic drinks or sucking citrus fruits, or as a feature of gastric regurgitation in bulimia, anorexia nervosa or alcoholism.

Teeth may be malformed for genetic reasons. Peg-shaped teeth may be normal variants (Fig. 69.5) or may be found in some ectodermal dysplasias (see p. 69.10). Taurodontism (see below) can be found in a range of dermatological disorders [2]. Genetic defects that may cause tooth discoloration include dentinogenesis imperfecta (Fig. 69.6), which may be seen in some patients with osteogenesis imperfecta, and amelogenesis imperfecta [3,4].

Teeth may be damaged during their development. Local infection or trauma, or unknown factors, may cause malformation of one or more teeth. The lower premolars are usually affected because there is caries and periapical infection related to their deciduous predecessors; such hypoplastic teeth are termed *Turner's teeth*. The upper permanent incisors may be malformed if there is trauma to the deciduous incisors. Radiotherapy or cytotoxic therapy may cause hypoplasia, as may congenital rubella or cytomegalovirus infection. However, classical *Hutchinsonian* (*screwdriver-shaped*) *incisors* and *Moon's* (*or mulberry*) *molars* of congenital syphilis are extremely rare.

Hypoplasia is relatively common in apparently healthy persons [5–10] and is also seen in early-onset malabsorption syndromes, many severe childhood illnesses (Fig. 69.7) and organ transplantation [11–13] and in some forms of epidermolysis bullosa (see below). Jaundice in the neonate or infant can produce greenish teeth.

Fluoride protects against dental caries but in high water supply concentrations over 2 ppm or if administered in excess amounts may produce significant fluorosis-discoloration and even hypoplasia. Fluoride, at the concentrations present in water supplies in resource-rich countries or given prophylactically even with care, may occasionally produce inconsequential, minute white flecks. Tetracyclines given to a pregnant or lactating mother may discolour the child's teeth and, if given to a child, particularly one under the age of 12 years, may cause significant, brown, intrinsic tooth staining (Fig. 69.8).

Fig. 69.7 Hypoplasia of teeth related to severe childhood respiratory infection.

Fig. 69.8 Pronounced intrinsic tooth discoloration from use of tetracyclines in childhood.

Taurodontism

Taurodont teeth have an enlarged pulp chamber and a more inferiorly placed root furcation in premolars and molars. They are not readily detectable on clinical examination and are therefore most easily diagnosed on radiographs (Fig. 69.9). However, on clinical examination, lack of constriction of the tooth at the neck may be suggestive of taurodontism. Taurodontism is generally most obvious in molars of both deciduous and permanent dentitions, and may be found in single or several teeth, with or without evidence of other disorders.

Most studies have shown an overall prevalence of the order of 2% with no sex predilection, but oriental people and some other racial groups are especially affected [1–13]. XXY and other syndromes with additional X chromosomes may be affected [4–6] as may other chromosomal anomalies [7–12]. Dermatological conditions with which taurodontism may be associated are shown in Table 69.5 [10].

Ectodermal dysplasia

Ectodermal dysplasia is typically characterized by developmental abnormalities in at least two different ectodermally derived systems [1]. Oral abnormalities are common, especially missing teeth and abnormally shaped teeth (Fig. 69.10). There are many variations, as discussed in the following sections and in Chapter 15, and current classification is based on clinical features.

X-linked hypohidrotic ectodermal dysplasia [2–4]

Hypodontia is common in X-linked hypohidrotic ectodermal dysplasia. Some anterior teeth are usually present but their crowns are typically conical or peg-shaped. The posterior teeth, when present, are smaller but otherwise normal. Overclosure of the jaws, together with maxillary hypoplasia and frontal bossing, give a characteristic facial appearance. There may be a degree of impaired salivary gland function.

Female carriers of this syndrome may have hypodontia and/or microdontia.

Autosomal recessive ectodermal dysplasia [2,5]

Dental and oral anomalies in this condition are identical to those in the X-linked form of ectodermal dysplasia, although relatives may have a normal dentition.

Hypodontia, taurodontism and sparse hair [6]

There are a few reports of a variant of ectodermal dysplasia in which there is taurodontism, and somewhat lesser hypodontia than in the more classic forms of ectodermal dysplasia.

Autosomal dominant hypodontia with nail dysgenesis [7]

Hypodontia, conical deciduous and permanent teeth, and dysplastic nails characterize this variant of ectodermal dysplasia.

Incontinentia pigmenti [8,9]

Synonym
- Bloch–Sulzberger syndrome

Hypodontia and retarded eruption affect both dentitions and the anterior teeth are small. The teeth tend also to be conical, often with accessory cusps.

Chondroectodermal dysplasia [10–14]

Synonym
- Ellis–van Creveld syndrome

This is a rare autosomal recessive condition that manifests with chondrodysplasia of tubular bones resulting in disproportionate dwarfism, polydactyly and syndactyly of hands and feet, severe dystrophic nails, bilateral partial clefts of the alveolar bone and malocclusion. Half of the cases have cardiac malformations.

The most obvious oral anomalies are the multiple fraena extending from the lips and buccal mucosae to the alveolar ridges of both jaws. Natal teeth, mild hypodontia or hyperdontia, malformed or small teeth and accessory cusps are common.

Cranioectodermal dysplasia [12]

Deciduous teeth are small and may have dysplastic enamel, although the condition is so rare that the permanent teeth have not been clearly described. There may be hypodontia or taurodontism. Dolicocephaly, hair anomalies and shortened arms, fingers and toes are associated.

Nance–Horan syndrome [13]

X-linked congenital cataracts with supernumerary teeth constitute the Nance–Horan syndrome. The incisor teeth may also be morphologically abnormal and can resemble Hutchinson's incisors of congenital syphilis.

Trichodental syndrome [14,15]

The trichodental syndrome is a rare, dominantly inherited condition in which there is fine short hair, thinning of the lateral ends of the eyebrows, hypodontia and/or conical teeth.

Trichodento-osseous syndrome [16–19]

Tight, curly hair, sclerotic cortical bone and oral anomalies (especially thin enamel) are found in this autosomal dominant condition. The hypoplasia–hypomaturation type of amelogenesis imperfecta, enamel hypoplasia, unerupted teeth and taurodontism may be associated.

Trichonychodental syndrome [20–26]

This autosomal dominant trait of fine, curly hair and thin dysplastic nails may be associated with taurodontism and enamel or dentinal developmental defects.

Curry–Hall syndrome [27]

Deciduous teeth are small and conical, and the incisors are often retained since their permanent successors may be congenitally absent. The remaining permanent teeth do erupt but are small. Other features include short limbs, polydactyly and nail dysplasia.

Otodental dysplasia [28–32]

Globe-shaped posterior teeth (globodontia) in both dentitions are the most common oral feature of this autosomal dominant condition, which is associated with sensorineural hearing loss. The incisors are not affected and the patients are otherwise well. Other oral anomalies may include taurodontism, microdontia and hypodontia.

Clouston syndrome [33] (see Chapter 15)

Palmoplantar hyperkeratosis, hair defects, nail dysplasia and oral white lesions characterize this autosomal dominant form of hidrotic ectodermal dysplasia. There may be diffuse, white lesions in the buccal mucosa, palate, tongue and elsewhere but reports of malignancy are rare.

Alstrom syndrome

Alstrom syndrome is a rare disorder characterized by early obesity, diabetes mellitus, loss of central vision, hearing loss and short stature. Light yellow-brown discoloured enamel bands have been observed on the anterior teeth in some patients [2,3].

Disorders affecting the periodontium

Gingival disorders affecting the periodontium

Bleeding

Bleeding from the gingival margins is common, and is usually a consequence of inadequate oral hygiene leading to the accumulation of dental bacterial plaque and thus gingivitis (Table 69.7), which is painless and causes only some mild erythema and bleeding on brushing or eating hard foods.

Chronic gingivitis affects many, if not most, healthy adults but the tendency to gingivitis and bleeding is slightly increased in patients taking oral contraceptives and in some pregnant women (especially during the second trimester).

Gingival haemorrhage may, however, also be an early feature in some vascular or platelet disorders and is commonly a problem, for example, in leukaemic patients.

Swelling

Localized gingival swellings (epulides) may be of local aetiology or can be manifestations of pregnancy, a neoplasm or systemic disease (Table 69.8).

Gingival swelling affecting many areas is most commonly seen in chronic gingivitis, may be produced by drugs such as phenytoin, ciclosporin (cyclosporin) and calcium channel blockers (Fig. 69.11), and is occasionally hereditary. Gingival swelling is

Fig. 69.11 Gingival hyperplasia in phenytoin therapy. Concomitant folate deficiency in this patient also caused mouth ulcers, seen in the maxillary buccal vestibule.

seen with hypertrichosis in both drug-induced hyperplasias and hereditary gingival fibromatosis.

A degree of gingival swelling may also be seen in herpetic stomatitis, pregnancy, OFG, and Crohn's disease. Rare causes include leukaemia, scurvy, Wegener's granulomatosis, sarcoidosis, amyloidosis, lipoid proteinosis, hypoplasminogenaemia, mucopolysaccharidoses and other disorders.

Redness

Chronic, marginal gingivitis is the usual cause of gingival redness, and then is usually restricted to the gingival margins and interdental papillae.

More widespread erythema, particularly if associated with soreness, in children is usually caused by primary herpes simplex stomatitis. In adults the main cause is desquamative gingivitis (usually due to lichen planus or mucous membrane pemphigoid—rarely by pemphigus or other dermatoses). At any age, chemotherapy or irradiation to the head and neck, or graft-versus-host disease can cause mucositis. Erythema is also occasionally induced by allergic responses, for example plasma cell gingivitis.

Telangiectasia may be a manifestation of hereditary haemorrhagic telangiectasia, primary biliary cirrhosis or systemic sclerosis, or may follow radiotherapy. Haemangiomas are usually isolated but may occasionally extend deeply and rarely involve the ipsilateral meninges, producing a facial angioma and epilepsy, sometimes with learning disability (Sturge–Weber syndrome). Intraoral haemangiomas may be seen in Maffucci's syndrome.

Localized red areas may represent trauma, erythroplasia, carcinoma, candidosis, lichen planus or lupus erythematosus. Kaposi's sarcoma may present as a red, purple, brown or bluish macule or nodule as may epithelioid angiomatosis. Hereditary mucoepithelial dysplasia is a rare cause of oral erythema. Irradiation-induced mucositis is a further cause of a red sore mouth.

White patches (Table 69.9)

White patches may be produced by debris ('material alba') or epithelial sloughing (Fig. 69.12). Thrush (acute candidosis) produces oral white patches.

Table 69.9 Main causes of oral white lesions.

Local
Materia alba
Candidosis
Frictional keratosis
Smoker's keratosis
Idiopathic keratosis
Carcinoma
Burns (including snuff and cocaine)
Skin grafts
Systemic
Candidosis
Lichen planus
Lupus erythematosus
Papillomas (some)
Hairy leukoplakia (mainly human immunodeficiency virus disease)
Syphilitic keratosis
Chronic renal failure
Inherited lesions (e.g. white-sponge naevus)

Fig. 69.12 Gingival hyperpigmentation of racial origin. The white lesion is due to accumulated oral debris—oral hygiene is very poor.

Leukoplakia is often caused by friction or smoking, occasionally with syphilis, candidosis or chronic renal failure, but most cases are idiopathic. Lichen planus and lupus erythematosus may present as white lesions. Rarely, lichenoid lesions are associated with various drugs, liver disease or graft-versus-host disease (GVHD). Carcinoma may present as a white lesion.

Inherited causes of white patches, such as white sponge naevus and dyskeratosis congenita, are rare [1,2].

Pigmentation

Gingival pigmentation is usually seen in dark-skinned races (but may be seen even in white people) (Fig. 69.12). Other common causes include amalgam tattoo and melanotic macules.

Addison's disease, Kaposi's sarcoma and melanoma are the most important acquired causes of pigmented lesions but drugs such as hydroxychloroquine and minocycline may also cause hyperpigmentation.

Ulcers

Gingival ulcers are sometimes self-induced (artefactual) [1,2]. Herpesviruses can cause gingival ulceration, often with ulcers elsewhere in the mouth. Acute ulcerative (necrotizing) gingivitis causes ulceration of the interdental papillae and, although usually a consequence of poor oral hygiene, it or a similar disorder is a rare complication of HIV infection, neutropenia or leukaemia, and in the malnourished or some immunosuppressed patients may spread to the cheek (*noma* or *cancrum oris*). Other bacterial infections (e.g. syphilis, tuberculosis) and mycoses (deep mycoses) are uncommon causes of ulceration. Aphthae (sometimes) and other causes of mouth ulcers (rarely) involve the gingiva (Table 69.10).

Table 69.10 Main causes of mouth ulcers associated with systemic disease.

Microbial disease

Hypereosinophilic syndrome
Eosinophilic ulcer
Necrotizing sialometaplasia

Blisters

Blisters may be seen as a result of burns or mucoceles, but the most important vesiculobullous disorders affecting the gingivae are pemphigoid (including cicatricial pemphigoid) and pemphigus and the typical presentation is of desquamative gingivitis. Vesicles may also be seen in viral infections, especially in herpes simplex stomatitis, chickenpox, herpangina and hand, foot and mouth disease [3–6].

Genetic disorders affecting the periodontium

Hereditary gingival fibromatosis

Aetiology. An autosomal dominant condition due to chromosome 2 or 5 anomalies, resulting in transforming growth factor (TGF)-β1 autocrine stimulation of fibroblast proliferation with alteration in expression of matrix metalloproteinases (MMP)-1 and MMP-2. A role for increased fatty acid synthase activity has also been suggested [1–6].

Pathology. The gingival connective tissue is mainly composed of thick, interlacing collagen fibres forming a dense, almost avascular, mass in which many fibrocytes have dark, shrunken nuclei. Mucoid material and some giant cells may be found.

Clinical features. There is generalized gingival enlargement, especially obvious over the anterior maxilla and during the transition from deciduous to permanent dentitions [1,7]. If the enlargement is gross, it may move or cover the teeth and even protrude from the mouth. The changes initially involve the gingival papillae and later the attached gingiva. The affected gingiva is usually of normal colour but firm in consistency, and the surface becomes coarsely stippled. Patients may also be hirsute (as may patients with drug-induced gingival hyperplasia) [8–19]. The prognosis is good, but gingival surgery is often indicated.

Although most patients have only gingival fibromatosis, there are occasional associations with supernumerary teeth or with Zimmermann–Laband, Rutherford, Cowden and Cross syndromes [20–25].

Juvenile hyaline fibromatosis (see Chapter 45)

Synonym
- Murray–Puretic–Drescher syndrome

Gingival enlargement may be seen in juvenile hyaline fibromatosis. It may precede tooth eruption or may present only in the first decade. It increases with age. Histology shows dilated capillaries in a hyaline periodic acid–Schiff (PAS)-positive matrix with pseudocartilaginous cells [1–7]. Juvenile hyaline fibromatosis and infantile systemic hyalinosis overlap associated with a novel mutation in capillary morphogenesis protein-2 gene has now been reported [8].

Hypoplasminogenaemia

Chronic gingival swelling and ulceration may be seen in this disorder in which there can also be ligneous conjunctivitis. Local treatments are rarely successful; plasminogen replacement is needed [1–6].

Neutrophil defects (see p. 69.56)

A number of genetic disorders affecting neutrophil counts or function can lead to early-onset periodontitis, often with oral ulceration [1,2] (see p. 69.18).

Leukocyte adhesion deficiency

Defects in cell-surface receptors on neutrophils and other leukocytes result in a range of disorders, especially recurrent cutaneous, respiratory and middle-ear infection, as well as periodontal destruction in both dentitions.

Local efforts to preserve the dentition, using debridement together with antimicrobials, have been of little value [1–5].

Papillon–Lefèvre syndrome (see Chapter 19)

This is a rare, autosomal recessive condition of palmoplantar hyperkeratosis with periodontal breakdown (periodontosis or periodontoclasia) that manifests from childhood [1–4] and is related to a defect in cathepsin C [5,6] with defective polymorphonuclear leukocyte function [7,8].

The teeth develop and erupt normally in both the deciduous and permanent dentitions but the gingiva become red, swollen and bleed easily with the formation of periodontal pockets, loss of alveolar bone, loosening and loss of the teeth. The teeth are involved roughly in the order they erupt. The deciduous teeth are often lost by the age of 5 years and the permanent teeth are almost invariably lost by the age of 16 years. There are no obvious abnormalities in either the tooth cementum or dentine.

Hyperkeratosis of the palms and particularly the soles appears at about the age of 3–5 years, concurrent with periodontal breakdown of the deciduous dentition. Similar plaques may also be seen on the lips, cheeks and eyelids. The affected skin shows diffuse hyperkeratosis, hypergranulosis and acanthosis. There may also be calcification of the dura and some patients have recurrent pyogenic infections [9,10].

Similar syndromes include Haim–Munk syndrome [11,12], late-onset Papillon–Lefèvre syndrome [13], a condition including arachnodactyly and acro-osteolysis [14], and Unna–Thost syndrome (see below).

Diagnosis is on clinical and radiographic grounds.

Retinoids may be useful in suppressing oral and cutaneous lesions and minimizing the pyogenic infections [15,16] and it is possible to retain the dentition for some years [17]. Intensive dental care is needed.

Unna–Thost syndrome

Synonym
- Hereditary palmoplantar keratoderma

The Unna–Thost variety of hereditary palmoplantar keratoderma may be associated with oral keratosis and/or periodontitis [1–4].

References

Congenital epulis

Synonym
- Granular cell tumour or myoblastoma

Epulis is the term applied to a swelling on the gingiva. Congenital epulis is a rare, benign, pedunculated, firm pink swelling on the maxillary alveolus, seen in an infant [1,2]. It can be a prenatal ultrasonographic diagnosis [3–5]. There is an 8:1 female predominance.

It is probably a reactive mesenchymal lesion and is usually treated by excision. Histology shows large, polygonal cells with a fine granular, eosinophilic cytoplasm.

Epstein's pearls

Synonym
- Gingival cysts of the newborn

Epstein's pearls are superficial, white, keratin-containing cysts seen on the palatal or alveolar mucosa of about 80% of neonates. They are symptomless and inconsequential, usually being shed within a few weeks, and sometimes found with cleft lip and palate [1–3].

Acquired disorders affecting the periodontium

Chronic gingivitis

This is an extremely common condition. Over 90% of dentate adults exhibit some degree of gingivitis. The accumulation of dental bacterial plaque because of inadequate oral hygiene produces non-specific chronic inflammation. It is painless but may manifest with bleeding from the gingival crevice. The gingival margins are red and slightly swollen [1–3]. Features may be exaggerated in pregnancy and in immune defects.

Dental advice on improved plaque control is needed. If untreated, chronic gingivitis may progress to periodontitis and tooth loss.

Fig. 69.13 Periodontitis.

Chronic periodontitis

Chronic periodontitis (inflammation of the gingiva and periodontal membrane) may be a sequel of chronic gingivitis usually because of plaque accumulation and calculus (tartar) [1]. Smoking is a risk factor. The gingiva detaches from the tooth neck, the periodontal membrane and alveolar bone are damaged, and an abnormal gap (pocket) develops between the tooth and gum. The tooth may slowly loosen and eventually be lost (Fig. 69.13). Features may be exaggerated in immune defects.

Diagnosis. Chronic periodontitis is typically seen in adults. It is painless but may be associated with bleeding, halitosis and a foul taste. Debris and pus may be expressed from the pockets (pyorrhoea), and there may be increasing tooth mobility.

Treatment. Although periodontal disease has a bacterial component, systemic antibiotics have no place in routine treatment. Management comprises improvement in oral hygiene [2], although in this case plaque accumulates below the gumline, within periodontal pockets. Toothbrushing and mouthwashes have effect only above, or very slightly below, the gum level and are therefore ineffective alone in the treatment of periodontitis. Surgical removal of the pocket wall and removal of diseased tissue may be needed to facilitate future cleansing, or attempts to regenerate lost periodontal tissue (such as guided tissue regeneration) may be indicated. Periodontal attention is therefore required.

Early-onset periodontitis

Periodontal breakdown (periodontitis) is usually a consequence of inflammatory destruction as a result of poor oral hygiene and the subsequent accumulation of dental bacterial plaque [1] and is seen mainly in adults. The host response and periodontal microbiota can both be implicated in a heterogeneous group of causes of early-onset periodontitis [2–12]. If present in children or adolescents, it can be a manifestation of severely neglected oral hygiene, such as seen in some patients with learning disability, or may be a feature of an immunocompromised host.

That host defences are extremely important in maintaining periodontal health is demonstrated well in the periodontal breakdown that may accompany leukaemias, leukocyte defects, diabetes and HIV infection. Periodontal breakdown is also a feature of Down's syndrome, Ehlers–Danlos syndrome type VIII and Papillon–Lefèvre syndrome.

Periodontal breakdown in a child or adolescent who is capable of maintaining good oral hygiene almost invariably suggests an immune or other systemic defect.

Fig. 69.14 Desquamative gingivitis.

HIV disease/AIDS

HIV disease can be complicated by necrotizing ulcerative gingivitis (see p. 69.77), periodontitis, candidosis, herpetic ulceration, Kaposi's sarcoma, lymphomas and other gingival lesions [1,2].

Desquamative gingivitis

In this fairly common condition, the labial gingiva are persistently glazed, red and sometimes sore but the gingival margins may be spared, differentiating desquamative gingivitis from chronic marginal gingivitis (Fig. 69.14).

Desquamative gingivitis typically affects middle-aged or elderly women and is usually a manifestation of mucous membrane pemphigoid or lichen planus [1–6]. Rarely, it may be seen in pemphigus, dermatitis herpetiformis, linear IgA disease, chronic ulcerative stomatitis with epithelial antinuclear antibodies or other dermatoses [4–6]. Allergic gingivitis has similar features.

Desquamative gingivitis tends to be chronic and recalcitrant. The underlying condition should be treated where possible [7]. Improved oral hygiene and topical corticosteroids in a nocturnally worn polythene splint may help. Dapsone or topical ciclosporin or tacrolimus may be beneficial in severe cases [8–10].

Allergic gingivostomatitis

Synonym

- Atypical or plasma-cell gingivostomatitis

Diffusely red, swollen gingivae with or without oral ulceration may occasionally follow exposure to various allergens and other substances. Such reactions have followed the use of certain chewing gums, confectionery such as mints, and dentifrices [1–7] and dental materials [8,9], particularly 'tartar control' dentifrices containing cinnamon or cinnamaldehyde [2].

Biopsy is usually not indicated and is fairly non-specific with epithelial atrophy, oedema and a variable cellular infiltrate in the lamina propria which, in the earlier reported cases due to chewing gum, was often predominantly plasmacytic [1,3,5–7]. The lesions resolve on withdrawal of the causal agent and reappear on rechallenge. Patch testing may be of value in diagnosis.

Idiopathic plasmacytosis (see also Plasma-cell balanitis, Chapter 71)

This term refers to red, velvety gingival lesions associated with a plasmacytic infiltrate. Most cases are restricted to the gingiva (atypical gingivostomatitis, plasmacyte gingivitis, allergic gingivostomatitis) [1,2], while a few have supraglottic laryngeal lesions [3]. Corticosteroids are the main treatment but irradiation may be required [4].

Fibroepithelial polyp

Synonym
- Fibrous lump

Fibrous lumps are common in the mouth and are seen mainly in adults. They appear to be purely reparative in nature. They may attain their full size (which rarely exceeds 2.5 cm diameter) quite rapidly, and then stop growing. Fibrous lumps should not be confused with the true fibroma, a benign neoplasm derived from fibroblasts, which is rare in the mouth (see below).

The variable inflammatory changes account for the different clinical presentations of fibrous lumps from red, shiny, soft lumps to those which are pale, stippled and firm [1]. Commonly, they are round pedunculated swellings arising from the marginal or papillary gingiva (epulides), sometimes adjacent to sites of irritation (e.g. a carious cavity). They are usually painless. They may reach quite a large size, but the prognosis is good.

Fibrous epulides should be removed down to the periosteum, which should be curetted thoroughly.

Fibroma [1]

The true fibroma, a benign neoplasm of fibroblastic origin, is rare in the oral cavity and many lesions in the past called fibromas were probably fibroepithelial polyps.

Histology shows marked proliferation of fibroblasts, with nuclei of uniform shape, size and staining characteristics.

The true fibroma is a continuously enlarging new growth, not necessarily arising at a site of potential trauma. It is a pedunculated growth with a smooth, non-ulcerated, pink surface.

Removal should be total, deep and wide.

Pyogenic granuloma (see Chapter 56)

Pyogenic granuloma commonly affects the gingiva, the lip or the tongue [1–3] (Fig. 69.15). Features may be exaggerated in pregnancy.

In these sites, the lesion should be excised completely. It will readily recur if excision is not adequate.

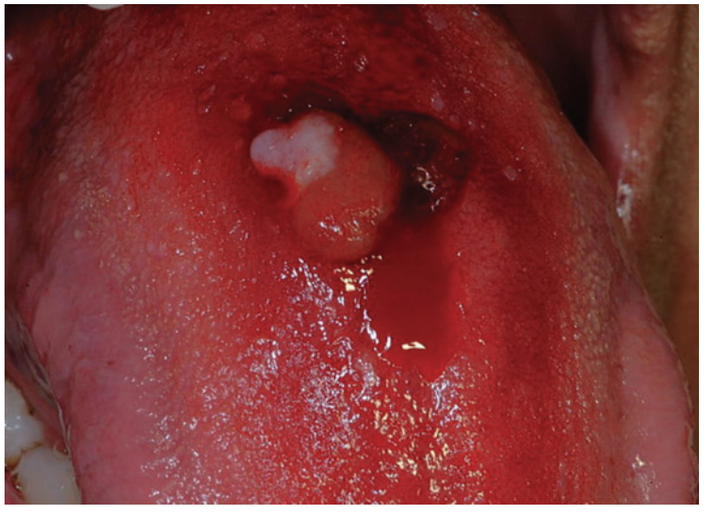

Fig. 69.15 Pyogenic granuloma of the tongue.

Giant cell epulis

Synonym
- Peripheral giant cell granuloma

The giant cell epulis probably arises because chronic irritation triggers a reactionary hyperplasia of mucoperiosteum and excessive production of granulation tissue. Giant cell granulomas are occasionally a feature of hyperparathyroidism.

The giant cell epulis characteristically arises interdentally, adjacent to permanent teeth that have had deciduous predecessors [1,2], that is not the permanent molars. Classically, the most notable feature is the deep-red colour, although older lesions tend to be paler.

This is a benign lesion which is cured by excision.

Pregnancy gingivitis and epulis

There can be an exaggerated inflammatory reaction to dental bacterial plaque in pregnancy, and chronic gingivitis may therefore be aggravated giving rise to ‘pregnancy gingivitis’ [1,2] and, occasionally, a pyogenic granuloma (pregnancy epulis).

Pregnancy gingivitis is characterized by soft, reddish enlargements, usually of the gingival papillae, varying from small, smooth enlargements to more extensive, ragged, granular lumps resembling the surface of a strawberry. Changes of pregnancy gingivitis usually appear about the second month of pregnancy, and reach a peak at the eighth month. Poor oral hygiene predisposes to these changes. A similar appearance may occur with oral contraceptives.

Sometimes there is a localized epulis (pregnancy epulis) that, although unsightly, is usually painless. Occasionally it ulcerates

or interferes with eating. Despite the vascularity, the immaturity of the vessels may lead to superficial ischaemia and ulceration. Larger lesions are prone to trauma, which may contribute to the ulceration.

Oral hygiene should be improved. There is one unconfirmed report of a beneficial effect of folic acid on pregnancy gingivitis [3].

Most lesions tend to resolve on parturition. An epulis requires excision only if it is being traumatized or is grossly unaesthetic [4].

Drug-induced gingival swelling

Gingival swelling (sometimes termed 'hyperplasia') is a recognized adverse effect of a few medications, especially phenytoin, calcium-channel blockers and ciclosporin.

Phenytoin

Phenytoin induces gingival swelling presumably by an effect on fibroblast activity. There is no correlation between the extent of overgrowth and the dose of phenytoin, its serum level, or the age and sex of the patient. Rather, the hyperplasia is aggravated by poor oral hygiene.

Phenytoin can produce a variable degree of gingival enlargement, which characteristically affects the interdental papillae first but which may later involve the marginal and even attached gingiva. The palatal and lingual gingivae are usually involved less than the buccal and labial gingivae [1–4].

The enlargement is characteristically firm, pale and tough, with coarse stippling, although these features may take several years to develop, and earlier lesions may be softer and redder (see Fig. 69.11).

The patient's level of plaque control should be improved [5] and a 0.2% aqueous chlorhexidine mouthwash may be helpful. Excision of the enlarged tissue may be indicated but the swelling unfortunately readily recurs, although this is less likely with meticulous oral hygiene, particularly if the phenytoin can be stopped. Folic acid may improve the condition and systemic isotretinoin may be of some value [2].

Calcium-channel blockers

Nifedipine can cause gingival swelling, typically affecting the papillae in a similar fashion to phenytoin [3,6]. Several other calcium-channel blockers have a similar effect [7]. Improved oral hygiene may reduce the hyperplasia [8]. Excision of the enlarged tissue may be followed by recurrence, and patients should be warned accordingly. If possible the medication should be changed.

Ciclosporin

Ciclosporin also causes gingival hyperplasia, initially of papillae [3,9]. Only about one-third of patients are affected, more commonly children, and this change may be lessened by meticulous removal of plaque before the drug is introduced.

Amphetamines

Amphetamines may cause gingival swelling [10].

Scurvy (see Chapter 59)

Scurvy (vitamin C deficiency) causes gingival swelling, bleeding and oral purpura, and although now rare in resource-rich countries, may still be seen [1].

Disorders affecting the oral mucosa or lips

Swellings

Mucosal swelling may be seen after trauma and in angio-oedema, Crohn's disease, orofacial granulomatosis, sarcoidosis, Wegener's granulomatosis, amyloidosis and other disorders. Localized swellings may be of local aetiology or can be manifestations of neoplasia or systemic disease.

Pigmentation

Mucosal pigmentation is usually seen in dark-skinned races (but may be seen even in white people) (see Fig. 69.12). Other common causes include amalgam tattoo and melanotic macules.

Addison's disease, Kaposi's sarcoma, melanoma, Laugier–Hunziker syndrome, pigmentary incontinence and other causes must be excluded. Peutz–Jeghers disease is the association of circumoral and sometimes intraoral melanosis with small-intestinal polyposis (see Chapter 62). Oral petechiae are usually caused by trauma or suction. More widespread purpura is most frequently

a manifestation of a bleeding tendency caused by thrombocytopenia and may also be seen in infectious mononucleosis, rubella, HIV infection, leukaemia or scurvy. Petechiae may also occur in amyloidosis.

Redness

Red lesions may be inflammatory, or represent erythroplasia, haemangiomas or neoplasms such as carcinoma, Wegener's granulomatosis or Kaposi's sarcoma [1,2].

Candidosis is a common cause of red lesions, which may be painful. Widespread erythema, particularly if associated with pain, is usually caused by primary herpes simplex stomatitis or a mucocutaneous disorder such as lichen planus or mucous membrane pemphigoid, rarely by pemphigus or other dermatoses and occasionally by allergic responses.

Localized red areas may represent erythema migrans, erythroplasia, carcinoma, candidosis, lichen planus, lupus erythematosus or Kaposi's sarcoma or epithelioid angiomatosis. Geographical tongue (erythema migrans) is a benign condition affecting <5% of the population and is usually asymptomatic. Kaposi's sarcoma may present as a red, purple, brown or bluish macule or nodule, as may epithelioid angiomatosis. Hereditary mucoepithelial dysplasia is a rare cause of oral erythema.

Telangiectasia may be a manifestation of hereditary haemorrhagic telangiectasia, primary biliary cirrhosis or systemic sclerosis, or may follow radiotherapy. Haemangiomas are usually isolated but may occasionally extend deeply and rarely involve the ipsilateral meninges, producing a facial angioma and epilepsy, sometimes with learning disability (Sturge–Weber syndrome). Intraoral haemangiomas may be seen in Maffucci's syndrome.

Lingual depapillation in deficiencies of iron, folate or vitamin B_{12} may produce the red tongue termed 'glossitis'. Geographical tongue may also produce red patches.

Mucositis can readily be induced by irradiation or chemotherapy.

Ulcers

Oral ulcers are often caused by trauma or recurrent aphthae (see p. 69.44). Malignant neoplasms may present as ulcers. Various infections or systemic disorders, particularly those of blood, gastrointestinal tract or skin, also produce mouth ulcers, as may drugs and irradiation (see Table 69.10).

Blisters

Blisters may be seen as a result of burns but the most important vesiculobullous disorders affecting the oral mucosa are pemphigoid (including cicatricial pemphigoid) and pemphigus (see Table 69.10). The bullae of mucous membrane pemphigoid may or may not be blood-filled and, in the former case, a bleeding tendency must be excluded. Blood-filled blisters may also be caused by localized oral purpura (angina bullosa haemorrhagica) or amyloidosis. The bullae of pemphigus are rarely seen as they break down rapidly to produce ulcers. Epidermolysis bullosa and erythema multiforme may present with oral bullae or vesicles, although ulcers are more common. Vesicles may be seen in viral infections, especially in herpes simplex stomatitis, chickenpox, herpangina and hand, foot and mouth disease.

Mucoceles, caused by extravasation of mucus from minor salivary glands, produce isolated blisters, typically in the lower labial mucosa.

White patches (see Table 69.9)

Thrush (acute candidosis) is a 'disease of the diseased' and produces oral white patches.

HIV infection causes hairy leukoplakia, a white lesion on the tongue (see p. 69.93).

Leukoplakia is often associated with friction or smoking, occasionally with syphilis, candidosis or chronic renal failure, but most cases are idiopathic. Lichen planus and lupus erythematosus may present as white lesions. Rarely, lichenoid lesions are associated with various drugs, liver disease or GVHD. Carcinoma may present as a white lesion.

Inherited causes of white patches, such as white sponge naevus and dyskeratosis congenita, are rare [1–5].

Genetic disorders affecting the oral mucosa or lips

This section discusses the main congenital causes of white or whitish lesions, pigmented lesions, red lesions, vesiculoerosive lesions, lumps and swellings, and some orocutaneous disorders.

White or whitish lesions

Sebaceous glands

Fordyce spots

Synonym
- Fordyce's granules

Fordyce spots are yellowish small grains seen beneath the buccal or labial mucosa. Fordyce spots are sebaceous glands containing neutral lipids similar to those found in skin sebaceous glands [1] but are not associated with hair follicles.

Fordyce spots are extremely common: probably 80% of the population have them. They are usually seen in the buccal mucosa, particularly inside the commissures (Fig. 69.16), and sometimes in the retromolar regions and upper lip [1–5]. Fordyce spots are often not noticeable in children until after puberty (although they are present histologically), and they seem to be more obvious in males, patients with greasy skin and the elderly, and they may be increased in some rheumatic disorders [6].

Fordyce spots are totally benign, although the occasional patient or physician becomes concerned about them or misdiagnoses them as thrush or lichen planus. Occasionally they may be mistaken for leukoplakia [7].

Fig. 69.16 Fordyce spots: sebaceous glands in the buccal mucosa.

No treatment is indicated, other than reassurance. The spots may become less prominent if isotretinoin is given [8]. CO_2 laser and 5-aminolaevulinic acid-photodynamic therapy have been reported as possible effective therapies for Fordyce spots [9,10].

Nevus sebaceus of Jadassohn

Synonym
- Linear naevus syndrome

Oral manifestations may rarely occur as fibroepitheliomatous nodules in patients with a sebaceous naevus of the skin but are extremely rarely seen in isolation [1–3]. Patients have a 10 to 20% risk of development of cutaneous or adnexal neoplasia [4].

Epithelium

Leukoedema

Leukoedema is not a mucosal disease but simply the name given to the faint whitish lines seen in some normal buccal mucosae, often prominent in black people. The whitish lines disappear if the mucosa is stretched—a diagnostic test [1–4]. Confusion with lichen planus should thereby be avoided.

Clouston syndrome

Palmoplantar hyperkeratosis, hair defects, nail dysplasia and oral white lesions characterize this autosomal dominant form of hidrotic ectodermal dysplasia. There may be diffuse white lesions in the buccal mucosa, palate, tongue and elsewhere but reports of malignancy are rare. See also Chapter 15.

White-sponge naevus

Synonyms
- Cannon's disease
- Pachydermia oralis
- White folded gingivostomatosis

Aetiology. A rare, familial disorder usually first seen in childhood and inherited as an autosomal dominant trait [1,2]; there appear

to be defects in keratins 4 and 13 with abnormal tonofilament aggregation [3–6].

Pathology. There is hyperplastic acanthotic epithelium in which gross oedema causes a basket-weave appearance. The superficial epithelium has a 'washed-out' appearance as it stains only very lightly.

Clinical features. The oral mucosa is almost invariably involved in white-sponge naevus. Painless, shaggy or folded white lesions typically affect the buccal mucosa bilaterally but may also involve other areas, although rarely the gingival margins. Similar lesions may also affect the upper respiratory tract, genitalia and anus [1,2].

Diagnosis. The family history and clinical examination are usually adequate to differentiate this from other more common causes of white lesions such as cheek biting, burns, lichen planus and candidosis.

Treatment. This is a benign condition with an excellent prognosis. Reassurance is all that is required, although some have suggested that tetracyclines clear the lesions [7,8].

Dyskeratosis congenita (see Chapter 15)

Synonym
- Zinsser–Engman–Cole syndrome

Dyskeratosis congenita usually presents with oral lesions between the ages of 5 and 10 years, when the tongue and sometimes the buccal mucosa and palate develop diffuse white lesions with a malignant potential [1,2]. The lesions resemble leukoplakia or lichen planus and show non-specific hyperkeratosis, a prominent granular cell layer and mild acanthosis [1–5].

Other manifestations include lesions of other mucosae, skin and appendages, and bone marrow dysfunction [6,7]. Other rare oral features include taurodont or hypocalcified teeth and mucosal hyperpigmentation.

Pachyonychia congenita (see Chapter 65)

Synonym
- Jadassohn–Lewandowsky syndrome

Pachyonychia congenita is a benign disorder associated with mutations in keratin 16 [1–4]. About 60% of patients have oral keratosis, 16% have natal or neonatal teeth, and 10% have angular stomatitis. Some patients also develop chronic intraoral candidosis [5–7].

The keratosis requires no treatment. Dental advice should be sought regarding natal or neonatal teeth.

Tylosis [1–5] (see Chapter 34)

Tylosis is an autosomal dominant syndrome of palmoplantar hyperkeratosis that may predispose to oesophageal carcinoma but although oral white lesions have also been described, there is little evidence that these are premalignant.

Focal palmoplantar and oral hyperkeratosis syndrome

Synonym
- Keratosis palmaris et plantaris

Focal hyperkeratosis at weight-bearing areas of the palms and soles, with hyperkeratosis of the attached gingiva and occasionally other sites, is an autosomal dominant trait [1–3].

Olmsted's syndrome [1–6] (see Chapter 19)

Synonym
- Congenital palmoplantar and periorificial keratoderma with corneal epithelial dysplasia

Perioral keratoderma may be seen associated with palmoplantar keratoderma and corneal epithelial dysplasia [4]. Reported associations include haemangioma and malignant melanoma [5,6]. Retinoids may help the keratoderma [6].

Hereditary benign intraepithelial dyskeratosis [1–4]

Synonym
- Witkop–von Sallmann syndrome

Aetiology. Hereditary benign intraepithelial dyskeratosis is a rare, benign, autosomal dominant condition associated with chromosome 4 anomalies, seen mainly in some groups of mixed ethnic origin, predominantly in North Carolina, USA.

Pathology. There is pronounced epithelial acanthosis, vacuolization in the stratum spinosum and eosinophilic cells apparently engulfed by normal squamous cells ('tobacco cells').

Clinical features. Oral milky white, smooth, somewhat translucent plaques appear in childhood and become more obvious by adolescence. These lesions affect predominantly the buccal mucosae, lips and ventrum of the tongue.

Ocular lesions include conjunctivitis with gelatinous conjunctival plaques, which become evident in infancy. There may be photophobia and eventual corneal involvement.

Oral biopsy is usually indicated for diagnosis.

Treatment. No treatment is required.

Darier's disease (see Chapter 39)

Oral lesions are seen in up to 50% of patients with skin lesions of Darier's disease. The oral changes are most marked in patients with the most severe skin changes and are typically flattish, coalescing, red plaques that eventually turn white and affect the keratinized mucosa of the dorsum of the tongue, palate and gingiva (Fig. 69.17) and then may resemble nicotinic stomatitis clinically [1–7].

Salivary duct anomalies, including dilatations with periodic strictures and indentations, may affect the main ducts [8,9].

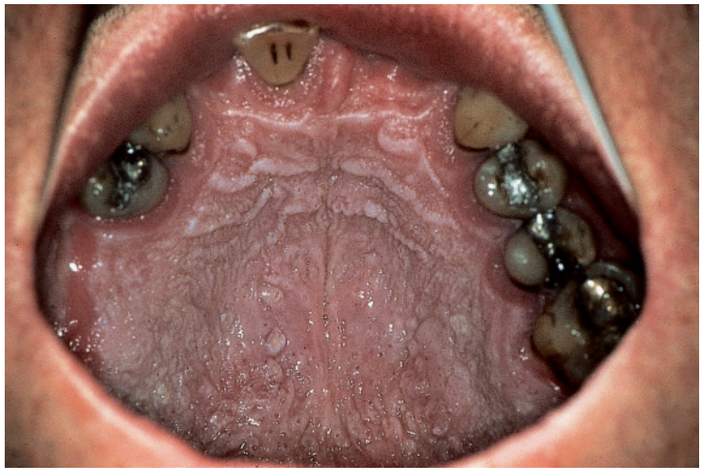

Fig. 69.17 Darier's disease: oral white lesions resemble those of nicotinic stomatitis.

Warty dyskeratoma [1–4] (see Chapter 19)

Synonym
- Focal acantholytic dyskeratosis

Warty dyskeratoma, oral warty dyskeratoma or focal acantholytic dyskeratosis is rare in the oral cavity but typically presents as a nodule or papule on the gingiva, palate or alveolar ridge. The histology is similar to that of Darier's disease and transient acantholytic dermatosis, with suprabasal epithelial splits and corps ronds.

Chronic mucocutaneous candidosis (see Chapter 36)

Chronic mucocutaneous candidosis includes a range of congenital disorders characterized by chronic candidosis involving mouth, nails and other sites. Persistent, adherent white lesions are seen in the mouth, often with angular stomatitis [1–4]; in candidosis–endocrinopathy syndrome, there may also be enamel hypoplasia [5,6] and, rarely, oral carcinoma [7,8].

Pigmented lesions (Table 69.11)

Most oral hyperpigmentation is racial in origin (see Fig. 69.12). Seen mainly in blacks and Asians it can also be noted in patients of Mediterranean descent, sometimes even in some fairly light-skinned people. It is most obvious in the anterior labial gingivae and palatal mucosa and pigmentation is usually symmetrically distributed. Patches may be seen elsewhere. Pigmentation may be

Table 69.11 Causes of mucosal pigmentation.

Malignant acanthosis nigricans

first noted by the patient in adult life and then incorrectly assumed to be acquired rather than congenital in origin.

Melanotic macule

The melanotic macule is an acquired, small, flat, brown to brown-black, asymptomatic, benign lesion, unchanging in character [1–4]. Oral melanotic macule is similar to the ephelis and lentigo.

Melanotic macules may be seen in up to 3% of normal persons, at any age. Melanotic macules are usually solitary, discrete, pigmented brown collections of melanin-containing cells. The macules are less than 2 cm in diameter, seen especially on the vermilion of the lips, gingiva, buccal mucosa or palate. Most on the lips are seen near the midline, on the lower lip vermilion. Most are solitary and seen in white adults and their colour ranges from brown to black [1,5,6]. Occasional cases are seen in HIV infection [7].

Clinically, the melanotic macule may resemble other lesions such as early melanoma and ephelides, although the latter tend to fade in winter and darken in summer. Histopathologically, the mucosal epithelium is normal apart from increased pigmentation of the basal layer, accentuated at the tips of rete ridges. There are no naevus cells or elongated rete ridges [3]. There is melanin in the epithelial basal layer and/or upper lamina propria. Occasionally they are seen along with melanonychia striata (Laugier–Hunziker syndrome, see below).

Melanotic macules can be excised to exclude melanoma or for cosmetic reasons, or removed by laser or hidden by lipstick [8–12].

Peutz–Jeghers syndrome (see Chapter 58)

Peutz–Jeghers syndrome is an autosomal dominant trait characterized by hamartomatous intestinal polyposis and mucocutaneous melanotic pigmentation, especially circumorally. Those affected have discrete, brown to bluish black macules mainly around the oral, nasal and ocular orifices. The lips, especially the lower, have pigmented macules in about 98% of patients (Fig. 69.18). Oral brown or black macules, unlike the circumoral lesions, do not fade after puberty. Mucosal and facial hyperpigmentation may also be seen in relatives [1–3].

Fig. 69.18 Peutz–Jeghers syndrome.

Intestinal polyps are found mainly in the small intestine in Peutz–Jeghers syndrome. They rarely undergo malignant change but if they produce intussusception, surgical intervention is required. There is a slightly increased risk of gastrointestinal carcinoma and carcinomas of the pancreas, breast and reproductive organs [4–9].

Ruby and argon lasers have been used to treat the pigmentation of the lips and oral mucosa [10] (see Chapter 78).

Laugier–Hunziker syndrome [1–12]

Synonym
- Laugier–Hunziker–Baran syndrome

Laugier–Hunziker syndrome presents with labial, oral mucosal and nail hyperpigmentation. A possible variant of this or Peutz–Jeghers syndrome has been termed *idiopathic lenticular pigmentation* [6], in which there are oral, labial, perianal and digital hyperpigmented lenticular macules. Similar patients have been reported previously [9–11]. Treatment with the Q-switched Nd-Yag laser has been reported [12].

Pseudoxanthoma elasticum
See Chapter 45.

Lentiginoses
The lentiginoses (or lentigenoses) include Peutz–Jeghers syndrome (Chapter 58) and the LEOPARD syndrome, which comprises:
- *l*entigines (multiple)
- *e*lectrocardiographic conduction abnormalities
- *o*cular hypertelorism
- *p*ulmonary stenosis
- *a*bnormalities of genitalia
- *r*etardation of growth and
- *d*eafness.

The lentiginoses also include the syndrome of arterial dissections with lentiginosis, Laugier–Hunziker syndrome, Cowden disease, Ruvalcaba–Myhre–Smith (Bannayan–Zonana) syndrome, and the centrofacial, benign patterned and segmental lentiginoses, all of which can be associated with a variety of developmental defects.

Centrofacial lentiginosis syndrome

Synonym
- Touraine's centrofacial lentiginosis

Centrofacial lentiginosis [1,2] is associated with bone abnormalities, malformations due to dysraphia, endocrine dysfunctions and neurological diseases.

References

Complex of myxomas, spotty pigmentation and endocrine overactivity

Synonyms
- Carney's syndrome
- Carney complex

This autosomal dominant trait causes cardiac and cutaneous myxomas, with mammary myxoid fibroadenomas, spotty cutaneous hyperpigmentation, primary pigmented nodular adrenocortical disease, testicular Sertoli cell tumours and growth hormone-secreting pituitary adenoma. It may present with oral hyperpigmentation and myxomas [1–5]. The hyperpigmentation in Carney complex is facial and occurs on the vermilion of the lips in about 35%, although about 8% have pigmented lesions on the oral mucosa and about 2% have oral myxomas, usually on the palate or tongue [2]. Carney complex differs clinically from Peutz–Jeghers syndrome in that hyperpigmentation is less common intraorally but more common on the conjunctiva, and other manifestations are also present.

Cases previously described as NAME syndrome (*n*aevi, *a*trial myxoma, *m*yxoid neurofibromas, *e*phelides) and LAMB syndrome (*l*entigines, *a*trial myxoma, *m*ucocutaneous myxoma, *b*lue naevi) may represent this complex, which also has close similarities to LEOPARD syndrome and the syndrome of arterial dissections with lentiginosis (see Chapter 58).

Inherited patterned lentiginosis in black people
This autosomal dominant condition is characterized by small, discrete, hyperpigmented macules on the face, lips, extremities, buttocks and palmoplantar areas [1]. No series of patients have

been reported with oral mucosal lesions or internal organ system abnormalities.

This condition can resemble other lentiginosis syndromes, especially Peutz–Jeghers syndrome, centrofacial lentiginosis syndrome and Carney complex.

Naevi

Pigmented naevi are much less common in the oral mucosa than in skin. Approximately half of naevi are histologically of the intradermal (intramucosal) type; one-third are blue naevi, many others are compound naevi and some are junctional naevi.

Pathology. They are formed from increased melanin-containing cells, are flat or raised, do not change rapidly in size or colour, are painless and are seen particularly on the palate. The intramucosal type of naevus is most common (about 60%), while another 25% are blue naevi. Compound and junctional naevi and combined naevi are rare in the mouth. The intramucosal naevus consists of a collection of melanocytic cells in the lamina propria without involvement of the epithelium. The blue naevus consists of spindle cells at any level in the lamina propria. The junctional naevus consists of clusters of benign naevus cells at the epitheliomesenchymal junction and the lamina propria is otherwise not involved.

Clinical features. Pigmented naevi are seen particularly on the vermilion border of the lip and on the palate or buccal mucosa [1,2]. These lesions are usually brown, macular, do not change rapidly in size or colour and are painless. The prognosis is good.

Treatment. Although there is no evidence that most pigmented naevi progress to melanoma [3], there has been concern expressed that junctional naevi may be a risk factor. Recent evidence does not support this [4].

However, pigmented naevi may resemble melanomas and if early detection of oral melanomas is to be achieved, all pigmented oral cavity lesions should be viewed with suspicion. Therefore, excision biopsy is recommended to exclude malignancy [3] and may also be performed for cosmetic reasons. This is particularly important if the lesions are raised or nodular [2,3].

Red lesions

Vascular anomalies

Hereditary haemorrhagic telangiectasia (see Chapter 48)

Synonym

- Osler–Rendu–Weber syndrome

This syndrome is characterized by multiple telangiectasia on the lips, perioral skin, oral and nasal mucosae [1,2] as well as the gastrointestinal tract. Occasionally there are colonic or hepatic complications [3–6]. Oral haemorrhage can be controlled by cryotherapy, cautery, infrared coagulation, Nd-Yag laser or intense pulsed light [7–9].

Haemangioma

Haemangiomas are usually deep red or blue–purple, blanch on pressure, are fluctuant to palpation, and are level with the mucosa or have a lobulated or raised surface [1,2]. Most are small and of no consequence [1,3].

Most haemangiomas are seen in isolation but a few may be multiple and/or part of a wider syndrome, such as Maffucci syndrome [4,5]. Large facial haemangiomas, which can involve the lips, may be associated with Sturge–Weber syndrome (Fig. 69.19) [4] or Dandy–Walker syndrome, or other posterior cranial fossa malformations [6,7].

Haemangiomas are at risk from trauma and prone to excessive bleeding if damaged (e.g. during tooth extraction). Occasionally, oral haemangiomas develop phlebolithiasis.

Oral lesions suspected of being haemangiomatous should not be routinely biopsied; aspiration is far safer. Kaposi's sarcoma and epithelioid angiomatosis should be excluded. After intravenous administration of contrast medium, enhancement is observed in haemangiomas in areas corresponding to those with high signal on T_2-weighted magnetic resonance imaging (MRI).

Oral haemangiomas are left alone unless causing symptoms, when they are best treated with cryosurgery or laser if small, or by ligation or embolization of feeding vessels if large.

Sturge–Weber–Krabbe syndrome [1–7] (see Chapter 18)

The haemangioma in the trigeminal area in Sturge–Weber syndrome is usually unilateral, may involve the mouth but fortunately rarely involves bone. It may be associated with hypertrophy of affected tissues and, if the patient is treated with phenytoin, with gingival hyperplasia [3,4].

Klippel–Trenaunay–Weber syndrome (see Chapter 18)

Haemangiomas of the buccal mucosa and tongue, macroglossia, maxillary hyperplasia and an anterior open bite have been recorded in this syndrome [1–8]. Post-extraction bleeding can be a problem [8,9].

Hereditary mucoepithelial dysplasia

Hereditary mucoepithelial dysplasia is an autosomal dominant dyskeratotic epithelial syndrome affecting oral, nasal, vaginal, urethral, anal, bladder and conjunctival mucosae, causing cataracts, follicular keratosis, non-scarring alopecia and terminal lung disease [1–5].

Pathology. The condition is probably a pan-epithelial cell defect of desmosomal and gap junction structure. Histochemically there is a lack of cornification and keratinization. Electron microscopy shows an abnormality in desmosomes and gap junctions, with a lack of keratohyalin granules, a paucity of desmosomes, intercellular accumulations, cytoplasmic vacuolization, and formation of bands and aggregates of filamentous fibres and structures in the cytoplasm resembling desmosomes and gap junctions. There is some acantholysis as well as benign dyskeratosis of individual cells [1,2]. Histologically the mucosal epithelium shows dyshesion, thinning of the epithelial layer and dyskeratosis. Mucosal Papanicolaou smears show lack of epithelial maturation, cytoplasmic vacuoles and inclusions, and individual cell dyskeratosis.

Clinical features. Red, periorificial mucosal lesions are typically noted during infancy and may persist throughout life. The oral lesions are painless, red macules or maculopapules and are seen predominantly on the palate and gingiva.

Severe photophobia, tearing and nystagmus in infancy herald the development of keratitis, corneal vascularization and lens cataracts.

In addition there may be various cardiorespiratory complications, especially potentially lethal bullous lung disease—spontaneous pneumothorax and bullous emphysema, terminating in cor pulmonale. Chronic rhinorrhoea and repeated upper respiratory infections frequently progress to bilateral pneumonia. Loss of hair, diarrhoea, melaena, enuresis, pyuria and haematuria may also be seen.

Vesiculoerosive disorders

Acrodermatitis enteropathica

Acrodermatitis enteropathica is a rare, autosomal recessive inborn error of metabolism resulting in zinc malabsorption and severe zinc deficiency [1–7].

Clinical features. Diarrhoea, mood changes, anorexia and neurological disturbance are reported, most frequently in infancy. Growth retardation, alopecia, weight loss and recurrent infections are prevalent in affected toddlers and schoolchildren. A vesiculobullous dermatitis with perioral involvement may be seen, often sparing the vermilion [2]. Zinc deficiency during growth periods results in growth failure and lack of gonadal development in males. Other effects of zinc deficiency include skin changes, poor appetite, mental lethargy, delayed wound healing, neurosensory disorders and cell-mediated immune disorders. Skin lesions and poor wound healing are observed in severe forms and the disorder can be lethal.

Diagnosis. Assays of zinc in granulocytes and lymphocytes provide better diagnostic criteria for marginal zinc deficiency than plasma zinc assays. In cases of doubt, zinc absorption tests using radioisotopes (^{65}Zn or ^{69m}Zn) may be performed. Levels of alkaline phosphatase are reduced.

Treatment. Management includes zinc sulphate 2 mg/kg daily, at least until adult life.

Epidermolysis bullosa (see Chapter 39)

Epidermolysis bullosa is characterized by blisters, sometimes preceded by white patches, which develop rapidly, particularly where there is trauma. Blisters rupture to produce ulcers, often with eventual scarring, particularly in the recessive dystrophic types [1–9]. Oral lesions are fairly common in dystrophic and lethal forms of epidermolysis bullosa but are rare in most simplex types except the superficial type, where they are found in 70% of patients [2,10–13]. Overall, oral mucosal lesions are found in about 30% of

Table 69.12 Oral manifestations in epidermolysis bullosa (EB).

patients with epidermolysis bullosa [1–5]. There is a predisposition to oral squamous cell carcinoma, mainly in the Hallopeau–Siemens type.

Dental hypoplasia and other defects and delayed tooth eruption may also be a feature, especially in junctional epidermolysis bullosa (Table 69.12) and, with the difficulty in maintaining adequate oral hygiene, there is a predisposition to caries [4,7].

Patients with recessive dystrophic epidermolysis bullosa suffer from severe growth inhibition due to reduced food intake as a result of severe oropharyngeal and oesophageal blistering or scarring, with smaller maxillae and smaller mandibles than normal [8,14–17]. Treatment has improved with modalities such as implants [17–19].

The oral manifestations in the various inherited forms of this condition are summarized in Table 69.12 and epidermolysis bullosa acquisita is discussed in Chapter 41.

Lumps and swellings

Hereditary angio-oedema

Synonym
- C1 esterase inhibitor deficiency

Hereditary angioedema (HANE) is a rare autosomal dominant disorder caused by C1-inhibitor deficiency. HANE mimics allergic angio-oedema (see Chapter 22), although it produces a more severe reaction, with oedema affecting the lips, mouth, face and neck region, the extremities and gastrointestinal tract after minor trauma [1–5].

Blunt injury is the most consistent precipitating event. The trauma of dental treatment is a potent trigger, and some attacks even follow emotional stress. Oedema may persist for many hours and even up to 4 days. Involvement of the airway is a constant threat. The mortality may be as high as 30% in some families but the disease is compatible with prolonged survival if emergencies are avoided or effectively treated.

Diagnosis. In 85% of cases plasma C1 esterase levels are reduced (type 1 hereditary angio-oedema) but in 15% the enzyme is present but dysfunctional (type 2 hereditary angio-oedema). In both types, plasma C4 levels fall but C3 levels are normal. Rarely, similar defects are acquired.

Treatment. C1 esterase concentrates are available for treatment [3,6–10]. Plasminogen inhibitors such as tranexamic acid can be used to mitigate attacks [3,11], although more effective agents are the androgenic steroids danazol and stanozolol, which raise plasma C1 esterase inhibitor levels to normal [1–4].

Focal dermal hypoplasia (see Chapter 15)

Synonym
- Goltz–Gorlin syndrome

Focal dermal hypoplasia is a rare, presumably X-linked, genodermatosis [1–3] involving developmental anomalies of tissues and organs of mesoectodermal origin. Thus there are abnormalities of the eyes, skin, musculoskeletal system, central nervous system (CNS) and oral structures.

Papillomas, usually of the oral mucosae and lips, dental anomalies and occasional cleft lip and palate are the main oral features [2–6]. The dental anomalies, seen in about half of affected individuals, include hypodontia, enamel defects and taurodontism [7–10].

Acanthosis nigricans (see Chapter 19)

Oral papilliferous lesions may be a feature of both familial [1,2] and malignant [1,3–8] acanthosis nigricans. Between 30 and 50% of patients with acanthosis nigricans secondary to neoplasia (malignant acanthosis nigricans) have oral lesions, which involve the tongue and lips predominantly.

Lymphangioma (see Chapter 48)

Lymphangioma is uncommon in the mouth. At least some are hamartomas and many are of similar structure to haemangiomas and can clinically resemble them, with a 'frog-spawn' appearance, but they contain lymph rather than blood (Fig. 69.20).

Lymphangiomas are usually solitary and affect the tongue predominantly. They are occasionally associated with cystic hygroma [1–7]. One study has found blue, domed lymphangiomas on the alveolar ridges of about 4% of newborn black children [3]. These lesions, which were usually bilateral, often regressed spontaneously.

Contrast-enhanced T_1-weighted MRI can be used to differentiate between lymphangiomas and deep haemangiomas [8]. Small lymphangiomas need no treatment. Larger lesions may require excision, although cryotherapy laser therapy and sclerotherapy can be useful and, more recently, radiofrequency ablation has been described [7,9].

A number of reports describe lymphangiomas presenting on the alveolar ridges of newborn children [3,10,11].

Dermoid cyst (see Chapter 18)

Dermoid cyst is a hamartoma, a development lesion commonly arising in the midline of the neck, above the mylohyoid. It occasionally occurs elsewhere such as the tongue, antrum and rarely the parotid gland [1–7].

Dermoid cysts usually become clinically obvious in the second decade of life and cause elevation of the tongue. Occasionally, dermoid cysts become infected and then painful.

Treatment of dermoid cyst is by surgical excision.

Lingual tonsil

The lingual tonsil is a mass of lymphoid tissue in the posterior third of the tongue, between the epiglottis posteriorly and the circumvallate papillae anteriorly [1,2]. It is usually divided in the midline by a ligament (Fig. 69.21). Although usually small and asymptomatic, it may become enlarged, especially in atopic individuals, in patients taking phenytoin or in some infections. It may be so prominent that it fills the vallecula and impinges against the epiglottis. If the lingual tonsil is large, it may cause a globus sensation, alteration of the voice, obstructive sleep apnoea or airways obstruction [3–8]. It tends to involute with increasing age.

Occasionally, there may be lingual tonsillitis with a red, swollen, painful tongue, fever and neutrophilia [9].

The condition must be distinguished from benign and malignant tumours of the tongue, including lingual thyroid, but the symmetry of the lingual tonsil and its midline division are helpful diagnostic pointers.

Treatment may be required if the enlarged tonsil causes symptoms. Surgery may be hazardous because of the copious blood supply to the tongue base. Electrocautery and cryotherapy are generally regarded as the safer procedures [1,10,11].

Lingual thyroid

Ectopic thyroid tissue may rarely present in the mouth. Some 10% of cadaver tongues contain thyroid tissue, although clinical presentation is much less common. Typically, there is an asymptomatic, smooth-surfaced lump in the midline of the base of the tongue, between the sulcus terminalis and epiglottis at the site of the foramen caecum [1–5]. Occasionally, a lingual thyroid may produce dysphagia, cough, pain or, rarely, airways obstruction [1–11].

Not all lingual thyroid tissue is functional, and function tends to decline with age. Where thyroid-stimulating hormone levels are high, thyroid hormone supplements are indicated [1,12]. Malignant change is rare in lingual thyroid, although follicular carcinomas have been recorded. MRI and ^{99m}Tc pertechnate scintiscanning is important to ensure the presence of normal thyroid tissue in the neck [13–16] before considering treatment of a lingual thyroid by surgery or radioiodine [1,2,17,18].

Multiple mucosal neuroma syndrome

The syndrome of multiple endocrine neoplasia (MEN) type 2b (also called type 3) is inherited as an autosomal dominant, although new cases often arise sporadically. The gene locus is on chromosome 10.

MEN2b is characterized by medullary carcinoma of the thyroid and phaeochromocytoma, in association with multiple mucosal neuromas and an abnormal phenotype—a striking facial appearance, with thick, slightly everted lips that usually have a slightly bumpy surface due to multiple neuromas [1–3]. These are actually mucosal and submucosal hamartomatous proliferations of nerve axons, Schwann cells and ganglion cells.

Lesions may also involve the tongue and commissures but are less frequent on the buccal mucosa, gingivae, palate, pharynx or larynx (Fig. 69.22). Ganglioneuromatosis may also occur throughout the gastrointestinal tract, and this may result in constipation or megacolon [4,5]. Ocular changes include yellowish masses on the conjunctivae, thickened corneal nerves and keratitis due to decreased tear production [5,6].

Most patients have an asthenic marfanoid habitus, with high arched palate, pectus excavatum, arachnodactyly and kyphoscoliosis, but the lens subluxation and cardiovascular abnormalities of Marfan's syndrome are not present [7–11].

Other congenital anomalies

Ankyloglossia

Ankyloglossia, or tongue-tie, is an uncommon and typically isolated anomaly in which the lingual fraenum is tight and the tongue cannot be fully protruded [1,2].

There may be a family history and sometimes deviation of the epiglottis or larynx [3]. The association of cleft palate with ankyloglossia is inherited as a semi-dominant, X-linked disorder previously described in several large families of different ethnic origins and related to chromosome Xq21: the T-box transcription factor gene *TBX22* is mutated [4–6].

Speech is not usually affected in patients with ankyloglossia but the ability to suckle [7] and to cleanse the buccal sulcus with the tongue may be, and there can be effects on jaw development [8]. If necessary, surgery to the fraenum will relieve ankyloglossia [2,9,10].

Fissured tongue

Fissured tongue (plicated or scrotal tongue) is a common condition affecting more than 5% of the population [1,2]. The cause is unclear, but it is often accompanied by geographical tongue (Fig. 69.23).

Patients with Down's syndrome often have a fissured tongue and it is a feature of the rare Melkersson–Rosenthal syndrome comprising recurrent orofacial swelling, facial palsy and plicated tongue.

Oral hair

Oral hair is a rare, innocuous anomaly [1,2], not to be confused with hairy tongue (see p. 69.93).

Various orocutaneous syndromes

Cleft lip

Cleft lip and/or palate are the most common congenital craniofacial abnormalities. Cleft lip occurs in about 1 per 1000 white-skinned neonates. The prevalence is higher in oriental neonates (about 1.7 per 1000 births) and lower in black neonates (approximately 1 per 2500 births) and appears reduced if women take multivitamins containing folic acid early in pregnancy [1,2]. Clefts are often accompanied by impaired facial growth, dental anomalies, speech disorders, poor hearing and psychosocial problems [3,4]. Clefts can be seen in over 300 different syndromes [5,6].

Cleft lip is not always complete (i.e. extending into the nostril). A cleft may involve only the upper lip or may extend to involve the nostril and the hard and soft palates. In about 9% of the cases, the cleft is associated with skin bridges or Simonart's bands.

Isolated cleft lip may be unilateral or bilateral (approximately 20%). When unilateral, the cleft is more common on the left side (about 70%).

Lips are more frequently cleft bilaterally (approximately 25%) when combined with cleft palate. Cleft lip and palate is more common in men. Cleft lip and palate comprises about 50% of the cases, with cleft lip and isolated cleft palate each comprising about 25%. About 85% of bilateral cleft lips and 70% of unilateral cleft lips are associated with cleft palate. One subgroup have cleft lip and palate with median facial dysplasia and cerebrofacial malformations [7,8], others with laryngotracheal oesophageal clefts (Opitz–Firas or G syndrome) or cranial asymmetry (Opitz or B syndrome) [9,10].

Clefts in the middle of the upper lip may be true or false. True median clefts have been described in association with bifid nose and ocular hypertelorism. Other cases of true median labial cleft are associated with polydactyly or other digital anomalies, constituting an autosomal recessive trait called *orofaciodigital syndrome II*.

Pseudocleft of the middle of the upper lip may occur in *orofaciodigital syndrome I*. A somewhat similar central defect, but of mild degree, is seen in chondroectodermal dysplasia (Ellis–van Creveld syndrome). Clefts in the lower lip are rare and usually median but may involve the mandible and sometimes the tongue. Management of cleft lip is discussed elsewhere [11–14].

Cowden's syndrome (see Chapter 15)

Synonym
- Multiple hamartoma syndrome

Cowden's syndrome may be associated with the *PTEN* gene [1] and multiple hamartomas [2,3]. Oral mucosal lesions may be found in the presence or absence of cutaneous stigma [3–9]. The oral lesions are typically smooth, pink or whitish benign fibromas found especially on the palatal, gingival and labial mucosae. Oral squamous carcinoma is a rare complication [10]. There may be overlap with Bannayan–Riley–Ruvalcaba syndrome [11–13].

Treatment with acitretin may lead to regression of the hypertrophic lesions of the lip and mouth [14].

De Lange syndrome

Synonym
- Amsterdam dwarf

Classical Brachmann or Cornelia de Lange syndrome presents with a striking face, pronounced growth and learning disability, and variable limb deficiencies. Most cases are sporadic [1,2]. About 50% of patients have been found to have heterozygous mutations in the NIPBL gene with some cases being caused by mutations in the X-linked *SMC1L1* gene [3]. A long philtrum and crescent-shaped mouth with down-turned corners is typical [4–6].

The characteristic face of classical de Lange syndrome is present at birth and changes little throughout life, although there is some lengthening of the face with age and the jaw becomes squared.

Double lip

Double lip is a developmental anomaly usually involving the upper lip. A fold of redundant tissue is found on the inner aspect of the involved lip [1,2]. It is reported to be common among some groups of Africans [3].

Double lip may occur alone or in association with other anomalies. The association with blepharochalasis (laxity of the upper eyelid skin) and sometimes non-toxic thyroid enlargement is known as *Ascher's syndrome* [4] (see Chapter 45).

Double lip requires no treatment except for cosmetic purposes.

Down's syndrome

The incidence of angular cheilitis is increased in people with Down's syndrome, caused by an increased level of *Staphylococcus aureus* and *Candida albicans*, possibly because of the immune defects [1–3]. Lip fissures may appear intermittently over a period of years or be intractable and long-standing (see p. 69.17).

Erythropoietic protoporphyria

Erythropoietic protoporphyria is an autosomal dominant disorder of ferrochelatase, resulting in inhibition of the conversion of protoporphyrin to haem.

Shallow elliptical or linear scars around the lips and linear perioral furrowing (pseudorhagades) are subtle changes that are pathognomonic when observed in children [1,2].

Focal mucinosis

Oral focal mucinosis is an uncommon clinicopathological entity considered to be the oral counterpart of cutaneous focal mucinosis and/or cutaneous myxoid cyst. The nature of the lesion is unclear but may be the result of fibroblastic overproduction of hyaluronic acid. It comprises a clinically elevated mass with a histological picture of localized areas of myxomatous connective tissue. Most of the lesions affect the gingiva and alveolar mucosa [1–5].

All these diseases share distinct histological features. There is an increased number of fibroblast-like cells in early lesions, whereas these are diminished or predominantly at the margin in advanced ones. The myxomatous areas show slight to absent reticulum and elastic fibres, and collagen fibres are fragmented and replaced by variable amounts of mucin. Vimentin is consistently present and correlates with the number of fibroblast-like cells, these being negative for S-100 protein, Leu7, desmin and alpha-SMA [6].

Gardner syndrome (see Chapter 15)

Multiple jaw osteomas are a feature of Gardner syndrome of familial adenomatous polyposis coli [1,2]. Some 80% of patients with familial adenomatosis polyposis coli have osteomas and 30% have dental anomalies such as supernumerary or impacted teeth, or odontomes [3–13].

Gorlin's syndrome (see Chapter 52)

Synonym
- Naevoid basal cell carcinoma syndrome

Odontogenic keratocysts (primordial cysts) of the jaws are a prominent feature of Gorlin's syndrome [1–4]. The syndrome is caused by mutations in the Sonic Hedgehog *patched* gene, a tumour-suppressor gene [5]. A single point mutation in one *patched* allele may be responsible for the various malformations found in the syndrome [5–10]. Inactivation of both *patched* alleles results in the formation of tumours and cysts (basal cell carcinomas, odontogenic keratocysts and medulloblastomas) [5].

The keratocysts should be surgically removed but have a tendency to recur. There are also occasional reports of oral neoplasms, notably fibrosarcoma, ameloblastoma and squamous carcinoma [6–12].

Kindler syndrome

Kindler syndrome is characterized by bulla formation, which starts at birth on areas of the skin that receive pressure and may lead to bilateral, incomplete syndactylies involving all web spaces [1–3].

Oral lesions may include atrophy of the buccal mucosa, trismus (an inability to fully open the mouth) and a form of desquamative gingivitis [4].

Histology shows classical features of poikiloderma, namely epidermal atrophy with flattening of the rete ridges, vacuolization of basal keratinocytes, pigmentary incontinence and mild dermal perivascularization. Ultrastructural studies demonstrate reduplication of the basal lamina with branching structures within the upper dermis and cleavage between the lamina densa and the cell membrane of the keratinocytes. Antibody against type VII collagen shows extensive broad bands with intermittently discontinuous and reticular staining at the dermal–epidermal junction.

Lip pits and sinuses

Dimples are common at the commissures. They should be distinguished from *commissural pits*, which are distinct, definite pits ranging from 1 to 4 mm in diameter and depth [1–3] present from infancy, often showing a familial tendency and probably determined by a dominant gene (Fig. 69.24). Their incidence is 1–20% in various population groups [2,4]; for example, in one series they were found in 12% of white people and 20% of black people [5]. Commissural pits are sometimes associated with aural sinuses or pits. Rarely, they may be infected and present as recurrent or refractory angular cheilitis.

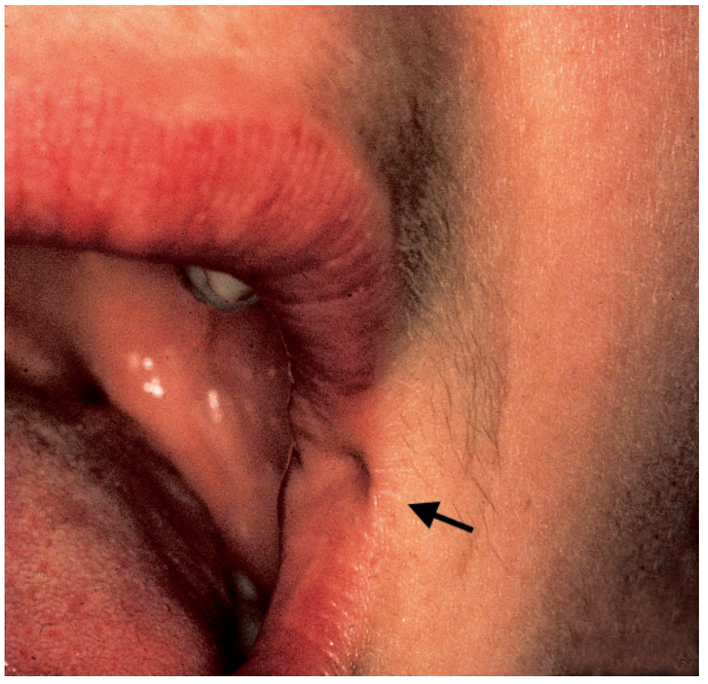

Fig. 69.24 Angular sinus (lip-pit), a congenital anomaly.

Congenital lip pits or sinuses are small, blind fistulae on the vermilion border [6]. They are usually bilateral and symmetrical, often just to one side of the philtrum. The pits may be up to 3–4 mm in diameter and up to 2 cm deep. They may communicate with underlying minor salivary glands. They may appear as isolated findings, but are often (67%) associated with cleft lip and/or palate (Van der Woude syndrome) [7–12]. This autosomal dominant syndrome [13,14] has a frequency of 1 in 75 000 to 1 in 100 000 in white populations (see Chapter 15).

Surgical removal may be indicated for cosmetic purposes.

Noonan's syndrome

Synonym
- Ullrich–Turner syndrome

Ullrich–Turner syndrome is caused by monosomy X or a structural abnormality of the second X chromosome. It is seen in females with a syndrome of short stature, sexual infantilism and a pattern of characteristic minor anomalies including pterygium colli. This syndrome was later called Noonan's syndrome, and it was shown that central giant cell lesions or cherubism of the jaws may be present [1–9]. Oral keratosis is sometimes seen [10].

Van der Woude syndrome

Van der Woude syndrome is a rare autosomal dominant syndrome [1] in which lower lip pits are associated with cleft lip and/or palate [2–7], sometimes seen with syndactyly or talipes equinovarus.

Von Recklinghausen's neurofibromatosis

Neurofibromatosis (NF) consists of distinct variants due to *NF* gene mutations [1]: type I (NF-I), often referred to as von Recklinghausen's disease or generalized neurofibromatosis; and type II (NF-II), a much less common disorder of bilateral acoustic schwannomas. The incidence of head and neck manifestations in patients with NF varies between 14 and 37%. Multiple neurofibromas may occur as a feature of NF; cosmetic lesions include pigmentary changes (café-au-lait spots) [2–6].

Neurofibromas may be seen mainly in NF-I. Neurofibromas may also be seen in NF-II, but bilateral acoustic neuromas are the hallmark of this disease and neurilemmomas and acoustic neuromas are the predominant neural tumours. Neurofibromas may also be part of the MEN syndrome (see Chapter 62).

Oral lesions are not uncommon in von Recklinghausen's generalized NF [7–16]. About two-thirds of patients have intraoral neurofibromas affecting predominantly the tongue, lips, buccal mucosa or palate. Neurofibroma represents a benign overgrowth

of all elements of a peripheral nerve (axon cylinder, Schwann cells and fibrous connective tissue), arranged in a variety of patterns. Enlarged fungiform papillae are found in about 50% of patients. About 60% of patients have radiographic evidence of disease, especially enlargement of the inferior alveolar canal or foramen, or branching of the canal.

Neurofibromas may occur multiply as a feature of NF but only rarely undergo sarcomatous change [17]. Other rare, malignant tumours include nerve sheath tumour [18], triton tumour [19] and Merkel cell carcinoma [20].

Xeroderma pigmentosum

Squamous cell carcinoma of the lip may arise in patients with xeroderma pigmentosum [1–3] and therefore it is crucial to institute sun protection. Oral retinoids such as etretinate or isotretinoin may be of prophylactic value [4–6]. Topical 5-fluorouracil or surgery may be used to treat potentially malignant lesions (see Actinic cheilitis, p. 69.123).

Mouth ulcers

The causes of mouth ulcers are diverse (Tables 69.10 & 69.13), partly because lesions such as vesicles rapidly break down in the mouth as a result of trauma, moisture and infection. Ulcers are usually caused by the following.

1 Local factors
2 Recurrent aphthous stomatitis
3 Neoplasms
4 Systemic conditions
  (a) Haematological
  (b) Gastroenterological
  (c) Dermatological

Table 69.13 Causes of mouth ulcers (see also Table 69.10).

Local causes (e.g. trauma)
Recurrent aphthae (and Behçet's syndrome)
Malignant neoplasms
Ulcers associated with systemic disease
Drugs
Irradiation of the oral mucosa
Disorders of uncertain pathogenesis

(d) Infective
(e) Vasculitis
(f) Iatrogenic
(g) Uncertain causes

5 Drugs.

Mouth ulcers of local aetiology

It is surprising that oral ulceration due to local factors is not more frequent. Accidental cheek biting or facial trauma may cause ulceration in any individual; the history is usually quite clear and a single ulcer of short duration (5–10 days) is present. Ulceration due to biting an anaesthetized lower lip or tongue following a dental local analgesic injection is a fairly common problem in young children.

Orthodontic appliances or, more commonly, dentures (especially if new) are responsible for many traumatic oral ulcers. These ulcers are usually clearly related to the appliance and have been a problem in the care of cleft-palate patients [1]. Chronic trauma may cause a well-defined ulcer with a whitish, keratotic halo [2].

The possibility of some other aetiology for ulcers of apparently local cause should always be borne in mind. Riga–Fede disease consists of ulcers of the lingual frenum in neonates with natal lower incisors [3]. Child abuse may cause ulcers, especially over the upper labial fraena. Self-mutilation may be seen in some psychologically disturbed patients [4,5], patients with learning disability, individuals with sensory impairment, and in Lesch–Nyhan syndrome [6–11]. Oral purpura or ulceration may be seen on the lingual fraenum or palate due to cunnilingus or fellatio respectively [12]. Other local causes of ulceration include thermal burns, especially of the tongue and palate (e.g. 'pizza burn'—now more common with microwave oven use), chemical burns from the holding of medicaments or drugs (e.g. aspirin or cocaine) against the mucosa [13,14], and irradiation mucositis.

Prognosis. Most ulcers of local cause heal spontaneously within 7–14 days if the cause is removed.

Treatment. Maintenance of good oral hygiene and the use of hot saline mouthbaths and 0.2% aqueous chlorhexidine gluconate mouthwash aid healing. A 0.1% benzydamine mouthwash may help give relief. Occasionally, mechanical protection with a plastic guard may help [8].

Patients should be reviewed within 3 weeks to ensure healing has occurred. Any patient with a single ulcer lasting more than 2–3 weeks should be regarded with suspicion and investigated further, usually by biopsy—it may be a neoplasm or other serious disorder.

Eosinophilic ulcer [1–7]

Synonyms
- Traumatic eosinophilic granuloma
- Traumatic ulcerative granulomatous disease

Eosinophilic ulcer is a rare, self-limiting disease that often appears on the tongue in older adults or children. Its aetiology remains obscure and may be associated with traumatic factors. Eosinophilic ulcers are unifocal, with a benign course. Pathological features show an extensive inflammatory cell infiltration, with predominantly eosinophilic cells throughout the submucosa and histological similarities to $CD30^+$ lymphoproliferative disorders [5]. The peripheral blood eosinophil count is normal. Diagnosis and treatment is with either conservative excision or incisional biopsy.

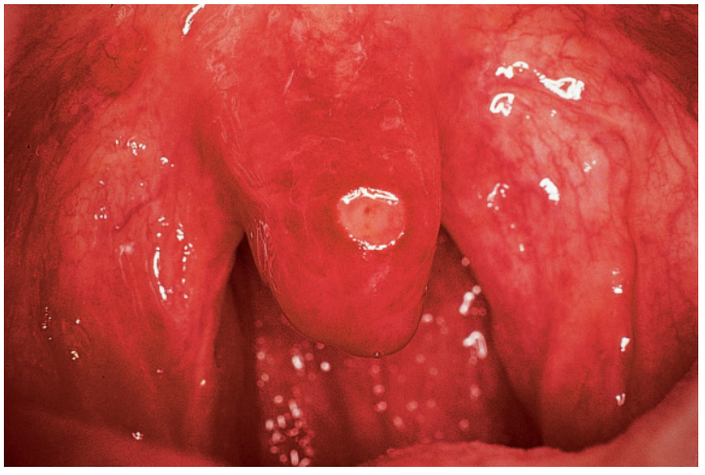

Fig. 69.25 Recurrent aphthae.

Table 69.14 Systemic and other factors that may occasionally underlie or be associated with recurrent aphthous stomatitis (RAS).

	Comments
Behçet's syndrome	Association of RAS with ocular lesions, genital ulcers and multisystem disease
Sweet's syndrome	See Chapter 50
Haematinic deficiency	In some studies, 10–20% of patients with RAS have deficiencies of iron, folic acid or vitamin B_{12}
Gastrointestinal disease	Malabsorption states (pernicious anaemia, coeliac disease and Crohn's disease) may precipitate RAS in a small minority
Endocrine factors	In some women, RAS is clearly related to a fall in progestogens in the luteal phase of the menstrual cycle; hormone therapy may be beneficial
Immunodeficiency	A few patients with RAS have an immune defect such as human immunodeficiency virus disease
Other factors	Trauma, certain foods, stress and cessation of smoking may play a part

Recurrent aphthous stomatitis

Synonyms
- Aphthae
- Canker sores

Recurrent aphthous stomatitis (RAS) is characterized by recurring episodes of ulcers, typically from childhood or adolescence, each lasting from 1 to about 4 weeks before healing. Aphthae typically are multiple round or ovoid ulcers with a circumscribed margin, erythematous halo and a yellow or grey floor (Fig. 69.25). The term 'recurrent oral ulcer' is rather imprecise and should be avoided [1–4].

Aetiology. The aetiology of RAS is not clear. A positive family history is found with about one-third of patients and there is an increased frequency of human leukocyte antigens (HLA)-A2, HLA-A11, HLA-B12 and HLA-DR2, supporting a genetic basis for susceptibility in some patients [1–4].

There are identifiable predisposing factors in some patients (Table 69.14). A minority (about 10–20%) of patients attending outpatient clinics with RAS have an underlying haematological abnormality, usually a low serum iron or ferritin, or deficiency of folate or vitamin B_{12}. A few have multiple deficiencies [5,6]. Up to 3% of RAS patients have coeliac disease but in others a gluten-free diet is of no value [7]. Patients with deficiency states often, but not always, have gastrointestinal symptoms, and their RAS is often of recent onset. Other aetiological factors in RAS can include stress, trauma and cessation of tobacco smoking. Ulcers similar to aphthae are also seen in Behçet's syndrome; Sweet's syndrome; HIV infection, cyclic neutropenia and other immunodeficiencies; and, rarely, in children in association with fever and pharyngitis (periodic fever, aphthous stomatitis, pharyngitis and cervical adenitis; PFAPA) [8,9]. Orogenital ulceration with aphthae is probably a forme fruste of Behçet's syndrome.

There is no evidence that RAS is an autoimmune disease [1–4]. There is no known association with systemic autoimmune disorders, none of the common autoantibodies are found, and RAS tends to resolve or decrease spontaneously with increasing age. The serum immunoglobulin levels are usually normal, although IgA and IgG may be increased, and immune complexes may be found.

It now seems likely that there is a minor degree of immunological dysregulation underlying aphthae. Attempts to implicate a variety of viruses or bacteria in the aetiology of RAS have largely been unsuccessful, but there may be cross-reacting antigens between the oral mucosa and microorganisms such as *Streptococcus sanguis* or its L form, or heat-shock protein [10].

Cell-mediated immune mechanisms appear to be involved in the pathogenesis of RAS. In the lesions, helper T cells predominate early on, with some natural killer cells. Cytotoxic cells then appear and there is evidence for an antibody-dependent cellular cytotoxicity reaction [1–4].

Clinical features. RAS is a common disease that probably afflicts at least 20% of the population. There is a high prevalence in higher socio-economic classes.

There are three main clinical types of RAS. Most common are minor aphthous ulcers, which account for 80% of all RAS. Some 10% of patients with RAS have major aphthous ulcers, and a further 10% suffer from a herpetiform type of ulceration (Table 69.15).

Minor aphthous ulcers (synonym Mikulicz ulcers). Minor RAS (MiRAS) occur mainly in the 10 to 40-year age group, and often cause minimal symptoms. MiRAS are usually 2–4 mm in diameter and found mainly on the non-keratinized mobile mucosa of the lips, cheeks and floor of the mouth, sulci or ventrum of the tongue. They are uncommon on the gingiva, palate or dorsum of the tongue. Only a few ulcers (one to six) appear at a time; they heal in 7–10 days and recur at variable intervals. MiRAS are usually round or ovoid, but are often more linear when in the buccal sulcus, a common site. The ulcer floor is initially yellowish but

Table 69.15 Main features of recurrent aphthous stomatitis.

	Minor aphthae	Major aphthae	Herpetiform ulcers
Age of onset	Childhood or adolescence	Childhood or adolescence	Young adult
Ulcer size	2–4 mm	May be 10 mm or larger	Initially tiny but ulcers coalesce
Number of ulcers	Up to about 6	Up to about 6	10–100
Sites affected	Mainly vestibule, labial, buccal mucosa and floor of mouth; rarely dorsum of tongue, gingiva or palate	Any site	Any site but often on ventrum of tongue
Duration of each ulcer	Up to 10 days	Up to 1 month	Up to 1 month
Other comments	Most common type of aphthae	May heal with scarring	Affects females predominantly

Fig. 69.26 Major aphthous ulcers.

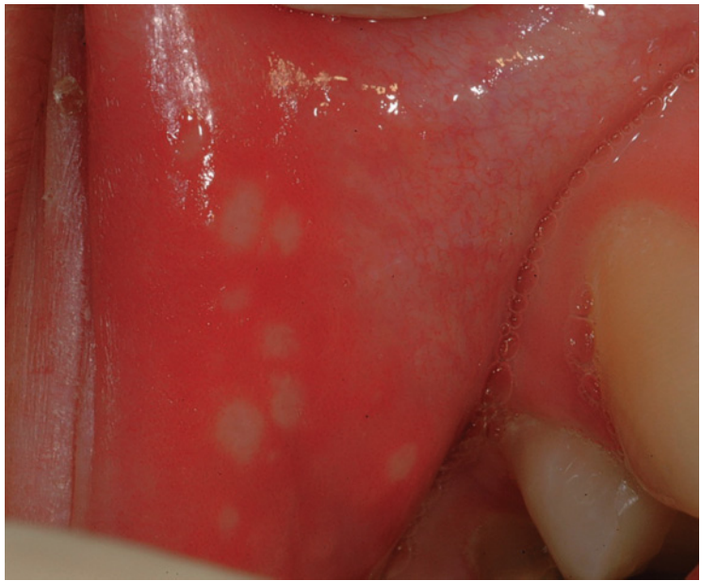

Fig. 69.27 Herpetiform ulceration

becomes greyish as epithelialization proceeds. There is an erythematous halo and some oedema but MiRAS heal with little or no evidence of scarring.

Major aphthous ulcers (synonym Sutton's ulcers). Previously known as periadenitis mucosa necrotica recurrens (PMNR), major RAS (MaRAS) are larger, recur more frequently, last longer and are more painful than MiRAS. They may reach a large size, even more than 1 cm in diameter. MaRAS are found on any area of the oral mucosa, including the dorsum of the tongue or palate. Usually only a few ulcers (one to six) occur at one time; they heal slowly over 10–40 days, and recur frequently. MaRAS are round or ovoid with an inflammatory halo, and may heal with scarring (Fig. 69.26). Occasionally, a raised erythrocyte sedimentation rate or plasma viscosity is found.

Herpetiform ulceration (Fig. 69.27). Herpetiform ulceration (HU) is found in a slightly older age group and there is a female predominance. Herpetiform ulcers are often extremely painful and recur so frequently that ulceration may be virtually continuous. HU begins with vesiculation, which passes rapidly into multiple, minute (2 mm), discrete ulcers at any oral site. The ulcers increase in size and coalesce to leave large ragged ulcers that heal in 10 days or longer. Their similarity to herpetic stomatitis gives herpetiform ulcers their name, but there is no evidence that herpes simplex virus is involved.

Prognosis. RAS in most patients resolves or abates spontaneously with age. An underlying, identifiable predisposing cause is particularly likely where RAS commences or worsens in adult life [5–10].

Diagnosis. Diagnosis is based on history and clinical features, since specific tests are unavailable. Biopsy is indicated only where some other cause of ulceration is suspected. To exclude relevant systemic predisposing factors it is often useful to perform:

- full blood count
- haemoglobin assay
- white cell count and differential
- red cell indices
- iron studies
- red cell folate level
- serum vitamin B_{12} measurements
- serum antiendomysial antibodies and IgA anti-tissue transglutaminase antibodies.

The relevance of HLA studies for differentiating RAS from Behcet's syndrome is discussed on p. 69.47.

Treatment. Few patients have spontaneous remission until after several years and thus treatment is often indicated [11–13]. Fortunately, the natural history of RAS is one of eventual remission in most cases.

Predisposing factors should be corrected. If there is an obvious relationship to certain foods, the causal food should be excluded from the diet [14]. Good oral hygiene should be maintained: chlorhexidine or triclosan mouthwashes help achieve this and may help reduce ulcer duration [1–4]. Topical minocycline and tetracycline mouthrinses may be of benefit [15].

Ulcer pain can usually be reduced, and the time to healing reduced, with hydrocortisone hemisuccinate pellets (Corlan) 2.5 mg or triamcinolone acetonide in carboxymethylcellulose paste (Adcortyl in Orabase) used four times daily; failing the success of these, a stronger topical corticosteroid (e.g. betamethasone, beclomethasone, fluticasone, mometasone, clobetasol) [16–18] or systemic corticosteroid (e.g. prednisolone) may be required.

Other therapies for RAS, such as sucralfate [19], colchicine and pentoxifylline (oxpentifylline), may have a role in individual cases but are not generally very effective or have adverse effects [3,20–23].

Thalidomide, in doses from 50 mg up to 300 mg daily, can frequently induce remission, especially in major aphthae, but its important teratogenic effects and the risk of neuropathy must be considered [22,24,25]. Topical tacrolimus may be effective but randomized trials are awaited.

There are multiple, other therapies available for RAS, including carbenoxolone, benzydamine, dapsone, cromoglicate, levamisole and many others, but generally their efficacy has not been well proven or they have unacceptable adverse effects [3].

Behçet's syndrome

Synonym
- Adamantiades syndrome

Definition. Behçet's syndrome (BS) is the association of RAS with genital ulceration and eye disease (especially iridocyclitis and retinal vasculitis) [1–6]. There may be a number of other systemic or cutaneous manifestations (Table 69.16).

Table 69.16 Behçet's syndrome.

	Features	Incidence (%)
Major criteria		
Oral	Aphthae	90–100
Genital	Ulcers	64–88
Neuro-ocular	Iridocyclitis	10–90
	Retinal vasculitis	
	Optic atrophy	
	Syndromes resembling disseminated sclerosis, pseudobulbar palsy or neurosyphilis	
	Meningoencephalitis	
	Others	
Dermatological	Pustules	48–88
	Erythema nodosum	
	Pathergy	
Minor criteria	Proteinuria and haematuria	
	Thrombophlebitis	
	Aneurysms	
	Arthralgias	

Aetiology. The aetiology of BS is uncertain but it appears to be becoming more common. There is a genetic background and, as in RAS, there are occasional familial cases and associations with HLA types, in BS particularly with HLA-B5 (Bw51 split). HLA-B51 or its B101 allele is significantly associated with BS in Japan, Korea, Turkey and France, as well as with the ocular manifestations in Britain. The MICA6 allele, a member of the polymorphic MHC class I-related gene A (MICA) family, is thought to be in linkage disequilibrium with HLA-B51 and has been shown to be significantly associated with BS in Japan and France [7,8]. HLA-DR/DQ haplotypes are more important than individual HLA-DR and HLA-DQ phenotypes for the development of mucocutaneous type of BS and for disease shift from RAS to mucocutaneous type of BS [9].

The aetiopathogenesis of BS is still unclear [6,10–12]. It does not appear to be infectious, contagious or sexually transmitted. The disease is found worldwide but is most common in the eastern Mediterranean countries and eastern Asia, along the Silk Road taken by Marco Polo. In these countries, it is a leading cause of blindness though this is not the case in resource-rich countries.

There are many immunological findings in BS:

- circulating autoantibodies against a number of components, including intermediate filaments found in mucous membranes, cardiolipin and neutrophil cytoplasm
- circulating immune complexes and changed levels of complement
- immunoglobulins and complement deposition within and around blood vessel walls
- decreased ratio of T-helper (CD4) cells to T-suppressor (CD8) cells.

