Zygomycosis

Synonyms
- Mucormycosis
- Phycomycosis

Zygomycosis is caused predominantly by species of *Rhizomucor*, *Absidia* and *Rhizopus*. *Cunninghamella bertholletiae* and *Saksenaea vasiformis* are less common causes. Although they are frequent in the natural environment, they are rare causes of invasive disease in patients made susceptible by poorly controlled diabetes, neutropenia or renal disease [1,2]. Fatal infections have been reported in patients with burns. Apart from invasion of necrotic burned areas or after severe trauma involving contact with soil, for example after a landslide, zygomycosis of the skin is uncommon. Lesions are progressive and necrotic ulcers similar to those described under necrotizing fasciitis.

Necrotizing infections of the skin associated with the application of dressings contaminated with *Rhizopus rhizopodiformis* [3], and with *R. microsporus* from wooden spatulae have been described [4]. Cutaneous lesions have been described in patients with lymphoma and kidney transplants [2]. Zygomycosis is usually diagnosed in autopsy or biopsy sections, based on the recognition of the broad and generally non-septate hyphae. As early treatment is essential, the use of frozen sections from skin lesions for rapid histopathological examination has been advocated. However, provided adequate samples are taken, they can be grown from tissue. Infections may respond to intravenous amphotericin, and recent results with lipid-associated amphotericin B formulations have been encouraging.

Unusual causes of skin lesions among opportunistic systemic mycoses

Most of the organisms that can invade the immunocompromised patient may cause skin lesions. Some of these infections, such as candidosis, zygomycosis and cryptococcosis, have been described previously. However, other organisms that can cause skin disease include *Aspergillus* [1,2], *Trichosporon* [3] and *Fusarium* [4]; all of these may affect the neutropenic patient.

Aspergillus and *Trichosporon* usually produce large, scattered necrotic lesions, although with the latter, smaller papules and pustules have been seen. *Fusarium* and, more rarely, *Acremonium* infection may produce target-like lesions, which may undergo central necrosis. In some cases of *Fusarium* infection, scattered skin lesions have been accompanied by digital cellulitis and superficial white onychomycosis caused by the same organism.

Skin involvement has also been described in a variety of invasive infections affecting the paranasal sinuses such as those caused by *Exophiala dermatidis*. Skin lesions in these infections develop in severely sick patients. However, skin biopsy will sometimes reveal the true diagnosis. Treatment for these infections is usually amphotericin B. The response rates in both *Fusarium* and *Trichosporon* infections are low, and a lipid-associated amphotericin B formulation is often used instead.

Cutaneous infection caused by *Pneumocystis jiroveci*

Pneumocystis jiroveci is an opportunistic fungal pathogen that is found in immunocompromised patients, including neonates, solid-organ transplant recipients and AIDS patients. *Pneumocystis* was previously regarded as a protozoan, but more recent DNA analysis has shown that it is best regarded as a fungus, although in certain structural features, such as its cell membrane, it differs from the fungal norm. Usually a pulmonary infection, it has rarely been found to cause skin lesions in AIDS patients [1]. The organisms stain with methenamine silver and appear as round, non-budding structures 5–10 µm in diameter. Treatment is with co-trimoxazole or pentamidine.

Infections caused by *Pythium insidiosum*

Infections caused by *Pythium* species (swamp cancer, Florida horse leech) were first recognized in animals in 1884, affecting mainly horses and mules. Since 1987, a number of cases of human infection have been reported, nearly all of them from Thailand and in farmers exposed to swampy areas. Affected patients have usually had severe infections with ascending gangrene of the lower limbs. Most have had an underlying haemoglobinopathy such as thalassaemia [1]. The organisms appear to invade blood vessels with large, sparsely septate hyphae, 3–20 µm in diameter, similar to those seen in zygomycosis. It is now recognized, however, that the organism is not a true fungus and is probably more closely related to the algae. It is possible to isolate *P. insidiosum* on glucose–peptone agar, but production of the characteristic motile biflagellate zoospores, necessary to speciate the isolate, requires special media and expertise [2].

There is no known effective treatment, apart from high doses of amphotericin B and amputation.

Protothecosis

Prototheca is generally accepted as a genus of achloric algae embracing three species of worldwide distribution: *P. wickerhamii*, *P. zopfii* and *P. stagnora*. The first two species are established as rare and opportunistic pathogens in humans [1]. Infections with green and blue-green algae, although recorded, are rarer still. Lesions confined to skin and subcutaneous tissues are generally located on exposed sites, and may be associated with trauma [2,3]. Papules, nodules, ulcers and multiple granulomatous lesions have all been described. In such cases, the organisms may be found in the dermis and epidermis. Protothecal bursitis, particularly of the olecranon bursa after injury, is also well documented, as are a few examples of widespread cutaneous, subcutaneous or deep infection in immunocompromised hosts including AIDS patients [4]. Colonization of nails has been reported, and *Prototheca* may occur as transients on the skin. Spontaneous recovery has occurred in one cutaneous infection. However, surgical excision is recommended for localized lesions, and systemic amphotericin B, ketoconazole [5] or itraconazole have proved effective on occasions.

Glossary

anamorph an asexual state.
anthropophilic adapted to humans.
arthroconidium a spore resulting from the breaking up of a hypha into separate cells; characteristic of parasitic form of ringworm fungi.
asexual reproduction not involving prior union of two nuclei.
blastospore a spore formed by budding.
cerebriform complex folding similar to the brain surface.
chlamydospore a thick-walled cell, intercalary or terminal, containing stored food and able to function as a spore.
clavate club-shaped.
cleistothecium a reproductive structure associated with the sexual state of ringworm fungi.
conidiophore a specialized structure of varying complexity that bears conidiogenous cells.
conidium an asexual spore.
dermatophyte a ringworm fungus.
dimorphic having two distinct forms, which often correspond to saprophytic and parasitic phases, respectively.
downy fluffy.
ectothrix dermatophyte hair infection with hyphae inside the hair and a sheath of spores outside the hair.
endospore spore formed internally (e.g. a sporangiospore).
endothrix dermatophyte hair infection with fungus confined to the inside of a hair.
faviform waxy, restricted honeycomb-like growth of certain dermatophytes.
floccose cottony.
fusiform spindle-shaped.
geophilic soil-inhabiting.
glabrous smooth, leathery.
grain compact agglomeration of fungal or actinomycete elements formed *in vivo*.
granular texture similar to icing sugar.
hypha one of the branching filaments, septate or non-septate, that make up the vegetative mycelium (q.v.) of moulds.
intercalary not terminal.
kerion an intensely inflammatory ringworm lesion.
macroconidium the larger of the two types of conidia in those fungi that bear large and small (microconidia) spores.
microconidium the smaller of the two types of conidia in those fungi that bear large and small conidia.
mycelium the collective name for a mass of hyphae.
mycosis a fungal disease.
obovate inverted egg-shape.
pleomorphic strictly having two or more forms; used frequently to describe non-sporing (sterile) cultures of dermatophytes.
powdery with a texture like face powder.
pseudohyphae hypha-like structure produced by elongation of budding yeasts lying end to end.
pyriform pear-shaped.
sessile without a stalk.
spiral vegetative hypha assuming spiral forms.
sporangium asexual reproductive body in *Zygomycetes*.
spore a reproductive unit; formed sexually or asexually, sometimes multicellular.
sporophore a spore-bearing structure.
tuberculate covered with peg-like outgrowths.
zoophilic adapted to an animal host.

Introduction

A parasite is defined as an organism that depends upon a living host for one or more of its essential metabolic requirements. This definition does not imply that the relationship necessarily damages the host, and occasionally two organisms benefit mutually from a close association, one extreme within a wide range of relationships.

Many terms have been used to describe the relationships between parasites and their hosts; but few can be given an exact or exclusive definition. It is not, for example, possible to draw a sharp line between so-called endoparasites living within the body, which, in the case of some intestinal worms, may not invade the tissues, and ectoparasites living on the body surface, which, like the scabies mite, may in fact penetrate the epidermis. Similarly, when more than one species of host is successively infected during the life history of a parasite, they are not described in consistent terms. The definitive or final host is usually designated as the one in which the parasite reaches sexual maturity, and the intermediate host is one in which it undergoes larval development or an asexual phase. Thus, the human is definitive host for the so-called pork tapeworm *Taenia solium*, but may also act as an intermediate host in harbouring the bladder worm or cysticercus stage, which normally occurs in the pig. On the other hand, the human—as well as the sheep, the cow and the pig—is the intermediate host for *Echinococcus granulosus*, the hydatid cyst, and the dog, which harbours the tapeworm stage in its gut, is the definitive host. This logic is not exactly applied. The human is usually regarded as the definitive host of the malarial parasite of the genus *Plasmodium*, though sexual maturity is reached only within the mosquito. In practice, the anthropocentric view usually prevails: when the life history of a parasite involves alternations of human and arthropod hosts, the human is designated the definitive host and the arthropod the intermediate host or vector. A consequence of such illogicality is that the parasite now appears to be host specific only in respect of the vector, and not in respect of the so-designated definitive host. Humans share hospitality for *Plasmodium* spp. with other mammalian species, which are termed reservoirs.

Parasites that affect humans exemplify a variety of life histories [1–10]. At one extreme are species that need not leave the host even from one generation to the next; *Sarcoptes scabiei* is an example. At the other extreme are species that are only dependent on the host for the briefest contact, such as the female mosquito, which needs only a single meal of human blood before she can reproduce. In between these limits, there is a range of types of contact between parasite and hosts. Some forms spend part of their life history free-living, and only part as ectoparasites or endoparasites. Ticks, for example, while remaining for most of the time on their hosts, may drop off to lay eggs in the soil, and the larvae of hookworms hatch from the egg in the soil before burrowing their way through the skin to become gut parasites. Another category would include those parasites that spend all of their lives in the host, except for an egg or cyst stage that is transferred to another host without the intervention of a free-living phase; the roundworm, *Ascaris lumbricoides*, is an example. Lastly, there are those parasites with one or more intermediate hosts or vectors. Examples of dermatological interest are the guinea-worm *Dracunculus medinensis*, for which

Schistosoma mansoni
S. haematobium
S. japonicum
Schistosoma spp.
Paragonimus spp.

the fresh-water crustacea of the genus *Cyclops* act as intermediate hosts, and *Loa loa*, a roundworm causing Calabar swellings, which is transmitted by flies of the genus *Chrysops*.

A number of biological considerations are of relevance to dermatological diagnosis and treatment. Cutaneous lesions may result from direct damage by or presence of the parasite, or develop indirectly at non-infected sites. In scabies, for example, inflammatory lesions are found in regions other than those that actually contain *Sarcoptes* spp. Skin disease due to parasites may be localized to a single site, or it may be only one manifestation of systemic infection. A parasite may enter the body via the skin, and may sometimes get no further, or the parasite may be ingested, when the skin lesions are either fortuitous, such as those caused by bladder worms, or serve as escape channels for propagation of the parasite, as are the ulcers caused by *Dracunculus* spp.

The principal groups of parasitic animals that cause skin disease are the protozoa, the helminth worms, which include the class Nematoda (roundworms) belonging to the phylum Nemathelminthes, the classes Trematoda (flukes) and Cestoda (tapeworms), both belonging to the phylum Platyhelminthes (Table 37.1), and the classes Insecta and Arachnida, both of the phylum Arthropoda.

The parasitic protozoa of dermatological interest include members of three classes. Belonging to the class Sarcodina is *Entamoeba histolytica*, an amoeba that infects the intestine causing amoebic dysentery, but which may occasionally invade the skin where it causes ulcers. Among the Flagellata (or Mastigophora) are classed the species of *Trypanosoma* that cause Chagas' disease, transmitted by species of 'kissing bugs', and African sleeping sickness, transmitted by tsetse flies: all these diseases have cutaneous manifestations. Other important flagellate parasites are the species of *Leishmania*, some responsible for systemic and others for superficial infections, which are also transmitted by insect vectors.

The nematodes include both parasitic roundworms and forms that live free in water or soil. Both free-living and parasitic forms go through a similar series of intermediate phases during their life cycle, but in soil-living forms all these stages take place in a single environment. In comparing the life histories of parasitic species, it is convenient first to consider species such as *Ancylostoma*, *Necator* and *Strongyloides* in which the eggs hatch in the soil to produce free-living larvae. *Strongyloides stercoralis* is an example of particular interest, because it is capable either of undergoing a complete life cycle free in the soil, or of infecting humans or other animals. Female worms living in the soil produce partially developed eggs, which soon hatch into rhabditiform larvae. These larvae undergo a series of four phase changes while growing into adults, and this free-living cycle is essentially similar to that of any non-parasitic soil nematode. When environmental conditions become unfavourable, however, the rhabditiform larvae develop into more slender filariform larvae, which are non-feeding but infective to mammalian hosts. These larvae can infect cats and dogs by being eaten, but in humans they usually penetrate by way of the skin, where they cause a transitory 'ground' itch. They enter the bloodstream and are carried to the lungs, whence after penetrating the alveoli they pass up the bronchi and the trachea to the buccal cavity. Thus, they are swallowed, eventually reaching the intestine where they develop to adults. A third type of life cycle, which is completely parasitic, can occur by the hatching and development of the larvae in the gut lumen. At the filariform stage, the larvae burrow through the mucosa into the blood vessels, and hence make their way via the lungs back to the intestine, where they mature.

The life histories of *Strongyloides* spp. provide some of the models for other species. In the hookworm, *Ancylostoma duodenale*, for example, eggs that pass out with the faeces hatch, within 24 h in moist warm soil, to rhabditiform larvae. These larvae grow rapidly, moult twice and in about a week become filariform, the stage that is infective to humans. The young worms crawl to a high point of moist vegetation and wait for a new host. They penetrate the skin, enter blood or lymph vessels where they are carried to the lungs, and undergo a migratory journey by way of alveoli, bronchi, trachea and buccal cavity to the small intestine. Here, a final phase occurs, and the young worm attaches itself to the intestinal wall, where it feeds and matures to an adult: by about 5 weeks after the original penetration of the skin it can produce new eggs. The American hookworm, *Necator americanus*, has a similar life history, and filariform larvae of other species, which do not infect the gut of humans, can nevertheless penetrate the skin and cause local 'creeping eruption'.

The problem of host infection has been solved in other ways by different species of nematodes. In the species *Ascaris*, the human roundworm, pairing of male and female worms occurs in the intestine of the host, and the eggs, each in a highly resistant capsule, pass out with the faeces. Growth and development of the embryo takes place within the egg, but the larvae do not hatch into the soil: the process is delayed until the eggs are ingested by

a new host. After hatching in the intestine, the larvae burrow through the intestinal wall to reach the lymphatic or blood vessels and make the same tour through the body as species of *Strongyloides* or hookworm larvae. The threadworm or pinworm, *Enterobius vermicularis*, another intestinal parasite of humans, differs from *Ascaris* spp. in that the eggs are not deposited in the intestine, but discharged by the female after it has crawled out through the anus of the host, and in that the larvae undergo no migratory journey after ingestion by a new host.

In species of *Dracunculus*, the guinea-worm, the problem of reinfection is solved by the role of an intermediate host, *Cyclops* spp., which is ingested by the definitive host. The adult worms live in the connective tissue of humans and other vertebrates, especially the tissue just under the skin, and they can migrate from one site to another. The cutaneous lesion is a hole in the host skin through which a part of the female worm projects and, when the infected host skin gets in contact with water, sets free large numbers of larval worms. *Trichinella spiralis* is an intestinal parasite of the human and a number of other mammals. The young larvae are shed from the female and burrow through the host tissues to the blood vessels, where they are carried to all parts of the body. The vast majority of the larvae encyst in striated muscles, where they gradually become encapsulated. The life cycle can continue only if the infected muscle is eaten by another host: humans usually become infected by eating undercooked pork. The human parasites, *Wuchereria bancrofti*, which lives in the lymphatic vessels, and *Onchocerca volvulus* and *Loa loa*, which live in connective tissue, all produce microfilarial larvae in the host. Infection of new hosts is by bloodsucking or tissue-feeding insects, respectively, mosquitoes (*Anopheles* spp.), coffee flies (*Simulium* spp.) and deer flies (*Chrysops* spp.).

Trematodes that infect humans all belong to the order Digenea. Flukes are parasites of various cavities of the body, such as the intestine, the ducts associated with the alimentary canal, the bladder or the lungs. Eggs are discharged to pass out of the body, where their further development requires water and a mollusc. The egg is either eaten by a snail or it hatches into a free-swimming, ciliated larva, known as a miracidium, which finds its way into a snail. In the snail, the miracidium gives rise to a sporocyst, and an asexual reproductive cycle takes place, producing a number of larvae known as rediae. Within each redia, there may develop either a further generation of rediae or a number of motile larvae known as cercariae. Cercariae can enter a new host in a number of ways. In the sheep liver fluke, *Fasciola hepatica*, they form cysts on blades of grass and are ingested by the host. In the human liver fluke, *Clonorchis sinensis*, the cercariae penetrate the skin of fish, where they encyst as metacercariae. Humans are infected by eating uncooked, infected fish. In the various species of *Schistosoma*, however, the cercariae enter the human host by way of the skin. Of particular interest is the fact that cercariae of flukes parasitic in various birds and mammals, which cannot fully infect humans, can actually enter the skin and cause cutaneous symptoms known as cercarial dermatitis or swimmer's itch.

The Cestodes, or tapeworms, are entirely parasitic throughout their life histories, and have at least two hosts, one of which harbours the adult stage in the gut, and a second that harbours the bladder worm stage in the body cavity or tissues. Humans may, for example, become infected with the tapeworm stage of *Taenia solium*, of which the bladder-worm stage normally occurs in the pig, or by the bladder worm of *Echinococcus* spp., of which the tapeworm stage occurs in the dog and other mammals. Cysticercosis, which may affect human skin, can occur also from *Taenia solium*. Cestodes belonging to the family Diphyllobothriidae, parasites of humans, other mammals and birds, have a so-called plerocercoid larva stage in copepod crustacea, fish or other aquatic animals. Larvae of this kind from intermediate hosts, such as frogs or snakes, may sometimes infect the skin of humans, causing a condition known as sparganosis.

Parasitic worms and protozoa cause a high proportion of the world's transmissible diseases, particularly in the tropics and subtropics, and they are responsible for some of the most dramatic and serious of the affections of the skin. Worms commonly causing cutaneous disease are shown in Table 37.1. In many instances, simple and effective preventive measures are available, which, when fully applied, should greatly reduce the world incidence. The global campaign for the eradication of guinea-worm is an example of a programme where simple steps have virtually eliminated what was once a common problem.

Infection with human nematodes

In these infections, the human is an obligatory host at some stage of the life cycle of the parasite. Helminths, including nematodes, may be long lived—up to 30 years for *Schistosoma* spp. and 17 years for *Onchocerca* spp. for example—and constant reinfection

in endemic countries gives rise to heavy worm burdens. All nematodes must spend part of their life cycle outside the human body, either on soil or in water, or in an insect, crustacean or vertebrate intermediate host. *Strongyloides stercoralis* is the exception to this rule: autoinfection with this worm permits lifelong infections in humans. With some species of nematode, the worm is masked from immune recognition, and large worm burdens may be tolerated with remarkably little clinical effect. With others, inflammation, often in response to naturally dying worms or their progeny, causes severe disease. By contrast, some helminths make excessive demands on the body's nutritional reserves.

Onchocerciasis

Synonyms
- Blinding filariasis
- River blindness
- Coastal erysipelas
- Mal morado

Aetiology and epidemiology. Onchocerciasis is a filarial disease caused by *Onchocerca volvulus*. The worm affects inhabitants of certain areas in tropical Africa, from Senegal right across to Tanzania, and in Yemen, Central America, southern Mexico, Guatemala, Colombia, Ecuador and Venezuela [1]. The clinical manifestations of onchocerciasis in the New World show subtle differences in appearance and distribution, but the infection is otherwise the same [2–4]. The disease has been estimated to affect over 19 million people, of whom the vast majority live in Africa. A comprehensive control programme is now reducing the disease burden throughout the endemic areas [1]. The male adult worms measure 20–45 mm, and the female 230–700 mm in length; much longer than any other insect-borne filariae. Their progeny are sheathless microfilariae occurring in two sizes, approximately 200 µm and 300 µm long.

The vectors of the disease are tiny, humpbacked black flies of the family Simuliidae (buffalo gnats). In Africa, the species *Simulium damnosum* is mainly, but not exclusively, responsible, causing very itchy bites as it transmits the disease. The larvae develop in the thoracic muscles of the flies, and 7 days after infection are fully developed in the labium of the proboscis.

Human infections with zoonotic onchocerca have been reported in the Crimean region, Illinois and Switzerland [5].

Pathology [6,7]. Mature worms and microfilariae are found in granulomatous dermal nodules (onchocercal nodules), often situated on the scalp of their hosts in Central America, but in Africa near bony prominences on the trunk and limbs or in the natal cleft. The nodules measure some 3–35 mm in diameter, and consist of an outer layer of fibroblasts, which contains the parasites in an organized, fibrinous exudate. Inflammatory cells and, sometimes, giant cells tend to accumulate around the worms. Calcification may also occur.

Microfilariae migrate mainly in the dermis. Their death causes an inflammatory response. The longer the disease lasts, the more these changes are replaced by fibrosis and atrophy of dermis and epidermis [7,8].

Fig. 37.1 Microfilaria of *Onchocerca volvulus* in the upper dermis. Note the absence of inflammation around the live organism. (Courtesy of Dr C. McDougall, Slade Hospital, Oxford, UK.)

The numbers of microfilariae vary greatly. In some instances, there is a dense, predominantly perivascular, reaction with mononuclear cells and eosinophils, but few microfilariae [9]. At its severest, this is accompanied by marked acanthosis and hyperkeratosis. The reason for this extreme reaction is unknown, but serum from patients with this form of onchocerciasis recognize a collagen antigen expressed by a specific nematode gene, suggesting that cross-reaction between antibodies to *Onchocerca* and human collagen might play a role in the pathogenesis of this condition [10]. Often in individuals with minimal clinical lesions and dermal inflammation, there is the highest density of dermal microfilariae (Fig. 37.1). In these patients, there is evidence of defective T-lymphocyte stimulation by certain filarial antigens, which can be reversed by treatment [11]. Conversely, activation of T-cell-mediated pathways is associated with the highly inflammatory forms such as lichenified onchodermatitis (LOD) (see below).

Microfilariae also invade the eye, where they cause keratitis, posterior choroiditis, uveitis and optic neuritis, which can lead to blindness. Reports of microfilariae in blood have been rare and sporadic, and this finding is usually associated with diethylcarbamazine (DEC) therapy [12]. In others, it is difficult to exclude the possibility of concomitant infection with other filarial worms.

Free microfilariae also penetrate superficial lymphatic vessels, and may be found in the urine, tears, sputum, cerebrospinal fluid (CSF) and, occasionally, in vaginal smears or irrigation sediment.

Fig. 37.2 Acute papular onchodermatitis in a Nigerian. Early in the disease the papules are usually urticarial.

Clinical features [1,4,7,13]. The commonest symptoms and signs are pruritus, onchocercal dermatitis, nodules and, in areas of high endemicity, blindness. The disease may be detectable as early as 6 months of age, and presents with pruritus, often confined to a limb or other circumscribed body site, and a non-specific papular rash worsened by scratching.

In many patients, however, the skin may appear clinically normal, even when microfilarial counts in skin snips are found to be high. The skin changes seen in onchocerciasis vary with the age of the patient, the location of the infection on the skin surface and the geographical and climatic region where the infection occurs. Nonetheless, it is possible to define certain changes that are common features in onchodermatitis, although their prevalence varies from area to area. These changes have been classified as acute papular onchodermatitis (APOD) (Fig. 37.2), chronic papular onchodermatitis (CPOD) (Fig. 37.3), lichenified onchodermatitis (LOD), atrophy and hypopigmentation [13]. In children and in the earliest cases in endemic areas, the skin has an infiltrated appearance, with obliteration of surface markings. This is confined to one skin area and is often accompanied by the appearance of small, itching papules or pustules (APOD). The oedematous features are often more pronounced in Europeans with the disease, when it may present with localized oedema [14]. In Europeans, blotchy erythema and urticated papules are common early signs. The early rash is usually seen on exposed sites, such as the shoulders and around the pelvis. In Central America, acute swelling on the face and cheeks with erythema and itching, known as erisipela de la costa, is also a manifestation of this acute phase. Patients may continue to present with this pattern over months and years in the early phases of the disease.

As the infection evolves, localized areas of scarring and CPOD (Fig. 37.3) are seen. These may coexist with the acute papular eruption, but chronic lesions are excoriated papules and flat-topped scars with hyperpigmentation and some lichenification. The buttocks and shoulders are common sites for this rash.

Lichenified onchodermatitis may well represent an extreme form of the last clinical pattern. When fully developed, it is a

Fig. 37.3 Chronic papular onchodermatitis. Lesions are starting to lichenify.

lichenified itchy rash confined to one limb or contiguous area (Fig. 37.4), commonly the leg, although sometimes two or more areas are affected [9,11]. The rash is composed of itchy papules and nodules, which become confluent. The lesion is characteristically hyperpigmented, and it is known in Arabic-speaking areas as Sowda. Gross enlargement of the regional lymph nodes is an important feature. Interestingly, it is found mainly in East Africa (Sudan [15], Ethiopia) and Yemen. It is less common in West Africa or South America. There is some evidence that this pattern of skin change is associated with very low microfilarial loads; it may also improve symptomatically over time with loss of itching and lichenification, but increasing microfilarial loads. LOD is mainly seen in teenagers and young adults.

Atrophy (Fig. 37.5) is probably a consequence of long-standing onchocerciasis. It may develop after any of the patterns described previously, or arise from apparently normal but infected skin sites. The commonest sites to detect early atrophic changes are over the buttocks, shoulders or lower limbs. The skin becomes dry and shiny, with fine wrinkles resembling tissue paper. An extreme form of this secondary ichthyosis is known as lizard skin. It is believed that degenerative changes leading to loss of dermal elastic fibres, combined with other factors, such as massive inguinal lymphadenopathy, may give rise to the hanging groin, which is an apron-like fold of skin in the inguinal region [16] containing lymph nodes. Depigmentation is a common feature of late-stage onchodermatitis [17]. It is most commonly seen bilaterally over the pretibial region, but may affect the inguinal regions, bony prominences and the shoulders (Fig. 37.6). The patches of hypopigmentation are spotty, with islands of normal-appearing skin, but large coalescent sheets of depigmentation are present in late-stage

Fig. 37.4 Late lichenified onchodermatitis (pachyderma).

Fig. 37.6 Depigmentation over the shin in late onchocerciasis (leopard skin). This is common in African endemic areas. Note the stick for the blind.

disease. The name leopard skin is used to describe this change. While it is important to recognize that other causes of hypopigmentation, such as amyloid deposition, may also produce such changes in certain endemic areas, the presence of leopard skin in the community is used as an indicator of the prevalence of onchocerciasis in the population.

In many, if not most, patients with chronic onchocerciasis, it is possible to feel nodules containing the adult worms (Fig. 37.7).

Fig. 37.7 Cutaneous oedema and cutaneous and subcutaneous nodules in a Nigerian with onchocerciasis.

They are usually found over the pelvic or pectoral regions, although the top of the natal cleft is often a good site to find them. In South and Central American cases, the nodules are often found on the head.

Other clinical variants of onchocerciasis may occur. These include an acute urticarial eruption seen in Zaire and, in Central America, an inflammatory rash accompanied by hyperpigmentation known as 'mal morado'.

In endemic areas where onchocerciasis is found, the majority of the population may be affected; they will also have other skin diseases. There is little evidence that the presence of onchocerciasis affects the clinical appearances of these. However, it has been suggested that lepromatous leprosy [18] and widespread tinea corporis [4] are commoner in certain patients with onchocerciasis.

The major complication of onchocerciasis is severe visual impairment and blindness. It is the commonest cause of blindness in endemic areas. Ocular manifestations range from punctate and sclerosing keratitis, associated with the presence of microfilariae in the cornea and anterior chamber, to retinal pigmentation, optic atrophy, scarring and blindness. Onchocerciasis may result in blindness rates in endemic communities of 5–10% [19].

Prognosis. In endemic areas, the rate of infection increases up to the age of 50 years and no relative immunity is acquired. Symptoms increase in severity without treatment until atrophic changes are complete.

Diagnosis. Clinically, the diagnosis is usually evident, but other causes of prolonged pruritus and lichenification must be excluded, particularly scabies. Typical burrows may be hard to find in patients with scabies, and great tenacity is needed to demonstrate an acarus. Skin snips for active microfilariae are taken with the corneoscleral punch or by raising a little 'tent' of skin with a needle. This is then shaved off with a very sharp blade without bleeding, placed in normal saline in a microtitre well covered with transparent adhesive tape, or placed under a cover slip and examined microscopically 1–4 h later. The buttocks and legs are often most heavily infected, and are most likely to yield microfilariae. Nodules may be excised and examined histologically for adult worms and microfilariae. The white-cell count shows a leukocytosis with relative eosinophilia. The filarial immunofluorescence test or enzyme-linked immunosorbent assay (ELISA) is positive in 60–90% of cases.

Treatment. The treatment of onchocerciasis has been improved significantly by the development of the microfilaricide, ivermectin. This drug is given orally in a single dose of 100–200 µg/kg [20]. This results in a prolonged suppression of microfilarial counts in skin snips, and improvement in skin symptoms and reversible eye changes [21]. Microfilarial counts remain very low for 6 months, then rise slowly but do not reach pretreatment levels within 1 year. Patients may be retreated after 6–12 months. In patients with low parasite loads, such as travellers returning from an endemic country, about 30% will *not* relapse after each treatment [22]. The drug is well tolerated and side effects are seldom severe. Side effects that are seen include pruritus, skin oedema, arthralgia, malaise and fever. In particular, no acute eye changes accompany therapy [23]. Ivermectin has become the mainstay of population-based programmes for the control and elimination of onchocerciasis with striking effect [24].

Fig. 37.8 Acute papular onchodermatitis in a European. Exacerbation and oedema are characteristic of the Mazzotti reaction following a dose of diethylcarbamazine.

The alternative drug regimen, now rarely used, involves the use of diethylcarbamazine (DEC), which may cause severe exacerbation of skin (Fig. 37.8) and eye disease, even blindness [25]. DEC kills the microfilariae and is given as follows:

1 First 3 days 1 mg/kg body weight once
2 Second 4 days 2 mg/kg body weight once
3 Second week 4 mg/kg body weight three times a day
4 Third week 4 mg/kg body weight three times a day.

In heavily infected patients, or in those with severe dermatitis or with eye involvement, prednisone may be given at a daily dose in adults of 40 mg, starting the day before DEC and continuing for a few days until the reaction has settled. Collapse and death have occurred in heavily infected patients during treatment. The sharp accentuation of symptoms after a single 50 mg dose of DEC may be used as a diagnostic test where skin snips are negative (Mazzotti's test). Repeated courses are usually necessary until the patient is symptom-free.

Ocular reactions need treatment with corticosteroid eye drops and mydriatics.

Suramin is a drug that kills adult worms (macrofilaricide). However, it can cause severe adverse reactions and is now seldom used. Another approach now seldom used is nodulectomy, usually combined with a microfilaricide. In South America, some studies have shown that nodulectomy alone without drugs may reduce microfilarial levels by over 60% by 5 months after surgery [26]. It may reduce the burden of eye disease but it does not cure the disease, nor reduce transmission. A further novel approach has been to destroy the endobacterium, *Wolbachia*, which results in sterilization of female adult worms. A clinical trial using doxycycline has demonstrated that this approach in selected areas can result in an effective reduction in macrofilaria [27].

Streptocerciasis

Streptocerciasis is an infection caused by the filarial nematode, *Mansonella streptocerca*. The disease is seen mainly in parts of West and Central Africa in rainforest areas, where it may be found in the majority of the population [1]. Chimpanzees in the endemic area may also be infected.

Adult worms of *M. streptocerca* can be found in the dermis, particularly around the upper trunk; microfilariae are also seen in the dermis.

The skin rash is rather similar to that seen with onchocerciasis, with acute or lichenified itching papules (Fig. 37.9). More widespread lichenification may also occur, and hypopigmented macules are common. Secondary enlargement of the local lymph nodes is seen in many patients. The diagnosis can be made by finding microfilariae in skin snips. These are less active than those of onchocerciasis, and the microfilarial tip may curl in a typical 'shepherd's crook' appearance. The main therapy is ivermectin.

Infections caused by two other *Mansonella* spp., *M. ozzardi* and *M. perstans*, are seen in Latin America and Africa, respectively, where the parasites are a cause of microfilaraemia; patients, however, are symptomless.

Lymphatic filariasis

Synonym
- Tropical elephantiasis

Aetiology and epidemiology [1]. This is a disease due to infection with the filarial worms *Wuchereria bancrofti*, *Brugia malayi* or *B. timori*, of which the first is the commonest. Most authorities agree that clinically the diseases caused by the two genera of filariae are indistinguishable. Infections due to *W. bancrofti* are more widespread than the others [2]. They occur between the latitudes of 40° north and 30° south. The areas with the highest incidence of infection are South-East Asia and sub-Saharan Africa. In the New World, there are fewer endemic foci: Guyana, Haiti and parts of Brazil. Control has been achieved in some other countries such as Taiwan and Japan. It is estimated that about 250 million people are infected. *Brugia malayi* is mainly confined to South-East Asia and as far north as Korea, particularly in rural rainforest areas [3]. The most restricted of this group is *B. timori*, which is found in certain of the Indonesian islands [4].

Transmission and pathology [4]. The disease is transmitted by many species of anthropophilic mosquitoes of the genera *Culex*, *Aedes*, *Mansonia* and *Anopheles*. In ingested human blood in which microfilariae are present, the organisms lose their sheaths in the mosquito's stomach, and in less than 24 h have entered the thoracic muscles. Metamorphosis proceeds, and mature larvae migrate to the labella 10 days after infection of the insect. Here they are ready to be transmitted to the next human by biting.

In humans, larvae pass through peripheral lymphatics, develop and migrate centrally and eventually grow into adults, which mate in lymphatics proximal to lymph nodes. Fertilized females discharge their microfilariae, which may be found in peripheral blood 12 months after the initial infection. The discharge is cyclical and occurs principally at night. These microfilariae can pass the placental barrier. The adults are found coiled up in dilated lymphatics.

Immunity to filarial infections is complex. Otherwise healthy individuals from within the endemic area have both antibody and T-lymphocyte-mediated immune responses. By contrast, those with active infections and episodic microfilaraemia may show reduced cellular immunity, suggesting that antigens from the organisms may modulate immunity. The worms may also carry symbiotic bacteria of the genus *Wolbachia*. These are antigenic, although their contribution to inflammatory reactions is unknown.

Pathology. The presence of adult worms in the lymphatics with the resulting inflammatory response is the cause of the main pathological feature—lymphatic obstruction (Fig. 37.10). Leakage of lymph may contribute to tissue damage. Circulation of microfilariae in the bloodstream has remarkably little effect, although their entrapment in the lungs may cause tropical pulmonary eosinophilia.

Clinical features. Many of those infected do not appear to develop signs of infection, and such signs that occur vary considerably from patient to patient [5–7]. The first signs are often swelling, tenderness and erythema on the arms, legs or scrotum. Swellings may be firm, and fixed nodules and urticaria have also been described at this stage. Cellulitis, which is common, may be mild or severe and is recurrent. In the severest form it presents with fever and sweats and the painful enlargement of lymph nodes, particularly the inguinal group. Lymphangitis can accompany some attacks. Milder forms of cellulitis with more localized erythema and tender swellings also occur repeatedly. Other complications include orchitis, which is commonly followed by hydrocoele and scrotal oedema, and recurrent epididymitis. Abscesses deep in the limb muscles, or more superficially located in lymphatics, occur.

Repeated attacks of oedema and cellulitis, often associated with interdigital cracking, may be followed over a number of years by evidence of lymphatic obstruction (Fig. 37.11). In males, these commonly present as hydrocoeles, but lower leg oedema and elephantiasis may also develop. Hydrocoele or thickening of the

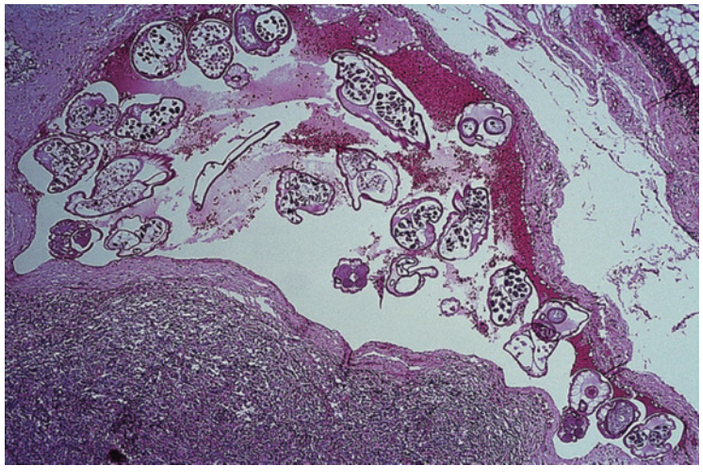

Fig. 37.10 Lymphatic filariasis (low power, H&E). Female adult *Wuchereria bancrofti* within lymph node sinus. Multiple cross-sections of worm are seen. (Courtesy of Professor S.B. Lucas, King's College London, UK.)

Fig. 37.11 Lymphangiogram showing tortuous, dilated lymphatic vessels in the leg of a patient with lymphatic filariasis from Mauritius.

scrotal skin is common in many endemic areas, and may affect up to 25% of the adult male population [8]. Limb oedema of a varying extent and nature is also common and passes through several grades of severity before becoming gross elephantiasis. This may be followed by recurrent episodes of secondary infection, and the appearance of warty thickening of the skin. The legs are usually affected, but arms, breast and genitalia may also be involved. A further complication is rupture of dilated abdominal lymphatics into the urinary tract, to produce episodic chyluria.

Diagnosis. In an endemic area, it may be possible to make the diagnosis on clinical grounds, before the stage at which microfilariae appear in the blood, as well as in the chronic condition. Biopsy of an enlarged lymph node may be diagnostic.

Microfilariae are demonstrated in the blood especially in acute cases, either in a thick blood film or by passing heparinized blood through a millipore filter, which retains the microfilariae, which can then be seen easily under the microscope. In the periodic form of filariasis, blood should be sampled between midnight and 02.00 hours.

An alternative procedure is to repeat blood films 1 h after a single dose of diethylcarbamazine (DEC) 100 mg. This releases more microfilariae into the circulation. However, some cases of filariasis do not appear to develop detectable filaraemia.

Another approach to diagnosis is the use of serology, where an indirect immunofluorescence or ELISA is positive in a high percentage of those affected, although it is not specific for each organism. An antigen detection system is also used [9]. A polymerase chain reaction (PCR)-based test has been applied to the detection of *W. bancrofti* genomic DNA in blood [10]. It is important to recognize the current deficiencies in the laboratory confirmation of this disease, as no single test is even 90% accurate.

Filarial lymphangitis must be distinguished from bacterial lymphadenitis, with its signs of a portal of entry. Genital lesions may resemble lymphogranuloma venereum with adenopathy and oedema. The Frei test will be negative.

Treatment. The management and elimination of lymphatic filariasis has become the focus of a group of research units, governmental organizations, non-governmental organizations (NGOs) and charities collectively known as the Global Alliance for the Elimination of Lymphatic Filariasis [11]. Two phases of their programme have been developed: parasite elimination and morbidity control. Parasite elimination depends on the use of chemotherapy through mass drug administration (MDA), which is also used for the treatment of individual patients. Diethylcarbamazine (DEC) has long been the main treatment [12,13], but is usually given with albendazole or as fortified salt in MDA programmes.

The dosage for individual patients is the same as for the treatment of onchocerciasis (see above), although higher doses at monthly intervals have also been given. The predominant effect of the drug is on the viability of microfilariae, but it has relatively little impact on adult worms. It may be necessary to repeat the course after a few months if microfilariae reappear in the blood.

No fatal complication has ever been reported from this use of DEC, but side effects occur, notably anorexia, nausea, vomiting, giddiness, headache, drowsiness and acute allergic reactions due to destruction of microfilariae and adult filariae.

Special care should be taken in areas where both lymphatic filariasis and onchocerciasis coexist, in view of the potentially serious nature of DEC reactions in the latter [8].

There is also experience with ivermectin, and it is effective in lymphatic filariasis. The drug works more rapidly than DEC, and microfilaraemia is reduced to 14–30% of pretreatment levels 6 months after therapy. There are also similar adverse reactions to ivermectin in patients with this condition. The dose is usually 400 μg/kg. Ivermectin does not kill adult worms, so recurrence of microfilaraemia is common and further treatments are often necessary [14]. Administration with DEC is an effective approach to MDA.

Morbidity control is approached through a combination of lower limb exercise and regular cleansing, combined with treatment of potential portals of entry of bacteria, such as infected web spaces which may be caused by fungal or bacterial infection [15]. There is evidence that this can reduce limb swelling considerably, even in late stages. These approaches are being developed across a range of endemic areas. Surgical approaches may improve the appearance of affected limbs either in the early stages by creating a lymph node–venous shunt, or by removing subcutaneous tissue and grafting of split-skin onto a muscle bed (Charle's operation) [16] in established elephantiasis. Repeated drainage and surgery may be required for severe hydrocoeles.

Loiasis

Synonyms
- Calabar swellings
- Fugitive swellings
- Loa loa filariasis
- African eye worm

Aetiology [1,2]. Human loiasis is restricted to the damp forest areas of West and Central Africa from 8° north to 5° south of the Equator, from the Gulf of Guinea across to the Great Lakes. It is particularly prevalent in the Cameroons and on the Ogowe River. Its distribution includes the coastal plain, and follows the Zaire River 500 miles inland. It is also found in southern Sudan. *Loa loa*, the eye worm, is transmitted to humans by blood-sucking tabanid flies of the genus *Chrysops* (deer fly, horse fly and mangrove fly), which bite by day, principally *C. silacea* and *C. dimidiata*. Infection is transmitted by the fly from person to person, and hill houses built at the level of the forest canopy or in cleared plantations are especially susceptible sites for the acquisition of the disease.

Pathology and clinical features [1,3]. Larvae are liberated from *Chrysops* spp. when it presses the labella against the skin to take a blood meal. They then enter the tissues through the puncture made by the proboscis. About 1 year after infection of the host, adult worms may appear under the skin or in the conjunctiva, but microfilariae in the blood are not discoverable until 5 months later [4]. The parasite migrates in fascial planes, from which microfilariae are released and travel up lymphatics to the bloodstream to be lodged in the lungs. The adult makes frequent journeys through the skin connective tissues, and has often been seen on the fingers, trunk, scalp, lingual frenulum, loose penile skin, eyelids, beneath the conjunctiva and in the anterior chamber of the eye [5]. These migrations may cause a pricking, itching, creeping sensation or may be symptomless, although when the parasite appears in the conjunctiva, considerable irritation is usual. When the eye is involved, unilateral palpebral oedema may develop and the worm may be seen actually crossing the eye (Fig. 37.12).

Fig. 37.13 Calabar swelling of dorsum of left hand in a European patient with loaiasis. In this case no microfilariae were seen in the blood.

In certain patients, including expatriates who come to live in an endemic area, these wanderings cause temporary, shifting, oedematous swellings—Calabar swellings. These affect mainly the arm and hand (Fig. 37.13), although they may appear on any part of the body. They develop rapidly and may be painful or itchy, lasting for several days.

Allergic manifestations, such as eosinophilia and angio-oedema, are often more severe in visitors who originate from a non-endemic area. They have been correlated with high IgG and IgE levels, and increased lymphocyte blastogenesis to filarial antigens [6].

Adult worms may die and calcify. Additional complications reported in loiasis include encephalitis, meningitis and glomerulonephritis [7].

The life expectancy of adult worms is at least 4 years, and may be as much as 15 years. Cases in immigrants have been reported in Australia, Zimbabwe and in North America [5,8].

Diagnosis [3,4]. Clinical diagnosis, based on the presence of Calabar swellings, the sighting of adult worms and eosinophilia in a patient from an endemic area, is usually reliable. Microfilariae may be demonstrated in a sample of daytime blood as for *Bancroftian filariasis* (Fig. 37.14).

Filarial serology by immunofluorescence or ELISA is usually positive, but not genus specific. It is particularly helpful in patients without microfilaraemia.

Treatment. One course of treatment with diethylcarbamazine (DEC) is usually curative. Side effects are few and mild, although there may be an allergic reaction with one or more large Calabar swellings, fever, malaise, swelling of joints, joint pains

Fig. 37.14 Microfilaria of *Loa loa* stained with Giemsa on a micropore filter, after filtration of 10 mL blood taken at 12.00 hours. (Courtesy of Mr A.H. Moody, Hospital for Tropical Diseases, London, UK.)

and pruritus. There is a risk of encephalitis in heavy infections with headache, giddiness, vomiting, purpura and eosinophilia. Steroid therapy starting 1 day before DEC will prevent severe reactions as in onchocerciasis (see above) and is recommended for all microfilaraemic patients. After DEC therapy, elongated subcutaneous nodules, indicating the presence of adult worms, may appear [8].

Ivermectin also produces good responses in loiasis, and reduces microfilaraemia [9]. It is given in doses of 200 µg/kg. While it is generally well tolerated, adverse events, such as impaired conscious state and arthralgia, can be seen in those with high levels of microfilaraemia [10]. Ivermectin does not kill adult worms, however.

Adult worms can sometimes be removed from the conjunctiva surgically.

Dracunculiasis

Synonyms
- Dracontiasis
- Guinea-worm
- Medina worm
- Dragon worm

Aetiology and epidemiology. Dracunculiasis is a chronic infection of humans due to the nematode, *Dracunculus medinensis* [1]. The disease occurs in India and West Africa as well as areas in East and Central Africa [2], Saudi Arabia, Yemen, Iran, Pakistan and the West Pacific. The disease was estimated to infect over 50 million people [3]. In some areas, it was particularly common: in Oyo state in Nigeria, for instance, it was found to infect 32% of a large survey population [4]. However, over the past 10 years there has been a highly successful campaign to eliminate this infestation, and the incidence of this disease has been reduced enormously to a few pockets of infection. This campaign organized through various different agencies and led by the Carter Foundation, Atlanta has been one of the success stories of tropical public health [3].

Pathology [5]. The adult female worm matures over a 1-year period in humans and discharges larvae through an ulcerated skin lesion. Millions of these larvae are produced, particularly on contact with water; these survive for 3–4 days and can develop further in copepods or water fleas (*Cyclops* spp. such as *C. leukarti*). After ingestion by the *Cyclops*, they pass through two developmental stages before reaching the infective third stage (L3) after 2 weeks. Humans are infected via drinking water containing infected *Cyclops* spp.; the larvae are released and penetrate the intestine. Further maturation occurs in the retroperitoneal space or other sites; mating occurs after about 3 months, and the males subsequently die. The females grow and migrate downwards, usually to the lower limbs. Aberrant migration can, however, occur [6]. The female penetrates the skin of the leg and can then discharge larvae after exposure to water. Each female contains 2–3 million larvae. Migration of the worm and larval forms is largely subclinical. Disease is associated with the presence of the adult female in subcutaneous tissue in the lower limbs.

Dracunculiasis is a disease found in poor rural populations. It can be spread in and around communal drinking or washing areas or wells.

Clinical features [1]. Immediately before the appearance of part of the adult female through the skin, there may be generalized symptoms such as fever, pruritus, urticaria and oedema [7]. Dyspnoea and diarrhoea may also occur. Usually, however, the first sign of the infection is the appearance of a small papule or vesicle, which expands and bursts over 4–5 days. When this occurs, commonly on the lower limb, there is intense localized itching. This is often followed by the emergence of part of the female worm through the skin (Fig. 37.15). The surrounding ulcer is covered with slough, which usually becomes secondarily infected. The worm itself is often palpable. Infections with two or more worms

Fig. 37.15 Guinea-worm. Adult female *Dracunculus medinensis* emerging from the skin of a Nigerian patient. (Courtesy of Dr R. Muller, CAB International Institute of Parasitology, St Albans, UK.)

may also occur. Eventually, the worms may be resorbed or calcify.

Secondary infection is very common, and may incapacitate the patient. It is a major cause of morbidity [7]. The common infecting organism is *Staphylococcus aureus*, but the open wound may also serve as a portal of entry for tetanus. Sometimes, *Dracunculus* may find its way into other sites [8], such as the knee joint, and cause intra-articular infection.

Diagnosis. The appearance of the worm under the skin is typical. However, the adult can be induced to shed larvae onto a glass slide, which can be examined microscopically, by applying water to the extruded segment. Worms may also calcify in tissue and can be visualized on X-ray [2]. There is usually an eosinophilia.

Treatment. The object of treatment is the removal of the worm. This is now facilitated by oral treatment with an oral benzimidazole, such as metronidazole or thiabendazole. After a few days, the inflammation lessens and it may be possible to extract the worm gently. It may be difficult to extract the worm if mebendazole is used [9]. The more traditional approach is to induce the worm to discharge larvae by applying water or ethyl chloride and to wind the free end around a matchstick. By gradually winding more and more of the worm onto the spool, the whole nematode can be recovered. It is important not to exert tension or the worm will break and cause severe allergic cellulitis. The procedure is therefore carried out slowly over a few days.

In addition, all cases should be treated with local antiseptics, tetanus toxoid and, if necessary, broad-spectrum antibiotics [7]. The drug treatment described above does not affect the larvae or prevent transmission. The latter is best accomplished by public health programmes designed to provide clean drinking water, by sieving or filtration to remove *Cyclops*. Chemical control of *Cyclops* using larvicides such as Temefos is also possible. Considerable progress has been made in the past decade in instituting effective public health measures for the control of dracunculiasis. Since 1986, the estimated prevalence has been reduced by 98% from an initial figure of 3.5 million [10].

Enterobiasis

Synonyms
- Threadworm
- Pinworm
- Seatworm
- Oxyuriasis

Aetiology. *Enterobius vermicularis* is the commonest human intestinal worm, with a worldwide distribution. It is more prevalent in cold climates, and is associated with crowding and poverty. Children are most commonly affected, and females more than males. Whole families and communities, notably schools, may be infected [1]. Male and female worms develop in the caecum, becoming mature 2–8 weeks after ingestion of fertile eggs. Gravid female worms migrate to the anus, and at night crawl on the perianal skin where they lay up to 16 000 eggs and expire. The eggs mature within a few hours. Transmission is by ingestion of eggs, most commonly carried by fingernails, because of the itching during sleep. Hands may also become contaminated through sharing a bed or bedroom. Occasionally, transmission is airborne from infected dust, in which eggs may survive for up to 13 days. Adult worms live for 6–12 weeks.

Pathogenesis. Gravid female worms migrating on the skin cause intense itching, although not in all infected people. It is not known whether an allergic reaction is involved. Adult worms may burrow

into the submucosa of the appendix or bowel and be associated with inflammation, although causation has not been clearly established. Female worms may migrate from the anus to the vagina, causing irritation and inflammation, and from there to the fallopian tubes or even peritoneal cavity, causing salpingitis and occasionally peritoneal nodules.

Clinical features. Anal and perineal pruritus at night, with sleeplessness and irritability, are the leading symptoms. Perineal intertrigo, nocturia, secondarily infected excoriations, localized urticaria [2], vulval irritation and mucoid discharge may occur [3]. Peritonitis and salpingitis [4,5] are described. It is important to realize, however, that a large number of infected children are asymptomatic.

Diagnosis. This may sometimes be made by seeing the 10-mm long female worms on the perineum at night, on toilet paper or in the stools. If possible, worms should be positively identified in a laboratory, to avoid confusion with proglotids of *Dipylidium caninum*. However, the best procedure is to wind a 6-cm strip of adhesive cellulose tape over the butt end of a test tube or a wooden spatula, sticky side outward. This is then rubbed over the perianal skin (preferably on waking) and the diagnostic eggs and adults stick to it. A drop of toluene is placed on a microscope slide and the tape is spread on it and examined microscopically.

Treatment. Of the several anthelminthic drugs available, mebendazole is probably the most effective, acting against all stages of the worm. In mass treatment campaigns, a single dose of 100-mg mebendazole cures over 90% of infections [6], but reinfection is common. More efficient is 100 mg twice daily for 3 days, repeated after 2 weeks. The whole family should be treated. In the interval, scrupulous attention should be paid to cleanliness of hands and nails on rising, after defecation and before eating. After each dosing, the bed linen is changed, and the bedroom vacuum cleaned. Even so, relapses may occur and periodic retreatment may be needed. Pyrvinium 5 mg/kg, piperazine 100 mg/kg and pyrantel pamoate 10 mg/kg are also effective.

Ancylostomiasis

Synonym

- Hookworm disease

'Ground itch', 'dew itch' and 'uncinarial dermatitis' all describe a variable and transient eruption due to skin penetration by larvae of the hookworms *Ancylostoma duodenale* and *Necator americanus*, and the roundworm *Strongyloides stercoralis*.

Aetiology. *Necator americanus* and *A. duodenale* are human hookworms very widely distributed in the tropics and subtropics. *Necator americanus* predominates in Central and South Africa, southern Asia and Melanesia, and is almost the sole hookworm in the New World and Polynesia. It rivals malaria in the store of misery and ill health that it creates [1]. *Ancylostoma duodenale* is the only human hookworm in Europe, the Mediterranean coast, central and northern Asia, and is more prevalent than *Necator* spp. in China, Japan and some parts of Indonesia.

Pathogenesis. The adult worms live in the jejunum with the head firmly attached to the mucosa and cause bleeding: *Necator americanus* 0.03 mL of blood per worm per day and *A. duodenale* 0.2 mL of blood per worm per day. They live for up to 5 years [2]. Bleeding leads to anaemia, hypoproteinaemia, digestive disturbances and retarded development [3]. Thousands of eggs are passed in the faeces. Eggs can survive varying periods of cold or drought, but under favourable conditions of warmth and humidity, hatch into motile rhabditiform larvae. After 5 days and further moults, the infective filariform larvae form. They migrate upwards through soil and grass and, after a period of contact of 5–10 min, can penetrate intact human skin. Walking barefoot is the commonest way of getting infected. Favourable places for transmission include soil around houses, places of work such as plantations and cultivated fields, and mines. Exceptionally, transmission occurs in England during a long hot summer, in playgrounds or picnic sites and formerly in mines where temperatures remain above 20°C [4].

After penetrating the skin, larvae migrate within a day or two via the bloodstream to the lungs, pass up the bronchial tree, are swallowed and pass down the oesophagus, reaching the duodenum and jejunum, where they mature in 4–6 weeks. In passing through the lungs they cause acute alveolitis or pneumonitis.

Clinical features. Larvae penetrating the skin cause ground itch: severe pruritus accompanied by erythema and often a papular or papulovesicular rash [5]. The rash is most commonly on the feet, and may be accompanied by a generalized urticaria. The rash is more common with *Necator* infections, and may become secondarily infected as a result of scratching. Larvae passing through the lungs cause a syndrome of cough, wheeze and dyspnoea, which lasts for several days. Adult worms in the gut cause abdominal pain, diarrhoea and, occasionally, melaena. Later, features of iron-deficiency anaemia, with haemoglobin levels as low as 5 g/dL, and hypoproteinaemia develop with pallor, oedema, puffy face and listlessness. Changes in the texture of skin and hair resemble those seen in kwashiorkor [6].

Diagnosis. Clinical and circumstantial evidence point to a diagnosis of ground itch. Löeffler's syndrome is characterized by eosinophilia and patchy pneumonitis seen radiologically. Established infections are diagnosed by demonstrating characteristic eggs in the faeces.

Treatment. Ground itch is treated symptomatically with an antipruritic cream, such as crotamiton with 1% hydrocortisone, or oral antihistamines. Pulmonary symptoms, if severe, respond to a few days' corticosteroids. Established infections respond to a 3-day course of albendazole or mebendazole or pyrantel pamoate [7]. Where ivermectin is used in community programmes with albendazole, it has also reduced the frequency of infections significantly. Oral iron is given for iron deficiency.

Strongyloidiasis

Synonyms
- Strongyloidal ground itch
- Larva currens

Strongyloides stercoralis is a widespread, parasitic roundworm with a life cycle and distribution similar to that of the hookworm, but with important differences [1]. It occurs in warm, especially damp, climates and is especially prevalent in South-East Asia.

Aetiology. Adult male and female worms, 3 mm long, live in the mucosal crypts of the duodenum and jejunum; eggs hatch quickly and rhabditiform larvae are passed in the faeces. In soil, they may either moult into infective filariform larvae, or set up a free-living cycle, with the production of more infective larvae. Infective larvae penetrate human skin, to establish new infections or augment existing ones. Alternatively, larvae mature in the gut and reinfect the patient by penetrating the mucosa or the perianal skin. This autoinfection is capable of maintaining the infection indefinitely, and predisposes to the syndrome of hyperinfection, in which extremely heavy worm loads build up and leave the confines of the gut, in patients who are immunosuppressed by corticosteroid drugs or Hodgkin's disease, or debilitated by advanced age, tuberculosis or other severe infection, ketoacidosis or burns [2].

Pathology [3]. Penetration of the skin by filariform larvae may cause dermatitis. Adult worms give rise to duodenitis and jejunitis, which may cause diarrhoea and malabsorption. Migrating larvae in the skin give rise to a weal-and-flare response, which follows the path of the larva. Hyperinfection causes severe enteritis with fluid loss, and paralytic ileus, pneumonia, meningoencephalitis and secondary Gram-negative bacterial septicaemia with shock and disseminated intravascular coagulation.

Fig. 37.16 Larva currens rash of *Strongyloides stercoralis*. The weal and flare will have disappeared in a few hours.

Clinical features. Ground itch of initial infection is similar to that seen in hookworm disease. Intestinal infection causes abdominal pain, diarrhoea and, if severe, weight loss or stunting of growth in children [4]. Associated allergic phenomena are common. Urticaria occurs in 66% of cases of strongyloidiasis among patients who have had the infection for over 45 years [5]: IgE levels are raised. Thirty per cent of these individuals also suffer from larva currens, the urticarial weal and flare of migrating subcutaneous larvae. Tracks are seen anywhere on the skin between knees and nipples (Fig. 37.16), but especially around the anus and buttocks. They move at a rate of several centimetres an hour and can traverse the abdomen in a single day, to be gone the next day: features that distinguish the rash from that of larva migrans (see below). Tracks may be several centimetres long or consist simply of one or more urticarial papules. Tracks may be linear or serpiginous but the rash may be less distinctive, mimicking a drug eruption [6].

Heavy infection causes severe diarrhoea, with fluid and electrolyte loss; signs of ileus may develop. Fever, abdominal distension, cough, dyspnoea, mental changes and unconsciousness may develop, and the patient may become shocked. Shock commonly indicates a complicating Gram-negative septicaemia. Cough, dyspnoea and chest signs suggest pneumonia. A widespread petechial or purpuric rash may be seen [7]. Strongyloides infections have also been associated with immune reconstitution syndrome in HIV-positive patients where increased generalized symptoms and pruritus were triggered by antiretroviral therapy [8].

Diagnosis [9]. Larvae of *Strongyloides* spp. are demonstrated in the faeces, by one of several concentration or culture techniques. Diagnostic yield is increased by examining samples of jejunal juice, most conveniently obtained by a 'string test' (Enterotest capsule) or jejunal biopsy. In a few centres, a strongyloides antibody test is available. Except in the hyperinfection syndrome, eosinophilia is common and tests for malabsorption may be positive.

Treatment. Ivermectin in a single oral dose of 200 µg/kg body weight, to be repeated on day 7, is also effective. For cases of

hyperinfection, ivermectin is given daily until symptoms resolve. Until recently, thiabendazole had been the drug of choice, given in a dose of 25 mg/kg body weight orally twice daily for 3 days, and repeated after 2 and 4 weeks. Side effects are common, and include headache, malaise, nausea and vomiting. Albendazole is also effective in a dose of 400 mg/day for 3 days, and is free of toxicity. Faecal and jejunal samples should be examined for larvae after 3 and 6 months.

Infection with nematodes of other animals

Nematodes that do not normally parasitize humans are often unable to mature or develop fully, or to home to their normal site in the body. Biologically, the human is a dead-end host. The infective larvae tend to wander, causing one of several forms of larva migrans, or the adult worm migrates, causing migratory allergic phenomena. Worms reach unusual sites and give rise to eosinophilic granulomas, occasionally in important sites, such as the eye, causing blindness, or the lungs, causing radiological confusion. In other infections, full development may take place and humans act as accidental intermediate hosts.

Cutaneous larva migrans

Synonyms
- Creeping eruption
- Sand-worm eruption
- Plumber's itch
- Duckhunter's itch

Cutaneous larva migrans in a clinical term for a distinctive cutaneous eruption that has numerous causes. The prime features, as the name suggests, are that the lesions creep or migrate, and that they are due to the presence of moving parasites in the skin. Visceral larva migrans also occurs (see below).

Aetiology [1]. Causes of creeping eruption include *Ancylostoma brasiliense*, *A. caninum*, *A. ceylonicum*, *Uncinaria stenocephala* and *Bubostomum phlebotomum*. These are all hookworms of various animals, of which the first, the dog hookworm, is the commonest cause of creeping eruption in humans. *Anatrichosoma cutaneum*, a parasite of monkeys in the Far East, is a rare cause. *Strongyloides stercoralis* causes a distinctive form of cutaneous larva migrans. *Dirofilaria repens* and *Spirometra* spp. cause a subcutaneous granuloma that may migrate very slowly. *Gnathostoma* spp. and *Loa loa* cause migratory evanescent subcutaneous swellings. Cutaneous myiasis due to larvae of flies of the genera *Gasterophilus* and *Hypoderma* may cause a creeping eruption similar to that caused by the animal hookworms. Only the helminths that cause creeping eruption are considered further here.

Adult hookworms live in the intestines of dogs and cats, and their ova are deposited in the animals' faeces. Under favourable conditions of humidity and temperature, the ova hatch into infective larvae, which will penetrate human skin. Sandy, warm, moist, shaded areas are particularly favourable, and numerous infections are acquired by children in sandpits, plumbers under houses, farm-workers under outbuildings, hunters in hides, gardeners from the soil and seabathers from the sandy shore above the ebb and flow of the tides. The condition is common in all warm climates, and may occur in northern Europe during a hot summer. Outbreaks in groups of holiday makers who mostly acquired the condition by direct skin contact with infested sand while on tropical beach holidays have been described [2].

Clinical [3]. The larvae may cause a non-specific dermatitis at the site of penetration where the skin has been in contact with infected soil. This is commonly the feet, hands and buttocks. They can then lie quiet for weeks or months, or immediately begin creeping activity with the production of a wandering thread-like line about 3 mm wide. This is exceedingly itchy, slightly raised, flesh-coloured or pink, and forms bizarre, serpentine patterns. Large numbers of larvae may be active at the same time, with the formation of a disorganized series of loops and tortuous tracks (Fig. 37.17).

The larvae advance at a rate of a few millimetres to a few centimetres daily, and are somewhat in front of the head of the track. The wanderings of an individual larva are usually confined to a relatively small area, but exceptionally it travels much further. Itching leads to scratching and secondary changes of dermatitis and bacterial infection. In later stages, these tracks are difficult to see, the path being marked by small itchy and discontinuous nodules.

The disease is self-limiting. Estimates for the natural duration of the disease vary considerably. This variation almost certainly depends on the species of larva observed, and this is usually unknown. In one study, 25–33% of larvae died every 4 weeks, whereas in another (presumed due to *Ancylostoma brasiliense*) 81% of lesions disappeared in 4 weeks [4]. Some persist for many months.

Larva migrans can be accompanied by Löeffler's syndrome of pulmonary eosinophilia, particularly in severe infestations [5].

Diagnosis. The classic clinical picture of wandering, advancing, serpentine and itchy lesions is easily recognized, but may be atypical, hidden by vesicles and scaling, or spoiled by scratching and secondary infection.

Fig. 37.17 Cutaneous larva migrans (creeping eruption). There are several tortuous, indurated, inflamed worm tracks, in some of which may be seen a blister that marks the head of the track.

Larva currens and migratory myiasis must be distinguished and, in the Orient, gnathostomiasis.

Biopsy in larva migrans is of little value, as the larvae have advanced beyond the clinical lesions.

Treatment. Ivermectin in a single dose of 200 µg/kg body weight is the main treatment [6]. Albendazole 400 mg/day by mouth for 3 days is also effective, although in some cases the responses are poor. An alternative choice of treatment is the topical application of 10% thiabendazole. Either the commercially available oral preparation may be used directly [7], or two 0.5-g tablets of thiabendazole are ground and mixed in 10-g petrolatum and applied twice daily. Well over 95% of the tracks clear within a week. Oral thiabendazole is less effective and more toxic.

Visceral larva migrans: toxocariasis

Many non-human and human helminths may be found migrating in human organs at some stage of their life cycle, but the syndrome of visceral larva migrans is synonymous with the severe form of toxocariasis.

Aetiology. This infection is caused by *Toxocara canis*, *T. cati* and *T. malayensis*, the common roundworms of dogs, cats and wild carnivores. The domestic dog is thought to be the most important source of human infection, and the prevalence of infection in dogs may be high, reaching 73% in New York State and 100% in puppies in Brisbane [1]. Infection is intense in puppies because of transplacental infection, which is augmented by infection from breast milk and contaminated bed litter [2]. Eggs are passed in dog faeces. Humans are most commonly infected by ingesting eggs in soil, or in contaminated food or water. Children are especially at risk when playing in parks or other areas frequented by dogs, or from domestic puppies that have not been regularly wormed. Ova remain infective on soil for many months.

The incidence of human infections is not finally established, but skin tests on apparently healthy subjects suggest that at least 2% of the general population of the UK acquire the infection [2]. The incidence is higher in those in close contact with animals, especially under primitive living conditions. Of a rural population in Pennsylvania, 54% were infected [3].

Pathogenesis. In humans, the second-stage larvae migrate from the intestine to most parts of the body, but notably to liver, lungs, muscles and brain where they eventually die in eosinophilic granulomas.

Clinical features. Most human infections are asymptomatic, or at least unrecognized. Persistent eosinophilia is, however, probably invariably present [4]; counts of over 25×10^9/L are common. In a proportion of infected children, the full syndrome of visceral larva migrans develops. The essential features, apart from eosinophilia, are cough and dyspnoea, failure to gain weight, muscle pains and sometimes fever. The liver is enlarged. Hyperglobulinaemia is frequent. The syndrome is self-limiting after a few months if reinfection is prevented.

Since so many cases are undiagnosed, the incidence of cutaneous manifestations is unknown. Generalized pruritus and urticarial or papular eruptions of the trunk and legs are most frequently reported. Migrating panniculitis, although rarely reported, is distinctive and perhaps pathognomonic: substantial, tender, subcutaneous nodules vanish after 1 or 2 weeks [3,5].

In a minority of infected individuals, who have never experienced visceral larva migrans, a wandering larva causes an ocular granuloma simulating a neoplasm [6].

Diagnosis. This is reliably confirmed by biopsy of the liver or of a cutaneous nodule. Fluorescent antibody and ELISA techniques are helpful [7]. Molecular methods also show promise in distinguishing between the main pathogens [8].

Treatment. Treatment responses are often unsatisfactory. Albendazole may prove to be the best treatment [9]; in the case of ocular infection, vitrectomy is often combined with medical treatment. Cure rates are low with diethylcarbamazine or thiabendazole.

Gnathostomiasis

Gnathostomiasis is an infection caused by *Gnathostoma spinigerum*, *G. hispidium* and *G. nipponicum*, the definitive host of which are cats, wild felines, dogs and certain other animals that eat fish, snakes and frogs [1]. Human gnathostomiasis occurs throughout South-East Asia, east of and including Bangladesh, China, Japan, Indonesia and the Philippines. The greatest number of cases is in Thailand. There are also reports from Mexico [1].

Aetiology. Adult worms live in the stomach of the carnivore. Eggs are passed in the faeces, hatch in water and are ingested by a species of *Cyclops*, in which they transform further. When *Cyclops* is ingested by frogs, snakes or fish the larvae develop to the third stage in the flesh of the animals, which in turn are eaten by the definitive host, thus completing the cycle. Humans are infected either by ingesting *Cyclops* in water or by eating inadequately cooked flesh of an intermediate host. Worms removed from a person are most commonly third-stage larvae or immature adults, which measure 2–4 mm long and are rust brown in colour due to ingested blood. The head of the worm is crowned by 4–8 rows of hooklets (Fig. 37.18) and the anterior half of the body is covered in leaf-like spines. Rarely, a mature male worm, up to 12 mm long, has been found [2].

Pathogenesis. Larvae ingested by humans wander, mainly in subcutaneous tissues and muscles, causing deep tunnels, which form the sites of episodes of inflammation or abscess formation. Histology shows intense infiltration with neutrophils, plasma cells, chronic inflammatory cells and especially eosinophils. Less common sites of infection include the brain and eye.

Clinical features. The commonest presentation is of intermittent, migratory, subcutaneous swellings, several centimetres in diameter. They are firm, warm, red, painful and last up to 4 weeks, before disappearing and returning nearby. They occur most commonly on the upper parts of the body, including the orbit. Abscesses may develop subcutaneously or in muscle [3].

Fatal encephalomyelitis has also been described [4]. Isolated swellings may simulate inflammatory or neoplastic disease of other internal organs.

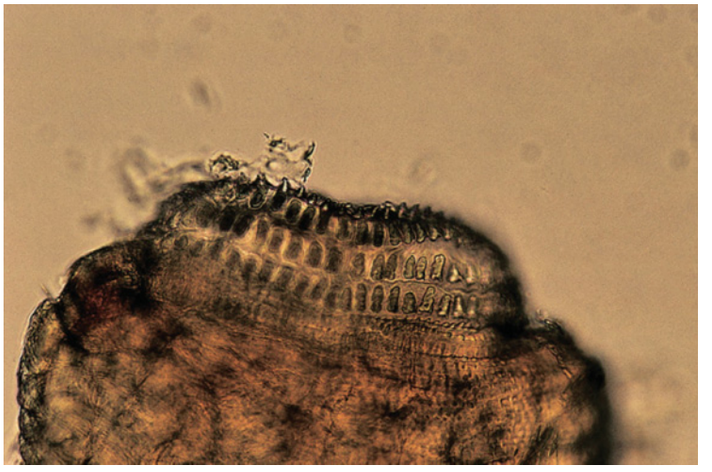

Fig. 37.18 *Gnathostoma spinigerum*. Head of adult worm that was extruded from a subcutaneous swelling in a patient from Bangladesh. The crown of hooklets is characteristic. (Courtesy of Dr P.L. Chiodini, Hospital for Tropical Diseases, London, UK.)

Diagnosis. Geographical history, clinical features and a peripheral eosinophilia suggest the diagnosis, which is confirmed by surgical extraction of the worm. Occasionally, a worm is expelled through the skin. A reliable serological test is available through some specialist centres.

Differential diagnosis. Other nematodes that may cause similar clinical pictures include *Lagochilascaris minor*, a cause of subcutaneous abscesses in Surinam and Central America, *Thelazia callipaeda*, which parasitizes the conjunctival sac in the Far East, and *Gongylonema pulchrum*, a cosmopolitan parasite of pigs, bears, hedgehogs and monkeys that causes migratory lesions in the oropharyngeal submucosa of humans [5].

Treatment. Albendazole in a dose of 400 mg/day for 21 days or ivermectin 200 µg/kg single dose are effective [6]. Other anthelmintics have not proven useful. Worms may be removed surgically. Treatment of worms of the face is important, to prevent ocular involvement [7].

Dirofilariasis

Aetiology. Dirofilariasis is an infection by filarial nematodes of the genus *Dirofilaria*. There are two forms of the disease:

1 Subcutaneous dirofilariasis caused by *D. tenuis* (*D. conjunctivae*), *D. ursi*, *D. subdermata* and *D. repens*
2 Pulmonary dirofilariasis caused by *D. immitis*, the dog heart worm.

Dirofilaria ursi and the related *D. subdermata* are natural parasites of bears and porcupines, respectively.

Subcutaneous dirofilariasis

Geographical distribution and life cycle. Most cases are reported from the southern USA, but there are occasional reports from Africa, Asia and South America. *Dirofilaria repens* is a subcutaneous parasite of dogs and cats and *D. tenuis* of raccoons in the USA. Transmission to humans is thought to be by mosquitoes.

Clinical features [1–3]. The lesion is usually a tender, occasionally migratory, subcutaneous nodule which develops over a few weeks. Common sites are eyelid, scrotum, breast, arm and leg. The worm may also be seen in the conjunctiva and is present within a foreign-body granulomatous reaction in the nodule (Fig. 37.19). Microfilariae are not found in the blood.

Diagnosis and treatment [4]. This is made by extracting the worm from the lesion, or by identifying it in an excised specimen. Treatment is by surgical removal.

Trichinosis

Synonyms
- Trichiniasis
- Trichinelliasis

Trichinosis is an infection of intestine and muscle, with *Trichinella spiralis*, a natural parasite of a wide range of carnivores. The human is normally an end host. A variety of allergic phenomena characterize human infection. Trichinosis is distributed worldwide. It is an important disease both in Europe and in the USA and has been found in Africa, south of the Sahara.

Aetiology. Encysted larvae of *Trichinella spiralis* are ingested in meat, hatch in the duodenum, penetrate the submucosa, and within 5 days have matured and mated and started producing 200–2000 invasive larvae, which reach muscles where they become encysted and infective to a fresh host within 21 days. The adult worms live less than 2 months. Cysts may calcify, but the larvae remain viable for many years and can outlive their dead host by 10 days [1].

Humans acquire the disease by eating raw or undercooked meat infected by *Trichinella spiralis*— such as bush pig in Africa, polar and black bear meat in Alaska and the Arctic. Entire polar expeditions have died of the infection after eating polar bear.

Pathogenesis. Intestinal infection causes partial villous atrophy and mucosal and submucosal inflammation. The deposition of larvae in muscles is associated with oedema, loss of cross-striations and basophilic degeneration (Fig. 37.20). The coiled larvae are surrounded by an inflammatory infiltrate of lymphocytes and macrophages until they become encapsulated.

Clinical features [2,3]. The disease may be symptomless or mild, but generally, after a moderate infection with the 'muscle worms', severe symptoms resembling acute food poisoning ensue rapidly. These are followed within a week by an acute illness with fever, generalized muscle pain and tenderness, sweating, periorbital oedema, conjunctivitis, some paralysis of the muscles of the tongue, jaw and respiration, with a transient maculopapular rash of the extremities, and splinter haemorrhages beneath the nails.

In severe infections, there is involvement of the heart and central nervous system (CNS). A necrotizing vasculopathy equivalent to classic polyarteritis nodosa is described [4].

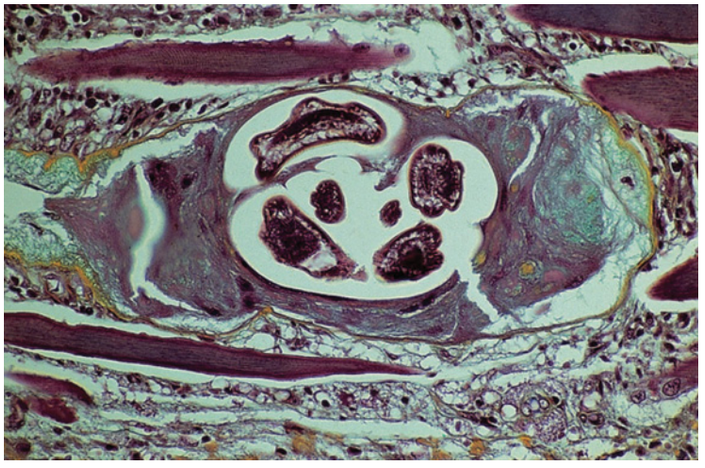

Fig. 37.20 Trichinosis. Medium-power view, Movat stain, showing *Trichinella* worm within a 'nurse cell' in skeletal muscle. There is surrounding oedema, muscle disruption and lymphocytic infiltrate. (Courtesy of Professor S.B. Lucas, King's College, London, UK.)

Diagnosis. Within a week of eating inadequately cooked meat, especially pork, clinical features suggest the diagnosis. Worms may be found in faeces in the second to fourth week of the infection, and after 4 weeks in biopsied muscle. The eosinophil count, erythrocyte sedimentation rate and serum creatine phosphokinase are all raised. After 3 weeks, antibodies become detectable. Bentonite flocculation and ELISA [5] are the tests most commonly used.

Treatment. Corticosteroids are life saving in suppressing allergic reaction at the height of larval spread. Mebendazole and thiabendazole reduce the severity of infection if given early enough in the acute disease, but albendazole is possibly more effective [6,7]. However, once the parasites are encysted in muscle antiparasitics are ineffective.

Infection with trematodes

Synonyms
- Flukes
- Flatworms

Trematodes are non-segmented, single-sex worms, flattened like a leaf and without a formal organ of attachment. Pairs of adult worms live in a hollow viscus (vein, gut, bile duct, lung), from whence eggs make their way into faeces, urine or sputum. The eggs must enter water, hatch and infect a species of snail, in which a cycle of development and multiplication occurs, resulting in the release of motile cercariae. These either penetrate human skin or enter a resting stage in aquatic plants, fish or crustacea, and are later eaten. Trematodes are important and common parasites of humans, especially in Africa and the Far East. They cause skin disease either as a result of cercarial penetration, by the ectopic deposition of adult worms or their eggs, or by causing allergic phenomena.

Schistosomiasis

Synonym
- Bilharziasis

Schistosomiasis or bilharziasis is a serious systemic disease due to different species of human schistosomes or blood flukes [1]. Rashes may occur during the invasive stage of this disease, when the skin is being penetrated by cercariae, and later there may be skin involvement at or near mucocutaneous surfaces, and less commonly at more distant sites on the trunk, following dissemination of ova.

A second group of non-human schistosomes cause cutaneous symptoms only. This situation follows penetration of cercariae into the skin, but further development of the flukes in humans is arrested and there are no sequelae. The condition 'swimmer's itch' or cercarial dermatitis is an example of this process.

Skin manifestations of this common disease of tropical and subtropical distribution are incidental features of the underlying disease. They may be grouped as follows [2]:

1 Schistosomal dermatitis
2 Urticarial reactions in the early weeks of the disease
3 Paragenital granulomas and fistulous tracts
4 Ectopic cutaneous schistosomiasis.

Ectopic sites of egg deposition probably arise through migration of adults via the paravertebral venous plexus.

Aetiology [3]. Schistosomiasis is caused by the human blood flukes *Schistosoma mansoni*, *S. japonicum* and *S. haematobium*. Two other species, *S. mekongi* and *S. intercalatum*, are more rarely associated with infection in humans.

Humans infected with *S. mansoni* and *S. japonicum* excrete eggs in the faeces, and with *S. haematobium* excrete eggs in the urine. On contact with water, these eggs develop into miracidia, which undergo further development in certain aquatic snails. From these, free-swimming cercariae are released, which are capable of

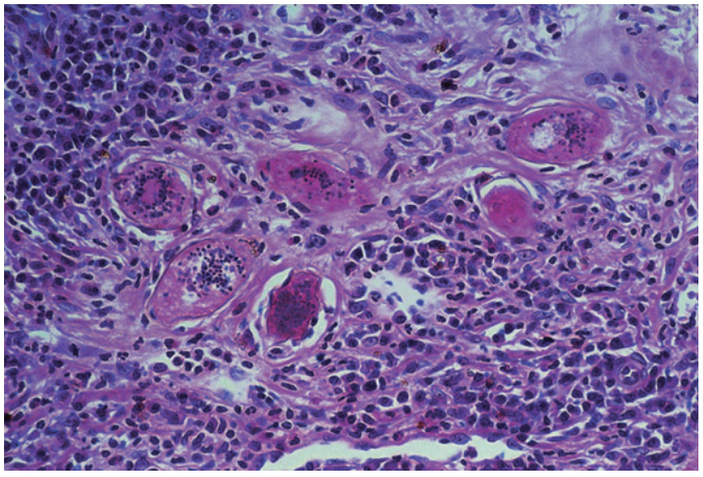

Fig. 37.21 Schistosomiasis of the vulva (medium power, H&E) showing six schistosome eggs with surrounding lymphoplasmocytic infiltration. (Courtesy of Professor S.B. Lucas, King's College, London, UK.)

Fig. 37.22 Schistosomiasis of the vulva and anus. Condylomatous lesions containing granulomas around schistosome ova. (Courtesy of Professor G. Nelson, Liverpool School of Tropical Medicine, Liverpool, UK.)

penetrating human skin to produce the infection [4]. The organisms can pass rapidly through the epidermis, and enter the venous blood within 24 h of contact with human skin. The larvae are then carried through the heart and lungs, and mature into flukes in the intrahepatic portion of the portal system.

Finally, the mature flukes pass from the portal system into pelvic veins, where eggs are laid. *Schistosoma mansoni* and *S. japonicum* localize primarily in the veins around the rectum and colon, while *S. haematobium* invades vesical and, sometimes, rectal veins with the production of haematuria and other urinary symptoms. Ova work their way out of the veins into the tissues, where they cause the formation of granulomas in which there is a pseudotubercle arrangement of inflammatory cells rich in eosinophils and histiocytes, and occasional giant cells, surrounding the diagnostic ova [5]. Lesions occurring away from the characteristic sites of egg deposition are termed 'ectopic' (Fig. 37.21). Disease due to the commonest agent, *S. mansoni*, is endemic in Africa and South America (especially the Nile delta and North-East Brazil). *Schistosoma japonicum* occurs in the Far East, and *S. haematobium* extensively in Africa (especially in the Nile and Rift Valleys), Arabia, Malagasy and South-West India [6].

High prevalence rates in workers immigrant to temperate climates [1,7], outbreaks among foreign personnel employed in endemic areas and occasional case reports of the disease in individuals who have left those areas, reflect the frequency with which infections such as schistosomiasis are encountered outside their endemic area. Infections may also be seen in short-term visitors to an endemic zone, particularly if they have swum in an infected lake or river.

Clinical features. Skin involvement may occur either as a result of the initial penetration of the skin by water-borne, free-living cercariae (an intermediate stage in the life cycle), during an immune-complex-mediated phase of the infection, Katayama fever [8], or in the later stages of infection following ectopic localization of worms or ova [9].

1 *Schistosomal dermatitis.* Penetration by cercariae of parts of the epidermis in contact with water may pass unnoticed, or cause an itchy papular eruption indistinguishable from swimmer's itch (cercarial dermatitis due to non-human flukes). The symptoms of itching usually last only for a few hours after leaving the water, although mild erythema may persist for longer. In sensitized individuals, however, papules and itching persist for about a week [2].
2 *Urticarial reactions.* Four to eight weeks after penetration of the skin by cercariae, urticaria may occur. This is particularly severe in *S. japonicum* infection, together with fever, purpura, malaise, arthralgia, abdominal cramps, diarrhoea and enlargement of liver and spleen. In some areas, for example China and Japan, this feature is so prominent that the disease is called 'urticarial fever' or Katayama disease. Eosinophilia is also typical. The symptoms resolve in about 4–6 weeks.
3 *Paragenital granulomas and fistulous tracts.* In areas of high endemicity, cutaneous bilharziasis of the perineum and external genital regions is not uncommon [10,11]. This follows direct spread of adult flukes to adjacent vasculature. Granulomatous genital condylomas occur, and fistulous tracts with extensive firm masses, honeycombed by sinuses, are characteristically found on the perineum, groins or buttocks (Fig. 37.22).

Ectopic cutaneous schistosomiasis [12–14]. Ova may become deposited in the skin as well as in other ectopic sites, such as conjunctiva, lungs and CNS. They arise following embolism of ova from adults, which are localized in abnormal sites, such as the paravertebral plexus [2]. The trunk is almost invariably the site of ectopic cutaneous involvement. The primary lesion is a flesh-coloured, firm papule reaching a size of 2–3 mm, and ovoid in shape. These papules agglomerate to form slightly raised plaques with irregular contours. Later still, some plaques develop a surface protuberance, and deepen in colour but retain their irregular, ovoid contours. The skin over old nodules may be deeply pigmented and scaly, and may later ulcerate. The para-umbilical area

Fig. 37.23 *Schistosoma haematobium* ovum in urine. (Courtesy of Mr A.H. Moody, Hospital for Tropical Diseases, London, UK.)

is a common site [12] but other areas may be involved (Fig. 37.22) and, in some cases, the lesions have a segmental or zosteriform distribution [7,14]. With treatment, these lesions slowly disappear in about 5 months. A facial hypopigmented plaque is described.

The major complications of schistosomiasis are due to infections affecting the liver (fibrosis), intestinal involvement and bladder infection, which may lead to carcinoma of the bladder. Other sites of involvement include the kidneys, heart, CNS and retina [4].

Diagnosis. The characteristic ova may be found in stools or urine (Fig. 37.23). On occasions, rectal biopsy is an alternative method of finding ova. The latter have a characteristic morphology. Serological methods are useful for screening. Immunofluorescence and ELISA are commonly used. Ectopic cutaneous schistosomiasis is diagnosed by biopsy. Histology shows epithelioid cell granulomas containing degenerate ova (Fig. 37.21).

Treatment. Praziquantel is given as a single dose of 20 mg/kg twice in 1 day, except in infections due to *S. japonicum*, where 20 mg/kg three times in 1 day is administered [15]. Cure rates are high with this regimen, and there are few side effects such as abdominal discomfort and headache. However, there are increasing reports of treatment failures and resistance has been recorded in laboratory testing [16]. Other drugs that are available include metrifonate for *S. haematobium* and oxamniquinine for *S. mansoni*. In early infections, the results of therapy are excellent, although reinfection is a continuing risk. Cercarial dermatitis resolves spontaneously. However, many of the complications of the infection such as hepatic fibrosis, portal hypertension and ureteric stenosis are irreversible, due to scar formation.

Cercarial dermatitis

Cercarial dermatitis is the name given to a group of skin disorders having a common aetiology—penetration of the skin by free-living cercarial stages of non-human schistosomes [1]. There are a number of local names for these conditions, such as swimmer's itch, clam digger's itch, sedge pool itch, koganbyo and sawah itch. While the clinical features of the condition are similar whatever the aetiology, there are three main types of cercarial dermatitis.

1 *Fresh-water avian cercarial dermatitis* [2,3]. This follows penetration of the skin by cercariae of avian blood flukes. The intermediate hosts are fresh-water molluscs. The flukes belong to the genera *Trichobilharzia*, *Gigantobilharzia* and *Ornithobilharzia*. The condition has been described from many different parts of the world including North America, particularly the lakes region of the USA, Canada, Europe, Africa and the Far East [2,4]. In some countries, it affects patients with particular occupations such as rice farmers working in the paddyfields.

2 *Sea-water avian cercarial dermatitis* [5]. This follows invasion of the skin by blood flukes whose definitive hosts are sea birds. While it is recorded less frequently than infections caused by fresh-water species, it accounts for the condition, seen in the Atlantic seaboard of the USA, known as clam-digger's itch. The intermediate hosts are marine molluscs. The term 'sea bather's eruption' is used to describe a variety of different rashes that may develop after sea bathing. It is likely that it includes a number of different conditions from jellyfish dermatitis to eruptions due to toxic algae. A sea water form of cercarial dermatitis is therefore one cause of sea bather's eruption [1].

3 *Fresh-water mammalian cercarial dermatitis* [4]. This has been reported mainly from the Far East, and the definitive hosts for the schistosomes in this condition are mammals such as water buffaloes.

Attempts to find common features connecting the likely locations for cercarial infections have not been entirely successful. It is apparent, however, that areas endemic for cercarial dermatitis usually have abundant, submerged vegetation harbouring the intermediate hosts. Hot spells of weather have also been associated with a higher risk of the development of symptoms [6].

Pathogenesis. The pathogenesis of cercarial dermatitis is not completely understood, although the kinetics of the clinical response suggest that sensitization is involved. The first phase of epidermal penetration is accompanied by dermal oedema, which is followed by a brisk neutrophil reaction.

Clinical features. Most forms of cercarial dermatitis have common features, although their intensity varies between different individuals [2]. The first sign of an infection is the development of a tingling sensation after contact with water. This lasts for about 1 h and there may be a fine macular erythema. After 10–15 h, there is usually a second phase with the appearance of multiple itchy papules with surrounding erythema. These may evolve into vesicles or oedematous lesions. The whole reaction takes about a week to resolve. The papules closely resemble small insect bites. There are no long-term sequelae.

Treatment. Treatment is entirely symptomatic. Although brisk rubbing with a dry towel seems sensible advice, there is no evidence that it prevents the second phase of responses [1]. Patients can be treated with antihistamines or topical applications such as crotamiton. Preventative measures are seldom called for as infections tend to be sporadic. Control of vegetation in endemic areas or of the snail population are possibilities, but seldom practised unless the more serious problem of schistosomiasis is also present.

Paragonimiasis

Infections caused by the lung fluke, *Paragonimus westermani*, are found in the Far East, West Pacific and in parts of India and Central Africa [1]. Similar species, *P. africanus* and *P. peruviana*, cause disease in the Cameroons and Central and South America, respectively [2]. In China, two rare species, *P. szechuanensis* and *P. hueitungensis*, have been recorded as causes of migratory subcutaneous nodules in humans. The adult worms are found in the respiratory tract, from which eggs are coughed up and swallowed, thus entering the faeces. Miracidia are released on contact with water and seek and penetrate snails. These in turn are the first intermediate hosts, and liberate cercaria, which then enter the muscles of fresh-water crustaceans such as crayfish. Human infection results from ingestion of inadequately cooked crabs and crayfish. Ingested metacercaria penetrate the intestinal wall and make their way through the diaphragm to the lungs. Adult worms encyst in the lungs (Fig. 37.24) and cause a chronic cough with fever and sweats. Brown-stained sputum is characteristic. Flukes may also reach ectopic sites such as the peritoneum, brain or skin.

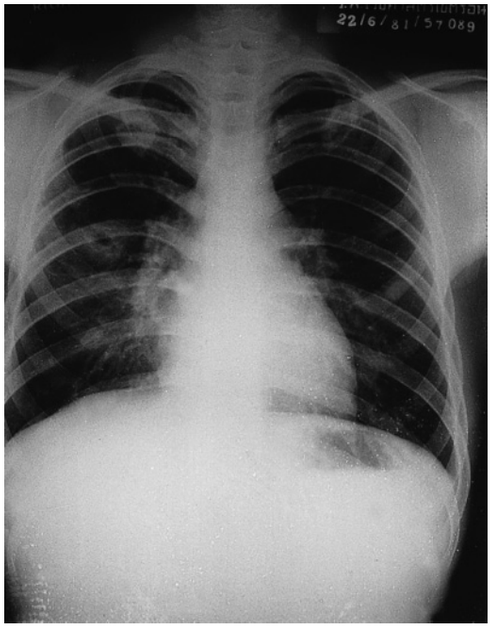

Fig. 37.24 Paragonimiasis. Chest X-ray showing three discrete opacities, in two of which cavitation is present, characteristic of the disease in Thailand. (Courtesy of Professor D.A. Warrell, Oxford Radcliffe Hospital, Oxford, UK.)

Skin lesions of paragonimiasis are large, mobile subcutaneous lesions, which develop into cold abscesses [3]. They can occur at any site including the conjunctiva, and may enlarge rapidly to reach a diameter of 10 cm or more. The larger lesions are often painful but they may rupture spontaneously.

The diagnosis can be confirmed by demonstrating the characteristic ova in sputum or in aspirates from cutaneous lesions.

This infection responds well to praziquantel in a dose of 25 mg/kg three times in a single day [4].

Infection with cestodes

Synonym
- Tapeworms

Tapeworms are flat, ribbon-like worms composed of a variable number of segments called proglottids. The anterior segment or scolex comprises the head, which carries hooks or suckers for attachment to the intestinal mucosa, and a narrow neck from which the proglottids develop. As the hermaphroditic proglottids mature, they become motile sacs full of eggs, which separate from the worm and pass in the faeces or wriggle through the anus. Adult tapeworms inhabit the intestinal lumen of a wide range of natural hosts. Eggs are taken up by an intermediate host and undergo often complex larval development; in some species, there may be two or more intermediate hosts, each supporting a different phase of larval development. The human is a natural host to certain tapeworms, and may be an accidental host to others. Generally speaking, infection with adult worms causes little or no disease, but infection with the larval stages may be serious [1].

Tapeworms that infect humans may be divided into two orders, Cyclophyllidea and Pseudophyllidea, within each of which certain species may cause skin disease.

Cyclophyllidea

Echinococcus granulosus and E. multilocularis. Tapeworms, respectively, of dogs and foxes. Larval stages cause echinococcosis, or hydatid disease in humans.

Taenia saginata. The beef tapeworm of humans. Causes taeniasis. No skin parasitization.

Taenia solium. The pork tapeworm of humans. Causes (i) taeniasis; and (ii) cysticercosis.

Multiceps multiceps. A tapeworm of dogs and wolves. Its larval stage (coenurus) may parasitize human brain and other organs [2].

Multiceps serialis. A tapeworm of dogs, wolves and foxes, whose larval stages may parasitize human muscle or subcutaneous tissue [3].

Multiceps brauni. A tapeworm of dogs whose coenurus may parasitize subcutaneous tissue and the eye in humans [2,4,5].

Pseudophyllidea

Spirometra spp. Tapeworms of carnivores. The larval forms (spargana) cause sparganosis in humans.

Diphyllobothrium latum. The fish tapeworm of humans. Causes diphyllobothriasis.

Echinococcosis

Synonym
- Hydatid disease

Two species in the genus *Echinococcus* parasitize humans with the formation of hydatids, namely *E. granulosus* and *E. multilocularis* [6]. Adult *E. granulosus* lives in the intestine of the dog and, if ova are accidentally swallowed by humans or other animals, hydatid cysts develop. Sheep are the commonest intermediate hosts. Similarly, adult *E. multilocularis* lives in the bowel of red fox and arctic fox. Mice, voles and lemmings are the intermediate hosts.

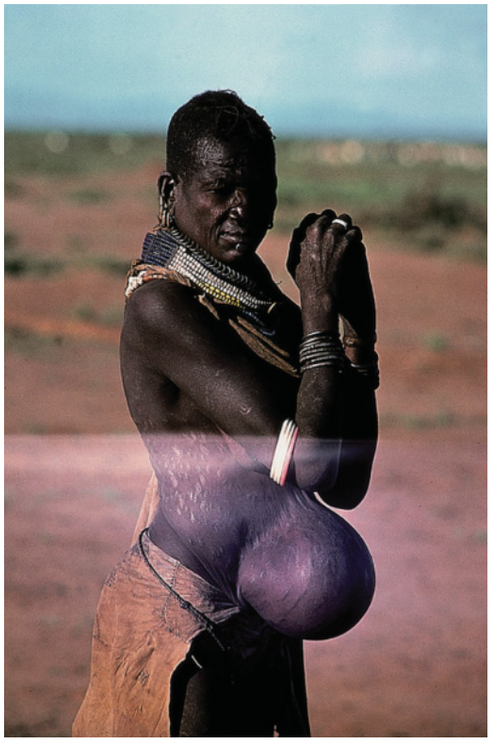

Fig. 37.25 Hydatid disease. Subcutaneous hydatid cyst presenting as a hernia, in a woman from Turkana, Kenya. (Courtesy of Dr C.N.L. MacPherson, Liverpool School of Tropical Medicine, Liverpool, UK.)

Pathogenesis. Humans become infected by ingesting eggs in food or water that has been contaminated by, usually, dog faeces. In endemic countries, especially those where sheep rearing is not accompanied by strict regulations, children's hands readily pick up the eggs from the coats of dogs. Eggs hatch in gastric acid and penetrate the wall of the duodenum, and are distributed via the bloodstream, mainly to liver and lungs, but bones and any other organ may also be infected. The larvae develop into fluid-filled cysts whose germinal layer produces numerous protoscolices, capable of becoming the scolices of adult worms after ingestion by the definitive host.

Cysts of *E. granulosus* tend to grow slowly and bud inwards, producing daughter cysts. Those of *E. multilocularis* may bud outwards, and thus spread through the tissues like a cancer.

Clinical features. The commonest manifestation is an enlarged liver. Leakage of antigenic fluid from the cyst may cause wheeze, urticaria and eosinophilia. Rupture of the cyst may cause local signs and anaphylaxis. Hydatid cysts (Fig. 37.25) may be palpable in muscle or subcutaneous tissues as firm, painless swellings, often up to the size of an orange. They may be fluctuant. The overlying skin is normal.

Diagnosis. Clinical diagnosis is aided by X-ray or computed tomography (CT) examination of the lungs and sonographic ultrasound of the liver.

Excision of a subcutaneous cyst is conclusive. Great care must be taken not to spill any cyst fluid, which may give rise to further cysts. Complement fixation and ELISA are useful serological tests.

Treatment. This is essentially surgical. Formalin 2% or silver nitrate 0.5% should be used as a scolicidal adjunct [7]. Albendazole [8] is used in conservative management.

Cysticercosis

Synonym
- Larval taeniasis

Aetiology. *Taenia solium*, the pork tapeworm, is responsible for producing human intestinal infection with the tapeworm (taeniasis), and the lodging of the larval stage (*Cysticercus cellulosae*) in numerous organs, especially subcutaneous tissue, muscle and brain, with the production of the disease cysticercosis.

In taeniasis, the adult *T. solium* lives attached to the wall of the small intestine and may reach a length of 7 m. Inadequately heated or frozen pork is the sole source of human infection with the adult worm, but humans and other primates may harbour the cysticercus stage.

Human infections with *Cysticercus cellulosae* are due to: ingestion of eggs in contaminated food or drink; eggs from an individual's own intestinal infection being introduced into the mouth on dirty hands; or internal autoinfection as a result of vomiting—eggs must be digested in gastric acid.

Taenia solium is an important human parasite with a wide, although shrinking, distribution. It is most frequent in Eastern Europe, China, Manchuria, Pakistan, India, Mexico and Central and South America. Its prevalence depends upon insanitary human faeces disposal and the eating of undercooked pork.

Pathology. The cysticerci are found most frequently in subcutaneous tissue and muscle, but may occur in any organ of the body, especially the brain. The growing cyst provokes a non-specific inflammatory reaction, which may be followed by fibrosis and eventual calcification.

Clinical features. Adult worms in the intestine cause little or no reaction, although the passing of writhing fragments is distressing. The cysticerci form nodules in subcutaneous tissue muscles (rarely with widespread muscular enlargement), eye [1], eyelid [2], lungs and brain and other organs, which may seriously interfere with function depending on their position. Major exacerbation of symptoms, such as epilepsy or intracranial obstruction, coincides with death of the larvae. The disease in the skin is known as cysticercosis cellulosae cutis, and the subcutaneous nodules formed are 1–2 cm in diameter (Fig. 37.26). They are rubbery and firm, rounded and painless and may remain unchanged for many years. Their numbers vary from one to hundreds, and when the diagnosis is entertained, search must be made for other lesions.

Fig. 37.26 Cysticercosis in a man from North India. A subcutaneous cyst is seen over the sternum. (Courtesy of Dr A.P. Hall, Hospital for Tropical Diseases, London, UK.)

Diagnosis. *Taeniasis*: eggs in the stool cannot be differentiated morphologically from those of *T. saginata*, but examination of gravid proglottids allows exact identification. *Cysticercosis*: the histology of an excised cyst is diagnostic. Serology is helpful, but cross-reactions occur with hydatid disease.

X-ray examination frequently shows calcification in muscle (Fig. 37.27), although rarely in brain. CT shows typical appearances in brain and muscle.

Treatment. Subcutaneous cysticerci are important only in as much as they point to the possibility of more serious cerebral infection, which should be looked for. Individual subcutaneous cysts may be removed surgically if desired. Cerebral disease is treated with praziquantel 25 mg/kg daily for 10 days, under steroid cover. Adult tapeworms are treated with praziquantel in a dose of 10 mg/kg once. Obstructive lesions of the brain require surgical relief.

Prognosis is good in taeniasis, but in cysticercosis it is serious when vital organs are involved.

Sparganosis

Sparganosis is a tissue infection with plerocercoid larvae or spargana of a number of species of pseudophyllidean tapeworms of the genus *Spirometra*. Patric Manson described the first case, in Amoy China in 1882. The Greek word sparganon means swaddling clothes, and describes the slender, ribbon-like character of the larval worm. The infection is common throughout Asia, especially the Far East, but also occurs in Australia, the Americas and southern Europe.

Aetiology. Adult spirometra parasitize the gut of canines and felines. Eggs passed into water develop into procercoid larvae in copepod hosts of the genera *Diaptomus* and *Cyclops*. These are eaten by frogs, lizards, snakes, birds and some mammals, including mice and monkeys, in which the plerocercoid larvae develop, in muscle sheaths. Humans are infected either by the application of raw flesh to the skin or eye, usually as a medicinal poultice, or through eating uncooked flesh or drinking water containing infected copepods.

Pathogenesis and clinical features [1]. Ingestion sparganosis occurs a variable time after eating infected flesh, or drinking infected copepods. The larvae penetrate the intestine and develop into spargana, particularly in subcutaneous tissues and muscle. The invaded areas become oedematous and form painful lumps, in the centres of which the white, ribbon-like spargana move. Their death results in very intense inflammation with destruction of tissue and massive eosinophilia [2]. Clinically, the lesions can assume a more nodular consistency with an insidious onset; they may last for several years and can also migrate. Localized elephantiasis also results due to lymphatic invasion.

Application sparganosis. The spargana migrate into the inflamed part causing an immediate, severe local pruritus. Subsequently, signs of sparganosis may be very hard to differentiate from those of the primary inflammation for which the flesh poultice was applied. Redness, pain and swelling increase in severity over a few days or very few weeks, and the worms become localized in small nodules surrounded by pus (Fig. 37.28). Ocular sparganosis frequently results in panophthalmitis and loss of the globe.

(b)

Fig. 37.28 (a) Fibrous, encapsulated, cold abscess from the groin, which contained (b) a 22-cm long sparganum. (Courtesy of Professor S.B. Lucas, King's College London, UK.)

Sparganum proliferum. This is a rare form in which the sparganum branches and divides, producing thousands of mainly subcutaneous spargana, which form subcutaneous nodules and itchy papules [3]. There may be a severe systemic illness with fever and eosinophilia.

Diagnosis. This is made from the history and by recovery of spargana after incision.

Treatment. This is by surgical removal and drainage.

Infection with protozoa

Of the protozoa that give rise to skin disease or may cause changes in the skin indirectly, only *Leishmania* are natural parasites of the skin, in the sense that part of their life cycle must be spent in it. Even so, humans are often simply an accidental host in a zoonotic infection. *Entamoeba histolytica* may occasionally invade the skin, usually as an extension of an existing visceral lesion. Free-living amoebae, of the genus *Acanthamoeba*, may cause a primary lesion in skin, eye or ear, before invading the brain [1]. *Trypanosoma*, of the species that infect humans in Africa and America, may cause florid chancres soon after inoculation, but thereafter cause rashes indirectly. *Toxoplasma* causes an exanthem as part of the secondary stage of the infection, and *Trichomonas*, a mucosal parasite, causes inflammation of skin adjacent to the infected mucosa. Cutaneous manifestations of malaria, due to several species of *Plasmodium*, are simply a reflection of the severity of the systemic infection, or of drug toxicity.

Malaria

Malaria is caused by parasites of the genus *Plasmodium*, and is transmitted to humans by the bites of numerous species of mosquito belonging to the genus *Anopheles*. It causes a febrile systemic illness, which may be fatal in expatriates and in children in endemic areas in the tropics, and is a major cause of chronic ill health [2].

The mosquito bite can give rise to considerable skin reaction, and the disease itself to numerous cutaneous manifestations. In the early cold stage of benign tertian malaria (*P. vivax*) there is vasoconstriction and gooseflesh; in the hot stage, flushing of the face and to a less extent other parts of the skin, and in the sweating stage, very profuse sweating. These manifestations are common to all diseases characterized by rigors caused by release of endotoxin or 'endotoxin-like' substances. Malaria commonly causes jaundice, and the skin in Europeans and Asians may have a curious grey or greenish hue. In severe malaria, there may be bleeding from the gums or gastrointestinal tract, and conjunctival petechiae may be seen, but cutaneous petechiae are rare. Herpes simplex and, occasionally, herpes zoster may develop.

Several of the drugs used in treatment of chemoprophylaxis cause skin problems. Chloroquine causes pruritus, especially in black people's skins, often severe enough to arrest treatment [3]. It responds to antihistamines, although the cause is unknown and there is never a rash. Various skin eruptions may occur, and psoriasis may be aggravated. Fansidar contains pyrimethamine and sulfadoxine. Epidermal necrolysis and Stevens–Johnson syndrome occur, sometimes fatally [4]. Quinine may cause rashes, notably toxic erythema and urticaria.

Amoebiasis

Amoebiasis due to *Entamoeba histolytica* is arguably the third most important human parasitic infection, after malaria and schistosomiasis, being especially prevalent in South-East Asia and Central America, but the organism is found in all warm and temperate parts of the world where hygiene is inadequate [1,2].

Aetiology. *Entamoeba histolytica* inhabits the lumen of the human caecum, colon and rectum. Free-living trophozoites 10–60 μm in diameter, encyst and divide. Cysts passed in the faeces may survive up to 30 days, depending upon conditions of humidity and temperature, and survive chlorination. They are transmitted in contaminated water or food, especially salads, or by hands or flies, or by male homosexual intercourse. Ingested cysts that survive gastric acid complete the cycle. Isoenzyme electrophoretic analysis of cultured isolates suggest that pathogenic and non-pathogenic strains (zymodemes) of *E. histolytica* exist, but these cannot be distinguished morphologically [3].

Pathogenesis. Trophozoites of a pathogenic zymodeme may, under conditions that have not been determined, invade the mucosa of the large bowel, causing amoebic dysentery [4]. Amoebae that escape the bowel into the bloodstream may set up metastatic lesions, which develop into abscesses, most commonly in the liver. Cutaneous amoebiasis (Fig. 37.29) [5] develops when invasive amoebiasis escapes from the bowel to contiguous skin, usually around the anus or a colostomy, or after appendicectomy, or when amoebae are implanted in another mucosa, most commonly the vagina, cervix uteri or glans penis, and rarely in the mouth. Rupture or surgical intervention of an amoebic abscess is a less common source of cutaneous infection. Amoebae lyse the skin and subcutaneous tissues and mucosae involved, producing necrosis and gangrenous sloughing. *Entamoeba histolytica* is one of the most powerful organisms in terms of its lytic capacity, and this is mediated through amoebapores following the binding to the host's tissue in a lectin-like manner [6].