These immunological changes mimic those seen in patients with RAS—various T-lymphocyte abnormalities (especially T-suppressor cell dysfunction), changes in serum complement and increased polymorphonuclear leukocyte motility. There is also evidence that mononuclear cells may initiate antibody-dependent cellular cytotoxicity to oral epithelial cells, and evidence of disturbance of natural killer cell activity.

The common denominator in all systems is vasculitis, usually leukocytoclastic vasculitis. Many of the features of BS (erythema nodosum, arthralgia, uveitis) are common to established immune complex disease and, indeed, immune complexes (usually antigen–antibody complexes) are found in the sera. The antigen responsible has not been reliably identified but may include herpes simplex virus or streptococcal antigens [13–16]. As in RAS, heat-shock proteins have been implicated.

Clinical features. BS is a chronic, multisystem disorder, most patients being male, usually in their third or fourth decade.

Because BS is rare and symptoms of the disease overlap symptoms of other diseases, it can be very difficult to diagnose. Spontaneous remission is common for patients with BS; this can add to the difficulty in diagnosis.

BS is characterized mainly by a triad of RAS [6,17,18], genital ulcers [15,16] and ocular lesions [19,20]. The CNS, heart and intestinal tract may be involved.

Table 69.17 Oculomucocutaneous syndromes.*

	Main lesions		
Disease	**Oral and genital**	**Ocular**	**Skin**
Behçet's syndrome	Aphthae	Uveitis	Erythema nodosum
Sweet's syndrome	Aphthae	Conjunctivitis, episcleritis	Inflamed papule or nodule
Erythema multiforme	Erosions	Erosions	Target lesions
Cicatricial pemphigoid	Bullae	Erosions	Occasional dome-shaped bullae
	Erosions	Scarring	
Pemphigus	Erosions	Erosions	Multiple, flaccid bullae
Reiter's syndrome	Ulcers	Conjunctivitis	Keratoderma blenorrhagica

* Ulcerative colitis, herpes simplex, syphilis, lupus erythematosus, mixed connective tissue disease and other disorders may also cause oral, cutaneous and ocular lesions.

One variant of BS (MAGIC syndrome) is associated with *m*outh *a*nd *g*enital ulcers and *i*nflamed *c*artilage [21,22]. Other oculomucocutaneous syndromes (Table 69.17) may cause similar manifestations [23,24].

Diagnosis. BS is usually diagnosed on clinical grounds, although findings of HLA-B5101 and pathergy are supportive, as are antibodies to cardiolipin and neutrophil cytoplasm. Disease activity may be assessed by serum levels of acute phase proteins or antibodies to intermediate filaments, or by erythrocyte sedimentation rate; all are raised in active BS.

Differential diagnosis is mainly from the following.

- Sweet's syndrome: aphthae, conjunctivitis, episcleritis, inflamed tender papule or nodule
- Erythema multiforme: erosions, target (iris) lesions
- Pemphigoid: bullae, erosions
- Pemphigus: erosions, multiple flaccid bullae
- Reiter's syndrome: ulcers, conjunctivitis, keratoderma blenorrhagica
- Ulcerative colitis
- Herpes simplex
- Syphilis
- Lupus erythematosus
- Mixed connective tissue disease.

The diagnosis is often made on the basis of RAS plus two or more of recurrent genital ulceration, eye lesions, skin lesions and pathergy [6,25,26].

Major criteria are:

1 RAS: in 90–100% of cases.
2 Recurrent painful genital ulcers that tend to heal with scars in 64–88% of cases. Genital ulcers are especially common in females with BS, and resemble RAS.
3 Ocular lesions: uveitis with conjunctivitis (early) and hypopyon (late), retinal vasculitis (posterior uveitis), iridocyclitis and optic atrophy. The most common ocular manifestation is relapsing iridocyclitis but uveitis, retinal vascular changes and optic atrophy may occur. Both eyes are eventually involved and blindness may result.

4 CNS lesions: meningoencephalitis, cerebral infarction, psychosis, cranial nerve palsies, cerebellar and spinal cord lesions, hemiparesis and quadriparesis.
5 Skin lesions: erythema nodosum, papulopustular lesions and acneform nodules. Venepuncture is, in some patients, followed by pustulation (pathergy).

Minor criteria are:

1 Arthralgia: large joint arthropathies that are subacute, non-migratory, self-limiting and non-deforming
2 Superficial or deep migratory thrombophlebitis, especially of lower limbs
3 Intestinal lesions: inflammatory bowel disease with discrete ulcerations
4 Lung involvement: pneumonitis
5 Haematuria and proteinuria.

However, very non-specific signs and symptoms, which may be recurrent, may precede the onset of the mucosal membrane ulceration by 6 months to 5 years. These include malaise, anorexia, weight loss, generalized weakness, headache, perspiration, decreased or elevated temperature, lymphadenopathy and pain in the substernal and temporal regions.

A history of repeated sore throats, tonsillitis, myalgias and migratory erythralgias without overt arthritis is also common.

Treatment. Unlike RAS, BS is not self-limiting. It causes morbidity (especially in terms of ocular and neurological disease) and mortality. Most patients present with oral and ocular disease but there follows a relapsing and remitting but variable course. CNS involvement, thromboses of major vessels and gastrointestinal perforation result in a poor prognosis. Few patients with BS have spontaneous remission and thus treatment is indicated [6,27,28].

Chronic morbidity is usual; the leading cause is ophthalmic involvement, which can result in blindness. The effects of the disease may be cumulative, especially with neurological, vascular and ocular involvement. Mortality is low but can occur from neurological involvement, vascular disease, bowel perforation, cardiopulmonary disease or as a complication of immunosuppressive therapy. In the face of the serious potential complications, patients with suspected BS should be referred early for specialist advice.

Topical treatment for RAS (see p. 69.46). Oral ulcers may respond to topical corticosteroids or 5-aminosalicylic acid [6,29]. Even nicotine patches may have some success [30].

Systemic treatment includes mainly colchicine 0.5–1.5 mg daily.

Other systemic treatments include corticosteroids, azathioprine, ciclosporin, chlorambucil, cyclophosphamide, dapsone, interferon-alpha, levamisole or thalidomide. Ocular lesions usually respond to ciclosporin, but tend to relapse when treatment is stopped. Thalidomide at a dose of up to 400 mg daily may be of value in recalcitrant orogenital ulceration, although it must be used with caution in view of the adverse effects of teratogenicity and neuropathy [31–34].

Sweet's syndrome (see Chapter 50)

Pustular lesions leading to aphthous-like ulcers may be found in Sweet's syndrome and there are occasional associations with BS and Sjögren's syndrome, each of which has oral manifestations. About 5% of patients in the UK with Sweet's syndrome have oral aphthous-like ulcers, although up to 30% of Japanese patients suffer these [1–5].

Malignant neoplasms

More than 90% of malignant neoplasms in the mouth are squamous cell carcinomas. Nearly 30% of all squamous cell carcinomas affect the lip; some 25% affect the tongue, the most common intraoral site [1–9]. Most intraoral cancers involve the posterolateral border of the tongue and/or the floor of the mouth (the 'graveyard' area). In betel chewing, the buccal mucosa is a common site for carcinoma [10].

Oral cancer is a significant world health problem, being overall the sixth most common malignant neoplasm. In parts of South-East Asia for example, particularly India, some 40% of all malignancy is oral cancer [11]. High levels are also seen in resource-poor countries such as Brazil, but also in parts of Europe such as areas of northern France and eastern Europe.

Oral squamous cell carcinoma

Cancer of the oral cavity is classified according to site:

- lip (International Classification of Diseases [ICD] 140)
- tongue (ICD 141)
- gum (ICD 143)
- floor of the mouth (ICD 144) and
- unspecified parts of the mouth (ICD 145).

Carcinoma of the lip

Squamous cell carcinoma is the commonest malignancy to affect the vermilion zone and, as with squamous carcinoma of the glabrous skin, it is usually due to actinic damage [1,12,13]. Like actinic cheilitis it is most common on the lower lip of fair-skinned, outdoor workers in sunny climates, and is relatively rare in pigmented skin [2–4]. Lip cancer is common in certain population groups in the UK, Romania, Hungary, Poland, Spain, Finland, Israel, Canada, the USA and Australia, but in most areas reported the incidence is falling [4–7,14–16].

Lip cancer generally occurs in men who are employed in outdoor activities such as farming and fishing [17,18]. Squamous cell carcinomas occur on the lower lip in 89%, with 3% on the upper lip and 8% at the commissures [19]. The buccal mucosa may also be involved, particularly in association with betel quid chewing [10].

Although sunlight is accepted as the major aetiological factor, some studies have shown a poor correlation between the incidence of lip cancer and the rate of annual solar radiation [20]. *Actinic radiation* may predispose to lip cancer. Facts that support such a relationship include the following.

- Lip cancer involves the more exposed lower lip, rather than the upper lip.
- There is a higher incidence of lip cancer in outdoor workers and rural populations than in office workers or urban populations.
- Fair-skinned more than dark-skinned people tend to develop lip cancer (as well as skin cancer and melanoma) in sunny climates.

Other risk factors may include low social class, tobacco smoking, syphilis, poor dentition, infection with herpes simplex virus [3,5,17,21] or human papillomaviruses [22], and immune suppression [23]; for example lip cancer is increased in immunosuppressed renal transplant recipients.

The initial features are a keratinous growth or swelling of the lip (Fig. 69.28), soreness and ulceration. Most lesions are amenable to surgical excision, with more than 70% surviving for 5 years.

Fig. 69.28 Squamous cell carcinoma of lip.

Intraoral carcinoma

Most intraoral carcinoma is squamous cell carcinoma [1–5]. In many countries there is evidence for an increase in oral squamous cell carcinoma (OSCC) over recent years [6–12], especially in young persons. There is marked inter-country variation in both the incidence of, and mortality from, OSCC [13]. In addition, there is also growing evidence of intra-country ethnic differences in incidence and mortality, especially in the UK and USA.

In resource-poor countries, particularly South-East Asia and Brazil, the incidence of OSCC varies widely in different areas and there are ethnic differences in incidence, often attributed to lifestyle habits.

In most resource-rich countries OSCC is uncommon. The incidence varies between countries and between different regions of the same country. For example, parts of France and Newfoundland have the highest incidence in the West, with about 10 times the incidence of oral carcinoma in the UK. Oral cancer is more than twice as common in Scotland than in England and Wales and, for example, even within Scotland there are regional differences.

Potentially malignant states. Some potentially malignant (precancerous) lesions that can progress to OSCC include especially [14,15] *erythroplasia* (erythroplakia), the most likely lesion to progress to severe dysplasia or carcinoma (see p. 69.102); and *leukoplakia* (see p. 69.89), particularly proliferative verrucous leukoplakia, sublingual leukoplakia, candidal leukoplakia and syphilitic leukoplakia.

Some other potentially malignant (precancerous) conditions include:

- lichen planus—there are also cases of dysplasia with a lichenoid appearance (lichenoid dysplasia)
- HPV infection
- discoid lupus erythematosus
- submucous fibrosis
- atypia in immunocompromised patients
- dyskeratosis congenita
- Fanconi anaemia
- Paterson–Kelly syndrome (sideropenic dysphagia, Plummer–Vinson syndrome).

One of the main features that appears to precede the onset of malignancy is epithelial dysplasia, although dysplasia can also be seen in regenerating tissue and some non-precancerous lesions such as ulcers, viral infections, candidal infections and granular cell tumours.

Dysplasia varies in severity, and it is the more severe grades that are associated with higher malignant potential.

Predisposing factors (risk factors) [1–5,10–12,14–19]. In the resource-rich countries, OSCC is seen especially in tobacco users, alcohol users, lower socio-economic groups and ethnic minority groups.

In resource-poor countries, OSCC is seen especially in tobacco users, alcohol users, 'betel quid' users (some 20% of the world's population use betel) and lower socio-economic groups. In peoples from parts of Asia, tobacco-chewing, along with a variety of ingredients in 'betel quid' (betel vine leaf, betel [areca] nut, catechu, slaked lime, together with tobacco), appears to predispose to OSCC, particularly when it is started early in life and is used frequently and for prolonged periods. Various other risky chewing habits, usually containing tobacco, are used in different cultures (e.g. khat, shammah, toombak).

Microorganisms such as *Candida* and human papillomavirus (HPV) have been detected in some potentially malignant lesions and some OSCC, where they may play a role. HPV is especially implicated in oropharyngeal and tonsillar carcinoma; HPV-16 is particularly implicated [20].

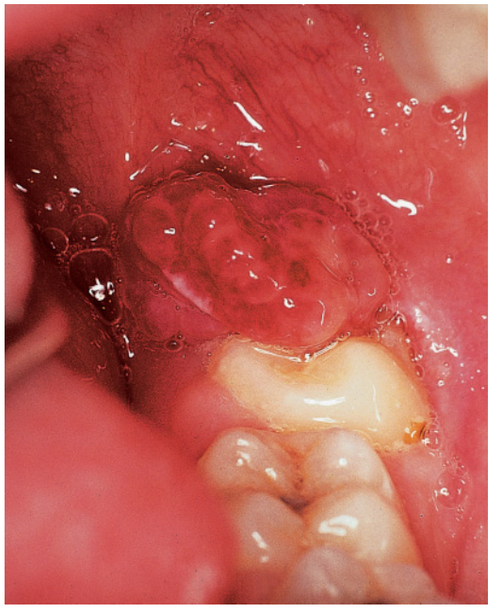

Fig. 69.29 Oral squamous cell carcinoma.

In contrast, diets rich in fresh fruits and vegetables and vitamin A may have a protective effect.

Clinical features. OSCC may present as the following [1–5] (Fig. 69.29).

- A red lesion (erythroplasia)
- A granular ulcer with fissuring or raised exophytic margins
- A white or mixed white and red lesion
- A lump sometimes with abnormal supplying blood vessels
- An indurated lump/ulcer, i.e. a firm infiltration beneath the mucosa
- A non-healing extraction socket
- A lesion fixed to deeper tissues or to overlying skin or mucosa
- Cervical lymph node enlargement, especially if there is hardness in a lymph node or fixation.

Enlarged nodes in a patient with oral carcinoma may be caused by infection, reactive hyperplasia secondary to the tumour, or metastatic disease. Occasionally, a swollen lymph node is detected in the absence of any obvious primary tumour.

In patients with OSCC for over 3 years, second primary neoplasms in the aerodigestive tract may be seen in up to 25% and in up to 40% of those who continue to smoke.

Diagnosis. Early diagnosis is important since it improves prognosis and minimizes the extent of interventions [21–25]. There should be a high index of suspicion, especially of a solitary lesion present for over 3 weeks: biopsy is invariably indicated. Clinicians should be aware that single ulcers, lumps, red patches or white patches, particularly if any of these persist for more than 3 weeks, may be manifestations of frank malignancy. Scalpel biopsy is required and toluidine blue staining may help highlight the most appropriate area for biopsy [5,26–30].

The whole oral mucosa should be examined as there may be widespread dysplastic mucosa ('field change') or even a second neoplasm and the cervical lymph nodes must be examined. Frank tumours should be inspected and palpated to determine extent of spread; for tumours in the posterior tongue, examination under general anaesthesia may facilitate this.

OSCC should be staged according to the TNM classification of the International Union against Cancer, where T represents tumour size, N nodal metastases and M distant metastases (Table 69.18), since this classification relates well to overall survival rate, that is the earlier the tumour, the better the prognosis and the less complicated the treatment.

Table 69.18 TNM classification of malignant neoplasms.*

Primary tumour size (T)	
Tx	No available information
T_0	No evidence of primary tumour
T_{is}	Only carcinoma *in situ*
T_1, T_2, T_3, T_4	Increasing size of tumour†
Regional lymph node involvement (N)	
Nx	Nodes could not be or were not assessed
N_0	No clinically positive nodes
N_1	Single clinically positive homolateral node less than 3 cm in diameter
N_2	Single clinically positive homolateral node 3–6 cm in diameter, or multiple clinically positive homolateral nodes, none more than 6 cm in diameter
N_{2a}	Single clinically positive homolateral node 3–6 cm in diameter
N_{2b}	Multiple clinically positive homolateral nodes, none more than 6 cm in diameter
N_3	Massive homolateral node(s), bilateral nodes, or contralateral node(s)
N_{3a}	Clinically positive homolateral node(s), one more than 6 cm in diameter
N_{3b}	Bilateral clinically positive nodes
N_{3c}	Contralateral clinically positive node(s)
Involvement by distant metastases (M)	
Mx	Distant metastasis was not assessed
M_0	No evidence of distant metastasis
M_1, M_2, M_3	Distant metastasis is present. Increasing degrees of metastatic involvement, including distant nodes

* Several other classifications are available, e.g. STNM (S, site).

† T_1, maximum diameter 2 cm; T_2, maximum diameter 4 cm; T_3, maximum diameter >4 cm; T_4, massive tumour >4 cm diameter, with involvement of antrum, pterygoid muscles, base of tongue or skin.

Investigations. The principles include the following.

1 Confirm the diagnosis histopathologically and determine the presence of malignant disease elsewhere.
   (a) Are bone, muscles or cervical lymph nodes involved?
   (b) Are there other primary tumours (typically in the upper aerodigestive tract—mouth, nares, pharynx, larynx, oesophagus)? There is controversy as to the need for endoscopy in all cases to detect such tumours.
   (c) Are there metastases, initially to regional lymph nodes and later to liver, bone and brain? Imaging may detect abnormalities that escape clinical examination. Sentinel lymph node biopsy may contribute to more targeted lymph node dissection strategies [34,35].

2 Ensure that the patient is as prepared as possible for the major surgery required, particularly in terms of general anaesthesia, potential blood loss and ability to metabolize drugs.
3 Address any potential dental or oral problems preoperatively, to avoid later complications such as osteoradionecrosis.

The following investigations are therefore almost invariably indicated.

- Lesional biopsy. Incisional biopsy, which is invariably required, should be sufficiently large to include enough suspect and apparently normal tissue. Red, rather than white, areas are most likely to show dysplasia, and hence should be biopsied. Attempts to highlight probable dysplastic areas before biopsy, for example by using toluidine blue dye, are unfortunately not reliable, but may be of some help in deciding which area is best to biopsy where there is widespread 'field change'. An excisional biopsy should be avoided unless the lesion is extremely small, since this is unlikely to have excised an adequately wide margin of tissue if the lesion is malignant, but will have destroyed for the surgeon or radiotherapist clinical evidence of the site and character of the lesion.
- Biopsy of equivocal neck lymph nodes.
- Jaw radiography (often rotating pantomography), although this is inadequate to exclude bone invasion.
- Chest radiography: important as a pre-anaesthetic check, especially in patients with known pulmonary or airways disease, and to demonstrate metastasis to lungs or hilar lymph nodes, ribs or vertebrae.
- MRI or computed tomography (CT) of the primary site, head and neck, and suspected sites of distant metastases, and MRI of the neck to delineate the extent of cervical node metastases. Some units routinely examine chest and abdomen. MRI is particularly useful for determining tumour spread, bone involvement and nodal metastases.
- Electrocardiography.
- Blood tests:
  — Full blood picture and haemoglobin.
  — Urea and electrolytes.
  — Liver function tests.
- Blood for grouping and cross-matching.

In selected cases, the following may also be useful.

- Bronchoscopy: if chest radiography reveals any lesions.
- Endoscopy of the upper aerodigestive tract: especially if there is a history of tobacco use.
- Gastroscopy: if a per-endoscopic gastrostomy is to be used for feeding.
- Liver ultrasound: if there is hepatomegaly or abnormal liver function.
- Doppler duplex flow studies: in planning radial free forearm flaps.
- Angiography: in planning lower limb free flaps.

Treatment. The prognosis of OSCC is around 30% survival at 5 years [5,6,31,32]. The major impact that treatment has had on the prognosis of oral cancer has been in relation to improved anaesthetic and medical care. Surgical reconstruction has also been markedly improved [32,33] and there are fewer side effects from modern radiotherapy [34].

The treatment of oral cancer involves one or a combination of radiotherapy, surgery and, very occasionally, chemotherapy. Serious consideration must be given to the complications of the various modalities [34,36,37] and the quality of life achieved [38–40].

There is now evidence that vitamin A derivatives may be of benefit in patients with premalignant lesions, and in preventing second primary neoplasms [41,42].

Verrucous carcinoma

Verrucous carcinoma is an uncommon, warty, white neoplasm that is rarely ulcerated [1–6]. It may develop from proliferative verrucous leukoplakia (see p. 69.89). Risk factors include a possible association with HPV and some verrucous carcinomas develop as a result of the local use of snuff or tobacco. Confirmation of diagnosis by biopsy is particularly important because verrucous carcinoma responds well to excision but, if irradiated, may undergo anaplastic change, with subsequent acceleration of growth and invasiveness [7]. Methisoprinol may be of value [8].

Florid oral papillomatosis

Florid oral papillomatosis is a rare but well-defined clinical entity of unknown pathogenesis. Risk factors include possible association with HPV, tobacco, and chronic inflammation or irritation.

Florid oral papillomatosis is essentially a verrucous carcinoma, a clinicopathological variant of squamous cell carcinoma also known by a confusing array of names such as Ackerman's tumour, Buschke–Loewenstein tumour, epithelioma cuniculatum, carcinoma cuniculatum and cutis papillomatosis carcinoides of Gottron.

Clinical features. The lesions are exuberant, warty or verrucous, and characterized by their benign appearance on histology, although this is usually associated with a marked capacity for recurrence and a tendency for carcinomatous change. Its apparent clinical benign nature may lead to lengthy periods of misdiagnosis, during which it slowly but relentlessly destroys and extends into underlying tissue but rarely metastasizes to lymph nodes [1–3].

Diagnosis. Biopsy is required, although to those unfamiliar with the diagnosis the relatively bland histological features are often more suggestive of verruca vulgaris or pseudoepitheliomatous hyperplasia than of squamous cell carcinoma. Alternatively, when it extends into underlying tissues, it may be mistaken for a benign adnexal tumour or even a cyst.

Treatment. Treatment in the early stage of the disease is usually successful. Etretinate therapy (200 mg/day) or chemotherapy with bleomycin may reduce the lesion bulk [4–6]. Surgical or laser excision is favoured. The use of radiotherapy is controversial since in numerous reported cases this has produced an anaplastic squamous cell carcinoma.

Basal cell carcinoma

Actinic radiation is a major aetiological factor in the development of basal cell carcinoma (BCC), greater than 85% occurring on the sun-exposed areas of the head and neck [1,2]. Fair-skinned

individuals who burn and those whose occupations require excessive exposure to sunshine are at greatest risk; the tumour is rare in dark-skinned persons, and 95% occur after the age of 40 years [3].

Other significant risk factors for the development of BCC include prior burns, vaccinations, irradiation, exposure to inorganic arsenic, genetic syndromes (e.g. xeroderma pigmentosum, naevoid BCC syndrome, albinism and Bazex's syndrome) and immunosuppression [4–10].

Clinical features. On the lip these manifest as a pearly, sometimes ulcerated, nodule or papule. Unlike squamous cell carcinomas, BCCs only rarely originate on the vermilion but commonly occur periorally [11–14]. In contrast to squamous cell carcinomas, BCCs more commonly arise on the upper than the lower lip. The lesions can also arise *de novo* on the vermilion [15] or occasionally the mucosa of the lip, although spread of a tumour from an adjacent site may rarely occur.

BCC has multiple forms that can be simplistically divided as follows.

- Nodular: the most frequent type around the lips presents as a waxy translucent nodule with fine telangiectasias, often ulcerated.
- Morphoeic: an atrophic plaque resembling a scar, with an aggressive infiltrative growth pattern and high rate of recurrence after excision.
- Superficial: appears as an erythematous plaque with elevated borders and central atrophy or ulceration. It is rare around the lips.

Although the tumour rarely metastasizes, it is responsible for considerable functional and cosmetic morbidity.

Multiple lesions are commonly encountered and the various forms have overlapping clinical features. BCC can be frequently pigmented, resembling melanomas and other melanocytic lesions. BCC may, of course, be a feature of naevoid BCC syndrome (Gorlin–Goltz syndrome, see p. 69.39). Furthermore, in addition to having a significantly increased risk for new skin cancers, patients with BCC have been shown to have an increased risk of developing non-cutaneous cancers, including respiratory cancers, testicular cancer, breast cancer and non-Hodgkin's lymphoma [16–18].

Diagnosis. BCC of the lips must be differentiated from other nodules, including squamous cell carcinoma, keratoacanthoma, trichoepithelioma and sebaceous adenoma. Since lesions that arise periorally are often aggressive, early detection and confirmation by biopsy will prevent infiltration and destruction of the underlying structures.

Treatment. Various treatment modalities for BCC include scalpel, electrosurgery, cryosurgery and laser surgery, radiation, curettage and intralesional chemotherapy or alpha interferon [19–21]. Selection of the treatment modality depends on size, site and histological pattern of the tumour as well as the age of the patient.

Since lip lesions are often of the nodular or morphoeic types, Mohs' micrographic surgery, utilizing microscopically controlled excision, potentially offers the highest cure rate with the greatest preservation of tissue. The cure rate for BCC is over 90%.

Keratoacanthoma

Keratoacanthoma is a benign, often rapidly growing lesion that probably arises from the supraseboglandular part of a sebaceous gland. Keratoacanthomas are common, self-limiting, proliferative tumours that arise most frequently in men after the sixth decade of life [1,2]. The lesions mimic squamous cell carcinoma both clinically and microscopically. Although some believe keratoacanthomas represent well-differentiated squamous cell carcinomas, significant differences between the two entities have been demonstrated [3]. A number of well-documented variants, many with generally distributed eruptive keratoacanthomas, have been described. One variant, Ferguson–Smith syndrome, is a familial trait.

Aetiology. The role of actinic damage is strongly supported by the fact that the majority of lesions occur on sun-exposed skin

(90%), with up to 10% occurring periorally or on the vermilion border of the lips. HPV has also been suggested as an aetiological agent [4], and increased numbers of keratoacanthomas have been reported in immunocompromised patients.

Clinical features. Keratoacanthomas often manifest at the vermilion border, as indurated, dome-shaped nodules displaying a characteristic central, keratin-filled, crusted and frequently darkened crater. Cutaneous lesions are asymptomatic but oral and lip lesions are frequently painful [5–7]. Intraoral keratoacanthomas are rare [8,9]. They usually appear as an ulcer with a rolled margin, clinically indistinguishable from squamous cell carcinoma, usually on the anterior or maxillary gingiva. It is unclear whether intraoral keratoacanthomas regress spontaneously, as all have been excised for diagnosis. Keratoacanthomas grow rapidly, attaining a size typically greater than 1 cm, may be locally invasive and result in significant tissue damage but, if left untreated, many undergo spontaneous involution after 1–2 months.

Diagnosis. Keratoacanthomas require differentiation from squamous cell carcinoma. When lesions develop intraorally or on the lips, they should immediately be subjected to biopsy for confirmation, since squamous cell carcinomas at these sites frequently metastasize.

Treatment. Management is often by surgical excision. Intralesional therapy with methotrexate or 5-fluorouracil can also be employed with excellent results [10,11]. Other suggested medical therapies include intralesional interferon alpha-2a and systemic isotretinoin [12,13].

Other oral malignant primary neoplasms

The following comprise up to 10% of all oral malignant tumours.

1 Salivary gland tumours
2 Malignant melanoma
3 Lymphomas: non-Hodgkin's lymphomas are increasingly seen in the fauces in HIV disease and immunocompromised persons
4 Sarcomas
5 Kaposi's sarcoma: oral Kaposi's sarcoma is typically seen in HIV disease or other immunocompromised persons and especially in the posterior palate as a brown or purple macule that becomes nodular and ulcerates
6 Some odontogenic tumours
7 Maxillary antral carcinoma (or other neoplasms)
8 Langerhans' cell histiocytosis
9 Neoplasms of bone and connective tissue
10 Other neoplasms.

Abrikossoff's tumour

Abrikossoff's tumour is a disease that develops between the second and sixth decades of life, more frequently among women and blacks. The head and neck area is affected in 45–65% of cases and, of these, 70% are located intraorally (tongue, oral mucosa, hard palate) [1,2].

The benign form shows polygonal cells with granular eosinophilic cytoplasm and small nuclei. The malignant form, however, is associated with a high mitotic index and pleomorphic cellular tissue.

The clinical feature of either is a swelling covered by mucosa of normal clinical appearance. Histological examination is required. The treatment is surgery.

Metastatic oral neoplasms

Metastases to the oral tissues are rare, accounting for only 1% of all oral tumours and most appear in bone, especially the mandibular premolar or molar area or condyle. Metastases may occasionally appear as an alveolar or gingival swelling or ulcer, or as described below. Most oral metastases originate from carcinomas of breast, lung, kidney, thyroid, stomach, liver, colon or prostate [1–12]. Tumour deposits arise from lymphatic or haematogenous spread.

Clinical features. Metastases usually present as a lesion arising in the jaw, sometimes only revealed coincidentally by imaging, at other times causing symptoms. In up to one-third of patients the jaw lesions are the first manifestation of the tumour.

Non-Hodgkin's lymphomas are frequently gingival or faucial in location.

Many metastases are asymptomatic but others manifest with:

- pain
- paraesthesia or hypoaesthesia
- swelling
- tooth mobility
- non-healing extraction sockets
- pathological fracture
- radiolucency or radio-opacity.

Diagnosis. Diagnosis is from history and clinical features supplemented by radiography and histopathology.

Treatment. Radiotherapy, surgery or chemotherapy.

Ulcers in association with systemic disease

Aphthae (see p. 69.44) or aphthous-like ulcers are occasionally associated with systemic disease. However, a wide range of systemic diseases, especially haematological, gastrointestinal and dermatological disorders, may cause other oral lesions which, because of the moisture, trauma and infection in the mouth, tend to break down to leave ulcers or erosions. Oral ulceration is also frequently caused by infections and can be caused by iatrogenic problems such as drugs or irradiation (see Table 69.13).

Haematological diseases

Deficiency states

Low iron, folate or vitamin B_{12} levels may predispose to aphthae. A few of these patients also have anaemia, sometimes with other oral features such as glossitis or angular stomatitis, but many have a deficiency state with no established anaemia [1–3]. Occasionally, patients with deficiency of B vitamins may develop other types of oral ulcer, and sometimes epithelial dysplasia [4].

Leukopenias and agranulocytosis

White cell dyscrasias and HIV infection are also often complicated by oral ulceration (Fig. 69.30). Oral ulceration may be a major symptom in patients with leukopenias, and may be the first manifestation of drug-induced agranulocytosis. Painful, deep, irregular ulcers, often with only a minimal inflammatory halo, involve the mouth and/or pharynx and tend to extend and penetrate slowly. In cyclic neutropenia, ulcers appear episodically at 21-day intervals in association with the neutropenic episodes. Severe periodontitis is often also a feature of leukocyte and other immune defects and the patients may suffer from recurrent infections elsewhere [1–5]. Methotrexate can cause oral ulceration in the absence of leukopenia.

Fig. 69.31 Herpes simplex lingual recurrence, and candidosis in leukaemia: similar lesions may be seen in HIV infection.

Leukaemias

Oral ulceration may be a prominent feature, especially in the acute leukaemias. Other oral manifestations of leukaemia include mucosal pallor, gingival haemorrhage, gingival swelling, petechiae and ecchymoses [1–7]. Oral infections with *Candida albicans* and Gram-negative bacteria including *Pseudomonas* species, *Escherichia coli*, *Proteus*, *Klebsiella* and *Serratia* species are common, especially in acute leukaemias, and may act as a portal for septicaemia [8]. Herpes simplex or zoster–varicella virus ulcers are also common (Fig. 69.31). Chemotherapy complicates the situation because it too can produce oral ulceration [1,7,9], as can bone marrow transplantation.

Other occasional findings include paraesthesia (particularly of the lower lip), facial palsy, extrusion of teeth or bone, painful swellings over the mandible and parotid swelling (Mikulicz's syndrome) [10,11].

Granulocytic sarcoma

Synonym
- Chloroma

Granulocytic sarcomas are rare in the oral cavity. Most present with swelling or symptoms related to skeletal involvement [1–4]. The maxilla is particularly involved [1,5–7].

Myelodysplastic syndromes

Oral manifestations in myelodysplastic syndrome include particularly ulceration but also paraesthesiae, petechiae, burning mouth, gingival swelling, xerostomia and herpes labialis [1–4].

Lymphomas

Some 2–10% of lymphomas present first in the oral cavity. Of these oral lymphomas, 80% are composed of follicular centre cells or post-follicular cells [1–6]. Lymphomas usually occur on the pharynx or palate, but occasionally on the tongue, gingivae or lips; they may appear as oral swellings, which sometimes ulcerate and may cause pain or sensory disturbance. Oral herpes zoster and herpes simplex infections are common in patients with lymphomas.

There is an increased incidence of oral lymphomas in HIV disease [7,8] including oral plasmablastic lymphomas [9–11].

Lethal midline granuloma. Lethal midline granuloma is the term sometimes used to include a spectrum of conditions including Wegener's granulomatosis, polymorphic reticulosis (lymphomatoid granulomatosis) and idiopathic midline destructive disease.

Wegener's granulomatosis. Although not a lymphoma, Wegener's granulomatosis is discussed here. Oral manifestations are common and may be the first sign of Wegener's granulomatosis [12–24]. A painless, progressive swelling of the gingiva in a previously healthy mouth, particularly associated with swollen inflamed papillae, should arouse suspicion of Wegener's granulomatosis. The gingival enlargement may have a fairly characteristic 'strawberry-like' appearance. Wegener's granulomatosis may also present with oral ulceration, failure of an extraction socket to heal or occasionally swelling of the lip or salivary gland.

Polymorphic reticulosis (synonym lymphomatoid granulomatosis). The most common oral presentation of polymorphic reticulosis is palatal ulceration but ulceration may occur elsewhere [20].

Idiopathic midline destructive disease [25–28]. Downward spread from nasal disease can lead to palatal necrosis and ulceration in idiopathic midline destructive disease. Occasionally the disease presents with delayed healing of an extraction socket.

Pseudolymphoma

Rare tumour-like lymphoproliferative infiltrates that lack the malignant potential of lymphomas may be seen intraorally, notably in the palate [1–3].

Histiocytoses

The histiocytoses typically produce lytic bone lesions but gingival swelling, periodontal destruction with loosening of teeth,

non-healing extraction sockets and mouth ulceration may be seen. ^{111}In-pentetreotide imaging may be useful in diagnosis of Langerhans' cell histiocytosis [1–9].

Multicentric reticulohistiocytosis

Oral lesions are seen in up to 50% of patients with multicentric reticulohistiocytosis [1,2]. Lesions are collections of histiocytes that form nodular or granular lesions, particularly in the labial or buccal mucosa. The temporomandibular joint may also be involved as part of the polyarthropathy.

Hypereosinophilic syndrome

Oral erosions affecting buccal, gingival or labial mucosae may be a feature of the hypereosinophilic syndrome [1–6] and may herald cardiac involvement [2]. Etoposide, interferon-α and hydroxyurea (hydroxycarbamide) may be effective therapy [4,5].

Hypoplasminogenaemia

Gingival swelling and ulceration are features of hypoplasminogenaemia.

Gastrointestinal diseases

Aphthae in gastrointestinal diseases are discussed on p. 69.44. Other types of mouth ulcer are also sometimes found in ulcerative colitis and Crohn's disease.

Pyostomatitis vegetans

The oral lesions termed pyostomatitis vegetans are deep fissures, pustules and papillary projections. Less than 50 cases have been recorded and most patients have had inflammatory bowel disease, that is ulcerative colitis or Crohn's disease [1–14]. The course of these lesions tends to follow that of the associated bowel disease [1–5,13].

Although the oral lesions may respond at least partially to topical therapy (e.g. corticosteroids), systemic treatment is often needed [1–5,13].

Orofacial granulomatosis (OFG)

Aetiology. Crohn's disease can affect the mouth but some patients appear to develop similar oral lesions because of an adverse reaction to various food additives, such as cinnamaldehyde or benzoates, butylated hydroxyanisole or dodecyl gallate (in margarine), or to menthol (in peppermint oil) or cobalt, although these reactions are by no means always relevant [1–16]. For example, the lesions in only one of nine patients in one study

Fig. 69.32 Orofacial granulomatosis (OFG)

had any relationship to food intake [15]. Nevertheless, cinnamon and/or benzoate-free diets may produce improvement [16]. The genetic background [17], any role of allergy [18] and diverse possible other aetiological factors such as *Mycobacterium paratuberculosis* [19] is unclear.

The term 'orofacial granulomatosis' is preferred in some centres since it is unclear where in the spectrum of Crohn's disease/sarcoidosis/allergy/infection these lesions (and related conditions such as Melkersson–Rosenthal syndrome and granulomatous cheilitis) lie [8,20–23].

Pathology. Non-caseating granulomas and lymphoedema may be seen but the granulomas tend to be sparse and deep, close to the muscle.

Clinical features. Ulcers classically involve the buccal sulcus where they appear as linear ulcers, often with granulomatous masses flanking them.

Mucosal lesions also include thickening and folding of the mucosa to produce a 'cobblestone' type of appearance and mucosal tags. Purple granulomatous enlargements may appear on the gingiva. The lips or face may swell (Fig. 69.32) and there may be splitting of the lips and angular stomatitis [24–26].

Diagnosis. The oral history is not specific, and investigation of the gastrointestinal tract is mandatory. Investigations such as chest radiography, serum angiotensin-converting enzyme and a gallium scan may be required to exclude sarcoidosis. Patch tests may be indicated to exclude reactions to various foodstuffs or additives.

Treatment. Elimination diets may be warranted in patients with OFG if allergy is suspected [11,16]. Topical or intralesional corticosteroids may effectively control the oral lesions [6]. Intralesional corticosteroid injections may also reduce the swelling. The injection of up to 10 mL triamcinolone (10 mg/L) into the lips after local analgesia may be effective [15,27–30]. The injections may have to be repeated every 4–6 months once a response plateau has been reached.

Clofazimine appears to be effective during the early stages and works by clearing granulomas. In a dose of 100 mg twice daily for 10 days, then twice weekly for 4 months, clofazimine appears to help the majority of patients [31–33].

Systemic corticosteroids are rarely indicated and in any event not all patients respond [29,31]. Metronidazole [3] or sulfasalazine [31] may be of value in some cases. Thalidomide has also been reported as beneficial [34].

Crohn's disease

Crohn's disease lesions are indistinguishable from OFG.

Dermatological diseases

Several dermatoses can be associated with oral ulcers or erosions; lichen planus (LP) is the most common, pemphigus the most serious and pemphgoid is intermediate.

Lichen planus (see Chapter 41)

Oral LP may affect up to 1–2% of the population and is probably about eight times more common than cutaneous LP. The oral mucosa may be involved alone or in association with lesions on skin or other mucosa, and oral lesions may precede, accompany or follow lesions elsewhere [1–7]. The association of oral LP with gingival involvement, together with vulvovaginal lesions, has been termed the *vulvovaginal–gingival syndrome*.

Aetiology. Most oral LP is idiopathic but significantly greater anxiety and depression are observed among patients with oral LP compared with controls [8,9].

Some lichenoid lesions may be related to dental materials: the prevalence of positive reactions to potential allergens in the North American Contact Dermatitis Group (NACDG) is higher in oral LP for chromate, gold and thimerosal [10]. Other lichenoid reactions may be caused by GVHD, drug use (e.g. non-steroidal anti-inflammatory agents), diabetes [11] or liver disease. Chronic liver disease, especially chronic active hepatitis and hepatitis C virus (HCV) infection, may be associated with erosive LP in persons of southern European, Japanese or some other extractions [12–14] and there may be anticardiolipin antibodies [15]. In persons of northern European extraction, oral LP is only rarely associated with liver disease or with hepatitis C, hepatitis G or transfusion-transmitted virus [16–18].

Pathology. The pathology is similar to that of cutaneous LP, although sawtooth rete ridges are rarely seen in oral biopsies, and other epithelial changes may be less distinct.

Clinical features. The common oral lesions of LP are bilateral, white lesions in the buccal and/or lingual mucosa. They may be reticular, papular or plaque-like (Figs 69.33–69.37). They are often symptomless but may cause soreness [1–6].

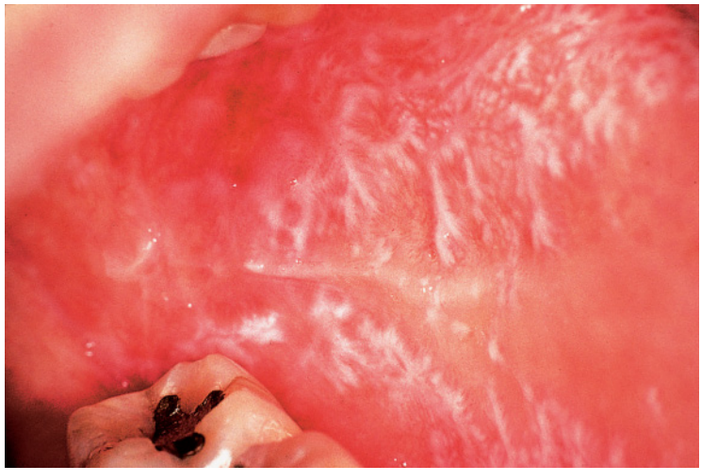

Fig. 69.33 Lichen planus: reticulopapular lesions in the common oral site, the buccal mucosa.

Fig. 69.34 Lichen planus: plaque-like lesions resemble leukoplakia.

Erosive LP, which frequently affects the dorsum and lateral borders of the tongue or the buccal mucosae on both sides, is uncommon. The erosions are often large, slightly depressed or raised with a yellow slough, and have an irregular outline (Fig. 69.34), but they are not always as painful as might be imagined. The surrounding mucosa is often erythematous and glazed in appearance, with loss of filiform papillae of the tongue, and there are often pathognomonic whitish striae. LP may also produce a desquamative gingivitis (see p. 69.106). Candidosis may complicate oral LP.

Reticular LP is the most frequent clinical presentation in both HCV-positive and HCV-negative patients. HCV-positive patients particularly have lip, tongue and gingival lesions [19].

Prognosis. There appears to be a predisposition for some oral LP, particularly the non-reticular forms, to develop carcinoma—possibly a risk of up to 5% over 10 years [1–6,20].

Fig. 69.35 Lichen planus on the tongue.

Fig. 69.36 Erosive lichen planus.

Fig. 69.37 Lichen planus on the gingivae

Diagnosis. Biopsy with immunofluorescence is often indicated to exclude keratosis, chronic ulcerative stomatitis with stratified epithelium-specific antinuclear antibodies, lichen sclerosus, lupus erythematosus, malignancy and other disorders.

Treatment. Treatment is not always necessary, unless there are symptoms. Unfortunately, although the natural history of cutaneous LP is one of remission in most cases, oral LP rarely remits, and thus treatment is indicated for symptomatic oral LP [1–6,21].

- Predisposing factors should be corrected. It may be wise to consider removal of dental amalgams if the lesions are closely related to these, or are unilateral [22], but there are no tests (e.g. patch tests) that will reliably indicate which patients will benefit from this.
- If drugs are implicated, the physician should be consulted as to possible changes in therapy. If there is diabetes or HCV infection, this should be treated by a physician.
- Improvement in oral hygiene may result in some subjective benefit. Thus good oral hygiene should be maintained. Chlorhexidine or triclosan mouthwashes may help.
- Antifungals may help, especially where there is candidal superinfection. Symptoms can be controlled with topical medication: topical corticosteroids, such as betamethasone sodium phosphate mouthwash and fluticasone propionate spray, cream or mouthwash or pastes containing fluocinonide, fluocinolone, triamcinolone, betamethasone valerate or clobetasol [23–26]. Topical tacrolimus has been used [27,28] but does not have FDA approval.
- Cessation of tobacco use is advisable and alcohol use should be minimized.

Mild LP. Topical corticosteroids are the mainstay of therapy (e.g. triamcinolone acetate, betamethasone or fluocinolone). Erosive and gingival lesions are often recalcitrant. Next, high-potency corticosteroids such as clobetasol, fluocinonide or fluticasone may be employed initially and then changed to a lower potency drug.

Moderate LP. If there is severe or extensive oral involvement, topical ciclosporin or tacrolimus may be of significant benefit, often being used with a high-potency or super-potent topical steroid such as clobetasol, fluticasone or mometasone. Topical creams or pastes can be applied in a suitable customized tray or veneer to be worn at night. This regimen is useful in the management of LP-related desquamative gingivitis recalcitrant to other therapies.

Severe LP. In severe LP in multiple sites, patients may require systemic corticosteroids, azathioprine, cyclophosphamide, hydroxychloroquine, acitretin, thalidomide or ciclosporin.

Dapsone is occasionally effective.

Other therapies for LP include retinoids, low-molecular-weight heparin [29,30] and many others, but either their efficacy has not been well proven or they have unacceptable adverse effects.

Patients with non-reticular LP should be monitored to exclude development of carcinoma; tobacco and alcohol use should be minimized.

Overlap syndromes

Lichen planus pemphigoides. Oral lesions in LP pemphigoides may be similar to those of LP or pemphigoid [1–5], clinically and histologically with direct immunofluorescence demonstrating linear deposits of immunoglobulin G and complement component C3 along the basement membrane [3].

Lichen planus/lichen sclerosus overlap syndrome. This may involve the oral and/or genital mucosa [6–8].

Lichen sclerosus (see Chapter 51)

Oral lichen sclerosus et atrophicus is uncommon but since it presents with whitish plaques, papules or a reticular pattern, or erosions, all features of LP [1–13], it may be underdiagnosed. Histologically, however, lichen sclerosus is characterized by epithelial atrophy with hyperkeratosis, oedema in the papillary corium but the lymphocytic infiltrate is not as closely associated to the epithelium as seen in LP.

It has been suggested that mucosal lichen sclerosus is more common than formerly thought and may even cause dysplasia [5].

Chronic ulcerative stomatitis with epithelial antinuclear antibodies

Chronic erosive or ulcerative stomatitis (CUSP) often presents as desquamative gingivitis with or without lesions on buccal or lingual mucosa and sometimes resembles LP, and may be associated with lichenoid histology, but is associated with antinuclear antibodies directed against stratified squamous epithelia [1–4]. These autoantibodies are directed against a 70-kDa epithelial nuclear protein homologous to the p53 tumour suppressor and the p73 putative tumour suppressor, and shown to be a splicing variant of the *KET* gene [5,6].

The lesions may respond to hydroxychloroquine [1–4].

Pemphigus (see Chapter 40)

Oral lesions are the rule in pemphigus vulgaris (PV) [1–9], but rare in the superficial forms of pemphigus [1].

Fig. 69.38 Pemphigus vulgaris: irregular persistent oral erosions.

Pemphigus vulgaris. The main antigen in PV is desmoglein (Dsg) 3. However, 50% of patients with PV also have autoantibodies to Dsg1 (the main antigen in pemphigus foliaceus) and the proportion of Dsg1 and Dsg3 antibodies appears to be related to clinical severity. Those cases of PV which are predominantly oral have only Dsg3 antibodies. Dsg1 autoantibodies are found in over 50% of cases of PV, and the frequency may differ with race since they are found in a significantly greater proportion of patients of Indian origin than white northern Europeans [1,10–14]; such variations may be HLA-related [5,15,16].

Typically, an individual patient develops a single variant of pemphigus, although cases have been described of transition to another variant, presumably through epitope spread, and the clinical manifestations of a single variant can change over time, possibly related to changes in the proportions of Dsg1 and Dsg3 autoantibodies.

The oral mucosa is almost invariably involved in PV and oral lesions are commonly the presenting feature (Fig. 69.38). Bullae appear on any part of the oral mucosa including the palate, but break so rapidly that they are rarely seen [1,5,9,17–23]. Usually, the patient presents with large, painful, irregular and persistent red lesions which, by the time they become secondarily infected, can be difficult to differentiate clinically from those of other erosive conditions, such as pemphigoid and other immune blistering disorders, although intact bullae are more commonly seen in these, whereas the Nikolsky sign is more often positive in pemphigus. Oral lesions of PV are typically seen in adults, rarely in childhood.

The prevalence of oral involvement varies: one multicentre study involving patients from several countries showed that Bulgarian patients with PV had oral mucous membrane lesions less frequently (66%) than Italian (83%) or Israeli (92%) patients [9]. Rarely in PV there can be an acquired macroglossia [22] or desquamative gingivitis [23–25].

Diagnosis should be confirmed by biopsy and immune studies. A biopsy of perilesional mucosa should be taken for haematoxylin and eosin stained sections and immunostaining (Table 69.19) and serum collected for autoantibody titres, which can help diagnosis

Table 69.19 Immunostaining in oral mucosal vesiculobullous disorders.

Disease	DIF	Oral mucosal deposits mainly:	Pattern of IF	IIF	Autoantibodies against:
Pemphigus	+	IgG C3	Epithelial intercellular	+	Epithelial intercellular cement

* Rarely vesiculobullous.

† Non-specific deposits.

and monitoring of disease activity. Differential binding of anti-Dsg antibodies suggests that both human skin and monkey oesophagus should be used in the diagnosis of PV, since patients with predominantly oral disease may only have Dsg3 antibodies, which are not always detectable using human skin [5,26]. ELISA may help [27].

Oral cytology is of little practical diagnostic value. Treatment is largely based on systemic immunosuppression using corticosteroids, with azathioprine, dapsone, methotrexate, cyclophosphamide, gold or ciclosporin as adjuvants or alternatives; this has significantly reduced the mortality [1,8,23–30]. Adverse effects of these drugs are common, though deflazacort may have fewer adverse effects compared with prednisolone [31].

Mycophenolate mofetil offers safer immunosuppression with possibly less nephrotoxicity and hepatotoxicity [32–35].

Mucosal lesions are recalcitrant, often only healing after skin lesions have resolved when immunosuppressive therapy is given, and they may persist even though skin lesions are controlled. Topical corticosteroids may then help, or possibly prostaglandin E_2 [36,37]. Tacrolimus topically may well prove to have a place in the control of oral lesions [38–40].

Anti-CD20 monoclonal antibody, rituximab, may be an effective alternative therapy for the treatment of refractory pemphigus vulgaris [41–45].

Paraneoplastic pemphigus. Apart from PV, the other important pemphigus variant affecting the mouth is paraneoplastic pemphigus, usually associated with lymphoproliferative disease or thymoma [1–6], although one case associated with OSCC has been reported [7]. Oral lesions may be the sole manifestation [8] and have been seen in all reported cases of paraneoplastic pemphigus [4,9–13]. Oral lesions may be seen in isolation [1].

Painful extensive stomatitis, painful paronychia and lichenoid papules may be seen, and histology may show lichenoid changes, acantholytic blister formation and apoptotic keratinocytes. Direct immunofluorescence is positive for IgG both in the epidermal intercellular spaces and along the basement membrane zone. Indirect immunofluorescence is similarly positive in a PV pattern.

There is often only a partial response to intravenous corticosteroids. Recent therapeutic advances include the use of anti-CD20 monoclonal antibody (rituximab) [14–16] and mycophenolate [17–19].

Other pemphigus variants. Oral lesions may be seen in less common pemphigus variants, especially in most cases with IgA pemphigus (intraepithelial IgA pustulosis or intraepidermal neutrophilic IgA dermatosis) [1–3], and in some cases of pemphigus associated with inflammatory bowel disease [4–10].

Subepithelial immune bullous diseases

A spectrum of immune-mediated subepithelial bullous diseases can present with oral blisters and/or erosions and/or desquamative gingivitis, and with immune deposits at the epithelial basement membrane zone. Several distinct groups, and probably several overlap syndromes, are now recognized to exist.

Mucous membrane pemphigoid (see Chapter 40). Mucous membrane pemphigoid is a mucocutaneous, immune-mediated, subepithelial blistering disease characterized by autoantibodies to different molecules in the basement membrane zone [1–10]. The mouth may be involved as part of a wider disease, though in many patients only oral lesions are seen [9]. Sera of oral pemphigoid patients selectively and specifically bind to human α6 integrin, a 120-kDa protein that appears to be a target antigen in this particular variant [3,8,11].

Fig. 69.39 Pemphigoid: vesicles and desquamative gingivitis.

Mucous membrane pemphigoid involves the oral mucosa in more than one-third of cases, commonly causing gingival lesions [1–3,10]. The usual lesion, desquamative gingivitis, is characterized by erythematous, glazed, sore gingivae (Fig. 69.39). Bullae are less common, and are seen particularly on the soft palate. They rupture to form erosions [1–3,7,11–13].

The bullae in mucous membrane pemphigoid are subepithelial and tend to persist for longer than those of pemphigus. Oral lesions may scar but this is uncommon. The bullae are typically filled with serous fluid and should be distinguished from superficial mucoceles (see p. 69.84), epidermolysis bullosa acquisita, dermatitis herpetiformis and linear IgA disease. Occasionally blisters are blood-filled, and then must be differentiated from angina bullosa haemorrhagica (see p. 69.84).

A biopsy is required for diagnosis [3,7,13]. Serum autoantibodies to epithelial basement membrane may be detected in a few patients (see Table 69.19) but many have immune deposits at the epithelial and mucous gland basement membrane zone. A very small minority of patients have an associated internal malignancy which should be excluded [8].

Topical corticosteroids usually help if the lesions are restricted to the oral mucosa; azathioprine may be an alternative [1,14–17]. Systemic corticosteroids may occasionally be required but tetracyclines with or without nicotinamide may help [17–21]. Dapsone may be useful, especially in the treatment of desquamative gingivitis [2,3,21–23]. Recalcitrant MMP may respond to tacrolimus, mycophenolate mofetil [7,24–26], intravenous immunoglobulins or infliximab [27–29].

Vegetating cicatricial pemphigoid (synonym pemphigoid vegetans). A subset of bullous pemphigoid, although clinically indistinguishable from pemphigus vegetans and sometimes producing oral blisters and erosions, vegetating cicatricial pemphigoid shows linear deposits of IgG and C3 at the epithelial basement membrane zone on oral biopsy but no circulating basement membrane antibodies [1,2].

Palate and gingiva have been especially involved in the rare cases described [2–4].

Dermatitis herpetiformis and adult linear IgA disease. Oral lesions may occur in dermatitis herpetiformis and in most patients with linear IgA disease. Macules, papules, petechiae, vesicles, bullae and erosions or desquamative gingivitis are the usual manifestations [1–13]. These disorders must be differentiated, especially from pemphigoid, angina bullosa haemorrhagica, superficial mucoceles and LP.

Salivary IgA antigliadin antibodies may be found but this is not useful diagnostically. Dapsone and sulfapyridine are the most effective therapeutic agents along with a gluten-free diet in dermatitis herpetiformis. Mycophenolate mofetil may be of benefit in the treatment of linear IgA disease [13].

Erythema multiforme (see Chapter 76).

Aetiology. The aetiology of erythema multiforme (EM) is unclear in most patients, but appears to be an immunological hypersensitivity reaction with the appearance of cytotoxic effector cells (CD8 T lymphocytes) in the epithelium, inducing apoptosis of scattered keratinocytes and leading to satellite cell necrosis.

EM has been classified into a number of variants—EM minor affecting one mucosa, EM major affecting two or more mucous membranes and Stevens–Johnson syndrome (SJS) where there is extensive skin involvement and associated mortality rate 5–15%. Toxic epidermal necrolysis (TEN) may be a severe manifestation of EM [1,2].

Predisposing factors. There may be a genetic predisposition, with associations of recurrent EM with HLA-B15(B62), HLA-B35, HLA-A33, HLA-DR53 and HLA-DQB1*0301. HLA-DQ3 has been proven to be especially related to recurrent EM and may be a helpful marker for distinguishing this herpes-associated EM from other diseases with EM-like lesions. Patients with extensive mucosal involvement may have the rare HLA allele DQB1*0402 [3].

The reaction is triggered by the following.

- *Infective agents*, particularly herpes simplex virus (herpes-associated EM), which is implicated in 70% of recurrent EM. Bacteria (*Mycoplasma pneumoniae*, and many others), other viruses, fungi or parasites are less commonly implicated [1,2,4–10].
- *Drugs* such as sulphonamides (e.g. co-trimoxazole), cephalosporins, aminopenicillins, quinolones, barbiturates, oxicam non-steroidal anti-inflammatory drugs, anticonvulsants, protease inhibitors, allopurinol and many others may trigger severe EM or toxic epidermal necrolysis in particular [1,2,11,12].
- *Food additives or chemicals* such as benzoates, nitrobenzene, perfumes, terpenes.
- *Immune conditions* such as BCG or hepatitis B immunization, sarcoidosis, GVHD, inflammatory bowel disease, polyarteritis nodosa or systemic lupus erythematosus (SLE).

Clinical features. Most patients with EM (70%), of either minor or major forms, have oral lesions. The oral mucosa may be involved alone or in association with skin lesions. Mucosal lesions begin as erythematous areas that blister and break down to irregular, extensive, painful erosions with extensive surrounding erythema. The labial mucosa is often involved, and a serosanguinous exudate leads to crusting of the swollen lips [1,2,13–18].

Mucosal erosions plus typical or raised atypical targets and epidermal detachment involving less than 10% of the body surface and usually located on the extremities and/or the face characterize herpes simplex-induced EM major.

Mucosal erosions plus widespread distribution of flat atypical targets or purpuric macules and epithelial detachment involving less than 10% of body surface on the trunk, face and extremities are characteristic of drug-induced Stevens–Johnson syndrome [19].

Diagnosis. A diagnosis of EM can be difficult to readily establish, and there may be a need to differentiate from viral stomatitides, pemphigus, toxic epidermal necrolysis and the subepithelial immune blistering disorders (pemphigoid and others). There are no specific diagnostic tests.

The diagnosis is mainly clinical; the Nikolsky sign is negative. It may be helpful to undertake serology for *Mycoplasma* pneumoniae or herpes simplex virus, or other microorganisms. Biopsy of perilesional tissue with immunostaining and histological examination may help, although pathology can be variable and immunostaining is not specific.

Treatment. Spontaneous healing can be slow, up to 2–3 weeks in EM minor and up to 6 weeks in EM major. Treatment is thus

indicated but controversial. No specific treatment is available but supportive care is important; a liquid diet and intravenous fluid therapy may be necessary. Electrolytes and nutritional support should be started as soon as possible. Oral hygiene should be improved with 0.2% aqueous chlorhexidine mouthbaths.

The use of corticosteroids is controversial [1,2,20–22].

- EM minor may respond to topical corticosteroids, although systemic corticosteroids may still be required.
- EM major should be treated with systemic corticosteroids (prednisolone 0.5–1 mg/kg/day tapered over 7–10 days) and/or azathioprine or other immunomodulatory drugs [1,2]. Levamisole [22,23] and thalidomide have occasionally been used to some effect [24,25]. Plasmapheresis possibly has a place in the management of severe disease.

Antimicrobials may be indicated [1,2,26,27].

- Aciclovir in EM related to herpes simplex virus (HSV). Give a 5-day course at the first sign of lesions, or give 400 mg three times daily for 6 months for prophylaxis in EM related to HSV [10]. Continuous therapy with valaciclovir 500 mg twice a day has also been reported to be effective [1,2,10,27].
- Tetracycline is indicated in EM related to *Mycoplasma pneumoniae*.

Toxic epidermal necrolysis (See Chapter 76)

Synonym
- Lyell's disease

Toxic epidermal necrolysis is a rare clinicopathological entity, with a high mortality, characterized by extensive detachment of full-thickness epithelium. Toxic epidermal necrolysis and Stevens–Johnson syndrome appear to be severity variants of the same disease, which differs from EM. The distinction from EM is unclear, however, but most cases of toxic epidermal necrolysis are drug-induced and the lesions are extremely widespread [1–6].

Recently, an increased number of cases in patients with HIV/acquired immune deficiency syndrome (AIDS) has been recorded [7–9].

Clinical features. Toxic epidermal necrolysis presents with cough, sore throat, burning eyes, malaise and low fever, followed after about 1–2 days by skin and mucous membrane lesions. Oral lesions can be seen in over 95% of patients with toxic epidermal necrolysis. The entire skin surface and oral mucosa may be involved, with up to 100% sloughing off. Gingival lesions are common and clinically are inflamed, with blister formation leading to painful, widespread erosions. The blisters and erosions may precede the skin lesions by a day or so and may persist [3–7,10–12].

Diagnosis. Sheet-like loss of the epithelium and a positive Nikolsky sign are characteristic. Biopsy of perilesional tissue with immunostaining and histological examination are essential to the

diagnosis. Histopathological examination is characteristic, showing necrosis of the whole epithelium detached from the lamina propria.

Treatment. Patients must be admitted to an intensive care unit as soon as possible for management [4,5,13–19]. There is no specific therapy for oral lesions but 2% lidocaine (lignocaine) and 0.2% aqueous chlorhexidine mouthbaths may provide symptomatic relief. Intravenous immunoglobulin (IVIG) has been proposed as a treatment for toxic epidermal necrolysis with varying effects reported [4,17].

Lupus erythematosus (see Chapter 51)

Almost 50% of patients with systemic lupus erythematosus (SLE) suffer from oral lesions, which begin as red patches that break down to irregular slit-like ulcers which often heal with scarring [1–4]. Lesions particularly affect the palate. Sjögren's syndrome may occur in SLE. Oral petechiae and herpetic infections are also common. Rarely, dental surgery has been followed by facial swelling [5].

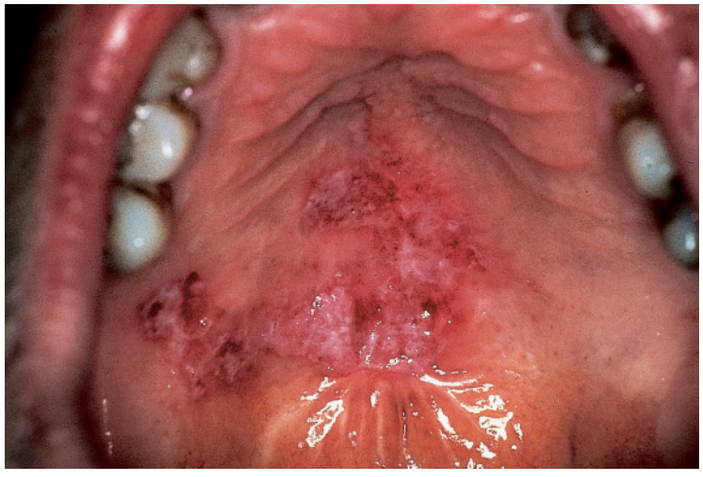

Fig. 69.40 Chronic oral lesions in discoid lupus erythematosus.

Similar erosions, with a white border, occur in discoid lupus erythematosus (DLE) (Fig. 69.40). DLE may predispose to oral carcinoma [6,7]. Oral ulceration has also been described in drug-induced lupus.

Systemic corticosteroids, often with an immunosuppressant, may be required in severe cases of SLE; topical steroids for DLE.

Other collagen–vascular diseases

Dermatomyositis and mixed connective tissue disease may be associated with non-specific mucosal erosions [1].

Oral involvement in Reiter's syndrome may include red patches or superficial painless mucosal erosions which may resemble erythema migrans (geographical tongue) both clinically and histologically.

Infective diseases

Oral ulceration is common worldwide in some viral infections, typically in the herpesvirus or enterovirus infections seen in childhood. It can also be seen in several bacterial diseases, notably acute necrotizing gingivitis (but also in tuberculosis and syphilis), but is rare in fungal infections in the resource-rich countries, although the deep mycoses may be responsible for infection in resource-poor countries, in travellers or in the immunocompromised.

Herpesviruses

Oral infection is common with the herpesviruses, which thereafter remain latent, are often excreted in saliva (especially in immunocompromised persons), and are sometimes implicated in clinical recurrences and malignant complications [1].

Herpes simplex stomatitis

Aetiology. HSV infection is a very common oral infection. In general, HSV-1 causes primary herpetic stomatitis (and the secondary infection of recurrent herpes labialis). There are no precise distinctions nowadays, presumably with more frequent orogenital and oroanal sexual practices, and oral infection with HSV-2 is also frequently seen [2–7].

With improving socio-economic circumstances and standards of hygiene, a larger number of children are not exposed to HSV and enter adult life without immunity. Cases of primary herpetic stomatitis are therefore now seen occasionally in adults, and the manifestations can be severe. HSV is usually transmitted in saliva and can be shed in asymptomatic individuals [8–11].

Clinical features. The incubation period is 3–7 days. Many infections with HSV occur in childhood and are subclinical and, where there is disease, it varies greatly in severity. In many it is trivial and misdiagnosed or passed off as 'teething' [4,7,12–14].

Primary herpetic stomatitis typically presents with malaise, anorexia, irritability, fever, enlarged and tender anterior cervical lymph nodes, and a diffuse, purple, boggy gingivitis (hence the alternative term *herpetic gingivostomatitis*), especially anteriorly, with multiple vesicles followed by round or ovoid ulcers 1–3 mm in diameter scattered across the oral mucosa and gingiva (Fig. 69.41) in an acute illness lasting only up to about 14 days [2,3,7,14]. In immunocompromised persons, diagnosis can be difficult since herpes may manifest with chronic ulcers [14–18].

Prognosis. Herpetic stomatitis resolves spontaneously in 7–14 days but HSV remains latent in the trigeminal ganglion. The most obvious sequel is that about one-third of patients are thereafter predisposed to recurrences [19]. HSV is shed intermittently into the saliva [8–11]. HSV is implicated in many instances of EM (see p. 69.70) and may cause chronic ulcers in the immunocompromised (see below) or occasionally ulcers following trauma to the mouth.

Diagnosis. The main differential diagnoses of herpetic stomatitis in otherwise healthy persons are chickenpox and other viral causes of mouth ulcers, and acute leukaemia. In immunocopromised persons, the differential is wider. A full blood picture, white-cell count and differential, and viral studies may therefore be required [2,3,7,14,20,21]. The latter include the following:

- Culture: this takes days to give a result.
- Electron microscopy: this is not always available.
- Polymerase chain reaction (PCR) detection of HSV DNA: this is sensitive but expensive.
- Immunodetection: detection of HSV antigens is of some value. Conventional enzyme-linked immunosorbent assays (ELISA) for serum antibodies have poor sensitivity and specificity; newer assays based on HSV glycoproteins are comparable with western blot assays. A rising titre of serum antibodies is confirmatory but only gives the diagnosis retrospectively.
- Smears for viral-damaged cells: now rarely used.

Fig. 69.41 Scattered ulcers and a furred tongue in primary herpetic stomatitis.

Treatment. Specific antiviral agents are most useful in the very early stages of disease (though most patients present later) and for immunocompromised patients who may otherwise suffer severe infection. Aciclovir or other antiviral medications may be indicated systemically [22–26].

For most, however, management is supportive with antipyretic analgesics (e.g. acetaminophen/paracetamol), sponging with tepid water and a high fluid intake. Analgesics (as elixirs or syrups for children) and, in adults, lidocaine mouthbaths help ease discomfort and 0.2% aqueous chlorhexidine mouthbaths aid resolution.

An antihistamine such as promethazine may help sedate an irritable child.

Recurrent labial HSV infection. Primary oral infection by HSV may produce perioral lesions (Fig. 69.42). However, recurrent herpes labialis involving the lip is the more common cause of blisters at the mucocutaneous junction (Fig. 69.43) [2–5,7,19]. The lesions arise at the mucocutaneous junction as itching papules which progress to vesicles, pustules and then scab. They are unsightly and occasionally become infected with *Staphylococcus* or *Streptococcus*, resulting in impetigo (Fig. 69.44). In immunocompromised persons, extensive and persistent lesions may result. In atopic persons, the lesions may spread to produce eczema herpe-

Fig. 69.42 Primary herpetic stomatitis with extraoral lesions.

Fig. 69.43 Herpes labialis.

Fig. 69.44 Impetigo.

Fig. 69.45 Eczema herpeticum.

ticum (Fig. 69.45). Aciclovir has been the standard treatment used as a 5% cream, although penciclovir 1% is reportedly more effective [27,28].

Recurrent intraoral HSV infection. Chronic oral herpetic ulcers, often with a raised white border and sometimes with a dendritic appearance, may occasionally affect apparently healthy individuals, especially at sites of trauma, for example following palatal infiltration of a local anaesthetic. Chronic indolent lesions, usually ulcerative or nodular, may be seen in patients with neutropenia or chronic leukaemia; in patients with more severe immunosuppression, such as acute leukaemia or HIV infection, more aggressive chronic ulcers may be seen [14–18,29,30]. Aciclovir or other antivirals may be indicated systemically [15,31].

Chickenpox (see Chapter 33)

Synonym
- Varicella

Chickenpox affects children predominantly and may present with mouth ulcers that resemble those of herpetic stomatitis, but there is no gingivitis [1]. There may be a contact history. Many primary infections with varicella-zoster virus are subclinical or produce so few lesions as to pass almost unnoticed. Varicella-zoster virus remains latent in sensory ganglia and may be reactivated to produce shingles.

Herpes zoster

Synonym
- Shingles

If shingles affects the maxillary or mandibular divisions of the trigeminal nerve, mouth ulcers are usually seen [2–4].

Clinical features. The pain of trigeminal zoster may simulate toothache. Severe pain often precedes, accompanies and follows the rash, and post-herpetic neuralgia may persist for months or years.

The rash is restricted to a dermatome and is unilateral, but sometimes a few chickenpox-type lesions can be found elsewhere. Oral ulcers appear in the distribution of the involved nerve division [3]. There is ulceration of one side of the tongue, floor of mouth and lower labial and buccal mucosa if the mandibular division of the trigeminal nerve is involved. One side of the palate, the upper gingiva and buccal sulcus are involved in maxillary zoster. Rarely, mandibular or maxillary zoster may disturb the formation of developing teeth [5–7] or cause jaw necrosis [6,7].

If the geniculate ganglion of the facial nerve is affected, there may be unilateral facial palsy, with vesicles in the ipsilateral ear and ulcers in the soft palate ipsilaterally (Ramsay–Hunt syndrome) [8–14].

Occasionally there is misdiagnosis of toothache, leading to extraction, the true diagnosis becoming apparent only when the rash appears. Zoster resolves spontaneously but post-herpetic neuralgia can be distressing.

Treatment. An underlying immune defect, such as AIDS or malignancy, should be excluded in patients with zoster, although most zoster is related simply to lesser problems in advanced age.

Treatment is mainly supportive but antivirals such as aciclovir can be useful. Analgesics are indicated in zoster, although the pain may prove refractory to even potent analgesics [15,16], when antidepressants such as amitriptyline and fluphenazine may have a place [17,18]. Treatment advances include lidocaine patches, opioid analgesics and gabapentin. Early recognition and treatment of high-risk herpes zoster patients with antiviral and analgesic therapies is mandatory [18].

Epstein–Barr virus infections (see Chapter 33)

Epstein–Barr virus (EBV) is responsible for infectious mononucleosis and is found in pharyngeal epithelium and appears in the saliva of patients and for several months after clinical recovery. Infection appears to be spread by close oral contact, especially kissing. It is typically a disease of the student population.

Infection is often subclinical. Infectious mononucleosis is also protean in its clinical manifestations, which include particularly lymphadenopathy, sore throat, fever, malaise and rashes. In the anginose type (sore-throat type), the throat is sore with soft-palate petechiae and a whitish exudate on oedematous tonsils [1–3]. There may be non-specific oral ulceration or pericoronitis [1]. The glandular type of infectious mononucleosis is characterized by generalized lymph node enlargement and splenomegaly; the febrile type is characterized by fever.

Similar syndromes may be caused by cytomegalovirus (CMV), human herpesvirus (HHV)-6, toxoplasmosis and HIV. Characteristic of infectious mononucleosis are large numbers of atypical mononuclear cells in the blood and a wide variety of serological changes, particularly heterophil antibodies, which are detectable by the Paul–Bunnell or Monospot tests, usually during the first or second week of illness [4]. Several other antibodies against EBV appear during the course of infectious mononucleosis, but the most frequent is the antibody to viral capsid antigen, the titre of which reaches a peak at about 4 weeks.

No specific treatment is available for infectious mononucleosis, but supportive care is important, not only because of the potential for airways obstruction but also because of the associated lassitude. Systemic corticosteroids are required if there is pharyngeal oedema severe enough to hazard the airway.

EBV is also commonly found in the mouths of immunocompromised patients [5–12] and is implicated in oral hairy leukoplakia, oral ulceration, advanced periodontal disease [13,14] and some oral lymphomas [15–18] although any relationship with other malignancies such as OSCC is controversial [19,20].

Cytomegalovirus infection

CMV may cause a glandular fever type of syndrome, and rarely causes oral ulceration. Indolent CMV-induced oral ulcers may be seen in immunosuppressed patients and in AIDS [1–7]. CMV has been implicated in the pathogenesis of periodontal disease [8].

Herpesviruses 6, 7 and 8

Oral lesions have yet to be demonstrated in infections with HHV-6 or HHV-7. However, HHV-8 is implicated in oral Kaposi's sarcoma [1–8]. Treatment with highly active antiretroviral therapy (HAART) may reduce HHV-8 infection [8,9], however, Kaposi's sarcoma-associated immune reconstitution following commencement of HAART has been reported [10–12].

Enteroviruses

Herpangina

Aetiology. Herpangina is caused by Coxsackieviruses mainly. The incubation period is 3–7 days and young children are predominantly affected.

Clinical features. Many infections are subclinical but features of the clinical syndrome include malaise, anorexia, irritability, low fever, slightly enlarged and tender anterior cervical lymph nodes and mouth ulcers, predominantly on the soft palate [1,2].

Diagnosis. There may be a contact history. It is possible to culture Coxsackieviruses in suckling mice if absolutely necessary. The main differential diagnosis is primary herpetic stomatitis, but in herpangina there is less fever, no acute gingivitis and ulceration is mainly restricted to the soft palate.

Treatment. The condition is self-limiting and treatment is supportive only.

Hand, foot and mouth disease (see Chapter 33)

Aetiology. Hand, foot and mouth disease is caused particularly by Coxsackie A viruses but sometimes by Coxsackie B viruses or enteroviruses [1,2].

Clinical features. The incubation period is 3–10 days and, although young children are predominantly infected, there are occasional outbreaks in adults. Many infections are subclinical but features of the clinical syndrome include the following.

- General features: malaise, anorexia, irritability and fever may be present but usually only in severe cases.
- Anterior cervical lymph nodes may occasionally be slightly enlarged and tender.
- Mouth ulcers are round or ovoid, usually sparse and may affect any site [3–8].
- Rash: painful, sometimes deep-seated vesicles may appear, usually on the hand and/or feet, particularly on digits or at the base of the phalanges.

Hand, foot and mouth disease is self-limiting and only rarely complicated by systemic illness such as encephalitis [9,10]. The condition tends to be more severe when it occurs in adults.

Diagnosis and management are as for herpangina.

Fig. 69.47 Untreated acute necrotizing gingivitis can lead to extensive gingival ulceration and irreparable damage.

Bacterial infections

Acute necrotizing (ulcerative) gingivitis and noma

Aetiology. There is no firm evidence of communicability of acute necrotizing gingivitis, although it may occur in epidemic form, especially in institutions or in the military (trench mouth). Viral respiratory infections, overwork and fatigue, smoking or immune defects may precede the onset of disease, suggesting depression of immunity as a predisposing cause. A similar lesion may be a feature of HIV infection and related diseases [1–5].

A mixed, mostly anaerobic, flora (the fusospirochaetal complex), consisting mainly of *Fusobacterium nucleatum* (*F. fusiformis* or *Bacillus fusiformis*) and *Borrelia vincentii*, is associated with this infection [6,7,13].

Clinical features. The mouth ulceration is usually restricted to the gingiva, specifically the interdental papillae, which appear blunted (Figs 69.46 & 69.47). The history is characteristic, with an acute onset of gingival soreness, bleeding and halitosis. Acute necrotizing gingivitis occurs especially in the anterior part of the mouth where the affected gingiva are extremely tender to touch and readily bleed on minimal pressure. Occasionally the ulceration extends elsewhere on the gingiva, or onto the adjacent mucosa. There is often enlargement of the cervical lymph nodes and there may be pyrexia and malaise.

Fig. 69.46 Acute necrotizing gingivitis showing typical ulceration of interdental gingival papillae. This was in HIV infection.

Prognosis. Failure to adequately treat acute necrotizing gingivitis may predispose to recurrence and, in malnourished or immunocompromised individuals, may lead to noma (cancrum oris) [3–13]. Similar lesions of gangrenous stomatitis are increasingly reported in HIV disease.

Diagnosis. Diagnosis is mainly from gingival lesions in primary herpetic stomatitis, leukaemias and HIV disease. A bacteriological smear may be helpful.

Treatment. Gentle cleansing with a hydrogen peroxide mouthwash and a soft toothbrush is remarkably effective. Oral metronidazole 200 mg should be given three times daily for 3–7 days to limit the tissue destruction. Penicillin is equally effective. The patient should also be referred for dental advice [1].

Syphilis

Oral ulcers may be seen at any stage but particularly in secondary syphilis [1–9]. In primary syphilis, a primary chancre (hard or Hunterian chancre) may involve the lips, tongue or palate. A small, firm, pink macule changes to a papule which ulcerates to form a painless, round ulcer with a raised margin and indurated base [4,10]. Chancres heal spontaneously in 3–8 weeks but are highly infectious and are associated with enlarged, painless regional lymph nodes.

Secondary syphilis follows after 6–8 weeks, with oral lesions in about one-third of patients [1,3,7]. These are highly infectious and are usually fairly painless ulcers (mucous patches and snail-track ulcers).

The most characteristic oral lesion of tertiary syphilis is a localized granuloma (gumma) that varies in size from a pinhead to several centimetres, affecting particularly the palate, or the tongue. Gummas break down to form deep, chronic, punched-out ulcers that are not infectious (Fig. 69.48). However, the most common oral manifestation of tertiary syphilis is leukoplakia, which particularly affects the dorsum of the tongue and has a high potential for malignant change [9].

Congenital syphilis may, when the permanent teeth erupt, present with dental anomalies such as Hutchinson's teeth (Fig. 69.49). Oral ulcers are rare.

Exudate from a suspected oral lesion of syphilis should be examined for treponemes by dark-ground microscopy; however, since the diagnosis can be confused by oral commensal treponemes, lesions should first be thoroughly swabbed with a sterile gauze or cotton-wool and then gently scraped with a sterile spatula, the scraping being examined immediately by dark-ground microscopy. Serology is indicated. Biopsy is not usually indicated, but lesions are characterized by a dense, plasma cell infiltrate [7].

Gonorrhoea

Oral mucosal erythema, sometimes with oedema and ulceration, is occasionally seen in oropharyngeal gonorrhoea. Oropharyngeal asymptomatic carriage of gonococci is more common, found in around 4% of those attending clinics for sexually transmitted diseases [1–5].

Tuberculosis

Oral lesions can develop in pulmonary tuberculosis but are not common. A chronic ulcer, usually of the dorsum of the tongue, is the most common oral presentation but jaw lesions or cervical lymph node involvement may be seen [1–12]. Atypical mycobacteria are not uncommonly involved.

Mycobacterial oral ulcers, particularly caused by *Mycobacterium avium–intracellulare*, have been reported as a complication of AIDS and occasionally in apparently healthy individuals [13–17]. Cervicofacial infection is occasionally caused by *M. chelonei*, usually in the form of lymph node abscesses, or occasionally as intraoral swellings [18–21].

Epithelioid (bacillary) angiomatosis (see Chapter 30)

Oral lesions clinically and, to some extent, histologically reminiscent of Kaposi's sarcoma have been seen in HIV disease [1–4], sometimes as the first manifestation of HIV infection [3].

Fungal infections

Oral fungal infections, apart from candidosis, rarely causes mouth ulcers in resource-rich countries, where they are usually seen only in immunocompromised or debilitated patients, including those with AIDS. However, they may be seen occasionally in otherwise healthy persons from the tropics (Table 69.20).

Aspergillosis. Rhinocerebral aspergillosis may ulcerate through to the mouth. This is a rare event, except in the severely immunocompromised [1–3]. Mandibular aspergillosis has also been reported [4].

Table 69.20 Rare orofacial fungal infections.

Infection	Oral manifestations
Aspergillosis	Aspergilloma Rhinocerebral type causes palatal necrosis Disseminated in immunocompromised patients
Blastomycosis	
North American	Oral ulcers or suppurating granulomas
South American (paracoccidioidomycosis)	Oral ulcers and lymphadenopathy
Coccidioidomycosis	Rarely oral ulcers
Cryptococcosis	Oral ulcers
Histoplasmosis	Lumps or ulcers in mouth
Phycomycosis (mucormycosis, zygomycosis)	Antral involvement with palatal ulceration in immunocompromised patients, especially diabetics
Sporotrichosis	Oral lesions rare

Occasionally, solitary aspergillosis arises as a consequence of endodontic treatment where root canal filling material enters the antrum [5–7] but this does not cause oral ulceration. Surgical debridement is usually indicated.

Geotrichosis. Geotrichosis is a rare, livid, sharply defined enanthema of the oral mucosa with ulcerations seen in immunocompromised persons, such as those with leukaemia or HIV infection. *Geotrichum capitatum* is responsible and there may also be pneumonic lung infiltrates [1]. Treatment includes amphotericin, 5-fluorocytosine and itraconazole.

Histoplasmosis. Oral lesions of histoplasmosis are uncommon. They are typically seen in chronic disseminated histoplasmosis, usually as a non-specific lump or ulcer on the tongue, palate, buccal mucosa or gingiva [1–8], sometimes in AIDS [9–15].

Mucormycosis. Rhinocerebral mucormycosis typically commences in the nasal cavity or paranasal sinuses and invades the palate to produce a black necrotic ulcer, although it might occasionally commence in the palate [1–4]. Most cases are seen in diabetics or in immunocompromised patients such as those with AIDS [4,5]. Biopsy and radiography are required for diagnosis. Treatment is surgical debridement together with amphotericin intravenously and/or azoles.

Protozoal infestations

Leishmaniasis is rare in northern Europe and the USA; it is not uncommon, however, in hotter climes and may cause ulcers in the mouth or more commonly on the lips [1–5], and is seen increasingly in HIV disease [6–10] or in other immunocompromised persons.

Immune defects

Human immunodeficiency virus infection [1–7] (see Chapter 35)

Oral ulceration in patients infected with HIV may be due to any of the causes of mouth ulceration (see p. 69.42), and aphthous-like ulcers are also seen. However, it is important to exclude infections, mainly herpesviruses. There are also occasional examples of mouth ulcers due to mycobacteria, *Rochalimaea*, syphilis, *Histoplasma*, *Cryptococcus*, leishmaniasis and others. Malignant disease (mainly Kaposi's sarcoma or non-Hodgkin's lymphoma) may result in lumps that can ulcerate.

Aphthous-like ulcers in HIV may respond to local treatment or, failing that, thalidomide at a dose of 200 mg a day has been shown in randomized double-blind, placebo-controlled trials to be effective in the treatment of HIV-related recurrent aphthous ulceration [8–10].

Other mouth ulcers should be treated as appropriate.

Vasculitides

Periarteritis (polyarteritis) nodosa

Transient submucosal oral nodules may occur singly or in crops along the path of vessels and especially in the tongue. Other mucosal lesions include erythema, papules, haemorrhages, ulceration or necrosis [1–4].

Giant cell arteritis

Synonym

- Horton's disease

Patients may suffer ischaemic pain during mastication, intermittent claudication of the tongue [1,2] or, rarely, facial palsy [3] or lumps [2,4,5]. Ulceration and necrosis of the tongue [6–18] or occasionally the lip [19] have also been observed [2,3].

Iatrogenic conditions

Mucositis

Aetiology. Mucositis, sometimes called *mucosal barrier injury*, is the term given to the widespread oral erythema, ulceration and soreness that is a common complication of a number of therapeutic procedures involving chemotherapy, radiotherapy or chemoradiotherapy, used largely in the treatment of cancer but also in the conditioning prior to bone marrow transplantation (i.e. haematopoietic stem cell transplantation). Mucositis appears 3–15 days after cancer treatment, earlier after chemotherapy than after radiotherapy.

Mucositis invariably follows external beam radiotherapy involving the orofacial tissues, and is also common in upper mantle head and neck radiation, and particularly in total body irradiation.

Some 40–90% of patients on chemotherapy develop mucositis. Patients on fluorouracil and cisplatin in particular develop mucositis, while etoposide and melphalan cause particularly severe mucositis. Oral mucositis is particularly severe after haemopoietic stem cell transplantation, because of radiation damage and myeloablation, and the course follows the polymorphonuclear leukocyte count.

The impaired mucosal barrier in mucositis predisposes to life-threatening septic complications; the prevalence of an oral focus in febrile neutropenia has been reported in up to 30% of cases [1–5].

Clinical features. Mucositis typically presents with pain (which can be so intense as to interfere with eating and significantly affect the quality of life), erythema, ulceration and sometimes bleeding.

Diagnosis is clinical and it is helpful to score the degree of mucositis in order to monitor progression and therapy.

Treatment. The basic strategies in management of mucositis aim at pain relief, efforts to hasten healing and prevention of infectious complications. However, prophylaxis is the goal.

Pain relief is usually achieved with opioids given by patient-controlled analgesia and benzydamine can aid relief. Oral cooling with ice chips ameliorates chemotherapy-induced mucositis [6–11].

Other treatments currently used but for which hard data for reliable efficacy are unavailable include the following.

- Medications to reduce salivation and thus exposure of the mucosa to chemotherapeutic drugs that are secreted in saliva
- Anti-inflammatory medications
- Cytokines such as interleukin (IL)-1, IL-11, TGF-beta3 and keratinocyte growth factor
- Granulocyte–macrophage colony-stimulating factor (GM-CSF) and granulocyte colony-stimulating factor (G-CSF) [12]
- Thalidomide: an angiogenesis-inhibiting drug
- Amifostine: a cytoprotector
- Melatonin: the pineal hormone
- Protegrin antimicrobial peptides, which possess activity against Gram-positive and Gram-negative bacteria and yeasts
- Low-energy lasers
- Other agents such as sucralfate, tretinoin, glutamine, vitamin E and misoprostol [1–4,9–12].

Monitoring microbial colonization and the institution of antiviral prophylaxis and antifungal prophylaxis, to avoid colonization and superinfection, is particularly important in patients with low neutrophil counts.

Invasive fungal infections of the oral cavity can be associated with systemic fungal infection and are indications for the use of liposomal amphotericin.

Bone marrow transplantation (haematopoietic stem cell transplantation)

Oral complications are common and can be a major cause of morbidity following bone marrow transplantation. Mucositis, infections, bleeding, xerostomia and loss of taste result from the effects of the underlying disease, chemotherapy or radiotherapy,

and GVHD. The ventrum of the tongue, buccal and labial mucosa and gingiva may be affected by ulceration or mucositis [1–8].

Graft-versus-host disease

The oral manifestations of acute GVHD consist of painful mucosal desquamation and ulceration, and/or cheilitis, and the presence of lichenoid plaques or striae. Small white lesions affect the buccal and lingual mucosa early on, but clear by day 14. Erythema and ulceration are most pronounced at 7–11 days, and may be associated with obvious infection. Candidosis is common, as is herpes simplex stomatitis (occasionally zoster) and oral purpura may occur, especially in adults [1–6]. Bartonella-related pseudomembranous angiomatous papillomatosis of the oral cavity has been reported secondary to bone marrow transplantation and oral chronic GVHD (CGVHD) [7].

The oral lesions in CGVHD are coincident with skin lesions, and include generalized mucosal erythema, lichenoid lesions, mainly in the buccal mucosa, and xerostomia. There may be depressed salivary IgA levels in minor gland saliva [8]. Xerostomia is most significant in the first 14 days after transplant and is a consequence of drug treatment, irradiation and/or GVHD. There may be an increased risk of developing OSCC in CGVHD patients [9,10].

Lip biopsy is useful in the diagnosis of CGVHD and should include both mucosa and underlying minor salivary glands [11]. Histology shows changes similar to those seen in Sjögren's syndrome.

Drugs

A wide range of drugs can occasionally induce mouth ulcers, by a variety of effects [1]. Oral use of caustics or agents such as cocaine can cause erosions or ulcers [2,3]. Oral ulcers are regularly produced by cytotoxic agents [4,5] (see Mucositis above). Aphthous-like ulcers may follow the use of the potassium channel blocking cardioactive agent nicorandil [6,7].

Drugs may also cause mucocutaneous lesions; ulcers of a lichenoid type may follow exposure to non-steroidal anti-inflammatory drugs and other agents, erythema multiforme may follow the use of a range of drugs (see p. 69.69) and drug-induced ulcers may also resemble toxic epidermal necrolysis or may have features reminiscent of other dermatological disorders.

The ulcers usually resolve in 10–14 days if the offending drug can be identified and withdrawn.

Acrodynia

Synonym
- Pink disease

Oral and perioral ulceration, hypersalivation, gingivitis and early tooth loss are features of acrodynia caused by mercury poisoning, now rarely seen [1].

Fig. 69.50 Angina bullosa haemorrhagica: a large blood blister in a typical site on the soft palate. The adjacent whitish lesions are from scarring after a previous biopsy.

Disorders of uncertain pathogenesis

Angina bullosa haemorrhagica

Synonym

- Localized oral purpura

This is the term given to a benign, fairly common condition of unknown aetiology that usually presents in the elderly with oral blood blisters. These subepithelial blisters are seen mainly in the soft palate and after a few hours rupture to leave ulcers (Fig. 69.50). The patients appear well otherwise, with no detectable immunological or bleeding disorder [1–5]. Occasional cases are related to the use of corticosteroid inhalers. Only symptomatic care is available.

Mucocutaneous lymph node syndrome

Synonym

- Kawasaki disease (see Chapter 30)

Mucocutaneous lymph node syndrome is a disorder of uncertain, but possibly infectious, aetiology. Male children are predominantly affected. At least one oral feature should be present for the diagnosis to be made. The oral and pharyngeal mucosa become generally red and sore and the lips dry and fissured. There may be oral ulceration and a 'strawberry tongue' appearance [1–4]. Cervical lymphadenopathy, conjunctivitis and fever also occur, followed later by the characteristic desquamation of the skin of the hands and feet. Early therapy with immunoglobulin is essential to avoid cardiac complications.

Superficial mucoceles

Superficial extravasation mucoceles of the intraoral minor salivary glands in the palate, buccal mucosa or labial mucosa are not uncommon, especially associated with oral LP in middle-aged or elderly women and rarely with chronic graft versus host disease [1].

This is a benign self-limiting condition that may cause confusion with vesiculobullous disorders [2–8].

Necrotizing sialometaplasia

Necrotizing sialometaplasia is an uncommon, benign, self-limiting condition seen predominantly in the posterior hard palate of young adult males, most of whom smoke tobacco [1–5]. An association with bulimia has been reported [6,7].

A painless deep ulcer persists for several weeks before spontaneously healing. Biopsy reveals necrosis and pseudoepitheliomatous changes probably resulting from squamous metaplasia following infarction of minor salivary glands. This benign lesion must be differentiated from malignancy.

Oral soreness

Most oral pain is of local aetiology, usually resulting from odontogenic infections. Neurological, vascular and referred causes are less common, but must also be excluded. Psychogenic pain is all too frequent and this is discussed below.

Chronic oral soreness may be particularly caused by ulceration, or by mucosal lesions in geographical tongue, LP or deficiency states. Geographical tongue and burning mouth syndrome are the common causes of a sore tongue. LP is the most common cause of chronic soreness in the buccal mucosae. Desquamative gingivitis is the common cause of persistently sore gingivae.

Geographical tongue

See p. 69.100.

Fig. 69.51 Atrophic glossitis in vitamin B_{12} deficiency.

Lichen planus

See Chapter 41.

Deficiency glossitis

Aetiology. Deficiency glossitis may be related particularly to deficiency of iron, folate or vitamin B_{12}, and may then be associated with angular stomatitis and/or mouth ulcers. Deficiencies of other B-group vitamins occasionally cause glossitis, usually in chronic alcoholics or in those with malabsorption [1–6].

Pathology. Epithelial atrophy, rarely with some dysplasia, is seen.

Clinical features. In anaemic glossitis the tongue is red, sore and smooth (Fig. 69.51). Occasionally pernicious anaemia can also produce red areas or patterns of red lines. In many other patients the tongue can become sore but appear clinically completely normal and such patients' complaints are liable to be mislabelled as psychogenic.

Diagnosis. A full blood picture and assays of iron, folate and vitamin B_{12} are essential in management, as sore tongue can be the initial symptom of a deficiency and can precede any fall in the haemoglobin level.

Treatment. The cause of the deficiency should be sought before replacement treatment is given.

Burning mouth syndrome

Synonyms
- Oral dysaesthesia
- Glossopyrosis
- Glossodynia

Burning mouth syndrome (BMS) most frequently affects middle-aged and elderly females [1–4].

Aetiology. Several organic lesions, for example haematinic deficiency states, erythema migrans, ulcers, mucositis, LP and candidosis, can cause oral soreness or burning sensation. BMS with a tongue of normal clinical appearance may be seen in deficiency states, and with psychogenic causes, drugs (e.g. angiotensin-converting enzyme inhibitors such as captopril, enalapril, lisinopril; protease inhibitors; cytotoxic agents; clonazepam) and diabetes mellitus. A monosymptomatic hypochondriasis or an underlying anxiety about cancer or a sexually transmitted infection with perhaps excessive tongue activity appear to be the basis for the complaint of BMS in many patients (Table 69.21) [1–15]. More recently, evidence for a neuropathic basis to BMS has emerged [12,14,16].