Clinical features [5,7]. Commonly, one or more lesions appear at the anus or on the buttocks and spread as sloughing, coalescing ulcers [8] (Fig. 37.30). The course of the disease varies from less than 2 weeks to as long as 2 years, the more rapid and destructive lesions tending to occur in the young. The skin lesion itself is not diagnostic and is either a deeply invading ulcer or an ulcerated granuloma (amoeboma). It is usually seen as a serpiginous ulcer with distinct, raised, thickened, often undermined, edges and with an erythematous rim about 2 cm wide, haemopurulent exudate and necrotic slough. It is intensely painful. Regional adenitis is usual.

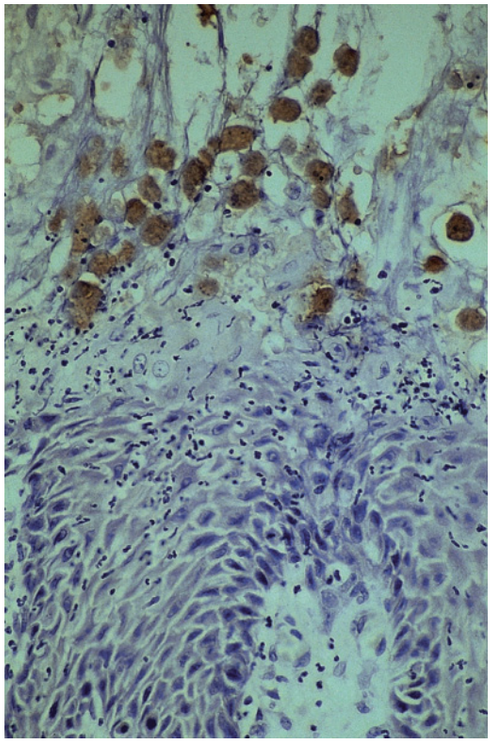

Fig. 37.29 Cutaneous amoebiasis. High-power view of skin biopsy, showing *Entamoeba histolytica* trophozoites on the epidermis, causing necrosis. The amoebae are stained with immunoperoxidase and are brown. (Courtesy of Professor S.B. Lucas, King's College London, UK.)

Fig. 37.30 Cutaneous amoebiasis. Rapidly spreading ulcer around a colostomy in a patient with intestinal amoebiasis. (Courtesy of Meddia (Medical and Diagnostic Services), Basel.)

All ages are affected. The vulva is particularly likely to be invaded in the infant with amoebic dysentery. Penile amoebiasis may occur in homosexual men [9], but invasive amoebiasis is not especially common in homosexual men or in patients with human immunodeficiency virus (HIV) infection [10].

Diagnosis. Cutaneous amoebiasis can spread very rapidly and terminate fatally, so early diagnosis is important. A solitary lesion may be mistaken for an epithelioma or for tuberculosis verrucosa cutis. On the penis when regional lymphadenopathy is present, syphilis or lymphogranuloma venereum may be confused. Examination of fresh material from the cutaneous lesion regularly discloses amoebae. Material should be taken from the edge of the ulcer avoiding necrotic tissue and examined at once under the microscope. The demonstration of motile trophozoites containing red blood cells is diagnostic. Histology of the ulcer edge will reveal amoebae, but the identification of the parasite in sections stained by haematoxylin and eosin may be difficult (Fig. 37.29). Amoebic trophozoites in faeces, biopsy, necropsy or abscess aspirate are revealed with much greater accuracy by immunofluorescence or immunoperoxidase staining. Serological tests are helpful, and the indirect immunofluorescent antibody test is positive in the serum of near 100% of patients with amoebic liver abscess, and in about 70% of patients with intestinal amoebiasis. Serial stool examinations should be performed.

The prognosis is serious in the neglected case, particularly in infants, but with early diagnosis and treatment it is good. It is important to appreciate that a history of dysentery is not essential to the diagnosis of amoebiasis of the skin.

Treatment. Treatment of invasive amoebiasis is with metronidazole [11]. The recommended adult dose is 800 mg orally three times a day for 10 days. This may be combined with diloxanide furoate 500 mg three times a day, or be followed by oral diiodohydroxyquin 650 mg three times a day for 21 days, to eliminate intestinal cysts.

Local cleaning of cutaneous ulcers with antiseptic solutions may be necessary.

Where a hepatic abscess needs to be drained, this is most safely done by needle aspiration.

Effective treatment is usually followed by complete healing of the skin without the need for plastic surgery.

Trichomonads

Three trichomonads occur in humans. *Trichomonas vaginalis* invades the vagina, urethra and prostate and is pathogenic, causing trichomoniasis. *Trichomonas hominis* is found in the intestine and *T. tenax* in the mouth and occasionally the lung: neither is considered pathogenic [1].

Trichomoniasis

Trichomonas vaginalis is found worldwide affecting all races, but is eight times commoner in black people than in white people [2]. It invades the vagina and urethra in women, causing vaginitis and vulvitis with a characteristic pale-yellow, frothy discharge [3,4]. Vulval soreness and pruritus with inflammation of the surrounding skin are common, whereas infection of Skene's or Bartholin's glands with abscess formation rarely occurs.

Trichomoniasis characteristically causes a copious discharge with vaginal soreness or irritation and urinary frequency. The odour of the discharge is often unpleasant, although this feature is not specific. In many cases, bubbles can be seen in the discharge and the vaginal mucosal and cervical surfaces are infected and sometimes covered with punctate haemorrhages. The pH of the discharge is usually higher than the normal 4.5.

Although commonest in the second and third decades, the infection may occur at any age and has been reported in nearly 17% of babies aged from 1 day to 11 months. Many adults are asymptomatic carriers, particularly males. It can be isolated from up to 15% of men with non-specific urethritis. Discharge in males is scant.

The condition is frequently associated with gonorrhoea [5]. Transmission is usually by sexual intercourse, with an incubation period of 4–21 days. Occasional non-sexual transmission has been reported. In males, the condition occurs with non-specific urethritis in up to 5% of cases, and balanitis may also occur [6]. The organism may be harboured in the prostate without symptoms.

Diagnosis. In women, diagnosis is usually easily confirmed by examination of a wet film by phase contrast or dark-field microscopy [7], but culture, usually in Feinberg–Whittington medium, gives the most reliable results. On the other hand, in males, examination of centrifuged urine or prostatic fluid following massage is only occasionally positive, and in many men it is not possible to confirm a clinical diagnosis. Examination of a stained dry film is neither easy nor reliable.

Sexual partners should always be examined, and in both sexes specimens taken to exclude other causes of sexually transmitted disease.

Treatment. Standard treatment is with metronidazole 400 mg twice a day for 5 days [8,9]. Alcohol should be avoided during treatment. Single-dose treatments have been advocated with this drug. Gastrointestinal disturbances are common. Benzimidazole drugs should be avoided in the first 3 months of pregnancy.

Clotrimazole has been shown to have some activity [6] and one 100-mg pessary daily for 6 days may be tried. Older remedies such as acetarsol pessaries or hydrargarphen pessaries, two a night for 3 weeks, are still valuable. Simple douching may relieve vaginal symptoms (20 mL of vinegar to 1 L of warm water).

Trypanosomiasis

Protozoa of the genus *Trypanosoma* cause the widespread tropical disease trypanosomiasis. There are African and American forms.

African trypanosomiasis

Synonym
- Sleeping sickness

Aetiology and epidemiology. The disease is endemic in a belt running across Africa, limited approximately by lat. 15°N and lat. 15°S. *Trypanosoma gambiense* is the cause in West Africa, and the more virulent *T. rhodesiense* in East Africa to the east and south of Lake Victoria [1]. Occasional cases are imported into countries where the parasite is not endemic [2].

The human is the main natural host of *T. gambiense*, and the disease is transmitted by blood-sucking tsetse flies of the genus *Glossina*, the intermediate hosts *G. palpalis* and other related species are the most important. On the other hand, *T. rhodesiense* (which morphologically resembles *T. gambiense* but is biologically very different) is transmitted by *G. morsitans* and related species. The natural hosts are wild animals, notably antelope, and the human is a 'dead-end' host.

Age, sex, race and occupation have no influence on susceptibility to trypanosomiasis, except in so far as they affect exposure to tsetse flies. *Trypanosoma gambiense* sleeping sickness tends to be an endemic disease, affecting rural communities, with localized outbreaks, while *T. rhodesiense* sleeping sickness causes sporadic infections in herdsmen, hunters and tourists. In some parts of the 'tsetse fly belt' the incidence is high, and, as the same flies transmit bovine trypanosomiasis to livestock, farmers cannot keep cattle and poverty and malnutrition are rife.

Intrauterine transmission has been recorded infrequently. Preventive measures involved removal of entire villages to tsetse-free land. Mass survey and treatment were very successful in reducing the infection rate in Nigeria from 10.9% (1931–40) to 0.14% (1958) [1].

Pathogenesis. Trypanosomes develop, at the site of inoculation by the tsetse fly, from metacyclic forms to mature forms in about

Fig. 37.31 Trypanosomal chancre due to *Trypanosoma rhodesiense* infection, appearing 6 days after the bite of the tsetse fly. The lesion is swollen, inflamed and haemorrhagic.

Fig. 37.32 Trypanosomal rash (same patient as Fig. 37.31). The maculopapular rash is becoming haemorrhagic.

10 days, and then enter the bloodstream. Within this time, the patient starts to develop an antibody response to the infection. The immunological reaction to the trypanosomes in the skin causes the chancre. The systemic clinical illness coincides with invasion of the bloodstream. The early pathology is, thereafter, mainly in the lymph nodes, at first those draining the sore and then generally, with an increase in lymphocytes and plasma cells, but the appearances are not specific, and trypanosomes are not easily seen histologically. In *T. rhodesiense* infections, the lymphoplasmocytic infiltrate is also found in the myocardium, and this myocarditis may be fatal. In late trypanosomiasis, the meninges become invaded with the same infiltrate, and then the brain, especially around the basal ganglia. Gliosis and cerebral atrophy follow. The cause of these pathological changes is poorly understood, although it is known that there is a polyclonal B-lymphocyte activation with the production of very high levels of IgM, and circulating immune complexes [3].

Clinical features [4,5]. Within a few days of the infected bite, a trypanosomal chancre starts to develop (Fig. 37.31). It is a round, raised, red, hot, tender lesion, 2–5 cm or more in diameter, spreading to cover, for example, the entire surface of the forearm over the ensuing few days. There may be a tiny central punctum, and a blister with fluid rich in trypanosomes may appear on its surface. The chancre is present in 70–90% of people infected with *T. rhodesiense*, less regularly with *T. gambiense*, but fades within a few weeks. It is usually accompanied by local lymphadenopathy. The chancre heralds the onset of fever and systemic illness and generalized lymphadenopathy, which characterize the second phase of the illness. This is rapid and severe in *T. rhodesiense* infections, but gradual, mild, intermittent or even absent clinically in *T. gambiense* infections [6].

During this phase of the illness, there may be oedema of hands, feet and face, and transient erythematous or urticarial rashes, which are often circinate or annular, poorly defined, pale centrally, and commonest on the trunk. The rash may be haemorrhagic (Fig. 37.32). They are difficult to see in African skins. When the CNS is invaded, the patient experiences behavioural changes, alterations in sleep patterns, extrapyramidal signs and finally coma. These occur months after the onset of *T. rhodesiense* infections, if the patient has not died in the secondary phase, and 1–3 years after the onset of *T. gambiense* infections. At this stage, pruritus and excoriations from scratching are common, and the patient is emaciated. Death is often due to intercurrent infection due to the immune suppression.

Diagnosis. Within a few days of the onset of fever, trypanosomes may be demonstrated in simple thin blood films in *T. rhodesiense* infections. However, in *T. gambiense* infections, thick films (Fig. 37.33) or concentration techniques [7] may be necessary. A more profitable approach is puncture and aspiration of the enlarged posterior cervical lymph nodes. Trypanosomes are seen undulating between the lymphocytes in the wet preparation, or well defined in a Giemsa-stained preparation. Cerebral involvement is

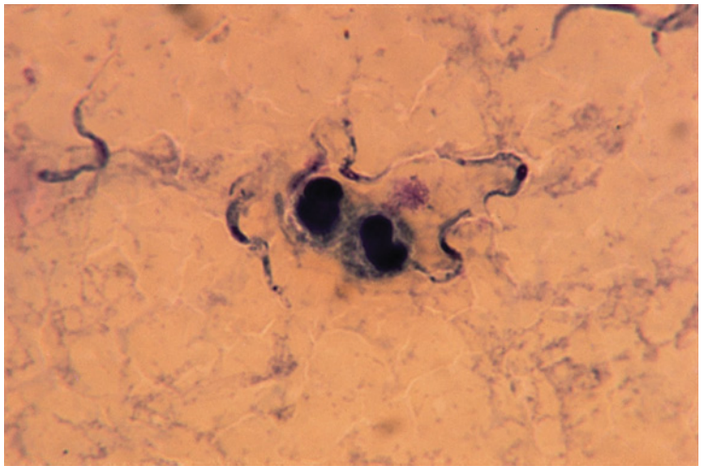

Fig. 37.33 Trypanosomes in a thick blood film, stained with Giemsa. (Courtesy of Dr P.L. Chiodini, Hospital for Tropical Diseases, London, UK.)

characterized by raised protein in the CSF, containing IgM, and a raised cell count comprising lymphocytes and morula cells (plasma cells distorted by vesicles of IgM). Serological tests, including ELISA and immunofluorescence, may be helpful. Serum IgM levels are often grossly elevated, and there may be an anaemia. On diagnosis, a lumbar puncture is mandatory to establish whether the CNS has been invaded.

Treatment. A single course of suramin, preferably, or pentamidine isethionate is usually sufficient, if given before CNS invasion. Dosages are: suramin sodium 200 mg (test dose) i.v., followed by 1 g/week for five doses; pentamidine isethionate 4 mg/kg i.m. on alternate days for five doses. Both drugs are seriously toxic [8].

After CNS invasion melarsoprol is used [7,8], often with corticosteroids [9].

American trypanosomiasis

Synonyms
- Chagas' disease
- South-American trypanosomiasis
- Trypanosomiasis cruzi
- Chagas–Mazza disease
- Schizotrypanosomiasis
- Opilacao

Definition. Chagas' disease is a parasitic disease of the tissues and blood caused by the flagellate *Trypanosoma* (*Schyzotrypanum*) *cruzi* and transmitted to humans and other mammals by blood-sucking bugs of the family *Triatomidae*. It occurs predominantly in rural areas in the tropical zones of the American continent.

Incidence. The insect vectors are widely distributed in the American continent from lat. 42°N in the USA to lat. 43°S in Argentina [1]. *Trypanosoma cruzi* attacks humans and other mammals, and the disease it produces can be regarded as a zoonosis. The area of distribution of the disease is more limited than the range of the reduviid bugs that transmit it, since those found at the two extremes of the continent are wild species, while the domestic types, concerned in the transmission of the infection to humans, occur between lat. 25°N in Mexico and lat. 28°S in Argentina [1].

Age does not influence the incidence of infection, although the acute forms are more frequently observed in children. The sexes are equally affected and there is no evidence of a racial factor. Occupation plays an important role because it is a rural disease and the vectors are found in rural dwellings, especially in huts or shacks with palm leaf roofs [2].

Aetiology. The disease is caused by *T. cruzi*, which bears some resemblance morphologically to the trypanosomes causing sleeping sickness in Africa. In the blood, the organism is 15–20 μm in length and of variable width, and has the typical undulant membrane and flagellum in an anterior position. The nucleus is central, the kinetoplast rod-shaped or oval and situated posteriorly. After transformation into the amastigote stage, *T. cruzi* multiplies only in tissue cells, being an obligatory tissue-cell parasite.

Vector. The disease is transmitted by blood-sucking insects of large size: Hemipteran, reduviid bugs (assassin or kissing bugs), belonging to the family *Triatomidae*, particularly *Panstrongylus megistus* (Brazil), *Triatoma infestans* (Southern Brazil, Uruguay, Paraguay, Bolivia, Southern Peru, Chile and Argentina) [1] and *Rhodnius proxlixus* (Venezuela, Colombia, Guianas and Central America). The larva, nymph and the adult insect can transmit the infection. They are active during the night. After ingestion, the trypanosomes multiply in the vector's intestine by longitudinal division, and within 3 or 4 weeks transform into the metacyclic form, which is infective to humans. Once the insect has been infected, it remains so for the rest of its life. The disease has many non-human reservoirs, including cats, dogs, monkeys, pigs, squirrels, rats, skunks, racoons, opossums, porcupines and armadillos.

Transmission occurs by contamination through small cuts and abrasions on the skin, or through the normal mucous membranes of the eyes and lips when the vector, at the moment of biting, deposits its stools containing the infective metacyclic trypanosome [2]. The bite wound itself may provide the portal of entry [3].

Pathology. The tissues react almost immediately to the penetration of the metacyclic trypanosomes, producing oedema and cellular infiltration, which cause subcutaneous swelling. The infection spreads rapidly to the lymphatics, and the regional glands become oedematous and infiltrated with plasma cells and lymphocytes. The spleen and liver enlarge. The trypanosomes penetrate immediately into the cells of the reticuloendothelial system at the site of the inoculation and transform into the leishmania form, later returning to the interstitial spaces and blood in the form of trypanosomes, penetrating again into the cells to repeat the cycle in different organs and systems. The most striking invasion is that of the spleen macrophages, the Kupffer cells of the liver and the cells of the striated muscles [4]. The inflammation and scarring that follows invasion of the myocardium may have serious consequences.

Clinical features. The great majority of infections do not present any clinical manifestations in the early phase. Signs of early disease appear on the fifth day after inoculation: these are both local and general. Eighty per cent of the acute cases show the portal of entry in the conjunctiva, as evidenced by the 'eye sign' or 'Romaña's sign', also known as the 'ophthalmoganglionar complex' (oculoglandular complex), characterized by unilateral oedema of the eyelids and inflammation of the lacrimal gland (Fig. 37.34). Cutaneous inoculation results in the 'cutaneous adenopathy complex' or 'inoculation chagoma' and is less common. The general manifestations consist of moderate to high fever accompanied by headache, myalgia, weakness, particularly pronounced in children, in whom the disease may end fatally from acute meningoencephalitis or myocarditis. Hepatosplenomegaly, oedema and various forms of exanthem ('schizotripanides') are frequent [1]. Forms called oedematous, neuropsychiatric, meningoencephalitic, respiratory, gastrointestinal and pseudotyphoid have been described [2]. The subacute and chronic forms almost always present with heart manifestations—chagasic myocarditis—and digestive manifestations, such as mega-colon and mega-oesophagus. Megasyndromes are common in Brazil but absent in Venezuela. Congenital forms transmitted transplacentally or by the mother's milk are rare.

Prognosis. This is serious in acute cases in children, especially in the meningoencephalitic form, and when the myocardium is extensively involved. In the subacute and chronic forms it depends entirely on the degree of involvement of the heart. Sudden death by thromboembolic accidents and by blockage of the conduction system of the heart may occur. Chronic heart failure is frequently observed in the advanced cases.

Diagnosis. In the acute phase, the diagnosis is made by finding the parasite in the blood by direct examination, or by means of stained thick and thin smears, lymph-gland biopsy, blood culture, animal inoculation and by the so-called xenodiagnosis of Brumpt: the reduviid bugs grown in the laboratory and free from infection are allowed to bite the forearm of the subject under suspicion and feed on the blood, after which the faeces of these insects are examined for metacyclic forms between 30 and 60 days later [2]. In the subacute and chronic forms, laboratory tests are of great help, particularly those based on the complement-fixation test using antigen from culture forms of *T. cruzi* (Machado–Guerreiro's test).

Fig. 37.34 Chagas' disease. Unilateral oedema of the eyelids and orbit (Chagas–Mazza–Romaña's sign). (Courtesy of Professor M. Miles, London School of Hygiene and Tropical Medicine, London, UK.)

Treatment. The acute stage (including congenital Chagas' disease and transfusion acute disease) should be treated with a trypanocidal drug, either nifurtimox (Lampit) given by mouth (8 mg/kg) for 60 or 90 days, or benznidazole (Rochagan), oral dose (6 mg/kg) for 30 or 60 days. A rare side effect is an exfoliative dermatitis. Both drugs produce anorexia, weight loss, headache and dizziness, gastric irritation and, occasionally, peripheral neuritis (12–30%). Allopurinol has recently been used [5].

Control. Improvement of environmental conditions should be attempted, especially those of the dwellings, eliminating palm leaf roofs. The insects can be destroyed with dieldrin and gamma benzene hexachloride. Chemotherapy of the infective cases may help to break the natural cycle of the disease.

Leishmaniasis

The leishmaniases are a group of diseases caused by several species of the genus *Leishmania*. Each species tends to occupy a particular zoogeographical zone and the disease is endemic in 88 countries. It has been estimated that 1.5 million new cases of cutaneous leishmaniasis occur annually and more than 80% of the total of cases affect individuals in developing countries. Brazil, Iran, Afghanistan and Sudan suffer the highest prevalence and the disease is a priority for public health in all hyperendemic regions of the world. The species are morphologically identical, and are distinguished by isoenzyme pattern and DNA analysis. Monoclonal antibodies have also proved useful for rapid identification of isolates, especially in the field [1]. Clinical patterns are poor indicators of species, although certain disease characteristics may be commonly associated with a particular species [2]. *Leishmania* spp. undergo a cycle of development in the gut of female sandflies, of the genera *Phlebotomus* in the Old World, and *Lutzomyia* and *Psychodopygus* in the New World.

In its vertebrate host, the amastigote form of the parasite is found in cells of the reticuloendothelial system or in the dermis following severe parasite load and mononuclear cell necrosis. It is round or oval, 2–3 µm in diameter, with no protruding flagellum. The nucleus and kinetoplast stain deeply with the Romanovsky stains, giving the organism its characteristic appearance. In the sandfly and in artificial culture media, *Leishmania* spp. are the elongated promastigote stage, motile with an anterior flagellum.

Sandflies find their precise requirements for temperature and humidity in a wide variety of niches, commonly in rodent burrows, and crevices and holes in banks, trees and houses in the Old World, and in tree canopies and forest litter in the New World [3]. Infection is transmitted by the bite of the fly, usually at night and outdoors; however, infected vectors can take a blood meal during the day if disturbed and also are responsible for inoculating parasites indoors within the household environment. Commonly, the infection is zoonotic; one species of *Leishmania* may be associated with one, or many, natural vertebrate hosts, which provide the reservoir of infection. Humans are commonly accidental hosts, although there are situations in which they may be the reservoir in an anthroponotic cycle. For these reasons, human leishmaniasis has a very wide geographical distribution and range of climate and altitude (Fig. 37.35), and different epidemiological patterns (Table 37.2) [4].

Human leishmaniasis is usually classified as cutaneous or visceral, but the species that cause visceral disease may also cause skin lesions. In South and Central America, skin disease due to parasites of the *L. brasiliensis* complex may be complicated by the

development of metastatic mucosal or mucocutaneous lesions. Mucosal disease is relatively rare with the other species [5].

Old World cutaneous leishmaniasis

Synonyms
- Oriental sore
- Bouton D'Orient
- Delhi boil
- Aleppo boil

Aetiology and epidemiology. Cutaneous leishmaniasis of the Old World is due to *L. major*, *L. tropica*, *L. aethiopica* and to *L. donovani infantum*, which is responsible for all the cutaneous disease on the northern Mediterranean littoral west of Greece and for some of the disease in North Africa [6,7] (Table 37.2). In endemic areas where transmission is stable, children are especially affected, and the cumulative rate of infection as determined by the presence of scars and positive leishmanin tests may approach 100%. In less stable situations, for example around oases, epidemics occur affecting all ages and sexes [8]. The disease is commonly imported into non-endemic countries by immigrants and returning travellers.

Pathogenesis. Sandflies inoculate the infective metacyclic promastigotes when taking a blood meal from the superficial vascular network in the human dermis. Inoculated promastigotes are taken up by histiocytes and newly immigrated monocytes, in which they multiply. Most inoculations do not seem to result in clinical disease as phagocytosis, and complement-mediated killing of leishmania parasites results in clearing of the infection. A minority of successful parasite inoculations result in localized or disseminated clinical cutaneous leishmaniasis. After a period of time, which depends on parasite species, size of inoculum, and the host's cellular immune response, a clinical lesion appears. This lesion comprises parasitized macrophages, lymphocytes and plasma cells, with little structure (Fig. 37.36) [9]. With time, piecemeal and focal necrosis of parasitized cells is found, probably the result of

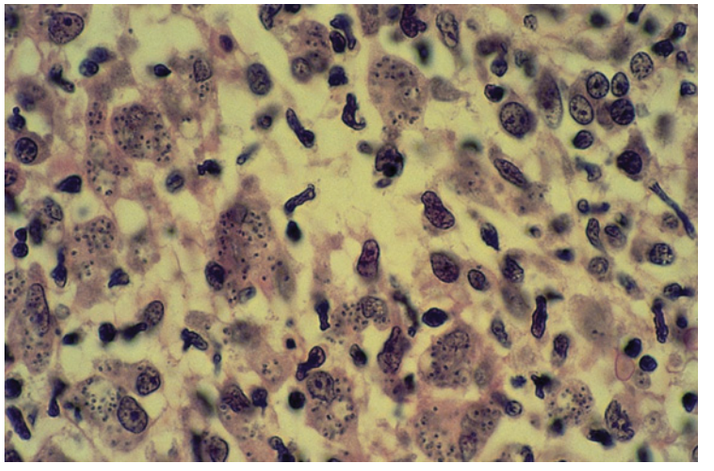

Fig. 37.36 Cutaneous leishmaniasis (high power, H&E); biopsy of early lesion, showing abundant amastigotes in macrophages, and a few plasma cells. (Courtesy of Professor S.B. Lucas, King's College London, UK.)

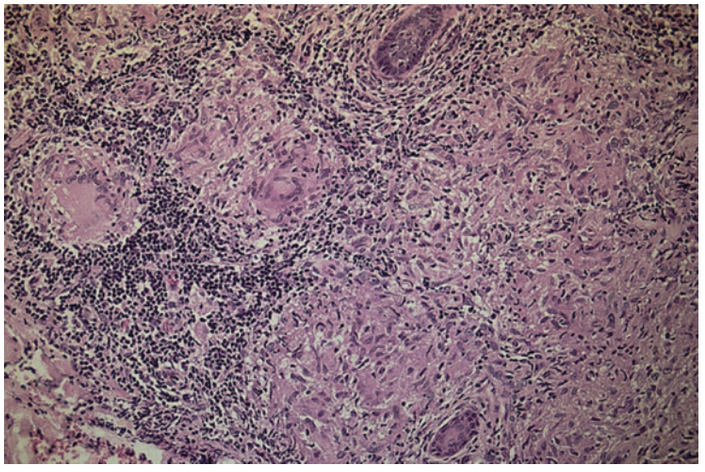

Fig. 37.37 Chronic cutaneous leishmaniasis. Granulomatous dermatitis without necrosis. There are no amastigotes to be found in this case, and the differential diagnosis may be difficult between the other granulomatous dermatitides. (Courtesy of Professor S.B. Lucas, King's College London, UK.)

antibody-dependent cell-mediated immunity. The overlying epidermis becomes hyperkeratotic and breaks down, causing an ulcer whose surface is covered in a crust composed of hyperkeratotic debris, dried exudate, dead cells, and live and dead parasites. This activity continues for several months, while the lesion appears clinically static. In other, especially chronic, cases the more classical epithelioid cell, and sometimes giant cell granuloma, develops with relatively little necrosis, but similar epidermal changes (Fig. 37.37). In these cases, parasites are difficult to find [10]. Rarely, when cell-mediated immunity fails to develop, as in diffuse cutaneous leishmaniasis, histology shows masses of parasitized, often vacuolated, macrophages, with little or no lymphocytic infiltrate, and a normal or attenuated epidermis [11].

Clinical features [12]. Most previously uninfected individuals are susceptible. The incubation period is usually measured in months, but ranges from a few days to over a year. One or more lesions occur on unclothed parts of the body, particularly on acral skin over bony prominences easily bitten by *Phlebotomus*, usually in a child. The face, neck and arms are the commonest targets. Lesions do not necessarily occur all at exactly the same time, but in endemic areas a family of children may all present with lesions and a history strongly suggesting infected sandfly bites all acquired in the same room on the same night.

The natural history of the lesions due to the four species tends to differ but there is much overlap, reflecting the variety in host response [2], so that lesions and their outcome are not always characteristic of the species (Table 37.3) [4]. The sequence of nodule, crusting, ulceration and healing with scar formation is common to all the self-healing sores.

Cutaneous leishmaniasis due to *L. major*: wet, rural or zoonotic cutaneous leishmaniasis [13,14]. After a short incubation period of less than 2 months, a red furuncle-like nodule appears at the site of inoculation (Fig. 37.38). After 2 weeks a central crust forms. The crust may persist (Fig. 37.39), or fall away revealing the underlying ulcer (Fig. 37.40). The ulcer and the raised, red margin enlarge over the next 2–3 months, and the lesion reaches a diameter of 3–6 cm. Multiple, small, secondary nodules (2–4 mm) sometimes occur around the lesion in lymphatics. Healing takes place in 2–6 months and leaves a scar. This type of cutaneous leishmaniasis is acquired in a rural area, where the infecting organisms are also rodent parasites and are poorly adapted to humans. It is an example of a zoonosis.

Table 37.3 Clinical features of cutaneous leishmaniasis. (Courtesy of Weatherall *et al.* [4].)

Parasite and lesion	Natural outcome	Treatment
Leishmania major		
Self-healing rural sores	3–5 months Disabling scars	Physical/topical/IL/nil Sb 20 mg/kg/day × 2–3 weeks (?Some unresponsive)
L. tropica		
Self-healing urban sores	10–14 months	Physical/topical/IL/nil Sb 20 mg/kg/day × 2–3 weeks
Leishmaniasis recidivans	>10 years destructive	Sb 20 mg/kg/day × 3–6 weeks
L. aethiopica		
Self-healing, nodular	2–5 years	Physical/topical/nil
Mucocutaneous	>10 years destructive	Pentamidine 4 mg/kg/week × 8
DCL	Persists, disfiguring	Pentamidine 4 mg/kg/week × months

Self-healing	?Duration	Physical/topical/nil Sb 20 mg/kg/day × 2–3 weeks

DCL, diffuse cutaneous leishmaniasis; Sb, antimony as pentavalent antimonial; IL, intralesional injection.

Cutaneous leishmaniasis due to *L. tropica*: dry, urban or anthroponotic leishmaniasis [15]. After an incubation period of more than 2 months, a small, brownish nodule appears, which becomes a slowly extending plaque 1–2 cm in diameter in about 6 months.

Fig. 37.38 Cutaneous leishmaniasis due to *Leishmania major*: early papules, one of which is starting to show central crusting.

Fig. 37.39 Cutaneous leishmaniasis due to *Leishmania major* from Saudi Arabia, showing marked and persistent crusting.

At this stage, shallow ulceration appears in the centre, which develops a closely adherent crust. Multiple secondary nodules occur much less frequently than in the 'wet' form. After 8–12 months, the lesion starts to regress and the ulcer heals, leaving a scar. The average time from nodule to scar is about 1 year, approximately twice as long as in the 'wet' form. Rare forms of viscerotropic infections by *L. tropica* have been described in war veterans who acquired the parasite in the Middle East and in cases of Indian kala-azar [16].

Cutaneous leishmaniasis due to *L. aethiopica* [11]. Lesions are most commonly central on the face, and single. Satellite papules accuminate into a large, spreading nodule that may not crust or ulcerate (Fig. 37.41). Lesions are seldom much inflamed, and heal over 2–5 years. If the sandfly bite has been on the mucosal border of the nose or mouth, primary mucocutaneous leishmaniasis (MCL) may develop, producing swelling of lips or nose, and persist for many years (Fig. 37.42), although without the gross destruction seen in Latin America caused by *L. brasiliensis*.

Fig. 37.40 Cutaneous leishmaniasis due to *Leishmania major* from Sudan. An ulcer with a raised edge.

Fig. 37.41 Cutaneous leishmaniasis due to *Leishmania aethiopica* from Kenya. A large nodule with many satellite papules and abundant parasites.

Cutaneous leishmaniasis due to *L. donovani* infantum [7]. Whereas infants infected with this parasite tend to get visceral leishmaniasis, adults are more likely to develop simple self-healing cutaneous disease, without concurrent or subsequent visceral involvement. The appearance and evolution of the lesions is typically slow and mild, when compared with that of *L. major*, with which it coexists in North Africa [6] (Fig. 37.43). Solitary mucosal lesions have occasionally been reported [5].

In addition to the classical self-healing sores, there are two types of cutaneous leishmaniasis that are chronic, and may not heal spontaneously.

Fig. 37.42 Nasal involvement, and marked inflammatory oedema in leishmaniasis due to *Leishmania aethiopica* in Ethiopia.

Fig. 37.43 Cutaneous leishmaniasis due to *Leishmania infantum*, from Spain. The fleshy nodule, with relatively little inflammation, is characteristic.

Leishmaniasis recidivans: chronic leishmaniasis, lupoid leishmaniasis [10]. It has been estimated that approximately 4% of *L. tropica* infections from Iran and Afghanistan will develop this chronic form of the disease. Brown-red or brown-yellow papules appear, usually close to a scar of an old lesion of cutaneous leishmaniasis or actually in the scar. They coalesce and form a plaque closely resembling lupus vulgaris, even to the formation of apple-jelly nodules (Fig. 37.44). The lesions frequently worsen in the summer and may ulcerate or form concentric rings. Rare keloidal and verrucous forms on the lower limbs are described. A psoriasiform type also occurs and may cover large areas of the body.

Fig. 37.44 Leishmaniasis recidivans (lupoid leishmaniasis) from Baghdad, showing active papules cropping in the edge of the scar of the healed sore. (Courtesy of Professor G. Rahim.)

The recidivans lesion is the result of a peculiar host reaction in which cellular immunity fails to sterilize the lesion, despite the presence of exaggerated hypersensitivity. Although not as destructive as lupus vulgaris, lupoid leishmaniasis may persist and spread slowly for many years [17]. Investigations to demonstrate the parasite or leishmanial DNA in the affected skin are commonly negative.

Diffuse cutaneous leishmaniasis: disseminated cutaneous leishmaniasis, leishmaniasis cutis diffusa. In the Old World this form of the disease is due to *L. aethiopica* and has certain characteristic features [11].

1. There is an initial lesion, which spreads locally, and from which the disease disseminates to other parts of the skin, often involving large areas (Fig. 37.45).
2. The lesions are nodules that do not ulcerate.
3. There is a superabundance of parasites in the lesions.
4. The histology is characteristic in that macrophages full of amastigotes predominate.
5. Internal organs are not invaded and there is no history of kala-azar.
6. The leishmanin test and other tests of specific cellular immunity are negative.
7. The disease progresses slowly and becomes chronic.
8. Treatment produces only gradual improvement and relapse is the rule.

Under the influence of treatment, the histology changes towards the tuberculoid in a proportion of patients, and they may recover completely. Cases of coincident leishmaniasis and leprosy have been described, and show that the immune deficiency of each condition is specific [18].

Diagnosis. In endemic areas, or in travellers returned from endemic areas, the clinical diagnosis is not difficult in the case of

Fig. 37.45 Diffuse cutaneous leishmaniasis due to *Leishmania aethiopica* in Ethiopia. The face is covered with infiltration and nodulation but there is no ulceration.

typical sores. A positive diagnosis of cutaneous leishmaniasis (Old World and New World types) can be suggested, and in most cases confirmed, by the presence of one or more of the following criteria:

1 History of exposure to an endemic area in the previous weeks or months
2 History of sandfly bites in the previous weeks or months
3 History of high-risk activities such as sleeping outdoors, jungle or desert trekking
4 Non-healing chronic nodular, violaceous ulcer for 4–6 weeks or longer
5 Demonstration of amastigotes in Giemsa-stained smears from infected skin by direct microscopy
6 Demonstration of intracellular amastigotes in the dermis of H & E sections of skin
7 Presence of leishmanial granulomas in the dermis in H & E specimens
8 Growth of promastigotes in Nicolle–Novy–MacNeal (NNN) culture medium from lesional specimens
9 Demonstration of leishmanial DNA by the PCR.

Deeper, subcutaneous sores (the so-called volcano lesion), sores arising from lymphatic spread, or chronic sores in which scarring predominates may present difficulties. Confirmation is through demonstration of the parasite. Usually, this is best achieved by making a smear of material from the sore and staining it with Wright's, Giemsa or Leishman's stain on a microscope slide. The smear may be made from the exudate from the sore, and is often positive even if purulent because secondary bacterial infection is unusual. Alternatively, a slit-skin smear is made, as for leprosy (Chapter 32), being careful to avoid taking blood from the nodular part of the lesion. Parasites are usually readily seen in sores that have not yet started to heal, but are difficult to see thereafter. Alternatively, material may be obtained through a needle or with a dental broach [19].

Ideally, material should also be cultured on NNN or similar medium. At the time of taking the lesional skin biopsy for histological examination, a portion of it should be cultured, and dab smears made from the cut surface of the other portion before it is fixed. Leishmania are harder to see and identify in sections than in smears. In chronic leishmaniasis especially, histology may not be able to distinguish leishmaniasis from sarcoidosis, tuberculosis or other tuberculoid pathologies. However, in acute forms with or without the presence of amastigotes, the presence of a granuloma has a high diagnostic sensitivity.

In all forms of cutaneous leishmaniasis, the leishmanin test will be positive once the stage of crusting has been reached [19]. The test is negative in the diffuse anergic forms. The leishmanin test, also called the Montenegro test, particularly in Central and South America, is a suspension of 5×10^6 cultured promastigotes of *Leishmania* spp. (*L. major* is commonly used for cutaneous diagnosis in Old World leishmaniasis) per mL of 0.5% phenol saline: 0.1 mL is injected into the volar surface of the forearm and the result read at 48–72 h. The antigen is normally standardized so that an induration of 5 mm or more, measured by the ballpoint technique, is positive [1]. While interpreting the result in an individual patient, it is important to take into consideration the prevalence rate in the control population. This intradermal skin test is not useful for the diagnosis of current cutaneous leishmaniasis as a positive result may indicate previous sensitization. Moreover, there are also problems of cross-reactivity amongst different *Leishmania* spp., and therefore the Montenegro test is not useful for particular epidemiological settings where infections by different *Leishmania* spp. overlap.

Molecular diagnostic tests to detect leishmanial DNA by PCR have been available for several years. Assays can be carried out by using nuclear DNA, and more recently the diagnostic sensitivity was significantly enhanced by using kinetoplast minicircle DNA [20]. The sensitivity of this test has been reported to be between 92% and 98% with 100% specificity by several authors [20]. A variety of clinical specimens, including cotton swabs and archival smears or paraffin-embedded skin sections, can be used as the DNA source for the PCR diagnosis. Ideally, the diagnosis of cutaneous leishmaniasis should achieve a species- and subspecies-specific level, as this has therapeutic and prognostic implications.

Treatment [21]. Most sores will heal spontaneously, but their duration cannot be predicted in an individual case. It is reasonable to try topical methods of treatment for simple sores, and to reserve the systemic use of pentavalent antimonials for problematic sores: these include sores where scarring would be disabling or severely disfiguring; sores that will not heal easily, for example on the lower leg or over a joint; sores involving mucosa or cartilage; or sores that might be due to parasites of the *L. brasiliensis* group.

Heating a sore to 40–42°C for several hours each day promotes healing but is technically difficult [22]. Small single sores may be frozen with carbon dioxide snow [23], curetted under local anaesthetic [24] or infiltrated with 1–2 mL sodium stibogluconate or meglumine antimoniate, on one or two occasions a few days apart. Careful attention to technique is essential [25]. Preliminary studies using the aminoglycoside aminosidine or paromomycin in an

ointment looked promising, but problems of formulation have yet to be solved [26]. Weekly intralesional sodium stibogluconate and daily oral itraconazole 100 mg or allopurinol 10–20 mg/kg for 6 to 8 weeks, have been successfully used to treat most *L. major*, *L. donovani* and *L. tropica* simple infections by the author (FVL).

Systemic treatment is with sodium stibogluconate or meglumine antimoniate by intravenous or intramuscular injection in a single daily dose of 20 mg antimony/kg, for as long as it takes to produce clinical and parasitological healing and a few days longer: usually 15–21 days [27]. Sores due to *L. brasiliensis* should be treated for the full 21 days [28]. *Leishmania aethiopica* is not sensitive to antimony at this dosage [29] and, when systemic treatment is justified, patients should be treated with pentamidine isethionate in a dose of 4 mg salt/kg once a week for as long as necessary [30]. Patients with diffuse cutaneous leishmaniasis require treatment for many months beyond clinical and demonstrable parasitic cure [30]. Leishmaniasis recidivans (lupoid) may respond to local infiltration after nodulectomy, or systemic antimonials. The additional use of steroids has helped some cases [14]. Severe scarring may require plastic repair. After healing, patients are normally immune to reinfection with the same species, although second sores in old age, or due to a parasite of a different zymodeme, have been reported. Cutaneous leishmaniasis in the immunocompromised host may manifest many years after exposure to the infective bite.

It is clear that the available treatments for cutaneous leishmaniasis are far from being satisfactory. Even more, reported therapeutic failures with pentavalent antimonials have been described as an increasing problem in endemic regions for visceral leishmaniasis in India and also as an emerging problem in New World cutaneous leishmaniasis amongst returned travellers to the UK [31]. Novel approaches include combination therapeutic regimens using antimonials and immunostimulating agents. Intravenous treatment with pentavalent antimonials results in a number of common adverse reactions and side effects including hepatic, pancreatic, musculoskeletal and cardiac toxicity. Elderly patients seem to be more frequently and severely affected by these symptoms.

American cutaneous leishmaniasis and mucosal leishmaniasis (MCL)

Synonyms
- American leishmaniasis
- South American leishmaniasis
- Espundia
- Pian bois
- Uta
- Chiclero's ulcer
- Bush yaws
- Picatura de pito

Aetiology and epidemiology. The site of development of leishmania in the gut of New World sandflies differs from that in Old World sandflies, and the parasites have been redesignated by the addition of the subgenus *vianna*, for example *Leishmania viannia brasiliensis* [32], but in this chapter the older, simpler terminology is retained, by which the parasites that cause disease in humans fall into the *L. brasiliensis* and *L. mexicana* complexes. American leishmaniasis is an endemic and mainly rural disease of damp, forested country in South and Central America [32]. It becomes epidemic among young people who go to work in the forests, 25% of young soldiers fighting in the jungle in certain areas and in villagers settled on land recently torn from the tropical forest. The optimum time for transmission is immediately after the rainy season.

Additionally, *L. b. brasiliensis* is becoming increasingly periurban [27], with a number of opportunistic hosts, including dogs and donkeys (whose true reservoir status is questionable). *Leishmania brasiliensis peruviana* is, by contrast, part of a mountainous zoonosis among peridomestic dogs, causing an endemic human infection that affects children especially. Vectors and reservoirs are given in Table 37.2. As increasing numbers of new species of parasite are identified, it is becoming clear that each is associated with its own complex of reservoir hosts and vector sandflies.

Pathogenesis. The pathology of the skin lesions does not differ significantly from that of Old World sores. The necrotic pattern, with ulceration of the overlying epidermis, is common [9]. Although recovery from an infection confers lifelong immunity against reinfection with the same species of parasite, that immunity does not develop early enough or adequately to prevent the blood-borne metastatic spread of parasites of the *L. brasiliensis* complex, especially *L. b. brasiliensis* itself, to the mucosa of the nose, mouth, palate or larynx. Here, they may later start to multiply and be recognized immunologically, and cause severe destructive lesions, known as espundia (Portuguese: a sponge) [33]. Histology of the mucosal lesion [34] shows a collection of lymphocytes and plasma cells around small arterioles in the nasal submucosa. Occasional leishmania are present in the vascular endothelial cells. Oedema, congestion and proliferation of vascular endothelium progress, leading to desquamation and necrosis of the overlying mucosa and underlying cartilage. Endarteritis and thrombosis add to the tissue destruction. Vascular supply is so reduced that only fibrous tissue remains.

Clinical features [35]. The main types of American leishmaniasis are as follows.

Cutaneous leishmaniasis due to *L. mexicana* complex. The vector of *L. m. mexicana* bites humans reluctantly, so only those who spend long periods of time in the forest, such as chicle collectors, are at risk. The lesions behave like those of *L. major* or *L. tropica*. Most are on the side of the face or behind the ears (Table 37.3). Lesions on the pinna of the ear may invade cartilage, take many years to heal and destroy the pinna [36]. *Leishmania mexicana amazonensis* is extremely common in forest rodents, but the vector is not anthropophilic, so human infections are rare. A large proportion of them give rise to diffuse cutaneous leishmaniasis, which does not differ significantly from its counterpart in the Old World, due to *L. aethiopica* [29].

Cutaneous leishmaniasis due to *L. brasiliensis* complex [37]. Sores are often large deep ulcers, usually with a raised edge. Sores due to *L. b. guyanensis* are often fleshy and protuberant, usually on the

Fig. 37.46 Mucosal leishmaniasis due to *Leishmania brasiliensis* in Brazil. The nasal septum anteriorly is most severely affected. (Courtesy of Dr L. Bakos, Porto Alegre, Brazil.)

Fig. 37.47 Severe mucocutaneous leishmaniasis from Brazil. (Courtesy of Professor P. Marsden, University of Brasilia, Brazil.)

limbs, often multiple, and resemble those of yaws, 'pian bois' [38]. This parasite and *L. b. panamensis* are especially associated with lesions along the draining lymphatics, but these may occur with any species. The lymphatic lesions may remain discrete small nodules, or may become inflamed and break through the skin to resemble the primary lesion. Lymphadenopathy is seldom marked.

American MCL [39,40]. Up to 40% of patients with sores due to *L. b. brasiliensis*, and a very much smaller proportion with sores due to *L. b. panamensis* and *L. b. guyanensis*, may develop mucosal lesions: 50% of mucosal lesions develop within 2 years of the appearance of the skin lesion, and 90% within 10 years. Delays of 35 years are recorded [33]. About 15% of patients with MCL give no previous history of a skin sore. The nasal mucosa is almost always affected, and in one-third of patients a second site is also involved, in the pharynx, palate, larynx or upper lip, in that order (Fig. 37.46). The usual initial lesion is a nodule on the inferior turbinate or septum, which causes stuffiness and obstruction. The destructive pathology perforates the septum and over years may destroy the nose, palate and lips (Fig. 37.47), which may become gross and protuberant, or scarred and constricted, causing difficulties in speech and eating. Death may supervene from secondary infection, starvation or laryngeal obstruction (Fig. 37.48). Spontaneous healing is virtually unknown.

Cutaneous leishmaniasis due to *L. b. peruviana*: 'uta' [35]. Lesions are less severe than those of *L. b. brasiliensis*. They heal spontaneously and are not known to cause MCL.

Fig. 37.48 Mucosal leishmaniasis from Brazil. A fatal case, showing the extensive laryngeal involvement. (Courtesy of Professor P. Marsden, University of Brasilia, Brazil.)

Diagnosis. The principles are the same as for cutaneous leishmaniasis of the Old World, but the differentials of syphilis, yaws, rhinoscleroma, sporotrichosis, histoplasmosis, leprosy and, especially, blastomycosis must also be considered. Lesions of sarcoidosis, lupus vulgaris and cutaneous T-cell lymphomas (CTCLs) can also resemble cutaneous leishmaniasis. For the diagnosis of MCL, the nasal lesion must be sampled, after careful cleaning, for culture, as well as examined by impression Giemsa smear and histology. Problems of contaminating infection can be avoided by inoculating some of the material into a hamster.

Treatment [12]. This is summarized in Table 37.3. Lesions due to *L. b. guyanensis* are particularly liable to relapse. Lesions due to *L. b. brasiliensis* should be treated systemically for a week beyond parasitological cure, in order to prevent MCL from developing

[28]. Previously untreated patients with MCL respond to pentavalent antimonials in a dose of 20 mg/kg/day, if given daily for 3–4 weeks [41]. Only 20% of relapsed patients will respond to the drug. Amphotericin is the drug of second choice, given in a dose of 1 mg/kg on alternate days for 2 months. Treatment that is inadequate in dose or duration leads to relapse and drug resistance. Secondary infection should be treated. Corticosteroids are useful to prevent laryngeal oedema that can otherwise complicate the start of treatment of laryngeal disease.

Cutaneous leishmaniasis in the returned traveller. Common and rare forms of cutaneous leishmaniasis are increasingly being described in non-endemic regions of the world. A recent retrospective survey at the Hospital for Tropical Diseases in London disclosed more than 50 new cases, including Old and New World cutaneous infections by *L. tropica, L. viannia braziliensis, L. major* and *L. donovani* complex. Patients with infections acquired in the New World manifested a more severe clinical picture and therefore sought medical referral at an earlier stage. The diagnosis was established by all four standard investigations including Giemsa smears for direct microscopy, H&E histology, parasitological culture and molecular diagnosis by PCR. Intravenous or intralesional treatment with sodium stibogluconate and other less frequently used agents resulted in cure for most of these patients [42]. Daily oral itraconazol or allopurinol in combination with weekly intralesional sodium stibogluconate has been successful in our hospital for most cases of simple cutaneous leishmaniasis. Educational strategies to increase the awareness of cutaneous leishmaniasis as an emerging problem in the UK are being directed at general practitioners, dermatologists and the public.

Visceral leishmaniasis

Synonyms
- Kala-azar
- 'Death fever'
- Dum-dum fever

Leishmania donovani donovani and its close relative *L. donovani infantum* are, by contrast with the other species of *Leishmania* that infect humans, normally viscerotropic, and cause a severe systemic infection, which may be accompanied by cutaneous manifestations.

Aetiology. There are four main zoogeographical zones in which visceral leishmaniasis is found (see Table 37.2). Transmission is peridomestic and tends to be stable in the Mediterranean focus. Dogs are the reservoir. Young children are most commonly affected. Infected adults tend to develop self-healing skin sores. In Brazil, peridomestic transmission from raiding foxes affects older children. A similar age group is affected in East Africa, where transmission takes place outside the houses in the evenings. In India, where the human is the reservoir, epidemics occur every 15 years or so and all age groups, previously uninfected, are susceptible. Travellers and tourists of any age group are susceptible in any of the four zones.

Pathogenesis. In over 90% of cases, the infection is subclinical and cutaneous hypersensitivity and immunity develop [43]. In the others, especially in the malnourished, the parasite invades and multiplies in reticuloendothelial cells of the spleen, liver, lymphoid tissue, bone marrow and gut submucosa. This reticuloendothelial bombardment is associated with the overproduction of polyclonal IgG, specific antibody production, and the formation of high titres of immune complexes and various autoantibodies. The spleen and, to a lesser extent, the liver become enlarged, and hypersplenism ensues, causing anaemia, leukopenia and thrombocytopenia. Organ function is usually well preserved until late in the disease, but specific and non-specific indices of cell-mediated immunity are depressed, and secondary infections are common and often fatal [44].

Clinical features [45]. After an incubation period of weeks to months, sometimes exceeding a year, fever develops, either insidiously or abruptly. The commonest additional symptoms are fatigue, discomfort from the presence of the enlarged spleen and cough, diarrhoea and epistaxis. Gross splenomegaly is the dominant physical sign; hepatomegaly, lymphadenopathy in some endemic zones, and signs of malnutrition, including pedal oedema, red, straight hair in Africans, and wasting also occur.

In a few cases in Africa, a primary skin sore has been described, like those of cutaneous leishmaniasis. Rarely, there may be an accompanying mucosal lesion. In Indian people especially, the skin of the face, hands, feet and abdomen becomes hyperpigmented, even black: kala-azar means black sickness. Despite epistaxis and sometimes jaundice, there is no evidence of cutaneous bleeding. In Iran, patients have been seen with numerous skin lesions [46].

Post-kala-azar dermal leishmaniasis (PKDL) (dermal leishmanoid). In 5% of East African patients, and 20% of Indian patients, a rash develops after the visceral disease has healed, either spontaneously or following treatment. A small proportion of patients with PKDL give no previous history of visceral disease. In Africa [47] the rash begins during convalescence, appearing on the cheeks, chin, ears and extensor aspects of forearms, buttocks and lower legs (Fig. 37.49). Usually, the rash comprises discrete papules, which on histological examination show a tuberculoid histology with scanty parasites. The leishmanin test is positive. The rash heals spontaneously over a few months. Presumably it represents the acquisition of specific cellular immunity that is clearing up scattered parasites that remained in the skin. Both cellular immunity and pentavalent antimonials are less efficient in the skin than in the viscera.

In India, by contrast, the rash appears 1–2 years after recovery, as hypopigmented macules, similar in appearance and distribution to those of lepromatous leprosy (Fig. 37.50). After a variable period of years or months, diffuse nodulation begins to develop in these macules (Fig. 37.51). The rash is progressive over many years and seldom heals spontaneously. The tongue, palate and genitalia may be involved. There may be lymphadenopathy, but the viscera are spared and there are no features of relapse of the previous systemic infection. Presumably, this condition represents

cellular immunity against a dermotropic mutant of *L. donovani.* PKDL is thought to represent the intraepidemic reservoir of infection of visceral leishmaniasis in India. Histology shows a poorly differentiated infiltrate of chronic inflammatory cells, with a variable number of leishmania in dermal macrophages [48]. The leishmanin test is usually negative, but becomes positive after successful treatment [49].

Diagnosis. In visceral leishmaniasis, parasites may be demonstrated in aspirates of spleen, bone marrow, liver or lymph node, in that order of likelihood (Fig. 37.52). In PKDL, slit-skin smears are usually positive. Antibodies to *Leishmania* spp. may be demonstrated by a variety of techniques: indirect immunofluorescence, ELISA and direct agglutination tests are commonly performed [50]. The leishmanin test is negative, except in African PKDL.

Treatment. For visceral leishmaniasis, sodium stibogluconate is used, as for cutaneous leishmaniasis for 21–30 days, according to the endemic zone [27]. African PKDL does not require further treatment. Indian PKDL is treated with a further course of sodium stibogluconate.

Visceral leishmaniasis in patients with HIV infection [51]

The main area of overlap of these two infections is in southern Europe, especially Spain. Leishmaniasis may be acquired prior to or after the HIV infection, and may thus be primary or secondary to the HIV infection. In some patients, typical characteristics of fever and splenomegaly have not been present, and serological tests have been negative. On occasion, the parasite has been discovered by chance, for example in the biopsy of Kaposi's sarcoma, and disseminated dermatofibroma-like lesions containing amastigotes have been described in a patient with acquired immune deficiency syndrome (AIDS) coinfected with visceral *L. donovani* [52]. Aspirates of bone marrow and spleen show extremely heavy parasitization. Relapse and mortality rates are high. Treatment should be prolonged and monitored by splenic aspirates.

Toxoplasmosis

Aetiology. The disease is caused by *Toxoplasma gondii*, a tiny sporozoon often assuming a crescentic shape, first identified in 1908 in a North African rodent, *Ctenodactylus gondii*. Cats are definitive hosts and a form of *Toxoplasma* cyst can be found in their faeces. Rodents and birds are the intermediate hosts. Larger mammals including humans are infected incidentally, by eating raw, infected meat or by ingesting oocysts in contaminated food or water.

Pathogenesis. The organism tends to invade the reticuloendothelial system and the endothelium of the blood vessels, forming granulomas with necrosis of affected tissues. Toxoplasmosis causes four types of disease in humans [1]:

1 An acute febrile lymphadenopathy
2 Fetal infection, causing brain damage
3 Ocular disease, usually due to reactivation of fetal infection
4 Disseminated disease in immunocompromised patients, including those with HIV infection, causing fulminating encephalitis.

Skin changes are uncommon and non-specific. In the congenital disease [1], macular and haemorrhagic eruptions predominate. Occasionally, abnormal hair growth and exfoliative dermatitis have been seen. In the acquired disease, macular, maculopapular, papular and haemorrhagic eruptions also occur and may be followed by scarlatiniform desquamation. A wide variety of other lesions have been described including bullae, nodules, livedo annularis, urticaria and an eruption like pityriasis lichenoides; conclusive evidence of a causal relationship is frequently wanting. A dermatomyositis-like syndrome is described [2,3].

Diagnosis is made on clinical evidence, and may be confirmed by demonstration of the organism in biopsy of lymph node, liver or spleen, bone marrow, or in cerebrospinal and ventricular fluid. Usually, the diagnosis is made serologically. Several methods are available, among them:

1 The Sabin–Feldman dye test, positive early and declining over 1–2 years, which measures mainly IgG antibodies
2 Direct agglutination of formalinized parasites—useful for screening, detects IgM and IgG antibodies
3 Indirect fluorescence—simple and safe, can be used to distinguish IgM from IgG antibodies, as can an IgM ELISA.

Treatment. The sulphonamides and pyrimethamine (Daraprim) act synergistically and are effective [4]. Severe side effects may occur due to interference with folic acid metabolism. For this reason, infections in immunologically normal individuals are not usually treated.

Mechanisms of skin injury by arthropods

Arthropods produce their effects on the skin by a variety of mechanisms [1–4], more than one of which may be implicated simultaneously.

Mechanical trauma

The puncture wound or laceration produced by the penetration of the skin seldom causes serious disturbance to the host. The nature of the trauma inflicted depends upon the structure of the mouthparts, which show wide variation between different species. There are two methods of feeding on blood: 'vessel feeders' insert the tip of their mouthparts into a capillary, and 'pool feeders' lacerate the skin, damage blood vessels, and feed on the extravasated blood. Vessel feeders include sucking lice (Anoplura) and most mosquitoes, and pool feeders include stable flies and tsetse flies.

Injection of irritant, cytotoxic or pharmacologically active substances

An injected substance may contain pharmacologically active agents that produce local or, if in sufficient quantity, systemic effects. Salivary secretions and sting venoms may contain various enzymes such as: hyaluronidase, proteases, peptidases and phospholipases; kinins; histamine-liberating agents; histamine; 5-hydroxytryptamine or acetylcholine.

Injection of potential allergens

The vast majority of reactions to arthropod bites or stings depend upon the presence in the host, of specific antibodies to antigenic substances in the arthropod saliva or venom. Investigation of extracts of venom sacs and salivary glands from many species, using modern immunological techniques, has demonstrated the presence of numerous antigens, some specific for a single species, and others common to several related species or even to related genera.

The type of reaction provoked by an arthropod bite or sting in an individual patient largely depends on previous exposure to the same or related species. When an individual is bitten for the first time by a species whose salivary secretions contain no directly injurious substance there is commonly no reaction. After repeated bites, sensitivity starts to develop, manifest by an itchy papule developing about 24 h after each bite, and persisting for several days. With prolonged exposure, an immediate weal reaction occurs, to be followed by the delayed papular reaction. After a further period of exposure, the delayed reaction no longer occurs, and eventually there is no reaction at all. The patient is then said to be immune. Mellanby [5] demonstrated this sequence of events with mosquito bites, and a similar response is seen with the bites of many other arthropods.

Some patients show a severe, systemic hypersensitivity to arthropod allergens, manifested by anaphylaxis. The antigenic substances in the venoms of Hymenoptera (bees, wasps, hornets) are more likely to induce severe systemic hypersensitivity reactions than are the antigens of most other insects.

The capacity of a patient to respond to an antigenic stimulus is also an important factor in determining the reaction to an

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

arthropod. The reactions of patients who are immunosuppressed, as a result of either disease or therapy, are modified. Examples of this include the occurrence of crusted scabies in immunosuppressed individuals, and the response to bites in patients with chronic lymphatic leukaemia, human immunodeficiency virus (HIV) infection, and Epstein–Barr virus-associated natural killer cell leukaemia/lymphoma (see p. 38.6).

Secondary infection
Bacterial infection may be introduced at the time of the bite, but commonly gains entry as a result of scratching, and may confuse the clinical picture. Compartment syndrome caused by streptococcal cellulitis complicating an insect bite has been described [6].

Invasion of the host's tissues
Certain flies cause myiasis, in which the host's tissues are invaded by larvae (see p. 38.8).

Contact reactions
Simple contact with the secretions of certain arthropods, or with their living or dead bodies, may provoke irritant or allergic contact reactions. For example, the secretions of blister beetles produce a severe irritant reaction, and repeated handling of cockroaches may induce contact urticaria and dermatitis.

Reactions to retained mouthparts
Persistent granulomatous papules or nodules may be provoked by retained mouthparts, for example those of ticks.

Transmission of disease
Many diseases have arthropod vectors, for example malaria (mosquitoes), leishmaniasis (sandflies) and typhus (lice).

Susceptibility to infestation or attack
There are a number of environmental and social factors that determine the range of arthropod species to which an individual is exposed.

Persons living and working in tropical climates tend to wear fewer clothes, and therefore expose larger areas of the body to bites and stings. Clothing itself is essential to the existence of the body louse, and areas of constriction of clothing affect the distribution of the skin lesions caused by certain mites (e.g. harvest mites).

Certain occupations carry an increased risk of reactions to arthropods [7]. Forestry workers, for example, may be exposed to the urticating hairs of the caterpillars of certain species of Lepidoptera, and dock workers handling foodstuffs may be attacked by mites infesting the cargo.

In some societies, humans are exposed to attack by the parasites of the domestic animals with which they cohabit.

Housing can influence exposure to arthropod attack in a number of ways. Overcrowded homes favour transmission of ectoparasites, such as lice and the scabies mite, and dilapidated housing provides an ideal habitat for bed bugs. Spiders and scorpions will take up residence in garages, outhouses and woodpiles.

The methods by which an arthropod is attracted to its host species include body heat, carbon dioxide in exhaled air (e.g. mosquitoes, ticks, fleas, bedbugs), and displacement of air or vibrations caused by the host (e.g. fleas) [8]. Human sweat contains mosquito attractants, and anhidrotic subjects are unattractive to mosquitoes [9,10]. The human skin microflora may be responsible for producing compounds that attract mosquitoes and, as there is variation in the microflora between individuals, body odour probably contributes to susceptibility to biting [11,12]. Human odour also appears to play a part in attracting sandflies [13]. Pregnant women appear to be more attractive to mosquitoes than the non-pregnant [14,15].

There is also a suggestion of increased susceptibility to mosquito bites in patients with HIV infection receiving antiretroviral therapy and suffering from lipoatrophy [16].

Alcohol ingestion also seems to promote mosquito attraction [17].

Certain species of flies are attracted to skin ulcers and purulent material, in which they lay their eggs.

Insect pheromones play a part in attacks by large numbers of Hymenoptera. Honeybees, when stinging, emit an alarm pheromone from glands in their sting chambers, and this guides other bees to attack an intruder.

Histopathology of arthropod bites and stings [1–3]
The histopathological changes associated with arthropod bites depend upon a number of factors, including the arthropod involved, the type of immunological reaction provoked, and the duration of the lesion.

In papular urticaria there is prominent papillary dermal oedema and a perivascular chronic inflammatory infiltrate with a significant admixture of eosinophils.

Fig. 38.1 Typical papular urticaria. In this case, in response to flea bites.

Bullous reactions develop beneath a more or less intact epidermis, and may be multilocular.

Chronic reactions often have a pseudolymphomatous appearance. The dermis contains a dense inflammatory infiltrate of lymphoid cells and histiocytes, with an admixture of eosinophils and plasma cells, and the presence of atypical mononuclear cells with hyperchromatic nuclei. Secondary lymphoid follicles with germinal centres are sometimes formed. Multinucleated cells may also occur. If retained mouthparts are present, there may also be giant cells of foreign-body type.

Additional histopathological features associated with particular arthropods are noted in the relevant sections of this chapter.

Clinical features of arthropod bites

The very large number of species of biting and stinging arthropods, their different feeding habits, and the variation in individual patients' responses to the various irritants and allergens injected determine the diversity of clinical features. The type and distribution of lesions produced by individual arthropods are discussed in the relevant sections throughout this chapter.

The most frequently encountered response is papular urticaria (Fig. 38.1). Initially, an extremely itchy urticarial weal develops at the site of the bite, and this is succeeded by a firm pruritic papule, which usually persists for several days. The weal and papule may show a central haemorrhagic punctum, and the papule may be surmounted by a tiny vesicle. Lesions are often grouped in clusters, and develop in crops at irregular intervals.

The number and distribution of skin lesions produced by the bites depend upon the type of exposure and the feeding habits of the arthropod involved. New bites by the same species will often cause a recrudescence of activity in existing lesions.

Fig. 38.2 Bullous lesions in response to arthropod bites. (Courtesy of Dr F.A. Ive, Durham, UK.)

Bullous reactions are common on the lower legs (Fig. 38.2), but may occur in other sites, especially in children. In the presence of lower limb venous hypertension, haemorrhagic or ulcerated lesions may develop. More severe local changes are sometimes found, with cellulitis and lymphangitis in the apparent absence of secondary infection. Eruptive pseudoangiomatosis-like lesions have also been reported as a response to arthropod bites [1,2].

Irritation is an almost constant symptom, and rubbing and scratching may increase the inflammatory changes, and induce eczematization. When the bites are very numerous, or if the local reaction is severe, there may be fever and malaise.

Secondary infection is a common complication, and may be manifest as impetigo, folliculitis, cellulitis and lymphangitis.

Anaphylactic shock is unusual except after Hymenoptera stings, but is occasionally seen with some other arthropods.

Bite reactions may persist for months. Tick attachment sites, in which the mouthparts may be retained, are the most likely to persist, but so may bites of mosquitoes and other arthropods.

Diagnosis

The diagnosis of arthropod bites is often self-evident, for example when the patient has spent the afternoon in the garden on a hot day in summer and subsequently develops typical lesions on

Fig. 38.3 Typical heavy scale in the coat of a dog suffering from *Cheyletiella* infestation.

Fig. 38.4 Typical 'pepper and salt' appearance of flea eggs and faeces in the debris from a cat's bedding.

exposed areas of skin. However, difficulty arises when the source of the bites is not immediately obvious.

The distribution of the bites may provide a clue to their origin, for example localization to the abdomen and thighs in cheyletiellosis or contact with sarcoptic mange in dogs, and involvement of the legs below the knees when the lesions are produced by cat or dog fleas. Patients should be asked about domestic pets; not only their own, but also those in the homes of close relatives who are visited regularly, as ectoparasites associated with pet animals are often the source of persistent arthropod bites. If the bites are not localized, but scattered all over the body, consider reactions to arthropods biting in the patient's bedroom, such as bird fleas, bird mites or bedbugs. Enquire if the patient has recently moved house. It may be that the previous owners of the new home kept pet animals, and have left a legacy of domestic flea infestation. Even if the house remained empty for a considerable time before the new owners took up residence, the flea population will be waiting in cocoons to emerge when the new occupants arrive. Adult fleas can survive starvation for variable lengths of time depending upon species and environmental conditions [1,2]—a newly emerged and unfed dog flea, *Ctenocephalides canis*, will survive for approximately 60 days. In the absence of their natural hosts, such animal flea populations will not usually survive for more than a few months.

If the history and examination do not suggest a possible source for the problem, or if the dermatologist wishes to confirm a suspected source, the following procedures may be useful [3,4].

1 The patient's pet animals should be examined, if possible, for signs of skin disease. Cheyletiellosis and canine scabies produce characteristic changes on an affected animal [5]. Skin scrapings will confirm sarcoptic mange, and vigorous combing of scale from the coat of a dog suffering from cheyletiellosis (Fig. 38.3) will provide material in which *Cheyletiella* mites may be identified. If the animal cannot be examined, the patient should be provided with a sheet of black paper, and asked to collect brushings or combings from the animal's coat for subsequent examination.
2 If domestic infestation with cat or dog fleas is suspected, this can often be confirmed by examination of debris from the pet's bedding. The patient is supplied with a large polythene bag and instructed to place the pet's bedding in the bag and shake it vigorously for a few minutes. The bedding is then removed, the bag sealed, and delivered to the dermatologist for microscopy of the debris. Macroscopically, flea eggs and faeces have a 'pepper and salt' appearance (Fig. 38.4), and the larvae are grub-like. For identification, adult fleas should be 'cleared' in 10% potassium hydroxide for 24 h so that the majority of the pigment is removed and the anatomical details revealed. Cat and dog fleas are readily identified, but if unfamiliar species are encountered, the help of an entomologist with an interest in Siphonaptera should be sought. Correct identification of fleas is important so that proper control measures may be carried out [6].
3 If problems from bird fleas or bird mites are suspected, it is often of value to examine dust obtained with a vacuum cleaner from bedrooms. This is, however, time consuming and requires some expertise.
4 It may be necessary to visit the patient's home to establish whether there are birds' nests under the eaves, which might be a source of fleas or mites, or to take specimens from household pets.
5 Mites that might have relevance to human dermatoses may be isolated from clothing, furnishings or bedding by the techniques described by Hewitt *et al*. [7].

An entomologist is often invaluable in these situations, not only for identification of arthropods, but also to advise about their relevance to the situation. An arthropod discovered at the scene of the crime may only be an innocent bystander.

In some cases, in spite of extensive efforts, the source of the bites remains unknown, and the dermatologist can then only treat the problem symptomatically with oral antihistamines, topical antipruritics and insect repellents.

Insect repellents [1–4]

There are several strategies that can be employed in attempts to avoid arthropod bites/stings and arthropod-related disease transmission, including protective clothing, insecticide-impregnated netting and repellents. With regard to the last mentioned, there are two principal categories of commercially available insect repellents—plant-derived essential oils and synthetic chemicals. The former group includes citronella, oil of eucalyptus, peppermint, tea-tree oil, lavender, soybean oil and neem oil. DEET (*N*,*N*-diethyl-*m*-toluamide [or *N*,*N*-diethyl-3-methylbenzamide]), the most widely used repellent, is an example of the latter.

Recently introduced repellents include DEPA (*N*,*N*-diethyl phenylacetamide), PMD (para-menthane-3,8-diol) and picaridin, a synthetic derivative of pepper.

Unfortunately, with many of these agents, their volatility means that the repellent effect is transient, and benefit can only be sustained by repeated application. In addition, effectiveness is often limited to a narrow spectrum of susceptible arthropods.

Class Insecta

Mosquitoes, gnats, midges and flies (Diptera)

The order Diptera is one of the largest of the insect orders. Diptera are two-winged flies with a single pair of membranous forewings, and with hindwings modified as balancing organs (halteres). Most feed on nectar, plant exudates or decaying animal and vegetable matter, but some are blood-sucking, and some have larvae parasitic on humans. To the dermatologist, the Diptera are important as biting insects and as the cause of myiasis, in addition to their capacity to transmit disease.

The Diptera are currently usually classified in two suborders based on characteristics shown by larvae, pupae and adults—the Nematocera and the Brachycera. Detailed information on the morphology, biology and medical importance of Diptera is provided in comprehensive texts by Kettle [1], and Lane and Crosskey [2].

Suborder Nematocera (long-horned flies)

The Nematocera are small flies with long, many-segmented, filamentous antennae. With a few exceptions the medically important species are blood-suckers.

Family Culicidae (mosquitoes)

Mosquitoes have worldwide distribution, and are responsible for the transmission of a number of diseases, including malaria, filariasis, yellow fever, West Nile virus and dengue fever. Human malaria is transmitted exclusively by *Anopheles* species. Both male and female mosquitoes will imbibe sweet juices from flowers or ripe fruit, but only the females pierce the skin and suck the blood of vertebrate animals. Most mosquitoes are nocturnal feeders, but a few species are diurnal. The eggs of mosquitoes are deposited on or near water, and adults develop via aquatic larval and pupal stages.

Family Psychodidae (sandflies)

These are tiny (2–3 mm long), hairy flies with lanceolate wings and long legs. They are widely distributed, especially in the tropics and subtropics.

Genus *Phlebotomus*. Species of *Phlebotomus* are vectors of cutaneous and visceral leishmaniasis in the Old World. *Phlebotomus* species are also vectors of sandfly or papatasi fever. *Phlebotomus* bites cause a condition known as harara (urticaria multiformis endemica) in Israel and the surrounding countries.

Genus *Lutzomyia*. *Lutzomyia* species are vectors of cutaneous and visceral leishmaniasis and bartonellosis in the New World.

Family Simuliidae [3]

Popularly known as blackflies, and with a worldwide distribution, these are small (2–6 mm) flies with a characteristic humped thorax, and short, broad wings. They breed only in areas of fast-flowing water, and bite during the day.

Over large parts of the tropics several species of blackfly are responsible for transmission of onchocerciasis—principally the *Simulium damnosum* complex (several closely related species) in West Africa, *S. neavei* in East Africa, *S. metallicum* in Venezuela and *S. ochraceum* in Guatemala. In temperate regions, the greatest problem caused by simuliids is their painful bites, and some species are such a persistent nuisance at certain times of the year that they may make large areas unpleasant to live or work in. In Yugoslavia, the notorious Golubatz fly, *S. columbaschense* (*S. columbaczense*), which bred in the Danube at Golubatz, caused both mortality among livestock and human misery until environmental changes eliminated it. In North America, the most troublesome biting species are *S. venustum*, which is holarctic and occurs from Alaska to Greenland and south to Texas and South Carolina, and *Prosimulium mixtum*, which occurs in the north-eastern USA and eastern Canada.

S. posticatum (the Blandford fly), formerly named *S. austeni* Edwards, is widely distributed throughout Europe and European Russia. In England, it is found in an arc running from East Anglia through Oxfordshire into Dorset. In the Stour valley area of Dorset, particularly in the region of Blandford Forum, the fly is notorious

for the severity of the reaction to its bites [4–6]. It had not been known as a pest in the UK prior to the 1960s. The eggs are laid in cracks in vertical river banks, a short distance above the water [7]. The larvae are concentrated in stretches of fast-flowing water immediately downstream of barrages and weirs, where they attach themselves to weeds or stones and feed on phytoplankton. Adults hatch in May, and are on the wing in May, June and early July. Females require a blood meal before oviposition, and although they will bite various wild and domestic animals, they appear to prefer humans and dogs. In the 1990s, biological control, using a bacterium (*Bacillus thuringiensis* var *Israelensis*) that selectively targeted the fly larvae, significantly reduced the severity of the problem.

Family Ceratopogonidae (biting midges; 'punkies'; 'no-see-ums')

These small flies (1–3 mm in length) have a worldwide distribution, and are notorious as biting pests. The biting midges of the West Highlands of Scotland (the commonest species of which is *Culicoides impunctatus*), for example, are an intolerable nuisance, and pose a problem to the Scottish tourist industry [8]. Males and females feed on nectar, but most females require a blood meal for maturation of the ovaries and egg production. There are four genera that suck blood: *Culicoides, Leptoconops, Austroconops* and *Forcipomyia* (subgenus *Lasiohelea*). They breed in rivers, swamps and marshes; they often occur in swarms and will readily attack any mammal in their vicinity. A few species enter homes and bite at night.

The genus *Culicoides* is widely distributed. *Leptoconops* species are largely restricted to the warmer parts of the Old and New World. *Austroconops* contains only one species, which is restricted to western Australia. *Lasiohelea* species are principally associated with tropical and subtropical rain forests.

Suborder Brachycera (circular-seamed flies, muscoid flies and short-horned flies)

The Brachycera are stout-bodied flies with short antennae, often composed of three segments, and never more than six.

Family Tabanidae

Many species of three genera of this family will attack humans—*Tabanus* (horse flies), *Chrysops* (deer flies) and *Haematopota* (clegs). They are large flies, and have a worldwide distribution. Only females suck blood. Tabanid flies act as vectors for loiasis and tularaemia, and some species may transmit anthrax mechanically [9].

Family Rhagionidae (snipe flies)

Species of *Symphoromyia* occurring in the Palaearctic and Nearctic regions are vicious biters. *Atherix* is another blood-sucking genus in the Nearctic and Neotropical regions, and *Spaniopsis* is troublesome in Australia.

Family Chloropidae (eye flies; frit flies)

These flies are about 2 mm in length. The adults of some species are attracted to open sores, body secretions, and the eyes, particularly eyes with a copious discharge. *Hippelates* and *Siphunculina* species are associated with humans and can act as mechanical vectors of yaws, conjunctivitis and streptococcal skin infection.

Family Muscidae (house flies; stable flies; tsetse flies)

This family includes the familiar house fly *Musca domestica* and the lesser house fly *Fannia canicularis*. These do not bite, but may act as mechanical vectors of disease. The muscids *Stomoxys calcitrans* (stable fly) and *Haematobia* species (horn flies) have mouthparts modified for sucking blood. They usually feed on large quadrupeds, but can inflict painful bites on humans. Tsetse flies are vectors of trypanosomiasis. They are confined to Africa south of the Sahara.

Family Hippoboscidae (flat flies; louse flies; keds)

Members of this family are blood-sucking ectoparasites of birds and animals. Several species of ked have been recorded as biting humans [10,11].

Members of several other families of Diptera are important in that their larvae may cause myiasis (p. 38.8).

Clinical features [12,13]. The clinical features of the bites of insects of this large and diverse order are variable. The nature of the pharmacologically active substances injected, and the degree of acquired allergic sensitivity to the antigenic substances in the saliva, are the main factors that determine the reaction. For most of the Diptera, the allergic component is by far the more important. The nature of any injected toxins is usually unknown and the effects attributable to them are usually slight. The clinical picture will also be influenced by the biting habits of the species concerned.

The reaction to mosquito bites is determined by previous exposure, and the sequence of events following multiple bites was elucidated by Mellanby [13]. In an individual not previously exposed, the bites produce no response. With subsequent bites, a delayed reaction occurs, consisting of pruritic papules, which develop approximately 24 h after the bites and persist for several days. After repeated bites for several weeks, the response changes, with the appearance of an immediate weal at the bite site. This resolves after about 2 h, to be replaced by the delayed reaction. Further exposure provokes the immediate reaction, but not the delayed response. Eventually, tolerance is acquired, and no reaction occurs. Studies of the bite reaction in relation to age have shown an increase in immediate reactions from early childhood to adolescence, and a decrease thereafter. The appearance and intensity of delayed reactions decreases with age [14]. It has been proved conclusively that the mosquito salivary glands are the source of the antigens responsible for the bite reactions [15].

Anaphylactic reactions to mosquito bites are rare [16]. Gaig *et al*. reported a patient with a serum sickness-like illness associated with mosquito bites [17]. Severe local reactions are not uncommon, and in highly sensitive subjects bullae, cellulitis and eczematization are often seen, especially on the legs. Gravitational factors probably play a role in the development of bullae on the legs [18]. Exaggerated hypersensitivity responses to mosquito bites have been reported in patients suffering from chronic lymphatic leukaemia [19–22]. However, although the clinical picture and histological features are typical of arthropod bites, in many cases patients

do not recall being bitten [21,23]. Exaggerated responses to mosquito bites have also been described in patients with HIV infection [24,25], and a chronic pruritic eruption in patients with AIDS in South Florida has been attributed to mosquito bites [26].

In recent years, there have been a number of reports from Japan of severe hypersensitivity to mosquito bites preceding the development of malignant histiocytosis [27–29]. This has now been characterized as a disease in which there is a triad of hypersensitivity to mosquito bites, chronic Epstein–Barr virus infection, and natural killer cell leukaemia/lymphoma [30–32]. It affects predominantly Japanese in the first two decades of life. The skin lesions are bullae, which develop at mosquito bite sites, undergo necrosis, and heal with residual scarring. Accompanying the skin lesions are systemic features, principally high fever and general malaise. Affected individuals die of haemophagocytic syndrome (malignant histiocytosis).

Multiple sandfly bites are responsible for the syndrome known as harara (urticaria multiformis endemica), which occurs in Israel and surrounding countries [33]. Skin lesions occur on exposed parts of the body, and are composed of urticated papules and papulovesicles, and bullous lesions, frequently with secondary infection.

The bites of Simuliidae, which may be very numerous, are on exposed skin. The sites of the bites are often marked by a small blood crust with surrounding ecchymosis. Within a few hours, small, pruritic papules develop, and these resolve after several days. However, severe reactions with marked oedema of the limbs and constitutional upset occasionally occur, and in some cases nodules and discoid eczematous areas persist at the sites of the bites for several months [34]. The bites of the Blandford fly occur most frequently on the legs, and women are principally affected [5,6]. The bites often produce a severe local reaction, with oedema and blistering, and may be accompanied by systemic manifestations, including pyrexia, arthralgia and meningism.

The biting midges of the family Ceratopogonidae generally cause small, papular lesions on exposed parts of the skin, but wealing and bulla formation may occur in sensitized individuals. Weal-like lesions, papules and persistent nodules have been described following bites from *Leptoconops torrens* in California [35].

Midges of the family Chironomidae are closely related to ceratopogonids. These midges do not bite, but hypersensitivity to their larvae, used as aquarium fish food and as bait, is well recognized [36,37], and includes contact urticaria [38] and protein contact dermatitis [39].

The bites of keds may be followed by the development of persistent pruritic papules [11].

The bites of horse flies and stable flies are often very painful and frequently become secondarily infected.

Myiasis

Myiasis is the infestation of body tissues of humans and animals by the larvae (maggots) of Diptera [1–6]. Parasitologically, flies may be classified into two main myiasis-producing groups: obligatory and facultative. Obligatory myiasis-producers always pass their larval stage parasitically in the body of an animal. Larvae of facultative myiasis-producers usually develop on decaying flesh or vegetable matter, but may infest wounds.

Clinically, myiasis can be classified according to the part of the body affected. Cutaneous myiasis includes wound myiasis, and furuncular myiasis, in which larvae penetrate and develop within the skin. In nasopharyngeal myiasis, the nose, sinuses and pharynx are affected, and ophthalmomyiasis involves the eye, orbit and periorbital tissues. Intestinal and urogenital myiasis involve invasion of the alimentary tract or urogenital system.

The flies responsible for myiasis in humans include the following groups.

Family Muscidae

Eggs of *Fannia canicularis* (lesser house fly) and *Musca domestica* (house fly) may be deposited on ulcers and give rise to wound myiasis [7].

Family Calliphoridae (blowflies)

Genus *Cochliomyia* (*Callitroga*). These New World screwworms are distributed in the Americas, but are no longer established in North America, following intensive eradication efforts involving the release of a huge number of sterile male flies. Cases of myiasis involve the larvae of only two species of *Cochliomyia*: *C. macellaria* and *C. hominivorax* (*americana*). The larva of *C. macellaria* is a facultative parasite, which may be responsible for secondary infestation of wounds. Larvae of *C. hominivorax* are obligatory parasites, which feed on living tissue and can penetrate unbroken skin [8–10], but they may also infest wounds.

Genus *Chrysomya*. The Old World equivalent of *Cochliomyia*, *Chrysomya bezziana*, the Old World screwworm, is important medically as the larvae are obligate parasites in wounds.

Genus *Cordylobia*. *Cordylobia anthropophaga*, the 'tumbu' fly, is widespread in tropical Africa south of the Sahara [11], and most reported cases of tumbu fly myiasis are acquired in Africa [12,13]. There are, however, reports of myiasis acquired elsewhere, including Spain [14], Portugal [15] and Saudi Arabia [16]. Tumbu fly myiasis occurring in two boys who had never been to Africa might have been acquired as a result of their father, who made frequent visits to Africa, bringing tumbu fly eggs back amongst his possessions [17]. *C.* (*Stasisia*) *rodhaini*, the only other species of *Cordylobia* known to infest humans, has a more limited distribution in tropical Africa, principally the rainforest areas. Extensive furuncular myiasis due to *C. rodhaini* has been reported in an Italian man who acquired the problem while working in Ethiopia [18]. Eggs are not laid on the host, but on sand or soil, especially if contaminated by urine or faeces. They may also be deposited on clothing and linen hanging out to dry. After hatching, the larva raises its cephalic end searching for a suitable host. In the wild, rats are the usual host, but around human habitation, dogs and humans are common hosts. The larva attaches itself by means of its oral hooks, and rapidly penetrates the skin. When development is complete, usually in 14–16 days, it drops to the ground to pupate.

Genus *Auchmeromyia*. Although strictly not a cause of myiasis, the larva of the fly *Auchmeromyia senegalensis*, the Congo floor maggot, is a blood-sucking parasite of humans. This fly occurs throughout tropical Africa, where it lives in native huts and lays its eggs in the soil of the floor. The larvae lie buried in the soil during the day, but emerge at night to feed on the sleeping occupants of the huts. Once engorged, they drop off the host and burrow back into the soil.

Other genera. Larvae of members of the genera *Phormia* (black blowflies) [19–21], *Lucilia* (greenbottle) and *Calliphora* (bluebottle) may also be secondary invaders of wounds in man. In a study of wound myiasis in urban and suburban USA (in which homelessness, alcoholism and peripheral vascular disease were frequent co-factors) the majority of species identified were blowflies, the most common being *Lucilia sericata* [22].

There has been a recent resurgence of interest in the use of maggots (usually those of the greenbottle, *Lucilia sericata*) for wound debridement, an added bonus of which is their ingestion of methicillin-resistant *Staph. aureus* (MRSA) [23].

Family Sarcophagidae (flesh flies)

Genus *Sarcophaga*. There are occasional reports of members of this genus infesting wounds [24].

Genus *Wohlfahrtia*. These flies are similar to *Sarcophaga* and are important myiasis-causing flies in camels and sheep. The larvae of *Wohlfahrtia magnifica* may be deposited in the ear, eye or nose, and cause extensive destruction of healthy tissue. Delir *et al*. reported an Iranian woman with a cavity in the left labium majus occupied by a number of *W. magnifica* larvae [25]. *W. magnifica* occurs in south-eastern Europe, southern and Asiatic Russia, the Middle East and North Africa. *W. vigil* and *W. opaca* are North American species whose females deposit larvae on the skin of young animals, resulting in furuncular myiasis. Lesions are identical to those of *Dermatobia*. Human furuncular myiasis occurs only in young babies, as the larvae are unable to penetrate adult skin [26].

Fig. 38.5 Third instar larva of *Dermatobia hominis* (the human botfly). Note the rows of backward-pointing spines.

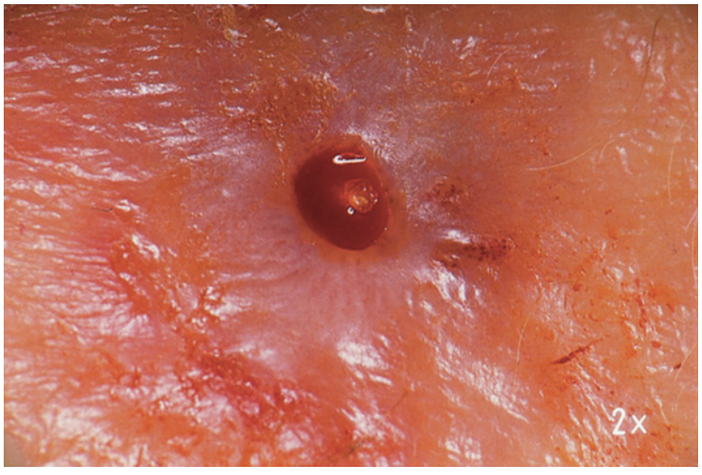

Fig. 38.6 Furuncle-like lesion produced by *Dermatobia hominis*. The tail of the larva is visible in the centre of the lesion.

Family Oestridae

Genus *Cuterebra* (rodent or rabbit botfly). Rabbits and rodents are the natural hosts for the larvae of these flies, which are sometimes responsible for human furuncular myiasis [27–29]. Baird *et al*. [30] reviewed 54 cases of North American cuterebrid myiasis.

Genus *Dermatobia* (human botfly). *Dermatobia hominis* is the only species in the genus. It is a bluebottle-like fly found in the neotropical areas of the New World, extending from southern Mexico to northern Argentina. It occurs in areas where temperature and humidity are relatively high, principally lowland forests. *D. hominis* causes cutaneous myiasis in a wide range of mammalian hosts, including humans, and is particularly important as a parasite of cattle.

The female fly does not deposit her eggs directly, but uses other insects, such as day-flying mosquitoes and blood-sucking flies, as vectors to carry her eggs to the host. She grasps the insect vector in midair and deposits a number of eggs on its abdomen. When the vector subsequently feeds on a potential host the eggs hatch and the larvae rapidly burrow into the skin (Fig. 38.5). Larval development lasts approximately 50–60 days, following which the larva emerges, drops to the ground and pupates. Human botfly myiasis should always be considered as a cause of boil-like lesions in patients who have recently returned from endemic areas [31–37].

Genus *Gasterophilus* (horse botfly). A form of migratory cutaneous myiasis known as 'creeping eruption' is caused by *Gasterophilus* larvae. The Gasterophilinae are mainly parasites of the alimentary tract of horses, but occasionally larvae of certain species of *Gasterophilus*, including *G. haemorrhoidalis* and *G. pecorum*, penetrate human skin.

Genus *Oestrus* (sheep nostril fly). *Oestrus ovis*, which develops in the nasopharyngeal passages of sheep and goats, and *Rhinoestrus purpureus*, which parasitizes horses, are occasionally responsible for human myiasis, especially ophthalmomyiasis [38,39].

Genus *Hypoderma* (warble flies). The larvae of *Hypoderma* species are obligate parasites of cattle. Man is an abnormal host for *Hypoderma*, and the larvae do not mature fully. After penetrating the skin, the larvae produce migratory subcutaneous swellings [40]. They may also invade the eye, producing severe damage. Marked eosinophilia may accompany infestation, and Starr *et al*. [41] reported a cattle rancher in whom an illness marked by pleuritis, pericarditis and myositis, and due to infestation with *H. lineatum*, mimicked the hypereosinophilic syndrome.

Clinical features [3–6,32]. The habits of the flies and their larvae determine the variations in the clinical manifestations for which they are responsible.

Traumatic or wound myiasis has been a serious complication of war wounds in tropical areas, and is sometimes seen in neglected ulcers or wounds in most parts of the world [42]. The eggs or larvae (maggots) can be seen, often in large numbers, in the suppurating tissues.

Obligatory cutaneous myiasis occurs in two main clinical forms; in both there may be mild constitutional symptoms and eosinophilia. Both occur mainly on exposed skin—often the face, scalp, arms or legs. In the furuncular form, boil-like lesions develop gradually over a few days. Each lesion has a central punctum, which discharges serosanguinous fluid. The posterior end of the larva, equipped with a group of spiracles, is usually visible in the punctum, and its movements may be noticed by the patient (Fig. 38.6). The lesions are often extremely painful. The inflammatory reaction around the lesions may be accompanied by lymphangitis and regional lymphadenopathy. Once the larva has emerged, or has been removed, the lesions rapidly resolve. The flies causing furuncular myiasis in humans are *Dermatobia hominis, Cuterebra, Cordylobia anthropophaga, Cordylobia (Stasisia) rodhaini, Wohlfahrtia* species and *Hypoderma* species. The inflammatory nodular lesions produced by *Hypoderma* species are migratory.

The second principal clinical form is a creeping eruption, resembling cutaneous larva migrans, in which a tortuous, thread-like red line with a terminal vesicle marks the passage of the larva

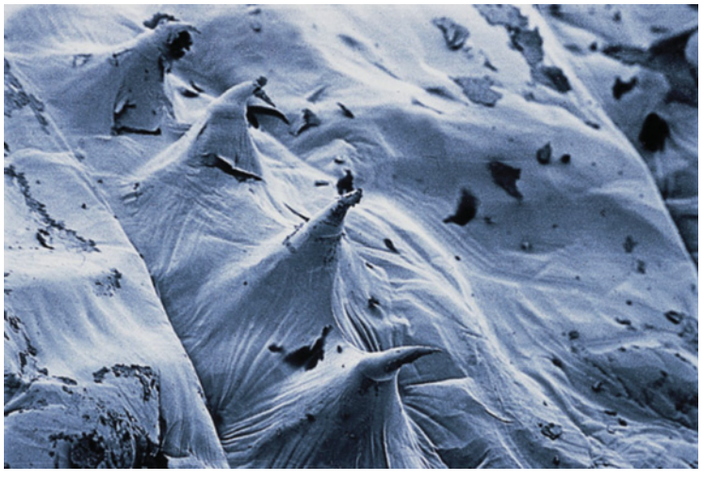

Fig. 38.7 Scanning electron micrograph of the spines on a *Dermatobia hominis* larva.

through the skin. The larva lies ahead of the vesicle in apparently normal skin. This form of myiasis is produced by *Gasterophilus* larvae.

Ultrasonography has been used to facilitate diagnosis and assist in location of *Dermatobia* larvae [43].

Treatment. The larva of *Cordylobia* can often be expressed by firm pressure around the edges of the lesion, but the punctum may require enlarging surgically.

The larva of *Dermatobia hominis* has a bulbous anterior end equipped with rows of spines (Fig. 38.7) that help to anchor it in the skin and make its removal by manual pressure difficult [44]. Traditional methods of treatment include occluding the punctum with pork fat [45,46], blocking the spiracles of the larva and stimulating premature extrusion. A similar result may be obtained with mineral oil, petrolatum or butter. Surgical management is most frequently recommended: the punctum is enlarged by cruciate incisions, and this enables removal of an intact larva [47]. The injection of lignocaine (lidocaine) underneath the nodule may be sufficient to push the larva out [48], and Li Loong *et al*. [49] also found that injection of 2 ml of 2% lidocaine into the blind end of the cavity facilitated non-surgical removal of the larva.

Ivermectin has been used both topically and orally in the management of myiasis [50–55].

Wound myiasis requires debridement and irrigation to remove larvae, and treatment of secondary infection.

Fleas (Siphonaptera)

Fleas are small (1–8 mm long), wingless, laterally compressed insects whose adults are blood-sucking ectoparasites of mammals and birds. Approximately 2000 species and subspecies are known. The larvae of fleas are not parasitic, but feed on organic material that they find in the nest or dwelling-place of the host [1,2].

The order Siphonaptera contains three families of medical importance.

Family Tungidae

This family contains tropical species that burrow in human skin (see Tungiasis, p. 38.12).

Family Pulicidae

Members of this family occur throughout the world, and some species transmit plague and murine typhus [3]. Cat fleas have been shown to be vectors of *Bartonella henselae*, the pathogen responsible for cat-scratch disease and bacillary angiomatosis [4,5]. Many species are important only for the irritability of their bites. The species most frequently parasitizing humans are the human flea, *Pulex irritans*, and the cat and dog fleas, *Ctenocephalides felis* and *Ctenocephalides canis*, but other species will bite humans in the absence of their normal host. The tropical rat flea, *Xenopsylla cheopis*, is the vector of bubonic plague.

The adult female flea lays her eggs during feeding on the host, and the eggs fall to the ground, where an important food source for the larvae is the faeces of the adult flea. The larvae subsequently form cocoons, and under suitable conditions of temperature and humidity the life cycle may be completed in a few weeks. However, the cocoon stage can sometimes last as long as a year, and the flea may emerge only in response to vibrations produced by the movement of possible hosts.

In a household occupied by infested pet dogs or cats, fleas in various stages of development are found in the animals' bedding, and on carpets and soft furnishings. In a survey carried out in the UK in 2005, the prevalence of flea infestation in domestic cats was 21.09% (98.93% of fleas were *C. felis*) and in dogs 6.82% (93.15% of fleas were *C. felis*) [6].

Family Ceratophyllidae

Species in this family are mainly parasitic on rodents and birds. Bird fleas overwinter in cocoons in birds' nests, and emerge in spring. At this time they can become household pests, as they may gain access to bedrooms from nests under the eaves.

Flea infestation in humans

Infestation with the human flea, *Pulex irritans*, occurs mainly in congested communities with low standards of hygiene. It is now rare in developed countries. Cat and dog flea infestation in the home is, however, common.

Animal fleas are common throughout the world, and persons in contact with domestic animals are frequently bitten. Severe attacks are sometimes experienced by individuals moving into premises long empty, but previously occupied by pet cats or dogs. The vibration caused by footsteps triggers the emergence of fleas from their cocoons. Attacks are more likely to occur when the fleas do not have access to their usual host. Household infestations with bird fleas may occur from nests or nest boxes on or near the house [7], and similar problems may occur in the workplace [8]. An outbreak of papular urticaria in a nursery school was traced to an infestation with dog fleas from a fox's burrow beneath the building [9]. Similar problems were caused by *Ctenocephalides felis* entering houses from raccoons which had bred in the cavity between two houses [10], and by *Pulex simulans* originating from a skunk in a basement [11].

Clinical features [12,13]. Flea bites usually provoke typical papular urticaria in a sensitized individual. Occasionally, the reaction is more severe, and bullae may occur. The lesions may be grouped in lines or irregular clusters. Cat and dog flea bites occur predominantly on the legs below the knees, and are most profuse around the ankles (Fig. 38.8), but they can also occur on the forearms. They are much more common in women than men, as trousers and socks protect the legs. Bites from bird fleas tend to be more extensive, as the sleeping occupants of bedrooms usually provide larger areas of exposed flesh.

Confirmation of flea infestation [14]. If flea infestation from pet animals is suspected, this can be confirmed by microscopical examination of debris from the animals' bedding material (p. 38.4).

Fig. 38.8 Typical distribution of cat or dog flea bites on the legs.

The principal sign of flea infestation in an affected animal is the presence of dried concretions of flea faeces on the animal's coat. Some animals will also have signs of flea allergy dermatitis, with areas of crusting and alopecia, most frequently on the lower back and the base of the tail.

If fleas from another source are suspected of causing bites, it may be necessary to examine samples taken with a vacuum cleaner from rooms, or to visit the suspect premises. It is important to identify the flea species responsible for an infestation so that efforts at eradication may be accurately directed at the source [15]. Cat fleas (Fig. 38.9), dog fleas and common bird fleas may be readily identified after 'clearing' in 10% potassium hydroxide for 48 h [3], but the help of an entomologist should be sought.

Treatment. In recent years, the development of topical and oral agents such as fipronil, imidacloprid, lufenuron and selamectin has revolutionized domestic cat and dog flea control [16].

Pest-control companies will deal with flea infestation from other sources.

Tungiasis

Aetiology. Tungiasis is caused by the sand flea *Tunga penetrans*, also known as the jigger, or chigoe. Originally a native of South America, it subsequently spread to Africa [1,2]. In recent years tungiasis has reappeared in Mexico [3], where it was previously last recorded in 1948. The ease of world travel has contributed to tungiasis being encountered in non-endemic areas [1,2,4–9].

T. penetrans is the smallest known flea (1 mm long). Its larvae develop in dry, sandy soil, and development from egg to adult takes about 3 weeks in favourable conditions. The impregnated female flea burrows into the feet of mammals, preferring humans and pigs. In humans, the fleas establish themselves between the

Fig. 38.10 Tungiasis, showing a characteristic lesion on the sole of the foot. (Courtesy of Dr N.H. Cox, Cumberland Infirmary, Carlisle, UK.)

toes, under the nails, and on the soles, but other parts of the body may be affected. Once embedded in the skin, the flea's abdomen enlarges to the size of a pea, and large numbers of eggs are produced. The eggs are subsequently gradually extruded over a period of 2 weeks, and the female flea dies and is sloughed from the skin [10].

Pathology. Anatomical components of the flea are sufficiently distinctive to enable a diagnosis of tungiasis to be made histologically [11].

Clinical features [2,12]. The presence of the fleas causes intense irritation. The typical appearance of an individual lesion is initially a black dot surrounded by a halo of erythema, followed by enlargement to form a mother of pearl-coloured papule with a central, dark punctum, produced by the enlarging flea abdomen (Fig. 38.10). Secondary infection is common, and tetanus has often complicated tungiasis in the past [13]. In severe cases, the feet may be honeycombed by multiple lesions, causing serious discomfort and disability. Use of the dermatoscope aids diagnosis by demonstrating the surface features [14,15].

Treatment [16]. The flea should be completely removed from the skin. This can be accomplished by enlarging the surface punctum and extracting the flea with tweezers, curettage and cautery, or excision.

A plant-based repellent, assessed in Brazil, proved to be extremely effective in preventing infestation with *T. penetrans* [17].

The unwary traveller may well acquire tungiasis, and those visiting endemic areas should be warned to wear stout shoes, and not to sit on the ground.

Bees, wasps and ants (Hymenoptera)

The adults of many species in this large order of insects have evolved a sting apparatus. The sting may or may not be barbed. Some use the sting in defence, and others use it offensively in hunting for food. Males have no sting apparatus. Humans are frequently stung by these insects, with reactions varying from local discomfort to fatal anaphylaxis.

The Hymenoptera are readily recognized by the narrow waist (isthmus) connecting the abdomen to the thorax. Some of the more important families include the following.

Superfamily Apoidea (bees)

Honeybees (Apis mellifera)

Honeybees possess a barbed sting. When humans are stung, the bee is unable to remove the sting. The sting and venom apparatus are avulsed from the bee's abdomen in its struggles, but the venom apparatus continues to function and pump in more venom.

'Africanized' honeybees, the product of interbreeding between bees from southern Africa and European species, have caused significant problems in recent years [1]. These aggressive ('killer') bees, which have characteristics of their African antecedents, including strong colony defensive behaviour, have migrated northward from Brazil to the southern USA.

Humblebees; bumblebees (Bombus spp.)

The sting is not barbed, and the bumblebee is therefore able to sting repeatedly. Most species are inoffensive, and only sting defensively when severely provoked.

Superfamily Vespoidea

Family Vespidae (social wasps)

This family includes wasps, yellow-jackets and hornets. Species of *Vespa, Vespula* and *Polistes* inflict painful stings. Wasps can also sting repeatedly, as they either have small barbs or none at all on their stings.

Superfamily Bethyloidea

These are small, solitary wasps. They sometimes become abundant in houses. They are parasitic on the larvae of *Lepidoptera* and *Coleoptera*. *Scleroderma domesticum, Epyris californicus* and *Cephalonomia gallicola* may inflict troublesome stings [2,3].

Superfamily Scolioidea

Family Formicidae (ants)

Many ant species are equipped with powerful stings, including the Australian jumper and bull ants [4,5], and *Solenopsis*, the fire ant. Fire ants, so called because of the burning pain of their stings, have been particularly problematic in recent years in the USA. There are several native species of fire ant in the USA, but it is the red and black imported fire ants *S. invicta* and *S. richteri*, inadvertently brought to the United States from South America, that have become troublesome pests [2,6–9]. *S. invicta* is also well established in two locations of the Brisbane area of Australia [10]. Wood imported from South America was the source of fire ants responsible for anaphylaxis in a woman in Málaga, Spain [11].

The fire ant first uses its powerful mandibles to grip its victim, and drives its non-barbed sting into the skin. It then rotates about the point of attachment of the mandibles and inflicts further stings in a circular pattern [7–9,12]. Although largely outdoor insects, fire ants may move into dwellings, causing problems for the inhabitants [13].

Species of *Pogonomyrmex* (harvester ants) may inflict multiple painful stings [2,14].

Venoms [15–29]

The composition of venoms is complex. Pharmacologically active and antigenic substances are both present, and an individual's reaction to the sting is determined partly by the quantity of the former, and partly by the degree of acquired hypersensitivity to the latter. Hymenoptera venom contains vasoactive amines, small polypeptides, and larger protein molecules. The components of vespid (wasps, yellow-jackets and hornets) venoms include histamine, serotonin, mast-cell degranulating peptide, wasp kinin, phospholipases, hyaluronidase and antigen 5. The three major allergens in vespid venoms are phospholipases, hyaluronidase and antigen 5. The venom of the honeybee contains histamine, mast-cell degranulating peptide, melittin, phospholipase A_2, hyaluronidase and acid phosphatase. The three proteins in honeybee venom which are important allergens are phospholipase A_2, hyaluronidase and acid phosphatase. In addition, the polypeptide melittin is also antigenic. Bumblebee venom appears to be chemically and antigenically related to honeybee venom [22].

Study of fire ant venom was impeded for many years by the extreme difficulty in obtaining sufficient amounts. The venom is composed of 90–95% water-insoluble piperidine alkaloids [23], which are not allergenic but are responsible for the local reaction at the sting site. When commercial-grade venom became available, several potent allergenic proteins were identified [8,24]. Antigenic similarity between fire ant venom, bee and wasp venoms and scorpion venom has been demonstrated [25,26].

Allergy to Hymenoptera venom is mediated by IgE antibodies. The antigenic substances in the venom of many Hymenoptera are more liable to induce high degrees of hypersensitivity of the immediate type than are the antigens of most other insects.

Clinical features [15,16,27,28]. Reactions to bee and wasp stings may be classified as local and systemic. Both may have a toxic or a hypersensitive mechanism. The typical local toxic reaction produced by pharmacologically active components of the venom is burning pain, which may be very severe, followed by erythema and oedema. This local reaction subsides in a few hours. The systemic toxic effects of multiple stings include hypotension, generalized vasodilatation, severe headache, vomiting, diarrhoea and shock, and the cumulative effect of a large number of stings may be fatal, particularly in children.

In some cases, hypersensitivity produces only a more intense local reaction manifest as increased oedema, usually developing within the first half hour, but occasionally delayed for several hours. If a generalized anaphylactic reaction occurs, this is usually within a few minutes of the sting. The manifestations of a generalized reaction may be classified as cutaneous (pruritus, erythema, urticaria and angio-oedema), respiratory (laryngeal oedema, bronchospasm), or vascular (tachycardia, hypotension, shock). These features may occur separately or in combination, and in varying degrees of severity.

Occasionally, late-onset reactions to stings occur [17]. In some patients, an urticarial reaction develops several hours after the sting, and in others a serum sickness-like reaction occurs, with urticaria, joint swelling and arthralgia.

A patient with a foreign-body granuloma and IgE pseudolymphoma following multiple bee stings has been reported [30], and another with an eosinophilic foreign body granuloma after multiple self-administered bee stings as treatment in traditional Korean medicine [31].

Skin lesions produced by fire ants typically occur in clusters [7–9]. The site of attachment of the mandibles may be marked by two minute haemorrhagic puncta. The initial reaction to the sting is the development of a weal, followed within a few hours by a vesicle. The fluid in the vesicle gradually becomes cloudy, and after 8–10 h the typical lesion is an umbilicated pustule on a red, oedematous base. The pustule subsequently ruptures, forming a crust, and after several days the lesions heal, frequently leaving small scars. Hand–foot syndrome associated with multiple fire ant stings has been described [32].

Systemic hypersensitivity reactions may also occur, and feature generalized urticaria and angio-oedema, wheezing, nausea and vomiting, and hypotension [7,33,34]. These manifestations may increase in severity with successive attacks, and fatal anaphylaxis can occur [9].

Treatment [28,35,36]. Local reactions to Hymenoptera stings may be treated with oral antihistamines. The treatment of choice for

anaphylaxis is intramuscular epinephrine (adrenaline) (in adults, a dose of 0.5 ml 1:1000 solution should be administered, and repeated after about 5 minutes in the absence of clinical improvement or if deterioration occurs after the initial treatment), followed by chlorpheniramine (10–20 mg, intramuscular or slow intravenous) and hydrocortisone (100–500 mg, intramuscular or slow intravenous) [36]. Patients at risk of an anaphylactic response to Hymenoptera stings should wear a device such as a MedicAlert warning bracelet, in case they are discovered unconscious following a sting. They should also carry a sting emergency kit, and receive instruction in self-administration of epinephrine.

The introduction of venom immunotherapy has reduced the risk of anaphylaxis in Hymenoptera-sensitive patients. It is thought to exert its beneficial effect by stimulating the development of IgG (blocking) antibodies against the venom allergens. This prophylactic measure is indicated in patients with a history of life-threatening reactions to stings, positive skin tests, and presence of venom-specific serum IgE. However, such therapy should only be carried out in specialized units.

Conventional advice with regard to honeybee stings is that the sting should be immediately scraped off, never pinched. A study by Visscher *et al*. [37] suggests that the method of removal does not affect the quantity of venom received and is therefore unimportant; the sting should simply be removed as rapidly as possible.

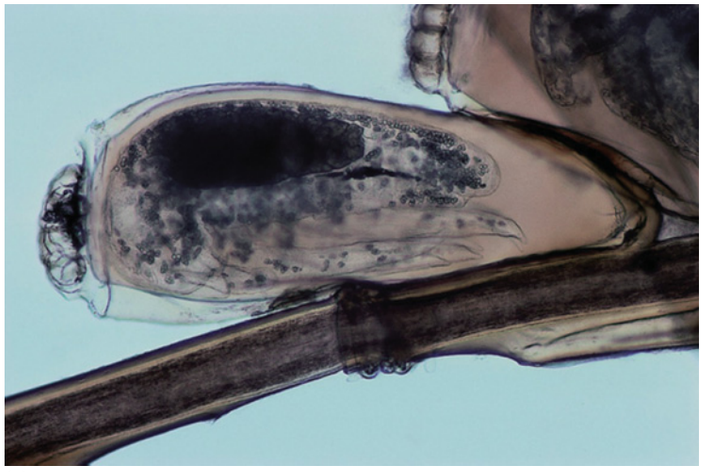
Lice (Phthiraptera)

Lice are members of the order Phthiraptera. They are wingless, dorsoventrally flattened insects, which are obligate ectoparasites of birds and mammals. The Phthiraptera are highly host-specific and spend their entire lives on the host. Members of the suborder Anoplura are blood-sucking ectoparasites of mammals.

Humans are parasitized by three species of Anoplura: *Pediculus capitis*, the head louse, *Pediculus humanus*, the clothing or body louse, and *Pthirus pubis*, the pubic or crab louse. Head lice and clothing lice are morphologically almost identical, and are capable of interbreeding, but on the host they maintain their territorial preferences. *Pthirus pubis* is morphologically quite distinct from *Pediculus*. It is a louse that has only one close relative in the insect world, a species living on gorillas (*Pthirus gorillae*) and the ancestor of human pubic lice. It is thought that our human ancestors acquired pubic lice from gorillas, perhaps by sharing their bedding material or by humans feeding on gorillas. Interestingly, chimpanzees, our closest primate relative, are parasitized by *Pediculus* species (*P. schaeffi*) but not by *Pthirus*, and orangutans do not have lice.

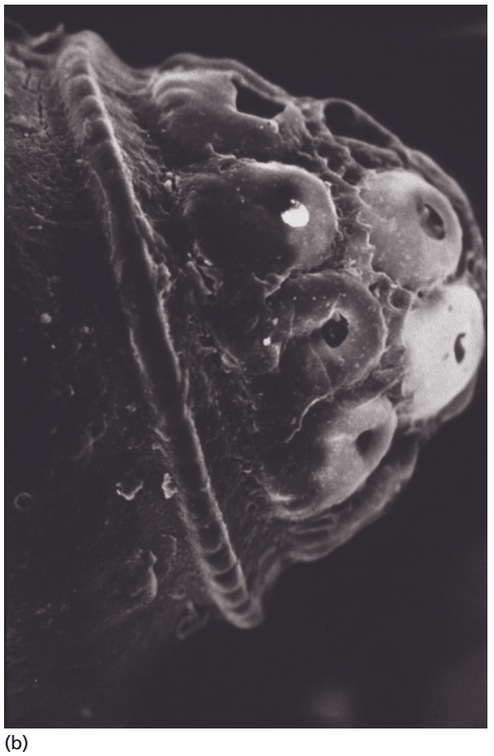
Pthirus is the correct zoological name for the crab louse—the name should have been *Phthirus*, but a misprint was inadvertently

Fig. 38.11 *Pediculus capitis*, the head louse.



accepted by the International Committee on Zoological Nomenclature [1].

Morphology and biology [1–12]



***Pediculus capitis* (head louse).** The adult female is a greyish white insect 3–4 mm long (Fig. 38.11). The male is slightly smaller. The claws on the legs are adapted for clinging to hair.

During her lifespan of approximately 40 days, the female lays an average of about seven eggs daily. The eggs are cemented to hair shafts with a chitinous cement material secreted by the female's accessory glands [13] (Fig. 38.12a). In temperate climates, in order to provide a suitable temperature for incubation, the eggs are attached to hair close to the surface of the scalp. They are oval, flesh coloured and have a lid (operculum) capping the free end of the egg (Fig. 38.12b). The operculum is pushed off by the emerging louse nymph. Once the louse has emerged, the empty egg case or 'nit' appears white, and is easier to see than the intact eggs close to the scalp surface. Eggs hatch in about 8 days and, following three moults, the louse nymph reaches maturity in approximately 10 days.

***Pediculus humanus* (clothing or body louse).** This louse is almost identical in appearance to the head louse, and its development is similar. Its natural habitat is the clothing of its host, and it only visits the skin to feed. Its eggs are cemented to clothing fibres, with a preference for clothing close to the skin. Seams are a favoured site for oviposition. It thrives in situations where normal hygiene is lacking. The clothing louse and its eggs will not survive high-temperature washing and ironing, and it is intolerant of temperature changes in its environment. It is therefore a parasite of individuals whose clothing is rarely changed or washed.

(b)

Fig. 38.12 (a) Head louse eggs cemented to a hair shaft. (b) Scanning electron micrograph of the operculum on a head louse egg.

***Pthirus pubis* (pubic or crab louse).** The crab louse is quite distinctive in appearance (Fig. 38.13) and habits from *Pediculus*. Its body is squat, and the second and third pairs of legs carry heavy, pincer-like claws. When static, the crab louse uses these huge claws to grip adjacent hairs close to the skin surface (Fig. 38.14). Its eggs are light brown in colour and, like those of the head louse, are cemented to the hair of the host (Fig. 38.15). It is adapted to living in hair of a particular density. Scalp hair, except at the scalp margins, is too dense, but the crab louse will colonize axillary hair, eyebrows, eyelashes, beard hair, and hair on the trunk and limbs, in addition to pubic hair. It is mainly sedentary, but becomes active

Fig. 38.13 *Pthirus pubis*, the crab louse.

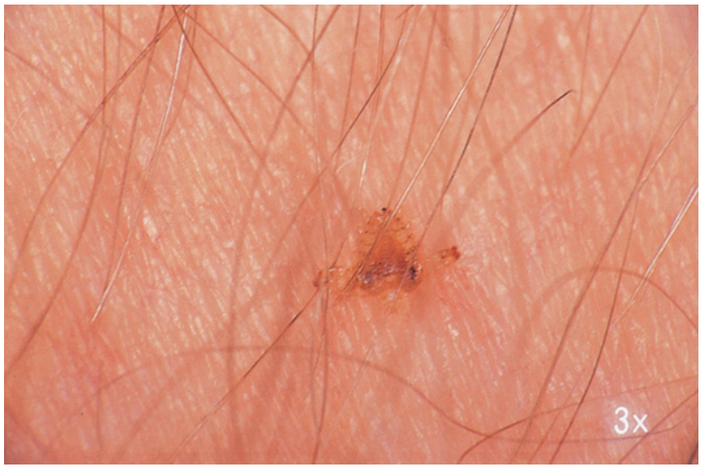

Fig. 38.14 Crab louse clinging to hairs on the abdomen.

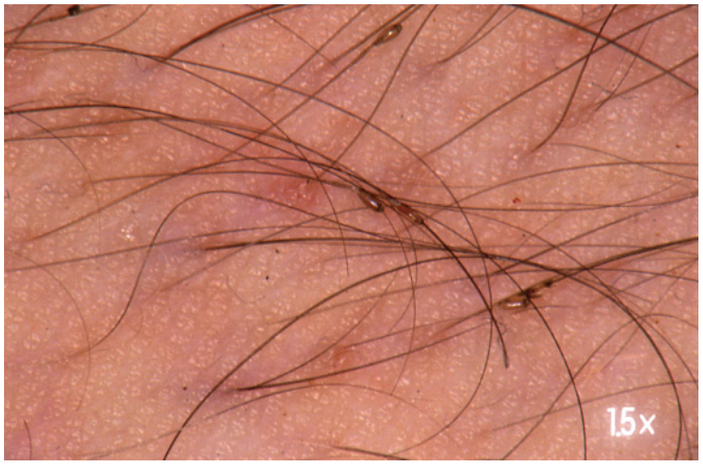

Fig. 38.15 Crab louse eggs attached to abdominal hair.

at night when the host is sleeping [14]. It moves by transferring its grip from one hair to another. The crab louse has difficulty moving when taken from its host, whereas head and clothing lice are quite mobile off the host.

Pthirus pubis is a specific parasite of humans, but its transfer to a dog has been recorded [15].

The Anoplura are vessel feeders (solenophages), introducing their mouthparts directly into a blood vessel to withdraw blood [16,17]. The components responsible for probing the skin and piercing a blood vessel are a group of stylets, which are kept withdrawn within the head unless the insect is feeding. In the front of the head is a small, snout-like tube, the haustellum, which is soft, eversible and armed with teeth. When the louse is about to feed, the haustellum is everted and the buccal teeth rotated outwards (Fig. 38.16a). The teeth cut into the epidermis and the haustellum is driven into the skin. It eventually comes to rest with the buccal teeth fully everted, anchoring the mouthparts (Fig. 38.16b). Once fixed in the skin, a bundle of stylets is pushed forward through the opening in the haustellum by protractor muscles within the head of the louse (Fig. 38.16c). The stylets are advanced into the dermis as a single bundle or fascicle, and probe for a small blood vessel.

Head lice (*Pediculosis capitis*)

Prevalence and epidemiology [1–3]. The head louse has a worldwide distribution, and head louse infection is common both in developed and developing countries. However, precise data on current prevalence are relatively sparse.

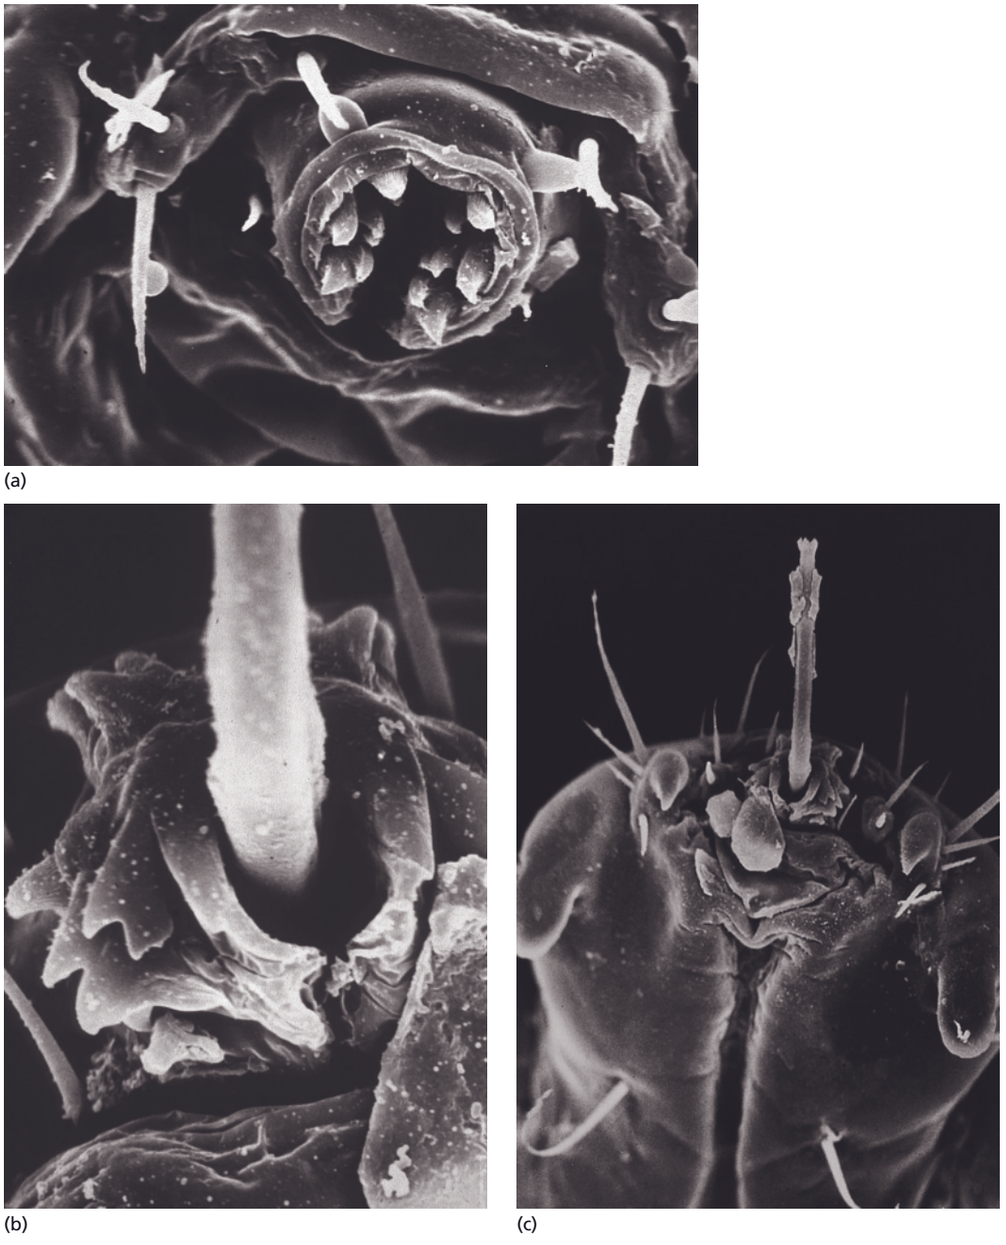

Fig. 38.16 Scanning electron micrograph of a crab louse showing: (a) haustellum with buccal teeth; (b) everted buccal teeth; (c) the protruded stylet bundle.

In England, in the past, head lice were common in industrial conurbations. In 10 industrial cities, in 1941, about 40% of preschool-age boys and 50% of girls had head lice [4]. In contrast, infection rates in rural communities were low. A survey of schoolchildren in 1975 [5] showed an overall prevalence of 2.44%, with the highest rates in the more deprived, central areas of large conurbations. Once again the infection rate was higher in urban than in rural areas. However, in the early 1980s, there was a resurgence of infection, and the increase occurred mainly in middle-class, often professional families, especially in suburban and rural areas [6]. Hence, in more recent years, the head louse has become classless and cosmopolitan. It is of interest to note that in a recent survey in Jordan, there was a significant association between social class and infection rates, there being much higher infection rates in lower socio-economic classes [7].

High rates of head louse infection have been reported from the USA, Canada and several other countries; a review by Gratz [1] provides a comprehensive survey of published information relating to prevalence.

Head lice are more common on children, particularly in the age range 3–11 years, than on adults, and most surveys have shown that girls are more frequently infected than boys. Behaviour patterns in girls and boys at different ages probably influence rates of infection [8]. For example, in primary schools children are organized into small groups around desks, and head to head contact is frequent. In addition, hair contact is probably more likely between

girls than boys. Older children tend to be more independent, and more separated from their peers. The contribution of hair length to infection is contentious. Some studies have not shown any correlation between hair length and louse infection rates, but in others children with longer hair have had higher infection rates. A survey from Israel, in which detection of infection was by means of a louse comb, rather than direct visual inspection, found a significantly higher infection rate in children with long and medium length hair than in those with short hair [9]. In the author's experience, in the UK, most adults with head lice are mothers who have acquired them from their children.

Several authors have noted a low incidence of head louse infection in black Americans [10–12], although infection rates in black Africans are high [1]. It has been suggested that the use of pomades by black Americans provides an environment unsuited to establishment of infection [10], but head lice are quite common in the Indian subcontinent, where hair oils and creams are frequently used [13]. A survey in Brazil found the same prevalence in blacks as in whites [14]. A factor which could influence transmission between ethnic groups is the specialization in the louse with regard to modification of the legs to grasp hairs of different cross-sectional shape [15].

It is thought that the majority of head louse infections are acquired by direct head-to-head contact, optimal conditions for transfer being when hairs are parallel and slow-moving [16]. Spread of lice is encouraged by poverty, poor hygiene and overcrowding. Overcrowding is perhaps the most important factor. Lack of hygiene alone does not encourage head louse infection.

There are conflicting opinions about the importance of fomites in transmission of head lice [6,17], and in practice the putative role of caps, scarves, combs and brushes is difficult to confirm or refute [18].

In Australia, an examination, employing a vacuum cleaner fitted with a filter, of classroom floors in schools in which there was an overall prevalence of head lice of 20.9%, did not reveal any lice on the floors [19], indicating that there is no requirement for anti-louse measures on carpets and floors.

Clinical features. Although many individuals are asymptomatic [20], scalp pruritus is the characteristic manifestation of head louse infection. Secondary bacterial infection may occur as a result of scratching, and concomitant head louse infection must always be considered in cases of scalp impetigo. Pruritic papular lesions may occur on the nape of the neck, and occasionally a generalized non-specific pruritic eruption develops [21]. In severe, neglected cases, pus and exudate may produce matting of the hair—a state that has been termed 'plica polonica', from its prevalence in Poland in the early part of the 20th century. However, matting of the hair can occur in the absence of louse infection, and it has been suggested that this term should be discarded [22].

The empty egg cases ('nits') are easily identified, and occur in greatest density on the parietal and occipital regions (Fig. 38.17). However, on naked-eye inspection, they may be confused with peripilar keratin casts ('pseudonits'; hair muffs) [23,24] or dried globules of cheap hair lacquer.

Detection of adult lice and nymphs provides evidence of an 'active' infection, whereas the presence of eggs and egg-cases alone merely indicates that infection has occurred at some time. The most reliable method of diagnosing current, active infection is by detection combing, which has been shown to be superior to direct visual examination of the hair and scalp [9,25–27]. This is an important criterion for several reasons:

1 It is recommended that individuals who do not have evidence of active infection should not receive chemical treatment [27].
2 Participants in clinical trials of pediculicides should have live lice or 'lice and eggs' present on the head before enrolment, not just eggs alone.
3 Children who do not have evidence of active infection may be inappropriately excluded from school [27–29].

Fig. 38.17 Numerous head louse eggs and empty egg cases.

Treatment [2,3,27,30–33]. Chemical pediculicides have been important in the control of head lice for many years. In the UK, malathion and carbaryl (carbaril) replaced lindane, following evidence of the development of resistance to organochlorines [34], although use of carbaryl was restricted when data was released which suggested a potential carcinogenic effect of long-term oral administration to rodents [35]. Both were originally shown to be efficient pediculicides and to have good, but not complete, ovicidal activity [34,36–39].

A few years later, pyrethrins synergized with piperonyl butoxide, and the synthetic pyrethroids permethrin and phenothrin [40–42] became available, and have been used in many parts of the world.

General guidelines for the use of these chemical pediculicides have included advice to repeat treatment after 10 days [43] because of limited ovicidal activity, and that lotion and liquid formulations are preferable to shampoos as the latter expose the insects to

relatively low concentrations of insecticide which, in the long term, will favour the development of resistance. Preparations with an aqueous basis are less likely to irritate an excoriated scalp than alcoholic solutions, do not irritate the bronchi of asthmatics, and are not flammable. Family members should be examined, and treated if they show evidence of active infection by the presence of live lice.

The formulation of the marketed products influences their efficacy, because components (excipients) other than the active ingredient may also have pediculicidal activity [44,45].

However, there is now evidence of widespread malathion and pyrethroid resistance [46–53], and the emergence of carbaryl resistance in the UK [48]. The last mentioned is of interest in that the restricted use of carbaryl in the UK was probably a factor contributing to the delayed emergence of resistance in comparison with malathion and synthetic pyrethroids, which have been widely available over-the-counter. Similarly, a factor in the continued efficacy of malathion demonstrated in a study in South Florida, USA, was probably the commercial failure, and therefore limited use, of previously marketed malathion preparations [54].

Hence, choice of chemical treatment for head louse infection should be guided not only by evidence of pediculicidal activity from well-conducted clinical trials, but also by local patterns of resistance [56]. From a practical point of view, if a correctly applied pediculicide has failed to eradicate an infection, a different pharmacological class of agent should be used—for example, change from a synthetic pyrethroid to malathion, or *vice versa*.

A new approach to treatment is the introduction of agents designed to asphyxiate lice [56,57]. As Elston [33] points out, there is little potential for the development of resistance, and parents who are concerned about the use of currently available chemical pediculicides on their children may be more willing to use these new products. A preparation containing dimeticone 4% has been marketed [56].

Physical treatment is an alternative to the use of chemical agents and, in the UK, the 'Bug Busting' (Community Hygiene Concern, London, UK) wet-combing method has been promoted as a treatment for head lice. The technique involves ordinary shampooing of the hair, followed by the application of generous amounts of conditioner, and combing using a fine-tooth comb to remove lice. This procedure is repeated every 4 days for 2 weeks [58–62]. A battery-powered device, the 'Robi comb', which kills lice as it is used to comb through the hair, is also available, and devices that deliver hot air to the hair and scalp are also said to be effective at louse eradication [63,64].

Simply shaving the head may be acceptable in some communities, but is not in others [65,66].

Other treatments that have been employed to eradicate head lice include crotamiton [67], and topical and oral ivermectin [68–70]. Although the results of oral ivermectin treatment were not impressive, it is likely that this is because ivermectin has no ovicidal activity, and two doses separated by an interval of 10 days would be more effective.

Oral therapy with cotrimoxazole has been reported to be effective in eradicating head lice [71,72]. This is probably because the antibiotic is ingested by the louse and affects its symbiotic bacteria [73]. These bacteria are essential for louse survival, and treatments directed at them might provide alternative means of louse control [74]. There is also a report of the efficacy of oral thiabendazole [75].

There is anecdotal, and some *in vitro*, evidence of pediculicidal activity of plant-derived essential oils such as lavender oil, tea tree oil [76] and neem [77,78].

Empty egg cases persist for some time until they are gradually worn away by repeated washing, but are otherwise difficult to dislodge, and their presence should not be a reason for excluding children from school [79].

A head louse repellent containing piperonal was produced several years ago [80] and, more recently, others containing plant-derived essential oils have been marketed. There is some evidence that citronella is an effective louse repellent [81], but repellency of other plant-derived oils is limited [82].

Useful sources for guidance on treatment of head lice include the UK CKS (Prodigy) Database (http://cks.library.nhs.uk/home) and the US Centers for Disease Control and Prevention site (http://www.cdc.gov/lice/).

Clothing/body lice (*Pediculosis corporis*)

Prevalence and epidemiology [1–3]. *Pediculosis corporis* occurs throughout the world, although it is now uncommon in developed

Fig. 38.18 Clothing lice and eggs.

Fig. 38.19 Crab louse eggs on the eyelashes.

countries. The clothing louse is the louse of poverty and neglect, and flourishes in overcrowded, unhygienic situations on individuals who rarely remove their clothing. In the Western world today, those harbouring lice are mainly vagrants.

The number of lice and eggs on the clothing varies greatly. In most infected individuals the population is small, but in some there may be thousands of lice.

The clothing louse is the vector of epidemic typhus, trench fever and louse-borne relapsing fever. Epidemic typhus has been responsible for huge mortality in the past [4,5].

Clinical features [3,6]. In most infected persons, itching is the principal complaint. Pruritus is the result of sensitization to louse salivary antigens. Others, who have not become sensitized or have acquired tolerance to the bites, are asymptomatic. The body is often covered in excoriations, and there may be secondary bacterial infection. In those who have harboured clothing lice for long periods of time the skin is often hyperpigmented (so-called 'vagabonds' disease'; morbus errorum), and this is probably a post-inflammatory phenomenon.

Lice and eggs should be sought in the clothing (Fig. 38.18).

Treatment. It is the clothing, not the patient, which requires treatment. Tumble-drying is a most effective means of killing both lice and eggs [2]. High-temperature laundering of undergarments and dry cleaning of outer clothing are also effective.

In dealing with large numbers of infected individuals, insecticides have been used to treat clothing. The emergence of lice resistant to dichlorodiphenyltrichloroethane (DDT) and lindane led to the introduction of malathion dusting powder [7,8] and, more recently, permethrin-treated clothing has been shown to be toxic to clothing lice [9].

Crab lice (*Phthiriasis pubis*)

Prevalence and epidemiology [1–3]. Crab lice are transmitted by close physical contact, usually sexual, and infection with these lice occurs most frequently among sexually active young adults. It is standard practice in genitourinary medicine (GUM) clinics to monitor prevalence rates of sexually transmitted infections, including crab lice. A marked decline in the number of female cases in one department in the UK led to the suggestion that waxing of pubic hair, particularly the fashion known as the 'Brazilian', was an important factor responsible for the decline [4]!

Because many patients with crab louse infection who attend GUM clinics are found to be suffering from other sexually transmitted infections [5–8], screening for these is indicated.

Clinical features. Itching, mainly in the evening and at night, is the principal symptom. Close inspection of affected areas will reveal lice grasping hairs close to the skin surface, and louse eggs attached to the hair shafts. Louse faeces are often visible as rust-coloured speckles on the skin and hair, and the underclothes may be spotted with altered blood.

When crab lice are discovered on the pubic area, other hairy areas of the body should be examined, as these lice may colonize eyebrows, eyelashes (Fig. 38.19), beard, axillae, areolar hair and the scalp margins [9–13]. In heavy infections in men, the hair on the trunk and limbs may be extensively colonized. A case has been reported in which the presence of an enormous population of lice was attributed to inappropriate use of topical steroids [14].

Blue–grey macules (maculae caeruleae) are occasionally seen on the skin [15–17], but their precise pathogenesis is unknown.

Bullous lesions attributed to crab lice have been reported [18,19].

In children, crab lice may colonize the eyelashes and scalp [20–23]. Infection in children is usually acquired by close physical contact with infected parents. As an isolated finding, it is not indicative of sexual abuse, although this may occasionally occur [24].

Treatment [3,25–31]. Malathion, pyrethrins with piperonyl butoxide, pyrethroids and carbaryl may be used to treat crab lice. In view of the possibility of involvement of axillary and body hair it is preferable to treat the whole of the trunk and limbs, and the scalp may also require treatment. Alcohol-based preparations may be irritating when applied to the scrotum, and an aqueous base is preferable. Treatment should be repeated after an interval of 7–10 days. All sexual contacts should also be treated.

Eyelash infection (phthiriasis palpebrarum). [32,33] Although mechanical removal of lice and eggs with fine forceps [34] or epilation of the lashes with their attached eggs are obvious remedies, these procedures are uncomfortable, and are not recommended. Cryotherapy has been used to destroy crab lice on the lashes [35], and the use of fluorescein in concentrations of 10–20% is also said to be effective [36].

Any ointment might be expected to interfere with the respiratory function of the louse by blocking its spiracles, and the use of a thick application of white soft paraffin (white petrolatum; Vaseline) twice daily for 2–3 weeks has been recommended [37,38]. Yellow mercuric oxide ointment was frequently used in the past, and physostigmine ointment was also a popular remedy, particularly among ophthalmologists [31,39–41]. A drawback is the ocular effect of physostigmine, which causes pupillary constriction and paralysis of accommodation. Oral ivermectin, given as two doses a week apart, cured four patients with eyelash crab lice [42].

Argon laser phototherapy has also been employed [43].

White soft paraffin is the treatment of choice.

Bugs (Hemiptera)

Family Cimicidae (including bedbugs) [1–4]

All the Cimicidae are blood-sucking, temporary ectoparasites of birds and mammals. Two-thirds of the species in this family are parasites of bats. It has been suggested that Cimicidae became

adapted to feeding on humans when cave dwellers took up residence alongside the bats.

Genus *Cimex*. *C. lectularius* (the common bedbug) is cosmopolitan, and common throughout Europe, North America, North Africa, North India, Siberia, North China, South Africa, Australia and South America. Until recently, bedbugs have been rare in the UK, but an increase in the number of cases referred to Brighton Public Health Laboratory Service in 1999 suggested that they might be becoming more common [5], and subsequently there has been evidence of a resurgence of these parasites in the developed world. This could be related to insecticide resistance and/or dissemination as a consequence of the increase in international tourism [4,6,7].

C. pipistrelli (the batbug), originating in a bat roost in a house, was responsible for itchy skin lesions in one of the house occupants [8].

C. hemipterus (the tropical bedbug) is less tolerant of low temperatures than *C. lectularius*. This bug is confined to tropical and subtropical regions, including India, Burma, Malaya, South China and Central Africa.

Genus *Leptocimex*. *L. boueti* has a limited distribution in West Africa, where it parasitizes humans and bats.

Genus *Oeciacus*. Several species are usually found on birds and in their nests, for example *Oeciacus hirundinis*, the martin bug [9] and *O. vicarius*, the swallow bug. They may invade houses from nests under the eaves, and will bite humans readily, but it is unlikely that they can complete their lifecycles on human blood, or take up residence in houses as bedbugs do.

Genus *Haematosiphon*. *H. inodorus*, the only species in this genus, is also known as the Mexican chicken bug. As the name suggests, its major host is the chicken, but it can be a serious pest in human domiciles if these are close to chicken roosts.

Ecology [4,10]. Bedbugs are 4–5 mm in length, with dorsoventrally flattened, oval bodies, the forewings reduced to scale-like pads, and the hindwings absent (Fig. 38.20). The mouthparts are modified into a proboscis adapted for piercing and sucking.

Female bedbugs deposit their pearly white, flask-shaped eggs in the crevices of floors and walls, in furniture, bedframes and mattresses. Each female lays about 300 eggs in her lifetime. The eggs hatch after about 10 days: the nymphal stage lasts approximately 6 weeks, during which time the bug moults five times.

Bedbugs normally feed at night, usually about an hour before dawn, but they may feed during the day if circumstances are favourable [11]. Searching for a food source is erratic, and is probably at random at distances greater than a few centimetres, but in the final approach to the host, both temperature and odour play a part in guiding the bug. Feeding time is relatively short (3–12 min). During feeding, the bedbug injects saliva containing an anticoagulant and anaesthetic. In the absence of a suitable food supply, however, adult bed bugs can survive starvation, in ideal circumstances, for a year or more.

Fig. 38.20 *Cimex lectularius*, the bedbug. (Courtesy of Oxford Scientific Films.)

In the absence of its usual host, *C. lectularius* will attack other animals, and Cimicidae normally parasitic on other hosts are similarly prepared to attack humans, invading houses from birds' nests or chicken runs.

Clinical features. The bites of the bedbug are painless, and the attention of the victim is only drawn to the bites by the reaction they produce. They commonly occur on the face and neck, hands and arms, but may occasionally be generalized. In the individual not sensitized by previous exposure, there may be no symptoms at any stage, and only a purpuric macule indicates the site of the bite. Late-onset reactions may occur in some cases [12]. In sensitized subjects intensely irritating weals or papules surmounted by haemorrhagic puncta are the characteristic reaction. In some cases where the reaction is severe, bullae predominate [13–16], and in one patient with bullous lesions it was demonstrated that their serum contained specific IgE antibodies against the *C. lectularius* salivary gland protein nitrophorin [17].

The bites of other Cimicidae are essentially similar, but their distribution depends on the method of exposure.

Bedbugs as vectors of disease [4]. It is not known with certainty whether bedbugs act as vectors for any disease in humans, but their possible role in the transmission of hepatitis B and C, and HIV infection, has been investigated [18–26]. Hepatitis B virus persists for up to 6 weeks in the bedbug's body [18,22,23]. It has been suggested that mechanical transmission to humans could occur via infected bug faeces, or when bugs are crushed during feeding. Hepatitis C virus RNA was not detected in bedbugs after feeding on blood with a high viral titre [22].

Initially, it was suggested that bedbugs might act as vectors for HIV [24], but it was later concluded that this is unlikely [25,26].

Haematosiphoniasis [27]. Haematosiphoniasis is the name given to the cutaneous lesions caused by the bites of *Haematosiphon inodorus* (the Mexican chicken bug). Polymorphic lesions, consisting of weals, papules, vesicles, pustules and scabs, occur predominantly on exposed parts of the body.

Family Anthocoridae

The Anthocoridae are related to the Cimicidae. Bugs of this family are mostly predacious on other insects, but are known to bite humans occasionally. *Lyctocoris campestris* is a cosmopolitan species closely associated with humans, for example in haystacks and granaries [1]. *Anthocoris kingi* and *Anthocoris nemorum* will also bite humans [2]. Another anthocorid bug, *Dufouriellus ater*, attacked many workers in a clothing factory in north-east England [3].

Family Pentatomidae

Palomena prasina (the green shield bug), a member of this family, has been reported as the cause of perioral blistering in a small child [1].

Kissing bugs, assassin bugs and cone-nosed bugs (Reduviidae)

The majority of species of Reduviidae are predators on other insects, and are commonly called assassin bugs for this reason, but some attack humans and other animals. Most species are encountered in North, Central and South America, but some occur in Africa, the Middle and Far East, and in Australia. The subfamily Triatominae is the most important medically, and includes those species which feed exclusively by sucking the blood of vertebrate animals. Adult triatomines are large insects, commonly measuring 20–28 mm in length. They have an elongated head with a prominent proboscis and long, four-jointed antennae (Fig. 38.21).

The Triatominae are largely confined to the western hemisphere, with the majority of species being distributed in North, Central and South America. In the USA, *Triatoma sanguisuga* has the widest distribution, extending from the south-eastern and Mid-Atlantic States westwards, including Texas. Triatomines feed on a wide range of hosts, and domestic species feed on humans and domestic animals. They are of medical importance as vectors of *Trypanosoma cruzi* in Chagas' disease [1,2].

Fig. 38.21 Cone-nose bug. (Courtesy of Oxford Scientific Films.)

Ecology. In nature, triatomine bugs form colonies in the habitat of their host, for example a small mammal's nest or animal lair. In the south-western USA, infestations are often found in the nests of wood rats. Some species, however, have become totally domesticated, and live and breed in human dwellings, laying their eggs in cracks and crevices in the floors and walls. The young hatch as nymphs, which are miniature versions of the adults. Nymphs and adults hide in crevices during the day and emerge at night to feed.

Clinical features [3,4]. The bites of the predatory species of reduviid bugs (assassin bugs) are purely defensive, and are usually extremely painful [5,6]. The bites of the blood-sucking Triatominae, however, are painless—this is essential to the parasite if it is to feed undisturbed. In an individual not previously exposed to the bites, there will be little reaction, but with repeated exposure hypersensitivity develops, and reactions ranging from pruritic papules to haemorrhagic nodules and bullae may occur.

Thrips (Thysanoptera)

Thrips ('thunder flies') are tiny, winged insects, 1–2 mm in length, and usually yellowish brown or black in colour. The name thrips is derived from the Greek, meaning 'wood louse'. The order Thysanoptera ('fringe wing') comprises about 5000 species with a worldwide distribution. The majority feed on plant juices and some are important agricultural pests [1]. Some species are predatory on other arthropods. A few species appear able to suck blood, and there are a number of reports that thrips can be responsible for skin lesions [2–7]. Most thrips, however, are unable to penetrate the human epidermis, and probably cause itching and prickling sensations only by their movement on the skin surface and their efforts to obtain water from perspiration.

Clinical features. Thrip bites, which occur on exposed skin, produce tiny puncta and small, pink macules or papules [2,4]. Large numbers of American soldiers in Hawaii developed hypoanaesthetic papular lesions surrounded by blanched halos, which, it was suggested, were caused by Cuban laurel thrips [8]. However, attempts to reproduce lesions by placing live thrips in contact with the skin were unsuccessful, and the cause of this distinctive dermatosis remains unknown [9].

Beetles (Coleoptera)

Beetles are insects whose forewings are modified to form hard wing cases for the membranous or reduced hind wings. There are over 370 000 known species, but it is likely that many more await discovery. They are mainly terrestrial and the majority feed on decaying animal or vegetable matter, but some are predaceous on other insects. Several species may provoke skin lesions and are of interest to the dermatologist.

Vesicating species [1–4]

Family Meloidae (oil beetles, blister beetles)

Most of the beetles in this group only cause problems when crushed on the skin, but some may emit their vesicating fluid without being crushed. The family is large and widely distributed. Many species contain the irritant cantharidin, which commonly is called 'Spanish fly'. Contact with the skin produces an irritant dermatitis and bullae. Cantharidin has an undeserved reputation as an aphrodisiac, which is unfortunate for a chemical capable of producing severe toxicity. It has been used in blistering plasters and hair restorers, and in the treatment of warts and molluscum contagiosum.

Lytta vesicatoria is perhaps the best known of the blister beetles. It is a large, bright metallic green beetle, which lives mainly in the Mediterranean region, but is sporadically found further north, occasionally as far as England.

Other vesicating species include *Epicauta* spp. (USA, Mexico, India, Sudan, Senegal) [5], *Mylabris* spp. (Nigeria, India) [6,7], *Psalydolytta* spp. (Gambia) [8] and *Cylindrothorax melanocephala* (Gambia) [8].

Family Staphylinidae (rove beetles) [9–11]

The genus *Paederus*, found worldwide, includes many species containing a vesicant, pederin, which is chemically distinct from cantharidin. Pederin is released when the beetles are crushed, provoking an acute irritant contact dermatitis. Lesions may be plaque-like, linear (when a beetle has been brushed off the skin, leaving a streak of pederin on the skin surface), or 'kissing' (when a beetle has been crushed between two flexural surfaces). A major outbreak of vesicular dermatitis on Okinawa in 1966 was traced to contact with the beetle *Paederus fuscipes* [12], and a number of other reports have documented *Paederus* dermatitis from several

parts of the world [13–18], including an outbreak which occurred in a military unit training in the Arizona desert during heavy rain and flooding [19]. A plague of whiplash rove beetles (*Paederus australis*) forced evacuation of an aboriginal community in the Northern Territory of Australia [20]. *P. sabaeus* has been responsible for several outbreaks of dermatitis in Africa at the end of the rainy season [21–23].

You *et al*. [24] reported a case of bullous contact dermatitis following the use of crushed *Paederus* beetles for the treatment of vitiligo.

Histopathological changes of *Paederus* dermatitis include intraepidermal and subepidermal blistering, epidermal necrosis and acantholysis [25].

It has been proposed that the biblical third, fourth and sixth plagues of Egypt might have been related to rove beetles and the bullous lesions they cause [26].

Family Oedemeridae [3]

Oxycopis vittata has been reported as causing a blistering dermatitis in Puerto Rico [27]. *Sessinia* species (coconut beetles) have caused blistering in the Gilbert Islands [7].

Thelyphassa lineata produced a bullous dermatosis in a large number of New Zealand Army personnel [28], and there is a report of blister beetle dermatosis in Hawaii caused by *Thelyphassa apicata* [29].

Family Paussidae

Cerapterus concolor, an inhabitant of ants' nests, can eject a blistering liquid when disturbed [30].

Family Tenebrionidae (darkling beetles)

Many species inhabit wood, flour and grain stores. *Tribolium castaneum* (the 'rust-red flour beetle') has caused a pruritic eruption in workers handling infested jute packing bags [31]. The secretion of *Tribolium* species is mainly composed of quinones.

Species of *Blaps* can eject defensive secretions which are irritant and cause blistering.

Clinical features [2–4]. Usually, lesions are produced only when the beetle is crushed on the skin. A weal forms rapidly and is followed by a blister after 12–24 h. The blisters are sometimes linear 'whiplash dermatitis'. A characteristic feature is the development of kissing lesions, where a blister comes into contact with another area. Blisters induced in a small child by *Mylabris bifasciata* were associated with severe systemic manifestations of cantharidin poisoning [6].

Allergenic species

Family Dermestidae [32]

The beetles in this cosmopolitan family feed on hides, woollen materials and stored food. The adult beetles are not known to be directly injurious to humans, but their larvae are covered with hairs, which may cause skin lesions.

Papular urticaria in a child, caused by the larvae of *Dermestes maculatus* Degeer, has been reported, but it was uncertain whether the reaction to the hairs was irritant or allergic [33]. *Dermestes peruvianus* was responsible for dermatitis, vasculitis, cervical lymphadenopathy and pulmonary nodular interstitial infiltrates in a man whose bed was colonized by the beetles [34].

The irritating hairs from the larvae of carpet beetles (*Anthrenus* spp.) may also cause skin lesions [35–37]. There is also a report of the damaging effect of *Anthrenus* larvae on paraffin-embedded tissue specimens, especially the sectioned surface of hyperkeratotic lesions [38].

Clinical features. The skin lesions are not distinctive. Dermatitis, urticaria and papular urticaria may occur.

Cockroaches (Dictyoptera)

Cockroaches are members of the order Dictyoptera, suborder Blattaria. They belong to one of the primitive orders of insects, being allied to crickets, grasshoppers, preying mantids and stick insects. Cockroaches were originally adapted to hot climates, but a number of species have established themselves in cool climates by living inside warm human habitations. They are active nocturnally, and are attracted to any organic material that may serve as food. This theoretically makes them potential mechanical vectors of pathogenic organisms. The main pest species are *Periplaneta americana*, *P. australasiae*, *Blatta orientalis* and *Blatella germanica*.

Clinical features [1,2]. Contact urticaria and dermatitis have been described in laboratory workers and others handling cockroaches constantly [3–5], and urticated papules developed in a medical records clerk exposed to copious insect debris containing fragments of *B. germanica* when clearing old case notes from a derelict hut [6]. Chronic urticaria in a child has been attributed to cockroach hypersensitivity [7].

Locusts (Orthoptera)

Sensitivity reactions, manifest as asthma and allergic rhinitis, are a recognized occupational hazard in those working with laboratory colonies of locusts [1,2]. The principal allergen appears to derive from the peritrophic membrane, which is present in the gut and surrounds faeces [2].

Contact urticaria to locusts has been reported by Monk [3] in a laboratory research worker who handled a large number of locusts. The patient produced a positive reaction to locust antigen on prick testing and a wealing reaction at the site of contact with a live locust. Similarly, worsening of asthma, and urticaria in an atopic research laboratory worker, on exposure to grasshoppers, has been described [4].

Butterflies and moths (Lepidoptera)

Many members of this large order are of importance to the dermatologist because of the irritant properties of the hairs or spines of the caterpillars and sometimes of the adults. Skin lesions in the majority of cases are produced by a combination of mechanical and pharmacological effects [1,2]. The offending caterpillars are distributed through many different families [1,3]. Some of the species that have been recorded as causing damage to human skin are shown in Table 38.1.

Aetiology of skin lesions [1,2,16,17,26–29]. The term 'lepidopterism' is applied to the ill effects on humans of a structure or product of some part of a moth or butterfly at any stage of its life history. Some authors apply the term 'erucism' to injurious effects from caterpillars, and 'lepidopterism' to ill effects from adults. In the majority of cases, damage to human skin and mucosae occurs as a result of epithelial penetration by the 'hairs' (setae) of caterpillars. In addition to a foreign-body reaction there is often an effect from venom. Setae develop from trichogen cells of the epidermis. They are hollow, and may function as sensory receptors or communicate with a poison gland cell and contain venom. They commonly have barbs, which hold them in place when they have penetrated the skin. In some families of moths, the caterpillars have clumps of much smaller setae known as 'dart hairs' or 'spicules', which are pointed at both ends and carry fine barbs. The point of attachment to the caterpillar is very narrow and easily fractured; hence, contact with the caterpillar may release huge numbers of these tiny darts. Such dart hairs are present in a number of species, including the brown-tail moth (*Euproctis crysorrhoea*) (Fig. 38.22) and the pine processionary caterpillar

Table 38.1 Some Lepidoptera species responsible for skin damage.

(*Thaumetopoea pityocampa*). Setae are also woven into cocoons, and into the webs of the silk-spinning caterpillars.

Spines are an extension of the cuticle of the caterpillar and contain venom. The spines either have a terminal plug of inspissated material at their open ends, which is released by pressure, or a weak point at which the spine fractures to allow the venom to escape. Poisonous spines occur particularly on the caterpillars of the moth families Cochlididae (Eucleidae; Limacodidae), Saturniidae and Megalopygidae.

The venoms present in the setae and spines of caterpillars of a number of families of Lepidoptera have been studied, but not fully elucidated. Some contain histamine, histamine liberators, serotonin and proteases [14,30–33]. Lamy *et al*. [34] isolated a protein, thaumetopoein, from pine processionary caterpillar hairs. This has a direct effect on mast cells, leading to degranulation, and explains the urticating properties of these caterpillars. However, IgE-mediated hypersensitivity also appears to be responsible for some reactions to *Thaumetopoea* [35–37], and Moneo *et al*. [38] have demonstrated a 15-kDa IgE-binding protein in a larval extract. Immediate and delayed-type reactions to *Euproctis pseudoconspersa* caterpillar venom extracts have also been demonstrated [39].

In some species—for example moths of the genus *Hylesia* (family Saturniidae)—irritating setae are carried by the adults. This genus is notorious for causing outbreaks of 'butterfly itch', 'moth dermatitis' or 'Caripito itch' [21] in tropical South America.

Clinical features [1,2,40]. Irritation may be experienced immediately after contact with the offending caterpillars, or may be delayed for hours or even days, depending on the species. Itching is followed by the development of small urticarial papules, sometimes surmounted by vesicles. Alexander [41] noted marked bruising in children who had been in contact with *Euproctis crysorrhoea* caterpillars. Urticaria and eyelid oedema may also occur, and Inal *et al*. [42] described severe orofacial oedema in a 15-month-old boy who had a pine processionary caterpillar in his mouth. In severe eruptions there may be constitutional symptoms of malaise and mild pyrexia. The severity and distribution of the eruption depend mainly on the route and intensity of exposure, but the most common sites are the exposed parts of the body. Lesions usually resolve in a few days. When contact with caterpillars is suspected as the cause of a dermatosis, Sellotape stripping of affected areas and subsequent microscopy may be used to demonstrate setae [43].

Contact with *Megalopyge* caterpillars [18,19] produces immediate, intense, burning local pain accompanied by a spreading erythema around the puncture sites. The affected area becomes oedematous, and there is often lymphangitis and regional lymphadenopathy. The local changes may be accompanied by pyrexia, headache, nausea and vomiting, particularly in children [44].

In the eye, caterpillar setae may cause a variety of changes ranging from conjunctivitis to ophthalmia nodosa [45,46] and even panophthalmitis.

Class Arachnida

Arachnida are readily distinguished from insects, as the adults have no wings or antennae and possess four pairs of legs. Unlike insects, where the body is divided into three segments (head, thorax and abdomen), arachnids have only two, the cephalothorax, from which the legs arise, and the abdomen.

The Arachnida are classified in seven orders, only three of which are of medical importance:

1 Araneae (spiders)
2 Scorpiones (scorpions)
3 Acari (ticks and mites).

Spiders (Araneae)

The appearance of many of the larger spiders inspires terror or disgust, but very few of the many thousands of species are dangerous to humans. Spiders are, for the most part, shy and avoid contact with humans. Almost all are venomous and bite, but only a few have chelicerae strong enough to penetrate human skin, and in most cases the bites are trivial. The European tarantula, *Lycosa tarantula*, which inspired the tarantella in Italy in the Middle Ages, inflicts a temporarily painful, but harmless bite. Some lycosid spiders in South America, for example *Lycosa antibucana*, cause severe swelling and lymphangitis. In the USA, the term 'tarantula' is erroneously applied to the large 'bird' or 'crab' spiders of the family Theraphosidae, which attack only when vigorously provoked, and whose bite may be painful but not dangerous. Some colourful species kept as pets, for example *Brachypelma smithi*, are among several that have urticating hairs capable of causing prolonged pruritus. Many spiders whose bites are dangerous, and sometimes fatal, are small, inconspicuous and unimpressive.

The clinical syndrome following the bite of a spider is known as arachnidism. The form of arachnidism caused by species of the

family Loxoscelidae is known as loxoscelism, and that by widow spiders (*Latrodectus* species) latrodectism.

Air transport of crates of fruit and other materials may introduce exotic species to countries in which they are unable to multiply but can survive long enough to attack humans.

Arachnidism [1–4]

Family Theridiidae

Genus *Latrodectus* (widow spiders). Spiders of this genus are widely distributed throughout the world. *Latrodectus mactans* (Fig. 38.23), the black-widow spider, occurs throughout subtropical and tropical regions. Other species have a similar, but more limited, range, although some extend to the temperate regions of Russia and Canada.

The female of *L. mactans* is glossy black, with a body length of 1.5 cm and a leg span of up to 5 cm. She normally spins her web in empty burrows or under stones, but may be found in dark corners of barns, garages, store rooms or outdoor lavatories. She bites humans only in self-defence. *Latrodectus* venom is considered to be one of the most potent toxins, exceeding that of snake venoms, but the dose injected is minute in relation to the body weight of a human victim. The toxins of all species of *Latrodectus* that have been studied appear to be closely related, and the symptoms from envenomation are similar.

Latrodectus hasselti, the red-back spider, is common in Australia [5]. A report from Fremantle documented 150 admissions for red-back spider bites over a 6-year period from 1982 to 1987 inclusive, and estimated the annual cases at between 830 and 1950 [6].

Latrodectus geometricus, the brown-widow spider, bites reluctantly, but is occasionally troublesome to vineyard workers in South Africa.

Clinical features (latrodectism) [1–3,7–10]. In the days of the outdoor lavatory, *Latrodectus* webs were often spun across the toilet seat, and this led to the frequent occurrence of bites on the buttocks and genitalia. The bite of *Latrodectus* species is fairly painless, but within a few minutes increasingly severe pain develops and becomes generalized. Cramp-like or colicky abdominal pain is particularly common. Puncta may be visible at the site of the bite, and there is local erythema and oedema. There is frequently profuse sweating, and neuromuscular involvement causes paraesthesiae, incoordination and paralysis. The pain begins to subside within 24 h, and other symptoms resolve within 2–3 days, although weakness and lethargy may persist for longer. However, without treatment the bite may be fatal in young children or in the elderly and frail.

Treatment. Species-specific antivenoms are available for *Latrodectus* bites, and there is evidence that red-back spider antivenom prevents toxicity of other widow spider venoms [11,12].

Family Hexathelidae

Genera *Atrax/Hadronyche* (Australia and south Pacific) and *Macrothele* (Taiwan and parts of eastern Asia)—funnel-web spiders. Perhaps the best known of these is the Sydney funnel-web spider, *Atrax robustus* [5] (Fig. 38.24), a large, aggressive spider that is nocturnal and predominantly insectivorous. It normally lives under rocks and logs, but the spread of the Sydney suburbs into its habitat provided similar hiding places under houses.

Clinical features [4,13,14]. The bite of funnel-web spiders is invariably painful. From the majority of bites, especially those of female spiders, no general symptoms follow, and recovery is uneventful. However, the large amount of venom from male spiders may cause severe systemic symptoms. Nausea and vomiting are early features, accompanied by abdominal pain, profuse sweating, piloerection, muscle fasciculation, lacrimation, excess salivation, dyspnoea and pulmonary oedema. Several fatalities were recorded prior to the development of an antivenom.

Treatment. The compression bandage-splinting method of first aid is effective in delaying onset of envenomation and may enhance local inactivation of venom. Severe reactions will require hospital admission and full supportive measures. Funnel-web spider antivenom is very effective.

Family Sicariidae (formerly Loxoscelidae)

Genus *Loxosceles* ('fiddleback', 'violin', 'brown recluse' spiders). There are a number of species of *Loxosceles* in North and South America, with about 13 in the USA, several of which are known to induce human skin necrosis: *reclusa, laeta, deserta, arizonica* and *rufescens* [4,15]. The most notorious is *L. reclusa*, the brown recluse spider, which is tan to brown in colour, with a dark-brown, violin-shaped marking on the dorsum of the cephalothorax—hence the names 'fiddleback' and 'violin' spider. *L. reclusa* is active mainly at night. Its natural habitat is in dark areas beneath rocks and in holes and caves. It is also found in homes, in areas that are dark, dirty and undisturbed, such as attics, cupboards and garages.

Loxosceles laeta also occurs widely in South America. *Loxosceles rufescens* is widespread in southern Australia.

Clinical features (loxoscelism) [1–4,8,16]. There are two distinct clinical forms of loxoscelism: necrotic cutaneous loxoscelism, and the much less frequent viscerocutaneous loxoscelism. The clinical manifestations depend upon the age and health of the victim, the amount of venom injected and the site of the bite—fatty areas such as the proximal thigh and the buttocks show more cutaneous reaction and extensive involvement of the entire subcutaneous layer.

In necrotic cutaneous loxoscelism, there is local damage to the skin and subcutaneous tissues, but systemic symptoms are mild. The bite of the spider is usually relatively painless. However, after an interval of minutes or hours, severe pain develops at the site, accompanied by erythema, oedema and a central bulla. In severe envenomation, a 'target' lesion is seen—central blue/purple discoloration surrounded by an ischaemic halo and an outer ring of erythema (the 'red, white and blue' sign). After 3 or 4 days, the central area becomes necrotic, and an eschar develops. The eschar is eventually shed, leaving an ulcer which may take a considerable time to heal. The size of maximum necrosis appears to be predictive of time to complete healing [16]. Robb *et al*. [17] described a patient with a generalized vasculitic exanthem following a brown recluse spider bite.

In viscerocutaneous loxoscelism, systemic involvement is indicated by pyrexia, severe malaise, restlessness and headache. Within 24 h of the onset of general symptoms, ecchymoses, jaundice, haematuria and haemoglobinuria indicate massive intravascular haemolysis, which may result in death [18].

Treatment [4,8,15]. *R*est, application of *I*ce *C*ompresses and *E*levation (RICE therapy) help to reduce inflammation and pain. Although dapsone has been said to be beneficial, its use is controversial and there is no prospective study demonstrating its efficacy [19].

Family Lycosidae (wolf spiders)

There are a few reports of bites by members of the genus *Lycosa* [4,20,21]. They usually cause only local pain, swelling and erythema, without cutaneous necrosis or significant systemic symptoms.

Other venomous species [3–5,22–25]

Spiders of several other families may cause unpleasant bites. Long-legged sac spiders of the genus *Chiracanthium* (family Miturgidae), which are found in many parts of the world, may cause local pain, oedema, and small areas of necrosis [4,24]. *Tegenaria agrestis* (family Agelenidae), the hobo spider (previously known as the aggressive house spider), is a cause of necrotic arachnidism in the north-west USA [4,23,24]. Members of the families Gnaphosidae, Salticidae (jumping spiders), Sparassidae (huntsmen spiders), and Oxyopidae (lynx spiders) all occasionally bite humans, but the effects are usually mild, unless there is secondary bacterial infection.

Public concern with regard to the toxic effects of white-tailed spiders (*Lampona cylindrata* and *L. murina*) is not supported by studies which have shown that these spiders are unlikely to cause necrotic arachnidism [26,27].

Scorpions (Scorpiones)

Scorpions are arachnids of the order Scorpiones, and are widely distributed in the tropics and subtropics. Their poisonous stings are responsible for considerable morbidity and mortality [1–3]. The venom is carried in the curved sting at the tip of the tail, which is swung over the scorpion's head to strike its prey. The principal components are neurotoxins [3,4], but some venoms also contain 5-hydroxytryptamine, histamine and kinins.

Many scorpions are quite harmless, and their stings of little consequence. Most of the dangerous species belong to the family Buthidae [5]. Species of *Androctonus* and *Buthus* are important in the Middle East and North Africa, and *Centruroides* species cause problems in the southern USA and Mexico. *Tityus* species are responsible for numerous episodes of envenomation in Brazil [6]. Throughout the world many of the deaths from scorpion stings are in infants and young children.

Australia has a number of species of scorpions (Fig. 38.25), but their stings are relatively innocuous [7].

Clinical features [8–12]. The effects of scorpion stings may be local or systemic, and they vary according to the species responsible. The local effects are usually immediate severe burning pain and hyperaesthesia, and there may be marked swelling. Systemic effects include restlessness, profuse sweating, muscle spasms, difficulty with speech, marked increase in salivary and lacrimal secretion, nausea, vomiting, convulsions, hypertension, cardiac arrhythmias, myocarditis and pulmonary oedema. Death is usually due to respiratory or cardiac failure.

Treatment [7,9,12]. Ice packs should be applied, and the injection of local anaesthetic around the sting site will help to reduce the pain. Specific antivenoms are available.

Ticks (Acari)

Ticks are large acarines, which are blood-sucking ectoparasites of vertebrates. They are important vectors of diseases such as tick-borne relapsing fever, a number of viral and rickettsial infections, and Lyme disease.

Morphology and biology [1]. Ticks are typical arachnids, possessing mouthparts referred to as the capitulum, an unsegmented body, and four pairs of legs in the adult. Larval ticks have three pairs of legs.

There are two major families: the Ixodidae (hard ticks) and the Argasidae (soft ticks). The term 'hard' refers to the dorsal chitinous shield or scutum, which is present in the Ixodidae but not in the Argasidae. In Ixodidae, the scutum covers the whole dorsum in the male but only a small anterior part in the female. In Argasids there is little difference between the sexes. The mouthparts of Ixodid ticks project forwards and are easily visible from above, whereas those of the Argasid ticks can only be seen from below. A conspicuous component of the mouthparts is the toothed hypostome (Figs 38.26 and 38.27).

Ixodid ticks have four stages in their life cycle: egg, larva, nymph and adult. The larva and nymph require blood meals before further development can occur, and the adult female (Fig. 38.28) also requires a blood meal before egg laying. The female lays one large batch of eggs and then dies. Some Ixodids use one host for larval, nymphal and adult stages (one-host ticks), whereas others require two or, more usually, three separate hosts.

To find suitable hosts the larvae, nymphs and adults climb low vegetation and raise the first pair of legs ('questing'), which carry sense organs (Haller's organ). These organs are sensitive to a number of stimuli, including the carbon dioxide in the exhalations of a potential host. If the host brushes past the vegetation the tick will immediately grasp the animal's coat. Argasidae undergo

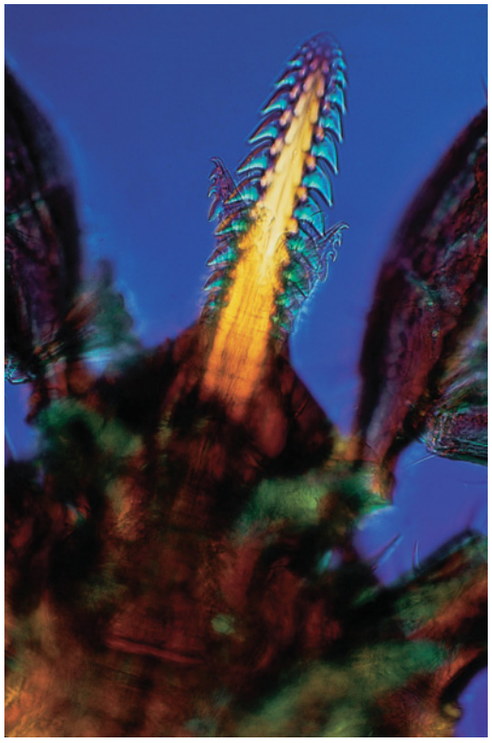

Fig. 38.26 Mouthparts of *Ixodes ricinus* nymph to show the toothed hypostome (interference contrast microscopy).

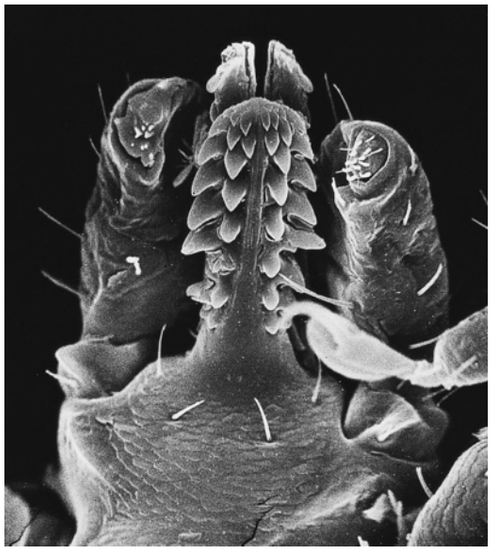

Fig. 38.27 Scanning electron micrograph of tick mouthparts.

several nymphal stages, and the adult female feeds a number of times during her lifetime, laying several batches of eggs. Ixodid ticks feed on the host for several days, whereas Argasids visit their hosts nocturnally to feed for only a few minutes. Argasids are mainly parasites of birds, bats and humans. Most ticks are essentially parasites of wild animals, and humans are incidental hosts.

(a)

(b)

Fig. 38.28 *Ixodes ricinus*, the sheep tick (engorged female). (a) Dorsal view. (b) Ventral view.

When attaching itself to the host, the tick uses its toothed chelicerae to cut into the epidermis, before thrusting the hypostome into the opening and gradually penetrating the dermis. The hypostome becomes anchored by a protein cement, produced by the salivary glands, which forms a cone around the hypostome and interlocks with its teeth [1,2]. Argasids, being rapid feeders, do not attach themselves as securely as Ixodid ticks.

Ticks as vectors of disease [1,3,4]. Within the large family of Ixodid ticks, there are several genera of medical importance, including *Dermacentor, Haemaphysalis, Rhipicephalus, Amblyomma, Hyalomma* and *Ixodes*.

Dermacentor species act as vectors for a number of diseases, including Rocky Mountain spotted fever, Siberian tick typhus, Colorado tick fever and several types of viral encephalitis.

Haemaphysalis species may also carry Rocky Mountain spotted fever, Siberian tick typhus and Colorado tick fever.

Rhipicephalus sanguineus (the brown dog tick) transmits *Rickettsia conorii*, the causative organism of boutonneuse fever (Mediterranean spotted fever). *Rh. sanguineus* is normally confined to the tropics, but it may be encountered in temperate climates in centrally heated houses [5]. Ticks of the genus *Amblyomma* transmit *Rickettsia africae*, the organism responsible for African tick bite fever, tularaemia and human granulocytic anaplasmosis (ehrlichiosis) [6–8]. In recent years, *A. americanum* (the lone star tick) has been recognized as a vector for *Borrelia lonestari*, the organism thought to be responsible for southern tick-associated rash illness (STARI), a Lyme disease-like infection [9].

Ixodes species are important vectors of certain haemorrhagic fevers and viral encephalitis, and also of Lyme disease (Chapter 30). They may also transmit babesiosis to humans [10]. The principal vectors of Lyme disease are the sheep tick *Ixodes ricinus* in Europe, and *Ixodes dammini* (East coast) and *Ixodes pacificus* (West coast) in the USA.

Various species of Argasidae may also act as vectors of disease, the most important being *Ornithodoros* species, which transmit tick-borne relapsing fever. In Israel, *O. tholozani* (the cave tick), which is endemic in the Middle East, is the vector of *Borrelia persica*, a causative agent of relapsing fever [11].

Pathology [3]. At the point of penetration of the tick mouthparts there is coagulation necrosis of the epidermis and papillary dermis [12]. Surrounding the hypostome is the homogeneous cement [13]. The punctured epidermis shows parakeratosis, spongiosis and frequently pseudoepitheliomatous hyperplasia. There is marked dilatation of upper dermal blood vessels, and a dense perivascular infiltrate of neutrophils and lymphocytes. Histology of the bite site several weeks after removal of the tick shows a perivascular and periadnexal infiltrate of lymphocytes, plasma cells and histiocytes [14,15]. Foreign-body giant cells may also be present in the infiltrate. If the hypostome has been damaged during removal of the tick, fragments of the mouthparts may be seen.

Clinical features [3]. In the case of Ixodid ticks, it is usually the parasite itself that attracts the patient's attention. Larvae, nymphs or adults may be discovered attached to the skin, and humans usually become accidental hosts when walking through, or sitting in, an area that contains ticks [16]. Larval ticks, sometimes referred to as 'seed ticks', are very small, and may go unnoticed unless present in large numbers [17–19]. Pruritic papules were a prominent feature of larval *Amblyomma* tick bites in a case reported by Fisher *et al*. [20]. A papular urticarial response to ticks has been reported in berry pickers [21], and the author has seen papular urticaria developing within a few days of contact with numerous larval ticks of *I. ricinus*.

Auto-eczematization has been reported in association with a tick bite granuloma [22]. Temporary alopecia may develop around the sites of tick attachment to the scalp [15,23]. Bullae [24] and extensive bruising [25] at the feeding sites of Argasid ticks have been reported, and anaphylaxis may be provoked by Ixodid bites [26]. In boutonneuse fever, there is an eschar (tâche noire; black spot) at the site of the bite of the infected tick (Fig. 38.29),

Fig. 38.29 Tâche noire on the leg in boutonneuse fever.

accompanied by a maculopapular rash, and African tick bite fever is associated with multiple inoculation eschars, often located on the legs [6]. The bites of the cave tick, Ornithodoros *tholozani*, produce characteristic deep red, crusted papules or nodules, with a central punctum [11]. The colour of engorged ticks has led patients to suspect they were melanomas [27].

Tick paralysis [28,29]

Tick paralysis is an ascending flaccid paralysis probably caused by a neurotoxin injected by the feeding tick. Occasionally, bulbar paralysis, respiratory failure and death occur. The site of action of the toxin appears to be in the region of the neuromuscular synapse. If the tick is removed, all the signs usually resolve rapidly, but sometimes recovery is slow. Children are more frequently affected than adults.

Tick paralysis occurs in particular localities in association with specific ticks [3]. Offending species include Dermacentor *andersoni* and *D. variabilis* (USA); *Ixodes holocyclus* (Australia); *I. pilosus* (South Africa); *I. ricinus, I. hexagonus* and *Rhipicephalus sanguineus* (Europe).

Lyme disease

See Chapter 30.

Tick removal

Various methods for removal of ticks have been suggested, including the application of iodine, ether, chloroform, petrol and

kerosene. Sherman [30] suggested a few drops of clear nail varnish, and Dolan and McKinsey [31] 2% lignocaine (lidocaine) jelly. Karras [32] also found viscous lidocaine to be effective.

Ticks should not be removed by a sudden forcible movement, as this will often leave the mouthparts embedded in the skin. Gripping the tick with forceps or tweezers, as close to the skin as possible, and gentle traction usually succeeds when other methods have failed [33]. There are also several commercially available tick-removal tools.

Mites (Acari)

Family Sarcoptidae

Scabies. Scabies in humans and other animals is caused by mites of the family Sarcoptidae, which includes *Sarcoptes scabiei*, the scabies mite, and *Notoedres cati*, a mange mite of cats.

The *Sarcoptes* causing scabies in humans and sarcoptic mange in many other animals are physiological variants of a single species, *S. scabiei*. Their host specificity is not complete, but they usually survive for only a short period on another host.

Human scabies. Human scabies has played a modest, but not insignificant role in history; the story of scabies has been related in detail by Hebra [1], Beeson [2], Heilesen [3], Friedman [4] and Parish [5].

Morphology and biology of the scabies mite [3,6–12]. *Sarcoptes scabiei* var. *hominis* has an ovoid body, flattened dorsoventrally. The adult female measures approximately 0.4 mm long by 0.3 mm broad, and the smaller male 0.2 mm long by 0.15 mm broad. The body is creamy white and is marked by transverse corrugations, and on its dorsal surface by bristles and spines (denticles). There are four pairs of short legs; the anterior two pairs end in elongated peduncles tipped with small suckers. In the female, the rear two pairs of legs end in long bristles (setae) (Fig. 38.30), whereas in the male bristles are present on the third pair and peduncles with suckers on the fourth.

Copulation occurs in a small burrow excavated by the female. After copulation, the fertilized female enlarges the burrow and begins egg laying. The burrow is not confined to the stratum corneum, but is inclined downwards into the epidermis. Eggs and mite faeces are deposited behind the female in the burrow. Approximately 40–50 eggs are laid by each female during a lifespan of 4–6

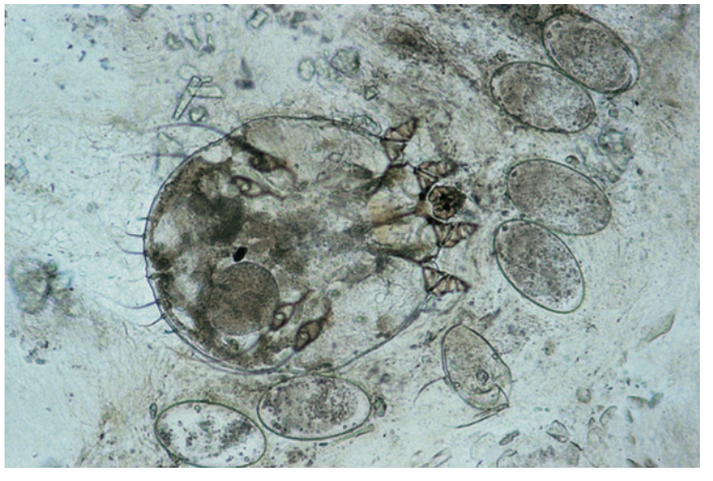

Fig. 38.30 *Sarcoptes scabiei*, the scabies mite. Female with eggs.

weeks, during which time she does not leave the burrow. Six-legged larvae emerge from the eggs after 3–4 days and escape from the burrow by cutting through its roof. The larvae then dig short burrows (moulting pockets) in which they transform into nymphs. After further moults, adult males and females develop.

The mites show a preference for certain sites in which to burrow, and appear to avoid areas with a high density of pilosebaceous follicles. The average number of adult female mites on an individual suffering from the common form of scabies is about 12 [13–15]. Only in crusted (Norwegian) scabies are large numbers of mites present.

Prevalence and epidemiology [1–6]. Scabies affects all races and social classes worldwide, but accurate figures of its prevalence are difficult to obtain. A study by Downs *et al*. [7] on data collected in the UK between 1967 and 1996 showed a high incidence of scabies in the late 1960s and early 1970s, a drop during the 1980s, and a rise throughout the 1990s. A Danish study, which assessed data collected between 1900 and 1975 [8], showed incidence rates in the 1960s and 70s similar to those in the UK study, and high incidence rates during the two World Wars. However, a rise in incidence started 2 years prior to hostilities on both occasions. Data from records kept in Edinburgh, UK also showed rises in incidence associated with the World Wars, but coinciding precisely with their onset [9].

Also noted by Downs *et al*. [7] were a higher prevalence in urban areas, the north of the UK, and in women and children, and greater frequency in the winter than the summer. Several other studies have noted this seasonal variation [10,11].

A decline in the number of cases of scabies in developed countries in the 1950s was followed by an upsurge in the mid-1960s, mentioned by several authors [12–14]. One suggested cause of the increased frequency of scabies in the 1960s was sexual promiscuity, but some authors believe this is unlikely in view of a lack of correlation with trends in sexually transmitted diseases [13,15]. A proposed explanation for the cyclical fluctuations in prevalence in developed countries is the 'herd immunity' theory [2,13]. This suggests that an epidemic of scabies confers a degree of immunity, so that a further epidemic will not occur until a new, susceptible population has arisen. However, the persistent high levels of scabies in many underdeveloped countries, without any marked cyclical variation, are evidence against this view.

Scabies is most common in children and young adults, but may occur at any age, and in the UK in recent years it has become frequent in the elderly in residential and nursing home environments. In a questionnaire survey of dermatologists in UK hospitals, reported in 2000 [16], respondents estimated that approximately 30% of all cases of scabies they encountered occurred in institutions such as care homes and hospitals. Although some outbreaks are related to cases of crusted scabies, others appear to originate from residents who have ordinary scabies with many burrows, and therefore a large mite population, or from infected carers. Close contact between residents and carers in these homes is common—for example, carers often hold the hands of residents to provide support when walking.

The overall sex incidence is probably equal.

Whereas all racial groups are susceptible, there are some differences between races, which are probably related to customs and social factors rather than inherent susceptibility. Some reports suggested that black Americans appeared less susceptible [17,18], but this was disputed [19]. In a study of a multiracial population in Hawaii [20], scabies was far more frequent in white people and Hawaiians than in Japanese and Filipinos, and this was thought to be related to family size and social customs.

Overcrowding, which is common in underdeveloped countries and is almost invariably associated with poverty and poor hygiene, encourages the spread of scabies.

Scabies is usually transmitted by close physical contact, such as prolonged hand-holding or the sharing of a bed. Indirect spread by clothing or bedding is unimportant in ordinary scabies, as demonstrated by the meticulous studies of Mellanby [21,22]. It is often suggested that fertilized female mites are responsible for transmission, although there is no firm evidence to support this contention, but it seems unlikely in view of their relatively small numbers and inclination to remain within their burrows. There are far greater numbers of immature mites on the skin surface, and their involvement in scabies transmission would appear more plausible.

A study from Sheffield, UK [23], showed that scabies was introduced into households mainly by schoolchildren and teenagers, especially by girls. The authors suggested that the frequent occurrence of scabies in teenage girls could be due to contact with younger children in large families, and the habit of holding hands. The commonest sources of infection were friends and relatives outside the home, and schools did not appear to play any appreciable part.

Away from the host, scabies mites survive for 24–36 h at room conditions (21°C and 40–80% relative humidity) [24], and live

mites have been demonstrated in dust samples collected in the homes of infected patients [25].

Immunology [1–6]. Allergic sensitivity to the mite or its products appears to play an important role in determining the development of lesions other than burrows, and in producing pruritus. However, the sequence of immunological events is unclear and requires further elucidation.

Evidence suggests that both immediate and delayed-type hypersensitivity are involved. Skin tests with mite extracts have given equivocal results, although positive immediate-type reactions to intradermal tests have frequently been obtained in patients within a few months of scabies infection. Normal IgE levels were reported in one series of scabies patients [7], but later studies have shown significantly elevated levels in many individuals [8–11].

Marked eosinophilia was a feature of two patients who had scabies coexistent with disorders of keratinization [12].

Involvement of delayed-type hypersensitivity in the production of inflammatory papules and nodules is suggested by the histological changes and predominance of T lymphocytes in the cutaneous infiltrate [13,14]. Experiments to determine if an extract of *S. scabiei* influenced cytokine expression by T lymphocytes showed increased production of IL-10, a finding which led to the suggestion that this may play a role in depressing the inflammatory and immune responses, and thereby in delaying onset of symptoms [15].

Other immunological findings include high serum IgG and IgM, and low IgA [7,10], with levels returning to normal after treatment. IgM and C3 deposits have been demonstrated at the dermo-epidermal junction in the region of burrows [16,17], and circulating immune complexes have been found in the serum after treatment of scabies [18].

The frequency of human leukocyte antigen (HLA)-A11 was found to be higher among patients with scabies than in a normal population in Norway [19].

Clinical features [1,2]. Itching is usually the most obvious manifestation of scabies. It is generally worst at night and when the patient is warm. The onset occurs 3–4 weeks after the infection is acquired, and coincides with a widespread eruption of inflammatory papules. Reinfection of a previously cured individual, however, provokes immediate symptoms [3].

Fig. 38.31 Numerous scabies burrows on the palm.

The pathognomonic lesions of scabies are burrows, which appear as slightly raised, brownish, tortuous lesions (Fig. 38.31). The point of entry of the mite, the most superficial part of the burrow, has a slightly scaly appearance, and at the distal end there may be a tiny vesicle, adjacent to which is the female mite. There may be few or many burrows, and in patients with a good standard of hygiene they may be difficult to find. Burrows occur on the wrists, the borders of the hands, the sides of the fingers and the finger web spaces, the feet, particularly the instep and, in males, on the genitalia. They are often present on the palms and soles of young children and the elderly. In adults other than the elderly, burrows may occur on the palms in women, but they are less frequently found on the palms in men, particularly heavy manual workers. Burrows on the trunk are uncommon in adults, but may be found in the elderly and in infants. They may be seen on the head and neck in babies, but rarely in adults. The scalp was, however, involved in an adult who was applying a topical steroid for seborrhoeic dermatitis [4], and scalp involvement in ordinary scabies may be a reason for relapse [5]. The reason for this pattern of distribution of burrows is not understood, but the mites appear to prefer non-hairy skin and areas of low sebum production.

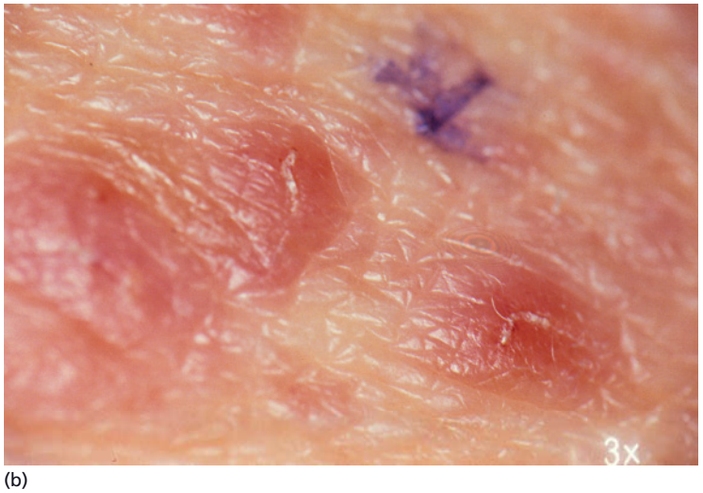
The pruritic papules that accompany the development of hypersensitivity occur predominantly around the axillae, in the periareolar regions, on the abdomen, particularly the periumbilical region, and on the buttocks and thighs. Histology shows epidermal spongiosis, with intraepidermal microabscesses containing neutrophils and eosinophils, and a dermal perivascular infiltrate of eosinophils, histiocytes and lymphocytes [6,7]. Indurated, inflammatory nodules sometimes occur, particularly on the axillae, groins, scrotum and penis. They are intensely itchy, and may persist for weeks or months after the scabies has been effectively treated [8–10]. The histological changes seen in these persistent scabies nodules may simulate lymphoma, with a dense, pleomorphic dermal infiltrate composed of plasma cells, eosinophils, lymphocytes, histiocytes and reticulum cells [6,11]. T lymphocytes are the predominant cells in the dermal infiltrate of both papular and nodular lesions [12,13].

Inflammatory papules or nodules, sometimes surmounted by burrows, on the male genitalia are characteristic of scabies (Fig. 38.32). The genitalia of males suspected of suffering from scabies should always be examined, as these lesions may provide an important diagnostic clue if burrows are difficult to find.

Fig. 38.32 Inflammatory papules on the penis in scabies.

Nail involvement in crusted (Norwegian) scabies is frequent, but it is uncommon in ordinary scabies [14]. Its presence may be a reason for relapse [15].

In addition to these primary manifestations, secondary features may occur, and can confuse the clinical picture. Eczematous changes are common, and may be widespread and severe. The inappropriate use of topical steroids may further modify the clinical picture to mimic other dermatoses (see crusted scabies)—so-called 'scabies incognito' [16]. Secondary infection, manifest as folliculitis or impetigo, may also be severe and extensive. In the tropics and subtropics, where nephritogenic strains of β-haemolytic streptococci may be responsible for secondary sepsis, glomerulonephritis occurs as a complication of scabies, but this must be exceedingly rare in temperate climates.



A bullous pemphigoid-like eruption may occur in association with scabies [17–25], and in many of the reported cases immunofluorescence studies showed immunoglobulin deposition in the basement membrane zone of the bullous lesions. The demonstration of circulating antibodies against BP180 and/or BP230 in two patients with scabies and bullous lesions [23] indicates that scabies may induce true bullous pemphigoid.

Cutaneous vasculitis is an unusual presentation of scabies [26–28].

Scabies in babies. The clinical features of scabies in infants and young children differ in certain respects from those in older children and adults [29,30]. In addition to the more extensive

(a)

(b)

Fig. 38.33 (a) Multiple truncal papules, surmounted by burrows (b), in an elderly woman.

distribution of burrows mentioned above, vesicular and vesiculopustular lesions on the hands and feet are frequent, extensive eczematization is often present, and there may be multiple crusted nodules on the trunk and limbs.

Bullous lesions have been described in a child [31].

Scabies in the elderly. Burrows commonly occur on the palms and soles, and may be very numerous. Truncal papulosquamous lesions, often surmounted by burrows, are common (Fig. 38.33). Secondary eczematization is often troublesome.

Diagnosis [1–3]. The typical history of pruritus with nocturnal exacerbations, and the distribution of the eruption of inflammatory papules, should suggest the diagnosis. The presence of genital lesions in males is pathognomonic. Absolute confirmation can only be made by the discovery of burrows and microscopical

examination. A burrow is gently scraped off the skin with a blunt scalpel, and the material placed in a drop of 10% potassium hydroxide or mineral oil on a microscope slide. The presence of mites, eggs or fragments of egg shells confirms the diagnosis.

Dermatoscopy is useful for detecting burrows and visualizing their contents [4,5], the mite in its burrow resembling a 'jet-with-contrail'.

Occasionally, burrows are difficult or impossible to find, and the diagnosis can then only be presumptive, based on the history, distribution of the papular eruption and the presence of contact cases within the family. However, in difficult diagnostic situations and atypical cases, polymerase chain reaction has been employed as a diagnostic tool [6].

Treatment [1–6]. There have been many suggested remedies for scabies. Sulphur has been used for centuries, and sulphur ointment is still employed in some parts of the world. Used excessively, or in high concentration, it may cause irritation, but 10% sulphur in yellow soft paraffin is, in general, safe and effective. A concentration of 2.5% may be used for scabies in infants and young children [1].

Rotenone, an extract of Derris root, was employed in the 1940s [7,8], but frequently produced scrotal dermatitis. Monosulfiram (chemically similar to disufiram (Antabuse)) was used as definitive treatment [9,10] and also, in the form of soap, as a prophylactic measure in communities where scabies was endemic [11–13]. An Antabuse effect could occur if alcohol was ingested during or soon after treatment [14].

There are several currently available scabicides. The choice of therapy is determined not only by efficacy and potential toxicity, but also by considerations such as cost, ease of application, the presence of secondary eczematization and the age of the patient.

Although for many years a hot bath and vigorous scrubbing of the sites of burrows was considered essential, Mellanby *et al*. [15] demonstrated that this was not necessary.

Benzyl benzoate. Although benzyl benzoate is now synthesized, it occurs naturally in balsams of Peru and Tolu: balsam of Peru has been used as a scabicide in the past. In 1937, the Danish dermatologist Kissmeyer [16] reported the effectiveness of benzyl benzoate in the treatment of 8000 cases of scabies, and it rapidly became popular [15,17–19]. Employed as a 25% emulsion, it should remain on the skin for 24 h. There are a number of suggested treatment regimens, but little has been published on their comparative efficacy. Most involve two or three applications, either within 24 h, on successive days, or separated by intervals of a week. Benzyl benzoate is irritant, and patients should be warned about overuse. Because it is effective and inexpensive, it is still used in many parts of the world.

Gamma benzene hexachloride (lindane). A single application, washed off after 12–24 h, is usually recommended, but it has been demonstrated that a 6-h application is equally effective [20]. Topical lindane is absorbed through the skin, especially if the barrier function of the epidermis is compromised [21–24]. There are a number of reports of adverse neurological effects, principally seizures, attributed to lindane [21,23,25–28], but toxicity was usually the result of excessive topical application or accidental ingestion. A comparison of percutaneous absorption of lindane and permethrin concluded than 5% permethrin cream is at least 40 times less likely to cause toxic effects than 1% lindane lotion [29]. However, critical assessment of lindane as a scabicide led to the conclusion that it is safe if used correctly [30,31].

There are anecdotal reports from several parts of the world, including the UK and USA, of lindane treatment failures, suggesting the emergence of lindane-resistant scabies mites.

Although still employed as a scabicide in some parts of the world, its use has been discontinued in several countries.

Malathion. Malathion 0.5% in an aqueous base is employed as a scabicide [32,33]. It should be left on the skin for 24 h, with a second application after an interval of a week.

Permethrin. Permethrin 5% dermal cream is an effective scabicide [34–36]. It should be washed off after 8–12 h, with a second application after an interval of a week. At present, it is the topical treatment of choice.

A survey of dermatologists in the UK revealed that the majority used permethrin cream for treating scabies, and about half reported treatment failures with malathion [37].

Other topical treatments include thiabendazole [38,39] and crotamiton [40]. Both have limited scabicidal activity, and several applications on consecutive days are required. Activity of essential oils against mites has been reported—including tea tree oil [41], neem, turmeric, bush tea essential oil, coconut oil and jojoba [42].

Ivermectin [5,43–45]. Ivermectin is structurally similar to the macrolide antibiotics, but does not have antibacterial activity. It is, however, active against a number of ecto- and endoparasites. It has been extensively employed in veterinary medicine, and in humans is used to treat filarial disease, principally onchocerciasis. It is not licensed for use in scabies in humans, with the exception of France. Glaziou *et al*. [46] compared oral ivermectin with topical benzyl benzoate for the treatment of scabies, and found that the former produced a higher cure rate. A comparison of the effectiveness of topical permethrin with oral ivermectin showed that a single application of permethrin is superior to a single dose of ivermectin, but two doses of ivermectin (with a 2-week interval between) are as effective as a single application of permethrin [47]. Comparison of ivermectin with lindane showed that they are equally effective [48]. It has also been reported that a specially

formulated topical ivermectin preparation was effective in treating scabies [49]. Oral ivermectin has proved particularly useful in the treatment of crusted scabies (see below). Ivermectin is apparently a safe drug with a low incidence of adverse effects. Many of the reported adverse effects have occurred in individuals given ivermectin for the treatment of filariasis, in whom serious reactions were thought to be related to death of the parasites [50]. A report suggesting a pattern of excess deaths in elderly people in a residential unit, who were given ivermectin to control a scabies outbreak, raised concerns about its safety [51]. However, the conclusions of this report were challenged [52,53], and other authors' findings regarding its safety are reassuring [54,55]. It also appears to be safe in children [56].

A single dose of 200 µg/kg body weight will be effective in many cases of ordinary scabies but, presumably because of a lack of ovicidal activity, higher cure rates are obtained with two doses separated by an interval of a week.

Because it is effective, inexpensive, and easy to administer, ivermectin might prove particularly useful in the management of institutional outbreaks of scabies (see below). Leppard and Naburi controlled an outbreak of scabies in a prison in Tanzania by giving ivermectin to 1153 prisoners [57].

Resistance to ivermectin in crusted scabies has been documented (see below) [58].

Liquid scabicides are most conveniently applied with a 2″ (5 cm) paintbrush. Scabicides should be applied to the whole body, except the head and neck, although the latter should be included if there is clinical evidence of involvement, and a non-irritant agent employed. Patients should be provided with written instructions explaining their treatment regimen and a warning against excessive use. They should be advised that itching will persist for a few days, but will usually resolve within 2 weeks. A topical antipruritic, such as crotamiton combined with hydrocortisone, may be used on residual itchy areas. All members of the family and close physical contacts should be treated, whether symptomatic or not. Disinfestation of clothing and bedding, other than by ordinary laundering, is not necessary.

Secondary infection should be treated with a systemic antibiotic. If eczematization is severe, a non-irritant scabicide should be used.

Treatment of infants and young children. Benzyl benzoate should be diluted with two or three parts water if used on infants and young children. Prolonged or repeated applications of benzyl benzoate or lindane should be avoided. Permethrin cream is the treatment of choice.

Scabicides in pregnancy and breast feeding. The literature is replete with cautionary advice relating to the use of scabicides in pregnancy, but having indicated which scabicides are best avoided authors rarely commit themselves to stating what they recommend. This is understandable in view of concern about potential toxic effects on the fetus but, to this author's knowledge, there is no documented evidence that any of the currently available scabicides has been responsible for harmful effects in pregnancy. Current UK Clinical Knowledge Summaries (CKS) guidelines suggest using permethrin, with malathion as an alternative. It is suggested that topical agents should be removed from the nipples before breast feeding, and reapplied thereafter.

Persistent scabies nodules. Potent topical steroids are usually used in treatment of these itchy nodules, but they are often slow to respond. Topical pimecrolimus was of benefit in a recalcitrant case [59].

Crusted scabies

Synonym
- Norwegian scabies

Table 38.2 Contributory factors associated with crusted (Norwegian) scabies.

Skin anaesthesia
Sensory neuropathy
Spinal injury
Hansen's disease
Mental impairment
Down's syndrome
Dementia
Physical incapacity
Paresis
Severe arthropathy
Epidermolysis bullosa
Immunosuppression
Drugs
Leukaemia/lymphoma
HIV/AIDS
HTLV-1 infection

The appellation 'Norwegian' derives from the description in Norway by Danielssen and Boeck [1] of a type of scabies in which huge numbers of mites were present in lepers. Hebra referred to this as 'scabies Norvegica Boecki' [2]. It has been suggested that 'Norwegian' should be discarded and replaced by 'crusted' [3,4].

Crusted scabies is an infection with *Sarcoptes scabiei* var. *hominis* in which the mite population is enormous, and may number millions. The grossly thickened horny layer is honeycombed with cavities which contain large numbers of mites, and these are shed into the environment of the patient [5]. An undiagnosed case of crusted scabies may be the source of an outbreak of common scabies.

Aetiology and pathogenesis [6,7] (Table 38.2). In common scabies, there are few mites, probably because scratching destroys the burrows. A good standard of hygiene may also help to control the mite population. In crusted scabies, the host's response to the mites is modified, allowing them to multiply.

Patients with skin anaesthesia secondary to sensory neuropathy or spinal injury obviously do not perceive itch and therefore do not scratch [8]. Patients who are mentally retarded or suffer from dementia may develop crusted scabies [9], and Down's syndrome is a frequent association [3,10–13]. The reason for this association with mental abnormality is not completely understood, but lack of appreciation of pruritus may be important.

In some patients who are physically severely incapacitated, as a result of paresis [14,15] or severe arthropathy, the main reason for the development of crusted scabies is probably a physical inability to scratch in response to itching. It has also been described as a complication of dystrophic epidermolysis bullosa [16], in which an inability to scratch because of an absence of fingernails may have been a contributory factor, and in a patient with epidermolysis bullosa simplex [17].

Crusted scabies may develop in patients who are immunosuppressed, either as a result of disease [18–20] or therapy [20–23]—including with infliximab [24]. In recent years there have been

Fig. 38.34 Crusted (Norwegian) scabies.

numerous reports of its occurrence in patients with HIV infection, and it is also an indicator of HTLV-1 infection [25–29]. Crusted scabies has also resulted from inappropriate use of potent fluorinated topical steroids [30–32] and pimecrolimus [33]. Suppression of sensitivity to the mites reduces itching, so there is less scratching and destruction of burrows.

Crusted scabies sometimes occurs in otherwise healthy individuals [34,35], and in northern Australia, where crusted scabies is a problem in the Aboriginal population, 42% of a series of 78 patients had no identifiable risk factors [36].

Clinical features [6,36,37]. Large, warty crusts form on the hands and feet (Fig. 38.34), and the palms and soles may be irregularly thickened and fissured. The nail apparatus is frequently affected, with masses of horny debris accumulating beneath thickened and discoloured nails (Fig. 38.35). Longitudinal nail splitting has been described [38]. Erythema and scaling occur on the face, neck, scalp (Fig. 38.36) and trunk, and may generalize. Localized genital crusting may also occur [39,40]. The extent of the erythroderma and the warty plaques varies greatly, and either may predominate. It has been suggested that *Staphylococcus aureus* colonizing burrows might play a part in initiating the erythroderma [41]. Itching is often absent or slight, but may occasionally be severe. Generalized lymphadenopathy is present in some cases, and blood eosinophilia and elevated IgE levels are common [36,42].

Crusted scabies may masquerade as hyperkeratotic eczema, psoriasis, Darier's disease [43], contact dermatitis [44] and Langerhans' cell histiocytosis [45].

The diagnosis is readily confirmed by examination of scrapings, which will be teeming with mites and eggs.

Fig. 38.35 Grossly dystrophic nails in crusted scabies.

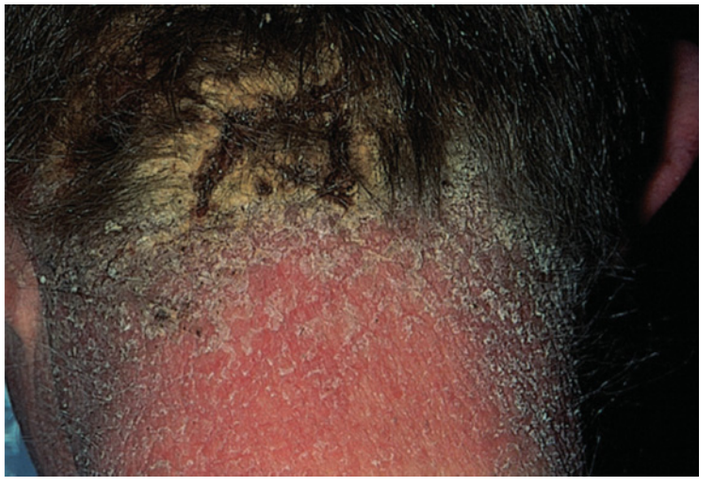

Fig. 38.36 Severe scalp involvement in crusted scabies.

Treatment [37,46–51]. A patient with crusted scabies should be admitted to hospital for treatment. They may be treated with topical scabicides, but prolonged therapy involving several applications is often required, and incomplete response is not uncommon. In recent years, ivermectin has become the treatment of choice for crusted scabies, either alone or in combination with a topical agent. The most effective regimen appears to be two doses of ivermectin (200 μg/kg body weight), separated by an interval of a week, combined with a topical scabicide. The nails should be cut short, and a topical scabicide applied beneath their free edges.

However, Currie *et al*. [52] reported evidence of resistance to ivermectin in two patients who had received multiple doses for recurrences of crusted scabies.

Institutional outbreaks of scabies. There are numerous reports of outbreaks affecting both patients and medical personnel in hospitals and residential care/nursing homes, and many of these are associated with undiagnosed cases of crusted scabies. Nursing and medical staff in contact with such a patient may develop the

common type of scabies, but frequently the first lesions seen are pruritic papules on the limbs, without any clinical evidence of burrows. The presence of papules and nodules surmounted by burrows, on the abdomen, buttocks and limbs of several contacts of a case of crusted scabies has been described [53].

The management of an institutional outbreak of scabies requires control measures to deal with all residents/patients and health-care workers [54–58]. In this situation, all the patients or residents should be examined to detect any cases of severe or crusted scabies, and such individuals should be isolated until cured. Any personnel coming into contact with such a patient should wear long-sleeved gowns and gloves. All individuals on an affected ward or in a residential home, and all medical and nursing staff and their families, should receive prophylaxis with a topical scabicide. Bedding should be laundered. It has been suggested that during treatment of institutional outbreaks, particular attention should be paid to the nails, in view of the subungual persistence of mites [59]. Cases of crusted scabies should be treated as outlined above.

Animal scabies

Transmission of animal scabies to humans is probably rare, because of the relative host specificity of the mites [1]. However, recurrent exposure to animal scabies mites can produce troublesome and diagnostically puzzling lesions.

Many varieties of *Sarcoptes scabiei* have been incriminated, including the following.

1 The mites causing sarcoptic mange in horses, cattle, buffalo, pigs, camels, monkeys, sheep and goats [2–7].
2 *Sarcoptes scabiei* var. *canis* commonly causes transient skin lesions in those in contact with infested dogs [8–14]. Exceptionally, scrapings from human skin have shown mites and eggs, and symptoms have persisted after contact with the animal has ceased [15]. Canine scabies has been experimentally transferred to humans [16]. Affected animals have areas of scaling and hair loss on the ears, face and limbs [17] (Chapter 2).
3 *Notoedres cati*, the cause of sarcoptic mange in cats, is almost unknown in the UK, but where it is endemic in the cat population, as in India [18] and Japan [19], human skin lesions may occur.

Clinical features. Skin lesions resulting from contact with animal scabies vary in extent and distribution, according to the mode of exposure. The eruption is usually composed of small, pruritic weals or papules, which are frequently excoriated, and resemble human scabies, but without burrows. Lesions from exposure to sarcoptic mange in dogs and notoedric mange in cats usually occur at sites of contact with the animal, principally the chest, abdomen, thighs and forearms.

Treatment. If contact with animal scabies is suspected, the diagnosis can only be confirmed by examining the suspect animal and obtaining skin scrapings from it. Affected animals should be treated by a veterinary practitioner.

Human skin lesions are self-limiting, and will resolve once exposure to the affected animal has ceased, or it has been treated.

Family Knemidokoptidae

Knemidokoptes mutans causes scaly leg in domestic poultry, and *Mesoknemidokoptes laevis* is a closely related mite which causes depluming itch in poultry—both have caused skin lesions in humans [1].

Family Psoroptidae

Mites of the family Psoroptidae cause mange in domestic animals. Species of *Chorioptes* and *Psoroptes* from cattle, horses and sheep have occasionally affected humans [1]. *Otodectes cynotis* is a common parasite in the ears of cats and dogs, and has been discovered in the ears of a patient suffering from otitis externa [2]. It was also considered to be responsible for a pruritic dermatosis in a patient whose dog was infested [3].

Family Listrophoridae

Listrophorus gibbus, a common parasite of the domestic rabbit [4], has been reported as causing papular urticaria in a child [5].

Mites of stored products [1,2]

Storage mite allergy is a well-recognized problem in certain occupations, including farmers, grain elevator workers and bakers. In addition to respiratory allergy, skin lesions can occur.

Family Acaridae

These mites attack flour, grain, dried meat, cheese and dried fruit.

Acarus siro is the most important pest of storage premises, and is found on flour, grain and, occasionally, cheese. It may cause skin lesions on those who handle these products.

Tyrophagus putrescentiae [3–6] is mostly found in stored food with a high fat and protein content such as dried eggs, ham, herring meal, cheese, nuts and copra. *Tyrophagus longior* is found on cheese, grain, hay and copra [7].

Suidasia nesbitti is particularly associated with wheat pollards and bran, and has been recorded as causing dermatitis in humans [8].

Rhizoglyphus species occur on flower bulbs and have caused dermatitis in persons handling stored bulbs.

Family Carpoglyphidae

Carpoglyphus passularum (*lactis*) is found on all kinds of dried fruit, and may cause dermatitis [9,10].

Family Glycyphagidae

Glycyphagus domesticus is a widely distributed species, often found in large numbers on plant and animal remains in houses and stables. It has also been found in flour, wheat, hay, tobacco, cheese and ham. *Glycyphagus destructor* is often abundant in hay, straw and grain.

Pathogenesis of food-mite dermatitis. It has been suggested that the dermatitis caused by these mites, which are not haematophagous, results from irritation by mite products, either faecal or secretory [5]. However, the pathomechanics of the response do not appear to have been studied in detail.

Dockers and warehouse workers handling stored products are most at risk, but shopkeepers and domestic workers are occasionally affected.

Clinical features [11]. The eruption provoked by these mites is sometimes called 'copra itch' or 'grocer's itch', and is often composed of minute, intensely pruritic papules or papulovesicles on exposed parts of the body, principally on the head and neck, and forearms, but occasionally more widespread. The appearance of the eruption on the face may suggest an acute contact dermatitis.

House-dust mites (HDM)

Dermatophagoides pteronyssinus, the HDM, was first discovered by Trouessart in dust shaken from tanned mammal skins [1]. It was subsequently established that it is widely distributed in the human environment in house dust and beds [2,3]. It occurs worldwide, and has been reported from all inhabited continents [4]. It is commonly associated with *Euroglyphus maynei* and *Dermatophagoides farinae*, which are related species in the same family, the Pyroglyphidae. In the USA, *D. farinae* appears to be more plentiful in house dust than *D. pteronyssinus* [5].

The largest numbers of mites are found in houses that are damp and inadequately heated [4]. Numbers vary seasonally, increasing in early summer to reach a maximum by early autumn. In the UK, numbers are low in winter and increase in spring, when temperature and relative humidity rise [6].

The main food of *D. pteronyssinus* is human skin scales [7]. Xerophylic moulds, especially *Aspergillus penicilloides*, are essential for the growth and survival of *D. pteronyssinus*. The moulds digest lipid in the scales which is toxic to the mites.

The major HDM allergens (Der p1 and Der f1) are present in the faecal pellets.

Role in atopic eczema [8–13]. The role of the HDM in the pathogenesis of atopic eczema remains controversial, although there is increasing evidence of involvement of HDM allergen in the disease.

Several studies have indicated that, in many individuals, the condition can be improved by techniques designed to reduce exposure to HDM allergen [14–20], although the benefits on clinical status appear to be greater in children than in adults [21], and it is not possible to predict which patients will benefit. One study demonstrated that the houses of patients with moderate to severe atopic eczema had more HDMs than controls [22]. Measures employed to reduce the HDM allergen load include regular vacuum cleaning of carpets, or their removal, bedding covers made of material such as microporous Goretex®, and the use of acaricides, including benzyl benzoate and permethrin [23].

Hepple and Macmillan [24] have attributed a case of purpuric dermatosis to house-dust mite allergy.

Pyemotes mites

Pyemotes mites are all primarily parasites of insects or their larvae. They only affect humans when the latter come into contact with the food of their natural hosts.

The mite *Pyemotes tritici* preys on the larvae of many species of insect infesting grain, straw or hay, and stored foodstuffs. Another species, *P. ventricosus*, preys on the larvae of wood-boring beetles, including the common furniture beetle *Anobium punctatum*. There has been some confusion about nomenclature of *Pyemotes* species [1].

Pyemotes mites have been responsible for attacks of dermatitis in those shovelling grain or coming into contact with infested straw [2] and husk rice [3]. The dermatitis has been referred to by a number of terms, including 'barley itch', 'grain-shovellers' itch', 'grain itch', 'straw itch', 'cotton-seed dermatitis' and 'acarodermatitis urticarioides'. *Pyemotes* dermatitis has been reported in shop workers coming into contact with wheat used for decorative purposes [4–6]. Dermatitis in workers in a food mixing shed at a piggery was attributed to *P. herfsi* [7], and *P. zwoelferi* was incriminated in dermatitis acquired by contact with a package of everlasting flowers [8]. Dermatitis in a fisherman handling crab pots made of cherry wood was probably caused by *P. beckeri* [9].

An outbreak of dermatitis in a small hospital in Queensland, Australia, was attributed to *Pyemotes* mites originating in an adjacent grain storage facility [10].

Clinical features [11,12]. The lesions are urticated papules surmounted by vesicles; occasionally they may be bullous. They are often very numerous, and their distribution depends upon the mode of exposure. In grain handlers, they are usually on the forearms and neck, but they may be profuse around the waist and in the groins.

Family Tydeidae

Dermatitis in eight woodworkers in Perugia, Italy, was attributed to contact with *Pronematus davisi* mites on wood imported from North America [1]. This mite has a worldwide distribution, and is widespread in North America, where it usually lives under bark.

Plant mites

Some mites of the family Tetranychidae ('spider mites') cause cutaneous irritation or urtication in humans [1–4]. These mites are phytophagous and occur on every type of crop and ornamental plant. The name 'spider mites' is derived from the silk webbing they produce from palpal glands.

Cheyletiella mites

Biology and epidemiology. Species of *Cheyletiella* mites are non-burrowing, obligatory parasites of certain mammals, predominantly dogs, cats and rabbits. The entire life cycle is completed on the host. Each egg is attached to a hair shaft by means of a fine thread, which is woven around it into a cocoon-like structure by the female mite. The adult mite develops via a larval and two nymphal stages. Adult mites move rapidly over the skin surface in pseudotunnels in keratinous debris. They use their hook-like palpi to attach themselves to the host while feeding on tissue fluids [1,2].

Cheyletiella mites were first reported as attacking humans by Lomholt [3] of Copenhagen, and in 1938 a case was reported from England [4]. It gradually became apparent that *Cheyletiella* infestation of dogs, cats and rabbits was common in most European countries, in the USA [5], in Canada [6] and in Australasia [7,8]. The distribution of these mites is likely to be worldwide. Many earlier reports incorrectly identified the species as *C. parasitivorax* when it was probably *C. yasguri*. It is now clear that *C. parasitivorax* is predominantly a parasite of rabbits, *C. yasguri* of dogs, and *C. blakei* of cats [9,10]. The three species are morphologically very similar, but distinguishable by the shape of a special sensory organ on the dorsal surface of genu I [10–12].

It is not clear from the limited information available whether the incidence of these mites is increasing, or whether infestation is becoming more frequently recognized. An investigation in the Netherlands [13] of 41 households, in which two or more cats were kept, showed *Cheyletiella* infestation of the animals in 27; 20% of the human contacts had skin lesions. Any age, breed or sex of animal may be affected. In dogs, cheyletiellosis is particularly common in boxers.

Most affected animals are asymptomatic, but some may suffer from pruritus. The most obvious sign of infestation is excessive dandruff, especially on the back, which is often known as 'walking dandruff' [14] or 'mobile dandruff' by veterinary dermatologists.

Clinical features in humans [15–17]. The typical clinical picture is of large numbers of intensely itchy papules (Fig. 38.37). Surmounting the papules there may be tiny vesicles, and older lesions may show small areas of necrosis. Bullous lesions may occur [18,19]. The distribution of lesions corresponds to areas of contact with an infested animal, the abdomen and thighs being frequently involved as a result of an animal sitting on its owner's lap. The chest and arms may also be affected from carrying the animal. Dobrosavljevic *et al*. [20] reported a woman whose skin lesions were accompanied by eosinophilia, 'increased immune complexes' and rheumatological symptoms.

(a)

(b)

Fig. 38.37 (a) and (b) Abdominal lesions in cheyletiellosis.

In a case with an extensive eruption, intradermal skin testing with an extract of *Cheyletiella* mites produced both immediate and delayed hypersensitivity responses [21].

Confirmation of the diagnosis [22]. The diagnosis may be confirmed by examination of combings from the animal's coat for the presence of mites. The suspect animal should be placed on a sheet of black paper, and the coat, particularly along the back, vigorously combed, preferably with a fine-toothed comb. The debris collected can then be examined microscopically (Fig. 38.38).

Fig. 38.38 *Cheyletiella yasguri.*

Treatment. The affected animal should be treated by a veterinary practitioner. Human skin lesions may be treated with a topical antipruritic. Once an animal has been treated effectively, there will be no further lesions on its owner.

Harvest mites (Trombiculidae)

Harvest mites belong to the family Trombiculidae. More than 1200 species of trombiculids have been described, and many may attack human beings or livestock [1]. They are parasitic as larvae, but free-living as nymphs and adults. The larvae may cause troublesome dermatitis (trombidiosis; scrub itch), and some are important vectors of rickettsial disease. They have many common names throughout the world, for example orange tawny (Ireland), chigger, red bug (USA).

The eggs are laid in soil. The six-legged larvae which emerge climb onto low vegetation to wait for suitable vertebrate hosts. On the host the larvae move to areas where the skin is thin, such as the ears, axillae, groins and genitalia. There they pierce the skin with their cheliceral claws and inject saliva, which has cytolytic properties, into the epidermis [2]. This action forms a tube-like canal (stylosome) through which the mites feed on tissue fluids and cell debris. Once engorged, they fall to the ground and develop into eight-legged adults via a nymphal stage. Nymphs and adults feed on vegetable debris and the eggs of insects and other arthropods.