Uncommon causes that may need to be considered include hypothyroidism, lupus erythematosus, hypersensitivity (to sodium metabisulphite, nuts, dental materials and other substances) and galvanic reactions to metals in the mouth [17–21]. However, BMS is often a medically unexplained symptom.

Table 69.21 Causes of burning mouth.

Local
Candidosis
Other infections
Geographical tongue
Lichen planus
Oral submucous fibrosis
Dentures
Systemic
Psychogenic
Cancerophobia
Depression
Anxiety states
Hypochondriasis
Deficiency states
Pernicious anaemia and other vitamin B deficiencies
Folate deficiency
Iron deficiency
Diabetes
Drugs (captopril)

Clinical features. Although the tongue is most frequently involved, the patient may also occasionally complain of burning lips, gums or palate. The burning sensation is usually bilateral and often relieved by eating and drinking [1,11,12]. In contrast, oral discomfort associated with inflammatory lesions is typically aggravated by eating.

Diagnosis. Oral examination very occasionally reveals an organic cause. Xerostomia should be excluded as this may predispose to candidosis. Laboratory screening for anaemia, diabetes, a deficiency state or candidosis should be undertaken.

Treatment. Few patients with BMS have spontaneous remission in the short term, and thus an attempt at treatment is indicated. Reassurance, treatment of any defined underlying organic abnormality and, occasionally, psychological treatment, antidepressants or psychiatric care are indicated, but active dental or oral surgical treatment, or attempts at 'hormone replacement', in the absence of any specific indication, should be avoided. However, treatment is rarely completely successful, although the condition only infrequently becomes severe. Fortunately, about 50% remit spontaneously over 6 or 7 years.

- Patients should avoid anything that aggravates symptoms, such as sparkling wines, citrus drinks and spices.
- Reassurance and attention to any factors such as dentures or haematinic deficiencies may be indicated. There are few treatments of proven benefit [12–22]. Cognitive–behavioural therapy or a specialist referral may be indicated [14,23].
- Some patients respond to medication:
  (a) effects of vitamin B are controversial [24–26]
  (b) topical benzydamine 0.01% rinse or spray [27,28]
  (c) although antidepressants must be given for at least 2–3 weeks to achieve any antidepressive effect, most patients with medically unexplained symptoms show benefit within 1 week [29–32]
  (d) topical capsaicin cream 0.025% (Zacin) or 0.075% (Axsain) [11]
  (e) clonazepam tablet sucked locally [14]
  (f) α-lipoic acid systemically [14,33].

White lesions

Acquired white lesions in the mouth are usually caused by materia alba (Fig. 69.52), cheek biting or chemical burns, but keratoses, infections, dermatoses (usually LP), neoplastic disorders and other conditions must be excluded (see Table 69.9).

Congenital lesions are discussed on p. 69.22.

Cheek biting

Synonym
- Morsicatio buccarum

A horizontal white line may be seen in the buccal mucosa of healthy people (linea alba) but can be exaggerated in tense individuals. Cheek biting causes a whitish, shredded appearance usually of the buccal or lower labial mucosa at the occlusal line (adjacent to where the teeth meet) (Fig. 69.53) [1–8]. The habit is most common in tense or anxious individuals who may also show bruxism, mandibular (myofascial) pain dysfunction or other oral features of psychogenic disorders. The lesion is benign but may simulate white-sponge naevus (see p. 69.23).

Burns

Chemical burns (due, for example, to holding mouthwashes in the mouth or drugs against the buccal mucosa) or burns caused by heat, cold or irradiation can cause white sloughing lesions of the mucosa [1–11]. Such lesions typically heal spontaneously within 1–3 weeks.

Lichen planus

See Chapter 41.

Candidosis

Up to 50% of the healthy population harbour *Candida albicans* as an oral commensal. Carriage is more common in cigarette smokers. *Candida* resides particularly on the posterior dorsum of the tongue [1–8].

Infection is likely to result from xerostomia, local disturbances in salivary flora such as occurs during broad-spectrum antimicrobial treatment, or depressed immune responses [1–4,9–13]. Of the several clinical presentations of oral candidosis, only thrush, candidal leukoplakia and chronic mucocutaneous candidosis present as white lesions; the other types, acute and chronic atrophic candidosis, are red (Table 69.22).

Thrush

Synonym
- Acute pseudomembranous candidosis

Aetiology. Healthy neonates, who have yet to develop immunity to *Candida* species, may develop thrush. In other patients, predisposing factors include antibiotic or corticosteroid use, xerostomia and severe T-cell immune defects associated with immunosuppression (e.g. given to prevent graft rejection in organ transplantation) or immunodeficiencies such as leukaemia or HIV disease. Thrush is a common and early feature of HIV infection and may be a portent of developing AIDS [1–4,10,12,13].

Table 69.22 Intraoral candidosis.

Type of candidosis	Usual age at onset	Predisposing factors*
Acute pseudomembranous candidosis (thrush)†	Any	Local: dry mouth, antimicrobials General: corticosteroids, leukaemia, HIV
Acute atrophic candidosis ('antibiotic mouth'; antibiotic sore mouth)	Any	Broad-spectrum antibiotics or corticosteroids
Erythematous candidosis		Any, HIV especially
Chronic atrophic candidosis (denture-related stomatitis)	Adults	Denture wearing, especially at night
Chronic hyperplastic candidosis (candidal leukoplakia)†	Usually middle-aged or elderly	Tobacco smoking, denture wearing, immune defect
Median rhomboid glossitis	Third or later decades	Tobacco smoking, denture wearing, HIV
Chronic mucocutaneous candidosis†	Usually first decade	Often immune defect; rarely endocrinopathy

HIV, human immunodeficiency virus.
* Immune defects can predispose to any form.
† White lesions.

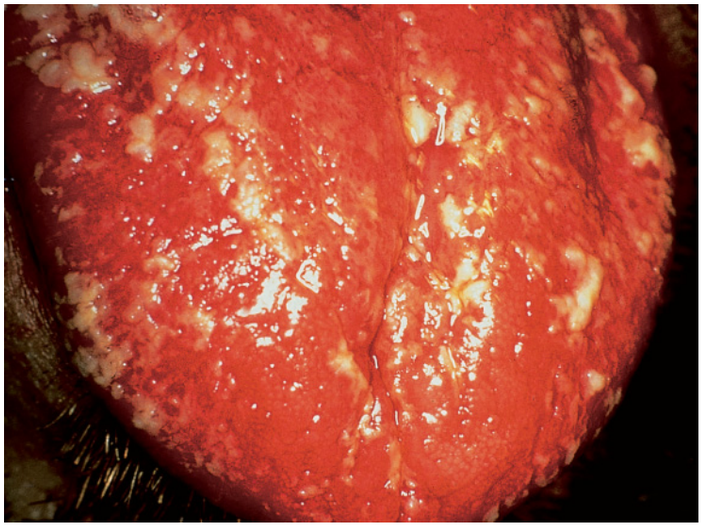

Fig. 69.54 Thrush: scattered white lesions on an erythematous background.

Clinical features. The soft creamy patches of thrush, which resemble milk curds, can be wiped off the oral mucosa with gauze, leaving an area of erythema (Fig. 69.54).

Chronic candidosis

Aetiology. The aetiology of chronic oral candidosis is unclear and in only a few patients can either a local cause or underlying immune defect be identified [1–3]. HIV/AIDS and chronic mucocutaneous candidosis syndromes are rare causes (see Chapter 36).

Clinical features. Long-standing oral candidosis may produce tough, adherent white patches (chronic hyperplastic candidosis or candidal leukoplakias) which can have a malignant potential, and may be indistinguishable from other leukoplakias except by biopsy. Candidal leukoplakias may, however, be speckled.

Diagnosis of candisosis. The diagnosis of oral thrush is usually clinical but it tends to be overdiagnosed by physicians. In contrast, erythematous candidosis is probably underdiagnosed. In immunosuppressed patients, a Gram-stained smear should be taken to distinguish thrush from the plaques produced by opportunistic bacteria. Hyphae seem to indicate that the *Candida* organisms are acting as pathogens and not simple commensals.

Suspected candidal leukoplakia should be biopsied, both to distinguish it from other non-candidal plaques and also because of possible dysplasia. Although candidal hyphae and a neutrophil infiltrate may be seen on haematoxylin and eosin staining, PAS will demonstrate the purple staining of the hyphae.

Treatment of candidosis.

Acute candidosis. Except in healthy neonates, possible predisposing causes should be looked for and treated. Topical polyenes such as nystatin or amphotericin, or imidazoles such as miconazole are often indicated but, in HIV infection, antiretroviral agents and fluconazole may be required.

Chronic hyperplastic candidosis. The oral lesions of chronic hyperplastic candidosis may respond poorly to the polyenes [6]. These cases, and some cases of chronic mucocutaneous candidosis, may respond only to flucytosine, ketoconazole, fluconazole, itraconazole, voriconazole or caspofungin [1,14–19].

Leukoplakia

The World Health Organization defines leukoplakia as a white patch or plaque on the mucosa that cannot be rubbed off and that is not recognized as a specific disease entity [1–4], which implies a diagnosis of exclusion (e.g. of LP, candidosis). The term is also used irrespective of the presence or absence of epithelial dysplasia, although there is a small malignant potential to some keratoses [1–6].

Leukoplakia is common in adults: around 1% are affected, although some populations show higher prevalences. Most cases are seen in the 50–70 age group [4,9–15].

Leukoplakia can be totally benign or sometimes can be precancerous or a marker for cancer elsewhere in the upper aerodigestive tract.

Oral keratoses

Aetiology. The cause of most keratoses is unknown (idiopathic keratoses or leukoplakia) but some are caused by chronic irritation, particular lifestyle habits or infective agents [16–31].

Tobacco-induced keratoses. Consumption of tobacco products has long been causally connected with oral cancer and is a common cause of keratosis. Tobacco use also predisposes to cancers elsewhere in the upper aerodigestive tract, bladder and other sites. Tobacco use should thus be discouraged; the drug amfebutamone or varenicline may help users break the habit.

Tobacco chewing. Tobacco is chewed in many parts of the world and may induce keratosis. In many communities from resource-poor countries, tobacco is a component of betel quid, along with areca nut and betel leaf, and sometimes slaked lime and spices. Sometimes betel is used without tobacco (pan or paan), though others use paan with tobacco. Oral carcinoma can result.

Reverse smoking (bidi). In some communities, especially in Asia, cigarettes are smoked with the lit end within the mouth. Palatal or other oral carcinoma can result.

Cigarette-induced keratoses. Mild keratosis may be seen especially on the palate, lip (occasionally nicotine-stained) and at the commissures, along with nicotine-stained teeth. Malignant change is uncommon.

Pipe smoking. Diffuse whiteness over the palate is termed 'smoker's keratosis' or 'stomatitis nicotina'. The palatal minor salivary gland orifices appear red against this white background. Malignant change is uncommon.

Cigar smoking. Cigar smokers may develop stomatitis nicotina and nicotine-stained teeth. Malignant change is uncommon.

Snuff dipper's keratosis and other smokeless tobacco lesions. Snuff may produce keratosis—white hyperkeratotic lesions caused by snuff-dipping (holding flavoured tobacco powder in the oral sulcus or vestibule), together with gingival recession at the site of use. Malignant change is rare.

Other aetiological factors

- Proliferative verrucous leukoplakia is often associated with HPV. Malignant change is uncommon.
- Candidal leukoplakias may be associated with an increased risk of malignant change, although it is uncommon.
- Syphilitic leukoplakia is rarely seen now. Malignant change is common.
- Hairy leukoplakia is caused by EBV and seen especially in HIV disease. Malignant change is not recorded.

Fig. 69.55 Homogeneous leukoplakia in the buccal mucosa.

Fig. 69.56 Speckled leukoplakia.

Clinical features. Leukoplakias vary in size: some are small and focal, others more widespread, occasionally involving very large areas of the oral mucosa; in other patients several discrete separate areas of leukoplakia can be seen. Leukoplakia has a wide range of clinical presentations, from homogeneous white plaques that can be faintly white or very thick and opaque, to nodular white lesions or lesions admixed with red lesions [1–4]. The malignant potential depends on the following.

Appearance. Homogeneous leukoplakia, the most common, presents with uniformly white plaques, common in the buccal (cheek) mucosa and usually of low premalignant potential (Fig. 69.55).

Non-homogeneous or heterogeneous leukoplakias are nodular, verrucous and speckled leukoplakias that consist of white patches or nodules in a red, often eroded, area of mucosa (Fig. 69.56). They have a high risk of malignant transformation and are therefore far more serious.

Site. High-risk sites for malignant transformation include the soft palate complex and ventrolateral tongue and floor of the mouth

Fig. 69.57 Sublingual keratosis.

(where sublingual keratosis has a particularly high risk of malignant change; Fig. 69.57). Sublingual keratosis is more common in women than men, has a typical 'ebbing-tide' appearance clinically and has a high malignant potential.

Aetiological factors.

- Proliferative verrucous leukoplakia is a diffuse white and/or papillary lesion seen in elderly patients, often associated with HPV, and shows an inexorable slow progression over one or two decades to verrucous or squamous cell carcinoma.
- Candidal leukoplakias may be associated with an increased risk of malignant change. Chronic candidal infection is common in speckled leukoplakias and *C. albicans* can cause or colonize other keratoses, particularly in smokers, and is especially likely to form speckled leukoplakias at commissures. It may be dysplastic and have higher malignant potential than some other keratoses. Candidal leukoplakias may respond to antifungals and cessation of smoking.
- Syphilitic leukoplakia, especially of the dorsum of tongue, is a feature of tertiary syphilis rarely seen now, although the malignant potential is high.
- Hairy leukoplakia is caused by EBV. It usually has a corrugated surface and mainly affects margins of the tongue almost exclusively. It is seen in the immunocompromised and is a complication of HIV infection. It is seen in all groups at risk of HIV infection. The condition appears to be benign and self-limiting. Leukoplakia in chronic renal failure causes similar symmetrical, soft keratoses, and may be caused by EBV.

Diagnosis. There are no signs or symptoms that reliably predict whether a leukoplakia will undergo malignant change, and thus histology must be used to detect dysplasia. Scalpel or punch biopsy is therefore generally indicated and is mandatory for those leukoplakias that exhibit the following characteristics:

- found in patients with previous or concurrent head and neck cancer
- are non-homogeneous, i.e. have red areas and/or are verrucous and/or are indurated
- in a high-risk site such as floor of mouth or tongue
- focal
- with symptoms
- without obvious aetiological factors.

Many would advise biopsy of all keratoses and leukoplakias.

Pathology. Keratoses show, to a varying degree, increased keratin production, change in epithelial thickness and disordered epithelial maturation. Mild dysplasia is not usually regarded as of serious significance. The presence of severe epithelial dysplasia is thought to indicate a considerable risk of malignant development [32,33]. Pagetoid dyskeratosis is considered a selective keratinocytic response in which a small part of the normal population of keratinocytes is induced to proliferate in response to friction [34]. Pagetoid dyskeratosis has been found in 42.2% of lip biopsies, more frequent in younger patients and in women. Pagetoid cells are more common in suprabasal location and in the labial mucosa. These cells show positivity for high-molecular-weight cytokeratin and negative reaction for low-molecular-weight cytokeratin, epithelial membrane antigen, carcinoembryonic antigen and HPV. The immunohistochemical profile is different from the surrounding keratinocytes, indicating premature keratinization. The morphological features of dyskeratotic pagetoid cells are distinctive and easily recognized as an incidental finding, thus preventing confusion with other important entities including an intraepidermal tumour.

The main differential diagnoses include white-sponge naevus, leukoedema, oral koilocytoses, hairy leukoplakia, pagetoid squamous cell carcinoma *in situ* and extramammary Paget's disease of the oral mucosa.

Prognosis. There is clear evidence of the malignant potential of some oral leukoplakias. Overall, around 2–5% of leukoplakias become malignant in 10 years and 5–20% of leukoplakias are dysplastic. Of leukoplakias with dysplasia, 10–35% proceed to carcinoma. Malignant change to carcinoma is most frequent in women older than 50 years and in large lesions. Interestingly, leukoplakias developing in non-smokers have a higher rather than lower risk of malignant change. However, some leukoplakias (15–30%) regress clinically, not only when supposed aetiological factors have been removed but also sometimes spontaneously.

At present, it is not possible to reliably predict which dysplastic lesions will progress to carcinoma and which will regress, and there is concern over observer and interobserver variation in diagnosis of dysplasia [35–39]. Over the recent past, much effort has gone into identifying tissue markers of malignant potential [40–43], in particular the genetic changes that underlie oral carcinoma, resulting in the identification of biomarkers such as DNA ploidy, p53, and chromosome 3 and 9 changes that might predict neoplastic change in potentially malignant lesions [42–54].

Treatment. Management can be difficult, not least because of the wide extent of some lesions, their frequent admixture with areas of erythroplasia (speckled leukoplakias), and controversy as to the prognosis and long-term benefit and effects of various therapies. Few controlled studies are available and there is no evidence of effective treatment in preventing malignant transformation of

leukoplakia [55,56]. Treatment is, therefore, empirical [55–58] but removal of known risk factors (tobacco, alcohol and trauma) is a mandatory first step following which the patient should be re-examined 3 months later. If the lesion persists, it should be removed [33,43,58–64].

Surgery (scalpel or laser excision) is an obvious option for the management of leukoplakias with a high predisposition to malignant transformation, such as leukoplakias that are:

- speckled
- verrucous
- from high-risk sites (e.g. floor of mouth/ventrum of tongue, or soft palate/fauces)
- in a patient with previous cancer of the upper aerodigestive tract
- dysplastic
- polysomic (aneuploidy or tetraploidy)
- positive for genetic markers such as mutated tumour-suppressor factor p53, or for loss of heterozygosity on chromosomes 3p or 9p—such advances in molecular biology mean that it should soon be possible to ascertain the malignant potential of leukoplakia from genetic and DNA studies.

Chemotherapy and chemoprevention are attractive possibilities [65–68]. Topical 0.5% bleomycin in dimethyl sulfoxide (dimethyl sulphoxide) has been evaluated [55,56,69,73]. Although topical or systemic vitamin A derivatives, methisoprinol and calcipotriol may induce regression of some leukoplakias and may inhibit their development, these agents have not been widely used, because of adverse effects or their uncertain long-term consequences [56,69–75] and randomized controlled trials are few.

Actinic cheilitis

See p. 69.123.

Hairy leukoplakia

Aetiology. Hairy leukoplakia (HL) is seen in severe immune defects, especially HIV/AIDS, and occasionally in the apparently immunocompetent [1–6]. HIV is not found within the genome of epithelial cells in HL and it is more likely that the features are a consequence of an opportunistic infection with EBV. It is now clear that normal human oral mucosa from HIV-negative and HIV-positive individuals may contain latent EBV [7–10]. A decreased frequency of HIV-related oral manifestations including oral hairy leukoplakia has been associated with the introduction of HAART [5].

EBV has been shown to be present in HL, especially in the upper layers of the epithelium. The oral site of predilection for HL appears to relate to the presence of EBV receptors only on the parakeratinized mucosae such as the lateral margin of the tongue. HL regresses on treatment with antivirals but fails to resolve with antifungals, despite the frequent presence of *Candida* species.

Pathology. Histological features of HL include hyperparakeratosis, hyperplasia and ballooning of prickle cells, few or absent Langerhans' cells, and only a sparse inflammatory cell infiltrate in the lamina propria.

Clinical features. HL is a white patch, usually seen on the parakeratinized mucosa of the tongue, frequently bilaterally (Fig. 69.58). The lesions are corrugated or have a shaggy or hairy appearance, are mostly symptomless and, unlike some oral keratoses, have no known premalignant potential [1,4,10,11]. The majority of the affected patients who are HIV positive appear

Fig. 69.58 Hairy leukoplakia. Found mainly in HIV infection, vertical white ridges on the lateral margin of the tongue.

eventually to develop AIDS. HL also occurs in HIV-negative persons [6,12–19].

Diagnosis. Some of the histological features typical of HL, especially the hyperparakeratosis, can be seen in oral white lesions other than HL in HIV-infected persons [20]. Not only are there oral lesions that mimic HL in HIV infection, but lesions similar to HL can be seen in other immunocompromised persons and even in some apparently healthy individuals. However, most cases can be distinguished from the HL of HIV infection by the absence of EBV DNA on histology and, of course, by presence of HIV serum antibody.

Treatment. HL really needs no treatment but in HIV/AIDS antiretroviral agents, aciclovir or ganciclovir may cause resolution.

Psoriasis (see Chapter 20)

The oral mucosa appears to be rarely involved in psoriasis, with less than 100 cases reported, although there are occasionally lip lesions or white oral lesions, especially in the buccal mucosa, or lesions clinically indistinguishable from geographical tongue (sometimes termed 'annulus migrans' or 'erythema circinatum'), particularly in generalized pustular psoriasis [1–15].

Koplik's spots (see Chapter 33)
White specks may be seen in the buccal mucosa in early measles.

Pigmented lesions

Congenital lesions are described on p. 69.26. The tongue is often discoloured due to superficial staining from foods, drinks or habits such as tobacco or betel use. Localized hyperpigmented lesions are usually due to pigmentary incontinence, amalgam tattoos, melanotic macule or naevi, although melanomas, Kaposi's sarcoma and epithelioid angiomatosis must be excluded. Generalized oral mucosal hyperpigmentation is usually racial in origin and only occasionally has a systemic cause, such as Addison's disease.

Furred, brown and black hairy tongue

Aetiology and pathology. Children rarely have a furred tongue in health but it may be coated with off-white debris in febrile and other illnesses.

Adults, however, not infrequently have a coating on the tongue in health, particularly if they are edentulous, are on a soft non-abrasive diet, have poor oral hygiene or are fasting. The coating appears more obvious in xerostomic and in ill patients, especially those who cannot maintain oral hygiene.

The coating in most cases consists of epithelial, food and microbial debris; indeed, the tongue is the main oral reservoir of some microorganisms, such as *Candida albicans* and viridans streptococci. The filiform papillae are excessively long and stained by the accumulation of squames and chromogenic microorganisms.

Habits such as tobacco and betel use, and various medicaments such as chlorhexidine or iron, can cause a black or brown superficial staining of the tongue (and teeth).

Occasionally, a brown hairy tongue may be caused by drugs that induce xerostomia, lansoprazole or antimicrobial therapy, when it may be related to overgrowth of microorganisms such as *Candida* species and may respond to withdrawal of the drug [1–5].

Clinical features. Black hairy tongue affects mainly the posterior part of the dorsum of the tongue, especially centrally (Fig. 69.59) [3–7].

Treatment. Patients with black hairy tongue may find the condition improves if they avoid habits or drugs that stain the tongue, increase their standard of oral hygiene, brush the tongue with a hard toothbrush, use sodium bicarbonate mouthwashes, chew gum or suck a peach stone. Topical tretinoin may be effective [8].

Pigmentary incontinence [1,2]

Melanin pigment ingested by macrophages in the upper lamina propria (pigmentary incontinence) may give rise to hyperpigmentation in LP, especially in dark-skinned people [1].

Tattoos

Amalgam tattoos are common causes of blue–black pigmentation, usually seen in the mandibular gingiva or at least close to the teeth (Fig. 69.60), or in the scar of an apicectomy where there has been a retrograde root-filling with amalgam used as root-end filling material [1–6]. The amalgam associates with elastin fibres [7]. Radio-opacities may or may not be seen on radiography. Similar lesions can result if, for some reason, pencil lead or other similar foreign bodies become embedded in the oral tissues [8,9].

Radiography may help to confirm the diagnosis. Biopsy may be indicated to exclude a melanoma but otherwise these innocuous lesions require no treatment.

Fig. 69.60 Amalgam tattoo in a common site. This was presumably related to filling of the deciduous predecessor.

Deliberate tattooing is a rare cause of oral pigmentation [10,11].

Body art

Tattooing of the lower lip may occasionally be seen. A tattooed lower lip in a Sudanese woman, for example, signifies that she is married [1]. The Wodaabe people of Nigeria and Cameroon may tattoo on the skin surface at the angle of the mouth, a practice which has its basis in ritual warding-off of the 'evil eye'. Similar tattoos may be seen on Bedouin women of North Africa. The vermilion may be tattooed red in some people in the Western countries. Tattooing of the chin is seen increasingly in Maoris ('Moki') and tattooing inside the lip may now be seen in resource-rich countries. Mathur and Sahoo [2] reported an instance of fatal septicaemia following the placement of tribal tattoo marks at the angle of the mouth in a Nigerian infant.

The practice of piercing oral and facial soft tissues and then placing foreign objects in the defects on a more or less permanent basis is one which has also been largely confined, until recently, to certain tribal groups in continental Africa and isolated Amazon regions of South America, for example the Suia and Txukahameis tribes of Brazil. This practice is now not uncommon in resource-rich countries [3–6]. Complications secondary to oral and facial piercings include pain, bleeding, dental fractures and gingival damage [3].

Food, habits, heavy metal and drug-induced hyperpigmentation

Causes (see Table 69.11) [1–4] can include:

- Foods and beverages (such as beetroot, red wine, coffee and tea).
- Confectionery (such as liquorice).
- Smoking tobacco—a fairly common cause (smoker's melanosis) and this may produce extrinsic discoloration but also intrinsic pigmentary incontinence, with pigment cells increasing and appearing in the lamina propria. This is especially likely in persons who smoke with the lighted end of the cigarette within the mouth (reverse smoking), as practised mainly in some Asian communities [5–7].
- Chewing betel may cause superficial brownish-red discoloration, mainly in the buccal mucosa (and on the teeth), with an irregular epithelial surface that has a tendency to desquamate, seen mainly in women from South and South-East Asia [8,9] (Fig.69.61). The epithelium in betel chewer's mucosa is often

hyperplastic, and brownish amorphous material from the betel quid may be seen on the epithelial surface and intracellularly and intercellularly, with ballooning of epithelial cells [8]. Betel chewer's mucosa is not known to be precancerous but betel use predisposes to submucous fibrosis and squamous cell carcinoma.

- Drugs such as chlorhexidine, iron salts, griseofulvin, crack cocaine, minocycline, bismuth subsalicylate, lansoprazole, and hormone replacement therapy. Drugs that cause intrinsic staining include the following [10–23]:
  - — Antimalarials produce a variety of colours in the mucosa, ranging from yellow with mepacrine to blue–black with amodiaquine.
  - — Minocycline may cause blackish discoloration of teeth, gingivae and bone, skin, sclera and even breast milk. Minocycline can, in a minority of patients, produce blue–grey gingival pigmentation caused by staining of the underlying bone, and some intrinsic faint bluish-grey staining, mainly near the anterior teeth.
  - — Busulphan, some other cytotoxic drugs, oral contraceptives, phenothiazines and anticonvulsants may also occasionally produce, or increase, brown pigmentation. Adrenocorticotrophic hormone (ACTH) therapy may also produce brown pigmentation, as may zidovudine and clofazimine.
  - — Gold may produce purplish gingival discoloration. Many of the heavy metals formerly implicated in producing oral hyperpigmentation (such as mercury, lead and bismuth) are not used therapeutically now, although industrial or accidental exposure is still occasionally seen [24]. Metallic sulphides deposited in the tissues were seen especially where oral hygiene was poor, with bacteria producing sulphides that resulted in pigmentation at the gingival margin (e.g. lead line).

Treatment. Some drug-induced hyperpigmentation resolves on cessation of exposure to the drug and improved oral hygiene, although resolution can take months or years.

ACTH-induced hyperpigmentation

Oral hyperpigmentation may be seen in ACTH therapy, Addison's disease, Nelson's syndrome or ectopic ACTH production (e.g. by bronchogenic carcinoma). The brown or black pigmentation is variable in distribution but is seen typically on the soft palate, buccal mucosa and at sites of trauma [1–7].

Oral mucosal melanotic macule, reactive type

Synonyms
- Melanoacanthoma
- Melanoacanthosis

Melanotic macules occasionally appear suddenly as reactive lesions following trauma [1–13]. Melanoacanthoma is a misnomer: most reported cases have been in black people as reactive lesions [4,12,14]. A hyperpigmented symptomless macule appears over a course of days or weeks (Fig.69.62). The course is benign, and some cases resolve spontaneously within 6 months.

Pigment-filled dendritic cells that appear to be melanocytes are found in the stratum malpighii but, in contrast to melanoma, basal layer melanocytes are not increased.

Excision biopsy may be indicated to exclude melanoma.

Malignant melanoma (see Chapter 54)

Oral malignant melanoma is rare. Most patients are over 50 years of age and there is a male preponderance.

Malignant melanoma may arise in apparently normal oral mucosa or in a pre-existent pigmented naevus, most commonly in the palate or maxillary alveolus [1–10]. Metastatic melanoma is rare [4]. Features suggestive of malignancy include a rapid increase in size, change in colour, ulceration, pain, bleeding, the occurrence of satellite pigmented spots, or regional lymph node enlargement. The prognosis is poor unless detected very early [2,3]. The optimal treatment is surgery [6,8].

The histology may show anaplastic spindle-shaped or squamoid cells. However, the histology is quite varied and staining with dopa or antibodies may be required to help the diagnosis. Most cases are positive for S-100, tyrosinase, and Mart-1/melana-A. Lesions suspected to be malignant melanoma should not be biopsied until the time of definitive surgical excision [11–15].

Kaposi's sarcoma (see Chapter 56)

Kaposi's sarcoma (KS) is seen predominantly as a consequence of HIV infection, mainly in men who have sex with men. It appears to be associated with HHV-8 [1–9]. Up to 50% of male homosexual AIDS patients have developed oral KS, although it appears to be declining in frequency and is rare in other HIV-infected patients.

Oral KS is the first presentation of HIV in 20–60% of affected patients, often associated with oral candidosis. KS affects the hard-palate mucosa in particular (Fig. 69.63). Up to 95% of lesions are seen in the palate, 23% in the gingiva and others on the tongue or buccal mucosa. A red-purple macule is the early lesion, progressing to a purple nodular swelling that may be extensive and ulcerated. Multiple lesions are common [3–6]. Lesions are often asymptomatic but more than 25% are painful and about 8% bleed. Oral KS is also occasionally seen in other non-HIV-infected immunocompromised patients.

Oral KS may regress occasionally spontaneously, or with HAART, zidovudine or systemic vinca alkaloids, etoposide or interferon, but the more usual treatment is local radiotherapy, laser removal or intralesional vinblastine. The latter produces fewer adverse effects than radiotherapy [10–19].

Purpura

Petechiae are usually caused by trauma, often from suction, but a bleeding tendency (as in infectious mononucleosis or HIV infection) or leukaemias must be excluded [1,2] (Fig. 69.64). Petechiae may be seen in Parvovirus-related papular-purpuric 'gloves and socks' syndrome [3].

Blood-filled blisters may be seen in localized oral purpura (angina bullosa haemorrhagica) and pemphigoid, and occasionally in amyloidosis. Rarely a purpuric lesion may be seen in pigmented purpuric stomatitis [4].

Red lesions

Many oral red lesions are inflammatory in nature, although epithelial thinning (in geographical tongue) and desquamation (in desquamative gingivitis) are fairly common, and epithelial atrophy is an important cause, especially in deficiency glossitis and erythroplasia. Telangiectases are usually red and haemangiomas purplish in colour.

Benign migratory glossitis

Synonyms
- Lingual erythema migrans
- Geographical tongue

Definition. A benign inflammatory condition of the tongue with map-like areas of erythema which are not constant in size, shape or location. Lingual erythema migrans is unrelated to cutaneous erythema migrans.

Aetiology. Unknown, but many patients with a fissured tongue (scrotal tongue) also have lingual erythema migrans. It is a common condition, affecting about 1–2% of the population [1–4]. A positive family history may be obtainable. HLA findings have been equivocal, with reports of associations with B15 and DR7 [5].

Some patients with lingual erythema migrans have atopic allergies such as hay fever and a few relate the oral lesions to a particular food, for example cheese, or to stress. Similar oral lesions may be seen in Reiter's syndrome, generalized pustular psoriasis and acrodermatitis continua of Hallopeau [6–9]. Purported associations with diabetes [10,11] may be coincidental.

Pathology. There is epithelial thinning at the centre of the lesion with an inflammatory infiltrate mainly of polymorphonuclear leukocytes [1,2].

Clinical features. Geographical tongue may be asymptomatic or cause a sore tongue. Patients of any age may be affected but why the condition sometimes gives rise to symptoms after it has been present asymptomatically for decades is unclear [8,12–14]. Geographical tongue is characterized by map-like red areas with increased thickness of intervening filiform papillae. Alternatively, there are rounded, sometimes scalloped, reddish areas with a white margin (Figs 69.65 & 69.66). These patterns change from day to day and even within a few hours. Rarely, other sites, such as the labial or palatal mucosa, are affected. The tongue is usually, but not invariably, affected simultaneously with the other sites [15]. There are no complications.

Fig. 69.65 Classical geographical tongue (lingual erythema migrans).

Fig. 69.66 Somewhat less obvious signs of lingual erythema migrans.

Diagnosis. Clinical examination usually suffices to differentiate the condition from LP, candidosis, psoriasis, larva migrans or deficiency glossitis.

Treatment. In those with no systemic disorder, no effective treatment is available except reassurance but benzydamine hydrochloride 0.15% spray or mouthwash may provide symptomatic relief.

Larva migrans (see Chapter 37)

Cutaneous larva migrans is rarely seen in the mouth, where it presents as irregular linear lesions with an inflammatory border resembling erythema migrans [1,2].

Venous lake

Synonyms
- Venous varix
- Senile haemangioma of lip

This is a bluish-purple soft swelling, 2–10 mm in diameter, usually seen on the lower lip of an elderly person, due to a venous dilatation (Fig. 69.67). The lesion is lined by a single layer of flattened endothelial cells with a thick wall of fibrous tissue. The lesion empties on prolonged pressure [1–4].

A venous lake may be only a trivial cosmetic problem or it can bleed severely after trauma. It can be excised, but careful cryotherapy, electrocautery, infrared coagulation or treatment with an argon laser [2–4] can also give good results.

Proliferative vascular lesions

Benign, atypical vascular lesions may exhibit cytological or architectural features that simulate angiosarcoma such that

considerable caution is required in diagnosis [1]. The head and neck region is a common location, particularly for lobular capillary haemangioma (pyogenic granuloma), while the lip is an especially common site for lobular capillary haemangioma [2–5] and intravascular papillary endothelial hyperplasia (Masson's haemangioma or pseudoangiosarcoma) [5,6]. Intravascular papillary endothelial hyperplasia is a benign, non-neoplastic, vascular lesion characterized histologically by papillary fronds lined by proliferating endothelium and probably represents an organizing thrombus. Seen mainly in the lip or tongue in females, it may simulate angiosarcoma histologically [7]. Excision suffices.

Vascular lesions such as epithelioid haemangioma, epithelioid haemangioendothelioma, spindle-cell haemangioendothelioma, acquired progressive lymphangioma, or angiosarcoma and KS may also occasionally be seen.

Varicosities

Bluish oral varicosities may often be seen in elderly patients, particularly in the ventrum and lateral margin of the tongue. They are benign and inconsequential.

Erythroplasia

Erythroplasia (erythroplakia) is a red velvety lesion level with, or depressed below, the surrounding mucosa. It is uncommon and affects patients of either sex in their sixth and seventh decades [1–4]. Erythroplasia usually involves the floor of the mouth, the ventrum of the tongue, or the soft palate (Fig. 69.68) [1–5]. With regard to the risk of erythroplasia, a more than additive interaction has been found between tobacco chewing and low vegetable intake, whereas a more than multiplicative interaction has been found between alcohol drinking and low vegetable intake, and between drinking and low fruit intake [6].

Some 75–90% of cases of erythroplasia prove to be carcinoma or carcinoma *in situ* or show severe dysplasia. The incidence of malignant change in erythroplasia is 17 times higher than in leukoplakia.

Areas of erythroplasia should be excised and sent for histological examination.

Fig. 69.68 Erythroplasia.

Erythematous candidosis

Oral candidosis can cause erythema and soreness of the oral mucosa, with or without the more usual thrush.

Denture-related stomatitis

Synonym
- Denture sore mouth

This common form of mild, chronic, atrophic oral candidosis occurs only beneath a denture, usually a complete upper denture, and is not often sore despite its name [1–4]. Dentures worn throughout the night, or with a dry mouth, favour development of this infection with *Candida* species mainly. It is not caused by allergy to the denture material and it is not clear why only some denture wearers develop the condition. It is a disease mainly of the middle-aged or elderly and is more prevalent in women than men [5–8]. Patients appear otherwise healthy. In some studies of institutionalized elderly patients, as many as 70% have been found to have denture-related stomatitis but overall it is considerably less common, particularly in normal, healthy subjects.

Denture-related stomatitis consists of mild inflammation and erythema of the mucosa beneath a denture (Fig. 69.69).

Aetiopathogenesis [9–15]. Dentures can produce a number of ecological changes, including the following:

Fig. 69.69 Denture-induced stomatitis showing diffuse erythema in the denture-bearing area.

- Changes in the oral flora
- Plaque accumulation between the mucosal surface of the denture and the palate
- Saliva present between the maxillary denture and the mucosa may have a lower pH than usual
- Accumulation of microbial plaque (bacteria and/or yeasts) on and in the fitting surface of the denture and the underlying mucosa.

In some persons, the cause appears to be related to a non-specific plaque [1,2,5–7,13]. This plaque undergoes sequential development, and is colonized by *Candida* organisms mainly. Although there is no increased aspartyl proteinase production from the *Candida* involved, the decreased salivary flow and a low pH under the denture probably results in a high *Candida* enzymatic activity, which can cause inflammation.

Yeasts such as *Candida* are isolated from up to 90% of persons with denture-related stomatitis and even 66% of all denture wearers. The most frequently isolated species is *Candida albicans*. Of the *C. albicans* isolates, 75% are serotype A and 25% serotype B, a significant increase in serotype B compared with a control group of non-denture-wearing HIV-seronegative individuals with oral candidosis. Resistogram strain-C is the most predominant (24% of total isolates), while strain A-CDE is the least (1.5% of total isolates). Adherence of *C. albicans* to denture-base materials *in vitro* is related to the hydrophobicity of the organism. When *Candida* is involved in denture-related stomatitis, the more common terms '*Candida*-associated denture stomatitis', 'denture-induced candidosis' or 'chronic atrophic candidosis' are used. However, denture-related stomatitis is not exclusively associated with *Candida* and, occasionally, other factors such as bacterial infection or mechanical irritation are at play [16].

Histological examination of the soft tissue beneath dentures has shown proliferative or degenerative responses with reduced keratinization and thinner epithelium.

However, it is not clear why only some denture wearers develop denture-related stomatitis, since most patients appear otherwise healthy. There have been few studies. Patients with denture-related stomatitis have no serious, cell-mediated immune defects but they may sometimes be deficient in migration inhibition factor and may have overactive suppressor T cells or other T-lymphocyte/phagocyte defects. Mean concentrations of serum interleukin 6 and tumour necrosis factor-α are statistically significantly higher and soluble TNF receptors lower in denture wearers compared with controls but there are no differences when stomatitis is present [17].

Predisposing factors. Dental appliances (mainly maxillary dentures), especially when worn throughout the night, or with a dry mouth, are the major predisposing factor. Diabetes, immunosuppressive therapy or a high-carbohydrate diet occasionally predispose [4,15,18–21] and HIV is a rare underlying factor [22].

Factors that are usually *not* significant include allergy to the dental material (if it were, denture-related stomatitis would affect mucosae other than just that beneath the appliance), trauma (the condition is more common beneath maxillary dentures than mandibular dentures, yet trauma is more common with the latter), pharmacological agents and smoking.

Clinical features. The characteristic presenting features of denture-related stomatitis are:

- Chronic erythema and oedema of the mucosa that contacts the fitting surface of the denture (usually a complete upper denture)
- The mucosa below lower dentures is rarely involved
- Erythema is restricted to the denture-bearing area
- Usually there are no symptoms
- Uncommon complications include angular stomatitis, and papillary hyperplasia in the vault of the palate.

Diagnosis. Denture-related stomatitis is a clinical diagnosis; the lesions have been classified into three clinical types (Newton's types), increasing in severity.

- Type 1: a localized simple inflammation or a pinpoint hyperaemia
- Type 2: an erythematous or generalized simple type presenting as more diffuse erythema involving a part of, or the entire, denture-covered mucosa
- Type 3: a granular type (inflammatory papillary hyperplasia) commonly involving the central part of the hard palate and the alveolar ridge.

Treatment. Any underlying systemic disease should be treated where possible.

The denture plaque and fitting surface is infested, usually with *C. albicans*. This must be removed regularly. Therefore, to treat and prevent recurrence of denture-related stomatitis, dentures should be removed from the mouth at night, cleaned and disinfected, and stored in an antiseptic. Cleansing is crucial to therapeutic success [23–25]. Denture cleansers can be divided into groups according to their main components: alkaline peroxides, alkaline hypochlorites, acids, yeast lytic enzymes, proteolytic enzymes and disinfectants such as hypochlorite. Denture soak solution containing benzoic acid completely eradicates *C. albicans* from the denture surface as it is taken up into the acrylic resin. An oral rinse containing chlorhexidine gluconate also results in complete elimination

of *C. albicans* on the acrylic resin surface of the denture, and in reduction of palatal inflammation. A protease-containing denture soak (Alcalase) is also an effective way of removing denture plaque, especially when combined with brushing. Hypochlorite is an effective anticandidal agent but can turn chrome cobalt dentures black.

The mucosal infection is eradicated by brushing the palate and using antifungals for at least 4 weeks. Effective agents include nystatin pastilles or suspension, amphotericin lozenges, miconazole gel or fluconazole suspension or tablets, administered concurrently with an oral antiseptic such as chlorhexidine, which itself has antifungal activity. Isolates are usually sensitive to amphotericin and nystatin but less sensitive to miconazole. Fluconazole is as effective as newer agents such as itraconazole. The cyclodextrin solution and the capsule preparations of itraconazole are equally effective adjuncts in the treatment but, because of side effects, the capsules are preferred. Miconazole lacquer or fluconazole in tissue conditioners applied to the denture fitting surface are also effective [4,26–36].

Surgery may be needed to excise papillary hyperplasia [37].

Acute candidosis

Acute oral candidosis may complicate corticosteroid or antibiotic therapy, particularly with long-term, broad-spectrum antimicrobials such as used in transplant or terminally ill patients [1–5]. There is widespread erythema and soreness of the oral mucosa, sometimes with thrush, particularly noticeable on the tongue.

HIV-associated candidosis

Candida infections in and around the mouth have increased greatly, particularly as the HIV epidemic has spread, and now other species (especially *C. krusei*) and antifungal resistance are serious clinical realities [1–10]. There may be transmission of *Candida* species from HIV-infected persons [9] and new species and clades are being recognized [10,11]. The most dominant oral species, in decreasing order of frequency, are:

- *C. albicans*
- *C. tropicalis*
- *C. glabrata*
- *C. parapsilosis*
- *C. krusei*
- Other *Candida* species such as *C. dubliniensis, C. africanus* and *C. inconspicua*
- Other genera (*Rhodotorula*, *Saccharomyces*, etc.), which are rare and transient.

Erythematous or atrophic candidosis may arise as a consequence of persistent, acute pseudomembranous candidosis when the pseudomembranes are shed, may develop *de novo*, or in HIV infection may precede pseudomembranous candidosis. The clinical presentation is of erythematous areas generally on the dorsum of the tongue, palate or buccal mucosa. Lesions on the dorsum of the tongue present as depapillated areas. Red areas are often seen in the palate in HIV disease. There can be an associated angular stomatitis and/or thrush.

Thrush is a well-recognized feature of T-cell immunodeficiencies, particularly after the severe T-cell immunosuppression necessary for organ transplantation and in other secondary immunodeficiencies, such as leukaemia, diabetes or HIV/AIDS. It is a common and early feature of AIDS.

Furthermore, with increasing use of antimycotic therapy, especially in HIV disease, there is a shift towards not only resistant *C. albicans*, as well as the appearance of novel species, but also other species such as *C. glabrata* and *C. krusei*. Thrush is characterized by white patches on the surface of the oral mucosa, tongue and elsewhere. The lesions develop to form confluent plaques that resemble milk curds, and can be wiped off to reveal a raw, erythematous and sometimes bleeding base. Complications of oropharyngeal thrush may sometimes present as lesions of the adjacent mucosa, particularly in the upper respiratory tract and the oesophagus. The combination of oral and oesophageal candidosis is particularly prevalent in HIV-infected patients. Antifungal therapy is indicated [10–12]. HAART reduces the frequency of candidosis [13].

Median rhomboid glossitis

Synonym
- Central papillary atrophy of the tongue

Aetiology. This red, depapillated, rhomboidal area in the midline of the dorsum of the tongue, just anterior to the sulcus terminalis, was formerly thought to be caused by persistence of the tuberculum impar. However, it is now thought to be associated with candidosis [1–6]. Multiple oral lesions may occasionally be present, especially a 'kissing' lesion in the palatal vault [7,8]. Smoking, denture wearing and, occasionally, immune defects (including HIV) and diabetes predispose to this lesion [4,9–11].

Pathology. Histology shows irregular, pseudoepitheliomatous, epithelial hyperplasia that may resemble a carcinoma but it is not a malignant condition.

Clinical features. There is typically a red central lesion of somewhat rhomboidal shape anterior to the sulcus terminalis on the dorsum of the tongue (Fig. 69.70). Occasionally, there is a nodular component. There may also sometimes be a coexistent erythematous candidosis in the palate [7,8], which some have termed 'chronic oral multifocal candidosis'.

Diagnosis. Median rhomboid glossitis is usually diagnosed on clinical grounds, although biopsy may be indicated, since some lesions are nodular and may simulate a neoplasm.

Fig. 69.70 Median rhomboid glossitis.

Treatment. Median rhomboid glossitis may respond to cessation of smoking and to the use of antifungals.

Desquamative gingivitis

This is usually caused by pemphigoid or lichen planus but is also seen in patients with pemphigus vulgaris and lupus erythematosus [1].

1 Jayakumar ND, Jaiqanesh R, Padmalatha O, Sheeja V. Systemic lupus erythematosus. *Indian J Dent Res* 2006; **17**: 91–3.

Loss of elasticity of oral tissues

Fibrosis of oral tissues can follow burns or irradiation. It may also be associated with habits such as the chewing of betel nut (areca), which predisposes to oral submucous fibrosis (see below) and may be caused by a connective tissue disorder such as scleroderma. Rarely it is occupational (polyvinylchloride workers). Epidermolysis bullosa and mucous membrane pemphigoid may cause scarring and the orofacial region is occasionally involved in multiple idiopathic fibrosis [1].

Oral submucous fibrosis

Aetiology. Oral submucous fibrosis is a chronic disease of the oral mucosa that appears to be caused by exposure to constituents of the areca nut. It is found virtually exclusively in persons from the Indian subcontinent; most of those affected chew areca nut with tobacco, betel leaf and lime [1–11].

Pathology. There is a subepithelial chronic inflammatory reaction with fibrosis extending to the submucosa and muscle. Epithelial changes range from atrophy to keratosis and there may be dysplasia.

Clinical features. Oral submucous fibrosis develops insidiously, often initially presenting with oral dysaesthesia and a non-specific vesicular stomatitis [2,11,12]. Later there may be symmetrical fibrosis of the cheeks, lips or palate, which may be symptomless and noted only as bands running through the mucosa. This can, however, become so severe that the affected site becomes white and firm, with severely restricted opening of the mouth.

Oral submucous fibrosis appears to be restricted to the mouth, although many patients are also anaemic. Oral submucous fibrosis may predispose to the development of oral carcinoma, which occurs in 2–10% of patients over a period of 10 years [9,13–16].

The diagnosis can be confirmed by biopsy.

Treatment. Management is difficult. Intralesional corticosteroids and jaw exercises may be useful in the early stages, but surgery may be needed to relieve the fibrosis [1,6,10,17]. Pentoxyfylline and lycopene have been used with some effect [6,10].

Systemic sclerosis (see Chapter 51)

Oral features are common in systemic sclerosis and are generally more obvious in those with diffuse than localized scleroderma. About 70% of patients have xerostomia, and there is an increase in both caries and periodontal disease. A characteristic finding is of increased width of the periodontal ligament space of all teeth on radiography [1–4]. There are mandibular erosions in the angle particularly, but also in the condyle, coronoid or digastric regions. Telangiectasia may be seen and most patients have restricted oral opening with linear wrinkles of the lips [3–6].

Lumps and swellings

Lumps in the mouth range from simple anatomical variants, which can cause the patient considerable concern, to lumps caused by inflammatory, cystic (Fig. 69.71), neoplastic and other disorders (Table 69.23).

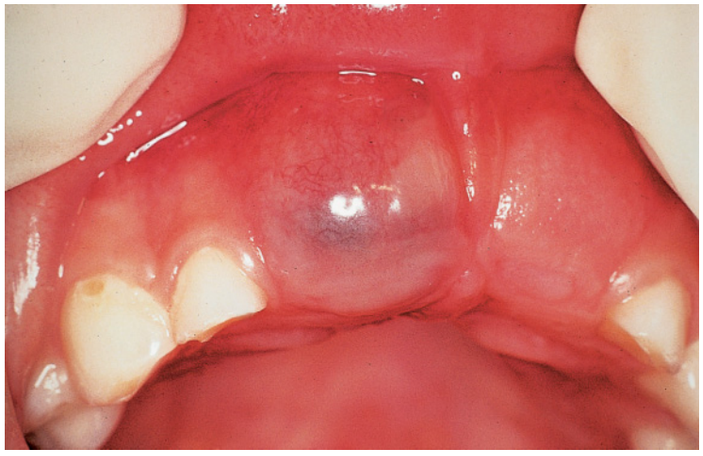

Fig. 69.71 Bluish, fluctuant swelling of an oral cyst, in this case an eruption cyst over an erupting maxillary permanent incisor. (The lesion on the maxillary canine is early dental caries.)

Foliate papillitis

The foliate lingual papillae may become inflamed and swell. Because of their location on the posterolateral tongue this may give undue concern about malignancy. The condition resolves spontaneously.

Angio-oedema

Oral swelling may be a feature of allergic angio-oedema and angio-oedema due to Cl esterase inhibitor deficiency. Allergic angio-oedema can occur secondary to antibiotic therapy, exposure to latex or ingestion of certain food substances and may be life-threatening. Angio-oedema due to C1-esterase inhibitor deficiency may be hereditary, first occurring in childhood, or acquired, with onset usually in adulthood. Type I hereditary angio-oedema exhibits low levels of functionally normal C1-esterase inhibitor while in the type II variant C1-esterase inhibitor is dysfunctional. The swelling may affect the lips, tongue or other areas and is often only mild and transient, although there is the potential for obstruction of the airway. Local anaesthetics [1] or more commonly angiotensin-converting enzyme inhibitors [2–12] may cause angio-oedema, which can occasionally be lethal [4]. It may respond to a sympathomimetic such as epinephrine or to antihistamines. Synthetic androgens have proven useful in reducing the frequency and duration of attacks [1,2].

Oral allergy syndrome

Oral allergy syndrome is the combination of oral pruritus, irritation and swelling of the lips, tongue, palate and throat, sometimes associated with other allergic features such as rhinoconjunctivitis, asthma, urticaria–angio-oedema, and anaphylactic shock, precipitated mainly by fresh foods such as fruits and vegetables, and sometimes by pollens because of cross-reacting allergens [1–6]. Cooking often destroys the allergens.

It may respond to antihistamines or to a sympathomimetic agent such as ephedrine which can be taken by mouth.

Osteoma mucosae

Synonym

- Osseous choristoma

There are rare cases of osteoma of the oral mucosa, usually in the tongue. Most have been in females in the third and fourth decades and have arisen as pedunculated, hard, painless lumps on the dorsum of the tongue immediately posterior to the foramen caecum [1–5]. They may arise from thyroid anlages. Simple excision suffices.

Abscesses

Most intraoral abscesses are odontogenic in origin, as a final consequence of dental caries. Most abscesses discharge in the mouth on the buccal gingiva but occasionally discharge palatally, lingually, on the chin or submental region (Fig. 69.72), or elsewhere. Very occasionally abscesses follow trauma or a foreign body, or rarely are related to unusual oral infections such as actinomycosis [1–3], nocardiosis or botryomycosis [4,5].

Drainage and appropriate antimicrobials are indicated [6–10]. Dental attention is required; dental abscesses are drained by tooth extraction, incision and drainage, or through the root canal (endodontics).

Sarcoidosis

Isolated nodules [1,2], gingival lesions [3], facial or labial swelling [4] and salivary gland involvement are the main oral or perioral lesions of sarcoidosis [5–11], but are uncommon. However, even where the mucosa is clinically normal, patients with sarcoidosis may have characteristic changes in palatal or labial salivary gland biopsies [9,12]. Intraosseous lesions are rare [13,14].

Pulse granuloma

Synonym
- Lewar's disease

Chronic mandibular periostitis caused by embedded vegetable matter of dietary origin is uncommon but typically presents as a submucosal lump over the lower alveolus. Histology shows amorphous hyaline material and a granulomatous inflammatory reaction [1–4]. Excision suffices.

References

Denture-induced hyperplasia

Synonyms
- Denture granuloma
- Epulis fissuratum

Fig. 69.73 Mucocele.

Where a denture flange is overextended and irritates the vestibular mucosa, a linear reparative process may result, eventually producing an elongated fibroepithelial enlargement known as denture-induced hyperplasia [1–4]. The pathology is that of a fibrous lump (see p. 69.20).

Firm, leaf-like, painless swellings are seen, usually in the buccal or labial vestibule.

A denture-induced granuloma should be excised and examined histologically, if modification of the denture does not induce regression [2]. Rarely, a denture granuloma arises because some other lesion develops beneath a denture and causes the mucosa to be irritated.

Mucocele (mucous cyst)

Synonyms
- Mucous retention cyst
- Ranula
- Mucocele
- Myxoid cyst of lip

Superficial mucoceles are seen mainly in lichen planus [1,2]; palatal lesions may be seen [3]. Deeper mucoceles are more common and are usually seen in the lower labial mucosa (Fig. 69.73), usually resulting from the escape of mucus into the lamina propria from a damaged minor salivary gland duct.

Mucoceles appear as painless dome-shaped, translucent, whitish blue papules or nodules [3–10]. Care should be taken to ensure that the lesion is not a salivary gland tumour with cystic change, especially when dealing with an apparent mucous cyst in the upper lip [11]. The cysts can be excised but they also respond well to cryosurgery, using a single freeze–thaw cycle [2,12,13].

Buccal fat-pad herniation

Trauma may rarely cause the buccal pad of fat to herniate through the buccinator muscle, producing an intraoral swelling [1–3]. This usually occurs in males under the age of 4 years. Surgery is indicated.

Oral papilloma

Aetiology. These are caused by HPV [1–5].

Pathology. Histology includes acanthotic and sometimes hyperkeratotic epithelium with occasional koilocytosis.

Clinical features. Papillomas can appear anywhere in the mouth, but are most common at the junction of the hard and soft palate. The papilloma is a white or pink, cauliflower-like lesion that may resemble a wart. Papillomas of normal colour may be confused with the commoner fibroepithelial polyps, although the latter are commonest at sites of potential trauma. Papillomas are common

Fig. 69.74 Warts on the lower lip in HIV infection. (There is also a healing herpes simplex lesion on the lip.)

in HIV-infected people and have increased with the introduction of HAART [3].

Prognosis. Unlike some papillomas of the larynx or bowel, oral papillomas are generally benign although some are dysplastic [3,6].

Diagnosis. Oral papillomas should be removed and examined histologically to establish a correct diagnosis.

Treatment. Excision must be total, deep and wide enough to include any abnormal cells beyond the zone of the pedicle.

Warts (see Chapter 33)

Common warts (verrucae vulgaris) and venereal warts (condyloma acuminatum) are both caused by papillomaviruses [1–8]. They are rare in the mouth (Fig. 69.74) but are more common in HIV disease. None is known to be premalignant. Most can be removed by excision, cryosurgery or laser, or podophyllum or imiquimod.

Focal epithelial hyperplasia

Synonym
- Heck's disease

Focal epithelial hyperplasia is a rare, benign, familial disorder with no sex predisposition, characterized by multiple, soft, circumscribed, sessile, nodular elevations of the oral mucosa [1–8].

Heck's disease occurs particularly in native Americans and in Inuits in Greenland but has been reported rarely from many other countries. The prevalence in Greenland and Venezuela approaches 35% [1,9,10].

Aetiology. The papillomaviruses HPV-13 and HPV-32 appear to be causal in patients with the genetic predisposition to focal epithelial hyperplasia [5–8,11–14].

Pathology. The characteristics of focal epithelial hyperplasia are local epithelial hyperplasia, acanthosis and elongated 'Bronze Age axe' rete ridges, together with a ballooning type of nuclear degeneration. Epithelial cells have a pseudomitotic appearance.

Clinical features. Among native Americans, focal epithelial hyperplasia mainly affects children and usually involves the lower lip, whereas in the Inuit and in white people the lesions are found mainly in the fourth decade and later and often affect the tongue. This is a benign asymptomatic condition, requiring only reassurance.

Papillary hyperplasia

Papillary hyperplasia may be seen in the vault of the palate, typically in persons with chronic denture-related stomatitis and occasionally in its absence [1–10]. It may require excision or laser removal.

Rhabdomyoma

Rhabdomyomas are rare but most extracardiac rhabdomyomas present in the mouth, typically as lumps in the floor of mouth, tongue or soft palate [1–5]. Most are seen in the sixth decade, predominantly in males. Surgery is effective provided total excision is achieved.

Rhabdomyosarcoma

Some 45% of soft-tissue sarcomas in the head and neck region are rhabdomyosarcomas. The most common oral presentation is a progressively enlarging mass; some 20% have enlarged regional lymph nodes [1–8]. In advanced disease there may be pain, paraesthesia, trismus or loosening of teeth. Intraosseous lesions have been reported [5].

The prognosis is poor. Treatment includes cytotoxic chemotherapy, surgery and radiotherapy.

Nodular fasciitis (see Chapter 56)

Nodular (pseudosarcomatous) fasciitis affects the head and neck in 20% of cases but rarely involves the mouth [1–7]. In the mouth, most cases involve the lips and buccal mucosae [7].

Verruciform xanthoma

Although verruciform xanthoma was originally described as a distinct oral entity, it is now also known occasionally to affect the

skin and non-oral mucosae [1,2]. The aetiology is unknown but may be a reaction to some irritant.

The lesions consist of parakeratotic verruciform epithelium, with large foamy xanthoma cells containing slightly PAS-positive granules and abundant lipid in the lamina propria between the epithelial pegs [3–10].

Verruciform xanthoma is usually a solitary symptomless lesion, typically on the gingiva, with a normal, pale, reddish or keratotic surface [1–10]. Excision is only rarely followed by recurrence.

Lipoma (see Chapter 46)

Lipomas are uncommon in the mouth, comprising less than 5% of oral benign tumours [1–8]. They present as slow-growing, spherical, smooth and soft semi-fluctuant lumps with a characteristic yellowish colour. Most involve the buccal mucosa or floor of mouth. Occasionally, although benign, they infiltrate. Histology shows adult fat cells gathered into lobules by vascular septa of fibrous connective tissue. Surgery is rarely indicated except for infiltrating lipomas.

Myxoma

Myxomas are rare in the oral cavity [1–5]. They can arise in bone or soft tissue and, although benign, are aggressive and difficult to eradicate because of the tendency to infiltrate normal tissue.

Macroglossia

The tongue may be congenitally enlarged (macroglossia) in Down's syndrome or Beckwith–Wiedemann syndrome or where there is an angioma. It may also enlarge in angio-oedema, gigantism, acromegaly or amyloidosis [1–7].

Myeloma and paraproteinaemias

Multiple myeloma very occasionally presents with an intraoral mass or oral bleeding. Bone lesions are more common. Solitary plasmacytomas may also be seen; indeed, some 80% of these rare tumours are found in the head and neck region but typically in the nasal cavity or pharynx rather than in the mouth [1–5].

Franklin's disease

Synonym
- Heavy-chain disease

Palatal oedema and oral ulceration have been described in a few patients with heavy-chain disease, but the former feature is not as invariable as initially described [1,2].

Thrombotic thrombocytopenic purpura

This may present with oral purpura and/or spontaneous gingival haemorrhage [1–3]. Gingival biopsy is a recommended investigation [4,5].

Amyloidosis (see Chapter 59)

In primary amyloidosis the tongue is enlarged and hard. There may also be yellowish submucosal nodules, lumps or petechiae (Fig. 69.75). Rarely, there are similar deposits elsewhere (e.g. in the soft palate), and jaw claudication, salivary gland swelling or xerostomia may occur [1–14].

Secondary amyloidoses rarely involve the mouth except in the case of multiple myeloma or haemodialysis-associated amyloid, which may occasionally produce oral nodules [9,15,16].

Some 10% of patients with oral amyloidosis have amyloid in their submandibular glands. Solitary intraoral amyloid is rare [17].

Congo red or thioflavine T staining of a biopsy usually confirms the diagnosis, although in extreme cases the deposits are seen on haematoxylin and eosin staining. Treatment is unsatisfactory but the underlying disease, where present, should be treated.

Oral manifestations of systemic diseases

Oral manifestations can occasionally occur in many systemic diseases (Tables 69.24–69.38). Space precludes all but a brief tabular synopsis here. Further details can be found elsewhere [1–10].

Table 69.27 Drug effects.

Tissue	Drug effect	Drugs commonly implicated
Teeth	Discoloration	Tetracyclines
		Chlorhexidine
	Root anomalies	Phenytoin
		Cytotoxic drugs
Gingiva	Swelling	Phenytoin
		Ciclosporin
		Nifedipine
		Diltiazem
Salivary glands	Dry mouth	Tricyclic antidepressants
		Phenothiazines
		Antihypertensives
		Lithium
Taste	Disturbed	Metronidazole
		Penicillamine
Facial movements	Dyskinesias	Phenothiazines
		Metoclopramide
Mucosa	Thrush	Broad-spectrum antimicrobials
		Corticosteroids
		Cytotoxic drugs
	Ulcers	Cytotoxic drugs
		Non-steroidal anti-inflammatory agents
	Lichenoid lesions	Non-steroidal anti-inflammatory agents
	Erythema multiforme	Barbiturates
		Sulphonamides

Table 69.28 Gastrointestinal diseases.

Disease	Oral manifestations
Pernicious anaemia	Ulcers
	Glossitis
	Angular stomatitis
	Red lesions
Any cause of malabsorption	Ulcers
	Glossitis
	Angular stomatitis
Any cause of regurgitation	Tooth erosion
	Halitosis
Tylosis	Leukoplakia
Crohn's disease (and orofacial granulomatosis)	Facial swelling
	Mucosal tags
	Gingival hyperplasia
	Cobblestoning of mucosa
	Ulcers
	Glossitis
	Angular stomatitis
Coeliac disease	Ulcers
	Glossitis
	Angular stomatitis
	Dental hypoplasia
Peutz–Jegher syndrome (small intestinal polyps)	Melanosis
Chronic pancreatitis	Sialosis (rarely)
Cystic fibrosis	Salivary gland swelling
Gardner's syndrome (familial colonic polyposis)	Osteomas

Table 69.29 Renal diseases.

Disease	Oral manifestations
Chronic renal failure of any cause	Xerostomia
	Halitosis/taste disturbance
	Leukoplakia
	Dental hypoplasia in children
	Renal osteodystrophy
Post renal transplant (immunosuppressed)	Bleeding tendency (especially if anticoagulated)
	Infections, particularly herpetic and candidal
	Bleeding tendency if anticoagulated
	Gingival hyperplasia if on ciclosporin
	Kaposi's sarcoma (rarely)
	Hairy leukoplakia (rarely)
Nephrotic syndrome	Dental hypoplasia
Renal rickets (vitamin D resistant)	Delayed tooth eruption
	Dental hypoplasia (rarely)
	Enlarged pulp

Table 69.30 Haematological diseases.

Disease	Oral manifestations
Deficiency of the haematinics (iron, folic acid or vitamin B_{12})	Burning mouth sensation
	Ulcers
	Glossitis
	Angular stomatitis
Sickle-cell anaemia	Jaw deformities
	Osteomyelitis or pain
Thalassaemia major	Jaw deformities
Aplastic anaemia	Ulcers
	Bleeding tendency
Haemolytic disease of newborn	Tooth pigmentation
	Enamel defects
Any leukocyte defect	Infections, especially herpetic and candidal
	Ulcers
Any cause of purpura	Bleeding tendency
	Purpura
Leukaemia/lymphoma	Infections
	Ulcers
	Bleeding tendency and purpura (in leukaemias only)
	Gingival swelling in myelomonocytic leukaemia
Multiple myeloma	Bone pain

Cheilitis

Synonym
- Inflammation of the lips

Cheilitis may arise as a primary disorder of the vermilion zone or the inflammation may extend from nearby skin or, less often, from the oral mucosa (Table 69.39) [1].

Table 69.40 Possible allergens in lipsticks and lipsalves.

'Chapping' of the lips

Chapping is a reaction to adverse environmental conditions usually caused by exposure to freezing cold or to hot dry winds. The keratin of the vermilion loses its plasticity, so that the lips become sore, cracked and scaly. The affected person tends to lick the lips, or to pick at the scales, which may aggravate the condition.

Treatment is by application of petroleum jelly and avoidance of the adverse environmental conditions.

Eczematous cheilitis

The lips are often involved secondarily to atopic dermatitis (see Chapter 24). The treatment is with emollients and topical corticosteroids. A potent steroid such as fludrocortisone may be required to bring the condition under control.

Contact cheilitis

Contact cheilitis is an inflammatory reaction provoked by the irritant or sensitizing action of chemicals. Many cases are caused by lipsticks or lipsalves but a large number of substances have been incriminated.

Lipsticks and lipsalves (Table 69.40). Lipsticks are composed of mineral oils and wax (which form the stick), castor oil as a solvent for the dyes, lanolin as an emollient, preservatives, perfumes and colours [1–7]. The dyes may include azo dyes and eosin, a bromofluorescein derivative. An eosin impurity used to be an important sensitizer [8] but is now rarely if ever used. Other ingredients occasionally incriminated include azo dyes, carmine, oleyl alcohol [9], lanolin, perfumes, azulene, propyl gallate [10], sesame oil [11], stearates [12], shellac and colophony [13,14]. Sunscreens in lipstick or lipsalve (e.g. cinnamic aldehyde) can also cause contact cheilitis [15]. Phenyl salicylate and antibiotics have also been incriminated [16,17]. Petrolatum chapsticks may cause an unusual form of acne with a single row of large open comedones along the cutaneous margin of the upper lip [18].

Mouthwashes and dentrifices [19–23]. Sensitizers used in some toothpastes include essential oils, such as peppermint, cinnamon, clove and spearmint; carvone along with imonene, pinene, phellandrene, dipentene, cineole, linalool, and esters of dihydrocuminyl alcohol and dehydrocarveol; bactericidal agents; propolis,

Table 69.41 Possible fruit and vegetable allergens.

Apple	Artichoke	Asparagus

Mango	Onion	Orange
Parsley	Parsnip	Peach
Pear	Pineapple	Plum
Potato	Tomato	

derived from resin collected by bees [24–26]; and tartar-control dentifrices, which contain pyrophosphate compounds [27].

Dental preparations. Mercury, eugenol, and plastics including epimine-containing materials can cause cheilitis [28–31].

Foods (Table 69.41). Peppermint, carvone, spearmint [32], citrus fruits [33], artichokes [34], nuts [35], pineapple [36], mangoes [37–39], asparagus [40], geraniol [41] and cinnamon oil [42,43] occasionally cause allergic cheilitis and perioral dermatitis. The oil on the peel of citrus fruits is irritant to the skin; in addition, some sweet oranges contain a weakly phototoxic agent that can cause a reaction in pale-skinned people [44]. Garlic may cause contact cheilitis [45].

Miscellaneous objects. Metal hair clips, metal pencils, the cobalt paint on blue pencils [46], nail varnish [47], and the metal, wooden, nickel and reed mouthpieces of musical instruments [15,48–52] may cause cheilitis.

Clinical features. Lipstick cheilitis is sometimes confined to the vermilion but more often extends beyond. There may be persistent irritation and scaling or a more acute reaction with oedema and vesiculation.

The other forms of cheilitis vary greatly in their clinical appearance. Those caused by foods commonly also involve the skin around the mouth. If a small, sucked object is responsible, the reaction may be confined to one part of the lips.

Diagnosis. If acute eczematous changes are obviously present, the diagnosis of contact cheilitis presents no difficulty. If the changes are confined to irritation and scaling, the various forms of exfoliative cheilitis must be excluded.

If an allergic reaction is suspected, patch tests should be carried out.

Treatment. Topical corticosteroids will give symptomatic relief but the offending substance must be identified and avoided.

Drug-induced cheilitis

Haemorrhagic crusting of the lips (Fig. 69.77) is a feature of erythema multiforme (particularly in Stevens–Johnson syndrome) (see p. 69.69), but cheilitis can also occur as an isolated feature of a drug reaction.

Aromatic retinoids such as etretinate and isotretinoin cause cheilitis, dryness and cracking of the lips in many patients [1,2].

Infective cheilitis

Viral. Lip infections with HSV are common, and VZV and HPV may also affect the lips. Rare viral infections such as orf [1–4] and vaccinia [5] can affect the lips.

Bacterial. Dental infection or occasionally a furuncle or carbuncle may cause swelling of the lip. Impetigo may mimic herpes labialis (see Chapter 33). Cancrum oris (fusospirochaetal infection) may cause labial and buccal necrosis [6–8].

The lip is the most common extragenital site for a primary syphilitic lesion. Most lip chancres in males tend to occur on the upper lip, in females on the lower lip. In secondary syphilis, moist, flat, papulonodular lesions (condylomata lata) often appear at the mucocutaneous junctions and on mucosal surfaces especially at the commissures [9,10]. The tropical treponematoses may present similarly to syphilis.

TB or leprosy may cause chronic lip swelling or ulceration [11].

Rhinoscleroma initially affects the nasal mucosa but may spread slowly to the upper lip, producing plaques or nodules with sunken centres. The extreme hardness of the infiltrations is characteristic. The lip can appear to fuse to the alveolar process but the overlying skin and mucosa remain normal.

Protozoal. Cutaneous or mucocutaneous leishmaniasis typically causes swellings on the upper lip with later enlargement and destruction of the lip [12–14], reflecting the three stages of oedema, granulomatous proliferation and then necrosis.

Fungal. Blastomycosis and paracoccidioidomycosis are uncommon causes of chronic ulceration affecting the lip, producing very similar clinical lesions to leishmaniasis [15].

Others. Red swollen lips with fissuring and exfoliation are prominent in mucocutaneous lymph node syndrome (Kawasaki disease).

Angular cheilitis

Synonym
- Angular stomatitis

Angular cheilitis is an acute or chronic inflammation of the skin and contiguous labial mucous membrane at the angles of the mouth [1–3].

Aetiology. Most cases in adults are due to mechanical and/or infective causes, but in children nutritional or immune defects are more prominent causes.

Infective agents. These are the major cause. *Candida* or staphylococci are isolated from most patients [4–7]. Permanent cure can be achieved only by eliminating the *Candida* beneath the upper denture [8,9]. Candidosis was probably responsible for some of the cases of cheilitis attributed to allergy to denture materials, since contamination of denture material by *Candida* may cause false-positive patch-test reactions [10].

Immune deficiency, such as diabetes and HIV infection, may present with angular stomatitis [11–13]. Outbreaks of acute pustular and fissured cheilitis may occur in children, particularly if they are malnourished, and in some cases streptococci or staphylococci have appeared to be causative [14].

Mechanical factors in edentulous patients who do not wear a denture or who have inadequate dentures, and also as a normal consequence of the ageing process, produce an oblique curved fold and keep the small area of skin constantly macerated. The recurrent trauma of dental flossing is a very rare cause of angular cheilitis [15].

Nutritional deficiencies, particularly deficiencies of riboflavin, folate, iron and general protein malnutrition, may produce smooth, shiny, red lips associated with angular stomatitis, a combination called *cheilosis* [1,16–18]. Crohn's disease or orofacial granulomatosis may be found in some [19].

Clinical features. Angular cheilitis presents as a roughly triangular area of erythema and oedema at one, or more commonly both, angles of the mouth (Fig. 69.78). Linear furrows or fissures radiating from the angle of the mouth (rhagades) are seen in the more severe forms, especially in denture wearers.

Diagnosis. This is usually obvious. *Candida* should be sought not only in the lesions but also beneath the denture.

Fig. 69.78 Angular cheilitis.

Treatment. Dentures should be removed from the mouth at night and stored in a candidacidal solution such as hypochlorite. Denture-related stomatitis should be treated with an antifungal. Miconazole may be preferable treatment for candidosis (cream applied locally, together with the oral gel) as it has some Gram-positive bacteriostatic action. New dentures that restore facial contour may help. The skin lesions should be swabbed and staphylococcal infection treated with fusidic acid ointment or cream at least four times daily.

Actinic cheilitis

Synonyms
- Actinic keratosis of lip
- Solar cheilosis

This is a premalignant keratosis of the lip caused by exposure to solar irradiation.

Aetiology. Actinic cheilitis is most common in hot dry regions, in outdoor workers and in fair-skinned people (skin types I and II). The vermilion of the lower lip receives a high dose of UV irradiation because it is almost at right angles to the rays of the midday sun and is poorly protected by keratin and melanocytes. Most actinic cheilitis is seen on the lower lip of fair-skinned men in their fourth to eighth decade of life [1].

Pathology. Histology shows a flattened or atrophic epithelium, beneath which is a band of inflammatory infiltrate in which plasma cells may predominate [2]. Nuclear atypia and abnormal mitoses may be seen in the more severe cases, and some develop into invasive squamous carcinoma [3–5]. The collagen generally shows basophilic (elastotic) degeneration [6].

Clinical features (Fig. 69.79). Actinic cheilitis tends to affect the lower lip of adults who have had prolonged exposure to sunlight [1,7]. In the early stages there may be redness and oedema, but later the lips become dry and scaly. Later still, the epithelium becomes palpably thickened with small greyish-white plaques and, eventually, warty nodules may form. Eventually these may undergo malignant change, the possibility of which must always be considered when ulceration develops or when there are other suspect features such as:
- A red and white, blotchy appearance with an indistinct vermilion border
- Generalized atrophy with focal areas of whitish thickening
- Persistent flaking and crusting [8,9].

Fig. 69.79 Chronic actinic cheilitis with leukoplakia. (Courtesy of Addenbrooke's Hospital, Cambridge, UK.)

Diagnosis. This is clinical.

Treatment. Treatment of actinic cheilitis is required to relieve symptoms and to prevent development of squamous carcinoma.
- Topical agents: 5% fluorouracil three times daily for 10 days is suitable [10,11]. Topical tretinoin [12], trichloracetic acid [13] or diclofenac gel [14] may also be effective.
- Vermilionectomy (lip shave) [15–17].
- Laser ablation [18–22].
- Photodynamic therapy [23–24].

Following treatment, prevention of recurrence by the regular use of a sunscreen lipsalve containing *p*-aminobenzoic acid probably gives the best protection [25,26]. Particular care should be taken to protect the vermilion of the lips with adequate sunscreens in patients with photosensitivity disorders such as xeroderma pigmentosum, and in those whose exposure to UVB is high, such as in farmers, fishermen, mountaineers, windsurfers and skiers.

Actinic prurigo (see Chapter 29)

Actinic prurigo is a type of familial photodermatitis, seen mainly in native Americans living at high altitudes [1–6] especially in Latin America, and in China [7]. It usually presents in young women as a photosensitive facial rash with pruritic lower lip cheilitis, and it may be associated with conjunctivitis, eyebrow alopecia and pterygion.

Actinic prurigo is due to enhanced sensitivity to sunlight and is distinguished from actinic cheilitis, which is due to prolonged and excessive exposure to UV irradiation, by the relative absence of epidermal dysplasia and solar elastosis [8]. Polymorphic light eruption is almost invariably present in the actinic prurigo of native Americans [9,10].

Treatment is with sunscreens, β-carotene, psoralen and UVA (PUVA), and antihistamines. Oral thalidomide may be tried [5,11,12].

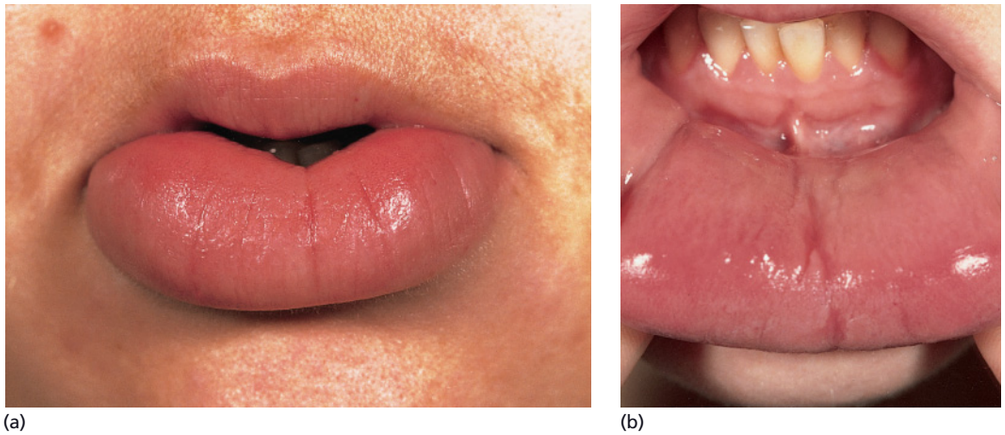
Glandular cheilitis

Definition. Glandular cheilitis is characterized by inflammatory changes and swelling of salivary glands in the lips [1–3].

Aetiology. This is an uncommon idiopathic condition which in a few cases has apparently been familial [4]. Although it was originally thought that the condition was due to inflammation of enlarged heterotopic salivary glands, the glands are often normal in size, depth and histology [5]. It is possible that the excessive salivary secretion from minor salivary glands in this condition might be an unusual clinical response to irritation of the lip from some other cause such as actinic damage or repeated licking.

Pathology. In the milder forms there is some fibrosis surrounding the salivary glands, while in the more severe forms there may be a dense chronic inflammatory infiltrate. Only rarely do patients show genuine hyperplasia of the salivary glands or duct ectasia.

Clinical features. The onset is at any age from childhood onwards. In simple glandular cheilitis, the lower lip is slightly thickened and bears numerous pinhead-sized orifices, from which mucous saliva can readily be squeezed. The upper lip is rarely involved [6].



In the more severe suppurative form (*Volkmann's cheilitis*) the lip is considerably and permanently enlarged, and subject to episodes of pain, tenderness and increased enlargement. The surface is covered by crusts and scales, beneath which the salivary duct orifices may be discovered. In the most severe forms there may be deep-seated infection with abscess formation and fistulous tracts.

The condition can evidently be premalignant; in some series 20–30% of cases progress to squamous carcinoma. This does, of course, support the suggestion that in many cases glandular cheilitis is a consequence of actinic cheilitis [5].

Treatment. Actinic cheilitis, if identified, should be treated appropriately. If the lips are grossly enlarged, excision of an elongated ellipse of tissue may be required; in other cases shave vermilionectomy may be all that is necessary. Other conditions such as atopic disease or factitial cheilitis would require different treatment.

Granulomatous cheilitis

Synonym
- Miescher's cheilitis

This is a chronic swelling of the lip due to granulomatous inflammation of unknown cause. Melkersson in 1928 [1] described labial oedema in association with recurrent facial palsy. Rosenthal in 1930 emphasized the role of genetic factors and added scrotal tongue to the syndrome. The full syndrome has since been called Melkersson–Rosenthal syndrome [2–4].

In Miescher's cheilitis the granulomatous changes are confined to the lip, and this is generally regarded as a monosymptomatic form of Melkersson–Rosenthal syndrome, although the possibility remains that these may be two separate diseases.

Aetiology. The cause is unknown, but there may be a genetic predisposition to Melkersson–Rosenthal syndrome [5]; siblings have been affected and a scrotal tongue may be present in otherwise normal relatives.

There is no convincing evidence that granulomatous cheilitis is due to an infective agent. Some cases may represent a localized form of sarcoidosis [6,7] or ectopic Crohn's disease [7–9] or orofacial granulomatosis. There is increasing evidence that some patients with granulomatous cheilitis are predisposed to Crohn's disease [9–11]. In some cases, granulomatous cheilitis is followed some years later by regional ileitis [12–16]. A few patients react to cobalt [17] or to food additives such as cinnamic aldehyde [18–21] and have no extra oral lesions, although these reactions are by no means always relevant; for example, in one study only one of nine patients had a relationship between cheilitis and food intake [22].

Pathology. Biopsy of the swollen lip or facial tissues during the early stages of the disease shows only oedema and perivascular lymphocytic infiltration. In some cases of long duration no other changes are seen, but in others the infiltrate becomes more dense and pleomorphic and small focal granulomas are formed, indistinguishable from sarcoidosis or Crohn's disease. Similar changes may be present in cervical lymph nodes [23–26]. In some cases, small granulomas occur in the lymphatic walls [27].

Clinical features. The condition affects the sexes equally. The earliest manifestations usually develop in childhood or adolescence but may be delayed until middle or old age. The earliest cutaneous manifestation is sudden diffuse or nodular swellings [10,11,28,29] involving the upper lip, the lower lip and one or both cheeks in decreasing order of frequency [8,26,30]. Labial swelling occurs in about 75% and facial swelling in 50% of patients [31]. Less commonly, the forehead, eyelids or one side of the scalp may be involved. The attacks are sometimes accompanied by fever and mild constitutional symptoms, including headache and even visual disturbance. At the first episode the oedema typically subsides completely in hours or days, but after recurrent attacks the swelling may persist, and slowly increases in degree (Fig. 69.80). It gradually becomes firmer and eventually acquires the consistency of firm rubber. After some years, the swelling may very slowly regress.

A fissured or scrotal tongue is seen in 20–40% of cases [11]. It is present from birth in some, which may indicate genetic susceptibility. There may be loss of sense of taste and decreased salivary gland secretion [26].

The regional lymph nodes are enlarged in 50% of cases [5] but not usually very greatly.

Facial palsy of the lower motor neurone type occurs in some 30% of cases. It may precede the attacks of oedema by months or years, but more commonly develops later. Although intermittent at first, the palsy may become permanent. It may be unilateral or bilateral, and partial or complete [26]. Other cranial nerves (olfactory, auditory, glossopharyngeal and hypoglossal) may occasionally be involved [32]. Involvement of the CNS has also been reported, but the significance of the resulting symptoms is easily overlooked as they are very variable, sometimes simulating disseminated sclerosis but often with a poorly defined association of psychotic and neurological features. Autonomic disturbances may occur.

Diagnosis. The essential feature of the syndrome is the granulomatous swelling of lip or face. In the early attacks clinical

Table 69.42 Macrocheilia: acute or chronic enlargement of one or both lips.

Acute	Chronic
Traumatic	Developmental
Infective	Familial idiopathic
Pyococcal	Double lip
Anthrax	Ascher's syndrome
Diphtheria	Lymphangioma
Primary syphilis	Haemangioma
Trichophytosis	Neurofibroma
Leishmaniasis	Mucopolysaccharidoses
Herpes simplex	Fucosidosis
Trichiniasis	Coffin–Siris syndrome
Angio-oedema	Acquired
Erythema multiforme	Post-traumatic
Actinic cheilitis	Post-infective on basis of developmental
Other forms of cheilitis	lymphatic defect
	Infective
	Tuberculosis
	Leprosy
	Rhinoscleroma
	Leishmaniasis
	Neoplastic
	Melkersson–Rosenthal syndrome
	Cheilitis glandularis
	Sarcoidosis
	Crohn's disease
	Orofacial granulomatosis

differentiation from angio-oedema may be impossible in the absence of either scrotal tongue or facial palsy. Persistence of the swelling between attacks should suggest the diagnosis, which can sometimes be confirmed by biopsy. However, the histological changes are not always conspicuous or specific.

In established cases, other causes of macrocheilia (Table 69.42) must be excluded. Ascher's syndrome associated with blepharochalasia is likely to cause confusion, although the swelling of the lip is caused by redundant salivary tissue and is present from childhood. Lymphoma is a rare differential diagnosis [33].

Treatment. Reactions to dietary components should be sought and possible antigens avoided. The injection of up to 10 mL triamcinolone (10 mg/L) into the lips after local analgesia may be effective [22,29,34–39]. The injections may have to be repeated every 4–6 months once a response plateau has been reached. This treatment has also been successfully combined with surgical reduction (cheiloplasty) [40–42]. The injections must be continued periodically after the surgery or there may be an exaggerated recurrence of the condition. Surgery alone is relatively unsuccessful [36,43].

Systemic corticosteroids are rarely indicated [44] since adverse effects may be a problem and not all respond [41,45]. Clofazimine appears to help the majority of patients [36,46–48], in a dose of 100 mg twice daily for 10 days, then twice weekly for 4 months. Metronidazole may also produce resolution in granulomatous cheilitis [37,49,50].

Other treatments which have occasionally been helpful include long-term penicillin, erythromycin, sulfasalazine (sulphasalazine), ketotifen or infliximab [51,52].

Exfoliative cheilitis

Synonyms
- Factitious cheilitis
- Le tic de lèvres

Exfoliative cheilitis is a chronic superficial inflammatory disorder of the vermilion borders of the lips characterized by persistent scaling (Figs 69.81 & 69.82). The diagnosis is now restricted to those few patients whose lesions cannot be attributed to other causes, such as contact sensitization or light (see actinic cheilitis, p. 69.123).

Aetiology. Many cases are now thought to be factitious, owing to repeated lip sucking, chewing or other manipulation of the lips [1–5]. There is no association with dermatological or systemic disease, although rare cases are seen in HIV infection. Some are infected with *Candida* species [6,7].

Fig. 69.81 Factitious cheilitis due to repeated lip sucking.

Fig. 69.82 Exfoliative cheilitis.

Clinical features. Most cases occur in girls or young women, and the majority have a personality disorder [8,9]. The process, which often starts in the middle of the lower lip and spreads to involve the whole of the lower or both lips, consists of scaling and crusting, more or less confined to the vermilion border, and persisting in varying severity for months or years. The patient often complains of irritation or burning, and can be observed frequently biting or sucking the lips. In some cases the condition appears to start with chapping or with atopic eczema, and develops into a habit tic.

In a large Russian series, almost half the cases had associated thyroid disease [10], but this observation has not been confirmed.

Diagnosis. Contact and active cheilitis must be carefully excluded. Chronic exfoliative cheilitis is readily contaminated by *Candida*. In such cases the clinical features are variable and may simulate carcinoma, LP or lupus erythematosus.

Treatment. Some cases resolve spontaneously [2,11] or with improved oral hygiene [12]. Reassurance and topical corticosteroids [1], or tacrolimus [4] may be helpful in some cases but others require psychotherapy, antidepressants or tranquillizers [3,5,11,13].

Plasma cell cheilitis

Synonym
- Plasma cell orificial mucositis

Plasma cell cheilitis is an idiopathic benign inflammatory condition, characterized by dense plasma cell infiltrates in the lips and other mucosae close to body orifices [1–5]. The condition has been reported (under a wide variety of names) to affect the penis, vulva, lips, buccal mucosa, palate, gingiva, tongue, epiglottis and larynx.

Plasma cell cheilitis is the counterpart of Zoon's plasma cell balanitis (see Chapter 71). It presents as circumscribed flat or elevated patches of erythema, usually on the lower lip in an elderly person. The cause is unknown, but it responds to the application of powerful topical corticosteroids such as clobetasol, or to the intradermal injection of triamcinolone [5,6], or to systemic griseofulvin [4,7].

A similar lesion, which tends to form a tumorous mass with a hyperkeratotic surface and needs to be differentiated from extramedullary plasmacytoma [8], has been called *plasma-acanthoma* [9,10].

Lupus erythematosus (see Chapter 51)

Involvement of the vermilion zone is quite common in both discoid erythematosus and SLE [1–3]. Discoid lupus can be premalignant [4–6], and should be treated vigorously with topical steroid ointments and sunscreens [7,8]. The cheilitis of SLE tends to be more severe, with erosions and haemorrhagic crusts.

Lupus erythematosus can be very difficult to distinguish from LP of the lips, both clinically and by histology (Fig. 69.83).

Lip fissure

A lip fissure may develop when a patient, typically a child, is mouth-breathing (Fig. 69.84). Otherwise the aetiology may be obscure, though sun, wind, cold weather and smoking are thought to predispose. A hereditary predisposition for weakness in the first branchial arch fusion seems to exist.

Lip fissures are common in Down's syndrome and the lips may also crack in this way if swollen, for example in cheilitis granulomatosa [1–6].

Clinical features. Most lip fissures are seen in males, typically median in the lower lip and chronic, causing discomfort and possibly bleeding from time to time. Contrary to the clinical impression that fissures are seen only in the lower lip, there is also a high prevalence in the upper lip.

Diagnosis. The diagnosis is clinical.

Treatment. Predisposing factors should be managed. Bland creams may help the lesion heal spontaneously. Otherwise, local applications of 1–2% silver nitrate, 0.5% balsam of Peru, salicylic acid and topical antimicrobials seem less effective than excision, preferably with a Z-plasty [7–10] or cryosurgery [11].

Lip ulcer due to calibre-persistent artery

A calibre-persistent artery is defined as an artery with a larger than normal diameter near a mucosal or external surface. When such arteries occur in the gut wall (Dieulafoy malformation) they may bleed, but in the lip they tend to cause chronic ulceration that can be mistaken for a squamous cancer. The ulcer is attributed to continual pulsation from the large artery running parallel to the surface, although the exact mechanism is obscure [1,2].

Ligation of the artery appears successful [3].

The terms 'breasts' and 'mammary glands' are often accepted as equivalent, but they are not strictly synonymous, because the breasts contain tissues (fat, vessels, nerves, etc.) other than the glandular elements.

In the evolutionary sense, the mammary glands are believed to be related to the apocrine sweat glands. They develop from ectodermal mammary ridges ('milk lines'). The classical view, derived from comparative anatomy, that the mammary ridges extend from the base of the upper limb bud to the base of the lower limb bud, is now questioned. It is considered that the mammary ridge extends only over the axillopectoral area [1].

The skin of the breast does not differ structurally from that of the neighbouring chest wall, but the skin of the nipple and areola is very highly specialized. There are individual and racial variations in the size, shape and colour of the nipple and areola. The periphery of the areola contains hair follicles, and the development of coarse terminal hairs in this site may be a cosmetic problem for some women.

The nipple is glabrous. Lactiferous ducts and sebaceous glands open only at its tip. Sensory nerve end organs are also confined to the tip of the nipple. The areola has clusters of large sebaceous glands [2] and the so-called tubercles of Montgomery. These elevations on the areola are produced by the glands of Montgomery [3]. Each of these is a combined sebaceous unit and lactiferous gland, with the lactiferous duct opening into the sebaceous duct close to the areola or occasionally directly onto the areola [1]. The glands of Montgomery are an integral part of the lactiferous apparatus, secreting milk during lactation.

The development of the breasts at puberty requires oestrogens and progesterone, and, in a more minor role, insulin, growth hormone, corticosteroids and prolactin. The adult breast consists of several lobes, each of which is drained by a ductal system ending in a lactiferous duct that opens at the nipple. Each lobe contains up to 40 lobules, and each lobule 10–100 alveoli, the basic secretory units [1].

The breasts enlarge during pregnancy, and the veins become prominent. The areolae also enlarge and become darker. This pigmentation decreases after parturition but does not fade completely.

Although most of the more serious diseases of the breast come within the province of the surgeon, the gynaecologist or the endocrinologist, there are some diseases that affect only the breast skin and are wholly the concern of the dermatologist, and others that may involve the skin and present difficult problems in differential diagnosis.

Supernumerary breasts or nipples; rudimentary nipples; hypomastia/amastia

Supernumerary breasts or nipples [1,2]

Supernumerary (accessory) breasts (polymastia) and the far more common supernumerary nipples (polythelia) usually develop along the course of the milk lines. Accessory glandular tissue most frequently occurs in the axillae [3], but rarely breast components occur in other sites [4–6].

Accessory breast tissue may consist of nipple, areola or glandular tissue singly, or in any combination (Fig. 70.1). The condition is very common in women, with an incidence of around 2–4%, although in the majority of cases the accessory nipple is insignificant, appearing as a small brown papule, usually on the chest wall, just below the breast. Much more rarely, the condition occurs in men, and in one case a fully developed breast developed on the posterior aspect of the thigh of a male [7]. A familial incidence in numerous cases suggests dominant inheritance (OMIM 163700).

Polythelia occurs as a component of a number of rare genodermatoses, and the Online Mendelian Inheritance in Man (OMIM) site is a useful reference source for these [www.ncbi.nlm.nih.gov/sites/entrez?db=OMIM].

A reported association between the presence of supernumerary nipples and urinary tract anomalies in children [8–10] prompted debate about whether to investigate the renal tract (by ultrasonography) in children with supernumerary nipples and no other obvious anomaly [11–13]. Some studies have not demonstrated an association [14,15], and specific mention has been made of the infrequency of such an association in black American infants [16,17]. However, there is evidence to indicate that the association is stronger in cases of familial polythelia, and it has been suggested that familial occurrence should prompt investigation of family members with renal ultrasonography [18,19].