Neotrombicula autumnalis, the European harvest mite, is widely distributed throughout Europe. In the UK [3], the larval mites are most numerous from May to October, with a peak in September. The most favoured natural host is the rabbit. *Neotrombicula autumnalis* is not known to transmit disease.

Eutrombicula alfreddugesi and *E. splendens* are the most common chiggers attacking man in the USA, and *E. batatas* is an important dermatitis-producing species in South America.

In South-East Asia, Australia and the Pacific Islands, trombidiosis is commonly caused by *E. wichmanni*, and species of *Odontacarus* and *Schoengastia* [4,5].

Species of *Leptotrombidium* including *L. akamushi*, *L. pallidum* and *L. deliense* are important vectors of scrub typhus (tsutsugamushi disease), caused by *Orientia tsutsugamushi* [6]. *L. akamushi* has a wide distribution, ranging from Japan and China southwards through South-East Asia to Indonesia and eastwards throughout the Philippines to New Guinea. *L. deliense* occurs in China, the Indian subcontinent, Malaya, Indonesia, the Philippines, New Guinea and Australia. The natural hosts of *L. akamushi* and *L. deliense* are rodents and insectivores. *L. subquadratum* has been reported as a cause of pruritus and dermatitis in dogs and humans in South Africa [7].

Clinical features [4,8,9]. Humans are infested while working in or walking through grass or low vegetation. The response to the bites of harvest mites appears to be determined by the irritant effect of

the mites' saliva and an acquired hypersensitivity to salivary antigens. Within a few hours, erythematous macules appear at the sites of the bites, and these gradually develop into extremely itchy papules or papulovesicles.

The distribution of lesions is determined by the preference of mites for thin skin, and the clothing of the host. Lesions commonly occur around the feet and ankles, the groins and genitalia, the axillae, the wrists and antecubital fossae, and areas constricted by clothing, such as the waistline. In heavy infestations, the whole body may be covered in lesions.

Chigger bites on the penis in children are responsible for a seasonal acute hypersensitivity reaction in the USA known as the 'summer penile syndrome' [10].

Trombiculid mite bites have provided evidence to implicate a suspect in a murder investigation [11].

Bird, rodent and reptile mites (Gamasida)

Family Dermanyssidae [1,2]

Dermanyssid mites are haematophagous parasites of birds and mammals. *Dermanyssus gallinae* (Fig. 38.39), the red poultry mite, is a common parasite of domestic and wild birds. Poultry keepers, veterinary practitioners and others in direct contact with birds are sometimes attacked. Other dermanyssid mites responsible for dermatitis include *D. hirundinis* and *D. americanus*. Avian mites may enter buildings from birds' nests via windows, ventilation grilles or air conditioners, causing skin lesions on the occupants [3–7]. Mites on cage birds may cause similar problems [8]. Lucky *et al*. [9] reported itchy papular lesions related to contact with pet gerbils infested with *D. gallinae* and *Ornythonyssus sylviarum* (see below), and reviewed other reported cases of avian mite bites.

Fig. 38.39 *Dermanyssus gallinae*: Comparison in size with the head of a match.

Liponyssoides sanguineus, the house mouse mite, is an ectoparasite of small rodents. It is of medical importance because it is the vector of *Rickettsia akari*, the agent causing rickettsial pox.

Family Macronyssidae [1]

Members of the Macronyssidae are haematophagous ectoparasites of birds, mammals and reptiles.

Ornithonyssus sylviarum (the northern fowl mite) and *O. bursa* (the tropical fowl mite) are pests of domestic and wild birds, and occasionally attack humans [10–13]. *Ornithonyssus bacoti*, although known as the tropical rat mite, is cosmopolitan, occurring in both tropical and temperate areas of the world. There are a number of reports of its effects on humans in close proximity to infested rats, mice, hamsters and gerbils [14–20].

Ophionyssus natricis, a snake mite, caused skin lesions in a family owning a pet python [21].

Clinical features [2,16]. The clinical effects vary according to the route and severity of infestation and the degree of the host's response. Most commonly, there is a profuse eruption of small, intensely itchy weals or papules, sometimes grouped, and often asymmetrical. The lesions may have a central punctum, and vesicles occasionally occur in the centre of the papules, especially in children. Because of the intense pruritus, excoriations are common, and secondary infection may occur.

There is no characteristic distribution, as this is determined by the situation in which the bites are acquired. Those handling infested poultry tend to have lesions on the hands and forearms, whereas persons attacked by mites in bedding have more extensive bites. Occasionally, lesions are grouped adjacent to areas of tight clothing around the waistline. Rossiter [22] reported otitis externa associated with *D. gallinae* in two poultry catchers.

In heavy infestations, the causative mites are often noticed by those affected, and any specimens obtained should be sent for identification to an entomologist familiar with Acari. When mite infestation is suspected, but no specimens are available, it may be necessary to visit the patient's home or workplace to determine the source of the problem.

Follicle mites (Demodicidae)

Demodex folliculorum (Simon), the follicle mite, is an obligate parasite of the human pilosebaceous follicle. It was first discovered in cerumen by the anatomist Jakob Henle in 1841, but it was the dermatologist Gustav Simon who provided the first complete description of the parasite, under the name *Acarus folliculorum*, in 1842 [1,2]. The generic name *Demodex* was created for it in 1843 by the zoologist Richard Owen.

Morphology and biology [1,3–5]. *D. folliculorum* measures 0.3–0.4 mm in length, and has an elongated, striated abdomen, giving it a worm-like appearance (Fig. 38.40). A morphologically distinct species, *D. brevis* Akbulatova, has been recognized [6]. *D. folliculorum* occupies the hair follicle, and the smaller *D. brevis* the sebaceous and meibomian glands.

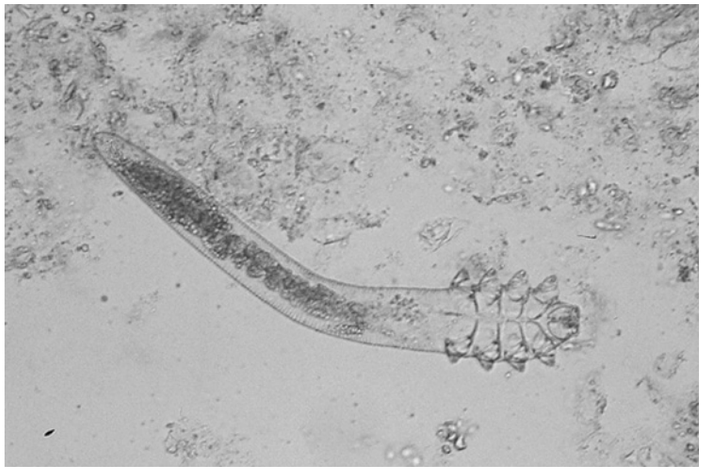

Fig. 38.40 *Demodex folliculorum*, the follicle mite.

The lifespan of *D. folliculorum* is thought to be approximately 2 weeks [5]. The heart-shaped eggs hatch to produce hexapod larvae, and the eight-legged adults develop via two nymphal stages.

Follicle mites show a predilection for areas of high sebum production [7] and they have been shown to contain lipase [8]. They are most numerous on the forehead, cheeks, nose and nasolabial folds, but they are also found on the scalp, in the external ear, in eyelash follicles and meibomian glands, and on the upper chest and nipples. They have also been discovered on the penis, mons veneris, buttocks and in ectopic sebaceous glands in the buccal mucosa [9]. *D. folliculorum* assumes a head-down position in the follicle, often with the tip of the abdomen protruding from the follicular orifice. Follicle mites are quite motile, and migrate from follicle to follicle. Most infested follicles contain two to six mites, but occasionally they are much more numerous. Mites have been isolated from individuals of all ages, except neonates [10]. Transmission to infants probably occurs as a result of close maternal contact. The prevalence of both *D. folliculorum* and *D. brevis* increases with age [11,12] and it is likely that with adequate sampling techniques mites could be discovered in some follicles in the entire adult population. The skin-surface biopsy technique is a useful method of assessing the population density and distribution of *Demodex* mites [13–15].

Pathogenicity. *D. folliculorum* has been implicated in the pathogenesis of a condition named *pityriasis folliculorum* [1–4]. This was originally described as occurring predominantly in middle-aged or older women who rarely washed their faces, but used large quantities of make-up and cleansing creams. The lack of washing and use of facial cosmetics were considered to be aetiological factors, but a similar appearance has subsequently been described in women who washed their faces regularly [4,5]. This dermatosis is characterized by diffuse facial erythema and follicular plugs, which impart a 'nutmeg grater' appearance to the skin. In reported cases, skin scrapings have contained unusually large numbers of *Demodex*, and the condition has responded to treatment with topical acaricides.

The question of the pathogenic role of *Demodex* in rosacea has prompted much debate in the past [6,7]. Although studies employing skin surface biopsy have shown statistically significant increases in the density of *Demodex* mites in the facial skin of patients with rosacea compared with controls [8–12], it is still not clear whether rosacea merely provides a suitable environment for multiplication of the mites, or whether the mites play a role in initiating the disease. Skin biopsies taken from patients with rosacea, following topical therapy with suphur, failed to show any correlation between clinical improvement and reduction in mite population [13]. In large studies of the histopathology of rosacea [14,15], *Demodex* was conspicuously absent from areas of inflammation in sections in which it was present elsewhere.

It has been suggested that a local, delayed hypersensitivity response to *Demodex* antigens might be partly responsible for the inflammatory component of rosacea [14], and the observation that most T-cells in the granulomatous infiltrate surrounding extrafollicular *Demodex* are helper-inducer T-cells [16] lends support to the hypothesis that the pathogenesis of rosacea involves a cell-mediated immune response. A recent report has also noted that bacterial antigens associated with *Bacillus oleronius*, isolated from *D. folliculorum*, have the potential to stimulate an inflammatory response in patients with papulopustular rosacea [17].

Although extrafollicular *Demodex* or fragments of *Demodex* may be found in the granulomatous lesions of rosacea [18,19], its role in their induction has not been established. The mite may simply be displaced because the hair follicles have been destroyed by the inflammatory process.

A view that the beneficial effects of metronidazole in rosacea might be mediated through an action against *Demodex* [20] was not supported by the finding that mites can survive high concentrations of this drug *in vitro* [21].

Rosacea-like eruptions in which large numbers of mites could be demonstrated and which responded to therapy with acaricides [2,22–25] or metronidazole [26] have been described. The effectiveness of acaricidal treatment can be evaluated by skin surface biopsy [27].

Demodex has been implicated in the causation of papular and papulopustular lesions in immunosuppressed individuals, including children with leukaemia [28–31], a patient with tumour stage mycosis fungoides [32], and patients with HIV infection [33–36].

Facial lesions attributed to *Demodex* have been described in immunocompetent children, in the form of a localized scaly patch [37], rosacea-like and pityriasis folliculorum-like lesions [38], and scalp lesions mimicking favus in another child [39].

A study of *D. folliculorum* density in perioral dermatitis suggested that increased mite density was a secondary phenomenon related to topical steroids, and also showed that mite density increased significantly in relation to the length of treatment [40].

Demodex is present in eyelash follicles, and has been implicated in the pathogenesis of blepharitis in some patients [41–43], although its importance as a cause is disputed [44]. The observation of fungal spores [45] and *Mycobacterium leprae* [46,47] within *Demodex* mites has led to the suggestion that the mites may act as vectors for these organisms.

Class Chilopoda (centipedes) and Diplopoda (millipedes)

Centipedes

Centipedes are elongated arthropods, with bodies composed of many segments, each bearing one pair of legs. They are nocturnally active carnivores, and feed on insects. Some of the giant species also feed on small mice and birds. The first pair of legs is modified, and provided with powerful hollow claws, which are used to grip prey and inject venom from poison glands in the basal segments of the legs.

The claws of smaller species of centipedes are unable to penetrate human skin, but some tropical and subtropical species, principally members of the orders Scutigeromorpha and the giant Scolopendromorpha, can inflict painful 'bites' [1–5]. The bites cause local pain, erythema and oedema, which may persist for several hours. Systemic symptoms include nausea, dizziness and pyrexia.

Millipedes

Millipedes also have multisegmented bodies, and most segments bear two pairs of legs (Fig. 38.41). They feed mainly on decaying vegetable matter, and are generally regarded as harmless, but some large tropical species can cause injury to humans when acting defensively. The injurious effects of the defensive secretions of the giant Spirobolid millipedes of tropical and subtropical zones are well known to the indigenous populations of these areas.

Millipedes have numerous 'repugnatorial' glands distributed along the body segments, which provide a chemical defence system, and it is the corrosive secretions of these glands which may cause burns on the skin. In the majority of species, these secretions ooze out and form droplets around the foramina of the

Fig. 38.41 Giant millipede. (Courtesy of M. Fogden/Oxford Scientific Films.)

glands, but a few species are capable of squirting the fluid for some distance [6,7]. Millipede secretions contain benzoquinones and hydroquinones.

Clinical features of millipede burns [1,6,8–10]. Children often try to pick up millipedes, and are therefore at most risk of burns from the corrosive defensive secretions. If millipede secretions enter the eye, they produce a severe irritant conjunctivitis. Contact with the skin produces a local burning sensation and a yellowish-brown stain, which gradually darkens to deep mahogany or purple–brown. This colour is produced by oxidation of the quinones in the secretions. The lesions blister within a day or two, but in the absence of secondary infection, will heal and desquamate in 10–14 days. The discoloration may persist for months. In dark-skinned individuals, persistent hypopigmentation is a common sequel.

Treatment [6]. Skin lesions should be washed with copious amounts of water to remove any remaining secretions, and the area cleaned with alcohol (a solvent of benzoquinones) if available. Blisters should be treated with a topical antiseptic. Ocular injuries should be dealt with by an ophthalmologist.

Other noxious or venomous invertebrates

Leeches (Hirudinea)

Leeches are classified in the phylum Annelida (segmented worms). Fresh-water leeches were used in bloodletting in Europe in the 18th and 19th centuries [1]. Although several species of leeches were used, the medicinal leech, *Hirudo medicinalis*, was the most popular. A large specimen of *H. medicinalis* may measure about 12 cm when fully extended. The body tapers towards each extremity, where it is provided with a muscular disc or sucker. Within the anterior sucker is the mouth, bordered by three jaws. Leeches attach themselves to the skin using these powerful jaws, and feed until engorged, when they release their grip and drop to the ground. Their saliva possesses anticoagulant, fibrinolytic, vasodilator and probably also anaesthetic properties. Some of the substances introduced by leeches during feeding are antigenic, and if sensitization to these substances develops the reaction to the bite may be urticarial or bullous [2]. Multiple pseudolymphomas have occurred following application of leeches to the legs [3].

In recent years, there has been a revival of interest in the use of leeches for therapeutic purposes. They are being employed in microvascular surgery to salvage replants or skin flaps whose viability is threatened by venous congestion [4,5], and also for drainage of large haematomas. Unfortunately, the use of leeches carries the risk of introducing wound infection, most frequently with *Aeromonas hydrophila*, a Gram-negative rod, but occasionally other organisms are involved [6–9]. *Aeromonas* is part of the normal gut flora of the leech, where it is thought to be essential to aid digestion of a blood meal, as proteolytic enzymes are virtually absent from the leech gut. Many plastic surgeons who use leeches employ antibiotic prophylaxis to protect against wound infection.

Jellyfish, sea anemones, corals (Cnidaria)

The phylum Cnidaria [1–3] includes the jellyfish, sea anemones and corals. All are aquatic and the majority are marine. Three of the four classes of the phylum have a medusa or 'jellyfish' stage in their life cycles. Cnidarians have tentacles bearing batteries of stinging cells (nematocysts) which are used for defence and capturing prey. Within each nematocyst is a spirally coiled thread that can be everted, uncoiled and forcibly ejected. In contact with prey, or with human skin, the nematocysts are discharged and the threads inject venom. The nature and toxic effects of the venom vary with species. Many species inflict at least some discomfort on humans, and some are potentially dangerous [3–7].

Class Hydrozoa. This class includes the fire corals and free-floating members of the subclass Siphonophora. The Siphonophora are colonial organisms in which a number of individuals, specialized for different functions, are structurally associated. Perhaps the best known siphonophoran is *Physalia*, the Portuguese man-of-war. This has the local name of 'bluebottle' in Australia. It has an air-filled float, which acts as a sail, and trailing tentacles. The nematocysts occur in 'batteries' or 'sting buttons' along the tentacles, and contact with them results in extrusion of numerous nematocysts and the inoculation of venom.

Class Cubozoa. Often referred to as 'box jellyfish', several species are dangerous to humans [3]. The most notorious is *Chironex fleckeri*, which has been responsible for a number of deaths in Australian waters. Other dangerous species include *Carybdea rastoni* (the 'jimble'), *Carukia barnesi* (the 'Irukandji') [8], the 'Morbakka' ('fire jelly'; Moreton Bay stinger) [9], and the Hawaiian box jellyfish, *Alatina moseri.*

Class Scyphozoa. The medusa is the dominant form of the life cycle. Jellyfish of this class are distributed worldwide, and some have medical significance. *Pelagia noctiluca* (the 'mauve stinger') is one of these, which is well known in the Mediterranean and Adriatic but has a wide distribution in the oceans of the world.

Class Anthozoa. This class contains several thousand species, including the sea anemones, the soft corals and the stony or true corals. Several species of sea anemone are known to inflict painful stings [2,3,10,11]. The reef-forming corals may cause injury to the skin with their nematocysts, or with their calcareous outer skeletons [12].

Clinical features [3,13–15]. Contact with *Physalia* tentacles usually results in a linear erythematous eruption accompanied by severe local pain. Because of the arrangement of 'sting buttons' of nematocysts there is a beaded pattern of local, small weals. In humans, pain and skin lesions are usually the limits of toxicity, but occasionally more severe reactions occur [16]. Haemolysis and acute renal failure in a 4-year-old girl [17], and fatalities, have been reported [18,19].

The local effects of box jellyfish tentacle contact are immediate, severe pain, and linear weals with a white, ischaemic centre. Larger weals may have a typical 'cross-hatched' or 'frosted-ladder' pattern corresponding to the architecture of the tentacles. Partial or full thickness skin necrosis may result. Box jellyfish may be responsible not only for local lesions but also for severe systemic effects, which may result in death [3,4,8,20–23].

In addition to acute skin lesions, which are regarded as toxic in nature, there may be delayed, persistent or recurrent eruptions at the original sites of cnidarian envenomation [24–31]. Recurrent episodes may be single or multiple, and may take the form of erythema, urticarial lesions, papules or plaques. A delayed hypersensitivity response to jellyfish antigens has been demonstrated by a positive patch-test reaction to a nematocyst preparation from *Olindias sambaquiensis* [32].

Other reported sequelae of jellyfish stings include erythema nodosum [33], cold urticaria [34] and Mondor's disease [35].

Envenomation by fire corals usually produces immediate burning or stinging pain, followed by urticarial lesions at the site of contact. These may in turn be followed by a localized vesiculobullous eruption, and subsequently chronic granulomatous and lichenoid lesions [36–38]. Stinging of an aquarium shop worker by a stony coral, *Euphyllia picteti*, has been reported [39].

Seabather's eruption [40–45]. Itchy, erythematous papules and weals occur predominantly under swimwear, and lesions are usually concentrated in tight-fitting areas (Fig. 38.42). The organisms become trapped under the bathing costume, and discharge of nematocysts is triggered. It is probable that a similar clinical picture can be produced by different coelenterates in different waters. In Florida, the Gulf of Mexico and the Caribbean, *Linuche unguiculata* (thimble jellyfish) appears to be responsible, and evidence has recently been presented that all three free-swimming stages of this jellyfish can cause seabather's eruption [46]. Specific IgG antibodies against *L. unguiculata* antigen have been demonstrated by enzyme-linked immunosorbent assay (ELISA) in patients with seabather's eruption [47]. Cases in the Long Island region, New York, have been attributed to larvae of the sea anemone *Edwardsiella lineata* [40].

Fig. 38.42 Seabather's eruption. (Courtesy of Dr R. MacSween, Kingston, Ontario, Canada.)

It should be noted that seabather's eruption as described above is completely distinct from 'swimmer's itch' or 'clam digger's itch', an eruption due to cercarial organisms and affecting mainly uncovered skin (Chapter 37), although both can occur in salt water and the terms are sometimes loosely applied.

Pathology. The acute changes in the skin resulting from cnidarian stings consist of intracellular oedema of keratinocytes, many of which have pyknotic nuclei, and a lymphocytic infiltrate in an oedematous superficial dermis [48]. Nematocysts were visible penetrating the epidermis in a 5-year-old child who suffered fatal envenomation from *Chironex fleckeri* [49].

Histology of recurrent reactions shows a spongiotic vesicular dermatitis with a dense perivascular lympho-histiocytic infiltrate, often containing large numbers of eosinophils [26,50]. There is oedema of the papillary dermis. Immunohistochemical studies suggest that Langerhans' cells and helper T lymphocytes play a central role, and that type IV delayed hypersensitivity is involved

in the pathogenesis of the lesions [50]. Epithelioid granulomas and large $CD30^+$ lymphocytes were present in a delayed reaction to a fire coral [51].

Treatment [3,15,52,53]. Inhibition of further discharge of nematocysts is an important aspect of first aid for some cnidarian stings. Vinegar inhibits discharge of the nematocysts of all the box jellyfish, and should be poured over the affected area of skin as soon as possible. It is available in containers on beaches in Australia. However, in other jellyfish, nematocyst discharge is not inhibited, and may be provoked by vinegar.

The application of cold packs provides relief of mild to moderate pain resulting from stings by *Physalia* and a number of species of jellyfish, but it has been demonstrated that heat appears to be even more effective in pain relief, probably by toxin inactivation. This observation may have wider therapeutic implications in the management of jellyfish envenomation [54,55].

An antivenom is available for use in *Chironex fleckeri* envenomation.

In Australia, protective clothing, in the form of Lycra 'stinger suits', is extremely useful in the prevention of jellyfish envenomation.

Sea mats (Bryozoa)

The Bryozoa are small, sedentary, colonial animals, which usually form mat-like encrustations on rocks, seaweeds or other surfaces. Severe occupational dermatitis resulting from contact with *Alcyonidium diaphanum* ('sea chervil') was originally described in North Sea fishermen, and named 'Dogger Bank itch' because of its association with the Dogger Bank fishing grounds. However, *A. diaphanum* is widely distributed in waters around the British Isles and mainland Europe [1,2]. The dermatitis occurs during the summer months, principally because the organism, which becomes detached in winter storms, proliferates in spring and summer, and is therefore encountered in greater amounts by fishermen. It is an acute papular, occasionally bullous, contact dermatitis on the hands, arms and face [3–6], which may have a photoallergic component [5]. The allergen is the (2-hydroxyethyl) dimethylsulphoxonium ion, a metabolite produced by the bryozoan [7,8]. Hypersensitivity to another bryozoan, *Electra pilosa*, has also been described [5,6].

Sea urchins (Echinoidea)

The Echinoidea, or sea urchins, form part of the phylum Echinodermata, which also includes the starfishes and sea cucumbers [1–3]. Sea urchins are usually spherical or ovoid, and are enclosed in a shell of closely fitting plates supplied with numerous moveable spines. The spines are formed by calcification of a cylindrical projection of subepidermal connective tissue. Situated between the spines are three-jawed pedicellariae, some of which are venomous. They are used to seize prey, and also in defence. In some species of sea urchins, the spines are also venomous.

Pathogenesis of skin lesions. Many species can cause unpleasant lesions of different types [4,5]—intense local pain and swelling following envenomation by spines or pedicellariae; secondary infection of the spine puncture wounds; development of implantation epidermoid cysts from fragments of epithelium driven into the wounds by the spines; late development of granulomatous skin lesions; synovitis, and joint damage if the spines penetrate joint cavities [6]; occasionally, systemic upset accompanies the local changes.

Pathology [7]. In chronic lesions a granulomatous inflammatory reaction predominates, with foreign-body or sarcoidal types the most frequent. Non-granulomatous chronic inflammation may also occur.

Clinical features [1,3–5]. Envenomation by sea urchins produces immediate burning pain, which may be very intense and persists for several hours. The degree of local swelling is variable, but is sometimes severe. In the absence of secondary infection, the puncture wounds heal within a week or two.

Delayed granulomatous reactions usually develop several months after the original injury, and take the form of bluish papules or nodules at the sites of penetration of the spines. On the digits, there may be diffuse fusiform swelling and limitation of movement. These lesions are very persistent if not treated.

A patient with a pruritic erythematous eruption on the knees and ankles following injury by a sea urchin produced a positive patch-test reaction to an extract of sea-urchin spines [8].

It has been suggested that *Mycobacterium marinum* may play a pathogenic role in some cases of sea urchin granuloma [9].

Treatment [4,5]. Immediate treatment consists of careful removal of spines and pedicellariae. Immersion of the affected area in hot water will provide pain relief. Local inhabitants in certain areas where sea-urchin injuries are common apply hot candle wax to the area [10]. The spines are difficult to remove surgically, but erbium-yttrium-aluminium-garnet (Er:YAG) laser ablation has proved effective [11]. If the spines have penetrated a joint, surgical exploration is advisable. The granulomatous lesions may be treated with intralesional steroid.

Sponges (Porifera) [1,2]

Tedania ignis (the fire sponge) is capable of producing a severe dermatitis, and has also been reported as inducing erythema multiforme-like lesions of the face, palms and soles 10 days after contact [3]. Dermatitis may also be caused by several other sponges, including *Neofibularia nolitangere* (the poison bun sponge) and *Microciona prolifera* (the red sponge).

Mollusca

The only important venomous univalve molluscs are cone shells of the genus *Conus* [1–3]. All the species of this genus possess a venom apparatus, and several species have caused human injury.

The stings are painful puncture wounds, with local ischaemia, cyanosis and numbness, the numbness quickly spreading to involve the whole body. The sting of some species, particularly *C. geographus* [2,4], may be fatal.

The very small floating mollusc *Creseis acicula* Rang has been incriminated as a cause of stings in bathers in Florida [5].

The tiny blue-ringed octopus (*Hapalochlaena maculosa*), a member of the Cephalopoda class of molluscs, and found mainly in Australian coastal waters, has been called the world's most deadly octopus. When agitated, the blue rings become very prominent. The bite of this octopus contains salivary toxins that may cause severe systemic symptoms culminating in death, usually from respiratory failure [6,7]. Cutaneous problems following *H. maculosa* bites include intense pruritus and urticaria [3,6,8].

Erythema, oedema and a burning sensation followed the bite of *Octopus apollyon*, succeeded by a persistent erythematous plaque and lymphoedema [9].

Noxious or venomous vertebrates

Venomous fish [1–3]

Numerous species of fish are capable of inflicting painful or even dangerous stings by means of dorsal or caudal spines provided with complex venom glands.

Venomous species are not confined to tropical waters. The lesser weeverfish, *Echiichthys vipera* [4,5], the spiny dogfish (*Squalus acanthias*) and several species of stingray occur on the Atlantic coasts, and can inflict serious stings.

In warmer waters, species of stingray, scorpionfish, catfish [6], rabbitfish, stonefish [7], the aptly named 'bearded ghoul', stargazers and toadfish are potentially dangerous. In many cases, injuries are the result of the victim inadvertently stepping on the fish in shallow water. The tail of the stingray carries serrated spines containing venom glands surrounded by an integumentary sheath. Treading on the fish results in a reflex 'whip' of the tail, which drives the spines into the skin, usually on the leg [8]. Several of these venomous species bury themselves in the sand in shallow waters, with their spines protruding, and are therefore a hazard to bathers.

Clinical features. Injuries commonly occur on the feet or legs, as a result of the victim stepping on the fish. Fish stings are usually immediately painful. They present as painful lacerations or puncture wounds. Intense pain may continue for several hours, and swelling and erythema around the wounds may simulate an infective cellulitis. With some species, systemic symptoms may occur. Raynaud's phenomenon affecting individual digits penetrated by weever fish spines has been reported [9,10]. Stingray spines may cause lacerations, or may be driven into the skin and break off. If the integumentary sheath ruptures, envenomation occurs. In severe stingray wounds, the affected area appears dusky or cyanotic, and later becomes erythematous or mottled, with necrosis of underlying fat and muscle [11].

The inflammatory infiltrate in one case of stingray envenomation contained numerous mononuclear cells, many of which were TIA+, suggesting that an immunological reaction might contribute to the delayed healing commonly seen after stingray injury [12].

Treatment. The venom of the weeverfish, like that of the stingray, stonefish and other venomous fish, is an unstable protein which is heat labile, and hot water is very effective in treating the stings [3,13–15]. The injured part should be immersed in hot water (someone other than the victim should gauge the temperature), and this will diminish the pain. An antivenom is available for stonefish stings.

Snake bites

The highest incidence of snake bites is in South America, West Africa, the Indian subcontinent and South-East Asia [1,2]. In India, there are an estimated 10 000 to 50 000 deaths a year, and in Burma, snake bites cause about 1000 deaths a year [3].

The effects of snake envenomation vary according to the composition of the venom, for example, bites of the spitting cobra (*Naja nigricollis*) produce local swelling and necrosis, haematological abnormalities and complement depletion [4]; the venom of the Malayan krait (*Bungarus candidus*) contains a toxin (bungarotoxin) that interferes with transmission at the neuromuscular junction [5]; marked coagulation disturbances occur after envenomation by Australian brown snakes (genus *Pseudonaja*) [6]. Surveys of deaths from snake bite in Australia [7,8] have shown that the majority were due to brown snakes.

Treatment [8]. The first-aid and field management of victims of snake bites in Australia changed when the compression bandage–splinting method of first-aid treatment was introduced by Sutherland [9], and shown to be effective [10]. This method consists of the application of a firm compression bandage to the limb that has sustained the bite, and its immobilization by splinting. The centripetal flow of venom is markedly impeded by this procedure. The offending snake should be killed if possible, and kept for identification by a qualified herpetologist. If the snake cannot be identified, venom detection kits are used on swabs taken from the bite site to determine the appropriate antivenom. Unfortunately, there is limited availability of antivenoms in other parts of the world [3].

Other animal bites

An enormous variety of other animals may occasionally bite humans. Most bites cause a variable degree of crushing and tearing of the skin, and the devitalized tissue readily becomes infected by the wide range of microorganisms found in the mouths of animals.

Dog and cat bites [1–5]

The highest incidence of dog bites occurs in school-aged children, and boys are bitten twice as often as girls. In contrast, wounds caused by cats occur more commonly in girls.

Most infections which develop from dog and cat bites are polymicrobial, and include aerobic (*Staphylococcus* species, *Streptococcus* species and *Corynebacterium* species) and anaerobic (*Bacteroides fragilis, Prevotella, Porphyromonas, Peptostreptococcus, Fusobacterium* species and *Veillonella parvula*) organisms. Cat scratch disease, caused by *Bartonella henselae*, can follow a bite from a cat. There are a number of other potentially pathogenic organisms, including the following:

Capnocytophaga (formerly dysgonic fermenter type 2 [DF2]) [1,4,6–8]

Capnocytophaga canimorsus is part of the normal oral flora of healthy dogs, cats and a number of other animals.

The majority of reported *Capnocytophaga* infections have been associated with exposure to animals, about 80% following exposure to or bites from dogs. Previous splenectomy and alcoholism are important predisposing factors, but infection may occur in perfectly healthy persons.

The spectrum of illness ranges from local wound infection to fulminant septicaemia. Skin lesions include a localized eschar at the site of the bite, cellulitis, non-specific macular or maculopapular lesions, erythema multiforme [5], petechiae, purpura fulminans and symmetrical peripheral gangrene. The more severe changes occur as a consequence of septicaemia and disseminated intravascular coagulation [6–8].

Confirmation of infection depends upon identifying Gram-negative rods within polymorphs on peripheral blood films, and isolation from blood and tissue cultures. The organism is sensitive to penicillin and ciprofloxacin.

Pasteurella multocida [1,4]

This is an aerobic Gram-negative coccobacillus, which is a normal component of the oral flora of dogs and cats, and is frequently

isolated from infected bites. It is a virulent pathogen, which provokes an intense inflammatory response and is likely to cause metastatic infection. Tenosynovitis is a consequence of infection, particularly in hand bites.

Seal finger

Seal finger may be encountered wherever sealing takes place, and amongst wildlife workers and others who handle seals in zoos and aquaria [9,10]. It is associated with *Mycoplasma* spp. carried by seals [11].

The usual clinical picture is of a painful, swollen, slightly erythematous finger. There are usually no constitutional symptoms. Many cases resolve spontaneously with no sequelae, but in others joint involvement may lead to synovitis, osteitis, fibrosis of periarticular tissues and disfiguring arthropathy.

Tetracyclines are the treatment of choice [12].

Rodent bites

There are a number of reports of anaphylaxis following rodent bites [13–15].

Human bites

Human bites are quite common, clenched fist injuries ('fight bites') being the most prevalent, and may introduce dangerous bacterial infection [4]. Necrotizing fasciitis caused by group A streptococci has resulted from a human bite on the calf (at a Bavarian Oktoberfest!) [16]. Transmission of herpesvirus types 1 and 2, and hepatitis B and C, has also been documented. An epidemic of hepatitis B was traced to a carrier in a residential institution for the mentally retarded who regularly bit his fellow residents [17]. Biting is also a possible transmission mode for HIV infection [18].

A traumatic neuroma following a human bite on the forearm has been reported [19].

The possibility of physical abuse should be considered in children with human bites. However, most bites in children are inflicted by other children [20].

Treatment [1,5,21]. All animal and human bites are potentially dangerous, and thorough irrigation with normal saline, exploration and debridement are recommended. UK guidelines [21] recommend antibiotic prophylaxis with co-amoxiclav (amoxicillin and potassium clavulanate) for all human bites, and that this agent should also be used for the prophylaxis of 'high risk' animal bite wounds (this includes hand, foot and facial injuries, puncture wounds, and people at risk of wound infection complications, such as those who are immunosuppressed, diabetic, have cirrhosis, are asplenic, or have prosthetic heart valves).

Rabies should be considered as a possible sequel to any animal bite if this occurs in countries in which the disease is endemic.

Introduction

The hereditary blistering disorders described in this chapter, although uncommon, may have a dramatic impact on the patient and their family, and severe economic consequences for their relatives and health services. These diseases have been the subject of intensive study in recent years, and the discovery of the causative genes underlying Hailey–Hailey disease, Kindler syndrome, and all the major types of epidermolysis bullosa (EB), has increased our knowledge not only of the pathogenesis of these disorders, but also of the normal biology of the skin. This is exemplified by the way the graded severity of the clinical features, and associated structural changes in the dermal–epidermal junction, of the dystrophic forms of EB, can be explained by the nature of the mutations in the *COL7A1* gene encoding the structural protein, collagen VII [1], as can differences in the severity of EB simplex be explained by the sites and types of mutations which occur in the genes encoding for keratins 5 and 14. The strategies used to track down the genetic causes of Hailey–Hailey disease, Kindler syndrome and EB provide interesting contrasts. In most forms of inherited EB, the candidate genes and proteins were suggested by earlier ultrastructural and immunohistochemical studies of the skin of affected patients before linkage and mutation analysis pinpointed conclusively the locus and identity of the causative gene. There were no similar clues to discovering the causative gene, *ATP2C1*, in Hailey–Hailey disease, or the gene associated with Kindler syndrome. Indeed, before it was found that mutations in *ATP2C1* could result in Hailey–Hailey disease [2] and in the gene encoding for the protein, kindlin, in Kindler syndrome, most dermatologists or skin biologists were unaware of their existence.

Knowledge of the ultrastructure and molecular composition of the epidermis and dermal–epidermal junction is necessary for understanding the tissue and molecular pathology that underlies this group of disorders.

Epidermolysis bullosa

J.-D. Fine, pp. 39.1–39.32

Definition and classification

EB comprises a group of genetically determined skin fragility disorders characterized by blistering of the skin and mucosae following mild mechanical trauma. The alternative term therefore is *mechanobullous diseases* [1]. The descriptive term *epidermolysis* is illogical because epidermal disruption is not the primary change in two of three main categories of EB. However, the name *epidermolysis bullosa*, as originally used by Koebner [2] in 1886, is now so well established in the literature that it is still the preferred term.

Classification of this complex and heterogeneous group of disorders is difficult, and not helped by the large variety of names and eponyms that have traditionally been used. Initial classification schemes were based largely on the mode of inheritance and clinical studies involving relatively few patients and families [3, reviewed in 4]. While these early observations were clearly important in establishing EB as an entity, a major step forward was made by Pearson [5] who used electron microscopy to show that the ultrastructural level of tissue cleavage (blister formation) in the skin is distinctive in the three major groups of EB: EB simplex, junctional EB and dystrophic EB. Subsequent studies have revealed a number of associated ultrastructural abnormalities, which have also proved to be important in the diagnosis and classification of EB [6–9]. In addition, the application of immunohistochemical studies, particularly a specialized form of immunofluorescence microscopy known as immunofluorescence mapping, has had a major role in differentiating certain forms of EB, and in helping to

Table 39.1 Revised classification system for epidermolysis bullosa (EB) [13].

Site of cleavage	Major EB type	EB subtypes	Targeted gene product(s)
Epidermolytic	EB simplex		
	Suprabasal	Plakophilin deficiency	plakophilin-1
		Lethal acantholytic EBS	desmoplakin
		EBS superficialis	unknown
	Basal	Localized EBS	keratins 5 & 14
		EBS, Dowling–Meara	keratins 5 & 14
		EBS, generalized other	keratins 5 & 14
		EBS, autosomal recessive	keratin 14
		EBS with mottled hyperpigmentation	keratin 5
		EBS with muscular dystrophy	plectin
		EBS, Ogna	plectin
		EBS, migratory circinate	keratin 5
		EBS with pyloric atresia	α6β4 integrin, plectin
Lamina lucidolytic	Junctional EB	JEB, Herlitz	laminin 5 (laminin 332)
		JEB, non-Herlitz	laminin 5 (laminin 332); type XVII collagen
		JEB with pyloric atresia	α6β4 integrin
		JEB, inversa	laminin 5 (laminin 332)
		JEB, late onset	unknown
		LOC syndrome	laminin 5 (laminin 332)
Dermolytic	Dystrophic EB		
	Dominant DEB	DDEB, generalized	type VII collagen
		DDEB, acral	type VII collagen
		DDEB, pretibial	type VII collagen
		DDEB, pruriginosa	type VII collagen
		DDEB, nails only	type VII collagen
		DDEB-bullous dermolysis of the newborn	type VII collagen
	Recessive DEB	RDEB, severe generalized	type VII collagen
		RDEB, generalized, other	type VII collagen
		RDEB, inversa	type VII collagen
		RDEB, pruriginosa	type VII collagen
		RDEB, centripetalis	type VII collagen
		RDEB, bullous dermolysis of the newborn	type VII collagen
Mixed	Kindler syndrome		kindlin-1

uncover the underlying molecular abnormalities by demonstrating specific antigenic changes in the dermal–epidermal junction of patients with different forms of the disease [10–12]. In 2008, a new classification system was proposed for EB which takes into account phenotypes and genotypes of EB discovered more recently, as well as selected entities (such as Kindler syndrome and plakophilin deficiency) which, although previously not included within the breadth of EB, share with more traditional forms of EB the presence of inherited mechanical fragility and blistering [13]. As a correlate, some entities were renamed so as to better facilitate their recognition by clinicians, and many of the eponyms were eliminated. This is summarized in Table 39.1.

This newly revised classification scheme, based on the recommendations of an international consensus group of clinicians with expertise in EB, supersedes two previously published schemes [14,15] and is targeted for use by clinicians. Whenever possible, molecular differences have been taken in account, although it is still believed that genotype–phenotype correlation is too weak within most EB types to argue instead for adoption of a classification system which first requires elucidation of mutations in every patient. The latter is further hampered by the inability of patients in some countries to readily afford DNA testing. Nevertheless, the ever increasing knowledge of the molecular basis of EB will doubtless continue to be crucial for enabling accurate diagnosis, mainly for genetic counselling and prognosis, and will eventually be the basis for gene therapy.

Prevalence and incidence

The most accurate data available on the incidence and prevalence of EB are derived from the National EB Registry (USA) project, a longitudinal study of approximately 3300 patients within the continental USA [1]. The incidence and prevalence of EB are estimated to be 19.60 per million live births and 8.22 per million population, respectively. Similarly, the incidence and prevalence rates for EB simplex are 10.75 and 4.60; junctional EB 2.04 and 0.44; dominant dystrophic EB 2.86 and 0.99; and recessive dystrophic EB 2.04 and 0.92, respectively. Comparison of these data with those derived from smaller populations (e.g. in Norway [2], Finland [3], Croatia [4], Northern Ireland [5], Scotland [6] and Italy [7]) suggests little if any differences reported across the major types and subtypes of EB (reviewed in [1]). These data suggest that there is no gender, racial, ethnic or geographical predilection for EB. It should be remembered, however, that these reported rates probably underestimate the true prevalence and incidence of EB, especially the clinically milder forms, because of recruitment or selection bias.

Epidermolysis bullosa simplex

EB simplex is the most frequent form of EB, accounting for at least 50% of patients enrolled by the National EB Registry (USA) [1].

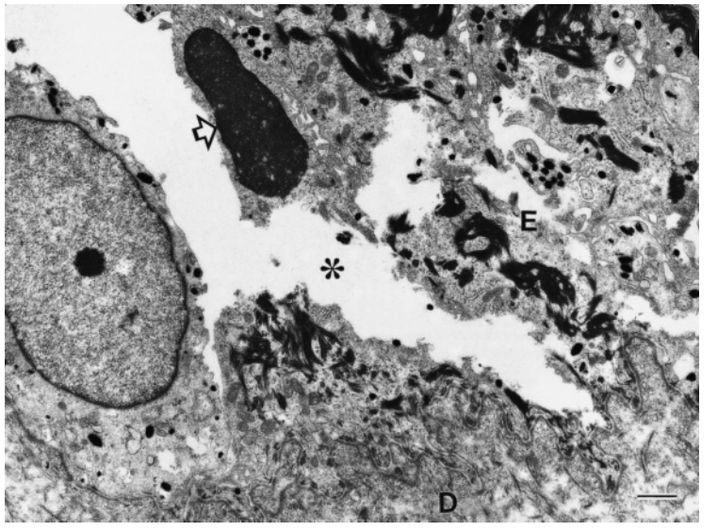

Fig. 39.1 Electron micrograph showing blister formation in epidermolysis bullosa simplex (Dowling–Meara). A split (*) is present in the epidermal basal layer (E), which contains electron-dense tonofilament (keratin) clumps (arrow). D, dermis; Bar = 1 μm. (Courtesy of Professor R.A.J. Eady, St John's Institute of Dermatology, London, U.K.)

Given the recognized underreporting of EB simplex, it is likely that at least two-thirds of all EB patients have this form of EB. The inheritance is chiefly autosomal dominant, and it is not uncommon to see affected individuals in three generations. Rarely, EB simplex may be transmitted as an autosomal recessive trait.

Molecular pathology [1,2]

In all forms of EB simplex, blister formation is intraepidermal. Most EB subtypes begin with the disruption of basal keratinocytes, although rare subtypes ('suprabasal') result from mechanical instability and cleavage within the uppermost epidermis. Genetic linkage analysis [3] and transgenic mouse experiments [4] led to the discovery that mutations in the basal keratin pair, K5 and K14, could result in EB simplex. It was shown that expression of mutant keratins in cultured cells gave rise to dense keratin aggregates [5]. Similar aggregates or keratin filament clumps were seen in the basal epidermis (Fig. 39.1) [6,7] or cultured keratinocytes [8] of patients with the Dowling–Meara form of EB simplex. Immunoelectron microscopic studies labelled the abnormal filament clumps with K5 and K14 antibodies [9]. In general, a correlation exists between the position of the mutation on the *KRT5* or *KRT14* genes and the resulting phenotype (Fig. 39.2). For example, the most severe form of EB simplex, the Dowling–Meara subtype, is usually caused by missense mutations in the initiation or termination peptides of the rod domains [10,11], which are evolutionarily highly conserved and thought to have a critical role in keratin filament assembly and structural integrity. Mutations in *KRT5* and

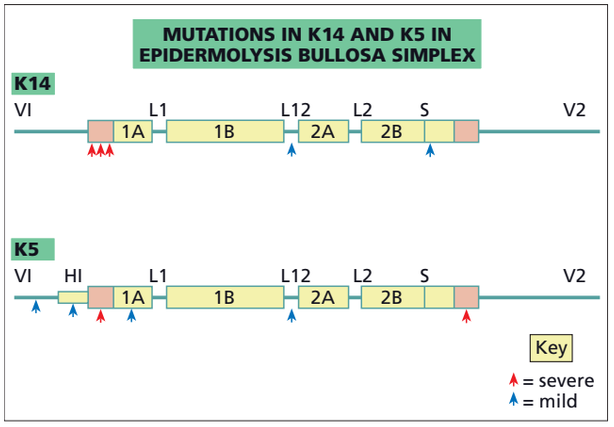

Fig. 39.2 Schematic representation of the type II (keratin 5) and type I (keratin 14) proteins, with position of mutations (arrowed). Each keratin has an α-helical rod domain (boxed areas) with head and tail domains at each end. The pink boxes represent the highly conserved helix boundary sequence motifs. The mutations causing Dowling–Meara epidermolysis bullosa simplex occur in these boundary peptides and are known to be highly disruptive to keratin filament assembly. (Modified from a figure provided by Professor E.B. Lane.) (Courtesy of Professor R.A.J. Eady, St John's Institute of Dermatology, London, U.K.)

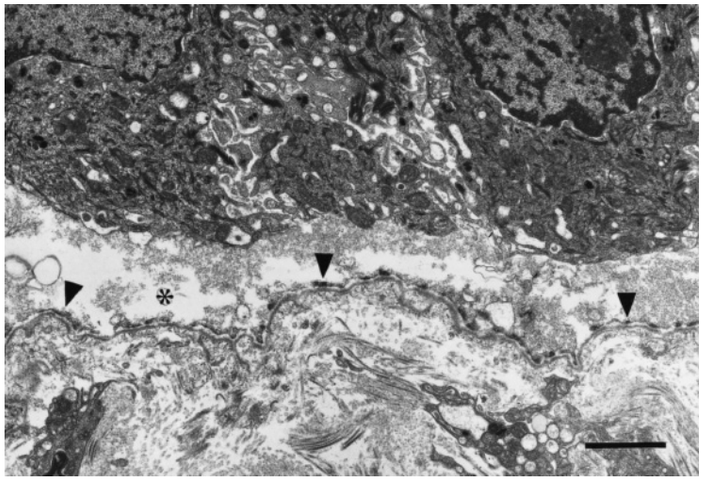

Fig. 39.3 Electron micrograph showing a low level of intraepidermal blister formation in epidermolysis bullosa simplex associated with muscular dystrophy. The split (*) is above hemidesmosomes (arrowheads) and associated plasma membrane. Bar = 2 μm. (Courtesy of Professor R.A.J. Eady, St John's Institute of Dermatology, London, U.K.)

KRT14 have also been described in localized EBS (formerly named Weber–Cockayne EBS) [12–14]. In this subtype of EB simplex, which is milder than the Dowling–Meara form, mutations occur outside the highly conserved boundary motifs, and chiefly in other parts of rod domain or the L12 linker region [13]. In the localized or non-Dowling–Meara generalized variants of EB simplex (formerly named Koebner EB simplex) and in the form of EB simplex associated with mottled pigmentation, the basal cell keratin filaments are not consistently abnormal and do not show the major changes that characterize Dowling–Meara EB simplex. A heterozygous C to T transition at base position 71 in the non-helical VI domain of *KRT5*, causing a proline to leucine substitution, has been reported in three unrelated families with EB simplex and mottled pigmentation [15,16]. The cause of the pigmentary changes is unknown. Recessive forms of EB simplex would appear to be very rare; however, at least two families with autosomal recessive EB simplex with a Weber–Cockayne phenotype have been recognized [17,18]. In three cases with widespread blistering, more in keeping with a Koebner phenotype, normal keratin filaments were absent in the basal epidermal layer, as was K14 protein expression [19–21]. However, K5 expression appeared normal. These cases were thought to represent the first functional knockouts of K14. Subsequently, a large kindred with EB simplex was described, also with ablation of K14, caused by a homozygous splice-site mutation [22]. A further autosomal recessive form of EB is associated with muscular dystrophy, and on occasion other abnormalities affecting the central nervous system. The ultrastructural level of tissue separation begins at a very low level in the basal cells, just above the hemidesmosomes and adjacent basal plasma membrane (Fig. 39.3) [23–28]. The level of cleavage in this form of EB may appear, in part, to be within the lamina lucida; therefore these ultrastructural findings, together with the clinical similarities of this form of EB with non-Herlitz junctional EB (see below), have led to the description of 'pseudojunctional EB' [28].

Immunofluorescence microscopy of skin from affected individuals shows diminished or absent staining for plectin [25–27], a 500-kDa protein, which is distributed among a variety of tissues, including stratified squamous epithelia, nerve and muscle [29,30]. Homozygous mutations in the plectin gene, *PLEC1* on chromosome 8q24, have been described in several families with the disease [26,27, reviewed in 31] and in two unrelated children with EB simplex associated with mucosal lesions in the respiratory tract, but without evidence of concurrent myopathy [32]. The rare autosomal dominant, Ogna form of EB simplex has also been found to be caused by a *PLEC1* mutation [33]. Recently two extremely rare entities, plakophilin deficiency and lethal acantholytic EBSEB simplex, both associated with suprabasal blistering, have been shown to result from mutations in the genes encoding for plakophilin-1 and desmoplakin, respectively [34,35].

Certain patients, who might otherwise have been diagnosed as having a form of junctional EB, by virtue of their clinical presentation or molecular findings, have been found to have an intraepidermal level of tissue cleavage in their skin, and have therefore been classified (or reclassified) as having EB simplex. This applies mainly to patients with EB associated with pyloric atresia [36,37], but has also been described in patients whose mutations result in deletions of the cytoplasmic domains of collagen XVII [38] or β4 integrin [39].

Clinical subtypes

The various clinical subtypes of EB simplex are as follows.

Suprabasal subtypes of EB simplex

Epidermolysis bullosa simplex superficialis

Epidermal cleavage is typically just beneath the stratum corneum. This autosomal dominant condition, originally reported in seven patients [1], is characterized by the presence of superficial erosions rather than intact blisters, similar to those seen in pemphigus foliaceous. Healing results in localized atrophic scarring or post-inflammatory hyperpigmentation. The finding of mutations within the type VII collagen gene, *COL7A1*, in one kindred with EB superficialis [2], suggested that the diagnosis was an atypical form of dystrophic EB rather than EB simplex in these cases. Further molecular studies are needed to clarify whether other patients with EB superficialis also have mutations in *COL7A1*.

Plakophilin-1 deficiency and lethal acantholytic EB simplex

Two recently recognized disorders, plakophilin deficiency and lethal acantholytic EB simplex, have been included among the

suprabasal subtypes of EB simplex. The former is an autosomal recessive form of ectodermal dysplasia associated with congenital skin fragility, caused by mutations in the plakophilin 1 gene [1,2]. It appears at birth and is generalized in distribution. Superficial erosions, oftentimes circinate in configuration, and, to a lesser extent, also blistering, are characteristic features of this entity. Other clinical findings may include abnormal nails, hypotrichosis, focal keratoderma, perioral and tongue fissures, constipation, oesophageal stricture, blepharitis, and absent or sparse eyelashes. Lethal acantholytic EB, as described by Jonkman *et al.* [3] in a single patient, is associated with mutations in the gene encoding for desmoplakin. Also autosomal recessive, it is present at birth and generalized in skin distribution. A characteristic feature is the presence of oozing erosions rather than frank blisters. Other findings include markedly abnormal nails, neonatal teeth, intraoral erosions and alopecia of the scalp. The gastrointestinal, genitourinary, and respiratory tracts are also involved.

Basal subtypes of EB simplex

Localized EB simplex (formerly Weber–Cockayne EBS)

This is the most common type of EB. The palms and soles (Fig. 39.4) are mainly affected, with the exception of the sides of the toes, where blistering may be particularly painful. Many patients have blisters only on the feet, and a minority (approximately 10%) will have blisters at other sites, such as the waist or neck, especially in hot weather and after friction from clothing or other sources. In the large majority of patients, blistering starts in childhood, but there are reports of the onset being delayed until early adult life, and brought out by strenuous physical activity [1]. The condition is always worse in warm weather. Hyperhidrosis of the feet is common; this increases friction, which also exacerbates blistering. The blisters usually heal without clinically significant scarring or milia formation, although both may infrequently be seen. Discrete and sometimes punctate calluses are very common, especially in adults. Although troublesome blistering or ulceration of the oral mucosa is rare, at least 25% of infants may develop occasional small intraoral lesions, especially palatal and worsened by trauma from feeding bottle nipples. The hair and teeth are normal; nail dystrophy is infrequent, and is usually localized and mild when it does occur.

Generalized epidermolysis bullosa simplex, non-Dowling–Meara variant (formerly Koebner EBS) [1,2]

This is one of the two major subtypes of generalized EB simplex. Although usually mild, approximately 60% of patients have localized scarring and approximately 16% have milia. Development of hair, teeth and nails is normal. The nails rarely may be involved by blisters, but are only temporarily shed. Blisters appear within the first year and may be present at birth. In infancy, they commonly appear on the occiput, back and legs, while in childhood the hands and feet are often affected, although the palms and soles are not preferentially involved, as in localized EB simplex. In common with other forms of EB simplex, blistering is worse in warm weather. Although blistering occurs throughout life, some patients are alleged to improve after puberty.

In some authors' experience, this subtype of EB simplex is rare in comparison with the localized or Dowling–Meara forms of EB simplex. At times it may be difficult to readily distinguish this EB simplex subtype from patients with documented localized EB simplex who are experiencing a severe flare. In particular, approximately 10% of patients with the localized form of EB will at some time have experienced blistering at sites other than the palms and soles (see above) [2]. Such individuals were recognized by Cockayne [3]. In the autosomal recessive cases, oral blistering with dental caries may be a feature, and nail dystrophy is common.

Dowling–Meara epidermolysis bullosa simplex

Synonym

- Epidermolysis bullosa herpetiformis

In 1954, Dowling and Meara [1] described four unrelated children (aged 3–7.5 years) with unusual trauma-induced or spontaneous

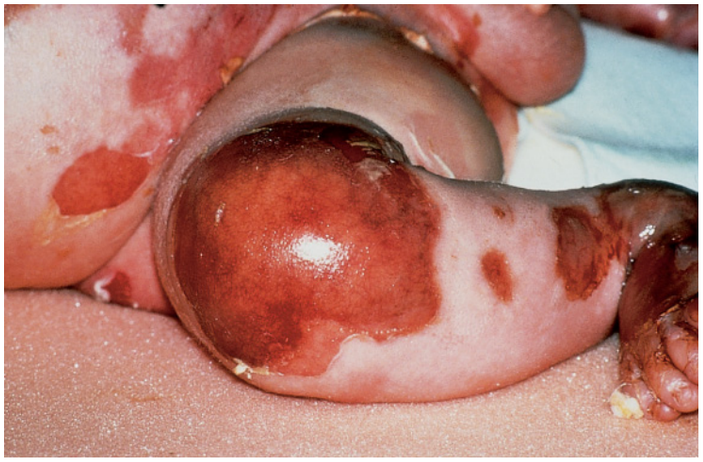

Fig. 39.5 Extensive erosions in a neonate with epidermolysis bullosa simplex (Dowling–Meara). (Courtesy of Professor R.A.J. Eady, St John's Institute of Dermatology, London, U.K.)

blistering. The blisters healed without leaving scars, and tended to occur in groups that were reminiscent of those seen in dermatitis herpetiformis. Similar cases have since been described [2–10]. In infancy, blistering may be severe and extensive (Fig. 39.5) with involvement of the mucous membranes, shedding of nails and formation of milia. The differential diagnosis at this age may include both the junctional and generalized recessive dystrophic forms of EB. Therefore, a diagnostic skin biopsy is mandatory. After several months, blistering of the palms and soles becomes more frequent, as it does elsewhere. The distinctive feature of this condition is spontaneous herpetiform, annular or arcuate blistering on the trunk, limbs and neck (Fig. 39.6). However, when the blistering is severe and widespread, this pathognomonic grouping of lesions may not be obvious, so the correct diagnosis may be missed, and patients misclassified as having generalized non-Dowling–Meara EB simplex. Healing of the blisters may leave mild hyperpigmentation; localized atrophic scarring affects approximately 40% of patients, and milia are seen in approximately 20%. Irregular hyperkeratosis of the palms and soles, eventually developing into a confluent keratoderma (Fig. 39.7), first appears in childhood, and may rarely lead to a flexion deformity of the hands, associated with a severe keratoderma [5]. The general condition tends to improve with age [2]. Clearing of skin lesions has been noted in some patients with a fever, and after warm saline soaks [2].

Epidermolysis bullosa simplex Ogna

This autosomal dominant condition was named after the village in Norway where the first affected family originated [1]. There is seasonal blistering of hands and feet, and occasionally elsewhere. This rare subtype of EB is distinguishable by a generalized bruising tendency, haemorrhagic bullae and onychogryphotic great toenails [1].

1 Gedde-Dahl T. *Epidermolysis Bullosa: a Clinical, Genetic and Epidemiological Study*. Baltimore: Johns Hopkins University Press, 1971.

Epidermolysis bullosa simplex with mottled pigmentation

This rare condition can be distinguished from other forms of EB simplex by the associated pigmentary changes [1–5], which are present at birth or appear during infancy. There is a reticulate pattern of small, tan-coloured macular lesions, which fade with age. They may cover the entire skin surface but preferentially involve the neck, upper trunk or extremities. Blistering may be localized, mimicking Weber–Cockayne disease, or become more generalized. Punctate keratoses on the palms and soles have been noted in some cases [2,3]. Mild localized skin atrophy and nail dystrophy are also features of the condition [5].

Autosomal recessive epidermolysis bullosa simplex with neuromuscular disease

Several families have been described in which skin fragility and blistering are associated with a neuromuscular disorder, chiefly muscular dystrophy [1–5], although myasthenia gravis [3] and spinal muscular atrophy [6] have also been described. The blisters, which affect the skin and oral mucosa, are present at birth or soon afterwards. Muscle weakness and wasting may be severe and evident in early childhood, or milder and detectable later in life. Mental retardation has been reported [2], as has early death [1]. The widespread blistering is associated with atrophic scarring, milia, nail dystrophy and alopecia, oftentimes mimicking junctional or dystrophic EB. Two children with homozygous null mutations developed supraglottic scarring and hoarseness; one required a tracheostomy [7].

Epidermolysis bullosa simplex with pyloric atresia

Pyloric atresia may rarely occur in the setting of EB simplex. Affected infants tend to have generalized skin disease. Although only a few cases have yet been reported, this entity appears to be as severe as junctional EB with pyloric atresia.

Lethal autosomal recessive epidermolysis bullosa simplex

A kindred of 13 Sudanese patients has been reported with the autosomal recessive form of EB simplex [1]. Blistering was present at or very shortly after birth and was generalized, with no associated scarring or milia, and with a predilection for the more distal portion of the limbs. The oral mucosa was only mildly affected, and the nails, teeth and hair were not affected. Most of the affected children died during the first 2 years of life; only one patient reached adolescence.

Electron microscopy of the skin of these patients was reported to reveal a paucity of tonofilaments in the basal epidermal cells. A published electron micrograph is reminiscent of the ultrastructural features seen in an unrelated case of North African origin whose autosomal recessive EB simplex was found to be caused by a homozygous null mutation in the keratin 14 gene [2].

Epidermolysis bullosa simplex, migratory circinate

Gu *et al*. [1] described two families with an autosomal dominant form of EB simplex characterized by migratory circinate erythema and postinflammatory hyperpigmentation. Present at birth, blistering was generalized in distribution. The underlying cause of this entity was a frameshift and delay stop codon in the keratin 5 gene.

Kallin's syndrome

The single report on this disorder [1] included two sisters whose surname was Kallin. Both had blistering chiefly of the hands and feet, nail dystrophy, absent teeth and alopecia. One sister was partially deaf. Light microscopy showed a mid-epidermal cleavage in the skin of one sister, and a substratum corneal split in the other. From the limited information available, it is uncertain whether Kallin's syndrome is a distinct form of EB. For this reason, it is currently not included within the latest classification system.

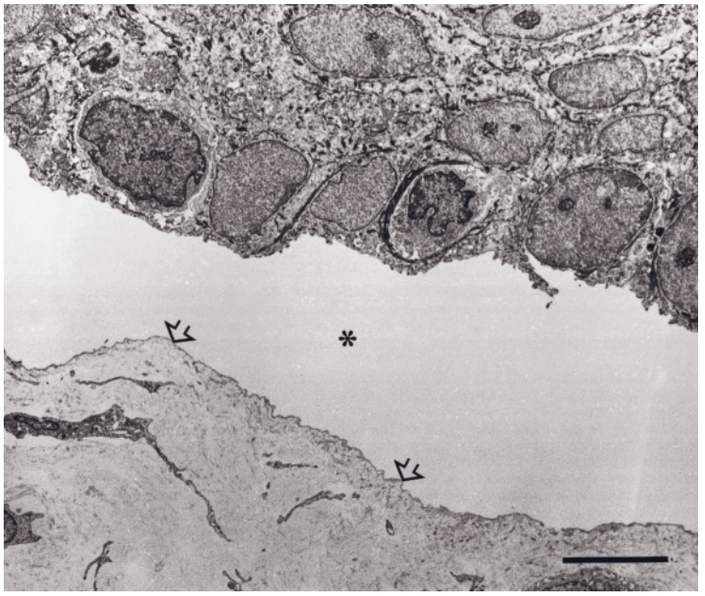
Junctional epidermolysis bullosa



All the variants of this disorder are characterized by autosomal recessive inheritance and by blister formation at the level of the lamina lucida. Conventionally, junctional EB is divided into two main categories: the Herlitz and non-Herlitz forms. Although the term EB letalis was originally ascribed to Herlitz JEB, this term is no longer recommended because it is well recognized that *any* EB subtype may also rarely have a lethal outcome, especially in infancy. The term *indeterminate* junctional EB has been used to classify infants who have diagnostic biopsy evidence of junctional EB, but who have not lived long enough to allow clinical segregation into the Herlitz or non-Herlitz subtypes. The term *EB atrophicans* has also been used to describe patients with junctional blistering and atrophic scarring [1]. We do not recommend the use of this latter term because other forms of EB may be associated with atrophic scarring, and the abbreviation 'EBA' could potentially cause confusion with its more usual association with EB acquisita.

Molecular pathology [1,2]

Electron microscopy shows that the level of tissue separation in all forms of junctional EB is through the lamina lucida of the basement-membrane zone immediately beneath the plasma membrane of basal epidermal cells (Fig. 39.8a). The hemidesmosomes tend to be sparse and very small, especially in the more severe forms of the disease (Fig. 39.8b) [3–5]. In addition, the hemidesmosome subbasal dense plates may be indistinct or attenuated [4,5], and the association between hemidesmosomes and the basal keratinocyte keratin filament network is reduced [5]. Keratinocytes from junctional EB patients have shown similar ultrastructural changes *in vitro* [6,7] or after grafting on to nude mice [8]. These hemidesmosome abnormalities are most prominent in the Herlitz form of junctional EB and the subtype associated with pyloric atresia. Although the latter is normally classified as a form of

A row of closely apposed basal keratinocytes is at the top of the split, and a continuous lamina densa (open arrowheads) is below. Bar = 5 μm. (b) In intact skin, hemidesmosomes (arrowheads) are sparse and much smaller than normal. Bar = 1 μm. (Courtesy of Professor R.A.J. Eady, St John's Institute of Dermatology, London, U.K.)

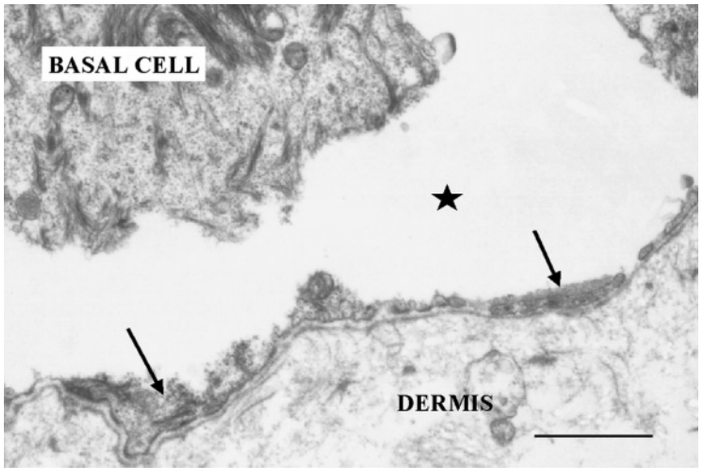

Fig. 39.9 Epidermolysis bullosa with pyloric atresia. A split (star) is present at a very low level in the basal epidermal layer, leaving fragments of basal cells at the base. Bar = 2 μm. (Courtesy of Professor R.A.J. Eady, St John's Institute of Dermatology, London, U.K.)

junctional EB, the ultrastructural level of cleavage is not consistently restricted to the lamina lucida, and may occur intraepidermally at a level just above the basal plasma membrane of the basal keratinocytes (Fig. 39.9) [9]. This is similar therefore to the level of tissue disruption occurring in the skin of knockout mice with ablation of the β4 integrin subunit [10]. It may also resemble the ultrastructural abnormality seen in patients with autosomal recessive EB simplex resulting from defects in plectin (see p. 39.4) [11–13]. In the non-Herlitz forms of junctional EB, the hemidesmosome ultrastructure is variable, and individual hemidesmosomes may show little if any discernible abnormality [4].

Immunofluorescence microscopy indicated an abnormality in the expression of the anchoring filament protein laminin 5 (also known as laminin 332) in the skin of patients with Herlitz junctional EB and in certain patients with non-Herlitz phenotypes [14–16]. Molecular analysis subsequently showed that the Herlitz form of the disease may be caused by mutations in any of the three laminin 5 genes, *LAMA3*, *LAMB3* and *LAMC2* (Fig. 39.10), encoding the α3, β3 and γ2 polypeptide chains, respectively, which copolymerize to form the heterotrimeric laminin 5 protein. The mutations reported so far in Herlitz junctional EB have been homozygous or compound heterozygous premature termination codon mutations [17–20]. These would be expected to result in the production of unstable RNA transcripts and a severely truncated non-functional protein, leading to reduced adhesion at the dermal–epidermal junction and marked skin fragility. The majority of mutations have been found in the *LAMB3* gene, with evidence for mutational hotspots leading to recurrent mutations R42X and R635X [21]. The mutation R635X was found in seven of 24 (29%) mutant alleles in a study of 12 British families with Herlitz junctional EB [22]. The mutation represents a C-to-T transition at a CpG dinucleotide and probably results from deamination of 5-methylcytosine to thymine, a recognized cause of human genetic disease [22].

Non-Herlitz junctional EB (previously known as generalized atrophic benign EB; GABEB) may also result from laminin 5 (laminin 332) gene pathology [23,24]. In a family with non-Herlitz

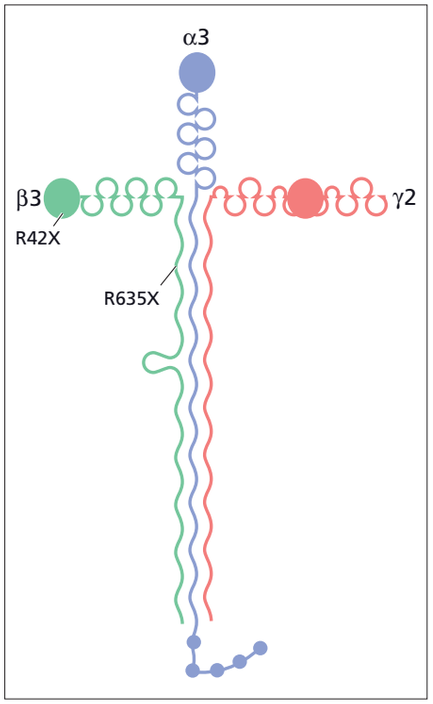

Fig. 39.10 Schematic representation of laminin 5, a heterotrimer comprising α3, β3 and γ2 chains encoded by the *LAMA3*, *LAMB3* and *LAMC2* genes, respectively. The relative positions of two premature stop codon mutations giving rise to R42X and R635X on the β3 chain are shown. These mutations together account for about 50% of all laminin 5 mutations underlying junctional epidermolysis bullosa. (Courtesy of Professor R.A.J. Eady, St John's Institute of Dermatology, London, U.K.)

EB, there was a premature termination codon mutation in exon 3 of one *LAMB3* allele and a missense mutation in exon 7 in the other allele. Exons 3 and 7 encode part of the domain VI on the short arm of the β3 chain. Because this globular domain is thought to be involved with the interaction between laminin 5 and other basement-membrane proteins, such as laminin 6, these mutations might therefore cause destabilization of the macromolecular network involved in adhesion at the dermal–epidermal junction [23].

Other patients with non-Herlitz junctional EB may instead have mutations in the *COL17A1* gene encoding another anchoring filament component, collagen XVII (also known as the 180-kDa bullous pemphigoid antigen [BP180] or BPAG2) [25,26]. The strong similarity in the clinical phenotype of non-Herlitz junctional EB patients with either collagen XVII or laminin 5 gene pathology suggests that the attribution of GABEB is not specific to a particular genotype. Evidence for the role of collagen XVII in odontogenesis is provided by the finding of a combination of a glycine substitution mutation in the helical domain of one *COL17A1* allele, and an internal duplication in the other allele, in a patient with fairly mild skin changes but severe dental abnormalities [27]. The patient's offspring inherited the glycine substitution mutation but had normal second *COL17A1* alleles. Interestingly, although their skins were clinically normal, they had inherited the dental anomaly.

Patients with the subtype of junctional EB associated with pyloric atresia may have a reduced expression of the α6β4 integrin in their skin, as shown by indirect immunofluorescence [28–30]. Staining for other antigens, including laminin 5, is usually normal. The α6β4 integrin is a hemidesmosome-associated heteropolymer and receptor for laminin 5. Knockout mouse experiments with targeted removal of the β4 and α6 subunits showed that homozygous (−/−) mice manifested widespread epithelial separation from the underlying stroma and major ultrastructural changes in the hemidesmosomes [10,31,32]. Mutations in genes for the β4 and α6 integrin chains, *ITGB4* and *ITGA6*, have been shown to underlie this form of EB [33–36] and, in some cases, the phenotype may be predicted by the nature of the mutations.

Clinical subtypes

Junctional EB has the following subtypes.

Herlitz junctional epidermolysis bullosa [1,2]

Synonyms

- Epidermolysis bullosa letalis
- Epidermolysis bullosa atrophicans generalisata gravis

Fig. 39.11 Facial erosions in junctional epidermolysis bullosa (Herlitz). (Courtesy of Professor R.A.J. Eady, St John's Institute of Dermatology, London, U.K.)

Fig. 39.12 Junctional epidermolysis bullosa (Herlitz). (Courtesy of Professor R.A.J. Eady, St John's Institute of Dermatology, London, U.K.)

Blistering and erosions are present at or soon after birth and rapidly become generalized. The whole skin is extremely fragile and lifting or turning the baby may cause extensive blistering or peeling away of the epidermis. Eroded areas are often very slow to heal. Healing may result in atrophic scarring. Milia are not generally seen, although they may occur after secondary infection. Involvement of the oral and pharyngeal mucosa is frequent and may be severe; hoarseness and stridor may indicate laryngeal or supraglottic involvement, most notably potentially life-threatening stenosis or stricture [3,4]. Vesicles have been reported in the trachea and bronchioles post-mortem [5,6]. There is no further risk of tracheolaryngeal compromise on or after about age 6. Many infants die early in infancy with overwhelming infection or from failure to thrive [7], but those surviving the first few months will often develop distinctive lesions characterized by non-healing, crusted erosions containing exuberant granulation tissue [1,8]. These typical lesions occur symmetrically around the nose and mouth (Fig. 39.11) but also in other sites including the neck, trunk, buttocks, and rarely within the uppermost respiratory tree (Fig. 39.12). The combination of chronic infection and loss of protein and iron from the skin, in addition to poor feeding, contributes to impaired healing and refractory anaemia [9]. The teeth show abnormal enamel formation, but normal dentine [10], and as a result are malformed, pitted and lost prematurely. Following blistering and erosions, the formation of exuberant granulation tissue on the nail folds and nail bed leads to shedding of the nails and bulbous changes of the fingertips (Fig. 39.13). Blisters may occur on the cornea, resulting in pain, erosions, scarring, and, very rarely, blindness [11]. A variety of genitourinary tract complications may occur including urethral meatal stenosis, urinary retention, hydronephrosis and bladder hypertrophy [12]. Squamous cell carcinoma, similar to that occurring in dystrophic EB (see below), may also occur in non-Herlitz junctional EB [13–15], at times with a fatal outcome. Keratoacanthoma has also been reported [16].

Generalized non-Herlitz junctional epidermolysis bullosa

Synonyms
- Epidermolysis bullosa atrophicans generalisata mitis
- Generalized atrophic benign epidermolysis bullosa (GABEB)

Hashimoto *et al*. [1] first described this condition in 1976. Hintner and Wolff [2] coined the acronym GABEB. The early clinical course may be similar to the Herlitz form of junctional EB with generalized skin fragility and blistering, but the patients usually survive to adulthood [2–8]. Although blistering persists, there is gradual lessening in severity of the disease with age. Mucous membranes are involved, but less severely than in the Herlitz form of junctional EB. The teeth show severe enamel defects (Fig. 39.14) and may fail to erupt normally. The nails are dystrophic and frequently missing, especially on the toes. Approximately 3–5% of patients may develop a degree of pseudosyndactyly, clinically suggestive of dystrophic EB. These patients were originally said to have 'cicatricial' junctional EB (see below). Typically, the lesions in non-Herlitz junctional EB heal with atrophic scarring, which can easily be mistaken for the scarring seen in dystrophic EB, especially on the lower legs (Fig. 39.15) or backs of the hands. Post-inflammatory hypopigmentation or depigmentation may be present in areas of scarring. An important sign of this form of EB is the poor hair development; the alopecia affects the scalp (Fig. 39.16), eyebrows and eyelashes, and body hair is also sparse or absent. Pigmented naevi, or acquired macular hyperpigmented lesions with irregular borders, are common [2–4]. Oesophageal stricture [2], laryngeal involvement [3], oral erosions [2,3,6], corneal ulcers [6,9], hypoacusis [1,2] and urethral stricture [10,11] have all been reported.

Fig. 39.17 Hyperkeratosis with erosions on soles in non-Herlitz junctional epidermolysis bullosa. (Courtesy of Professor R.A.J. Eady, St John's Institute of Dermatology, London, U.K.)

Localized junctional epidermolysis bullosa

Localized forms of non-Herlitz junctional EB have been recognized [12,13]. Typical clinical manifestations include nail dystrophy, dental enamel changes and blistering involving the lower legs and feet only [10,12]. In a second report of two affected sisters, the skin was generally fragile, but the atrophic changes were most noticeable on the lower legs and dorsa of the feet. The nails were dystrophic, but hair and teeth appeared normal [13]. Chronic, painful erosions associated with hyperkeratosis were present on the soles. In the rare form of 'inverse' non-Herlitz junctional EB [14,15], the whole skin is fragile and blistering starts during the neonatal period in rather generalized distribution. Later, the lesions affect chiefly the groin, perineum and axillae ('inverse' sites). Healing may result in small, atrophic, white streaks. Dysplastic teeth, erosions of the cornea and feet (Fig. 39.17) and nail dystrophy, are all features.

Junctional epidermolysis bullosa with pyloric atresia

This rare disorder is normally included as a subtype of junctional EB, although, not uncommonly, the true level of blistering has been found to be in the cytoplasm of basal keratinocytes, just above the plasma membrane, rather than within lamina lucida. These latter cases therefore might more appropriately be classified as EB simplex (see p. 39.3) and have therefore now been also included under this major EB heading. Many with this disorder have now been reported [1], yet only a few have survived beyond the first few months of life. Blistering is usually present at birth, following a pregnancy complicated by polyhydramnios. The lesions are usually widespread and can result in atrophic scarring. The teeth are hypoplastic, lacking normal enamel, and the nails are dystrophic. Early attempts at feeding result in vomiting, which is not bile-stained. In a series of five patients [2], four died at the age of 1–2 months; the fifth survived for over 4 years, but had constant haematuria and dysuria and recurrent urinary tract infections. Hayashi *et al.* [1] have made a strong case for surgical correction of the congenital pyloric atresia. Of the five patients in their report, four (aged 17 months to 16 years) were moderately well, despite complications such as retarded growth and hydronephrosis. The fifth patient died of respiratory distress, probably caused by aspiration, and had renal complications. The variable clinical outcome in this disorder will probably be explained, to some degree, by the nature of the mutations affecting either the α6 or β4 integrin subunits [3].

Late-onset junctional epidermolysis bullosa

Synonym
- Epidermolysis bullosa progressiva

This condition was originally named EB dystrophica–neurotrophica by Gedde-Dahl because of the association of partial deafness [1]. The onset is delayed until childhood or adolescence, and nail dystrophy is a common presentation. Blistering occurs on the hands and feet. Later, knees and elbows are involved. Progressive atrophic changes lead to early loss of fingerprint patterns and mild finger contractures. The tooth enamel may be defective and the tongue papillae may disappear [2]. The oral mucosa is sometimes involved. The ultrastructural changes are said to be distinctive and show widening of the lamina lucida with deposition of amorphous material. The hemidesmosomes are ultrastructurally normal [2–4]. The molecular basis is unknown.

Cicatricial junctional epidermolysis bullosa

Three patients have been reported in whom blistering had healed with scarring and resulted in loss of nails, alopecia, syndactyly and contractures. The oral mucosa was involved and there was stenosis of the anterior nares [1]. Based on findings through 1999 [2], in which about 3% of all of the National EB Registry patients were found to have some degree of pseudosyndactyly, this rare phenotype has been included under the heading of non-Herlitz junctional EB. There is no evidence that this form of junctional EB has a distinct genotype.

Laryngo-onycho-cutaneous syndrome (LOC syndrome)

Synonym
- Shabbir's syndrome

This disorder, described by Shabbir *et al.* [1], included 22 patients from 13 mostly consanguineous Pakistani families. It starts in infancy and affects both sexes. Chronic erosive lesions affect the face, mainly around the nose and mouth, and, to a lesser extent, the limbs, trunk and genitalia. The nails are also involved and the third constant feature is hoarseness. The teeth may be notched. In a detailed study of three children, Phillips *et al.* [2] emphasized the additional feature of conjunctival lesions, which were also constant in their patients. Although originally considered as an entity distinct from junctional EB, LOC syndrome has recently been included as a subtype, since it is associated with mechanical fragility of the skin, ultrastructural features of the hemidesmosomes consistent with junctional EB, and mutations in the laminin 5 gene.

Dystrophic epidermolysis bullosa

The dystrophic forms of EB are characterized by skin fragility, blistering, scarring, nail changes and milia formation. Unlike junctional EB, there are both autosomal recessive and autosomal dominant subtypes. Recent studies have shown a number of genotypic and phenotypic differences between these two major subtypes of dystrophic EB, and a number of newer clinical variants have emerged. However, the definition of the subtypes of dystrophic EB is somewhat arbitrary, representing more quantitative than qualitative phenotypic differences [1]. Genotype–phenotype correlation is relatively weak among recessive dystrophic EB patients, and there are no significant hotspots within the *COL7A* gene.

Molecular pathology [1–3]

In contrast to EB simplex or junctional EB, in which several genes are now recognized in the pathogenesis of these disorders, both autosomal dominant and recessive forms of dystrophic EB are caused by mutations in a single gene, *COL7A1*, which encodes the anchoring fibril protein, type VII collagen.

Ultrastructurally, the level of blistering or tissue cleavage in all dystrophic forms of EB is immediately below the lamina densa of the epidermal basement membrane, at a site normally occupied by anchoring fibrils (Fig. 39.18) (see Chapter 3 for a fuller description of these and other structures in the basement-membrane zone) [3].

Quantitative electron microscopy and immunoelectron microscopy have shown that anchoring fibrils in dystrophic EB are reduced in number, morphologically altered or completely absent [4,5]. Immunofluorescence staining of the skin of patients using antitype VII collagen antibodies showed that the normal bright linear staining is absent in severe generalized recessive dystrophic EB, but present in dominant dystrophic EB [6–8]. In the milder or more localized form of recessive dystrophic EB, the

immunoreactivity may be attenuated or normal in intensity. In the 'inverse' form of recessive dystrophic EB, type VII collagen is normally expressed but the anchoring fibrils are structurally abnormal [9]. These ultrastructural and immunohistochemical findings indicated that type VII collagen was the candidate gene for at least the recessive forms of dystrophic EB and probably for the dominant form too. These clues were supported by genetic linkage of both dominant and recessive forms of dystrophic EB with the type VII collagen gene locus [10–13], which had been mapped to chromosome 3p21 [14]. Other studies showing abnormalities of collagenase in skin and dermal fibroblasts from patients with recessive dystrophic EB indicated that the collagenase gene was also a candidate [15]. However, this was not borne out by subsequent linkage analysis [16,17] although many experts still believe that altered collagenase activity may play a secondary role in the aberrant wound healing seen in recessive dystrophic EB.

Cloning and sequencing of the human type VII collagen gene (*COL7A1*) and cDNA revealed that the gene is highly complex, containing a total of 118 exons within approximately 32 kb of genomic DNA [14,18–21]. Type VII collagen is a homotrimer (α_1[VII]$_3$) in which each pro-α chain has a large amino-terminal non-collagenous domain (NC-1), a central collagenous domain of Gly-X-Y repeats with several interruptions, and a small carboxy-terminal non-collagenous domain (NC-2). The formation of antiparallel dimers involves cleavage of the NC-2 domain [22]. Anchoring fibrils consist of laterally associated aggregates of the dimers.

Numerous *COL7A1* mutations have been documented. The most severe (Hallopeau–Siemens) subtype of recessive dystrophic EB is caused by premature termination codon mutations on both *COL7A1* alleles [23–26]. Heterozygote carriers of these mutations are phenotypically normal, and it is presumed that a truncated polypeptide, encoded by the mutant allele, is unable to take part in triple helix formation without its collagenous domain, leaving the wild-type polypeptide free to form normal trimers [1]. Ultrastructural morphometric analysis has shown that the number of anchoring fibrils is reduced to about half the normal value in the heterozygotes [27]. In the milder forms of recessive dystrophic EB, typically a premature termination codon mutation on one allele combines with a missense mutation or in-frame deletion on the second allele [28]. The net result is thought to be synthesis of type VII collagen molecules that assemble into unstable and relatively weak anchoring fibrils.

Detailed studies correlating clinical, ultrastructural and immunofluorescence changes with different combinations of mutations in *COL7A1* have helped in the understanding of the phenotype diversity in recessive dystrophic EB [29,30]. Dominant dystrophic forms of EB have been shown exclusively to be associated with glycine substitutions within the triple helical collagenous domain of the type VII molecule, characterized by a Gly-X-Y repeating amino-acid sequence [1,31]. These mutations are thought to have a dominant negative effect on the processing or function of the normal gene product. The amino acid substitutions are likely to destabilize the triple helix, impair the normal secretion of the molecules and make them susceptible to intracellular degradation. Assuming equal expression of both normal and mutant alleles, only approximately 13% of the triple-helical molecules will be normal [1]. This would help to explain the ultrastructural observations of reduced numbers of anchoring fibrils, some of which appear normal [4,5].

In the absence of a positive family history, it is often difficult to determine whether a single patient with mild to moderately severe dystrophic EB will have autosomal recessive or *de novo* dominant

disease. Recent molecular studies of *COL7A1* have established that the vast majority of such cases are recessive in nature. Nevertheless, a small number of *de novo* dominant patients have been documented. Three patients with *de novo* dominant disease were found to have the same glycine substitution mutation, G2043R in *COL7A1*. This mutation is the most common *COL7A1* mutation in dominant dystrophic EB throughout the world. These cases emphasize the importance of molecular analysis in providing accurate genetic counselling in patients with apparent sporadic dystrophic EB [32,33].

In addition to their occurrence in classical forms of dominant dystrophic EB, glycine substitution mutations have been demonstrated in rarer variants including Bart's syndrome [34], pretibial dystrophic EB [35] and EB pruriginosa [36,37]. Other types of *COL7A1* mutations may also occur in EB pruriginosa [37].

Considerable research is now being focused on the mechanisms of carcinogenesis in recessive dystrophic EB. In one intriguing study utilizing a mouse model, data were presented which suggested that the tendency for recessive dystrophic EB keratinocytes to develop into squamous cell carcinomas was dependent on expression of the NC1 domain of type VII collagen [38]. Very recently, however, other data were published which suggest that this proposed mechanism, as elegant as it appears, is an oversimplified one, since tumours have also now been proven to occur in patients lacking any detectable expression of type VII collagen [39].

Clinical subtypes

Dystrophic EB has the following subtypes.

Autosomal recessive forms

Severe generalized recessive dystrophic epidermolysis bullosa (formerly named Hallopeau–Siemens variant) [1]

Synonyms

- Polydysplastic epidermolysis bullosa
- Epidermolysis bullosa dystrophica generalisata gravis

Bullae are present at birth or appear in early infancy. The clinical presentation may include localized absence of skin ('Bart's syndrome') especially affecting the hands, feet and lower legs in a flame-shaped, glove or sock-like distribution [2]. The skin can be extremely fragile in this form of EB. Blisters develop spontaneously or after the mildest trauma on any part of the skin and may be haemorrhagic. Healing lesions leave atrophic scars like cigarette paper; thicker scars may occur particularly over the large joints, such as the knees. Milia formation is a nearly constant feature. Although the whole of the skin is fragile and at high risk of developing blisters, the main sites of predilection are those subjected to repeated friction and other forms of physical trauma. These include the knees, elbows, hands, feet, back of the neck, shoulders and over the spine (Fig. 39.19). Ulcers over the spine or shoulders may heal extremely slowly. Chronic erosions and ulcers tend to become covered with a slough, often associated with heaped-up crusting and scaling, increasing the risk of secondary infection. Occasionally these lesions heal with excessive granulation tissue, reminiscent of that seen in Herlitz junctional EB. Pruritus is frequent, and constant rubbing and scratching may induce blisters. Considerable pain may be associated with dressing changes.

The scalp is often involved. Hair growth on the scalp and body is impaired and scarring alopecia may occur (Fig. 39.20). During childhood, repeated blistering with progressive scarring causes fusion ('pseudosyndactyly') of adjacent fingers and toes [3]. If left untreated, the digits then undergo progressive contractures and gradually become encased in a cocoon-like covering of thin scar tissue (Fig. 39.21). Disuse of the hands results in bony resorption and muscle atrophy.

Non-cutaneous epithelia are also at risk of developing blisters, erosions and scars. Oral lesions may be severe, leading to marked

Fig. 39.22 Dental changes and blistering on lips in generalized recessive dystrophic epidermolysis bullosa. (Courtesy of Professor R.A.J. Eady, St John's Institute of Dermatology, London, U.K.)

ankyloglossia and microstomia. Patients are often unable to protrude the tongue outside the mouth, or to open the mouth normally. The gums are fragile, and gentle tooth brushing may induce epithelial disruption with bleeding. The lingual papillae are lost and the surface of the tongue becomes smooth, shiny and atrophic. Although there is no evidence for a primary abnormality of dental enamel in dystrophic EB, the teeth are at a high risk of developing caries (Fig. 39.22) because of prolonged exposure to food. This stems from a reduced ability to chew the food normally and diminished circulation of saliva. Oral secretory immunity may be compromised [4]. In one series, the frequency of caries in the recessive dystrophic form of EB was about five times greater than in dominant dystrophic EB [5]. The loss of dentition has several ramifications. First, the intake of solid food is impaired, with potential consequences affecting the patient's nutrition and tendency to suffer with constipation. Secondly, there is a secondary loss of bone within the alveolar ridges of the jaw, preventing later corrective dental treatment such as the use of tooth implants.

Oesophageal involvement is a serious and invariable complication of this form of EB [6–9]. It may occur very early in life, even in infancy, and by the age of 20–30 years will have affected most patients. Blistering in the oesophagus may cause acute pain and dysphagia, manifesting with difficulty in swallowing solids. With time, partial or complete obstruction may result from oesophageal stricture, caused by scarring and fibrosis; or from web formation [7,9]. Stricture occurs more frequently in the upper third of the oesophagus, and may be multiple. In time, the oesophagus is thought to shorten as a result of fibrosis and is then possibly at additional risk from gastro-oesophageal reflux. Rare complications of oesophageal involvement include spontaneous perforation [8] and bringing up an oesophageal cast. Oesophageal involvement is another cause of poor nutrition.

Perianal blistering, erosions and painful fissures are common in childhood [7]. Later, anal stenosis from scarring may develop. These changes will contribute to a child's reluctance to defecate, leading to faecal retention, abdominal pain and bloating. Chronic constipation and eventual faecal impaction are also common. A low-fibre diet adds to this complication [6]. A minority of patients may experience urethral meatal stenosis [10].

The main ocular complications include symblepharon, which in its more severe form may involve joining of the lid margin to the peripheral cornea; limbal broadening, which is often asymptomatic; corneal erosions; and corneal opacity or scarring, presumably resulting from recurrent corneal blisters and erosions [11–13].

General physical development is retarded. Most patients are very thin and have a short stature. Some blood vitamin and trace metal levels are low [14] and immune function may be impaired because of reduced natural killer cell activity [15]. Severe refractory multifactorial anaemia adds to management problems. Osteopenia and osteoporosis are not uncommon in patients with severe generalized recessive dystrophic EB.

An important sequela of this form of EB is the development of squamous cell carcinomas, which occurs in the majority of patients with both major subtypes of generalized recessive dystrophic EB, as well as a subset of those with inverse disease. These are often multiple primary tumours which, histologically, are usually well differentiated. They may be difficult to identify clinically at an early stage, appearing as a non-healing erosion or crusted or hyperkeratotic lesion. In keeping with other scar carcinomas, these tumours behave aggressively and often metastasize, eventually with a fatal outcome. Life-table analysis from the National EB Registry [16,17] indicates the high probability of death within 5 years of diagnosis of the first squamous cell carcinoma. Patients as young as 13 years may be at risk of developing cancer [18]. These tumours usually arise in any chronically scarred area of skin (Fig. 39.23). Less frequently, they may occur in mouth (including the tongue) and very rarely within the oesophagus [19]. The large majority of carcinomas are on the limbs, often in areas of chronic, non-healing ulceration [20]. The tumours tend to recur locally, despite primary treatment using an apparently wide-surgical excision or Mohs' surgical resection. Recurrences and metastases are generally unresponsive to chemotherapy or radiotherapy. There is also a low but increased risk of developing malignant melanoma in childhood [16], but the incidence of other internal malignancies does not appear to be increased. Systemic amyloidosis is a further complication [21,22] that may involve internal organs

Fig. 39.23 Squamous cell carcinoma arising in an area of chronic scarring in a patient with generalized recessive dystrophic epidermolysis bullosa. (Courtesy of Professor R.A.J. Eady, St John's Institute of Dermatology, London, U.K.)

such as the heart or kidneys. The lifetime risk of death from renal disease, either due to glomerulonephritis (presumably post-streptococcal) or amyloidosis, is about 12% for patients with severe generalized recessive dystrophic EB [23].

Most patients experience a delay in development of secondary sexual changes. Despite the severity of the skin disorder, sexual function may be sufficiently normal in some female patients to undergo an uncomplicated pregnancy with the vaginal delivery of a normal healthy child (R.A.J. Eady & S. Bewley, unpublished observations 1996) [24].

Generalized recessive dystrophic epidermolysis bullosa, other (previously named non-Hallopeau–Siemens subtype)

The condition shares several cutaneous and extracutaneous features with severe generalized recessive dystrophic EB, but is generally much milder. The skin and mucosae are very fragile, but lesions, including nail changes, milia and atrophic scarring, tend to be more localized, and similar to those seen in classical dominant dystrophic EB (Fig. 39.24). Growth retardation and anaemia are usually mild. Pseudosyndactyly, oesophageal involvement and squamous cell carcinoma may also occur, but these complications are usually milder or less frequent than in Hallopeau–Siemens dystrophic EB.

Inverse recessive dystrophic epidermolysis bullosa [1,2]

The primary areas of blistering and scarring include the groins, axillae, neck (Fig. 39.25) and lumbar area. Traumatic corneal erosions and oesophageal lesions are common. Nail dystrophy, mucous membrane involvement and dental changes are similar to those in the generalized form of the condition. Patients are also at risk of developing squamous cell carcinoma.

Autosomal dominant forms

Generalized dominant dystrophic epidermolysis bullosa

Synonym

- Hyperplastic (Cockayne–Touraine) and albopapuloid (Pasini) variants

A problem with most classifications of EB [1] has been the convention of subdividing the majority of cases of dominant dystrophic EB into the mutually exclusive Cockayne–Touraine or Pasini variants. In 1928, Pasini described a single family whose EB was distinguished by the presence of numerous white papules that he called 'albopapuloid' lesions. In other respects, it is unclear how such individuals can confidently be distinguished from those with the so-called 'Cockayne–Touraine' phenotype. It has been said that one form tends to be more severe than the other, but the issue is clouded by the fact that albopapuloid lesions, which are most often seen on the trunk (Fig. 39.26), are probably not specific, and variations in the onset and severity of the disease have been described, even within the same kindreds [1,2]. Differences in ultrastructural and biochemical findings have also been reported (see [1] for review). The histogenesis of albopapuloid lesions is unclear, and reports have alluded to both epidermal and dermal abnormalities, including alterations of collagen and elastic tissue (reviewed in [2]). For those reasons these particular eponymous descriptions have been abandoned and, in the absence of genotypic proof to the contrary, are both included under the heading of generalized dominant dystrophic EB. The main feature of dominant dystrophic EB is that the skin is generally less fragile than in severe generalized recessive dystrophic EB. Blisters usually follow sharp knocks or glancing blows rather than mild friction, and therefore can be difficult to induce for a diagnostic skin biopsy. Indeed, of all forms of EB, including EB simplex, skin from patients with dominant dystrophic EB is the least likely to be induced to blister following conventional diagnostic techniques. Blisters mainly occur in skin overlying bony prominences, such as the knees and ankles, and dorsa of the hands or feet. The most consistent findings are localized scarring with milia formation and dystrophic nails. Nail dystrophy is probably the most important diagnostic feature of the disease, especially in adults, because many patients have only limited scarring, which becomes less noticeable with age. The nail plates, particularly of the large toes, are often diminutive (Fig. 39.27) or entirely absent, where the normal nail is replaced by atrophic scar tissue. Blistering in the mouth is usually mild and the teeth are generally normal. However, perianal lesions may cause considerable pain, especially in children. In rare kindreds, an occasional family member may present solely with nail dystrophy.

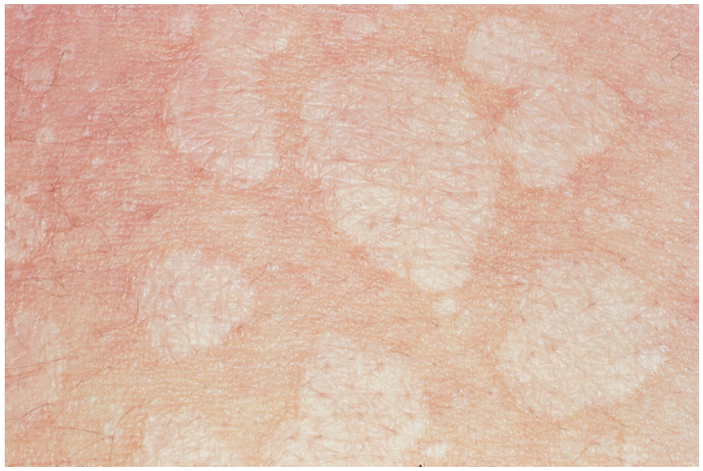

Fig. 39.26 Albopapuloid lesions on the lower back of a patient with dominant dystrophic epidermolysis bullosa. (Courtesy of Professor R.A.J. Eady, St John's Institute of Dermatology, London, U.K.)

Fig. 39.27 Nail changes and scarring of skin on the backs of toes in dominant dystrophic epidermolysis bullosa. (Courtesy of Professor R.A.J. Eady, St John's Institute of Dermatology, London, U.K.)

Clinically, it is often impossible to distinguish this form of dominant dystrophic EB from the localized recessive dystrophic forms, making genetic counselling impossible in the absence of a positive family history or accurate molecular diagnosis.

Congenital localized absence of skin

Synonym
- Bart's syndrome

In 1966, Bart described a kindred with localized absence of the skin over the lower legs associated with cutaneous blistering and mucous membrane and nail involvement [1]. The condition, which appeared to follow an autosomal dominant mode of inheritance, was thought to be a form of EB simplex [2]. However, localized absence of the skin has been reported by others in association with simplex [3], junctional [4,5] and dystrophic EB [6]. In view of these findings, congenital localized absence of the skin should be regarded now as a manifestation of EB, instead of a separate entity or syndrome. The original family described by Bart has since been shown to have dominant dystrophic EB, caused by a glycine substitution mutation in *COL7A1* [7].

Pretibial dystrophic epidermolysis bullosa

In 1946, Kuske [1] reported a patient with itching, blisters, atrophy and scarring on the shins. There were further reports of similar patients [2,3]. In one family with a dominant transmission of the disease, the clinical features were variable [3]. Several authors have referred to this condition as pretibial EB [4–6], given the tendency for the lesions to develop in the pretibial areas. Lesions are usually violaceous, mimicking lichen planus. Nails on both hands and feet tend to be dystrophic. This condition is an autosomal dominant one.

Epidermolysis bullosa pruriginosa

In 1994, McGrath *et al.* [7] delineated a group of eight patients with a highly distinctive phenotype in which the overriding symptom is severe pruritus. The authors named the condition 'EB pruriginosa' to highlight this combination of clinical features. EB pruriginosa presents either at birth with mild acral blistering and erosions, or during infancy or childhood. Violaceous papular and nodular lesions, often in a linear arrangement, are mainly confined to the shins (Fig. 39.28) and forearms, although rare lesions may occur on the trunk. In adults, the lesions are chiefly lichenified plaques. Histologically, a split may be evident at the dermal–epidermal junction, although frank blisters are rarely seen. Apart from scarring with milia, toenail dystrophy is a consistent finding in adult patients.

Most cases are sporadic. However, both autosomal recessive and dominant inheritance is recognized [8]. The cause of the severe pruritus is unknown; however, a number of patients have raised blood levels of immunoglobulin E (IgE) (R.A.J. Eady, unpublished observations 1997), suggesting a possible atopic background. Clinically, EB pruriginosa has to be distinguished from lichen simplex, hypertrophic lichen planus, Nékam's disease, cutaneous amyloidosis and dermatitis artefacta [9]. It shares several features with the pretibial form of dystrophic EB, but is clinically much more striking.

Bullous dermolysis of the newborn

In 1985, Hashimoto *et al.* [1] reported a newborn with blistering developing on the extremities soon after birth. The bullae quickly resolved and there was apparently no scarring or milia formation. However, others have subsequently reported focal atrophic scarring, milia, and/or nail dystrophy, as well as more generalized blistering, in some affected family members. The name 'transient bullous dermolysis of the newborn' was coined to describe this uniquely self-limited clinical course associated with a sublamina densa level of cleavage. Ultrastructurally, the basal epidermal keratinocytes were shown to contain electron-dense stellate bodies. The skin condition resolved completely and a year later there were only mild residual pigmentary changes. Later, Fine *et al.* [2] used immunofluorescence and immunoelectron microscopy to show that these intracellular inclusions contained type VII collagen, and that the underlying dermal–epidermal junction usually lacked normal anchoring fibrils and type VII collagen staining (Fig. 39.29). The phenotype of these patients resembled a mild dominant or localized recessive form of dystrophic EB, and included small

numbers of tense blisters, milia and mild focal atrophic scarring. Fine *et al.* [2] further demonstrated that these immunohistochemical features tended to revert to that of normal non-EB skin, showing intense uniform linear immunostaining of the dermal–epidermal junction with antibodies to type VII collagen, at about the time most blister formation had ceased. It was thought that this phenomenon represents a transient secondary abnormality in packaging, transport or incorporation of a presumably mutated type VII collagen into the dermal–epidermal junction during early infancy in these patients. Since rare patients continue to develop blistering beyond infancy, the condition has recently been renamed bullous dermolysis of the newborn.

The clinical and microscopic features were later confirmed by Schofield *et al.* [3] in other patients. Smith and Sybert [4], however, described similar ultrastructural and immunocytochemical findings in a patient with recessive dystrophic EB whose prognosis was poor. Phillips *et al.* [5] also showed that the presence of

intraepidermal type VII collagen in infancy was not always predictive of a good clinical outcome.

One of the kindreds reported by Fine *et al.* [2] has since been shown to have a *COL7A1* mutation typical of dominant dystrophic EB [6]. *COL7A1* mutations have also been reported in other cases [7].

Recessive dystrophic EB, centripetalis

A patient was reported who had generalized blistering at birth but within the first year of life had her skin disease activity confined to the hands and feet [1]. Over several decades her blistering slowly progressed proximally, in centripetal manner, with active blistering and milia only along the active edges and atrophic scarring and nail dystrophy distally. At the time of death in late adulthood from unrelated causes, no blistering was yet present on the trunk, face, or neck. A *COL7A1* mutation was demonstrated.

Diagnosis

Despite the impressive advances in the molecular genetics of different forms of EB, the initial diagnosis still relies largely on a careful clinical examination, enquiry into the family history and establishing the level of blister formation [1]. Because the clinical features may be unhelpful or even misleading, especially in a neonate, the diagnosis will often rely on microscopic analysis of a skin biopsy. Electron microscopy and immunofluorescence mapping are still the best methods for evaluating EB skin samples. The cryopreserved tissues obtained for immunofluorescence mapping may also be stained with specific monoclonal and polyclonal antibodies so as to provide additionally useful diagnostic information. Ideally, tissue should be acquired at the same time for evaluation by both techniques.

Skin biopsy

The main objectives of skin biopsy are first to establish the level of blistering or tissue separation and, secondly, to search for other clues that may be indicative of the underlying disorder and therefore helpful in the diagnosis. The importance of the correct biopsy technique cannot be overstressed. Most blisters that are clinically evident, and especially those with bloodstained contents, are often more than 12 h old and therefore too old for diagnostic purposes. Older blisters may cause severe diagnostic difficulty because false-negative immunostaining caused by proteolytic antigen degradation, re-epithelialization under the blister roof and multiple cleavage planes may all occur. A sample of non-blistered skin that has been gently rubbed to produce a mild erythema is preferable, because this will usually contain a cleavage plane with few if any secondary changes.

Because the diagnostic signs are mostly seen in and around the dermal–epidermal junction, shave biopsy samples are preferable to thicker specimens when electron microscopy is being contemplated. Small punch or shave biopsies may be obtained for immunofluorescence mapping. Care must be taken to ensure that a sufficient amount of dermis is present, to allow examination of the entire dermal–epidermal junction. It is often better to take two or three small pieces for different types of examination, such as electron microscopy and immunofluorescence. Attempts to subdivide a larger biopsy specimen can result in detachment of the epidermis from the dermis and spoil the sample for critical microscopic analysis. The samples should be immediately immersed in suitable fixative for electron microscopy, or in a freezing liquid, such as isopentane precooled with liquid nitrogen, after embedding in OCT Tissue-Tek Compound (Miles Inc, Diagnostics Division, IN 46515, USA), for immunofluorescence. The samples can then be stored in a –70°C freezer or in liquid nitrogen until required for analysis. Michel's transport medium can be used for both immunofluorescence and electron microscopy [2], although the ultrastructural preservation will be variable and often inadequate for detailed electron microscopic analysis.

Electron microscopy

The chief purpose is to demonstrate the level of tissue separation or blistering [1,2]. As indicated in the sections on molecular pathology of EB subtypes, the split is intraepidermal in EB simplex, in junctional EB it is through the lamina lucida, just below the lowermost plasma membrane of basal cells, and in dystrophic EB it is beneath the lamina densa. In Kindler syndrome the cleavage plane may be within and above the lamina lucida. Other ultrastructural features important for diagnosis are that hemidesmosomes are

generally sparse and small in the more severe forms of junctional EB [3,4] and anchoring fibrils are reduced in number, absent or structurally abnormal in dystrophic forms of EB [5–7]. A clear distinction cannot be made between the dominant and localized recessive dystrophic forms, even with morphometric analysis of anchoring fibrils [3]. Intraepidermal electron-dense stellate bodies are a marker of bullous dermolysis of the newborn (Fig. 39.29). In the Herlitz form of junctional EB and in the form of EB associated with pyloric atresia, hemidesmosome plaques are often minute, and subbasal dense plates are severely attenuated or absent.

In EB simplex, the most striking changes are seen in the Dowling–Meara form, where tonofilament clumping in basal keratinocytes (Fig. 39.1) is pathognomonic [8]. In the rare generalized or autosomal recessive forms of EB simplex, the tonofilaments may be severely depleted or absent from the basal cells. In EB superficialis, the cleavage level is usually subcorneal. Despite their value in diagnosis in most instances, the ultrastructural features in a given diagnostic biopsy sample can be difficult to interpret. Briggaman [9] has illustrated how the level of cleavage may appear to vary, not only between skin samples from the same patient but also within the same sample.

Antigen mapping

As an alternative to electron microscopy, the level of blister formation can be determined using indirect immunohistochemical staining [1–3]. The aim is not to look for reduced expression of skin antigens, but to stain the dermal–epidermal zone using antibodies to proteins that are strongly expressed in both normal skin and skin from patients with different forms of EB. For example, sera from bullous pemphigoid patients or, preferably, an anti-BP230 antibody can be used to stain the lower surface of basal cells (containing hemidesmosomes), and antikeratin 14 antibody to stain the cytoplasm of basal epidermal cells. Anti-type IV collagen antibody will stain the lamina densa of the epidermal basement membrane, whereas anti-laminin-1 antibody will stain the upper lamina lucida. In EB simplex, all antibodies (except antikeratin) stain only the base of the split. Antikeratin stains the roof and the floor (but this is difficult to see in low-level separations). In junctional EB, antikeratin, anti-laminin-1 and bullous pemphigoid antibodies stain the roof; whereas anti-type IV collagen staining is on the floor. In dystrophic EB, all antibodies stain only the roof of the split.

Use of specific antibody probes

This method can be very valuable in diagnosis when used together with electron microscopy or antigen mapping. The purpose is to demonstrate a reduction in, or absence of, expression of certain antigens in the dermal–epidermal junction, which may be indicative of specific abnormalities in junctional and dystrophic forms of EB, as well as Kindler syndrome [1]. Several relevant studies have already been referred to under the sections on molecular pathology of EB subtypes.

In Herlitz and some non-Herlitz cases of junctional EB, caused by laminin 5 mutations, abnormal staining for laminin 5 can be shown using monoclonal antibodies GB3 [2] and K140 [3] (Fig. 39.30). In non-Herlitz junctional EB (generalized atrophic benign EB) with BP180 defects, staining is reduced with anti-BP180, but not with antilaminin 5 antibodies [4]. Antibodies to the α6 or β4 integrin chains will show reduced staining in the skin of patients with EB associated with pyloric atresia [5].

The monoclonal antibody 19-DEJ-1, recognizing 'uncein', an anchoring filament antigen possibly representing a protein with homology with a non-muscle myosin (J.-D. Fine, unpublished data), shows reduced or absent staining in all forms of junctional EB and in approximately 25% of individuals with recessive dystrophic EB [6,7]. LH 7.2 monoclonal antibody, reacting with the amino terminal of the type VII collagen molecule, is probably the most widely used antibody for the diagnosis of recessive dystrophic EB [8]. In cases of EB simplex associated with muscular dystrophy, reduced or absent staining will be found using antibodies to plectin, or HD1 (an antigen that is homologous with plectin) [9–11]. Kindlin-1 staining will be reduced in skin specimens from patients with Kindler syndrome.

Molecular diagnosis

With the discovery of over 10 distinct genes underlying different variants of EB, DNA-based techniques have had an increasingly important application in the diagnosis and prenatal diagnosis of

EB. The information gained from molecular diagnosis is especially useful for genetic counselling and prognosis. When a patient is first seen in the clinic or neonatal unit, it is important to make provision for molecular diagnosis in the management plan, and obtain venous blood or cheek mucosa brushings (collected in ethylenediamine tetra-acetic acid tubes, and *not* in heparin or citrate) for subsequent DNA extraction and analysis in the laboratory.

An example of the power of molecular diagnosis is the ability to discover whether a patient has a dominant or recessive form of dystrophic EB, where neither the family history, a skin biopsy nor the clinical phenotype has been able to provide the information. In a cohort of some 180 families in which distinct *COL7A1* mutations had been identified, there was evidence of only one case derived from a *de novo* germ-line-dominant mutation in a parent [1]. This implies that the large majority of apparently sporadic 'new' cases, with no known family history of EB, are likely to have a recessive rather than a dominant form of dystrophic EB [1]. However, the presumptive *de novo* occurrence of a glycine substitution mutation has also been reported [2,3]. The possibility of germ-line mutations inherited in patients with 'sporadic' dominant dystrophic EB should also be considered [4]. Molecular diagnosis can be valuable in the differentiation of Herlitz from non-Herlitz EB (e.g. in a child) where the skin biopsy findings, including the immunofluorescence results, are equivocal.

The developments in the molecular genetics of the dystrophic and junctional forms of EB have already had a major impact on prenatal diagnosis. First trimester DNA testing is now an option for couples at risk of having affected children (see Chapter 16). Knowledge of mutation 'hotspots' within a population can reduce the time and expense of extensive screening for mutations that might otherwise be necessary [5]. The issue of mutation screening of family members of affected individuals, or unrelated partners, often arises during genetic counselling. In relatives not known to be at high risk of either being a carrier of a recessive gene and therefore of having an affected child, genetic screening may not be offered, or even encouraged. However, there are rare instances where prior screening may have averted an affected pregnancy [6].

Differential diagnosis

Differentiating EB from non-EB, or one form of EB from another, can be very difficult, especially in the neonatal period. At this stage, the following disorders may need to be included in the differential diagnosis of EB: bullous congenital ichthyosiform erythroderma; staphyloccocal scalded skin syndrome; bullous impetigo; incontinentia pigmenti; neonatal herpes simplex; autoimmune bullous disease, such as pemphigus or herpes gestationis, acquired transplacentally; aplasia cutis; focal dermal hypoplasia; and Gunther's disease.

In infants, older children or adults, some autoimmune bullous diseases, such as bullous pemphigoid, cicatricial pemphigoid or linear IgA disease, may show overlapping features with junctional EB or Dowling–Meara EB simplex. EB acquisita may resemble dystrophic EB. Usually the timing of the onset of blistering will allow inherited EB to be distinguished from the autoimmune immunobullous disorders. Pachyonychia congenita, skin peeling syndrome and ichthyosis bullosa of Siemens may rarely be confused with EB in older children or adults.

In the past, Mendes da Costa disease [1] was considered to be a form of EB simplex. The pathogenesis of this rare X-linked disorder, reported in a Dutch family, is still poorly understood. Although blisters are seen, they are not trauma induced [2]. As such, this entity is no longer included within the current classification system for EB.

Treatment

At this point in time there is no specific treatment for any form of EB, and the mainstay of clinical management is based on protection and avoidance of provoking factors. In the more severe forms of EB, it should be remembered that the whole skin and other stratified squamous epithelia, including the oral mucosa, are extremely fragile and vulnerable to blistering from the slightest friction or scrapes. In the milder forms, blistering may not always result from mild friction and may only follow sharp knocks to the skin. Major challenges include the treatment of the neonate with severe generalized disease and the older child, adolescent or adult with the chronic disability that accompanies the severe form of recessive dystrophic EB.

Management of neonates and infants

Because severe blistering and erosions may be associated with junctional, dystrophic or simplex forms of EB in the neonate, an early objective is to establish the diagnosis from an appropriate skin biopsy (see above). This may be particularly relevant for a newborn with Dowling–Meara EB simplex, where the clinical appearance may be confused with Herlitz junctional EB or even dystrophic EB, suggesting a much graver prognosis. The early management of neonates with EB should, where possible, be undertaken in a specialist neonatal or paediatric unit, which has the expertise, staff and resources to manage these vulnerable

babies. A key to successful treatment is expert nursing care. Paediatric nurse specialists with experience of caring for babies and children with EB are often best placed to help with coordinating hospital treatment, training parents and non-specialist nurses at other centres to handle and treat the patients, and prepare for the child's return home. In these specialist centres [1], babies with EB are nursed on thick foam pads, which are covered by a silk sheet. This allows the babies to be held, fed and nursed without subjecting them to undue trauma. The erosions are cleaned with sterile normal saline and covered in comfortable non-adherent dressings. Some EB specialists may prefer to use a topical antiseptic such as stabilized hydrogen peroxide cream (Hioxyl, Quinoderm, UK) or 1% chlorhexidine cream, rather than topical antibiotics, chiefly because of the risk of emergence of antibiotic-resistant bacteria. Another preference is to treat open wounds with 1% silver sulfadiazine cream (Flamazine, Smith and Nephew, UK) or an ointment containing polymyxin B or bacitracin. The topical antibiotic mupirocin is not recommended for regular use, especially in hospital practice, because of the emergence of mupirocin-resistant *Staphylococcus aureus* [2,3]. However, its use for short periods (up to 7 days) in the home, for localized infected areas, is normally safe and effective [4]. Among the newer dressings now favoured for use in children and older patients are Mepitel and Mepilex (Molynycke, Luton, UK). Mepitel is a porous, mildly adherent silicone-based material, which can be left in place for up to 7 days. Any exudate is usually able to pass through the holes in this dressing to be absorbed by a secondary gauze dressing, which can be changed more frequently. Mepilex has a foam backing which provides more protection where needed.

Management of severe generalized recessive dystrophic epidermolysis bullosa

Patients with the more severe forms of recessive dystrophic EB will often survive into middle age and will therefore require continuing care throughout life [5]. Ideally, they should be seen at 6-monthly intervals in a multidisciplinary clinic with expertise to help with the particular needs of these patients. Special precautions should be taken in the use of adhesive tapes, sphygmomanometer cuffs, tourniquets and any other instruments or appliances that might lead to blister formation or shearing of the skin or mucous membranes. The following systems require particular attention.

Oral and dental care [6,7]

Microstomia, intraoral fibrosis and tethering of the tongue (ankyloglossia) make access and examination of the teeth and mucosa difficult. Treatment should start in early childhood, so the involvement of a paediatric dentist with specialist knowledge of the dental complications affecting children with EB is important. Wherever necessary, reconstructive measures should be applied to permanent and primary teeth, to maintain function. These include treatment of caries, and meticulous cleaning of tooth surfaces. Crown placement and even tooth implants (in adults) have been used successfully in some patients. More frequent preventive measures include daily fluoride supplements and the use of a mouthwash containing sodium fluoride and aqueous chlorhexidine.

Fig. 39.31 Barium swallow radiograph showing constriction in the upper oesophagus in recessive dystrophic epidermolysis bullosa. (Courtesy of Professor R.A.J. Eady, St John's Institute of Dermatology, London, U.K.)

Gastrointestinal tract and nutrition [8–12]

Dysphagia and pain on swallowing are common. Oesophageal strictures may be demonstrated by X-ray examination (including barium swallow and cine radiography) (Fig. 39.31) or by endoscopy. Oesophageal spasm, often accompanying an acute obstruction, can sometimes be relieved by administration of calcium-channel blocking agents. More permanent blockage requires an endoscopically guided balloon dilatation [8], which will usually have to be repeated, perhaps several times each year. More radical treatment has included surgical excision of the stricture followed by anastomosis, and colonic interposition [9]. Most patients have gastro-oesophageal reflux, which should be treated with a proton pump inhibitor to prevent further damage to the lining of the oesophagus with the risk of secondary scarring and oesophageal shortening. Constipation is inevitable and often chronic in these patients. The cause is complex and associated in some degree with inadequate fibre in the diet. A high-fibre diet is therefore important, and patients who have difficulty in eating sufficient fibre may benefit from nutritional supplements such as Enrich (Abbot Laboratories Ltd, Maidstone, Berks, UK). Osmotic and stimulant laxatives, as well as faecal softeners, may all have a role and be prescribed according to an individual patient's needs. Lactulose is often the first choice of laxative to be used in treating constipation in children and adults.

Anal blistering and erosions contribute to the constipation and faecal retention, especially in children. Glycerol suppositories used in conjunction with a topical anaesthetic preparation may help. If faecal impaction occurs, more drastic measures, including

manual removal of faeces under general anaesthesia, may be required.

Trying to ensure adequate nutrition with a balanced diet is especially important to maintain growth in children [10,11]. A deficiency of vitamins and trace elements (including zinc and iron) is frequent [12]. Comprehensive nutritional supplementation is only partly effective in maintaining adequate growth, and controlling anaemia and wound healing. The advice of an EB dietician is essential. Feeding through a gastrostomy allows appropriate nutrition in addition to the administration of supplements such as iron, zinc and multivitamins, which children may find difficult to take by mouth [13]. Gastrostomy feeding can be delivered overnight in the home [13]. Parenteral nutrition has also been used [10].

Eyes

External abrasions should be dealt with urgently; they usually require topical treatment with an antibiotic and anaesthetic. Scarring of the lids following blistering may result in inadequate lid closure and loss of normal protection to the eyes. Plastic surgical reconstruction may be indicated. Artificial tears are a useful lubricant.

Musculoskeletal system

Although early exercises and physiotherapy may be helpful, the progress of finger and hand contractures with eventual mitten-type deformity is virtually inevitable. Contractures and tight tethering by scar tissue may also affect elbows and knees. Surgical release of the contracted fingers is a highly specialized procedure and requires skin grafting and postoperative splinting [14–16]. The benefit from surgery is only temporary because most patients need further surgical treatment within a few years. The feet may be involved in a similar process, but a 'degloving' procedure is not recommended, because the foot deformities do not usually prevent the patients from standing or walking.

Anaemia

All patients with the more severe forms of recessive dystrophic EB are anaemic, and the picture is that of an anaemia of chronic disease. Despite the administration of oral iron supplements, the iron stores are usually low as assessed by serum ferritin levels. In patients with widespread lesions and secondary infection, the serum ferritin may not accurately reflect the need for supplementary iron. Instead, the serum iron level may be a better indicator of the requirement for iron replacement in these patients. Parenteral iron is painful if given intramuscularly, especially where the muscles are thin and wasted. Anaphylaxis is a potential risk of intravenous administration. Venofer (Synar-Med, UK), an iron hydroxide preparation, can be given intravenously, and has been used repeatedly in several dystrophic EB patients, with a good response and no serious side effects [17,18]. The haemoglobin levels generally increased, and the patients' sense of well-being improved. Transfusion of packed red cells may be required, especially when the blood haemoglobin level falls below approximately 7.00 g/dL, or when the patient becomes short of breath and more easily fatigued than usual.

Bony abnormalities

Virtually all patients have bony changes, mainly osteoporosis [19]. The cause is multifactorial, and is related to poor nutrition, relative immobility in some patients and previous treatment with systemic glucocorticoids. This last point is especially relevant in older patients. Regular checking of bone density, especially of the hips and spine, usually by dual-energy X-ray absorptiometry (DEXA), is now part of routine management. Treatment with calcium supplements and biphosphonates may be indicated.

Genitourinary tract abnormalities

Patients may infrequently develop a variety of genitourinary and renal complications. Urological intervention is recommended whenever function is compromised although occasionally this has resulted in worsened scar formation. Dialysis has been successfully performed in rare patients having endstage renal disease.

Systemic treatment

Long-term systemic corticosteroid treatment is not used now because of the high risk of complications, and phenytoin, which had appeared to control blistering in certain patients in an open study [20], did not prove to be more effective than placebo in a controlled trial [21]. Other systemic drugs that have been tried with mixed results in small numbers of patients include vitamin E [22,23], minocycline [24], ciclosporin [25,26] and retinoic acid [27]. Although, theoretically, the systemic use of a retinoid such as isotretinoin or acetretin might reduce the risk of squamous cell carcinomas in these patients, there is no evidence yet in support of this presumably lifelong treatment. In addition, in a recent phase 1 trial of low-dose isotretinoin in recessive dystrophic EB, some of the patients treated complained of increased mechanical fragility, blistering and/or itching as the dosage approached 0.5 mg/kg/day [28].

Skin grafting

Autologous split-thickness skin grafts have had short- to longer-term beneficial effects in the treatment of chronic ulcers or erosions in patients with generalized recessive dystrophic EB [29] or pretibial EB [30,31]. The treatment was found to be more effective when allogeneic keratinocytes were added to the split-skin grafts [31]. Cultured keratinocytes have also been used successfully in the treatment of junctional EB [32,33]. Repeated applications of autologous [32] or maternally derived [33] cells were used in the treatment of facial erosions in three children, and allogeneic keratinocytes were effective in promoting re-epithelialization of extensive erosions on the trunk and upper limbs of an infant [34]. Similar benefit was seen in a patient with recessive dystrophic EB [35]. The effects of applying allogeneic keratinoyctes to split-skin graft donor sites on the thigh were studied in 10 patients with severe recessive dystrophic EB [36]. There was no overall difference in the rate of wound healing, in comparison to similar non-treated sites. However, the treatment was effective in relieving pain in several patients.

Skin bioequivalents have also been used in the treatment of EB simplex, junctional EB [37,38] and dystrophic EB, with mixed results [37–39]. Concerns have been raised about the relative efficacy, especially in the long term, of treatment with bioequivalents,

including the commercially available Apligraf (Novartis), until more comprehensive data based on controlled trials become available [40]. Anecdotal evidence from the National EB Registry suggests that such treatments are often either ineffective or any benefits may be relatively short lived (J.-D. Fine, unpublished data).

Pain management

Patients with EB frequently experience severe pain, which is unresponsive to conventional treatment with non-opiate-based or non-steroidal anti-inflammatory agents. Unfortunately, systemic opiates are addictive and tend to exacerbate chronic constipation, making their chronic use highly undesirable. However, recent experience has found that the use of topical opiates, including diamorphine, may be effective in the treatment of pain in EB patients, reducing the need for powerful systemic analgesia (E. Pillay, F. Keane and R.A.J. Eady, unpublished data). Its use is particularly beneficial when chronic pain is associated with chronic ulcers and erosions, accompanied in some patients by squamous cell carcinoma. Amitriptyline is useful in pain management in both adults and children [41]. Amitriptyline and cognitive–behavioural techniques were effective in relieving chronic pain and discomfort in an 11-year-old child with junctional EB [41]. Oral midazolam 0.33 mg/kg administered 20 min prior to baths and dressing changes substantially improved the patient's tolerance of wound care [42].

Cancer and recessive dystrophic epidermolysis bullosa [43]

Squamous cell carcinomas are expected to occur in nearly every patient with Hallopeau–Siemens disease, as well as in a minority of patients with non-Hallopeau–Siemens and inverse forms of recessive dystrophic EB (Figs 39.32 & 39.33). Meticulous surveillance, preferably with the aid of serial photography, should be performed regularly (at least every 6 months), from the age of 10 years, and any suspicious lesion should be immediately biopsied. Those lesions that fail to reveal cancer histologically, and yet remain atypical in appearance or healing pattern, such as a non-healing erosion, should be re-biopsied, because it is possible to miss an early squamous cell carcinoma, given the tendency of these tumours to be well differentiated histologically and to show only focal areas of neoplastic change. Wide surgical excision is recommended, and careful serial follow-up examinations should be implemented, seeking possible local or regional recurrences. Amputation of an affected limb may eventually be required in some cases. Although still unproven, there may be a role for sentinel node biopsy in the management of these patients. There is also no evidence yet in support of using the Mohs' surgical technique instead of conventional wide surgical excision. Regional metastases, for example those arising within the axillary vault, may benefit from at least partial surgical debulking, even if extensive, to reduce the size of non-healing, painful, malodorous or chronically infected lesions. Neither chemotherapy nor radiotherapy has been shown to provide lasting benefit in the treatment of primary or secondary tumours. However, radiotherapy, like surgery, may be used for reducing the tumour mass. In most patients it does not appear to make blistering worse (J.-D. Fine, unpublished data, 2007).

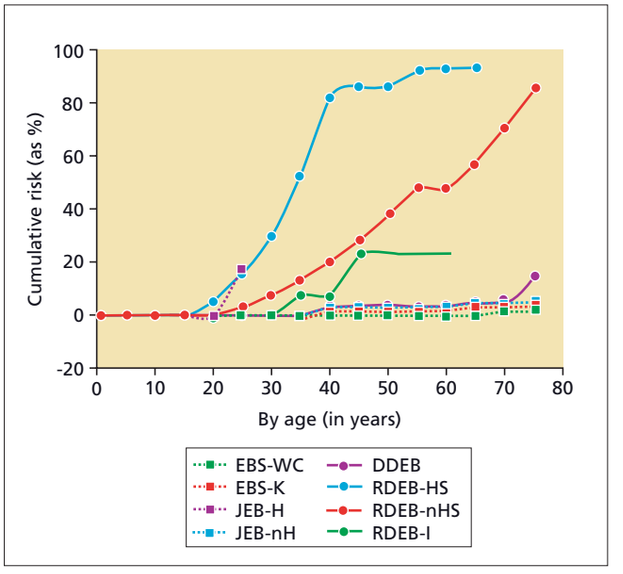

Fig. 39.32 Cumulative risk of death from squamous cell carcinoma in different forms of epidermolysis bullosa, per data from the National EB Registry, 1986–2002. (J.-D. Fine, [43].)

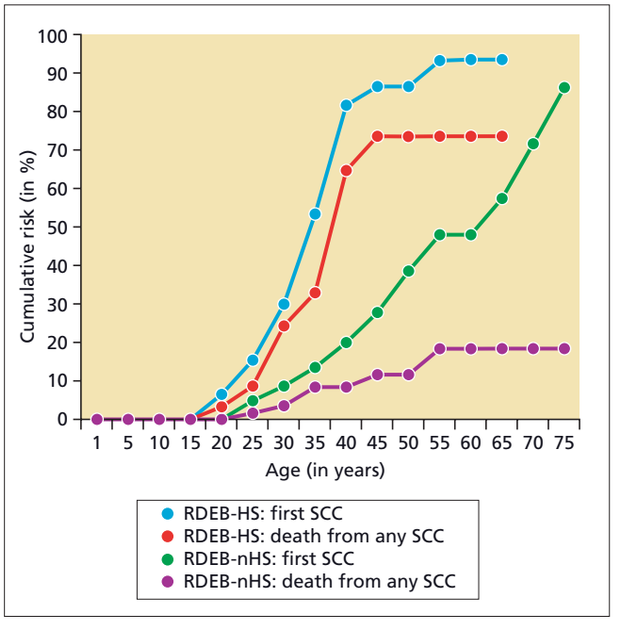

Fig. 39.33 Cumulative risk of developing first squamous cell carcinoma (SCC), and death from SCC in recessive dystrophic epidermolysis bullosa, per data from the National EB Registry, 1986–2002. (J.-D. Fine, [43].)

Treatment of epidermolysis bullosa simplex

Heat and humidity lower the threshold for blistering in patients with EB simplex, and measures to reduce both these factors are therefore important. Patients with Weber–Cockayne or Dowling–Meara EB simplex should wear well-fitting well-ventilated shoes,

preferably with a soft inner lining. Cotton socks are preferable to wool or synthetic fibres, and double-layer sports socks provide extra protection from friction and absorb sweat well. The application of aqueous solutions containing alcohol or glutaraldehyde [44] has been found useful, but is not necessarily recommended as glutaraldehyde is potentially irritant and toxic. Iontophoresis and the application of aluminium chloride hexahydrate [45] have also been used in attempts to suppress sweating. However, in a controlled trial of 20% aluminium chloride hexahydrate for the treatment of Weber–Cockayne EB simplex, there was no difference between the active drug and placebo in suppressing blistering [46]. In two small case series or clinical trials, oral tetracycline was noted to be effective in reducing the rate of blistering in some patients with EB simplex [47,48].

Newer forms of treatment, including gene therapy

Newer specific methods of treating EB have been slow to emerge. However, it is likely that genetically engineered growth factors and other cytokines that are able to influence wound healing will soon be available for clinical trials, or even clinical practice [49]. Such advances could clearly have an important impact on the management of chronic erosions in junctional and dystrophic EB, although their potential role in the treatment of lesions in internal organs, such as the oesophagus, may be less clear. There is a pressing need for an effective means to halt and possibly reverse the relentless progression of digital fusion and hand contractures seen in recessive dystrophic EB. Another critical need is the development of the means whereby squamous cell carcinomas can be prevented from occurring in these patients, as well as more effective means of treatment if they should arise.

Although as yet unavailable for use in routine clinical practice, gene therapy [50–55] is nevertheless a realistic goal for the future treatment of more severe autosomal recessive forms of EB. There are numerous obstacles, but each is potentially surmountable, given time and sufficient resources. Different methods of introducing DNA into skin or skin cells *ex vivo* are currently being explored. The objective is to introduce one normal allele into somatic cells that, in recessive forms of EB, would have two mutant genes. The strategy includes finding effective and safe methods for targeting 'normal' genes into the right place (e.g. the nucleus of an epidermal stem cell) and keeping the gene activated under controlled conditions. The introduced gene must be able to undergo transcription and translation in the synthesis of an appropriate product, such as a basement-membrane protein, which then has to be secreted by the cells and incorporated into the extracellular matrix in a way that will allow it to be functionally effective. The gene product may be at risk of being rapidly degraded, neutralized (by autoantibodies), shed (inside a differentiating keratinocyte) or being otherwise inactivated. As part of a proof-of-principle trial, a few patients with non-Herlitz junctional EB have now undergone grafting with small skin bioequivalents containing the corrected laminin-5 gene, following removal of the genetically abnormal epidermis. These grafts have remained blister-free for over a year, suggesting that this technique might indeed have eventual clinical applicability in autosomal recessive forms of EB. Further clinical trials are currently underway.

For autosomal dominant disorders, including dominant dystrophic EB or EB simplex, the strategy will be different. Under these conditions, rather than introducing a further normal gene, the objective will be to try to inactivate or nullify the action of the mutant gene, which usually exerts a 'dominant-negative' effect on its normal paired allele. One approach involves antisense DNA and RNA strategies [55], which currently are being explored particularly for use in the treatment of cancer. Another possible approach being investigated is to up-regulate another structural protein within keratinocytes (for example, another minor keratin in patients with EB simplex) so as to override the structural instability caused by the presence of keratin 5 or 14 mutations.

A direct result of the recent advances in the molecular genetics of different forms of EB has been the development of DNA-based first-trimester prenatal diagnosis. This has already been used for the benefit of many couples at high risk of having affected children (see Chapter 16). The introduction of preimplantation genetic diagnosis will broaden the available options in the overall management of those affected by EB.

Hailey–Hailey disease

S.M. Burge, pp. 39.32–39.37

Synonym
- Familial benign chronic pemphigus

Hailey–Hailey disease (Mendelian Inheritance in Man (MIM) accession number 169600) is a rare intraepidermal, blistering disease that is inherited as an autosomal dominant with a prevalence of around 1 in 50 000. The condition, which was described by the Hailey brothers in 1939, is characterized by recurrent vesicles and erosions, usually affecting the neck, axillae and groins [1–3].

Aetiology. Hailey–Hailey disease is caused by mutations in one copy of *ATP2C1*, a gene on chromosome 3q21 that encodes the human secretory-pathway Ca^{2+}/Mn^{2+}-ATPase isoform 1 (hSPCA1) on the Golgi membrane. The wide variety of mutations do not cluster to 'hotspots' in the gene or correlate with phenotype [4–7]. Protein expression is reduced and SPCA1 haploinsufficiency is the mechanism for the dominant pattern of inheritance [8–10]. Darier's disease (MIM 124200), a condition that shares many clinical and pathological features with Hailey–Hailey disease, is caused by mutations in the *ATP2A2* gene encoding a calcium ATPase located in the sarco/endoplasmic reticulum (SERCA2) (see Chapter 19).

Pathogenesis. Intracellular Ca^{2+} stores play a pivotal role in maintaining epidermal integrity, but it is not yet entirely clear how loss of one functional allele of *ATP2C1* leads to the changes in adhesion that typify Hailey–Hailey disease [11–14].

ATP2C1 is expressed by keratinocytes, but immunohistochemical data are conflicting. Some authors suggest the gene is most highly expressed in the undifferentiated basal cell layer of normal epidermis [15] while others have found labelling of both basal and suprabasal cells [14]. The gene product, SPCA1, regulates the concentration of both Ca^{2+} and Mn^{2+} in the Golgi complex. Mutations in *ATP2C1* may preferentially affect the skin because keratinocytes are unable to compensate for partial loss of SPCA1 [16].

Reduced Ca^{2+} or Mn^{2+} stores in the Golgi, increased cytosolic Ca^{2+} concentrations, abnormal Ca^{2+} oscillations (cycles of release and uptake) and/or decreased cellular ATP stores in Hailey–Hailey disease may affect a wide range of cellular processes including gene transcription, keratinocyte signalling, post-translational modifications or trafficking of adhesion proteins, the assembly of adhesion junctions and keratinocyte differentiation [14,15,17–21]. Normally, extracellular Ca^{2+} concentrations increase fourfold between the basal and superficial epidermal layers, but this calcium gradient is attenuated in Hailey–Hailey disease with a marked reduction in the total [Ca^{2+}] in the granular layer [18]. The attenuated gradient may alter keratinocyte differentiation, proliferation, adhesion and/or motility [20,21].

Cultured Hailey–Hailey disease keratinocytes demonstrate abnormal adhesion [22–24], impaired calcium metabolism [5,25], reduced expression of involucrin (a marker of differentiation) [19] and impairment of Ca^{2+}-induced actin reorganization [17]. *In vitro* acantholysis is reduced by corticosteroids, serine protease inhibitors and vitamin D_3 analogues, but not by retinoids [24,26].

Ultraviolet irradiation (UVB) aggravates Hailey–Hailey disease and has been used to detect carriers of the disease gene [27]. UVB reduces the expression of *ATP2C1* mRNA in cultured normal keratinocytes [28], but the reduction is inhibited by corticosteroids, retinoids, ciclosporin and vitamin D_3 [29]. Although UVB impairs the adhesion of cultured keratinocytes from patients with Hailey–Hailey disease, this impairment is no greater than in normal keratinocytes suggesting that other factors may be necessary for UVB to provoke acantholysis *in vivo* [30].

A number of pro-inflammatory cytokines down-regulate the expression of *ATP2C1* [28,29] and this may explain why insults such as friction, freezing or suction induce acantholysis in the normal looking skin of affected patients and how cutaneous infections exacerbate disease [3,31]. In rats, oral lithium suppresses the expression of both SERCA2 (the cause of Darier's disease) and PMR1 (the homologue of SPCA1) [32], but exacerbations of Hailey–Hailey disease have not been reported in patients taking lithium, although lithium does exacerbate Darier's disease (see Chapter 19).

Histopathology. Acantholytic clefts and bullae form above the basal cells. The suprabasal cells separate partially from one another, so clusters of loosely coherent cells float in the bullae. Widespread partial acantholysis gives the epidermis the appearance of a 'dilapidated brick wall' (Fig. 39.34). In contrast to autoimmune pemphigus, intracellular IgG and complement are not detected in the epidermis.

The primary event appears to be dissolution of the desmosomal attachment plaque [33]. Keratin filaments separate from desmosomal plaques and aggregate in perinuclear whorls [34–36].

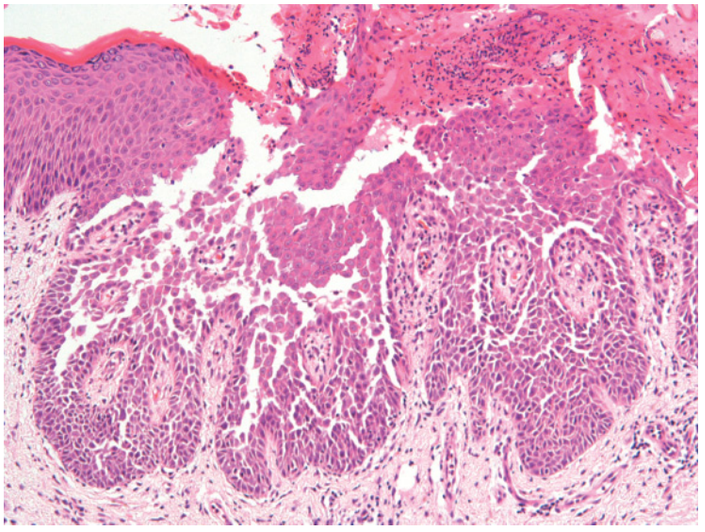

Fig. 39.34 Skin showing prominent spinous layer acantholysis giving the so-called 'dilapidated brick wall' appearance. There is overlying scale crust, but little dyskeratosis. (Courtesy of Professor R.A.J. Eady, St John's Institute of Dermatology, London, U.K.)

The components of desmosomes, adherens junctions, gap junctions and the cytoskeleton are distributed normally in uninvolved skin. Desmosomal components, E-cadherin and connexins are internalized in acantholytic cells [37–40] and extracellular epitopes of cadherins are lost [41]. The expression of P-cadherin is up-regulated in a number of acantholytic conditions including Hailey–Hailey disease [42].

Clinical features. The condition usually presents in the third or fourth decade [1]. Flaccid vesicopustules, crusted erosions or expanding circinate plaques appear in areas exposed to friction such as the sides of the neck, axillae, groins and perineum. Involvement may be restricted to one site but can be generalized [2]. Lesions extend peripherally, healing in the centre (Fig. 39.35). Flexural disease may be hypertrophic and malodorous with soft, flat, moist vegetations and fissures (rhagades) (Fig. 39.36).

Itch and pain are common and flexural disease may be disabling, particularly if the groins are affected. Even mild disease may reduce quality of life [3,4]. Asymptomatic, longitudinal, white bands are present in the nails of some patients [1] (Fig. 39.37). Mucosal involvement is uncommon, but conjunctival, oral, oesophageal and vaginal involvement have been described [1,5].

Hailey–Hailey disease may koebnerize into inflammatory conditions such as psoriasis or seborrhoeic dermatitis [6,7] and is exacerbated by cutaneous insults causing inflammation such as contact dermatitis, UVB irradiation, sweating, friction, cutaneous infections or scabies [1,8–10].

Complications. The possibility of allergic contact dermatitis should be considered in patients with Hailey–Hailey disease but, although allergies have been described, the frequency of positive

Fig. 39.35 Hailey–Hailey disease. Spreading annular plaque with a crusted rim. (Courtesy of Professor R.A.J. Eady, St John's Institute of Dermatology, London, U.K.)

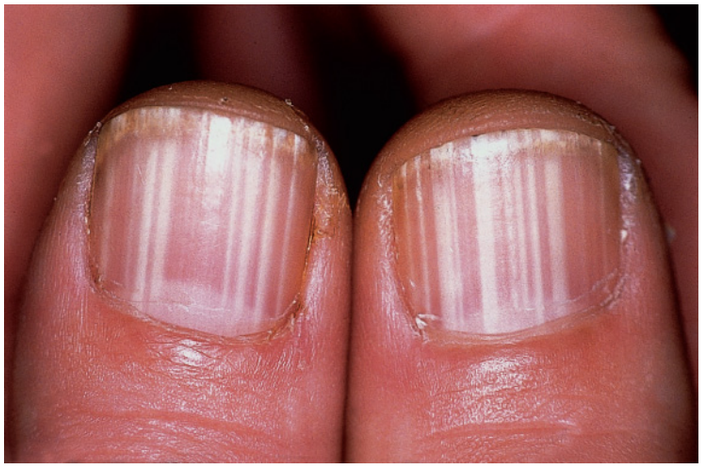

Fig. 39.37 Hailey–Hailey disease. Longitudinal white bands in the nails may be a helpful diagnostic sign. (Courtesy of Professor R.A.J. Eady, St John's Institute of Dermatology, London, U.K.)

patch tests is probably not increased [11,12]. Hailey–Hailey disease may be diagnosed serendipitously in the patch test clinic, when removal of adhesive tapes used for holding the patches in place causes extensive, painful erosions [8,13].

Human papillomas virus has been found in perineal verrucoid lesions [14,15]. Rarely, carcinomas have been reported in skin affected by Hailey–Hailey disease, sometimes linked to infection with human papillomas virus [16–19]. The incidence of squamous cell cancer (SCC) of skin and oesophagus is increased in aged mice that are heterozygous for the mutation in SPCA1 [20]. Large studies are needed to determine if mutations in SPCA1 predispose to the development of SCC in humans, but published clinical experience does not support such an association.

Affective disorder has been reported to cosegregate with Hailey–Hailey disease in three families [21–23].

Prognosis. Remissions are common and the condition may improve in old age [1,24].

Differential diagnosis

Clinical. Misdiagnosis is frequent [1,25,26]. Lesions may simulate impetigo, eczema, candida intertrigo or tinea corporis. Hailey–Hailey disease should be considered in patients complaining of 'reactions' to adhesive dressings [13]. Herpes simplex virus causes painful exacerbations, which may be difficult to differentiate from vesicular Hailey–Hailey disease [27,28]. Severe disease may simulate erythema multiforme or toxic epidermal necrolysis [2]. Hypertrophic vulval lesions may suggest malignancy [1].

Diagnostic difficulties are compounded because Hailey–Hailey disease may respond to the treatments such as antibacterials or topical corticosteroids that are used for some of these conditions, but longitudinal white bands in the nails may help to confirm the diagnosis [1,29].

Vegetating flexural disease occurs in both pemphigus vegetans and Darier's disease. Oral lesions distinguish pemphigus vegetans. Darier's disease is characterized by hyperkeratotic papules as well as a distinctive nail dystrophy (see Chapter 19).

Localized perineal papules and plaques with an acantholytic histology have been reported in patients without other features of Hailey–Hailey disease [30–32]. The relationships between this condition, Hailey–Hailey disease and Darier's disease might be clarified by genetic studies.

Histological. Hailey–Hailey disease must be differentiated from Darier's disease and pemphigus. Epidermal hyperplasia and suprabasal separation occur in both Darier's disease and Hailey–Hailey disease, but acantholysis tends to be more widespread in fully developed lesions of Hailey–Hailey disease while dyskeratosis with corps ronds and grains is more prominent in Darier's disease [33]. In pemphigus, the acantholytic cells are less well preserved and immunoglobulin and complement are deposited between the keratinocytes.

Investigations. The diagnosis should be confirmed by skin biopsy. Fungal, viral and bacterial infections exacerbate and perpetuate disease and should be excluded by culture. Patch testing should be considered in patients with long-standing disease.

Treatment. Simple measures should be tried to reduce skin friction and keep flexures dry, including weight loss if appropriate, loose cool clothing and absorbent pads in skin folds.

Combinations of moderate to potent topical corticosteroids with antibacterial and/or antifungal agents may be effective, particularly if topical steroids are applied promptly to early lesions, but no controlled trials have been performed [1]. The potency of topical corticosteroids should be reduced as soon as possible to prevent atrophy [34]. Systemic corticosteroids have been recommended for widespread disease [25,35,36]. Treatment may up-regulate SPCA1 expression either indirectly through an effect on cytokine production or by a direct effect on keratinocytes [37,38].

The role of antiseptics, antibiotics and/or topical antifungal agents as steroid-sparing agents is unproven, but long-term antimicrobial treatment appears to be helpful [1,25,39]. Topical tetra-

cyclines, aminoglycosides, fusidic acid or imidazoles may be added to a topical corticosteroid. Topical aminoglycosides may have the added benefit of reversing the effects of pathogenic nonsense mutations by inducing readthrough of stop mutations [40]. Low-dose oral tetracyclines, erythromycin or flucloxacillin should also be entertained. Oral treatment of herpes simplex should be considered in patients with unresponsive, painful disease.

Without controlled trials the evidence base for the efficacy of any of the following is poor: ciclosporin topically and orally (3–4 mg/kg/day) [41–43], topical tacrolimus [44,45], topical vitamin D_3 analogues [46,47], oral retinoids [48–50] and etanercept [51].

Botulinum toxin (axillary or inframammary) may help by reducing sweating [52–54], as may breast reduction [55].

Although ultraviolet light may exacerbate Hailey–Hailey disease, PUVA was apparently effective in some patients [56,57]. Suberythemal UVB controlled both psoriasis and co-existing Hailey–Hailey disease in another patient [58]. Superficial radiotherapy may produce temporary benefit [59].

The long-term benefit of any surgical approach is equally uncertain, but many have been recommended for recalcitrant disease including: cryosurgery [25], excision with or without grafting [60,61], dermabrasion [62,63], electrodesiccation [64], various forms of laser surgery [53,65–67] and photodynamic therapy [68]. Outcomes are not always satisfactory [69,70].

Segmental Hailey–Hailey disease

A linear acantholytic dermatosis with the clinicopathological features of Hailey–Hailey disease has been described affecting one side of the body. These features may be explained by a localized postzygotic mutation in *ATP2C1* resulting in type 1 mosaicism [1].

A patient with a family history of Hailey–Hailey disease presented in infancy with a linear acantholytic dermatosis following Blaschko's lines, but typical Hailey–Hailey disease involving body folds appeared in the third decade. This patient has a type-2 mosaicism with segmental lesions superimposed on the ordinary phenotype. A germline mutation affected one allele, but a postzygotic mutation early in development affected the other allele resulting in loss of heterozygosity and severely affected segmental lesions [2].

Introduction

The bullous diseases discussed in this chapter, although uncommon, have a dramatic impact on the patient and their relatives and have severe economic consequences for the family and health services. These diseases have been the subject of intensive investigation in recent years, and the study of both the genetic and autoimmune diseases has made major contributions to our knowledge of the biology of the skin. The identification of the specific target antigens for the autoantibodies in the autoimmune bullous diseases has led to the discovery of many components of the desmosome and the adhesion complex linking the epidermis to the dermis (Fig. 40.1; also see Fig. 40.11). In parallel with this work has been the realization that mutations of these same proteins are the basis of some of the genetic bullous diseases. The molecular biology of the genetic abnormalities is beginning to reveal how the fine structure of these proteins enables them to perform their function (see Chapter 39).

The immunological diseases are classified largely by their clinical presentation, histopathology and immunopathology. The increased use of immunoblotting and immunoelectron microscopy to define these diseases has revealed that the target antigens and specific epitopes may be common to more than one clinical entity. Thus, the clinician is still the final arbiter for diagnosis.

A comprehension of the ultrastructural anatomy and composition of the areas under discussion greatly facilitates an understanding of the diseases that produce chronic blistering of the skin and mucous membranes (see Chapter 3).

The immunobullous diseases are characterized by pathogenic autoantibodies directed at target antigens whose function is either cell-to-cell adhesion within the epidermis or adhesion of stratified squamous epithelium to dermis or mesenchyme. These target antigens are components of desmosomes or the functional unit of the basement membrane zone known as the adhesion complex and are shown in Figs 40.1 and 40.11. The clinical, immunopathological and immunogenetic features of these diseases are shown in Tables 40.2, 40.3, 40.5 and 40.6. Dermatitis herpetiformis is the one possible exception, as the relevant target antigen has not yet been identified.

The most important techniques for the investigation of patients with immunobullous disease are histopathology, and direct and indirect immunofluorescence. Research techniques such as immunoblotting and immunoelectron microscopy may refine the diagnosis in the individual patient but do not replace the clinical findings [1].

Intercellular adhesion in the epidermis

Adhesion between keratinocytes is mediated predominantly by cell adhesion molecules of the cadherin family, localized in two specialized intercellular adhesion junctions: desmosomes and intermediate or adherens junctions. Desmosomes are small, electron-dense structures that link the intermediate filament within cells to the plasma membrane and to adjacent cells. The possible arrangement of desmosomal components is illustrated in Fig. 40.1. The major adhesion components of desmosomes are the desmosomal cadherins, desmogleins and desmocollins. The cadherins are transmembrane glycoproteins each having an extracellular domain, a transmembrane domain and a cytoplasmic domain, which links to the cytoskeleton. Adhesion is probably regulated by complex interactions between the cytoplasmic domains of cadherins and cytoplasmic proteins such as catenins or plakoglobin [1–3] (for a detailed discussion see Chapter 3).

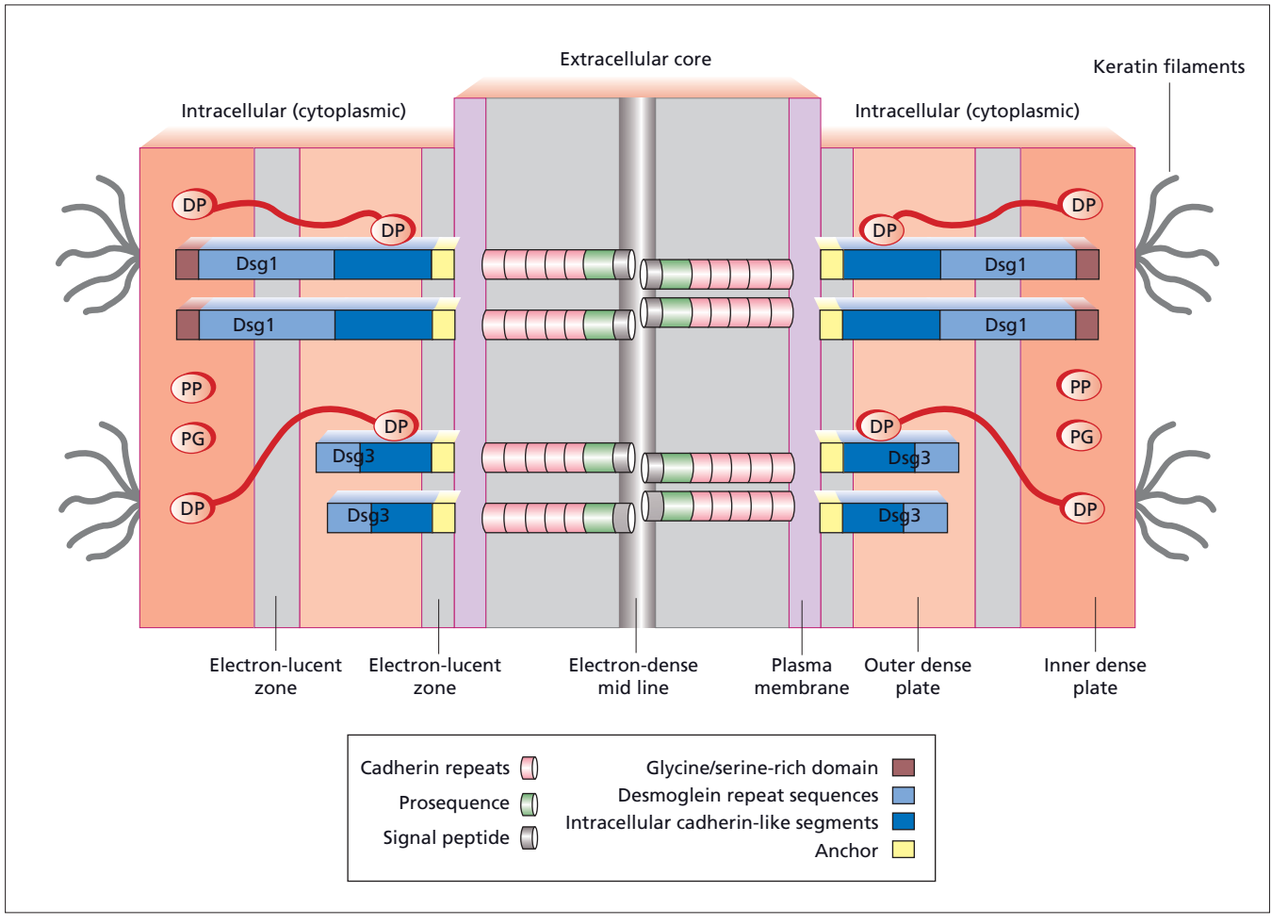

Fig. 40.1 Diagrammatic representation of the molecular components of the desmosome. DP, desmoplakin; Dsg1, desmoglein 1; Dsg3, desmoglein 3; N, amino terminal; PG, plakoglobin; PP, plakophilin. (Courtesy of Dr J. Allen, Oxford Radcliffe Hospital, Oxford, UK.)

The desmoglein subfamily comprises at least three related proteins: desmoglein-1, desmoglein-2 and desmoglein-3. Desmoglein-1 is recognized by sera from patients with the autoimmune blistering disease pemphigus foliaceus and some with pemphigus vulgaris. Desmoglein-1 is also the target of protease-mediated damage by staphylococcal exotoxins [4]. Desmoglein-3 is the target antigen in pemphigus vulgaris. The desmocollins also exist in more than one isoform, and are recognized by sera from some patients with IgA pemphigus.

The expression of desmosomal cadherins varies during differentiation, and expression in human skin differs from that in mucosal epithelium. Desmoglein-3 is expressed only in the basal and suprabasal layers of the epidermis whereas desmoglein-1 is found throughout the epidermis, particularly in the upper layers [5–7]. In mucosae, desmoglein-3 is strongly expressed throughout whereas desmoglein-1 is expressed only weakly [8,9]. In neonatal epidermis, the distribution of desmogleins resembles that of the adult mucosa [10,11].

Desmosomes have well-defined, submembranous plaques, containing non-glycosylated proteins plakoglobin, desmoplakins-1 and 2 and plakophilin. Plakoglobin, present in both desmosomes and adherens junctions, may interact with cadherins to regulate adhesion [12,13]. Desmoplakin-1 and 2 belong to a multigene family of intermediate filament organizing proteins (plakins), which includes the bullous pemphigoid antigen (BP230), present in the hemidesmosomes of the basement membrane zone, and plectin, a widely distributed intermediate filament-associated protein [12]. Less well characterized plakins, localizing to the desmosome, are envoplakin and periplakin [14]. Plakin autoantibodies are present in the blistering disease paraneoplastic pemphigus, a condition which is associated with lymphoid malignancies, thymomas or poorly differentiated sarcomas [15]. Keratin intermediate filaments insert into the desmosomal plaque, where their amino termini interact with the carboxy termini of desmoplakin. Desmoplakins, plakoglobin, and possibly also plakophilin-1, are attached to desmosomal cadherins and to each other in a complex arrangement [3,16,17].

Adherens junctions

Epithelial cadherin (E-cadherin) is present in adherens junctions. Interactions between cytoplasmic domains on E-cadherin and cytoplasmic proteins called catenins are essential for normal adhesion. Plakoglobin, which is similar in structure to β-catenin, may also form complexes with E-cadherin [12]. Vinculin and α-actinin, cytoplasmic proteins present in adherens junctions, may link to bundles of actin microfilaments to influence the organization of

the filaments. These are not currently identified as target antigens in immunobullous diseases.

Intraepidermal immunobullous diseases

Blisters form within the epidermis in the pemphigus group of immunobullous diseases. The antibodies in these diseases react with intercellular adhesion molecules. Immunoreactants are deposited between keratinocytes, intercellular bridges disappear and keratinocytes separate from one another, a change known as acantholysis.

Pemphigus

Definition. Pemphigus derived from the Greek *pemphix* meaning blister or bubble. The term 'pemphigus' once covered most of the bullous eruptions of the skin, but diagnostic tests have improved and the bullous diseases have been reclassified. A number of distinct subgroups of pemphigus have emerged and many of the autoantigens have been identified. The antibodies are directed against epidermal cadherins, a family of calcium-dependent cell–cell adhesion molecules. The two major subtypes, pemphigus vulgaris and pemphigus foliaceus, are distinguished by the level of cleavage within the epidermis. Splitting is suprabasal in pemphigus vulgaris and its rare vegetating form, pemphigus vegetans. Blistering is more superficial in pemphigus foliaceus and related subtypes.

The classification of pemphigus, its clinical features, immunopathology and immunogenetics are summarized in Tables 40.1, 40.2 and 40.3.

Table 40.1 Types of pemphigus.

Pemphigus vulgaris

Paraneoplastic pemphigus

Pemphigus vulgaris and pemphigus vegetans

Aetiology. Pemphigus vulgaris affects all races and both sexes [1]. It is a disease of middle age, which affects children rarely, but patients are younger at presentation in India than in Western countries [2].

Pemphigus vulgaris accounts for around 70% of all cases of pemphigus and may be the commonest autoimmune blistering disease in Eastern countries, such as India, Malaysia, China and the Middle East [2–4]. The Jewish race, especially Ashkenazi Jews, have an increased susceptibility to pemphigus vulgaris [1]. In South Africa, pemphigus vulgaris is commoner in Indians than in Black or Caucasian races [5]. Pemphigus is less common in the West.

Predisposition to pemphigus is linked to genetic factors. First-degree relatives of patients with pemphigus vulgaris are more susceptible to the development of autoimmune diseases than are controls [6,7] and have a higher incidence of circulating antidesmoglein antibodies [8]. Certain MHC class II genotypes are common in patients with pemphigus vulgaris and cross racial barriers. Alleles of HLA-DRB1*0402 and -DRB1*1401, -DQB1*0503 subtypes confer disease risk [9–13] and may do so by structural change in peptide binding sites, influencing antigen presentation and recognition by T cells [12,14]. In British and Indian patients certain haplotypes of the desmoglein-3 gene also confer risk for pemphigus vulgaris and this appears to be additive to the effect of HLA-DR [15]. Susceptibility may also be determined by genes encoding immunoglobulins [16] or by genes within the HLA class I antigen processing machinery [17].

Table 40.2 The intraepidermal immunobullous diseases: clinical features.

Disease	Patients	Cutaneous distribution	Mucosal involvement	Lesions	Disease associations	Treatment	Prognosis
Pemphigus vulgaris	Middle age	Scalp, face, flexures, may be generalized	Always oropharynx, conjunctiva, genital	Flaccid blisters, erosions, flexural vegetations	Autoimmune disease, thymoma	Steroids, immunosuppressives, dapsone	Variable, may remit
Pemphigus vegetans	Middle age	Flexural	Oral	Vesicles, pustules, erosions, vegetating plaques		Steroids, immunosuppressives, dapsone	Variable, may remit
Pemphigus foliaceus	Middle age	Scalp, face, chest, upper back, rarely generalized 'seborrhoeic'	None	Scaly papules, crusted erosions, erythroderma		Steroids (topical, intralesional, systemic), immunosuppressives	Benign but chronic
Endemic pemphigus foliaceus	Children, young adults	Head, neck, generalized	Uncommon	Flaccid blisters, erosions, verrucous lesions, erythroderma		Steroids, immunosuppressives, antimalarials	Chronic mortality <10%
Intercelluar IgA dermatosis	Adults, children	Axillae, groins, face, scalp, proximal limbs	Uncommon	Flaccid pustules annular or circinate configuration	IgA monoclonal gammopathy	Dapsone	Chronic indolent
Paraneoplastic pemphigus	Adults, children	Upper body, palmoplantar	Severe mucositis	Polymorphous, bullae, erosions, 'target lesions'	Lymphoproliferative disease, Castleman's, other malignancies	Tumour resection, steroids, immunosuppression	Very poor

Table 40.3 The intraepidermal immunobullous diseases: immunopathology and immunogenetics.

Disease	Direct IMF	Isotype	Target antigens	Antigens (kDa)	Epitopes	Location	Immunogenetics
							MHC class I and II
Pemphigus vulgaris/ pemphigus vegetans	Intercellular	IgG (few IgM, IgA)	Desmoglein 3, sometimes desmoglein 1 desmocollins	130	Amino-terminal of extracellular domain	Desmosome	DRB1*0402 DRB1*1401
Pemphigus foliaceus	Intercellular	IgG	Desmoglein 1, sometimes desmocollins	160	Amino-terminal of extracellular domain	Desmosome	HLA-DRB1*14
Endemic pemphigus foliaceus	Intercellular	IgG	Desmoglein 1, sometimes desmocollins	160	Amino-terminal of extracellular domain	Desmosome	Several susceptibility alleles, all with same amino acid sequence in *DRB-1* gene DRB1*0102 DRB1*0404, *1402 or *1406
Paraneoplastic pemphigus	Intercellular and subepidermal	IgG	Plakins (desmoplakin, envoplakin BP230, periplakin)		Various	Desmosomes, BMZ; stratified, simple and transitional epithelia	Unknown

BMZ, basement-membrane zone; HLA, human leukocyte antigen; IMF, immunofluorescence; MHC, major histocompatibility complex.

Pemphigus occurs in patients with other disorders characterized by immunological disturbances. Thymoma or myasthenia gravis have been reported in a number of patients. Some have all three diseases [1]. Pemphigus may develop in patients with lupus erythematosus (see Pemphigus erythematosus, below). Bullous pemphigoid and pemphigus have coexisted [18]. Pemphigus has been reported in patients with lymphoproliferative diseases such as Castleman's tumours (see Paraneoplastic pemphigus, below). Viral DNA (herpes simplex, EB virus, human herpes viruses 6 and 8) has been detected in some skin biopsies or peripheral blood mononuclear cells from pemphigus patients [19,20] and pemphigus has coexisted with HIV infection [21]. An epidemiological review of Iranian pemphigus vulgaris patients suggested a positive correlation with oral contraceptive use and pesticide exposure but a possibly protective effect from cigarette smoking [22].

Pathogenesis. Autoantibodies against the surface of keratinocytes occur in pemphigus and both clinical and experimental observations indicate that circulating autoantibodies are pathogenic [1].

Pemphigus vulgaris antigen

The pemphigus vulgaris antigen, also known as desmoglein-3, is the desmosomal cadherin involved in mediating intercellular adhesion in the epidermis [2]. Pemphigus antibody binds to an extracellular domain on the amino-terminal region of desmoglein-3 where it may have a direct effect on the function of the desmosomal cadherins [3,4].

Desmoglein-3 is found in desmosomes [4] and possibly elsewhere on the cell membrane of keratinocytes [5]. It is detected early in keratinocyte differentiation, primarily in the lower epidermis [6–9] and is expressed more strongly in buccal mucosa and scalp skin than in skin from the trunk [10]. This contrasts with the pattern of expression of the pemphigus foliaceus antigen, desmoglein-1, which is present throughout the epidermis, more intensely in the upper layers, but only weakly expressed in mucosae [11].

Antibodies in pemphigus

Desmoglein antibodies. Where both desmogleins are expressed, it has been suggested that one molecule is able to compensate for the loss of function of the other [12] and the distribution of lesions in different forms of pemphigus is consistent with the epidermal distribution of the different desmoglein isoforms. Pemphigus vulgaris patients who only have desmoglein-3 antibodies tend to have lesions limited to the mucous membranes [13–15], where the relative lack of desmoglein-1 is unable to compensate, thus leading to acantholysis. Pemphigus vulgaris patients with antibodies to both desmogleins usually develop widespread mucocutaneous blistering [13,15,16] with bullae confined to the suprabasal epidermis, the location where both cadherins appear to be essential to maintain cell–cell adhesion. In general, cases evolving from mucosal-dominant to mucocutaneous pemphigus vulgaris or from pemphigus vulgaris to pemphigus foliaceus, or more rarely *vice versa*, the shift in clinical features usually correlates with changes in the reactivity of serum against the different desmoglein isoforms [17–21]. However, cases where there is no correlation between antibody profile and clinical phenotype are well recognized, indicating that antidesmoglein antibodies alone are not the sole effectors of pemphigus [22–25].

Although there is homology between desmogleins-1 and 3, the antibodies are not thought to be cross-reactive. One interpretation for this phenomenon is 'epitope spreading', that is tissue damage from a primary autoimmune or inflammatory response results in exposure of new epitopes on the same or another molecule to produce a secondary autoimmune response [26]. Desmoglein-1 antibodies are commoner in Indian patients, suggesting that antibody profile does not simply reflect disease duration, but is determined by other, possibly racial, factors [27].

The pathogenicity of desmoglein antibodies is supported by several lines of evidence. Most studies have shown a correlation between disease activity and titre of antibody [28–30]. Transplacental transfer of maternal pemphigus vulgaris antibodies may cause transient blisters in the newborn [31]. In the neonatal mouse model, passive transfer of pemphigus vulgaris IgG causes suprabasal acantholysis [32]. Blistering is prevented by prior absorption of antibodies with the extracellular domain of the pemphigus vulgaris desmoglein-3 antigen [33]. Acantholysis can be induced

in mice by desmoglein-3 antibodies alone but is greatly enhanced by addition of desmoglein-1 antibodies [34].

Autoantibody production is T-cell dependent and autoreactive Th1 and Th2 cells specific for desmoglein-3 occur in pemphigus vulgaris [35]. The pathogenecity of desmoglein antibodies depends on their titre and subclass. Patients with active disease have antibodies of both IgG1 and IgG4 subclasses, but the IgG4 antibodies are pathogenic [36,37]. Pathogenicity is also related to epitope specificity, disease activity correlating with reactivity against non-conformational NH_2-terminal epitopes of the desmoglein 3 ectodomain [38,39].

Non-desmoglein antibodies. Pemphigus vulgaris sera may also contain autoantibodies to desmocollins [40,41]. Antibodies to e-cadherin have also been detected, some but not all of which cross-react with desmoglein-1 [42].

Antibodies to non-cadherin antigens have also been reported. Antidesmoplakin in addition to antidesmoglein antibodies have been reported in severe pemphigus vulgaris [43]. Antibodies to cholinergic receptors have been observed in pemphigus sera [44] and cholinergic agonists can inhibit acantholysis induced by pemphigus sera *in vitro* and have an apparent steroid-sparing effect *in vivo* in pemphigus [45]. The relative contribution and significance of all the various antibodies described in pemphigus remain to be elucidated [46,47].

The mechanism of acantholysis

The mechanisms involved in cell separation (acantholysis) are not fully understood. One hypothesis is that antibody binding may cause direct inhibition of the adhesive function of desmogleins by 'steric hindrance' [38]. However, separation between desmosomes is not the earliest event and keratinocyte shrinkage and collapse of the cytoskeleton precede visible acantholysis [48].

Binding of pemphigus vulgaris antibody results in activation of a variety of intracellular signalling pathways with phosphorylation of keratinocyte proteins, including activation of EGF-receptor and phosphorylation of its downstream substrates (p38 mitogen-activated protein kinase (p38MAPK), Fas apoptotic cascade) [49,50]. Specific inhibition of p38MAPK can prevent pemphigus vulgaris blistering *in vivo* in mice [49,50].

Pemphigus antibody fixes components of complement to the surface of epidermal cells [51]. Pemphigus antibodies can induce acantholysis in complement-deficient mice [52]. In skin organ cultures and epidermal cell cultures acantholysis can occur in the absence of complement [53], although addition of complement enhances pathogenicity. Antibody binding may activate complement with the release of inflammatory mediators [54] and recruitment of activated T cells [55].

Complement activation in pemphigus is increased by interleukin (IL)-1-α and tumour necrosis factor (TNF)-α [56]. IL-1, thromboxane B_2 and leukotriene B_4 are present in blister fluid [54]. TNF-α and IL-6 are found in serum and lesional skin of pemphigus patients and can induce plasminogen activators and plasmin activity [57–60]. Treatment of pemphigus with infliximab, monoclonal antibody to TNF-α, produces rapid, albeit short-lived, reduction of blistering [61].

Proteinase inhibitors, antibodies to plasminogen activators and inhibitors of plasminogen activators can block the acantholysis induced by pemphigus antibodies in experimental models [57,62]. However, acantholysis induced by pemphigus antibodies occurs in plasminogen activator knockout mice [63] and plasminogen activator activity does not correlate well with disease activity in models of pemphigus [64], nor does proteolysis account for all the ultrastructural changes seen in epidermal cells damaged by pemphigus vulgaris antibodies [65].

Pathology. The earliest histological changes consist of intercellular oedema with loss of intercellular attachments in the basal layer. Suprabasal epidermal cells separate from the basal cells to form clefts and blisters. Basal cells remain attached to the basement membrane but separate from one another and stand like a 'row of

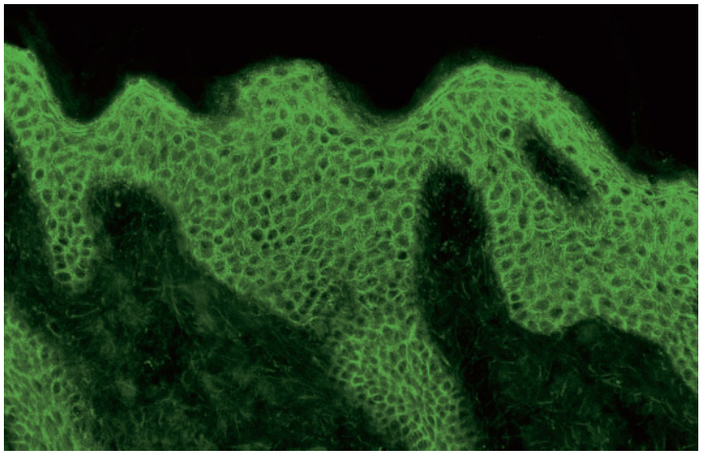

Fig. 40.2 Immunofluorescence showing intercellular IgG throughout the epidermis of a patient with pemphigus vulgaris.

tombstones' on the floor of the blister. Blister cavities contain some acantholytic cells. A smear taken from the base of a blister or an oral erosion (Tzank preparation) contains acantholytic cells. Clefting may extend into the walls of adnexae. Blistering is preceded by eosinophilic spongiosis in some cases. The superficial dermis has a mild, superficial, mixed inflammatory infiltrate which includes some eosinophils [1].

Electron microscopy has shown that widening of the intercellular space is followed by splitting of the desmosome junctions. When the cells separate from each other, the intracellular cytokeratin tonofilaments retract around the nucleus and the desmosomal plaques disappear. The attachment of basal cells to the basement membrane is not affected [2,3].

The diagnosis of pemphigus is confirmed by direct immunofluorescence which shows IgG deposited on the surface of keratinocytes throughout the epidermis, in and around lesions (Fig. 40.2). IgG1 and IgG4 are the most common subclasses; C3, IgM and IgA are present less frequently than IgG. Direct immunofluorescence may be the most sensitive method for diagnosing oral pemphigus [4].

Circulating pemphigus autoantibodies are detected by indirect immunofluorescence in over 80% of patients. The use of more than one substrate improves sensitivity, oesophageal substrate being preferable for the detection of antibodies to desmoglein-3 [5]. A disadvantage of immunofluorescence methods is the difficulty in distinguishing pemphigus vulgaris from pemphigus foliaceus on staining pattern alone. Recombinant desmogleins (DG1 and DG3) have been used recently to develop a sensitive and specific ELISA assay for serodiagnosis of pemphigus [6,7]. Using ELISA over 95% of pemphigus vulgaris patients have detectable desmoglein-3 antibodies and around 50% have desmoglein-1 antibodies. In appropriate dilutions, antidesmoglein-1 ELISA assays can be used to monitor disease activity [8].

Antibodies may be detected in patients without pemphigus [9]. Pemphigus-like circulating intercellular antibodies have been reported in conditions such as thermal burns [10], toxic epidermal necrolysis [9], penicillin reactions [11], staphylococcal scalded skin syndrome [12] and in first-degree relatives of relatives of pemphigus patients [13,14].

Clinical features of pemphigus vulgaris. Nearly all patients have mucosal lesions, and pemphigus vulgaris presents with oral lesions in 50 to 70% of patients. These may precede cutaneous lesions by months or be the only manifestation of the disease [1–3]. Intact bullae are rare in the mouth. More commonly patients have ill-defined, irregularly shaped buccal or palatal erosions, which are slow to heal (Fig. 40.3). The erosions extend peripherally with shedding of the epithelium [4]. Other mucosal surfaces may be involved, including the conjunctiva [5], nasal, pharynx [6], larynx, oesophagus [7,8], urethra, vulva [9] and cervix [10].

Most patients develop cutaneous lesions. Involvement may rarely remain localized to one site [11] but more commonly becomes widespread. The disease has a predilection for the scalp, face, axillae, groins and pressure points (Figs 40.4 & 40.5). Flaccid blisters filled with clear fluid either arise on normal skin or an erythematous base. The contents soon become turbid or the blisters rupture, producing painful erosions which extend at the edges as more epidermis is lost. At this stage, firm sliding pressure with a finger will separate normal-looking epidermis from dermis, producing an erosion—the Nikolsky sign. The Nikolsky sign is positive in pemphigus and more rarely in toxic epidermal necrolysis. Blisters can also be extended by vertical pressure, a phenomenon which occurs in many blistering diseases. Healing occurs without

scarring but pigmentary change and acanthomas may occur in resolving lesions [12].

Lesions in skin folds readily form vegetating granulations, and flexural pemphigus vulgaris merges with its variant pemphigus vegetans. Nail dystrophies, acute paronychia and subungual haematomas have been observed in pemphigus [13,14]. Rare patients are described with typical suprabasal pemphigus vulgaris type lesions but confined to the skin and sparing the mucosae despite antibodies to desmoglein-1 and 3 [15,16]. It is unknown whether these are transient presentations capable of clinical or serological evolution.

Severe pemphigus in pregnancy may be associated with fetal prematurity and death, but it is difficult to separate the effects of treatment from those of the disease. Generally, the baby is healthy [17] although neonatal pemphigus may occur with mucosal or mucocutaneous lesions which, generally, are short-lived [18–20].

Prognosis. The severity and natural history are variable, but before treatment with Contico steroids most patients with pemphigus vulgaris died [21]. Treatment with systemic steroids has reduced the mortality to between 5% and 15% [2,22], but some of these patients succumb to the complications of therapy. Morbidity and mortality are related to the extent of disease, the maximum dose of prednisolone required to induce remission and the presence of co-morbidities [2,21,23–25]. Disease activity generally decreases with time and most relapses occur in the first 2 years after diagnosis [26]. The outlook is worse in Jews [22] and in older patients [25].

Pemphigus vegetans

Definition. Pemphigus vegetans is a rare variant of pemphigus vulgaris which is characterized by vegetating erosions, primarily in flexures. Two subtypes are recognized: Neumann pemphigus vegetans and Hallopeau pemphigus vegetans. These may be considered to form a clinical spectrum from the severe Neumann type to the mild Hallopeau type [1].

Aetiology/pathogenesis. Antibodies react with the 130 kDa pemphigus vulgaris antigen and possibly other antigens in both types of pemphigus vegetans [2–6]. Antibodies in the Hallopeau type also react with desmocollins 1 and 2 [7]. Complement fixation might be responsible for the marked cutaneous infiltration of neutrophils and eosinophils, which is so typical in pemphigus vegetans [3].

Pathology. The vegetating lesions are hyperkeratotic, papillomatous and acanthotic. Some suprabasal clefts may contain eosinophils but few acantholytic cells are present. Intraepidermal eosinophilic abscesses may be present in older lesions. Early lesions in the Neumann type show suprabasal acantholysis and intraepidermal vesicles without eosinophils. Eosinophilic spongiosis or eosinophilic microabscesses are common in the early pustular lesions of the Hallopeau type [8]. The dermis contains a heavy infiltrate of lymphocytes and eosinophils with few neutrophils.

Fig. 40.6 Pemphigus vegetans. Vegetations with no evidence of blistering. (Courtesy of Dr R.J. Pye, Addenbrooke's Hospital, Cambridge, UK.)

Direct immunofluorescence demonstrates intercellular IgG sometimes with C3. Circulating intercellular antibodies can be detected in most patients by indirect immunofluorescence.

Clinical features. The disease affects chiefly middle-aged adults. Involvement of the oral mucosa is almost invariable. Lesions are primarily flexural, although vegetations may occur at any site [8]. The subdivision into Neumann and Hallopeau types is mainly of historical interest.

Neumann type (Fig. 40.6). Vesicles and bullae rupture to form hypertrophic granulating erosions, which bleed easily. The lesions evolve into vegetating masses exuding serum and pus. The edges are studded with small pustules. Erosions at the edge of the lesions induce new vegetations, which eventually become dry, hyperkeratotic and fissured.

Hallopeau type (synonyms pyodermite végétante, pyoderma vegetans). Pustules rather than vesicles characterize early lesions but these soon progress to vegetating plaques. As in the Neumann type, the vegetations are studded with pustules. In one patient, pemphigus foliaceus preceded the onset of pemphigus vegetans of Hallopeau [9].

Prognosis. The course of the Neumann type of pemphigus vegetans is similar to pemphigus vulgaris but is generally prolonged. The Hallopeau type is more benign and spontaneous remission is possible.

Differential diagnosis of pemphigus vulgaris and pemphigus vegetans. Patients with mucosal lesions present to dental surgeons, oral surgeons and gynaecologists. Erosions may simulate acute herpetic stomatitis, erythema multiforme, aphthous ulcers or bullous lichen planus. Bullae are transient in the mouth and biopsies of erosions may not be diagnostic. Smears taken from the base of an erosion may show acantholytic cells (Tzank preparation). Direct immunofluorescence is the most accurate way to diagnose mucosal pemphigus [1]. Specimens may be posted to a suitable laboratory in Michels medium if facilities for snap-freezing and storage of the tissues are not available [2]. Indirect immunofluorescence may be a useful confirmatory test.

The diagnosis is less difficult when the patients have cutaneous blisters or erosions. Blisters in pemphigoid are tense and may be haemorrhagic. A Tzank preparation taken from the base of a blister in pemphigoid has no acantholytic cells. The diagnosis of pemphigoid is confirmed histologically by showing subepidermal bullae with immunoreactants in the basement membrane zone.

Acute erythema multiforme is a short-lived disorder that may blister, but is easily differentiated from pemphigus histologically.

Blistering in dermatitis herpetiformis is subepidermal and direct immunofluorescence of involved and uninvolved skin shows a granular deposition of IgA in the basement membrane zone.

Vegetating, pustular lesions in flexures must be differentiated from chronic infections or Hailey–Hailey disease (benign familial chronic pemphigus). Vegetating plaques mimicking pemphigus vegetans have been seen in IgA pemphigus [3] and paraneoplastic pemphigus [4]. The hyperkeratotic lesions of chronic pemphigus vegetans may simulate cutaneous tumours. The histology may be misinterpreted if immunofluorescence studies are not performed [5].

The histological differential includes Darier's disease, Hailey–Hailey disease (benign familial chronic pemphigus) and transient acantholytic dermatosis (Grover's disease). These conditions have distinctive clinical features in addition to negative immunofluorescence studies. Eosinophilic spongiosis may be an early histological manifestation of either pemphigus or bullous pemphigoid [6]. Immunofluorescence studies are needed to confirm the diagnosis.

Treatment of pemphigus vulgaris and pemphigus vegetans. The introduction of corticosteroids has greatly reduced mortality, but a significant morbidity remains [1]. Numerous steroid regimens, with and without immunosuppressive agents, have been recommended but randomized, controlled trials for regimens are few. Treatment has been the subject of a number of reviews [2–4].

Monitoring activity of disease

In the acute phase the progress of the disease should be evaluated clinically. Once blistering stops and erosions heal, changes in the titre of circulating pemphigus antibody may help in guiding the dose of steroids [5,6]. Direct immunofluorescence studies of normal skin have also been recommended to predict remission or relapse [6].

Topical therapy

Patients who present with oral disease and mild cutaneous involvement may remain in this localized phase for months. Potent topical or intralesional steroids may reduce the requirement for oral steroids. Topical anticholinergic gel (pilocarpine gel) is reported to help healing of oral erosions [7].Good oral hygiene, including treatment of periodontal disease, is important.

Opportunist infection is the major cause of death in patients with widespread blistering who are also immunosuppressed. Potassium permanganate and topical antiseptics may help reduce the risk of cutaneous infection, whilst topical nystatin, amphotericin or one of the imidazoles will reduce the risk of oral candida.

Systemic therapy

Corticosteroids. Prednisolone with an adjuvant is the preferred treatment for pemphigus vulgaris [3]. Prednisolone 1.0 to 1.5 mg/kg/day in combination with topical or intralesional steroids is sufficient to control disease in many patients. The dose should be titrated to the clinical response [8] but it is important to stop oral steroids when the disease is inactive rather than maintain patients on a homeopathic dose [9].

Patients with generalized disease may require more aggressive immunosuppression to suppress blistering, but the major difficulty in managing these patients is achieving a balance between the risks associated with high-dose steroid therapy and those of poorly controlled disease. High doses of prednisolone, 120–240 mg/day, have been recommended for severe pemphigus, but the risks are considerable [1,10,11]. Prednisolone 60–100 mg/day or IV pulses of either 1 g methylprednisolone or 100 mg dexamethasone are safer alternatives [9,12,13].

Adjunctive treatments. A number of immunosuppressive agents have been recommended as adjuncts to oral steroids [2,3,14]. Azathioprine is widely used in a dose of 2.5 mg/kg/day. The combination of prednisolone and azathioprine is more effective than prednisolone alone both in terms of mortality and remission [3,15,16]. One randomized, controlled trial of pemphigus treatment found azathioprine to be the most effective steroid-sparing agent, followed by cyclophosphamide (pulse therapy) and mycophenolate mofetil [17]. Another trial found azathioprine and mycophenolate mofetil to be equally effective [18]. Azathioprine may be an effective monotherapy in mild cases, although the therapeutic effect is delayed for 3 to 5 weeks.

Cyclophosphamide alone is not effective in pemphigus, but cyclophosphamide 1–3 mg/kg/day is an effective alternative to azathioprine in combination with steroids. The combination is more effective than steroids alone [3,14,19]. Monthly IV pulses of cyclophosphamide with dexamethasone combined with low-dose oral cyclophosphamide have been used with great success [12,16,20]. Remission was maintained with low doses of oral cyclophosphamide [12].

Mycophenolate mofetil (2 g/d) has been found helpful as a steroid sparing agent in some [21–23]. One randomized, controlled trial found mycophenolate mofetil to be a less effective adjunct than azathioprine [17], while another smaller trial found no difference in efficacy between the two [1].

Tetracycline in combination with prednisolone has been reported as useful in an uncontrolled study [24]. A small controlled study showed superiority over prednisolone and azathioprine [25]. Oral or intramuscular gold in addition to steroids reduces mortality and increases the number of patents in remission [3,14].

Ciclosporin alone is not helpful in the acute phase of the disease. Ciclosporin, 5 mg/kg/day, has been used in combination with steroids, particularly in patients with haematological abnormalities [14,26–28]. However, a comparative study found no advantage over prednisolone alone [29]. Topical ciclosporin mouthwash has been found to be helpful in severe oral pemphigus [30].

Dapsone has been advocated as an adjunct in some patients with mild disease [19,31]. A prospective, placebo-controlled study of dapsone as an adjunct with prednisolone showed a modest steroid-sparing effect [32].

Methotrexate is seldom used as there were concerns about toxicity with the high doses that were used [14]. One retrospective review of the literature suggested that methotrexate neither reduced mortality nor changed the number of patients in remission [3]. Others have found that moderate doses of methotrexate (10–17.5 mg/week) permitted withdrawal of prednisolone in steroid-dependent patients [33].

Depletion of B-lymphocytes using the anti-CD-20 monoclonal antibody rituximab has produced remission in some [34] but not all [35] patients with treatment-resistant disease. Life-threatening sepsis is a serious concern.

Removal of circulating antibodies by plasmapheresis [14] or by immunoadsorption [36,37] has induced remission, but concomitant immunosuppression with steroids or cyclophosphamide is needed to prevent a rebound increase in the synthesis of antibody. Sepsis is a serious complication.

Other therapies tried for resistant cases of pemphigus include PUVA and extracorporeal photophoresis [14]. High dose intravenous immunoglobulin (IVIg) is capable of inducing rapid remission but the benefit is short-lived [38,39]. IVIg has been reported as beneficial as a steroid-sparing agent [40]. Acetretin has been used in conjunction with prednisolone in pemphigus vegetans [41] and the TNF blockers infliximab [42] and etanercept [43] have also been reported as beneficial.

Pemphigus foliaceus and its variants

Definition. Blistering in this group of autoimmune diseases is high in the epidermis, either in the granular layer or just beneath the stratum corneum.

Aetiology. Pemphigus foliaceus is less common worldwide than pemphigus vulgaris and in most parts of the world probably accounts for only 10–20% of cases of pemphigus [1–5]. Endemic pemphigus foliaceus is common in rural parts of South America, particularly certain states of Brazil, where it also known as fogo selvagem (wild fire) [6] and in rural Tunisia [7]. It is probably triggered by an environmental factor (see below). Pemphigus foliaceus is also more common than pemphigus vulgaris in Mali, Libya and in South Africa, where it predominantly affects black races [8,9]. Susceptibility to pemphigus foliaceus has been correlated with the presence of HLA-DR4, DR-14 and DR-1 alleles, but unlike pemphigus vulgaris no single allele has been associated with the disease. Sporadic and endemic forms of PF show similar HLA susceptibility alleles. Susceptibility to both sporadic and endemic PF is also associated with a single nucleotide polymorphism in the gene for desmoglein-1 and a cytokine (IL-6) gene polymorphism predisposes to endemic pemphigus foliaceus [10].

Pathogenesis. Experimental evidence suggests that autoantibodies in all forms of pemphigus foliaceus are pathogenic.

Pemphigus foliaceus antigen. Sera from all forms of pemphigus foliaceus recognize epitopes located in the extracellular aminoterminal domain of desmoglein-1, a 160-kDa desmosomal cadherin [11–14]. The epitopes recognized by autoantibodies in endemic pemphigus foliaceus may differ from those in the non-endemic form [15]. Rare cases of pemphigus foliaceus evolving into pemphigus vulgaris develop antibodies to desmoglein-3 [16–21]. A small subset of pemphigus foliaceus sera have both desmoglein-3 and desmoglein-1 antibodies in the absence of clinical evolution [22]. Some sera, particularly from endemic pemphigus foliaceus, also contain autoantibodies directed against desmocollins 1 and 2 [23,24]. Cases of pemphigus foliaceus with antibodies to desmoplakin [25] and to keratinocyte cholinergic receptors [26] have also been reported. Their significance is unknown.

Localization of antigen. Immunoelectron microscopy has demonstrated that the antibodies bind exclusively to desmosomes [27,28]. Pemphigus foliaceus antigen (desmoglein-1) is expressed more strongly in skin from their upper torso than from the lower torso or scalp [29]. In culture the antigens are only expressed by stratified keratinocytes [30]. Although direct immunofluorescence may be positive around keratinocytes throughout the epidermis, pemphigus foliaceus sera bind to significantly more desmosomes in the upper epidermis than the lower epidermis, the reciprocal of the pattern with pemphigus vulgaris sera [31], thus the pattern of binding correlates with the histological level of split in the epidermis. Antibody binding may have a direct effect on the function of the desmosomal cadherins in the upper epidermis, causing detachment of keratinocytes. Desmoglein-1 is present but only weakly expressed in mucosae [32] accounting for the lack of mucosal involvement in pemphigus foliaceus.

Antibodies. Patients with both sporadic and endemic forms of pemphigus foliaceus have anti-DG1 antibodies, the titre correlating both with the extent and activity of the disease [33,34]. Recently, using more sensitive ELISA techniques, anti-DG antibodies (both DG1 and DG3) have also been detected in unaffected individuals living in areas where endemic pemphigus foliaceus is prevalent [35,36]. Subsequent development of pemphigus foliaceus in some of these individuals was preceded by a marked increase in antibody titres [35]. The pathogenic autoantibodies in all forms of pemphigus foliaceus are predominantly in the IgG4 subclass [12,37,38]. Immunohistological staining for desmosomal

components appears abnormal in skin from patients with pemphigus foliaceus, possibly altered by binding of autoantibodies [39,40].

Pathogenicity. Purified IgG fractions induce loss of cell adhesion in skin organ cultures and neonatal mice with the typical histological findings of pemphigus foliaceus. Complement is not required. Antigen-specific immunoadsorption of the autoantibodies prevents blisters [41,42].

Proteases. Proteolysis may augment the acantholytic process as in pemphigus vulgaris (see above). High concentrations of plasminogen induce foliaceus-like acantholysis in cultured skin. Pemphigus foliaceus antibodies stimulate epidermal cells to secrete plasminogen activator, but secretion is reduced by corticosteroids. Antibodies against the plasminogen activator, urokinase, block acantholysis induced by pemphigus foliaceus IgG [43].

Pathology. In early lesions, vacuoles form in the intercellular spaces in the upper levels of the epidermis. These coalesce to form clefts and superficial bullae high in the granular layer or immediately below the stratum corneum. Bullae contain fibrin, some neutrophils and scattered acantholytic keratinocytes. Eosinophilic spongiosis [1] or neutrophilic spongiosis [2] may precede blisters. Frank neutrophilic pustules have been described [3]. Older lesions are acanthotic, papillomatous and hyperkeratotic with focal parakeratosis. Dyskeratotic cells in the granular layer of older lesions distinguish pemphigus foliaceus from pemphigus vulgaris [4]. A mixed inflammatory infiltrate of eosinophils and neutrophils occupies the superficial dermis.

Direct and indirect immunofluorescent findings are usually indistinguishable from pemphigus vulgaris with intercellular IgG and C3 throughout the epidermis. Occasionally intercellular staining is restricted to the upper layers of epidermis, both on direct and indirect immunofluorescence [5]. Rarely, intercellular IgA is detected by direct immunofluorescence [6]. Indirect immunofluorescence is positive in over 85% of pemphigus foliaceus sera, ELISA detects anti-desmoglein-1 antibodies in up to 71% of patients but immunoblotting is less sensitive (43%) [7].

Electron microscopy demonstrates loss of desmosomes, detachment of keratin tonofilaments and dyskeratosis [4].

Clinical features. Pemphigus foliaceus is less severe than pemphigus vulgaris. Most cases are idiopathic but penicillamine and other drugs containing thiol groups, for example captopril, have been implicated (see section on induced pemphigus, below). The onset is usually insidious with scattered, scaly lesions involving the 'seborrhoeic' areas: scalp, face, chest and upper back (Figs 40.7 & 40.8). Localized disease slowly extends. Blistering may not be obvious because the cleavage is superficial and the small flaccid blisters rupture easily. Scales separate leaving well-demarcated, crusted erosions surrounded by erythema, sometimes with small vesicles along the borders. Erosions are both painful and offensive. Eventually the patient may become erythrodermic with crusted, oozing red skin (Fig. 40.9). Oral lesions are uncommon [1].

Fig. 40.7 Pemphigus foliaceus. Well-demarcated crusted lesions scattered over the chest.

Fig. 40.8 Pemphigus foliaceus. Sharply demarcated areas of erythema, crusting and scaling with no obvious bullae.

Although the antibodies in pemphigus foliaceus can cross the placenta, the neonate is not usually affected [2]. In two cases in which the neonate did develop pemphigus foliaceus, both mother and neonate had very high antibody titres [3,4].

Clinical variants of pemphigus foliaceus

Pemphigus resembling dermatitis herpetiformis. A rare and atypical variant of pemphigus resembles dermatitis herpetiformis in its early phase (pemphigus herpetiformis) [5,6]. Widespread

Fig. 40.9 Pemphigus foliaceus. This man became erythrodermic and then developed widespread, painful erosions.

clusters of pruritic papules and vesicles develop on an erythematous background. Biopsies show subcorneal pustules, eosinophilic spongiosis or features of dermatitis herpetiformis without acantholysis but immunofluorescence studies reveal intercellular staining. Patients possess circulating IgG intercellular autoantibodies which recognize either desmoglein-1 [7,8] or desmoglein-3 [8,9] or neither antigen [8]. The condition usually evolves into classical pemphigus foliaceus but has also been described preceding pemphigus vulgaris [7]. In general the clinical course is benign.

Pemphigus erythematosus (Senear–Usher syndrome). Pemphigus erythematosus is a variant of pemphigus foliaceus, originally described by Senear and Usher [10–12]. Patients have immunological features of both lupus erythematosus and pemphigus, that is granular IgG and C3 at the basement membrane zone, intercellular IgG and C3 in the epidermis and circulating antinuclear antibodies [13]. The antibodies recognize the pemphigus foliaceus antigen, desmoglein-1 [14]. Progression to systemic lupus erythematosus is rare. Pemphigus erythematosus may be associated with myasthenia gravis or thymoma [13,15].

Erythematous, scaly lesions over the nose and cheeks in a butterfly distribution simulate cutaneous lupus erythematosus or seborrhoeic dermatitis. Sunlight may exacerbate the disease. Lesions on the trunk, either localized or generalized, are similar to those in pemphigus foliaceus. Oral mucosa is involved rarely.

Differential diagnosis. Pemphigus foliaceus may resemble seborrhoeic dermatitis or impetigo, but the histological and immunological features are diagnostic. Pemphigus erythematosus needs to be distinguished from both seborrhoeic dermatitis and chronic cutaneous lupus erythematosus. Pemphigus may simulate dermatitis herpetiformis both clinically and histologically, but immunopathological studies differentiate the diseases. Histological features may not be diagnostic in the early stages. Eosinophilic spongiosis may be an early manifestation [16]. Immunofluorescence studies should always be performed if pemphigus is suspected.

Treatment of pemphigus foliaceus and its variants. These superficial forms of pemphigus usually respond to potent topical or intralesional steroids or, if control is inadequate, prednisolone 20–40 mg/day. Azathioprine or cyclophosphamide are effective adjuncts to oral steroids in severe cases. Hydroxychloroquine 200/mg twice per day has also been recommended as adjuvant therapy [17]. Intravenous immunoglobulin has been reported as effective in resistant cases [18,19].

Dapsone 100–300 mg/day may be effective as a monotherapy or given in combination with oral steroids [20]. Dapsone 100–300 mg/day is the treatment of choice for pemphigus with dermatitis herpetiformis-like lesions (pemphigus herpetiformis), but retinoids have been suggested as a second-line therapy in these patients [21,22]. Mycophenolate mofetil has been used as a steroid-sparing agent [23,24].

Nicotinamide 1.5 g/day combined with either tetracycline 500 mg four times per day or minocycline 100 mg/day appeared effective in superficial pemphigus in one uncontrolled study [25] but these results were not substantiated [26]. High-dose intravenous immunoglobulin has been used successfully in severe pemphigus foliaceus, resistant to other therapies [19].

Prognosis of pemphigus foliaceus. Pemphigus foliaceus is generally regarded as a benign disease which responds well to treatment and may remit. However, like pemphigus vulgaris it can also pursue a very chronic course over many years and be subject to repeated relapse [27]. There are rare reports of pemphigus foliaceus evolving both clinically and immunopathologically into pemphigus vulgaris [28–33]. Pemphigus erythematosus may persist as localized disease for years. The clinical course is often similar to pemphigus foliaceus.

Endemic pemphigus foliaceus

Synonyms
- Fogo selvagem (wild fire)
- Brazilian pemphigus foliaceus

One form of pemphigus foliaceus is endemic to certain parts of South America. Histologically and immunopathologically it resembles the non-endemic form and is distinguished from it by its unique epidemiological features, including geographical and temporal and familial clustering of cases, high prevalence in the young, and association with certain HLA haplotypes [1].

Endemic pemphigus foliaceus occurs clustered in certain subtropical states of Brazil [1–4]. For a recent review see Culton *et al.* [5]. Endemic foci have also been reported in Columbia, El Salvador, Paraguay and Peru [1–4,6]. An endemic focus has also been observed in rural Tunisia and Libya [2–4].

Aetiology and pathogenesis. Passive transfer studies demonstrate the pathogenicity of desmoglein-1 antibodies [7] which as in idiopathic pemphigus foliaceus are of IgG4 subclass. Sera recognize epitopes located in the extracellular aminoterminal domain of desmoglein and may be different from those involved in non-endemic disease [8]. Some sera also contain autoantibodies directed against desmoglein-3 [9] and desmocollins-1 and 2 [10,11]. Autoantibodies bind to oral mucosa as well as to skin [12]. Mucosal involvement clinically virtually never occurs but there may be ultrastructural abnormalities, for example widening of the intercellular spaces and desmosomal changes [13].

Using sensitive ELISA techniques, it is now clear that the prevalence of antidesmoglein-1 antibodies is high among normal subjects living in an endemic area. The background prevalence of desmoglein-1 antibodies is 20% in the general population, chiefly comprising non-pathogenic IgG subclasses or targeting a non-pathogenic domain of desmoglein-1 [14,15]. IgM class anti-Dsg1 antibodies are common in FS patients and in unaffected Amerindians in their native environment but are absent in migrants to urban areas [16]. Antidesmoglein-3 IgG has also been detected by ELISA in 43% of patients with fogo selvagem (without mucosal disease) and also in 20% of unaffected Amerindians [17]. The significance of desmoglein-3 antibodies is unknown.

The seroepidemiological evidence suggests that endemic pemphigus foliaceus is precipitated by an environmental factor, possibly a biting insect. The disease is endemic in newly developed jungle areas of Brazil that are being used for agriculture, but endemic foci are eradicated by urbanization. Rural labourers are at greatest risk. The incidence of disease is greatest at the end of the rainy season when insects are most abundant. Black fly (*Simuliidae*) bites are a risk factor for the disease [1]. Desmoglein-1 antibodies are especially prevalent in individuals with insect-transmitted parasitic diseases compared to those with non-insect borne infections. No infectious agent, chemical toxin or pollutant has yet been isolated.

Possibly, exposure to components of insect vector salivary antigens triggers the formation of antibodies which cross-react with human epidermal antigens [18]. In susceptible individuals, the immune response may become pathogenic by epitope spreading to target the pathogenic domains of desmoglein-1 [14] or by IgG subclass switching to produce pathogenic IgG4 [19].

A significant number of cases have an affected family member [1]. In one Brazilian population the susceptibility allele was identified as HLA-DRB1*0102. In two other Brazilian populations different alleles of the HLA-DRB1 gene (DRB1*0404, *1402 or *1406) have been linked to the development of endemic pemphigus foliaceus [6,20]. All alleles involved in predisposition to disease share

the same amino acid sequence in the DRB1 gene. Inheritance of this sequence may determine susceptibility when individuals are exposed to the appropriate environmental agent [1].

Clinical features. Endemic pemphigus foliaceus affects children and young adults, with a peak incidence in the second and third decades, whereas other forms of pemphigus foliaceus affect middle-aged adults [21,22].

Patients present with flaccid bullae which rupture easily leaving superficial erosions. Nikolsky's sign is positive. The head and neck are involved at first. The burnt appearance and burning sensation, particularly on sun exposure, gives the disease its popular name, fogo selvagem, Portuguese for 'wild fire'. The disease slowly spreads acrally and may become generalized. Oral mucosa is usually spared.

Some patients develop widespread bullae with pyrexia, arthralgia and malaise. Generalized erythroderma may supervene. Chronic disease is frequent with disseminated verrucous lesions that simulate prurigo nodularis. Plaques may vegetate. Hyperpigmentation is a feature of inactive disease.

Growth retardation, common in affected children, responds to treatment with oral corticosteroids. Adults who were affected in childhood may have azoospermia. Patients may show signs of chronic depression [21,22].

Although antibodies to desmoglein-1 cross the placenta, the disease is rarely transmitted from affected mothers to the neonate [23], except in rare cases with high titre antibodies [24]. Desmoglein-3 is more highly expressed in neonatal than adult skin and this may be protective [25].

Treatment. Treatment is similar to other forms of pemphigus foliaceus. Topical steroids are effective in localized disease or as an adjunct to systemic treatment. Most patients respond to systemic steroids alone, but verrucous plaques may be resistant to therapy. Immunosuppressive agents, gold and antimalarials have been recommended [22,23].

Prognosis. Before the advent of corticosteroids 40 to 60% of untreated patients died. Now less than 10% die, often as a result of the complications of treatment. Spontaneous remissions have been reported.

Induced pemphigus

Drugs may exacerbate or induce pemphigus. Drugs containing a sulphydryl group (thiol drugs) such as penicillamine and captopril are the best studied, but pemphigus can also been attributed to non-thiol drugs, including other ACE inhibitors, for example enalapril [1], ramapril [2], fosinopril [3], and the angiotensin II receptor blockers candesartan and telmisartan [4]. Other drugs implicated in pemphigus are nifedipine, the penicillins, cephalo-

sporins, pyrazolon derivatives, chloroquine, hydoxychloroquine, rifampicin, montelukast and interferon [5–8].

Pemphigus vulgaris and foliaceus have been induced by radiotherapy [9–11] and pemphigus vulgaris by thermal burns [12] and electrical injury [13]. Apparently, dietary factors, particularly vegetables of the *Allium* group, have triggered pemphigus [14]. Human herpes virus-8 DNA sequences have been reported in peripheral blood mononuclear cells and skin from pemphigus patients [15,16]. Their significance is disputed [17].

Aetiology and pathogenesis. Alleles of HLA-DR4 predispose to pemphigus vulgaris and a susceptibility allele is also carried by individuals with drug-induced pemphigus [18]. Perhaps drugs act to trigger disease in genetically predisposed individuals. Thiol drugs provoke acantholysis *in vitro*, possibly by increasing the activity of plasminogen activators. An active amide group in the molecule of non-thiol drugs may be responsible for inducing disease [5].

Clinical features. Pemphigus foliaceus or pemphigus erythematosus are the most common patterns of pemphigus induced by drugs. Drug-induced pemphigus vulgaris and pemphigus vegetans are rare. Most patients have circulating autoantibodies with the same antigenic specificities as in other forms of pemphigus [19,20].

Prognosis. Forty to 50% of patients with thiol-drug-induced pemphigus recover spontaneously when the drug is withdrawn [5] with rapid decline in desmoglein antibody levels [21]. Only 15% of the cases induced by non-thiol drugs remit following drug withdrawal [5].

Intercellular IgA dermatosis and subcorneal pustular dermatosis

These two conditions share clinical and histological features. Immunofluorescence studies were negative in classical subcorneal pustular dermatosis. Although there is overlap, the relationship between the diseases has not been defined, and so they are considered separately here.

Intercellular IgA dermatosis

Synonyms
- IgA pemphigus foliaceus
- Intraepidermal neutrophilic IgA dermatosis
- IgA herpetiform pemphigus
- Intercellular IgA vesiculopustular dermatosis

Over 50 cases have been reported of patients presenting with vesicopustular or vesicobullous eruptions with intraepidermal antikeratinocyte IgA detected in perilesional skin on direct IMF. These comprise a heterogeneous group clinically, histologically and immunologically. Some may be variants of subcorneal pustular dermatosis (see below), others may be a form of pemphigus, but the relationships between these conditions have still to be clarified [1,2].

Pathology. A neutrophil-rich polymorphonuclear infiltrate in the epidermis is observed. Two types are distinguished based on the level of pustule formation and IgA deposition [1]: the subcorneal pustular dermatosis type (subcorneal pustules) and the intraepidermal neutrophilic type (intraepidermal pustules). However, microabscesses at various levels have been observed and may depend on the age of the lesion [2]. Acantholysis is usually sparse or absent but is occasionally pronounced, mimicking either pemphigus vulgaris or pemphigus foliaceus histologically.

Pathogenesis. The hallmark of these disorders is intercellular IgA deposition in the epidermis, either at different levels or throughout. Circulating IgA is either undetectable or present in low titre

[2–4] and a few cases have coexisting IgA and IgG [5]. Desmocollin-1, a desmosomal component located mainly in the upper epidermis, has been identified as the target antigen in cases with subcorneal pustules [6–8] but also occasionally in the intraepidermal neutrophilic type [5]. In an ultrastructural study of antigen localization, cases with subcorneal pustules showed deposits predominantly in the extracellular spaces between keratinocytes at desmosomes, suggesting reactivity with the extracellular domain of desmocollins [9]. One case of subcorneal pustular dermatosis had IgA antibodies to both desmocollin-1 and desmoglein-1 [10].

In patients with intraepidermal neutrophilic pustules, antigens resembling desmogleins-1 [6] or 3 [8,11–13] have been implicated. In other cases the target antigen could not be identified. Standard immunoblotting is frequently negative, probably because the target epitopes are conformation dependent [8,14]. Immunoelectron microscopy in cases with intraepidermal neutrophilic pustules showed deposits mainly in the intercellular spaces in non-desmosomal areas, suggesting that IgA may target a non-desmosomal transmembranous protein [9].

Clinical features. The disease chiefly affects adults, though childhood cases have been reported [1,2]. Patients with both types have flaccid vesicles or pustules arising on either erythematous or normal skin. The lesions may be pruritic and show a circinate or annular configuration with central clearing and evolve to crusted or scaly erythematous macules. The sites of predilection are the axillae and groins. Other sites are elsewhere on the trunk, face, scalp and proximal limbs. In some cases the flaccid pustules resemble those seen in subcorneal pustular dermatosis of Sneddon–Wilkinson. Others may resemble pemphigus foliaceus or pemphigus herpetiformis [15–17]. Flexural, oozing, verrucous plaques mimicking pemphigus vegetans have been described in a child [18]. Nikolsky's sign is usually negative and mucosal involvement is unusual. Most run a chronic, indolent course.

The most frequently reported association is with monoclonal IgA gammopathy in the subcorneal type [19,20], a feature it has in common with classical subcorneal pustular dermatosis. Other cases have been linked with HIV infection, inflammatory bowel disease, gluten sensitive enteropathy [21–25], rheumatoid arthritis [2] and thiol drugs [26].

Treatment. These neutrophilic dermatoses respond well to dapsone [3,4,27] but poorly to steroids [3]. Other reported therapies are etretinate [3,27,28], isotretinoin [29], PUVA [28], immunosuppressives [16], plasmapheresis [30] and colchicine [12,31].

Subcorneal pustular dermatosis

Synonym
- Sneddon–Wilkinson disease

Definition. A chronic, relapsing, pustular eruption, mainly involving the trunk, which affects women over 40 years of age. Pustules are subcorneal.

Background. This disorder was separated from bullous impetigo in 1956 [1]. The exact nosological position of subcorneal pustular dermatosis remains controversial. Some cases may be a variant of pustular psoriasis whereas others appear to overlap with the subcorneal pustular variant of IgA pemphigus [2].

Pathogenesis. The pathogenesis is obscure. The salient feature is subcorneal accumulation of neutrophils. Culture of the pustules is sterile. Subcorneal pustular dermatosis has been reported in association with various types of immune dysfunction. Monoclonal gammopathy, usually IgA (occasionally IgG), has been reported often. The paraproteinaemia is usually benign but IgA myeloma also occurs. Other reported associations are pyoderma gangrenosum, inflammatory bowel disease and rheumatoid arthritis [3–7]. The condition has also been observed at the injection site of recombinant human granulocyte–macrophage colony-stimulating factor in a patient with IgA myeloma [8]. Excess production of TNF-α has been implicated in the pathogenesis of neutrophil activation [9].

In classical subcorneal pustular dermatosis, immunofluorescent studies are negative. However, a possible subgroup with identical clinical and histological features to the 'classical' type have intercellular IgA deposition in the upper epidermis [10,11]. Desmocollin-1 is the target antigen in these cases and a study of antigen localization by post-embedding immunoelectron microscopy, showed deposits predominantly in the extracellular spaces between keratinocytes at desmosomes, suggesting reactivity with the extracellular domain of desmocollins [12]. One case of subcorneal pustular dermatosis had IgA targeting both desmocollin-1 and desmoglein-1 [13]. There are also examples of 'classical, immunofluorescence-negative' cases in whom intercellular epidermis IgA deposits were detected on repeat immunofluorescence testing [11], in one case after a latent period of many years [14]. The relationship between the intercellular IgA dermatoses, regarded as part of the pemphigus spectrum, and classic subcorneal pustular dermatosis remains unclear (see above).

Pathology. Biopsies from early lesions show a perivascular inflammatory infiltrate with neutrophils and occasional eosinophils. Neutrophils migrate through the epidermis, without forming spongiform pustules, to collect beneath the stratum corneum in subcorneal pustules. The pustules sit on the surface of the epidermis rather than being an integral part of it. A few acantholytic cells may be found in old lesions [1]. Ultrastructural studies show cytolysis of single cells and invasion by neutrophils [15].

Both direct and indirect immunofluorescent studies are negative in classical cases [16], but recently some cases have been described with clinical features resembling classic subcorneal pustular dermatosis but with intercellular IgA within the epidermis [17–19].

Fig. 40.10 Subcorneal pustular dermatosis. Annular lesions with a scaly margin and surrounding pustules. Pus has accumulated in the lower half of the flaccid pustule leaving clear fluid in the upper half.

Clinical features [1,20,21]. The disease is more common in women than in men and usually affects individuals between 40 and 50 years of age. The eruption occurs mainly in flexures and on the flexor aspect of the limbs. The face is almost never affected, nor are the mucous membranes. The primary lesion is an oval, pea-sized flaccid pustule, which arises on normal skin or a slightly erythematous base. Characteristically, pus accumulates in the lower half of a fully developed pustule, leaving clear fluid in the upper half (Fig. 40.10). Pustules rupture easily and tend to coalesce, forming annular or serpiginous patterns with a scaly edge. The eruption fades to leave faint hyperpigmentation but successive waves of pustules pass across the previously affected areas. The interval between active and quiescent phases varies from several days to several weeks.

Prognosis. The condition is benign but chronic, with an average duration of 5.8 years [1]. The presence of myeloma worsens the outlook.

Diagnosis. The differential diagnosis includes impetigo, pustular psoriasis, pemphigus foliaceus, dermatitis herpetiformis, intercellular IgA dermatosis and acute generalized exanthematic pustulosis.

Pathogenic organisms are cultured from pustules in impetigo and the condition responds to antibiotics.

Pustular psoriasis, either of the acute von Zumbusch type with small pustules or the spreading annular type, may resemble subcorneal pustular dermatosis. Spongiosis is not a feature of subcorneal pustular dermatosis, but spongiform pustules, which are an integral part of the epidermis, are characteristic of pustular psoriasis [22]. Subcorneal pustular dermatosis, unlike pustular psoriasis, responds to dapsone. Some authors consider that subcorneal pustular dermatosis is part of the spectrum of pustular psoriasis [23].

'Atypical cases' reported as examples of subcorneal pustular dermatosis may be unusual presentations of pustular psoriasis.

Biopsies from early lesions of pemphigus foliaceus may show subcorneal pustules with very little acantholysis. Direct immunofluorescence will show intercellular IgG in the epidermis in pemphigus.

Acute generalized exanthematic pustulosis is distinguished by its acute onset in a febrile patient with a history of exposure to a candidate drug. The histology shows spongiform pustules [24].

Treatment. Dapsone 50 to 150 mg daily is the treatment of choice. Though the response to dapsone is slower than in dermatitis herpetiformis, most patients obtain partial, if not complete, relief. Sulphpyridine and sulphamethoxypyridazine have been used as alternatives. Treatment can often be weaned or stopped without relapse. Some cases do respond to potent topical corticosteroids [25] or oral steroids [9] but in general steroids are ineffective even in large doses. Etretinate [6,18,26] and acetretin [27] have been used. Isotretinoin was found ineffective at a dose of 0.5 mg/kg/d [28]. Broad-band UVB [29], narrow-band UVB [30,31], PUVA [18,32] and Re-PUVA have also been reported as effective. Colchicine [33] and topical tacalctiol [34] have been recommended. There are individual cases reports of the use of etanercept [35], combination adalimumab and mycophenolate mofetil [36] and infliximab, which produced rapid but short-lived benefit [37]. In cases associated with myeloma, the skin lesions may improve when the paraprotein is reduced by chemotherapy [19].

Paraneoplastic pemphigus

A distinctive form of pemphigus has been described in association with a variety of underlying neoplasms [1] most commonly B-cell

lymphoproliferative disorders but also thymoma, sarcomas and carcinomas [2,3]. Some cases have been linked with the use of fludarabine chemotherapy [4,5]. The clinical features overlap with erythema multiforme and lichen planus pemphigoides. Patients have severe mucosal erosions and polymorphous cutaneous signs including blisters, erosions, particularly on the upper body, and palmoplantar target lesions [1,2,6–10]. An exceptional case, associated with thymoma, had no mucosal involvement despite antibodies to cadherin and plakins typical of paraneoplastic pemphigus (PNP). In two-thirds of cases, PNP occurs with an existing neoplasm; in the remainder the neoplasm is detected after the mucocutaneous disease has occurred [2] and in one case no underlying neoplasm was found over 8 years of follow-up [11]. Biopsies show necrosis of keratinocytes or vacuolar interface dermatitis in addition to suprabasal clefting with acantholysis [12], but the specificity of these histological findings has been questioned [13].

Direct immunofluorescence reveals immunoglobulin and/or complement at the basement membrane zone as well as on the surfaces of keratinocytes. Indirect immunofluorescence is positive in both non-stratifying (simple and transitional) epithelia and stratifying epithelia [14].

Antibodies are predominantly antiplakin antibodies of the IgG1 subclass. Their pathogenicity has been established by passive transfer studies. The autoantibodies recognize a complex of antigens on immunoblotting and immunoprecipitation. These are members of the plakin family of proteins and include desmoplakin-1 (250 kD), envoplakin (210 kD), periplakin (190 kD), plectin (500 kDa) and the 230-kDa bullous pemphigoid antigen [1,15–19]. Epitope mapping shows that major antigenic sites recognized by PNP sera lie in linker subdomains of envoplakin and periplakin [20,21]. Antiplakin antibodies are not specific to PNP and have also been detected in patients with severe erythema multiforme [22], toxic epidermal necrolysis [23], bullous pemphigoid [24] and pemphigus foliaceus [25,26]. Antidesmoglein antibodies have been detected in PNP in some [19,27–29] but not all cases [30]. Clinically indistinguishable lichenoid mucocutaneous but seronegative disease has been reported in four patients with lymphoproliferative neoplasms treated with rituximab. These cases suggest that PNP can occur despite blunting the antibody response by rituximab and that cell-mediated effects may also play a role [31]. Paraneoplastic pemphigus is a multisytem disease. Passive transfer of PNP sera to mice produces autoantibody deposits in skin, upper digestive and respiratory tract epithelia, kidney, urinary bladder, and smooth and striated muscle [32]. Predisposing HLA alleles may differ in different populations, HLA-DRB1*03 being associated in French cases [33] and HLA-Cw*14 in Chinese patients [34].