The association of various mammary anomalies (supernumerary breasts; breast aplasia/hypoplasia/athelia; 'wide set' nipples) with anomalies of the kidneys/ urinary collecting system has been assessed by Urbani and Betti [20], who suggested a classification composed of four subsets: (i) pure 'mammo-renal syndromes' which occur as sporadic conditions and are characterized by the involvement of mammary tissue and kidney alone, without evidence of other developmental defects (e.g. Fleisher syndrome: 'wide set' nipples and bilateral renal hypoplasia); (ii) mammo-renal syndromes associated with chromosomal disorders (e.g. Turner phenotype: 'wide set' nipples and horseshoe kidney/bifid renal pelvis/unilateral renal hypoplasia); (iii) mammo-renal syndromes associated with dysmorphic genetic syndromes (e.g. Kallmann syndrome: breast hypoplasia and horseshoe kidney/unilateral renal agenesis); (iv) acro-mammo-renal syndromes, characterized by an additional coexistence of acral (limb) defects (e.g. Poland syndactyly: breast and nipple hypoplasia with unilateral renal hypoplasia).

An accessory nipple may be confused with a pigmented naevus. If functional breast tissue is present, enlargement at puberty or in pregnancy may be embarrassing or painful. Simple excision is advisable, as carcinoma may occur.

Rudimentary nipples

The association of absent or rudimentary nipples with abnormalities of the scalp and ears has been reported as an autosomal dominant trait [1–3]. Rudimentary nipples are also a feature of the ablepharon-macrostomia and Barber–Say syndromes, the other features of which include absence of the eyelids or ectropion, macrostomia, ear anomalies, redundant skin, abnormal genitalia, and hypertrichosis in the Barber–Say syndrome [4,5].

Hypomastia/amastia [1]

Very small breasts are fairly common in otherwise normal women, in whom they may cause considerable psychological distress. There is some evidence of an association between hypoplastic breasts (defined as a breast size of 200 ml or less) and mitral valve prolapse [1]. Becker's naevus is occasionally associated with unilateral breast hypoplasia [2,3], possibly as a result of high androgen-receptor activity on the affected side, and with areolar hypoplasia in males [4,5]. Unilateral symbrachydactyly and ipsilateral aplasia of the sternal head of the pectoralis major muscle, aplasia of the breast and absence of axillary hair are features of the Poland syndrome (OMIM 173800). Breast hypoplasia or aplasia is a feature of the *AREDYLD* (acrorenal field defect, ectodermal dysplasia, and lipoatrophic diabetes) syndrome (OMIM 207780).

Breast hypertrophy

Unusually large breasts may be problematic for a number of reasons, and postural abnormalities, backache and psychological disturbance may prompt referral to a plastic surgeon for a reduction mammoplasty. A dermatologist may be consulted about associated problems such as submammary intertrigo.

Breast enlargement in the setting of HIV infection is a relatively recently described phenomenon. It may be a component of the lipodystrophy syndrome (lipomastia), or there may be true gynaecomastia (see below). Breast ultrasonography allows these two states to be differentiated [1].

References

Gigantomastia (macromastia)

Gigantomastia is a condition in which the female breasts enlarge rapidly until they reach an enormous size. The overlying skin may become inflamed, oedematous and tender, and there may be striae or even severe ulceration associated with breast necrosis [1]. The condition may occur at puberty [2–4] or during pregnancy [1,5,6]. The aetiology is obscure, but a suggested cause is increased sensitivity of the breast tissue to normal levels of circulating hormones. The condition is occasionally familial [7,8]. Penicillamine therapy can also cause gigantomastia [9–11]; treatment with danazol was of benefit in one such case [11]. Bromocriptine may be of benefit in patients in whom the condition occurs during pregnancy, but in many patients, and certainly in pubertal cases, reduction mammoplasty or simple mastectomy is usually required [12].

Gynaecomastia [1–4]

Gynaecomastia, which may be defined as benign enlargement of the male breast caused by proliferation of the glandular

Table 70.1 Causes of gynaecomastia.

Physiological
Neonatal
Adolescent
Old age
Endocrine disorders
Hypogonadism, e.g. Klinefelter's
Excess oestrogen or chorionic gonadotrophin, e.g. from testicular tumour
Hyperthyroidism
Other disorders
Starvation, cachexia or refeeding
Renal disease and haemodialysis
Liver disease
Paraplegia
Erythroderma
HIV/AIDS
Idiopathic
Drugs (see Table 70.2)

components, can occur as an isolated defect or as a manifestation of a wide range of different pathological states in which it may be a valuable diagnostic sign. The multiplicity of syndromes associated with gynaecomastia reflects the complexity of the hormonal mechanisms concerned in breast enlargement. The patient complains of enlargement of the breast, which may be unilateral or bilateral, and is often tender.

Gynaecomastia can be distinguished from fatty enlargement of the breast in obesity (pseudogynaecomastia) by grasping the breast between thumb and forefinger and moving the digits up towards the nipple with the patient supine. In gynaecomastia a rubbery, mobile, disc-like mound will be felt beneath the areola.

Oestrogens stimulate and androgens inhibit development of breast tissue, and gynaecomastia occurs as a result of a disturbance of the ratio of free androgen to free oestrogen, with a relative increase in oestrogen levels. Peripheral conversion of androgens to oestrogen by aromatization contributes to oestrogen production. Local susceptibility of hormone receptors or local hormone conversion presumably play a role in unilateral gynaecomastia.

The histopathological changes [5] are related to the duration of gynaecomastia and not to its cause. At early stages, there are active proliferating ducts in a vascular fibroblastic stroma. Later, there is progressive fibrosis and hyalinization, and the number of ducts is reduced.

Gynaecomastia may be either physiological or pathological. Some of the causes are listed in Table 70.1.

Physiological gynaecomastia

There are three peaks in the age distribution of physiological gynaecomastia. It occurs in most male neonates due to transplacental passage of oestrogen from the mother. It is usually bilateral, but may be unilateral, and it regresses spontaneously. Some enlargement of the breast occurs at puberty in about 38% of normal boys [6]. The peak incidence is around the age of 14 years. It is unilateral in about 25% of cases. The degree of enlargement is usually slight, but may be sufficient to cause embarrassment and anxiety. Spontaneous regression usually takes place within a few months, but the enlargement occasionally persists for 2–3 years.

Gynaecomastia also appears to be frequent over the age of 65, increasing with age.

Gynaecomastia in endocrine disorders

Gynaecomastia occurs in a very wide range of endocrine disorders. Primary or secondary reduction of testicular androgen production is of special importance. Some tumours of the testis are associated with gynaecomastia, notably seminoma, Leydig-cell tumour, Sertoli-cell tumour and certain teratomas. Gynaecomastia occurs in most men with Klinefelter syndrome, and there is an increased risk of breast cancer in this syndrome [7,8], although other causes of gynaecomastia do not appear to be associated with an increased risk of cancer [1]. In other endocrine disorders, gynaecomastia is less common, but it may occur in association with tumours or hyperplasia of the adrenal gland, pituitary tumours and hyperthyroidism [9]. It may be an accompaniment of the use of human growth hormone as antiageing therapy [10].

Gynaecomastia in other disorders

Gynaecomastia may occur during starvation or on resumption of a more adequate diet after prolonged starvation [11]. Chronic renal failure and haemodialysis may also be associated with gynaecomastia [12–14], although the incidence of gynaecomastia in dialysis patients has decreased in recent years. Hepatic cirrhosis is usually listed as a cause of gynaecomastia, but one study found that palpable gynaecomastia was not a uniform feature in advanced cirrhosis, and that its prevalence was similar to that in a non-obese, non-cirrhotic, age-matched control population [15]. Gynaecomastia occasionally occurs in association with erythroderma [16]. Gynaecomastia in HIV-infected males is multifactorial, and contributory factors include hypogonadism, chronic hepatitis C virus coinfection and hyperprolactinaemia [17], as well as the influence of antiretroviral therapy (see below).

Drug-induced gynaecomastia [18–32]

Some of the drugs that may produce gynaecomastia are listed in Table 70.2. They produce their effect by different mechanisms, for example spironolactone and cimetidine are antiandrogens, and neuroleptic drugs produce hyperprolactinaemia. Testosterone might act by peripheral aromatization to oestrogens. Gynaecomastia is a common accompaniment of hormone therapy for prostate cancer [19] (Fig. 70.2).

True gynaecomastia, as opposed to breast hypertrophy secondary to lipodystrophy syndrome (lipomastia), can occur with all currently available classes of antiretroviral agents. The mechanism responsible is unclear, but suggestions include a direct effect of highly active antiretroviral therapy (HAART) mimicking the action of oestrogen or progesterone on breast tissue, an elevation of the oestrogen : androgen ratio, or improvement in the T-helper cytokine response after starting HAART [17,32,33]—cytokines produced during the immune restoration process have an effect on breast tissue, resulting in gynaecomastia; once immune restoration has occurred, the cytokine levels fall, and the gynaecomastia resolves spontaneously.

Table 70.2 Drugs that produce gynaecomastia.

Amiloride
Anabolic steroids
Antiandrogens, e.g. cyproterone acetate, flutamide
Amiodarone
Amphetamines
Androgens
Busulphan
Cannabis
Captopril
Chorionic gonadotrophin
Cimetidine
Cyproterone acetate
Cytotoxic agents
Diazepam
Diethylpropion
Digitalis
Domperidone
Finasteride
Highly active antiretroviral therapy (HAART)
Isoniazid
Ketoconazole
Melatonin
Methyldopa
Metoclopramide
Methotrexate
Nifedipine
Nitrosoureas
Oestrogens
Omeprazole
Penicillamine
Phenothiazines
Phenytoin
Reserpine
Spironolactone
Tricyclic antidepressants
Vincristine

Fig. 70.2 Gynaecomastia in a man taking stilboestrol for carcinoma of the prostate.

Finasteride treatment of male androgenic alopecia may be associated with gynaecomastia [34,35], and it has also been recorded in individuals who have used oestrogen-containing hair preparations [36,37] and in a men's hairdresser who had massaged the scalps of his balding customers with an oestrogen-containing lotion [38].

Gynaecomastia in three prepubertal boys was attributed to topical application of lavender and tea tree oils, both of which were shown to have oestrogenic and antiandrogenic activities [39].

Management of gynaecomastia [3,40]**.** In the majority of patients, history and examination will suggest the likely cause of the gynaecomastia. Careful examination for underlying disease and a full drug history are required, particularly if the gynaecomastia is symptomatic, progressive or of recent onset in an adult, but it should be remembered that a large proportion of otherwise normal men have some slight gynaecomastia. In unilateral disease, particularly in older men, breast cancer should be excluded. Spontaneous resolution occurs in many 'physiological' cases, or following cessation of the causative drug when it is drug related. For cases with considerable breast discomfort, or if the condition is severe enough to cause embarrassment, treatment with tamoxifen [41], clomiphene or danazol has been employed. The surgical approach of choice is excision and liposuction via a periareolar incision.

Black galactorrhoea

Galactorrhoea is sometimes caused by drugs such as phenothiazines. In one patient taking perphenazine, the droplets of milk were stained black, due to the concomitant administration of minocycline for acne [1]. The pigment that produces the black discoloration of breast milk in women taking minocycline is thought to be due to an iron chelate of minocycline within macrophages [2].

Morphoea [1]

If morphoea occurs on the chest wall prior to or during breast development, severe hypoplasia of the breast may result [2,3] (Fig. 70.3a,b). A feature of generalized morphoea is sparing of the nipples and areolae. Christianson *et al*. noted that the skin was pinched or squeezed like 'rising biscuits on a platter' [4] (Fig. 70.4a,b). Localized morphoea at the site of radiotherapy for breast cancer [5–10] is a well-documented entity; distant lesions have been reported in addition to involvement of the irradiated skin [11].

Silicone breast implants and autoimmune disease

In the early 1990s, a major controversy arose about a possible relationship between silicone gel breast implants and subsequent development of connective tissue disease. Although the most common specific disease was scleroderma, many cases had a non-specific syndrome. Because of safety concerns, the US Food and Drug Administration imposed a moratorium on the use of such implants in 1992. The UK Medical Devices Directorate reviewed the scientific evidence relating to connective tissue disease and silicone gel breast implants and, in April 1992 presented a report to an independent Expert Advisory Group. The Group concluded that, on the basis of all available data, there was no evidence of an increased incidence of connective tissue disease associated with silicone gel breast implants [1]. An Independent Advisory Committee in Canada concluded that there was an absence of evidence establishing that women with silicone gel implants were more likely than those without such implants to have autoimmune disorders [2]. The issue provoked intense medicolegal activity, with approximately 400 000 women involved in a class action lawsuit against implant manufacturers in 1997, and many others elected to litigate individually [3].

Although a retrospective cohort study of 395 542 female health professionals, involving self-reported data, suggested a small increased risk of connective tissue diseases among women with breast implants [4], numerous controlled epidemiological studies did not demonstrate any statistically significant association between a recognized connective tissue disease and silicone breast implants [5], and three meta-analyses of the data failed to show an association [6–8]. However, the controversy continued [9,10]. Further studies showed no evidence of an association [11,12], and the UK Independent Review Group on Silicone Gel Breast Implants concluded that these implants were not associated with any greater health risk than other surgical implants, and if there was any risk of connective tissue disease it was too small to be quantified [13]. At about the same time as this report was issued, a settlement of the medicolegal issues was proposed [14].

A more recent, long-term study from Denmark adds to the significant body of data against any link between silicone breast implants and autoimmune disease [15]. In 2006, the US Food and Drug Administration approved the use of silicone gel-filled implants, 14 years after they were taken off the market [16].

Adnexal polyp of neonatal skin [1,2]

This small, usually solitary, tumour, occurs mainly on the areola of the neonate. The lesion is firm and pink but becomes dry and brown and falls off within a few days of birth. Histologically it contains hair follicles, eccrine glands and vestigial sebaceous glands. A survey in Tokyo showed that the condition occurred in 4% of 3257 newborn infants.

Inverted nipple

Inverted nipple is common, affecting up to 10% of adult females [1], and potentially leading to functional problems with breast-feeding and psychological distress. There are three main causes: congenital, periductal inflammation and tumour infiltration. It is also important to remember that in postmenopausal women it may result from the involutional process of periductal fibrosis. In most cases the abnormality is congenital, and the fault lies in failure of the normal eversion process [2]. The lactiferous ducts are shortened and there is a reduction in the amount of dense connective tissue that is present beneath a normal nipple [3]. The abnormality is usually bilateral, but may affect only one nipple.

Many women with inverted nipples are able to breastfeed without difficulty, probably because the nipple itself plays a relatively small part in the anatomical aspects of suckling, as the infant makes a 'teat' from the surrounding breast tissue as well as the nipple [2].

If inverted nipples pose a cosmetic problem, surgical correction may be considered. Numerous techniques have been described, suggesting that none is ideal. Procedures that involve division of the lactiferous ducts are probably more effective, but breast function is destroyed. More recent suggestions for treatment involve body-piercing devices [4–6].

The duct ectasia/periductal mastitis complex [1]

A number of pathological processes contribute to the clinical features of this complex. These features include nipple discharge, subareolar abscess, mammary duct fistula and nipple retraction. It is a rare occurrence in males, but has been described in association with HIV infection [2].

Hyperkeratosis of the nipple/areola

On the basis of reported cases, hyperkeratosis of the nipple and areola is considered to be a rare condition. The classical Levy–Franckel classification includes three categories [1,2]:

1 as an extension of an epidermal naevus (in which involvement tends to be unilateral and both sexes may be affected);
2 in association with ichthyosis (in which involvement is bilateral and both sexes are affected);
3 a naevoid type, usually bilateral, and occurring predominantly in women in the second or third decade of life.

Pérez-Izquierdo *et al*. [3] suggested an alternative classification of two types:

1 idiopathic or naevoid (unilateral or bilateral);
2 secondary, divided into:
   i local (unilateral or bilateral): acanthosis nigricans, verrucous naevus, or seborrhoeic keratosis
   ii systemic (bilateral): dermatosis, ichthyosis, malignant lymphomas, Darier's disease, chronic eczemas
   iii drug related: diethylstilboestrol, spironolactone.

Another classification proposed by Mehanna *et al*. [4] includes a suggestion that the term 'naevoid' should be replaced by 'idiopathic'.

Whether described as naevoid or idiopathic, there is a distinct entity of verrucous thickening and brownish discolouration of the nipples and areolae which occurs predominantly in women in the second or third decade of life [5], in the absence of associated skin disease. It is usually bilateral, although unilateral involvement has been described [6,7], and it occasionally occurs in men [8]. Histology shows hyperkeratosis, filiform acanthosis and papillomatosis, and keratin plugging.

Hyperkeratosis of the nipples may also occur in association with ichthyosis, ichthyosiform erythroderma, acanthosis nigricans, Darier's disease (in association with other skin lesions, but also described as an isolated presenting phenomenon) [9], T-cell lymphoma [10,11], and chronic graft-versus-host disease [12]. It has also been described in men with carcinoma of the prostate treated with oestrogens [13,14].

An appearance resembling verrucous naevi around both areolae has been described as a manifestation of inadequate hygiene [15].

Suggested treatments for naevoid hyperkeratosis include topical retinoic acid [3], topical calcipotriol [16], cryotherapy [6], carbon dioxide laser [17], shave excision [18], tangential excision using a radiofrequency surgical unit [19], and removal of the areola and reconstruction with a skin graft [20]. Calcipotriol has also been effective in treating nipple hyperkeratosis associated with acanthosis nigricans [21].

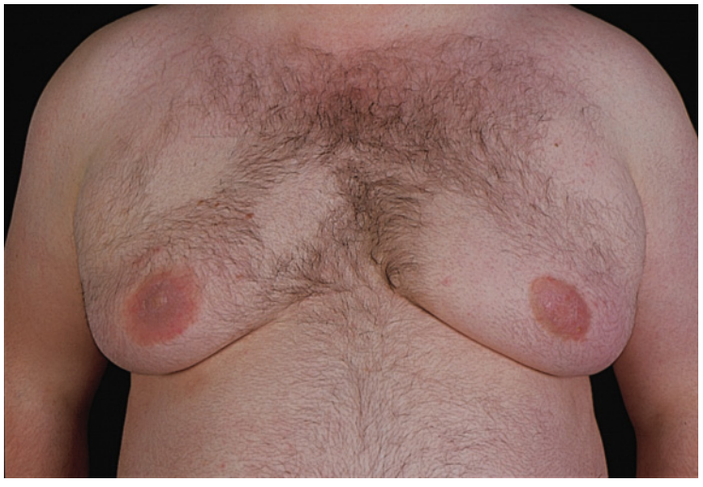
Eczema of the nipple/areola

Although eczema of the nipple and areola occurs mainly in women (Fig. 70.5a,b), it is an occasional occurrence in men (Fig. 70.6a,b); it may be unilateral or bilateral [1,2]. Often no cause can be



(a)

(b)

Fig. 70.5 (a and b) Severe bilateral nipple eczema in a young woman.

(a)

(b)

Fig. 70.6 (a and b) Bilateral nipple eczema in a man.

established, although there is an association with atopy [3,4] (for which it is a minor diagnostic criterion as defined by Rajka and Hanifin), and it may occur during breast feeding [5].

Contact dermatitis is a possibility, and allergic contact dermatitis of the nipples has been reported in a breastfeeding woman using a beeswax nipple protector [6], and two others applying Roman chamomile ointment [7]. Irritation from friction must also be considered (see jogger's and cyclist's nipple), and unilateral nipple dermatitis in three women with large asymmetrical breasts was attributed to friction between the larger breast and the seam of the brassière cup [8].

Treatment of nipple eczema is with mild-to-moderate potency topical steroids.

The intermittent course, more severe itching, indefinite margin and lack of distortion of the nipple help to distinguish eczema from Paget's disease (Chapter 53, Fig. 70.7). Erosive adenomatosis of the nipple (see p. 70.12) may have an eczematous appearance, and a case of clear cell acanthoma presenting as nipple eczema has been described [9]. If the diagnosis is at all doubtful, biopsy should be performed, particularly if there has been no response to topical steroids.

'Cracked' nipples in lactation

Many women experience discomfort, irritation and fissuring of the nipples early in the puerperium when they are trying to establish breastfeeding. Anatomical features, such as relatively flat nipples, contribute to the development of this problem. Mastitis and deep abscesses may occur due to penetration of the broken skin by pyogenic bacteria. The problem is, in essence, one of friction and irritancy resulting from vigorous suckling, and can be eased considerably by the judicious use of gentle cleansing and emollients such as white soft paraffin.

Jogger's and cyclist's nipples [1,2]

Long-distance runners of either sex may suffer from irritation of the nipples caused by prolonged friction against a shirt. The problem is more pronounced in women who do not wear a brassière. The condition is self-healing and prevention includes the application of petrolatum or powder to the nipples to reduce fric-

tion, and the use of a sports brassière. Tomi *et al*. [3] reported three refractory cases who responded to treatment with topical tacrolimus.

Cyclists may suffer from cold injury to the nipple as evaporation of perspiration and wind chill combine to lower the temperature of the nipple on a cold day [4]. Pain, which may last for several days, soreness and tenderness are the result. Cycling jackets made of wind-resistant fabric offer a solution.

Guitar nipple

Musical instruments may be responsible for a number of dermatoses [1], and Curtis [2] described traumatic swelling at the base of the nipple in three girls, aged between 8 and 10, who were learning to play classical guitar. Pressure from the edge of the soundbox was responsible.

Nipple piercings

Body piercing has been practised in some societies since antiquity, but it has usually been confined to the ears and nose. In recent years it has become 'fashionable' in Western countries, and devotees indulge not only in piercings on the face and ears, but also the genitalia and nipples [1]. Nipple piercings may cause problems due either to trauma or infection [2,3] or to the development of allergy to the metal. Lactiferous ducts may be damaged when the nipple is pierced, but this does not appear to lead to problems with breastfeeding [4].

Tassel ornaments suspended from the breasts have been popular in some cultures, particularly in the Middle East, for many generations. Some dancers have their nipples pierced to accommodate a ring from which ornaments are suspended and this can cause breast duct ectasia [5].

Artefactual breast disease

There are relatively few reports of artefactual breast disease, but the features of reported cases are as varied and bizarre as factitial lesions elsewhere on the body [1–6]. Pyoderma gangrenosum of the breast has occasionally been misdiagnosed as artefactual disease, leading to delay in introducing treatment.

Vasculitis of the breast

Vasculitis affecting breast tissue is rare. It may occur as part of a systemic vasculitis, or as localized disease. There are several reported cases of polyarteritis nodosa presenting as tender breast nodules [1,2], and the simultaneous occurrence of polyarteritis nodosa and post-irradiation morphoea has been reported [3]. Breast lesions may also be a feature of Wegener's granulomatosis, sometimes as an initial manifestation [4–6].

Lupus panniculitis [1–4]

Synonyms
- Lupus erythematosus profundus
- Lupus mastitis

Lupus panniculitis can result in breast nodules which may be mistaken for carcinoma [5]. Coarse calcification may be seen on mammography [6]. Lesions are usually chronic and disfiguring. The treatment of choice is antimalarial therapy.

Sarcoidosis of the breast [1–6]

Although involvement of the breast with sarcoidosis is rare, it is important to be aware of its occurrence, as it mimics breast carcinoma. It can present as solitary or multiple, unilateral or bilateral subcutaneous masses, which may be associated with other manifestations of the disease or occur as an isolated phenomenon. Lesions may be fixed or mobile, tender or non-tender, and with or without palpable axillary lymphadenopathy.

Erosive adenomatosis of the nipple [1–5]

Synonyms
- Benign papillomatosis of the nipple
- Florid papillomatosis of the nipple ducts
- Papillary adenoma of the nipple
- Subareolar duct papillomatosis
- Superficial papillary adenomatosis

Definition. A complex, benign tumour arising from the lactiferous ducts of the nipple.

Incidence. This is an uncommon tumour, which occurs mainly in middle-aged women, but it can occur at any age [6], and occasionally in males [7–9]. In one case, the lesion developed 10 years after treatment for carcinoma of the prostate by bilateral orchidectomy and diethylstilbestrol [10].

Pathology [1,4,11–14]**.** The lesion consists of tubules, with an inner layer of columnar cells and an outer layer of cuboidal myoepithelial cells. A major feature is the presence of superficial keratocysts lined by both squamous and columnar epithelium, and filled with keratin flakes and an eosinophilic material, apparently secreted by the columnar cells. The cysts seem to reproduce the terminal portion of the nipple duct system. Within some of the superficial cysts or ducts, foreign-body giant cells may be seen. Some degree of intraluminal growth (intraductal papillomatosis) is present in many cases. This ranges from small papillary epithelial tufts to almost complete occlusion of the lumina by solid epithelial plugs, and there may be evidence of apocrine decapitation secretion. The overlying epidermis may show acanthosis and hyperkeratosis.

The major histopathological diagnostic pitfall is confusing erosive adenomatosis with sweat gland tumours, and as it may also be difficult to differentiate from papillary breast carcinoma immunohistological techniques are of value in demonstrating the layer of myoepithelial cells [12,13].

Clinical features. These are variable. The condition may start with a blood-stained or serous discharge, and the nipple may be enlarged, eroded, crusted or eczematous. There may be a small nodule on the nipple, and the symptoms may be worse in the premenstrual phase. The condition is commonly misdiagnosed as Paget's disease or eczema. It is usually unilateral, but bilateral involvement has been reported [15,16], and it has been described in an accessory nipple [17].

Treatment. Excision is curative—either simple local excision, or partial or complete resection of the nipple, depending on the size of the tumour [18]. There are reports of successful treatment by cryosurgery [19] and Mohs' surgery [20].

Breast telangiectasia

White and Jeffes [1] described a 77-year-old man with bilateral patches of perfectly circular, symmetrical telangiectasia of the areolae. The condition had been present for as long as he could remember, with no associated abnormalities.

Blue areolae were one feature of a familial disorder named 'hereditary acrolabial telangiectasia' [2], and Schlappner and Shelley reported a 35-year-old woman with symmetrical essential telangiectasis of the breasts, recurrent aphthous stomatitis and hypersplenism [3].

Mammary duct fistula [1]

Synonym
- Recurrent subareolar abscess

This condition typically occurs in a young adult woman who has a history of recurrent abscesses in a breast that has been treated by surgical drainage or has discharged spontaneously. There is typically partial inversion of the nipple and a scar or scars at the edge of the areola.

The condition is treated by passing a probe into the opening of the discharging sinus, along the track of the fistula and out of the nipple. The fistula is then laid open (fistulotomy) and left to heal by granulation, or the whole tract is excised (fistulectomy) and the wound allowed to granulate.

Breast abscess [1]

Breast abscesses may be classified as lactational (occurring in the puerperium) and non-lactational. The majority of lactational abscesses are caused by *Staphylococcus aureus*, and present as a painful, red, swollen breast, associated with fever.

Non-lactational abscesses include subareolar abscesses, which are seen mainly in women in their reproductive years in association with the duct ectasia/periductal mastitis complex, and peripheral abscesses, which occur as typical inflammatory breast abscesses in postmenopausal women. The former is associated with a mixed bacterial spectrum, and the latter with *Staph. aureus*. Lactational abscesses are now uncommon in comparison with the frequency of non-lactational lesions [2].

Breast cancer (Fig. 70.8)

This common and important condition lies in the province of the surgeon rather than the dermatologist, but all physicians have a duty to detect and diagnose early breast cancer, which can sometimes be discovered on routine examination. Inspection and palpation of the breasts should be included in any full examination. The breasts should be inspected with the arms by the side, above the head, and pressing on the hips, because in some cases these manoeuvres will demonstrate a visible mass, a change in contour of the breast, or early retraction or dimpling of the skin caused by a breast cancer. The dermatologist should also remember that redness or oedema of the breast skin may be due to underlying cancer. Breast cancer can also cause flattening, broadening or inversion of the nipple. It is important that all four

Fig. 70.8 Advanced carcinoma of the breast.

quadrants of the breast, including the axillary tail and axillary lymph nodes, should be palpated.

The dermatologist should examine the breasts carefully in all patients presenting with skin disease that may be associated with systemic malignancy, for example acanthosis nigricans or dermatomyositis.

The term *peau d'orange* is applied to dimpled oedematous or indurated skin resembling the surface of an orange. The finding of peau d'orange should lead to an intensive search for underlying carcinoma. Rarely, it occurs in the absence of any clinically palpable tumour. It has also been reported as a complication of anasarca, nephrotic syndrome and cardiac failure [1].

Breast cancer frequently involves the skin, and there are several different clinicopathological types of cutaneous involvement [2]. These include Paget's disease of the nipple, inflammatory metastatic carcinoma (carcinoma erysipeloides), carcinoma en cuirasse, telangiectatic metastatic carcinoma, nodular metastatic carcinoma, alopecia neoplastica, carcinoma of the inframammary crease and metastatic mammary carcinoma of the eyelid. Carcinoma metastatic to the eyelids is a rare phenomenon, and breast carcinoma is responsible for a sizeable proportion of these cases. Involvement may be unilateral, with the right eyelids affected more frequently than the left [3], or bilateral [4–7]. In many of the reported cases the histology has shown prominent histiocytoid features [2].

Pigmented primary carcinoma of the breast is rare, and may mimic malignant melanoma clinically and histologically [8,9]. Metastatic melanoma may be responsible for inflammatory changes in breast skin [10].

Other conditions that may mimic breast carcinoma include postsurgical lymphoedema [11] and sarcoidosis [12].

Virgili *et al*. [13] described four patients with what were thought to represent cutaneous tumour-related granulomatous lesions following mastectomy for carcinoma of the breast. The lesions developed on the arm on the same side as the previous mastectomy.

Post-radiotherapy telangiectasia can be a considerable cosmetic problem, and treatment with the hyfrecator [14] or pulsed dye laser [15] may be of significant benefit.

Breast cancer in men

Breast cancer in men is relatively rare, accounting for around 0.2% of all cancers in men in the USA and less than 1% of all cases of breast cancer [1].

Risk factors include conditions associated with reduced testicular function, excess oestrogen exposure, Klinefelter's syndrome [2] and a family history of breast carcinoma. Case–control studies indicate that the disease is commoner in black men and in those who have never married [3].

The mean age of presentation is 60–65 years, and is approximately 5 years older than that for breast carcinoma in women.

As in women, the clinical features include a breast mass, which is typically subareolar, nipple inversion, and nipple discharge [4] (Fig. 70.9). Infiltrating ductal carcinoma is the predominant histological type. Paget's disease may be the presenting feature [5,6].

Basal cell carcinoma of the nipple/areola [1–6]

This is a very rare lesion. It can occur in either men or women, usually in old age. It usually presents as a red, eczema-like patch of the nipple or areola and runs a long indolent course. Biopsy is essential to differentiate it from Paget's disease.

Malignant melanoma of the nipple/areola

Malignant melanoma of the nipple/areola is rare [1]. It may mimic Paget's disease [2], and a rare pigmented variety of Paget's disease mimics malignant melanoma clinically, histopathologically and dermoscopically [3].

Paget's disease, which is a marker of an underlying breast carcinoma, is discussed in Chapter 53.

Fig. 70.10 Hair sinuses in a sheep-shearer. (Courtesy of Dr W. Bowers, Treliske Hospital, Truro, UK.)

Hair sinus of the breast

Hair sinus of the periareolar area of the breast has been observed in women engaged in sheep shearing (roustabout's breast) and hairdressing [1] (Fig. 70.10), and in canine beauticians whose work leaves them covered in dog hairs [2]. The lesions are similar to the interdigital pilonidal sinuses that may occur in barbers and dog groomers [3]. The histology shows a granulomatous reaction. Repeated breast abscesses in female sheep shearers may provoke concern about the ability to breastfeed or even lead to women contemplating mastectomy. This problem prompted the manufacture, in New Zealand, of a protective brassière, the Baa Bra [4].

Seborrhoeic warts

Synonym
- Basal cell papillomas (Chapter 52)

These are particularly common in the submammary creases in middle-aged or elderly women, often in association with intertrigo (Fig. 70.11). Seborrhoeic warts may also occur as sharply demarcated papules or plaques on the nipple and areola [1].

Reference

Fig. 70.11 Submammary seborrhoeic warts.

Mondor's disease (Fig. 70.12)

Synonym
- Sclerosing periphlebitis of the chest wall

Mondor's disease, a condition described in 1939 by H. Mondor [1], is usually regarded as a superficial obliterative phlebitis affecting the thoracoepigastric, lateral thoracic or superior epigastric vein. It occurs mainly between the ages of 30 and 60 years and affects women much more frequently than men [2,3]. Risk factors cited for the development of the condition include large pendulous breasts, strenuous physical activity [4], direct trauma, breast surgery [5,6] and sentinel node biopsy [7], and infection near the affected vessels. Breast cancer is an occasional cause [8] and mammography is recommended even when no mass is palpable [9–11]. Mondor's disease has characteristic mammographic and sonographic features [10,11]. It has also been described in association with metastatic axillary adenopathy 2 years after radical mastectomy for breast carcinoma [12], and in a patient with metastatic lung cancer in the breast [13]. In a case of recurrent Mondor's disease of the thoracoepigastric vein, resolution occurred after excision of a lipoma that was in close proximity to the vein [14]. It is a rare occurrence in pregnancy [15,16]. Other causes include intravenous drug abuse, following use of the breasts as injection sites [17], jellyfish stings [18], protein S deficiency [19], electrocution [20] and a lupus erythematosus-like syndrome probably induced by procainamide [21]. However, often no cause is apparent. Rarely, the condition is bilateral [21], and in one such case potential aetiological factors included breast surgery, the use of oral contraceptives, hereditary protein C deficiency and anticardiolipin antibodies [22].

There may be some tenderness or discomfort, but there are often no symptoms until the patient discovers a red linear cord running from the lateral margin of the breast, crossing the costal margin and extending to the abdominal wall. The cord is 2–3 mm in diameter and is attached to the skin but not to the deep fascia. It is usually only a few centimetres long, but may extend to 30–40 cm.

Fig. 70.12 Mondor's disease of the chest wall. (Courtesy of Professor A.Y. Finlay, University of Wales College of Medicine, Cardiff, UK.)

The symptoms subside in a few weeks and there are no known complications.

Other conditions that may involve the breast

- *Vitiligo* sometimes shows a striking symmetrical involvement of the breasts.
- *Psoriasis* may be provoked by the trauma of suckling, and flexural psoriasis can be problematic in the submammary region.
- *Pityriasis rosea* commonly presents with a herald patch on the breast, and has been reported as a localized eruption on one breast [1].
- *Cutaneous larva migrans* may occur on the breast when women have lain 'topless' on a tropical beach in the prone position.
- *Neurofibromas* have a predilection for the nipple/areola [2] (Fig. 70.13).
- *Scabies* often produces papules around the nipple, which may persist after treatment.
- *Granular parakeratosis* may occur in the submammary regions [3,4].
- *Lichen sclerosus* confined to the areola has been reported [5].
- *Fox–Fordyce disease* (Chapter 44) may produce intensely irritable papules on the areolae.
- *Carney complex* (myxomas, spotty pigmentation and endocrine overactivity) is associated with breast myxoid fibroadenomas and ductal adenomas [6,7].
- *Cowden's syndrome* (multiple hamartoma syndrome) is an autosomal dominant disorder associated with hamartomas of various tissues and an increased risk of breast cancer, usually ductal carcinoma [8].
- *Hidradenitis suppurativa* of the breasts tends to affect the inter- and inframammary folds [9].
- *Diffuse dermal angiomatosis* (a reactive angiomatosis [10]), may involve the breasts and response to treatment with isotretinoin has been reported by McLaughlin *et al*. [11]. In another case reported by Yang *et al*. [12] the condition was associated with an occluded subclavian artery, and resolved when a stent was inserted in this.
- *Mucinosis of the areolae* has been described as a presenting feature of mycosis fungoides [13].

Fig. 70.13 Neurofibromatosis, showing the predilection of this condition for the nipple/areola.

Introduction

A number of common skin diseases affect the umbilical, perianal, genital and genitocrural skin only incidentally, and may present in these areas with unusual features. These will be dealt with briefly or by cross-reference to their full description elsewhere. However, those conditions that are entirely or predominantly confined to these regions are discussed in detail.

General approach to the patient and the problem

Clinical assessment begins with the history and examination. Patients with anogenital symptoms may be embarrassed and present late, or present to specialties (urology, gynaecology, general or colorectal surgery, genitourinary medicine) where training and experience are not focused on dermatological diagnosis and management.

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

Itching, rashes and tumours are the major components of general dermatology and the anogenital area is not spared. The pruritic diseases that may affect the anogenital region are listed in Tables 71.1–71.3. Itch occurring in the absence of specific diagnostic skin lesions is not usually confined to the anogenital area, but if so it should not be labelled as psychogenic until all possible causes have been excluded. The intensity with which itch can be perceived in the anogenital area may be a result of the vagaries of cortical representation afforded the region in the sensorium as well as anxiety about exposure to sexually transmitted disease and anogenital cleanliness.

The symptomatology of anogenital dermatology is more extensive than the standard symptomatic presentation of skin disease. This obliges the clinician to elicit symptoms resulting from sexual dysfunction (e.g. soreness, pain, bleeding or tearing on intercourse) and the components of sexual function (erection, lubrication, libido, ejaculation, orgasm, fertility), urinary dysfunction (frequency, discharge, dysuria) or colorectal symptomatology (pain, bleeding, discharge).

History taking must involve attention to the sexual history (orientation, marital status, last sexual activity—when; how (vaginal, oral, anal); contraception), regular partner(s), partner

symptomatology, and drug history (topical and systemic, prescribed and over-the-counter). The personal and family history of atopy, psoriasis and seborrhoeic dermatitis is often relevant. Smoking habits should be documented; smoking is a risk factor for anogenital cancer.

Complete examination is mandatory because common diagnoses will be reached with the assistance of important signs at extragenital sites. Often the patient will not have had his/her genitalia or perineum examined. The practice of anogenital dermatology demands careful inspection and often requires internal examination and urinalysis. Drawings are made and photographs obtained. Signs are described using conventional and specific terminology (e.g. posthitis, phimosis).

Intertrigo describes any dermatosis occurring in skinfolds; frictional abrasion and a degree of epithelial loss may result in erosion that renders the site especially susceptible to secondary infection (e.g. with *Candida*). Causes are listed in Tables 71.4 and 71.5.

Pigmentary change is common. Causes of anogenital hypopigmentation and leukoderma include striae, vitiligo, lichen sclerosus, viral warts, leukoplakia and post-inflammatory changes (Table 71.6). Rarer causes include *Candida*, extramammary Paget's disease, mycosis fungoides and melanoma. Common causes of anogenital hyperpigmentation include tattoos, purpura, lentigines, naevi, pseudoacanthosis nigricans and post-inflammatory changes (Table 71.7). Rarer or potential causes include Addison's disease, Nelson's syndrome, genital melanosis, Laugier–Hunziker syndrome [3], Peutz–Jeghers syndrome [4,5], LAMB syndrome (lentigines, atrial myxoma, mucocutaneous myxoma, blue naevi) [6,7], LEOPARD syndrome, Ruvalcaba–Myhre–Smith syndrome [8,9], acanthosis nigricans, eruptive melanotic macules and papules associated with internal adenocarcinoma [10], acral lentiginous melanoma, drugs and metals. Both post-inflammatory hypo- and

hyperpigmentation are possible after acute and chronic inflammation from diverse causes; both may be more pronounced in ethnically darker skin. Lichen planus, fixed drug eruptions and recurrent herpes simplex are the common causes of post-inflammatory hyperpigmentation. Genital trauma from a zipper injury can lead to macular pseudolentiginous lesions on the glans and shaft of the penis.

A mucosal white patch or plaque is sometimes called leukoplakia (Table 71.8). This is not a diagnostic term, and it is unhelpful as it evokes connotations from oral medicine of premalignancy or even frank neoplasia.

Anogenital ulceration requires meticulous elucidation. The principal causes are benign aphthae, sexually transmitted and non-sexually transmitted infection, cancer and artefact. Tables 71.9 and 71.10 list all the causes. Several causes can co-present, especially in HIV/AIDS.

Commonly required investigations include microbiology or virology of a swab or smear, scrapings for fungal microscopy and culture, scrapings for mite identification, skin biopsy, Wood's light to demonstrate vitiligo and erythrasma, and blood tests (e.g. antistreptolysin O titre (ASOT), HLA B27, HIV). Investigations pertinent to the evaluation of sexually transmitted diseases are not

discussed further, but it bears re-emphasis that if a diagnosis of a potentially sexually transmitted disease is reached (warts, molluscum contagiosum, herpes simplex, scabies, pediculosis) then the patient should be referred for a genitourinary opinion and advised to inform their partner(s) so that they may be screened also.

The opinion of another specialist may be necessary and should be sought as dictated by the urological, gynaecological, colorectal or genitourinary situation. Combined clinics are the ideal.

Genitocrural dermatology

Introduction

The genitocrural folds represent a region of the body that is particularly prone to intertrigo and flexural forms of common dermatoses, probably because of koebnerization. Moisture and friction also lead to maceration and fissuring, and secondary infections readily supervene. Vegetating reactions can prove resistant to treatment. Itch may be prominent in psoriasis, infections and infestations of the area. Crab louse and *Oxyuris* infestation must be excluded as primary causes of rash. Lichenification occurs readily.

Inflammatory dermatoses

Intertrigo

Intertrigo is a generic name for an inflammatory dermatosis involving the body folds, notably those of the submammary and genitocrural regions. There may be no clear distinction between constitutional and infective causes (listed in Tables 71.4 & 71.5). Physical factors such as obesity, sweating, friction, incontinence and faecal soiling may cause erythema or fissuring, and render the skin vulnerable to the effects of other agents. Initially, it is marked by soreness or slight itching, and a superficial mild erythema of the apposed surfaces. Secondary infection occurs rapidly,

and the condition is then perpetuated as an infective dermatitis. In eczematous subjects this will take on the physical characteristics of eczema; in others, the infection may progress to crusting, pustular or vegetating lesions. The organisms concerned are *Staphylococcus aureus*, rarely the haemolytic *Streptococcus*, *Escherichia coli*, *Proteus* spp. and, occasionally, *Pseudomonas aeruginosa*. In infants, diabetics and the obese, yeasts are often present. Latent diabetes should be borne in mind when the disease is refractory to treatment. Overtreatment may compound the irritation or lead to a sensitization dermatitis.

Candidosis and contact dermatitis are differentiated by the history, the appearance and microscopic examination. The diffuse macerated erythema, often with fissures at the apex of the fold and without a sharply defined edge, distinguishes non-specific intertrigo from psoriasis and dermatophytosis, although scrapings and culture should always be undertaken. Mistakes in diagnosis arise from failure to recognize that two or more aetiological factors may coexist [1]. In India, *Trichosporon* species, which normally cause white piedra trichomycosis, have been implicated in causing cutaneous lesions resembling genitocrural intertrigo [2]. Langerhans' cell histiocytosis (see Chapter 55) has a predilection for the perineum or inguinal regions [3] and is a rare cause of genitocrural intertrigo; likewise extramammary Paget's disease. Congenital syphilis may present as intertrigo in an infant.

In the early stages, the condition can be controlled by avoidance of friction and tight clothing. Driving or sitting for long periods should be avoided. In severe cases, the patient must rest in bed, preferably with groins unclothed and bedclothes lifted by a cradle, the apposed skin surfaces being kept apart with appropriate dressings. Obesity, diabetes and incontinence should receive attention. Wet dressings are often useful initially in acute cases, and may be followed by bland or mild antibacterial creams or lotions. The aniline dyes and magenta paints still have a place in therapy. In general, lotions, paints and powders are more acceptable than creams. Nystatin, hydroxyquinoline and imidazoles can be applied alone or with topical steroids for a few days.

Genitocrural dermatitis

Lichen simplex is a result and/or cause of severe and spasmodic itch; the psychological mechanisms involved are similar to those discussed in relation to pruritus vulvae and pruritus ani. The 'giant' form of lichenification described by Pautrier [4] may be extremely resistant to treatment. Local treatment with corticosteroid applications is supplemented by reassurance, rest and sedation. All factors provoking local itching must, as far as possible, be removed.

Contact dermatitis (see Chapters 25 & 26) may present suddenly with pruritus, oedema and erythema, or insidiously as a gradual intensification of a pre-existing dermatitis. Sensitization to applied medicaments, contraceptives or, in men, industrial or other contact agents transferred by hand may be responsible for allergic contact dermatitis, especially if the scrotum and thighs are also affected. Irritant contact dermatitis is common and caused by excessive or exuberant use of soap and toiletries. A good example is nappy (diaper) rash where urine, occlusion, friction and *Candida* contribute to the clinical presentation. Classically, the convex surfaces are affected and the flexures are spared, distinguishing it from psoriasis. Nappy rash has become much less common with the availability of absorbent disposable paper napkins. A severe erosive form (Jacquet's dermatitis) is still occasionally seen in children with urinary or faecal incontinence.

Constitutional eczema should be considered in the differential diagnosis of napkin erythema in an infant (see Chapter 17). In adults, the genitocrural and lower abdominal folds are likely to be involved in seborrhoeic or intertriginous dermatitis.

Miscellaneous

Psoriasis and lichen planus are recognized by their special characteristics, although the diagnosis may be difficult when they arise in an exclusively flexural distribution. In the flexures and at anogenital sites, seborrhoeic dermatitis and psoriasis may be indistinguishable. Inverse pattern psoriasis refers to the manifestation of the disease on intertriginous skin in the axillae, natal cleft, gluteal folds, groins and in the preputial sac and on the glans of the uncircumcised male; its occurrence at these sites is probably enhanced by the Koebner phenomenon. Lichen planus has a propensity to cause ovoid hyperpigmented patches in the flexures and annular lichen planus is also common at these sites [5]. Treatment of intertriginous psoriasis and lichen planus is complicated by the need to control concomitant *Candida* infection and to avoid striae from potent topical steroids; topical calcineurin inhibitors show promise [6,7]. A psoriasiform genitocrural and perineal intertrigo has been reported in hereditary mucoepithelial dysplasia [8].

Impetigo herpetiformis frequently starts in the groin with small inflammatory yellowish-green pustules, which rupture to produce scabs and crusts. Acrodermatitis enteropathica and the acquired zinc deficiency syndrome [9] may well be overlooked as causes of genitocrural dermatitis. The distinction of Jacquet's eruption from congenital syphilis and from the exuberant plaques and nodules of infantile gluteal granuloma [10,11] is important. Hidradenitis suppurativa usually involves the area widely, although localized lesions are sometimes seen.

All forms of pemphigus and pemphigoid (especially pemphigus vegetans [12] and pyodermite végétante [13]) affect this region, and juvenile pemphigoid and pemphigoid gestationis affect it selectively and sometimes exclusively. Pemphigus vegetans must be distinguished from vegetating forms of pyoderma, which are not uncommon in the groins, and from blastomycosis and other mycoses, verrucoid forms of tuberculosis and granuloma inguinale. Cicatricial pemphigoid [14] may affect the groin. Benign familial pemphigus (Hailey–Hailey disease) involved the groins or genitalia in 14 out of 21 patients in one series [15]. It can involve the groins in isolation. Secondary infection with herpes simplex has been reported after treatment with retinoids [16]. Very rarely, papular and verrucoid plaques similar in appearance to genital warts have been reported [17]. HPV 5 infection and its response to topical imiquimod has been reported [18]. Darier's disease (see Chapter 19) involving the flexures is mild in most patients but does occur in the vast majority. It can be very sore and malodorous. The intertriginous features are similar to those of Hailey–Hailey disease. There have been several reports of a genital, inguinal and perineal eruption, with clinical and histological similarity to Darier's disease and Hailey–Hailey disease, called

genitocrural papular acantholytic dermatosis. The patients had no rash elsewhere, no family history and negative immunofluorescence [19]. Subcorneal pustular dermatosis extends outwards from the inguinal folds as flaccid pustules, rapidly rupturing to form gyrate and circinate crusted lesions. Dystrophic forms of epidermolysis bullosa may cause separation of the skin during delivery or, if less severe, bullae and erosions at these sites of friction.

Clear cell papulosis is a rare condition of Asian or Hispanic children where there may be asymptomatic white papules in the pubic area and 'milk line' (i.e. axillae and on the trunk); it is not known whether it is a sequel of extramammary Paget's disease [20].

Toxic epidermal necrolysis may present as desquamation, sometimes involving the whole region. Severe erythema multiforme involves the genital or anal mucosa in half of the cases. Necrolytic migratory erythema also extends in waves from this area [21].

Inguinal (Hexsel's) hyperhidrosis is a focal type of hyperhidrosis confined to the groins. It begins in adolescence and is debilitating and difficult to treat; botulinum toxin can be effective [22].

Infections

Erythrasma

Erythrasma (see Chapter 30) is a common genitocrural infection, especially of the male. It is caused by *Corynebacterium minutissimum*, an organism that is normally a commensal but which in warmer climates may become pathogenic. Tawny, slightly scaly macules are seen on the upper inner thighs. In the inguinal folds, erythrasma may present as an intertrigo and can be macerated and eroded. It is not usually very itchy, but can be slightly sore. Lesions are usually also found in the axillae or toe webs. It may coexist with *Trichophyton rubrum* [1] and candidosis. Pruritus ani has also been reported [2]. Erythrasma is a clinical diagnosis confirmed by demonstration of coral pink fluorescence under Wood's light (resulting from a porphyrin produced by the bacterium). Treatment is with topical clindamycin, erythromycin or an imidazole, or with oral erythromycin. It is prone to recur.

Candidosis

Candidosis (thrush) presents as an intertrigo. Symptoms of burning and soreness are more common than itch. Coalescent red patches or plaques involve the folds, often with superficial erosions. Pustulosis extends out onto the skin of the abdomen, buttocks or thighs from the irregularly marginated intertriginous lesions. It can be a primary infection, particularly in infants, and in pregnancy and diabetes, but *Candida* may be more often a secondary pathogen in anogenital dermatoses. Observing the signs of candidosis or demonstrating the presence of the organism does not prove that it is the cause of all the symptoms and signs. *Candida albicans* is such a ready opportunist because it is a part of the resident flora of the gastrointestinal tract and may be retrieved from intertriginous areas, including the preputial folds, in the absence of symptoms and signs. A search for an underlying dermatological or medical cause should be undertaken. The symptoms and signs of *Candida* may be more florid than the underlying predisposing cause. Obesity predisposes to candidal intertrigo but medical causes include diabetes mellitus, iatrogenic immunosuppression and systemic antibiotic treatment. Although oropharyngeal candidosis is almost invariably found in HIV infection, anogenital candidosis is not generally associated, perhaps because it is overlooked or because many patients take long-term imidazole antifungals orally.

Underlying disease should be identified and treated, and predisposing factors rectified. Treatment includes topical nystatin, clioquinol or an imidazole, often very usefully combined with hydrocortisone or a moderately potent corticosteroid. If the infection is severe, an oral imidazole may be indicated.

Tinea cruris

Tinea (see Chapter 36) is a common disease of the groins and is usually caused by *Trichophyton rubrum* [3]. It is generally rare

in women, but occurs more frequently in hot climates. Spread occurs onto the thighs, buttocks and pubis. Many patients are misdiagnosed and/or partially treated with topical corticosteroids and/or topical antifungal agents. Tinea and *Candida* may complicate other dermatoses such as psoriasis. Tinea incognito/occulta is therefore common. There is a fine peripheral scaling (eczema marginé of Hebra). Cases have been described in infants [4].

Microscopy will confirm the clinical diagnosis, and in tinea incognito/occulta there are numerous fungal elements.

Dermatophyte infection of the anogenital skin usually requires oral treatment with griseofulvin, terbinafine or itraconazole. Topical treatments often fail because the anatomical complexity of the area makes topical treatment difficult, and there may be reinfection from concomitant involvement of feet or hands, toe or fingernails.

Miscellaneous infections

Bacterial or candidal infections complicate intertrigo, eczema, napkin erythema, scabies and many tropical diseases. Vincent's organism, *Pseudomonas aeruginosa* and a wide variety of Gram-negative organisms are commonly found. The 'blue underpants' sign may point to a *Pseudomonas* crural intertrigo [5]. Bullous impetigo occurs in childhood, often secondary to scabies. Gangrenous ecthyma of infants may, very rarely, affect the inguinocrural area. Gangrene has followed operations for inguinal hernia [6]. Giant condylomata acuminata may infiltrate the groin [7]. Sacral herpes zoster may present with groin lesions and retention of urine or constipation.

Phthiriasis pubis is sometimes overlooked as a cause of pruritus in the female. In the hirsute male, the infestation may be widespread. Oxyuriasis (threadworms) can cause localized urticaria as well as pruritus. Scabies in children is diffuse, and the inguinal glands are often enlarged from secondary infection. 'Seabather's eruption' affects the bathing trunk area.

Schistosomiasis and amoebiasis cause phagedenic necrosis, fistulae and pseudoelephantiasis, and may also give rise to granulomas and condylomatous masses [8]. Onchocerciasis causes depigmentation, nodules, atrophy, lymphadenopathy and a 'hanging groin' [9]. Trichosporosis is a common cause of genitocrural intertrigo in India, with symptoms of itching or burning. Scaly papules may accompany the intertrigo. Coexisting dermatophyte, *Candida*, trichomycosis and erythrasma infection may be found. Dequalinium chloride is used topically in India [10]. Trichomycosis presents with malodour and discoloured broken hairs [11], which should be distinguished from those of trichorrhexis nodosa, caused by repeated scratching [12]. Blastomycosis, actinomycosis and other deep fungal infections (see Chapter 36) simulate tuberculosis, but are more prone to form fissures, sinuses and vegetating or exuberant granulomatous lesions. They are distinguished by histological and bacteriological examination.

Among chronic infections, tuberculosis, tertiary syphilis and leishmaniasis are diagnosed by their characteristic features, which are described elsewhere. Congenital syphilis can be overlooked as a cause of genitocrural intertrigo in an infant. In tropical countries, tuberculous inguinal lymphadenopathy may be a cause of genitocrural lymphoedema. Amoebiasis involves the groins and perineum by extension from the anus.

Sexually transmitted diseases are fully discussed in Chapter 34. Granuloma inguinale affects the genitalia in less than half of cases, causing coalescing nodules, serpiginous ulcers and fungating masses. The buboes and fistulae of lymphogranuloma venereum are characteristic. Vulval (rarely scrotal) lymphoedema and elephantiasis may occur in both diseases.

Miscellaneous

In the 'short bowel syndrome', kwashiorkor-like changes include an 'enamel paint skin' [1].

Dowling–Degos disease (reticulate pigmented anomaly of the flexures) involved the flexures in eight out of 10 patients [2], but may be restricted entirely to the vulval skin [3]. It is a rare autosomal dominant disorder characterized by spotted and reticulate pigmentation of the flexures. There may be comedone-like lesions on the neck, comedones and pitted scars near the angle of the mouth, epidermoid cysts, pilonidal sinus, hidradenitis suppurativa, multiple seborrhoeic warts and squamous cell carcinomas [4].

Acanthosis nigricans almost invariably affects the groins. Pseudoacanthosis nigricans can present as a macerated intertrigo and with secondary infection. These can be distinguished from each other and from lichenification in pigmented skins by a rubber silicone impression technique [5]. Calcinosis involving the upper inner thighs may resemble pseudoxanthoma elasticum [6].

The following entities are encountered in the genitocrural area:

Angiomas, lymphangiomas and angiokeratomas—diffuse angiomas or lymphangiomas may cause irregular subcutaneous swellings; angiokeratoma corporis diffusum may be a feature of several very rare congenital diseases affecting lysosomes, with the pinhead-sized lesions of Anderson–Fabry disease (β-galactosidase deficiency) occurring around the lower limb girdle and upper thighs from the navel to the knees; a male case with no

recognizable enzyme abnormalities has been described [7]. Epidermal naevi are not uncommon. Seborrhoeic warts may be mistaken for viral warts [8] or Bowenoid papulosis, as may melanocytic naevi or acrochordons. Papilliferous (intradermal) naevi and skin tags (acrochordons) often become large and pedunculated on the inner aspect of the thighs. Inguinogenital epidermoid cysts may become infected; lesions containing molluscum contagiosum have been described [9]. Pilar cyst, including giant forms, is much rarer [10].

Pubic hair problems are relatively rare in men, whereas women may be troubled by hirsutism or pili incarnati. Alopecia areata can affect the pubic hair, but usually as part of more widespread involvement as in alopecia universalis. Loss of pubic hair occurs in secondary syphilis and has been reported in primary systemic amyloid [11]. Pubic (and axillary) hair loss occurs in the Graham Little–Piccardi–Lassueur and androgen insensitivity syndromes [12]. Trichotillomania of the pubic hair has been described [13,14].

Vitiligo is common in the groins.

Extramammary Paget's disease can involve the genitocrural folds and present as an intertrigo.

Carcinoma erysipeloides (due to anogenital cancer) [15] is probably more common in the genitocrural area than reports would suggest. Carcinoma of the cervix, bladder and prostate may be the cause [16].

Male genital dermatology

Introduction

Male patients with non-venereological and non-urological skin problems commonly present to genitourinary or urology clinics where the training and expertise are not orientated to adequate dermatological diagnosis and treatment [1].

Careful dermatological evaluation, including a full history and complete examination, usually allows confident clinical differential diagnosis. A biopsy and other investigations are sometimes indicated. It is important to consider the possibility of sexually transmitted disease or a urological disorder and refer accordingly; combined clinics are useful.

History taking and the primary symptomatology of anogenital dermatology are discussed on pp. 71.1–71.4. It may be necessary actively to elicit symptoms caused by sexual dysfunction (e.g. male dyspareunia), and it should be remembered that male sexual function amounts to more than erectile potency; libido, ejaculation and orgasm are the other components [2].

Complete examination is mandatory to elicit important signs at extragenital sites. The physical examination of the male at any age is incomplete without examination of the genitals and scrotum (but this is frequently not carried out in general clinical settings) and urologists teach that there are three primary reasons for careful examination of the scrotum: pain, swelling and absence of contents. The presence or absence of the prepuce, phimosis or paraphimosis should be sought and the foreskin retracted gently (if present). The gluteal and crural folds should be parted to allow adequate inspection. Sometimes it is useful to elicit dermographism of the inner thighs. Urinalysis completes the physical examination.

Findings specific to the male genitalia include phimosis, paraphimosis, balanitis and posthitis. Phimosis ('muzzling') refers to a non-retractable foreskin. The literature can be confusing; Rickwood [3] has defined it as scarring of the tip of the foreskin. There are several possible causes of phimosis (Table 71.11). In adults, phimosis is usually the consequence of disease processes. It has also been attributed to titanium formulated in proprietary topical preparations [4]. Diabetes was diagnosed in 36% of men between 17 and 59 years of age presenting with phimosis of less than 2 years' duration, with no specific preputial pathology identified histologically [5]. In boys, the histological findings may be normal in nearly half of those circumcised [6].

Chancre with balanitis of Follman
Mucous patch
Mycoplasma
Trichomonas vaginalis
Lymphogranuloma venereum
Non-syphilitic spirochaetal ulcerative balanoposthitis
Tinea
Amoebiasis
Myiasis
Scabies
Eccrine syringofibroadenomatosis
Erythroplasia of Queyrat
Kaposi's sarcoma
Chronic lymphatic leukaemia
Fixed drug eruption

Table 71.15 Causes of dorsal perforation of the prepuce.

Hidradenitis suppurativa
Pyoderma gangrenosum
Florid condylomata
Podophyllin
Chancroid
Herpes simplex

Paraphimosis refers to a foreskin fixed in retraction. Although some authors have used the term to describe a foreskin that is tight in retraction around the flaccid penile shaft, 'waisting' or 'constrictive posthitis' may be better terms [7]. Rickwood [8] has said that paraphimosis results from abuse not disease of the foreskin, but some medical causes can be identified (Table 71.12).

Balanitis is inflammation of the glans penis; posthitis is inflammation of the prepuce [9]. Balanoposthitis means inflammation of the glans and prepuce, and can be regarded as a special form of intertrigo (Tables 71.13 & 71.14). By definition therefore, balanoposthitis cannot occur in the circumcised male. Generally, dermatologists feel that balanitis, posthitis and balanoposthitis are probably more commonly caused by inflammatory and precancerous dermatoses than do genitourinary physicians, who teach that most cases are caused by infection, usually with *Candida* [10,11]. However, the evidence for *Candida* as a cause for balanoposthitis is not strong [12].

General aspects of anogenital ulceration are discussed on pp. 71.3–71.4 and in Tables 71.9 and 71.10. The principal causes of male genital ulceration are sexually transmitted and non-sexually transmitted infection, cancer and artefact [13]. Several causes can co-present, especially in HIV/AIDS. Dorsal perforation of the prepuce is a recently highlighted complication of several ulcerative penile diseases, sexually and non-sexually acquired, as listed in Table 71.15 [14,15]. Penile necrosis is a rare but devastating presentation with an important differential diagnosis.

Special investigations appropriate to anogenital cases are discussed on pp. 71.3–71.4. In genitourinary clinics, application of 3–5% acetic acid to the penis is used as an aid to the clinical diagnosis of viral warts and is held to reveal subclinical infection [16], but is not in routine use in dermatological practice. Human papillomavirus (HPV) polymerase chain reaction (PCR) screening suggests that the acetowhite test is not very specific [17–20]. Peniscopy is not generally practised by dermatologists. A penis biopsy can be highly informative in selected cases [21]. It is safe to use small amounts of adrenaline with the local anaesthetic. Beware of the distal ventral midline area where the urethra is very close to the skin surface. It is often not necessary to suture a punch biopsy site.

Structure and function of the male genitalia

The penis is the male organ of urinary elimination and sexual function for the insemination of the female. The prepuce and its secretions provide physical and immunological protective functions, and it has erogenous properties (e.g. the penile dartos muscle and the corpuscular receptor-rich ridged band), but none of these is indispensable for erogenous function in copulation [1]. The scrotum maintains the testes at the ideal temperature for spermatogenesis. The male genital structures are illustrated in Fig. 71.1. The anatomical position is that of full penile erection.

The anatomy is explained by the embryology [2]. At about the third week of fetal development, mesenchymal tissue from the primitive streak forms cloacal folds around the cloacal membrane, joined anteriorly and cranially to form the genital tubercle, posteriorly and caudally to form an annulus. The cloacal membrane is thus divided into urogenital and anal membranes craniocaudally, and lateral genital swellings appear as precursors of either the scrotum or labia majora.

Fetal and testicular androgens then induce lengthening of the genital tubercle to form first an urethral groove and then the urethral canal. The urethral epithelium of the penis is therefore derived from endoderm. Initially, it is incomplete cranially where the glans has developed from the genital tubercle. The glandular urethra and the meatus form from an invading canalizing cord of ectoderm. The scrotal swellings fuse posteriorly at about 14 weeks but are empty until birth.

The prepuce [1] is formed by a midline fusion of ectoderm, neuroectoderm and mesenchyme, resulting in a pentalaminar structure consisting of (from the inner layer outwards) squamous mucosal epithelium, lamina propria, dartos muscle, dermis and glabrous skin. The preputial fold progressively extends, but there is also an ingrowth of a cellular lamella. It then fuses with the mucosa of the glans. The female analogue is the clitoral hood.

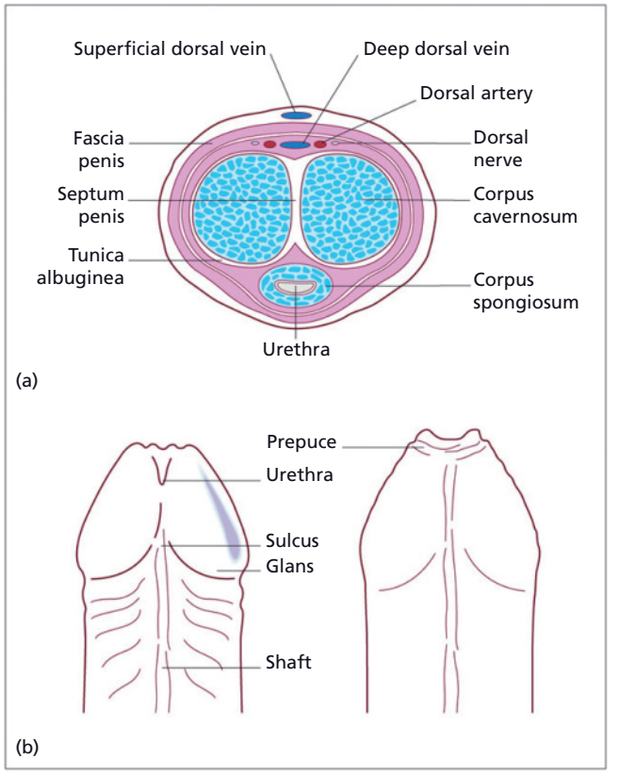

Fig. 71.1 (a) Cross-section of the body of the penis. (b) Circumcised and uncircumcised glans penis. (Adapted from *Last's Anatomy*, 9th edn. Reproduced from Bunker C.B. *Male Genital Skin Disease*, © 2004, with permission from Elsevier.)

The anogenital area is densely endowed with eccrine and apocrine sweat glands. Also in plentiful number are holocrine sebaceous glands, usually in association with hair follicles but also occurring as free glands at some sites such as the anal rim or around the coronal sulcus (Tyson's glands). These secretions exist to lubricate hair, lubricate the mucocutaneous junctions to assist in the voiding of excreta and protect the epithelia from irritation, and to lubricate the penis for sexual activity (probably mainly the retraction of the foreskin rather than the penetration of the introitus and vagina).

Pubic hair appears in puberty as vellus hair that is focally replaced by terminal hair. The pattern of pubic hair in men is different from that in women, and its distribution varies widely between men. McGregor [3] defined three patterns (Fig. 71.2). Generally, the abdominal wall, pubic mound, groins, scrotum and perineum are hairy but the natal cleft, perianal skin, distal penile shaft, prepuce and glans are hairless.

The pattern of keratinization of the epithelium is different throughout the anogenital area, particularly at the mucosal junctions, the prepuce and distal penile shaft and the glans in the circumcised male. The spectrum of differentiation of the male urogenital tract is manifest in the expression of differing epithelial cytokeratins [4].

Normal variants

Normal male genital variants include pigmentary variation, hair variation (as above), skin tags, pearly penile papules, sebaceous prominence, melanocytic naevi, prominent veins, angiomas and angiokeratomas, common congenital abnormalities and circumcision.

Skin tags are common in the groins, especially of obese men. They may catch on clothing, bleed and become infected. Treatment is by electrocautery or scissor amputation and cautery. Fibrosed haemorrhoids result in perianal skin tags. Larger, fleshier, more oedematous skin tags should arouse the suspicion of Crohn's disease. They can predate gastrointestinal disease by several years. Sigmoidoscopy and biopsy should be considered [1].

Pearly penile papules are common; they may be found in up to 50% of men [2,3]. They present as flesh-coloured, pink, smooth, rounded, 1–3 mm papules, occurring predominantly around the coronal margin of the glans, rarely on the glans, in rows or rings (Fig. 71.3). Ectopic lesions on the penile shaft have been reported [4]. They are frequently mistaken for warts and misdiagnosed as Tyson's glands or ectopic sebaceous glands of Fordyce. The patient is often an anxious adolescent. The histology is that of angiofibroma. The lesion is analogous to other acral angiofibromas such as adenoma sebaceum, subungual and periungual fibromas, fibrous papule of the nose, acquired acral angiofibroma and oral fibroma [5]. Reassurance is usually sufficient but cryotherapy and laser treatment can be effective [6,7].

Sebaceous gland prominence, Tyson's glands, sebaceous hyperplasia and ectopic sebaceous glands of Fordyce are all virtually synonymous, common, normal variants of the skin of the scrotal sac and penile shaft, but they may cause concern to the patient (Fig. 71.4). They have been held to be very rare or their presence doubted at all [8]. Fordyce's condition also commonly affects the vermilion border of the lips. Naevoid linear lesions on the penile shaft have been seen [9–11]. The glans can be affected [12]. Reassurance is usually all that is required, but dysmorphophobia can occur.

Congenital and acquired melanocytic naevi are common. It is possible that naevi on the penis occur more frequently in patients with the atypical naevus syndrome, but this has not been formally documented. Genital epithelioid blue naevus is very rare [13]. A man who developed multiple blue naevi on the glans penis has been described [14]. Spitz naevus has been described [15]. Divided or 'kissing' naevus (analogous to the entity recognized on the eyelids) has been reported, with one component located on the

Fig. 71.5 Scrotal angiokeratoma of Fordyce. (Courtesy of Dr D.A. Burns, Leicester, UK.)

glans and the other on the distal penile shaft or prepuce, separated by uninvolved skin across the coronal sulcus [16–18]; melanoma developed in one case [19]. Large 'bathing trunk' naevi frequently involve the anogenital area and pose significant management problems, including the risk of melanoma (see Chapter 54).

Prominent veins are common, if not universal, and occasionally give rise to concern. Vascular white spots are sometimes seen on the glans, and are possibly analogous to Bier's spots seen on the palms and forearms.

Cherry Campbell de Morgan angiomas may, unusually, be confined to the genitalia. Angiokeratomas on the genitalia have also confusingly been given the Fordyce eponym (Fig. 71.5). They are multiple, rarely solitary, blue to purple, smooth, 2–5 mm papules on the scrotum, and rarely on the penile shaft [20] and glans [10,21]. The role of local venous hypertension in causation is controversial [22]. Angiomas and angiokeratomas may bleed following trauma. The differential diagnosis includes angiokeratoma corporis diffusum, acquired capillary and cavernous haemangiomas, Masson's tumour, glomus tumour, epithelioid haemangioma, bacillary angiomatosis, Kaposi's sarcoma and epithelioid haemangioendothelioma. One case of florid genital angiokeratomatosis has been associated, perhaps coincidentally, with corporeal papular xanthomatosis [23]. Hyfrecation, electrocautery or laser ablation [24] can be offered, but lesions recur. Appearing in some contexts, such as HIV infection or follow-up for genital cancer, they can cause alarm [25]. Most patients are content with reassurance, and a biopsy is not usually necessary.

The foreskin

The prepuce has been present in primates for 65–100 million years and its function is controversial [1–4]. It is usual for it to be adherent to the glans at birth. Four per cent of boys have a retractable foreskin at birth, 15% at 6 months, 50% at 1 year and 80–90% at 3 years; the process should be complete by 17 years [5]. The foreskin varies in length and retractability: 'short' and 'long' variants are seen.

Circumcision

Circumcision has been performed for religious, cultural or medical reasons throughout history [1]. Worldwide, it has been estimated that approximately 25% of men have been circumcised [2]. Routine neonatal circumcision is controversial [3–6]. The UK General Medical Council (GMC) undertook a review of infantile circumcision in 1997, which 'demonstrated widely conflicting views in society that neither doctors nor the GMC can resolve' [7].

During infancy, circumcised boys have a higher incidence of penile problems than the uncircumcised, but after infancy the situation is significantly reversed [8,9]. Circumcision reduces the retrieval of pathogenic microorganisms from the penis [10]. Many have concluded that circumcision protects men from cancer of the penis and urinary tract, and sexually transmitted infections including HIV [11,12]. However, the incidence of penis cancer is low in countries where circumcision is uncommon [13], so other factors are important in penile carcinogenesis (see pp. 71.40–71.41). Also, the effects of circumcision on the other outcomes may be small [14] (e.g. urethritis may be more common in the circumcised, whereas ulcerative disease is more common in the uncircumcised). Circumcision protects men from inflammatory genital dermatoses including psoriasis, seborrhoeic dermatitis, lichen planus and lichen sclerosus [15]. This fact may be related to the occlusion and moisture consequent on the presence of the prepuce; O'Farrell *et al.* observed penile wetness in hardly any circumcised men, yet it is present in 40% of uncircumcised men with 'balanitis' [16].

Circumcision is important in the management of disorders of the penis and the foreskin, including dermatological disease. However, variability exists between clinicians in the indications for circumcision, especially in children. They include true phimosis, recurrent balanoposthitis, lichen sclerosus, penile lymphoedema, intraepithelial neoplasia and carcinoma.

The consensus is that circumcision has insignificant adverse effects on health, but it is not risk- or complication-free: bleeding, infection, necrosis, adhesions, bridges, fistula, keloid, concealed or buried penis, amputation, necrosis, excessive excision of penile skin, meatal stenosis, meatitis and meatal ulcer, cysts, chordee, hypospadias and epispadias, amputation neuromas, abnormal sexual behaviour, psychological distress and dysmorphophobia [17–27]. In some third world settings the complication rate can be very high [26], implying that better training is required if circumcision is going to become more commonly adopted as part of HIV-prevention strategies [12]. 'Uncircumcision' describes preputial restoration performed throughout history for various reasons [28,29].

As circumcised men age and become obese the penis may retract into the pubic mound—the 'vanishing penis syndrome'. This phenomenon can create a 'pseudoforeskin', especially if the initial circumcision was inadequate or incomplete, and this favours development of dermatoses found characteristically only in uncircumcised men, such as Zoon's balanitis and lichen sclerosus [30].

Congenital and developmental abnormalities

Congenital and developmental anomalies are common, reflecting the complicated embryogenesis and subsequent sexual differentiation of the anogenital region. The dermatologist may not be called upon to make a primary diagnosis, but needs to be aware of syndromic associations as well as anatomical and functional abnormalities because these additionally predispose the area to dermatoses and infections. Naevi are discussed above. Other

common abnormalities include meatal pit, sacral pit, hypospadias, median raphe cysts, canals and sinuses, and ambiguous genitalia [1–3].

Rarer anomalies include hypospadias variants, epispadias, penile hypoplasia, mucoid or urethral cysts, dermoid cyst, juvenile xanthogranuloma, buried penis, urethral atresia, penoscrotal transposition, congenital lymphoedema, lymphangiectasia, lymphangioma, giant preputial sac, megaprepuce, accessory scrotum, haemangiomas, strawberry naevus, white sponge naevus, os penis, true aposthia and faun tail [2,4–6].

This is not the place exhaustively to catalogue all of the syndromes that may be associated with one or other of the above common or rarer anomalies; however, examples include anogenital haemangiomas in the PELVIS syndrome [7], anogenital lymphoedema in Hennekam syndrome [8], the micropenis of the MORM and Kabuki make-up syndromes [9,10], the cribriform scrotal atrophy associated with an unusual form of ectodermal dysplasia [11], and genital leukoplakia associated with dyskeratosis congenita [12].

Trauma and artefact

Penile haematoma and rupture

The genitals may be readily traumatized, including by sexual activity. The penis is very vascular but haematoma formation and 'fracture' (penile rupture) are quite rare [1,2]. Pain, swelling and deformity associated with the history of a cracking noise during strenuous or contorted intercourse characterize the diagnosis. Splitting of the tunica albuginea of the corpus cavernosum can result in urethral damage, haematoma and retention. The prognosis is generally good but Peyronie's disease can occur [3]. Injection of drugs for erectile dysfunction can be complicated by haematoma.

Sclerosing lymphangitis

Non-venereal sclerosing lymphangitis/penile venereal oedema/Mondor's phlebitis/localized penile (venereal) lymphoedema/penile lymphocoele presents with a serpiginous mass in the coronal sulcus. The lesion usually arises after prolonged or frequent sexual intercourse with a passive or unenthusiastic partner; subsequent sexual activity may result in tenderness and enlargement. The circumferential scar left by circumcision may be a predisposing factor. There may be spontaneous resolution, or surgical excision may be needed [4]. It is not known whether lymphangitis or phlebitis is the cause [5]. True phlebitis of penile and scrotal veins has been reported in three patients, of whom one had been injured by a golf ball, but the other cases were idiopathic [6]. Its occurrence after taking tadalafil for erectile dysfunction has been used to argue for an anatomical variation in the distal draining subcoronal venous emissary arcade [7]. Thrombophlebitis of superficial penile and scrotal veins is analogous to Mondor's phlebitis of the chest wall (see Chapter 70), but it may be associated with polyarteritis nodosa and thromboangiitis obliterans [8]. Penile thrombophlebitis has been misdiagnosed as Peyronie's disease, and has also been the initial manifestation of a paraneoplastic migratory thrombophlebitis resulting from pancreatic cancer [9]. Given the circumstances that usually create the problem patients should be screened for underlying sexually transmitted infection, despite the appellation [10].

Strangulation of the penis

The penis may be strangulated by ring devices [11,12], including vacuum erection equipment [13], condom rings [14], rubber bands, string, rings (washers), nuts, bushes and sprockets, which are placed deliberately on the penis by the patient for masturbation or to prolong erection [15,16]. In boys, strangulation can occur following experimental use of rubber bands, string or thread to control enuresis, or can result from encoiled hair after circumcision [17]. Penile strangulation—the tourniquet syndrome—causes pain, swelling, urethral fistula, pseudoainhum, gangrene and amputation.

Foreign body

Self-instrumentation of the external genitalia may have an autoerotic, psychiatric, therapeutic (relief of itch [18]), aiding voiding, cleaning) or accidental aetiology [19]. Complications include frequency, haematuria, abscess, retention, fistulae and calculi. The diagnosis is made by palpation and radiography. Endoscopic removal is usually possible for foreign bodies below the urogenital diaphragm.

Glass beads, spheres of plastic or small round smooth stones (even pearls) may be introduced under the skin of the penis for erotic reasons, causing clinical and radiographical confusion. In the Philippines, this practice is called 'bulleetus', in Sumatra 'persimbraon', in Korea 'chagan ball' and in Thailand 'mukhsa' or 'tancho' [20–22]. Extrusion of a testicular prosthesis has been reported as a cause of scrotal ulceration [23].

If oil, petroleum jelly or silicone is used then a paraffinoma, silicone granuloma or (sclerosing) lipogranuloma can result.

Lipogranuloma

Patients may take it upon themselves to inject various substances with the aim of maintaining erection or enlarging the penis. The consequences may not be desirable. Infection is an obvious risk [24]. Mineral oil, petroleum jelly and silicone introduced into the genital skin can elicit lipogranuloma or paraffinoma. Most cases are self-induced, either to increase penile size or enhance sexual pleasure, but some may be accidental [25,26]. One patient injected his penis with an industrial high-pressure pneumatic grease-gun [27]. Idiopathic cases attributed to endogenous fat liberation have been reported, predominantly from Japan [28]. The psychological consequences may be debilitating [29].

Dermatitis artefacta and mutilation

Dermatitis artefacta of the genitalia does occur. Lesions are typically geometrical, angulated and rectilinear. Sometimes they are induced by needles, knives or cigarette burns, and extraneous foreign material may be introduced into the skin (lipogranuloma and silicone granuloma are discussed above).

Psychotic patients may mutilate their genitalia, as may transvestites [30], but non-psychotic genital self-mutilation can also occur. Australian aborigines create a slit in the penis by opening the urethra ventrally, thereby creating hypospadias; this is called subincision [31,32]. Biopsy and other investigations may be necessary to exclude penile cancer. It is important also to consider pyoderma gangrenosum, which is rare but frequently omitted from the differential diagnosis of penile ulceration by non-dermatologists.

Child abuse

Physical and sexual child abuse should be considered in the differential diagnosis of cutaneous disease of the anogenital area in children (Table 71.16), but signs should be interpreted with caution and re-examination should be avoided [33–37]. Child abuse may be erroneously suspected (Table 71.17) when the anogenital area is involved by a dermatosis or a diarrhoeal illness [38].

The significance of anogenital warts in suggesting possible child sexual abuse is controversial. However, early recognition as a marker for child sexual abuse is in the child's long-term best interest [39].

Miscellaneous traumatic and arterial conditions

Sometimes the penis is bitten by another individual or an animal [40]. Purpura and ecchymoses may develop after oral sex ('love bites') or the use of vacuum erection devices [13]. Post-traumatic neuromas may be encountered and be mistaken for genital warts or pearly penile papules [41]. Degloving injuries can occur in accidents with industrial or agricultural equipment [42]. Electrical burns are rare [43]. Sex aids can result in abrasions, eczema and ulceration. Self-circumcision might be attempted, with adverse consequences [44]. Anogenital tattoos are commonplace [45].

Localized gangrene of the scrotum and penis resulting from arterial embolization with particulate matter complicating accidental femoral self-injection of heroin in an addict has been reported [46]. Scrotal gangrene from a snake bite has been described [47].

Inflammatory dermatoses

Urticaria and dermographism

These are usually generalized eruptions (see Chapter 22) but it has been proposed that they may account for some of the symptomatology in some patients with unexplained genital itching (and pruritus ani—see below). Stroking the inside of the thigh might induce a weal; indeed, stroking can cause itching without any discernible redness or wealing [1,2]. Contact urticaria is discussed below. Lisinopril has been reported to cause genital angio-oedema [3].

Eczematous dermatoses

Itching and lichenification, particularly around the scrotum, are common presenting problems. Contributory factors include preexisting dermatoses such as xerosis, atopy and psoriasis, sedentary occupations, motor car and aeroplane travel, and tight underclothing and trousers.

Irritation is a key adverse exogenous influence to which anogenital sites are vulnerable, and sweat, sebum, desquamated corneocytes, dirt, excreta, sexual secretions, clothing, detergents, toiletries, cosmetics, contraceptives and some therapeutic topical treatments are all potential irritants.

Frequently underrated are the effects of overwashing and the excessive use of soap and toiletries, especially in the presence of skin symptoms or urinary or bowel problems, and particularly if patients feel that they might have been exposed to a sexually transmitted disease.

Lichen simplex

Lichen simplex is common around the male genitalia. It is not usually a flexural condition but can be seen on the penile shaft and scrotum (Fig. 71.6). Giant forms (of Pautrier) occur, giving a pineapple appearance [4]. The skin may be broken by excoriations and become secondarily impetiginized or colonized by *Candida*.

Treatment follows the lines of management (above and below) relating to irritants, with emphasis on the relief of scratching, soap substitution and moisturization, and occlusion of the area if possible with a bland dressing—wet if the skin is fiercely eczematized. A potent topical corticosteroid ointment can be used for a few days and then tailed off. Preparations containing tar or combinations of antibacterial, anticandidal and antifungal agents are also useful. Two cases of extensive giant lichen simplex of the scrotum have been successfully treated by hemiscrotectomy [4].

Irritant contact dermatitis

Anogenital irritants are discussed above and listed in Table 71.18. Friction [6], maceration, overwashing, and concomitant anorectal or urological disease are the chief influences. There may be an association with atopy; Birley [7] diagnosed irritant dermatitis in 72% of patients presenting to a genitourinary clinic with 'balanitis' (probably meaning balanoposthitis) of whom a possible 67% had a history of atopy, but none of these patients was patch tested. An irritant scrotal dermatitis in cellists has been described [8]. Topical 5-fluorouracil used to treat keratoses at extragenital sites has caused genital irritant dermatitis [9]. Acute or chronic, sterile or superinfected (with staphylococci or *Candida*, or both), eroded or hyperkeratotic presentations are seen, depending on the scenario. A good example is nappy (diaper) rash (see Chapter 17).

Management follows lines similar to those for pruritus ani (see p. 71.86). Irritants should be identified and eliminated or reduced. Advice is given about soap substitutes, moisturizers, towels and toilet paper. Topical corticosteroid ointments, with or without antibiotic and anticandidal agents, are employed to control the dermatitis. Oral antihistamines are useful. Topical local anaesthetics should be avoided because of the risk of sensitization. Occasionally, secondary infection may be severe; a swab should be taken and oral antibiotics and oral antifungals prescribed.

A more acute picture (itch, burning or pain, swelling, erythema, vesiculation) may occur if highly irritant chemicals in high concentration are accidentally or deliberately used on the genitalia. Patients with a genital rash who are frightened that it may have been sexually acquired will sometimes self-treat with unsuitable preparations and in the process increase their morbidity and conceal an underlying sexually transmitted disease or a dermatosis. Treatment is with potassium permanganate soaks, very potent topical corticosteroid creams (sometimes systemic corticosteroids) and systemic antibiotics.

Allergic contact dermatitis

The risks of allergic contact dermatitis of the genital skin come about from: (i) direct contact with the allergen (e.g. medicaments—even coal tar allergy has been reported [10]), contraceptive usage and prosthetic limbs in amputees [11]; or, very rarely, (ii) transfer of allergen (e.g. urushiol as in poison oak, poison ivy and poison sumac dermatitis) to the genitalia [12] and possibly subsequent exposure to sunlight (e.g. psoralens from fig or citrus plants, as in phytodermatitis); and (iii) involvement in a more generalized eczematous response (e.g. to a medicament or dressing used on venous eczema or ulceration, as in the autosensitization/secondary spread/secondary generalization syndrome).

Eczematous symptomatology can appear approximately 1 week after first contact with the allergen if previously unsensitized, or within a few hours if already allergic. The patient may present with pruritus ani [13] or paraphimosis [14]. More immediate symptomatology and acute erythema and angio-oedema suggest a contact urticaria, which can occur with some of the rubber constituents of condoms and gloves [15–17].

The principles of management are the identification of the potential allergen (Table 71.19) and its likely source, and then its elimination. There may be clues to these factors at presentation but subsequent patch testing is often required. Following patch testing, Bauer *et al.* [18] made a final diagnosis of allergic contact dermatitis in 35% of patients with anogenital skin problems. Allergic contact dermatitis can persist even after withdrawal of the trigger allergen. Management is otherwise as for irritant contact dermatitis, lichen simplex and pruritus ani (see above and p. 71.86).

The most common relevant sensitivities are to rubber, contraceptives, preservatives and fragrances in toiletries and medicaments, and the active agents (antibiotics, steroids, anaesthetics) in medicaments.

Genital rubber dermatitis is not confined to young sexually active male condom users and their partners [19–22]. Incontinent men who use external urinary collection devices (Paul's tubing) are also at risk. Latex allergy may be a problem in patients with spinal cord injury using rubber products for the management of urinary difficulties; life-threatening anaphylactic reactions have occurred [21]. Condoms made from lamb caecum are available for rubber-allergic patients, but they may provide less protection against sexually transmitted disease than latex. Creating hypoallergenic condoms by washing in an ammonium solution to remove the residues of the accelerator chemicals that actually cause the hypersensitivity has proved unsuccessful [23]. Patients may become sensitized to the spermicide [19].

Celandine juice [14] and clothing dye dermatitis of the scrotum [24] have been reported.

Atopic dermatitis

Genital skin disease caused by atopic dermatis (AD) is not uncommon but rarely occurs in isolation, unlike other common chronic dermatoses such as seborrhoeic dermatitis and psoriasis. It is not known how genital AD is related to circumcision, sexual activity and sexually transmitted disease. Evidence of atopy was found in a possible 67% of a total of 72% of patients diagnosed as having irritant dermatitis from a consecutive series of men presenting to a genitourinary clinic with 'balanitis'—probably balanoposthitis [6]. AD in HIV/AIDS is discussed in Chapter 35.

Radiodermatitis

Radiodermatitis (see Chapter 79) is not usually a diagnostic challenge or a therapeutic problem in the acute stage after radiotherapy to the anogenital skin for skin disease or internal cancer. In the chronic state, there may be pruritus together with the typical poikiloderma. Radiotherapy has been used for the treatment of numerous anogenital dermatoses over the years, including Bowen's disease, erythroplasia of Queyrat, squamous carcinoma, psoriasis, Peyronie's disease and pruritus ani [25]. Radiotherapy confers a long-term increased risk of skin cancer, especially basal cell carcinoma. There is concern that radiotherapy for Bowen's disease or erythroplasia of Queyrat may increase the subsequent risk of invasive carcinoma.

Seborrhoeic dermatitis

Genital involvement is frequent with this common dermatosis. The groins and penis may be the only sites involved. A good history (including family history) and careful examination of other sites typically affected aid the diagnosis. On the scalp, the face, in the flexures and at anogenital sites seborrhoeic dermatitis and psoriasis may be indistinguishable. Seborrhoeic dermatitis in HIV/AIDS is discussed in Chapter 35.

Diagnosis is established on clinical grounds, including response to therapy, and it is not usually necessary to perform a biopsy.

No treatment may be required other than reassurance that it is not sexually transmitted or related to poor hygiene. However, treatments that diminish the *Malassezia* load and reduce irritation and eczematization can be successfully and safely used long term. These include topical antifungals (such as clioquinol, nystatin and imidazoles) as ointments, creams, lotions or shampoos, and mixtures of the same agents with mild and moderately potent topical corticosteroids used alongside emollients and soap substitutes. In severe cases, patients with concomitant seborrhoeic folliculitis, or in patients with HIV/AIDS, treatment with an oral imidazole and/or an oral tetracycline may be suitable.

Psoriasis

Approximately 2% of the population are said to have psoriasis but it is possible that many more than 2% of men may have or have had anogenital psoriasis at some time; it is certainly a common anogenital diagnosis in isolation.

Psoriasis and its clinical manifestations are discussed in Chapter 20; the relationship of psoriasis to HIV/AIDS is discussed in Chapter 35. Anogenital presentations of psoriasis may be vague in symptomatology and non-specific on examination. It is not usually itchy; significant itch should arouse suspicions of another dermatosis such as an eczematous dermatitis or tinea. Soreness occurs with superinfection, especially with *Candida*. Other typically affected sites should be examined for signs of the disease. Genital appearances may be challenging to interpret, especially in the uncircumcised patient, because a mucosal site is affected rather than keratinized skin. The diagnosis is usually easier in the circumcised male where the morphology is similar to extragenital lesions.

Inverse pattern psoriasis refers to the manifestation of the disease on intertriginous skin in the axillae, natal cleft, gluteal folds, groins and in the preputial sac and on the glans of the uncircumcised male, where its occurrence is probably brought about by the Koebner phenomenon.

Usually, the diagnosis of psoriasis is clinical, but a biopsy may be necessary (e.g. of a solitary mucosal lesion in an uncircumcised individual) to distinguish psoriasis from Zoon's balanitis, lichen planus, erythroplasia of Queyrat or Kaposi's sarcoma. Bowen's disease and extramammary Paget's disease may be misdiagnosed as psoriasis when there are single or several foci on the penile shaft and/or in the groins.

Topical treatment includes emollients, soap substitutes, corticosteroids combined with antibiotic and antifungal agents or weak tar solutions. Strong crude tar preparations should be avoided at this site given that anogenital skin has a propensity to increased absorption of topical agents and because of the risk of genital cancer; one of the first occupational diseases described was scrotal carcinoma in chimney sweeps. Dithranol is usually avoided in this region. The vitamin D analogue calcipotriol can be helpful. Topical ciclosporin (100 mg/mL in wet dressings three times daily) has been advocated [26]. Topical calcineurin inhibitors show promise [27,28]. Phototherapy is contraindicated because of the risk of anogenital cancer. Severe anogenital psoriasis can be an indication for systemic treatment.

Reiter's disease or syndrome (part of the same continuum as psoriasis in genetically predisposed individuals) is discussed in Chapter 20. Characteristic, sometimes severe, involvement of the penis (circinate balanitis) occurs. The penile lesions have the same histopathology as psoriasis [29]. Circinate balanitis responds to topical calcineurin inhibitors.

Zoon's balanitis

Aetiology. Zoon's plasma cell balanitis (ZB) is a disorder of the middle-aged and older uncircumcised male [1,2], although an analogous condition has been reported to afflict the vulva (see p. 71.61), mouth, lips [3] and epiglottis [3,4]. Since Zoon's original reports there have been many accounts in the literature, but the aetiology remains uncertain.

The evidence suggests that ZB is a chronic, reactive, principally irritant dermatosis brought about by a dysfunctional prepuce. Retention of urine and squames between two tightly apposed and infrequently and inadequately separated and/or inappropriately bathed, commensally hypercolonized, desquamative, secretory epithelial surfaces leads to a disturbed 'preputial ecology' and excessive frictional trauma (ZB is often located on the dorsal aspect of the glans and/or the adjacent prepuce, sites of maximal friction on foreskin retraction), and irritation by urine [5–8]. There is no evidence of an infectious cause, and immunohistochemical findings suggest that ZB represents a non-specific polyclonal tissue reaction [9,10], consistent with an irritant dermatosis.

Fig. 71.7 Zoon's balanitis. Symmetrical moist erythema of glans and prepuce. (Courtesy of Professor C.B. Bunker, with permission from Medical Illustration UK, Chelsea & Westminster Hospital, London, UK.)

Clinical features. The presentation is classically indolent and asymptomatic, although staining of the underclothes with blood has been reported [11]. Well-demarcated, glistening, moist, bright red or autumn brown patches involve the glans and visceral prepuce, with sparing of the keratinized penile shaft and foreskin (Fig. 71.7). The navicular fossa may be involved. Other signs include dark red stippling—'cayenne pepper spots'—and purpura with haemosiderin deposition, solitary or multiple lesions of differing sizes (guttate or nummular), characteristically symmetrical about the axis of the coronal sulcus and 'kissing'. Although vegetative and nodular presentations have been recorded, atypical or unusual morphology should be viewed with great suspicion and biopsied [7,8].

Histopathology. The classic histology is of epidermal attenuation with absent granular and horny layers, and diamond- or lozenge-shaped basal cell keratinocytes with sparse dyskeratosis and spongiosis. There is a band of dermal infiltration with plasma cells of variable density. Extravasated erythrocytes, haemosiderin and vascular proliferation are also seen. Although Zoon stressed the presence of the plasma cell infiltrate in this condition, the plasma cell numbers can be very variable [7,8,12].