Paraneoplastic pemphigus is generally refractory to all treatments. Oral steroids, azathioprine, ciclosporin, mycophenolate mofetil and plasmaphoresis have been tried [1,2,8,9,35,36]. Most patients deteriorate inexorably, with death usually secondary to sepsis, gastrointestinal bleeding, multiorgan failure or respiratory failure [2,35]. Cases associated with benign or low-grade neoplasia, such as thymoma or Castleman's disease [8,37–39], may remit partially after surgical removal of the neoplasm. One case associated with non-Hodgkin's lymphoma evolved into typical pemphigus vulgaris after a 4-year disease-free interval [40].

Structure of the dermoepidermal junction

The basal keratinocytes of the epidermis are separated from the underlying dermis by the basement membrane, a two-layered structure on electron microscopy comprising the lamina lucida, the major components of which are laminins and the lamina densa. Above the lamina lucida, straddling the plasma membrane of the epidermal basal cells are discrete, electron-dense structures, the hemidesmosomes. Fine structures, the anchoring filaments, traverse the lamina lucida, particularly in the region of the hemidesmosomes, and appear to terminate in the lamina densa, rich in both laminin 5 and type IV collagen [1]. Beneath the lamina densa and appearing to embed in the upper dermis are curved structures, the anchoring fibrils, composed of type VII collagen (Fig. 40.11) [2]. The laminins are glycoprotein molecules composed of three chains (α, β and γ) bound through disulphide bonds. There are at least 15 different laminin isoforms, which are tissue and development specific. Recently, the nomenclature for the laminin family was revised to assign three-digit numbers to each laminin isoform. For example, the laminin isoform composed of α3β3γ2, formerly known as laminin-5 (also termed kalinin, epiligrin, ladsin or nicein) is now called laminin-332 [3].

The intracellular plaque of the hemidesmosomes contains a 230-kDa polypeptide, a member of the plakin family known as BP230 or BPAg1 as it binds to sera of patients with bullous pemphigoid [4]. Other components of the intracellular plaque are plectin (MW 500 kDa) and the less well characterized antigens HD1, IFAP300 and P200. The intracytoplasmic keratin intermediate filaments (keratins types 5 and 14), organized into tonofilaments, loop down and insert into the hemidesmosomes where they interact with the carboxyterminals of BP230 and plectin.

The transmembrane components of the hemidesmosome include BP180/collagen XVII and α6β4 integrin (see Fig. 40.11). Collagen XVII (MW 180 kD, also known as BP180 as it binds bullous pemphigoid sera) comprises an intracellular globular domain, where its NH_2 terminal interacts with the NH_2 terminal of BP230 [5], with additional stabilizing interactions with both plectin and β4 integrin [6]. The long extracellular collagenous domain of collagen XVII is shed by the physiological action of proteases [7] and interacts both with α6 integrin [6] and with the β3 chain of laminin 5 (laminin-332) in the region of the anchoring filaments. Laminin 5 (laminin-332) also interacts with other laminin isoforms, with both β4 and α6 integrin [8] as well as being the principal ligand for type VII collagen, the main component of the anchoring fibrils. Hence laminin serves as a bridge between the transmembrane hemidesmosomal molecules and the dermal matrix molecules.

These structures collectively form the adhesion complex of the dermoepidermal junction, with continuity running from the keratin filaments within the epidermal cells via the hemidesmosomes, the anchoring filaments and through to the anchoring fibrils embedded in the dermis. In normal skin mechanical stability and adhesion between the epidermis and dermis depends on the integrity of the adhesion complex components. Mutations of these molecules produce skin fragility and blistering, and are considered in Chapter 39. Autoantibody-mediated diseases have been described in relation to BP230, BP180, P200, α6 and β4 integrin, laminin 5 (laminin-332) and type VII collagen, and these are considered in this chapter. There are also case reports of autoimmune bullous disease with antibodies to type IV collagen and plectin.

Subepidermal immunobullous diseases

These bullous diseases include a number of clinical entities (Table 40.4). However, there is clinical overlap and it is not uncommon for individual patients to be difficult to classify clinically (Fig. 40.12). The histology and immunofluorescence similarly are not always distinctive, and the identification of the target antigens for these diseases has demonstrated that not only are the antigens and their specific epitopes common to many of the entities, they are often multiple within a patient. In addition, new antigens are still being described. It seems likely that many as yet poorly characterized or undiscovered molecules within the anchoring complex of the basement-membrane zone can be the targets for autoantibodies in the subepidermal blistering diseases. The expectation that perhaps the immunogenetic constitution of the individual might determine the disease has been only partially fulfilled. Thus, the clinical overlap is reflected in immunopathological and immunogenetic overlap (Fig. 40.12) and is shown in Tables 40.5 and 40.6.

The subepidermal autoimmune bullous diseases are, with the exception of dermatitis herpetiformis, characterized by autoanti-

bodies directed against components of the adhesion complex (see Fig. 40.11). The use of the patient's sera to identify these antigens and their genes has made a major contribution to cell and molecular biology. The mechanisms by which the autoimmune process is initiated and how the combination of antibody with antigen results in blistering are in the process of being elucidated. However, evidence is accumulating that the autoantibodies are pathogenic and animal and other experimental models have demonstrated this with regard to many of the autoantigens, as described below.

Bullous pemphigoid

Synonym
- Pemphigoid

Definition. A blistering disease of elderly people which often starts with pruritus and urticated and erythematous lesions. Later, large, tense blisters develop both on erythematous and on normal skin and there may be mucosal involvement with blisters and erosions. The blisters are subepidermal and intact epidermis forms the roof. Autoantibodies, chiefly IgG, to the epidermal basement-membrane zone are found in the skin and blood [1].

The clinical features, immunopathology and immunogenetics are summarized in Tables 40.5 and 40.6, and see Figs 40.13 and 40.14.

Table 40.5 The subepidermal immunobullous diseases: clinical features.

Disease	Patients	Cutaneous distribution	Mucosal involvement	Lesions	Associations	Treatment	Prognosis
Bullous pemphigoid	Elderly (few infants & children)	Trunk, limbs, flexures	Common, minor	Urticated plaques, tense blisters, (milia)	Neurological disease Psoriasis see text	Steroids, dapsone, immunosuppressives	3–6 years' duration
Mucous membrane pemphigoid	Middle–old age	Infrequent (30%)	Major, severe	Erosions, blisters, gingivitis, milia *Scarring*	Autoimmune disease	Steroids, dapsone, immunosuppressives	Chronic
Pemphigoid gestationis	Pregnant women	Umbilicus, generalized	Minor	Urticated plaques, tense blisters	Autoimmune thyroid disease	Steroids	Remits postpartum
Linear IgA disease chronic bullous disease of childhood	Children	Perineum, face, trunk, limbs	Majority (few severe)	Urticated plaques, annular lesions, tense blisters		Dapsone, sulphonamides	3–4 years' duration (few persist)
adult linear IgA disease	Young adults to elderly	Trunk, limbs	Majority (few severe)	Urticated plaques, tense blisters, papulovesicles	Ulcerative colitis, rare lymphoma	Dapsone, sulphonamides	3–6 years' duration (few persist)
Epidermolysis bullosa acquisita	Adults & children	Generalized, variable	Some (few severe)	Urticated plaques, tense blisters, milia *Scarring*	Inflammatory bowel disease	Steroids, dapsone, immunosuppressives	Persists
Bullous SLE	Adults	Generalized, variable	Minor	Urticated plaques, tense blisters	SLE	Dapsone	Transient
Dermatitis herpetiformis	Young adults (some children and elderly)	Symmetrical, elbows, knees, buttocks	Minor	Papulovesicles	Gluten-sensitive enteropathy, lymphoma	Dapsone, sulphonamides, gluten-free diet	Persists

Aetiology. Bullous pemphigoid is an affliction of elderly people, with onset usually after 60 years of age, with a mean of 80 years [1], but the condition can occur in the under-forties, and about 80 cases have been described in children, the youngest being 10 weeks or less at onset of their disease [2–6]. The risk of developing bullous pemphigoid increases with age [1,7]. Bullous pemphigoid is the commonest immunobullous disease in Western Europe. In France and Germany, the incidence of bullous pemphigoid is estimated to be six to seven cases per million population per year [8,9] and is similar in Singapore [10]. In the UK, the rates are higher and increasing, being 14 per million in Scotland [11] and 30 per million in central UK [1,12]. However, in other countries of the Middle and Far East bullous pemphigoid appears to be rarer [13], and more likely to develop in Indians than Chinese [10,14,15]. Recent work suggests that in Northern Europeans HLA-DQ7 may be associated with bullous pemphigoid but only in men [16,17]. This association does not exist in either Chinese or Japanese patients [18,19].

Pathogenesis. Bullous pemphigoid provides one of the best models for an autoimmune disease. The disease is characterized by IgG autoantibodies to hemidesmosome-associated proteins within the adhesion complex (see Fig. 40.11). The target antigens have been characterized and their genes cloned (see below). The autoantibodies have been shown to be pathogenic and complement to be necessary for blister formation [1–3]. Current knowledge of the pathophysiology of bullous pemphigoid has recently been summarized [4].

The two major bullous pemphigoid antigens are BP230 and BP180, which are associated with hemidesmosomes (see Fig. 40.11) and are the products of genes located on different chromosomes [5].

BP230, also known as BPAG1, was the first to be characterized and has a molecular weight of 230 kDa [6,7]. BP230 is intracellular and localized to the dense plaque [8]. The gene for BP230 has been cloned and resides on the short arm of chromosome 6 [9,10]. It is known to have isoforms which are differentially expressed in epithelial and neuronal tissue [11]. The portions of BP230 antigen that are the target for the autoantibodies (immunodominant epitopes) are located chiefly at the carboxy terminal end which mediates the interaction of keratin intermediate filaments with hemidesmosome [12,13].

BP180, also known as BPAG2 and collagen type XVII, has a molecular weight of 180 kDa [6,14], and is a transmembrane molecule with collagenous domains and a long extracellular portion, which is shed under physiological conditions (see Fig. 40.11) [15,16]. The gene for BP180 has been cloned and is situated on the long arm of chromosome 10 [5,15]. It is located in the hemidesmosome and the extracellular portion interacts with the anchoring filaments [8,17]. The extracellular region adjacent to the transmembrane portion, the NC16A domain, is the immunodominant epitope, however other epitopes are found in many regions of the molecule, including the intracellular region, the shed collagenous ectodomain and the carboxy terminal (see Fig. 40.11) [8,18–23]. This extracellular location makes it a likely candidate for pathogenic autoantibodies.

There are reports of other target antigens in individual patients, the most common being p200, 200 kDa weight, which is associated with the epidermis and dermis [6,24,25].

After 20 years of research it is still unclear as to which autoantigen is the most important in the pathogenesis of bullous pemphigoid. Two animal models have demonstrated that the BP180 autoantibodies in bullous pemphigoid are pathogenic. In the first

model, injection of bullous pemphigoid autoantibodies into rabbit cornea produced subepidermal blisters and immune deposits of IgG and C3 along the basement-membrane zone [1]. Other attempts were unsuccessful until molecular biology demonstrated that the chief epitope differed in mice and humans. Antibodies were raised to the immunodominant mouse epitope of BP180, and these antibodies produced immunopathological bullous pemphigoid in neonatal mice [2]. Early models for pathogenicity of BP230 were successful only with the use of epidermis damaged by UV [26], but more recently a model similar to that for BP180 has induced bullous pemphigoid in mice [3].

The formation of blisters begins with autoantibody deposition, which binds C3 along the dermoepidermal junction [27]. These antibodies are directed at BP180 and BP230 and are mainly of the IgG subclass, predominantly IgG1 and IgG4 isotypes [28]. There is a change with disease duration and remission in the relative amounts of inflammatory IgG1 and less inflammatory blocking IgG4 [29], although IgG4 can contribute to the inflammatory process [30]. The pivotal role of complement has been demonstrated using the mouse model used previously to deduce the autoimmune basis of bullous pemphigoid [2]. Mice depleted of complement did not develop blisters following the injection of pathogenic rabbit BP180 antibodies, and $F(ab')_2$ fragments of the IgG antibody, which cannot bind complement, did not produce disease when injected into animals [31]. Blister formation in C5 deficient mice could be restored if fragments of C5a were injected with the pathogenic anti-BP180 IgG. C5a fragments are thought to stimulate the recruitment of neutrophils to the site of inflammation [31]. The importance of neutrophil recruitment in the pathogenesis of this disease has been shown using the mouse model. Mice depleted of neutrophils by pre-treatment with an antineutrophil serum become resistant to the pathogenic effects of BP180 antibodies [32], indicating that the inflammatory response in bullous pemphigoid is in part mediated by neutrophils. Macrophages too are essential [33]. The role of proteases in blister formation has been shown using mouse models either genetically deficient for neutrophil elastase or with elastase inhibitors, and by demonstrating that elastase can cleave BP180 *in vitro* and *in vivo* [34]. Eosinophil infiltration occurs [35] and releases a 92 kDa-gelatinase (gelatinase B or MMP-9) at the blister site that can cleave BP180 [36]. Mice genetically deficient for gelatinase B did not produce blisters after infusion with antibodies to BP180, unless reconstituted with neutrophils from normal mice [37].

All these data taken together suggest a mechanism for blister formation. Autoantibodies bind to the bullous pemphigoid antigens and activate complement. Complement components set off an inflammatory cascade attracting leukocytes, degranulating mast cells and releasing inflammatory mediators. The activated inflammatory cells release lysosomal enzymes and proteases, cleaving the target antigens and disrupting the hemidesmosomes, resulting in blister formation.

There is accumulating evidence for the role of T cells, both Th1 and Th2, directly by producing inflammatory cytokines and indirectly by production of the autoantibodies in bullous pemphigoid, most of this work concerns reactivity to BP180 but reactivity to BP230 has also been demonstrated [38–41].

Pathology. The blister in bullous pemphigoid is subepidermal with an intact and often viable epidermis forming the roof. The blisters may contain numerous eosinophils and neutrophils. Biopsies of blisters and from erythematous areas of skin show a dermal inflammatory infiltrate containing many eosinophils and neutrophils with lymphocytes and histiocytes. Eosinophilic spongiosis may also be seen. There are patients with bullous pemphigoid in whom the dermal infiltrate is so intense in the papillae that it cannot be distinguished from dermatitis herpetiformis. Old blisters may demonstrate re-epithelialization along the base giving an artefactual intraepidermal blister. Biopsies taken from apparently normal and non-inflamed skin are non-diagnostic or normal.

The findings with immunofluorescence are summarized in Table 40.6 and in a review [1]. Positive direct or indirect immunofluorescence or ELISA to BP180 [2] and BP230 [3] is essential to confirm the clinical and histological diagnosis.

Direct immunofluorescence studies should not be performed on a blister, as the immunoreactants are often lost from the roof of a blister. They are best performed on a perilesional biopsy (within 2 cm of a lesion). The biopsy for immunofluorescence can also be taken from clinically uninvolved skin, the front of the thigh or flexor forearm, if this is more convenient or there are no active lesions, and from mucosal surfaces [4,5]. A 3–4 mm punch biopsy is ideal, and need not be deep. The biopsy will show either IgG and C3, or C3 alone along the basement-membrane zone (Fig. 40.13); deposition of IgA and IgM may also occur. The patient's biopsy can be split by incubation in 1 mol/L sodium chloride (salt-split skin) to provide additional information as to the localization of the target antigens, as the immune deposits should be associated with the hemidesmosomes, and thus present on the epidermal side of the split (roof of the artificial blister) [1,6]. The raising of a suction blister in the patient can give similar information but is cumbersome [7].

Indirect immunofluorescence can be performed on blood, blister fluid and urine (although less often positive), the latter two being useful substitutes for blood with an uncooperative child or adult [8,9]. About three-quarters of bullous pemphigoid patients have a circulating IgG autoantibody to the basement-membrane zone. False positives are rare, and the finding of circulating antibodies is diagnostic. The circulating autoantibodies in bullous pemphigoid react with the epidermal side of normal human skin that has been split by prolonged incubation with salt or suction (Fig. 40.14) [7,10,11]. The use of salt-split skin increases the sensitivity of autoantibody detection and differentiates patients with bullous pemphigoid from those with epidermolysis bullosa, and is to be recommended as a routine technique [10]. There are rare, dermal-binding bullous pemphigoid patients and these can only be identified with immunoelectron microscopy or immunoblotting [12].

Recently, the use of ELISA techniques to detect antibodies against specific epitopes has begun to be used as a routine diagnostic test in some centres [2,3,13,14].

There is a change with time from inflammatory IgG1 to less inflammatory, blocking IgG4 associated with diminution in disease activity, even though an overall diminution in titre may not be seen [15].

Occasionally, patients with bullous pemphigoid have pemphigus-like antibodies, and the diseases may co-exist. This may relate to the homology between BP230 and desmoplakin [16,17].

Immunoelectron microscopy demonstrates that the autoantibodies are deposited in the lamina lucida *in vivo* [18], but in contrast bind to the target antigens in association with the dense plaque (antibodies to BP230) and hemidesmosome (antibodies to BP180) *in vitro* [19].

Immunoblotting demonstrates that the majority of patients have circulating autoantibodies that react with the BP230 and BP180 antigens. The individual patient may react with either or both [20,21]. There is some suggestion that patients who have autoantibodies to BP180 may have more severe or prolonged disease

[22–24]. A clinical pattern indistinguishable from bullous pemphigoid may be seen with other target antigens.

Fig. 40.15 Bullous pemphigoid. Figurate erythema with large tense bullae. (Courtesy of Dr R.J. Pye, Addenbrooke's Hospital, Cambridge, UK.)

Clinical features. Bullous pemphigoid commonly starts with itching and a non-specific rash on the limbs that may be either urticaria-like or occasionally eczematous and rarely may simulate vesicular eczema. The pruritus may persist for many months. The urticarial prodrome usually lasts 1–3 weeks before blisters occur. The eczematous prodrome may precede the blisters by several months. Severe irritation with a faint, dusky erythema in a figurate pattern may sometimes precede blister formation (Fig. 40.15). These changes may closely resemble erythema multiforme or dermatitis herpetiformis. Sudden generalization of the true eruption of bullous pemphigoid follows the prodromal phase and most of the body may be affected within a week.

Blisters may arise on erythematous and on normal skin and may be associated with dermal oedema. The blisters are tense and dome shaped, obtaining a diameter of many centimetres (Figs 40.15 & 40.16). They appear mainly on the flexural aspects of limbs and on the central abdomen. Their contents are usually clear serous exudate, although occasionally this is bloodstained. The blisters are tough and may remain intact for several days, the contents often becoming jelly-like with coagulated fibrin. In some

blisters, the fluid is reabsorbed and the epithelium settles back in place like a skin graft. Those that do rupture leave erosions that heal rapidly, leaving mild post-inflammatory changes. Erythema may persist at the sites of previous blisters for many weeks or months. Milia may be profuse during the healing phase (Fig. 40.17). Mucosal lesions occur less frequently and are less severe than in mucous membrane pemphigoid and pemphigus vulgaris and are usually confined to the mouth. The oral lesions consist of small blisters that, like those of the skin, may remain intact and, if they rupture, heal rapidly.

In infants the distribution of the lesions is often acral and in older children involvement of the genital region occurs in almost half [1].

The acute phase is usually accompanied by leukocytosis and eosinophilia, but fever is uncommon, and in spite of extensive blistering (Fig. 40.15) the patients' general condition remains good. Fresh crops of small blisters may continue to occur even after apparent control has been achieved with treatment.

Induced bullous pemphigoid and associated diseases

There are no well-defined causal agents, although a number of agents have been associated with the development of bullous pemphigoid. Several drugs have been implicated [1], including furosemide [2,3], spironolactone [4], sulphasalazine, penicillins [5–7], penicillamine [8], β-blockers [9] and enaxoparin [10]. These patients tend to have a younger average age than those in the idiopathic group. A case–control study suggests that antipsychotic drugs and aldosterone antagonists are associated with the development of bullous pemphigoid [11]. Whether or not the drugs are exerting a direct effect on the immune system is not yet known.

Local irritation and damage to the skin have all been implicated in the induction of bullous pemphigoid [12]. UV light or PUVA have been described as precipitating or exacerbating bullous pemphigoid [13–17]. Other physical agents, including thermal burns, wounds, localized trauma, skin grafts and radiotherapy, have also been reported to induce bullous pemphigoid in normal skin [12,18]. There have been a number of case reports of bullous pemphigoid associated with radiotherapy for breast cancer [19,20]. Topical 5-fluorouracil has induced bullous pemphigoid, but the role of topical chemical irritants such as anthralin (dithranol) and tar is less clear. Immunization has been reported to induce bullous pemphigoid, especially in children, but there is no association overall with influenza immunization [21–24]. The mechanisms may be alteration or exposure of epitopes of adhesion complex proteins, or a change in the host immunological response.

Bullous pemphigoid is associated with certain other diseases; however, as it occurs in an elderly population these patients often have other disorders at the same time. To determine whether the associations truly exist, prospective age-controlled studies are necessary. There are many individual case reports of bullous pemphigoid in association with autoimmune diseases, although a case–control study did not show an overall association [25]. However, other systemic diseases have been reported in association with bullous pemphigoid. These include diabetes mellitus [26,27], rheumatoid arthritis [28–30] and ulcerative colitis [31–33]. There is an association with multiple sclerosis [34,35] and other neurological diseases, including Parkinson's disease and dementia [36–39]. There are numerous reports of bullous pemphigoid in patients with psoriasis, the blisters may be localized to the plaques of psoriasis or independent of them, and in some instances therapeutic anthralin or UV radiation appeared to be the trigger [14,37,40]. A case–control study suggested an association between psoriasis and bullous pemphigoid [41]. Bullous pemphigoid can occur in the setting of lichen planus (see below and Chapter 41).

There is controversy about the association between bullous pemphigoid and malignancy. Initially, most large series concluded that there is no or only a very small increase in incidence of malignancy in bullous pemphigoid patients compared with age- and sex-matched controls, although the association may exist in individual patients [42]. However, a large series of more than 1000

bullous pemphigoid patients in Japan showed a 5.8% incidence of malignancy (with gastric carcinoma being the commonest), which was significantly higher than that of age-matched controls [43]. A similar incidence was reported in Chinese patients with bullous pemphigoid [44,45] and in Italy [46]. The carcinoma may express the bullous pemphigoid antigens and evoke an immune response.

Pemphigoid nodularis

This entity presents great diagnostic difficulty. The patients present with intensely itchy nodules, suggesting a diagnosis of prurigo nodularis; blisters are rarely reported by the patient or seen, but when present are diagnostic [1]. It may occur in children [2]. The immunopathology and the antigens are the same as in ordinary pemphigoid [3]. The eruption may be generalized or localized to the shins. It is often difficult to treat [1].

Localized disease

An unusual variant of bullous pemphigoid is the localized form of the disease, which occurs in 5 to 30% of patients with bullous pemphigoid, usually limited to the lower extremities, and responding well to treatment [1–3]. Localized disease, of course, may progress to generalized disease.

Localized vulvar pemphigoid

This rarely reported entity is characterized by recurrent blistering confined to the vulva of young girls, which does not result in scarring [1,2]. A localized desquamative vaginitis has also described [3].

Pemphigoid vegetans

This is a rare variant with circumscribed hypertrophic lesions with crusts or erosion, and pustules or vesicles at the periphery. The lesions chiefly affect intertriginous areas [1–3].

Lichen planus pemphigoides

Bullous pemphigoid can occur in the setting of lichen planus in both adults and children. Tense, subepidermal blisters arise from the lesions of lichen planus and normal skin. The blistering usually responds rapidly to treatment and is short lived [1–5]. The disease is immunopathologically identical to bullous pemphigoid although there are antibodies to a characteristic epitope of BP180 [6] (see Chapter 41).

Differential diagnosis. It may not be possible to diagnose accurately the early urticaria-like, eczematous and erythematous prodromal eruptions, but the possibility of bullous pemphigoid should always be considered in the elderly patient with irritable, fixed erythematous lesions. The lower leg in elderly people seems particularly prone to develop blisters, and it must be remembered that eczema or oedema at this site may blister.

When blisters have appeared, it is usually possible to differentiate bullous pemphigoid from pemphigus vulgaris on clinical grounds alone. The large, tense, tough blisters of bullous pemphigoid can be distinguished from the smaller, flaccid, more easily broken blisters of pemphigus, and the severe mucosal lesions of pemphigus vulgaris are a further distinguishing feature. Clinically, typical cases of bullous pemphigoid may be found to be linear IgA disease or epidermolysis bullosa acquisita on investigation. More atypical cases of bullous pemphigoid with small or absent blisters and/or annular lesions may resemble dermatitis herpetiformis, linear IgA disease, erythema multiforme and a final differentiation must then be on histological grounds. Direct and indirect immunofluorescence should confirm the diagnosis.

A more difficult task may be separating mucous membrane pemphigoid from bullous pemphigoid. The generalized eruption of mucous membrane pemphigoid may be clinically and histologically indistinguishable from bullous pemphigoid, and bullous pemphigoid may evolve into mucous membrane pemphigoid [1]. However, involvement of the mucous membranes with scarring is characteristic of mucous membrane pemphigoid.

Prognosis. Untreated bullous pemphigoid runs a chronic, self-limiting course over a number of months or years. Remission may occur within a few months or the eruption may continue for many years. The disease duration is usually 3–6 years, with most patients achieving complete remission off treatment. Bullous pemphigoid can be fatal, particularly in the active blistering phase in elderly people, and about one-third of untreated patients died; the results are similar in some recent series [1–3]. Bullous pemphigoid patients have double the risk of death compared to the general population [4]. The features that predict a poor prognosis and mortality are age, generalized disease, low Karnofsky score, low albumin and high doses of steroids [3,5–9]. Localized disease is very responsive to treatment and more of these patients appear to go into remission.

Treatment. The aim of treatment is to suppress disease activity with the minimum dose of drugs necessary. Bullous pemphigoid patients are elderly, commonly on many drugs and very susceptible to adverse drug reactions and side effects. During prolonged treatment, it is advisable to aim for the presence of a blister once every few weeks so as to be certain that the patient is not being over treated. The treatment of bullous pemphigoid has recently been the subject of a systematic review and UK guidelines have been produced [1–3].

Topical and systemic steroids are the mainstay of treatment. For localized BP, very potent topical steroids are often sufficient. Topical steroids should be considered in all patients. Intensive topical therapy with potent steroids, clobetasol propionate, applied all over twice daily, can give good control with fewer side effects than high-dose systemic steroids [4]. This is often not practical, however topical steroids can still aid control and may reduce the dose of systemic agents. The recommended initial dose of prednisolone is 20 mg/day or 0.3 mg/kg/day in localized or mild disease, 40 mg/day or 0.6 mg/kg/day in moderate disease, and 50–70 mg/day or 0.75–1 mg/kg/day in severe disease. Measures to prevent osteoporosis should be implemented from the start of systemic steroid therapy, whenever practicable. For mild to moderate disease, tetracyclines and nicotinamide should be considered. Steroid dosage can often be reduced quite quickly over the course of a few weeks to a dose of 15–20 mg/day and thereafter more slowly. The majority can be managed on doses of less than 10 mg/day prednisolone, which can be slowly withdrawn. One reducing regimen is reduction by 1 mg/month once the dose is below 10 mg/day. Immunosuppressants cannot be recommended routinely, but should be considered if the steroid dose cannot be reduced to an acceptable level. Azathioprine is the best established immunosuppressant and ideally thiopurine methyltransferase (TPMT) activity testing should be assessed prior to initiation of treatment to guide dosage. A recent study suggests that mycophenolate mofetil is a useful alternative immunosuppressant [5]. Methotrexate may be considered in patients with additional psoriasis [1]. The role of biological therapies is still unclear. Two successful cases of the use of the TNF blocker, etanercept, in patients with psoriasis and bullous pemphigoid are reported [6,7]; however, those patients treated with negative results are not reported. Rituximab has been reported to be both successful and unhelpful in a few cases [7–9].

There may be occasional flares that will require temporary increases in therapy.

Corticosteroid therapy has lowered the morbidity from the disease considerably and most patients achieve remission off all therapy, but significant mortality of bullous pemphigoid still remains at 15–40%, and is nearly always treatment related or related to the general condition and age of the patients. However, treatment is essential to control this distressing disease.

Mucous membrane pemphigoid

Synonyms
- Cicatricial pemphigoid
- Benign mucosal pemphigoid
- Ocular pemphigus
- Scarring pemphigoid
- Oral pemphigoid
- Brunsting Perry pemphigoid

Definition. A chronic blistering disease of the mucosa that may involve the skin, and usually results in permanent scarring of the affected area, particularly the conjunctiva. This entity is defined on the basis of the clinical picture and was renamed mucous membrane pemphigoid in 2002 [1], having been previously known as cicatricial pemphigoid. The new entity includes patients formerly diagnosed as oral pemphigoid and some linear IgA disease and epidermolysis bullosa acquisita patients, and excludes Brunsting–Perry pemphigoid. Brunsting–Perry pemphigoid will, however, still be discussed in this section as some patients have mucosal involvement and identical cutaneous signs.

The clinical features, immunopathology and immunogenetics are summarized in Tables 40.5 and 40.6, and Figs 40.13 and 40.14.

Aetiology. Mucous membrane pemphigoid is a disease of late middle to old age [1,2], but can affect children and teenagers and is more common in females [3–5]. The annual incidence in Western Europe is approximately 1–2 per million [3,4,6] and is probably less in China and the East [7,8].

There is an association with HLA-DQB1*0301(DQ7) in all types of mucous membrane pemphigoid [9–18].

Pathogenesis. Mucous membrane pemphigoid is assumed to have a pathogenesis similar to bullous pemphigoid. Some but not all patients have circulating autoantibodies, usually of low-titre that recognize proteins in the adhesion complex.

The reasons for the localization of mucous membrane pemphigoid to mucosal areas and limited areas of skin, and the scarring pattern are still not understood (see below). The antigens are identical to those of bullous pemphigoid in many patients, although the binding site of the autoantibodies seems to be associated more with the anchoring filament than the hemidesmosome.

The major autoantigens in mucous membrane pemphigoid are all components of the basement-membrane zone (Fig. 40.11), and are associated with the hemidesmosome, the anchoring filament and the anchoring fibrils (see below). There are experimental models for the pathogenicity of the autoantibodies in mucous membrane pemphigoid. An animal model for laminin 5 (laminin 332 in the new nomenclature), an anchoring filament component, has been developed and complement binding is not required for blister formation [1,2]. There are *in vitro* experimental models of pathogenicity of other antibodies in mucous membrane pemphigoid [3–5].

Immunoblotting and immunoprecipitation have shown multiple target antigens [6,7]. Many patients' autoantibodies target the bullous pemphigoid antigens, BP230 and BP180 [8,9]. BP180 is considered to be the major antigen with numerous different epitopes, including the shed ectodomain and the carboxy terminal which seems to be the major site for autoreactivity in oral pemphigoid (see Fig. 40.11) [10–15].

Some patients' antibodies bind to the α6 or β4 subunits of the α6β4 integrin and there is evidence that these are pathogenic [5,16–18]. There seems to be a correlation with antibodies to the α6 subunit in oral pemphigoid and the β4 subunit and ocular involvement [7,19].

A minority of patients have dermal-binding antibodies with salt-split skin target laminin 5 [20] and the most bind to the α3 subunit of laminin 5 [6,21] and are associated with laryngeal involvement [22–24]. In a few patients with typical mucous membrane pemphigoid the dermal binding antibodies target collagen VII [25].

The autoantibodies in mucous membrane pemphigoid may be IgG and/or IgA, and the presence of a dual antibody response is a marker for more severe disease [26–29]. In children IgA antibodies are associated with a worse prognosis [30]. There is evidence of involvement of T cells and release of γ-interferon and also of TNF [31,32].

The mechanism for the scarring is still unclear. The demonstration of the autoantibodies is more difficult than in bullous pemphigoid, and other mechanisms may be involved. Many patients share target antigens and HLA-DQB1*0301(DQ7) with bullous pemphigoid and thus the scarring cannot be attributed solely to the site of the immune reaction or to differing immunogenetics. The nature of the inflammatory response and the cytokine network activated (see above) is a current focus for investigation, and probably determines the outcome of the lesions.

Pathology. Histological examination of a blister is helpful only if the blister is intact and recent. Biopsy of an erosion is rarely helpful. Blisters in the mouth and on the skin show subepithelial or subepidermal blister formation, but often lack distinctive and diagnostic features. There are usually fewer eosinophils present in the cutaneous lymphohistiocytic infiltrate than in bullous pemphigoid. At a later stage there is fibrosis, the distinctive feature of mucous membrane pemphigoid. The conjunctiva shows invasion of the epithelium by inflammatory cells and an appearance of granulation tissue in the submucosa. The corneal epithelium may later be transformed into an epidermis-like structure.

The findings with immunofluorescence are summarized in Table 40.6 and Figs. 40.13 and 40.14, and there is a detailed review [1].

The site for biopsy for direct immunofluorescence often presents a problem. The involvement of mucosal surfaces may mean that there is no perilesional area accessible to the dermatologist. However, it is worth taking a 3–4-mm punch biopsy or shave biopsy from uninvolved skin and from the inner lower lip [2]. The help of other specialities is needed to take biopsies from bulbar conjunctiva and other mucosal surfaces. The direct immunofluorescence findings are of linear basement-membrane zone IgG or C3, and less commonly IgA and IgM [3,4]. Not all patients with the clinical disease have positive immunofluorescence; in one series, the conjunctiva was most frequently positive [2].

Using indirect immunofluorescence, the serum in mucous membrane pemphigoid does not always contain detectable circulating autoantibodies. The use of salt-split skin increases sensitivity and often demonstrates the presence of IgA autoantibodies that are not detected on intact skin [5–7]. The majority of the sera bind to the epidermal aspect of split skin (see Fig. 40.14). However, there are some that bind dermally [5–7], and these usually have circulating antibodies to laminin 5 [8] or rarely collagen VII [7]. The use of intact or salt-split mucosa does not improve the overall sensitivity [9]. ELISA is used in some centres to identify circulating antibodies to the NC16A domain of BP180. IgG autoantibodies are most commonly detected and are usually of the IgG1 and IgG4 isotypes, with IgG4 being present in nearly all cases [10]. IgA autoantibodies are present in a minority of cases and are all IgA1 [5]. ELISA techniques are available in some centres for B180 [11] and laminin 5 [12].

The immunoelectron microscopy data suggest that the antigens of mucous membrane pemphigoid are within the lamina lucida or associated with the lamina densa [13–15]. Thus, the antigens or their epitopes do seem to differ in their location from those of bullous pemphigoid.

There are multiple target antigens including BP180, BP230, α6β4 integrin, laminin 5 and collagen VII [7], explaining the variation in immunofluorescence patterns.

Fig. 40.19 Mucous membrane pemphigoid. Recurrent bullae and ulceration of the penis resulting in some scarring. (Courtesy of Dr R.J. Pye, Addenbrooke's Hospital, Cambridge, UK.)

Clinical features. The striking features are the recurring blisters on either a mucous membrane or an area of skin often near one of the orifices (Fig. 40.18) [1], together with the tendency for scars to form at these sites. The initial site may be any mucous membrane including the conjunctiva, the oral mucosa and those of the nose, larynx, pharynx, oesophagus, penis (Fig. 40.19), vulva, vagina and anus.

Oral lesions occur in the majority of patients [1]. In the mouth, vesicles or small blisters, which remain intact for some time, may be seen and when erosions form they are slow to heal. Persistent, extensive erosions may be present in the buccal mucosa and especially the palate. Desquamative gingivitis with eroded bleeding gums and occasionally blisters is common (Fig. 40.18). Localized oral pemphigoid was the name previously given to patients in whom there were only oral lesions without scarring. Adhesions may develop between the buccal mucosa and the alveolar process and around the uvula and tonsillar fossae. Extension of the disease to the pharynx and oesophagus causes dysphagia and may give rise to strictures that can result in weight loss, often necessitating surgical intervention [2].

The disease can involve the larynx, manifesting with hoarseness and in rare cases may give rise to strictures causing stridor and even asphyxiation requiring surgical intervention [3–5].

Deafness from involvement of the middle ear has been reported [6].

The genitals are involved in half of female patients, with blisters and erosions of the vulva [7]. Scarring leads to obliteration of the vulval architecture with labial fusion, introital shrinkage and end-

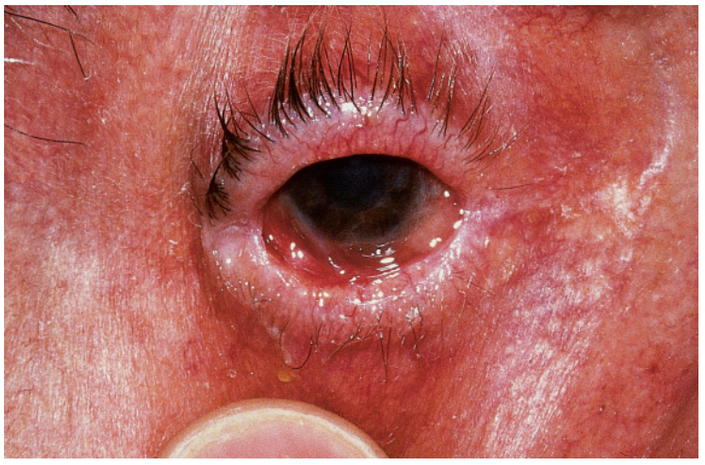

Fig. 40.20 Mucous membrane pemphigoid. Severe scarring and blindness. (Courtesy of Dr R.J. Pye, Addenbrooke's Hospital, Cambridge, UK.)

stage scarring that may be indistinguishable from lichen sclerosus [8]. The penis may be involved with blisters and erosions and adhesions may form between the prepuce and the glans penis.

Conjunctival lesions may start in one eye but will later involve both. At first, there may be a simple conjunctivitis causing redness, soreness and discomfort, and this may last for years, with alternating periods of activity and remission. Occasionally, episodes of blistering may be associated with pain and discomfort, and blisters or erosions may rarely be visible on the tarsal conjunctiva. Scarring can also occur without any preceding symptoms. There is progressive scar tissue formation, with forniceal shrinkage, linear scarring, formation of symblepharon, adhesions between the palpebral and bulbar conjunctiva, and corneal involvement. It becomes difficult to move the eyes. The conjunctive become shrunken and dry and the lower lids become inverted causing entropion (Fig. 40.20). In the final stages, the cornea becomes dry and opaque, the 'statue eye'. The conjunctivae are eventually affected in many patients, but other areas may be involved for several years before the eyes become affected.

Two types of skin lesion may occur, the most common of which is a generalized bullous eruption such that an initial diagnosis of bullous pemphigoid is made [9]. The second type is an localized to erythematous plaque, which becomes the site of the recurring blisters with subsequent scarring and hyperpigmentation. These localized lesions are often near affected mucosal surfaces. The scalp may be involved and the scarring and atrophy produce permanent alopecia. In 1957, Brunsting and Perry [10] described a group of patients who developed subepidermal bullous skin lesions that left scars; these patients apparently did not develop mucous membrane involvement. However, in many such patients mucosal involvement does ensue and they are best regarded as part of mucous membrane pemphigoid.

Associated diseases. There is an association with autoimmune disease, both organ and non-organ specific [1] and with lichen sclerosus [2] with which it may share clinical similarities in the genital area as well an association with HLA-DQ7 (DQB1*0301) [3,4].

There is no association with malignancy [5] overall nor in patients with α6β4 integrin subunit antibodies [6,7]. However, there does seem to be an association of laminin 5 antibodies and malignancy (antiepiligrin mucous membrane pemphigoid) [8,9] with several case reports [10–14].

Prognosis. Mucous membrane pemphigoid is a chronic debilitating and mutilating disease. It can affect the general health causing blindness, weight loss, respiratory, sexual and urinary problems. Impairment of vision is the most important complication, with some patients becoming blind in both eyes. Rare cases may die from laryngeal stenosis or complications of treatment. Unlike bullous pemphigoid, it does not appear to be self-limiting, and prolonged remissions are rare [1,2] except in localized oral or skin disease [3]. The disease often extends over many years with periods of activity and extension followed by quiescent phases. Very rarely, carcinoma has arisen in chronic oral lesions and oesophageal lesions [4].

Differential diagnosis. The oral lesions, which may appear first, are difficult to differentiate from pemphigus vulgaris or from erosive lichen planus. Desquamative gingivitis may be a manifestation of local oral pemphigoid, mucous membrane pemphigoid or lichen planus and these diseases may be difficult to distinguish. The clinical signs elsewhere differentiate these conditions, but there are patients in whom initial differentiation may be impossible.

End-stage scarring of the conjunctiva may resemble scarring that can occur as a result of severe infective conjuctivitis, chronic allergy, reactions to topical drugs, erythema multiforme and toxic epidermal necrolysis, or burns. Similarly the end-stage scarring of the genital region may mimic the commoner lichen sclerosus (although both conditions may co-exist) and erosive lichen planus. The history of the mode of onset and the evidence of other active lesions should be helpful. The generalized skin eruption is indistinguishable from that of bullous pemphigoid; however, the presence of mucosal lesions and scarring favour the diagnosis of mucous membrane pemphigoid. Fixed scaly patches near the face and scalp may resemble pemphigus erythematosus.

Histological examination of a recent blister but not an erosion is helpful. Direct immunofluorescence on perilesional or clinically uninvolved mucosa and skin and indirect immunofluorescence are diagnostic if positive.

Treatment. Treatment is difficult and a systematic review has demonstrated how little evidence there is for the treatments used [1,2]. The disease activity fluctuates without treatment, and most treatments modify disease activity rather than totally suppressing it [3]. Treatment approaches have been summarized by an international consensus [4].

Local treatments are crucial and may be sufficient to control the disease to an acceptable level [3,5]. Secondary infection of oral and genital mucosa with candida is common and should be sought and treated with oral fluconazole or equivalent.

Systemic treatments are required for severe mucosal and laryngeal lesions and the control of generalized bullous eruptions, but are not always successful. The best evidence is for the use of cyclophosphamide in severe ocular disease, and for dapsone or sulphonamides in moderate to severe disease [1,2,6–8]. Dapsone and sulfamethoxypyridazine or sulphapyridine may be of value in controlling oral and cutaneous blistering and ocular disease [9,10]. Azathioprine is used but there are no large trials to support its use, similarly there are no large trials to support the use of the alternative mycophenolate mofetil, although there are encouraging reports of its benefit [11,12]. There are recent reports that systemic tetracyclines alone or combined with nicotinamide may be helpful for oral lesions [13]. The use of intravenous immunoglobulins has been advocated, although chiefly by one centre [4,14–16]. There are case reports of success with biological therapies. Several cases have responded to the TNF blockers etanercept [17–19] and infliximab [20,21]. The results with rituximab are not so encouraging; of two patients only one responded [22,23].

The usual approach is to start with the least toxic therapies in mild to moderate disease. In rapidly advancing disease threatening sight or airway more aggressive treatment is needed.

Oral lesions are often helped by local treatment with topical steroids, as mouthwashes, sprays or applications, or tetracycline mouthwashes. The sprays and mouthwashes may also help the pharynx and oesophagus. There are several anecdotal reports of the use of topical tacrolimus [24–27], but our own experience is not as good. Tetracyclines and nicotinamide can be helpful [5]. Oesophageal strictures may necessitate dilatation, which gives excellent results. Tracheotomy, which may need to be permanent, can be life-saving if there is stridor. Intralesional infiltration with mitomycin has been used to prevent recurrent laryngeal scarring [28].

The management of ocular disease needs to be performed by an ophthalmologist with experience in treating mucous membrane pemphigoid, and includes topical steroids and subconjunctival injections of corticosteroid suspension and mitomycin [29], which may be temporarily effective for conjunctival disease, but neither of these treatments nor systemic dapsone, cyclophosphamide, intravenous immunoglobulins, and/or corticosteroids will halt the progress in every case. Surgery to the lashes, division of adhesions and grafting may be required. Some patients will become blind.

Genital lesions may respond to potent topical steroids or to the combination of topical steroid and tetracycline. Vulval adhesions may require surgical division, and a Fenton's procedure to enlarge the introitus may be required in sexually active patients. Circumcision may be required in men.

Persistent skin erosions on the scalp or face can be helped by potent topical steroids.

The role of mucosal grafts is controversial and in the eye may have an adverse effect [30], although autologous stem cell transplantation may be useful in the future [31].

Mucous membrane pemphigoid is frustrating for the patient and the physician, and the patients endure many years of discomfort and morbidity, and rarely mortality from the disease and its treatment.

Pemphigoid gestationis

Synonym

- Herpes gestationis

Definition. Pemphigoid gestationis is an intensely pruritic, bullous eruption that may develop in association with pregnancy or rarely the trophoblastic tumours, hydatiform mole and choriocarcinoma.

The clinical features, immunopathology and immunogenetics are summarized in Tables 40.5 and 40.6, and Figs 40.13 and 40.14.

Aetiology. Pemphigoid gestationis is a rare condition that may affect from one in 10 000 to one in 60 000 pregnancies [1,2]. In Western Europe, the incidence is approximately 0.5 per million population [3,4]. It has been reported from Tunisia [5,6] and Kuwait [7]. It does occur in Afro-Caribbeans, but is very rare in the Far East [8].

The disease arises only in the presence of paternal-derived tissue, that is the fetus, and rarely hydatiform mole or choriocarcinoma, and thus tissue expressing HLA antigens from the father [9–12]. The fathers are more often HLA-DR2 than the control population [13]. It is considered that an HLA mismatch between mother and fetus triggers an immune response that cross-reacts with the maternal skin. There is clinical evidence of placental insufficiency (see below) and immunohistochemical findings of immune activation in the placenta [14,15], and affected mothers have high titres of antibodies to HLA class 1 antigens [16].

The mothers in the UK and USA frequently manifest the autoimmune haplotype, HLA-B8, -DR3 and -DR4 [9,17,18], and this association has been verified in a Mexican population [19], as has the association with HLA-DR3 in an Arab population [7]. They also have, as predicted for this HLA haplotype, a linkage disequilibrium with certain immune-response genes and thus a high incidence of the C4 null allele, which influences clearing of immune

complexes [20]. The immunogenetics of the mothers increase susceptibility to the development of pemphigoid gestationis.

Pemphigoid gestationis is associated with other autoimmune diseases (see below), implying an autoimmune basis [9,21,22].

The clinical course of pemphigoid gestationis may be modified by changes in oestrogen and progesterone levels; exacerbations may occur with oral contraceptives, and the severity may vary during the menstrual cycle [9,22].

Pathogenesis. The autoantibodies are directed at the same hemidesmosome target antigens as bullous pemphigoid, BP180 and less commonly BP230 [1,2]. The NC16A domain, the extracellular region of BP180 adjacent to the transmembrane portion (Fig. 40.11), is the immunodominant epitope [3] with the antibody response mostly restricted to this region [4–8]. This extracellular location makes it a likely target for pathogenic autoantibodies. The same epitopes are recognized by the autoantibodies and T cells [5]. There is a report of a target antigen of 200 kDa in an individual patient [9].

An animal model has demonstrated that autoantibodies to BP180 are pathogenic and require complement (see above, bullous pemphigoid) [10,11]. Use of immunosorbent techniques against epitopes within the NC16A domain prevents dermoepidermal separation induced by the antibodies [12].

There is evidence of involvement of T cells and eosinophils in blister formation [13,14].

The autoantibodies react with the basement membrane of amnion placenta from the second trimester on and are found in the fetal skin and cord blood [15–18]. BP180 is expressed in the syncytial and cytotrophoblastic cells of normal placenta and in epithelial cells of amniotic membrane, and may be involved in the invasion of extravillous trophoblasts during placental development as well as the integrity of amniotic basement membrane [19]. Although the exact pathomechanism of pemphigoid gestationis is still largely unknown, the clinical symptoms of pemphigoid gestationis are initiated after the expression of collagen XVII in placenta during the first trimester of pregnancy.

The autoantibodies are IgG antibodies of the IgG1 and IgG3 subclasses [20,21]. These IgG1 antibodies avidly bind C3, and often this binding is detected rather than the IgG antibodies themselves. There is a single case report of IgA antibodies [22].

Pathology. The histopathology of the early urticated lesions of pemphigoid gestationis shows epidermal and papillary dermal oedema with occasional foci of eosinophilic spongiosis. The bullous lesions are subepidermal and contain numerous eosinophils. The split is through the lamina lucida.

The findings with immunofluorescence are summarized in Table 40.6, and Figs 40.13 and 40.14. Direct immunofluorescence studies show that in all active cases of pemphigoid gestationis there is C3 deposition at the basement-membrane zone. In some cases, IgG is also found. C3 and IgG deposition are found in the placenta and fetal skin [1–4].

Indirect immunofluorescence studies demonstrate binding of C3 to the basement-membrane zone; this serum factor was known as the HG factor. Although conventional immunofluorescence techniques are able to demonstrate IgG in only about 25% of cases, it is now clear that the autoantibody is an IgG of the IgG1 subclass [5,6]. The autoantibodies bind to the epidermal side of salt-split skin [7]. IgG antibodies can be detected by ELISA [8,9].

Immunoelectron microscopic studies have confirmed that IgG is deposited along the basement-membrane zone, chiefly within the lamina lucida and localized to the proximal part of the anchoring filament [10–12].

Immunoblotting and ELISA techniques have shown that the major antigen recognized by the circulating autoantibodies is BP180 [13–15].

There may be evidence of a villitis of the placenta [16].

Clinical features. Pemphigoid gestationis may begin at any time between 4 weeks' gestation and 5 weeks postpartum, with the majority presenting in the second and third trimester [1,2]. Almost half of cases develop in the first pregnancy. There is a high risk of recurrence in subsequent pregnancies; the onset is likely to be earlier than in the previous one and the disease may be very different in severity. In many cases, the disease becomes relatively quiescent in late pregnancy, only to flare severely immediately postpartum [1]. Usually, the disease lasts several weeks to months, on average 6 months, but sometimes it can continue for years afterwards [2]. The likelihood of prolonged disease is increased by older age, multiparity and mucosal involvement [3].

Pemphigoid gestationis is intensely itchy. The condition characteristically begins around the umbilicus, and then spreads to the abdomen, thighs, limbs, palms and soles (Figs 40.21 & 40.22). Involvement of the oral cavity is relatively rare. Early in its course, the eruption consists of urticated papules, plaques, target lesions and annular wheals, associated with marked pruritus (Fig. 40.21); subsequently, vesicles and larger blisters appear (Fig. 40.22).

Neonatal pemphigoid gestationis may occur in 3% pregnancies [2], with positive direct immunofluorescence in the neonate [4,5],

due to transfer of antibodies across the placenta. It usually resolves rapidly without treatment [2,4,5].

Associated diseases. Pemphigoid gestationis is associated with other autoimmune diseases, 14% in a recent study [1], particularly with Graves' disease (10%), hypothyroidism, vitiligo, alopecia areata and autoimmune thrombocytopenia [1–3].

Prognosis. Pemphigoid gestationis tends to improve postpartum, but it may be weeks, months or years before there is complete resolution. In rare cases the disease may evolve into bullous pemphigoid [1,2]. There are often flares with menstruation. There are usually dramatic flares with the oral contraceptive, which is contraindicated while the disease is still active, but can often be used subsequently.

There are reports of persistent disease postpartum and these cases are more likely to have previous disease and to be older [1,3].

Once pemphigoid gestationis has occurred, it is likely to recur in subsequent pregnancies, and may be more or less severe. About 8% of subsequent pregnancies are spared [4]. Although a change in partner does not increase the risk of developing pemphigoid gestationis, it is unclear whether it alters the risk of recurrence [4]. Patients should be counselled as to the risk of recurrence, but not advised against having further pregnancies because they have had pemphigoid gestationis.

The modern view is that pemphigoid gestationis is associated with premature delivery and a risk of low birth weight [5–8]. The fetal prognosis is worse when there is early onset of the disease, reflecting more prolonged duration of placental insufficiency, and when there is blistering, perhaps because of more severe microseparation and placental damage [8,9]. Deliveries from mothers with pemphigoid gestationis should take place in departments that have facilities for special care of the newborn.

Differential diagnosis. The main problem is the differentiation of pemphigoid gestationis from the much more common eruption that begins in later pregnancy, termed polymorphic eruption of pregnancy (see Chapter 8). This usually begins in the stretch marks and almost never blisters. The histopathology often differentiates the two conditions, and immunofluorescence and ELISA is negative in polymorphic eruption of pregnancy.

Treatment. In mild cases of pemphigoid gestationis, topical potent or very potent steroids can be successful, and this was so in almost 20% in recent retrospective studies [1–3]. They are often combined with a systemic antihistamine (using one suitable for use in pregnancy) [1,2]. Once the blisters develop, systemic steroids are usually necessary. Moderate disease responds to 20–30 mg/day of prednisolone, severe disease may need 40–80 mg/day of prednisolone. Prednisolone dose can usually be reduced fairly rapidly to a much lower maintenance dose. The use of systemic steroids does not seem to have an adverse effect on pregnancy outcomes, other than reflecting severe disease [4]. Because postpartum exacerbations are so frequent, it is worth increasing the corticosteroid dose temporarily at the first sign of a flare.

Plasmapheresis can be considered in the most severe cases [5]. The role of dapsone is unclear and the drug can cause haemolytic disease in the neonate [2]. There is only anecdote to support the use of pyridoxine [6].

Postpartum treatment can be a problem if the mother wishes to breastfeed, as the drugs pass into the breast milk. Antihistamines can cause drowsiness in the baby, steroids at high doses (more than prednisolone 40 mg/day) may cause adrenal suppression, and dapsone may cause haemolysis. The paediatricians should therefore be consulted in this situation. In the non-breastfeeding woman there are reports of the successful use of tetracyclines, sometimes with nicotinamide [7–9]. Immunosuppressive treatment, including cyclophosphamide and immunomodulating treatments such as intravenous immunoglobulins [10–13], immunoapheresis [14] and rituximab [15] have also been used, mainly postpartum.

Linear IgA disease

Synonyms

- Chronic bullous disease of childhood
- Juvenile dermatitis herpetiformis
- Juvenile pemphigoid
- Linear dermatitis herpetiformis
- Linear IgA bullous dermatosis

Definition. Linear IgA disease is a chronic, acquired, subepidermal disease of children and adults, with cutaneous and mucosal involvement, characterized by IgA basement-membrane antibodies. The disease responds to dapsone and has a tendency to remit.

Two main clinical syndromes are distinguished, chronic bullous disease of childhood, beginning in childhood, and adult linear IgA disease, beginning any time in adult life. They differ in their age of presentation and to some extent as regards their clinical signs, but there is much overlap, and the immunopathology and immunogenetics are common to both diseases.

The clinical features, immunopathology and immunogenetics are summarized in Tables 40.5 and 40.6.

Aetiology. Linear IgA disease affects all ages from babies of a few months to the elderly. The majority of children present as toddlers or preschool children, although a few have presented as neonates [1,2]. Teenagers and young adults also present with the disease and there is a second peak over 60 years [3]. Linear IgA disease is one of the less common subepidermal blistering diseases in western Europe with an incidence of less than 0.5 per million, chiefly adults [4,5]. It is commoner in China where it is about one third as common as bullous pemphigoid and one-third are children [6]. It has been reported from the Middle East (Kuwait) and South East Asia [7–10]. There seem to be more children with the disease in developing communities, for example China, Malaysia, Sri Lanka, India, Thailand, Tunisia, Kuwait, Mali, Uganda and black children in South Africa than in Western Europe [6,11–20].

The sex incidence is about equal or there may be a slight excess of female patients.

There is a strong association between linear IgA disease and the extended autoimmune haplotype HLA-B8, -CW7, -DR3 in UK and black South African patients and possession of this haplotype is

associated with an early disease onset [14,21]. This extended haplotype is in linkage disequilibrium with a high producing allele of tumour necrosis factor (TNF), and this association exists in linear IgA patients and confers a worse prognosis [21].

Pathogenesis. The autoantibodies in linear IgA disease are IgA, and this is unusual for an autoimmune disease, and are usually IgA1 and monomeric [1–3]. However, IgG antibodies can also be detected by immunoblotting techniques, although their antigen repertoire is more limited [4–6].

The IgA antibodies are directed at a number of different target antigens within the adhesion complex. The major antigen in linear IgA disease is BP180/collagen XVII and its shed ectodomain, formerly known as LAD1 with molecular weights of 97 and 120 kDa. There are also antibodies to BP230 and a unique antigen LAD285, which has a molecular weight of 285 kDa [5–10]. The autoantibodies recognize many different epitopes on BP180, including the NC16A domain [11–13]. T cell responses to BP180 have been demonstrated [14]. Collagen VII, the anchoring fibril component, is a rare antigen and is almost never associated with a mechanobullous scarring phenotype, unlike classical epidermolysis bullosa acquisita (see below) [15–18]. There are other unidentified dermal antigens [6,19].

There is indirect evidence that the antibodies are pathogenic, in that they cause splitting of skin in culture and binding of neutrophils to the basement-membrane zone [20,21]. An animal model has demonstrated that IgA mouse monoclonal antibodies passively transferred to SCID mice with human skin grafts can produce neutrophil infiltration and basement membrane vesiculation in a third of mice tested [22].

Pathology. The histological features are not specific for the condition. The subepidermal vesicles may contain numerous eosinophils suggestive of pemphigoid. In some blisters, neutrophils predominate and dermal capillary microabscesses are seen, suggesting dermatitis herpetiformis. Others show subepidermal blisters with non-specific features. An old blister will give misleading results. In a child, it is not always worthwhile performing a biopsy on a lesion, as the direct immunofluorescence will give the diagnosis and is often easier and less traumatic to perform.

The findings with immunofluorescence are summarized in Table 40.6 and a detailed review has been published [1]. Direct immunofluorescence can be carried out on clinically uninvolved skin, and the back is often convenient (and out of sight) in a child. The forearm is the least satisfactory site [2] and mucosal biopsies from the mouth, but not necessarily the conjunctiva, are also positive [3].

In all cases, there is linear deposition of IgA along the basement-membrane zone. There may also be other immunoreactants, IgG, IgM or C3, on direct immunofluorescence [4,5]. Direct salt splitting of the biopsies or the raising of suction blisters in patients shows that the deposition of the autoantibodies can be associated with the epidermal aspect of the artificial blister, with the dermal aspect or both [6,7].

The significance of the rare, linear, granular pattern of IgA deposition at the basement-membrane zone is still unclear [4]. Some patients with this pattern have true dermatitis herpetiformis and others may have autoantibodies to unusual target antigens.

Indirect immunofluorescence for IgA basement-membrane zone antibodies is more often positive in children (about 80%) than adults (about 30%) [5]. The titres are usually low, of the order of 1:5 or 1:10, but occasionally much higher. The use of normal human skin split through the lamina lucida with suction or more commonly 1 mol/L salt increases the sensitivity and gives additional information as to the site of the target antigen. The majority of sera demonstrate a binding to the epidermis, implying an antigen associated with hemidesmosomes or the upper lamina lucida; a few have a combined pattern, and a larger minority bind to the dermal aspect of the artificial blister, suggesting a lower lamina lucida or dermal antigen [5,6,8].

Blister fluid is an alternative to serum for indirect immunofluorescence and may be easier to obtain in a child [9]. However, urine did not prove a practical alternative [10].

The presence of IgG autoantibodies on direct or indirect immunofluorescence causes problems with disease definition, and has been used to define a further entity, mixed immunobullous disease (see below) [11–13].

Immunoelectron-microscopy studies have shown that the immunoreactants and target antigens are either associated with the hemidesmosomes, within the lamina lucida, in the subbasal lamina zone or in a mirror-image pattern on each side of the lamina densa [14–20].

Immunoblotting studies have demonstrated a variety of target antigens, in keeping with the multiple localizations found with split skin and immunoelectron-microscopy studies. The antigens include both epidermal and dermal associated antigens, and the major one is BP180 (see above).

Clinical features (Figs 40.23 & 40.24). The clinical features of children and adults will be described separately as they are distinctive.

Fig. 40.23 Chronic bullous dermatosis of childhood. Cluster of blisters with new blisters forming around an older lesion (string of pearls). (Courtesy of Dr R.J. Pye, Addenbrooke's Hospital, Cambridge, UK.)

Fig. 40.24 Linear IgA disease. Intact tense bullae on the thigh and annular lesions. (Courtesy of Dr P. Hudson, Peterborough Hospital, Peterborough, UK.)

Chronic bullous disease of childhood. The mean age of onset is under 5 years; it is usually acute and the initial attack more severe than subsequent recurrences. Symptoms vary from absent or mild pruritus to severe burning. The face and perineum are involved, particularly in younger children. The perioral area, the eyelids, ears and scalp may be affected. The involvement of the perineum and vulva (Fig. 40.23) has been mistaken for sexual abuse in some patients. The eruption may spread to the trunk, thighs, limbs, and hands and feet. The lesions comprise urticated plaques and papules, and annular, polycyclic lesions often with blistering around the edge, the string of pearls sign. Large blisters may develop and become very extensive, they are occasionally haemorrhagic, and usually arise on previously normal skin. Papules and vesicles also occur.

Mucosal involvement is common. The mouth may be involved with ulcers and erosions, and hoarseness may indicate pharyngeal involvement. There can be nasal stuffiness and bleeding. The eyes are often sore or gritty and there is conjunctivitis [1]. The children who progressed to conjunctival scarring and blindness are best regarded as having mucous membrane pemphigoid [1–4].

Linear IgA disease of adults. This commences at any age from the postpubertal teenager to the ninth decade, most commonly after the age of 60 years. The onset may be insidious or more usually abrupt. Symptoms vary from mild pruritus to severe pruritus and burning. The trunk is almost always involved, and the limbs, face and scalp, hands and feet are commonly affected. The lesions comprise urticated plaques, papules and vesicles, and blisters. The blisters may arise from normal skin or from urticated plaques (Fig. 40.24) and can be haemorrhagic. The characteristic annular lesions with blistering around the edge are less common than in the children (Fig. 40.23). Milia are almost unknown.

Mucosal involvement is common [1]. The mouth may be involved with ulcers and erosions. Hoarseness indicates pharyngeal involvement. There is often nasal stuffiness, crusting and bleeding. The eyes are often sore or gritty. Involvement of the genitals and also the vagina can occur. Those few patients that progress to scarring, including blindness, are best regarded as having mucous membrane pemphigoid [5–7].

Dermal-associated linear IgA disease

Previous case reports and a study of 17 patients with dermal-binding IgA antibodies found such patients to comprise more than 15% of linear IgA patients, and to be more commonly adult, but otherwise not to have any distinguishing clinical features [1–3]. There does not seem to be a mechanobullous scarring phenotype for linear IgA disease when associated with dermal antigens including collagen VII. Patients with classical scarring mechanobullous IgA epidermolysis bullosa acquisita with antibodies to collagen VII are very rare and both those reported progressed to a mucous membrane pemphigoid-like phenotype [4,5].

Linear IgA mucous membrane pemphigoid

Patients with typical clinical signs of mucous membrane pemphigoid, who have linear IgA on direct immunofluorescence should, following the International Consensus on Mucous Membrane Pemphigoid, be regarded as having mucous membrane pemphigoid [1]. Interestingly, this has been described in several children and some adults, and the case of linear IgA desquamative vaginitis is also best regarded as such [2–8].

Mixed immunobullous disease

A small number (16) of patients with a dual antibody response of IgA and IgG autoantibodies have been studied. This immunopathological finding was seen in both children [1–3] and adults [4,5]. In most cases the patients had a clinical picture compatible with linear IgA disease and a good response to dapsone or sulphonamides. The exact position of this entity is still unclear, but for practical purposes the patients are best managed as linear IgA disease.

Induced linear IgA disease and associated diseases

A number of precipitating factors are observed, namely infection and antibiotics (penicillins) in about a quarter of adults and more children [1,2], and the presence of building work in the home in about half the adult patients and three-quarters of the children [3]. The significance of these findings is unclear. Drug-induced linear IgA disease is commonly reported, vancomycin being the drug most frequently implicated [4–7] and diclofenac and other non-steroidal anti-inflammatory drugs less commonly [8–13]. However, a large range of drugs has been reported [10,14,15]. Local skin trauma has initiated the disease in some cases [1,2,16].

Patients with linear IgA disease were originally thought to have dermatitis herpetiformis, but it is now clear that this is a totally distinct disease and there is no overall association with gluten-sensitive enteropathy [1,17,18]. There is an association with ulcerative colitis and other inflammatory bowel disease in a small number of patients [19–21]. There is no overall association with autoimmune disease, although autoantibodies are common [1]. There is one child reported with an autoimmune lymphoproliferative disorder in association with linear IgA disease [22].

There is an increased incidence of lymphoproliferative disorders in adults with linear IgA disease, which may occur after remission of the skin disease [2,23–26], and a single report in a child [27]. There are a number of case reports of various cancers in association with linear IgA disease, of which bladder and renal cancer are the commonest, but there is no overall increase [2,28,29].

Prognosis. Spontaneous remission occurs in the majority of patients after an average of 3–6 years, the TNF genotype of the patient influencing disease duration [1–3]. Initially, there were no reports of chronic bullous disease of childhood extending beyond puberty, but cases have now been documented [2,4]. Some of these patients are women of childbearing age. In pregnancy, often there is improvement or remission of the disease from the second trimester, and the women may be able to discontinue all drugs, however there is usually a relapse postpartum at about 3 months [5]. There does not seem to be any fetal damage [5].

Differential diagnosis. In the young infant, bullous impetigo may resemble the initial lesions, but its response to antibiotics will differentiate it. Genetic epidermolysis bullosa is often present at birth and the family history further differentiates it. Bullous papular urticaria rarely affects the face or genital region and is usually of short duration. Childhood bullous pemphigoid may give a similar clinical picture, but the deposition of IgG and C3 at the basement-membrane zone is diagnostic. The adult disease is frequently confused with atypical erythema multiforme, neurotic excoriations and nodular prurigo, dermatitis herpetiformis and most commonly bullous pemphigoid. Histology is helpful and direct immunofluorescence is essential for diagnosis.

Treatment. A few patients have mild disease and can be controlled with topical steroids alone. The treatment of the children can be difficult, because side effects limit dosage, but the drugs used are identical in children and adults. The favourable reports of erythromycin suggest that this should be tried as first-line treatment in children [1]. Dapsone in doses starting at less than 0.5 mg/kg, which often means giving it as 25 mg on alternate days or less in young children, and 25–50 mg/day in an adult, may be slowly increased to a dose of 1 mg/kg or a little more in a child and 100–150 mg in an adult to keep the patient comfortable and without significant side effects. Too rapid an increase in the dose often results in haemolytic anaemia, which does not reach its maximum for a month. A fall in haemoglobin with a low mean corpuscular volume (MCV) indicates iron deficiency (due to intravascular haemolysis) rather than pure haemolytic anaemia. Patients at risk of glucose-6-phosphate dehydrogenase deficiency should be screened prior to treatment. Methaemoglobinaemia is common, reaching a steady state after about 2 weeks, and may cause cyanosis, breathlessness and angina. Hepatitis, the dapsone syndrome (lymphadenopathy and hepatitis) and agranulocytosis are serious, usually early, complications. Motor neuropathy may occur. Most complications occur in the first 3 months. Sulphonamides are alternatives. Sulfapyridine is often poorly tolerated and may cause an allergic reaction, hepatitis or agranulocytosis,

and is used at doses of 250 mg to 3 g daily, which usually controls the eruption rapidly, but the dose may need frequent adjustment. Sulfamethoxypyridazine (adult dose 250 mg to 1.5 g daily) is an alternative, which is often better tolerated. Dapsone and sulfonamides can be combined. Some patients do not respond to either of these, and corticosteroids may need to be added. Disease in a few patients is very difficult to control and may need azathioprine or ciclosporin [2]; isolated case reports suggest that mycophenolate mofetil may be useful in children and adults [3–5]. Success has been reported in small numbers of patients with other antimicrobials including tetracyclines and nicotinamide/niacinamide [6–8], penicillins [9–11] and erythromycin [1]. Colchicine has been used successfully in children and adults [12–16]. There are case reports of the successful use of intravenous immunoglobulin [17–21]. The association with TNF alleles would predict that TNF antagonists might be helpful, but there are no reports of the use of biologics.

The cutaneous lesions are always much more responsive than the mucosal lesions, which can be treated with topical steroids (see mucous membrane pemphigoid).

In view of the ultimate spontaneous recovery in the majority of patients, attempts should be made to avoid over-treatment and the production of side effects with steroids.

Epidermolysis bullosa acquisita

Synonyms
- Acquired epidermolysis bullosa
- Dermolytic pemphigoid

Definition. Epidermolysis bullosa acquisita (EBA) is a rare condition in which patients may have chronic acquired, trauma-induced, subepidermal blistering or a clinical picture indistinguishable from bullous pemphigoid. There is a distinctive immunopathology, and the disease was defined in terms of the target antigen, namely collagen VII. However, patients exist with the same clinical pattern in whom antibodies to collagen VII cannot be identified [1], and antibodies to collagen VII are found in patients with mucous membrane pemphigoid (see above) [2,3]. In addition, there are patients with antibodies to both collagen VII and laminin 5 [4,5]. EBA needs to be redefined to encompass the distinctive clinical features and target antigen. It is interesting that this acquired mechanobullous disease was named for its clinical resemblance to genetic dystrophic epidermolysis bullosa (Chapter 39) and that the molecular basis of both these diseases is collagen VII.

The clinical features, immunopathology and immunogenetics are summarized in Tables 40.5 and 40.6 and Fig. 40.25.

Aetiology. EBA can occur at any age. It has been described in children and adults [1–5]. The original reports from the USA included many African-American patients, and it may be more common in African and Oriental races [6–10]. It is one of the rarest subepidermal bullous diseases in Western Europe, with an incidence of about 0.25 per million, but may be more common in the middle and far East [7–9,11–13].

There is an association with HLA-DR2 in the USA [6] but not in Korean patients [14].

Pathogenesis. Collagen type VII, the major component of the anchoring fibrils, is the target antigen recognized by autoantibodies from patients with EBA [1]. Collagen type VII is expressed at the dermal aspect of the basement membrane zone, originating and terminating in the lamina densa (Fig. 40.11) and interacts with laminin 5 and the dermal matrix [2]. It comprises a globular amino non-collagenous domain (NC1) and a collagenous triple helix (Col-1), and the gene is located to the short arm of chromosome 3 [3]. The autoantibodies in EBA are directed at epitopes chiefly within the fibronectin-like region at the NC1 domain [4–9] and in particular the N-terminal 227 amino acids (residues 1 to 227), which contains homology with cartilage matrix protein [10]. However, antibodies to Col-1 and non-collagenous 2 domain (NC2) have also been demonstrated [2,9,11,12] and may be more common in childhood cases [13].

The autoantibodies are IgG, and of all IgG isotypes, although the IgG1 and IgG4 isotypes may predominate in the chronic mechanobullous forms [14–16]. Some of the antibodies bind complement [16,17]. There are patients with antibodies to additional antigens, particularly laminin 5 [18,19]. Cases have been described with IgA antibodies, usually without an EBA clinical phenotype [20–24].

There is evidence that the autoantibodies are pathogenic. Complement-binding autoantibodies from patients with EBA bind to skin and attract neutrophils to the basement-membrane zone [25,26] and also induce blistering in the presence of neutrophils in sections of human skin [27]. Animal models in which the clinical, immunopathological and histological features of the disease were induced in neonatal mice using antibodies to collagen VII (both raised against mouse collagen VII and purified human antibodies) have demonstrated that the antibodies are pathogenic [28–31]. Granulocyte-derived elastase and gelatinase B are required for blister formation [32].

Pathology. The blistering is subepidermal, but the precise histological findings depend on the stage of the disease. In inflammatory disease, there is a heavy predominately neutrophil infiltrate. In the mechanobullous, non-inflammatory phase, there is usually an absent or sparse infiltrate.

The findings with immunofluorescence are summarized in Table 40.6 and shown in Fig. 40.25, and a detailed review has been published [1]. On direct immunofluorescence, linear IgG at the basement-membrane zone is found in all patients, and linear IgA and IgM may also be seen [2]. C3 has been reported in most cases. The basement membrane staining may be broader than that seen in bullous pemphigoid, and a diagnostic U-serrated pattern has been described [3]. Patients' skin split through the lamina lucida with suction (applied *in vivo*) or with 1 mol/L salt demonstrates the IgG antibodies to be bound to the dermal aspect of the blister [4].

Positive indirect immunofluorescence has been demonstrated in approximately half the patients tested, with circulating autoantibodies binding to the basement-membrane zone. However, if skin is separated through the lamina lucida using 1 mol/L sodium chloride, or suction, and then used as substrate, the fluorescence is seen on the dermal aspect of the artificial blister (floor of the split skin) (Fig. 40.25) [5]. EBA serum is negative on toad skin [6,7]. An ELISA technique is more sensitive, but is not in routine use [8].

Electron microscopy has shown dermolysis and cleavage in the upper dermis with preservation of the basal lamina, but no reduction in the number of anchoring fibrils [9]. Amorphous material has been found beneath the basal lamina, sometimes in a band-like distribution [9–11].

Immunoelectron microscopy has shown that the IgG was deposited in the upper dermis beneath the basal lamina and within the sublamina densa zone [9]. Immunogold studies demonstrate that the autoantibodies bind to the non-collagenous ends (NC1 domain) of the anchoring fibrils and elsewhere [12,13].

Immunoblotting and ELISA techniques demonstrate that EBA autoantibodies recognize proteins of 290 kDa and 145 kDa, shown to be collagen VII, and that the immunodominant epitopes are within the NC1 domain, but that other regions are immunogenic (see above) [8].

Clinical features. There are many reports of EBA in children [1–22]. Early in the disease, clinical manifestations may be very variable and may mimic a number of bullous dermatoses including bullous pemphigoid and linear IgA disease. Blisters may be serous or haemorrhagic, tend to be localized to areas of trauma, especially on the dorsa of the hands, tops of the feet and elbows, and heal with scarring, milia and hyperpigmentation (Fig. 40.26). Nails may be dystrophic but are often normal. Some patients are indistinguishable from bullous pemphigoid, although some of these evolve into a more typical mechanobullous picture [23,24]. Mucosal involvement is variable but both erosions and intact blisters may be present in the mouth, larynx and oesophagus, and may cause dysphagia and laryngeal stenosis, and ocular involvement and blindness have been reported.

IgA EBA and IgA EBA mucous membrane pemphigoid. A number of patients have been described as IgA EBA, with IgA antibodies to dermal antigens and collagen VII. However, there are two different clinical entities with this immunopathology. There are linear IgA disease patients who are indistinguishable from other linear IgA patients [1–3] and there are patients with a mucous membrane pemphigoid phenotype [4–6].

Induced EBA and associated diseases. A number of conditions have been associated with EBA. There is an association with inflammatory bowel disease, both ulcerative colitis and Crohn's disease [1–6]. Collagen VII is expressed in human colon, and autoantibodies to collagen VII react with the epithelial mesenchymal junction, moreover antibodies to collagen VII are present in Crohn's disease and to a lesser extent in ulcerative colitis, suggesting that cross reactivity and epitope spreading may explain this association [7].

There are reports of EBA in association with multiple myeloma, amyloidosis and lymphoma [8–13]. Individual cases have been associated with carcinoma [14–16].

The association with systemic lupus erythematosus is discussed below under bullous systemic lupus erythematosus.

Drug-induced EBA has been described [17]

Prognosis. The prognosis is very variable. Those patients with a bullous pemphigoid-like picture may go into remission. However, patients with mechanobullous disease or a mucous membrane phenotype tend to have disease that is difficult to suppress and is very prolonged.

Differential diagnosis. Cases of EBA are often confused with dominant dystrophic epidermolysis bullosa, bullous pemphigoid or porphyria cutanea tarda. Clinically, the mechanobullous epidermolysis bullosa acquisita patients most closely resemble mild dominant dystrophic epidermolysis bullosa, but the lack of family history, late onset and positive direct immunofluorescence distinguish them. The lesions on the hands may mimic porphyria cutanea tarda but this can be ruled out by porphyrin studies. Bullous pemphigoid presents the greatest diagnostic problems, because the direct immunofluorescence may be similar in these conditions. The conditions may be separated by using salt-split skin as a substrate for indirect immunofluorescence and the additional finding on electron microscopy of cleavage beneath the basal lamina and the deposition of IgG in the dermis.

Treatment. The rarity of the condition has precluded proper trials but the mechanobullous variant is characterized by resistance to usual treatment modalities. A systematic review identified only 10 reports of studies on two or more patients (20 adults and 11 children) [1]. Much of the information on treatment is anecdotal; corticosteroids, azathioprine, ciclosporin, vitamin E, gold, dapsone, sulfonamides, colchicines and photophoresis have been reported to give inconsistent benefit [2]. Mycophenolate mofetil has been reported as helpful in a few cases [3–5]. Intravenous immunoglobulins and subcutaneous immunoglobulin (by home administration) can improve the condition, however the response is not universal [2,6,7]. Rituximab has been reported to be successful in several case reports [8–12].

Steroids in combination with dapsone or sulfonamides are probably the best first-line treatment, certainly in children [1].

Bullous systemic lupus erythematosus

Synonym

- Vesiculobullous systemic lupus erythematosus

Definition. An autoimmune blistering condition, often transient, that occurs in the setting of systemic lupus erythematosus [1,2]. There is some controversy as to whether the term bullous systemic lupus erythematosus should include all subepidermal autoimmune bullous diseases that arise in patients with systemic lupus erythematosus or should be reserved for those patients with dermal antigens [2–4].

The clinical features, immunopathology and immunogenetics are summarized in Tables 40.5 and 40.6, and Fig. 40.25 and in a review [2].

4 Vassileva S. Bullous systemic lupus erythematosus. *Clin Dermatol* 2004; **22**: 129–38.

Aetiology. Bullous systemic lupus erythematosis (BSLE) occurs only in patients with systemic lupus erythematosus. It affects young adults, chiefly women, often of African or Hispanic descent, and has been reported in children [1–3]. It is very rare in Western Europe with an incidence of 0.2 per million [4,5] and has been reported from China and Singapore [6,7]. In the USA, there is an association with HLA-DR2 [8].

Pathogenesis. The bullous disease is mediated by autoantibodies to the basement-membrane zone, as demonstrated by positive direct immunofluorescence at the basement-membrane zone. The autoantibodies initially were demonstrated to react with collagen and to bind to fibronectin-like domains of the NC1 terminal [1,2] and also the cartilage matrix protein subdomain [3]. However, as more cases have been studied it has become obvious that other dermal and epidermal antigens can also be involved, and in some cases no circulating autoantibodies can be detected [4–8]. Basement-membrane autoantibodies have also been detected in patients with systemic lupus erythematosus without blisters, although other groups have not confirmed this [4,5,9]. Collagen VII antibodies do not seem to contribute to the lupus band in patients without BSLE [10].

Both IgG and IgA autoantibodies are involved [5,6].

The target antigens and immunogenetic susceptibility are, in many patients, shared with EBA, and yet in general they differ in clinical presentation. The reasons for these marked differences in the clinical phenotype are intriguing but unexplained, but do not relate to complement fixing properties [11].

11 Gandhi K, Chen M, Aasi S *et al.* Autoantibodies to type VII collagen have heterogeneous subclass and light chain compositions and their complement-activating capacities do not correlate with the inflammatory clinical phenotype. *J Clin Immunol* 2000; **20**: 416–23.

Pathology. Histologically, the bullae are subepidermal with a neutrophilic infiltrate, occasionally resulting in microabscesses resembling dermatitis herpetiformis.

The findings with immunofluorescence are summarized in Table 40.6. Direct immunofluorescence shows linear bands of IgG, IgA, IgM and C3 in the basement-membrane zone.

With indirect immunofluorescence, circulating antibodies, when present, may bind to the basement-membrane zone and to either the dermal, as shown in Fig. 40.25, or the epidermal aspects of split skin, or may be absent [1,2].

Immunoelectron microscopy studies have demonstrated that circulating IgG autoantibodies bind below the lamina densa [3].

2 Gammon WR, Briggaman RA. Bullous SLE: a phenotypically distinctive but immunologically heterogeneous bullous disorder. *J Invest Dermatol* 1993; **100**: 28S–34S.
3 Hall RP, Lawley TJ, Smith HR *et al.* Bullous eruption of systemic lupus erythematosus. Dramatic response to dapsone therapy. *Ann Intern Med* 1982; **97**: 165–70.

Clinical features. The onset of the disease is usually in patients with already established systemic lupus erythematosus. There is widespread blistering, which may include both vesicles and larger tense blisters, and there may be erythematous macules as well. All cutaneous sites may be involved. Mucosal lesions are uncommon. In some patients, the eruption is photosensitive. Post-inflammatory hyperpigmentation may occur. The occurrence of the bullous eruption is not related to flares of the systemic disease, and shows clinical similarities to bullous pemphigoid and dermatitis herpetiformis. The classical epidermolysis bullosa phenotype of a mechanobullous eruption with milia and scarring (see above) is rare [1,2]. In many patients, the disease is transient.

2 Eckman JA, Mutasim DF. Bullous systemic lupus erythematosus with milia and calcinosis. *Cutis* 2002; **70**: 31–4.

Associated disease. Bullous systemic lupus erythematosis, by definition, only occurs in the setting of systemic lupus erythematosis. Vesiculobullous skin eruptions are uncommon but well recognized in patients with systemic lupus erythematosus, occurring in less than 10% of SLE patients, whilst true BSLE was reported in 1/73 British and 1/186 Italian patients [1,2]. The classical widespread bullous skin eruption appears to be unrelated to the other systemic manifestations, exacerbations or the severity of the systemic lupus erythematosus [3–6]. There are many reports of other autoimmune diseases, pemphigus, bullous pemphigoid, linear IgA disease, dermatitis herpetiformis and reactive bullous diseases, erythema multiforme and toxic epidermal necrolysis in association with systemic lupus erythematosus, but all the subepidermal ones are best regarded as BSLE [7,8].

8 Vassileva S. Bullous systemic lupus erythematosus. *Clin Dermatol* 2004; **22**: 129–38.

Prognosis. Most patients have a transient eruption. However, patients with the rare mechanobullous and scarring picture have a poorer prognosis.

Differential diagnosis. The presence of blistering in a patient with systemic lupus erythematosus can be due to photosensitivity, acute lupus or a drug eruption. The histopathology and immunopathology will distinguish bullous systemic lupus erythematosus.

Treatment. Some of these patients appear to have responded to steroids used to control their systemic lupus erythematosus. Dapsone has been shown to be very effective as first-line treatment and also in patients with steroid-resistant blistering [1–9]. Methotrexate has also been reported to be helpful [10]. Rituximab may be useful [11].

Dermatitis herpetiformis

Synonym
- Duhring–Brocq disease

Definition. Dermatitis herpetiformis (DH) is a rare, intensely pruritic, chronic, recurrent, papulovesicular disease. The eruption is symmetrical and pleomorphic, consisting of erythematous, urticarial, papular, vesicular or bullous lesions (Fig. 40.27). There is an underlying gluten-sensitive enteropathy that may be asymptomatic. The mechanism by which ingestion of gluten induces granular IgA deposition in the skin and blistering is still obscure (see below).

The characteristic clinical and immunopathological features are shown in Tables 40.5 and 40.6.

Fig. 40.27 Dermatitis herpetiformis. Intact tense bullae on the elbow. (Courtesy of Dr R.J. Pye, Addenbrooke's Hospital, Cambridge, UK.)

Aetiology. Dermatitis herpetiformis is a disease of all ages. In Italy and Hungary it commonly presents in childhood [1–3], in the UK in young and middle-aged adults, with a slight male preponderance, and in southern Sweden it may present in old age [4]. The incidence is more than 3000 per million in Ireland, 200–390 per million in Sweden, 110 per million in Scotland and Finland, and probably less elsewhere in Europe [4,5]. Dermatitis herpetiformis is rare in the Far East.

There is a family history of dermatitis herpetiformis or coeliac disease in 10.5% of patients and it has been reported to be both concordant and discordant in monozygotic twins [6–13].

All patients have an underlying gluten-sensitive enteropathy, although this may be asymptomatic. Others will have been investigated for abdominal pain, and may be misdiagnosed. There is an association with exposure to infection with adenovirus, as has been observed in coeliac disease [14].

HLA studies in patients who on clinical and immunological criteria have dermatitis herpetiformis, have shown identical findings to coeliac disease. There is a very strong association with DR3 and DQw2 [5,15–18].

18 Sachs JA, Leonard J, Awad J *et al.* A comparative serological and molecular study of linear IgA disease and dermatitis herpetiformis. *Br J Dermatol* 1988; **118**: 759–64.

Pathogenesis. The characteristic finding is deposition of IgA in a granular pattern in the papillary dermis (Fig. 40.28), although IgM, IgG and C3 may be found. The IgA deposits are gluten dependent, and are slowly cleared from the skin once gluten is removed from the diet [1,2]. The mechanism by which gluten causes the IgA deposition in the skin is still unknown, although non-immunological binding of gliadin to reticulin has been shown [3]. The IgA deposits are often, but not exclusively, associated with the microfibrils [4,5]. The antigen within normal human skin to which IgA antibodies from dermatitis herpetiformis sera bind is still unknown.

The IgA deposits have been shown to be chemoattractant to neutrophils [6]. C3 has been demonstrated in the papillary dermis of both lesional and perilesional skin. Properdin and factor B have been found and support the suggestion that complement is activated via the alternative pathway [7]. C5 and fibrin are often detected in similar sites [8]. The activated fraction, C5a, is highly chemotactic for neutrophils and may contribute to the inflammatory change at the papillary tip. Lymphocytes also play a role, with the neutrophils, in initiating an inflammatory cascade [9].

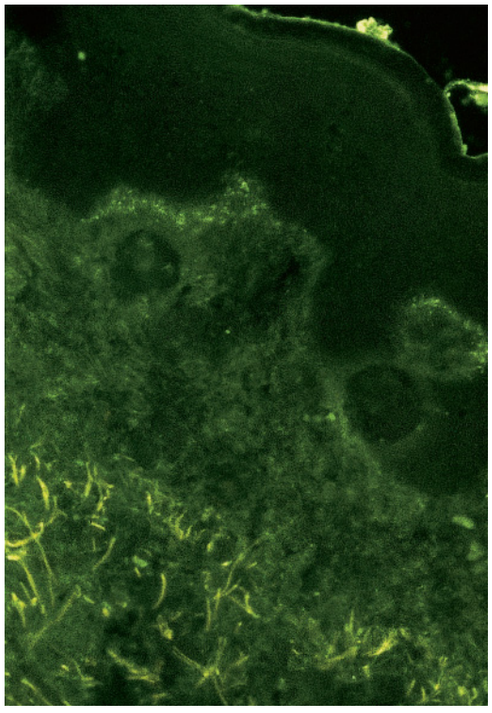

Fig. 40.28 Dermatitis herpetiformis. Direct immunofluorescence demonstrating granular IgA deposition in the dermal papillae. (Courtesy of Dr J. Allen, Oxford Radcliffe Hospital, Oxford, UK.)

Characterization of the IgA deposits has shown the IgA to be almost exclusively IgA1 and to be both monomeric and polymeric, with J chains and secretory components present [10–12]. These data suggest that the IgA is derived from mucosa and serum.

In 1967, the link with gluten sensitive enteropathy (coeliac disease) was established [13]. Further studies showed that the small-bowel changes of villous atrophy were secondary to gluten sensitivity and responded to gluten-free diet [14]. The gluten-sensitive enteropathy is present in all patients though is difficult to demonstrate in some [15]. Patients were found to have antireticulin antibodies and antigluten or antigliadin antibodies [15–19]. IgA endomysial antibodies, directed at smooth muscle, are frequently found in dermatitis herpetiformis and coeliac disease and fall with the introduction of a gluten-free diet [20,21].

One of the most exciting developments of recent years has been the recognition that autoantibodies and T-cell reactions to tissue transglutaminases, and in particular transglutaminase 2, are relevant to the pathogenesis of coeliac disease [22]. These antibodies have been demonstrated in dermatitis herpetiformis [23–25]. In addition, it is now clear that the previously recognized antireticulin and endomysial antibodies, in coeliac disease and dermatitis herpetiformis, are associated with these antibodies [26] and require transglutaminase 2 to bind to tissues [27]. The tissue transglutaminases cleave gliadin into antigenic peptides and this may contribute to their role in pathogenesis [28]. There is a difference in autoantibody profile between dermatitis herpetiformis and coeliac disease, in that IgA antibodies to epidermal transglutaminases (tissue transglutaminase 3) are more common in DH than coeliac disease [29,30]. The IgA precipitates in the dermis contain epidermal transglutaminases [29], and there is co-localization of the granular IgA deposits and the epidermal transglutaminases in the upper dermis and blood vessels, thus DH may be an immune complex disease [31,32]. However, the precise chain of events leading to IgA deposition in the skin and blistering has still to be unravelled [9]. The serum of patients with DH does not contain antibodies that bind either to human skin or to mouse models [33,34]. An animal model using genetically primed DQ8 mice has shown that in a minority gluten can induce blisters with the characteristic histology and granular IgA deposition, however this was not associated with circulating antibodies to skin, endomysium, gluten, gliadin, or tissue transglutaminases, nor with enteropathy [34].

Pathology. Diagnostic histological changes are best seen in the vicinity of early blisters or in lesions that have not yet blistered. Neutrophils and eosinophils accumulate within the dermal papillae and form microabscesses. The surrounding collagen is degraded, resulting in detachment of the epidermis and a subepidermal vesicle. Multilocular vesicles may coalesce to form blisters; at that stage the cellular infiltrate is mixed and distinction from pemphigoid may be difficult.

The characteristic immunofluorescence findings are shown in Table 40.6 and Fig. 40.28. Direct immunofluorescence is always positive [1]. However, sometimes when there is a high degree of clinical suspicion, serial sections and multiple biopsies may be necessary to confirm the diagnosis. The biopsy (a 3–4-mm punch biopsy is sufficient) should be taken from clinically normal skin. The forearm or buttock is usually suitable. There are granular deposits of IgA in the dermal papillae (Fig. 40.28). There may also be C3 and IgG.

The diagnostic significance of the rare, linear, granular pattern of IgA deposition at the basement-membrane zone is still unclear [2]. Some patients with this pattern have true dermatitis herpetiformis and others may have autoantibodies to unusual target antigens.

Indirect immunofluorescence is negative for basement-membrane zone or dermal autoantibodies. However, if monkey oesophagus is used, IgA endomysial antibodies may be detected [3]. Immunoblotting studies are negative.

Electron microscopy shows that the blisters are subepidermal and can occur beneath the basal lamina. In the lesions, the basal lamina may be fragmented or lost. However, in adjacent skin the basal lamina may be thickened and reduplicated. The basal cells show cytolysis, but these changes are probably secondary to the effects of the inflammatory cells [4].

Ultrastructurally on immunoelectron microscopy, the IgA deposits appear to be closely associated with the dermal microfibrillar bundles [5,6]. However, immunogold studies have shown that not all of the IgA is associated with any recognizable structure [6].

Gastrointestinal investigations. All the abnormalities found in coeliac disease may be found in dermatitis herpetiformis [7]. A full blood count may reveal anaemia. The additional signs on the blood film depend on whether it is due to iron deficiency or folate deficiency. There may also be Howell–Jolly bodies on the film, indicating splenic atrophy [8]. There may be antireticulin antibodies and antigliadin antibodies as well as antiendomysial antibodies and antibodies to tissue transglutaminases. A jejunal biopsy will demonstrate signs of gluten-sensitive enteropathy in almost all cases; these signs may be a raised intraepithelial lymphocyte count or in more severe cases a flat biopsy.

Clinical features. Dermatitis herpetiformis presents mainly between the ages of 20 and 55 years, but can present both in childhood and old age. The onset may be acute or gradual, and pruritus is usually the first and predominant symptom. Early lesions on the skin are erythematous papules, urticarial weals or groups of small vesicles often excoriated so rapidly that it may be impossible to find one intact. The vesicles are usually grouped together on plaques of erythema, and rarely blisters 1–2 cm in diameter occur (Fig. 40.27). This happens more frequently in relapses when suppressive treatment has been discontinued. Papules without blistering are not uncommon and eczematous changes that may be lichenified are sometimes seen. Progressive pigmentation of the sites of the skin lesions occurs in some patients. The distribution of the lesions is characteristic. The extensor aspects of the limbs, especially the knees, just below the point of the elbows, buttocks and the natal cleft, are affected in the majority of patients (Fig. 40.27). The axillary folds, shoulders, trunk, face and scalp are all frequently involved. In partially suppressed disease the scalp and chin are often the sited effected. Oral lesions are common but asymptomatic [1].

Provocation or exacerbation by iodides either by mouth or by patch test is not specific for dermatitis herpetiformis and is now considered outmoded as a diagnostic test [2,3]. Skin cleansers containing iodine and iodine-containing preparations must be avoided, as they can exacerbate dermatitis herpetiformis.

There may be a feeling of malaise with the acutely active disease. In addition, constitutional symptoms due to the gluten-sensitive enteropathy can be present. The patient may experience bouts of abdominal pain, constipation and diarrhoea, and be undernourished. A diagnosis of irritable bowel is not uncommon. Patients are often tired and lack a feeling of well-being.

Associated diseases. There are often associated autoimmune diseases, particularly thyroid disease, pernicious anaemia and diabetes [1,2]. There is an association with thyroid disease in up to 30% of patients [3]. A variety of organ-specific and non-organ-specific autoantibodies have been detected in patients with dermatitis herpetiformis, notably thyroid antibodies [4].

Lymphoma is a well-recognized complication of dermatitis herpetiformis, as are other malignancies [5–12], although a recent study contradicts this [13]. Moreover, the protective role of a gluten-free diet for the lymphomas has been established [11,12,14].

Prognosis. The disease runs a very long course with exacerbations and remissions [1]. Ten per cent of patients experience remissions. Acute infection and even emotional disturbances may precipitate an attack. A strict gluten-free diet will result in remission of the skin and the gut.

Interestingly, patients with dermatitis herpetiformis on a normal diet or a gluten-free diet do not have a decreased life expectancy, despite the slight increase in mortality from lymphoma, perhaps because of a reduction in ischaemic heart disease [2–6].

Differential diagnosis. The diagnosis should be suspected when any persistent, pruritic, symmetrical eruption resists topical treatment. In view of the pruritus and involvement of the axillary folds and buttocks, many patients are thought to have scabies, but the absence of burrows or of contact cases should help with the diagnosis. The most difficult diagnostic problem is the group of patients with chronic exudative eczema, papular urticaria and chronic prurigo, some of whom may be dapsone responsive. The histology and the lack of IgA deposition should help establish the correct diagnosis.

Treatment. The treatment of dermatitis herpetiformis has been reviewed [1]. Dapsone is the most widely used treatment for dermatitis herpetiformis. The dose needed for the average case is 100–200 mg/day but a few may require 400 mg/day. It is wise to start at 25–50 mg/day in an adult and slowly increase to a dose that keeps the patient comfortable and without significant side effects. Too rapid an increase in the dose often results in haemolytic anaemia, which does not reach its maximum for a month. A fall in haemoglobin with a low MCV indicates iron deficiency (due to intravascular haemolysis) rather than pure haemolytic anaemia. Patients at risk of glucose-6-phosphate dehydrogenase deficiency should be screened prior to treatment. Methaemoglobinaemia is common, reaching a steady state after about 2 weeks, and may cause cyanosis, breathlessness and angina. Hepatitis, the dapsone syndrome (lymphadenopathy and hepatitis) and agranulocytosis are serious, usually early complications. Motor neuropathy may occur. Most complications occur in the first 3 months. Sulfapyridine (up to 3 g/day) or sulfamethoxypyridazine 0.5–1.5 g/day is an alternative in patients who cannot tolerate dapsone; side effects include nausea, lethargy, haemolytic anaemia and bone-marrow suppression, their incidence increasing with doses above 1 g/day [2]. Although systemic corticosteroids are in the main ineffective and not indicated, topical steroids may be helpful in lessening symptoms [3]. Heparin, with or without tetracyclines, in combination with nicotinamide/niacinamide are advocated for patients who cannot tolerate dapsone or sulfonamides [4,5].

A gluten-free diet is the treatment of choice in the long term. It has been shown not only to improve the enteropathy, but also to allow discontinuation of drug therapy. The patients put on weight, lose their abdominal symptoms and often feel generally much better. In order to obtain strict adherence to the diet, the patient needs to be highly motivated, intelligent and leading a regular life. Sometimes it may be wise to postpone starting the diet until a more settled period. Wheat must be avoided, but oats certified free of gluten are usually tolerated, although a few patients may have reactions to oat proteins [3,6–8]. Unlike patients with coeliac disease, ingestion of small quantities of gluten does not always precipitate symptoms. The help of a dietician and the Coeliac Society are essential. It is usually many months and sometimes years before patients are able to reduce their dapsone requirements. Often dapsone can be discontinued altogether after 2–3 years on a strict gluten-free diet, but some patients take much longer [9]. Reintroduction of gluten in selected patients produced a relapse in skin lesions [10,11]. The gluten-free diet after 5–10 years protects patients from lymphoma, and this is an additional reason to recommend a gluten-free diet [12].

Definition of lichenoid eruptions

The term 'lichenoid' is used by clinicians to describe a flat-topped, shiny, papular eruption resembling lichen planus (LP), or by histopathologists to describe a type of tissue reaction consisting principally of basal cell liquefaction and a band-like inflammatory cell infiltrate in the papillary dermis [1]. The prototype of all lichenoid eruptions is LP itself but a number of other diseases may develop a lichenoid tissue reaction [2,3] and will be discussed here. Lichenoid aspects of graft-versus-host disease are addressed in Chapters 51 and 62.

Pathogenesis

Immunological aspects. LP is thought to be an immunologically mediated disorder [1], not least because a lichenoid eruption may be seen as part of graft-versus-host disease [2–4] (see Chapters 51 and 62). Cloned murine autoreactive T cells produce a lichenoid reaction in recipient animals following injection [5]. T cells, both $CD4^+$ and $CD8^+$, accumulate in the dermis, while $CD8^+$ T cells infiltrate the epidermis, in LP lesions; it has been proposed that $CD8^+$ cytotoxic T cells recognize an antigen (currently unknown) associated with the major histocompatibility complex (MHC) class I on lesional keratinocytes and lyse them [6–10]. T-cell receptor (TCR) repertoires are skewed in tissue samples and in peripheral blood mononuclear cells of patients with oral LP [11].

T cells and keratinocytes express interferon-γ (IFN-γ) and interleukin-6 (IL-6) [6], and T cells also express lymphocyte function associated antigen-1 (LFA-1) [8] and secrete IFN-γ *in vitro* [12]. Mononuclear cells infiltrating the skin, the majority of which are $CD8^+$, as well as basal keratinocytes, express tumour necrosis factor-α (TNF-α) and TNF-R1 [12]. Activated T cells secreting IFN-γ induce keratinocyte expression of human leukocyte antigen (HLA)-DR [13], and the presence of epidermotropic T cells correlates with that of HLA-DR-expressing keratinocytes and Langerhans' cells [14]. NF-kappaB-dependent inflammatory cytokines TNF-α, IL-1-α, IL-6 and IL-8 are detected at increased levels in salivary fluid and serum from patients with oral LP [15,16]. The role of chemokines in the pathophysiology of lichenoid tissue reactions in regard to recruitment and local activation of cytotoxic Th1 cells and plasmacytoid dendritic cells has recently been reviewed [17]. Infiltrating $CD8^+$ T cells, as well as keratinocytes, express a variety of different chemokines [18–20]. RANTES (regulated upon activation, normal T-cell expressed and secreted) secreted by T cells may trigger mast cell degranulation with consequent release of TNF-α, which in turn up-regulates lesional T-cell RANTES secretion; such mechanisms may contribute to chronicity of T-cell infiltration and clinical disease [21]. Lesional type I IFN cytokines produced by plasmacytoid dendritic cells play an important role in LP by recruiting autoreactive cytotoxic $CD8^+$ T lymphocytes via IP10/CXCR3 interactions [22]. Type I IFN-inducible chemokines include CXCL9, the CXCR3 ligand, which is a significant marker for LP [23], and CXCL10, which is expressed exactly where cytotoxic lymphocytes invade the basal epidermis and cause keratinocyte death [24]. IFN-γ, IL-4 and IL-18 gene polymorphisms seem to promote disease susceptibility and progression of oral lichen planus in ethnic Chinese subjects [25,26].

Keratinocytes are also type I IFN producers in LP skin lesions [23]. Keratinocyte cytokines may up-regulate expression of cell surface adhesion molecules on, and migration by, T cells [27–29]. $CD1a^+$ Langerhans' cells and factor $XIIIa^+$ cells are increased in LP [8,30,31] and may be involved in antigen presentation to T cells. Activin A, a transforming growth factor-β (TGF-β) family member induced by pro-inflammatory cytokines and which promotes Langerhans' cell differentiation and activation, is increased in the

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

upper epidermis and dermis in LP [32]. Vascular endothelial expression of the adhesion molecules intercellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1) is also elevated [8]. Mast cell degranulation [33], and T-cell secretion of matrix metalloprotein (MMP) 9 [34], may contribute to basement membrane disruption, enabling migration of $CD8^+$ T cells into the epithelium. Granzyme B^+ T cells have been observed close to apoptotic keratinocytes [35]. Over-expression of bone morphogenic protein (BMP-4), another member of the TGF-β family, may contribute to apoptosis of epithelial cells in oral LP through up-regulation of p53, MMP1 and MMP3 [36]. Over-expression of MMP-2, MT1-MMP, and especially MMP-9, may be involved in malignant transformation in oral lichen planus [37].

Genetics. There may be a genetic susceptibility to idiopathic LP. Familial cases are reported [1–6], and a familial incidence of 10.7% was quoted in one series [4]. LP has also been reported in monozygotic twins [7,8]. An association with HLA-3 and HLA-5 has been documented [9], although others found no such association [10,11], as have associations with HLA-B7 [1], HLA-28 in Jews with LP and carbohydrate intolerance [12], HLA-DR1 [13], HLA-DR10 [14], and HLA-DRB1*0101 [15]. Genetic heterogeneity in LP has led to a suggestion that idiopathic cutaneous, and purely mucosal, LP may each have a different pathogenesis [16].

Viruses. An epidemiological association of LP with hepatitis C virus (HCV) infection has been recorded, especially in patients from Italy, certain parts of France, Spain, Japan and Pakistan [17–24], and HCV RNA has been isolated from lesional skin in patients with LP and chronic HCV infection [25,26]. Thus, an HCV-related

product has been postulated as a possible antigen in LP. However, no association between LP and HCV infection has been noted in patients from Northern Europe including the UK, the USA or Nepal [24,27–31]. It has been suggested that the observed geographical differences with regard to HCV infection and LP could be related to immunogenetic factors such as the HLA-DR6 allele, significantly expressed in Italian patients with oral LP and HCV infection [17,18]. LP has been associated with human herpesvirus type 7 replication [32].

Dental amalgam. Another putative antigen in oral LP is mercury in dental amalgam; 87–97% of patients with oral LP associated with dental amalgam fillings benefit from amalgam removal [33–38], but only 28–39% have positive patch test reactions to amalgam or inorganic mercury. Patients who improve following removal of amalgam, but in whom patch testing is negative, are presumed to have an irritant reaction to amalgam. A recent study reported that the presence of amalgam or of gold is not associated with an increased risk of oral LP, but corrosion of amalgams, and a 'galvanic effect' from dissimilar dental materials in continuous contact with the mucosa (bimetallism) are associated with an elevated risk of oral LP [39].

Miscellaneous. LP has been induced by radiotherapy [40], and has been reported to have been confined to a radiation field [41]. Anxiety and depression [42] and stress [43] may be risk factors for the development of LP.

Incidence

LP has a worldwide distribution with no overt racial predisposition. LP represented about 1.2% of all new patients in London [1] and Turin [2], 0.9% in Copenhagen [3] and 0.38% in India [4]. Hypertrophic cases were reportedly common in Nigeria [5]. Both oral and cutaneous LP have rarely been reported in childhood [3,6–13]. Familial cases are recorded (see above). There was an over-representation of South Asians in a series of childhood cases in Birmingham, UK [13].

Histology [1,2]

The earliest finding is an increase in epidermal Langerhans' cells [1], associated with a superficial perivascular infiltrate of lymphocytes and histiocytes, impinging on the dermal–epidermal junction (DEJ). Mild spongiosis is followed by vacuolar alteration and clefting along the DEJ, with accumulation of necrotic keratinocytes (colloid bodies) [3].

The characteristic histological changes are best seen in biopsies of fully developed LP papules [4] (Fig. 41.1). The centre of the papule shows irregular acanthosis of the epidermis, irregular thickening of the granular layer, and compact hyperkeratosis. The mid-epidermal cells appear larger, flatter and paler than usual [4]. In oral LP, epithelial proliferation is increased [5]. Parakeratosis is rarely found in idiopathic LP, in contrast to some drug-induced lichenoid tissue reactions. A focal increase in thickness of the granular layer and infiltrate corresponds to the presence of Wickham's striae [6]. Degenerating basal epidermal cells are transformed into *colloid bodies* (15–20 μm diameter) which appear singly or in clumps [7–9]. The rete ridges may appear flattened or effaced (*'saw-tooth' appearance*), and focal separation from the dermis may lead to Max Joseph spaces (Fig. 41.2). In older or hypertrophic lesions, the number of colloid bodies is considerably reduced. In 'active' LP, a *band-like infiltrate* of lymphocytes and histiocytes, rarely admixed with plasma cells [10,11], obliterates the DEJ. Epidermal melanocytes are absent or considerably decreased in number [4], while *pigmentary incontinence* with dermal melanophages is characteristic. When the disease is becoming inactive, the infiltrate, with melanophages, becomes sparser and is arranged around papillary blood vessels, which may show ectasia and surrounding fibroplasia.

In hypertrophic LP, the epidermis may show a pseudoepitheliomatous appearance with extreme irregular acanthosis. Follicles

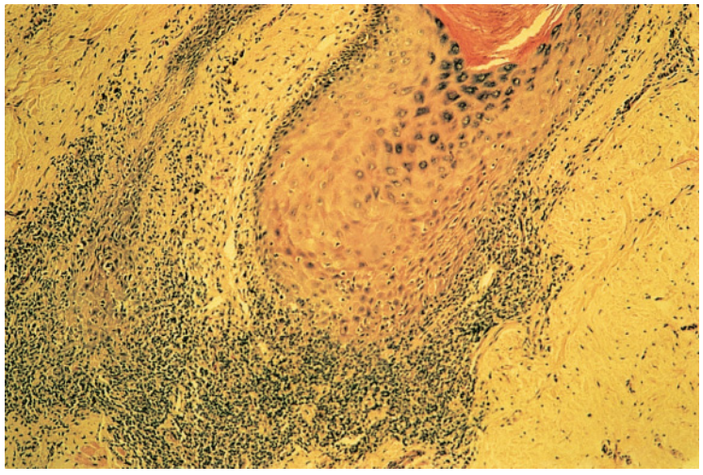

Fig. 41.4 Lichen planus. Photomicrograph of follicular lesion. Higher power, H&E × 40. (Courtesy of St John's Institute of Dermatology, King's College London, UK.)

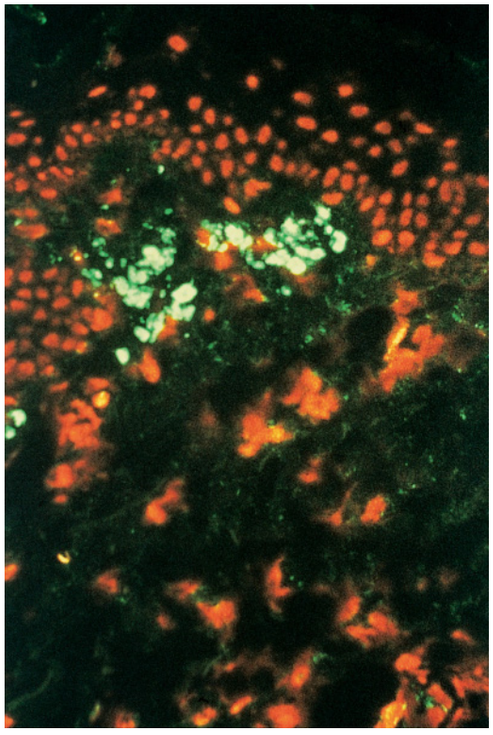

Fig. 41.5 Lichen planus. Photomicrograph of direct immunofluorescence. Bright fluorescence of cytoid bodies with anti-IgM × 100. (Courtesy of St John's Institute of Dermatology, King's College London, UK.)

may be expanded and at times have a 'cyst-like' appearance. The infiltrate may not appear very 'band-like', but serial sections will usually show foci of basal cell liquefaction and colloid body formation, often around the follicular epithelium. Long-standing cases usually demonstrate coexistent dermal fibrosis adjacent to the inflammatory changes.

In atrophic LP, the epidermis may be greatly thinned almost to the level of the granular layer, although relatively compact hyperkeratosis remains. The rete ridges are usually completely effaced with relatively few colloid bodies. The papillary dermis shows fibrosis and loss of elastica.

In follicular lesions (Figs 41.3 & 41.4), an infiltrate extends around, and may permeate, the base of the hair follicle epithelium, with follicular keratin plugging [12,13].

In mucosal LP, the epithelium is usually thinned with parakeratosis, although both types of keratinization may be seen [14]; the epithelium may resemble epidermis from skin, plasma cells may be prominent in the 'band-like' infiltrate, and colloid bodies are fewer than in typical cutaneous papular LP. The erythematous subtype of oral LP is associated with increased cell proliferation compared with the reticular form [15]. Moderate or severe epithelial dysplasia on oral biopsy should probably be regarded as an increased risk for subsequent cancer development [16].

Bullous LP is rare; blister formation takes place predominantly between the basal lamina and cytomembranes of basal keratinocytes (i.e. intrabasal) [7], such that there is a wide separation between the epidermis and infiltrate.

Direct immunofluorescence (IMF) shows globular deposits of IgM (Fig. 41.5), and occasionally IgG and IgA, representing apoptotic keratinocytes, around the DEJ and lower epidermis, with fibrin deposition at the region of the DEJ [17–19]. Direct IMF studies may be useful in differentiating LP from lupus erythematosus or LP pemphigoides [20,21], and can be carried out on routine histological material [22].

A clinicopathological study of lichenoid dermatitis concluded that it was usually possible to provide a specific diagnosis [23]. Occasionally, lichenoid dermatitis can become generalized and

clinically mimic an exfoliative dermatitis; such eruptions are usually triggered by drugs [24].

Benign lichenoid keratoses (BLKs) are usually solitary but may be multiple [25–27], and show characteristic lichenoid infiltrates of lymphocytes, occasional parakeratosis, and apoptotic bodies in the epidermis without nuclear atypia of keratinocytes; rarely, the histology may show features of mycosis fungoides [28]. Malignant melanoma may be associated with a lichenoid tissue reaction [29], and melanoma *in situ* with lichenoid regression may mimic a BLK histologically [30].

Clinical features

LP is characterized by shiny, violaceous, flat-topped polygonal papules which retain the skin lines, and which vary in size from pinpoint to a centimetre or more across; they may be closely aggregated or widely dispersed. The size of the papules is often fairly uniform in an individual patient, but minute and large papules coexist in some cases. White lines, known as Wickham's striae [1] (Fig. 41.6), may traverse the surface of the papules. Papules can remain discrete or appear in groups, in lines or in circles. Linear lesions often appear along scratch marks or in scars (Koebner phenomenon) (Fig. 41.7), while annular lesions may be formed either by groups of papules arranged in rings or by single, large papules clearing in the centre and leaving an active margin.

Fig. 41.8 Lichen planus. Annular lesion on shaft of penis. (Courtesy of St John's Institute of Dermatology, King's College London, UK.)

Annular lesions are especially common on the penis (Fig. 41.8) and rarely may be the predominant type of lesion present, leading to atrophy later [2].

A variant in which groups of 'spiny' lesions resembling keratosis pilaris develop around hair follicles (lichen planopilaris) (Fig. 41.9) is not uncommon. Lichen planopilaris more often forms only a minor feature of the disease, but occasionally this type of lesion may predominate.

Although a few cases evolve rapidly and clear within a few weeks, the onset is usually insidious. In most cases, the papules eventually flatten after a few months, often to be replaced by an area of pigmentation that retains the shape of the papule and persists for months or years. There may be a gradual change in colour from pink to blue to black. The residual pigmentation may be intense, especially in dark-skinned races, or almost imperceptible in fair-skinned individuals. New papules may form while others are clearing. Some papules persist much longer, enlarge and thicken, and develop a roughened surface with a prominent violaceous hue, so-called hypertrophic LP. Such lesions may resolve with atrophy or scarring. More warty lesions are seen occasionally. Areas of pigment loss are described in black South Africans [3]. Co-localization of LP and vitiligo has been reported [4].

LP can affect any part of the body surface, but is most often seen on the volar aspect of the wrists (Fig. 41.10), the lumbar region and around the ankles. The ankles and shins are the commonest sites for hypertrophic lesions. When the palms and soles are affected, the lesions tend to be firm and rough with a yellowish hue (Fig. 41.11) [5,6]. A rare, erosive, flexural variant of LP has

Fig. 41.9 Lichen planopilaris. Hyperpigmented follicular 'plugged' lesions in frontal scalp hairline. (Courtesy of St John's Institute of Dermatology, King's College London, UK.)

been described [7]. Isolated lesions of LP have been reported to involve one or both eyelids [8,9] or the lips [10–12]. Milia have been recorded in LP [13], and LP was confined to a radiation therapy site in one patient [14].

Mucous membrane lesions are very common, occurring in 30–70% of cases, and may be present without evidence of skin lesions. They are, however, much less common in black people. The buccal mucosa and tongue are most often involved, but lesions may be found around the anus, on the genitalia, in the larynx and, very

rarely, on the tympanic membrane of the ears or even in the oesophagus. White streaks, often forming a lacework, on the buccal mucosa are highly characteristic (Fig. 41.12). They may be seen on the inner surface of the cheeks, on the gum margins or on the lips. On the tongue, the lesions are usually in the form of fixed, white plaques, often slightly depressed below the surrounding normal mucous membrane, especially on the upper surface and edges (Fig. 41.13). Ulcerative lesions in the mouth are uncommon, but may be the site of epitheliomatous transformation (Fig. 41.14). There may be striking pigmentation of oral LP in darkly

pigmented races [15]. Diabetes is a possible associated disease of oral LP [16,17], and candidiasis may coexist with LP in some patients.

Itching is a fairly consistent feature in LP and ranges from occasional mild irritation to more or less continuous, severe itching, which interferes with sleep and makes life almost intolerable; occasionally, itching is completely absent. Hypertrophic lesions usually itch severely. Paradoxically, there is seldom evidence of scratching, as the patient rubs, rather than scratches, to gain relief. Itching at sites without visible skin lesions can occur. Burning and stinging are less common complaints. In the mouth, the patient may complain of discomfort, stinging or pain; ulcerated lesions are especially painful. Great discomfort may be caused by hot foods and drinks.

Variants

LP principally involving mucous membranes

Lesions confined to the mouth, or with minimal accompanying skin involvement, are not uncommon [1–6], and account for about 15% of all cases [1]. The prevalence of oral LP was 1.5% among the villagers of Kerala in southern India [7], possibly related to chewing tobacco, and ranges between 0.5% and 2.2% of the population in other epidemiological studies [2,8]. The lesions do not differ from those found in connection with skin lesions, but, being confined to the mouth, may lead to great difficulty in diagnosis. They are often referred first to a dental surgeon. Distinct clinical subtypes such as reticular, atrophic, hypertrophic and erosive forms are well recognized; more than one type may be present [2]. On the tongue and buccal mucosa, they are most likely to be mistaken for leukoplakia and on the gum margin for gingivitis or chronic candidiasis, or the latter may coexist. Other conditions that must be excluded are 'smoker's patches', which characteristically involve the palate, and white-sponge naevi, in which the mucous membrane is thickened, irregularly folded and feels soft to the touch. These occur mainly on the floor of the mouth and histologically many of the prickle cells are vacuolated. It is important to bear in mind the possibility of a lichenoid drug reaction in patients with oral lichenoid changes (see below). Oral lichenoid reactions may be asymmetrical on the buccal mucosa and occur adjacent to dental amalgam fillings. If patch testing reveals mercury allergy, changing to another type of filling may prove beneficial [9–14].

Very occasionally, LP lesions extend to the larynx or oesophagus [15–19]. Oesophageal LP may result in dysphagia and the formation of benign strictures.

In young men, the lesions are sometimes restricted to the genitalia and/or the mouth [20,21]. Genital lesions, which are usually characteristic, may be present on the penile shaft (see Fig. 41.8), glans penis, prepuce or scrotum. Ulceration is very unlikely, and syphilis can usually be excluded without difficulty; the presence of buccal mucosal lesions will usually confirm the diagnosis. Circumcision may be helpful [20].

Lesions on the female genitalia are fairly common [22–29]; they may occur alone, be combined with lesions in the mouth only, or be part of widespread involvement. The clinical presentation of LP of the vulva spans a spectrum from subtle, fine, reticulate papules to severe erosive disease accompanied by dyspareunia, scarring and loss of the normal vulvar architecture. The condition should be distinguished from lichen sclerosus or leukoplakia, but this may be difficult when there is coexisting atrophy or vaginal stenosis. The association of erosive LP of the vulva and vagina with desquamative gingivitis has been termed the *vulvovaginal–gingival syndrome* [21,23] (Fig. 41.15). Coexisting vulval lichen sclerosus and lichenoid oral lesions have been described [30].

Hypertrophic LP

This usually develops during the course of a subacute attack, but occasionally only hypertrophic or warty lesions are found. They most often occur on the lower limbs, especially around the ankles; venous stasis has been put forwards as an explanation (Fig. 41.16). The development of hypertrophic lesions greatly lengthens the course of the disease, as they may persist for many years. When such lesions eventually clear, an area of pigmentation and scarring may remain and there is often some degree of atrophy. They must be distinguished from lichen simplex chronicus and lichen amyloidosus (papular). Multiple cutaneous horns overlying hypertrophic LP are recorded [1], as are keratoacanthoma [2,3] and malignant transformation [4–6] arising in hypertrophic LP, as well as metastatic squamous cell cancer [7].

Follicular LP [1]

Synonym
- Lichen planopilaris

Follicular lesions usually appear during the course of typical LP, but occasionally they predominate and diagnosis may then be difficult. Absence of arrector pili muscles and sebaceous glands, a perivascular and perifollicular lymphocytic infiltrate in the reticular dermis and mucinous perifollicular fibroplasia within the upper dermis with absence of interfollicular mucin, and superficial perifollicular wedge-shaped scarring are characteristic features of the histology [2]. Presentation with alopecia of the trunk is recorded [3]. Follicular lesions occurring in the scalp are accompanied by some scaling and are likely to lead to a scarring alopecia (Fig. 41.17). Very rarely, the scalp alone is involved. The so-called *Graham Little–Piccardi–Lassueur syndrome* comprises the triad of multifocal scalp cicatricial alopecia, non-scarring alopecia of the axillae and/or groin, and keratotic lichenoid follicular papules [4–9]. The clinical, histological and IMF overlap between this syndrome and LP with follicular involvement (lichen planopilaris) suggest that both are variants of LP. Progressive *frontal fibrosing alopecia*, a scalp condition that affects elderly women in particular and which frequently involves the eyebrows, has been regarded by some authors as a clinically distinct variant of lichen planopilaris [10], and is certainly associated with mucocutaneous lichen planus [11]. Onset of lichen planopilaris has been anecdotally associated with etanercept therapy [12].

Follicular LP must be distinguished by biopsy from keratosis pilaris, Darier's disease, follicular mucinosis, lichen scrofulosorum and, in the scalp, from lupus erythematosus.

Linear LP

Linear lesions as a Koebner effect are frequently found in LP. Isolated linear lesions, usually made up of small papules in close apposition, sometimes becoming confluent, are rare [1,2]; they are more common in childhood [3]. Linear LP lesions are usually only a few centimetres in length, but long, narrow linear lesions extending the whole length of a limb may occur. Such cases may overlap with epidermal naevi, and the term lichenoid epidermal naevus has been introduced [3]. Multiple linear LP lesions following the lines of Blaschko have been reported [4–6], as has a linear drug eruption to nicergoline [7]. Multiple linear LP was documented in a patient with human immunodeficiency virus (HIV) infection [8]. Segmental LP was co-localized with vitiligo in one case [9]. Zosteriform LP has been described [10–14] (Fig. 41.18). The histology of linear or zosteriform LP is characteristic, and enables distinction from other linear dermatoses such as lichen striatus, linear naevi and linear psoriasis. Interestingly, linear lichenoid lesions may occur in graft-versus-host disease [15–17].

Actinic LP

Synonym
- Lichen planus subtropicus

'Actinic' or (sub)tropical LP generally occurs in children or young adults with dark skin living in tropical countries; virtually all cases originate from the Middle East, East Africa or India [1–5]. Lesions occur on exposed skin (usually the face) as well-defined annular or discoid patches, which have a deeply hyperpigmented centre surrounded by a striking hypopigmented zone (Fig. 41.19).

Erythematous actinic LP has been associated with oral erosive LP and chronic active hepatitis [6]. Sunlight exposure appears to be central to the pathogenesis of actinic LP [7], although evidence for photo-induction of lesions in actinic LP is still lacking [8]. Actinic LP may mimic melasma [9]. There is a histological spectrum comprising: a form with features of classical idiopathic LP; an intermediate form (lichenoid melanodermatitis) with foci of spongiosis and parakeratosis; and a more overtly eczematous type [10]; all share striking pigmentary incontinence. Some of these 'hybrids' of actinic LP may not be mere variants of LP. Actinic LP has been treated with acitretin and topical corticosteroids [11] and with ciclosporin [12].

LP pigmentosus [1–3]

This is a pigmentary disorder seen in India or in the Middle East, which may or may not be associated with typical LP papules. The macular hyperpigmentation involves chiefly the face, neck and upper limbs, although it can be more widespread, and varies from slate grey to brownish black; it is mostly diffuse, but reticular, blotchy and perifollicular forms are seen [3]. The duration at presentation ranged from 2 months to 21 years in one series [3]. Occasionally, there is a striking predominance of lesions at intertriginous sites, especially the axillae [4,5]. The mucous membranes, palms and soles are usually not involved, but involvement of mucous membranes has been observed [6]. LP pigmentosus has been anecdotally reported in association with acrokeratosis of Bazex [7].

Annular LP [1]

Although small annular lesions are common in LP, cases showing a few large annular lesions only are unusual. They may be widely scattered, and usually have a very narrow rim of activity and a depressed, slightly atrophic, centre (Fig. 41.20). Much less often, the margin is wide, and the central area is quite small. Annular lesions are characteristically found on the penis (see Fig. 41.8), sometimes associated with lesions on the buccal mucosa. The differential diagnosis includes granuloma annulare. A distinct entity termed annular lichenoid dermatitis of youth [2,3] has been described, characterized by persistent asymptomatic erythematous macules and round annular patches with a red-brownish border and central hypopigmentation, mostly distributed on the groin and flanks, in children and adolescents. Histology reveals a lichenoid dermatitis with necrosis/apoptosis of the keratinocytes limited to the tips of rete ridges.

Atrophic LP

Lesions tend to be few in number; the atrophy may be the result of faded annular lesions [4,5], or resolved hypertrophic lesions on the lower legs especially. The histology is likely to be non-specific, but allows lichen sclerosus or guttate morphoea to be excluded.

Guttate LP

Lesions are widely scattered and remain discrete, may be all small (1–2 mm across), or larger (up to 1 cm) (Fig. 41.21), and individual lesions seldom become chronic. Guttate psoriasis must be differentiated.

Acute and subacute LP with confluence of lesions

In these forms, small lesions are widely distributed; where they become confluent, eczema may be simulated. Colour changes may be marked, with individual lesions initially red but progressing rapidly to black as they fade. Successive crops may occur, such that the total time for clearance may be little different from other forms; a small minority clear in under 3 months. Differential diagnosis includes pityriasis rosea in the earliest phase, and eczema later; drug-induced lichenoid eruptions may present in this fashion.

LP of the palms and soles

Although lesions on the volar aspect of the wrists or at the ankles occur in more than 50% of cases of LP, lesions on the adjacent palms and soles are less common, lack the characteristic shape and colour of lesions elsewhere, and are firm to the touch and yellow in hue [1,2] (see Fig. 41.11). They may be broadly sheeted or show up as punctate keratoses [3]. Vesicle-like papules are recorded [4]. Itching may be absent. When such changes occur in isolation, diagnosis is very difficult; syphilis, psoriasis, callosities and warts must be excluded.

A rare, very chronic, form of LP involves large, painful indolent ulcers on the sole of one or both feet [5], with gradual, permanent loss of toenails; there may be secondary webbing of the toes [6]. The sole may resemble lichenified dermatitis or psoriasis rather than LP before the ulcers appear. The onset is insidious and there may be no other evidence of LP, although cicatricial alopecia has been associated in some cases.

Complications

Hair. Alopecia is uncommon in LP, but most often occurs in small areas on the scalp, producing patches of atrophic cicatricial alopecia [1–5] (see Fig. 41.17). It results from follicular destruction by the inflammatory infiltrate, with scarring. Areas of alopecia may continue to appear, or to extend, for months after the skin lesions have faded. The final result is one of pseudopelade [2,5]; this is probably best considered as a clinical entity due to a number of independent conditions, of which LP is only one. Lichen planopilaris is more common in women and about half will develop involvement of glabrous skin, mucous membranes or nails [1]; it may occur in children [3]. Tumid forms of LP follicularis have been described in which clusters of milium cysts and comedones develop [6]. LP pilaris has been reported in association with dermatitis herpetiformis [7].

Nails. Nail involvement occurs in up to 10% of cases, but is usually a minor feature of the disease [8,9]. The majority of cases present during the fifth or sixth decades; long-term permanent damage to the nails is rare [10]. Fingernails are more frequently affected than toenails [10], with initial involvement of two or three fingernails before subsequent involvement of the remaining digits. The most common changes are exaggeration of the longitudinal lines and linear depressions (Fig. 41.22), due to slight thinning of the nail plate. These changes usually occur in the context of severe generalized LP, although skin lesions may not be seen in the vicinity of the affected nail. Elevated ridges may be seen on the nail [9]. Adhesion between the epidermis of the dorsal nail fold and the nail bed may cause partial destruction of the nail (pterygium unguis) (Fig. 41.23). Rarely, the nail is completely shed; there is usually clinical evidence of LP at the base of the nail before shedding. Nails may partially regrow or be permanently lost (Fig. 41.24); the nails of the great toes are the ones most often affected.

LP has been shown to cause childhood idiopathic atrophy of the nails [11]. LP of the nails in childhood is rare [12], but may overlap with the condition of twenty-nail dystrophy of childhood (idiopathic trachyonychia); the exact relationship is unclear [13–18]. The rare variant of LP that causes ulceration of the soles is often accompanied by permanent destruction of several toenails. LP of the nail bed may give rise to longitudinal melanonychia [19], hyperpigmentation, subungual hyperkeratosis or onycholysis [9], or changes mimicking the yellow nail syndrome [20,21].

Fig. 41.23 Severe lichen planus of fingernails showing involvement of nail fold areas and early pterygium formation. (Courtesy of St John's Institute of Dermatology, King's College London, UK.)

Mucous membranes. Squamous cell cancer developing on mouth lesions is uncommon, but is a potential danger, especially with ulcerated lesions [22–30], although the incidence varies greatly in different series. Lesions may occur on the lip (Fig. 41.25), the buccal mucosa or the gum margin. It has been postulated that high expression of cyclo-oxygenase (COX)-2 reported in oral lichen planus may be of aetiological significance in the development of

Fig. 41.24 Severe, destructive lichen planus of toenails. (Courtesy of St John's Institute of Dermatology, King's College London, UK.)

squamous cell cancer [31]. Squamous cell cancer arising on LP cutaneous lesions [32] and anogenital lesions [33–35] is definitely a rare phenomenon. Cicatricial conjunctivitis [36] and lacrimal canalicular obstruction are recorded [37].

Associated conditions

Idiopathic LP has been reported in association with diseases of altered or disturbed immunity, including ulcerative colitis [1–4], alopecia areata [2,4,5], vitiligo [4], dermatomyositis [6], morphoea and lichen sclerosus [7], systemic lupus erythematosus [8,9], pemphigus [8] and paraneoplastic pemphigus [10,11]. In addition, LP has been observed in association with thymoma [5,8,12,13], myasthenia gravis [3,4,13], hypogammaglobulinaemia [5,14], primary biliary cirrhosis [15–17], especially in those treated with penicillamine, and primary sclerosing cholangitis [18]. The literature with regard to LP and HCV infection is reviewed in the section on pathogenesis above. In Italy, possibly because of a higher prevalence of hepatitis B virus (HBV) and HCV infection, patients with LP seem more prone to develop liver disease, including chronic active hepatitis [19–23]. A high prevalence of anticardiolipin antibodies has been documented in patients with HCV-associated oral LP [24]. Elsewhere, the association between LP and chronic active hepatitis or primary biliary cirrhosis is unusual and probably coincidental [25–27]. Overall, the majority of patients with LP live to old age, despite an association with autoimmunity [28].

LP has also been associated with diabetes mellitus [29]. Anecdotally, LP has occurred in patients with Castleman's tumour (giant lymph-node hyperplasia) [30] or with generalized lichen amyloidosus [31]. LP has been described in certain tattoo reactions, particularly in those areas where there is coexisting mercury hypersensitivity to the injected dye [32,33].

Differential diagnosis

Typical cases of LP need be distinguished only from lichenoid eruptions induced by drugs or colour developer. Less typical cases of LP may be mistaken for plane warts, eczematous eruptions with lichenification from scratching [1–3], pityriasis rosea, and other lichenoid eruptions such as papular lichen amyloidosus. Occasional cases of LP without itching must be distinguished from secondary syphilis [4–6], systemic lupus erythematosus [7], atypical mycobacterium infection [8] and sarcoidosis [9].

The differential diagnosis of the special variants has already been mentioned; in case of doubt, a biopsy should establish the diagnosis. Although erythema dyschromicum perstans (ashy dermatosis) has a characteristic clinical appearance, it has been regarded as simply a macular variant of LP (LP pigmentosus) [10–12].

Prognosis [1–5]

Occasional cases clear in a few weeks, but skin lesions more usually subside within 9 months in about 50% of cases, and in 85% have cleared within 18 months, unless treated with systemic corticosteroids or potent topical steroids. Itching disappears first, then papules flatten, to be replaced by a corresponding area of post-inflammatory hyperpigmentation.

If hypertrophic patches develop, they are likely to persist for many more months, and occasionally for 20 years or more. The development of large, annular lesions is also a poor prognostic sign. Hair fall is usually permanent. Mucous membrane lesions clear more slowly than those on the skin and may remain visible for years after all evidence of the skin lesions has cleared [5]. Only 13% of patients with oral LP under follow-up in a large series went into remission [6], although mucous membrane lesions in Indian people were reported to be short-lived and without a tendency to malignancy [7]. About one case in five relapses, and frequent attacks occur in a small minority of cases.

Treatment

A large number of different forms of medication have been advocated, without adequate controlled trials [1]. Symptomatic treatment is usually sufficient, and largely consists of the use of the fluorinated topical steroid creams and ointments. These should be of the 'potent' variety (e.g. fluocinonide 0.05%, clobetasol proprionate 0.05%) to have any real chance of being effective. They are

recommended for comparatively small areas, but in a diluted form (e.g. 1 : 4 in white soft paraffin) can cover much larger areas. Oral antihistamines such as promethazine hydrochloride, alimemazine tartrate, chlorphenamine maleate or hydroxyzine hydrochloride may be helpful for pruritus. Hypertrophic lesions may be treated with occlusive dressings of tar or flurandrenolone tape, topical steroid preparations under polythene occlusion, or intralesional steroid injection. Topical tacrolimus is often advocated for mucous membrane LP (see below) and has been reported as effective in ulcerative LP of the sole [2]. Skin grafting has also been used for ulcerative lesions on the soles [3]. Topical calcipotriol is of limited use [4]; topical aloe vera gel was reported as helpful in oral LP [5].

Systemic corticosteroids, either stimulated by injection of adrenocorticotrophic hormone (ACTH) or tetracosactrin (Synacthen®), or administered as prednisolone at 20 mg daily for about 6 weeks and thereafter gradually reduced, may be of great value in treating the 5% of severe cases with marked irritation, ulcerative mucous membrane lesions, or progressive nail destruction or alopecia [6]. Equivalent doses are sufficient to retard growth in children [7]. Some relapse is liable to occur on discontinuation of systemic steroids, but the disease is self-limiting and corticosteroid therapy eases the patient through the worst part of its course.

Other agents used in treating severe cutaneous or erosive LP have included acitretin [8], itraconazole [9], metronidazole [10–12], low-molecular-weight heparin (enoxaparin) [13,14], tetracycline antibiotics [15], sulfasalazine [16], broad or narrow-band ultraviolet B phototherapy [17–19], oral or bath photochemotherapy with psoralen and UVA (PUVA) [19–22], Re-PUVA (retinoids with PUVA; this combination, however, has anecdotally induced dramatic hyperpigmentation) [23], ultraviolet A1 phototherapy [24], cyclophosphamide [25], azathioprine [26–28], methotrexate [29], recombinant IFN-α-2b [30], basiliximab [31], mycophenolate mofetil [32], and systemic ciclosporin (cyclosporin) [33–35]. Topical and systemic ciclosporin have been used to treat ulcerative LP of the feet [36,37]. Systemic ciclosporin [38,39] and thalidomide [40–42] have been helpful in management of lichen planopilaris of the scalp. Efalizumab [43] and alefacept [44,45] have been used for generalized or erosive LP.

Mucous membranes. Treatment of oral lesions has been reviewed [46,47]. Topical lidocaine (lignocaine) gel or diphenhydramine may alleviate discomfort, and topical tetracycline may be useful [48]. Topical corticosteroids, such as triamcinolone in Orabase®, clobetasol propionate as an ointment or a paste [49–52], corticosteroid lozenges (Corlan®), betamethasone (Betnesol®) mouthwashes 0.5 mg three to four times daily [53], or fluticasone propionate spray [53], are often beneficial. Vaginal hydrocortisone suppositories have been advocated [54,55]. The use of silastic prosthetic devices to enhance the delivery of topical corticosteroids to mucosal surfaces (e.g. vagina and oral) has been documented [56]. Intralesional steroid injections may be used but are painful [57]. Reactivation of human papillomavirus may occur at genital sites with topical steroids [58]. Topical ciclosporin for chronic mucosal LP has been of variable benefit and is expensive [59–62]. There has been a spate of papers on the merits of topical tacrolimus or pimecrolimus in oral, genital and perianal mucous membrane LP [63–69].

Extensive ulcerative lesions should be treated with systemic steroid preparations, but the starting dose will need to be higher than for treatment of skin lesions. Oral ciclosporin can be effective [70]. Griseofulvin [71], dapsone [72], hydroxychloroquine [73], retinoids (either topical in the form of retinaldehyde [74], isotretinoin gel (0.1%) [75], or tazarotene [76], or systemic as with etretinate [77], isotretinoin [78] or acitretin [79]), and thalidomide [80], have all had their advocates. The heparinoid sulodexide, given systemically, was judged as effective as topical ciclosporin [81].

Carbon dioxide and Nd : Yag laser therapy [47,82], as well as the 308-nm UVB excimer laser [83], have been utilized in the treatment of oral LP, as have efalizumab [84] and extracorporeal photochemotherapy [85]. Surgical excision of persistent ulcers has been recommended [86], and malignancy demands immediate surgery combined with radiotherapy.

'Mixed' LP/discoid lupus erythematosus disease patterns

Discoid lupus erythematosus (DLE) and LP are usually considered as distinct entities with characteristic clinical, histopathological and immunopathological features, with basement membrane deposition of IgG in DLE [1,2]. However, similarities between LP and DLE have been noted [3]. In addition, there have been several reports of patients showing overlapping features of both disorders [4–12]. Chronic atrophic DLE-like lesions on the head, neck and upper trunk may accompany reticular white lesions in the oral cavity, and combinations of lichenoid or verrucous lesions are seen. Eyelid involvement is recorded [13]. The association of extensive generalized LP with subacute cutaneous DLE has been documented [14]. Both ciclosporin [14] and acitretin [15] can be of benefit in treating LP/DLE overlap syndrome.

Bullous LP and LP pemphigoides

Lichen ruber pemphigoides was first described by Kaposi in 1892 [1]. Bullous LP and LP pemphigoides were in the past differentiated solely on clinical and histological criteria [2], but can now be differentiated using IMF procedures and immunoelectron-microscopy [3,4]. In bullous LP, blisters arise only on or near the lesions of LP, as a result of severe liquefaction degeneration of the basal cell layer [5]. Histologically, there is subepidermal bulla formation with typical changes of LP, and direct and indirect IMF is negative [3]. The eruption is usually only of short duration [3].

In LP pemphigoides [6–9], the LP tends to be acute and generalized and is followed by the sudden appearance of large bullae on both involved and uninvolved skin (Fig. 41.26). Occasionally, even in LP pemphigoides, blisters may arise only on the lesions of LP [10]. LP pemphigoides has been precipitated by PUVA [11] and has evolved into pemphigoid nodularis [12]. An LP pemphigoides-like eruption has been reported to overlap with paraneoplastic pemphigus [13,14]. In LP pemphigoides, the histology shows

Fig. 41.26 Lichen planus pemphigoides. Large bulla arising on and around vicinity of lichen planus around ankle. (Courtesy of St John's Institute of Dermatology, King's College London, UK.)

a subepidermal bulla with no evidence of associated LP [3]. Direct IMF shows linear basement-membrane-zone deposition of IgG and C3 in perilesional skin [3,9]. Immunoelectron-microscopic studies reveal deposition of IgG and C3 in the base of the bulla and not in the roof as found in bullous pemphigoid [15].

Immunoblotting data have revealed that circulating autoantibodies in LP pemphigoides react with an epitope within the C-terminal NC16A domain of bullous pemphigoid 180-kDa antigen, and also with a 200-kDa antigen detected in bullous pemphigoid [16–21]. It seems that epidermal damage from liquefaction degeneration in LP exposes basement-membrane antigens, and consequent stimulation of autoantibody production.

The mean age of patients with LP pemphigoides is lower than that of those with classical bullous pemphigoid, and the course of the disease also tends to be less severe. Nevertheless, some cases require treatment with systemic steroids or azathioprine and fatalities occur [9]. A combination of corticosteroids and acitretin has been used [21,22].

Lichen nitidus [1]

Lichen nitidus is a rarer condition than idiopathic LP and is clinically characterized by the presence of pinpoint to pinhead-sized papules, which are usually asymptomatic, flesh coloured, with a flat, shiny surface.

Aetiology. The view that lichen nitidus represents a variant of LP tends to be supported by the fact that early, tiny LP papules may be clinically and histopathologically indistinguishable from lichen nitidus [2,3]. Immunophenotypic studies also reinforce the association between LP and lichen nitidus [4]. However, some authorities favour a separation into two dermatoses, because of histopathological differences, or differences in cytokine expression in lichen nitidus [5]. Surprisingly, direct IMF studies in lichen nitidus have given negative results [6,7]. However, ultrastructural studies have shown identical changes in lichen nitidus and LP [6].

Histology. The histology of a typical papule is characteristic. The papule is formed by an intense infiltrate situated immediately below the epidermis and is well circumscribed. The infiltrate consists of lymphocytes and histiocytes and there are often a few Langhans' giant cells (Fig. 41.27). Sometimes, plasma cells are numerous in the infiltrate [8]. The overlying epidermis is flattened and sometimes there is liquefaction degeneration of the basal cell

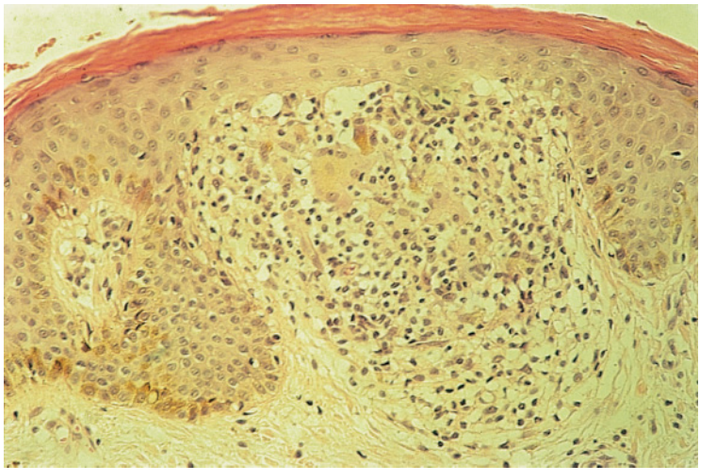

Fig. 41.27 Lichen nitidus. Typical histology showing the focally dense infiltrate containing a few giant cells. H&E × 100. (Courtesy of St John's Institute of Dermatology, King's College London, UK.)

Fig. 41.28 Lichen nitidus. Close-up of aggregated, pinhead-sized papules. (Courtesy of St John's Institute of Dermatology, King's College London, UK.)

Fig. 41.29 Lichen nitidus. Aggregates of pinhead-sized papules on shaft of penis. (Courtesy of St John's Institute of Dermatology, King's College London, UK.)

layer. The rete ridges at the margin of the infiltrate are elongated and tend to encircle it. Although tuberculoid in appearance, there is never true tubercle formation or caseation. The histology of a palmar lesion may show a deep parakeratotic plug, which distinguishes it from the palmar lesions of LP [9]. Perifollicular granulomas can occur in spinous and follicular lichen nitidus, which may simulate lichen scrofulosorum [10]. Perforating lichen nitidus has also been described [11].

Incidence. In its characteristic monomorphic form, lichen nitidus is rare, but lesions of lichen nitidus occurring in association with LP are more common [3]. The age incidence tends to be lower than that of LP. Most cases occur in children or young adults. Familial lichen nitidus has rarely been observed [12].

Natural history. Typical lichen nitidus may clear in a few weeks or last a very long time, and may show little or no response to treatment. There have been no large series reporting the natural history of this disorder. With our present knowledge, its course is unpredictable.

Clinical features. Typical lichen nitidus papules are minute, pinpoint to pinhead sized, and have a flat or dome-shaped, shiny surface. They usually remain discrete, although they may be closely grouped (Fig. 41.28). They are found on any part of the body but the sites of predilection are the forearms, penis (Fig. 41.29), abdomen, chest and buttocks. The eruption is sometimes generalized [13,14]. When the palms or soles are involved, the changes can be those of a confluent hyperkeratosis resembling chronic fissured eczema, or there may be multiple, distinctive, minute papules [15,16]. On the palms, the minute papules can become purpuric [9] and may occasionally resemble pompholyx [17]. Such cases may lack lesions of lichen nitidus elsewhere, so a biopsy is essential to confirm the diagnosis [9,15].

Linear lichen nitidus has been described, but is exceptionally rare [18]. The development of lesions along scratch marks is not uncommon. The lesions are flesh coloured or reddish brown. Although intense pruritus can occur [14], the lesions are generally quite symptomless.

Coexistence with LP is common, and Wilson and Bett [3] claim that lesions clinically identical to those of lichen nitidus can be found in 25–30% of all cases of LP. Nail pitting may coexist with lichen nitidus [19], or the affected nails may appear rough due to increased linear striations and longitudinal ridging [15,20]. An actinic variant has been documented [21].

Mucous membrane lesions occur occasionally and are much rarer than in LP. Krook [22] described a generalized case as having mucosal lesions mainly on the hard palate and maxillary alveolar margins, which consisted of fairly closely grouped, greyish yellow, round, sharply demarcated, discrete papules up to 1 mm in diameter; many were petechial. In other cases, lesions occur that are similar to those in LP.

Lichen nitidus must be distinguished from lichen scrofulosorum [10], where there are grouped follicular papules in small patches on the trunk, and from keratosis pilaris, where there are horny follicular papules mainly on the extensor surface of the limbs. In cases of doubt, a biopsy usually clarifies the diagnosis.

Lichen nitidus has been described in association with Crohn's disease [23], trisomy 21 and congenital megacolon [24].

Treatment. As the disease is often asymptomatic and eventually self-limiting, no treatment is required in most cases, but fluorinated topical steroid preparations may be recommended if treatment is demanded, for example for lesions on the penis, and can be dramatically successful [25]. Clearance of generalized lichen nitidus has been described with sun exposure [26], PUVA [27] or

narrow-band UVB phototherapy [28,29], and astemizole [13,30,31]. Acitretin can lead to a gradual improvement in palmoplantar lichen nitidus [32].

Symptomatic lichenoid reactions

Lichenoid reactions occur in persons handling developer used in the processing of colour films. Many drugs may produce an eruption identical with or similar to LP.

LP-like contact dermatitis due to contact with colour developing agents and methacrylic acid esters

An LP-type eruption was reported in up to 25% of persons exposed to chemicals in colour developer [1–5]. Lesions began in areas of contact with the developer, but sometimes extended widely; the mucous membranes were usually spared. Resolution was slow, and lesions persisted for months, with residual pigmentation lasting for a year or more. The responsible chemicals were substituted paraphenylene diamines. Current automated equipment minimizes contact with these, and LP-like eruptions due to this source are now rare [5]. Two types of reaction were observed—acute (eczematous) and subacute (lichenoid)—but either evolved into the other. It is not clear why exposure to colour developers caused a spongiotic dermatitis in some patients and a lichenoid dermatitis in others [5]. Patch-test reactions were usually positive to the substituted paraphenylenediamine and were eczematous in nature, but might become lichenoid [4].

LP-like lesions have developed on sites exposed to methacrylic acid esters used in the car industry [6]. As dental devices contain methacrylic acid esters, it is possible that methacrylic acid esters may be one of the causative agents in oral LP [6]. Other inducers of contact lichenoid eruptions include dental restorative materials, musk ambrette, nickel, aminoglycoside antibiotics and gold.

Lichenoid eruptions due to drugs

The reader is also directed to Chapter 75, Table 75.8, as well as to information on individual drugs. The mechanisms by which drugs induce a lichenoid tissue reaction are unknown, but they may develop as a result of autoreactive cytotoxic T-cell clones directed against a drug/class II MHC antigen complex, such that keratinocytes and Langerhans' cells are viewed by the immune system as 'non-self'. Macrophage migration inhibition factor (MIF) assays are significantly increased in lichenoid drug eruptions [1].

Histology. The pattern of an LP-like eruption can be indistinguishable from idiopathic LP, although the cellular infiltrate tends to be more pleomorphic and less dense; helpful histological features indicative of a drug reaction include the following: focal

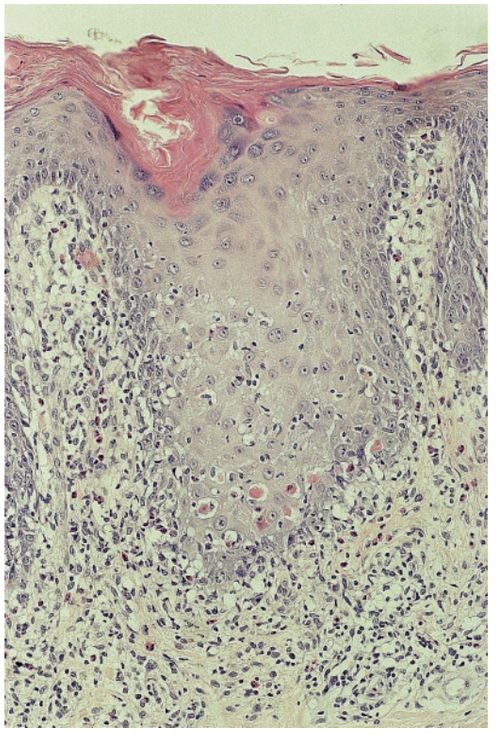

Fig. 41.30 Lichenoid drug eruption (gold). Photomicrograph showing the presence of higher level cytoid bodies with several eosinophils amongst the lichenoid infiltrate. H&E × 20.

parakeratosis; focal interruption of the granular layer (Fig. 41.30); cytoid bodies situated higher in the granular and cornified layers; presence of a few eosinophils; exocytosis of lymphoid cells into the upper epidermis; and a deeper perivascular infiltrate [2]. Later, there may be scarring with destruction of the sweat glands. The histopathology of photodistributed, as opposed to non-photodistributed, lichenoid drug eruptions has been shown to be often indistinguishable from that of idiopathic LP [3]. Occasionally, the degree of lymphoid epidermotropism may simulate mycosis fungoides [4]. The IMF findings in lichenoid drug eruptions are identical to those in idiopathic LP [5].

Clinical features. Lichenoid drug eruptions tend to be extensive, and may develop weeks or months after initiation of therapy; they may progress to an exfoliative dermatitis [6,7]. Lesions may be rather more psoriasiform than in idiopathic LP (Fig. 41.31), and oral involvement is rare. Long-lasting, deep hyperpigmentation, alopecia and skin atrophy with anhidrosis due to sweat gland atrophy may develop. Resolution of the skin eruption may be slow after cessation of therapy, on average from 1 to 4 months, but up to 24 months with gold [8]. Difficulties may arise with antimalarial lichenoid tissue reactions in patients with pre-existing lupus erythematosus [9].

Causative drugs. The list of drugs causing LP-like eruptions continues to increase steadily. Gold has probably been the most common drug producing an LP-like eruption [1]; oral involvement tends to be rarer in LP-like drug eruptions, but occasionally it can be severe and involve the oesophagus [2]. Mercury-induced lichenoid eruptions are recorded [3], and may be of particular relevance in oral LP (see above). During the Second World War, millions of troops took mepacrine to prevent malaria, and many cases of an LP-like eruption occurred [4]. Mepacrine (quinacrine) lichenoid eruptions may be followed by skin cancers, up to 34 years later. Photodistributed lichenoid lesions [6] may be seen with quinine and quinidine [5–8], demeclocycline [9] and other tetracyclines, thiazide diuretics [10] (Figs 41.32 & 41.33), furosemide (frusemide), diazoxide, amlodipine [11], chlorpromazine, carbamazepine, 5-fluorouracil, pyritinol, ethambutol [12], thioridazine [13], solifenacin [14] and sparfloxacin [15].

Other drugs implicated include: various vaccines [16–23]; streptomycin, isoniazid [24], pyrazinamide [25], cycloserine [26]; pyrimethamine [27]; levopromazine; methyldopa, the α-blocker terazosin [28], and β-blocking agents including propranolol [29], oxprenolol [30], labetalol [31] and nebivolol [32]; sulphydryl drugs such as penicillamine [33], tiopronin [34], captopril [35–37] and enalapril [38]; non-steroidal anti-inflammatory drugs (NSAIDs)

Fig. 41.32 Lichenoid photodermatitis occurring in a patient with a long history of thiazide ingestion. (Courtesy of Dr D.H. McGibbon, St John's Institute of Dermatology, King's College London, UK.)

Fig. 41.33 Close-up of dorsum of finger shown in Fig. 41.32.

[39] including acetylsalicylic acid [40], naproxen [41] and salsalate [42]; levamisole [43]; proton pump inhibitors [44]; the sulfonylureas chlorpropamide and tolazamide [45], glyburide and glimepiride [46,47]; carbamazepine [48]; the statins simvastatin [49], pravastatin [50], and fluvastatin and lovastatin [51]; the antiplatelet drugs clopidogrel [52] and ticlopidine [53]; sildenafil [54,55]; propylthiouracil [56]; interferon and ribavirin treatment of chronic hepatitis C [57,58]; antihistamines [59] including chlorpheniramine [60], roxatidine and ranitidine [61]; isotretinoin [62]; alendronate [63]; PUVA therapy [64]; ursodeoxycholic acid given for neonatal hepatitis [65]; imatinib [66–68]; intravenous immunoglobulin [69]; etanercept [70,71] and adalimumab [72]. Lichenoid reactions have been documented at the sites of injection of granulocyte colony-stimulating factor [73].

Ulcerative lesions may occur with hydroxyurea [74,75], methyldopa, propranolol and lithium carbonate. Oral LP lesions are associated with drugs metabolized by major cytochrome P450-enzymes [76]. Oral involvement may be caused by NSAIDs, gold salts, penicillamine, sulphonylureas, angiotensin-converting enzyme (ACE) inhibitors, methyldopa, allopurinol, ketoconazole, antiretroviral agents including zidovudine [77], clopidogrel [52] and lithium carbonate [78]. Social use of betel nut is relatively common in India and South-East Asia; the product that is chewed, betel quid, is a mixture of substances, including the areca nut and betel leaf, and is associated with oral LP [79,80]. An LP pemphigoides-like eruption has been reported following administration of captopril, cinnarizine [81], simvastatin [82] and oral Chinese herbal therapy [83]. Bullous lesions are recorded with labetalol and tiopronin; LP pigmentosus with gold; and exfoliative dermatitis with nifedipine. Lichenoid photoeruptions have been described in advanced HIV infection; black patients are disproportionately affected and all were taking potential photosensitizing drugs [84]. Hydroxyurea has induced a lichenoid chronic graft-versus-host disease-like acrodermatitis [85].

Treatment. Treatment is to withdraw the drug; with gold eruptions, dimercaprol (BAL) or ethylene diamine tetraacetic acid (EDTA) may be used. Subsequent treatment is symptomatic, but severe cases may require corticosteroid therapy as outlined for idiopathic LP.

Nékam's disease [1–4]

Synonyms
- Keratosis lichenoides chronica
- Orokeratosis striata lichenoides
- Lichen ruber moniliformis
- Lichen verrucosus et reticularis

The variety of synonyms used implies that there is no complete consensus of agreement about this rare disorder. The great majority of cases are adults between the ages of 20 and 40 years [2], although children are occasionally affected [5]. Nékam's disease is characterized by violaceous, papular and nodular lesions typically arranged in a linear and reticulate pattern (Figs 41.34 & 41.35), most marked on the extremities and buttocks, and accompanied by a seborrhoeic dermatitis-like eruption on the face. Nékam's original case was also associated with palmoplantar keratoderma [6]. The individual lesions are erythematous verrucous papules covered by a hyperkeratotic plug that can only be removed with difficulty, revealing irregular indentations and prominent capillary loops [1,7]. In extensive Nékam's disease, the lesions tend to be symmetrical bilaterally, mainly involving the antecubital fossae, extensor forearms, lumbosacral area and buttocks, posterior thighs, popliteal fossae, and less commonly the oral cavity and genitalia. Oral manifestations occur in 50% of patients, recurrent aphthous ulcers, larger chronic ulcers or erythrokeratotic papules being the commonest oral features [2]. The nails can become thickened, longitudinally ridged and prone to paronychia [8]. Cases have followed trauma [9] and erythroderma [10]. A limited variant of Nékam's disease presenting with erythematous hyperkeratotic papules and plaques on the face, clearing in the summer months, has been described in two young siblings [11].

Histologically, changes are often non-specific and consistent with a chronic dermatitis, but lichenoid features can be seen [1,7]. Some authors [1] believe that the condition is an unusual variant of LP, while others [12] consider that it is a distinct entity. A case of Nékam's disease associated with porokeratotic histology and amyloid deposition may also point against the view that Nékam's disease is a subset of LP [13]. A possible association of Nékam's disease with glomerulonephritis and lymphoproliferative disorders has been commented on [2]. The course of the dermatosis is chronic and progressive and very resistant to therapeutic approaches, but has shown a favourable response to photochemotherapy without [14,15] or with [16] acitretin; etretinate [17] and photodynamic therapy [18] have been reported to be helpful.

Structure and distribution

The sebaceous gland (Fig. 42.1) is holocrine [1]; its secretion is formed by the complete disintegration of the glandular cells. The cells are replaced by cell division at the periphery of the lobes or acini of the glands, with the consequence that differentiating cells are displaced towards the centres of each acinus. The average transit time of the cells, from formation to discharge, has been given as 7–25 days in the human gland [2], a figure similar to that estimated for the rat [3,4]. However, the dynamics of the human gland are complicated. The gland consists of a series of lobes, each with a duct lined by a keratinizing squamous epithelium. The lobule ducts converge towards the main sebaceous duct, which normally opens into the pilary canal, whose epithelium is continuous with the surface epidermis.

Within any one glandular unit, the acini vary in differentiation and maturity: some are completely undifferentiated, showing little or no lipid accumulation in any of their cells, and some are full of lipid-laden cells (Fig. 42.2) that extend to the outer periphery of the acinus [5]. New acini can arise from the walls of the ducts, grow into sebaceous units and fuse with adjacent ones. Three proliferative regions were recognized by Plewig *et al.* [6,7] using ^{3}H-thymidine autoradiography. The duct displayed fast cellular migration with a renewal time of 2–4 days. An undifferentiated cell pool, with a renewal time of 4–7 days, could be distinguished from the differentiating lipid-producing cells in the glandular fundus, with a replacement time of between 14 and 25 days [8]. The synthesis and discharge of the lipid contained in the sebaceous cells require more than a week [9].

Sebaceous glands occur over much of the body, although not normally on the palms or soles, and only sparsely on the dorsal surfaces of the hand and foot. Sebaceous glands are largest and most numerous on the face, scalp, upper trunk, in the external auditory meatus and on the anogenital surfaces. On the scalp, forehead, cheeks and chin, for example, there are between 400 and 900 glands/cm^2; elsewhere there are less than 100 glands/cm^2 [10–12].

In a few sites, sebaceous glands open directly to the surface of the skin and are unrelated to hair follicles. Examples of such glands are the Meibomian glands of the eyelids and the Tyson's glands of the prepuce [13]. Free sebaceous glands are also found on the mucocutaneous surfaces of the female genitalia, the areolae of the nipples, and ectopic sites such as the tongue and the cervix uteri [14]. Free sebaceous glands in the margin of the upper lip are often visible to the naked eye as pale-yellow bodies, which vary in size from minute specks to about 1.5 mm in diameter; they are known as Fordyce's spots [15].

Jeremy, Skin Research Centre, Institute of Molecular and Cellular Biology, Faculty of Biological Sciences, University of Leeds, UK.)

Many mammals have specialized aggregations of sebaceous units that function as scent glands [16–19] and include tubular 'apocrine' units (Chapter 44). Of special interest as possible models for the study of compounds that affect sebaceous activity [20] are the costovertebral organs of the golden hamster [13,20–23], the supracaudal gland of the guinea pig [24,25], the abdominal gland of the gerbil [26] and the preputial glands of many species of rodents [27].

Development

The development of sebaceous glands is closely related to the differentiation of hair follicles and epidermis [1,2]. Around the third week of fetal life, the epidermis consists of a single layer of undifferentiated cells, but by the fourth week an outer periderm and a basal stratum germinativum can be distinguished. Between the 10th and 12th weeks, a stratum intermedium becomes apparent, and at about the same time developing hair germs are quite distinct (Chapter 3). In the following weeks, the follicles extend downwards into the dermis and the rudiments of the sebaceous glands appear on the posterior surfaces of the hair pegs; by 13–15 weeks, the glands are clearly distinguishable.

The cells at first contain glycogen which lingers at the periphery of the gland, but is quickly lost at the centre, where large lipid drops are visible at 17 weeks [3–5].

At the point of their origin from the follicle, centrally positioned cells degenerate to form a lumen, and surrounding cells keratinize to form the sebaceous duct [6]. The glands become multi-acinar by the formation of buds on the peripheral wall.

Sebaceous glands are functional from their formation; sebum is the first demonstrable glandular product of the human body. Their development and function before birth and in the neonatal period appear to be regulated by maternal androgens and by endogenous steroid synthesis by the fetus [7]. Hydroxysteroid dehydrogenases and 5α-reductase, which reduces testosterone to 5′α-dihydrotestosterone (5′α-DHT), are present after 16 weeks [8,9]. The glands reach a peak of activity in the third trimester, and their secretion forms part of the vernix caseosa. The vernix lipids resemble sebum in their content of fatty acids, squalene and wax esters, but also contain sterols and sterol esters [10]. Sebaceous glands remain active in the neonatal period, but then involute and remain quiescent until puberty [11].

Ultrastructure, histochemistry and immunocytochemistry of the sebaceous gland and duct

Undifferentiated sebaceous cells at the periphery of the gland are rich in ribonucleoproteins and stain with basic dyes [1]. As the cells move towards the centre of each lobe their lipid content rises and they become progressively acidophilic. All cells have numerous mitochondria appearing as short or wavy rods. The undifferentiated cells contain coarse, osmium-staining particles around the nucleus; as differentiation proceeds, these particles increase in number and size and develop lipid droplets in their centres, which gradually enlarge. This complex corresponds to the Golgi body; at completion of sebaceous synthesis it is no longer recognizable.

In studies with the electron microscope [2–4], the undifferentiated cells at the periphery of the gland can be seen to rest upon a basement membrane, and to be connected with each other by desmosomes. The membranes of the granular endoplasmic reticulum are coated with ribosomes, and there are in addition particles of ribonucleoprotein and glycogen scattered free in the cytoplasm. At this stage, the Golgi zones are usually inconspicuous; the nucleus is relatively very large. Differentiation of the cell becomes evident with the appearance of one or more small sebum vacuoles within it. During the active phase of lipid synthesis, the cytoplasm becomes packed with smooth-surfaced membranes of the endoplasmic reticulum. In some partially differentiated cells, a large Golgi zone becomes apparent; typically, it consists of parallel, smooth-surfaced, thick membranes, slightly dilated cisterns and small vesicles. The Golgi appears to be the centre where lipid aggregates to form sebum vacuoles. At an early stage of sebaceous transformation, one of the cisterns in the Golgi zone becomes more dilated than the others, and forms the centre of the developing sebum vacuole. At a later stage, the smooth membranes of Golgi apparatus and the endoplasmic reticulum become orientated around the edge of the developing vacuole, forming a sort of 'husk'. The fully differentiated cells contain very large sebum vacuoles, which compare in size with the nucleus; the cell may have a complement of more than 60 (Fig. 42.3). In the final stages of differentiation, the mitochondria become widely separated, indicating that their numbers have decreased, and the nucleus becomes irregularly shaped, with clumping of the nucleochromatin and dispersal of the nucleolar material. Lysosomes are prominent in peripheral and other cells in the early stages of differentiation, but are found at all stages [2]. They may be concerned with hydrolysing precursors of sebaceous lipids or the breakdown of mature cells.

The sebaceous cells of prepubertal and hypogonadal males are qualitatively similar to those of normal adults, even though the glands are smaller [1].

Immunocytochemical techniques, supported in some instances by investigating messenger RNA (mRNA) expression of the peptide, performed both on human skin biopsies and on

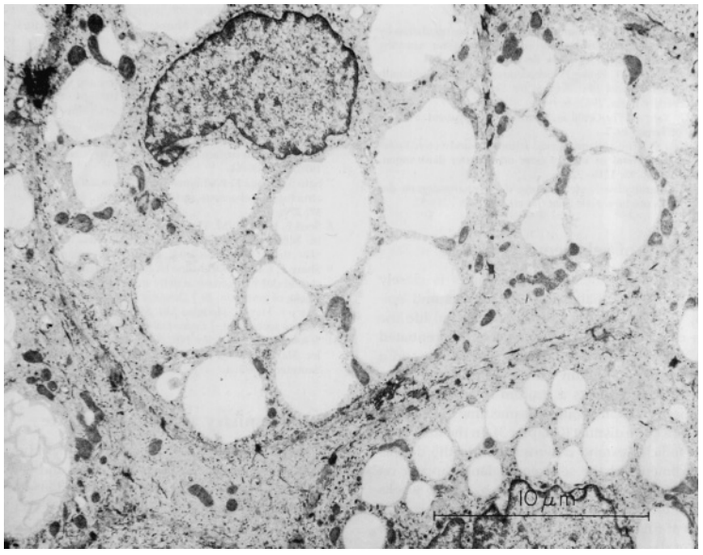

Fig. 42.3 Transverse section of the sebaceous gland of a 24-week fetus. The cytoplasm of the cells is honeycombed with spaces occupied by lipid droplets, which have been leached away during processing. (Courtesy of Professor A.S. Breathnach, St John's Institute of Dermatology, London, UK.)

immortalized sebocytes, have helped our understanding of the hormonal and cytokine control of the sebaceous gland and duct in health and disease [3]. Androgen receptors are present both in the gland and the duct [4].

Peroxisome proliferator-activated receptors (PPARs) are members of the nuclear hormone receptor family that form heterodimers with retinoid X receptors and act as transcriptional regulators of a variety of genes including those involved in lipid metabolism in adipose tissue, liver and skin [5,6].

There are three subtypes (PPAR-α, γ and δ); localization studies on whole specimens of human skin have demonstrated that all subtypes are present in sebaceous glands and pilosebaceous ducts of both acne-involved and non-involved skin as well as healthy skin [7,8]. Each subtype is expressed in the basal layer of the sebaceous gland with PPARγ expression noted in differentiated cells within the gland [9]. The specific identity of endogenous ligands that act on PPARs in the skin is not yet known. Potential ligands include fatty acids, eicosanoids and other lipids found in the skin and sebaceous glands. It has been shown that PPARs play a role in regulating sebum production and that selective modulation of their activity may lead to novel therapies for the treatment of acne [9].

Sebocytes are target cells for several neurohormones. Immunocytochemical studies have shown that human sebocytes express melanocortin MC1 and MC5 receptors and are target cells for α-melanocyte-stimulating hormone (α-MSH) [10]. MC5-R has been shown to correlate with sebocyte differentiation and this suggests a regulatory role for MC5-R in human sebaceous lipid production [11].

The sebaceous gland constitutively expresses other cytokines (Figs 42.4 & 42.5) without any influence of external factors. Interleukin-1 (IL-1) is present in the normal human sebaceous gland [12] and mRNA for IL-1-α, IL-1-β and tumour necrosis factor-α

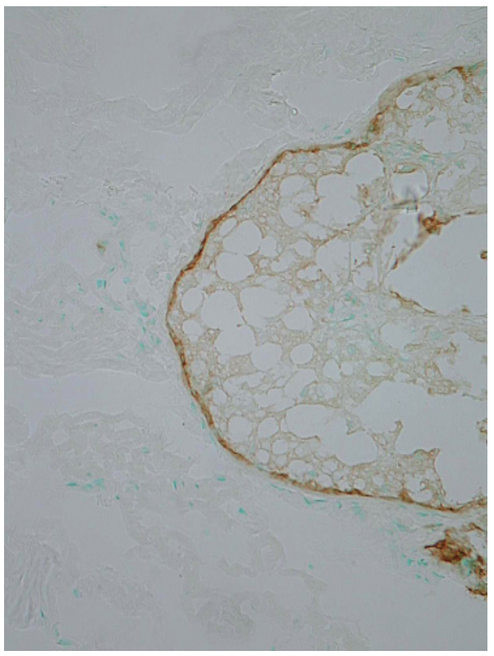

Fig. 42.5 Sebaceous gland edge IL-1RTII: immunohistochemical labelling for interleukin-1 receptor type II expression (brown staining) clearly expressed by the basal cells at the periphery of the sebaceous gland. (Courtesy of Dr D. Holland and Dr A. Jeremy, Skin Research Centre, Institute of Molecular and Cellular Biology, Faculty of Biological Sciences, University of Leeds, UK.)

(TNF-α) are also present in the sebaceous glands. Cultured human sebocytes also express IL-1-α at the mRNA and protein levels. The presence of such cytokines may relate to the development of inflammation [13].

Composition and biosynthesis of sebum

Sebum is a complex mixture of lipids, which varies widely from species to species [1–3]. The analysis of human sebum is complicated by several factors. The principal difficulty is that the surface film contains not only sebum, but also lipid from the keratinizing epidermis and possibly from eccrine glands. In addition, the pure sebaceous secretion undergoes degradation as it passes through the ducts or on the skin surface as a result of bacterial lipase activity [4]. Some material, for example hydrocarbons, may also be acquired from environmental sources.

Surface lipid can be collected by simple non-invasive tests, such as wiping the skin with a sponge soaked in an organic solvent such as hexane or ether [5]. However, skin biopsies are necessary to investigate sebum synthesis and the analysis of pure sebum. Incubation of isolated human sebaceous glands showed that acetate and glucose appeared to be equally efficient as substrates for triglycerides but not for squalene [6].

An unusual feature of sebaceous lipogenesis is a partial or complete inhibition of cholesterol biosynthesis at some point in the pathway. Thus, in human and in some other animal glands, there is little or no conversion of squalene to cholesterol and squalene remains a major product.

In vivo studies suggest that the synthesis of some sebaceous lipids is indirect, with newly synthesized fatty acids becoming first incorporated into phospholipids and later recycled into non-polar lipids. In human scalp, the label of intradermally injected ^{14}C acetate is immediately taken up by squalene, wax esters and triglycerides, but as the cells mature the proportion in wax esters increases [7].

Human skin surface lipid consists of glycerides, free fatty acids, wax esters, squalene, cholesterol esters and cholesterol. Lipid production varies according to site, for example 5–10 μg/cm^2 were recovered from the trunk and limbs of subjects who washed 3 h prior to extraction, compared with 150–300 μg/cm^2 from the forehead [8]. When amounts were in the range 5–10 μg/cm^2, the skin surface lipid contained virtually no wax esters or squalene. However, as the quantity of surface lipid increased, so did the proportion of wax esters and squalene, while at the same time the proportions of cholesterol esters decreased. The proportion of each of the constituents became nearly constant when the amount of lipid reached 50–100 μg/cm^2.

These results are consistent with the view that wax esters and squalene are produced by the sebaceous glands only, and not by the epidermis. When the surface lipid is as low as 4–10 μg/cm^2 no sebum is present, and this level of lipid represents that contributed by the epidermis. However, when the surface lipid is greater than 100 μg/cm^2, its composition approximates to that of sebum. The percentage proportions of constituents are shown in Table 42.1. It may be concluded from these figures that the sebaceous glands do not, to any great extent, convert squalene to sterols, whereas in the epidermis squalene synthesized in the lower layers is rapidly and totally converted to sterols, either to precursors of vitamin D or to cholesterol. Squalene is unique to sebum and is virtually unique to humans [2].

Between birth and sexual maturity, surface lipid undergoes two distinct changes [9,10]. Shortly after birth it resembles adult sebum, presumably because maternal hormones have activated the sebaceous glands. Thereafter and up to 8 years of age, the wax esters and squalene remain low, and epidermal lipids, that is cholesterol and its esters, are high. In this age range, sebum constitutes less than half the total surface lipid of the forehead, compared with 95% or more in the adult. Between 8 and 10 years of age, the wax esters and squalene rise to about two-thirds of the adult level, and between 10 and 15 years the composition comes to resemble that of the adult.

Free fatty acids constitute 10–30% of the human skin surface fat [11–13], but occur in only small amounts in the skin lipids of most other animals. This difference is presumably due to the rather

Table 42.1 Comparison between constituents of sebum and epidermal lipid.

Constituents	Sebum (%)	Epidermal lipid (%)
Glycerides (plus free fatty acids)	57.5	65
Wax esters	26.0	—
Squalene	12.0	—
Cholesterol esters	3.0	15
Cholesterol	1.5	20

unique bacterial flora of humans, in particular *Propionibacterium acnes*, and its lipase action on sebaceous triglycerides. Analysis of pure sebum from isolated human sebaceous glands showed the presence of triglycerides, but not free fatty acids, monoglycerides or diglycerides [14,15]. It thus seems that, prior to secretion, all the fatty acids are combined as triglycerides, which are subsequently subjected to lipolytic activity by enzymes present in the sebaceous ducts and on the skin surface. This conclusion is reinforced by the demonstration that the skin surface can hydrolyse triglycerides of exogenous origin; when ^{14}C-labelled tripalmitin was spread on the back, labelled free fatty acids were isolated from the surface fat 3 h later [7].

The fatty acid components [1–3,16] have both odd- and even-numbered carbon chains up to C25 in length, although more than half are C16 and C18 compounds. They are both saturated and unsaturated, and of particular interest is the presence in both classes of unusual branched chains. These are of two kinds, one having an even number of carbons with the methyl group attached to the penultimate (iso series), the other having an odd number of carbons with the methyl group attached to the antepenultimate (antiso series). Such branches are present in the chains of the wax esters, which are virtually limited to 18 carbons and produced only by the sebaceous glands and, in higher proportion, in the longer chains of the sterol esters, which probably arise from both sebaceous glands and epidermis.

It is possible to modulate sebum composition as a result of dietary, hormonal or drug manipulation. Although various effects have been ascribed to diet, there is no evidence from either humans or experimental animals that any components of sebum are directly derived from ingested fats. In humans, most of the unsaturated fatty acids in the surface film are Δ6 compounds, whereas dietary lipids are Δ9 compounds [3]. Prolonged starvation of human subjects [17,18] decreased the rate of sebum synthesis by about 40%, without any decrease in the actual amount of squalene, which thus rose as a proportion of the total surface lipid.

Administered hormones can also influence the composition of the skin surface fat. In rats, testosterone, at the same time as increasing the amount of sebaceous secretion (see below), increases the ratio of palmitate to stearate and the ratio of oleate to stearate; oestrogens and antiandrogens antagonize these effects [19–21]. In female patients prescribed co-cyprindiol (35 μg ethinyl oestradiol and 2 mg cyproterone acetate [CPA]) there is a significant increase in sebaceous linoleate, which might explain in part the anticomedogenic effect of the therapy [22]. A reduced sebaceous linoleate may induce comedogenesis. Oral isotretinoin not only significantly reduces sebum production, but produces a notable change in lipid composition, including a great reduction in sebaceous-related lipids (i.e. squalene, wax esters and fatty acids) [23].

For comprehensive discussions of lipid biosynthesis in the sebaceous glands, the reader is referred to detailed references [3,24].

Functions of sebum

Several functions have been ascribed to sebum, but they are by no means undisputed. In humans, it has been stated that the lipid film both controls moisture loss [1] from the epidermis and protects the skin from fungal and bacterial infection. The colonization of the skin by *P. acnes* may have an immunomodulatory role. Aggregations of holocrine glands play an important part in scent production in many mammals, and components of sebum may possibly contribute to body odour [2].

It was believed that the sebaceous lipids were essential factors for the barrier function of the skin. This is clearly not so. A healthy

prepubertal child who produces no sebum has no impaired barrier function. Certain surface free fatty acids markedly reduce the growth of pathogenic organisms, such as *Staphylococcus aureus*, *in vitro* [3], and suppression of sebaceous gland activity by isotretinoin may be followed by impetigo towards the end of a 4-month course [3]. Circumstantial evidence supports the view that sebum, or at least the product of its hydrolysis, is fungistatic. Fungi causing tinea pedis preferentially colonize areas that are not supplied with sebaceous glands: ringworm of the scalp becomes rare after puberty, when sebum production increases.

Propionibacterium acnes is unique to humans and this fact may equate with the rather unique composition of human sebum. Shuster [4] made the interesting suggestion that the capacity to develop delayed immune hypersensitivity may be augmented and maintained by the *P. acnes*, which colonizes sebaceous glands in adults. A sequel of this may be an enhanced immunoregulatory effect, producing some protection against cancers such as leukaemia and melanoma, which occur less frequently in acne patients [5].

The sebaceous gland has also been shown to secrete vitamin E into the upper layers of facial skin. This mechanism may in part serve to protect skin surface lipid and the upper stratum corneum from harmful oxidation [6].

Measurement of sebaceous activity and sebum production

Various methods have been used for collecting lipids from human skin, and for measuring their production [1]. They include swabbing by pads soaked in solvent [2], washing lipid solvents over areas of skin circumscribed by rings, caps or apertures of bottles [3–6] and absorption on paper [7,8]. Another method is removal by pressing a ground-glass plate on the skin followed by photometric assessment [9–14]—for both stages an instrument known as a Lipometer®/sebometer has been devised [15]. The rate of sebum production has been calculated from the squalene content of skin biopsies [16]. Analysis of the ratio of wax esters/(cholesterol plus cholesterol esters) may provide an indirect measure of lipid synthesis per sebaceous cell [17–19].

A simple, practical, but time consuming, method for measuring human sebaceous secretion is to place a pad of specially absorbent cigarette papers for 3 h on a delineated area of the forehead, and then to extract the sebum with diethyl ether. In view of circadian changes in secretion [20], the measurement should be carried out between standard times. It does not give the absolute sebum production rate, which is indefinitely sustainable [21], but it is valuable for comparative purposes, and provides more reproducible results than many other methods. The method that follows was originally devised by Strauss and Pochi [7,8].

Fig. 42.6 Patient with a firm but comfortable headband which is holding in place the special absorbent papers for measurement of sebum production.

1 Two areas on either side of the forehead (2.0 × 3.5 cm) are delineated by pre-cut Micropore® tape.
2 A pad of four or five cigarette papers is placed carefully, to avoid creasing, over the forehead and held in place by a gauze pad and a stocking-weave bandage encircling the head (Fig. 42.6).
3 In order to remove the accumulated surface lipids, two or three pads are so applied for 10–15 min and then discarded. After 30–40 min, close examination of the final paper in contact with the forehead will reveal a follicular pattern of sebum emerging from the follicles.
4 A pad of papers of known weight (previously prepared by washing in ether and being allowed to dry) is then applied. At the end of a 3-h collection period, the lipid-containing papers are then reweighed [22].

Control papers must be used to control for variation in environmental factors (such as humidity), which may influence the weight of the papers. Precision in weighing techniques is essential. The weight of sebum multiplied by the time of collection and divided by the area of collection provides a figure, which is referred to as the sebum excretion rate (SER).

The sustainable rate of sebum production on the forehead can be measured by first depleting the follicular reservoir by an application of an aqueous gel of bentonite clay, into which a rectangle of non-woven polyester cloth is pressed. The cloth is removed after 14 h, and the sebum is then collected for 3 h on two discs of clay, each 2 cm in diameter. The lipid is extracted and quantified by thin-layer chromatography [23–25] or by weighing [26]. The

method also makes possible an estimation of the extent of the follicular reservoir [26]. According to Saint-Leger and Cohen [27], the forehead can be defatted with 70% ethanol and the rate of sebum excretion is then linear.

The introduction of a sebum-absorbent tape (Sebutape®) (Figs 42.7 & 42.8) has made it possible to observe the lipid output of individual follicles [28,29]. Computerized image analysis has been used for quantification [30–32].

Several authors have described methods for the isolation, from skin biopsies, of whole human glands [33,34] or sebaceous cells [35], and their cultivation *in vitro* for study of their activity. These techniques reflect reasonably well the *in vitro* situation. In particular, the sebocyte culture system has provided much information on the hormonal and cytokine control of the sebaceous gland [36]. Sebum production in the rat has been measured by total immersion of animals in lipid solvents [37], by changes in hair fat lipid [38,39], or by absorption of lipid on paper from areas denuded of hair [40]. To study responses to hormones, the size of the sebaceous glands has also been estimated from histological sections using planimetry [41]. Mitotic activity, estimated after injecting the rats with colchicine, which arrests mitoses in the metaphase, has also been used as a measure of glandular activity [41]. Other experimental models, such as the preputial glands of rodents [42], which can be dissected out and weighed, or the visible costovertebral glands of the hamster [43,44], to which hormones can be topically applied, have been reviewed by Ebling [1].

When interpreting the results of animal experiments it is important to realize that the reactions of supposed homologues of the sebaceous glands may vary not only from species to species but also within species. Thus, the responses to hormones of the preputial and sebaceous glands of the rat may not be identical. Moreover, because of the miscellaneous parameters involved, it is also important to understand the relationships between the different facets of sebaceous activity. The rate of secretion of sebum depends on two factors: the synthetic capacity of each sebaceous cell and the rate of production of the cells. The size of the glands depends partly on both these things, but also of critical importance is the time taken for each cell to mature and pass through the gland, i.e. the turnover time or cell life. If, for example, the rate of production of cells were doubled, with a consequent increase in sebum production, no alteration in gland size need occur if at the same time cell life were halved. As a general principle, it seems to be true that, the greater the mitotic rate, the lower the turnover time [45]; but in practice the changes do not keep pace with each other, and glands under stimulation do increase in size as well as in rate of secretion.

Endocrine control of sebaceous gland activity [1]

The link between sebaceous gland activity and puberty has been recognized for many years [1]. Pioneering work was performed on the rat, which has a simple unilobular sebaceous gland, and on the Syrian hamster, whose flank organ is a good model for the human sebaceous gland. The development of techniques to grow human sebocytes and ductal cells in culture [2–4] has confirmed and built on previous observations of human physiological and pathological states. This section will concentrate on the human sebaceous gland, with reference to animal work where the evidence in humans is lacking or uncertain.

Androgens

Androgens are responsible for the development and maintenance of sebum secretion in both sexes. They are without doubt the most important hormones controlling sebaceous gland activity. The level of sebum excretion at birth is similar to that in adults [5]. There is a significant correlation between maternal and neonatal sebum excretion rate (SER) perinatally. This observation suggests an important role for the maternal hormonal environment on the infant's sebaceous glands [6]. The sebaceous glands regress to become minute during the prepubertal period, but undergo vast enlargement at puberty, when the sebum output of males increases

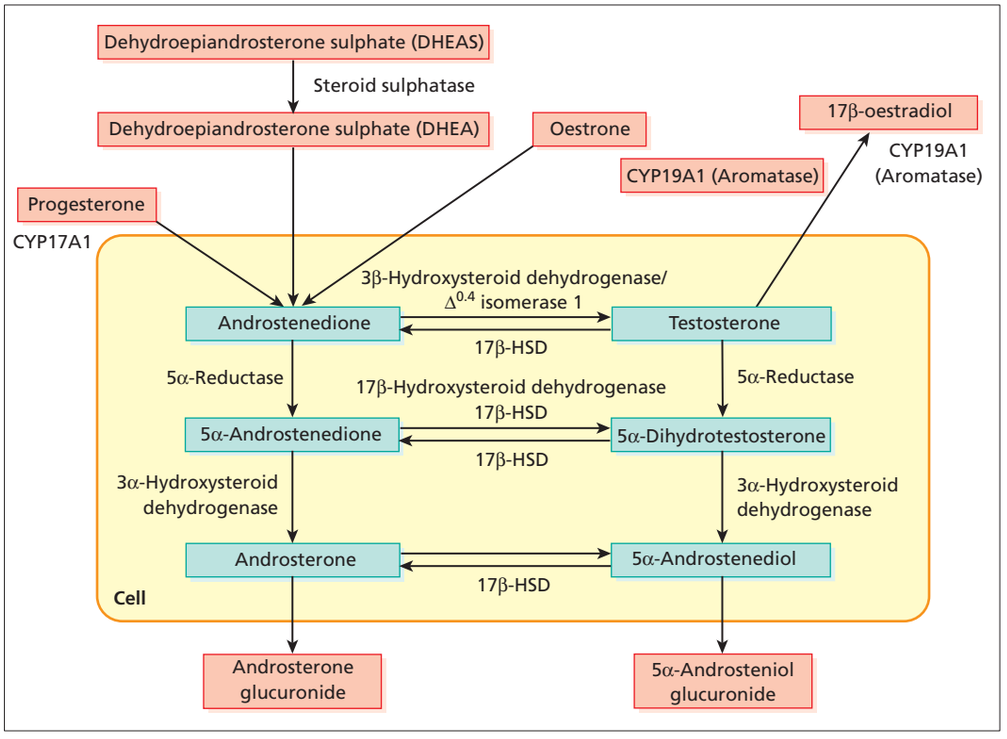

Fig. 42.9 Diagrammatic representation of androgen metabolism in the skin.

more than fivefold [7]. Sebum production remains essentially unchanged in both sexes until around the age of 60 years, when it declines [8]; paradoxically, in old age the sebaceous glands become larger because cell turnover is decreased [9].

The majority of potent androgens are produced by peripheral target tissues. The biological activity of testosterone on the skin is in the main induced by its conversion to 5α-DHT by the enzyme 5α-reductase [10]. Testosterone and 5α-DHT stimulate 5α-reductase mRNA and 5α-reductase activity and exert their effects through binding to androgen receptors identified in the keratinocytes of the basal layer of the sebaceous gland and the outer root sheath of the hair follicle but not keratinocytes elsewhere [11,12]. There are two isoforms of the enzyme 5α-reductase and it is the type-II isoenzyme that is important for most androgen action in sexual organs [13–15]. However, sebocytes [14] and epithelia [16] in the pilosebaceous unit possess the type I isoenzyme, and individuals who are genetically deficient in type II 5α-reductase still develop normal sebaceous glands and suffer from acne [17,18]. There is evidence from cell culture experiments that androgens stimulate the growth of sebocytes and other components of the pilosebaceous unit by action on specific stromal components, and interact with retinoic acid to regulate directly sebocyte differentiation [19,20]. 5α-DHT is 5–10 times more potent than testosterone in its interaction with the androgen receptor but both stimulate proliferation in the target cells. The impact of these androgens on human sebocyte proliferation is site dependent, facial sebocytes being the most affected [21].

Sebaceous glands possess many enzymes for the interconversion of androgens. The enzyme 3β-hydroxysteroid dehydrogenase (3β-HSD) acts on dehydroepiandrosterone (DHEAS) to convert it to androstenedione. There are two isozymes of 3β-HSD; type I is found in the skin [22].

The major isozymes of steroid metabolizing enzymes that are active in human sebaceous glands are illustrated in Fig. 42.9.

17β-hydroxysteroid dehydrogenase (17β-HSD) is a reversible enzyme, of which several types have been cloned, that can oxidize and reduce androgens and oestrogens. It converts androstenedione to the more potent testosterone or oxidizes the latter back to the less potent form. Type II is the most active in sebaceous glands, where it can oxidize testosterone to androstenedione, so possibly protecting the skin from excess testosterone [23]. Administration of testosterone dramatically increases the size of the sebaceous glands and the sebum output of prepubertal boys (Fig. 42.10). In adult males, the glands are almost but not completely maximally stimulated by endogenous androgen [24–27]. Adrenal androgens increase sebum production [27,28] but require conversion to testosterone within the sebaceous gland.

Eunuchs secrete about half as much sebum as normal males, but substantially more than prepubertal boys [29]. Sebum production by eunuchs is quantitatively correlated with the urinary excretion of 17-hydroxycorticoids and 17-oxosteroids [30]; thus, the activity of the sebaceous glands of eunuchs appears to be dependent on adrenal androgens.

The secretion of sebum by adult women is only a little less than that of normal men. Up to the age of 50 years it is greater than in castrated men, but after that age it falls [7]. This, as well as the fact that women generally have less adrenal androgens than men, suggests that sebaceous glands are affected by extra-adrenal sources of androgen. Evidence also implicates secretion or conversion of androgens and oestrogens in the ovary and conversion in the skin

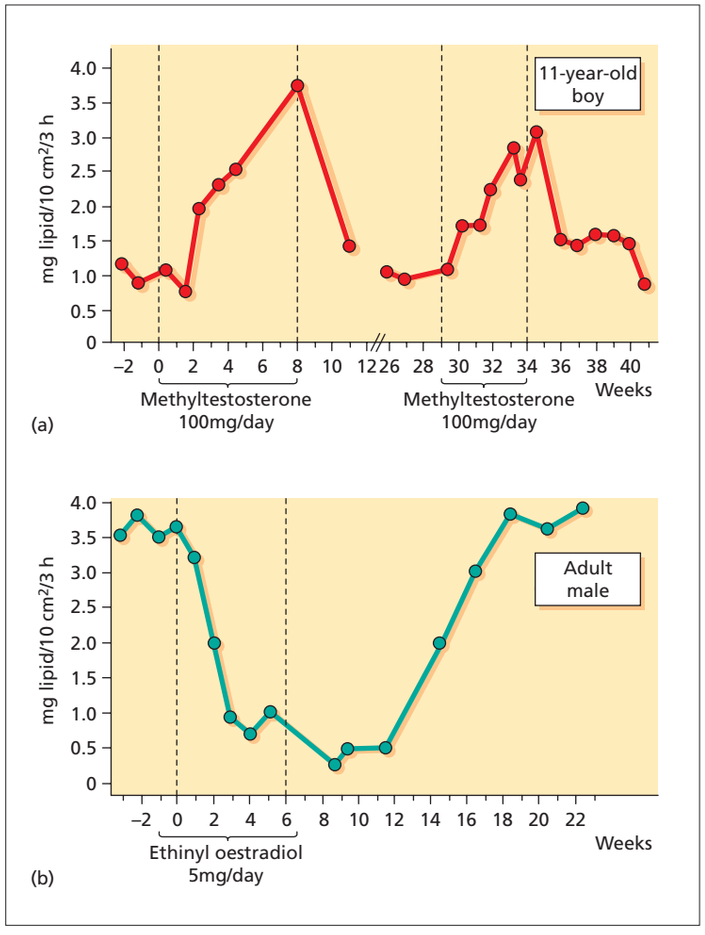

Fig. 42.10 (a) Sebum output of an 11-year-old boy given two courses of methyltestosterone orally (100 mg/day). Sebaceous secretion promptly rose with androgenic stimulation and quickly declined to the original level when the drug was stopped. (b) Suppression of sebum production in an adult male given 5 mg of ethinyl oestradiol orally daily for 6 weeks. In this subject the decrease was readily detectable in 2 weeks and was nearly maximal after 3 weeks. Sebum production returned to pre-oestrogen levels approximately 11–12 weeks after discontinuation of oestrogen. (From Strauss *et al.* [27].)

[31]. However, there is only a small reduction in skin-surface lipid following bilateral oophorectomy [29].

Progesterone

The effect of progesterone on sebaceous glands has been a matter of dispute. The fluctuation of sebum production in women during the menstrual cycle has been blamed on progesterone [32], but this has not been proved experimentally. Progesterone administration can produce acne [33], and when given to elderly women it increases sebum production [34], but no such effect could be demonstrated in young women [35,36]. Progesterone is a competitive inhibitor of 5α-reductase and might be expected to reduce sebaceous gland activity; in humans its sebosuppressive effect is minimal [37–39]. Experiments in the rat showed varied responses, depending upon when progesterone was administered in relation to birth, puberty, castration and oophorectomy [39–43]. The progesterone receptor is only expressed in basal keratinocytes [44].

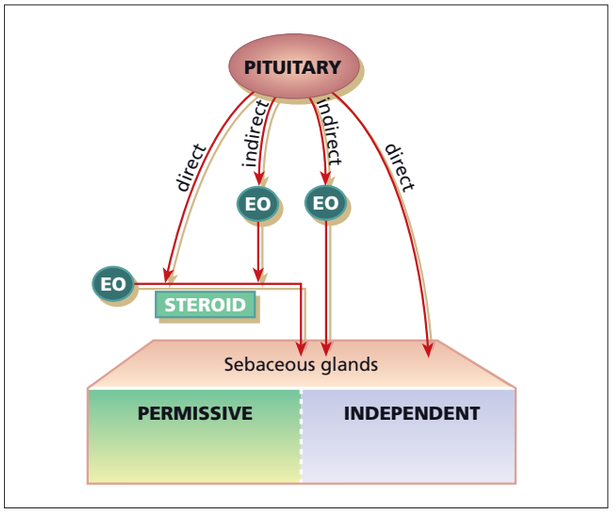

Fig. 42.11 Possible ways in which pituitary hormones may affect the sebaceous glands. The effect may be direct or indirect, and in addition may be either independent or permissive, in the sense that the pituitary hormone facilitates the response of another hormone, for example a steroid. EO, endocrine organ.

Adrenocortical hormones

Sebum production post adrenalectomy for Cushing's syndrome has been shown to fall [28]. Adrenocorticotrophic hormone (ACTH) causes hypertrophy of sebaceous glands in prepubertal human males and postpubertal human females [45], and increases the size of sebaceous glands [41,46] and sebum production [47] in hypophysectomized and gonadectomized rats.

Glucocorticoids stimulate sebocyte proliferation [48]. It has been suggested that glucocorticoids can aggravate sebaceous gland diseases due to their stimulatory effects on proliferation and differentiation in the presence of growth factors [49]. Hydrocortisone given to a prepubertal boy caused enlargement of sebaceous glands [45]. Sebum production is decreased in adrenal insufficiency, but replacement of glucocorticoids has no effect [28,50].

Pituitary hormones

The pituitary has a major effect on sebaceous gland activity (Fig. 42.11). The pituitary acts indirectly through its various target glands, and as a result of a direct action by some of its hormones on sebaceous glands. Gonadotrophins stimulate sebum secretion in the human male [51], but probably do not have any direct independent action on the sebaceous gland.

ACTH has an effect through adrenal androgens. Patients with hypopituitarism and those with isolated growth hormone deficiency have low levels of sebum [52], while patients with acromegaly show increased sebum secretion [53,54]. Growth hormone levels can be raised in prepubertal boys by supplemental testosterone administration, through increased growth hormone-releasing hormone secretion [55].

Growth hormone (GH) is secreted by the pituitary gland and acts on peripheral tissue to stimulate production of insulin-like growth factors (IGFs). There are two forms, IGF-1 and IGF-2; the former is the most prevalent. It has been suggested that GH may be involved in acnegenesis [56], and is likely to be involved

in sebaceous gland development. GH stimulates sebocyte differentiation but not proliferation, and augments the effect of 5α-reductase on sebaceous lipid synthesis [57]. *In vitro* IGF-1 and insulin stimulate sebocyte proliferation and differentiation especially with GH [57]. In addition, IGF-1 is thought to be involved in the induction of 5α-reductase [58].

Acne can be exacerbated by hyperprolactinaemia [59].

Alpha-melanocyte-stimulating hormone (α-MSH) is a member of the propiomelanocortin peptide family, which includes ACTH. α-MSH is an important stimulator of sebaceous gland growth and development in the rat [60,61] and has synergistic action alongside testosterone [42,61,62]. In human sebocytes, *in vitro* α-MSH has been shown to stimulate proliferation through its binding to MC1 and lipid synthesis through binding to MC5 [63]. Slight elevations of plasma concentrations of α-MSH have been found in Cushing's disease [64].

The drug levodopa decreases the seborrhoea of Parkinsonism, but has no effect in normal subjects. Increased sebaceous gland activity in pregnancy [65], lactation [66] and after taking phenothiazine drugs could be due to a pituitary-derived sebotrophic factor [1].

Oestrogens

Oestrogens undoubtedly depress sebaceous activity, especially in pharmacological doses. They decrease the size of sebaceous glands when injected into rats [67–69] or when given orally to adult human males [27], and have also been shown to reduce sebum production in both animals [70–72] and humans [27,73–76]. Oestrogens have also been shown to directly suppress an enhanced sebaceous gland function [77]. On the grounds that it was not possible to demonstrate a local, as distinct from a systemic effect by topical application of oestrogen ointment to the human forehead [27], it has been suggested that oestrogens may act by reducing endogenous androgen production [51]. This view that they suppress gonadotrophin secretion by the pituitary receives support from the finding that sebum-suppressing doses of oestrogen reduced the levels of testosterone in the plasma and urine of normal men [76], although not from the evidence that they suppressed sebum secretion in eunuchs [30].

Evidence from animal experiments favours the hypothesis that oestrogens act peripherally and directly upon the sebaceous glands [48,68,78–82]. The major active oestrogen is oestrodiol, which is produced from testosterone in the ovary adipose tissue and other peripheral tissues. Oestrodiol can be converted to the less potent oestrogen, estrone, by the action of 17β-hydroxysteroid dehydrogenase (17β-HSD) enzyme. Both aromatase and 17β-HSD are present in the skin. Oestrogen receptors of the β-isotope are strongly expressed in many cells of the skin and the α-isotope is found in coenocytes and dermal fibroblasts *in vitro* [83].

Hormonal actions on sebocytes in culture

Data from corneocytes in culture have supported the *in vivo* evidence presented in the previous sections. Several groups [2,48,84–87] have made significant contributions. Zouboulis's group [48,86,87] has established an immortalized human sebaceous gland cell culture system that has been passaged over 50 times; cells have been cloned and show no signs of senescence after 4.5 years *in vitro*, whereas normal human sebocytes can only be grown for three to six passages. These immortalized sebocytes have large cytoplasm profiles with abundant organelles, including vacuoles and myelin figures, which indicate lipid synthesis. The cells express molecules typically associated with human sebocytes such as keratins 7, 13 and 19. Functional studies have revealed that the synthesis of the sebaceous lipids is virtually identical to that of the human sebaceous gland cells. They also showed an increased cell proliferation after the addition of 5α-DHT, and a significant inhibition in the proliferation of these immortalized cells after the addition of retinoids, in particular 13-*cis*-retinoic acid (13-*cis*-RA).

These culture systems have demonstrated that the skin is a factory of androgen metabolism [48,86,87]. Studies on immortalized sebocytes have demonstrated that the four major enzymes involved in the intracellular activation and deactivation of androgens are: (i) 3β-hydroxysteroid dehydrogenase Δ^{4-5} isomerase (Δ^5–3β-HSD), (ii) 17β-hydroxysteroid dehydrogenase (17β-HSD), (iii) 5α-reductase and (iv) 3α-hydroxysteroid dehydrogenase (3α-HSD). Three-beta-hydroxysteroid dehydrogenase Δ^{4-5} isomerase (isotype 1), which converts dihydroepiandrosterone to androstenedione, is almost exclusively located in the sebaceous glands. Sebaceous glands express isoforms 2 and 3 of 17β-HSD, and thus are able to reversibly convert androstenedione to testosterone [88]. Five-alpha-reductase isotype 1, which irreversibly metabolizes testosterone to 5α-DHT, is also predominantly expressed in the sebaceous glands [16]. Zouboulis's group also demonstrated that corticotrophin-releasing hormone (CRH) is a sebaceous gland autocrine hormone, and is a biphasic regulator of lipogenesis in human sebocytes [89]. The evidence was obtained from sebocyte cell culture experiments and suggests that human sebocytes possess a complete CRH/CRH-receptor system. These proteins are expressed at the mRNA and protein level. It may be that stress-related acne could be explained by a local hormonal pathway.

In contrast, keratinocytes have different expression and metabolic rates of some of these enzymes. For example, sebocytes are able to synthesize testosterone from adrenal precursors and to inactivate them in order to maintain androgen homeostasis, whereas keratinocytes are responsible for androgen degradation. These unique expressions of differing androgen activity in different cutaneous cells suggest that there may be differentially programmed duties of skin cell populations for androgen metabolism [48,86–88].

In addition to androgens, other physiological and pharmacological candidates have been reported to control the development of sebocytes and to stimulate the proliferation of human sebocytes. Growth factors such as epidermal growth factor (EGF), transforming growth factor-α (TGF-α) and basic and fibroblast growth factor are paracrine and autocrine mediators of the proliferation and differentiation of a wide variety of cells [90,91]. Studies on hamster sebocytes have shown that these growth factors have mitogenic activity and act as antilipogenic factors [91].

For more detailed information on human skin as a target and endocrine gland the reader is referred to review papers [92,93].

Retinoid control of sebaceous gland activity

Interest in retinoid metabolism within sebocytes and the sebaceous gland was stimulated by the excellent clinical effectiveness of 13-*cis*-RA (isotretinoin) in severe acne. Other retinoid drugs including retinoic acid and all-*trans*-RA (tretinoin) have been shown to have a clinical effect in acne. Retinoids exert their effect through cell proliferation, lipid synthesis and keratin expression.

13-*cis*-RA reduces the size of sebaceous glands through prolongation of the maturation of basal sebocytes, suppresses sebum production up to 90% by inhibiting sebaceous lipid synthesis and *in vivo* and *in vitro* inhibits terminal sebocyte differentiation [1]. Despite the superb efficacy of this agent, the molecular basis for the unique sebostatic activity is still not fully understood. Sebocyte proliferation and lipid synthesis are suppressed when cells are cultured in the absence of vitamin A [2] and in an immortalized human sebaceous gland cell line, the addition of retinoids to culture medium significantly reduced sebocyte proliferation [3]. Its stereoisomers tretinoin and al-tretinoin (9-*cis*-retinoic acid) are inferior to isotretinoin in terms of sebum suppression, reducing sebocyte proliferation, and hence efficacy in acne. Pharmacological quantities of 13-*cis*-RA or all-*trans*-RA have also been shown to suppress sebocyte proliferation and lipid synthesis in a dose-dependent manner [4]. The superior effect of 13-*cis*-retinoic acid has been attributed to delayed initiation of retinoid inactivation under incubation of sebocytes with 13-*cis*-RA as this leads to high intracellular levels of tretinoin. 13-*cis*-RA acid down-regulates the expression of keratins 5, 6, 14 and 16 and up-regulates keratin 7, whereas all-*trans*-RA down-regulates keratin 5, 6 and 16 expression and up-regulates the expression of keratin 19 [4]. All-*trans*-RA is thought to be the active metabolite of isotretinoin within cells following enzymic conversion from 13-*cis*-RA. Evidence comes from the preferential binding of all-*trans*-RA to retinoic acid receptors (RARs) [4]. The antiproliferative effect of retinoids on human sebocytes *in vitro* was found to be mediated by RAR [5]. Figure 42.12 illustrates probable interconversion of retinoids within cells.

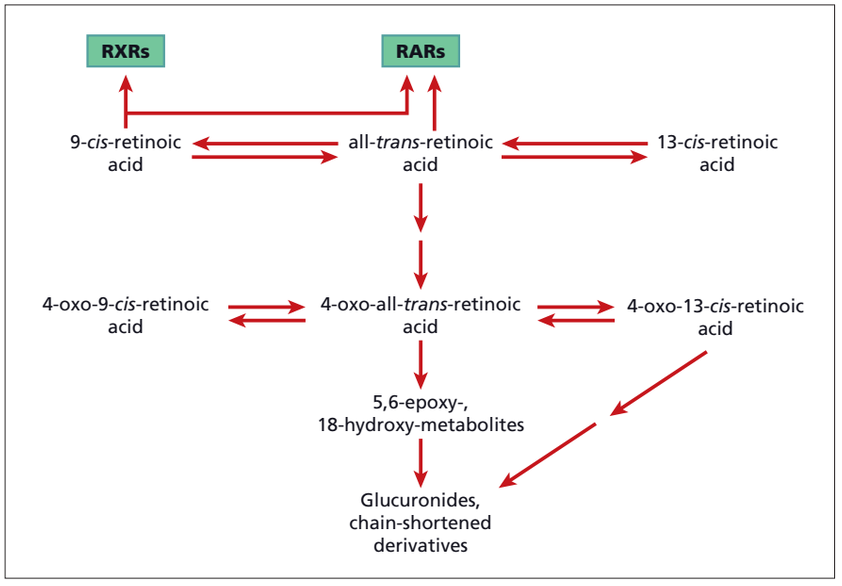

Fig. 42.12 The likely retinoid pathways of isotretinoin metabolism in the sebaceous gland. RAR, retinoic acid receptor; RXR, retinoid X receptor. (Reproduced with the kind permission of Dr U. Wiegand, Roche, Basel.)

Human sebocytes are naturally eliminated by apoptosis on their way to terminal differentiation before their death and holocrine secretion [6]. Nelson *et al*. confirmed that isotretinoin-induced apoptosis was not evident within a 24-h treatment period, but detected marginal apoptosis after 48–72 h; the effect was specific to sebocytes [7]. This process of cell cycle arrest and apoptosis of sebocytes provides an explanation for the significant reduction in size, shape and lipid content of sebaceous glands post treatment with isotretinoin. Terminal differentiation of human sebocytes is associated with increased cell volume, increased lipid synthesis and accumulation of lipid droplets. Skin surface lipids alter post treatment with isotretinoin, demonstrating a marked decrease in wax esters, reduction in squalene and relative increase in cholesterol [1]. This inhibitory effect of 13-*cis*-RA on sebaceous lipids has been attributed to inhibition of terminal sebocyte differentiation [8], and is probably mediated by both RXR and RAR [3,5].

A study has demonstrated the specific and significant presence of CYP26A1 expression in epithelial cells of sebaceous glands of healthy human skin, which may provide new insights into pathogenesis and treatment of conditions affecting the sebaceous follicle [9].

Inhibitors of sebaceous activity

Acne is associated with increased sebum secretion and proliferative activity of sebaceous glands. Much effort has therefore gone into developing treatments for acne that reduce sebaceous gland activity.

Possible mechanisms include reducing the circulating levels of serum androgens through an effect on the pituitary, adrenal or gonads, or by affecting the transport of androgens (Fig. 42.13). Alternatively, the pharmacological/physiological suppression of androgens could be achieved through a direct effect on sebocyte metabolism. Such mechanisms include blocking enzyme activity (5α-reductase type 1, Δ^5–3β-HSD, cytochrome p450), or by blockage of androgen or retinoid receptors.

The effect of topically applied hormones shows a considerable species difference between animals and humans. Some topical therapies significantly reduce sebum excretion in animals but have no effect in the human. The most likely explanation is anatomical, as the animals under investigation have sebaceous glands situated very close to the epidermis, whereas the human sebaceous gland is relatively deep in the dermis and connects to the epidermis via a long pilosebaceous duct, making it more difficult for these topical compounds to reach the gland. Clinical benefit does not occur until sebum suppression achieves a minimum of 30%.

Co-cyprindiol (Dianette® and Estelle 35®), which contains 35 µg ethinyl oestradiol and 2 mg cyproterone acetate (CPA), reduces

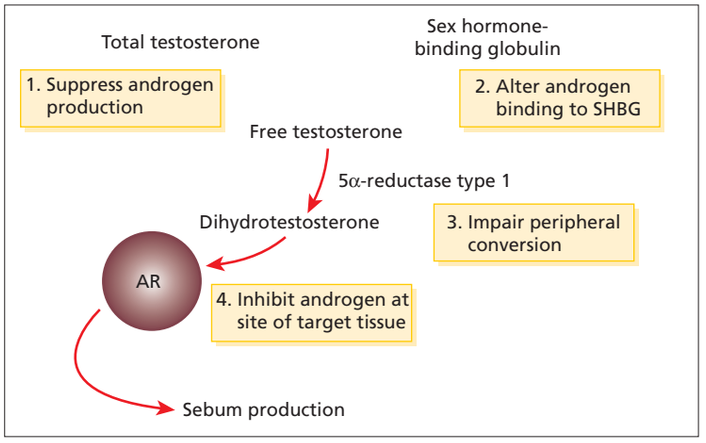

Fig. 42.13 Possible mechanisms for reducing circulating androgens. AR = androgen receptor within the sebaceous gland.

sebum excretion by 28% [1–3]. When combined with additional CPA (100 mg/day) from the fifth to the 14th days of cycle, the sebum suppression rises to 68%.

Topical CPA was ineffective when applied in 50% dimethylsulfoxide (DMSO) or in cetomacrogol [4–5], but did have some effect in an ethanol base [6]. Other topical agents said to be effective [7–12] include 17α-propyltestosterone, 17α-mesterolone and flutamide, but none have been shown to be of clinical benefit in patients with acne. Inocoterone, another non-steroidal receptor blocker, reduces sebaceous gland activity when applied topically to rat and hamster sebaceous glands [13,14], and lacks any systemic effects. However, in adult males topical inocoterone produced a small reduction in sebum excretion and a minor improvement in clinical acne [15]. Seventeen substituted α-chloro and 17β-sulphinyl steroids have been suggested as inhibitors of sebaceous activity [16], but have been disappointing in humans. Spironolactone, given systemically, has been shown to inhibit the hamster flank organ [17], and, given topically, to block androgen activity in sebaceous glands of the hamster pinna [18]. However, there was no effect on sebum excretion when applied topically to humans [19]. In contrast, spironolactone given orally significantly reduces sebum excretion in humans in a dose-dependent manner; there is a reduction of around 30% with 100 mg/day, and a reduction of 60–70% with 200 mg/day [20]. Oral administration of the H_2-receptor antagonists ranitidine and cimetidine reduces sebum excretion in humans [21], but not to a clinically significant level, and these drugs lack effect when applied topically [22].

Substances that inhibit the conversion of testosterone to DHT also reduce sebum production [23]. Topical progesterone, which may achieve a reduction in the rate of sebum excretion [24,25], has a relatively small and temporary sebosuppressive effect in humans, unlikely to be of any clinical benefit to the patient with acne.

Certain derivatives of vitamin A, in particular isotretinoin (13-*cis*-RA), have marked effects on the sebaceous glands when given systemically. They have been shown to reduce the size of the hamster flank organ [26] and human sebaceous glands [27], in which they profoundly inhibit sebum excretion [28–30]. Isotretinoin reduces 5α-reductase activity in human liver and skin [31–33], and has been shown to reduce the binding capacity of the androgen receptor in back skin [33]. Isotretinoin reduces the synthesis of DNA and the incorporation of a lipid precursor ^{14}C-acetate in human sebaceous glands *in vitro* [34,35]. The metabolism of retinoids in the human sebaceous gland has been described above (see also section on oral isotretinoin below). Topical retinoids, in contrast to certain oral retinoids, have no effect in reducing sebum production or excretion.

It has been assumed that topical antibiotics do not influence sebum production or sebum excretion. However, it has been shown that topical erythromycin plus zinc acetate (Zineryt®) reduces SER by about 20% (using Sebutape® technology), in contrast to topical erythromycin alone [36]. The mechanism for this is unclear, but may relate to the drug affecting sebum outflow from the duct and is unlikely to have any impact on clinical efficacy.

Acne vulgaris

Definition. Acne is a chronic inflammatory disease of the pilosebaceous units (Fig. 42.14)

It is characterized by seborrhoea, the formation of open and closed comedones, erythematous papules and pustules (Fig. 42.15) and in more severe cases nodules, deep pustules and pseudocysts (Fig. 42.16). In many cases a degree of scarring will ensue.

Four major factors are involved in the pathogenesis: (i) increased sebum production, (ii) hypercornification of the pilosebaceous duct, (iii) abnormality of the microbial flora especially colonization of the duct with *P. acnes*, and (iv) inflammation.

Natural history. The condition usually starts in adolescence and frequently resolves by the mid-twenties [1]. Prevalence data is variable depending on the time of the study and population assessed. In one community based study, acne was noted in 56% of boys and 45% of girls aged between 14 and 16 years and noted to be moderate to severe in 11% [2]. A peak in prevalence and severity occurs between 14 and 17 years in females, when 40% are affected, and 16 and 19 years in males, when 35% are affected [1]. A study from the USA [3] indicated that the prevalence by the mid-teens was virtually 100%. On the other hand, only about 20% of sufferers needed the help of a physician. A study of adolescents in New Zealand identified acne in 91% of male and 79% of female students studied. Severe acne was noted in 6.9% of males and just 1.1% of females [4]. A population-based prevalence study from Australia demonstrated that the overall prevalence rates were 36.1%, ranging from 27.7% in 10–12 year olds to 93.3% in 16–18

Fig. 42.16 Deep-seated inflammation resulting in an acne cyst. (Courtesy of Dr A. Yung, Auckland, New Zealand.)

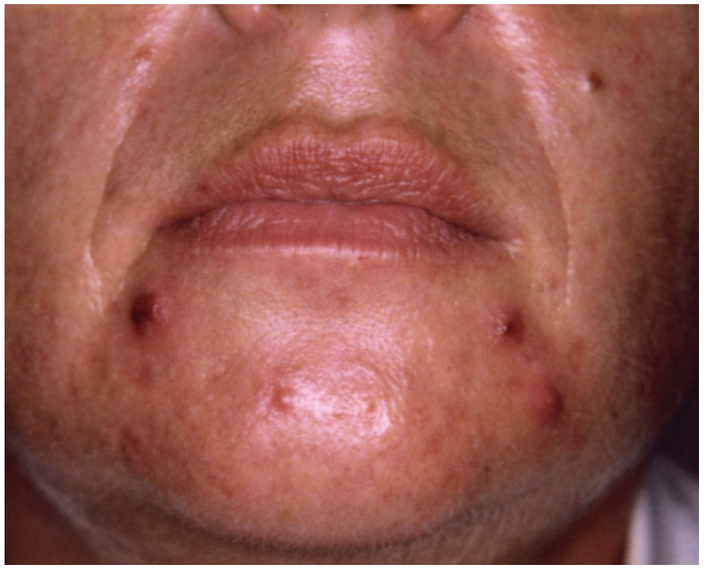

Fig. 42.17 Persistent acne in a mature female demonstrating deep-seated inflammatory lesions with a predilection for the perioral region.

year olds. It was less prevalent in boys between 10 and 12 years, but between 16 and 18 years of age boys were more likely to have acne than girls. Moderate to severe acne was present in 17% of students (24% boys, 11% girls). Comedones, papules and pustules were the most common clinical features and 1:4 cases had scarring [5]. A further study in Portugal confirmed a high prevalence rate of 82.4% in 10–12 year olds and identified that only 44% of cases sought treatment [6].

In those patients with very mild disease the problem is referred to as physiological acne. Acne develops earlier in females than in males [1,7], which may reflect the earlier onset of puberty. Significant prepubertal acne is only rarely found to be a cutaneous marker of an endocrine abnormality but should be considered in early-onset acne (see Table 42.2). Mild, comedonal acne can be the first sign of pubertal maturation; significant comedones usually precede inflammatory lesions by 2–3 years, and early mid-facial comedones are recognized as a marker of subsequent disease [8,9]. Some subjects show small, non-inflamed lesions by the age of 8–9 years [1]. Site of involvement is linked to the age of onset of the disease, with inflammatory lesions in the midline of the face presenting early in sexual maturation [5].