Differential diagnosis. The differential diagnosis includes erosive lichen planus, psoriasis, seborrhoeic dermatitis, contact dermati-

tis, fixed drug eruption, secondary syphilis, histoplasmosis [13], erythroplasia of Queyrat [14] and Kaposi's sarcoma. A confident clinical diagnosis is not always possible or safe [6,8,15], so a biopsy is advisable, and the pathologist should be asked to look for concomitant disease. Frank cases of lichen sclerosus, lichen planus, Bowenoid papulosis and penile cancer often appear to have ZB-like changes on clinical examination and on histology [8,15]. In other words, the signs of ZB may be secondary to underlying preputial disease [8]. It is likely that some of the clinical and histological variants that have been reported [16–18], and a recent claim that ZB *per se* is a premalignant condition in a single case report [19], are a consequence of this phenomenon. ZB indicates a dysfunctional foreskin and a more sinister dermatosis may be concealed [8].

Treatment. Although ZB can improve with altered washing habits and the intermittent application of a mild or potent topical corticosteroid (with or without an antibiotic and anticandidal agent), it usually persists or relapses [7,8]. Case reports concerning the use of topical calcineurin inhibitors have appeared [20,21] but these agents should be used with circumspection in the setting of a dysfunctional foreskin and the attendant risk of penis cancer, long term. It has been claimed that Erbium : YAG or carbon dioxide laser treatment is effective [8,22–25]. Circumcision is curative [7,8]. Again, the pathologist should be asked to examine the whole specimen for signs of another underlying dermatosis.

Lichen sclerosus

Aetiology. Lichen sclerosus is discussed in Chapter 51. The aetiopathogenesis is not known. Poorly understood features are the predilection for the genitalia generally and in males, specifically the uncircumcised [1], the association with organ-specific autoimmune disease and the propensity to progress to squamous carcinoma [2–6]. HPV (types 6, 16 and 18) has been reported to be present in 70% of cases of childhood penile lichen sclerosus [7,8], and in 17.4% of adult cases (types 16, 18, 45) compared with 8.7% of normal males [9] in one study, and in 33% of adult cases (types 16, 18, 33, 51) in another [10]. Topical steroid treatment of lichen sclerosus may lead to HPV reactivation [11]. But the epidemiology and clinical tenor of lichen sclerosus is not that of an infectious or sexually transmitted disease [5,12]. There is probably a bimodal pattern of prevalence [13–15]. Anatomical abnormality and trauma seem to be contributing factors [5,16]. Specifically, lichen sclerosus has been related to hypospadias and its repair [17,18]. The presence of the histopathological features of lichen sclerosus in a percentage of acrochordons (skin tags) has led to the suggestion that occlusion of flaccid skin is a pathogenic factor [19]. The evidence points to male genital lichen sclerosus being due to chronic exposure of susceptible epithelium to urine [20]. Some men 'dribble'.

Clinical features. Lichen sclerosus of the penis may be asymptomatic, but diverse, often vague, symptomatology is usually encountered. Patients may describe itching, burning, bleeding, tearing, splitting, haemorrhagic blisters, any manner of symptoms signifying sexual dysfunction or dyspareunia, discomfort with urination and narrowing of the urinary stream, and/or they may be concerned about the changing anatomy of their genitalia [21]. Other presentations are non-retractile foreskin (phimosis) (Fig. 71.8), foreskin fixed in retraction (paraphimosis) and urinary retention, even renal failure.

Genital, like extragenital, lichen sclerosus can manifest as atrophic leukodermic patches or plaques, or lilac, slightly scaly patches with telangiectasia and sparse purpura (Fig. 71.9). Predominant purpura, bullae, erosions and ulceration may be encountered [5,22,23]. The signs may be subtle, with meatal 'pin hole' narrowing, slight tightening of the retracted prepuce because of sclerotic plaques and bands, with or without difficulty in retraction—incomplete paraphimosis or 'waisting' due to a constrictive posthitis (Fig. 71.10) or they may be florid, with severe changes caused

Fig. 71.8 Lichen sclerosus causing phimosis. (Courtesy of Dr D.A. Burns, Leicester, UK.)

Fig. 71.10 Lichen sclerosus. Sclerotic band of the prepuce causing 'waisting'. (Courtesy of Professor C.B. Bunker, with permission from Medical Illustration UK, Chelsea & Westminster Hospital, London, UK.)

Fig. 71.9 Lichen sclerosus. White plaques and haemorrhagic areas on the glans. (Courtesy of Dr D.A. Burns, Leicester, UK.)

both by the lichen sclerosus and by associated and confusing Zoon's balanoposthitis-like changes: adhesions, loss of anatomical definition and dissolution or effacement of the normally sharply defined architectural features, especially of the frenulum and the coronal sulcus. The navicule meatal fossa may be abnormal. Post-inflammatory hyper- and hypopigmentation are occasionally seen.

Whereas posthitis xerotica obliterans refers to chronic damage to the prepuce by lichen sclerosus, balanitis xerotica obliterans (BXO) properly describes involvement of the glans penis (although the term has been used imprecisely). BXO can be a consequence of other scarring dermatoses such as lichen planus and cicatricial pemphigoid [24].

Genital lichen sclerosus is more common than extragenital or oral disease, but there may (rarely) be concomitant involvement of these sites. In adults, anogenital lichen sclerosus is said to be about 10 times more common in women than men. Perianal disease is very rare in the male. The involvement of the anterior urethra can be serious; 29% of patients undergoing urethroplasty for urethral stricture had pathological evidence of lichen sclerosus [25].

The first report of genital lichen sclerosus in boys appeared only in 1977 [13]. Lichen sclerosus may be much more frequent than is generally supposed in young boys, being diagnosed histologically in 14–95% of prepuces removed for phimosis [15,18]. The development of secondary phimosis in school-age boys is highly suggestive of lichen sclerosus [14]. In the older male, persistent primary

phimosis or the secondary development of phimosis in a previously retractable foreskin may be related to lichen sclerosus [5].

Most cases of genital lichen sclerosus can be diagnosed clinically. Lichen planus and the much rarer mucous membrane pemphigoid are in the differential diagnosis. A biopsy should be performed if there is clinical doubt or if the lesion is eroded or verrucous.

Histopathology. The histology is described in Chapter 51. The occasional association of endarteritis led originally to the usage of the term 'obliterans' [26]. In two cases in boys, a dermal lymphohistiocytic and granulomatous phlebitis has been found, and one also had evidence of HPV [27]. A 'garland-like' basal lamina has been found ultrastructurally [28]. Sometimes, lichen sclerosus may be difficult to differentiate from lichen planus, and criteria to assist, in the vulva, have been proposed by Fung and LeBoit [29]. The histological features may simulate mycosis fungoides [30].

Treatment. Guidelines for the management of lichen sclerosus have been published by the British Association of Dermatologists [31]. Contact with soap and urine should be avoided. A very potent topical corticosteroid (usually clobetasol propionate) used under supervision is effective [5,32–34] and usually problem free, but herpes simplex and wart reactivation have been reported [11,31]. The plasticity of the epithelium at this site seems to allow significant remodelling, with the relief of phimosis, improvement of incomplete phimosis or 'waisting'/constrictive posthitis, improvement in the histological changes and avoidance of circumcision [5,21,33]. Topical clobetasol propionate has been shown to relieve undifferentiated 'phimosis' in many boys and so obviate the need for circumcision [34]. Secondary candidal and bacterial infection should be treated. There are reports of the efficacy of long-term systemic antibiotic therapy (penicillin and azithromycin) in cases of lichen sclerosus thought to be associated with *Borrelia* infection [35,36]. Testosterone propionate ointment, oral stanozolol, freezing with ethyl chloride, liquid nitrogen cryotherapy, carbon dioxide laser and adrenocorticotrophic hormone (ACTH) have been used but are not recommended [5].

If medical treatment is not possible or fails, then surgery may be indicated. Circumcision, frenuloplasty, meatotomy and sophisticated plastic repair, depending upon the clinical presentation, can be offered. Carbon dioxide laser circumcision has been described [37]. In boys, complete circumcision is the treatment of choice because all affected tissue is removed and any secondary involvement of the glans probably regresses or resolves [14]; it is the unproven impression that this phenomenon also occurs in most adult patients. About 40% of patients will respond to medical treatment: the majority of the remainder will be cured by surgery, usually circumcision [38]. Persistent disease requires individualised follow-up and management. Residual burnt-out disease on the glans may improve with long-term topical retinoid treatment. Lichen sclerosus can recur in donor grafts from unrelated sites [22,39].

Squamous carcinoma of the penis is the most serious potential complication of lichen sclerosus [5]. Early microinvasive disease might be difficult to diagnose clinically against a background of lichen sclerosus [40]. A risk of 2–9.5% is suggested by the literature, depending on length of follow-up; the latent period may be one to three decades [5,6,41–44]. Verrucous carcinoma (Buschke–Löwenstein tumour) has been associated with previous lichen sclerosus [45]. Carcinoma complicating lichen sclerosus constituted one-third of all cases of penile cancer seen by Campus *et al.* [46] and, of 20 patients with penile squamous cell carcinoma (SCC) studied by Powell *et al.* [47], 11 had a clinical history and/or histological evidence of lichen sclerosus. Involvement of the glans penis confers a greater risk [44].

The effect of medical and surgical treatment on the subsequent incidence of penile cancer is not known [48,49]. Liatsikos *et al.* [50] report SCC of the glans developing in one of eight patients followed-up after circumcision for lichen sclerosus. Patients should be followed-up long term, especially if circumcision has not been performed or if symptoms persist or recur after any form of treatment.

Lichen planus

Aetiology. Lichen planus is discussed in Chapter 41. It is a common inflammatory dermatosis with a particular predilection for the orogenital epithelium [1]. The aetiopathogenesis of lichen planus is not known. Drugs can cause a generalized lichenoid eruption; a case of a lichenoid drug eruption confined to the penis resulting from propranolol has been reported [2].

Clinical features. Lichen planus can present in, and remain localized to, the anogenital area, including the groins and perianal skin. Like the classical disease at other sites, it presents as itchy red–purple papules, patches, plaques and annular lesions (Fig. 71.11). It may also present as phimosis [3,4]. The male genitalia represent the commonest site for the annular subtype of lichen planus [5]. The Koebner phenomenon may partly explain the orogenital predilection [6].

Occasionally, an erosive form is encountered. There is a male equivalent of the vulvovaginal syndrome of Hewitt—the genito-gingival syndrome—with chronic erosive gingival and genital lesions [7]. In most cases, anogenital lichen planus is self-limiting, although some patients remit and relapse. Adhesions can form and contribute to phimosis. Post-inflammatory hyperpigmentation can persist for months or years. A case of paraneoplastic lichen planus with orogenital and cicatrizing conjunctival involvement in a patient with thymoma has been reported [8].

Chronic mucosal erosive lichen planus is associated with a risk of progression to squamous carcinoma, but most reports of this

concern oral lichen planus. There are rare reports of squamous carcinoma eventuating from chronic penile dermatoses thought to be lichen planus [9–11].

Lichen nitidus has an affinity for the penis. It can be difficult to diagnose because the signs may be subtle, even when the lesions are widespread.

The differential diagnosis of anogenital lichen planus includes psoriasis, Zoon's balanitis, lichen sclerosus, viral warts, Bowenoid papulosis and porokeratosis. A biopsy is frequently necessary for diagnostic purposes and in the follow-up of cases of chronic anogenital disease if erosive, ulcerative or verrucous features arouse concern about the development of squamous carcinoma.

Treatment. Potent and ultrapotent topical corticosteroids usually suffice for treatment. Patients are told to continue with the treatment until the lesions are non-itchy and flat; they are warned about post-inflammatory hyperpigmentation. Reactivation of genital warts may occur [12]. Topical and oral ciclosporin have been used [13,14], but there has been a report of squamous carcinoma arising in lichen planus of the penis treated with topical ciclosporin [15]. Topical calcineurin inhibitors should be used with caution [15–17]. Circumcision may be necessary for phimosis [18] and should be considered in refractory erosive disease [19], the rationale being that the abolition of koebnerization influences and facilitates resolution of the lichen planus. Photodynamic therapy was used inadvertently in one patient with lichen planus of the glans penis, to good effect [20].

Non-specific balanoposthitis

Clinical experience and histological evidence indicate that non-specific balanoposthitis is a real entity [1,2]. However, in practice it is a diagnosis of exclusion, sexually transmitted disease, eczematous dermatoses, psoriasis, Zoon's balanitis, lichen planus, lichen sclerosus, cicatrizing pemphigoid and penile carcinoma *in situ* having been clinically considered and eliminated by special investigations, including biopsy, and failure to respond to specific treatments. Non-specific balanoposthitis is a manifestation of a dysfunctional foreskin. Patients generally present with dyspareunia, and may have variable signs, including eczematous, lichenoid and Zoon-like inflammation, and even scarring. *Candida* and other organisms may be retrieved, but they probably represent secondary opportunistic infection. Diabetes should be excluded. Specific and non-specific interventions may be tried, such as avoidance of contact with soap and urine and other irritants, treatment for candidosis and other infections, and medical treatment for lichen sclerosus and lichen planus. Invariably these treatments fail and the patient is cured by circumcision. A prior clinical diagnosis may be overturned at this stage by foreskin histology showing lichen sclerosus, lichen planus or carcinoma *in situ*, but there will always be cases where a thorough histological examination of the excised prepuce fails to reveal more than non-specific chronic inflammatory changes.

Ulcerative disease and penile necrosis

The causes of genital ulceration are listed in Tables 71.9 and 71.10, and the causes of penile necrosis in Table 71.20. Many of the causes are discussed in this or other sections.

Aphthous ulceration of the penis and scrotum can occur, including in HIV/AIDS (see Chapter 35), but specific exclusion of sexually transmitted diseases and consideration of other causes of genital ulceration, especially Behçet's syndrome, is necessary. The causes are obscure and the histology is non-specific.

Five cases of spontaneous scrotal ulceration in young, previously fit men have been described [1]. Histology showed non-specific vasculitis, and spontaneous resolution occurred. This entity may be related to idiopathic scrotal panniculitis and fat necrosis. It is distinct from other causes of the acute scrotum in prepubertal boys. It presents as acute, tender, sometimes painful, swelling (classically, but not always, after swimming in cold water). Masses may be palpable in the scrotal wall. Otherwise, the boy is well, with no fever or leukocytosis. Idiopathic scrotal necrosis in a 2-month-old boy has been documented by Sarihan [2],

Warfarin
Fixed drug eruption

where trauma, extreme cold and Fournier's gangrene were excluded. Management is expectant and conservative [3,4]. In adults, one case of idiopathic scrotal panniculitis has been reported [5] and another associated with pancreatitis [6].

Subtle or severe orogenital ulceration can occur in erythema multiforme or the Stevens–Johnson syndrome (see Chapter 76).

Adamantiades-Behçet's disease is discussed in Chapter 50. Recurrent genital ulceration is not mandatory for the diagnosis; if patients do not have genital ulceration then they must have ophthalmic and dermatological involvement or a positive pathergy test [7]. In practice, there are many patients who have an incomplete syndrome. Other anogenital manifestations include epididymitis and urethritis [8], spontaneous haematocoele from venous rupture resulting from lymphocytic venulitis [9], and erectile dysfunction [10]. The genital ulcers in men can be very painful and occur anywhere in the anogenital area, including the perianal skin. Generally, they are larger, deeper, fewer and less recurrent than those in the mouth. Patients with relapsing polychondritis and Behçet's disease have been reported, and the acronym MAGIC (mouth and genital ulcers with inflamed cartilage) syndrome has been proposed [11,12]. The histology of Behçet's disease is usually non-specific and does not enable it to be distinguished from idiopathic aphthae, although sometimes necrotizing vasculitis can be present.

Scrotal involvement can occur in Hailey–Hailey disease [13].

Degos' malignant atrophic papulosis (see Chapter 50) can cause painful penile ulceration, that may precede the development of the eruption elsewhere and be associated with fatal involvement of other organs, despite aggressive treatment [14,15].

Fig. 71.12 Pyoderma gangrenosum in a patient with severe seronegative arthropathy. (Courtesy of Dr F.A. Ive, Durham, UK.)

The hypereosinophilic syndrome involves the skin in up to 50% of cases, with orogenital ulceration, erythroderma and urticaria. It may occur in HIV infection [16].

Wegener's granulomatosis may present with glans penis ulceration and necrosis; repeated ANCA estimation may be needed and it may be some time before systemic manifestations declare themselves [17–21].

There has been one case report of a patient with erythema elevatum diutinum causing penile ulceration [22]. Three cases of necrobiosis lipoidica have been reported presenting as erythematous ulcerated lesions of the glans penis. One patient was diabetic and also had lesions on the legs [23]; the others had penile lesions only, and were treated with oral pentoxifylline [24,25].

There are a number of case reports of pyoderma gangrenosum (see Chapter 50), including the variant superficial granulomatous pyoderma [26], involving the penis and scrotum in adults and children (where the anogenital area is a site of predilection as well as the head and neck) (Fig. 71.12) [27,28]. Genital pyoderma gangrenosum may occur following local trauma such as urological surgery [29,30] or treatment for cancer [31], or complicate ulcerative colitis [32] or chronic lymphocytic leukaemia, or it may be idiopathic [33–36]. Pyoderma gangrenosum is a diagnosis made when other causes of purulent ulceration, such as infection (sexually acquired and exotic or rare, including Fournier's gangrene), malignancy and artefact have been excluded. Systemic treatment is usually required but one case has responded to topical tacrolimus [37].

Calciphylaxis (see Chapter 62) is a rare and serious complication of chronic renal failure in which extending ischaemic gangrenous necrosis affects acral tissues and sometimes the thighs, buttocks and genitals [38–43].

Ulcers in the penoscrotal region have been reported to appear 2 to 4 weeks after Chikungunya, a novel togavirus arboviral infection that causes fever, headache and arthralgia [44].

There has been one case report of primary cutaneous T-cell lymphoma of the penis presenting with a 2-year history of 'recurrent balanitis', a preputial ulcer and phimosis [45].

Pilonidal sinus

Pilonidal sinus very rarely affects the penis, but when it does it is usually in the coronal sulcus [1,2]. Some of the reported cases have been complicated by actinomycosis [1,3], and one has been associated with a dermoid cyst [4].

Penile acne

There is no literature on this condition but it is occasionally encountered. Patients have comedones, papules, pustules and inflammatory nodules of the proximal shaft of the penis. The differential diagnosis should include chloracne (see Chapter 42). Patients respond to conventional treatment for acne.

Peyronie's disease

Peyronie's disease [1,2], which affects middle-aged and older men, is a localized fibrotic disorder involving tissue immediately adjacent to the erectile tissues. It presents with pain and curvature on erection, a sensation of a cord within the penis, palpation of a lump or knot, decreased erection distal to the plaque, interference with intercourse and progressive impotence. It may be subclinical in many men, given that 23% of autopsies have shown histological evidence of the condition [1]. Psychological complications and marital difficulties occur. The penis curves towards the lesion, with dorsal curvature being most common. Peyronie (a physician to Louis XIV) described nodules as 'rosary beads' but plaques vary in size. It has been associated with systemic sclerosis [3,4], and such patients may have penile Raynaud's phenomenon [5]. It has occurred as a complication of the use of a vacuum erection device [6], but in most men the cause is unknown. Some evidence has been advanced for an autoimmune pathogenesis [7]. A case complicating chronic-graft-versus host disease has been reported [8].

The differential diagnosis includes congenital curvature, fibrosis secondary to trauma or urethritis and abscess, syphilitic gumma, lymphogranuloma venereum, and infiltrative tumours (e.g. lipogranuloma). Penile thrombophlebitis as the initial presentation of a paraneoplastic migratory thrombophlebitis resulting from pancreatic cancer has been misdiagnosed as Peyronie's disease [9].

In some men there may be spontaneous regression. Treatments include intralesional corticosteroid injection [10], including delivery by Dermojet [11]. Surgery is avoided, but some specialized techniques are available [12]. Symptomatic relief has been claimed following iontophoresis of drugs such as dexamethasone, lidocaine (lignocaine) and verapamil [13].

Drug reactions

The penis is a site of predilection for fixed drug eruption (see Chapter 75). The symptoms are itch or burning. The eruption is acute, with an erythematous plaque, sometimes with central blister formation, erosion and ulceration. Cases have occurred in men after congress with sexual partners who have taken the drug to which they were known to be sensitive: co-trimoxazole, diclofenac, isosorbide and aspirin are the drugs cited [1,2]. The differential diagnosis of penile fixed drug eruption includes herpes simplex and erythema multiforme.

Ulceration has been reported following the inadvertent subcutaneous injection of papaverine for the treatment of erectile impotence [3]. Dequalinium is a topical antibacterial that was used for the treatment of impetigo and moniliasis in the 1950s and 1960s, but it caused a necrotizing balanitis with ulceration when used for the treatment of balanitis in uncircumcised men [4]. Warfarin necrosis can affect the genitalia [5]. All-*trans*-retinoic acid has been reported to induce scrotal ulceration in a patient with acute promyelocytic leukaemia [6]. Foscarnet is a recognized cause of genital ulceration in HIV-infected patients [7–9]. Nicorandil is a newly recognized cause of anogenital and peristomal ulceration [10–12]. Erosion following the use of topical steroids has been seen. Penile argyria due to chronic application of silver sulfadiazine has been reported [13].

Miscellaneous inflammatory dermatoses

Bottomley and Cotterill [1] have described an acutely tender erythematous scrotum associated with zinc deficiency in a patient with Crohn's disease. Necrolytic migratory erythema can be localized to the genitalia [2]. Skin fragility and ulceration in the anogenital area are features of prolidase deficiency [3].

Autoimmune bullous diseases such as pemphigus can involve the penis (the glans is the usual site) (Fig. 71.13), but very rarely in isolation [4]. Pemphigus vegetans presenting with a 4-year history of indolent tender balanitis, where the glans penis was involved with a moist vegetative plaque with beefy red erosions separating irregular hyperkeratotic mounds, has been reported [5]. Linear immunoglobulin A (IgA) disease commonly involves the mucosae. Mucosal lesions of bullous pemphigoid are uncommon; their presence suggests another diagnosis or an underlying neoplasm. Pelvic girdle lesions are often seen, but rarely in isolation.

Cicatricial pemphigoid (or 'benign') mucous membrane pemphigoid) is a rare variant of bullous pemphigoid in which blisters affect the skin and the mucous membranes. Skin lesions are usually less widespread than in bullous pemphigoid and they may heal with scarring. Oral lesions predominantly involve the palate and gingivae, but there may be oesophageal involvement with dysphagia, and conjunctival disease can lead to blindness. Involvement of the penis may be with blisters, erosions, ulcers, transcoronal adhesions, scarring and phimosis [6–8]. Although direct immunofluorescence is usually positive, circulating antibodies to the basement membrane zone are rarely found. The disease often responds poorly to oral steroids, but dapsone or other sulpha drugs such as sulphamethoxypyridazine can be effective. Regular haematology screening is mandatory with dapsone because of the risk of agranulocytosis.

One patient with Darier's disease developed a HPV 16-associated squamous carcinoma of the scrotum during oral isotretinoin treatment; he had not previously had radiotherapy to the genitocrural area [9]. Genitocrural papular acantholytic dermatosis can involve the penis, as can granuloma annulare. Erythematous smooth, round and linear nodules are described in the latter. Most patients are uncircumcised. Extragenital granuloma annulare is uncommon in these patients.

Occasionally, patients with generalized cutaneous sarcoid present with genital lesions [10]. Tender erythematous induration of the distal shaft of the penis and several yellowish subcutaneous nodules on the glans have been described [11]. A case presenting with penile ulceration has been reported [12]. Importantly, sarcoid can masquerade as testicular malignancy [13–15].

A granulomatous lymphangitis may be found histologically in the investigation of penile lymphoedema [16]. It can be a rare feature of the Melkersson–Rosenthal syndrome. Crohn's disease can involve the penis and scrotum, presenting as penoscrotal lymphoedema or erosions and ulcers [17–23].

A soft-tissue mass in the penis associated with systemic amyloid has been reported [24]. A handful of cases of primary localized cutaneous amyloid of the penis appear in the literature [25]. Primary amyloid of the urethra is very rare indeed, but accurate diagnosis is essential, as its presentation simulates carcinoma, with dysuria, bloody discharge and tender induration of the penis [26], or as an obstructive voiding syndrome, with tender periurethral masses and irregular urethral strictures [27].

One case each of eccrine syringofibroadenomatosis with penile involvement manifesting as a balanoposthitis [28], benign mucinous metaplasia with a preputial 0.6 cm papule replacing the superficial epidermis [29], and mucinous syringometaplasia with an ulcerated papule on the shaft of the penis [30] have been reported.

Acute scrotum is a clinical syndrome defined as acute painful swelling of the scrotum or its contents, usually in boys, accompanied by local signs and general symptoms [31]. The critical differential diagnosis is torsion of the testis or spermatic cord. Other causes include idiopathic scrotal oedema, epididymitis, orchitis, hernia and haematocoele. Thromboangiitis obliterans has been found in two cases [32]. Acute scrotal swelling may be a physical sign of primary peritonitis in children and infants [33] or secondary peritonitis resulting from appendicitis, healed meconium peritonitis in the neonate, haemoperitonitis (ruptured spleen) and pseudotorsion resulting from ventriculoperitoneal shunts inserted for hydrocephalus that have migrated into the scrotum from the peritoneum. Acute idiopathic scrotal oedema usually affects children aged 4–12 years old. Allergy, infection (umbilical sepsis), trauma, insect bites, urinary extravasation and Henoch–Schönlein purpura have all been considered as causes. It is rare in adults, but cases in association with septic diabetic foot have been reported [34].

Henoch–Schönlein purpura/anaphylactoid purpura/allergic vasculitis may affect the genitalia. Ureteritis, renal pelvic haemorrhage and pain and swelling of the spermatic cord have been reported. The incidence of scrotal involvement ranges from 2 to 38%. Penile shaft involvement is less common and involvement of the glans very rare [35]. In some cases, the presentation has masqueraded as testicular torsion, resulting in unnecessary surgical exploration. Ultrasonography can help to distinguish between them [36]. However, testicular torsion can also be a real and serious complication of Henoch–Schönlein purpura [36].

Acute haemorrhagic oedema of childhood may present as tenderness, redness and swelling of the penis and scrotum with the development of more widespread haemorrhagic lesions [37]. The differential diagnosis includes acute febrile neutrophilic dermatosis, erythema multiforme, Henoch–Schönlein purpura and child abuse. The prognosis for complete recovery is excellent. Acute inflammation of the scrotum in patients with familial Mediterranean fever can occur [38]. It is manifested by pain, erythema and swelling, fever, leukocytosis and elevated erythrocyte sedimentation rate (ESR). It may occur in isolation or accompanying peritonitis. The differential diagnosis includes torsion, orchitis and epididymitis in boys.

Polyarteritis nodosa may be associated with testicular and epididymal involvement, with scrotal pain and swelling. In one case these were the sole presenting features and testicular biopsy provided the diagnosis [39–41].

There has been one patient who presented with 'inaugural' painless erythematous papules on the penis that histologically showed granulomatous vasculitis, leading to the diagnosis of Churg–Strauss syndrome [42].

Non-sexually transmitted infections

Staphylococcal cellulitis

Cellulitis may affect the penis. Piercing and genital jewellery predispose to infection. Cellulitis and abscess formation can

complicate cysts, sinuses and fistulae, and sexually transmitted infections. The exact relationship between episodes of acute infection and chronic penile oedema, which often is complicated by cellulitis, is uncertain.

Anogenital infection is a serious complication in patients with malignant disease, and potentially life-threatening necrotizing fasciitis and Fournier's gangrene may occur.

Streptococcal dermatitis/perianal cellulitis

This syndrome in children [1] probably also has a corollary in adults [2], but it is much more common in boys in whom, if the penis is involved, there may be dysuria, erythema and swelling of the penis and balanoposthitis. Bullous necrotic erysipelas of the penis due to *Streptococcus pyogenes* has been reported [3].

Chronic penile oedema

Chronic penile lymphoedema is a relatively rare, reactive, disfiguring condition that causes sexual dysfunction and phimosis [4]. It has been called tumorous lymphoedema or elephantiasis verrucosa nostra [5]. Evidence of streptococcal infection may be present, and this could lead to irreversible lymphatic damage. Other cases seem to be idiopathic and are perhaps brought about by primary hypoplastic lymphatics. Some patients have a coexistent penile dermatosis. Few cases of chronic penile oedema have been reported [4,6,7] and the aetiopathogenesis may have been misunderstood.

Penoscrotal oedema has also been attributed to continuous ambulatory peritoneal dialysis [8], amputation of septic limbs in diabetes [9], acute necrotizing pancreatitis [10], streptococcal infections [11], and Crohn's disease, which may be occult and asymptomatic [12]. Filariasis and pelvic mass lesions should be excluded. Penile venereal oedema has been associated with gonococcal and herpes infection, and scabies infestation, and resolves after treatment of the underlying disease [13]. Similarly, childhood penile oedema is self-limiting [14]. It is possible that some cases of chronic penile oedema are related to any of the above factors and/or temporally unrelated but repetitive sexually transmitted disease. A persistent lymphatic insult from whatever cause could result in an inflammatory process affecting genital and pelvic lymphatic vessels and nodes. Imaging of lymphatic channels is not particularly helpful [15].

Patients with chronic penile oedema present with chronic swelling of the penis, foreskin, scrotum, pubic mound, buttocks and thighs, which may be warm and red. There may be intercurrent attacks of cellulitis and/or erysipelas with systemic upset. Acute attacks require admission to hospital and treatment with systemic broad-spectrum antibiotics; a short course of prednisolone may also be helpful. Investigations should be directed at elucidating possible underlying causes (such as streptococcal infection (ASOT), Crohn's disease and sarcoid) and predisposing factors, as discussed above (see also Tables 71.25–71.27). All cases of penoscrotal oedema should be treated aggressively at first presentation, because the more chronic the genital lymphoedema the more difficult it is to treat, both medically and surgically [16]. Aims of management of chronic penile oedema must be prophylaxis against further infective episodes and aggressive treatment of relapses.

Long-term treatment with erythromycin, clarithromycin, clindamycin, trimethoprim or ciprofloxacin appears to ameliorate and stabilize the process, and improves the appearance and function of the penis. The success of this approach supports the importance of infection as a factor in the perpetuation, if not initiation, of the process. Medical control with antibiotics then allows surgical intervention in the form of circumcision. Plastic repair may be necessary after excision of affected tissue [17,18].

Ecthyma gangrenosum

Ecthyma gangrenosum has a predilection for the acral and anogenital regions, and may affect the penis in isolation, leading to gangrene [1]. The prognosis is poor. A case has been reported that was probably caused by direct arterial septic embolization of the penis from femoral heroin injection [2].

Fournier's gangrene

Fournier's gangrene is analogous to necrotizing fasciitis and Meleney's gangrene. In 1883, the Parisian dermatologist Alfred Fournier described five cases of spontaneous genital gangrene and ulceration, but Baurienne (1764) probably first reported this condition [3]. The disease begins with urethral or appendageal polybacterial infection. Most of the organisms isolated are resident urethral

Warfarin necrosis

or lower gastrointestinal flora, and most patients have mixed infections. In children, staphylococci and streptococci are most commonly isolated [4]. A necrotizing vasculitis, possibly exotoxin-mediated, ensues with devastating consequences for involved skin, subcutis, fascia and muscle. It is held to be the human counterpart of the local Shwartzman phenomenon [5,6]. Painful, erythematous swelling of the genitals (particularly the scrotum [7], where a dark red or a black spot may appear [8]), perianal or lower abdominal skin, no suppuration, crepitus [9], marked systemic toxicity (may be absent in children [4]), and urinary retention, describe a typical presentation. Necrosis of skin and deeper tissues can occur rapidly, and there is a very high mortality unless the diagnosis is made promptly and radical management undertaken. Plain X-rays may show soft-tissue gas [10]. Predisposing factors are listed in Table 71.21. Preceding surgery, including vasectomy and instrumentation, including genital piercing [11], especially in patients with the listed risk factors, is particularly important. The differential diagnosis is given in Table 71.22.

If a diagnosis of Fournier's gangrene is made, radical surgical debridement of all affected tissue is undertaken and broad-spectrum systemic antibiotic therapy initiated. Plastic repair can be undertaken if the patient survives [7]. Hyperbaric oxygen, high-dose systemic steroids and unprocessed honey treatment have been used [6,12–14]. In adults, the mortality is approximately 25%. Children can be treated with more conservative surgery, and their mortality rate is lower [4,15].

Trichomycosis pubis

Trichomycosis pubis causes asymptomatic yellow, red or black micronodules around hair shafts [1]. Pubic and axillary hair may be involved. The skin is normal but the sweat may be discoloured. Trichomycosis pubis is rare in Western dermatological practice but is common in the Middle East [2], and may occur concomitantly with trichosporosis in India [3]. It is caused by *Corynebacterium* spp. The differential diagnosis includes true mycoses such as white or black piedra. Treatment is with topical benzoic acid, salicylic acid, clindamycin or naftifine [1].

Tuberculosis

Tuberculosis of the penis is rare [4] but important given the resurgence of the disease. Primary penile ulceration (solitary and multiple), with or without inguinal lymphadenopathy, caused by sexual infection or contact with infected clothing may occur [5], or the ulceration may be secondary to tuberculosis elsewhere (e.g. the lung) [6]. A cold abscess (presenting as erectile impotence) has been reported [7]. Tuberculides have involved the penis, including in isolation [8].

Non-syphilitic spirochaetal ulcerative balanoposthitis

This condition is recognized in the Tropics and South Africa, presenting as large serpiginous foul-smelling ulcers in uncircumcised men, associated in some with non-tender inguinal lymphadenopathy. Treatment is with penicillin or metronidazole [9].

Yaws

An ulcerated, crusted and papillomatous lesion has been reported on the prepuce as part of disseminated early yaws (with other skin

lesions elsewhere) in a patient in an endemic region. Several family members were also infected. The genital lesion probably arose from autoinnoculation [10].

Candidosis

Genitourinary physicians maintain that *Candida* can be the cause of urethritis and balanoposthitis [11] and cause erosive disease of the glans and prepuce. The glans penis and prepuce may be eroded. *Candida* of the penis (with a prevalence of approximately 10% of that of vaginal candidosis) has attracted very little research interest [12]. However, *Candida* may be more often a secondary pathogen than a sexually acquired infection. Observing the signs of candidosis, or demonstrating the presence of the organism, does not prove that it is the cause of all the symptoms and signs. An underlying dermatological or medical cause should be excluded. The symptoms and signs of *Candida* may be more florid than the underlying predisposing cause. Medical causes include diabetes mellitus, iatrogenic immunosuppression and systemic antibiotic treatment. Although oropharyngeal candidosis is almost invariably found in HIV infection, candidal balanoposthitis is not generally associated, perhaps because it is overlooked or because many patients take long-term imidazole antifungals orally.

Candida albicans is such a ready opportunist organism because it is a part of the resident flora of the gastrointestinal tract and may be retrieved from intertriginous areas, including the preputial folds, in the absence of symptoms and signs. Candidal balanoposthitis could be a sexually transmitted disease that may have an affinity for the anatomically or physiologically abnormal penis, or in individuals predisposed by other factors or disease, and where there is chronic vaginal or anal carriage in a partner. Screening should be performed for other sexually transmitted diseases.

Diagnosis is discussed in Chapter 36. Underlying disease should be identified and treated, and predisposing factors rectified. Treatment includes topical nystatin, clioquinol or an imidazole, often very usefully combined with hydrocortisone or a moderately potent corticosteroid. In severe disease, an oral imidazole may be indicated.

Tinea

Tinea of the penis or scrotum is uncommon and when it occurs it is usually associated with crural disease. Rarely encountered is the occurrence of tinea on the glans penis as a seat of itch or pain, and producing an erythematous patch or a crop of scaly papules [13–18]. Penile tinea in India has been associated with occlusion resulting from the wearing of a langota—a T-shaped piece of cloth tied over the genitalia [15].

Deep fungal infections

Although histoplasmosis is a common cause of disseminated fungal infection in the USA, urological and anogenital disease (usually ulceration and adenopathy in an ill patient) is rare [19,20]. An otherwise well man with a small warty nodule on the glans penis has been reported [21]. One patient with a penile ulcer transmitted the disease venereally to his wife [22]. In blastomycosis, although the genitourinary tract (prostate and epididymis) is involved in 20–30% of cases [23], involvement of the genital skin is rare. However, lesions of the prepuce and perianal skin have been recorded [24,25]. Paracoccidioidomycosis can be the cause of scrotal swelling and genital nodules and erosions [26]. Zygomycosis is usually regarded as rhinocerebral infection but a diabetic with purulent lesions of the penis has been described [27].

Miscellaneous infections

Bacillary angiomatosis (see Chapter 35) is important in the differential diagnosis of AIDS-related Kaposi's sarcoma. A case in which

the presenting tender red nodules affected the scrotum and groins has been published [1].

Buruli ulcer of the penis and scrotum due to *M. ulcerans* is a rare disease. Medical treatment is disappointing and lesions need excision and grafting [2].

Male genital involvement with leprosy is uncommon, but there are reports, and it may occur in isolation [3–5].

The penis is rarely affected by pityriasis versicolor and probably almost never in isolation [6,7]. However, *Malassezia* yeasts may colonize both the circumcised and uncircumcised penis [8]. Occasionally, the anterior pelvic girdle is the site involved.

One case only of superficial phaeohyphomycosis manifesting as multiple, 1–3 mm, pigmented papules, resembling seborrhoeic keratoses, on the scrotum of an HIV-positive patient has been described. Microscopy showed a mass of mycelia, and two dematiaceous fungi were cultured [9].

Genital herpes simplex may be acquired non-sexually (e.g. during contact sports such as rugby football [10]). A phenomenon of chronic erosive and verrucous herpes as part of immunoreconstitution disease has been described in HIV infection [11].

Sacral herpes zoster is discussed in Chapter 33. Lesions may be found on the scrotum and penis [12], and urinary retention and constipation can occur.

It is not unusual for the herald patch of pityriasis rosea (thought now to be due to HHV6/7) to appear on suprapubic skin or in the groin. Incomplete or limited presentations (e.g. affecting the pelvic girdle) are not rare, although careful examination may elicit another patch on the neck or in the axilla.

A distinctive sequel of Chikungunya (a novel togavirus arboviral infection that causes fever, headache and arthralgia) may be ulcers in the penoscrotal region [13]. Amoebiasis can rarely present as a painful ulcerative balanitis, with swelling, frequency, dysuria and retention [14]. Self-inoculation from concomitant intestinal infection, by heterosexual intercourse where the female partner has amoebic vaginitis, or by sodomy, are the putative mechanisms. Amoebiasis as the cause of genital ulceration should lead to the suspicion of underlying HIV infection [15].

Cutaneous leishmaniasis can affect the genitalia [16,17]. An erythematous scaly plaque on the glans [18] and a sporotrichoid distribution on the shaft of the penis [19] have been reported. Post-kala-azar dermal leishmaniasis of the penis and scrotum has been described. Rarely, genital skin lesions may lead to the diagnosis of schistosomiasis. They occur because ova shed by worms enter the perineal vessels [20]. The papules and nodules may be skin-coloured, pink or brown, scattered or grouped, affecting the penis and scrotum. They can spread onto the perineum and around the anus, and may develop into soft, warty, vegetating lesions. Ulceration is rare and, even more rarely, concomitant carcinoma has been reported [20].

The anogenital consequences of onchocerciasis are 'leopard skin' hypopigmentation (the scrotum is commonly involved), ileal crest and scrotal nodules, 'hanging groin', and scrotal enlargement [21,22]. The differential diagnosis of the scrotal enlargement includes bancroftian filariasis [23]. Other filarial infections can lead to mild hydrocoele or gross elephantiasis. Filariasis can cause secondary lymphangiectasis. Excision, grafting and genital reconstruction can be undertaken [24].

Dermatological aspects of sexually transmitted disease

MRSA

MRSA presents increasing challenges in general dermatology. There is emerging evidence that community-associated MRSA can be a sexually transmitted disease [1].

Syphilis

Syphilis (see Chapter 34) is endemic throughout the world. It is enjoying a resurgence in both heterosexual and homosexual populations [2]. All manifestations of syphilis can affect the genital region [3]. In 1899, primary syphilis was reported in New York to be a complication of Mosaic circumcision rites in newborn Jewish boys where rabbis used the mouth as a means of stopping

haemorrhage [4]. Balanoposthitis can complicate and obscure penile chancre. The granulomatous gumma may affect the genital area as an ulcer, a white plaque or as an atrophic scar. Pseudochancre redux describes gummatous (tertiary stage) recurrence at the site of the primary chancre [5]; it is very rare.

Viral warts

The burden of genital infection with HPV is enormous [6]. Circumcised men are more likely to have genital warts than the uncircumcised, but when warts are present in uncircumcised men they are more likely to be distally situated [7]. The risk of acquiring genital warts is significantly reduced by using condoms [8]. Clinically inapparent disease may present as balanoposthitis [9]. Subclinical or latent genital HPV infection may be 100 times more common than classical condylomas [10]. The prevalence of HPV in the genital tract of men is similar to that in women, and is between 3% and 45% depending on the age and population [11]. The estimated lifetime risk of acquiring HPV sexually is greater than 50%, and may be 80% [10]. Only 25% of the population of the USA were thought to have no prior or current genital HPV infection in 1997 [12]. The 5% acetic acid test is not a very specific aid to the identification of warts or dysplastic lesions [13]. Accurate diagnosis of HPV infection can probably only be achieved by molecular methods [14]. Congenital and acquired immunosuppression increases the susceptibility of the anogenital region to HPV infection and reactivation and progression to dysplasia and frank malignancy [15]. Topical steroid treatment of genital dermatoses may reactivate genital warts [16].

The clinical diagnosis of HPV infection is usually certain, but condylomata lata (secondary syphilis), lichen planus, molluscum contagiosum, Bowenoid papulosis and pearly penile papules enter the differential diagnosis. Solitary lesions have a wider differential diagnosis, including giant condyloma, squamous carcinoma and transitional cell carcinoma of the distal urethra, which can present as a warty lesion at the urethral meatus [17]. Biopsy should be performed if there is diagnostic doubt. Patients with anogenital warts and their partners may require full sexually transmitted disease and sometimes colorectal assessment. Treatment can be challenging [3,6].

Molluscum contagiosum

Molluscum contagiosum is discussed in Chapter 33. Young men are commonly seen with penile and pubic lesions and it is assumed that this is a sexually transmitted infection, but this may not always be the case.

Human immunodeficiency virus infection

Ulcerative genital disease is a risk factor for HIV [18,19], but anogenital ulceration may be a consequence of HIV infection (see Chapter 35) [20]. Table 71.23 lists the main causes. Biopsy, with special stains and culture, is mandatory. Other genital problems in HIV, such as psoriasis, warts, intraepithelial neoplasia, squamous carcinoma and Kaposi's sarcoma, are discussed elsewhere.

Phthiriasis

Phthiriasis (see Chapter 38) can present with marked genital and pubic itching with few overt physical signs, or as an infected genitocrural and pubic eczema that conceals the underlying primary signs. In hirsute men, the abdomen, chest, axillae and thighs may also be involved. Screening for other sexually transmitted diseases should be offered to the patient and partner(s).

Table 71.23 Causes of penile and scrotal ulcers in HIV infection.

Pseudomonas
Syphilis
Chancroid
Herpes simplex
Penicilliosis
Amoebiasis
Fournier's gangrene
Squamous cell carcinoma
Kaposi's sarcoma
Drugs (e.g. foscarnet)

Fig. 71.14 Papules on the penis in scabies. (Courtesy of Dr C. White, University Hospital of North Durham, Durham, UK.)

Scabies

Scabies (see Chapter 38) may present with anogenital itch, 'folliculitis' (including of the buttocks) and penile, scrotal and pubic nodules (Fig. 71.14). An AIDS patient with single non-pruritic, 'crusted' lesion on the glans penis has been described [21]. Topical pimecrolimus has been used with benefit in the treatment of steroid-resistant post-scabies nodules [22].

Miscellaneous infections

Human bite injuries acquired during orogenital contact usually heal well but a penile ulcer infected with the oral flora organism *Eikenelia corrodens* has been reported [23].

Benign tumours

The following entities are all encountered in the male genital area: pearly penile papules (angiofibromas); angiomas and angiokeratomas, and angiokeratoma corporis diffusum; basal cell papillomas (may be mistaken for viral warts [1] or Bowenoid papulosis); melanocytic naevi; inguinogenital epidermoid or (much rarer) pilar (including giant forms) cysts; these may become infected, and lesions containing molluscum contagiosum have been described [2,3].

Fig. 71.15 Scrotal calcinosis. (Courtesy of Dr D.A. Burns, Leicester, UK.)

Median raphe cysts

Congenital cystic median raphe anomalies may remain unobtrusive until adulthood. Cystic or nodular and linear swellings of the ventral penis occur near the glans. In adolescence or adulthood they may become traumatized or infected with staphylococci, gonococci or *Trichomonas* and present as tender, erythematous, purulent nodules [4]. Histologically, they are either dermoid or mucoid, depending on their embryology or epithelial lining [5]. Very rarely, the basal epithelial lining of the cysts may contain melanocytes, imparting a brown-black pigment to the lesion [6].

Mucoid cysts

These are rare lesions that are present at birth or develop in childhood as small, flesh-coloured, mobile cystic papules or nodules with no punctum, commonly on the ventral glans or foreskin, rarely in the perineum. They can be asymptomatic, become infected or interfere with intercourse. The histological features suggest that they arise from ectopic urethral tissue during embryological development [7].

Scrotal calcinosis

Scrotal calcinosis is a relatively common, benign, idiopathic disorder presenting as solitary or multiple, hard, smooth, white papules or nodules on the scrotum, rarely the penis (Fig. 71.15). Interestingly, these lesions are much rarer on the vulva [8]. Occasionally, they may become secondarily inflamed or infected following trauma.

Their occurrence was first described by Hutchinson [9]. Their origin has been debated: they have been said to arise from epidermoid cysts, eccrine duct milia, eccrine epithelial cysts, dystrophy of the dartos muscle, trauma and the presence of foreign bodies [4,10–20]. Scrotal calcinosis may occur after meconium peritonitis, with leakage of meconium through the processus vaginalis, and in testicular tumours such as teratomas, gonadoblastomas and Leydig cell tumours [17]. In endemic areas of onchocerciasis, calcified scrotal cysts may be caused by the living or dead nematodes, and patients have evidence of the disease elsewhere [21,22]. Onchocercal nodules are more common on the iliac crests and the rib cage (see Chapter 37).

The unsightly and embarrassing lesions can be treated by incision and eventration under local anaesthesia.

Idiopathic calcinosis of the penis is very rare [23]. A man who presented with a dome-shaped nodule on his glans has been described; the dystrophic calcinosis here was thought to derive from syringoma [24]. Other associations are trauma, self-injection with papaverine, Peyronie's disease and cytotoxic chemotherapy [23]. Metastatic calcinosis is due to renal failure and secondary hyperparathyroidism.

Verruciform xanthoma

Verruciform xanthoma mainly affects the mouth (see Chapter 69). The genitalia are the next most frequently involved area, where it presents as a painless, yellow-brown or red, verrucous, sessile or papillary plaque. Fewer than 20 cases have been reported [25]. The histological findings are hyperkeratosis, focal parakeratosis, acanthosis and fat-filled foam cells in the papillary dermis. Verruciform xanthoma is thought to represent epidermal degeneration, with keratinocyte lipid then taken up by dermal macrophages [26] or fibroblasts to form the foam cells. HPV 6 has been implicated in one case [27] but excluded in another [28]. Treatment is by surgical excision.

Miscellaneous benign tumours

Naevus comedonicus of the glans penis, generally devoid of pilosebaceous structures, has been reported [29]. Keloid is rare, but can complicate circumcision [30–32], and other surgery and trauma [33,34]. Keloid has been simulated on the dorsum of the penis by chronic oedema caused by a condom catheter [35]. Dermoid cyst affecting the penis, presenting with pain, swelling and suppuration from abscess formation, has been reported [36].

Acanthosis nigricans almost always affects the groins. In pseudoacanthosis nigricans, the associated obesity is almost always responsible for intertrigo and skin tags.

Penile colloid degeneration has been described, presenting as a dermal plaque of the dorsal shaft [37].

Some cases of multiple syringomata localized to the penis have been described, mimicking genital warts or lichen planus [38–41].

Other benign tumours that have been reported rarely to affect the genital area include apocrine cystadenoma [42,43], syringocystadenoma papilliferum [44], mixed syringocystadenoma papilliferum and papillary eccrine adenoma occurring in a scrotal condyloma [45], composite adnexal tumour [46], dermatofibroma [47], reticulohistiocytoma [48], giant cell fibroblastoma [49], connective tissue naevi (scrotum) [50], fibrous hamartoma of infancy [51], leiomyoma [47,52], genital smooth muscle hamartoma (scrotum) [53,54], traumatic neuroma [55], neurofibroma, neurilemoma, granular cell myoblastoma [47,56–58], varicosities/venous lakes, acquired capillary and cavernous haemangioma [47] (other angiomatous lesions are very much rarer, and controversy exists as to whether they represent a true neoplasm, herniation of the corpus spongiosum or vascularization of a haematoma or thrombus [59]), Masson's vegetant intravascular haemangioendothelioma [60], angiokeratoma circumscriptum of Mibelli [61], glomus tumour [50,62], port-wine stain, strawberry naevus [63–65], haemangiomas and PELVIS syndrome [66], epithelioid haemangioma [67], epithelioid haemangioendothelioma [47,68], pyogenic granuloma [69], angiolymphoid hyperplasia with eosinophilia/Kimura's disease (penis and spermatic cord) [70–72] and lymphangioma circumscriptum [73,74].

Precancerous dermatoses and carcinoma *in situ*

Squamous hyperplasia

Such lesions consist of white patches or plaques. Although it is the most common epithelial abnormality found in association with invasive squamous carcinoma of the penis, histologically there is *no* cytological atypia; acanthosis and orthokeratotic hyperkeratosis are found [1].

Penile horn

It is rare for cutaneous horn to affect the penis [2]. Multiple lesions have been described in a 70-year-old man [3]. The underlying causes include pseudoepitheliomatous micaceous and keratotic balanitis [4], verrucous carcinoma [5–8] and squamous carcinoma [9]. Chronic inflammation and recent circumcision for long-standing phimosis are said to be important predisposing factors. The lesion is premalignant or, in one-third of cases, malignant at presentation, with squamous carcinoma the underlying pathology. Treatment should be dictated by precise diagnosis achieved by adequate excision and histology of the whole lesion. Follow-up is mandatory because recurrence may occur.

Porokeratosis

Genital porokeratosis of Mibelli is rare, but classical lesions have been reported on the penis and scrotum. It may be commoner in Asian populations [10]. Pruritus and ulceration may occur [11]. Porokeratosis may be confused with psoriasis, Bowen's disease, granuloma annulare or lichen planus; biopsy differentiates these conditions [12]. Topical 5-fluorouracil and imiquimod have been used for treatment [13,14].

Pseudoepitheliomatous micaceous and keratotic balanitis

Pseudoepitheliomatous micaceous and keratotic balanitis (PEMKB) is a rare penile condition. It presents as thick, scaly, micaceous

patches (possibly a cutaneous horn) on the glans penis in older, uncircumcised men [4,15]. Perimeatal hyperkeratosis may cause multiple urinary streams on micturition—a 'watering-can penis' [16]. Histological examination shows hyperkeratosis, parakeratosis, acanthosis, prolongation of the rete ridges and mild lower epidermal dysplasia, with a non-specific dermal inflammatory infiltrate of eosinophils and lymphocytes. Some consider that PEMKB is a form of locally invasive verrucous carcinoma [17], others that it is a variant of lichen sclerosus [18]. Metastastic spread has not occurred except where there was a penile horn [19], and in one patient who developed an aggressive soft-tissue sarcoma of the penis [20]. Recurrence is common. Topical 5-fluorouracil, radiotherapy and surgery are the principal treatment choices [4].

Erythroplasia of Queyrat, Bowen's disease of the penis and bowenoid papulosis

Erythroplasia of Queyrat (EQ), Bowen's disease of the penis (BDP) and bowenoid papulosis (BP) are three clinical variants of carcinoma *in situ* of the penis [1–3]. Penile intraepithelial neoplasia (PIN—corresponding to cervical, vulval and anal intraepithelial neoplasia; CIN, VIN and AIN) is the term favoured by some, and may be a convenient umbrella term, but there is no formal consensus on clinicopathological classification (particularly 'grade') and clinical utility. An alternative expression 'squamous intraepithelial lesion' (SIL) has been proposed, and qualified by the descriptor 'high-' or 'low-grade' [4]. EQ, BDP and BP all describe disorders of the penis predominantly in uncircumcised white men, although EQ has been recorded in a circumcised man [5]. CIN, VIN and AIN are terms analogous to PIN.

Although EQ and BDP are synonymous in describing carcinoma *in situ* of the penis, BD is used to refer to squamous carcinoma *in situ* at other cutaneous sites. EQ should be used to describe red shiny patches or plaques of the 'mucosal' penis (glans and prepuce of the uncircumcised). BDP should be used to describe red, sometimes slightly pigmented, scaly patches and plaques of the keratinized penis. This distinction has not always been made in the literature. BP is analogous to, but clinically different from, EQ and BDP. The term should be used to describe multiple warty lesions, which are often pigmented in keratinized sites, and more numerous and more inflamed at 'mucosal' sites (Fig. 71.16). BP lesions are less papillomatous, smoother topped, more polymorphic and more coalescent than common genital viral condylomata acuminata, and occur in younger, sexually active men, as opposed to the patches or scaly plaques of EQ and BDP, respectively, seen in older men. BP may be associated with a lesser risk of squamous carcinoma than EQ and BDP. It is associated with HPV infection (especially HPV 16) and HIV infection. Voltz *et al.* [6] found anogenital warts in 16% of all HIV-positive males, nearly half of whom showed histological signs of intraepithelial neoplasia.

The aetiology of EQ, BDP and BP is unknown. Local carcinogenic influences in uncircumcised men such as poor hygiene, smegma, trauma, friction, heat, maceration, inflammation, phimosis, dermatoses such as lichen sclerosus and smoking (tar metabolites in urine) have been proposed [7]. PIN can be found in men being screened for HPV infection [8]. HPV is particularly implicated in BP [9]. Indeed, BP is probably virus-induced epithelial dysplasia associated mainly with HPV 16, but other types have been found [10–12]. EQ has been shown to be associated with co-

infection with the rare epidermodysplasia verruciformis-associated HPV 8 and the genital high-risk HPV 16 [13]. There is a high prevalence of PIN in male sexual partners of women with CIN [14,15], but many patients with PIN have consorts with no evidence of warts or CIN.

Immunosuppression is important; 50% of HIV patients with anogenital warts had squamous carcinoma *in situ* on histology [6]. Nothing is known about the influence of immunogenotype. The evidence confirming that EQ/BDP may result in squamous carcinoma has been reviewed comprehensively [7,16]. The risk of progression of BP to invasive squamous carcinoma is not known, but is probably low in the absence of other risk factors, especially immunocompromise. The grade of the intraepithelial neoplasia and the development of invasive carcinoma are related to age [17]. *p53* mutations do not appear to be important in male genital carcinogenesis [18].

Some patients with these lesions may be quite young [19]. There may be several foci of BDP or EQ and they may occur concomitantly. The non-specificity of the clinical appearances makes for an important differential diagnosis, which includes psoriasis, lichen sclerosus, erosive lichen planus, ZB and extramammary Paget's disease. The differential diagnosis of BP includes lichen planus, common warts, seborrhoeic warts, naevi and condylomata lata. A biopsy is indicated in instances where the clinical diagnosis is uncertain. Aynaud *et al.* [20] have shown that shrewd clinical interpretation predicts which lesions will show squamous carcinoma histologically and which will contain oncogenic HPV. Occasionally, it may be necessary to perform a second biopsy if the initial histology is inconclusive. It has been suggested that, where glans and shaft are both involved, the glans may be the preferential biopsy site. On histological examination, there are the features of an intraepithelial carcinoma. Secondary amyloid deposition has been reported histologically in one case of BP [21].

Treatment. Treatment depends on many factors. Circumcision removes a major risk factor for cancer and provides extensive tissue for histology. Topical 5-fluorouracil as a 5% cream is a well-established conventional option for the treatment of BDP, EQ and BP [1–3] but there have not been any clinical trials.

Other treatments include cryosurgery, curettage and electrocautery, excisional surgery, glans resurfacing, Mohs micrographic surgery, laser and photodynamic therapy [1–3,22,23]. Radiotherapy should be avoided. Topical imiquimod may help some patients [24–26]. Patients presenting with these conditions should be counselled and screened for HPV and other sexually transmitted diseases, including HIV infection. They should stop smoking. Sexual partners should be advised to seek assessment. Follow-up should be long term [2,3,17].

Squamous carcinoma

Genital squamous carcinoma is sometimes called epidermoid carcinoma. The aetiology is not clearly understood but HPV is implicated [1]. Diagnosis and management can present difficulties. Squamous carcinoma should be suspected in all nodulolcerative genital disease, especially in the context of lichen sclerosus, lichen planus, hidradenitis suppurativa, intraepithelial neoplasia and immunocompromise. Genitourinary and urological

assessment should be sought. Proctoscopy and sigmoidoscopy are necessary to exclude anorectal cancer. Suspect lesions should be biopsied.

Carcinoma of the penis

Incidence and aetiology. Carcinoma of the penis accounts for less than 1% of deaths from cancer in the USA and causes 100 deaths per year in the UK (unchanged over several decades). It constitutes 10–20% of tumours seen in males in either underdeveloped countries or in areas where early circumcision is not routinely practised [2–8]. In India, the incidence of carcinoma of the penis is about five times that in the UK [9].

The earliest stages of penis cancer and precancer form a spectrum of disease [10]. Although some penile cancers arise *de novo*, others develop from premalignant states, which may be misdiagnosed or may be difficult to diagnose [11], and there are the issues of multifocality and field change [12] to acknowledge.

The precise aetiology of the types of PIN, verrucous carcinoma and frank invasive squamous carcinoma of the penis is unknown, as is their precise relationship to the various types of precursor lesion. However, Cubilla *et al.* [13] have defined several types of preceding epithelial abnormality: squamous hyperplasia and SIL (squamous, basaloid or warty, high or low grade).

Risk factors for penis cancer are listed in Table 71.24. The presence of a foreskin, HPV infection and lichen sclerosus are the most important considerations [5,8]. Neonatal circumcision protects against penile carcinoma [5,14–16]. Circumcision in later life may reduce the risk but does not abolish it, especially if the circumcision was performed for penile disease [17–19]. However, there have been very rare cases in Jews and others circumcised at birth [20–22]. The incidence of penis cancer is low in Japan and Denmark, where circumcision is rare [23,24], so other factors are important in carcinogenesis.

Table 71.24 Risk factors for squamous carcinoma of the penis.

Uncircumcised
Phimosis
Long foreskin
Poor hygiene
Chronic irritation, inflammation, scarring
Smoking
Lichen sclerosus
Lichen planus
Human papillomavirus
HIV
Squamous hyperplasia
Bowen's disease
Erythroplasia of Queyrat
Bowenoid papulosis
Giant condyloma/verrucous carcinoma
Photochemotherapy
Iatrogenic immunosuppression
Renal transplantation
Systemic lupus erythematosus
(Radiotherapy)

Phimosis and balanitis are known risk factors for penile cancer [2,5,14,25–27]. The possession of a 'long' foreskin may be important [28]. Poor personal and sexual hygiene [15] and phimosis may lead to the retention of smegma and development of balanitis. However, the carcinogenicity of human smegma has not been ascertained [29,30], and it is not widely appreciated that phimosis is a physical sign and not a diagnosis. Hence, there may be more in the carcinogenic propensity of phimosis than simply physical retention of smegma.

Lichen sclerosus is a common cause of phimosis in males and it predisposes to penile carcinoma [5,8,31–37]. Powell *et al.* [38] found that half of patients with penis cancer had a clinical history and/or histological evidence of lichen sclerosus. Chronic erosive and hypertrophic lichen planus are premalignant conditions, and lichen planus is a cause of phimosis [39,40]. Chronic irritation and inflammation or scarring are all risk factors for squamous carcinoma of the skin generally and the penis is no exception; penis cancer complicating a burn scar and a chronic sinus tract have been reported [41,42]. Quantifying the malignant potential of the precancerous dermatoses, BDP, EQ and PIN, is not possible, but they are acknowledged risks for penile cancer [43–45].

Smoking is a risk factor, independent of phimosis, for penile carcinoma [9,27], and is also a recognized risk factor for anal [46] and cervical cancer [47,48]. Smoking may cause squamoepithelial cancer, not only in parts of the body in contact with smoke but also at distant sites by dissemination of carcinogens in the circulation or in secretions. The presence of tobacco-specific nitrosamines in the preputial secretions of rats has been demonstrated [49].

Penile carcinoma is a complication of psoralen and UVA therapy (PUVA) [50–53], and possibly other treatments for psoriasis [54]. The photodye treatment of genital herpes simplex ceased in the 1970s because of the occurrence of BDP in young men who did not have other risk factors for erythroplasia [55]. However, increased UV exposure of the genitals from sunlamps and sunbeds had not led to an increase in genital skin cancer in the USA by 1986 [56].

Although penile cancer is associated with multiple sexual partners and previous sexually transmitted disease, including HIV, the epidemiological features are not those characteristic of a sexually transmitted disease [29]—unlike carcinoma of the cervix and, to a lesser extent, anal carcinoma. In cervical cancer, the evidence is that it is a sexually transmitted disease and that HPV is the aetiological agent [57–60]. Yet penile cancer puts wives and consorts at risk of cervical cancer [61] and there is a high prevalence of HPV, condylomas, SIL and PIN in sexual partners of women with CIN [62–64]. In India, the incidence of cervical cancer is lower in Muslim women compared with Hindus and Christians [65]. HPV is implicated in penis cancer [1,5,8,66,67], but its role is still uncertain, as many patients have no evidence of infection [5,8,36]. Oncogenic HPV types 16 and 18 have been incriminated [5,8,68–76]. In Brazil, Villa and Lopes [70] found HPV 18 in seven out of 18 penile squamous carcinomas and, in Argentina, Picconi *et al.* [76] found HPV DNA in 71% of 65 penis cancers, 81% of which were 'high-risk' HPV with a predominance of HPV 18. Gregoire *et al.* [77] associated HPV with higher grade, more aggressive squamous carcinomas of predominantly the glans penis, showing basaloid changes. Rubin *et al.* associated HPV positivity with a

Fig. 71.17 High-grade dysplasia and invasive squamous carcinoma. (Courtesy of Professor C.B. Bunker, with permission from Medical Illustration UK, Chelsea & Westminster Hospital, London, UK.)

Fig. 71.18 Squamous carcinoma. Severe background lichen sclerosus. (Reproduced from Bunker C.B. Skin conditions of the male genitalia. *Medicine* 2001; **29**: 9–13, by kind permission of The Medicine Publishing Company.)

subset of basaloid and warty carcinomas, at a total prevalence of 42% [78]. The overall frequency of HPV in penile squamous carcinoma suggests that a proportion of these cancers can arise from HPV-associated SIL [13,77]. As in vulval cancer [79,80], a bimodal hypothesis of HPV-related and non-HPV-related causation has evolved [13,81].

Penis cancer has been reported to complicate immunosuppression in renal transplantation [82] and HIV infection [83] (see Chapter 35: risk increased × 5–6). It has also occurred in a circumcised man with psoriasis treated with etanercept: he had previously received methotrexate, ciclosporin and hydroxyurea [84]. Topical immunosuppressive agents should be used with extreme caution for genital dermatoses, especially in the uncircumcised, because of the risk of squamous carcinoma [85–88].

Clinical features. Itch, irritation, pain, bleeding, discharge, ulceration or the discovery of a mass are the presenting symptoms of squamous carcinoma. There is often a long history of preceding problems with the penis and foreskin manifest as dyspareunia, balanoposthitis or phimosis and dysuria. Irregular nodular and ulcerative morphology is found on examination (Figs 71.17 & 71.18) and there may be background BDP, EQ and BP, lichen sclerosus or lichen planus. Undiagnosed, untreated disease is destructive and mutilating [89]. Phimosis should be regarded as a sinister situation, not least because it impedes complete inspection and palpation of the glans and coronal sulcus. The inguinal lymph glands must be palpated, although in penile cancer only 50% of enlarged glands will be found to contain tumour [3]. The concomitant presence of sexually transmitted diseases and immunocompromise should be excluded [90]. The differential diagnosis includes the manifestations of intraepithelial neoplasia (and the differential diagnosis of these), erosive or ulcerative sexually transmitted disease, basal cell carcinoma, Kaposi's sarcoma, pyoderma gangrenosum and artefact. Genitourinary and urological assessment should be sought.

Histopathology. Diagnosis is confirmed histologically by incisional or excisional biopsy. An incisional biopsy should be of adequate size and depth, and it may be necessary to sample several sites. The biopsy(ies) may need to be performed by a urologist under general anaesthesia. Patients who have negative or equivocal biopsies, but who have risk factors or in whom there is a high index of suspicion, should be followed-up closely and rebiopsied if indicated. Staging should not be based on incisional biopsies [91].

Histologically, squamous carcinoma manifests tongues of invasive atypical keratinocytes penetrating the dermis, and contains foci of aberrant and ectopic keratinization called squamous pearls [26]. Background histological signs of lichen sclerosus are commonly found in penile cancer in men, as in vulvar cancer [38]. Cubilla *et al.* [12] have identified four histological types of squamous carcinoma of the penis:

1 **Superficial spreading** (42%): a biphasic infiltrative and radially extensive carcinoma *in situ* contiguously involving several

anatomical sites or compartments (glans, coronal sulcus, foreskin, even urethra)

2 **Vertical growth** (32%): unifocal high-grade deeply invasive, unassociated with carcinoma *in situ*

3 **Verrucous** (18%): low-grade, papillary or endophytic (see below)

4 **Multicentric** (8%): two or more independent primary tumours without contiguous field change.

Verrucous carcinoma is discussed below. Sarcomatoid carcinoma and spindle cell carcinoma of the penis are rare variants [92–94].

These observations have implications for the pathogenesis of the different types, and in determining management in individual cases.

Carcinoma of the scrotum

Squamous carcinoma of the scrotum has been recognized in chimney sweeps (exposed to carcinogens in soot) [1], mule spinners (exposed to carcinogens in lubricating oils for the spinning jenny in the cloth industry), Persian nomads (who travelled with pots of burning charcoal between their legs) and Indian jute oil processors [2–6]. Oil-mist exposure in industry continues to be widespread and, apart from scrotal cancer, has been associated with other cutaneous problems (such as contact dermatitis and oil acne) and respiratory diseases, including cancer [7].

Other individuals at risk of scrotal squamous carcinoma include those with a history of psoriasis treated with arsenic, coal tar, UVB and PUVA [8–13], previous radiotherapy treatment [8], scrotal HPV infection, hidradenitis suppurativa, Bowen's disease and multiple cutaneous keratoses and epitheliomas [14–18]. Rarely, black men may be affected [19].

The presentation of scrotal carcinoma is similar to that of penis cancer, with itch, irritation, pain, bleeding, discharge, ulceration or the discovery of a lump, and irregular nodular and ulcerative clinical features. A pigmented squamous carcinoma of the scrotum has been reported [20]. The differential diagnosis includes the manifestations of intraepithelial neoplasia (and the differential diagnosis of these), erosive or ulcerative sexually transmitted disease, basal cell carcinoma, Kaposi's sarcoma, pyoderma gangrenosum and artefact. The diagnosis is confirmed by biopsy.

Treatment of squamous carcinoma

The treatment of anogenital squamous carcinoma is not generally the province of the dermatologist. The overriding general principle is to offer adequate surgical excision, including circumcision, for disease of the penis. The penile surgery may need to be radical, total or partial, depending on location and extent [1–3]. To conserve tissue and minimize residual sexual dysfunction, conservative techniques are increasingly used, with narrow excisional margins [4,5] and innovative plastic repair [6], as are laser treatment [7] and Mohs micrographic surgery [8–11] for squamous carcinoma of the penis, but the concepts of field change and the implications of infection by HPV and multifocality must be considered. There is a place for sentinel node biopsy. Radiotherapy may be offered as an adjunct to surgery or as definitive alternative treatment. Combination chemotherapy has been used for palliation and proposed for adjuvant treatment of carcinoma of the penis, but remains under evaluation [12].

Lymphatic or haematogenous dissemination of genital cancer dictates individualized multidisciplinary treatment. The management of ilioinguinal lymphadenopathy is controversial [12,13].

The prognosis of penis cancer relates to the extent of inguinal lymphadenopathy [14,15] and involvement of the corpus [16]. It does not correlate with HPV status [17]. Penile cancer puts wives and consorts at risk of cervical cancer [18]. In black men who develop penile cancer there is a substantial risk (18%) of the later development of a second primary malignancy [19].

The prognosis for scrotal carcinoma is not good, despite apparently adequate primary surgical treatment: the 5-year mortality is 50–60% [20,21].

Verrucous carcinoma/giant condyloma/ Buschke–Löwenstein tumour

Buschke–Löwenstein tumour and verrucous carcinoma can probably be regarded as synonymous, both terms representing verrucous, low-grade, well-differentiated squamous carcinoma. It is perhaps more accurate and more clinically useful to consider giant condyloma as a separate HPV-related entity with a better prognosis, but the matter is controversial [1–6].

Verrucous carcinoma is rare. It produces dramatic polypoid or cauliflower-like clinical lesions (Fig. 71.19). Presentation as a penile cutaneous horn has been described [7–9]. Although locally deeply invasive, the tumour is well demarcated from sur-

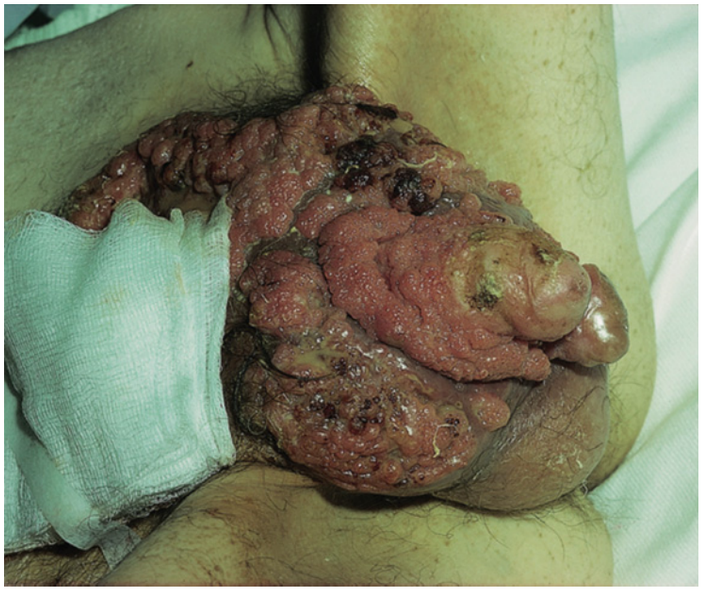

Fig. 71.19 Gross condylomas of Buschke–Löwenstein of the penis. (Courtesy of Professor R.M. MacKie, Glasgow University, Glasgow, UK.)

rounding tissue and is unlikely to metastasize. Both sexes can be affected.

A specific aetiology for verrucous carcinoma of Buschke–Löwenstein has not been unequivocally identified, but an origin from genital warts is likely. HPV types 6 and 11 are the most commonly associated [1,3,4,10–16]. A patient taking ciclosporin for psoriasis developed a verrucous carcinoma containing HPV 6 and 16 [17]. Multiple HPV types were found in a transplant patient [18]. Tumours containing several HPV types may be mixed, containing verrucous carcinoma adjacent to squamous carcinoma [19]. Tumours occurring on background lichen sclerosus, rarely chronic hidradenitis suppurativa and very rarely lichen planus, have occurred [20–23].

If verrucous carcinoma is suspected, then a deep surgical biopsy must be performed. The tumour has a different histology from squamous carcinoma, showing deep lobular invaginations of well-defined proliferative epithelium consisting of typical clear pale keratinocytes [24]. Frank squamous carcinoma [25] and foci of invasive squamous carcinoma [26] have been reported in some cases of anogenital verrucous carcinoma. Ultrastructurally, verrucous carcinoma is distinct from condyloma acuminatum but similar to SCC [27].

Clinical, histological and virological differences may distinguish verrucous carcinoma (potential for aggressive lethal behaviour) from Buschke–Löwenstein tumour, and giant condyloma (no malignant potential), and this distinction could direct treatment [2,3,11,13,16].

Surgical excision is the treatment usually recommended (e.g. glansectomy [28] or penectomy). Mohs micrographic surgery [29–31], cryotherapy [32], laser treatment [33], interferon-α [34–37], radiotherapy [38] or bleomycin [39] are alternatives.

The prognosis can be poor because the verrucous carcinoma might continue to grow and invade locally, causing death by exsanguination from femoral arterial invasion or cachexia [40]. Even with treatment, recurrence and progressive malignant transformation do occur [41,42], so follow-up is necessary.

Other malignant neoplasms

Extramammary Paget's disease

Extramammary Paget's disease (EMPD) is discussed in Chapter 53. EMPD presents as irritating, itchy, burning, red scaly patches or plaques that may be solitary or multifocal. EMPD can occur anywhere in the anogenital area, including the glans penis [1–3]. Penile EMPD is frequently misdiagnosed as psoriasis, eczema [4], or Bowen's disease. An 'underpants' pattern of erythema has been reported in a number of patients [5]. Subclinical EMPD has been documented, where the skin looks normal macroscopically but is involved microscopically. EMPD behaves indolently, spreading by local extension and metastasis [6,7].

The concurrence of genital and extragenital EMPD is extremely rare, but overt and latent axillary EMPD can coexist and change daily in association with penile and pubic EMPD [8]. Also very rare is depigmented EMPD of the genitalia, evoking the differential diagnosis of vitiligo, hypopigmented mycosis fungoides and lichen sclerosus [9]. A focus of cutaneous squamous carcinoma has been reported complicating genital EMPD [10].

Diagnosis is by biopsy. Histological examination shows nests of large vacuolated cells with circular nuclei and foamy pale cytoplasm in the epidermis (Paget's cells). Dermal involvement signifies a poor prognosis. Pagetoid dyskeratosis can be found in a number of benign lesions such as naevi, skin tags and lentigines [11]. Pale cells resembling Paget's cells can be seen incidentally in benign papular intertriginous conditions, and in nearly 40% of prepuces sent for histological examination following circumcision for phimosis [11–13]. Anogenital Paget's disease can be accompanied by epidermal hyperplasia similar to fibroepithelioma of Pinkus [14]. Immunohistochemical and enzyme histochemical evidence points to sweat gland epithelium as the source of Paget's cells in EMPD [15]. The distribution along the 'milk line' has led to the suggestion that the 'clear cells of Toker' are the histogenic precursors of both clear cell papulosis and mammary and extramammary Paget's disease, respectively [9]. HPV is not present [16], but the c-erbB-2 oncoprotein may have a role in the pathogenesis of EMPD [17].

Mammary Paget's disease is an epidermal manifestation of an underlying breast adenocarcinoma [18]. EMPD is found in areas rich in apocrine sweat glands, such as the axillae and anogenital region and it can also be associated with an underlying malignancy [6]. In a large series, 24% of patients had a proximate cutaneous adnexal adenocarcinoma, 12% were found to have a concurrent, and another 17% to have a non-concurrent internal malignancy [19].

Although properly regarded as a type of carcinoma *in situ*, EMPD may itself become invasive and metastatic [20–22]. There may be subjacent carcinoma (e.g. in periurethral glands) [23] or distant carcinoma (e.g. prostate [24] or bladder [25]), or both (e.g. periurethral glands and bladder [26]). Pagetoid epidermal invasion of inguinal cutaneous metastatic mesothelioma of the tunica vaginalis of the testis has been reported [27].

Treatments used for EMPD include cryotherapy and topical 5-fluorouracil [28], wide excisional surgery [20], micrographic surgery [29,30], radiotherapy [7,31] and photodynamic therapy [3,7,20,28–33]. Topical imiquimod shows much promise [34]. Excision of an underlying neoplasm, if present, can cause regression of the EMPD [35].

Malignant melanoma

This is a very rare condition of the penis (fewer than 100 cases reported). It is estimated to account for 1–1.5% of all malignancies of the penis [1,2] and less than 0.15% of all melanomas [3]. Melanoma is even rarer on the scrotum, with only four cases appearing in the literature [4,5].

Genital melanoma presents as a pigmented macule or as a pigmented or amelanotic papule or nodule, possibly developing from a lentiginous area or pre-existing dysplastic naevus or 'kissing' naevus, that may ulcerate or bleed [1,2,6–14,15]. Multifocal melanoma of the glans penis has been reported [16]. Patients are usually middle-aged or older, although it has been reported in a boy [17]. It is exceedingly rare in Asians and has not been reported in black people (although a case of melanoma of the urethra has been seen) [18].

Sixty to 70% of lesions occur on the glans. There may be a family history of melanoma and other atypical or 'dysplastic' naevi on examination. The inguinal and other nodes, as well as the abdomen, should be palpated. Forty to 50% of patients have lymphatic or other metastatic dissemination at the time of presentation. Clinically atypical lesions should be biopsied and the histology critically reviewed [7,11]. Malignant melanoma of any histological subtype may be encountered [19].

Treatment is by primary excision. Subsequent management depends on the Breslow thickness of the lesion and complete clinical staging. Radical surgery and chemotherapy may be needed, but the prognosis is poor for all melanomas that have already metastasized [1,17,20].

Kaposi's sarcoma

Solitary Kaposi's sarcoma (KS) of the penis was very rarely seen before the HIV epidemic and cases are still occasionally seen in HIV-negative patients [1–3], but genital KS is essentially an HIV-associated problem. It presents on the penis or scrotum, perineum or perianal skin in one of its classic forms: purple, slightly scaly patches or plaques, nodules or ulcerative lesions [4]. More atypical presentations that have been seen include engorgement with hypervascularity [5], penile lymphoedema [6] and phimosis. The differential diagnosis includes cellular naevus, histiocytoma, angioma, angiokeratoma, pseudo-Kaposi's sarcoma [7], bacillary angiomatosis and melanoma.

Miscellaneous malignant neoplasms

Although basal cell carcinoma is the most common type of skin cancer, it is rare in the anogenital area, although over 100 cases have been reported [1], including one case report of fibroepithelioma of Pinkus affecting the base of the penis [2]. A case of multiple erosive scrotal basal cell carcinomas with metastasis has been described [3].

Fibrosarcoma, haemangiopericytoma, leiomyosarcoma, malignant fibrous histiocytoma, epithelioid sarcoma, dermatofibrosarcoma protuberans and spindle cell sarcoma may occur, presenting as painful or painless nodules, masses or swelling with dysuria and erectile difficulties (e.g. masquerading as Peyronie's disease) [4–6]. Other rarities include Merkel cell carcinoma [7], malignant eccrine poroma [8], malignant schwannoma [4,9] and solitary reticulohistiocytic granuloma of the scrotum [10]. Scrotal angiosarcoma complicating oedema following surgery and radiotherapy for carcinoma of the rectum has been described [11].

Involvement of the penis with Langerhans' cell histiocytosis is very rare; fleshy papules on the dorsal penis, a painful nodule of the prepuce and penile ulceration have been reported [12,13].

Mycosis fungoides can be confined to or concentrated in the genital region. Localized perianal involvement [14], a solitary plaque on the penis [15] and response to treatment with imiquimod have been described [15,16].

Although lymphoma is the most frequent secondary tumour of the testis, it is rare in other parts of the male urogenital tract [4]. Penile lymphoma can present as painless subcutaneous nodules, erythematous swelling, phimosis and ulceration [17–22]. There may be no evidence of systemic lymphoma. Ulcerating scrotal lymphoma has been reported [23], as have scrotal and penile ulceration resulting from leukaemic infiltration [24,25].

Metastases to the penis are rare, but several hundred cases have been reported [26]. They are usually secondary to cancer of the urogenital tract [27] or gastrointestinal system, or other common cancers such as of the lung [28], and present with pain, swelling, priapism, urinary symptoms or haematuria. A very rare cause is secondary melanoma [26,29].

Miscellaneous

Penile melanosis

Pigmentary change is dealt with in the general introduction on pp. 71.2–71.3, and causes of anogenital hypo- and hyperpigmentation are listed in Tables 71.6 and 71.7.

Pigmented macules are not uncommon on the glans and shaft of the penis [1,2]. They are benign but, because they may be large or enlarging, with irregular edges and multifocal and variegated pigmentary patterns, they arouse concern about atypical melanocytic proliferation and acral lentiginous melanoma. Such clinical concerns should lead to biopsy [3]; it is important to decolourize slides from deeply pigmented lesions because large quantities of melanin can obscure cytological detail [2]. Post-inflammatory hyperpigmentation (e.g. lichen sclerosus, lichen planus) may be the cause in many patients. Some cases have been associated with previous treatment with anthralin, PUVA therapy for psoriasis, or diabetes [4,5]. The eruptive appearance of melanotic macules and papules in the anogenital region may be associated with advanced metastatic adenocarcinoma [6].

On histological examination there may be increased basal epidermal pigmentation, with or without benign lentiginous melanocytic hyperplasia, or an increase in basal melanocyte number. Breathnach *et al.* [7] have proposed that depigmentation is an essential element of penile melanosis and demonstrated melanocytic hyperplasia in areas of hyperpigmentation.

Penile melanosis is the term for lesions without lentiginous hyperplasia [5,8]. Revuz and Clerici [8] proposed the grouping of penile melanosis, vulvovaginal melanosis and the predominantly oral mucosal hyperpigmentation of the Laugier–Hunziker syndrome under the umbrella of essential melanotic hyperpigmentation of the mucosa. Lenane *et al.* [9] used the term genital melanotic macules.

Patients ask for treatment of penile melanosis as it is unsightly and embarrassing, but options are limited [2]. Laser treatment may help [10].

Acral lentiginous melanoma is very rare but important [11,12].

Hypopigmentation

Striae as a consequence of growth or weight surges are common around the pelvic girdle, or represent a complication of topical corticosteroid application [13]. Initially, they are often purple–red in colour. Vitiligo is a commonly observed affliction of the male genitalia, although patients may be unaware of it and clinicians might not always observe it [14]. Penile vitiligo attributed to the use of topical imiquimod for the treatment of genital warts has been described [15].

Pain and swelling

Some presentations of many entities can be painful but generally pain is an unusual presentation for a dermatosis. Swelling is more common and may be painful or not. A common factor in many but not all causes of swelling may be oedema or lymphoedema. Rigorous clinical evaluation is important [1,2]. Causes of anogenital lymphoedema and penoscrotal swelling are listed in Tables 71.25–71.27.

Iatrogenic swelling and lymphoedema

Congenital defects of the inguinal canal and other non-inguinal peritoneal leaks can lead to scrotal and penile swelling as a

Low-hanging penis
Loss of fat
Nodules
Deformed shaft

manifestation of dialysate oedema in patients with end-stage renal failure treated by continuous ambulatory peritoneal dialysis [3]. Genital oedema is commonplace in intensive care units, because of the practice of maintaining a raised right heart filling pressure. Radical cancer surgery and/or radiotherapy to the anogenital area and the lymphatics can cause swelling because of lymphoedema, early or delayed [4]. Chronic oedema, resembling keloid, of the penis has been caused by a condom catheter for neurogenic bladder [5].

Increasingly, patients seek plastic surgery to the penis [12] for psychosexual reasons (e.g. dysmorphophobia), but surgery can result in significant complications (Table 71.28).

Idiopathic lipogranuloma

Cases of characteristic, spontaneously resolving, painless, Y-shaped swelling of the scrotum embracing the penile root, with sclerosing eosinophilic lipogranuloma on histology and electron microscopy (but no exogenous lipids) and associated with blood eosinophilia (one patient had arthralgia), have been reported from Japan [14].

Priapism

Priapism is defined as the prolonged, painful erection of the penis, unassociated with sexual desire and not relieved by ejaculation. Although not predominantly a dermatological concern, it has an important differential diagnosis. The principal causes [1,2] are listed in Table 71.29. It results in impotence in more than 50% of those affected [3,4] and can lead to gangrenous penile necrosis [5].

Veno-occlusive priapism can be distinguished from arterial priapism [1]. Veno-occlusive priapism results from persistent obstruction to venous outflow from the lacunar spaces. It is a potential vascular emergency because, as the corporeal bodies expand to maximal volume, an obstructed outflow causes decreased arterial inflow, with the potential for ischaemia, pain, fibrosis and hence impotence. Arterial priapism is usually secondary to trauma, such that a damaged cavernosal artery causes unregulated blood flow to the lacunar spaces; it is thus non-ischaemic [1].

Dermatological non-disease, dysaesthesia and chronic pain syndromes

'Dermatological non-disease' may be the diagnosis where there is a paucity or even absence of primary dermatological signs to account for florid symptomatology. Genital symptoms include itching, excessive redness, burning and discomfort—in some cases so severe that it prevents the patient from sitting down. Dysmorphophobia, depression and psychosis may be present, and attempted suicide is a real risk in such patients [1,2].

Itching of the urethra may lead to insertion of a foreign body in an attempt to relieve the sensation [3], or this might be done for sexual gratification.

Patients with symptoms of itching, burning and pain localized to the penis or scrotum are not uncommonly encountered. The skin is usually completely normal. The situation is analogous to vulvodynia in women, and terms such as penodynia and scrotodynia have been coined to describe the syndrome in men. Doxepin, dosulepin amitriptyline and paroxetine can afford some relief.

Fisher [4] has defined the red, burning scrotum syndrome as 'persistent redness of the anterior half of the scrotum that may involve the base of the penis . . . usually accompanied by a persistent itching or burning sensation and hyperalgesia'. It is a chronic condition that is resistant to treatment and its cause is unknown [4,5]. Accompanying the erythema there may be telangiectasia. It is related to idiopathic penile and scrotal pain syndromes [6]. Prednisolone and antidepressants have given some relief to some patients.

Localized dermographism should be sought by stroking the inside of the thigh, because such patients may be helped by oral antihistamine treatment.

The possibilities of zinc deficiency and necrolytic migratory erythema should be entertained.

Chronic urogenital and rectal pain syndromes include penile pain (penodynia), scrotodynia, orchialgia, prostatodynia, coccygodynia, proctalgia fugax, perineal pain, the descending perineum syndrome and vulvodynia [7–9]. The neuroanatomy of the pelvis is complicated and the neurophysiological basis of the pathogenesis of these syndromes is poorly understood, but their clinical presentations are well recognized. The differential diagnosis is addressed above.

The *koro syndrome* is a psychiatric disorder characterized by fear of genital retraction (i.e. the penis shrinking, retracting or disappearing into the abdomen), acute anxiety and fear of death and genital pain. There is rarely real associated genital pathology. Although originally thought to be a culture-specific condition in South East Asia and China it has been observed in the West, without fear of death [10].

A diagnosis of a chronic pain syndrome implies the prospect of considerable psychological morbidity. Treatment is challenging and only empirical at best. Most agree that invasive and

irreversible procedures should be avoided if at all possible. Multidisciplinary management is recommended [6].

Female genital dermatology

Introduction

Disorders of the vulval epithelium have proved confusing to the many and varied specialists who have been involved in their diagnosis and treatment. The difficulty has arisen because the majority of the problems are dermatological and the specialists—gynaecologists, urologists, paediatricians and genitourinary physicians—have had little or no training in dermatology. The problem is compounded by the fact that the normal characteristics of common diseases at this flexural site are lost or modified, making the diagnosis difficult even for an experienced dermatologist. Over the years, classifications of vulval disorders have been devised to help, but unfortunately these have only resulted in further confusion. There is no need for a separate classification for vulval disorders, as the current classifications that exist for dermatology and pathology can be used [1,2].

Dystrophy, leukoplakia and kraurosis vulvae have all now been abandoned as diagnostic terms [3]. Over the years, the term leukoplakia has unfortunately had the sinister implication that it always represented a premalignant condition [4], but now leukoplakia is used as a descriptive term only and may represent anything from a patch of lichen simplex to an SCC. Similarly, squamous cell hyperplasia is not a diagnosis but a histological description, and can be seen in many disorders including psoriasis, candidosis and hypertrophic lichen planus.

Vulval clinics have been an important step forward in the diagnosis and management of women with vulval problems [5,6]. These clinics ideally should be multidisciplinary, with input from dermatology, gynaecology, genitourinary medicine and pathology. It is important that there are links with other specialists, including paediatricians and plastic surgeons, as well as psychologists and psychosexual therapists.

The development of these clinics has been extremely important, not only for improved patient care but also for the valuable interdisciplinary education of the doctors involved.

An accurate diagnosis depends on a thorough history, examination of the affected skin and skin at extragenital sites, and pertinent investigations. The history must include the chief complaint, how long it has been present, how the problem changes in certain circumstances (e.g. variation with the menstrual cycle), what treatment has been prescribed and what were the effects of the treatment. A drug history is important, and should include direct questioning about over-the-counter oral and topical medications, oral contraceptives and hormone replacement therapy (HRT). The latter two are included in this direct questioning as patients do not always consider these as medications, particularly if the HRT is in a topical formulation. A personal and family history of autoimmune disease, atopy or psoriasis should be established, and any known skin sensitivities. The patient should also be asked about vaginal discharge, urinary symptoms and bowel function. Finally, as the vulva is important for normal sexual function, it is important to include relevant questions on problems with intercourse where appropriate.

The complaint of irritation has many meanings and it is sometimes helpful to ask the patient exactly what they mean by the term. It may be the sensation of itch, dryness, pain, burning or rawness. This point is important as a patient with itch will scratch or rub the skin, and the response will be lichen simplex or lichenification, whereas with discomfort or pain there will be no such change as the patient avoids touching the area.

Lichen simplex and lichenification. Lichen simplex and lichenification are terms used to describe the exaggerated normal rhomboidal patterning of the skin surface. Lichen simplex is used to describe the changes seen on apparently normal skin secondary to itching and rubbing, although the provoking symptom of itch may be initiated by a low-grade dermatosis such as psoriasis or seborrhoeic eczema. The term lichenification is used for similar changes arising on a background of a visible dermatosis.

The lesions of lichen simplex tend to be in one isolated area, usually on the labia majora or mons pubis. They are well defined, with a pale grey or white surface.

The histological changes of lichen simplex and lichenification are similar, except that there are the changes of the background dermatosis in the latter. There is hyperkeratosis, acanthosis, a prominent granular layer, lengthened rete ridges and a chronic inflammatory dermal infiltrate. In addition, lamellar thickening of the papillary dermis and perineural fibrosis can be seen. Twelve cases of what was termed multinucleated atypia of the vulva have been reported [7], but this is thought to be a non-specific change found in lichenified skin [8,9].

Treatment of the underlying dermatosis will usually resolve the lichenification. In cases of lichen simplex with no underlying dermatosis, the treatment is the application of a potent topical steroid to encourage a disruption of the itch–scratch cycle. A soap substitute should be introduced and possible irritants avoided. If these measures are unsuccessful, patch testing should be performed to exclude the possibility of an unsuspected allergen.

The examination is often very embarrassing for the patient, so it must be carried out sympathetically to ease any tension. It is important that there is good lighting, and a means of magnification. The skin and the mucosae in the anogenital area are exam-

ined for changes in colour, epithelial integrity and texture. If there is scarring this will be seen in loss of characteristic features (e.g. introital narrowing, loss of the labia minora or sealing of the clitoral hood). The examination must also include inspection of other flexural sites and mucosae, the scalp and nails. It is also useful to determine if the patient exhibits dermographism [10]. The vagina and cervix should be examined in patients who have dermatoses that affect mucosal surfaces and in patients with symptoms of dyspareunia, vaginal discharge or postcoital bleeding. Investigations are determined by the specific problem and include microbiological assessment. The investigation of the common bacterial or fungal problems can be easily performed by a dermatologist but if an exotic bacterial or sexually transmitted infection is high on the differential diagnosis, it is important to involve a genitourinary physician in the investigation and work-up of these patients and their partners. A biopsy is important, particularly in cases where there is no response to treatment. If a biopsy is performed, it is important to let the pathologist know what area has been biopsied, as the vulva is a mucocutaneous junction and the normal histological changes of a mucosal epithelium differ significantly from those of cornified epithelium and may be misinterpreted as pathological changes. Other investigations include those performed routinely for skin problems elsewhere (e.g. patch testing, examination with Wood's light, Tzanck smears). Some investigations are not the usual remit of the dermatologist but are necessary in patients with anogenital dermatoses, and will include a cervical smear and proctoscopy.

On occasions, the vulval changes are not caused by a primary problem of the vulval skin but are the secondary consequences of pathology at another site (e.g. an irritant vulval dermatitis resulting from a vaginal discharge because of cervical, uterine or vaginal pathology).

Diagnosis and management of vaginal discharge

The diagnosis usually falls into one of the following categories: physiological, iatrogenic, infective, inflammatory or neoplastic (Table 71.30).

Table 71.30 Causes of vaginal discharge.

Physiological
Ovulation
Iatrogenic
Medications (e.g. tamoxifen, oral contraceptive pill)
Infective
Candidosis
Bacterial vaginosis
Cervicitis
Inflammatory
Lichen planus
Mucous membrane pemphigoid
Pemphigus
Erythema multiforme
Stevens–Johnson syndrome
Vaginal adenosis
Cervical erosion
Neoplastic
Langerhans' cell histiocytosis
Vaginal, uterine or fallopian tube tumours
Foreign body

Physiological. Between 5 and 10% of women complaining of vaginal discharge do not have an infection. The discharge may be caused by an excess physiological secretion of mucus, usually resulting from cervical erosion or an increase in the amount of vaginal transudate. The discharge is thick, with a grey-white appearance, and is odourless and non-irritant. Vaginal pH is normal.

Iatrogenic. This is usually secondary to medications that have an effect on the vaginal epithelium (e.g. tamoxifen, which has oestrogenic effect on the vagina); oral contraceptive pills can cause cervical erosion and an increase in vaginal discharge. There is one report of an orange-coloured vaginal discharge due to a laxative containing the anthroquinone danthron [11].

Infective. This is the most common cause of a vaginal discharge, and a pH greater than 6 is highly predictive of an infectious cause [12]. Bacterial vaginosis is the usual diagnosis [13]. The patient complains of excessive, grey watery discharge, associated with a 'fishy' malodour, which is worsened with intercourse. Vulval irritation is slight or absent in this group, and the smell is the most distressing symptom. The condition is invariably associated with infection by a small aerobic Gram-negative rod known as *Gardnerella vaginalis*, after its discoverer Gardner [14]. It would appear that this organism alone is incapable of causing infection, and non-specific vaginitis is now regarded as a complex interrelationship between *Gardnerella* and anaerobic species of bacteria [15], two of which belong to the genus *Mobiluncus*. The fishy odour of the discharge can be accentuated by the addition of an alkali such as 10% potassium hydroxide (the Whiff test). A wet mount of a vaginal smear in saline will identify 'clue cells'. These are vaginal epithelial cells with a granular cytoplasmic appearance and indistinct cellular outlines. This indistinct border is caused by the attachment of the small Gram-negative rods to the cell. Bacterial vaginosis is not always sexually acquired—its incidence is equal in virginal and sexually active groups [16,17]. This type of abnormal bacterial colonization may be associated with preterm delivery and late miscarriage in pregnant patients [18]. Treatment is with metronidazole 400 mg twice daily for 5 days or 2 g as a single dose.

Patients with infective cervicitis will also present with an increased vaginal discharge. The four most common pathogens involved are *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *Trichomonas vaginalis* and herpes virus hominis. *Chlamydia trachomatis* has been grown from the cervices of 50% of women with mucopurulent cervicitis [19]. The main symptoms are discharge, deep pelvic pain and dyspareunia.

Infestation with thread worms, *Enterobius vermicularis*, has also been recorded as a cause of a vulvovaginitis [20].

Inflammatory. Vaginal or cervical ulceration and erosion resulting from inflammatory conditions can give rise to an increased vaginal discharge. The most common inflammatory conditions are

lichen planus and pemphigus [21]. The diagnosis is often missed, particularly if these sites are affected in isolation. There is a chronic odourless discharge, which may be blood-tinged. The patient will also complain of postcoital bleeding if she is sexually active. An accurate diagnosis requires a biopsy, and immunofluorescence studies should be performed both on tissue and serum. Examination of eyes and mouth may help if the patient also has disease at these sites. Treatment requires topical steroids in the form of foams or pessaries that are currently used for inflammatory bowel disease.

Neoplastic. Tumours of the fallopian tubes, uterus, cervix and vagina may all cause an increased vaginal discharge. Rarer causes of a chronic vaginal discharge include Langerhans' cell histiocytosis.

A persistent discharge in young children should be investigated as it is often associated with a medical or social problem [22].

Management of vulval disorders depends upon the diagnosis, but general measures include the use of a soap substitute and avoidance of irritants (e.g. bubble baths, shampooing hair in the bath). If there is an incontinence problem, a barrier ointment helps to protect the skin. Weak potassium permanganate solution or Burow's solution can be used when there is erosive disease. Topical steroids are best used in an ointment formulation to avoid the irritant effect of preservatives and alcohol. Many of the patients are elderly and may have difficulty treating themselves. It is often helpful to take time in the clinic, using a mirror, to explain exactly where the treatment should be applied.

Structure and function of the female genitalia

The vulva is the collective term for the structures that comprise the female external genitalia. Anatomically, it is the region known as the urogenital triangle, bounded anteriorly by the symphysis pubis, the pubic rami laterally and the transverse perineal body posteriorly. The vulval structures included within this area are the mons pubis, paired labia majora and labia minora, clitoris and vulval vestibule. The epithelia that cover the vulva change from skin on the outer aspects to mucosa on the innermost region.

The mons pubis lies in front of and above the upper part of the symphysis pubis. It is softly rounded because of a thick cushion of subcutaneous fat. The epithelium is densely covered in hairs and possesses all the adnexal structures usually found in skin.

The labia majora are paired, rounded folds of skin and are the homologue of the scrotum. They extend downwards and backwards from the mons pubis and meet posteriorly in the midline to form the posterior commissure, which lies approximately 2 cm anterior to the anus. The epithelium is similar in structure to that on the mons pubis in that there is a thick layer of adipose tissue and a dense distribution of hair on the outer surfaces of the labia. Hair is absent from the inner surfaces but numerous sebaceous glands remain. The inner aspects of the labia majora fuse into the outer aspects of the labia minora laterally, forming the interlabial sulci. The labia majora enclose an elliptical fissure which is known as the pudendal cleft—this contains the vestibule with the openings of the vagina and urethra.

The labia minora are the equivalent of the prepuce, and part of the ventral portion of the penis and the floor of the spongy part of the male urethra. They are paired pendulous folds, which lie between the labia majora and the vulval vestibule. Anteriorly they split into two folds on each side, which fuse in the midline. The superior folds cover the clitoris like a hood, forming the prepuce of the clitoris, and the lower folds fuse on the inferior aspect of the clitoris, forming the clitoral frenulum. Posteriorly, the labia minora fuse to form the fourchette, and sometimes form a depression in the midline, the fossa navicularis. The labia minora possess little subcutaneous fat. Their epithelium lacks hair but there are numerous sebaceous glands and sweat glands. The epithelium is cornified but its barrier function is not as effective as skin elsewhere.

The clitoris is the homologue of the penis and contains all the vascular and muscular structures found in its male counterpart.

Fig. 71.20 Vestibular papillae.

The end of the clitoris is surmounted by a small rounded tubercle, the glans clitoris.

The vestibule is usually considered as part of the vulva, although many anatomy books refer to it as the vestibule of the vagina. It is the area that lies between the labia minora and contains the openings of the urethra and vagina. The vaginal opening is partially closed by the hymen. When the hymen is ruptured, its remnants form rounded crenulations, the hymenal caruncle. The fold between the hymenal caruncle and the vestibular floor is the nymphohymenal sulcus. Sometimes a clear line of demarcation between the labia minora and the epithelium of the vestibule can be seen, Hart's line. The vestibule is a mucosal epithelium and lacks hairs and sebaceous glands. On each side, the duct of the major vestibular gland, Bartholin's gland, can be seen sited between the hymenal ring and posterior part of the labium minus. The ducts of the minor vestibular glands, Skene's glands, open on either side of the urethral orifice. The epithelial surface is usually smooth, but occasionally tiny frond-like papillae may be seen distributed symmetrically laterally and posteriorly on the vestibule (Fig. 71.20). These vestibular papillae are a variant of normal and not related to HPV infection.

Normal flora

The skin of the perineal area has a higher pH, temperature and degree of humidity than skin elsewhere and, because of its proximity to the vagina and rectum, harbours many of the flora from these sites [1,2]. The main resident organisms are micrococci, diphtheroids and lactobacilli. Lactobacilli are probably the most common organisms, particularly on the mucosal surfaces, as the glycogenated epithelium of the vagina, under the influence of oestrogen, encourages colonization by them. The lactobacilli in turn metabolize the glycogen to lactic acid, which keeps the vaginal pH at approximately 4.5, restricting the growth of many organisms.

Normal variants

Angiokeratomas are small (1–4 mm) vascular papules found on the labia majora. They vary in colour from red to blue-black and are normally asymptomatic, but can become quite large and bleed if traumatized, particularly in pregnancy.

Sebaceous gland hyperplasia is seen on the inner aspects of the labia majora and labia minora where the glands do not usually have an associated hair unit. The glands open directly onto the surface, and may be very prominent and numerous. The yellow uniform papules are often best seen when the skin is stretched. Prominent and numerous glands may be associated with pruritus and sometimes they become inflamed and painful in the week prior to the menses. Occasionally, they can become very large and be mistaken for a sebaceous gland adenoma [1].

Vestibular papillomatosis is the term used to describe the occasional normal finding of myriad tiny filiform or soft frond-like projections on the vestibular epithelium and inner aspects of the labia minora. These lesions have had various names in the past, including papillomatosis labialis, hirsuties papillaris [2], hirsutoid papillomas of the vulva [3], vestibular papillae [4], pseudocondylomas, vestibular microwarts and vulval squamous papillomatosis [5]. The last two suggest that HPV is implicated but the evidence now suggests that the known HPV types are not associated with these papillae [6–8]. Clinically, vestibular papillae are unlike the lesions induced by HPV as they are symmetrically arranged and each papilla has a solitary base. Histologically, problems arise if the pathologist is unaware that the tissue is the vestibule, which has heavily glycogenated epithelial cells that become vacuolated on processing and may resemble koilocytes. The problem is also compounded by the fact that koilocyte-like lesions can be found on vulval biopsies, but these are not necessarily associated with HPV infection [9]. Currently, it is believed that this entity is a normal variant and the female equivalent of pearly penile papules.

Varicosities of the labial veins may occur unilaterally in association with limb varicosities, or appear in pregnancy. Other changes in pregnancy include a fall in the pH and increased pigmentation. At the menopause, vascularity decreases and the sebaceous glands become less active.

Congenital and developmental abnormalities [1]

Ambiguous external genitalia

In a newborn, the external genitalia may not be phenotypically characteristic of either male or female. It is critical that gender assignment is not made on immediate assessment of the neonate. A full work-up with a multidisciplinary team, including a paediatric endocrinologist, is essential. The initial clinical assessment includes metabolic state of neonate, size and differentiation of the phallus, position of the urethral meatus, labioscrotal folds and pigmentation, palpation for gonads in the labial folds and inguinal areas. If gonads are absent it is very likely that the infant is XX and has been virilized *in utero* due either to adrenal production by the fetus or maternal ingestion or production of androgens. If there are palpable gonads then the infant may be XY and the phenotypic changes due to under-virilization *in utero*. The underlying mechanisms are often complex, and further investigations would include ultrasound of pelvis to assess presence of uterus and ovaries, blood for karyotype, glucose, urea and electrolytes, testosterone, FSH, LH and 17-hydroxyprogesterone.

An attempt at classification of these abnormalities is based on gonadal differentiation, but the classification is still evolving. Essentially there are five main groups:

1 Female pseudohermaphrodite—two ovaries
2 True hermaphrodite—ovary and testis
3 Male pseudohermaphrodite—two testes
4 Mixed gonadal dysgenesis—testis and streak gonad
5 Pure gonadal dysgenesis—two streak gonads.

Congenital adrenal hyperplasia accounts for 60% of these intersex changes producing a female pseudohermaphrodite.

Labial problems

There may be persistence of most caudal elements of the milk line in the labia majora, and there is great variation in the size and symmetry of normal labia minora. There may be very marked hypertrophy of the labia minora, some cases of which are examples of neurofibromatosis [2].

Labial adhesions may occur as an inherited familial trait [3] or in association with abnormal sexual differentiation. In general, most occur in the neonatal period and early infancy, and usually divide spontaneously by the time the child is 6 years old. No intervention is necessary unless there is a problem with urination. Some cases of labial adhesions result from lichen sclerosus.

Accessory labioscrotal folds are well described in males, usually in association with a perineal lipoma. They are extremely rare in women and only two cases have been reported [4].

Clitoral problems

The clitoris may be absent because of a failure of the genital tubercle to fuse, remain hypoplastic [5], or be enlarged because of congenital adrenal hyperplasia. The Lawrence Seip syndrome, which is a congenital generalized lipodystrophy with the onset of insulin-resistant diabetes around the time of puberty, may also result in clitoral hypertrophy. There are clitoral tumours that may mimic genital sexual ambiguity (e.g. haemangioma, neurofibroma, lipoma [6–8]), and a pseudocyst of the clitoris caused by a build-up of keratinous debris under clitoral hood adhesions in lichen sclerosus.

Virilization of the external genitalia may also occur with maternal ingestion of testosterone or synthetic progestogens in the first trimester, and if taken later in pregnancy there may be clitoral hypertrophy alone.

An imperforate hymen is usually discovered at puberty and is caused either by failure of the epithelial cells of the hymen to degenerate or by scarring after an inflammatory reaction in the hymen at birth.

Trauma and artefact

Factitial dermatitis

There are various causes of vulval trauma, including accidental injury, obstetrical tears, damage at the time of surgery in a nearby site and coital and sexual mutilation, both cultural and self-induced [1].

Nymphohymenal tears induced by sexual intercourse are not uncommon and may mimic the symptoms of vulval vestibulodynia (see p. 71.82).

Sclerosing lipogranuloma [2] is a granulomatous response induced artefactually.

Female genital mutilation [1,2]

Ritual and cultural female genital mutilation (FGM), although banned in most European countries, is still forced on many women

worldwide. Although it is unusual in Western society, many cases are now being seen in the UK because of the rise in immigration of women who have had previous FGM.

There are four types of operation performed, which vary according to the country and culture:

1 Clitoridectomy: removal of the clitoris and/or the clitoral hood (Sunna circumcision)
2 Excision: removal of the clitoris and part or all of the labia minora
3 Narrowing of the introitus by cutting and apposing the labia minora and/or the labia majora, with or without excision of the clitoris (infibulation), leaving a tiny opening for urination and menstruation
4 All other practices which might involve cauterization, applying corrosive material, piercing or cutting of the clitoris, surrounding skin or vagina.

FGM may be carried out at any age from the neonate to the adolescent. It is often performed without an anaesthetic in unhygienic circumstances. There may be damage to the urethra and vagina at the time of the operation, and later there may be severe damage to the urethra, bladder or anal sphincter during delivery in those who have had infibulation. Many of the women who have had FGM experience difficulties with sexual intercourse, urination and pregnancy and seek help in the clinics of their new country of residence, where unfortunately many of the health-care professionals have not encountered their specific problem. There are now a number of clinics being set up to deal specifically with these patients. The initial findings of a specialized clinic set up by a central London maternity unit found that many of the patients referred to them for problems in pregnancy were reluctant to volunteer the fact that they had been circumcised, and less than 10% refused to continue the tradition of FGM [3].

Dermatological manifestations of sexual abuse of children

Childhood sexual abuse is not the usual domain of the dermatologist, but occasionally it can be encountered when a dermatological opinion is sought on a genital skin problem. Lichen sclerosus and other dermatoses can be mistaken for sexual abuse [1–4], but sometimes the sexual abuse may be the initiating or exacerbating factor of the dermatological condition [5]. The possibility of sexual abuse sometimes has to be considered in a child whose lichen sclerosus, despite appropriate treatment and compliance, has not responded as expected. Sexual abuse always has to be excluded in the child who presents with a sexually transmitted disease [6,7], but conditions such as molluscum contagiosum, bacterial vaginosis [8] and genital warts are not necessarily indicative of sexual activity, and can be acquired by non-sexual means [9,10]. Genital warts in children may carry both genital and skin-type viruses [11]. If gonorrhoea or semen is found the situation is clear-cut, with the exception of neonatal infection and gonococcal eye disease [12]. Herpes simplex infection of the prepubertal genitalia is relatively uncommon and sexual transmission may be implicated in both HSV-1 and -2 infections [13]. In a review of six cases, sexual abuse was proved in four. In the two innocently acquired cases, HSV-1 infection of the oral cavity immediately preceded the genital signs [14].

There are strict protocols for the examination and assessment of a child who is suspected to be a victim of sexual abuse [15]. It is important that this evaluation is carried out by a skilled specialist, usually a paediatrician [16].

HIV has rarely been reported as being transmitted by sexual abuse of children [17,18], but direct transmission is possible, and sexual abuse may be a risk factor for HIV in later life [19–21].

Inflammatory dermatoses

Eczema

Atopic eczema can involve the vulva but the eczematous dermatoses affecting the vulva in isolation are seborrhoeic eczema, irritant contact dermatitis and allergic contact dermatitis.

Seborrhoeic eczema

This condition has both eczematous and psoriasiform features, sometimes making differentiation between it and psoriasis difficult. The inguinal and genitocrural folds, labia majora, mons pubis, perineal body and perianal skin are the usual sites involved. Vulval involvement may be associated with skin changes on the scalp and changes at other flexural sites. Histological examination is not always helpful, as there may be features of both eczema and psoriasis. There is moderate acanthosis with slight spongiosis and a mild dermal inflammatory infiltrate.

Irritant contact dermatitis

The barrier function of the vulval skin is impaired, as measured by transepidermal water loss [1], and there is an increased susceptibility to irritant contact eczema [2,3]. The problem may occur because of the dampness and maceration secondary to a heavy vaginal discharge, or increased contact with urine in the incontinent patient. Contact with irritant chemicals in topical agents, particularly cleansing agents, bubble baths, disinfectants, lubricants, perfumed products, deodorants and medicaments (e.g. 5-fluorouracil, podophyllotoxin and dequalinium), may all be responsible for an irritant dermatitis.

Allergic contact dermatitis

In spite of the frequent use of topical agents in the vulval area, allergic contact dermatitis is extremely rare in clinical practice. However, high incidences of contact dermatitis in vulval dermatoses have been reported [4,5]. An explanation for these unexpected high incidences may be that the patients in the studies had perianal skin involvement as well as vulval involvement, and allergic contact dermatitis to topical medicaments is more frequently encountered in perianal skin. One study has shown a higher incidence of positive patch tests in patients with anogenital dermatoses if both the genital and perianal areas are involved, compared with dermatoses affecting the genital skin alone [6].

There are reports of allergy to vaginal preparations and an intrauterine device [7–9], sanitary wear [10] and condoms [11]. Oestradiol may rarely cause a localized allergic contact dermatitis at a transdermal patch site, or generalized contact dermatitis with oral therapy [12].

Allergic contact urticaria

The two most common causes of contact urticaria in the vulvovaginal area are latex and semen [13], and there is usually a history of atopy [14]. Seminal fluid usually induces an urticarial immediate type I reaction and rarely produces a type IV contact allergy. There are reports of mixed sensitivities; one patient was allergic to semen and latex and another to her husband's semen and sweat [15,16]. However, semen itself may not be the responsible allergen, the problem being caused by a medication or other allergen carried in the seminal fluid [17–19]. Specific immunotherapy against semen has been successfully employed on occasion [20]. A fixed eruption to seminal fluid has been reported [21], and familial allergy to semen [22].

Psoriasis

The pattern of psoriasis affecting the anogenital skin is most frequently flexural. The areas involved include the genitocrural folds, mons pubis, outer aspects of the labia majora, the perianal skin and the natal cleft (Fig. 71.21). The characteristic silvery scaling is absent in these occluded sites and the main clinical picture is intense erythema with a well-defined margin. Rarely, there may be some scarring associated with vulval psoriasis, with loss of the labia minora and fusion of the clitoral hood.

Fig. 71.21 Fissured psoriasis in the natal cleft.

Fig. 71.22 White patches of lichen planus in the interlabial sulci.

The histology is not always typical, and there may be marked spongiosis and papillary oedema.

Reiter's disease (circinate ulcerative vulvitis)

Circinate balanitis is well recognized but the corresponding vulvitis is much rarer [1–4]. The lesions may be eroded, ulcerative or scaly. Histologically, the changes are of those seen in pustular psoriasis [5], with hyperkeratosis, parakeratosis, psoriasiform hyperplasia, an absent granular layer and collections of polymorphs in the epidermis.

Lichen planus [1–3]

Lichen planus (LP) can affect the vulva in isolation or at the same time as a generalized eruption, when approximately 20% of patients will have genital lesions. The vulval lesions are similar to those seen at other sites and may be violaceous or erythematous papules, white (Fig. 71.22) or annular plaques, and erosions with or without a lacy white border. These lesions may all ulcerate. Wickham's striae occur infrequently (Fig. 71.23). If the vulva is affected in isolation, the disease is more often erosive, with most of the lesions around the labia minora, clitoris and clitoral hood. Confluent white and red patches will also be seen in this variant.

Fig. 71.23 Delicate white striae of lichen planus, with the labia minora flattening and fusing into the surrounding skin.

A careful examination of the oral mucosae is helpful, as LP may be found on the tongue, palate, gingivae and lateral buccal mucosae.

The other clinical forms of vulval LP include the following.

1 **Pigmented flexural lichen planus** (Fig. 71.24). This variant of LP can affect the vulval area, particularly the mons pubis, the inguinal and genitocrural folds. The characteristic and striking finding is brown pigmented patches, some so deeply pigmented

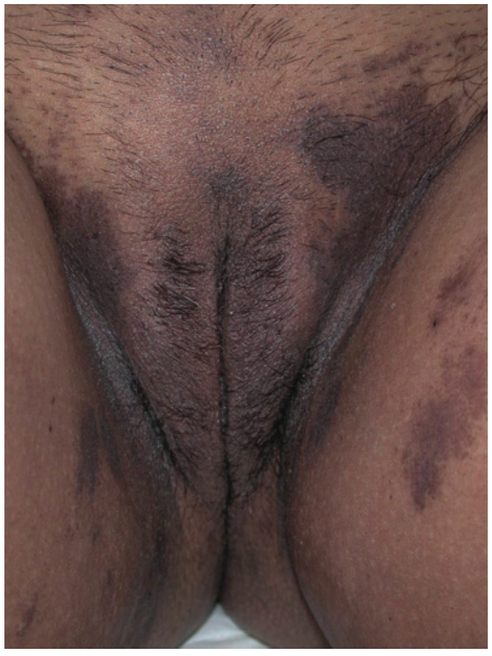

Fig. 71.24 Patches of pigmented flexural lichen planus.

Fig. 71.25 Lichen planus: vulval aspect showing glazed erythema and distortion of the architecture, with a remnant of the left labium minus and buried clitoris above it.

that they resemble melanocytic naevi. If the disease is seen in the early stages, a violaceous erythema is also observed. This form of LP is also found in the inframammary areas and axillae.

2 **Vulvovaginal–gingival lichen planus** (VVG-LP) (syndrome of Hewitt and Pelisse; desquamative vaginitis). This distinctive erosive form of LP is clinically very similar to mucous membrane pemphigoid [4,5]. In the past, many cases labelled desquamative vaginitis were probably this entity [6,7]. VVG-LP principally affects the inner aspects of the labia minora, vestibule and vagina. The condition is chronic and painful, and there is an increase in vaginal discharge, dysuria, dyspareunia and postcoital bleeding. Clinically, the epithelia are eroded and often there is a distinctive fine white lacy border. There may be marked loss of architecture (Fig. 71.25). The anal margin may also be involved. The vaginal lesions are velvety red erosions or bright red, glazed erythema, which is friable and bleeds when touched. Vaginal synechiae and adhesions develop, leading in some cases to vaginal stenosis. The cervix may also be involved [5,8,9]. Oral LP lesions can occur at any site, but the characteristic finding is an intense erythema of the gingivae, which may be asymptomatic (Fig. 71.26). Unusual extragenital lesions have been described on the conjunctiva [10], lacrimal gland canal [11], oesophagus [12–15] and the auditory canal [16]. The manifestations of this syndrome do not necessarily all occur synchronously.

3 **Lichen planopilaris.** This has been described on the vulva [17].

Fig. 71.26 Lichen planus. Intense glazed erythema of gingiva.

Histopathology. On cornified epithelium there is hyperkeratosis, irregular acanthosis with a typical saw-tooth appearance of the rete pegs, an increased granular layer, and disruption of the basal layer with a closely apposed dermal band-like lymphocytic infiltrate. The acanthosis and hyperkeratosis are marked in the hypertrophic form, and because of the chronicity of this form the characteristic band-like infiltrate is not obvious but will be found focally. Eosinophilic colloid bodies may be seen. Immunofluorescence studies reveal uneven staining of the basement membrane zone for fibrinogen and IgM, cytoid bodies and, on occasion, IgG or IgA.

Differential diagnosis. The main differential diagnosis is usually lichen sclerosus, but mucous membrane pemphigoid and

morphoea could also be included. In some cases, the differentiation between lichen sclerosus (LS) and LP can be extremely difficult, even impossible, as the two diseases share so many features in common [18,19]. If a definite diagnosis cannot be made on a combination of clinical, histological and immunofluorescence findings and response to treatment, it is perhaps best to consider the case as an overlap of the two disorders. Frequently, there are cases of LP misdiagnosed as Zoon's vulvitis.

Treatment. First-line treatment is with potent topical steroids. If the vagina is involved, a topical steroid can be introduced with a vaginal applicator, or steroid foams or suppositories that are available for inflammatory bowel conditions can be used [20]. Topical retinoids are useful for hyperkeratotic and hypertrophic LP, and recently topical tacrolimus [21] and pimecrolimus have been used [22]. Other treatments tried with variable success include oral steroids, oral and topical retinoids, methotrexate [23], ciclosporin [24] and azathioprine.

Zoon's vulvitis

It is likely that plasma cell vulvitis (PCV; vulvitis circumscripta plasmacellularis) is not a single disease entity but represents a reaction pattern to another inflammatory condition. A plasma cell-rich infiltrate in a vestibular biopsy may be a misleading finding, because plasma cells are commonly found in inflammatory conditions of the vestibule as it is a mucosal epithelium.

Many of the cases are examples of unrecognized dermatoses such as LP, and in others the persistent change may represent a chronic post-inflammatory phenomenon.

The first descriptions of the female equivalent of ZB were by Garnier and Zoon [1–3]. The lesions described in these reports were erythematous patches with a glazed appearance, with the histological findings of a plasma cell-rich dermal infiltrate and no cytological atypia. The disorder followed a chronic but benign course. It appears to be less common in women, and in one series of 20 cases there was only one female [4].

Most of the reports of this condition in women describe the lesions in the vestibule and labia minora, whereas the typical site in men is the glans and prepuce. The glans clitoris is rarely, if ever, affected.

Histology. The criteria needed to make the diagnosis have varied in the literature, and there is some doubt whether PCV is a distinct clinicopathological entity, as many of the reports of vestibular Zoon's are probably LP [5].

The essential features are epidermal thinning, absent horny and granular layers and distinctive lozenge-shaped keratinocytes with widened intercellular spaces; in the dermis there is a dense inflammatory infiltrate composed largely of plasma cells, with dilated blood vessels and usually much haemosiderin. Russell bodies and dermal-epidermal splitting have also been described [6].

Treatment. Treatment depends on the underlying inflammatory dermatosis responsible for this histological change. In the majority of cases this is LP, and a potent topical steroid should be tried. If the inflammatory phase of disease has resolved and the patient is complaining of a sensation of rawness or burning, then topical 5% lidocaine can be effective. Finally, a barrier ointment such as Vaseline petroleum jelly may offer some relief if there is an irritant component to the problem.

Chronic vulval purpura

It is not uncommon to find patients with purpuric patches, often at the vestibule, in which haemosiderin and plasma cells are found without any specific epidermal change, and the term chronic

vulval purpura may be a more accurate description [7]. An association with lichen aureus has been suggested, as pressure factors are thought to be relevant in the extravasation of blood [8].

Lichen sclerosus [1–5]

Lichen sclerosus (LS) was first described as a variant of LP with a tendency to affect the genital area. The old terms leukoplakia, leukoplakic vulvitis and kraurosis vulvae were clearly applied to examples of LS or LP, and the use of these terms led to confusion. The term vulval dystrophy was introduced in the 1960s in an attempt to overcome the problems in distinguishing and classifying vulval dermatoses characterized by pallor and scarring [6]. This terminology unfortunately proved unsuccessful in its objectives, as its use discouraged attempts to differentiate between disorders such as LS, LP and mucous membrane pemphigoid. In 1983, the Terminology Committee of the International Society for the Study of Vulvovaginal Dermatoses recommended a new classification with discontinuation of the term dystrophy [7]. The term vulval squamous cell hyperplasia was introduced with this classification (see p. 71.52).

Aetiology and pathogenesis. The aetiology is still unknown but there is mounting evidence that LS is a genetically determined autoimmune disorder. A positive family history is recognized and the disorder has been described in twins, both identical [8] and non-identical [9]. An association of LS with other autoimmune disease in females has been noted [10]. Attempts to establish a specific HLA linkage in patients with LS were initially inconclusive [11], but a later study has shown an increased incidence of DQ7 [12]. Similar findings have been reported in LS in girls [13]. The role of *Borrelia burgdorferi* as an aetiological trigger is controversial. A study in the UK showed no evidence histologically of spirochaetes but did show 'cocci' with a Fite stain, which later proved to be mast cells when stained with toluidine blue [14].

Clinical features. LS can affect females of any age, but the majority of patients are either prepubertal or menopausal. There is still uncertainty whether LS in prepubertal girls remits spontaneously at puberty. The presenting symptom is usually itching, which is often severe and distressing.

The classical lesions seen on the extragenital skin are ivory white papules and plaques with follicular delling. Anogenital disease

Fig. 71.27 Oedema and ecchymosis of lichen sclerosus.

tends to be characterized by flatter lesions of atrophic whitened epithelium, which may become confluent, extending around the vulval and perianal skin in a figure-of-eight configuration. There may also be oedema, purpura, bullae, erosions and ulceration (Fig. 71.27). The sites most commonly affected are the genitocrural folds, the inner aspects of the labia majora, labia minora, clitoris and clitoral hood. Vestibular involvement is rare and vaginal lesions do not occur, as LS seems to spare non-cornified stratified squamous epithelia (mucosal epithelium). Perianal lesions occur in approximately 30% of female patients, in contrast with men who do not seem to develop perianal involvement. Extragenital lesions occur in 10% of women with vulval disease. The extragenital areas may be truncal, at sites of pressure, upper back, wrists, buttocks and thighs. The Koebner phenomenon has also been reported at sites of radiotherapy [15], scar tissue [16], vaccination [17] and congenital haemangioma [18]. Facial [19], lip [20], scalp [21] and nail involvement [22] have been recorded.

Lesions of LS in the oral cavity are extremely rare and occur on a site in the mouth that has cornified stratified squamous epithelium, the tongue [23]. Many of the reports of oral involvement in the literature have often not been confirmed histologically [24] and may have been examples of LP. It is not uncommon for patients with vulval LS to have coexistent oral LP [25].

LS is a scarring dermatosis and the changes that can occur on the vulva include loss of the labia minora, and sealing over of the clitoral hood, burying the clitoris (Fig. 71.28). Introital narrowing resulting from anterior and posterior labial fusion sometimes results in a tiny opening into the vestibule. Milia may occur [26].

Histology. The classic histology is a thinned epidermis with flattening of the rete pegs. The underlying dermis is hyalinized and

Fig. 71.28 Lichen sclerosus. Pallor and atrophy of the vulval skin with loss of the labia minora and burying of the clitoris.

Fig. 71.29 Squamous cell carcinoma arising on a background of lichen sclerosus.

there are often extravasated red cells. Below the hyalinized area is a band-like zone of chronic inflammatory cells. There is an absence of elastic fibres in the upper dermis. There have been attempts to grade the histological appearances but there is probably little correlation between the timing of a lesion and its histological appearance [27].

In some cases the epidermis is thickened, and this is LS with squamous cell hyperplasia. It is found in approximately 30% of cases of LS in association with vulval SCC [28].

There are abnormalities of the basement membrane, but it is uncertain whether these are a primary or secondary event [29]. Immunofluorescence studies are usually negative or demonstrate non-specific fibrin deposition at the dermal–epidermal junction. There is also an alteration of the elastin and fibrillin in the affected dermis [30].

Differential diagnosis. Vitiligo, mucous membrane pemphigoid, LP and morphoea may present with a similar clinical appearance. There can be clinical and histological overlap between morphoea, LP and LS, and they may represent a spectrum of disease rather than three distinct conditions [31].

Lichen sclerosus and vulval malignancy

There is undoubtedly an association between vulval SCC and LS that was probably underestimated in the past (Fig. 71.29) [32]. The incidence of SCC developing on LS in clinical practice is of the order of 4% or less [1]. However, in retrospective reviews of pathological specimens of vulval carcinoma, histological evidence of LS is found in approximately half of the cases [33–35]. These series included patients presenting with SCC as well as those on long-term follow-up for LS. A longitudinal cohort study of 211 patients showed that the number of invasive SCCs significantly exceeded that in an age-matched group [36]. The oncogenic HPV types do not appear to be implicated in the development of SCC on LS [37,38]. It is not known whether good control of LS reduces the risk of neoplastic change.

The histological patterns associated with SCC arising on LS include epithelial hyperplasia and differentiated intraepithelial neoplasia (dysplastic changes that are confined to the basal layers).

LS has been reported in association with verrucous carcinoma [39,40], basal cell carcinoma [41] and melanoma [42–44]. However, malignant melanoma is known to be difficult to diagnose in the presence of LS [45].

Treatment. The current and recommended treatment for uncomplicated LS is the potent topical corticosteroid, clobetasol propionate. There are no randomized controlled trials providing evidence for any particular corticosteroid or treatment regimen being more effective than any other. The regimen currently recommended for a newly diagnosed case is initially clobetasol propionate once nightly for 4 weeks, then alternate nights for 4 weeks, and twice a week for a further month. A 30-g tube of clobetasol propionate should last 12 weeks, and the patient is then reviewed [46]. The clobetasol propionate is then used as and when required to control itching. Most patients seem to require 30–60 g annually. Some patients go into complete remission and do not require further treatment. Others will continue to have flares and remissions and they are advised to use clobetasol propionate as required. A soap substitute is also recommended and an information sheet on LS, including instructions for the use of the topical steroid, is provided.

Topical testosterone currently has no role in the management of LS. It is expensive and is not as effective as clobetasol propionate [47]. Recent reports have suggested the use of the calcineurin inhibitors tacrolimus [48] or pimecrolimus [49] as steroid-sparing alternatives. The use of these topical immunosuppressants should be limited to the treatment of the rare cases of LS that prove unresponsive to a potent topical steroid. The treatment should be a short course and it should not be used long term as the safety of these immunosuppressants is still unknown, particularly as the condition carries a risk of neoplastic change. Ciclosporin [50] and UVA1 [51] have also been used to treat recalcitrant disease.

Surgical excision of affected vulval skin is not necessary in the management of most cases of LS and it should be used exclusively for the management of functional problems caused by post-inflammatory scarring [52,53], premalignant lesions and malignancy.

Crohn's disease

Anogenital lesions occur in approximately 30% of patients with intestinal Crohn's disease, either as a direct extension of active intestinal disease or as metastatic disease. Vulval disease may present many years before intestinal involvement, and in some cases there is vulval oedema only, with no evidence of granulomatous inflammation [1,2]. The more usual presentation is ulceration, abscess, sinus and fistula formation, with a granulomatous histology. There may be deep linear fissures (knife cut sign) along the skin creases.

A separate form of vulval granuloma akin to the orofacial lesions seen in Melkersson–Rosenthal syndrome has been described [3,4].

Treatment. If genital Crohn's disease is the presenting problem it is important to involve a gastroenterologist in management, as these patients need a full work-up to assess if there is intestinal disease as well. In ulcerative disease it is essential to exclude any fistulous tracts. In patients who have no systemic disease topical measures may be sufficient to control the cutaneous lesions, that is an ultrapotent topical steroid or topical tacrolimus [5]. Severe disease may respond to oral steroids but recalcitrant ulcerative anogenital lesions and fistulous tracts may require infliximab [6].

Ulcerative and bullous disorders

Any of the blistering disorders of the skin can occur on the vulva and vagina, either as part of the generalized disease or in isolation. Diagnosis can be more difficult in the latter case.

There are many causes of vulval ulceration and some features are important in narrowing down the differential diagnosis. It is helpful to divide them into acute and chronic types.

Fig. 71.30 Solitary benign aphthous ulcer of the left labium minus.

Acute genital ulceration

Benign aphthae

Many eponymous names have been assigned to acute vulval ulcers and several of these disorders are probably examples of benign aphthae. Reiter's syndrome may be associated with an ulcerative vulvitis [1].

Benign aphthae of the vulva may or may not occur with concomitant oral lesions. The age of onset is in childhood, about the age of 6 years, and there may be a family history. The lesions are usually multiple and small, and less commonly solitary or few and larger—referred to as giant aphthae. Sometimes there are premenstrual exacerbations once the menarche is reached. The aetiology remains unknown but herpetic infection should always be excluded.

The lesions are superficial and painful, with a yellow base surrounded by a red areola. They are distributed most frequently on the labia minora, and heal quickly (Fig. 71.30).

Sutton's ulcer (periadenitis mucosa necrotica recurrens) was originally reported in the mouth [2], but vulval lesions have also been given this label. The ulcer is characterized as being solitary, painful and recurring [2]. This type of ulceration, in the light of today's knowledge, would now be regarded as an example of benign aphthosis or a manifestation of Behçet's syndrome. Lipschutz's ulcer, described 2 years after Sutton's report, encompassed three types of ulcer (ulcus vulvae acutum), two of which today would be assigned to either aphthous ulceration or Behçet's syndrome. Only one is still regarded as being a separate entity [3]. This remaining form of ulceration is sometimes associated with a systemic infection such as infectious mononucleosis [4,5], typhoid or paratyphoid fever. Epstein–Barr virus (EBV) has been isolated from the ulcers [6], and there is one case of a mistaken diagnosis of lymphoma [7]. The Lipschutz-type ulcer usually affects adoles-

cent girls and has a rapid onset. The ulcer may be very deep and large, and has a surrounding red areola and a thick adherent slough. It is most often solitary on one side of the vulva, usually the inner aspect of the labium minus, but lesions may occur bilaterally. Healing is spontaneous, but may take several weeks and leaves some scarring. Relapses may occur over 18 months but this is unusual.

Treatment includes analgesics, potassium permanganate soaks and the application of a topical steroid with or without a topical tetracycline. In very severe ulceration, a short course of oral steroids may be required.

Erythema multiforme

The pattern of recurrent acral erythema multiforme is rarely associated with genital lesions, whereas oral lesions are nearly always present. The vulva and vagina are more frequently affected in Stevens–Johnson syndrome, often with erosions. Vaginal stenosis and adenosis may be post-inflammatory complications.

Bullous fixed drug eruptions

These are less common (or less commonly recognized) on the vulva than on the penis, where the commonly implicated medications include paracetamol, fluconazole and tetracycline. It is now rare to see cases involving phenolphthalein, sulphonamides and barbiturates.

Chronic genital ulceration

Any chronic fixed ulcer of the genital mucosa must be considered malignant until proved otherwise. The differential diagnosis of chronic ulceration includes the diseases listed below, which are discussed fully in the relevant sections of this and other chapters.

1 **Genetic**. Epidermolysis bullosa, Hailey–Hailey disease and Darier's disease may all be responsible for chronic recurring ulceration. Exacerbations may follow friction, infection, irritants and herpes simplex infections.
2 **External trauma—**nymphohymenal tears, dermatitis artefacta and radiation damage. Nymphohymenal tears may occur with sexual intercourse but most heal spontaneously. They tend to occur around the nymphohymenal sulcus, usually in the inferior segment at the 5 and 7 o'clock positions (Fig. 71.31). Those that do not heal can be excised radially.
3 **Malignancy**. The two most common malignant ulcers of the vulva are squamous cell carcinoma and basal cell carcinoma. Melanoma may also present as an amelanotic ulcerating nodule. Langerhans' cell histiocytosis may present with vulval and vaginal ulceration.
4 **Infection**. Chronic infective ulcers occur in tuberculosis, actinomycosis and other deep mycoses. The late stages of lymphogranuloma venereum cause ulceration and scarring.
5 **Inflammatory**. LS, LP and lupus erythematosus can all cause chronic ulceration. Pyoderma gangrenosum may be mistaken for malignancy on the vulva [8]. Hidradenitis suppurativa and Crohn's disease can sometimes be difficult to distinguish, particularly if they occur together. Pilonidal sinuses have been recorded on the vulva and clitoris [9].

Fig. 71.31 Tear of the right inferior aspect of the nymphohymenal sulcus.

Fig. 71.32 Erosions in vulval mucous membrane pemphigoid.

Several of the autoimmune bullous diseases affect the vulva. Juvenile pemphigoid, mucous membrane pemphigoid (Fig. 71.32), pemphigus vulgaris and vegetans may all present with vulval and vaginal ulceration.

Non-sexually transmitted infections

Bacterial infections

Staphylococci

Staphylococcus aureus is usually the causative agent in infective folliculitis, boils and abscesses of the vulva. It is often associated with an underlying problem (e.g. diabetes, immunosuppression). Pseudofolliculitis is a sterile folliculitis that may follow shaving or waxing and is caused by the newly regrowing hairs inducing an inflammatory reaction. It is a foreign body reaction and results in changes from mild inflammation to the formation of abscesses and sinuses. A staphylococcal folliculitis on the buttocks may occur secondary to the pruritus induced by intestinal infestation with pin worm.

Menstrual toxic shock syndrome is caused by *Staph. aureus* superantigenic toxins and is associated with fever, hypotension and macular erythema.

Histology. The impetiginous lesion shows subcorneal pustules filled with neutrophils and some spongiosis, with a moderate inflammatory response in the papillary dermis.

The acute folliculitis may be superficial, with a subcorneal pustule present at the follicular opening, or deep and associated with a perifollicular abscess, and destruction of the follicle wall and sebaceous gland. Chronic deep intrafollicular abscesses may have the additional features of fibrosis and foreign body giant cells.

Streptococcal infections

β-haemolytic Lancefield group A bacteria may be the cause of vulval cellulitis. The erythema and oedema may be extreme, and vesicles and bullae develop. There are usually associated systemic signs. The infection arises at sites of trauma where there is a wound and it is commonly seen following a vulvectomy with lymphadenectomy. If there is residual lymphoedema then further attacks of cellulitis are more common. Streptococcal dermatitis usually affects the anogenital area of children [1].

Synergistic bacterial gangrene

This severe and rapidly extending disease is caused by the synergistic effect of a microaerophilic streptococcus and *Staphylococcus aureus* (see Chapter 30).

Hidradenitis suppurativa

This chronic and debilitating condition is dealt with fully in Chapter 30, but mention is made here as staphylococcal and streptococcal infection have a secondary role. The primary problem is an abnormality of the follicular epithelium of the apocrine gland ducts, which starts with a spongiform infundibular folliculitis [2]. *Streptococcus milleri* is often found as a secondary pathogen [3].

Histology. This is characterized by distension and inflammation of apocrine ducts, with polymorphs in and around the ducts. The apocrine glands may become necrotic, with an infiltrate of lymphocytes, plasma cells and macrophages. Sinuses are lined by keratinized epithelium. Fibrosis and a foreign body reaction with granulomatous changes are common. Pseudoepitheliomatous hyperplasia may be seen, and at least nine cases of SCC have been reported—two of these were in females with buttock lesions [4].

Treatment is with long-term antibiotics, and in some cases oral isotretinoin may be helpful. The important differential diagnosis is Crohn's disease, but hidradenitis suppurativa and Crohn's disease may coexist [5,6].

Gram-negative bacilli

Pseudomonas aeruginosa is a common problem in patients with bladder problems but it is not a cause of vulvovaginitis. There has been a report of blue staining of napkins in infants with this infection [7].

Despite its name, *Trichomycosis* is caused by species of corynebacteria, which lead to red, yellow or black nodules on the shafts of the axillary and pubic hairs (see Chapter 30). Histological examination shows that these nodules consist of concretions of bacteria. The hair shafts may be damaged [8].

Diphtheria, caused by *Corynebacterium diphtheriae*, is rare in developed countries. Vulval infection takes the form of ulcers, often with a greyish membrane. It has been described in children [9,10] and in adults [11,12].

Mycobacterial infections

Vulval tuberculosis, caused by *Mycobacterium tuberculosis*, is uncommon in the UK. It may occur by means of haematogenous spread from foci outside the genital tract, by distal spread from the upper genital tract, or as a primary exogenous infection contracted from sputum or sexual intercourse. Vulval tuberculosis has been reported in a renal transplant patient [13], and three cases were described in a series of 26 patients with genital tuberculosis [14]. Genitourinary tuberculous infection is more common in HIV-positive subjects. In a primary infection the initial lesion may be inconspicuous, the main feature being a caseating lymphadenopathy. In other cases the lesions are masses or nodules that may ulcerate and lead to lymphoedema [15]. Bartholin's gland may be involved [16].

Leprosy (see Chapter 32)

The female genital tract may be involved in infection by *Mycobacterium leprae* [17], but vulval lesions are rare [18]. Pubic hair may be lost [19].

Higher bacterial infection

Higher bacteria is the name assigned to those bacteria that, like filamentous fungi, are capable of forming true branches. They include the genera *Streptomyces*, *Actinomyces* and *Nocardia.*

Actinomycosis

The Gram-positive acid-fast organisms responsible for actinomycosis are predominantly *Actinomyces israelii* and *Actinomyces gerencseriae*. They may colonize intrauterine devices and are usually asymptomatic, but invasion of the genital tract can occur [20,21]. Genital infection usually arises from bowel disease [22]. Lesions of the vulva alone have been reported [23].

Mycoplasmas

Mycoplasma hominis and *Ureaplasma urealyticum* are found in the vagina and rarely cause disease. There are rare reports of *M. hominis* being isolated from cases of Bartholin's abscess [24,25].

Abscesses of Bartholin's gland may be caused by pyococcal organisms, gonococcus and *Chlamydia trachomatis* [26]. In one study, only 21 of 109 cases were caused by staphylococci, whereas 50 were caused by *Escherichia coli* and 46 by *Streptococcus faecalis* [27]. The abscess results from distal blockage of the duct. The patient presents with fever, malaise and a tender swelling arising posterior to the origin of the labium minus. Episodes of bartholinitis may be mild and recurrent until fibrosis supervenes.

Fungal infections

Candidal vulvovaginitis

Candida and *Torulopsis* are both yeasts that can infect the vulva and vagina. *Torulopsis* accounts for very few infections, whereas *Candida albicans* is the most frequently isolated.

Candida albicans is dimorphic, with both yeast and mycelial forms. It is a non-pathogenic commensal in the intestinal tract in 30% of the normal population. Infection in women is usually a vulvovaginitis. Changes in host factors are probably responsible for transition to pathogenicity, and are generally not directly associated with sexual contact. Factors related to cell-mediated immunity are doubtless important, but as yet are ill-understood. Pregnancy, diabetes, possibly oral antibiotics, high-dose oestrogen oral contraceptive pills and immunosuppression may all be predisposing factors. The primary infection arises in the vagina, causing inflammation and a heavy white curdy discharge, which then leads to a secondary vulvitis with well-demarcated sheets of erythema on the outer aspects of the vulva, sometimes extending on occasions into the genitocrural folds and perianally. There may be a scaly or vesiculopustular edge. Beyond this edge lie grouped or isolated superficial small pustules, which rupture rapidly, leaving a slightly scaly periphery. In all cases of candidal vulvovaginitis, but particularly in the middle-aged patient, late-onset diabetes should be considered, and appropriate tests carried out.

Diagnosis is confirmed by direct microscopy and culture.

Treatment of vulvovaginal candidiasis requires vaginal pessaries or creams and/or oral imidazoles.

In some cases of vulval eczema and psoriasis, *Candida* is cultured from skin swabs, but the candidal overgrowth is a secondary problem arising on a background of an inflamed epithelium. Treating the dermatosis alone with a topical steroid will usually resolve the problem, without the addition of anticandidal agents.

Dermatophyte fungi

Dermatophyte infections of the vulval skin are uncommon in cooler climates. The sites affected are usually the inguinal folds and perianal area. The causative agents are *Trichophyton rubrum* or *Epidermophyton floccosum*. The vulval epithelium in the adult seems to be relatively immune to dermatophyte infections. The lesions are erythematous and scaly, with a spreading raised

circinate edge. Folliculitis is also seen, particularly in the perianal area. Tinea incognito may also occur perianally following the injudicious use of a topical steroid in the presence of an unrecognized dermatophyte infection. The diagnosis is usually made by direct microscopy and culture of skin scrapings, and treatment is usually oral terbinafine or griseofulvin because the skin is hair-bearing.

Miscellaneous fungal infections

Pityriasis versicolor classically occurs on the trunk, but in severe widespread infection there may be vulval involvement [1,2].

The black and white forms of piedra (trichosporosis) are caused by *Piedraia hortai* and *Trichosporon beigelii*, respectively, the latter acting synergistically with a corynebacterium. The hair-bearing parts of the vulva can be affected with black and white nodules along the hair shafts [3]. The diagnosis is made by microscopy and culture.

Vulval phycomycosis has been described [4]. Subcutaneous infections occur in children and young adults. Histologically, the epidermis is unremarkable but subcutaneously there are deep granulomatous masses containing hyphae.

There is one case report of chromomycosis (chromoblastomycosis) affecting the vulva [5].

Cryptococcus neoformans can induce painless ulceration of the vulva in the immunosuppressed patient [6].

Infections with protozoa

Infection with *Trichomonas vaginalis* causes a frothy, malodorous, greyish-green, watery discharge, and a bright red vaginal mucosa studded with petechiae. The vaginal discharge may cause a secondary vulvitis, with erythema and swelling of the vestibule and labia minora. Colonization of the urethra and paraurethral glands often occurs. The diagnosis is made by microscopic examination of wet preparations and culture.

Treatment is with metronidazole 400 mg twice daily for 5 days or 2 g in a single dose.

The flagellate protozoan *Leishmania tropica* causes cutaneous, mucocutaneous and visceral forms of leishmaniasis. The vulva is mainly affected by the cutaneous form, which is endemic in areas of the eastern Mediterranean, Asia Minor and India; and to a lesser extent by the mucocutaneous form, found in Central and South America. An example of sexual transmission from post-kala-azar dermal leishmaniasis has been reported [1]. Transmission of infection is usually by sandflies. The lesions are nodular or ulcerative.

Entamoeba histolytica is found worldwide and intestinal amoebiasis may be transmitted from the bowel to other areas, including the genital tract, although such involvement is rare [2]. It appears as warty or ulcerative masses of the vulva, perineum and cervix. Live amoebae may be recovered from scrapings, or the organism seen as a small eosinophilic body in an inflammatory histological reaction.

Vulval schistosomiasis is usually caused by *Schistosoma haematobium*. The lesions are chronic, scarring and granulomatous, and may ulcerate and calcify [3–5]. Histologically, there is inflammation surrounding the organisms and their remains, with granuloma formation and many eosinophils. Ova may be found in the vagina, urine and faeces.

Viruses

Three groups of viruses are important causes of infection in the genital area: the poxviruses, papillomaviruses and herpesviruses. Other viruses seldom give rise to distinctive clinical pictures, although vulval lesions may occur as part of a generalized viral infection.

Genital HPV infection and herpes simplex are discussed later in the section on sexually transmitted infections (see p. 71.70).

The most common poxvirus is mollusum contagiosum virus, two types of which have been identified. There is no relationship between virus type and anatomical distribution of lesions [1]. Vulval lesions in childhood are common and usually acquired innocently, but they are more likely to be acquired sexually in adults. Lesions are often found on the mons pubis and labia majora, and if inflamed they may mimic folliculitis. The clinical diagnosis is straightforward when there are multiple pearly lesions with an umbilicated centre, but solitary large lesions can cause diagnostic problems. It is the solitary giant lesion that may miss immediate diagnosis until it is biopsied. Lesions of molluscum contagiosum can be profuse and large in immunosuppressed women, especially in those with AIDS. The condition is more fully described in Chapter 35.

Other poxvirus infections of the vulva are rare, but there are isolated reports of orf [2] and cowpox [3].

Herpes simplex (see below)

- **Varicella-zoster virus.** This may also affect the vulva if the third sacral dermatome is involved. It may be accompanied by bowel and bladder dysfunction [4].
- **Epstein–Barr virus.** This has been found rarely in genital ulcers at the time of infectious mononucleosis [5–7]. EBV may also be shed from the cervix [8] but there is no link with vulval malignancy [9].

- **Cytomegalovirus (CMV).** CMV inclusions were seen in a biopsy, and a positive culture for CMV was obtained in an infant with congenital HIV disease who presented with pustular and ulcerative lesions on the perineum [10].

Malakoplakia of the vulva [1–4]

Malakoplakia (meaning 'soft plaque') is a granulomatous response to infection. It is not usually caused by one specific agent but the organisms involved include *Escherichia coli*, *Pseudomonas* and *Staphylococcus aureus*. Malakoplakia most often affects the urinary or gastrointestinal tract but cutaneous lesions may occur on the vagina, vulva and perineum. Involvement of Bartholin's gland has been described [5]. The lesions include persistent plaques, ulcers, nodules and sinuses. There is often underlying immunosuppression, the aetiology of which may include malignancy, dermatomyositis [6], lupus erythematosus, rheumatoid arthritis and organ transplantation [7].

Histopathology. There are confluent sheets of histiocytes with eosinophilic granular cytoplasm and small eccentric nuclei. Round, sometimes laminated structures are found with these cells and are known as Michaelis–Gutmann bodies. The histiocytic infiltrate may be mixed with neutrophils, lymphocytes and plasma cells, with associated granulation tissue. Electron microscopy of malakoplakia shows that the histiocytes contain numerous phagolysosomes within which there may be occasional intact and partly digested bacteria.

Dermatological aspects of sexually transmitted disease

A brief outline of the main sexually transmitted diseases that can affect the vulval skin is given below. Fuller descriptions of the individual diseases are given elsewhere (see Chapters 30 and 33–35).

Herpes simplex virus

Once this sexually transmitted DNA virus is acquired it lies dormant in dorsal root ganglia and can give rise to recurrent symptomatic lesions. It exists in two types: I and II. Type I usually affects non-genital sites and type II is responsible for 50–80% of genital infections. Ninety-five per cent of infections are acquired sexually and the rest are cases of autoinoculation or non-sexual contact. The lesions are typically painful vesicles or ulcers, which are often multiple in primary infection but are fewer and usually localized to one side with recurrences. There may be prodromal symptoms of tingling or tender enlarged inguinal nodes. Paraesthesiae may occur, affecting S2–4, which may lead to urinary retention. Pain and oedema may also lead to retention, particularly in primary infections. It is important to obtain a definite diagnosis with a positive culture of HSV, and it is necessary to perform the test as soon as the blisters arise, as the virus is harder to culture from older lesions. However, a negative test does not exclude an infection with HSV.

The treatment is either oral aciclovir 200 mg five times daily for 5 days, valaciclovir 500 mg twice daily for 5 days or famciclovir 250 mg three times daily for 5 days.

Suppressant therapy is sometimes required for patients with frequent recurrences (six or more in a year).

Human papillomavirus infection

HPV is a small DNA virus, and is discussed in more detail in Chapter 33. Those that most commonly infect the vulval skin are HPV 6, 11, 16 and 18. The warty lesions are known as condylomata acuminata. Extensive vegetating masses can cover the vulva and perianal area, particularly in diabetes, pregnancy and immunocompromised patients. Patients with genital warts should be screened for other sexually transmitted diseases. Secondary syphilis may also present with extensive papulosquamous lesions and has to be considered in the differential diagnosis.

Types 16 and 18 are linked with cervical and anogenital intraepithelial neoplasia and SCC.

The histology of genital warts is characterized by the koilocyte, a vacuolated squamous cell with a basophilic and pyknotic nucleus in the upper part of the epidermis; it is important not to confuse it with the heavily glycogenated clear cells of vestibular epithelium. Other histological features are elongated dermal papillae, acanthosis, a prominent granular layer often containing koilocytes, and a stratum corneum of variable thickness.

Treatment. Podophyllotoxin is the recommended initial treatment. It is applied twice daily for 3 consecutive days each week

for 4 weeks. This treatment is contraindicated in pregnancy because of the theoretical risk of teratogenicity. Diathermy, hyfrecation, topical trichloroacetic acid, cryotherapy and carbon dioxide laser have been used with variable success. These treatments are successful in patients where the lesions are few or filiform in morphology.

The new immune response modulating cream, imiquimod, is now used for resistant cases or patients with extensive lesions. This has to be used with care as it also induces an inflammatory response in patients who have a background dermatitis. It should not be used in patients who have benign vulval aphthous ulcers.

In pregnancy, only cryotherapy or destructive techniques with cautery or hyfrecation can be used safely.

Prevention. Prophylactic vaccination prior to exposure is now available for HPV types 6, 11, 16 and 18 [1]. A programme for the routine vaccination of girls aged 12–13 years against HPV 16 and 18 has been started in the UK.

Gonorrhoea

The urethra, cervix and rectum may be infected by *Neisseria gonorrhoea* and spread occurs to the endometrium and fallopian tubes. Vulval involvement is rare in adults, and infection is sited in the paraurethral and Bartholin's glands, resulting in painful abscess formation. In children, the infection is usually a result of sexual abuse, and an acute vulvitis may develop [2].

Syphilis

The causative organism is *Treponema pallidum* and vulval lesions may occur in both early and late syphilis. The primary chancre is an ulcerative lesion and is usually accompanied by unilateral or bilateral lymphadenopathy. In secondary syphilis, condylomata lata, flat-topped warty papules, affect the vulva, as may also mucous patches, which are greyish white moist-looking lesions. Gummas, which are a manifestation of tertiary syphilis, are extremely rare on the vulva, and clinically they occur as either single or multiple swellings or nodules.

Bullous, papular, papulosquamous lesions and mucous patches occur on the vulva in early congenital syphilis and condylomata lata may develop later.

The diagnosis of syphilis is made by dark ground microscopy, immunofluorescence of scrapings or serology.

Histologically, the findings are very variable but, typically, early lesions show inflammation with perivascular plasma cells and lymphocytes together with an endarteritis. There is marked epithelial hyperplasia in lesions of condylomata lata, with a prominent perivascular lymphocytic and plasma cell infiltrate.

Chancroid [3]

This sexually transmitted disease, caused by *Haemophilus ducreyi*, is rare in the UK [2] as it is normally found in tropical and semitropical countries, although the incidence is falling in Africa [3]. Single or multiple small tender ulcers appear on the labia majora, perineum and perianal area, and may also affect the vagina and cervix. The inguinal lymph glands are involved in half of cases and the adenitis is unilateral in most. Buboes develop, which are fluctuant, and rupture leaving extensive ulceration. Co-infections with *Treponema pallidum* or HSV are frequent.

Diagnosis may be confirmed by culture of scrapings from the ulcer base or aspirated pus. Microscopy of scrapings or pus will show Gram-negative coccobacilli. PCR may also be used. The histological features include epithelial hyperplasia adjacent to the ulceration, with three relatively distinct zones at the base of the ulcer. The superficial zone consists of a thin band of neutrophils, fibrin and necrotic debris; the middle zone of oedema with thin-walled, dilated and vertically orientated blood vessels; and the deep zone of a dense perivascular infiltrate of lymphocytes and plasma cells. A Giemsa or Brown–Brenn stain may reveal organisms in the superficial zone staining blue or red, respectively.

Treatment. Azithromycin, ceftriaxone, ciprofloxacin or erythromycin can be used. The recent guidelines issued by the US Centers for Disease Control and Prevention (CDC) should be consulted (http://www.cdc.gov/std). Special considerations should be given to patients with HIV infection.

Donovanosis [4]

Synonyms
- Granuloma venereum
- Granuloma inguinale

The causative organism is *Calymmatobacterium granulomatis*, formerly known as *Donovania granulomatis*. The disease is sexually transmitted and found in New Guinea, India, South Africa and Brazil. Papules or nodules break down to form ulcers with a rolled edge. Large areas are involved, and granulomatous masses may involve any part of the genitocrural area, although the lymph nodes themselves are not affected. The vagina and cervix may be involved. Scarring and lymphoedema may ensue.

Histopathology shows epithelial hyperplasia adjacent to the ulcer, sometimes with spongiosis and intraepithelial neutrophilic abscesses, and a dense dermal or submucosal infiltrate with neutrophilic abscesses surrounded by plasma cells, histiocytes and lymphocytes. The organisms occasionally are visible with silver stains, which show intracytoplasmic inclusions (Donovan bodies), seen as black oval or rod-shaped structures in the cytoplasm of histiocytes. The organisms are more reliably demonstrated on smear preparations than tissue sections.

Chlamydia (lymphogranuloma venereum)

Chlamydia trachomatis is a Gram-negative intracellular bacterium that is an obligatory parasite. The serovars L1–3 cause lymphogranuloma venereum, which occurs in tropical and subtropical countries. The incubation period varies from a few days to a few weeks. A small papule develops on the vulva, usually at the fourchette, heals quickly and is followed weeks later by striking lymphadenopathy. The nodes may form a suppurative mass that heals with scarring, leading to lymphoedema, which may be gross. Generalized chronic infection leads to abscess and fistula formation, and finally genital and anal strictures and elephantiasis [5].

Rectal lesions present as a proctocolitis with subsequent stricture formation.

The histology of the vulval ulcers is non-specific, but the affected nodes show epithelioid cells and giant cells, and later stellate abscesses develop that are surrounded by epithelioid cells, granulomatous tissue and plasma cells. Fibrosis and necrosis are seen in chronic lesions.

Benign tumours [1,2]

Most of the tumours that arise on the anogenital skin are similar to those that occur on the skin elsewhere. Fibromas arise from deeper connective tissue structures, particularly those surrounding the introitus and perineal body. They usually occur on the labia majora, are often pedunculated or pendulous, and can attain a very large size. Fibroepitheliomatous polyps (skin tags) are usually solitary and appear as soft wrinkled polypoidal nodules. There is a fibrovascular connective tissue core covered by squamous epithelium, which may be atrophic or, more commonly, mildly acanthotic and hyperkeratotic. Cellular atypia is occasionally seen in the stromal cells. Lipomas develop from the fatty tissue of the labia majora, but there have been reports of localization to the clitoris [3], as has also been reported with haemangiomas [3,4].

Two types of lymphangioma may occur on the vulva: lymphangioma circumscriptum, which are localized thin-walled vesicles [5], and cavernous lymphangioma, which arise in childhood and present as a soft compressible mass, which, although usually located in the labia minora, can involve the whole of the vulva [6]. Acquired lymphangiectasia is discussed on p. 71.81.

Melanocytic naevi include junctional, intradermal and compound types, which generally share the same clinical and histological features as naevi at other sites of the body, with the exception that in premenopausal women vulval naevi sometimes have atypical histological features [7]. The atypia may extend into the adnexal structures, but the overall symmetry of the lesion, with cellular maturation in the deeper dermis, should help to distinguish it from a truly malignant lesion. Sometimes, differentiation from melanoma can be difficult and evaluation by an experienced dermatopathologist may be necessary.

Epidermal cysts of the vulva may develop from epithelial implants following surgical trauma, from epidermal inclusions occurring at fusion sites during embryogenesis, or from obstructed sebaceous gland ducts that have undergone squamous metaplasia. They may be single or multiple, and occur most commonly in the labia majora. Steatocystoma may present as a solitary cyst in the vulval region [8]. Calcified nodules have been recorded [9].

Syringomas

These are considered to be adenomas of the intraepidermal eccrine sweat gland ducts. They do not require treatment as they are usually asymptomatic, although there may be pruritus [10]. Vulval syringomas are multiple, bilateral and symmetrical, although a solitary lesion may occur. One case was reported that had the typical histological features of a syringoma mixed with pilosebaceous elements [11].

Papillary hidradenoma

This sweat gland adenoma with apocrine differentiation occurs almost exclusively in the anogenital region of middle-aged white women. It has been associated with anogenital glands [12]. It is a firm asymptomatic papule or nodule, which can occasionally be painful, and occurs most commonly on the labia majora, interlabial sulcus, lateral surfaces of the labia minora or perineal region [13]. Although usually single, there are occasionally multiple lesions. Curiously, when they are multiple all the lesions tend to develop on one side of the vulva. In most patients, the covering epidermis remains intact, but in a proportion the elevated epithelium may become ulcerated [14].

Malignant change within a papillary hidradenoma has been reported, producing apocrine carcinoma [15] and adenosquamous carcinoma [16].

Fox–Fordyce disease

In this condition, described in detail in Chapter 44, the apocrine ducts become blocked, with retention of sweat. Itchy skin-coloured papules appear on the mons pubis, labia majora, axillae and on the breast. They develop around the time of puberty and there are menstrual exacerbations. There is some improvement in pregnancy and after the menopause.

Mucinous cysts

Mucinous cysts of the vulva are not uncommon. They are usually found in the vestibule where they develop secondary to obstruction of the duct of one of the many minor vestibular mucus-secreting glands. The cysts are of urogenital sinus origin and not, as was once thought, of Müllerian origin [1,2].

Bartholin's duct tumours

These are very rare and there is debate as to whether they are true neoplasms or better regarded as examples of hyperplasia or hamartoma [1,2].

Neurofibroma and neurofibromatosis

Vulval neurofibromas may occur either as solitary lesions with no other features of neurofibromatosis, or as part of generalized neurofibromatosis. In one series, 18% had vulval lesions [1]. Vulval neurofibromas have also been described as one component of a localized neurofibromatosis of the female genitourinary tract [2,3]. Some cases have led to confusion by mimicking an intersex problem [4–7].

7 Ravikumar VR, Lakshmanan DA. Solitary neurofibroma of the clitoris masquerading as an intersex. *J Pediatr Surg* 1983; **18**: 617.

Glomus tumour

There are rare reports of this tumour on the labia minora giving rise to dyspareunia [1,2].

References

2 Katz VL, Askin FB, Bosch BD. Glomus tumor of the vulva: a case report. *Obstet Gynecol* 1986; **67**: 43–45S.

Leiomyoma

Vulval leiomyomas are uncommon [1,2], and there is no association with uterine leiomyomas. It is unclear whether these tumours originate from the smooth muscle of the vulval erectile tissue, from the muscular elements of the round ligament, or from the myoepithelial cells of Bartholin's gland.

Vulval leiomyomas occur during the reproductive years and usually present as well-circumscribed, painless, non-tender nodules or swellings in the labia. Lesions may enlarge in pregnancy. A clitoral leiomyoma can cause a mistaken diagnosis of an intersex disorder. A clitoral leiomyoma associated with a leiomyoma of the oesophagus has been reported [3].

Other benign tumours

Rarer tumours include granular cell myoblastoma [1,2], which presents as flesh-coloured, occasionally pedunculated or ulcerated lesions. Verruciform xanthomas have a predilection for the oral mucosa and the genital skin. They are rare on the vulva [3,4]. Clinically, they present as solitary plaques or warty lesions and vary in colour from yellow to grey or pink. There is acanthosis, papillomatosis and parakeratosis, and the presence of foamy macrophages in the papillary dermis and tips of the elongated rete ridges distinguishes this entity from a viral wart. Nodular fasciitis presents as a painless mass and has rarely been reported on the vulva [5].

Urethral caruncle and urethral prolapse, which are common, can sometimes be mistaken for neoplasms. A urethral caruncle occurs in postmenopausal women as a red fleshy lesion around the urethral meatus and is a chronically inflamed eversion of the urethral mucosa. It may measure from a few millimetres to a few centimetres in diameter and is usually asymptomatic; it may cause dysuria or bleeding if ulcerated. Histologically, it is essentially the same as a pyogenic granuloma, showing a highly vascular connective tissue with a heavy inflammatory infiltrate of lymphocytes and plasma cells. Enmeshed in this inflamed stroma are varying quantities of glandular structures or solid islands of urethral epithelium.

Prolapse of the urethra may occur at any age. Histologically, there is marked oedema of the underlying connective tissue, and the overlying urethral mucosa may be focally ulcerated. The underlying stroma shows marked vascular distension and engorgement, often with thrombosis. The epithelial inclusions typically seen in a urethral caruncle are not present.

Precancerous dermatoses

Vulval intraepithelial neoplasia (VIN)

This term was introduced by the International Society for the Study of Vulvovaginal Diseases (ISSVD) in 1986 to replace the previous terms—dystrophy with atypia, Bowen's disease, bowenoid papulosis, erythroplasia of Queyrat and squamous carcinoma *in situ* [1,2]. It is defined as loss of the normal orientation and architecture of the epithelium with cellular atypia. It was also graded into VIN 1–3, according to the percentage of the epithelium involved. The term 'VIN differentiated', was used for cases where there was severe atypia that was confined to the basal area but was often coincident with an SCC. The 1986 classification also included EMPD and melanoma *in situ*.

The three-tier grading of VIN is misleading as there is interobserver variation in the grading [3] and in clinical practice many cases of VIN 1 with basal atypia are not truly premalignant but reparative (e.g. LP), or proliferative as in a benign condyloma.

The VIN types that do carry a malignant potential are either those that have atypia involving two-thirds to full thickness of the epithelium (undifferentiated VIN [VIN 2 and VIN 3]), or severe atypia confined to the basal layers with fairly normal differentiation of the upper layers (differentiated VIN). In addition to the basal changes, the rete ridges may be long and forked with keratin pearls. This change on a background of LS/LP represents either very early invasive disease or heralds its imminent onset.

Therefore, in 2004, the ISSVD proposed replacing the three-tier grading system with two types of VIN, undifferentiated and differentiated. This classification eliminates the term VIN 1 and replaces the terms VIN 2 and 3 with 'undifferentiated VIN'. 'Differentiated VIN' remains as the term reserved for the severe atypia confined to the basal layers, most often seen on a background of a chronic scarring dermatosis. It was also proposed that vulval EMPD and melanoma *in situ* should not be included in the VIN classification [4,5].

Undifferentiated vulval intraepithelial neoplasia

Synonyms
- Bowen's disease
- Bowenoid papulosis
- Carcinoma *in situ*
- Carcinoma simplex

There is two-thirds to full thickness loss of cellular stratification throughout the epidermis, with large hyperchromatic cells, dyskeratosis, multinucleated cells and numerous typical and atypical mitoses. Originally, two distinct histological types of VIN were described: bowenoid, characterized by individual cell keratinization and abnormal cellular differentiation, and basaloid, with atypical parabasal cells extending throughout the full thickness of the epithelium. However, both types can sometimes be found in the same histological section so it is no longer considered helpful to distinguish the two.

Fig. 71.33 Vulval intraepithelial neoplasia. Erythematous patches with one warty plaque inferiorly on the inner aspect of the right labium minus.

Multifocal anogenital disease is strongly associated with the oncogenic papillomaviruses, particularly HPV 16 and 18 [6,7] and almost exclusively occurs in smokers. The condition is caused by a failure of the host to mount an immune response to the HPV. Patients who are immunocompromised have a higher incidence of this problem, but the majority of young women with this problem do not have an identifiable immunodeficiency. In addition to being multifocal, VIN may be associated with multicentric disease, with lesions of intraepithelial neoplasia involving the cervix, vagina and perianal skin. Up to two-thirds of patients with VIN have a current or past history of CIN [8].

Clinically, the lesions of intraepithelial neoplasia can be solitary or multiple. The morphology of the lesions is also very diverse, with lesions that resemble viral warts, plaques that may be shiny and smooth, skin-coloured, red or white, or others that are warty and pigmented and resemble seborrhoeic keratoses. Less commonly, the lesions may be large and papillomatous, particularly perianally, where they may be polypoid. The main symptom is pruritus, which can be severe and troublesome (Figs 71.33–71.35).

Vaginal involvement is uncommon. Initially, it was felt that BP could be distinguished histologically from Bowen's disease but time has proved this not to be the case.

The risk of progression to invasive disease is estimated as 10% or less in multifocal disease [9], but this risk is likely to be higher in immunocompromised patients, perianal disease and in the older woman with a solitary plaque [10].

Fig. 71.34 Vulval intraepithelial neoplasia. Solitary warty plaque.

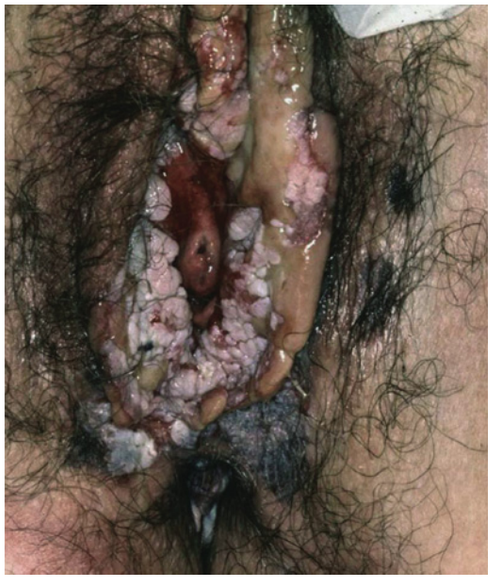

Fig. 71.35 Vulval intraepithelial neoplasia. Pigmented seborrhoeic keratosis-like lesions.

Differentiated VIN

This form of VIN is reportedly rare, but perhaps it is underdiagnosed due to the subtle histological changes that occur. The atypia is confined to the basal layers, and this type of VIN is seen most commonly on a background of lichen sclerosus where there is already a microinvasive carcinoma, or just prior to the development of invasive disease. There may or may not be epithelial hyperplasia as well. To date there has been no strong association of this type of VIN with the known oncogenic HPV viruses.

Pagetoid VIN (pagetoid Bowen's disease, pagetoid squamous cell carcinoma in situ)

A rare histological variant of VIN which resembles extramammary Paget's disease is known as pagetoid VIN or pagetoid Bowen's disease. Pagetoid Bowen's disease has been reported extragenitally and genitally in males. There is one report of vulval involvement [11]. Unexpectedly, the abnormal cells in pagetoid VIN are CK7-positive, like true Paget's cells of EMPD, but mucin stains and cam5.2 are negative [11].

Treatment. This is tailored to the individual patient's needs. In the case of a solitary lesion of differentiated or undifferentiated VIN that is amenable to simple excision, this is the treatment of choice. In the woman with extensive undifferentiated disease, surgery would be mutilating physically and distressing psychologically, and does not guarantee a cure as the risk of recurrence is significant [12]. Such patients require regular and long-term follow-up, with biopsies of suspicious areas. Thick or polypoid lesions should be excised, as early invasive changes are difficult to detect in these areas [13]. Cryotherapy is not effective, but 5-fluorouracil can be used successfully for lesions of the labia minora, vestibule and clitoral area. It is not effective on the hair-bearing parts of the vulva, probably because of the deep adnexal structures, which can all be involved. Laser vaporization has a high recurrence rate, particularly if the hair-bearing parts of the vulva are involved, and there is the additional danger that early invasive disease may be missed and therefore inappropriately treated. It is also extremely painful postoperatively.

Imiquimod has proved very effective in the treatment of multifocal undifferentiated VIN in younger patients and recurrent disease after surgical excision [14]. However, it is currently unlicensed for the treatment of VIN.

As VIN is a multicentric problem, the other sites that need to be monitored are the cervix, vagina and perianal area. If there is perianal disease, anoscopy should be performed to exclude involvement of the anal canal.

The development of HPV vaccines, which became licensed in Europe for preventative management in 2006, will hopefully have an impact on HPV-related VIN [15].

Squamous cell carcinoma

The most common vulval malignancy by far is squamous carcinoma, followed by basal cell carcinoma, adenocarcinoma, melanoma and verrucous carcinoma [1].

Aetiologically, there appear to be two types of vulval squamous cell carcinoma [2–5]. The first and largest group occurs in elderly women on a background of a chronic dermatosis such as LS or LP. The second type, which accounts for approximately 40% of cases, occurs in younger women and is associated with intraepithelial neoplasia associated with oncogenic-type HPV infection. A link with HPV has not yet been established with the first group [6].

In the 1990s, the staging of vulval cancer was replaced by a combined clinical and surgical staging [7]. One of the reasons for this change was to remove the term 'microinvasive carcinoma of the vulva', as at that time its definition was misleading. In this new classification, stage I tumours are less than 2 cm diameter and are further subdivided into Ia and Ib. Ia are lesions with less than 1 mm depth of invasion. There are some difficulties as to how this measurement should be made. The most recent recommendation is to measure from the dermal–epidermal junction of the nearest dermal papilla to the deepest point of invasion [8]. Lymph node dissection is mandatory for all lesions greater than 1 mm but can be avoided in those with stage Ia. There are three histological types of SCC: keratinizing, basaloid and warty carcinomas.

Keratinizing tumours are those seen in the older women, which are not HPV-related, and the basaloid and warty tumours are those found in younger women with HPV-related VIN.

There is also an adenoid variant of SCC with acantholysis in the centres of some of the infiltrating nests, producing cystic spaces lined by cubocolumnar nests. These pseudocysts do not contain mucin, which differentiates them from adenosquamous cell carcinoma.

There have also been reports of vulval cancer in patients with Fanconi's anaemia [9,10].

Treatment. Surgical excision is tailored to the individual, and is determined by the size and site of the tumour.

The overall 5-year survival is approximately 75%, which rises to 90% or greater in those with no nodal metastases. The main reason for failure of treatment is the inability to control lymphatic and distant metastases, lymphatic spread being the most important factor. The vulval lymphatics drain to the inguinal and femoral nodes and from there to the pelvic nodes. Central lesions (those placed near the clitoris, urethra, vagina, fourchette and perianal area) have a bilateral lymphatic drainage, and it is important in these cases that the inguinofemoral nodes on both sides are excised. Radiotherapy is used as an adjuvant in patients with positive nodes and in those with inoperable tumours. It is also sometimes used as a primary treatment in tumours of the anus and urethra, to reduce their size before surgery and to try to preserve sphincter function.

Other malignant neoplasms

Verrucous carcinoma

Synonym
- Giant condyloma of Buschke–Löwenstein

This tumour occurs in older women, and many arise on a background of LS [1]. Clinically, the lesions appear as a warty plaque or cauliflower-like tumour, which can ulcerate and become extremely large (Fig. 71.36). There is not a strong association with HPV [2].

The histological changes include epidermal acanthosis, with large bulbous rete ridges which compress and push down the underlying stroma. There is very little cellular atypia and the few, if any, mitoses are confined to the basal layers. The upper keratinocytes are often paler and there is a loss of the granular layer. Lymph node and distant metastases occur rarely.

Treatment is wide local excision. Radiotherapy is not used as it is associated with a worse prognosis, probably because it can induce anaplastic transformation [3]. Oral retinoids may also be helpful [4].

Basal cell carcinoma

Vulval basal cell carcinomas are not uncommon, and present as an eroded plaque, which may be pigmented. Less commonly, the tumour may form a nodule or ulcer. They occur most frequently on the labia majora (Fig. 71.37) [1].

Histologically, the appearances are identical to BCCs seen elsewhere. Inadequate excision accounts for a high recurrence rate and metastases to regional lymph nodes [2]. Mohs surgery is often recommended to ensure adequate local excision [3,4]. Patients with vulval basal cell carcinomas frequently develop basal cell carcinomas at other sites [5].

Adenocarcinoma

Primary adenocarcinoma unrelated to underlying glandular adnexae is exceedingly rare. The lesion usually presents as a painless subcutaneous nodule which, as it expands, becomes fixed and painful. The tumour can invade deeply into fat, muscle or bone and may be associated with a Bartholin's gland abscess. Adenocarcinoma may be associated with EMPD.

Many of the mucinous carcinomas that arise are possibly of cloacal origin [1].

There is one report of a mucinous carcinoma with neuroendocrine differentiation [2].

Melanoma

Vulval melanomas account for approximately 5% of vulval malignancy. Any of the variants of melanoma may occur on the vulva, and the clinical and histological features are the same as for melanomas elsewhere (Fig. 71.38). However, in one cohort of 219 patients, 27% of lesions were amelanotic [1,2]. Melanomas at this site carry the same prognosis according to the Clarke level of invasion, the Breslow thickness and the presence or absence of a vertical growth phase. Lesions occur most commonly on the inner aspects of the vulva on the labia minora and periclitoral area [3]. They may be mistakenly diagnosed as EMPD histologically.

Vulval extramammary Paget's disease

EMPD is discussed in Chapter 53. EMPD is a rare dermatosis, and is distinct from Paget's disease of the nipple, which is always associated with underlying breast neoplasia. The vulva is the most common site for EMPD, which is subdivided into primary and secondary disease. Primary, or cutaneous EMPD, is an intraepithelial adenocarcinoma arising in the epidermis or the epithelia of the local skin appendages. Secondary EMPD is epidermal involvement from a non-cutaneous internal neoplasm, either by direct extension or metastasis. The two most common tumours associated with secondary vulval EMPD are anorectal adenocarcinoma and urothelial carcinoma of the bladder or urethra. Other associated tumours reported include cervix, endometrium and ovary [1,2].

The differentiation between primary and secondary disease is not always straightforward clinically and sometimes relies on immunohistological investigations [3,4].

Additional changes to the vulval EMPD classification have been proposed, based on aetiology [5]. The primary and secondary categories are retained, but each is divided into three types. The primary category consists of primary intraepithelial disease, primary with invasion, and EMPD as a manifestation of an underlying primary adenocarcinoma of a vulval skin appendage or subcutaneous vulval gland. The secondary category has three groups according to the tumour from which it arises: EMPD secondary to anorectal adenocarcinoma, EMPD secondary to urothelial carcinoma and EMPD secondary to an adenocarcinoma or related tumour at other sites.

It is important to distinguish primary from secondary EMPD as management depends on the correct diagnosis.

Clinical features. Clinically, the lesion is typically a moist, red, oozing plaque, which looks like impetiginized eczema or psoriasis. The associated symptoms include pruritus and burning (Fig. 71.39).

Histopathology. There is frequently epidermal hyperplasia. The epidermis is infiltrated with pale-staining Paget's cells. The Paget's cells are PAS-positive and diastase-resistant, and stain with Alcian blue and markers for the simple keratins. In the lower epidermis, the tumour cells may compress the basal cells.

Treatment. In primary EMPD, excision of visible disease is often recommended for treatment and to exclude underlying appendageal adenocarcinoma. Sometimes in the very elderly, with extensive disease or recurrence after vulvectomy, this is not always an option that the patient wishes to accept. Patients should be regularly monitored, and topical steroids can be used if there is troublesome pruritus. Topical 5-fluorouracil, bleomycin and imiquimod have been used, as well as oral retinoids, with some success. The recurrence rates are high after carbon dioxide laser and radiotherapy.

In secondary disease, the treatment is directed predominantly at the associated carcinoma.

Langerhans' cell histiocytosis

The anogenital skin may be one of the sites involved in disseminated Langerhans' cell histiocytosis (LCH), but lesions may occur at this site only. Perianal ulceration is the most common presentation in adults and children [1,2], and genital involvement is more common in women [3,4]. The lesions may be plaques, nodules, erosions, ulcers or pustules. The Letterer–Siwe form consists of a seborrhoeic dermatitis-like eruption on the intertriginous zones and scalp. Some of the lesions may be purpuric.

Lymphomas

Non-Hodgkin's lymphoma of the vulva is more frequently reported [1,2] than Hodgkin's lymphoma [3]. Non-Hodgkin's lymphoma has also been reported post-transplantation [4] and in association with HIV infection [5].

Miscellaneous

Pigmentary disorders

Hypopigmentation

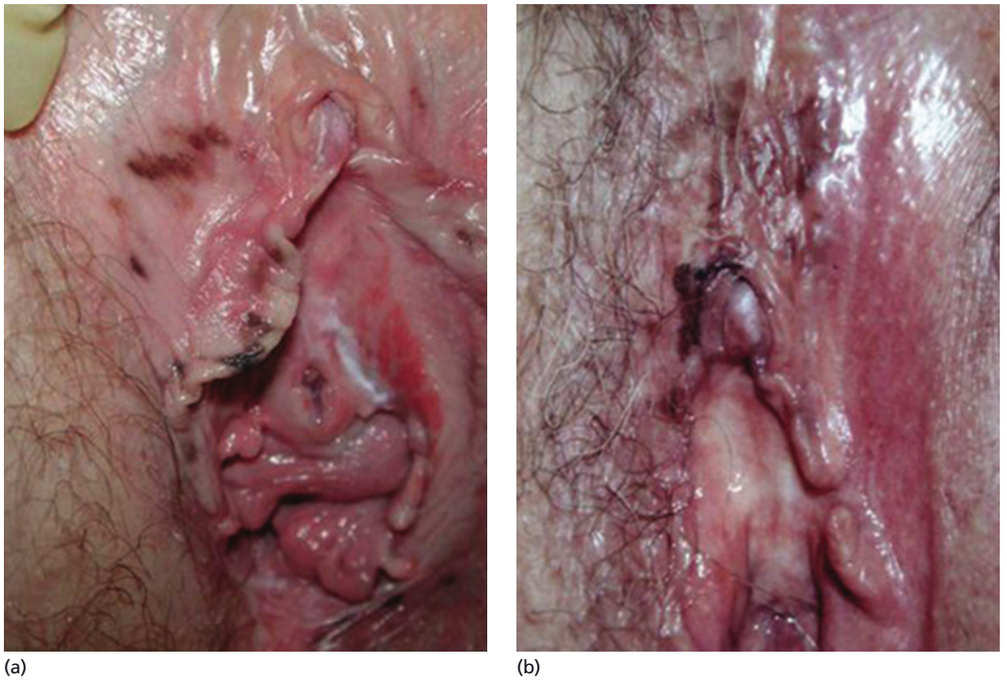
As at other sites, this can be naevoid, a post-inflammatory problem or vitiligo.

Hyperpigmentation

The increased pigmentation may be caused by haemosiderin, which results in a reddish-brown discoloration, and it is the result of extravasation of red blood cells. It is seen in capillaritis, urethral caruncle, lichen sclerosus, Zoon's vulvitis and chronic vulval purpura. However, increased pigmentation is more commonly related to melanin. There is considerable variation in the distribution and amount of melanocytes and melanin in the normal vulva, depending on site, age, ethnicity and hormonal status.

Post-inflammatory pigmentation may follow any inflammatory dermatosis, particularly if there has been a disruption of the dermal–epidermal junction and in darker skins. It is a common sequela of LP and sometimes LS, and of a fixed drug eruption. Trichomycosis and chromidrosis may cause some discoloration.

Vulval melanosis. Intense macular hyperpigmentation of vulval skin can be difficult to categorize, and a biopsy is essential for an accurate diagnosis and to exclude malignant melanoma (Fig. 71.40a) [1]. If the lesions are widespread and accompanied by oral pigmentation, they may be considered as examples of Laugier–Hunziker syndrome [2,3]. The term vulval melanosis is used for those cases where there is extensive macular pigmentation affecting the vulval skin, with the histological changes of basal hypermelanosis and a slight increase in the number of melanocytes. There may also be some pigmentary incontinence, but there is no abnormal junctional melanocytic proliferation (Fig. 71.40b) [4–8]. There have been other suggested terms: idiopathic lenticular



(a) (b)

Fig. 71.40 (a) *In situ* melanoma. (b) Vulval melanosis.

mucocutaneous pigmentation [9] and genital lentiginosis, particularly if there is melanocytic hyperplasia [10].

The accepted view is that vulval melanosis is a benign condition, but there are no long-term follow-up studies reported. Therefore, most clinicians advise continuing observation, using photographs or diagrams as an aid.

Lentigines. Vulval lentigines may be sporadic or part of a syndrome (e.g. LAMB syndrome) [11,12]. There is an increase in the number of basal melanocytes, with increased melanin in the epidermis and stratum corneum. Pigment-laden macrophages are found in the papillary dermis, and the rete ridges are elongated.

Acanthosis nigricans. This condition is usually associated with insulin resistance and rarely with malignancy. Initially, the appearance is of a dark and velvety thickening of the skin in the genitocrual folds and upper inner thighs, which later becomes warty. Skin tags may also occur.

Dowling–Degos disease. This rare inherited disorder presents in about the fourth decade with freckle-like lesions in flexural areas. It may be confined to the vulva [13].

Necrolytic migratory erythema

This rare dermatosis occurs on the anogenital skin and lower abdomen and is characterized by extensive eroded erythema with crusting and a desquamative, serpiginous edge which spreads out centrifugally. It was initially regarded as a paraneoplastic syndrome always associated with an underlying pancreatic glucagonoma, but a similar clinical picture is seen with zinc and protein deficiency and there are now a number of reports of necrolytic migratory erythema occurring with liver diseases in the absence of a glucagonoma [1].

The histology shows a loss of the granular layer and upper epidermal necrosis.

Vulval oedema, lymphoedema and lymphangiectasia

Oedema, hereditary angio-oedema [1] and dermographism [2] may all involve the vulva. Vulval oedema may be the only manifestation of Crohn's disease [3].

Lymphoedema occurs when there is impairment of the lymph drainage and it is a frequent complication following surgery and lymphadenectomy for vulval carcinoma. Lymphangiectasia is acquired dilatation of the skin lymphatics secondary to obstruction of the lymphatic vessels. It is most frequently reported following treatment of cervical carcinoma with surgery and/or radiotherapy [4–6]. Lymphangiectasia may be very profuse in Crohn's disease, and carbon dioxide laser treatment can be used in patients with troublesome lymphorrhoea [7]. Repeated episodes of cellulitis may also result in lymphangiectasia, but there may be an underlying abnormality of the lymphatics that predisposed the patient to the cellulitis initially. Lymphangiectasia may be mistaken clinically for viral warts [8].

Endometriosis

Endometriosis occasionally occurs on the vulva or in the vagina as a direct implantation. The condition may follow a previous surgical procedure [9,10], and occur in episiotomy scars after delivery [11,12]. It presents as firm bluish nodules, which become tender or bleed during menstruation. Clear cell adenocarcinoma has arisen in vulval endometriosis [13].

Genital papular acantholytic dyskeratosis

This was first described in 1984 [14], and is characterized by the presence of multiple papules or, less frequently, a single papule or plaque-like lesion on genital skin [15–18]. Cases with disseminated lesions have been described [19]. The histological changes are similar to those seen in Darier's disease or Hailey–Hailey disease, but there is no family history or evidence of these diseases at other sites. It is considered a distinct entity, although it may represent a forme fruste of Hailey–Hailey or Darier's disease. A case with positive immunofluoresence has been reported [20].

Vulval pain syndromes

Vulvodynia

The term vulvodynia was first introduced in 1983 by the ISSVD to categorize those patients who complained of a chronic sensation of burning or rawness of the vulval skin [1]. Initially, vulvodynia included several subcategories [2], but these proved unsatisfactory in the light of further experience [3]. The classification is still evolving [4].

A diagnosis of vulvodynia should be strictly reserved for those patients who have the symptoms of pain or discomfort for 3 months or more in the absence of any visible abnormality or explanation that would account for their symptoms. If any active dermatosis or dermographism is found that could account for the symptoms then that condition is the diagnosis rather than vulvodynia.

There have been many advances in our knowledge and understanding of pain in general, and the existence of complex regional pain syndromes is now well recognized. Chronic pain syndromes are rarely caused by primary psychiatric disorders as originally thought, but are the result of peripheral and/or central neuronal sensitization.

In the 1990s, it was felt that vulvodynia fulfilled many of the criteria of a complex regional pain syndrome. In clinical practice there appeared to be two major types of vulvodynia: vestibulitis and dysaesthetic vulvodynia. The main differentiation between the two was that vestibulitis was characterized by pain localized to the vulval vestibule that was precipitated by touch alone, whereas dysaesthetic vulvodynia was diffuse vulval pain that occurred spontaneously and which might or might not be aggravated by touch.

The 1999 meeting of the ISSVD recognized that there was a need for further changes in the nomenclature to fit in with the classification used for chronic pain syndromes elsewhere. It was suggested that the term dysaesthetic vulvodynia be retained for vulval pain that was diffuse, constant and spontaneous. Localized pain triggered by touch alone, previously termed vestibulitis, would be referred to by the newer and more accurate term vestibulodynia. It was also proposed that in those cases where the pain is localized

at another site this should be specified (e.g. clitorodynia if the pain is localized to the clitoris). There will probably be further changes to terminology as our knowledge about these chronic pain syndromes increases.

Vestibulodynia

Synonym
- Vestibulitis

The term vulval vestibulitis was first defined as a triad of clinical signs and symptoms that included dyspareunia, vestibular tenderness to light touch and erythema of the vestibular epithelium [5]. This syndrome was certainly recognized earlier, and terms such as focal vulvitis, hyperaesthesia of the vulva and vestibular adenitis had been used to describe the condition. It is usually a disorder of younger women, who present with the complaint of secondary dyspareunia. Most patients give a history of a precipitating event and some recall that it started during a particularly stressful time. Vestibulitis is not an inflammatory condition [6], and for this reason alone vestibulodynia is a better term. There is no evidence to support an association with chronic infection with either *Candida* or HPV. The aetiology remains unknown and it is currently best categorized as a chronic pain syndrome [7]. The majority of patients affected by vestibulodynia are psychologically normal but they do have higher anxiety and somatization scores [8,9]. Patients also seem more susceptible to irritants, not only on the vulval skin but also at other sites (e.g. hand dermatitis, poor tolerance to earrings if made of base metals). However, patch testing is usually negative [10]. It is important to assess if the patient is dermographic, as dermographism may mimic or exacerbate vulvodynia. Sometimes it is helpful to perform an examination after recent intercourse as nymphohymenal tears, fourchette or vestibular fissuring and herpes simplex infection can all be overlooked as the cause of recurrent vulval pain precipitated or exacerbated by intercourse.

Dysaesthetic vulvodynia

Dysaesthetic vulvodynia is most frequently seen in older, postmenopausal women who are often not sexually active and there is usually no precipitating event of thrush or a urinary tract infection that the patient can recall. The pain is spontaneous and often occurs independently of touch. Many of these patients are depressed, but it is difficult to establish whether this is a primary phenomenon or secondary to chronic pain. Much of the literature on the psychological profiles of patients with vulvodynia is difficult to interpret, as very often the distinction between vestibulitis (touch-provoked pain) and dysaesthetic vulvodynia (spontaneous) pain is unclear. A form of dysaesthetic vulvodynia probably more accurately labelled post-inflammatory vulval hyperaesthesia is a frequent problem following inflammatory conditions of the vulva, particularly the vestibule. It is seen most frequently following LP, when the patient still has symptoms despite the fact that the dermatitis has responded to treatment. The use of 5% lidocaine ointment usually resolves this problem.

Some of the younger patients who develop dysaesthetic vulvodynia initially had vestibulodynia.

Treatment. Management requires an unrushed and sympathetic consultation, with time spent explaining the problem of pain syndromes and the rationale for the planned treatment. Initially, topical agents are used, which include a soap substitute, avoidance of irritants and regular application of the local anaesthetic 5% lidocaine ointment. The other topical 'caine' anaesthetics should be avoided because of the risk of contact sensitivity, which is rare with lidocaine. If the patient is dermographic, an oral antihistamine should be added. If the topical measures are of no benefit or only partially effective, a tricyclic antidepressant may be used for its central action on pain. Alternative medications include pregabalin, gabapentin and carbamazepine. If there are secondary psychological or sexual issues, the input from a specialist in this field will be important. Biofeedback may improve some patients, particularly if there is associated vaginismus [11]. Finally, if there has been no improvement despite adequate doses of the medications suggested above, then advice from a Pain Clinic should be arranged. The patients may also wish to join a self-support group; in the UK this is the Vulval Pain Society.

Perineal and perianal dermatology

Introduction

Dermatologists should be able to assess these areas competently and know when to involve colleagues in other disciplines. The perineum includes the perianal skin, groins and scrotum or vulva. It is important to be familiar with the anal and perianal manifestations of intestinal disease [1]. Although they are usually nonspecific, the particular skin manifestations of tuberculosis, amoebiasis, schistosomiasis and Crohn's disease may lead to diagnosis of the underlying disease by their typical histology. Clues to

internal malignancy and systemic disease may be provided by perianal skin symptoms and signs. This topic includes the differential diagnosis of pruritus ani and the presentations or complications of sexually transmitted diseases including HIV, endocrinopathies and internal and haematological malignancy: important entities and situations include perianal HPV infection, extramammary Paget's disease, pyoderma gangrenosum, Fournier's gangrene and Langerhans' cell histiocytosis. All are discussed below.

Pruritus ani is a symptom, not a diagnosis, unless qualified as constitutional or idiopathic, and, in roughly half of patients with pruritus ani, a cause will be established after dermatological evaluation [2–7]. The topic is discussed at length below (see pp. 71.85–71.87).

Inflammatory and infectious disorders of the area may be difficult to differentiate. The presence of an infective condition in this area may overlie and disguise a more important lesion of the colon or rectum [1], or signify an STD or underlying immunocompromise, whether iatrogenic or acquired.

The differential diagnosis of anogenital ulceration is addressed on p. 71.3 and in Tables 71.9 and 71.10. Many banal conditions take on a vegetating appearance in this area, especially in hot humid climates and in the presence of infection. For these, the term dermatitis vegetans can be used.

Elephantiasis forms of progressive tuberculosis [8] and syphilis are now seldom seen, but deep fungal infections must not be overlooked.

Anal and perianal symptoms and signs in homosexual males [9] have become of greater significance because of the increasing prevalence of AIDS [10–12]. Whatever the presentation of the patient, it is important to look for infective conditions and suspect the possibility of two or more concomitant diseases. Painful lesions of the anus in homosexual men are common [13], and may include traumatic lesions and herpes genitalis. Anorectal sepsis, including chronic intersphincteric abscesses, anal fistulae, fissures and ulcerated haemorrhoids were seen more frequently in a group of male homosexuals than in heterosexuals [14]. Anal intraepithelial neoplasia may be clinically subtle and invasive carcinoma is not rare. The dermatology of HIV infection is discussed generally in Chapter 35, and of the perianal and anal area below.

Structure and function

The anus is principally for the evacuation of faeces from the gastrointestinal tract [1], but may also be an organ of sexual utility.

The deep natal cleft, the inguinal (crural) folds and the infragluteal folds are special sites because they are areas where two layers of skin come into close apposition. Together these sites function as part of the hinge between the lower limbs and the trunk, as well as abutting the mucocutaneous junctions of anus and genitalia. The natal cleft is deep and firmly fixed to underlying fibrous and fascial tissues, and its sides are steep and closely apposed. Mucous discharges, excreta and moisture are retained easily within it. Proximity to the genital organs and anus give it a special physical and psychological importance.

The perineum is endowed with numerous eccrine sweat glands whose function is retained after lumbar and thoracolumbar sympathectomies. Sweating may be caused by an alternative parasympathetic sudomotor pathway from the fourth sacral anterior root. Apocrine glands are present but many are functionless. A variable number of sebaceous glands are present both in pilosebaceous units and as individual 'free' sebaceous glands at the transitional part of the anal canal.

The cloacal membrane is where ectodermal and endodermal tissues are in direct apposition caudally in the embryo. The separation into urogenital membrane and anal membrane with the formation of the perineum at about 7 weeks of gestation is brought about by the separation of the cloacal portion of the hindgut by the urorectal septum growing caudally between the allantois anteriorly and the hindgut posteriorly, thus partitioning the cloaca into the urogenital sinus anteriorly and the anorectal canal posteriorly. The anal membrane disintegrates at about 9 weeks to open into an ectodermal anal pit formed in the posterior cloacal folds.

Congenital and developmental abnormalities

Gross anomalies will be seen only incidentally by the dermatologist because of skin complications. Minor abnormalities such as haemangiomas, skin tags (acrochordons) and papilliferous acanthomas are common on the inner sides of the thighs and infragluteal region. Pigmented, hairy naevi may involve one or both buttocks. Involvement of the buttocks with atypical naevi is a feature of the dysplastic naevus syndrome. Dermatologist should be aware of some syndromic presentations.

Developmental cysts, fistulae, sinuses and tumours

These are not uncommon, and frequently become infected. They may be mistaken for hidradenitis suppurativa or furuncles. Dermoid cysts occur on or adjacent to the perineal raphe and scrotum. Cloacal sinuses form fistulae from the anus to the adjoining skin; others involve the urethra and perineum.

Chordoma cutis

Chordomas [2] arise from the embryonic precursor of the axial skeleton, the notochord. They can involve the skin of the perineum, sacral area and buttocks by direct extension, recurrence or metastasis. They present as single or multiple, smooth, skin-coloured, non-tender nodules. Sacrococcygeal pain of a persistent nature may precede the diagnosis for years, in a manner that may mimic the presentation of sacral cysts [3], and require scanning procedures to differentiate between them.

Miscellaneous congenital abnormalities

Congenital hypertrichosis over the midline in the lumbosacral area—faun tail—is a sign of underlying spinal dysraphism (e.g. spina bifida occulta). Pilonidal sinus is discussed on pp. 71.26 and 71.87. This is not the place to list exhaustively all the syndromes with perianal manifestations, but an example is the periorificial keratotic plaques of Olmsted syndrome [4].

Trauma and artefact

Anal trauma is not uncommon. The two most common causes of acute painful anal ulceration in homosexual men are trauma and herpes simplex. Primary syphilis, chancroid, lymphogranuloma venereum, granuloma inguinale and amoebiasis, in decreasing order of frequency, are much less common [1]. Foreign bodies are occasionally inserted into the rectum. Anogenital tattoos have become commonplace [2].

Pressure sore

Pressure sores (decubitus ulcers) in the sacral area are common. In elderly, debilitated or bedridden patients, a persistent patch of erythema on the sacral or ischial region is a sign of impending ulceration. Squamous carcinoma is a potential complication, as with all chronic ulceration.

Umbilical artery catheterization

Unilateral skin necrosis of the buttock has been reported following indwelling umbilical artery catheterization [3–5], probably resulting from thrombosis leading to occlusion of the inferior gluteal artery. A similar case was caused by misdirection of the tip of the arterial catheter [6].

Child sexual abuse

The significance of anogenital warts in suggesting possible child sexual abuse is controversial. However, early recognition as a marker for child sexual abuse is in the child's long-term best interest [7].

Inflammatory dermatoses

The causes of perianal inflammation in infants are dealt with in Chapter 17. In adults, inflammation may result from the coexistence of several factors: haemorrhoids, anal discharge, proctitis, the presence of fissures or the effect of scratching. Five common conditions cause diagnostic difficulties: seborrhoeic dermatitis, psoriasis, contact dermatitis, lichen simplex and mycotic infections. *Oxyuris* infestation is sometimes postulated but seldom confirmed in adults. Phthiriasis pubis must be excluded.

The lesions of seborrhoeic dermatitis are brownish red, with branny or large, greasy scales towards the edge, extending beyond and outside the fold, and involving other areas of the body.

Psoriasis has a smooth glazed surface and a dull red hue, and is often fissured; other signs of the disease are nearly always present.

Contact dermatitis is markedly inflamed, and has an ill-defined, spreading border. Irritant dermatitis results mainly from detergents; allergic dermatitis can have many causes (Table 71.19). In 43 suspected cases, neomycin (27%) and 'caine mix' (24%) were the most frequent offenders; quinolines (7%), lanolin (7%) and ethylenediamine (5%) were less common [1]. When resulting from a medicament, the hands may be involved. Other reports concern biocide preservatives and fragrances in moistened toilet tissue [2–5], lidocaine [6,7] and tetracaine (amethocaine) hydrochloride [8] used in topical antipruritics for piles, and mitomycin C [9]. The role of food allergy in causing perianal symptoms is debatable [10]. Anoreceptive homosexual men may be susceptible to condom hypersensitivity.

Gross lichenification (lichen simplex) simulates psoriasis but is usually unilateral, except when it involves the perianal area. It may occur as a small, intensely irritable area, localized to the edge of the anus in one site, which is indicated exactly by the patient.

In all cases of perianal and perineal inflammation, the urine should be tested for glucose, and swabs and scrapings examined for organisms; tinea especially should be suspected, particularly if there has been prior use of topical corticosteroids which modify the features and thus create diagnostic confusion.

A vaginal or rectal examination is mandatory. Any irregularity of the bowels that causes straining or soiling should be corrected.

Pruritus ani

The symptom complex of pruritus ani has many causes; it is not a diagnosis unless qualified as constitutional or idiopathic. Fifty per cent of patients with pruritus ani will have a cause after dermatological evaluation [1–6]. Pruritus ani is seen especially in middle-class, middle-aged, white males [7]. It occurs less frequently in females, either alone or with pruritus vulvae. It can be associated with most forms of anal disease and with skin conditions involving the perianal area. The contributory factors are complex and may complement or perpetuate each other. Anal itching occurs to a variable degree with any inflammatory or eczematous condition of the skin of that area, with anal fissures, whatever their aetiology, and with malignant tumours. Mycotic infection often causes intense pruritus, and diabetes must be excluded in all severe or persistent candidal infections. Threadworm infestation is a well-recognized cause in childhood and occasionally in adults. Idiopathic anal itching, in which there is no obvious primary dermatological cause, is discussed further here. Lichenification, excoriation and secondary bacterial and candidal infection (induced by scratching) can supervene, and a contact dermatitis can be caused by overwashing and treatment, both self-directed and physician-prescribed.

The common factor linking most cases of pruritus ani is faecal contamination [2,8]. Faeces are themselves irritant and may generate perianal itch [8,9]. The itch may be triggered by a bowel movement or wiping with toilet paper, but often occurs at night, waking the patient from sleep. Faeces also contain potential allergens and endopeptidases of bacterial origin [10,11]. In the presence of pre-existing skin disease (e.g. seborrhoeic dermatitis or flexural psoriasis), or even in the absence of visible disease, these enzymes are capable of inducing both itching and inflammation [12].

Pruritus ani may be associated with anal leakage resulting from coexisting anal disease or an exaggerated rectoanal inhibitory reflex [13] and anal sphincter dysfunction [14], or be precipitated by broad-spectrum antibiotics and diarrhoea. Hypertrophy of anal papillae is probably not relevant [15]. Many patients have a dermatosis and some will have irritant or allergic contact dermatitis [16–18].

Psychological factors often contribute to pruritus ani, particularly when the itching appears to be out of proportion to the changes observed. However, as Whitlock [19] points out in a careful review, the evidence is unsatisfactory, except perhaps in primary lichen simplex. Psychosexual connotations of suppressed homosexuality do not withstand critical assessment. It is quite understandable, however, that prolonged pruritus ani can lead to tension, irritability or depression, and the treatment of this is an important part of the management of the condition. Idiopathic pruritus ani has been attributed to stress and anxiety, and sedentary occupations.

The causes of faecal contamination are as follows (more than one factor may be operative).

- **Difficulty in cleansing the area.** This may be caused by the following factors:
  - — Simple obesity: poor ventilation and maceration have an additional role.
  - — Frequency of defaecation: patients with a colostomy never suffer from perianal itching. Patients with pruritus ani are rarely constipated, although they may sit long at stool owing to faulty training techniques, with resultant prolapse or haemorrhoids and soiling [2,14,20]. Patients frequently admit to two or more motions a day. They are often tense individuals in whom everyday problems induce a profound colonic reflex, resulting in defaecation and soiling.
  - — Anatomical factors: it is often noted that the anus is deeply placed. The association of this 'funnel anus' with marked hirsutism causes mechanical problems in the maintenance of hygiene.
- **Anal leakage.** This may result from the following factors:
  - — Local causes: such as haemorrhoids, perianal tags or fissures, which interfere with the efficient functions of the anus.
  - — Primary anal sphincter dysfunction: anal canal manometry studies have shown that leakage of infused saline occurs early [13], and in one common group of patients the sphincter relaxes in response to rectal distension in a more rapid and profound manner than in a control group [14]. The arrival of faeces or flatus in the rectum may then regularly result in reflex faecal soiling.
- **Bacterial contamination.** This is frequently a secondary cause, but rarely a primary cause alone. However, cross-infection of staphylococci may occur (e.g. between the ears and the anus).
- **Food and drink**. The role of ingested metabolites or food chemicals in inducing pruritus ani is still uncertain and virtually unexplored, but anecdotal evidence in individual cases is sometimes compelling [21].

Clinical features. Clinical features vary somewhat, with possible contributions from the effects of rubbing, secondary infection, contact dermatitis or an underlying psoriatic diathesis.

- Lichen simplex may be present in a 'pure' form, often localized to a small area at the edge of the anus or slightly away from it. The perception of itch from 'easily alerted' nerve endings is more acute in those of anxious temperament or at times of psychic trauma or fatigue.

- A more general area of maceration, lichenification and fissuring—the 'mossy bank' anus—may be present. The architecture of the anal margin may be distorted by haemorrhoids, tags, oedema and infection. There is usually a gross degree of discharge [14].
- Features of acute eczema may be caused by secondary infection of possibly minimal seborrhoeic dermatitis or psoriasis, or by contact dermatitis. The last mentioned should always be suspected when there has been any sudden change of pattern or intensity of a rash. The fingers may also be involved. One of the most common offenders is the 'caine' group of drugs [22], often self-prescribed.
- Intense erythema with no obvious features of eczema may occur. This tends to vary in intensity over short periods, and probably represents the pruritic stage of the next group.
- There may be no visible abnormality at the time of examination. These patients may have noticed erythema at times, or intense itching, and commonly give a story of an intermittent sensation of wet anal margins and slight faecal soiling. It is in this group that dyskinesia of the sphincter appears to be a primary factor.

Diagnosis. A full history is essential and a search for underlying disease must be carried out. It is important to exclude staphylococcal infection, folliculitis, erythrasma, *Candida*, tinea, warts and thread/pinworms, and to establish whether there are other underlying skin diseases such as psoriasis [23], atopic dermatitis, lichen planus, lichen sclerosus or EMPD [15]. Anal fistulae are particularly prevalent in chronic pruritus ani [24]. However, the majority of patients with piles, skin tags, fissures, warts, diarrhoea or faecal soiling do not itch [3]. Systemic diseases that have been associated with pruritus ani include lymphoma, pellagra, hypovitaminosis A and D and diabetes mellitus [4].

A rectal examination and referral for proctoscopy and sigmoidoscopy may be indicated [25]. In the young, threadworms should be sought with the Sellotape test or by stool examination for parasites. Patch testing is helpful to explore sensitivity to lanolin, medicaments, rubber, perfumed paper, etc.

Treatment. Management [2] begins with attention to the patient's washing habits. Soap is replaced with a suitable substitute and a moisturizer prescribed. A moisturizer (others recommend talcum powder) should be applied after each wash. A barrier preparation can be pre-applied to the perianal skin before the bowels are opened. Washing in a bidet after defaecation is preferable to wiping with toilet paper, if possible. Rubbing with toilet paper should be discouraged and dabbing recommended. Premoistened toilet papers should be avoided because of the potential irritancy of the moisturizing agent, which may be alcohol, and the risk of developing allergic sensitivity to fragrance or preservative components. Underwear should be loose and preferably made of cotton. Patients are best advised not to use topical anaesthetics in order to avoid sensitization to their constituents [26].

Coffee consumption might be curtailed [21]. Any other foods, such as nuts, that provoke the pruritus should be excluded from the diet, and a high-fibre diet should be encouraged if there is any history of constipation or haemorrhoids [27].

Local applications should be mild and soothing. A topical corticosteroid/antibiotic/antifungal preparation is useful for acute episodes. A wick of bandage impregnated with hydrocortisone 1% and silicone 10% inserted in the natal cleft is anti-inflammatory and lubricating. Other treatments that have been advocated include zinc paste with 1–2% phenol, St Mark's lotion, half-strength Castellani's paint, weak (0.05–0.25%) silver nitrate solution (if wet), cryotherapy, oral antihistamines, corticosteroid suppositories, intralesional triamcinolone, a 10-day tapering course of prednisolone, and intralesional methylene blue, with or without marcaine/epinephrine/xylocaine [3,4,28,29]. Caution should be exercised with topical steroid treatment because the anal skin is 'quasi-occluded' and is easily damaged by fluorinated corticosteroids.

Concomitant proctological disease (haemorrhoids, fissures, anal spasm and occult mucosal prolapse) should be treated, if found [30]. When active pathology such as fissures, haemorrhoids or anal spasm are present, surgery will be needed. Lord's stretch procedure [31] has proved helpful. The long-term results are particularly satisfactory in those patients with strong ultra-low-pressure waves [27]. However, it may not always relieve the pruritus [32]. Simple excision of anal tags is unhelpful in relieving symptoms [15].

Some authorities see a psychosexual significance in pruritus ani in men [19], and this may rarely require attention. Patients should be reassured that they do not have cancer [1].

Danthron erythema

This form of irritant contact dermatitis is caused by the use of a laxative containing danthron [1,2]. It is seen in those with Hirschsprung's disease or encopresis, and sometimes in elderly incontinent patients [2–4]. Danthron (1,8-dihydroxyanthroquinone) is reduced in the large bowel to 1,8-dihydroxyanthron, which is the active agent [2]. This is chemically identical to dithranol, and the lesions produced by faecal incontinence are equivalent to dithranol 'burns'. A bizarre livid erythema in the perianal area, groins, thighs and buttocks, with sharp outlines, corresponds to the area of contact with the faeces. Danthron erythema is easily differentiated from other causes of perianal or inguinocrural lesions.

Lichen sclerosus et atrophicus

The perianal skin is rarely involved alone in women, but is involved in up to two-thirds of the cases in which the vulva is affected [5], forming a characteristic figure-of-eight distribution. One case of carcinoma has been reported [6]. Perianal lichen sclerosus probably never occurs in males.

Anal fissure

Small erosions and fissures may occur in the sulcus beneath oedematous haemorrhoids or in any area of dermatitis. The presence of even a small fissure in an area of dermatitis maintains the pruritus and prolongs the course.

A true anal fissure is a midline linear perianal ulcer; 90% posteriorly, 10% anteriorly. Many are idiopathic; the cause is probably related to defaecation of hard stool causing pressure trauma and necrosis, or it may be a post-operative complication. Sexually transmitted diseases and Crohn's disease should be excluded. Intense pruritus, pain, bleeding, mucous discharge and constipation constitute the symptomatology. On examination there may be a 'sentinel pile' at the anal pole of the ulcer. Management is surgical: proctoscopy is mandatory if the aetiology is in doubt, and especially if the fissure extends to the anal margin or within. Benign fissures are superficial and not indurated, but when persistent they may be painful and cause bleeding, especially in the elderly. Unless they heal quickly under treatment, a biopsy should always be performed to exclude malignancy.

Small erosions and excoriations frequently heal with treatment for anogenital pruritus. If they are hidden between haemorrhoids or anal tags, protective pastes are helpful. Fissures in psoriasis and seborrhoeic dermatitis are difficult to heal, particularly in the natal cleft. If the underlying disease is satisfactorily controlled, the lesion will heal without special attention. Intralesional corticosteroids may be effective in non-infective inflammatory conditions.

Anal fistula

A perianal fistula is a communication between the anal canal and the perianal skin. Most are on the midline posteriorly, but there may be multiple openings. The origin is from infection and abscesses within the anal glands, but Crohn's disease, foreign body and tuberculosis are classic causes and hidradenitis suppurativa is an important differential diagnosis. Squamous carcinoma is a rare complication. The presentation is usually of pruritus ani related to seropurulent discharge but there may be pain resulting from abscess formation. Surrounding skin may be indurated. Management is surgical.

Pilonidal cyst/sinus

Pilonidal sinus probably derives from the perineal pilosebaceous unit and precursor pits (not the common congenital sacral pits) associated with trapped hairs [7,8]. Clinically, pilonidal sinus constitutes part of the 'follicular–occlusion tetrad' alongside hidradenitis suppurativa, acne conglobata and dissecting cellulitis of the scalp. Symptoms include itch, pain, recurrent abscess, purulent discharge and persistent nodule. Pilonidal sinus occurs in the midline. The sacrococcygeal location is the most common site but it can occur on the pubis, anterior perineum and, very rarely, the penis. It may present as a nodule or cyst, often with a pigmented or hairy surface, which ruptures and quickly becomes infected (Fig. 71.41). The sinus usually extends to the sacrum and causes sacrococcygeal fistulae with deep ramifications. This heals if the track is thoroughly cleaned. Treatment is surgical [8,9]. Squamous carcinoma can supervene [10].

Hidradenitis suppurativa

Hidradenitis suppurativa ('chronic perianal pyoderma' in Japan) (see Chapter 30) can give rise to all degrees of inflammation and scarring. Friction and pressure accentuate the inflammatory changes that invade the fat and cause further granulomatous change extending widely over the buttocks and thighs. Persistent perineal sinuses are frequent, and deep lesions cause anal fistulae. In mild cases, only a few isolated lesions are present. Secondary bacterial invasion, often from the gut [1], is an important complicating factor. Seven cases have been associated with an oestrogen–progesterone contraceptive pill [2].

There is a clinical spectrum overlapping with chronic folliculitis (e.g. of the buttocks and 'penile acne'). In established hidradenitis, bridged comedones, folliculitis and furunculosis, deep burrowing discharging sinuses, nodules, cysts, fluctuant abscesses, scarring and fibrosis in the groins and axillae, the natal cleft and buttocks [3] may all be present. Some patients may also have conglobate acne, dissecting cellulitis and pilonidal sinus. Hidradenitis is more common in black and Mediterranean individuals. It affects the axillae preferentially in women and the perineum in men. A urethral–cutaneous fistula and phimosis have been reported [4]. Scarring from the disease and its treatment can be extensive. The morbidity of hidradenitis may be severe, interfering with sitting, sleeping, walking, defaecation and sexual activity, and responsible for depression. Disease that has persisted for more than 20 years carries a significant risk of progression to SCC [5–7] and rarely verrucous carcinoma [8].

Differential diagnosis. Hidradenitis is usually a clinical diagnosis. Swabs should be taken for bacteriological evaluation and to guide therapy, but the patient should be fully evaluated for sexually transmitted diseases should the presentation be in any way suspicious. An important differential diagnosis of acneiform disease presenting at any site is chloracne (see Chapter 42). A biopsy may be necessary to exclude carcinoma or Crohn's disease. Perineal Crohn's disease mimics hidradenitis, with its granulomatous inflammation, ulceration and fistula formation, but it is less painful. Also, the disease is absent from the axillae and it is rare for patients to be free of overt gastrointestinal symptoms. Very florid perianal disease can be seen in myeloma and leukaemia [9], and in homosexual men and in AIDS [10].

Mild or localized forms are frequently misdiagnosed as furunculosis or 'infected cysts', and confusion occurs with severe acne, developmental fistulae and lymphogranuloma venereum. The relatively painless recurrences in the same or other sites, and oblique sinuses that end in soft swollen inflamed nodules, are characteristic.

Treatment. This is challenging [11]. Small localized sinuses may be phenolized successfully, and early lesions may respond to intralesional corticosteroids. Recurrent or extensive lesions may require a more radical approach. Marsupialization (as with pilonidal sinuses) [12] and diathermy destruction of the affected tissue have been very successful in some cases, even those involving the scrotum. Treatment with carbon dioxide laser, can be effective [13,14]. The use of Silastic foam dressing may facilitate healing [15]. Otherwise, plastic surgery with complete excision of all the involved skin may be required [16]. Long-term antibiotic therapy (erythromycin, flucloxacillin, ciprofloxacin, metronidazole) is often given 'blind', but is seldom of lasting value, although elimination of specific secondary invaders such as *Streptococcus milleri* [1] has given good results. Oral prednisolone can be used alongside antibiotics to control intercurrent exacerbations. Isotretinoin (1 mg/kg) for 6–8 months has been used with mixed results, but is occasionally helpful in difficult cases [17,18]. Antiandrogen therapy has yet to be evaluated. Infliximab and other TNF 'biologicals' show promise [19].

Crohn's disease

Synonym
- Regional ileitis

It is a well-known aphorism that Crohn's disease can affect any part of the gut and its cutaneous borders from the mouth to the anus. The cutaneous manifestations of Crohn's disease are listed in Table 71.31. Perianal disease may occur in up to 75–90% of patients [1–8]. Table 71.32 lists the perianal features of Crohn's disease [9]; it includes those common to most chronic diarrhoeal illnesses such as pruritus ani, skin maceration, and erosions with secondary infection. Perianal manifestations of Crohn's disease in childhood are a major cause of morbidity, but only rarely progress in a destructive manner (Fig. 71.42) [9].

Clinical features. The skin tags of Crohn's disease are larger, thicker and harder than ordinary tags. Deep, undermined, angulated fissures with cyanotic edges may fuse to form 'flying buttress' skin bridges, characterized by relative lack of pain. Fistulae are less common than fissures; they may be asymptomatic even when multiple. Pain usually means that an abscess has formed because of blockage of a fistula. Multiple external openings can be encountered all over the buttock, on the scrotum and on the thigh; a distinctive sign is the cyanotic hue of the indurated skin. Anal stenosis, faecal incontinence and carcinoma are complications [10].

Fig. 71.42 Crohn's disease: perianal lesions. (Courtesy of Dr D.I. McCallum, Inverness, UK.)

Clinical diagnosis may be achieved based on symptoms, signs and investigation results (e.g. radiography and gut biopsy) consistent with Crohn's disease. Any anal lesion in a patient who is known to be suffering from Crohn's disease is likely to be perianal Crohn's [11]. Difficulty arises when the anogenital disease represents the first manifestation. Histologically positive perianal disease of all clinical types may predate frank gastrointestinal

Crohn's disease by several years [12], including in children [9]. The relative lack of pain, multiplicity of lesions, oedema of skin tags and eccentricity of fissures are important pointers [11]. Biopsy of skin lesions is helpful, and sigmoidoscopy and biopsy of intestinal mucosal lesions is mandatory. Swabs should be taken and the patient fully evaluated for sexually transmitted diseases should the presentation be in any way atypical.

Differential diagnosis. The differential diagnosis includes the causes of pruritus ani and non-specific anal fissures and fistulae. Similar, although less extensive, lesions occur, but much less commonly, in ulcerative colitis, and only very rarely in diverticulitis [2]. Hidradenitis suppurativa presents with nodules, sinuses and purulence but is more painful; other sites may be involved and severe acne is often present. Florid perianal disease can be seen in myeloma and leukaemia [11]. Proctitis, perianal ulceration, abscess, fissure and fistula are prevalent in homosexual men and those with HIV/AIDS [13]. Perineal pyoderma gangrenosum has been misdiagnosed as Crohn's disease. A solitary granulomatous nodule, with or without ulceration, creates a differential diagnosis that includes sarcoid, schistosomiasis, leishmaniasis, tuberculosis, atypical mycobacterial infection, deep fungal infection, granuloma inguinale, lymphogranuloma venereum, chancroid, amoebiasis and syphilis. Florid condylomata acuminata, anorectal carcinoma (presenting with an ischiorectal abscess) [14], and other mucocutaneous malignancies (basal cell carcinoma, Kaposi's sarcoma and amelanotic malignant melanoma) may rarely be encountered.

Treatment. The treatment of the anogenital manifestations of Crohn's disease depends on the treatment of active intestinal disease. This has been transformed by advances in immunosuppressive treatment [15,16]. Local measures include soaks with potassium permanganate and aluminium acetate, potent or very potent topical corticosteroid/antibiotic combinations and oral antibiotics (as for hidradenitis). A role has been advocated for long-term oral metronidazole (20 mg/kg/day in divided doses) [17,18]. Perianal abscess may respond to sulfasalazine and anal fissure to prednisolone and azathioprine [4]. The surgical philosophy is conservative [3,9,15]. Resection of the affected segment of bowel does not always cure the lesions or prevent their recurrence, especially at ileostomy or colostomy sites.

Miscellaneous inflammatory dermatoses

Radiodermatitis is occasionally encountered following previous treatment for *in situ* or frank carcinoma or, decades ago, pruritus ani. LP involving the buttocks and perianal region is extremely irritable and may become excoriated or hypertrophic; LP must be considered in the differential diagnosis of pruritus ani and perianal fissures. Solitary involvement of the perianal skin may occur (Fig. 71.43).

Behçet's disease occasionally presents with multiple shallow ulcers and fissures of the anal margin.

Calciphylaxis sometimes affects the thighs and buttocks [1–3].

Fig. 71.43 Perianal lichen planus. (Courtesy of Dr F.A. Ive, Durham, UK.)

Acrodermatitis enteropathica should be considered in the differential diagnosis of perianal eczema, psoriasis or candidosis in the paediatric setting, or in the presence of gastrointestinal disease causing malabsorption syndromes (e.g. Crohn's disease), extensive gastrointestinal surgery such as small intestinal bypass, malnutrition in alcoholism and recent prolonged parenteral nutrition where zinc supplementation may not have been optimal. A reticulate eczematous eruption may be found on the extensor aspects of the limbs in alcoholics but has also been reported to affect the perianal and scrotal skin [4,5]. Other deficiency diseases with some similarity to acrodermatitis enteropathica are pellagra, maple syrup urine disease and neonatal citrullinaemia. Hereditary mucoepithelial dysplasia is associated with perineal intertrigo [6].

Cicatricial pemphigoid [7] may affect the groin, perineum and perianal skin, and may cause anal stenosis. The drug clonidine may have been responsible in one case [8]. Pyodermite végétante can be distinguished by the histology and by immunofluorescence studies. Ulcerative colitis may be present [9]. Hailey–Hailey disease can involve the perianal skin [10].

The anus is involved in about 5% of cases of Stevens–Johnson syndrome. A connection has been recognized between epidermolysis bullosa acquisita [11] and inflammatory bowel disease, particularly Crohn's disease [12–14].

Fixed drug eruption may produce striking pigmentation. Prolonged use of potent topical corticosteroids causes a dusky erythema, atrophy or induration. Nicorandil is a newly recognized cause of anogenital and peristomal ulceration [15,16].

Eruptive perianal (and penoscrotal) melanotic macules and papules can indicate internal adenocarcinomatosis [17].

Primary systemic cutaneous anosacral amyloid has a predilection for the anogenital region, particularly the sacrum, in elderly Japanese people [18–20]. Moderately pruritic pigmented macules and glossy hyperkeratotic lesions fan out in lines from the anus. There are no systemic changes. Amyloid deposits are seen in the upper reticular dermis and around hair follicles. It is thought to represent an ageing process.

'Infantile' gluteal granuloma [21–23] (see Chapter 17), usually affecting infants of 4–6 months, may also occur in incontinent elderly patients [24].

Infections

Folliculitis and furunculosis

The anogenital area, particularly the buttocks and thighs of men, can be susceptible to infection with *Staphylococcus aureus*. Severe involvement with furunculosis and abscesses suggests an overlap with hidradenitis suppurativa. Although the high temperature and humidity of this area, combined with pressure [1] and friction, encourage colonization by staphylococci, primary pyococcal infections are now uncommon in countries with cultural or acquired habits of cleanliness. The perineal carriage of staphylococci [2] may not cause local lesions in the host, but is especially important in acting as a reservoir from which *S. aureus* may be disseminated to other sites or to eczematous lesions elsewhere. In adults, the carriage rate is of the order of 13–22%; in neonates it may be higher. Some persons are better 'dispersers' of staphylococci than others, and the organisms may remain (and even increase) after washing. The risk of dispersion of staphylococci from this site is of obvious importance in hospital operating theatres, where attempts have been made to minimize it by the provision of special clothing [3]. Nasal carriage, diabetes and immunodeficiency should be considered. Bacterial perianal infection is commonly seen in leukaemic patients [4].

Staphylococcal cellulitis

Cellulitis and abscess formation can complicate cysts, sinuses and fistulae. The differential diagnosis is given in Table 71.33.

Table 71.33 Differential diagnosis of anogenital cellulitis. (After Bunker [5]. © 2004, with permission from Elsevier.)

Hidradenitis suppurativa
Crohn's disease
Staphylococcal cellulitis
Streptococcal cellulitis
Gonococcal cellulitis
Fournier's gangrene and necrotizing fasciitis
Extramammary Paget's disease
Carcinoma erysipeloides (bladder and prostate)

Anorectal infection in patients with malignant disease is serious and potentially life-threatening [6]. Although some cases of anorectal cellulitis will respond to antibiotics alone, necrotizing fasciitis and Fournier's gangrene are risks. Swelling and fluctuance signifying abscess formation may develop late. It is difficult to decide on the timing of surgery. Perianal infiltration, ulceration or abscess occurs in 5% of haematological malignancies and may rarely be the presenting feature [7].

Streptococcal dermatitis/perianal cellulitis

This syndrome in children [8] probably has a corollary in adults [9]. A child may present with pruritus, painful defaecation, anal soreness and redness (without nappy/diaper rash) and satellite pustulosis of the buttocks. Examination of the anus shows a pronounced, sharply demarcated, boggy erythema and causes discomfort to the child. Rarely, there may be a systemic presentation with fever and rash [10]. It is much more common in boys, and the penis may be involved. An association with acute guttate psoriasis has been reported [11,12]. Group A β-haemolytic streptococci is the usual cause, although *S. aureus* has been retrieved from one child who also had satellite pustules on the buttocks [13]. Proctocolitis has occurred [14]. Perianal disease may be misinterpreted as sexual abuse [15]. Streptococcal infection of the upper respiratory tract in other members of the family may be found. Communal bathing has been blamed for outbreaks. Treatment is generally with systemic penicillin or topical mupirocin, or erythromycin if clinically less acute [16].

Perianal abscess

Perianal/anorectal/ischiorectal abscess presents with painful swelling and suppuration and is commonly complicated by anal fistula. The likeliest cause of perianal abscess is infection of the anal glands, but trauma (e.g. impacted fish bone), diabetes and anal cancer predispose to its development. Crohn's disease, hidradenitis, tuberculosis and *Enterobius vermicularis* (threadworm/pinworm) [1] should be considered.

Ecthyma gangrenosum

Gram-negative organisms are seldom pathogenic unless the balance of the skin flora is grossly disturbed. *Pseudomonas aeruginosa* may be found in deep ulcers and fissures. Ecthyma gangrenosum has a predilection for the anogenital (and acral) extremities. The prognosis is poor. Ill patients with leukaemia may develop a necrotizing anorectal ulcer caused by *Pseudomonas*, presenting with severe anal pain, anorectal ulceration and septicaemia. Anorectal ulceration may be the portal of entry of the infection or a consequence of it [2]. The mortality is high.

Thread/pinworms

Thread/pinworms can cause pruritus ani. Excoriations, eczematization and impetiginization may be present, but often there are few physical signs. Perianal abscess may occur very rarely [1].

Common mycoses

Candidosis causes a bright red, glazed area, often with outlying small pustules, and may spread to the groins or natal cleft. Microscopy and culture distinguish it from other fungal infections, and from psoriasis and pyococcal infections.

The well-defined, scaly, circinate edge, the spread and the chronicity of *Trichophyton rubrum* infection offer clues to diagnosis, which can be confirmed by microscopy and culture. However, prior treatment with corticosteroids may disguise the appearance. The possibility of fungal infection should therefore be considered in all unusual forms of perianal dermatitis.

Necrotizing infections

A number of overlapping, severe gangrenous and necrotizing diseases may affect the anorectal and perineal (and genital) skin and subcutaneous tissues. Although they may often be a complication of surgery or trauma, they are mentioned here because of the crucial importance of their early recognition and treatment (see also Chapter 30 and p. 71.31). These conditions are described under several names [3]:

Clostridial and non-clostridial gangrene [3–5]; streptococcal cellulitis and myositis; streptococcal toxic shock syndrome; synergistic necrotizing cellulitis; necrotizing fasciitis [6–8]; Meleney's progressive bacterial synergistic gangrene [9]; synergistic gangrene [10]; Fournier's gangrene.

Clinical features. Although middle-aged and elderly subjects are most often affected, the conditions can follow trauma in young adults, and the prognosis in the latter, given vigorous early treatment, is good [3]. They have also been described in children [11], particularly following circumcision or scalds, but sometimes after a bout of severe diarrhoea [12], or even spontaneously [13]. The problem may present as a primary perirectal abscess in the perineum (or on the scrotum or labia). Pain is generally the first symptom, and may be severe. A distinct dusky red to black spot may appear in affected tissue and is of ominous significance. Tenderness and a dusky erythema extend with extreme rapidity to involve wide areas, and all the perirectal and perineal spaces (hence the terms fasciitis and myositis). Crepitus is an important feature, as is the presence of a dark brown, turbid fluid without pus. Many patients are diabetic [3,7] or leukaemic; in these, the mortality is much higher than the overall rate of 12–25% [7]. A perianal distribution, old age and delay in treatment also greatly reduce the survival rate.

Bacteriology. Swabs should be taken from the margin of the lesion [10]. An immediate Gram stain will distinguish clostridial infections by the finding of large Gram-positive rods. *Clostridium perfringens* was the most common organism in one series [3], but other clostridia, aerobic and anaerobic streptococci, and *Pseudomonas* species [11] have all been isolated. Anaerobes may easily be missed. A wide variety of secondary organisms are commonly cultured.

Treatment. Early recognition and immediate and aggressive treatment are essential in this devastating condition. Electrolyte and fluid balance must be established, and high-dosage antibiotic therapy started without waiting for the result of culture. This will normally consist of intravenous penicillin (24–30 million units/day [3]) together with a broad-spectrum antibiotic, usually an aminoglycoside or a cephalosporin; this regimen can be modified later.

The most important single therapeutic manoeuvre is rapid and extensive debridement of all affected tissue. Other surgical procedures, such as colostomy, may also be necessary. The value of hyperbaric oxygen [14] is disputed.

Dermatological aspects of sexually transmitted disease

Gonorrhoea can result in anal inflammation and discharge, or an oedematous perianal dermatitis with multiple fissures and erosions.

Chancroid may cause extremely painful anal lesions instead of the classic multiple soft chancres. The initial rapidly ulcerating papule of granuloma inguinale (see Chapter 34) may occur in the perianal region in homosexual males. It is soft, painless and bleeds easily on trauma. It may be hypertrophic, sclerotic or phagedenic. There is normally no regional adenopathy, but a 'pseudobubo' may be present. In the anal canal, the lesion never extends beyond the stratified epithelium and strictures do not occur, but anal stenosis or, rarely, epitheliomatous change can supervene.

Lymphogranuloma venereum is increasing in frequency in homosexual men. It causes an ulcerative proctitis and is often misdiagnosed as ulcerative colitis or Crohn's disease [1]. If undiagnosed, lymphogranuloma venereum causes widespread vegetating and scarring lesions of the genitoperineal area. The Frei and complement fixation tests distinguish it from hidradenitis suppurativa.

Syphilis (see Chapter 34) [2] is becoming more common in homosexual men. It should never be forgotten as a possible cause of anal ulceration. Anal chancres are often mistaken for fissures; at the anal margin their significance may not be appreciated. Pain on defaecation or at night may be severe if there is secondary infection of the chancre, but is often absent. The posterior midline is the site of election. Bilateral lymphadenopathy is extremely rare with other perianal ulcers. Dark-ground examination may not be diagnostic if lubricants or ointments have been used. Discharge and bleeding, fissures (especially laterally) and fistulae should also arouse suspicion of anorectal primary syphilis. Painful syphilitic proctitis in the absence of anal lesions can occur [3,4]. Moist, flat condylomata lata (Fig. 71.44) can affect all anogenital intertriginous sites, and the differential diagnosis includes intertrigo as well as warts, lichen planus and bowenoid papulosis. The granulomatous gumma may affect the anal area as an ulcer, a white plaque or as an atrophic scar.

Perianal viral warts (condylomata acuminata) (Fig. 71.45) occasionally occur in infants and young children, but they are

Fig. 71.44 Condylomata lata. (Courtesy of Dr S.C. Gold, London, UK.)

Fig. 71.45 Perianal condylomata acuminata. (Courtesy of Dr F.A. Ive, Durham, UK.)

normally seen in young adults, and are not always sexually transmitted. They may be extraordinarily profuse, extending into the anal canal, especially in homosexuals or in immunodeficient (congenital or acquired) subjects in whom there is also a higher risk of progression to dysplasia and frank malignancy [5]. For example, anogenital warts are common in HIV-positive males, nearly half of whom show histological signs of intraepithelial neoplasia. The clinical diagnosis of HPV is usually certain but condylomata lata (secondary syphilis), LP, molluscum contagiosum and BP enter the differential diagnosis. Solitary lesions have a wider differential diagnosis, including giant condyloma and squamous carcinoma. Biopsy should be performed if there is diagnostic doubt or if dysplasia or worse is suspected. Morphology and histology cannot distinguish virus-associated from non-virus-associated lesions; molecular techniques may be preferable but are not yet routinely available [6]. Patients with anogenital warts, and their partners, may require full STD and sometimes colorecral assessment. Anogenital HPV can be very difficult to treat.

A phenomenon of chronic erosive and verrucous herpes simplex as part of immunoreconstitution disease has been described in HIV infection [7].

Table 71.34 Causes of anal ulceration in HIV infection.

Idiopathic
Haemorrhoids
Fissures
Sepsis (abscess, fistula)
Syphilis (chancre)
Herpes simplex
Cytomegalovirus
Kaposi's sarcoma
Non-Hodgkin's lymphoma
Squamous carcinoma

Human immunodeficiency virus infection

Perianal disease can be problematic in homosexual men [8]. Table 71.34 lists the main causes of anal ulceration in HIV infection. Biopsy with special stains and culture is mandatory.

Other problems in HIV infection, including psoriasis, warts, intraepithelial neoplasia, squamous carcinoma and Kaposi's sarcoma are discussed in Chapter 35.

CMV has been recorded in persistent perineal ulcers in immunosuppressed patients [9]. EBV DNA has been found in epithelial cells from the anal canals of asymptomatic HIV-positive male homosexuals, indicating possible sexual transmissibility [10]. Herpes simplex, gonorrhoea and anal warts were commonly associated in a US study on early HIV positivity [11]. Similar findings relate to a central African group with more advanced disease [12]. The importance of primary rectal syphilis has been emphasized [3]. Amoebiasis [13] may be overlooked. Dark-ground examination, and culture and microscopy for ova, should be obligatory [14]. In the absence of organisms, if pus cells are found, a rectal biopsy is indicated. Kaposi's sarcoma of the rectum can occur in HIV-positive males [15]. The relationship of KS to anoreceptive anal intercourse and HHV 8 is discussed in Chapter 35 [16,17].

Miscellaneous infections

Erythrasma, present also at other sites, was found in 15 of 81 patients with pruritus ani examined using Wood's light [1]; all were males. In infants, coxsackie infections can cause a transient papular or papulovesicular eruption of the perianal area and buttocks. An erythematous, desquamating, perineal eruption occurring in the first week of the disease may be the first cutaneous feature in up to two-thirds of children with Kawasaki disease [2].

Fournier's gangrene and its differential diagnosis (Table 71.22) are discussed on pp. 71.30–71.31 and 71.92–71.93. Anorectal presentation is more serious than urogenital disease because the presentation may be more cryptic and there may be a longer delay in diagnosis [3].

Perianal tuberculosis (see Chapter 31) [4] is seen where tuberculosis is common, but must always be considered, even in Western Europe [5]. A primary lesion is exceptional; the accompanying unilateral lymphadenopathy is an important feature. Indolent, irregular, painful ulcers, fistulae and abscesses may be difficult to distinguish from those accompanying Crohn's disease [6]. Lupus vulgaris and verrucous tuberculosis may spread widely over the buttocks and postanal region, or assume a fungating and vegetating appearance. Tuberculosis cutis orificialis is thought to arise from autoinoculation of organisms contained in swallowed sputum from pulmonary lesions [7]. It may occur in the immunocompromised and has been reported in association with Evans' syndrome (autoimmune haemolytic anaemia and immune thrombocytopenia) [8]. Perineal scrofuloderma (secondary skin involvement from underlying lymph node disease) may cause diagnostic confusion [9]. Pyoderma gangrenosum, Crohn's disease, hidradenitis, neoplasia, artefact, sexually transmitted diseases, amoebiasis and deep mycoses appear in the differential diagnosis [10].

Daughter yaws, initially papules but rapidly becoming ulcerated crusted plaques, have a predilection for periorificial sites on the face and around the perineum.

The giant condyloma of Buschke–Löwenstein (see pp. 71.44 and 71.76–71.77) is rare: it is probably HPV-related [11].

Non-genital herpes simplex (see Chapter 33) occurs frequently around the pelvic girdle. Vaccinia, which was usually acquired by indirect transmission [12], is now never seen. Perianal orf occurs occasionally [13]. Perianal CMV ulceration is extremely rare in the immunocompetent. It occurs in HIV infection (see below), and has been reported in a man with prior perianal HSV on immunosuppressive medication for idiopathic thrombocytopenic purpura [14].

Sacral herpes zoster [11] is rare and can be cryptic in presentation; when involving S2–S4 or, less commonly, the ileoinguinal segment of L1–L2, it may cause significant morbidity from acute cystitis or urinary or faecal retention [15–17]. Hospitalization and urological and colorectal assessment are required, and treatment should be with intravenous aciclovir. AIDS has presented as anogenital herpes zoster [18].

Trichosporosis is a common cause of genitocrural and perianal intertrigo in India. Symptoms are itching or burning. Accompanying the intertrigo may be scaly papules. Coexisting dermatophyte, *Candida*, trichomycosis and erythrasma infection may be found. Topical dequalinium chloride is used for treatment in India [19].

Amoebiasis (see Chapter 37) of the perianal skin [20] is usually associated with bowel infections but, where the disease is endemic, direct inoculation of abraded skin or operation wounds can occur. Abscesses and fistulae may at first be indolent and symptomless. Ulcers typically extend slowly, with serpiginous outlines, firm cord-like edges and a whitish slough [21]. Sometimes, however, progression is rapid and remorseless, until a phagedenic ulcer completely destroys the perianal and sacral tissues [22]. A black, foul-smelling eschar is surrounded by a violaceous edge, resembling pyoderma gangrenosum. The patient is extremely ill. Vegetating or condyloma-like lesions of intermediate severity occur less frequently. Amoebiasis should be suspected when such a lesion occurs unexpectedly in the course of 'ulcerative colitis' or in a prolonged, mild, undiagnosed colitis. Cases have been described in infants [23]. Destructive perianal and buttock ulceration may masquerade as squamous carcinoma; however, very rarely, concomitant carcinoma has been reported [24]. The diagnosis is made by finding the *Entamoeba* species in a biopsy specimen from the edge of a lesion (which is always secondarily infected) or by examination, while warm, of a fresh high sigmoidoscopy swab. Treatment with metronidazole may be dramatically effective, but in severe cases surgery may also be required.

Perineal granulomatous lesions are a rare manifestation of schistosomiasis (bilharziasis), which may present as pruritic papules in the genital, umbilical and perineal regions in countries where it is endemic [25,26]. It is usually preceded by rectal or intestinal symptoms. The papules and nodules may be skin-coloured, pink or brown, scattered or grouped, affecting the penis, scrotum and vulva. They can spread onto the perineum and around the anus, and may develop into soft warty vegetating

lesions, but remain relatively asymptomatic. Genital lesions simulating warts have been seen in travellers returning from endemic areas [27]. The unusual occurrence of anogenital lesions results from ova shed by worms that have entered the perineal vessels [25]. Viable or calcified ova are found in the dermis.

The perianal region is an extremely rare site for cutaneous leishmaniasis. One case presenting as an itchy plaque has been described. The patient frequently defaecated in the open when hunting in Sardinia and presumably thereby came to be bitten by the *Phlebotomus* vector [28].

Larva currens, caused by *Strongyloides stercoralis*, commonly occurs around the anus and on the buttocks and is therefore a cause of excoriations at these sites [29]. Likewise, cutaneous larva migrans resulting from the dog hookworm *Ancylostoma brasiliense* may occur around the pelvic girdle.

Perianal histoplasmosis and blastomycosis have also been recorded. Actinomycosis has resulted in multifocal perineal and buttock ulceration in glucose-6-phosphate dehydrogenase (G6PD) deficiency [30]. Ulcerating and vegetating lesions, often unrecognized and of long duration, have followed trauma in patients with actinomycosis [31]. Correct diagnosis depends on histological confirmation, but the yellow or red granular pus should arouse suspicion [30].

Classical lesions of scabies commonly involve the buttocks, and nodules are sometimes seen in the perineum.

Benign tumours

Many entities are encountered in the perineal/perianal area. Angiomas and angiokeratomas are common; basal cell papillomas may be mistaken for viral warts or BP, as may melanocytic naevi; inguinogenital epidermoid cysts may become infected, and lesions containing molluscum contagiosum have been described; pilar cyst, including giant forms, is much rarer. Giant congenital perineal haemangiomas can be associated with widespread anogenital abnormality involving the genitalia, lower GI tract, urinary tract and spinal cord (PELVIS syndrome) [1].

Haemorrhoids

Haemorrhoids/piles (Latin *pila*, a ball) are dilatations in the venous system draining the anus, mucosal prolapse or loose tethering of mucosa to the anal wall [2]. Symptoms are rectal bleeding, mucous discharge, pruritus ani and prolapse. The complications of piles are thrombosis, strangulation, ulceration, fibrosis, infection and abscess, which give rise to pain. Patients presenting with these symptoms should be assessed by a proctologist, and by proctoscopy and sigmoidoscopy. Signs depend on the presentation. Perianal skin tags from fibrosed piles are extremely common. The differential diagnosis includes distal bowel cancer, as well as naevi, Crohn's disease, KS and perianal metastases. Treatment is the domain of the colorectal surgeon and gastroenterologist.

Premalignant dermatoses and frank malignancies

The anogenital area is not exposed to solar radiation, the principal cutaneous carcinogen. Treatment of pruritus in the past with radiotherapy or tar preparations, and the use of radiotherapy for gynaecological malignancy, carry theoretical hazards and can occasionally be incriminated in carcinogenesis. However, they do not appear to have influenced greatly the frequency of perineal tumours. Post-granulomatous scarring is an important back-

ground to perianal malignancy in some parts of the world, and other chronic inflammatory processes, such as LS, are a potential hazard. There are cases where condylomata acuminata have preceded SCC of the anal or perianal skin [3,4] and HPV has become a major suspect in the precancerous process.

Porokeratosis

Anogenital porokeratosis of Mibelli is rare, but classic lesions have been found on the penis, scrotum and in the natal cleft. Ulceration may occur [5]. Porokeratosis may be confused with psoriasis, Bowen's disease, granuloma annulare or LP. Histopathology confirms the diagnosis [6].

Anal intraepithelial neoplasia

Anal intraepithelial neoplasia (AIN) describes full-thickness dysplasia of the anus and perianal skin [7]. It can present relatively asymptomatically as red, shiny or scaly patches like Bowen's disease, or as warty lesions like BP. AIN is frequently associated with homosexuality, anal warts, HPV and HIV, although it is not a prominent feature of other conditions involving immunosuppression. Women with anogenital Bowen's disease have an increased risk of intraepithelial neoplasia or invasive malignancy elsewhere in the genital tract [8,9], and a full gynaecological examination is thus obligatory in such cases. The risk of AIN progression to carcinoma may not be as low as originally thought [10]. Immunoreconstitution with highly active antiretroviral treatment (HAART) may not achieve regression of AIN [11]. Routine screening of the HIV-positive patient with anal cytology is advocated [11]. Treatment options are similar to those for PIN (see p. 71.39). Topical imiquimod shows promise [12]. Expert proctological advice should be sought. Relapse is common.

Carcinoma of the anus

Anogenital squamous carcinoma is sometimes called epidermoid carcinoma. Fifty-six per cent of all anal carcinomas are of the squamous variety [13]. They are slightly more common in women, but seem to be more aggressive in men [14]. In Denmark, the incidence of anal carcinoma has tripled since 1960 to 0.74 cases per 100 000 population [15].

Although associations with smoking, cervical intraepithelial dysplasia and changing sexual habits, including homosexual anal intercourse, have been postulated [15,16], and coexistent Crohn's disease has been said to be associated with a 10-fold increase in anal carcinoma [17], the aetiology is not clearly understood. HPV is implicated [18,19], especially in verrucous carcinoma (see below) [20]. Anal carcinoma is often associated with a history of anogenital warts. More than 90% of anogenital condylomata contain HPV 6 or 11, although these subtypes are not associated with cancer, and it is rare for condylomata to contain HPV 16, which has a well-documented association with anal carcinoma. Homosexual men have a higher incidence of both perianal warts and anal carcinoma (both *in situ* and invasive), and this may be related to receptive anal intercourse [16], and HPV as well as other sexually transmitted diseases such as gonorrhoea, herpes simplex and *Chlamydia trachomatis* infection [21]. These infections are also risk factors for anal carcinoma in heterosexual men and women, as is cigarette smoking [22]. A role for seminal fluid prostaglandins in homosexual anal cancer has been proposed [23]. Immunosuppression, including by HIV infection, is a risk factor for AIN and anal cancer [24] (see Chapter 35: increased risk ×50). A case of Peutz–Jeghers syndrome associated with anal squamous carcinoma has been reported [25].

Diagnosis can present difficulties. Symptoms may include bleeding, pain, presence of a mass and change in bowel habit. Examination will reveal a hard mass that may be flat, raised or polypoid [26]. Squamous carcinoma should be suspected in all noduloulcerative anal and perianal disease, especially in the context of LS, LP, hidradenitis suppurativa, intraepithelial neoplasia and immunocompromise.

Regarding the differential diagnosis [27], it must be appreciated that anal carcinoma often presents with similar symptoms to benign anal lesions such as piles and fissures (pruritus, discomfort or pain, and bleeding). The most common tumours of the anal margin are viral warts, which are distinguished by their multiplicity, their lack of induration and ulceration, and their rapid evolution. Rarely, these may give rise to anal carcinoma [28]. Syphilitic condylomas are also multiple and not indurated. A syphilitic chancre of the anal margin or canal may be more easily mistaken for carcinoma. Amoebiasis and tuberculosis must also be considered. The differential diagnosis includes the manifestations of intraepithelial neoplasia (and the differential diagnosis of these), erosive or ulcerative sexually transmitted disease, basal cell carcinoma, Kaposi's sarcoma, hidradenitis suppurativa, Crohn's disease, pyoderma gangrenosum and artefact. The differential diagnosis also includes ischiorectal or perianal abscess [29–31]. Colorectal assessment should be sought. Proctoscopy and sigmoidoscopy are necessary to exclude anorectal cancer [29–31].

An important consideration in the management of anal carcinoma is the preservation of sphincter function, and this frequently involves combined radiotherapy and chemotherapy [32,33]. Surgical excision of the tumour, and of the inguinal lymph nodes when these are involved, is the treatment of choice. For small, well-differentiated tumours, particularly adenocarcinomas, a local excision and repair is the ideal. Small squamous carcinomas may respond well to radiotherapy. Lymphatic or haematogenous dissemination of anogenital cancer dictates individualized multidisciplinary management. The prognosis for anal carcinoma is variable [33].

Extramammary Paget's disease

Extramammary Paget's disease (EMPD) is discussed in Chapter 53. Perianal EMPD is a rare but important diagnosis [1]. Seventy-three per cent of cases of EMPD present as pruritus ani [2,3]. The association with an underlying malignancy is variable. Two reviews of the literature revealed only a 25% association [4,5]. Despite this, a search for a primary adenocarcinoma of underlying secretory glands should be carried out in perianal EMPD [6]. In some cases, the primary tumour is an anorectal, or even more distant, carcinoma [7,8]. The primary tumour and the Paget's cells in the epidermis are usually mucus-secreting. Paget's cells are generally believed to be derived from sweat gland epithelium [9]. Anorectal carcinomas (see below) may arise from rectal mucosa or from the intramuscular glands. In the latter case, the malignant cells may track to the buttock through the ischiorectal fossa, and the Paget's plaque may begin at a distance from the anal margin, rather like an ischiorectal abscess. Topographical studies have shown that the plaque of Paget's disease is much larger than the visible lesion [10]. Extensive surgery may be necessary, with micrographic margin control and plastic repair [11]. Photodynamic therapy and laser treatment have been used [12].

Miscellaneous malignancies

Extramucosal anorectal carcinoma may present as an inflammatory rather than a malignant condition (e.g. as a chronic fistula-*in-ano*) and so is not biopsied (or not biopsied deeply) and the diagnosis is missed or delayed; there are many cases in the literature of cancers arising from anal glands adjacent to the anorectal wall and not emergent from the mucosa [1]. The pattern of the intramuscular glands and of the wide range of tumours that arise from them resemble genitourinary rather than intestinal endothelial structures and cancers [2].

Cloacogenic carcinomas constitute only 2–3% of anorectal cancer, but may behave aggressively [3]. They derive from remnants of the cloacal membrane proximal to the pectinate line where there is an area of 'transitional mucosa' (between keratinized and non-keratinized squamous epithelium) penetrated by the anal glands. It may on occasion mimic a basal cell carcinoma both in clinical and histological appearance [4]. Most rectal cancer is adenocarcinoma (columnar epithelium).

Although basal cell carcinoma is the most common type of skin cancer, it is rare in the anogenital area, but over 100 cases have been reported [4,5]. Anorectal melanoma accounts for only 1% of all tumours of this area [6]; it may occur concomitantly with melanosis of the gastrointestinal tract [7].

Anogenital Kaposi's sarcoma is essentially an HIV-related problem.

Fibrosarcoma, haemangiopericytoma, leiomyosarcoma, malignant fibrous histiocytoma, epithelioid sarcoma, dermatofibrosarcoma protuberans and spindle cell sarcoma may occur, presenting as painful or painless nodules, masses or swellings [8]. Other rarities include Merkel cell carcinoma [9], malignant eccrine poroma [10] and malignant schwannoma [8,11].

Non-Hodgkin's lymphoma of the perianal area has been described in HIV/AIDS [12].

Perianal infiltration, ulceration or abscess occurs in 5% of haematological malignancies [13]. Chronic lymphocytic leukaemia has presented as a painless firm white mass at the anal orifice, associated with weight loss and inguinal lymphadenopathy [14]. Perianal ulceration and suppuration have been reported as the presenting manifestations of primary lymphoma of the anus [15].

Perineal/perianal metastases from transitional cell carcinoma of the distal urethra [16], from rectal carcinoma [17], and from epidermoid anal canal carcinoma [18] have occurred. Carcinoma erysipeloides has been observed in the perineum and on the thigh in carcinoma of the bladder and prostate [19].

A periorificial form of Langerhans' cell histiocytosis/eosinophilic granuloma may cause ulcerating and vegetating lesions within the anal canal and in the perianal skin [20,21].

Miscellaneous

Effects of topical corticosteroids

The prolonged use of potent topical corticosteroids for inflammatory conditions of the groins or perianal area can produce misleading appearances. Tinea incognito [1] is well recognized, but a persistent, deep, livid erythema of the perianal skin may not be regarded as primarily infective. Striae occur readily on the upper and inner thighs. Multiple perianal comedones followed the application of a topical corticosteroid for 3 years [2].

Chronic perianal pain and the 'perineal syndrome'

A number of names have been given to sensations of pain localized to the anogenital region in the absence of evident organic cause [3,4]. Proctalgia fugax affects young adult males, and occurs chiefly at night in the form of a sudden cramp-like pain, which resolves in a few minutes. 'Coccygodynia', 'descending perineum syndrome' and 'chronic idiopathic anal pain' chiefly affect females. The pain is described as dull and throbbing. In 35 such patients, it was noted that the pain was precipitated by sitting, and that these three conditions differed from proctalgia fugax [3]. Electrophysiological studies gave variable results. There was a high incidence of previous sciatica and damage to the pelvic floor musculature. Results of treatment were disappointing. Rarely, sacral cysts and even chordoma can present with this symptomatology.

Such patients will present to surgeons or gynaecologists; however, dermatologists may be confronted by a similar problem in which a patient complains of short-lived episodes of intense burning, which may be accompanied by sweating, limited to the perineum or occasionally the scrotum. Attacks occur without warning, but may be brought about by a full rectum. In one patient, the attacks were severe enough to cause him to stop walking for some minutes. The patients tend to be stressed individuals, as are those with proctalgia fugax [4]. The skin is entirely normal.

The mechanism is unknown. Two patients appeared to have been helped by propantheline, suggesting a cholinergic mechanism [5]. However, the condition may also fall into the group of 'dermatological non-disease' [6], in which the perineum was affected in eight out of 24 patients. It has also been reported in children suffering from intrafamilial stresses [7] (see also pp. 71.51–71.52 and 71.81–71.82).

Umbilical dermatology

Introduction

The umbilicus is considered here for convenience. Although the umbilicus is not strictly part of the anogenital apparatus, its evolution and connections link it to the pelvic region.

Structure and function

At birth, the umbilical cord contains two arteries and a vein, the rudimentary urachus (allantois) and the vitelline (omphalomesenteric) duct, enveloped in Wharton's jelly. After separation and retraction of the stump, an umbilicus of variable depth is formed. Persistence of the urachal or vitelline ducts at this 'carrefour embryologique' may cause trouble in early or later life. A deeply retracted umbilicus may be the site of infection or foreign bodies.

Congenital and developmental abnormalities

Such abnormalities are all rare, but more common in males, and usually brought about by failure of obliteration of the omphalomesenteric duct or urachus [1]. They present as sinuses, fistulae, cysts or polypoid tumours.

Patent urachal duct

The umbilical opening is lined by skin or a pouting mucous membrane. Urine may be seen to escape from it, particularly in the elderly, when an obstruction to micturition exists.

Persistent vitelline duct and polyp

If a connection with the intestine persists, it may become inflamed or cause a faecal umbilical discharge. More commonly, the remains of the duct give rise to a polyp in later life [2]. This may be accompanied by intermittent bleeding or a more persistent mucoid discharge, sometimes profuse. A symptomless, sterile umbilical discharge should always arouse suspicion. The histopathological features are those of intestinal mucosa. It may be mistaken for a pyogenic granuloma [3].

Periumbilical 'choristia'

Under this title (meaning dysgenetic translocation of tissue), Bellone *et al.* [4] described extending, crusted, erythematous, periumbilical plaques, in which islands of intestinal mucosal cells were found in the epidermis.

Omphalocele

This form of abdominal hernia appears to be more common in African people. In 5 years in Ibadan, 33 cases were seen [5]. The minor form is caused by herniation of the umbilical cord; a major form is probably because of a fault of embryonic folding of the fetus.

Trauma and artefact

The umbilicus in the newborn

Haemorrhages may occur from slipped ligatures. The cord normally separates within a week of birth, and the raw surface is epithelialized by day 15. During this time, the umbilicus is prone to infection, especially in maternity hospitals and nurseries. Impetigo (pemphigus neonatorum) or, rarely, more severe bacterial infections may occur (see below). The 'absent navel' syndrome has been described as a sign of dystrophic epidermolysis bullosa [1].

Talc granuloma

This lesion, which is probably more frequent than is recognized, occurs in infants and very young children. It is distinguished histologically from a pyogenic granuloma (on which it may supervene) by the doubly refractile talc crystals [2].

Pyogenic granuloma

This is a dull-red fleshy polypoid lesion, often pedunculated. Bleeding readily takes place from trauma. If it occurs early in life, it may be confused with a capillary haemangioma.

Ileoumbilical fistula

This may follow laparotomy for Crohn's disease, or may rarely occur spontaneously [3].

Omphalith

In deeply set umbilici, an accumulation of sebum and keratin may lead to the gradual formation of a hard, stone-like mass, which may remain unnoticed for many years until discovered accidentally or revealed by secondary infection or ulceration.

'Spontaneous gangrene'

This can occur without catheterization, possibly owing to minor trauma to the umbilicus [4]. Very rarely, the bladder and kidney may also be involved.

Unilateral skin necrosis of the buttock has been reported following indwelling umbilical artery catheterization [4–6], probably caused by thrombosis leading to occlusion of the inferior gluteal artery. A similar case was caused by misdirection of the tip of the arterial catheter [7].

Inflammatory dermatoses

Eczematous conditions and psoriasis

Allergic contact dermatitis is usually brought about by medicaments. Irritant dermatitis from soap and quaternary ammonium compounds also occurs. Psoriasis commonly involves the umbilicus. A urachal sinus has presented as periumbilical dermatitis [1].

Miscellaneous inflammatory dermatoses

A pilonidal sinus may occur [2]. Granulomas [3] may present as such, or with an associated discharge, infection, bleeding or profuse sterile purulent exudate. The umbilicus is not infrequently involved in bullous and cicatricial pemphigoid; it may be the site of presentation of the latter (see Chapter 40).

Perforating pseudoxanthoma elasticum occurs in the umbilicus, and was the only site involved in six obese, multiparous, American black females [4]. It is only rarely associated with systemic problems [5,6].

Pregnancy, Addison's disease and other pigmentary disorders increase the pre-existing pigmentation. Acanthosis nigricans causes acanthotic and papillomatous lesions in the perineum. Periumbilical staining (Cullen's sign) occurs in acute pancreatitis, and occasionally in ruptured ectopic pregnancy or with duodenal ulcer perforation [7].

Umbilical haemorrhage has been described as a complication of cirrhosis following gross ulceration of the umbilical vein [8].

Infections

Infection of the umbilicus in the newborn used to carry a high mortality. It still occurs in some countries. A number of bacterial organisms may be responsible, but staphylococcal, *Pseudomonas* and clostridial species [9] are the most important. Minor forms consist of oozing, crusting and cellulitis, but a spreading oedematous erythema, progressing to necrotizing fasciitis, is of very serious import. Septicaemia and its complications may supervene [10]. At any time in later life, but usually after middle age, the umbilicus may be the seat of intertrigo or candidosis. This is more common in the obese or in those with poor personal hygiene. Genital and perianal warts can occasionally be associated with similar lesions within the umbilicus [11]. Foreign bodies, inserted by children or psychotics, may be overlooked as a cause of purulent infection in a deeply set umbilicus. The periumbilical skin is a common site of schistosomiasis when it affects the skin [12]. Disseminated strongyloidiasis has presented with subumbilical excoriations [13] and periumbilical purpura, where larvae were demonstrated in the skin biopsy [14].

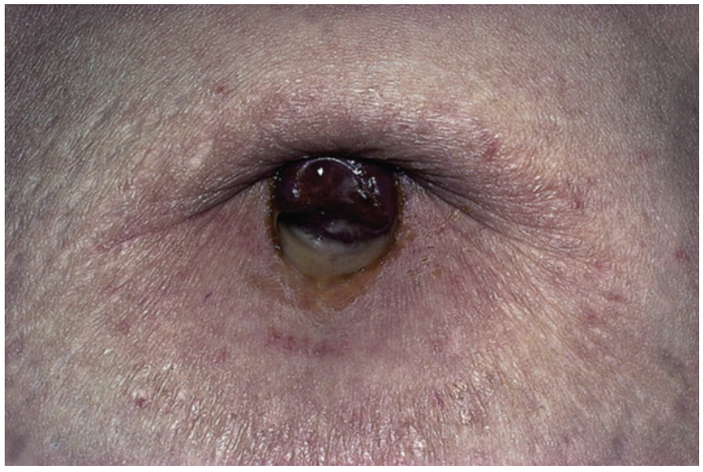

Fig. 71.46 'Sister Joseph's nodule'. (Courtesy of Dr J. Marks, Newcastle-upon-Tyne, UK.)

Tumours and implantations

The umbilicus is a site of implantation of endometriomas [15], which may clinically resemble melanomas. A unique case of postoperative endosalpingosis has also been reported [16]. Colonic mucosa was implanted in an infant, after colostomy for Hirschsprung's disease [17]. A single case of carcinoid of the umbilicus has been noted [18]. Extramammary Paget's disease has also been recorded [19,20].

Skin metastases from neoplasms of the digestive tract occurred in only 3% of 2187 cases [21], but the umbilicus is a characteristic site, especially for cancer of the stomach (Sister Joseph's nodule) (Fig. 71.46), which was the primary source in 33 out of 40 cases [22]. The ovary, uterus and colon are responsible for most of the others [23–25], but origins from pancreas [26], prostate [27], leiomyosarcoma of the small intestine [28], and malignant peritoneal mesothelioma [29] have been described. The lesions usually present as firm, irregular nodules, but can occasionally infiltrate diffusely, or ulcerate and produce a fetid discharge. Such metastases were the presenting sign in 18 out of 40 cases, and were a major diagnostic feature in 28 cases [30]. The prognosis is always poor, but not entirely hopeless [31]. Histological identification of the site of the primary tumour may be difficult, and proved possible in only 21 of 85 cases [32,33]. Fine-needle aspiration of the nodule is not particularly helpful in reaching a diagnosis [33]. CT and surgical intervention are obligatory, because it may represent the earliest and only metastasis [25].

The dermatology consultation

What do patients want?

Over the last 60 years there has been a fundamental shift in the power balance in medical consultations. The traditional model for the doctor–patient relationship consisted of the patient in relative or total ignorance of health matters seeking both basic information about their disease and trustingly accepting whatever advice the doctor gave. Every clinician knows that there still are some consultations where this is still the model—sometimes appropriately in certain social or cultural circumstances. Many consultations today, however, are based on a relationship of mutual respect, but on the patient's side informed by prior knowledge about the disease and on the doctor's side a realization that options of management need to be discussed so that a joint agreed approach to investigation and management needs to be reached after explanation, discussion and negotiation. Growth in the understanding of the impact of skin disease on quality of life has led to the concept of 'patient-centred care' [1], with an emphasis on effective two-way communication in dermatology consultations. Trust in the doctor's knowledge and skills has to be earned from each patient rather than being taken for granted. Greater attention to, and investing greater time in meeting, patients' expectations may not only be of benefit to the patient, but help you to be a happy dermatologist [2]!

Insight into patients' attitudes and needs from the consultations may be gained from work carried out in primary care. In a survey of patients' priorities in the consultation, the most valued attributes of care in order were: a thorough physical examination; seeing a physician who knew them well; seeing a physician with a friendly manner; having a reduction in waiting time of one day; and having flexibility of appointment times [3]. High value was also placed on interest being shown in patient's ideas, enquiry about patient's social and emotional well-being and involvement of the patient in decision making. However, in an examination of the value placed by patients on shared decision taking in primary care, patients valued a 'doctor listens' attitude and easily understood information above shared treatment decisions, more information and longer consultation time [4]. A Swiss study on shared decision taking revealed that 66% of patients supported leaving decision making concerning acute respiratory tract infections to their general practitioner [5]; the nature of the decision being taken may influence the desire of the patient to be involved.

Jobling [6] stated that patients with skin disease wish for 'a sound diagnosis, clear information, and unambiguous, practical and realistic advice on what can and should be done about it, if anything, forming the basis of a joint decision'. In a survey of over 2000 patients and parents of patients with atopic eczema, expectations of the initial consultation with the dermatologist included (in order) different or better treatment, more detailed information about eczema, confirmation of the diagnosis, more detailed advice on the use of treatment, to be cured and reassurance [7]. From the doctor's perspective [8], dermatology patients would seem to need understanding, knowledgeable carers and staff who care;

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

they also need to be able to express their concerns and have their worries allayed. However, when dermatology patients were actually asked what was most important to them, the attribute of greatest importance was the expertise of the doctor, followed by thorough care and convenience [9].

From the perspective of a clinical dermatologist, the aspects of patient consultation that seem to provoke that most positive patient feedback are listening and showing evidence of listening, taking interest in specific items brought to the consultation by the patient (such as written lists of preparations used, photographs of the rash, press cuttings or Internet printouts), thoroughly examining the patient and tactfully offering to examine affected areas that the patient may have been to embarrassed to mention. Giving clear information about the diagnosis, backed up by written information, is, of course, important but sensing and addressing unspoken concerns is probably the most appreciated aspect of a successful consultation. Stating clearly that a skin problem is not cancer and does not imply any cancer risk is very reassuring, and is important to remember in situations where to the dermatologist it is obvious that there is no malignancy potential. Similarly, stating clearly that there is no risk of infection or of other members of the family 'catching' the condition may simply address the patient's main worry.

How can dermatologists encourage patients to communicate better with them? Patients often feel inhibited from asking questions—they are aware that the clinic is busy, time is limited, or the doctor does not look them in the eye or frequently interrupts [10]. Patients may be helped to get the most out of a consultation by the use of written prompts [11], but patients may not want to be labelled difficult and doctors may perceive such prompting as leading to excessive consultation time. The questions most frequently asked by patients with atopic dermatitis were identified and used to create a patient information leaflet and an interview prompt form for use by patients [12]. Such 'tailor-made' prompts may be helpful to improve patient satisfaction and communication. However, even if communication is good during a consultation, the patient may not recall later much of what was said. All patients who received a copy of the letter written by the dermatologist to the general practitioner found this useful [13]; there was an increased feeling of involvement in health care decisions and improved recall. This exercise was carried out at low cost. However, when given the opportunity to request copy letters in a trauma and orthopaedic clinic, only 0.3% of patients actively requested copies [14].

Despite a growing awareness of the importance to patients of the effects of skin disease on their lives, quality of life discussion was absent in 40% of routine general dermatology consultations monitored [15]. There was a relationship between type of decision taken at psoriasis consultations and the mean impairment of quality of life score of groups of patients in whom that decision type was taken [16]. However, there was a wide variation in scores of patients within each decision category, suggesting that in some patients inappropriate decisions may have been taken as the dermatologist was not aware of the extent of the patients' life quality impairment.

Given the central importance of patients' attitudes and the impact of skin disease on the emotional health and quality of life of dermatology patients, it is of concern that currently there is little or no formal training in communication skills or psychotherapy in the training of most dermatologists. Many dermatologists become from experience 'amateur psychodermatologists' building their insights into the patients' problems constructively into their routine consultations. However, there is a body of basic knowledge that should be incorporated into routine dermatology training [17], and some patients would benefit from seeing dermatologists with a specific extra training in this field. The psychological needs of patients with melanoma, for example, can be challenging [18], and there should be special education specifically for managing this group of patients.

It is important for dermatologists to have some insight into aspects of diseases that are not necessarily mentioned by patients, but which may influence their attitudes and compliance. About 15–20% of patients attending dermatology outpatients have used complementary and alternative medicine to treat their skin problem [19,20]. It may be helpful for dermatologists to raise this issue in consultations.

In larger teaching hospitals it is common for undergraduate or postgraduate dermatology students to be present during some outpatient consultations. The presence of students may influence the nature of the consultation. It is reassuring that 94% of patients enjoyed the interaction with a medical student and were comfortable disclosing information [21], however 22% of patients also wanted time alone with the physician; 99.5% of patients were satisfied with a trainee dermatologist participating in their care [22].

There have been attempts to understand patients' attitudes towards consultations delivered by or involving teledermatology. There is a high acceptance of real-time teledermatology consultations [23]. Key aspects of the outcome of the consultation, such as receiving a diagnosis, treatment and adequate explanation, lead to satisfaction, rather than whether or not the consultation was face to face or a teleconsultation [24]. A nurse-led store and forward teledermatology clinic was found to be convenient, but 40% of patients, and especially those with poor health-related quality of life, would have preferred to have had a face to face consultation with a dermatologist [25]. It seems, however, that for many patients being directly with a dermatologist for the consultation is not the highest priority.

In fact, for many patients with skin problems, having advice from a dermatologist in any format is not necessarily the priority. Slightly greater satisfaction has been reported by selected patients from consultations with general practitioners with a special interest in dermatology, compared to consultations with dermatologists. Aspects of the consultation such as greater accessibility and timeliness were of greater importance to the patient than the choice of who provided the advice [26].

In many dermatology practices worldwide, patients may come from a variety of cultural and linguistic backgrounds. It is obvious, but worth stating, that if the dermatologist and patient are not fluent in the same language, the quality of information flow will be inhibited. The use of translators will contribute but patient dissatisfaction, non-compliance and poorer clinical outcome may result from language problems [27].

Chren suggested a series of questions that should be addressed if we are to be able to critically assess the effectiveness of a der-

matology consultation [28]. These include 'Were the goals of the intervention defined explicitly?', 'Do the outcomes measured and evaluated reflect these goals?' and 'Was accurate and unbiased measurement of these outcomes performed?' We should indeed consider how we could better assess the effectiveness of our consultations.

Risk–benefit analysis and communication of risk

When a therapeutic decision is taken in dermatology, there is nearly always an assumed or overt analysis of the risk to the patient of the planned course of action compared with an assessment of the likelihood and magnitude of possible benefit. Very often the risks involved are very low and the benefits are considerable, for example the risks of developing an allergic reaction to an emollient compared to the emollient reducing the shedding of scales and embarrassment of psoriasis. However, more concerning risks are frequently encountered, such as the 'known' risks of skin cancer following UVB phototherapy; an extensive literature review counter-argued that UVB phototherapy remains a very safe treatment [1]. Dermatologists frequently face the major twin problems of having to take decisions where the absolute risks of the therapy are not known and where the likely benefit has not been quantified. In addition, methods to communicate risk to patients in an understandable and meaningful way are not well developed in dermatology. Even basic drug information provided by dermatologists is deficient when topical medications are prescribed [2].

When new drugs are developed, vast resources are used to try to demonstrate their safety. However, most of the safety data submitted at the time of registration of new therapies is based on data from within controlled clinical trials, with their strict entry criteria. It is only when drugs are used widely in the community that some side effects become apparent. This is why postmarketing surveys and side-effect reporting systems are so important. Another systematic approach to gathering information about the real risks of therapies is through creating national registries, such as that for psoriasis patients treated with the biological therapies [3]. When psoriasis patients' views were sought about the balance of risks and benefits of systemic therapies, they prioritized low risk of skin cancer and liver damage [4]. This view reflects the views of British dermatologists who considered that the risks of skin damage, followed by the risks of skin cancer, are the most important side effects of therapies for psoriasis [5].

The problems of risk–benefit analysis are not, of course, only related to drug therapy. Clinical decisions about congenital melanocytic naevi, for example, with associated costs, may be taken because of concern about malignancy risks that might in fact be low [6].

It is now possible to measure risk communication and decision making effectiveness in consultations [7], though little work has yet been carried out in dermatology [8]. Where attempts have been

made in other medical disciplines to improve risk communication through counselling, the supportive or emotional aspects of the counselling were of more benefit than the giving of information [9]. Training of doctors in risk communication in general practice did not increase doctors' confidence in risk communication. Consultation time constraints were of greater importance than lack of training in providing better risk communication with patients [10]. Before advocating the devotion of resources to try to improve risk communication in dermatology it will be important to establish that such intervention improves outcomes such as patient satisfaction with consultation; in general practice this has been difficult to establish [11].

Factors influencing clinical decision taking

If decision taking in clinical dermatology were a straightforward process of applying textbook guidance about therapy or national guidelines across all patients, life would be simple. The reality is that every patient (and doctor) is different and there are many unquantifiable and unrecognized influences on daily decision taking which make the process much more complex than the narrow application of evidence-based medicine. Some of the wider influences on decision taking, listed in Table 72.1, include patient-related factors, cultural considerations, patient's family and work aspects, geographical and economic aspects, doctor-related factors, type of health care provision and pharmaceutical company activities. It is the interplay of these multiple factors that provides the daily and infinite range of clinical challenges, still best described by the concept of 'the art of medicine'.

Communication of bad news and realistic prognosis

In many dermatology consultations it is necessary to communicate bad news; a newly diagnosed disease may be chronic rather than curable or a lesion may malignant. The ability to successfully

communicate bad news involves many skills, including respect, tact, empathy, support and information precision [1]. Ideally, consultations where significant bad news is given should be planned for and include follow up [2]. 'Hit and run' deliveries of bad news should be avoided [3]. Physicians should sit and not stand when giving bad news; physicians who sit are perceived by patients as more compassionate [4]. The involvement of family members is of great importance when giving bad news, as the lives of partners and other close family members (the 'greater patient') are likely also to be affected by bad news for the patient. Their contribution to the subsequent caring for the patient is important, and their own needs should not be forgotten. When patients are told about a diagnosis of malignant melanoma, the subsequent psychological morbidity is related to the methods of communicating the news [5]. The following were linked to lower anxiety: preparing the patient for a possible diagnosis of cancer, having people wanted by the patient present, giving as much information as desired, providing written information, discussing the patient's questions the same day, talking about the patient's feelings and being reassuring.

Patients want to know the likely long-term outcome of their skin disease: what can they reasonably expect and what do they need to plan for? In some aspects of dermatology practice, especially concerning skin malignancies, there are good data available about overall cure rates and life expectancy. However, the prognostic data over many inflammatory skin diseases are poor, despite their high prevalence. In many situations, insufficient long-term population-based studies exist to give accurate long-term prognosis. The clinical practice of dermatologists is usually selective as of course those patients with the most severe and intractable disease are seen most frequently; 'clinical experience' as a guide to prognosis may therefore be unwittingly biased. While endeavouring to use the most accurate data available, it is important to be honest with patients about the deficiencies in knowledge about prognosis. Beware of giving specific times without cautionary explanation, as patients easily misinterpret 'average' data as being related to them individually.

Concordance (compliance/adherence) with therapy

Hippocrates warned that '(the physician) should be aware . . . that patients often lie when they state they have taken their medicine'. Dermatology patients may not deliberately lie, but there may be many reasons why patients do not carry out a therapy regimen. It is essential that the clinician understands these potential difficulties and takes steps within the consultation to plan therapy which is practical and with which the patient agrees. Although it is self-evident that lack of using therapy will result in lack of effectiveness, it has been demonstrated that there is a direct relationship between better medication adherence and greater reduction in severity, at least in the topical therapy of psoriasis [1]. The terms 'concordance' or 'adherence' are now preferred over 'compliance', as the concept of compliance with treatment implies a patient passive in the treatment decision process—a situation likely to ensure inadequate or inappropriate use of therapy. Concordance issues are of relevance to practically every dermatology consultation [2]. This subject has, however, even wider implications than the issue of optimizing care for individual patients; unless compliance rates are understood, the calculation of cost–effectiveness of different therapies is likely to be inaccurate [3]. Serup *et al*. [4], Hodari *et al*. [5] and Lee and Maibach [6] have reviewed the broader dermatological and Richards *et al*. [7] and Feldman *et al*. [8] the psoriasis specific aspects of adherence. Although the consideration of concordance issues in dermatology usually focuses on topical therapies, other important therapies, such as the use of compression in the treatment of venous leg ulcers, are also often ineffective because of lack of adherence [9].

Monitoring and realities of adherence

When systemic drugs are used in an outpatient setting in cardiology and internal medicine clinics, there are widespread discrepancies in drug usage, with 76% of patients not taking the planned medication correctly [10]. The likelihood of a patient taking oral medication as planned is inversely proportional to the number of times per day that the drug should be taken [11]. There are similar problems with patients using topical preparations [12]; moreover, adherence to topical therapy may be much worse than to systemic therapy [13]. The scale of this issue was emphasized by two studies from Copenhagen which showed that 30% of patients did not collect their medication after receiving a prescription [14] and that most first-time patients with skin conditions under-dose new topical treatments, using a median of 35% of the appropriate dosages [15].

Surprisingly, adherence to prescribed topical preparations may not be 100% even in the supervised conditions of an in-patient dermatology ward [16]. Even in a controlled research setting, when a patient is asked to record the therapy used for skin disease there is poor correlation between reported treatment use and weighed ointment usage [17], with patients self-reporting almost twice the usage as that calculated from weighing used tubes [18]. Electronic monitoring of treatment containers ('the spy in the tube') has also revealed that patients over report adherence in patient logs [19]. The use of such devices allows a more precise method of adherence measurement in clinical trials [20] and has shown that even in the special circumstance of a clinical trial, where high motivation and encouragement about adherence to therapy might be expected, during a clinical trial of topical therapy adherence declined from 85% to 51% over 8 weeks. In a routine clinic setting in which electronic compliance monitoring was not revealed to the patients, there was very poor (32%) compliance in children treated for atopic dermatitis [21].

Influences on adherence

Influences on adherence include the degree of motivation of patients, the extent to which their quality of life is impaired by their disease and the attitude of the patient towards their disease and their relationship with their doctor [22]. In psoriasis, the greater the impairment of life quality of a patient, the poorer the compliance with treatment [23]. Being female, married, employed and not paying for prescriptions were all associated in psoriasis with increased medication adherence and higher life quality. Higher adherence also seems to correlate with increasing years of age [20]. In acne, young females with greatly impaired quality of life and males with little impairment of quality of life are especially prone to non-adherence [24].

A longitudinal study [25] has shown that dissatisfaction with care and psychiatric morbidity are significantly and independently associated with poor medication adherence; the physician's interpersonal skills play a major influence in medication adherence. The strongest predictor of adherence to skincare treatment in childhood atopic dermatitis is a good doctor–patient (mother) relationship [26]; the study draws attention to the crucial role of relatives in adherence. However, this role may not be confined to atopic dermatitis. A range of skin diseases may result in the quality of life of partners and families of patients (i.e. the greater patient) being severely affected [27]. As these close family members are likely to play some role in helping the patient with treatment, they need to be involved in discussions aimed at improving adherence.

Factors associated with poor adherence

There are particular cultural and age-related issues in trying to maximize the likelihood of adolescents taking medication effectively. This is of particular relevance to acne therapy [28]; the use of topical therapy that has a more rapid onset of action is likely to be an advantage in increasing its usage. It is also important to give patients a realistic idea of how quickly they are likely to experience benefit, to try to avoid patients giving up on therapy before a drug has had a chance to work. Key influences in the compliance of acne patients in attending follow-up clinic appointments were gender, race, method of payment and type of treatment [29]. Although attendance at clinics may not necessarily correlate with use of therapy [29], in another acne study being female, married, employed and not paying for prescriptions were all associated with increased medication adherence [30].

Quality and frequency of topical applications

In a study of over 1200 patients with psoriasis across Europe, the main reasons for non-compliance were that the treatment 'was too sticky', 'does not work' and 'takes too long to rub in' [31]. This study emphasized the great importance of cosmetic acceptability in the successful treatment of psoriasis. Other factors that are likely to improve adherence with therapy include patient education about how to apply topical preparations and the use of as few different preparations as possible. Realistic and simple regimens with, preferably, once-daily applications are much better than regimens with frequent applications, but a simple manoeuvre such as using a cream in the morning and an ointment at night may improve adherence [32].

Topical corticosteroids

When topical corticosteroids were introduced into clinical practice in the 1950s their great benefit to patients with inflammatory disease was immediately apparent. It is unlikely that the phobia surrounding their use, especially in children, would have been predicted. The phobia comes from a lack of understanding about the different potencies of corticosteroids available and a concern over side effects, the risk of which is minimal if they are used correctly. Lack of understanding may lead to inappropriate under use and consequent poor control, especially of atopic dermatitis [33]. Surprisingly, however, the mother's anxiety about using topical corticosteroids did not influence reported use of topical steroids in a Japanese study [26]. Fear of side effects concerning the use of topical corticosteroids is not confined to childhood atopic dermatitis and parental anxiety. Adults with atopic dermatitis apply too little topical steroids and the use of appropriate amounts results in improved Severity Scoring of Atopic Dermatitis (SCORAD) scores [34]. Adults with psoriasis also deviated from steroid treatment instructions because of safety concerns [35]. Other reasons included frustration with medication efficacy and inconvenience of use. It is important that clinicians are aware of this issue and address it in discussions of advice about their use. An approach to improving treatment compliance in occupational dermatitis has been the concept of a specialist nurse led 'eczema school' to contribute to the education of patients and carers [36].

Patient attitudes and depression

Only 33% of patients with psoriasis who were asked to apply an ointment twice daily actually did so [12]. Patients with psoriasis who report that they have not complied with treatment are more likely to believe that both psoriasis and their treatment interfered with their quality of life [37]. Self-reported non-adherer patients with psoriasis demonstrate more negative views towards all aspects of health care [38]. In both psoriasis [23,39] and in acne [30] adherence with therapy is poorer the greater the severity of the disease. There is a strong correlation between the presence of depressive symptoms in older patients and lower rates of topical medication usage for psoriasis [40]. It is possible that having severe skin disease leads to poor life quality, which in turn leads to a degree of depression and a sense of 'giving up'. This may result in poor concordance with therapy and in turn further deterioration in the disease. Strategies are needed to break this negative feedback loop. It is likely that treatment failure is much more often due to non-adherence than has been previously recognized. It is encouraging that adherence to biological therapies appears to be higher than to other psoriasis medications [41].

Techniques in the clinic

A very basic problem concerning adherence is that physicians may not have insight into the frequency and extent of adherence issues in everyday consultations. A simple technique, the 'yesterday use' question, has been suggested [42] to heighten awareness and introduce the subject in a non-threatening way into a consultation. The patient is asked whether or not they applied any medication the previous day, and if so how often. However, adherence to topical therapy may increase around the time of visits to a dermatologist and so it has been suggested that the timing of follow-

up appointments could be chosen to try to enhance compliance [43]; increasing frequency of visits might increase adherence [21].

Realistic information

The use of therapy that gives early improvement is preferable but where this is not possible the patient must understand the reality of the likelihood of speed of improvement. The patient must have the opportunity to express concerns about treatment so that unfounded fears can be allayed. For patients with psoriasis, even more important than the speed of action of a topical treatment is the opportunity to be involved in the decision taking [44]. Joint discussion and decisions between doctor and patient should be taken; this involvement by patients in the decision process is critical to adherence [45]. Patients need information about possible side effects and how to handle them: for example if a patient is warned that there may be transient stinging, the patient may continue to use a drug instead of being alarmed and stopping it. Clear instructions should be given about how long a drug should be used for; this may reduce the possibility of side effects from over use of topical corticosteroids [35]. The cost and affordability of therapy is an obvious factor in many health care settings.

Strategies for improvement

There is a major challenge for dermatologists to identify those factors that contribute to non-adherence and to develop strategies that make it more likely a patient will use medication appropriately and in their best interests. Individualized patient education, continuous treatment support with assessment of medication-taking behaviour and developing better communication skills should all be considered [45]. Specific advice for psoriasis is given by Feldman *et al*. [8]. Where educational messages about the importance for renal transplant patients of sun protection were given in a specialist dermatological setting, there was a high compliance with sunscreen use and other sun-avoidance measures [46].

Better interprofessional communication and collaboration, especially between the pharmacist and other providers, are required [47]. It has been proposed [48] that pharmacy labelling of topical corticosteroids should reflect the low risk of harm from their use and that topical corticosteroid products should include clear 'fingertip unit' [49] instructions to guide patients on how much to use.

Elwyn *et al*. [50] have proposed a series of 'concordance tasks' for clinicians: elicit the patient's views on the possibility of having to take medicine; explore those views with the patient; inform the patient of the pros and cons of taking and not taking medicine; involve the patient in the treatment decisions—over time, if necessary, and after reflection. These concepts are closely intertwined with the encouragement of patient motivation. Richards and Fortune [51] have also suggested some practical, detailed strategies for the development of a collaborative treatment approach in psoriasis to enhance adherence. These involve strategies that enhance motivation for behaviour change, for strengthening commitment and for follow-through. A series of practical suggestions to improve compliance with the treatment of children with atopic dermatitis are given in Table 72.2 [52].

Table 72.2 Solutions to improve compliance in childhood atopic dermatitis [52].

Take longer with the first consultation
Write out instructions
Keep therapy simple
Make sure the parents can afford it
Ask about side effects
Go along with a desire to have the child allergy tested
Demonstration of treatment application
Motivation of child as well as parent
Support groups
Hospitalization
Follow up your patient
Be friendly

Measurement of disease

Why measure disease?

Skin disease is so visible that the drive for measurement of disease for basic clinical purposes has been slow. It is helpful, however, to be able to measure skin disease for several clinical reasons. Initial assessment of the clinical severity of skin disease is likely to influence clinical decision taking. Having comparative measures may be useful in patient follow-up to assess progress with therapy. Measures may also be helpful in the doctor–patient relationship to inform discussion of management decisions. For clinical research it is essential to be able to compare disease severity between patients and before and after intervention.

Historical perspective

Measurement methods in dermatology have been described from the 19th century, but interest has accelerated over the last 40 years [1]. Multiple non-validated techniques were used in the 1970s and 1980s for the assessment of psoriasis [2]. Over the last 20 years, most researchers have gravitated to using the same method (Psoriasis Area and Severity Index, PASI) and there has been the additional use of quality of life measures [3]. The use of non-invasive methods to measure various physical properties of the skin developed from the 1970s but only recently has the instrumentation become sufficiently user-friendly, available and reliable to envisage regular clinical use.

What can be measured?

When a patient is being assessed in the clinic, the clinician takes into account a variety of facets of information. These include key aspects of the patient's history, current symptoms, clinical signs and the impact that the patient is experiencing because of the disease. All of these aspects may potentially be measured. The most widely used methods focus on recording clinical signs, using semi-objective approaches.

Measurement methods

Inflammatory disease

The Dermatology Index of Disease Severity (DIDS) has been proposed [4] for use across all inflammatory skin diseases. It consists of assessments of functional impairment and of percentage of body surface area involvement, categorizing each patient into one

Table 72.3 Methods of psoriasis measurement.

Psoriasis Area and Severity Index (PASI) [6]

Six-Area Six Sign Atopic Dermatitis Severity Score (SASSAD) [37]
Patient Orientated Eczema Measure (POEM) [36]
Three-Item Severity Score (TIS) [39]
Objective Severity Assessment Atopic Dermatitis (OSAAD) [41]

of five stages. It has been tested in a wide range of dermatoses and shown to be responsive to change [5].

Psoriasis

A range of methods for psoriasis measurement is listed in Table 72.3. The most widely used system, the Psoriasis Area and Severity Index (PASI), was introduced as a methodology for a clinical trial of a retinoid [6] but without any supporting validation data concerning its repeatability or observer variation. It began to be widely used in the 1990s, despite evidence of its weaknesses [7]. The PASI system requires the observer to give separate scores for redness, thickness and scaling ('erythema, infiltration and desquamation' in the original description) for four body areas [6]. An estimate is made of the percentage area involvement in each of these areas and all scores placed in a formula to give an overall score from 0 to 72. The vast majority of patients with psoriasis have a score of less than 10. A self (patient) administered and validated method based on the PASI, the Self Administered PASI (SAPASI) [8], allows the possibility of measurement in large, population-based surveys [9]. There have been attempts to modify the PASI concept [10], but such suggestions have largely not been followed. The current reality is that the PASI system, although fundamentally flawed, is used so widely that it has become a way of comparing across all studies and so researchers are generally reluctant to choose alternative, though better, methods. There is considerable information about the concurrent use of the PASI, the most commonly used disease severity measure, and the Dermatology Life Quality Index (DLQI), the most commonly used quality of life outcome measure; patients in whom there is a very great improvement in PASI also show the greatest improvement in DLQI scores [11].

The simplest scoring system is the Physician's Global Assessment (PGA); this correlates reasonably well with PASI scores and may be suitable where a rapid and easy, global assessment is all that is required [12]. The Lattice System Global Assessment has been proposed [13] as an alternative and better-validated measure [14] than PASI. In the Lattice System there is an estimation of body surface area and of average plaque thickness, erythema and scale; the results are combined to reach an overall descriptor [13]. Another proposal is the Copenhagen Psoriasis Severity Index [15] in which erythema, plaque thickness and scaling are each assessed on a four-point scale at each of 10 sites, giving a score range of 0 to 90. By not involving assessment of area, the inherent inaccuracies of this are avoided.

The Salford Psoriasis Index (SPI) is an important contribution to the ongoing and as yet unresolved debate about the best way to measure psoriasis [16]. This measure acknowledges that there are three separate aspects to the assessment of a patient's psoriasis severity and it is meaningless to try to present these data as a single overall score. There are therefore three scores for clinical severity (based on the PASI), psychological impact (a simple overall score) and the history of the psoriasis, including for example history of admission for treatment. This concept of separate scores is analogous to the multiple score system used for staging some systemic malignancies. The SPI may be well suited to describing or categorizing patients. However, only the clinical severity and psychological scores are amenable to change following intervention.

Photographs may be used to record and to assess psoriasis. Where a panel of experts is used to assess photographs there is accurate and consistent global assessment [17].

There are special considerations to the measurement of psoriasis in specific sites such as the scalp or nails, or specific presentations such as pustular psoriasis of the palms or soles. The Nail Psoriasis Severity Index (NAPSI) has been used in several clinical studies [18] and there is information concerning interobserver error [19]; scoring for nail-bed features was more reliable than for nail-matrix features. A simpler variant of the NAPSI has been proposed [20,21].

Atopic dermatitis

A simple method to differentiate between mild, moderate and severe atopic dermatitis incorporated extent of disease, history and disturbance of sleep by itching [22]. This method has since been refined as the Nottingham Eczema Severity Score (NESS) and initially validated in pre-school children [23]. Although several different methods of disease measurement had been described by the 1990s, none was satisfactory [24]. A review of outcome measures of disease severity in atopic eczema identified 13 scales [25]. Only five had been tested for reliability; the most widely validated measure was the Severity Scoring of Atopic Dermatitis (SCORAD) index [26]. A more recent, systematic review identified 20 outcome measures and concluded that only SCORAD, Eczema Area and Severity Index (EASI) and the Patient-Orientated Eczema Measure (POEM) perform adequately [27] (Table 72.4).

SCORAD was created in 1993 [26] to meet the need for a validated methodology; there are further guidelines for its use [28] and experience of the practicalities of its use [29,30]. SCORAD brings together scores for clinical signs, disease extent and patient symptoms, including a question on sleep. However, subjective symptoms do not necessarily correlate well with sign measurement in atopic dermatitis [31] and the use of a modified 'objective

SCORAD' which omits pruritus and sleep is now recommended by the European Taskforce on Atopic Dermatitis [30,32].

The Eczema Area and Severity Index (EASI) can be learnt rapidly and used reliably in the clinical trial setting [33]; there is experience of its use in a large study [34]. A self-administered version of EASI has been validated [35].

The Patient-Orientated Eczema Measure (POEM) [36] is completed by patients and incorporates seven symptoms: itchiness, sleep, bleeding, weeping or oozing clear fluid, cracked skin, flaking, dry or rough. The frequency of each over the last week is recorded, giving a total score of 0 to 28. The POEM score correlates well with quality of life scores [36].

The Six Area Six Sign Atopic Dermatitis (SASSAD) severity score [37,38] has the major advantage of not incorporating any attempt to estimate area of involvement. Estimation of area in atopic dermatitis is much more difficult than for psoriasis as there is often no clear delineation between normal and abnormal skin. The six signs recorded are erythema, exudation, excoriation, dryness, cracking and lichenification. Each sign is scored at six different sites. However, a very simple Three Item Severity Score [39], measuring only excoriations, erythema and oedema/papulation may provide as much information about current severity of atopic dermatitis as more detailed measuring techniques [40].

The subjective nature of most scoring systems and the inevitable variation of scoring between observers has been a spur to develop instrument-based, objective approaches to atopic dermatitis measurement. The Objective Severity Assessment of Atopic Dermatitis (OSAAD) score incorporates measurements of stratum corneum barrier function (transepidermal water loss) and hydration (stratum corneum capacitance) with computer-assisted measurements of extent of the disease [41]. OSAAD scores correlate with the SCORAD index and also with serum levels of interleukin-16 [42].

Hand dermatitis

Some skin diseases when occurring at specific sites cannot be measured using scoring systems designed for situations when the disease affects wide areas of the body. One example is hand eczema. The Hand Eczema Severity Index (HECSI) [43] requires scoring erythema, infiltration/papulation, vesicles, fissures, scaling and oedema at five sites on the hands. The area of involvement at each location is recorded and a final score calculated. Good inter- and intraobserver reliability was demonstrated, and the HECSI has been used in a population-based study of hand eczema [44]. Similarly, the Osnabrueck Hand Eczema Severity Index (OHSI) [45] is based on scoring six clinical signs. A photographic guide has been proposed for assessing the morphological severity of hand dermatitis [46]. Four photographs are used to illustrate each of five levels of severity from clear to very severe. The Occupational contact Dermatitis Disease severity Index (ODDI) is an amalgam of assessment over the previous 2 months of disease course, treatment, clinical signs and work-related activities [47]. The validity and reliability of this instrument have been demonstrated.

Acne

There have been many methods described to measure acne, ranging from global assessments to lesion counting [48]. Several methods to try to measure acne were used in the 1960s and 1970s but the Leeds technique [49] dominated acne measurement for the following two decades. Two methods were described in this paper, the grading technique and the counting technique. The grading technique divided patients into grades from 0 to 10, with seven subgroups between 0 and 2. Photographic guides to the grades were given, but the importance of also palpating lesions was stressed. This system was based on experience from the pre-isotretinoin era, and the severity of acne in grades above 2 is now rarely seen. The counting technique involves direct counting of non-inflamed and inflamed lesions, including superficial papules and pustules, deep inflamed lesions and macules. The revised Leeds acne grading system [50] also includes numerical grading systems for the back and chest as well as for the face.

A simpler, photographic standard-based grading method, using a 0–8 scale, was used successfully in a number of clinical trials [51]. Parallel-polarized and cross-polarized photography, videomicroscopy and fluorescence photography can now all be used in acne assessment [52].

The Echelle de Cotation des Lesions d'Acne (ECLA) or 'Acne Lesion Score Scale' system has demonstrated good reliability [53]. ECLA scores do not correlate with quality of life scores and the use of both disease sign scores and quality of life scores is suggested [54].

Methods to specifically measure post-acne scarring are also needed; a global scarring grading system has been proposed with four grades of scarring described [55]. The Echelle d'Evaluation Clinique des Cicatrices d'Acne (ECCA) [56] consists of recording the number of each of six types of acne scars. The overall count is an approximation: none, a few, limited number or many. This is a relatively simple method that shows initial reliability.

Rosacea

Clinicians and patients assess rosacea differently, with patients focusing on papules and pustules and clinicians taking more note of erythema [57]. A wide variety of methods have been used to measure rosacea but there are no standard, validated methods [58,59].

Cutaneous lupus erythematosus

The Cutaneous Lupus Erythematosus Disease Area and Severity Index (CLASI) [60] consists of two scores, one summarizing the current activity of the disease and the other measuring the damage done. Erythema, scale/hyperkeratosis, mucous membrane damage, acute hair loss and non-scarring alopecia are all assessed at 13 anatomical sites.

Symptoms

The most dominant dermatological symptom is itch. Attempts are often made to record itch in clinical studies, usually with a single global question related to itch, either alone or as part of other standard tools such as the SCORAD or DLQI. Studies have recorded frequency of scratching as a surrogate measure of itch, either by direct observation or by the use of instruments such as the DigiTrac that detects wrist movement [61]. It has been suggested that the objective measure of wrist activity should substi-

tute for the pruritus and sleep components of SCORAD [62]. The Itch Severity Scale records the frequency of itch at different times during the day and asks the patient to choose a description of the specific sensation [63]. The site of itch is recorded on a body chart and there are questions about mood, sexual desire/function and sleep.

Objective measures

Over the last 30 years many methodologies have been developed to objectively measure various physical properties of skin; the use of ultrasound to measure skin thickness was one of the first technologies applied [64]. This method has been applied most frequently to the measurement of thickness of psoriatic plaques [65,66]. Barrier function of the skin is most effectively assessed *in vivo* by measuring transepidermal water loss (TEWL) [67]. Such measurements may be influenced by ambient temperature and humidity and so there has been some refinement of methodologies available [68]. There have been some early applications of optical coherence tomography to the skin, initially to measure epidermal thickness [69]. Serup, Jemec and Grove have produced an excellent source of information concerning all aspects of non-invasive methods of assessing the skin [70].

Several techniques have been described to try to measure skin colour, including erythema [71], and guidelines proposed for standardized procedures [72]. The problems inherent in assessment of skin colour illustrate that measurement of 'objective' properties of skin may encounter a range of variable influences as diverse as the influences on 'subjective' measures. Erythema, for example, is influenced by local light conditions, instrument-related variables and individual properties such as physical activity or menstrual cycle. Despite this, devices are now becoming available that are relatively simple to use and may have applications in aiding clinical work [73]. Skin pigmentation is primarily influenced by melanin and a variety of techniques have been used to measure pigmentation [74], including by diffuse reflectance spectroscopy [75].

Other skin properties, such as elasticity [76], hydration or surface topography, can be measured, though mostly the ability to measure has not been translated yet into use of such measurement in routine clinical work. Stratum corneum hydration is usually measured using capacitance techniques and this approach has led to a novel method of imaging the skin surface using capacitance images [77].

An accurate way to measure of the area of involvement of skin disease is needed for many clinical record and research purposes. Most subjective methods have wide variability between observers. Although it might seem that objective area methods should be relatively easy to create, following advances in image analysis, progress has been slow, partly because of the challenges of dealing with distortion caused by body contours and partly because of the difficulties in defining the margins of skin disease. Computer-aided analysis of manually outlined lesions on photographs [78] may enhance the accuracy of area estimation, but 'old-fashioned' point counting of photographs seems to be as reliable as digital planimetry in assessing the area affected by vitiligo [79].

Quality of life impairment by skin disease

What does quality of life mean?

Being able to assess the impact of skin disease on patients is essential in order to understand and meet what they really need [1]. There is, however, considerable controversy about the definition of quality of life and whether it can be meaningfully assessed [2,3]. There have been several attempts to define quality of life and the closely associated concept of health-related quality of life (HRQoL) [4]. There is a need for all outcome measures used in dermatology, including quality of life measures, to be properly validated. There is too little information in the literature about the absolute meaning of different overall quality of life measurement scores or the interpretation of degrees of change in scores.

Why measure quality of life?

All clinical dermatologists are aware of the impact that skin disease may have on their patients. Attempts to develop methodology to measure the adverse impact of skin disease on quality of life started in the 1980s [5] and within two decades have become firmly established [6]. Measurement may be helpful for several reasons.

Clinical therapeutic research. When new drugs are assessed, the primary outcome measures are usually clinical measures such as the degree of scaling or the area of skin affected. Pharmaceutical companies and regulatory authorities are realizing that although these measures of disease activity are important, a patient-orientated outcome adds a meaningful extra dimension. There may be a 50% improvement in a PASI score, but if the handicap experienced by the patient is only slightly improved because visible skin remains abnormal, the intervention may not have been successful from the patient's point of view. A quality of life standard may even be better than body surface area measurement for identifying patients with severe psoriasis [7]. The addition of (not the replacement by) a HRQoL measure may be essential to make a proper assessment. In the evaluation of psoriasis, HRQoL measures are indeed now used frequently, whereas they were not used at all 20 years ago [8], and the introduction of new therapies for atopic dermatitis has also been supported by such information [9]. It has been possible to 'go back' and re-compare long-established therapies, using for the first time HRQoL outcome measures [10,11]. The impact of biological therapies for psoriasis on HRQoL has been documented in detail, for example in the assessment of the effects of etanercept [12] and adalimumab [13]. As the same measure has been used in most of such studies, it has been possible to derive some comparative data, even though no such prospective studies exist [14]. Despite these changes in attitudes to and use of HRQoL measures in clinical studies in dermatology, these instruments are usually recognized only as secondary outcome measures, partially because of the need for higher levels of validation of many measures currently used [15].

Although the main use of HRQoL assessment of therapeutic intervention has related to inflammatory skin disease, such measurement may also be used to compare surgical therapies, for example in the treatment of non-melanoma skin cancer [16].

Health service research and audit. Within some health care systems it is mandatory to produce evidence of the effectiveness of care given, and to have systems in place to monitor effectiveness and assess improvement against agreed criteria. An essential part of this process involves using patient-orientated measures and simple validated HRQoL questionnaires are well suited for this need [17,18]. The use of these measures can give additional insight into the acceptability of new methods of providing dermatology advice, such as teledermatology [19]; they have also been used to measure the effects of dermatology consultations in secondary care [20] and to compare the effectiveness of dermatology clinics between primary and secondary care [21].

Sound epidemiological data are essential for the planning of health services; HRQoL data can measure the extent of problems caused by skin disorders in a community [22] and be used to compare the HRQoL of people with specific skin diseases such as psoriasis to the general population [23]. National registries for diseases, such as that for psoriasis in Sweden, may include HRQoL data in order to assess the total burden of disease and the effectiveness of treatment [24]. A national survey of psoriasis patients in Germany has demonstrated, by gathering HRQoL data, the high percentage of psoriasis patients with a serious reduction in HRQoL [25].

Research into psychological aspects of dermatology and patient behaviour. Quality of life measures can be used to gain insight into patient attitudes; stress resulting from the anticipation of other people's reactions to their psoriasis contributed more to the variance in patients' disability than any other variable [26]. It is important that the problems relating to adherence with treatment, often not recognized by dermatologists, are better understood. Quality of life indices have been used to provide patient orientated measures in studies of compliance in psoriasis and acne.

Political/resource allocation. Patients with skin diseases are often not given priority for resource allocation in health care systems. Conditions that result in death are much more likely to find political support for service development. It is the responsibility of dermatologists to argue for appropriate resource allocation and appropriate funding of dermatology services and of the education of doctors about skin problems. One way in which the arguments for this can be strengthened is by using HRQoL data that demonstrate the devastating effects of skin disease on patients' lives [27–29]. If general HRQoL measures are used it is possible to quantify the effects of skin disease and to demonstrate the importance of skin disease in comparison to diseases of other

organs [30,31]. Similarly, the use of measures within dermatology can draw attention to the major problems experienced by some conditions to which, up to now, not enough attention may have been given. Examples include erythropoietic protoporphyria [32], hyperhidrosis [33] and hidradenitis suppurativa [34], all of which have high mean HRQoL scores indicating very major impact on quality of life.

It may be necessary to demonstrate and defend the value of dermatology clinical services whose benefit is self-evident to clinicians, for example in-patient dermatology facilities [35–37], or patch testing [38]. Dermatology-specific measures can also be used to demonstrate the value from the patients' point of view of expensive or novel therapy. A particular challenge when planning dermatology services is to understand and differentiate between need and greed when assessing the demands of patients; this may be clarified by the use of HRQoL data [39].

Estimating the burden of skin disease. Skin disease has major financial consequences; there are both direct medical costs and costs from lost productivity. In psoriasis the impact on productivity is not associated with objective clinical severity, but is associated with HRQoL [40]. The value of the additional burden on quality of life can also be expressed in financial terms, using willingness to pay methodology and HRQoL data. It is estimated that for all skin disease in the USA in 2004, the costs were: direct, $29.1 m; lost productivity, $10.2 m; and economic burden on quality of life, $56.2 m [41].

Informing clinical decisions. Most dermatologists probably consider that they have a reasonably accurate insight into the impact of skin disease on individual patients. The assumptions that are made influence clinical decisions, for example whether or not to start a patient on a systemic therapy which has risks of side effects. Unfortunately, dermatologists may not have as much insight as they think into the degree of their patients' problems [42–44]; impairment of sexual life, for example, is frequent in patients with psoriasis [45], even though the clinician may be unaware of this. Similarly, dermatologists are not good at identifying psychological distress in patients with psoriasis and, even in those patients in whom it is recognized, usually take no further action [46]. The use of a standard HRQoL measure may therefore potentially inform a clinician more accurately about their patient and allow better judgement concerning risk–benefit of therapy change. This will only become relevant on a routine basis if the absolute meaning of HRQoL scores can be more clearly understood.

It has been suggested that current severe psoriasis can be defined by using a combination of physical and quality of life descriptors [47]. The Rule of Tens for assessing psoriasis severity is:

current severe psoriasis = Body Surface Area (BSA) involved > 10% *or* PASI > 10 *or* DLQI score > 10

If this is met, the patient should be considered to have current severe psoriasis, for which active therapy should be considered [47]. The British Association of Dermatologists' subsequent guidelines [48] for the use of the biological therapies use a variation on this concept. They suggest that PASI ≥ 10 or BSA ≥ 10% *and* DLQI > 10 should be the criteria for etanercept or efalizumab to be used in the treatment of psoriasis. The National Institute for Health and Clinical Excellence (NICE) guidance is similar [49], but for the use of infliximab the criteria are PASI ≥ 20 *and* DLQI > 18 [50]. A European consensus has also suggested the use of the Rule of Tens as an indicator of moderate to severe psoriasis when decisions are taken concerning etanercept therapy for psoriasis [51]. These guidelines therefore now encourage physicians to actively investigate and take into account HRQoL information in making decisions about therapy.

How do quality of life measures relate to other clinical indices?

It seems obvious that there is likely to be a relationship between the clinical severity of skin disease and the impact of the disease on life quality. However, there are many influences on the disability experienced and individual patients show a wide variation in their responses to similar degrees of disease. There is conflicting evidence, for example in atopic dermatitis in children, where in one study the CDLQI was significantly correlated with the SCORAD [52] and in another the correlation with SCORAD and the Eczema Severity Score was poor [53]. Quality of life scores and scores from POEM correlate well; however, POEM includes a HRQoL question concerning sleep [54]. The particular body site affected is an important factor, with visible sites such as the face or the hands having much greater significance to a patient: there was only poor correlation between disease severity in hand eczema and quality of life scores [55].

The psychological attitudes of patients to their disease vary widely and these influence the degree of disability experienced [56]. Clinical scoring systems may reflect sign changes which are not of relevance to a patient's life; for example in psoriasis, the successful reduction of scaling and thickness may result in a large percentage reduction in the PASI score but if the redness persists the quality of life improvement may be much less [57]. In a cluster analysis of classical measures of clinical status of psoriasis (PASI, SAPASI) and of quality of life indices (Skindex-29, DLQI, PDI, IPSO) in over 700 patients, the instruments clustered in these two distinct groups [58]. This study stressed the need for comprehensive assessment of severity of psoriasis using both objective and patient-rated measures. There have, however, been attempts to broadly correlate these two concepts of measurement; it has been argued [59] that a 50% reduction in the PASI (PASI 50) represents a meaningful change in a patient's life and so could be considered a clinically significant endpoint when psoriasis is assessed. In patients with severe psoriasis treated with infliximab, despite a lack of correlation between absolute PASI and DLQI values, significant reductions of PASI are likely to correlate with significant improvements of HRQoL [60].

Quality of life measures should not be used instead of clinical measures as they are designed to assess a completely different, though interrelated, aspect of skin disease.

Methods of measuring quality of life in dermatology

There are several approaches to the measurement of health-related quality of life. One depends on fixed questionnaires that are scored. A second approach uses questionnaires that allow a variable response, taking into account the particular values of the patient. Another method is to assess the value that a patient of society places on the presence or absence of particular disease states—the utility approach. The US Working Group on core measures of the burden of skin diseases identified 40 health-status quality of life measurement instruments for skin disease [1]. Decisions concerning which measures are appropriate to use can be difficult; there is guidance over general principles [2,3]. A recent critical review of generic and dermatology-specific HRQoL instruments recommended for research studies the use of a combination of the SF-36 and Skindex-29 [4]; however, in the busy clinical environment a different approach is necessary, preferably using a simple, short questionnaire. There are comparisons of assessment of quality of life in cutaneous disease [5] and in psoriasis [6], and there is advice about understanding quality of life research [7] and quality of life research methodology [8]. Minimum criteria to create and establish new instruments have been suggested [9]. For example, one basic aspect of the use of a standardized questionnaire in the measurement of HRQoL is the requirement in the instrument validation process to demonstrate that it is appropriate to report grouped answers data as a single score. There are techniques to address whether or not instruments are uni-dimensional [10,11].

Some techniques are designed for use across all disease states, some for use across a range of diseases of the same organ system and some for use in patients with specific diseases. Most published questionnaires are designed for adults, but there have been techniques described for measuring HRQoL in children with skin disease and in infants with atopic dermatitis. HRQoL measures usually assess the impact of skin disease at a particular time (e.g. 'today') or over a fixed period of time (e.g. 'over the last week'). This time restricted design allows comparison of data before and after intervention. However, the long-term 'importance' or impact on a patient's life may not be captured by these indices. Patients with basal cell carcinomas at the time of presentation to dermatologists generally have little or no reduction in their current quality of life [12] but, of course, if the disease was not treated there could be major problems in the future. If HRQoL measures are used to inform priorities for resources in a health care organization, these measures should therefore not be used in isolation.

What do quality of life scores mean?

Quality of life scores are often poorly reported in published clinical studies, with insufficient information given to properly interpret the data presented [13]. One crucial aspect often not addressed is the clinical relevance of changes in score. Significant statistical differences may be proven but if the absolute magnitude of the changes is not equivalent to a noticeable change in patient experience there may be no benefit to the patient; this is true for both objective disease measures and for patient-reported measures [14].

Measuring HRQoL in the clinic is not of benefit to the clinician or patient unless the scores can be interpreted in a simple and meaningful way. Of the many questionnaires that have been described, very few have validated descriptions for the interpretation of the scores. Ideally, there should be information about the minimal important difference (MID) of score that is of relevance to patients. A complementary approach is to develop descriptive bands to interpret scores; this has been described for the DLQI [15].

Where HRQoL measures are used in international studies, validated translations should be used. However, even after the completion of an accurate translation of meaning, further work may be necessary to create a validated, culturally adapted measure. It has been suggested that psoriasis patients from different countries respond differently to items from both the DLQI and Skindex, despite having the same underlying HRQoL impairment [16]. There is a need to develop patient-reported outcome cross-cultural instruments to ultimately allow patient-reported measures to be accepted as primary outcome measures in therapeutic trials [17].

Quality of life measures used in dermatology

General health measures

General health measures are designed for use across a wide range of disease states. They are needed in order to draw comparisons between the impact of skin diseases, the impact of diseases of other systems and the general population. Examples include the SF-36 [18], the Sickness Impact Profile (SIP) [19], the Nottingham Health Profile (NHP) [20] and the EuroQol EQ-5D [21]. The WHOQOL-26 is a 26-question instrument with physical, psychological, social relations and environment domains [22]. A completely different approach is taken by the Patient Generated Index, which is an individualized quality of life measure where a subject identifies the key ways in which their life is specifically being affected, and ranks and assigns importance to each aspect [23]. This approach is excellent for gaining insight into individual patients' problems, but is cumbersome and unsuitable for large surveys.

Many of these general health measures have been used in dermatology. In many investigations both a generic measure and a

The aim of this questionnaire is to measure how much your skin problem has affected your life OVER THE LAST WEEK. Please tick one box for each question.

1. Over the last week, how **itchy, sore, painful** or **stinging** has your skin been?
2. Over the last week, how **embarrassed** or **self conscious** have you been because of your skin?
3. Over the last week, how much has your skin interfered with you going **shopping** or looking after your **home** or **garden**?
4. Over the last week, how much has your skin influenced the **clothes** you wear?
5. Over the last week, how much has your skin affected any **social** or **leisure** activities?
6. Over the last week, how much has your skin made it difficult for you to do any **sport**?
7. Over the last week, has your skin prevented you from **working** or **studying**?
   If "no", over the last week how much has your skin been a problem at **work** or **studying**?
8. Over the last week, how much has your skin created problems with your **partner** or any of your **close friends** or **relatives**?
9. Over the last week, how much has your skin caused any **sexual difficulties**?
10. Over the last week, how much of a problem has the **treatment** for your skin been, for example by making your home messy, or by taking up time?

Please check you have answered every question. Thank you.
© AY Finlay, GK Khan, April 1992.

Each question is answered either "Very much" (score 3), "A lot" (score 2), "A little" (score 1) or "Not at all" (score 0). Questions 3 – 10 also have the option "Not relevant" (score 0). The first part of question 7 has the choices "Yes" (score 3),"No", or "Not relevant". The second part of question 7 has the choices "A lot", "A little" or "Not at all". The maximum score (indicating highest possible impairment of quality of life) is 30 and the minimum 0. Further information: www.dermatology.org.uk.

Fig. 72.1 The Dermatology Life Quality Index (DLQI) [43].

dermatology-specific measure have been used together [24]. The UK Sickness Impact Profile has been used in psoriasis [25,26] and atopic dermatitis [27]. The SF-36 has been used in psoriasis [28,29], acne [30] and atopic dermatitis [31]. The GHQ-12 has been shown to be of value in assessing psychological distress in patients with skin disease [32], and specifically in vitiligo [33].

The EuroQol EQ-5D is of growing importance as it is being used by European drug licensing authorities as a comparative tool and as a basis for utility analysis [34]. It has been used in acne [30], psoriasis [24] and pyoderma gangrenosum [35].

The WHOQOL-26 has been used in studies of melasma [36] and urticaria [37] and in assessing the impact of tacrolimus ointment in atopic dermatitis [38]. The initial 100-question version, the WHOQOL-100, is responsive to change in psoriasis [39].

There are several separate methods used to detect or measure depression or other psychological problems in dermatology patients. One example, the General Health Questionnaire, is designed to detect psychiatric disorder and is reliable when used in dermatology patients [32]; it may be used for example to detect suicidal ideation [40]. Depression can be detected using the Mini International Neuropsychiatric Interview questionnaire as a screening method [41]. There is a strong interrelationship between psychiatric co-morbidity and quality of life impairment [42].

Dermatology-specific measures

Dermatology-specific measures are useful when comparisons need to be made between the impact of different skin diseases, or where there is a need to measure change before or after intervention in any skin disease. Having a single simple measure that can be used across all skin disease is of great practical advantage, especially in a busy clinical setting.

The two dermatology-specific measures that have been most widely used are the DLQI [43] and Skindex [44]. Other measures that have been described include the Dermatology Quality of Life Scales [45], the Dermatology-specific Quality of Life instrument [46], a German instrument, the DIELH [47], the VQ-Dermatol, developed in France [48], and a measure for use in Turkish patients [49]. The Freiberg Life Quality Assessment (FLQA) questionnaires combine a common core module relevant to all skin diseases with a disease-specific module [50].

The DLQI and Skindex mainly measure physical, psychological and social functioning. As not all aspects affected are encompassed by these measures, a broader instrument, the Impact of Chronic Skin Disease on Daily Life (ISDL), has been developed [51]. This has five categories: physical functioning, psychological functioning, stressors, illness cognitions and social support. The measure has good reliability and validity but, with over 72 items, takes 20–25 min to complete.

The Dermatology Life Quality Index

The DLQI consists of 10 questions covering a wide range of ways in which patients' lives are affected by skin disease (Fig. 72.1). Each question is answered by a simple tick-box method and scored 0–3. The DLQI takes on average only 2 min to complete [52]. Experience of the DLQI, including validation studies, has been summarized [53]; by 2007, there were 272 articles describing the use of the DLQI in a wide range of skin conditions and in 55 languages worldwide [53,54]. Validation studies have been carried out in the UK, in secondary care [43] and primary care [55], Spain [56,57], Germany [58], Denmark [59], the USA [60], Norway [61], Italy [62], Poland [63], Iran [64], Brazil [65] and Japan [66]. Its use has also been described in over 32 countries. When illustrations are added next to the text of the DLQI, the questionnaire tends to be completed more rapidly but there is an influence on the way the questionnaire is answered [52]. Descriptive score bandings for the DLQI are given in Table 72.5. In psoriasis [67] and urticaria [68] a score change of about 3 is needed for a patient to experience a minimum important change in HRQoL; preliminary work had indicated a figure of 5 in a general dermatology population [69].

Although the DLQI is copyrighted, clinicians may freely use it in routine clinical practice without seeking permission and without charge [54].

Table 72.5 Descriptive score bandings for the Dermatology Life Quality Index (DLQI) [15].

Score	Meaning
0–1	no effect on patient's life
2–5	small effect on patient's life
6–10	moderate effect on patient's life
11–20	very large effect on patient's life
21–30	extremely large effect on patient's life

Skindex

Skindex has been developed and extensively validated in four versions with 61 [44], 29 [70], 16 [71] or 17 [72] questions. Further validation studies have been carried out in Spain [73], Italy [74], Turkey [75], Saudi Arabia [76], Japan [77] and Germany [78]. There is extensive experience of the use of this measure in a wide range of languages, countries and dermatology diseases. The appropriateness of using Skindex in psoriasis along with the generic SF-29 has been emphasized [6]. Skindex-29 scores have now been categorized into four levels to aid the interpretation of scores [79].

Disease-specific measures

Questions in disease-specific measures reflect as closely as possible the problems encountered by patients with that disease, and so disease-specific measures have the potential of being the most sensitive to change. They are, therefore, particularly suitable for comparative purposes within a cohort of patients with the same disease. However many skin conditions, such as widespread inflammatory skin diseases, affect patients' lives in broadly similar ways, and so dermatology-specific measures can also be used. There is, therefore, no urgent need for a disease-specific measure to be created for every skin disease.

Psoriasis

A landmark study of quality of life issues in over 17 000 patients from the USA with psoriasis [1], using a study-specific questionnaire, demonstrated the major impact that psoriasis can have on patients' lives and revealed that many patients with psoriasis do not feel that their physicians are aggressive enough with their therapy. A study of 18 000 patients from Europe [2] reached similar conclusions, with over 70% reporting only low to moderate satisfaction with the available treatment options. The greatest impact reported was on daily living activities, especially affecting clothing choice, bathing routine and sporting activities.

The Psoriasis Disability Index (PDI), originally described in 1987 [3] and revised in 1995 [4], has been extensively used [5] and is available in over 20 languages [6]. The PDI has been used in major surveys [2,7]. However, it may be suboptimal for

widespread use in patients with mild–moderate psoriasis because of insensitivity to lower levels of disability and lack of evidence to support scoring with a single score [8].

The stigmatizing effects of psoriasis can be recorded using a 33-item disease-specific questionnaire [9]. This questionnaire was used in the development of another technique for measuring stigma across all dermatology patients, the Questionnaire on Experience with Skin complaints (QES) [10]. The QES has been used to demonstrate the high stigmatization experienced by patients with psoriasis compared to patients with other skin diseases [11] and has also been applied to patients with vitiligo [12]. The stress caused by the impact of psoriasis on quality of life has been measured [13] using the final 15-item version of the Psoriasis Life Stress Inventory [14].

The Impact of Psoriasis Questionnaire (IPSO) [15] has been gradually refined and following Rasch analysis an 11-item version has been shown to have improved internal consistency [16]. Regrettably, most HRQoL studies in dermatology assess changes over a relatively short period of time [17], but the IPSO was the measure used on the longest dermatology HRQoL follow-up study, reporting changes in a cohort of psoriasis patients over 11 years [18].

The Salford Psoriasis Index (SPI) consists of three independent scores describing Signs (disease activity), Psychosocial disability, and history of Interventions [19,20]. The SPI therefore records an important aspect of psoriasis that is taken into account by clinicians in daily practice—the past history of the disease. This approach may be of great value in the recording, monitoring and classification of this chronic disease.

PSORIQoL is a 25-item questionnaire that assesses the impact of impairment and disability from psoriasis on the patient's perception of quality of life [21]; a US version has been validated [22]. Another questionnaire, the 12-item PQoL-12 [23], has been incorporated in a psoriasis severity assessment tool, the Koo-Menter Psoriasis Instrument [24].

The above and other measures used in psoriasis have been described in more detail [25] and critically reviewed [26].

Atopic dermatitis

The CDLQI and the DLQI have been used extensively in the monitoring of patients with atopic dermatitis but several disease-specific approaches have been described. In a large, managed care organization in the USA, patient-assessed severity of atopic dermatitis demonstrated a stronger correlation with the DLQI and CDLQI than did provider-assessed severity, emphasizing the importance of directly assessing the patients' attitudes [27]. Indeed, patients with atopic dermatitis are able to accurately determine their disease severity and quality of life [28]. Assessment of the burden of atopic dermatitis has been reviewed [29].

The Psychosomatic Scale for Atopic Dermatitis (PSS-AD) is a simple 12-item scale to measure the 'psychosomatic pathology' of adult atopic dermatitis [30]. The PSS-AD has been initially validated and may be useful to help identify patients who would benefit from psychological intervention. In adults there is an interrelationship between perceived stigma and atopic dermatitis severity, both of which are strong predictors of quality of life impairment [31].

A Childhood Atopic Dermatitis Impact Scale (CADIS) consisting of 45 items has been developed. This measure combines assessment of the impact on the quality of life of affected young children and on their families [32]; these are two interdependent but separate concepts. Further validation of the measure has demonstrated correlation with SCORAD scores [33].

The Parents' Index of Quality of Life in Atopic Dermatitis (PIQoL-AD) has been developed [34] to measure the parent's assessment of the impact of atopic dermatitis on the affected child (not the secondary impact on the parent, see below). Importantly, the minimum meaningful score difference has been estimated: a change of 2 to 3 points [35]. In contrast to the PIQoL, the Dermatitis Family Impact questionnaire (DFI) seeks to assess the impact of having a child with atopic dermatitis on the quality of life of the family [36].

The lives of infants with atopic dermatitis may be severely disrupted, even though the affected children may not be able to explain their distress, or have the insight to know that what they are experiencing is abnormal. The Infant's Dermatitis Quality of Life Index (IDQOL) [37,38] encapsulates and measures the impact of atopic dermatitis on infants.

Acne

The compact five-question Cardiff Acne Disability Index [39] was derived from the Acne Disability Index [40]. This simple instrument has demonstrated reliability [41] and has been validated in French [42] and Persian [43]. There is good correlation between the CADI and the CDLQI [44]. The Assessments of the Psychological and Social Effects of Acne (APSEA) questionnaire [45] has 15 questions, some of which relate to the overall impact and some to the recent past.

The Acne Quality of Life Scale (AQOL) [46] has nine questions that relate specifically to the social impact of acne. The Acne-specific Quality of Life Questionnaire (Acne-QoL) [47] has 19 questions and was designed for use in clinical trials. A four-question condensed version of this, the Acne-Q4, is likely to be more practical to use [48].

Other disease-specific measures

The number of disease-specific measures is gradually increasing. Such questionnaires include those described for ulcers [49], urticaria [50], excessive axillary sweating [51], scalp dermatitis [52], for women with androgenetic alopecia [53], for melasma [54,55], skin cancer [56], rosacea [57] and to assess bother related to hirsutism in women [58].

Site-specific measures

Nail disease, especially when the fingernails are affected, may have an impact on HRQoL that is out of proportion to the very small body surface area affected. This impact may be detected by the Skindex-29 [59], and two nail-disease-specific instruments have been developed [60,61].

Patient-specific and utility measures

Health-related quality of life measures are, or should be, derived from information gathered from patients' experiences and not from health care professionals' concepts of what they suppose to be the impact of disease. Despite this, all fixed questionnaires suffer from the disadvantage that, for an individual patient, the impact of different aspects of life quality impairment may be different from the weighting assigned in the questionnaire or the specific issues may be missed altogether. The Patient Generated Index [1] overcomes these problems by being structured in a different way; patients are asked to identify the five ways in which their life is most affected and then assign them comparative values. This technique is effective for identifying an individual's specific problems, such as in atopic dermatitis [2].

Different approaches are used to create measures of the concept of patient preferences, for example towards attitudes to risk or to different treatments or outcomes [3]. Utility measures, for example, assess the hypothetical value placed by people on their health. There are a variety of methodologies. Standard gamble, time trade off and vertical rating scales have been proposed [4] as a way of informing decisions about methotrexate therapy for psoriasis. The willingness to pay (WTP) method is to ask patients how much they would be prepared to pay for a cure of their disease if such a cure existed. This has been used in acne [5], psoriasis [6–8] and atopic dermatitis [7,9]. WTP information showed strong test–retest reliability in an onychomycosis study [10].

Another approach is to ask patients to consider how much time they would be prepared to give up for the sake of a cure. These 'trade off' questions can be related to years of shortening of life, as in the Quality Adjusted Life Year (QALY), or be related to hours' trade off. The time trade off (TTO) method has been described in psoriasis [6,8] and in atopic dermatitis [9]. The TTO method has demonstrated that patients with atopic dermatitis and psoriasis would choose a 40% shorter life expectancy in order to avoid uncontrolled skin disease [11]. In contrast to the concept of hypothetical time that a patient would be prepared to give up, there is no correlation between the measurement of actual time spent on treatment and quality of life scores [12], though there is with SCORAD [13]. The TTO questions have been used to calculate comparative mean utilities across a range of skin diseases: the lowest mean utility was for bullous disorders [14]. These utilities can be compared with data from non-dermatological disease.

The QALY method was first applied in dermatology in acne [15]. The advent of the highly effective but also very expensive biological drugs for psoriasis resulted in considerable further attention being given to the concept [16]. The resulting QALY information has played a key role in influencing criteria for the use of these drugs. QALY calculations may use standard dermatology HRQoL information, such as DLQI data, to compare the cost effectiveness of different drug regimens [17].

There has been an attempt to bring together descriptors of a health state and the use of the standard gamble technique as a basis for the calculation of QALYs [18]. This was applied to atopic dermatitis and included information from parents of children with atopic dermatitis as well as values of the general public. Such cost–utility analyses may be undertaken to demonstrate whether or not the use of particular therapies can be justified on economic grounds. The information that is used in such analyses may include HRQoL data; an example is an analysis of the few situations where topical tacrolimus for the treatment of atopic dermatitis can be justified on economic grounds [19].

Children and the greater patient family impact

Children

The assessment of quality of life impairment in children is more difficult than in adults because of issues relating to communication, rapid change in lifestyle at different ages and differing rates of maturing. The different general measures and disease-specific measures have been systematically reviewed [1]. Several atopic dermatitis specific measures for use in children have been described (see above).

The Children's Dermatology Life Quality Index (CDLQI) [2] was designed to be used by children between the ages of 4 and 15 years old. It can be completed unaided by older children but parents can help younger children as necessary. Key areas that are enquired about are given in Table 72.6. An illustrated cartoon version, using the same text, has been validated [3]. Overall, children preferred the cartoon version and completed it more rapidly than the text-only version. There are over 20 different validated language translations of the CDLQI. The CDLQI has been used in the assessment on children's lives of the effects of atopic dermatitis, the impact of admission for treatment, the impact of a nurse consultant and the effect of new topical and systemic anti-inflammatory agents. It has also been used to demonstrate a relationship between HRQoL scores and objective measures of skin function in atopic dermatitis [4]. The CDLQI was cross-validated with a generic HRQoL proxy measure for children, the Children's Life Quality Index [5]. This demonstrated that HRQoL impairment in children with chronic skin disease is at least equal to that experienced by children with many other chronic diseases of childhood.

The difficulties in measuring life quality changes in children are even greater in the very young. The Infant's Dermatitis Quality of Life Index (IDQOL) is an attempt to record the impact of atopic dermatitis on infants [6].

The Pediatric Symptom Checklist [7], which consists of 35 questions answered by the parent, has been used for psychosocial screening in paediatric dermatology clinics.

Adolescents

The lives of individuals aged from 12 to 18 years are characterized by mental and physical development, increasing independence, emerging sexuality and intimacy, and emotional changes. Skin disease may profoundly affect adolescents in a variety of specific ways, including psychological, social, lifestyle, education and employment [8]. Major, long-term life decisions, for example over which career to follow, may be influenced by having skin disease at that time. Although the CDLQI has been used in children up to the age of 15 years and the DLQI can be used in those aged 16 years or over, there are special aspects of life quality impairment experienced by adolescents that might be captured more appropriately by measures designed specifically for this age group.

Family impact—the greater patient

When a patient is affected by a skin disease, the lives of those closest to the person are usually also affected. The extent of this effect may be profound but not be realized by health care professionals. The concept of 'the greater patient' has been proposed to describe the wider family unit, including the partner or close relatives, whose lives are all affected by an individual having skin disease [9].

The impact of skin disease on the greater patient was first understood in atopic dermatitis; having a child with this condition can have a major impact on the functioning of a family, for example in causing sleep disturbance of the parents [10]. Two disease-specific methods [11,12] measure this secondary impact, and another questionnaire records both the impact on an affected child and on the parents [13]. The Dermatitis Family Impact questionnaire (DFI) [11] has been used to demonstrate the relationship of childhood dermatitis severity to family life quality [14]. In infants, the DFI and IDQOL scores correlate well; both improve following initial consultation with a dermatology team [5]. Support groups for children with atopic dermatitis and their families [15] may help to address some of these greater patient issues. The families of adults with atopic dermatitis also experience a secondary impact. The sex life of 36% of partners of adult patients with atopic dermatitis were affected by the appearance of the skin disease [16].

Following detailed qualitative interviews of partners and relatives of patients with a variety of skin diseases [9], a 10-item questionnaire, the Family Dermatology Life Quality Index, has been validated [17,18]. Key areas affected and enquired about are given in Table 72.7. This instrument allows, for example,

comparison between the secondary impact of different skin diseases. Its use has confirmed that eczema has a greater secondary impact than acne [19].

The importance of understanding the attitudes and beliefs held by patients with psoriasis and their partners has been stressed [20]. There is a major impact on the greater patient specifically in psoriasis [21]; the Psoriasis Family Impact questionnaire has been developed to assess the psoriasis-specific issues [22]. New ways are needed to develop interventions to address these impacts on partners and family members and to critically assess outcomes [23].

Practical clinical use of measures: a vital sign?

Clinicians use a subjective view of the QoL of their patients to inform many decisions. A better understanding of this impact and the subsequent realization of the need for early and effective therapy, has led to a focus on new models for health care delivery, 'patient-centred care' [24] or 'patient-based medicine' [25]. Better communication and engagement in a dialogue of negotiation with a patient over management is at the heart of this change in emphasis.

In psoriasis there is a relationship between the type of management decision taken (for example whether or not to start on ultraviolet or systemic therapy) and patient-rated HRQoL [26]. However, there is a lack of HRQoL discussion during dermatology outpatient consultations [27]. In an observational study of inflammatory skin disease consultations, there was a greater patient reported HRQoL impact experienced by those patients in whom HRQoL issues were discussed than in those in whom these issues were not raised [28]. Where DLQI information was made available on a routine basis in a general dermatology clinic, treatment decisions were influenced in 9% of consultations, mainly in patients in whom there was high HRQoL impairment [29].

Patient-generated information about their skin disease, as assessed by HRQoL outcome measures, should be encouraged to become one of the vital signs of skin disease, essential for understanding the patient's disease and informing its appropriate management [30]. However, there remain many methodological challenges both in the appropriate capturing and use of HRQoL data; it has been stressed that QoL assessment cannot replace effective patient–physician communication [31].

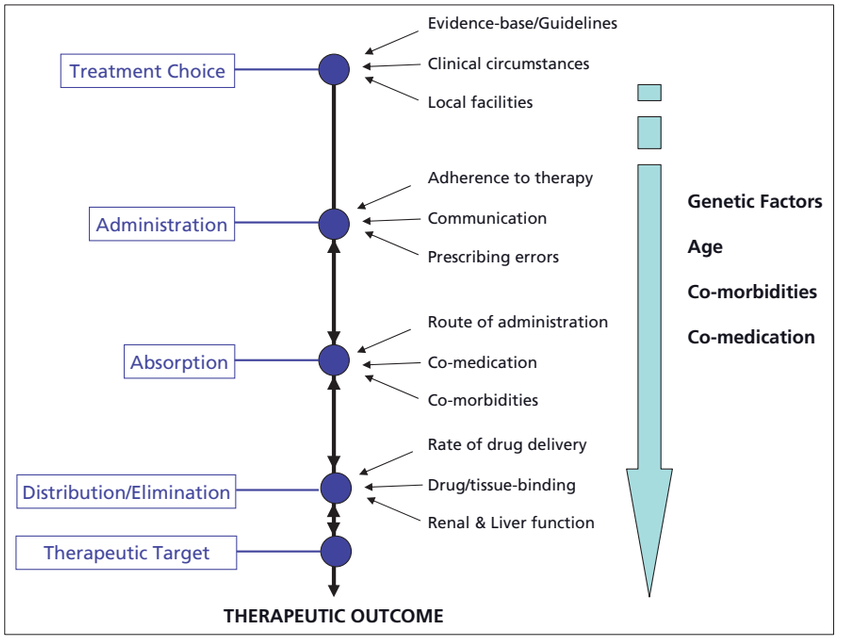

Fig. 72.2 An overview of the relationship between the dose of any particular drug and therapeutic outcome. Multiple, often interdependent, factors impact at critical points (dark blue circles) along the pharmacological pathway, some of which are relevant throughout (light blue arrow).

General principles of therapy

The term 'therapy' encompasses any intervention or approach aimed at treating or preventing disease, and within the context of traditional dermatological practice includes general measures (e.g. avoidance of irritants), conventional medicines, physical treatments (e.g. phototherapy, surgery, laser, liquid nitrogen), psychological interventions, occupational therapy and rehabilitation. Complementary and alternative medicine is also widely used by patients with dermatological disease.

An abiding principle in medicine is 'to help, or at least to do no harm' [Hippocrates]. Therapeutic interventions are at the core of disease management, but it is a sobering fact that 3–6% of hospital admissions are due to adverse drug reactions [1–3] and, of these, half could have potentially been avoided [4]. On the other hand adherence to prescribed therapy, especially for chronic conditions, is poor with the NHS spend on unused or unwanted medicines estimated at £100 million annually [5]. No drug is without risk, but every effort should be made to ensure that for any given intervention (and this includes no specific therapy), the likelihood of benefit exceeds the likelihood of harm. This requires (and is not always achievable) an accurate diagnosis, clear objectives for treatment that have been agreed between clinician and patient, a treatment choice based on sound evidence relevant to the clinical situation, an adequate therapeutic trial of the chosen intervention, and timely review of the patient to determine the outcome of treatment, adverse events and the need for ongoing therapy. Clear communication, mutual respect and understanding between clinician and patient are fundamental to successful therapeutic outcomes.

Topical and systemic treatments

Before initiating any therapeutic measures, a comprehensive assessment of the patient is essential, considering the disease that requires treatment in the context of the whole patient and shared treatment goals. Each therapeutic intervention in a patient can be considered a trial (of $n = 1$) with appropriately defined 'outcome measures' and timelines for judging success or failure. This is perhaps especially important in dermatological practice. The rarity of many skin diseases and historic lack of investment in drug development means that robust evidence to guide treatment choice and optimize drug use is often unavailable. Added to this, many drugs are unlicensed so that clear documentation of benefit (or harm) is also important. Continuing an ineffective or insufficiently effective treatment exposes patients to the ongoing risk of adverse events and expense quite apart from suboptimal management of their skin disease.

Factors that affect therapeutic outcome

Multiple factors determine the relationship between the dose of any particular drug and outcome (Fig. 72.2) and thus therapy needs to be carefully and precisely tailored to the needs and clinical circumstance of each patient. This can be a highly complex, dynamic process that requires constant re-evaluation and refinement during the course of treatment.

Patient adherence to treatment

The extent to which patients follow instructions they are given for a prescribed medication (i.e. adherence) varies enormously from missing an occasional dose to completely stopping treatment, and

therefore may or may not be relevant to treatment outcome. Non-adherence to treatment is very common but few patients will declare it to health care professionals voluntarily and assessment is best approached in a non-judgemental way. It arises for multiple and complex reasons which fall into two main overlapping categories: unintentional and intentional non-adherence. Examples of *unintentional* non-adherence include poor comprehension or recall of the details of the prescribed therapeutic regimen, difficulties applying or taking a medicine and lack of access or ability to pay for treatment. *Intentional* non-adherence, when a patient decides not to take the prescribed medicine, arises due to patients' beliefs, concerns or problems associated with their condition and/or prescribed medicine [6]. In general, patients wish to minimize the number of medicines they take and where there are multiple treatments given, may prioritize one over the other. They will evaluate for themselves the side effects and efficacy of any given treatment—and of course, the effectiveness of treatment in skin disease is manifestly obvious—and may stop therapy to see the outcome. Factors that may improve adherence include providing clear written and verbal communication about how, why and when the treatment needs to be taken, using the simplest dosing schedule possible, and employing various techniques to remind and support patients depending on the particular situation (e.g. telephone reminders, dosette boxes) [7]. Dermatology nurse specialists can play a key role in improving adherence to therapy through patient education and support, practical demonstration of where and how to apply topical treatments and, in some instances, application of treatments in formal outpatient settings. Unlicensed 'special manufacture' medicines ('specials') are widely used in topical therapy but can be associated with erratic supplies and hence poor adherence; in the UK, use of 'specials' has been rationalized and manufacture limited to fewer approved centres in order to address this issue [8].

Medication errors

Some side effects and adverse reactions to drugs are accepted risks of treatment and, whilst they can be minimized with careful prescribing and medicine use, they are unavoidable. In contrast, those arising as a consequence of errors in prescribing, dispensing and/or administration of medicines are, by definition, avoidable. The steps involved between writing a prescription and the patient receiving the medicine are multiple, and each is subject to potential error. Medication errors that lead to serious or fatal adverse events invariably occur due to a series of events, and reflect human error arising in the context of certain predisposing environmental or system factors [9]. Reasons for errors include inadequate knowledge of the patient, their clinical condition, drug history and known allergies, inadequate knowledge of the drug being prescribed, drug dose calculation errors, illegible handwriting, and confusing drug names and product labelling [10–14]. The commonest source of error is in the prescription itself [10,15]. In hospital, often the most junior member of the team with the least knowledge and experience is tasked with prescribing; this in itself is a risk, but also fails to create a culture where prescribing is perceived to be important [12]. Additional factors that predispose to errors include repeated interruptions when writing a prescription and depression in the prescriber [12,16].

Poor communication amongst clinicians, particularly where care crosses or is transferred from one clinical setting (e.g. hospital) to another (e.g. primary care), is also a significant source of error both in relation to the dose and type of medication to be used, and also, as importantly, review and monitoring of the treatment [10,11]. In this situation, a disconnect can arise between the prescriber who initiated the treatment and the clinician responsible for ongoing care, so the necessary adjustments in drug therapy and monitoring fail to occur and/or drug errors remain unchecked for prolonged periods of time, with sometimes catastrophic results. This was specifically identified as a major contributory factor in a review of 137 adverse events arising in relation to methotrexate, which included 25 deaths and 26 serious incidents requiring hospital admission in the UK and also the commonest reason in ambulatory care for adverse drug reactions leading to hospital admission [10].

Certain types of medication are subject to frequent medication errors [3,15]. Drugs with a narrow therapeutic index and/or where the therapeutic dose is close to the toxic dose (e.g. chemotherapeutic agents, anticoagulants, narcotics), drugs with an unusual dosing schedule that patients may easily confuse (e.g. once-weekly methotrexate), or drugs requiring intravenous administration where the speed of infusion or extravasation of drug into tissue can lead to problems (e.g. rapid immunoglobulin infusion and risk of thromboembolic events). Patient groups vulnerable to medication error include infants and children [17], where complex dose calculations are required using drugs that may not be licensed for use in children, and older patients due to communication difficulties, polypharmacy and presence of co-morbidities.

Whilst something is known about the cause and prevalence of medication errors, there is relatively little good evidence to indicate which interventions effectively reduce error [9,18]. Prescribing is no longer the sole remit of doctors and extends to nurses, pharmacists and physiotherapists, all of whom need to take professional responsibility for their prescribing practice. Prescribers need to be supported by appropriate training in clinical pharmacology and the practicalities of prescribing with ready access to clear guidelines and protocols on use of drugs. Clearly defined 'care pathways' can also provide clarity over where responsibility lies for prescribing and monitoring, as has been implemented as part of the UK National Patient Safety Agency alert on methotrexate [19]. However, all humans are subject to errors and lapses and so additional, multiple checks need to be in place. Pharmacists play a critical role in cross-checking scripts (although knowing that this safeguard is in place has been identified as a source of inaccurate or lazy prescription writing in hospital practice [12]). Numerous and varied information technology initiatives focusing on all aspects of the prescribing pathway have been developed, although not all are necessarily associated with a reduction in error risk. For example, electronic prescribing has been shown to reduce the incidence of illegible scripts and adverse drug reactions [20] but automated alerts about potential drug interactions and dose errors have been shown to overwhelm the prescriber so that the excessively frequent alerts are ignored. It seems likely, though, that further refinement of existing systems and new developments in this area will yield substantial benefit.

New MHRA legislation on standards for product labelling should help to reduce confusion and thus minimize dispensing errors. Perhaps most important of all, ensuring the patient is fully briefed on the treatment plan can allow patients themselves to correct mistakes.

Drug pharmacokinetics and pharmacodynamics

The amount of drug delivered to the site of therapeutic action depends on the mode of administration, pattern of drug absorption, distribution, metabolism and elimination (i.e. pharmacokinetics). Multiple variables also affect drug target responsiveness to fixed drug concentrations (i.e. pharmacodynamics). All these elements therefore need to be related to the clinical circumstances of the individual patient requiring the treatment.

Route of administration and drug delivery. The decision as to whether a topical or systemic approach is required will depend on the nature, extent, site and severity of disease, practicability, and patient choice. Topical therapy is relatively safe, and for this reason, in general, is the preferred option whenever possible. In instances where topical therapy alone is insufficiently effective, a combined topical and systemic approach may minimize the dose requirement of potentially more toxic systemic drug therapy. Oral drug administration is convenient for patients but bioavailability is highly variable and dependent on drug characteristics (e.g. lipophilicity, pH), concomitant food intake (e.g. chelation of tetracyclines by calcium in milk) and rate of gastric emptying. Drug formulation is also important [21]. Enteric coated preparations are useful for drugs that cause significant gastric irritation such as prednisolone, but may be incompletely dissolved and absorbed; similarly, controlled release preparations have relevance where the half-life of the drug is short (<4 h) but are associated with wide inter-patient variation and risk of 'dose dumping' when the dosage form fails. Parenteral administration (intravenous, intramuscular, subcutaneous) circumvents the gastrointestinal tract with consequent improved drug bioavailability, and for some drugs (e.g. biological therapy) is currently the only mode of administration. Subcutaneous administration has recently gained wide acceptance in dermatology with the advent of self-administered biological therapies in psoriasis, and also has relevance for older drugs such as methotrexate, as a substitute for intramuscular use.

Novel methods of drug delivery aim to limit systemic drug exposure (and therefore toxicity) and/or optimize bioavailability, particularly for large macromolecules (including DNA and proteins) either by facilitated access to the systemic circulation through traditional routes (skin, lung, gut) or by harnessing the specificity of the immune system to target drug action once inside the body (see Chapter 74). Advances in transdermal drug delivery systems for example, include use of chemical enhancers, iontophoresis, electroporation (where short, high-voltage pulses disrupt the lipid bilayer of the skin), cavitational ultrasound (already approved for optimizing delivery of topical lidocaine), microneedles (painless, spontaneous dissolution) and thermal ablation [22]. Inhalation also offers potential for rapid systemic delivery of small-molecule drugs and can confer better bioavailability than oral ingestion given the much lower concentrations of drug-metabolizing enzymes in the lungs compared to the gastrointestinal tract [23]. Inhalation also offers a potentially promising route for peptides and proteins, as exemplified by inhaled human insulin [24].

Distribution. Following absorption or systemic administration, a drug is distributed into interstitial and intracellular fluids. Initially, well perfused organs such as liver, kidney and brain receive most of the drug, with skin and fat levels accumulating more slowly [21]. The degree to which a drug is bound to plasma proteins and tissues determines blood–tissue partitioning, which in turn can be affected by disease states. Preferential accumulation of drugs in certain tissues may also be of clinical relevance. For example, retinoids tend to preferentially accumulate in adipose tissue so that dosing may need alteration in obese patients. Albumin is a major carrier for acidic drugs, which when reduced by liver, renal or malnutritional disease can lead to elevated levels of unbound drug and increased clearance. On the other hand, α_1-acid glycoprotein binds basic drugs and so if it is increased in acute inflammatory states, unbound drug levels may be correspondingly reduced.

Metabolism [21]. Drug metabolism is traditionally described as occurring in two phases. Phase 1 reactions, catalysed by cytochrome P450 (CYP or P450), flavin-containing mono-oxgenases (FMO) and epoxide hydrolases (mEH, sEH), lead to oxidation, reduction or hydrolysis of the drug. Usually this results in loss of drug function, but for some drugs (so-called pro-drugs), results in drug activation (e.g. mycophenolate mofetil is an ester pro-drug, which is hydrolysed to biologically active mycophenolic acid by plasma esterases). Phase II reactions lead to conjugation of the phase I product, which inactivates potentially toxic phase I metabolites, and facilitates drug elimination as a consequence of improved water solubility and increased molecular weight. Drug-metabolizing enzymes are found in most tissues in the body, including the skin, but are found in the greatest quantity in the gastrointestinal tract (liver, small and large intestine). Liver disease may impact on drug metabolism but the degree to which this occurs cannot be predicted from standard measures of liver function.

Excretion. Drugs are eliminated from the body either unchanged or as drug metabolites, with the kidney being the principle site of drug and drug metabolite elimination. Renal function is therefore a critical factor in determining drug bioavailability and potential toxicity and when reduced due to age, disease or concomitant therapy (e.g. NSAIDs, diuretics) becomes a very common source of adverse drug reactions.

Pharmacodynamics. For any given concentration of drug at the site of action, responsiveness will vary between and within individuals. Relevant contributory factors include age, concomitant medication, the disease being treated and genetic factors (see below).

Age

Age is major determinant of therapeutic outcome. Drug pharmacokinetics and pharmacodynamics are altered in the very young and in older people, although available drug-specific information

is limited largely because these groups are often excluded from clinical trials. There are also age-specific considerations that are pertinent to medical errors, adherence to treatment and co-therapy.

Children. Growth and development during childhood is associated with marked physiological change, especially during infancy and puberty, with consequent, non-linear changes in drug disposition [25]. Systemic exposure to topically applied therapies is more likely in infants and children, compared to adults. During infancy, this relates in part to the presence of a thinner stratum corneum in the preterm neonate and, during childhood, due to increased cutaneous perfusion and hydration of the epidermis compared to adults. The ratio of total body surface area to body mass in infants and young children also far exceeds that in adults. Orally administered drugs also require normalization of drug dose for either body weight or body surface area due to liver and renal developmental change. Hepatic drug metabolizing enzymes are expressed at very low levels at birth, and then undergo distinct patterns of isoform-specific developmental changes in the first year of life, with levels of activity in children exceeding those of adults. The glomerular filtration rate increases rapidly during the first 2 weeks of life and then rises steadily until adult values are reached at 8 to 12 months of age [21,25].

Older people. Ageing is associated with a number of progressive physiological changes including cutaneous atrophy, reduction in lean body mass, 40% reduction in hepatic blood flow, reduced activity of hepatic enzyme activity (especially CYP phase I) and reduced renal function. The decline in glomerular filtration rate has been estimated to be around 1 mL/min/year (or less) after middle age and is a critical determinant of disposition for many drugs. The high prevalence of co-morbidities such as hypertension, diabetes mellitus and ischaemic heart disease, together with widespread use of nephrotoxic therapies such as diuretics and NSAIDs, contribute to this decline. In completely healthy older people, renal function may not necessarily be reduced significantly. Collectively, physiological and pathological change in older people tends to increase drug bioavailability and reduce drug metabolism and elimination (for a comprehensive review see [26]), so accounting for the general advice to start drug therapy at the lowest possible dose and increase the dose slowly. Pharmacodynamic responses to drugs may also change with age—the increased effect of drugs that depress the CNS is a good example—or the pathophysiology of the disease itself may be different from younger people, as in the case of psoriasis where genetic susceptibility loci are distinct in late-onset disease.

Polypharmacy is common with 20 to 40% of older people taking five or more medications, with consequent impact on medicine adherence and risk of drug interactions. All these factors lead to increased variability in drug response with age. Adverse drug reactions are also more common, and tend to be more severe and less likely to be recognized or reported by the patient [1,3,11,27].

Conception, pregnancy and lactation

Any drug exposure prior to, during or after conception can result in an adverse fetal outcome; this risk, which is closely related to drug dose and duration, should always be considered when prescribing and the patient fully informed of the potential hazard [28]. The pre-implantation period (fertilization to implantation) is considered the 'all or nothing' period since injury will result either in embryonic loss, or, if only a small number of cells are affected, the embryo survival, as the remaining cells are not yet committed to a particular path of development and can therefore compensate for the loss. Drug exposure during the embryonic period (week 2 to week 9) carries the greatest risk of fetal malformation as this is when organogenesis occurs. Nevertheless, maternal drug exposure at any period may be associated with longer-term, functional or developmental changes that are not immediately apparent. For example, in a cohort of 31 children born to mothers exposed to isotretinoin, nearly half had evidence of developmental delay, regardless of whether the children had structural malformations at birth [29]. Drugs given just before term or during labour can have adverse effects on labour or on the neonate (e.g. sedative antihistamines), whilst ongoing maternal drug use post-pregnancy may be secreted in breast milk. In men, the effects of drugs on spermatogenesis are increasingly recognized, with those that directly interact with DNA (e.g. methotrexate, azathioprine) linked to increased incidence of congenital abnormalities [30].

Thalidomide, acitretin and isotretinoin are notable examples of drugs with specific, known risks of teratogenicity, and all of these are used in dermatology with rigorous pregnancy prevention plans attached. For the majority of drugs, however, there is insufficient evidence to properly categorize the level of risk and since very few drugs can be considered completely safe, exposure should be minimized as far as possible. Topical therapy is generally safe since systemic, and therefore fetal, exposure, is minimal.

Drug disposition can alter significantly during pregnancy [31], with most of the changes beginning during the first trimester and peaking during the second trimester [28]. Overall these physiological changes tend to increase the volume of drug distribution, reduce the amount of albumin-bound drug, and increase hepatic and renal clearance, with consequent variable effects on drug concentration depending on the drug. The impact of pregnancy on the disease being treated is also variable with, for example, both improvement and deterioration documented in psoriasis [32] and atopic eczema [33].

Drug interactions

Drug effect may be significantly altered by co-administration of another drug with consequent impact on efficacy and/or induction of toxicity. The principal mechanisms underlying most drug interactions relate to drug-metabolizing enzymes and transporters. Whilst all major drug-metabolizing enzymes have been associated with drug–drug interactions, cytochrome P40 enzymes are the major contributors to clinically relevant drug interactions with CYP1A2, CYP2C9, CYP2C19, CYP2D6, CYP3A, CYP2C8 and CYP2B6 38 most commonly implicated [34]. For example, ciclosporin is extensively metabolized by CYP3A isoforms. Co-therapy with erythromycin or itraconazole, both potent inhibitors of CYP3A, can therefore lead to significantly increased levels of ciclosporin, whereas phenytoin, a potent inducer of CYP3A, may reduce ciclosporin levels. Alternative remedies are also relevant

here. St John's wort contains a potent inducer of CYP3A (hyperforin), for example, and has been reported in association with reduced levels of ciclosporin, whilst echinacea variously inhibits intestinal CYP1A2 and CYP3A and induces hepatic CYP3A activities [35].

Drug–transporter interactions arise either due to a change in activity (either increased or decreased) or competition at the transporter site. For example, the activity of the efflux transporter P-glycoprotein, which normally acts to reduce gastrointestinal absorption and increase biliary excretion of drugs, is inhibited by intraconazole and ciclosporin, with resultant increase in relevant drug substrate levels (e.g. fexofenadine) [36].

Aside from these pharmacokinetic mechanisms, drugs may interact at a pharmacodynamic level. This may be used to therapeutic advantage—prednisolone is often combined with azathioprine or mycophenolate mofetil in order to achieve the same level of immunosuppressant effect, whilst reducing the toxicity of steroid monotherapy, for example, but may equally give rise to adverse events such as the synergistic nephrotoxicity seen when ciclosporin is combined with NSAIDs.

Biological therapy is one of the most rapidly developing areas of therapeutics, although relatively little is known about mechanisms underlying their disposition, and by implication, drug–drug interactions. In contrast to (small) drugs, these large molecules are cleared primarily via the reticuloendothelial system and/or through antigen-specific pathways via phagocytosis, endocytosis and renal clearance. Relatively few clinically relevant drug interactions have been reported to date, but they do occur. For example, interferons have been shown to variously inhibit and induce specific CYP isoenzymes, and concomitant administration of weekly methotrexate significantly decreases the clearance of adalimumab, an interaction that is used to therapeutic advantage [37].

Pharmacogenetics

An individual's genetic makeup is critical in determining drug response. Genes encoding drug-metabolizing enzymes, transporters and drug targets may all be subject to functionally relevant polymorphisms and are estimated to account for 15–30% of inter-individual variation in drug response.

Pharmacogenetics (the study of the relationship between individual gene variation and drug effect) offers the potential to identify those at risk of adverse drug reactions and those likely to respond (or not) to a particular treatment *prior* to drug exposure. As is the case with genetic factors in general, phenotypic–genotypic associations are strongly influenced by ethnicity, and this is especially relevant when considering the clinical applications of pharmacogenetic testing.

Inter-individual variation in drug-metabolizing enzyme activity has historically been described in terms of phenotypic variants (e.g. fast and slow acetylators, slow and fast 'metabolizers') which are now known to originate from specific genetic variants (NAT2 and CYP2D6 polymorphisms, respectively in this example) and more than half the drugs cited in adverse drug reaction studies are metabolized by at least one enzyme with a variant allele known to be associated with poor metabolism [38]. The polymorphic enzyme thiopurine methyltransferase (TPMT) which catalyses a key step in azathioprine metabolism illustrates this concept well. Three common SNPs [39,40] associated with loss of enzyme function have been identified and linked to risk of bone marrow suppression due to excess accumulation of biologically active thioguanine nucleotides. Determination of thiopurine methyltransferase (TPMT) status (either by measuring enzyme activity directly, or less commonly, by genotyping) is now accepted best practice in dermatology and meets several of the criteria necessary for a pharmacogenetic test to be clinically valuable. First, it allows identification of a small subset of people in whom a drug is absolutely contraindicated due to the risk of developing a severe adverse reaction—one in 300 individuals are homozygous for loss of function TPMT gene variants and show complete absence of TPMT enzyme activity with consequent predictable, potentially fatal, bone marrow aplasia on exposure to azathioprine. Second, it identifies a further subset of patients who may benefit from a drug but who might, without prior dose adjustment, have had to discontinue it—10% of the population carry one loss of function TPMT gene variant and although at risk of bone marrow suppression with standard dosing, tolerate azathioprine if the dose is reduced. Thirdly, TPMT testing is widely available and results are easy to interpret [41]. It therefore provides additional, clinically relevant information which directly impacts on prescribing and ultimately patient outcome. Even so, since TPMT loss of function allelic variants account for less than 30% of all adverse reactions associated with azathioprine, additional mechanisms possibly involving other polymorphic drug-metabolizing enzymes, must operate [42].

Polymorphisms in genes encoding drug transporters also influence drug response. Methotrexate toxicity, for example, is associated with specific polymorphisms in SLC19A1 (a member of the solute carrier transporter superfamily) [43] which controls influx of methotrexate into cells, whilst variants in efflux transporters ABCC1 and ABCG2 (members of the second major drug transporter superfamily, ATP binding cassette transporters) predict methotrexate efficacy [44]. Variants in the ABCB1 gene (also known as the multidrug resistance 1 gene, *MDR-1*, since it was originally identified as a factor underlying anticancer-drug-resistant tumour cell lines) can influence the pharmacokinetics of many drugs, including calcineurin inhibitors (particularly tacrolimus) since it encodes P-glycoprotein, a transporter that limits intestinal absorption and facilitates biliary excretion of lipophilic drugs [45].

Much pharmacogenetic research has focused on genetic factors underlying differences in drug pharmacokinetics which has been largely driven by prior detailed knowledge about drug metabolic pathways. Genetic variation in drug targets also plays a major role in determining drug response. One example close to use in clinical practice, is Vitamin K epoxide reductase (VKORC1), the target for warfarin, where common SNPs are associated with a lower dose requirement and shorter time to optimal International Normalized Ratio (INR) [46]. Drug targets of specific relevance to dermatology practice where SNPs have been reported to influence treatment response include vitamin D receptors and response to topical vitamin D analogues [47], intracellular metabolic pathways of folic acid, purine and pyrimidine and metabolism and response to methotrexate [43,48].

Genes may also influence drug response through involvement in the underlying disease process. Certain HLA class I alleles appear to confer drug- (and ethnic-) specific risk of severe cutaneous reactions, possibly by functioning to present specific drug or drug metabolites for HLA restricted T-cell activation. HLA-B*5701 is strongly associated with hypersensitivity reactions to abacavir which ordinarily occur in up to 7% of patients treated. Avoidance of abacavir in (white) individuals who carry the HLA-B*5701 allele reduces the risk of hypersensitivity by 50% and pre-testing is now part of routine practice [49]. Presence of HLA–B*1502 in Han Chinese (but not in Europeans) is so tightly associated with carbamazepine-triggered Stevens–Johnson syndrome and toxic epidermal necrolysis that the estimated sensitivity and specificity of pre-testing in patients approaches 100% and 97%, respectively [50]. Isolated use of HLA markers is probably only useful for predicting risk where the association is especially strong, and this is not always the case. For example, whilst HLA-B*5801 is associated with allopurinol-induced Stevens–Johnson syndrome/toxic epidermal necrolysis it is only present in around half of the affected individuals [51].

The pharmacokinetic and pharmacodynamic profile of a particular drug reflects the sum of multiple processes, each of which is potentially subject to genetic variation. Significant duplication within biological systems also means that deletion of one metabolic pathway, for example, may not necessarily result in a significant reduction in overall metabolism of the drug. Thus establishing the clinical relevance of specific polymorphisms is not straightforward. Genome-wide association studies, using response or toxicity to a particular drug as the phenotype, may better determine the major predictors of drug response. Furthermore, this genetic complexity needs to be put into the context of known clinical variables in order to properly achieve 'personalized' medicine. Promising algorithms incorporating multiple pharmacogenetic markers with important clinical factors have been developed to facilitate this for warfarin anticoagulation and methotrexate use in rheumatoid arthritis, and appear to better predict drug response than standard clinical parameters alone [48,52].

Cosmetic camouflage

Cosmetic camouflage is very useful in the management of a wide range of dermatological problems ranging from scarring to vitiligo, and vascular anomalies such as port-wine stains. In the UK, the Red Cross offers a voluntary service and in some hospitals the occupational therapists and/or dermatology nurses are trained to do this work. Cosmetic camouflage has been shown to improve quality of life [1]. Cosmetic tattoos may sometimes be useful in vitiligo, reconstructive surgery and to mask scars [2].

The role of complementary and alternative therapy in the context of a general consultation

The term alternative medicine was originally introduced to refer to whole medical systems where the causes of disease, methods of diagnosis and approaches to treatment are completely different to conventional medicine. Complementary medicine (or therapies) on the other hand, refers to those methods that can be used alongside or to 'complement' conventional medicine. The distinction between alternative and complementary therapy is not absolute however, and these terms are often used interchangeably, and increasingly together, that is 'complementary and alternative medicine' (CAM). A brief outline of the commonly used approaches with information on additional resources is listed in Table 72.8.

What actually constitutes CAM, and what constitutes conventional medicine, will depend on the setting (for example, traditional Chinese medicine is part of conventional medicine in China, and yet part of CAM in the UK) and it may also change with time. Some CAM for specific indications may move into mainstream medicine; NICE has recently recommended acupuncture or spinal manipulation (osteopathy and chiropractic treatments) as first-line interventions in the early management of non-specific low back pain, for example. CAM is widely used by the general population, with prevalence figures varying from 20% in the UK [1] to around 50% in the USA [2]. These treatments are also available in the context of mainstream medicine with, for example, around half of general practitioners in the UK providing access to some CAM therapies [3] and two-thirds of Scottish general practitioners prescribing herbal or homeopathic medicines [4].

As is the case for any therapeutic intervention, benefit should outweigh the risk of potential harm. That robust evidence to indicate this is the case for CAM as applied to the spectrum of diseases in which it is used remains a contentious issue. CAM encompasses a very diverse array of different types of intervention from physical treatments involving various types of massage and manipulation through to potent herbal remedies with significant, established toxicity [5], and many of these are well-established and popular among patients. Ascertaining evidence for efficacy may be challenging in this situation, even for interventions such as herbal remedies which lend themselves to conventional methods of efficacy assessment. It is also worth noting that adverse reactions to CAM are probably under-reported [6] and so absence of known adverse effects (as is the case with conventional drugs) does not exclude the possibility of harm. 'Harm' might also include the enormous financial resource expended by health care systems collectively, and by patients individually, on treatments where benefit is not properly established. Relatively few interventions have been subject to rigorous RCT evaluation [7,8]. What published evidence there is may be difficult to access and/or interpret due to publication bias (such that negative findings on CAM are more likely to be found in mainstream journals and positive findings to be found in CAM), incomplete listing of CAM journals on mainstream databases and qualitative differences in trial design and outcome measures in CAM (reviewed in [6]).

Nevertheless, around 50% of patients seen in a dermatology outpatient setting have tried, or are using CAM specifically for

Table 72.8 Commonly available and widely used forms of complementary and alternative medicine are listed together with a brief overview of the intervention and underlying philosophy.

Therapy	Definition	Additional points
Aromatherapy	Use (by inhalation, massage and/or bathing) of essential oils extracted from flowers, leaves, twigs, bark, roots and fruits to promote and enhance the health and well-being of an individual.	The International Federation of Professional Aromatherapists maintains a register of practising members: http://www.ifparoma.org
Acupuncture	Insertion of a fine, solid needle(s) into the skin at particular points on the body, for disease prevention, therapy or maintenance of health. Based on the traditional Chinese philosophy that health is dependent on the body's motivating energy (chi or Qi) moving through a series of meridians (channels) beneath the skin. Disturbance of this flow as a consequence of physical, mental and emotional factors can be restored by inserting needles into the skin.	The British Acupuncture Council is the UK's main regulatory body for the practice of traditional acupuncture: http://www.acupuncture.org.uk/
Chiropractic	Diagnosis, treatment and prevention of mechanical disorders of the musculoskeletal system, and the effects of these disorders on the functions of the nervous system and general health. There is an emphasis on manual treatments including spinal adjustment and other joint and soft tissue manipulation.	Statutory regulation through the General Chiropractic Council (GCC): http://www.gcc-uk.org/page.cfm British Chiropractic Association: http://www.chiropractic-uk.co.uk/
Traditional Chinese herbal medicine	Chinese herbal medicines are taken, or made, from natural plants, with one or several herbs being used as the basic drug for treatment of a disease, with additional herbs used to treat various symptoms. These are combined to form a prescription, in order to boost or disperse energy (Qi).	Within Europe, registration of herbal medicines mandates adverse event reporting, but not rigorous demonstration of clinical efficacy [13]. The EMEA Committee on Herbal Medicinal Products (HMPC) approves monographs containing information on indications, restrictions on its use, drug interactions and side effects and provides a regulatory framework for licensed approval of herbal medicines.
Herbalism	Use of plant remedies native to Britain, Europe and North America with choice of herb being determined by understanding of the significance of the signs and symptoms in the individual.	
Homeopathy	Oral use of typically herbal or mineral solutions in very low concentrations ('microdose'). Successive dilution following by vigorous shaking (succession) of the Mother Tincture is used to increase the effectiveness of preparations (a process known as potentization). Homeopathy is based on the principle that 'like cures like' so that administering a substance that provokes a symptom in a healthy person, can be used to treat the same symptom in a patient with the disease (Greek derivation *homois*, similar and *pathos*, suffering).	Potential risk associated with confusion with herbal remedies.
Osteopathy	Osteopathy is a system of diagnosis and treatment using touch, manipulation, stretching and massage, with a focus on musculoskeletal problems (though a few schools claim benefits across a wider spectrum of disorders).	The General Osteopathic Council regulates the practice of osteopathy in the United Kingdom. By law osteopaths must be registered with the General Osteopathic Council in order to practise in the UK: http://www.osteopathy.org.uk

Further information is available through NHS Evidence—Complementary and Alternative Medicine [14]. The Cochrane collaboration have established the Complementary Medicine Field to facilitate the systematic review of existing randomized controlled trials (RCTs) [15] and inform areas for future research.

their skin problem, and by far the most common of these, is herbal remedies. The following broad themes are useful to consider in the context of a general consultation

Why is the patient using CAM?

CAM use in general, and also in dermatology specifically, tends to be more common in women, those under 65 years of age, and in people on higher incomes and/or professional backgrounds [9]. Most patients use CAM in the context of conventional medicine, and do so in order to optimize conventional treatments, or through dissatisfaction with standard treatments.

Evidence suggests that individuals who access CAM are more likely than non-users to prefer an active or collaborative role in treatment decisions, to believe that psychological factors have a role in the origin of the illness and in the promotion of health and to place value on an holistic approach to their management with focus on treatment of the individual rather than symptoms [10]. Most practitioners of conventional medicine would argue that these are important factors in any medical consultation, irrespective of the setting. Users also tend to perceive natural or unconventional treatments as safe and to be concerned about toxicity associated with conventional medicines [10]. Insight into why a particular patient is using or has used CAM can be enormously valuable and may reveal beliefs and perceptions about their skin disease and treatment that are highly pertinent to the overall management.

What CAM is the patient using and is there any potential for harm?

Most patients will not voluntarily declare that they are taking or using CAM, so it is crucial to make specific enquiry in a non-judgemental, open way, including use for both dermatological and other indications as both may be relevant.

Herbal remedies are by far the most commonly used CAM by dermatology patients [9,11], and some of these are already known to be associated with toxicity [5] and important interactions with pharmaceutical drugs [12]. There is sometimes confusion over terminology between herbal treatments, which are possibly hazardous, and homeopathy, which is generally safe. Contamination of preparations by additional, undeclared, products is an additional hazard. In Europe, traditional herbal remedies sit under EMEA regulation, and manufacturers are required to comply with certain standards of production and labelling. Products sourced from the Internet or locally mixed herbal remedies will not necessarily be subject to scrutiny. Herbal products are, by their very nature, subject to variation in potency and availability and prescribed treatments are often mixed or changed during a course of treatment. Collectively, these factors therefore often make it difficult to assess any potential risk of herbal therapy in the context of conventional pharmaceutical agents.

A further potential source of harm arises due to the involvement of more than one health care professional managing a disease. This is an established risk even within the mainstream health care system where the principles underlying the diagnosis and management of disease follow the same construct, so there is added complexity in CAM where this is not the case, and patients are accessing care from CAM professionals in parallel with mainstream medicine. It is therefore important to be at least familiar with the various types of CAM and possible toxicities. Depending on the type of CAM being used by the patient, communication with the patient's CAM professional may also be helpful.

Patient self-help groups

The formation of patient self-help groups in dermatology has been stimulated by several factors. First, the quality of care and information provided to patients with skin diseases may not always have been optimal. Patients with common skin diseases may not always have access to experts in dermatology and patients with rare skin diseases may find that the knowledge of their professional carers is limited. Some patients wish to have the opportunity to meet, learn from and discuss mutual problems with others who have experienced first hand the same disease. Although the dermatologist tends to focus on the patient with skin disease, the patient's partner or close family, the 'greater patient' [1], are also affected by and concerned about the disease and may get benefit from patient self-help groups. This has been illustrated by the large number of parents of children with atopic dermatitis who gain benefit from atopic dermatitis groups [2]. Some people with skin disease develop sufficient insight into their disease and the limitations of its current management that they wish to help the advance of understanding of the disease by raising funds for research. By grouping together, patients may be able to advocate changes in the approach of health care systems to the care of their disease. The Internet has provided a massive stimulus to the effectiveness and outreach of patient self-help groups.

Dermatologists have recognized for over 20 years that patient self-help groups in dermatology may play a very helpful role in improving patient care [3]. Dermatologists are now encouraged to support and seek the help of patient self-help groups, especially to assist in education and support of patients [4].

A large number of dermatology patient self-help groups have now arisen in many countries. Links are given to over 46 dermatology patient self-help groups in the UK on the British Association of Dermatologists' website [5] and there are many more in the USA—a list is maintained by the University of Iowa [6]. In Germany, the existence of over 2000 self-help groups concerned with skin problems has been reported [7]. As the quality of the help provided by this wide range of groupings varied considerably, dermatologists were encouraged to make an effort to become well informed about the groups in their region.

There has been positive experience from the involvement of dermatology staff with self-help groups. When staff and patients jointly set up a support group to facilitate the development of positive coping strategies this contributed positively to the psychological well-being of individuals [8]. In the management of alopecia areata patient support groups are an important resource that should not be overlooked [9].

Despite ready availability of information, many patients are not aware of self-help groups concerning their disease. Dermatologists should be encouraged to make this information available to patients, by mentioning their existence to patients during consultations and by providing phone numbers and

website information. In the UK, the British Association of Dermatologists distributes to every dermatologist posters with information about the UK self-help groups for display in dermatology clinic waiting areas [5].

Dermatologists have the good fortune to work on the most accessible organ of the body. This gives us numerous advantages and greatly facilitates not only the diagnosis but also the treatment of skin disease. Whilst systemic administration of drugs is often necessary in dermatology, many inflammatory and neoplastic conditions can be effectively managed using the wide range of locally applied physical or pharmacological modalities that are available. The latter are the subject of this chapter which reviews the pharmacological treatments used topically, that is by application to the surface of the skin. Some of these are time-honoured treatments which have been used for a century or more, whilst others belong to the ever expanding range of newer and increasingly potent agents constantly being developed and formulated for topical use.

Topical treatment offers the potential to achieve high concentrations of a drug in the skin with minimal exposure of other organs. This can greatly increase efficacy and also safety relative to systemic administration. When side effects do occur, they are most likely to take the form of localized reactions.

Prescribing topical treatment

Prescribing topical medication requires careful consideration of several factors if optimal results are to be achieved. When the treatment contains an active pharmaceutical agent it is necessary to specify the concentration of the drug, the vehicle and the frequency of application. The patient requires advice on the quantity to be used, precisely where it should be applied and often further explanation about precise timing of application in relation to bathing and other treatments. The prescriber needs to be aware of the hazards associated with a topical treatment, particularly the likelihood of the medication inducing irritant or allergic reactions. It is also important to understand the factors that influence systemic absorption.

Drug concentration

Conventions for defining the concentration of a drug in topical formulations can be summarized as follows:

- The concentration of a drug contained in a topical medication is usually written as a percentage representing the proportion of the formulation, by weight, which is the active constituent. A concentration of 1% indicates that 1 g of drug will be contained in 100 g of the formulation. A wide range of concentrations can be specified in this way. Thus salicylic acid may be used in concentration as high as 60% for treatment of plantar warts or corns, whereas calcitriol is used at a concentration of 0.0003% in treatment of psoriasis. A very low concentration such as this is more often written as 3 μg/g.
- A frequently used alternative, especially for liquid preparations, is to express the percentage of the drug as a proportion of the volume of the formulation, thus a 1% solution contains 1 g of drug in 100 ml of the formulation. The abbreviations w/w (weight in weight) and w/v (weight in volume) are often employed to indicate which convention is being used.
- Another convention often used to describe the concentration of a solution is in 'parts'; thus a 1 part in 1000 solution of

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

potassium permanganate contains 1 g in 1 L of solution, which could be expressed as 0.1% (w/v).

The efficacy of a topically applied drug is usually not proportionate to the concentration. Doubling or halving the concentration of a drug often has a surprisingly modest effect on the response. In the case of topical corticosteroids, for example, different concentrations of active drug often have a similar biological effect [1]. However, the effect of changing the concentration in an individual case may be much greater than the apparent effect when two concentrations are compared in a clinical trial. There may also be differences between adults and children. As discussed below, the difference in efficacy between two concentrations of tacrolimus appears to be larger in adults than in children.

Choice of vehicle

Topical medication must be applied to the skin in a suitable vehicle. This term encompasses all the constituents of the formulation apart from the active pharmaceutical agent. The properties of some types of vehicle are summarized as follows:

Ointments are semi-solid vehicles composed of lipid, for example White Soft Paraffin British Pharmacopoeia (BP) (Petrolatum). They have useful occlusive and emollient properties. Some ointments contain emulsifying agents such as polyhydric alcohols (macrogols, polyethylene glycol), or cetostearyl alcohol (e.g. emulsifying ointment BP). The latter have the advantage of being less greasy, with good solvent properties, and are easily washed off. Ointments require fewer preservatives than other vehicles since they contain no water and do not sustain growth of microorganisms.

Creams are semi-solid emulsions containing both lipid and water. Emulsions are suspensions, either of lipid droplets in water or water droplets in lipid (see emulsifiers). In the former category are aqueous or vanishing creams, for example Aqueous Cream BP. These are water-miscible, cooling and soothing, and are well absorbed into the skin. In the latter category are water-in-oil (W/O) creams, for example Oily Cream BP. These are immiscible with water and more difficult to wash off. They are emollient, lubricant and mildly occlusive (but less so than ointments).

Pastes are semi-solid preparations containing a high proportion of finely powdered material such as zinc oxide or starch. Protective (fatty) pastes are greasy and therefore messy and water insoluble. They are difficult to apply and remove, but their stiffness permits accurate localization of the paste and any constituent medication. They are occlusive, protective and hydrating. The consistency of these pastes can be 'softened' by adding oils or 'hardened' with hard paraffin. Drying pastes, also called cooling pastes, are mixtures of powder with liquid. These are non-greasy, water-miscible and easy to apply and remove. They are drying and soothing, and can be used in conjunction with dressings as paste bandages or as vehicles for active medicaments.

Lotions are liquid formulations which are usually simple suspensions or solutions of medication in water, alcohol or other liquids. Those containing alcohol often sting, especially when applied to broken skin. When left on the skin the liquid will evaporate leaving a film of medication on the surface. Aqueous suspensions of powders such as calamine which require shaking prior to each application are known as **shake lotions**.

Gels might be regarded as thickened lotions. They are semi-solid preparations containing high-molecular-weight polymers, such as carboxypolymethylene (Carbomer BP) or methylcellulose. Lotions and gels are especially suitable for treating the scalp and other hairy areas of skin. Like lotions, gels tend to dry when left on the skin. Gels can provide cosmetically acceptable formulations for use on the face.

Powders applied directly to the skin are also known as **dusting powders**. They can reduce friction (talc) or excessive moisture (starch). They are occasionally used to deliver drugs such as antifungal agents applied to the feet.

Paints are liquid preparations, either aqueous, hydroalcoholic or alcoholic (**tinctures**), which are usually applied with a brush to the skin or mucous membranes and then evaporate. Collodion preparations are also sometimes referred to as paints.

Collodions, for example Flexible Collodion BP, are liquid preparations consisting of cellulose nitrate in organic solvent. They evaporate rapidly to leave a flexible film which can hold medicaments in contact with the skin. They are most frequently used to apply salicylic and lactic acids to warts. They may also be used as protectives to seal minor cuts and abrasions. They are easy to apply and water repellent, but inflammable.

Microsponges [2] are a novel approach to formulation involving the use of porous beads, typically 10–25 μm in diameter, forming a reservoir loaded with the drug. This approach has been used for cosmetics and sunscreens as well as medications such as benzoyl peroxide and retinoids. The aim is to provide sustained release of the drug whilst reducing irritation.

Liposomes are structures comprising an aqueous phase surrounded by a lipid capsule, ranging widely in diameter from several nanometers to several microns. They may contain several lipid layers so that the structure can be likened to that of an onion. Under certain conditions liposomes can release their contents close to a target cell, fuse with the cell membrane, or be endocytosed by the cell [3]. They can be formulated into creams and gels. This technology is used in cosmetics but has so far had little impact on dermatological treatment. However, it may prove useful for reducing irritation from topical use of agents such as tretinoin, benzoyl peroxide and dithranol and reducing the staining of skin and clothes from the latter [3–5]. Liposomes do not appear to penetrate intact into the intracellular compartment of the epidermis although an *in vitro* study using reconstructed human skin has suggested that liposomal lipids can be incorporated into the intercellular lipids of the stratum corneum and cell membranes in the uppermost viable layers of the epidermis [6].

The choice of vehicle depends on the anatomical site to be treated and the condition of the skin. As a rule, acutely inflamed skin is best treated with fairly bland preparations which are least likely to irritate. Moist or exudative eruptions are conventionally treated with 'wet' medications such as lotions or creams, whilst dry skin responds well to the occlusive action of ointments. Hair-bearing skin, especially the scalp, can be treated with medicaments formulated into shampoos, lotions, gels or mousse. The cosmetic properties of the vehicle assume particular importance

when treating the face. Oily skin affected by acne is often best treated with lotions, whilst the more sensitive skin affected by rosacea may benefit from the emollient effect of a cream.

The formulation of vehicles is discussed further below.

Frequency of application

The frequency of application must be specified in order to maximize the response whilst avoiding side effects such as irritation. Excessive frequency of application may also result in unnecessary systemic exposure to the drug. Emollients should be applied frequently enough to maintain their physical effect. This may require several applications daily. Active preparations are usually applied just once or twice a day. As a general rule, twice daily application of drugs such as corticosteroids or deltanoids is only marginally more effective than once daily application, whilst requiring double the amount of medication and increasing systemic exposure to the drug. The pharmacological actions of a drug may persist long after it has left the surface of the skin. Thus the ability of a potent topical corticosteroid to inhibit flares of atopic dermatitis when applied just twice weekly [7] seems unlikely to be explained simply by persistence of a reservoir of the drug. Increasing the interval between applications can be a useful method of gradually reducing the intensity of a treatment, especially when it is difficult to do so by using a lower concentration or less potent agent.

Quantity to be applied

The total quantity to be dispensed should be specified and it is helpful to inform the patient how long the prescribed quantity is expected to last. There is a tendency, especially in the case of topical steroids, for patients to be overcautious in their interpretation of the advice to 'apply sparingly' which will be found on the package insert. Minute quantities are rarely effective. Conversely, inappropriate use of active medicaments as emollients is not only wasteful but often hazardous. The potential for systemic absorption must be taken into account when prescribing, for example, topical corticosteroids, deltanoids or salicylic acid.