By 20 to 25 years the tendency is for acne to resolve slowly [10]. However, in 7–17% of individuals clinical acne persists beyond the age of 25 years [11] (Fig. 42.17) with physiological acne in females having a prevalence of 24% [12]. A study from Denmark suggested that there has been a decrease in the prevalence of acne in females, and this may relate to the widespread use of oral contraceptives [13]. On the other hand, some clinicians consider that they are now seeing an increase in the number of patients with mature acne. In another study [11], 25% of acne patients referred to an acne clinic had a mean age of 24 years. Most had acne persisting from adolescence, but 8% had late-onset (age over 25 years) acne. This may be a reflection of a more demanding and articulate group of mature acne patients [14]. At the age of 40 years, significant lesions are still present in 1% of males and 5% of females [10]. On the other hand, questionnaire-based studies in France [15] and in the USA [16] have shown that as many as 80% of patients treated for acne have some level of disease activity that persists into the 30 to 40-year age range.

Factors that underlie the resolution of acne are not understood, nor are the relative persistence in females. Recent studies on the natural history of acne are limited, because improved treatment has modified the prevalence, severity and age of presentation to dermatological clinics [17].

Genetic factors. Several studies have shown that genetic factors influence susceptibility to acne [18,19]. A survey in Germany [20] showed that acne had been present in one or both parents of 45% of schoolboys with acne but in only 8% of parents of boys without acne. A genetic influence is confirmed by the very high concordance between monozygotic twins, in whom the SER is virtually identical. Comedone numbers are also similar in identical twins but not in dizygotic twins, which suggests a genetic role in comedone formation [19]. Furthermore, in three pairs of identical twins, severe nodular acne developed at approximately the same time in each pair. On the other hand, in less than half of affected dizygotic twins did both twins have acne [20]. Patients with persistent acne have a strong family history of persistent acne, in contrast to patients with adolescent acne [11]. A correlation between neonatal acne and familial hyperandrogenism has been suggested [21].

The decreased incidence of atopic dermatitis in acne sufferers [22] may be genetically determined, but could be explained by the low sebum excretion in patients with eczema. The association of very severe acne with the XYY syndrome [23,24] has been recorded.

Racial studies provide an insight into genetic and environmental factors. Acne in black Americans is less evident than in white Americans, who, in turn, have more severe acne than Japanese [25]. The incidence of acne is said to be low in Inuits, who eat a diet rich in fish, but increases markedly when they change to a 'Western' (Canadian) diet with more saturated fats. Similar changes have been noted in Japanese people who immigrate to Hawaii and consume an American-style diet [25].

Although evidence of familial clustering exists [26], and to date a few acne candidate genes have been proposed [27], some of them related to androgen and steroid metabolism [28], research is currently limited. Understanding the genetic basis for acne could potentially identify new therapeutic options and help to identify those more prone to scarring. Further research is required in this area.

The size of the problem [1]. A person is more likely to develop acne than any other disease [2]. The major burden of acne is experienced during the teenage years, but acne may continue as a clinical problem into the twenties and older. Data are more reliable for school-aged children than for those in the later teens or older because of the ease of data capture.

Studies of European schoolchildren in Switzerland in 1931 [3], Newcastle upon Tyne, England, in 1971 [4] and Glasgow, Scotland, in 1989 [2] have shown a consistent level of maximum prevalence, approaching 100% for 16–17-year-old boys and 85–100% in 16-year-old girls. However, the same period has seen a major reduction in severity. In the 1931 study, 57% of boys and 19% of girls had severe acne [3]. These figures had changed to 30% and 20% in 1971 [4] and changed to 35% and 13% respectively in a further study in Newcastle upon Tyne in 1981 [5]. By 1989, the Glasgow study showed no schoolchildren with severe acne, only 1.8% of boys with moderate acne and no girls with worse than mild acne [2]. Only the Newcastle upon Tyne and Glasgow studies were randomized cross-sectional views. Similar prevalence levels were found in New Zealand [6] and Southern Australia [7], but both countries showed significantly larger numbers of school students with the more severe grades of acne than were found in the UK. Unfortunately, most studies have been affected by selection bias due to place of work, educational institution or hospital/surgery attendance. Questionnaire based surveys in the USA and the UK [8,9] have shown a lower prevalence, as might have been expected from the Glasgow study, which found clinical acne in 18% of boys, many of whom denied the presence of spots.

The clinical problem of acne in older patients in their twenties and thirties appears to be increasing [8–12], but better epidemiological data are required.

The size of the problem is also influenced by patients' beliefs and perception [13,14]. Twelve per cent of teenage boys denied the presence of clinical acne [2] and, in another study, 49% of patients believed their acne to be curable within 6 months [13].

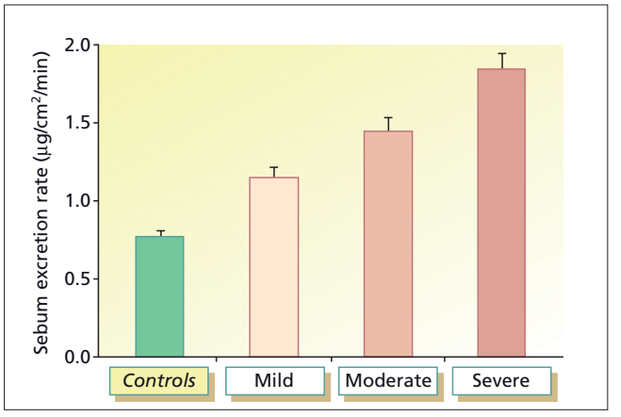

Fig. 42.18 Correlation between acne severity and sebum excretion.

Table 42.2 Outline of mechanisms leading to high sebum production.

Excessive androgen production
Increased availability of free androgen which may be associated with a relative reduction of sex hormone binding globulin (SHBG)
An amplified target response mediated through the conversion of testosterone to more active dihydrotestosterone
An increased capacity of the intracellular receptor to bind androgens

Aetiology of acne

The four major factors involved in the aetiology of acne are:
1 Seborrhoea
2 Comedo formation (comedogenesis)
3 Colonization of the intrafollicular duct with *P. acnes*
4 Inflammation.

Seborrhoea

The most obvious function of the sebaceous glands is to produce sebum and excess sebum production is a prerequisite for the development of acne [1]. The level of sebum secretion correlates reasonably well with the severity of the acne (Fig. 42.18) [2,3].

Sebaceous activity is regulated by androgens of gonadal or adrenal origin [4–6]. Androgen-insensitive subjects lack androgen receptors; they do not produce sebum and do not develop acne [5]. Systemic administration of testosterone and dehydroepiandrosterone (DHEAS) increases the size and secretion of sebaceous glands [6]. These two facts support the essential role of androgens in sebum stimulation. Clinical observations pointing to the importance of androgens in acne include the development of early acne in association with increased levels of DHEAS, a precursor of testosterone. The rise of DHEAS in prepubescent children is associated with an increase in sebum production and development of comedonal acne [7]. Androgens regulate sebaceous gland function through binding to nuclear androgen receptors (ARs) [8]. Immunohistochemistry has demonstrated that sebaceous glands have the highest AR density within the skin [9]. Table 42.2 outlines mechanisms leading to high sebum production.

There is general agreement that plasma testosterone levels are not abnormally high in males with acne [10–12]. In females with acne, the situation is more complicated. Some investigators have found testosterone levels to be normal [13–15], while others have found raised levels [16–18], albeit often lower than in males with no acne whatsoever. Most studies have shown that mean SHBG levels are significantly below normal, with free testosterone consequently above normal. However, results from studies are conflicting, and many of the studies included patients who were older than the modal value for all female acne patients, and not infrequently had other features of endocrine disease, such as significantly irregular menstruation and hirsutism, so fell within the definition of polycystic ovary syndrome (PCOS). Lawrence *et al.* [16] found that only 41% of their acne patients had free testosterone levels above normal. Lucky *et al.* [17] measured a number of androgens and their precursors, as well as SHBG, and found that 52% of non-hirsute women with acne had at least one abnormal hormone level. Cibula *et al.* [19] found that 81% (73 of 90 patients) had an elevation of at least one androgen hormone of the four that they measured. In their study, 21% had hirsutism and 50% had polycystic ovarian syndrome, but there was no correlation between the severity of acne and abnormalities of the sex hormones. Darley *et al.* [20] examined 38 women with acne and found high serum testosterone in 26%, low SHBG in 45% and high prolactin in 45%, but 24% had no hormonal abnormality at all. The majority of potent androgens are produced by peripheral target tissues. This peripheral androgen metabolism is important, for example increased androsterone metabolism has been reported in females with normal circulating androgen levels [21]. Hyperinsulinaemia results in a lowering of SHBG, thereby influencing androgen levels [22]. However, post-meal transient hyperinsulinaemia does not seem to play a role in hyperandrogenaemic acne patients [23].

In conclusion, androgenic hormonal balance may be disturbed to some degree in female acne patients; however, this does not establish a causal link and at least a quarter of all cases remain unexplained. There are no correlations between the severity of

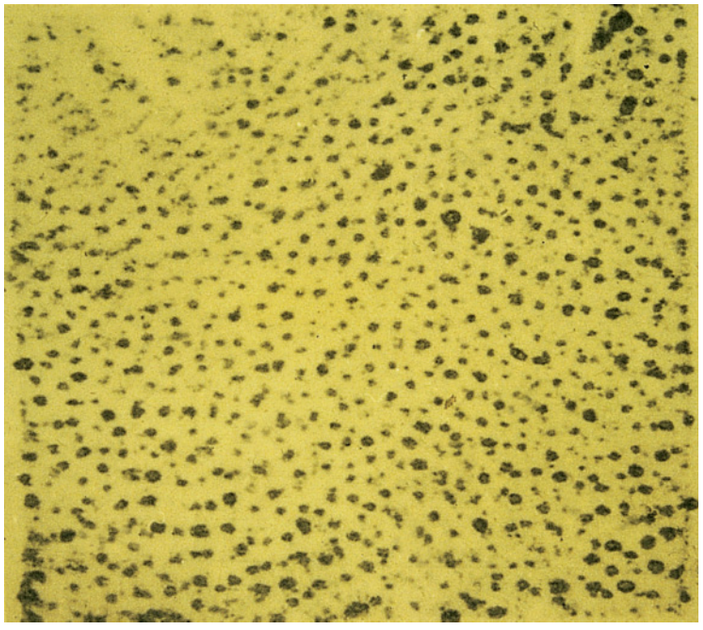

Fig. 42.19 Homogeneous sebaceous outflow in a normal subject.

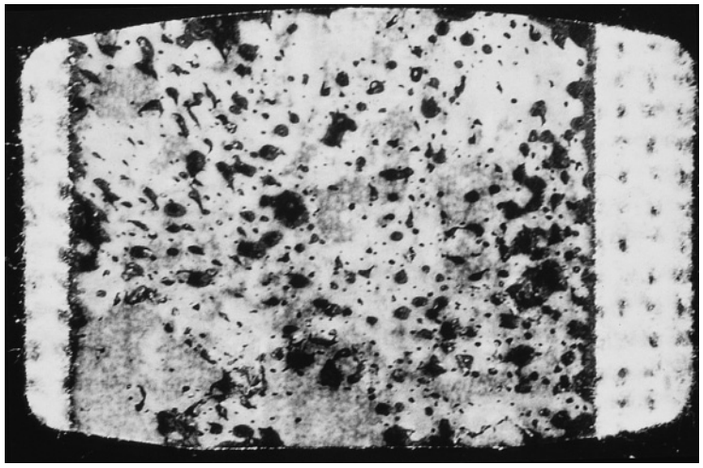

Fig. 42.20 Heterogeneous sebaceous outflow in an acne subject.

Table 42.3 Indications for endocrine evaluation of acne patients.

Reason for investigation:
Severe/sudden acne
Therapy-resistant acne
Rapid significant relapse post isotretinoin
Additional signs of hyperandrogenism
Irregular menses
Hirsutism
Hyperseborrhoea
Unusual clinical presentation
Multiple comedones
Hyperseborrhoea
Mature onset/perioral distribution

acne, hirsutism and menstrual irregularity [24]. Moreover, if the development of acne were simply related to systemic hormone levels, it should have a similar frequency on the face, back and chest, but this is not so. In general, acne patients are not endocrine misfits.

Androgen effects on the pilosebaceous unit are reasonably well characterized although the variability in the response of the pilosebaceous unit is not completely understood [25]. Testosterone and DHT act through a single nuclear androgen receptor, with dihydrotestosterone (DHT) being the most active ligand.

The fact that acne does not occur simultaneously on all susceptible sites correlates with the finding that sebum excretion varies from follicle to follicle (Figs 42.19 & 42.20) [26]. In acne patients, there is marked heterogeneity in individual follicular sebum excretion. This allows us to hypothesize that certain follicles may be prone to acne [27] and that an enhanced peripheral (end organ) response to androgens is a probable factor in many subjects. Weak prohormones (DHEA, DHEAS and androstenedione) only act after conversion to more potent androgens testosterone and 5α-DHT. Sebaceous glands in acne-prone regions show abnormally high 5α-reductase activity *in vitro* [28]. In addition, abnormally high levels of plasma DHT and urinary 5α-androstanediols, considered by some to be biological markers of cutaneous androgen metabolism, have been identified in some female acne patients [13]. Data on androgen receptors in acne suggest that androgen action on the sebaceous gland may be independent of serum hormone levels [29]. There are two forms of 5α-reductase [30]. 5α-reductase type I is the most relevant in acne supported by the fact that finasteride, an inhibitor of type II 5α-reductase, does not reduce sebum production [31] and the fact that patients with a deficiency of type II 5α-reductase have normal sebum levels [31]. Regional differences in the activity of type I 5α-reductase in isolated sebaceous glands from various body sites also support the end-organ hyper-responsiveness theory for acne [32–35].

Unless patients with acne show other features of hyperandrogenism it is not necessary to investigate for an endocrinopathy [36]. An endocrine evaluation may be indicated in adult females. Table 42.3 summarizes the need for investigation.

A medical history and physical examination should be performed before embarking upon relevant blood tests. Polycystic ovarian syndrome (Fig. 42.21) is the most frequently associated hormonal disease [37].

In most acne clinics, the majority of female patients with acne have no other clinical features of the syndrome, which consists of hirsutism, relative infertility or irregular menstruation [37]. There is no correlation between the presence of ovarian cysts and the severity of the acne [38]. Late-onset adrenal hyperplasia due to a partial deficiency of 21-hydroxylase should be considered in patients with persistent problems with their acne [39] and may rarely cause severe acne in boys [40]. It is very rare to find virilizing tumours that present as acne alone. When thought necessary, appropriate initial tests should include measurement of total testosterone, SHBG, androstenedione, dehydroepiandrosterone (DHEA), prolactin, follicle-stimulating hormone (FSH) and luteinizing hormone (LH) [41]. Hormonal levels should ideally be taken early in the menstrual cycle (day 1–3). If late-onset congenital adrenal hyperplasia is suspected, then a 09.00 cortisol and

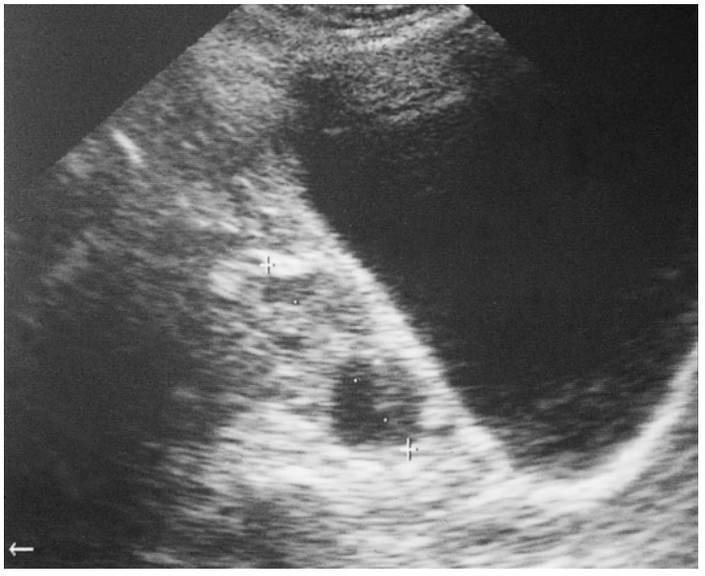

Fig. 42.21 Ultrasound of the pelvis showing polycystic ovaries.

Table 42.4 Investigations required to identify an endocrine problem in acne patients.

Androgen profile: *testosterone, SHBG, 17(OH)—progesterone, DHEAS*
FSH, LH, ± oestradiol
Prolactin/thyroid function tests
Assessment of glucose tolerance/insulin resistance; GTT, lipid profile
Suspected Cushing's: dexamethasone suppression test (will also help to identify congenital adrenal hyperplasia along with DHEAS, 17(OH) progesterone

17α-hydroxyprogesterone measurement should be performed. Either the adrenal gland or the ovary may produce excess androgens. Serum dehydroepiandrosterone sulphate (DHEAS) levels can be used to screen for an adrenal source of excess androgen production, patients with a serum DHEAS greater than 21.7 µmol/L may have an adrenal tumour. Some adrenal tumours may also produce testosterone. Values of DHEAS in the range of 10.8–21.7 µmol/L may be seen with congenital adrenal hyperplasia, which is often associated with a slightly raised cortisol and a 17α-hydroxyprogesterone level of greater than 12.8 µmol/L. An ovarian source of excess androgen can be suspected in cases where the serum total testosterone is elevated. A raised serum testosterone and an increased LH level are seen in patients with polycystic ovarian disease. The LH:FSH ratio is not always elevated in PCOS and is not necessarily a diagnostic measure. Table 42.4 outlines investigations required to identify an endocrine problem.

High elevations in serum testosterone may indicate an ovarian tumour.

The possibility that other hormones may affect the sebaceous glands, either directly or by enhancing their response to androgens, should not be neglected. In acromegaly, the rate of sebum excretion (SER) is high and correlates with skin thickness and growth hormone levels [42]. The SER is low in individuals with isolated growth hormone deficiency, who therefore do not have associated acne [43]. In clinical practice, these endocrinopathies

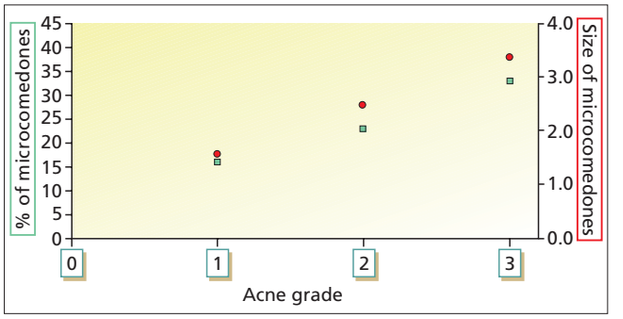

Fig. 42.22 Correlation between the number and size of microcomedones and acne severity.

are rarely encountered as presenting features in the dermatological clinic.

Sebaceous lipid composition

Human sebaceous glands secrete a mixture containing squalene and wax esters as well as cholesterol esters, triglycerides and some free cholesterol [44]. It is recognized that bacterial hydrolases, especially from *P. acnes*, convert the triglycerides to free fatty acids on the skin surface [45]. There is also evidence to suggest that sebaceous glands can synthesize free fatty acids [46]. The role of individual lipid components in causing acne is uncertain. Lipids may be involved in ductal hypercornification, or may be essential to the growth (stimulation and inhibition) of bacteria. Sampling of skin-surface lipids has shown that patients with acne tend to have higher levels of squalene and wax esters, lower levels of fatty acids [47–49], and a more frequent occurrence of particular free fatty acids [50,51]. Linoleic acid is significantly reduced in epidermal and comedonal lipids, and this may relate to ductal hypercornification.

Comedone formation (comedogenesis)

An important feature in the aetiology of acne is the presence of ductal hypercornification, which can be seen histologically as microcomedones, and clinically as blackheads, whiteheads and other forms of comedones such as macrocomedones. There is a significant correlation between the severity of acne and the number and size of follicular casts (microcomedones), the presence of which is a measure of comedogenesis [52] (Fig. 42.22). Follicular casts (microcomedones) can be sampled by applying cyanoacrylate gel to the skin surface, followed by pressing a glass microscopic slide on top for 1 min [53,54]. The sample can be analysed by low-power microscopy or by digital image analysis [46,47] (Fig. 42.23).

Comedones are due to abnormalities in the proliferation and differentiation of ductal keratinocytes. They represent the retention of hyperproliferating ductal keratinocytes/corneocytes in the duct. The hyperproliferation has been confirmed by showing an increase in ^{3}H-thymidine labelling of comedones [55] and increase in the Ki-67 labelling (a marker of cell turnover) of ductal keratinocytes (Fig. 42.24) [56]. Ki-67 labels nuclear antigen expressed by cells in the late G1, S, M and G2 phases of the cell cycle [57]. This technique has also shown an increase in the proliferation of ductal keratinocytes of 'non-affected' follicles, which were biopsied as

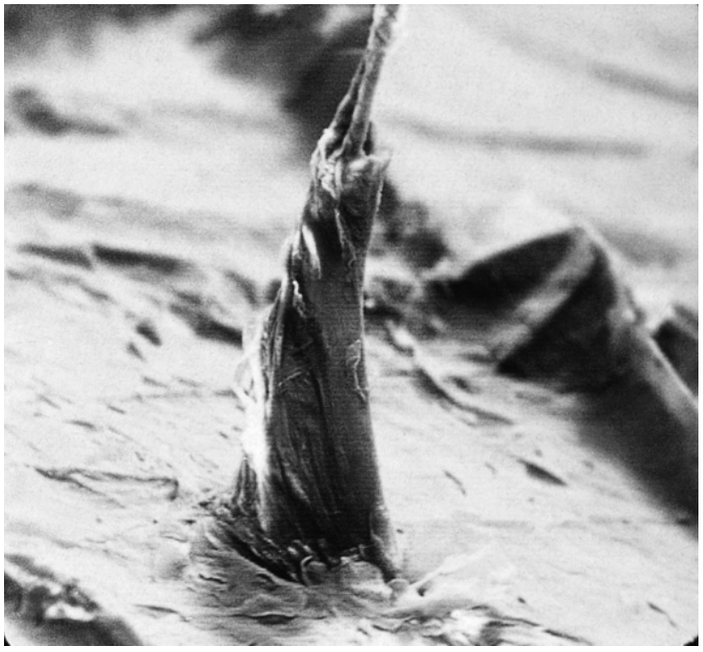

Fig. 42.23 Scanning electron microscopy of a microcomedo that has been sampled from an acne-prone skin using the skin-surface biopsy technique.

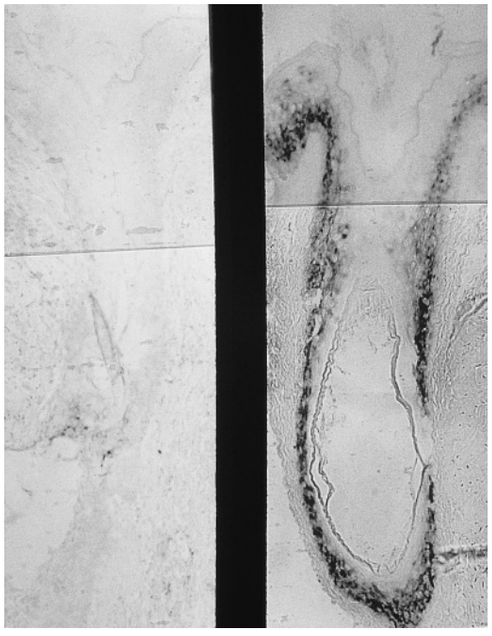

Fig. 42.25 *In situ* hybridization for keratin 6 (a marker of hyperproliferation) demonstrates little activity in a normal follicle (left) and considerable activity in a comedo (right). (Courtesy of Dr D.B. Holland, Department of Microbiology, Leeds General Infirmary, Leeds, UK.)

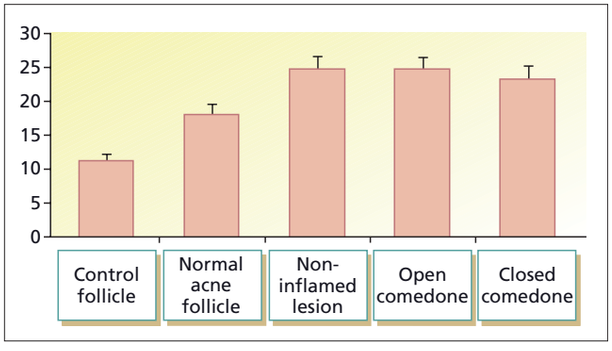

Fig. 42.24 Uptake of Ki-67, a marker of keratinocyte proliferation, in control skin, microcomedones and clinical comedones.

clinically 'normal' follicles from an area affected by acne [56]. This fits with the histological observation of microcomedones being found in 30% of tissue sections of clinically 'normal' skin taken from skin adjacent to acne lesions. Further evidence of ductal hyperproliferation is the presence of keratins 6 and 16 (keratin markers of hyperproliferation) in microcomedones and comedones (Fig. 42.25) [58]. The primary abnormality that gives rise to hypercornification is not related to changes in keratin expression [58,59]. There is as yet no evidence to suggest that comedogenesis may be related to failure of ductal keratinocytes to separate. Studies of involucrin expression and desmosomes, which are features of terminal differentiation, have shown no difference between follicles from acne and control biopsies [60].

Several factors have been implicated in the induction of keratinocyte hyperproliferation, and include sebaceous lipid composition, androgens, local cytokine production and bacteria.

Of the abnormal sebaceous lipids in acne patients, the linoleate levels may be relevant. Examination of polar lipids recovered from comedones shows that the acryl ceramides contain only 6% linoleate among the esterified fatty acids, compared with 45% in normal human epidermis [61,62]. Similarly, linoleic acid is reduced in sebum from acne subjects, but returns to normal with resolution of acne following treatment with isotretinoin [63] and antiandrogens [64]. In animal experiments, a low linoleate produces hypercornification, which may parallel the increased scale found in comedones. In these animals, a low linoleate produced a decreased epidermal barrier function, which might have rendered the comedonal wall more permeable to inflammatory substances. Membrane-coated granules [65–67] are probably more related to barrier permeability than cell separation, and are decreased in comedones, but the significance of this is as yet unclear.

Other lipids have been incriminated; in particular, free fatty acids and squalene have been blamed for inducing comedones [68,69] in the rabbit-ear model [70]. The development of a human model for comedogenesis has, however, suggested that the rabbit model is inappropriately over reactive [71]. Laboratory animals do not develop whiteheads or inflamed acne lesions, even though the rabbit ear readily produces comedones [72]. The rhino mouse is an alternative useful model for comedogenesis [73]. From experiments in the rhino mouse, it has been suggested that comedone formation may be associated with an abnormality in apoptosis (programmed cell death) [74]. Evidence is accumulating to propose that androgens may play an important role in comedogenesis. There is a correlation between comedone numbers in early acne and DHEAS levels [75]. Cells of the pilosebaceous duct have androgen receptors [76], and 5α-reductase type I is also present in these cells both in health and in disease [77–79]. Antiandrogen

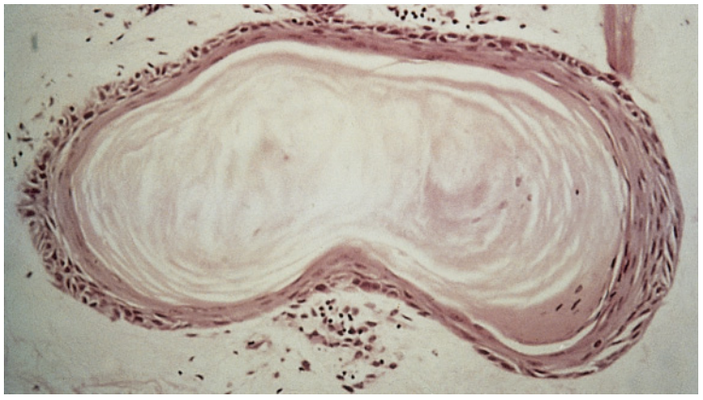

Fig. 42.26 An *in vitro* comedo, induced by interleukin-1-α (IL-1-α). (Courtesy of Dr T. Kealy, Cambridge University, UK.)

drugs, such as cyproterone acetate (CPA) in the drug co-cyprindiol (Dianette® and Estelle 35®), reduce comedones. Co-cyprindiol also increases the sebaceous linoleate concentration [64], and thus antiandrogen therapy could modulate comedogenesis both directly and indirectly by influencing sebaceous lipid.

Cytokine production by ductal keratinocytes is also likely to be important. Kealey and colleagues developed an excellent *in vitro* model for growing and studying the duct [80–82]. IL-1-α is present in many comedones at levels that are likely to be biologically and pathologically relevant [83]; IL-1-α induces comedogenesis (Fig. 42.26). Furthermore, EGF markedly disrupts the duct comedo *in vitro* [82]. Kealey and colleagues have also demonstrated that IL-1-α acts on the fundibular keratinocytes to induce cornification [83] and that EGF and TGF-α inhibit sebum secretion [84].

Bacteria are thought not to be involved in the initiation of comedones. Electron microscopy of early non-inflamed lesions taken from prepubertal and early pubertal individuals has demonstrated few or no bacteria [85]. Mourelatos *et al*. demonstrated a lack of propionibacteria in comedones in a temporal study assessing early acne development in children [86]. Other work quantifying bacteria from comedones suggests that follicular colonization is unrelated to comedogenesis [87]. Biopsy and culture of early non-inflamed lesions has shown that 30% of these are without bacteria [88], suggesting that ductal bacteria are not needed for the initiation of cornification in the development of comedones.

Comedones are temporary structures. Using markers of cell cycling (Ki-67) and keratinocyte proliferation, it has been shown that, like the hair follicle, normal pilosebaceous follicles and comedones undergo cyclical growth [89]. Extracted blackheads refill over 2–6 weeks. Functionally, some comedones are blocked [90], but others can become blocked temporarily following skin hydration [91], and this obstruction is associated with a decrease in outflow of sebum. Such observations could help to explain tropical acne and premenstrual flare of acne [92].

Certain external chemicals may contribute to comedogenesis. These substances include the ingredients of some cosmetics such as isopropyl myristate, propylene glycol, and D and C red dyes [93]. It has been suggested that the excretion of products from the sebaceous gland occurs through an organized acellular tubular conduit—the sebolemmal sheath produced by the sebaceous duct cells; rupture of this sheath may contribute to comedogenesis [94]. However, this concept has yet to be confirmed by others.

Relationship between *P. acnes* and acne

Acne is not an infectious disease in the classical sense; however, inflammatory acne can be viewed as an infection of the blocked pilosebaceous ducts with propionibacteria which are trapped by cornified plugs within the follicular ducts [95]. The three major organisms isolated from the surface of the skin and the pilosebaceous ducts of patients with acne are *P. acnes*, *Staphylococcus epidermidis* and *Malassezia furfur* [96]. There are three major subgroups of the propionibacteria—*P. acnes*, *P. granulosum* and *P. avidum*. Almost certainly *P. acnes* and, to a lesser extent, *P. granulosum* are the most important. Nevertheless, as they live in association with *S. epidermidis* and *M. furfur*, the latter organisms probably have some control over the growth of *P. acnes* [97]. The cornified plug within the pilosebaceous duct obstructs sebum outflow, allowing propionibacteria to multiply but preventing them and their products of metabolism from escaping onto the skin surface. Adolescence and its attendant seborrhoea are associated with a significant increase in *P. acnes* numbers [86,98] but there is little or no relationship between the number of bacteria on the skin surface and the severity of acne [99–101]. There is a much closer relationship between follicular organisms recovered from 4 mm punch biopsies and the severity of the disease [102]. In a study examining the cutaneous microflora from biopsies of 26 papules and 48 normal follicles in patients with persistent and late-onset acne compared with individuals with adolescent acne and normal control volunteers without acne, the microflora consisted in the main of *Propionibacterium*, staphylococci and *Malassezia*, and at all sites there were significantly more *Propionibacterium* spp. than the other two microorganisms. Female facial skin and male back skin showed significantly higher numbers of microorganisms in the upper parts of the follicles when compared with those from control volunteers [102]. There was a bimodal distribution of microbial colonization, with about 90% of normal follicles and about 10% of acne follicles having no detectable viable microorganisms. There were fewer microorganisms in normal follicles than in inflamed lesions. Although the presence of microorganisms, especially *P. acnes*, cannot be deemed to be singularly responsible for the onset of the inflammatory lesion, the significant difference between the number of inflamed lesions, which were colonized, when compared with normal follicles, lends support to the theory that these microorganisms are involved in the inflammatory process at some point. The entrapment of propionibacteria adds to inflammatory processes via a number of mechanisms. Concentrations of powerful hydrolytic enzymes rise to levels at which tissue damage is inevitable. The *P. acnes* genome sequence recently published has demonstrated that the organism produces many more such enzymes than previously thought [103]. Intrafollicular bacteria will also die and lyse *in situ* producing immunologically active intracellular products within the duct. Stress related proteins may increase as a result of the trapped bacteria such as GroEL/HSP60 and DNAκ/HSP70 [104]. It seems plausible that damage to the basement membrane may well ensue, permitting leakage of comedonal contents into the dermis, thereby triggering the adaptive immune response to ductal antigens. The infiltrate around early inflamed

lesions is predominantly comprised of $CD4^+$ T cells and macrophages consistent with a delayed-type hypersensitivity (DTH) reaction [105]. This DTH response may be to an autoantigen or a persistent microbial pathogen. If the dominant antigen is not microbial it may well be that propionibacteria augment the response to the autoantigen by acting as a mitogen [106] or via adjuvant activity [107]. There is also the possibility of cross-reactivity between human and bacterial homologues of stress related proteins.

Recent evidence suggests that antigen-specific responses are secondary to an innate immune reaction which renders healthy-looking follicles in acne-prone skin subclinically inflamed [105]. Microcomedones are absent from these visibly normal-looking follicles. IL-1-α is a key mediator of inflammation and comedogenesis [82,108]; it is not clear what triggers its release from ductal keratinocytes to start the inflammatory cascade. One theory relates to the possible activation of Toll-like receptors either by pathogen-associated molecular patterns (PAMPs) or endogenous ligands. The theory is that *P. acnes* cell walls or a component thereof would act as the PAMP and activate TLR-2 on keratinocytes thereby inducing NF-κB and switching on the production of pro-inflammatory cytokines including IL-1α. *P. acnes* has been shown to activate TLR-2 on keratinocytes [109] and monocytes [110] leading to the production of pro-inflammatory cytokines such as IL-8 and in the case of keratinocytes human-beta-defensin-2 (HBD-2) but significantly not IL-1-α. Other endogenous ligands such as breakdown products of hyaluronan, HBD-2, free fatty acids and heat shock proteins may also activate TLRs on keratinocytes [111,112]. *P. acnes* are not evident in juvenile comedones so this mechanism is not likely to be important as an initial event but may contribute to a second innate response in more established lesions.

The microenvironment within the pilosebaceous unit produced by the bacteria is probably more important than their absolute numbers for the development of acne lesions. *In vitro*, it has been shown that oxygen tension, pH and nutrient supply markedly affect the growth of *P. acnes*, and the bacterial production of active substances such as lipases, proteases, hyaluronate lyase, phosphatase and smooth muscle contracting substances [113–115]. *In vivo*, the pH of blackheads markedly varies between 3.6 and 6.7 [116], and this is likely to affect the bacteria. Oxygen tension is also likely to be important. *Propionibacterium acnes* grows well at low oxygen tensions. In the presence of light at high oxygen concentrations, *P. acnes* grows well, but growth is inhibited because of photodamaging reactions involving excess oxygen and endogenous microbial porphyrins [117]. These factors could determine whether or not a follicle develops into a non-inflamed comedo and, subsequently, into an inflamed lesion.

The role of inflammation in the pathogenesis of acne

The precise sequence of events involved in the initiation, subsequent augmentation and resolution of acne has been a challenge to acne researchers for a number of years.

It was previously thought that hyperproliferation and abnormal differentiation of the ductal keratinocytes initially gave rise to the formation of the microcomedone. It was believed that from the microcomedone further hyperproliferation could occur, leading to accumulation of corneocytes and sebum in the lumen of the intra-follicular duct, so forming a horny plug and developing into a clinically evident comedone. Diffusion of components from the follicle lumen into the dermis with inflammation resulted in the clinically inflamed papule or pustule recognized in acne (Fig. 42.27).

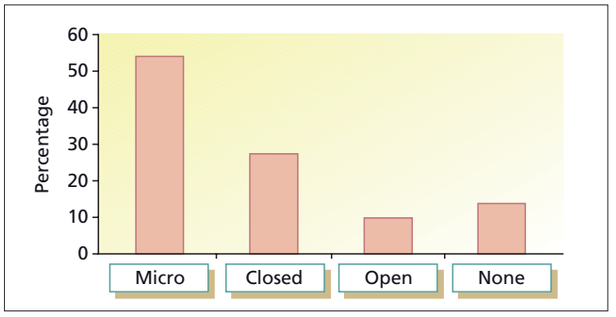

Fig. 42.27 Most, but not all, early inflamed lesions are associated with a microcomedo or clinical comedo.

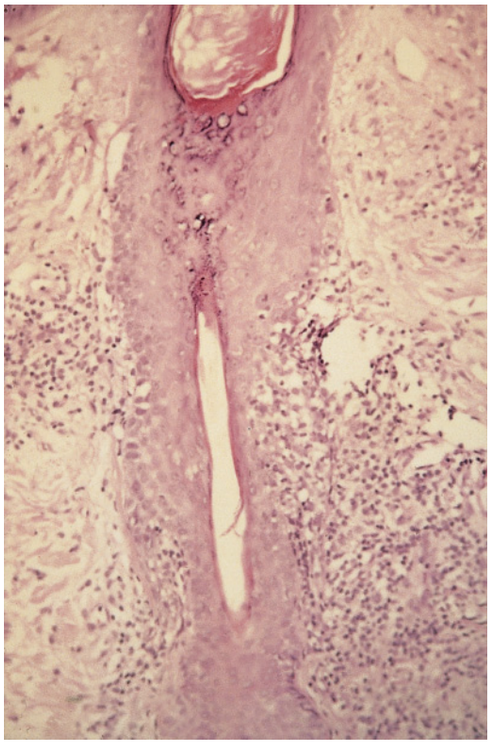

Fig. 42.28 An early inflamed papule (6 h). Note spongiosis and a lymphocytic infiltrate but no obvious rupture of the duct.

However, examination of both non-inflamed and inflamed lesions has led to the conclusion that these are two separate mechanisms affecting the same type of follicle and that many inflamed lesions do not present with a microcomedo within their histological features. Jeremy *et al*. [105] confirmed that inflammation in acne occurs prior to hyperproliferation of the follicular wall (Fig. 42.28). This study demonstrated that inflammation is dominated by $CD4^+$ T helper cells and a macrophage infiltrate, and that these cells were present in clinically normal skin around uninvolved

follicles from acne patients in acne-prone sites. The majority of the T cells were skin homing, memory/effector cells and were abundant in numbers much greater than the level of surveillance T cells found in normal skin. However, macrophage numbers were similar to those of clinically evident inflamed lesions. Despite the increased inflammatory infiltrate, there was no increased amount of cellular HLA-DR expression, suggesting that the cells were not activated. The number of Langerhans' cells in the perifollicular dermis and surrounding epidermis was reduced, indicating migration of these cells to skin-draining lymph nodes. Neutrophils were not observed in the infiltrate, suggesting that the initiation of inflammation by $CD4^+$ T helper cells was a response to antigenic stimulation. The inflammatory processes occurred in the absence of hyperproliferation and abnormal differentiation in the uninvolved follicles which were similar to those of control follicles. This absence of hyperproliferation was supported by the lack of microcomedonal features. In addition, the follicular wall was intact, verified by continuous immunolabelling of laminin and collagen IV along the basement membrane. The data from this study therefore showed that subclinical inflammatory events occur before hyperproliferative events and are the earliest events seen in acne lesion formation.

Transcripts for cytokines IL-12, TNF-β and IFN-γ have been reported as evident in uninvolved follicles from acne prone sites [118]. These cytokines are typically secreted by CD4 type 1 T helper cells which are effectors of the adaptive immune response, suggesting that acne is an inflammatory disorder mediated by a Th1 response.

As outlined previously, there is strong evidence to implicate *P. acnes* as an initiating factor in the adaptive immune response in acne. As the basement membrane of the follicle wall remains intact in uninvolved follicles, a soluble antigen, as yet undiscovered, could be a trigger for inflammation. It is unlikely that *P. acnes* is implicated in this, as the soluble products of *P. acnes* do not stimulate T-cell responses [106]. However, *P. acnes* may be implicated as the lower infra-infundibulum is very thin and the wall consequently very fragile; it could be possible for *P. acnes* to be exposed to Langerhans' cells in this location.

One hypothesis is that linoleic acid, which is known to be deficient in acne, could lead to a change in the integrity of the barrier function within individual follicles [119]. It is possible that the presence of *P. acnes* at this normal point would allow interactions with Langerhans' cells in the follicle wall, which would result in presentation and stimulation of CD4 T helper cells within the skin-draining lymph nodes, and the development of an adaptive immune response.

It is also feasible that inflammation may be driven by an innate immune response. The presence of CD4 memory/effector T cells may be a result of the up-regulation of vascular marker E-selectin which is a receptor for skin homing T-cells, and could result in selective migration of cells into the local tissue.

Interleukin-1-α (IL-1α) could also be an initiating factor, as it can induce the up-regulation of vascular adhesion molecule expression such as ICAM-1, E-selectin and Elam-1. This could result indirectly in monocyte migration into the perifollicular dermis. It is still not clear what factors are responsible for the increase in IL-1-α. The disturbance in barrier function may lead to transepidermal water loss into the follicular lumen so changing the ductal microenvironment, promoting the growth of *P. acnes* and increasing its population. This would lead to a greater opportunity for *P. acnes* and viable keratinocytes to interact in the follicle wall leading to the release of pro-inflammatory cytokines IL-1-α, TNF-γ and granulocyte macrophage colony stimulating factor [104]. In addition, linoleic acid deficiency identified in certain acne follicles [120] can lead to the release of pro-inflammatory cytokines, for example IL-1-α and TNF-γ from epithelial keratinocytes, into the dermis, so stimulating an inflammatory cascade [121].

Leukotriene B4 (LTB4) is a pro-inflammatory mediator synthesized from arachidonic acid. Synthesis of LTB4 is catalysed by 5-lipoxygenase and is increased by inflammatory mediators including complement fragments, TNF-α and interleukins. Leukotriene precursors are synthesized in the sebaceous gland [122]. LTB4 induces recruitment and activation of neutrophils and monocytes. It also stimulates the production of a number of pro-inflammatory cytokines and mediators that augment and prolong tissue inflammation. These events are independent of bacteria. Limited data from pharmacological inhibition studies support a role of LTB4 in the pathogenesis of neutrophil-medicated tissue damage. A preliminary, small-scale clinical study of an oral anti-inflammatory agent that specifically blocks the formation of LTB4 showed a 70% reduction in inflammatory lesions at 3 months in patients with acne [123]. These data support the suggestion that bacterial involvement may not always be necessary for expression of inflammation.

Recent studies have provided new insights into the development of acne lesions and their resolution, and have provided significant evidence for inflammatory events. It would appear that individual sensitivity and tolerance to potential causal antigens, as well as variance in exposure to antigens, may result in differences in the way an individual responds which determine the clinical manifestations. The integrity of the skin and/or ductal barrier function will influence the type of acne lesion that develops. This emphasizes the need to assess clinical lesions carefully, and to tailor medication according to the acne type.

Mechanisms inducing acne scarring

Scarring is a consequence of abnormal resolution or wound healing following the damage that occurs in the sebaceous follicle during acne inflammation (Fig. 42.29).

A cell-mediated immune response has been found to be involved in the inflammatory events in acne; such a response not only contributes to the clearance of antigen but also to tissue damage. Previously, no attention has been paid to the influence that such a response may have on the resolution of acne lesions. The inflammatory response has been implicated as an important component in the development of scars [124]. Holland *et al.* [125] investigated the differences in cell-mediated immune responses in developing and resolving inflamed lesions between those acne patients who were prone to scarring, and those with the same degree of inflamed acne who were not prone to develop scarring. The numbers and activation states of lymphocytes, macrophages and endothelial cells were examined in biopsies of timed inflamed lesions of known duration at less than 6 h, 24 h, 48 h, 72 h and 6/7 days, using standard immunohistochemical methods.

Fig. 42.29 Significant scarring resulting from severe facial acne. (Courtesy of Dr V. Bettoli, University of Ferrara, Italy.)

Clear differences in the cellular infiltrate present in lesions from the two groups of patients were identified. In acne patients who were not prone to scarring, the time course was typical of a type IV delayed hypersensitivity response. In developing lesions there was significant angiogenesis and vascular adhesion molecule expression, with a large influx of activated CD4 T cells, macrophages (CD68) and Langerhans' cells (CD1a). Cell recruitment peaked at 48 h, after which there was a decrease in leukocytes, cellular activation and a return to normal levels of blood vessels and vascular adhesion molecules in resolving lesions. Of the CD4 T cells, 50% were skin homing memory effector cells (CD45RO, CLA) and naïve cells (CD45RA) cells, whilst the remainder were unclassified ($CD45RO^-$, $CD45RA^-$, CLA^-), which suggests that effective resolution occurred by both non-specific/innate and adaptive immune mechanisms.

In lesions from acne patients who were prone to scar, a predominantly adaptive immune response was present, which was persistent and up-regulated in resolving lesions. The number of CD4 T cells was approximately half of those found in lesions of non-scarrers, but a high percentage of these cells were skin homing memory/effector cells, suggesting that these patients were sensitized to the causative antigen(s). In developing lesions, although the numbers of macrophages, blood vessels and vascular adhesion molecules were high and similar to those present in lesions of non-scarrers, the numbers of Langerhans' cells and the level of cellular activation was low, and comparable to levels found in normal skin, indicative of an ineffective response. However, in resolving lesions, there was an up-regulation of the response with greater cellular activation, and a further influx of macrophages and skin homing memory/effector cells. Certainly, the strong macrophage presence represents a dominant force in this response. Thus, it may be interpreted that, in patients prone to scarring, there is a chronic delayed-type hypersensitivity reaction provoked by a persistent antigen which these patients are initially unable to eliminate.

The different inflammatory cell profiles elicited by the two patient groups could explain the different qualities of repair observed. Lymphocytes and macrophages secrete an extensive array of cytokines and growth factors that are known to modulate dermal fibroblast recruitment, proliferation and phenotype, and will affect fibroblast functions such as wound remodelling and contraction, both contributory factors in scarring. This model suggests that the type and magnitude of the inflammatory response in 'resolving' lesions from patients with such a dominant macrophage presence, would lead to abnormal healing and pathological scarring. It is possible that the management of either numbers or activation states of inflammatory cells during the development and resolution stages of acne may help to control scarring.

Resolution of acne

This can be considered in two ways, resolution of individual lesions and resolution of the disease as a whole. The evolution of acne has received considerable attention; its resolution has been largely ignored. Limited studies suggest that the resolution is not related to reduction of sebum production or changes in surface bacteria [97]. The relationships between ductal hypercornification, inflammatory mediators, changes in the host response and resolution are obscure. Pierard [26] has shown that individual sebaceous glands function at different rates in acne patients. Resolution may be associated with specific changes in these acne-prone hypersecreting glands. Resolution of individual lesions could relate to cytokine activity within the pilosebaceous duct. For example, EGF and TGF-α are *in vitro* not only associated with disruption of the follicle but also with inhibition of sebaceous secretion [85]. Could this switch off an acne-prone follicle—albeit temporarily—and convert it into a non-acne-prone follicle?

Biological significance of acne, sebum and *P. acnes*

Activity of the sebaceous glands is unlikely to be essential for healthy skin, because prepubertal skin appears perfect unless severely challenged by soap and water! Yet the ubiquity of both hypersecretion of sebum and the presence of *P. acnes* suggests that their apparent undesirability may be outweighed by some selective advantages: the possible biological role of sebum is discussed above and it has been suggested that *P. acnes*, which enhances immune responses, may provide protection against malignant haematological disease [126], although not against solid tumours [127]. Independent of bacterial colonization, there is now evidence that the sebaceous gland is an immunocompetent organ [128].

Clinical features

Acne is a polymorphic, inflammatory disease of the skin which occurs most commonly on the face (in 99% of cases) (Fig. 42.30) and to a lesser extent on the back (60%) and chest (15%) [1]. Seborrhoea is a frequent and distressing feature [2,3]. The clinical picture can vary from very mild comedonal acne, with or without sparse inflammatory lesions, to aggressive fulminant disease with associated systemic upset.

Non-inflamed lesions are the earliest lesions to develop in younger patients [4] and embrace both open (blackheads) and closed (whiteheads) comedones. Open comedones represent dome-shaped papules in which there are dilated follicular outlets filled with keratin. The apparent black colour is thought to be due to melanin deposited within the cellular debris. Comedones frequently appear in a mid-facial distribution and when evident early in the onset of the disease indicate a poor prognosis [4] (Fig. 42.31). Closed comedones or whiteheads are generally 1 mm in diameter, skin coloured and have no visible follicular opening. These lesions are often inconspicuous and require adequate lighting and stretching of the skin to be seen. Most patients have a mixture of lesions [5].

There are also several subtle subtypes of comedones whose presence may influence response to therapy [6]:

- 'Sandpaper' comedones consist of multiple, very small whiteheads, frequently distributed on the forehead (Fig. 42.32), which produce a roughened, gritty feel to the skin.
- 'Macrocomedones' (Fig. 42.33) are large whiteheads or occasionally blackheads greater than 1 mm in diameter. Both mac-

Fig. 42.31 Midfacial comedones correlate with poor prognosis when present early in the course of the disease.

Fig. 42.32 A patient with sandpaper acne. Note the very small, multiple whiteheads.

Fig. 42.33 Multiple macrocomedones (closed comedones) which are only seen clearly on stretching the skin. (Courtesy of Dr A. Yung, Auckland, New Zealand.)

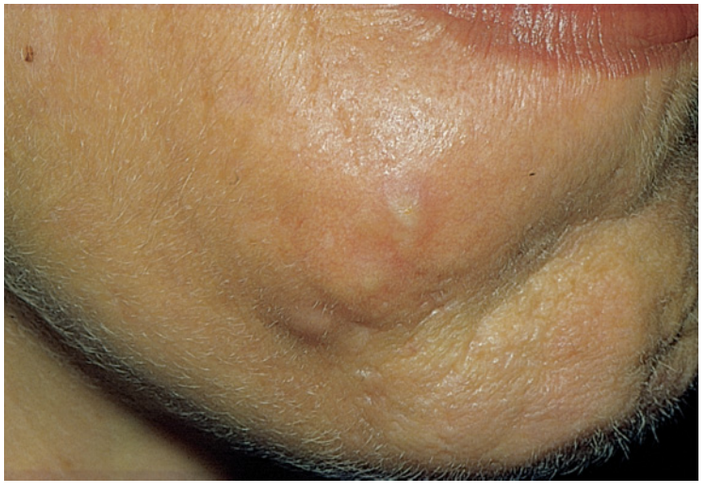

Fig. 42.34 This patient had submarine comedones requiring stretching of the skin in order for them to be detected.

rocomedones and sandpaper comedones respond poorly to conventional topical treatments.

- 'Submarine' comedones are large comedonal structures greater than 0.5 cm in diameter and are resident more deeply in the skin; they are frequently the source of recurrent inflammatory nodular lesions (Fig. 42.34).
- Secondary comedones may be produced after exposure to dioxins (chloracne), pomades (pomade acne), topical steroids and other drugs (drug-induced acne).

Inflammatory lesions arise from the microcomedo or non-inflammatory lesions and can develop into superficial or deep lesions [7]. The superficial lesions are usually papules and pustules (5 mm or less in diameter) (Fig. 42.35), and the deep lesions are deep pustules and nodules (Fig. 42.36). The term nodulo-cystic acne is incorrect. Acne 'cysts' are not true cysts because they are not lined by an epithelium. It is therefore more accurate to describe such lesions as nodules [8].

Fig. 42.35 Multiple superficial papules.

Fig. 42.36 Deep inflammatory nodules.

Nodules are seen more frequently in males and when exudative or haemorrhagic are particularly disfiguring and uncomfortable (Fig. 42.37). Nodules may extend deeply and over large areas showing little surface involvement. Sinus formation (Fig. 42.38) between nodules and/or deep pustules leads to devastating cosmetic effects and inevitable scarring [9,10]. These lesions are frequently very tender, chronic and resistant to treatment and although they usually emerge slowly over a few days, they may occur acutely within a 24-h period. There is usually no obvious reason for an acute episode, although eruptive and severe inflammatory acne has been reported alongside glandular fever [11].

Fig. 42.37 Exudating haemorrhagic lesions.

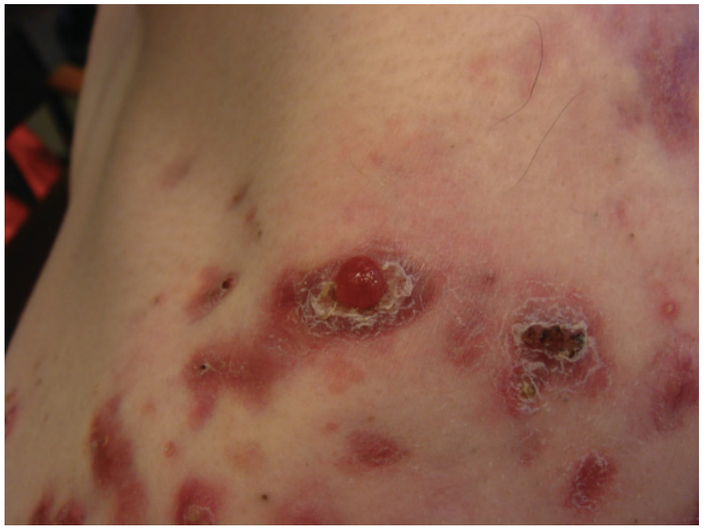

Fig. 42.39 Pyogenic granulomas rarely occur in acne and/or as a result of acne treated with isotretinoin. (Courtesy of Dr V. Bettoli, University of Ferrara, Italy.)

Fig. 42.38 Sinuses and nodules in severe acne. (Courtesy of Dr A. Yung, Auckland, New Zealand.)

Fig. 42.40 Post-acne keloid scar.

Itching is a rare symptom of acne, but may be evident and possibly relates to the release of histamine-like compounds from *P. acnes* [12].

Pyogenic granulomas develop very infrequently [13,14] in patients with very severe disease of the trunk (Fig. 42.39). They can also be precipitated during the early phase of treatment with oral isotretinoin. Inflammatory and haemorrhagic nodules are also a feature of acne conglobata, which is characterized by extensive acne found particularly on the trunk. There are usually many grouped polyporous comedones, which are frequently inflamed and result in scarring. Acne conglobata is characteristically a chronic disorder, and may last up to 40–50 years of age.

Inflammatory macules are often not recognized as a physical sign of acne; these represent regressing lesions that may persist for many weeks and contribute markedly to the general inflammatory appearance [5]. Although the classification of lesions may be helpful in choosing the appropriate management, it must not be forgotten that inflammatory lesions frequently change from one type to another.

Scarring usually follows deep-seated inflammatory lesions, but may also occur as a result of more superficial inflamed lesions in scar-prone patients. Close inspection under a bright light may reveal some scarring, albeit mild, in up to 90% of patients who attend a dermatologist [15]. Scars may show increased collagen (hypertrophic scars and keloids) or be associated with loss of collagen (i.e. ice-pick scars, depressed fibrotic scars, atrophic macules and perifollicular elastolysis). Keloids (Fig. 42.40) by definition extend beyond the extent of original inflammation and are most prevalent on the trunk. Hypertrophic scars in contrast to keloids do not extend beyond the extent of the original inflammation. Atrophic macular scars are frequently multiple, and represent soft distensible lesions. They often retain a vascular hue for many

Fig. 42.41 Ice pick scars on the cheeks. (Courtesy of Dr V. Bettoli, University of Ferrara, Italy.)

Fig. 42.42 Post-inflammatory hyperpigmentation more common in III/IV skin types.

months before becoming white and less conspicuous. Ice-pick scars (Fig. 42.41) are small, jagged, firm atrophic scars, most evident on the cheeks. Ice-pick scarring can result from comedones alone. Perifollicular elastolysis (PFE) is commonly found on the trunk and consists of multiple, follicular, atrophic looking lesions, sometimes seen without evidence of acne [16]. Calcification is a rare complication of scarring [17,18].

Persistent post-inflammatory hyperpigmentation, seen most frequently in pigmented skin (Fig. 42.42) and post-inflammatory erythema are both common and cosmetically disfiguring features of acne. The pigmentary change may take many months to resolve and in some cases can be permanent.

Associated features. Certain diseases that occlude the follicular pores, including hidradenitis suppurativa [19] and dissecting folliculitis (perifolliculitis capitis abscedens et suffodiens) [20], of the scalp may accompany acne, and are classified as the follicular occlusion triad when accompanied by acne conglobata. All conditions have in common a deep, recurrent, chronic folliculitis that results in abscess formation, sinus tract formation and scarring. These diseases are discussed later in this chapter.

Physiological and environmental factors that influence acne

There are many myths about factors that might help or aggravate acne.

Diet

Dietary factors, particularly sweets, chocolate and fat, are frequently regarded by patients and clinicians as a cause or aggravator of acne [1,2]. However, there is still a paucity of scientific evidence to prove a causal relationship between diet and acne. Chocolate has been reported to have no significant influence as a trigger for acne; however, the methodology used in these old studies had significant shortcomings [3–7]. Severe dietary

restriction, resulting in marked weight loss, reduces seborrhoea, but cannot be considered as routine treatment [8]. Acne occurs less frequently in Zambia, Nigeria and Japan [9], where diets differ markedly from those in Western Europe, but the lower incidence could be due to other environmental or genetic factors. A detailed epidemiological study of Kitavan islanders of Papua New Guinea and Aché hunter-gatherers of Paraguay failed to find a single male or female with significant acne [10]. The authors proposed that the absence of acne was due to dietary factors, but these are closed communities in which genetic and environmental factors other than diet must play a very significant part. The authors suggest that the diet in the Western civilization has a high glycaemic index which can lead to hyperinsulinaemia and result in a cascade of endocrine triggers, including increased insulin-like growth factor 1, altered retinoid signalling and increased androgens, thereby mediating acne pathogenesis. These theories would be difficult to test as this would require an experiment such as raising Western children on a strict Papa New Guinea diet.

A further study has demonstrated a correlation between an exacerbation of acne and worsening diet in a group of university students in a pre-examination period. However, the dietary variable was only evaluated by a subjective, self-assessed diet quality measure and the main factor examined was effect of examination stress [11].

The possible effect of nutrition on the age of puberty may be relevant, as acne is more likely after the start of sexual development, and this occurs when the body weight attains about 48 kg [12]. Acne may be an effect of starvation and is seen in patients with anorexia nervosa. Dieting behaviour may be adopted to control acne and this approach has been reported as a risk factor for anorexia nervosa [13]. The trend of increased weight among children and earlier puberty may be reflected in an earlier onset of clinical acne [14].

One study identified a positive association between acne and intake of total milk and skim milk, and suggested that the presence of hormones and bioactive molecules in milk might be linked to this association [15].

A randomized, double-blinded, controlled trial in Australia examined the effect of diet on facial acne in men aged 15 to 25. 27 men who ate a high glycaemic load (HGL) diet were compared with 27 who ate a low glycaemic load (LGL) diet with more complex carbohydrates and protein. Both groups used a mild cleanser to wash and acne medications were avoided during the study. Both groups had fewer acne lesions after 12 weeks but the group taking the LGL diet had significantly fewer lesions. The authors suggest that the LGL diet resulted in less insulin and insulin growth factor production, which theoretically should reduce androgen-mediated acne. However, the LGL diet resulted in significantly more weight reduction than the HGL diet, suggesting that weight loss might be the trigger for this positive effect [16]. There are a number of hypotheses that have been presented in the literature implicating diet in acne pathogenesis [17]. However, to date the debate regarding acne and diet continues, and further robust controlled studies are required to support this concept and provide us with compelling evidence linking nutrition to acnegenesis.

Premenstrual flare

About 70% of women complain of a flare 2–7 days premenstrually [12,14]. It is unlikely that any possible variation in sebum excretion during the menstrual cycle [18] could be substantial enough to explain the flare. Possibly, flaring is related to a premenstrual change in the hydration of the pilosebaceous epithelium [19]. Progesterone and oestrogen also have both pro- and anti-inflammatory effects [20]. Up-regulation of aspects of the inflammatory response would make some teleological sense at this vulnerable time.

Sweating

Up to 15% of acne patients notice that sweating causes a deterioration in their acne, especially if they live or work in a hot humid environment; for example, for a cook, ductal hydration may be the responsible factor [21].

Ultraviolet radiation

Patients and doctors alike accept that natural sunlight often improves acne, but there is no scientific evidence for this belief. The cosmetic effect of tanning may be the entire explanation. Artificial UV radiation appears to be less satisfactory than natural radiation, and psoralen and UVA (PUVA) has been reported to very uncommonly induce acne lesions [22]. Furthermore, UV radiation may enhance the comedogenicity of sebum [23,24].

A recent systematic review examining the direct evidence for a positive effect of sunlight exposure on acne confirmed that evidence was lacking. Although there was some evidence to suggest that various spectra of artificial light may be beneficial this could not be generalized to natural sunlight [25]. Other important considerations for not advocating natural sunlight as treatment for acne relates to the potential long-term sequelae of sun exposure including an increased risk of melanoma and non-melanoma skin cancer, an increased risk of photosensitivity whilst on some acne medications, particularly tetracycline and isotretinoin, and the interesting reported association of acne with decreased risk of melanoma [26].

Occupation

Hydration of the ductal stratum corneum may induce acne in such occupations as catering and steam cleaning. Patients dealing with oil may develop an acneiform oil folliculitis, particularly on their trunks and limbs, but usually need their overalls to be very heavily contaminated. The induction of chloracne by accidental release of halogenated hydrocarbons or other chemicals is discussed elsewhere in this chapter.

Smoking and acne

One cross-sectional study has shown a linear relationship between acne prevalence and the number of cigarettes smoked daily but did include patients over a wide age range [27]. Other studies have not confirmed this association [28,29]. Investigations have revealed that cigarette smoke contains high amounts of arachidonic acid and polycyclic aromatic hydrocarbons, which induce a phospholipasic A2-dependent inflammatory pathway [30]. This effect may further stimulate arachidonic acid synthesis [31]. Smokers have also been shown to have a higher saturated fat and

lower polyunsaturated intake in their diet, principally due to lower linoleic acid intake when compared to non-smokers. [32].

Psychosocial effects of acne

Data from the older literature suggested that it is unlikely that stress alone induces the formation *de novo* of acne lesions [33,34]. However, one study assessed acne grade before and during exams and confirmed that stress can induce acne. In addition, the authors demonstrated that acne itself induces stress, and the 'picking' of spots will aggravate the appearance [35]. This is particularly obvious in young females who present with acne excoriée [36,37]. Corticotrophin-releasing hormone induces the synthesis of sebaceous lipids *in vitro* [38] and adrenocorticotrophic hormone evokes adrenal dehydroepiandrosterone to regulate skin inflammation [39]. These current findings indicate that central [40] or topical stress [31–38] may indeed influence the feedback regulation, thus inducing the development of clinical inflammation in early acne.

There have been many studies over the years investigating the specific psychological effects produced by acne. Studies have shown that many acne patients experience shame (70%), embarrassment and anxiety (63%), lack of confidence (67%), impaired social contact (57%) and a significant problem with unemployment [41,42]. Severe acne may be related to increased anger and anxiety [43]. Clinical depression has been demonstrated in acne patients and the prevalence of active suicidal ideation is higher in acne patients than reported in the general population. Of note, the psychological impairment does not necessarily correlate with the clinical severity of disease [44]. There have been reports of acne patients committing suicide [45].

Appearance is an important factor in social and emotional functioning. Appearance, particularly facial appearance, represents an important aspect of one's perception of body image [46]. From psychosocial research, it is known that physically attractive strangers attribute more positive qualities such as friendliness, intelligence and higher social skill levels to each other, compared with physically unattractive strangers. This effect is strongly reinforced through television commercials and the media, in which a cosmetically acceptable appearance is inherently linked to social success.

Over the last decade, there has been renewed interest in the measurement and identification of disease disability and impact of disease on quality of life; skin disease and acne is no exception. Questionnaires including disease specific, dermatology specific, general health and utility measures have been developed.

Several groups have developed simple questionnaires to better understand the impact of acne in inducing anxiety, depression and impaired quality of life. These questionnaires are very helpful; they take only a few minutes for the patient to complete and assist the physician in quantifying the psychological and social effects of the disease and allow an appreciation of the overall response to therapy. Combinations of generic and dermatology-specific questionnaires are available and have been used with these aims in mind [47–61].

General health measures assess a variety of diseases and include the Sickness Impact Form (SIP) [62], the Short-Form 36 (SF-36) [63] and the General Health Questionnaire (GHQ). These tools have been used in acne and allow comparison between skin diseases and a spectrum of other diseases. The Dermatology Life Quality Index (DLQI) represents a specific measure of disability in skin disease and provides a comprehensive and practical way of assessing the impact of skin disease [57]. Disease-specific questionnaires that relate specifically to acne include the Cardiff Acne Disability Index (CADI), the Assessment of the Psychosocial Effects of Acne (APSEA) from Leeds and the Acne Quality of Life Scale (Acne-QOL) [52,57]. Utility measures assess the hypothetical value that people place on their health. Values may be expressed in financial ways or time frames, for example how much would a patient pay to cure their disease?

Comparisons with other chronic illnesses have shown that acne patients have levels of social, psychological and emotional disability that are similar to those reported by patients with 'more serious' diseases such as asthma, epilepsy, diabetes or arthritis [61]. Acne also affects functional abilities. Patients are prone to embarrassment and social withdrawal, depression, anxiety and anger. There are still many misconceptions held about acne in different communities and cultures and younger acne patients are subject to bullying, teasing and stigmatization from their peers.

The use of quality of life and psychosocial questionnaires is essential to adequately understand just how the disease is affecting a patient, and can aid in assessing the efficacy of therapy. Newton *et al.* [62] demonstrated in 111 patients that treatment with oral isotretinoin or combined oral and topical antibiotics subsequently improved quality of life. Similarly, Kellett and Gawkrodger demonstrated significant psychological and emotional effects of acne which improved with oral isotretinoin [63].

Differential diagnosis

Acne is rarely misdiagnosed. The commonest mistaken diagnosis is rosacea, which occurs in older patients and lacks comedones, nodules, cysts or scarring. The presence of facial flushing and specific triggers, including heat, spicy food or alcohol, may indicate rosacea. Rosacea patients may also have ocular involvement, but rarely have truncal lesions. Some patients appear to have features of both diseases and clinical acne may evolve into more typical rosacea later in life.

In females, confusion with perioral dermatitis is possible, but in these patients the lesions itch, the skin is dry and there are no comedones.

Whiteheads (closed comedones) may be confused with milia. Milia represent subepidermal keratin cysts predominantly infraorbital in distribution. They are very common and can occur in association with, although unrelated to, acne.

Folliculitis due to Gram-negative organisms can complicate acne therapy [1], and rarely *Candida* or *S. epidermidis* folliculitis may present as multiple pustules. Demodex folliculitis can also

Fig. 42.43 Acne and keratosis pilaris coexisting on the upper arms.

Fig. 42.44 Typical distribution of *Pityrosporum* folliculitis.

present as non-responsive acne. Plane warts, particularly on the face, can also cause confusion, as can pseudofolliculitis barbae.

Acne may occur on the limbs but occasionally inflammatory keratosis pilaris may coincide or masquerade as acne (Fig. 42.43).

Pityrosporum folliculitis presents on the upper trunk as moderately ill-defined, superficial plaques, among which are scattered many papules or pustules (Fig. 42.44). It is likely, but unproven, to be a host reaction to *M. furfur*, which is a normal skin commensal [2–4].

Rarely, dermatitis herpetiformis may present as a vesicular pustular facial eruption, but it is usually very itchy unlike acne. Linear IgA disease can also present very uncommonly as a papular facial rash without comedones. Biopsy, including immunofluorescence studies, is essential to confirm diagnosis.

Rare diseases that may produce diagnostic difficulties include acne agminata (granulomatous rosacea) and tuberous sclerosis.

Fig. 42.45 A persistent 'acne nodule' due to a dental sinus.

Acne agminata presents as an asymptomatic papulopustular eruption. The lesions are light-brown in colour (somewhat darker in black skin) and on diascopy may reveal an apple jelly colour. There are reports of successful treatment with steroids and isotretinoin in the literature [5,6]. Tuberous sclerosis lesions are relatively monomorphic papules, often with a brownish appearance.

Micropapular sarcoid of the face can occur, and one case report attributed its appearance to selective perifollicular absorption of oils present in certain bubble gums [7].

The severe papulopustular eruption associated with zinc deficiency can be mistaken for marked acne, and several cases have been reported after prolonged intravenous feeding without zinc supplementation [8].

Acne necrotica (varioliformis) is associated with itching and smallpox-like scars, usually on the trunk. Biopsy shows a necrotizing lymphocytic folliculitis [9]. It can be mistaken for severe acne excoriée, but the response to isotretinoin can be excellent [10].

Behçet's disease may produce an acneiform eruption. A dental sinus can be confused with a persistent facial acne nodule (Fig. 42.45). Epidermoid cysts may become inflamed and be mistaken for acne nodules. Of course, acne may coexist alongside one of these alternative diagnoses.

Acneiform drug eruptions are discussed in this chapter and in Chapter 75.

Acne scarring can mimic scarring due to hydroa vacciniforme, ulerytherma oophryogenes, acne keloidalis [11,12], varioliform atrophy and porphyria cutanea tarda.

Treatment

General principles of acne treatment

Acne management aims to alleviate symptoms, clear existing lesions, limit disease activity so preventing new lesions and scars developing, and avoid negative impact on quality of life. Successful management of acne is dependent on detailed patient discussion and education, and should include a comprehensive assessment including personal and family history, a record of present and previous therapies and response to these treatments, careful physical examination and psychosocial review. Selection of treatment must take into consideration a strategy that the patient can adhere to [1–3]. The cause of the acne should be discussed, as should the goals and expected outcome; patient expectation should also be discussed. Patient leaflets are a very valuable tool. Most cases of acne clear spontaneously as the patient matures through adolescence into adulthood; however, even mild cases can persist for 4–6 years and in severe cases the natural history could be in excess of 12 years. Patients should be reassured that there are treatments available that can significantly limit the disease duration, but should be informed that response is slow and resolution is directly linked to good adherence.

Outcome measures

The severity of clinical acne is assessed visually according to the extent of disease and number of lesions. There are a number of outcome measures that have been utilized in the literature but they can be divided in the main into grading or counting. The evaluation can be further divided into: (i) overall or 'global' assessment; (ii) separate evaluations of individual lesions, for example comedones, papules, pustules, nodules; and/or (iii) evaluation according to the predominant lesion type, that is inflammatory or non-inflammatory.

In the clinic environment, global grading is very useful when assessing. A grading scale similar to that shown in Figs 42.46–42.49 is recommended. Good lighting for examination is essential. The acne can be graded on a scale of 0 to 10 on the face, back and chest. Little practice is required to become reasonably proficient and produce consistent assessments from one time frame to another [4].

Lesion counts are essential for clinical trials but not practical for use in the day-to-day clinic [5]. Other important outcome measures that should be considered in assessment of therapy include patient satisfaction, speed of action and adherence to therapeutic regime, tolerability and adverse effects of therapy, evidence of scarring and impact or changes in quality of life measures.

Fig. 42.46 Mild acne.

Fig. 42.47 Mild to moderate acne.

Choice of therapy

This is largely determined by the severity and extent of the disease but should be tempered by a number of other factors including duration of disease, response to treatments, predisposition to

Fig. 42.48 Moderate acne.

Fig. 42.49 Severe acne.

scarring, post-inflammatory erythema and pigmentation, as well as patient preference and cost. By adopting this approach treatment can be tailored to an individual patient [3].

Patients with mild acne usually receive topical therapy alone; patients with moderate acne receive oral and topical therapies; patients with more severe acne should be started on systemic antibiotic therapy but the need to commence oral isotretinoin should be considered early in the course of their disease and may well be used first line in those patients demonstrating poor prognostic factors which are associated with more severe disease, as outlined in Table 42.5 [6].

Table 42.5 Poor prognostic factors in acne.

Family history
Early onset:
mild facial comedones
early and more severe sebum production
early onset relative to menarche
Hyperseborrhoea
Site of acne:
truncal
Scarring
Persistent

Treatment selection should also be based on a logical understanding of the pathophysiology of acne and impact of therapies on these aetiological factors. A panel of experts with an interest in acne has put together an algorithm based on evidence, where available, and expert opinion in an attempt to improve outcomes in acne, as outlined in Table 42.6.

Topical acne therapies

No single topical agent is able to impact on all of the main aetiological factors implicated in acne pathogenesis and no one agent has a significant sebosuppressive effect (Table 42.7).

The most widely used topical drugs are benzoyl peroxide (BPO), retinoids, antibiotics and azelaic acid, either as monotherapy or in combinations [7–9]. Up until recent years it was suggested that topical retinoids should be limited to the treatment of comedonal lesions because of potential to aggravate inflammatory acne. It has now been shown that topical retinoids have some anti-inflammatory activity and also impact on the microcomedo, which represents the precursor of non-inflammatory and inflammatory lesions [1,7]. As a result of these findings, topical retinoids are now ideally combined with antimicrobials and should be considered in treating acne from the onset of acne management. Topical BPO, antibiotics or azelaic acid have predominantly anti-inflammatory activity in acne and can be used safely in combination with topical retinoids, with the exception of tretinoin which is inactivated if used simultaneously with BPO.

Topical retinoids

Retinoic acid (vitamin A acid) is available in 0.01 up to 0.05% concentrations as either a gel or a cream [10–14]. A newer formulation, the so-called microsponge or polymer formulation, is said to be less irritant than original formulations [11–13]. Isotretinoin 0.05% gel is a second-generation retinoid similar in efficacy to benzoyl peroxide [15] and topical tretinoin [16]. A third-generation retinoid, adapalene 0.1% cream or gel, has significant and rapid anti-inflammatory action and has a greater benefit/risk ratio than tretinoin [17–21]. In the USA and a few other countries, there

is a fourth-generation retinoid on prescription for acne called tazarotene [22,23].

Vitamin A acid and other retinoids reduce abnormal growth and development of keratinocytes within the pilosebaceous duct. The reversal of hypercornification within the follicular canal as well as the induction of the follicular epithelium helps to 'unplug' the follicle [24]. This also inhibits development of the microcomedo and non-inflamed lesions resulting in less-anaerobic conditions with fewer *P. acnes*, making the microenvironment less favourable for the development of inflammation. In addition, some of the novel retinoids reduce rupture of the comedones into surrounding skin which results in less inflammation [9,25,26]. Tretinoin binds to cytosolic retinoid acid-binding protein (RAR) with high affinity, but adapalene does not bind at all. Tretinoin has high affinity for all nuclear receptors, but adapalene has selective affinity for RAR-α and RAR-β [27]. Some of the actions are receptor modulated. Adapalene also has anti-inflammatory actions, notably against leukotriene [28]. *In vitro*, adapalene and tretinoin down-regulate TLR2 expression and function, which in turn influences the production of pro-inflammatory cytokines [29–33]. These studies concluded that 0.1% adapalene and 0.025% tretinoin are equally effective against total lesion count, with adapalene demonstrating greater activity at 1 week. Percentage reductions in non-inflammatory lesions reached up to 83% with both products at 12 weeks and inflammatory lesions were reduced by up to 70%. Higher concentrations of adapalene were more effective but associated with more irritancy and erythema. All current studies demonstrate that 0.1% adapalene causes less irritation than 0.025% tretinoin but that the rate of irritancy of both agents increases with higher concentrations. The active comedolytic and anti-inflammatory effects of topical retinoids supports their use in the treatment of mild acne and their activity on the microcomedo, recognized as the precursor to non-inflammatory and inflammatory lesions, suggests that they should also be used in moderate to severe acne along with topical and oral antimicrobial therapy. BPO inactivates tretinoin so the two agents should be alternated morning and evening and not used simultaneously. As local irritancy is a recognized adverse effect of all topical retinoids, they should be commenced at lower concentration and duration of application should be gradually increased as tolerated. Due to

potential photosensitivity, topical retinoids are ideally applied in the evening.

Few comparative data for retinoids against other agents are available; studies comparing tretinoin versus BPO are equivocal and confirm a similar side effect profile [34–37]. Isotretinoin 0.05% was less effective in reducing inflammatory and non-inflammatory lesions than 5% BPO and slower to resolve inflammatory lesions in one study [15]. A four-arm, randomized, controlled study of a novel retinoid/BPO combination product available in some countries comparing a once daily application of the combination product 0.1% adapalene plus 2.5% BPO, against 0.1% adapalene or 2.5% BPO as monotherapy or vehicle for inflammatory acne demonstrated that the combination product is superior with a success rate of 27.5% clear or nearly clear against 15.4% for BPO, 15.5% for adapalene and 9.9% for vehicle [37]. This suggests that adapalene 0.1% has similar efficacy to 2.5% BPO in inflammatory acne. Some formulations are available over-the-counter in a number of countries.

Benzoyl peroxide (BPO)

BPO is currently available in a number of different formulations and concentrations (2.5%, 5% and 10%) either alone or in combination with imidazole, hydroxyquinolone, glycolic acid, zinc lactate and in some countries adapalene 0.1% [38–42]. Some formulations are available over-the-counter. BPO is a powerful antimicrobial [40,43] and rapidly destroys both surface and ductal *P. acnes* and yeasts [43]. The lipophilic nature of BPO allows it to penetrate the pilosebaceous duct. Once applied to the skin it decomposes to release free oxygen radicals with potent bactericidal activity in the sebaceous follicles and anti-inflammatory action [32,43,44]. BPO has only mild comedolytic activity but has been shown in randomized controlled trials to reduce the number of non-inflamed lesions [15,34,45,46] by decreasing follicular hyperkeratosis [47]. It does not impact on sebum production [48,49].

Four randomized, controlled trials have examined different concentrations of BPO [34,50–53] and no evidence to date supports a dose–response effect but potential adverse effects, including irritancy and bleaching, are increased with the 10% concentration [34]. A number of randomized, controlled trials have examined BPO combination with antibiotics against the topical antibiotic (clindamycin, erythromycin, meclocycline and metronidazole) alone and found the combination preparations have superior activity to monotherapy against inflammatory and non-inflammatory lesions [53–56]. In studies in which BPO was used as the comparator monotherapy, results were equivocal with some studies suggesting better efficacy with combination treatments and others demonstrating no difference [53–55,57]. BPO combined with 3% erythromycin has greater activity against *P. acnes* and results in better efficacy than 3% erythromycin alone [58].

One randomized, controlled trial demonstrated similar efficacy with 5% BPO when compared to oral tetracycline and minocycline in mild to mild–moderate acne and found it to be extremely cost effective [45]. BPO washes 6–10% may offer a useful approach in patients also utilizing antibiotics for acne as they have the potential to act against fully sensitive bacteria and reduce antibiotic resistant strains of propionibacteria.

Topical antibiotics

Topical antibiotics used in the treatment of acne include clindamycin, erythromycin and tetracycline [59–64]. They are used in concentrations of 1–4%, usually in a cream or lotion base. Topical antibiotics have some effect on the non-inflamed lesions by reducing perifollicular lymphocytes which are involved in comedogenesis [1,9]. They also significantly reduce numbers and function of *P. acnes* [65–67]. Some topical antibiotics also have a direct anti-inflammatory action via an antioxidant effect on leukocytes [68].

A number of randomized, controlled trials have investigated these topical antibiotics against their vehicle [45,69–79]. Most studies used twice daily applications and most were statistically underpowered to conclusively determine differences between the active agent and their vehicle. However, in the larger randomized, controlled trials 55–60% reduction in mean inflammatory lesion count was demonstrated at 12 weeks with little impact on non-inflammatory lesions [32]. Topical clindamycin has been compared to topical erythromycin in mild to severe acne [80–84] with no overall consistent differences in clinical outcome. However, overall improvement in severity has been demonstrated with topical clindamycin when compared to topical tetracycline [85,86]. Combinations of erythromycin with zinc or benzoyl peroxide are superior to single therapies [63,64,87,88]. A randomized controlled trial comparing combination product clindamycin/BPO with zinc/BPO did not show any convincing clinical benefit of one product over another at 12 weeks [89].

Two systematic reviews examining acne management have identified comparative data on the use of oral versus topical antibiotics [32,90]. Other randomized controlled trials have studied the difference between the different routes of administration [57,91–93]. It is clear that oral antibiotics have a delayed onset of activity so shorter studies may bias the study in favour of the topical agent [94]. Many of these studies were underpowered and/or too short making it difficult to draw definitive conclusions. A detailed analysis of 144 clinical trials of topical antimicrobial therapy rejected over 50% because of poor trial design [95]. Adequate conclusions could not be drawn from the remaining data because of the different protocols, but BPO emerged as a successful treatment and was probably similar in effectiveness to topical erythromycin and clindamycin, with topical tetracycline being the least effective. The clinical benefit of topical 3% erythromycin can be improved by combining it with either zinc or 5% benzoyl peroxide [63,64,87,96–98].

One large, randomized, controlled trial in a community care setting showed that topical Benzamycin® and its components given separately (erythromycin and 5% benzoyl peroxide) were more effective than oral tetracycline and minocycline [45].

There has been an alarming increase in worldwide resistance of *P. acnes* to antibiotics [99–102]. There is evidence to show some correlation between *P. acnes* resistance and clinical improvement and with erythromycin clinical failure [45,100,103]. However, the association between colonization and antibiotic resistant strains is complex and it is important to recognize that even if some specific antibiotic resistant strain of *P. acnes* is reported microbiologically it does not necessarily mean that the acne will be clinically resistant to this antibiotic. If the concentration of the antibiotic at the relevant skin site is equal to or greater than the minimal inhibitory

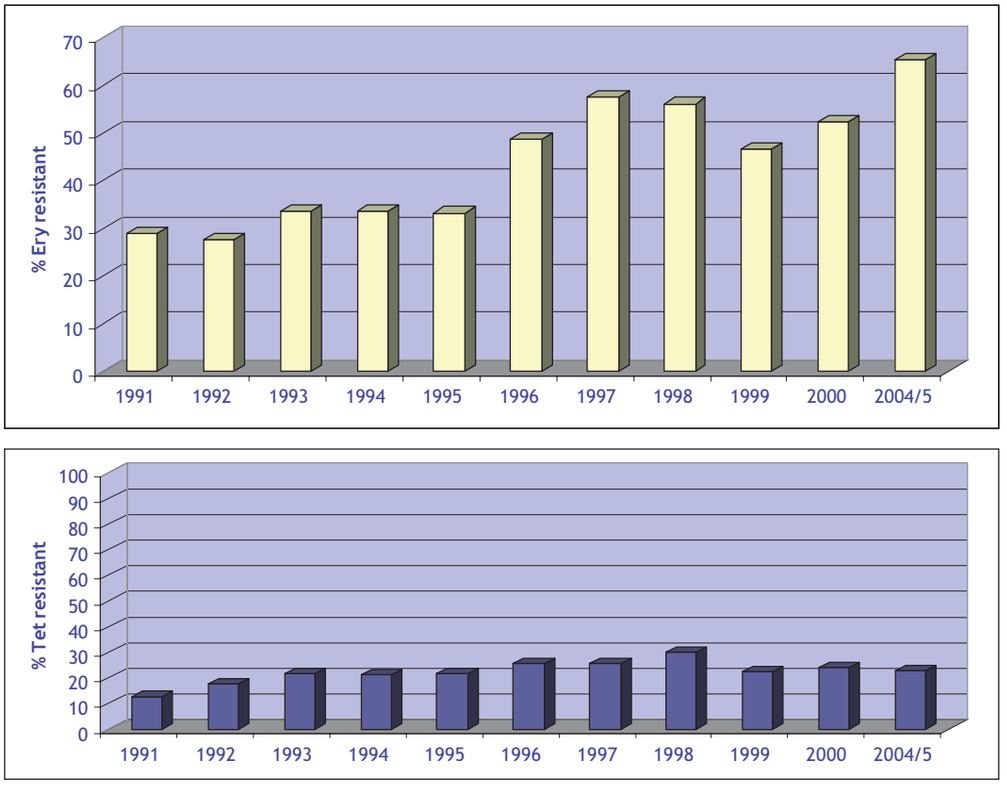

Fig. 42.50 Increase in the prevalence of erythromycin and tetracycline resistant *Propionibacterium acnes* in Leeds, UK. (Courtesy of Dr A. Eady and Dr J. Cove, Department of Microbiology, University of Leeds, UK.)

Table 42.8 Reasons to suspect possible resistance to oral and/or topical antibiotic therapy.

Reasons to suspect possible antibiotic-resistant *P. acnes*	Comments
Failure to respond to antibiotic therapy	Confirm good compliance
Deterioration in acne despite continuing antibiotic therapy	Patients often confirm initial good results
History of poor compliance	This will lend itself to resistance emerging
Multiple courses of oral and topical antibiotics	Particularly when used as monotherapy

Table 42.9 Strategies to avoid antibiotic resistant propionibacteria emerging. (Courtesy of Dr A. Eady, Department of Microbiology, Leeds University, UK.)

Strategy to avoid propionibacterial resistance emerging	Comments
Avoid inappropriate use of topical and systemic antibiotics	Use oral antibiotics for 3 months in the first instance and only continue if clinical improvement continues
If extending the duration of oral antibiotics utilize combination therapy	Combine with an agent that reduces the likelihood of promoting antibiotic propionibacterial resistance e.g. benzoyl peroxide
If repeated courses of antibiotics are required and the initial clinical response was favourable, re-use the same drug	This will avoid multiple resistant strains emerging
Avoid prescribing different oral and topical antibiotics concomitantly	This will avoid multiple resistant strains emerging
Consider using topical retinoids and non-antibiotic antimicrobials wherever possible	These do not promote resistant isolates and when used with antibiotics may achieve more rapid efficacy so reduce the duration of the antibiotic course
Topical benzoyl peroxide (BPO) can be used for 7 days between antibiotic courses	BPO is fully active against sensitive and resistant strains of *P. acnes* and able to eradicate resistant isolates
Remember to check medical adherence	Poor adherence to antibiotic therapies promotes resistance

concentration (MIC) of this *P. acnes* strain, the patient will be clinically responsive. In addition, many antibiotics with antiacne properties achieve efficacy via anti-inflammatory mechanisms of action [104], which can offset problems with antibiotic resistance.

A Health Technology Assessment conducted between 1998 and 2000 in general practice in the UK identified 18% of acne patients with tetracycline-resistant strains of *P. acnes*, 47% with erythromycin-resistant and 41% with clindamycin-resistant strains [45]. Up to 61% of patients referred to specialist acne clinics in Leeds, UK, had resistant *P. acnes* (Fig. 42.50). Resistance is most frequently seen to erythromycin and clindamycin. Resistance to more than one antibiotic is seen in 18% of patients. Table 42.8 outlines possible reasons to suspect resistance to antibiotic therapies. Antibiotic prescribing policies have been advocated in an attempt to control/reduce the levels of resistance (Table 42.9) [105,106].

A systematic review examined the results from clinical trials investigating the use of topical erythromycin and clindamycin for inflammatory acne to establish whether or not there has been a decrease in efficacy since their introduction in the mid 1970s. In 50 eligible trials identified, a gradual reduction in the efficacy of topical erythromycin was identified whilst the efficacy of clindamycin over the same time frame remained stable. The authors postulated that the reduced efficacy of erythromycin probably related to the development of antibiotic resistant propionibacteria [107]. Greater numbers of resistant *P. acnes* have been demonstrated on the skin of close contacts of acne patients using antibiotics compared with controls [108]. In addition clinicians working within the field of acne harbour significantly more resistant propionibacteria than clinicians working in an environment unrelated to acne. Given the fact that the resistance is due to a mutant gene [109], it is likely that *P. acnes* resistance is going to last for many years. BPO is fully active against sensitive and resistant strains of *P. acnes* and combining topical BPO with oral antibiotics or topical erythromycin results in less resistance both *in vitro* and *in vivo* [110].

Azelaic acid

Azaleic acid (1:2 heptanedicarboxylic acid) is available as a 20% cream for acne [111,112]. It is not sebosuppressive and has been reported to reduce the numbers and function of *P. acnes* [113,114], but recent studies have thrown doubt on this observation. Azelaic acid reduces comedones by normalizing the disturbed terminal differentiation of keratinocytes in the follicle infundibulum [115]. A direct anti-inflammatory effect has been demonstrated [116].

A number of randomized controlled trials have compared azelaic acid to placebo, vehicle, BPO, tretinoin and 2% erythromycin [117–121]. In mild to moderate papulopustular acne the studies would suggest that 20% azelaic acid has similar efficacy to 5% BPO, 0.05% tretinoin and 2% topical erythromycin at 5–6 months, with reductions in inflammatory lesions of up to 84%. In comedonal acne 20% azelaic acid had similar activity to 0.05% topical isotretinoin with approximately 80% reduction in comedonal lesion counts at 6 months [119]. Clinical experience with azelaic acid has not delivered the improvement suggested by the original clinical trials.

Topical nicotinamide

Topical nicotinamide 4% has anti-inflammatory actions and does not induce *P. acnes* resistance [122,123]. Double-blind studies have shown it to be better than the vehicle alone against inflamed lesions, although the improvement with the placebo was considerable (32–76%) [124]. A comparison of 4% nicotinamide gel demonstrated it to be similar in efficiency to 1% clindamycin gel [125].

Salicyclic acid

2% Salicylic acid has been shown to be more effective in reducing non-inflammatory and inflammatory acne lesions than alcoholic vehicle at 12 weeks in a randomized controlled trial [126,127].

Topical dapsone

Topical dapsone 5% gel has been shown in two placebo-controlled trials to improve acne severity better than vehicle in the magnitude of 40.8% success for the active preparation compared with 32.8% for vehicle [123,128,129]. Comparative studies against other active agents are required to assess the potential benefit of this novel preparation.

Other topical therapies for acne

The efficacy of other topical treatments has not been established by controlled studies.

- **Sulphur**: a long-standing antiacne therapy, which may be both comedogenic and comedolytic [130–132]. Sulphur is unpopular because of its smell, and is rarely used.
- **Resorcin**: the many formulations of resorcin appear to be totally ineffective [133].
- **Steroids**: a few topical preparations contain weak corticosteroids but proof of their efficacy is lacking. Potent steroids such as clobetasol propionate (Dermovate®) applied twice a day for 5 days can dramatically reduce the inflammation in an active inflammatory nodule [134].
- **Complementary therapies**: data have been published on the potential value of traditional 'herbal' medicines from the eastern hemisphere. So far the clinical benefits of certain plant alkaloids have not been established [135]. A recent systematic review of randomized clinical trials examining tea tree oil (TTO) in dermatological conditions, including acne, concluded there was no compelling evidence to demonstrate that TTO is efficacious in any dermatological conditions, however there were some promising data suggesting that TTO might be effective for acne and further investigation was advocated [136]. A further review examined the empirical evidence for the efficacy of complementary therapies in acne and concluded that many of the therapies were biologically plausible but in general poor methodology had been used in studies. The authors concluded that further rigorously conducted trials were required to define efficacy and adverse effect profiles of currently used complementary therapies for acne [137]. It is very important that all new treatments are validated for safety and efficacy against standard medicines before their release to patients.

Selecting topical therapy

Patients with mixed lesions should be prescribed therapy active against comedones, inflammatory lesions and microcomedones from the outset. Given the fact that the microcomedo is the precursor to inflammatory and non-inflammatory lesions, even patients with predominantly inflammatory acne should be prescribed a topical retinoid as part of their regimen [9]. Topical therapy should be prescribed alone for mild acne, in conjunction with appropriate oral acne therapy for moderate acne, and as maintenance therapy after oral therapy has stopped.

Topical therapy may be necessary for many years. It is also important to stress to the patient that topical therapy should be applied to all areas of skin within the active site and not just visible lesions as clinically normal looking skin in an acne-prone site is likely to have many evolving microcomedones. The concept of acne prevention must be stressed to the patient.

In conclusion, combined topical therapies should be used for patients with mild inflammatory acne. Topical retinoids have anti-inflammatory and comedolytic activity which makes them suitable for treatment of comedonal and mild to moderate inflammatory disease and they should therefore be used at the onset of treatment combined with topical or oral antimicrobials. Topical retinoids are also advocated in conjunction with oral antibiotics in patients with moderate and severe acne [1,9] and as maintenance treatment after cessation of systemic treatment [1,9]. Selecting therapies that work synergistically and impact on as many aetiological factors as possible will enhance treatment success. Products that combine preparations should in theory be more convenient for patients to use and so aid adherence [3].

Oral therapy

Systemic therapy for the treatment of acne includes antibiotics, hormones, isotretinoin and, occasionally, steroids [1]. Other drugs such as dapsone [2], clofazimine and vitamin A acid (10–20 mg/day) [3] are occasionally used but evidence to support their effectiveness is limited. Oral zinc has also been advocated in acne management and is discussed later on in this section.

Oral antibiotics

Oral antibiotics are the most widely prescribed agents in acne and are indicated for severe acne, moderate facial acne not responding to topical therapies and/or extensive truncal acne.

Cyclines (tetracycline, oxytetracycline, doxycycline, lymecycline, minocycline) have excellent efficacy and are the antibiotics of choice [4–10]. The second generation cyclines may aid adherence and of these lymecycline and doxycycline should be used in preference to minocycline [11]. Macrolide (erythromycin, azithro-

mycin or clindamycin) prescribing for acne has increasingly fallen out of favour due to the emergence of antibiotic-resistant strains of *P. acnes* in line with extensive erythromycin usage in the past [11,12]. Erythromycin remains the preferred option in female patients who are, or might become, pregnant or are breastfeeding [13] and in children varying from 8 to 12 years (depending on national licences) when tetracylines are contraindicated due to potential musculoskeletal problems and discoloration of dentition.

Clindamycin is highly lipophilic and very effective in acne but adverse effects including diarrhoea seen in 5–20% of cases and potential pseudomembranous colitis from overgrowth of *Clostridium difficile* have rightly discouraged prescribers from using it [14,15].

Oral azithromycin has been reported to be effective for acne in four open and two investigator-blinded trials. Regimens have varied but intermittent dosing schedules have been advocated (250 mg three times a week) due to the long half-life of 68 h [16,17]. As azithromycin is commonly used to treat a variety of systemic infections its use should also be restricted and discouraged in acne. This philosophy should also apply to cephalosporins and fluoroquinolones although there are documented cases of acne that have improved with these agents [16]. Exceptions to this rule may include short-term use for extremely refractory disease and/or evidence of Gram-negative folliculitis where other agents are not acceptable.

Trimethoprim (400–600 mg/day) has similar efficacy to tetracycline [18] but does not have a licence for acne and is reserved as a third-line antibiotic for acne or for cases where there is proven resistance to other agents. It has been used successfully in cases that have become refractory to first or second-line antibiotics over time [19–21]. Trimethoprim may also be used in young patients in whom tetracyclines are contraindicated. However, as trimethoprim is used for treatment of some potentially serious cutaneous and systemic infections, such as those caused by CA-MRSA, it is advisable to limit use to selected cases [21].

Response to systemic antibiotics is variable. Young males with marked seborrhoea and truncal acne respond less well than females with purely facial acne [10]. Patients who require antibiotics should be given 1 g/day of tetracycline or where indicated erythromycin in divided doses [22]. There is no evidence to support the need for this to be four times a day. The major disadvantage of tetracycline is the prerequisite for it to be taken half an hour before food and not with milk to avoid reduced absorption [23]. Second-generation tetracyclines, doxycycline, lymecycline or minocycline, are less likely to be affected by food [24–26] and can be taken once daily, which may enhance patient adherence. The perception that they are more active as a result of their lipophilicity resulting in greater concentration within the pilosebaceous duct is not supported with good evidence. Table 42.10 outlines dosage regimens for systemic antibiotics recommended for the treatment of acne and considers potential adverse effects.

Many systematic reviews and publications have failed to find any evidence to suggest that there are any clinical benefits between any of the tetracycline antibiotics. In the Western world, minocycline is used very extensively. This may in part have resulted from claims that antibiotic-resistant *P. acnes* is less likely to emerge with minocycline use. However, with the increased use of minocycline there has been an increased trend of minocycline-resistant *P. acnes* emerging [27–30]. A Cochrane review published in 2003 found no evidence to suggest that minocycline should be prescribed in preference to other tetracyclines [31]. Other reviews have confirmed that minocycline should not be used as first-line therapy [32,33]. There are many studies examining the efficacy of individual antibiotics against placebo; however, the methodology and quality of these studies is poor and very few compare one active agent with another. A large randomized, controlled trial conducted in UK community practice demonstrated that oral minocycline and oral tetracycline were of similar efficacy to each other and comparable in terms of efficacy to topical BPO. Hence, given the cost and the increased side-effect profile of oral minocycline, minocycline should not be the first choice of oral antibiotic therapy in acne [34].

Table 42.10 Systemic antibiotics in the treatment of acne vulgaris: dosage and adverse effects.

Antibiotic tetracyclines	Dosage	Adverse effects
Oxytetracycline	500 mg twice daily half hour pre food and not with milk; makes adherence to medication problematic for some	Common: GI upset Rare: onycholysis, photosensitivity, benign intracranial hypertension
Lymecycline (not available in the USA)	300–600 mg daily	As oxytetracycline but tolerated better
Doxycycline	100–200 mg daily	As oxytetracycline Photosensitivity (dose dependent)
Minocycline	100–200 mg daily	Rare but serious: headaches and dizziness associated with benign intracranial hypertension, pigmentary changes, autoimmune hepatitis/LE-like syndrome
Erythromycin	500 mg twice daily	Common: GI upset, nausea, diarrhoea
Trimethoprim	200–300 mg twice daily	Maculopapular rash Rare: hepatic/renal toxicity/agranulocytosis

How long and what dose?

A number of publications have proposed how antibiotics should be administered to achieve optimal therapeutic response whilst avoiding antibiotic resistance [11]. Suggestions include restricting the duration of antibiotics, use of combination regimens from the onset of therapy to expedite response and reduce duration of antibiotic courses, utilization of benzoyl peroxide either to reduce the emergence or to treat antibiotic resistant strains of *P. acnes* and avoidance of using chemically dissimilar antibiotics and regular switching of antibiotics. The question of how long antibiotics should be given in acne has not been adequately researched

in randomized, controlled trials and recommendations made in publications are not backed by hard evidence. It has been stated that 3 weeks is required before any obvious improvement is noted [35,36] and that a minimum of 3 months extending to 6 months in conjunction with topical therapy is required to achieve maximum benefit [11,22]. However, one controlled study comparing five antimicrobial regimes for mild to moderate facial acne in the community suggested that maximum improvement was reached at 6 weeks with both oral antibiotics and topical BPO [34].

There is a paucity of randomized, controlled trials examining different dosages of antibiotics in acne. One non-randomized, controlled study confirmed that patients on oral erythromycin in combination with topical 5% BPO responded better on 1 g compared to 500 mg daily. The relapse rates within 1 year were also significantly lower in the high-dose group [22]. Further reports suggest that higher doses of tetracycline [37,38] and oxytetracycline [39] are more effective in recalcitrant and severe acne. In patients with non-responding disease, minocycline limited dose–response studies have shown that doubling the dose of minocycline to 200 mg/day is more effective than continuing on an average dose of 100 mg where acne has not responded [40]. Daily doses of doxycycline (100 mg), minocycline (100 mg) and lymecycline (408 mg) are said to be equally effective, provided *P. acnes* is not resistant to doxycycline and lymecycline [41–45].

Subtherapeutic doses of doxycycline have been reported as effective in the treatment of moderate acne via non-antimicrobial mechanisms of action [46].

A correlation between sebum excretion rate and degree of improvement was noted in a retrospective study examining 255 patients treated with oral oxytetracycline, erythromycin and minocycline. Interestingly, this correlation was not noted with trimethoprim. The higher the sebum extraction rate the less well the patients responded to their systemic therapy. The authors hypothesized that this may be related to dilution of the antibiotic within the intrafollicular duct and as a result of this suggested that when the sebum excretion rate was greater than 2.5 $\mu g/cm^2$ a higher daily dosage of antibiotics might be required (lymecycline 600 mg, doxycycline and minocycline 200 mg) [47]. When prescribing higher doses of antibiotics patients and physicians should be wary about increased adverse effects [11].

Mechanisms of action

There are several potential mechanisms of action for oral antibiotics; as well as their antibacterial activity, they have anti-inflammatory effects [48–53]. Tetracycline and erythromycin are bacteriostatic, especially in larger doses. In smaller doses oral antibiotics do not reduce the number of organisms, but they do affect their function. The magnitude of reduction of *P. acnes* achieved by oral antibiotics does not correlate well with clinical efficacy [54]. Support for the important role of antibacterial therapy in the management of acne includes the fact that *P. acnes* is integral to the mediation of inflammation in acne, successful treatment with antibiotics is associated with significant reductions in *P. acnes* and colonization of the skin with antibiotic-resistant strains of *P. acnes* is associated with reduced clinical efficacy. Antibiotics can also inhibit various enzyme activities and modulate chemotaxis, lymphocyte function and pro-inflammatory cytokines, in particular TNF-α, IL-1 and IL-6 expression [51–53].

Combining oral antibiotics with topical preparations

Oral antibiotics should not be used as monotherapy in acne and should always be combined with topical agents. Combining BPO with antibiotics results in superior efficacy, this may be in part due to the relative lack of activity when used as monotherapy against non-inflammatory lesions. There is also evidence that such combinations prevent, reduce or eliminate bacterial resistance and can achieve significant clinical improvement in patients already colonized with antibiotic resistant strains of *P. acnes*. Intermittent usage of BPO during extended courses of antibiotics is recommended to eliminate resistant strains [11,55]. Topical retinoids may also be safely combined with antibiotics and are likely to enhance efficacy by acting on the microcomedo and non-inflammatory lesions [55,56]. The use of oral and topical antibiotics does not proffer any benefit and may select for resistant strains if chemically dissimilar preparations are used.

Side effects of topical treatments and oral antibiotics

Topical agents. The most common side effect of topical acne products is a primary irritant dermatitis (Fig. 42.51) which often subsides with time and can be managed by reducing frequency of application, using emollients and if severe short-term application of a type I potency topical corticosteroid [1,2]. Some topical therapies have a comparatively lower irritant profile than others. Azelaic acid is relatively non-irritant [3], the novel topical retinoids are less irritant than some of the older established retinoids such as tretinoin and less likely to produce an early treatment flare [4–6]; and the newer formulations of tretinoin (microsponge or polymer based) are said to be less irritating than the early formulations [7–9]. Certain antibiotic/benzoyl peroxide combinations are less irritating than benzoyl peroxide alone [10], possibly explained by the anti-inflammatory action of the antibiotic. Allergic contact dermatitis has been reported with BPO but is rare with other

Fig. 42.51 A typical primary irritant dermatitis from topical anti-acne therapy.

topical agents. From animal studies and much clinical experience there is no evidence to support the claims that benzoyl peroxide and vitamin A acid induce skin carcinomas, and continued use of these two drugs is recommended [11,12]. Benzoyl peroxide bleaches clothes and hair and the patient must be informed of these inconvenient side effects.

Retinoids are associated with teratogenicity but significant absorption of topical retinoids has not been demonstrated [13,14]. In light of the potential hazard of systemic absorption, female patients using topical retinoids should be advised to avoid pregnancy and to discontinue therapy immediately if they do conceive whilst using a retinoid. Patients should also be advised that they will be more susceptible to photosensitivity when using topical retinoids.

Oral antibiotics. All oral antibiotics for acne can produce mild adverse effects but oral tetracycline and erythromycin are both relatively safe [15,16] (Table 42.11). Gastrointestinal effects, especially colic and diarrhoea, may occur in 5% of patients and are seen most commonly with erythromycin and doxycycline [17]. Vaginal candidiasis occurs in up to 6% of female patients.

Uncommon complications of oral tetracycline therapy include onycholysis (Fig. 42.52) [18], oesophagitis with ulceration [19], fixed drug eruptions [20] and photosensitivity (Fig. 42.53), including porphyria-like cutaneous changes [21]. Doxycycline causes a dose-dependent phototoxic rash in up to 3% of patients [22]; appropriate photoprotection should be recommended. Widespread drug eruptions are rare except with trimethoprim, where the incidence is 2.5% [23]. Tetracyclines (reported most commonly on minocycline) may rarely cause headaches as a result of benign intracranial hypertension [24–27]; these generally resolve quickly on drug withdrawal. This side effect is dose dependent and the patient should be carefully informed.

Caution should be adopted when prescribing tetracyclines in children due to the potential problems with permanent discoloration of the teeth.

Minocycline may result in pigmentary changes in the skin and mucosa. The time course of onset and time to resolve is variable although cumulative exposure may correlate with the changes [28]. Pigmentary changes may present in three forms: blue-grey pigmentation in sites of inflamed lesions and scars (acne and non-acne) (Figs 42.54 & 42.55); generalized dark-grey discoloration in

Fig. 42.56 Minocycline pigmentation in the sclera.

sites unrelated to acne; and pigmentary changes in sun-exposed sites [26,28–35]. The pigmentation is due to a melanin–drug complex and lasts for an average of 8–15 months post therapy. It lasts longer in older patients. If therapy is required, local lesions can be treated reasonably successfully with the Q-switched ruby laser [33]. The brown-grey pigmentation due to minocycline may also occur in the nails, oral mucous membranes [35] and sclera [36] (Fig. 42.56). At these sites, the pigmentation tends to last for longer than it does in the skin. When present in the mucous membranes, only a small percentage of affected patients are aware of its presence [37], particularly if the tongue is affected. Even more uncommon but quite dramatic is black breast milk due to minocycline therapy [38,39].

Minocycline has been used in a large number of acne patients worldwide. Reports of serious systemic minocycline-induced side effects have prompted much debate [40–44]. These serious side effects are all relatively uncommon. Drug hypersensitivity syndrome (DHS) has been reported within 3 months of treatment. This is characterized by fever, malaise, arthralgia and a diffuse exanthematous skin eruption. Systemic involvement may include pulmonary eosinophilia and hepatitis. DHS commonly occurs within 2–6 weeks of commencing the agent and repeat exposure to the causative drug may result in recurrence of DHS within a few days. Early recognition and withdrawal of the agent are mandatory. DHS has also rarely been reported with trimethoprim [45].

A lupus-like reaction has been reported with minocycline, this reaction occurs much later, usually at about 6–48 months of chronic treatment. These patients are usually female and present with fever, malaise and polyarthralgia. A cutaneous rash is not always evident but urticaria, vasculitis and non-specific erythema have all been reported. Some of these patients have concomitant liver disease, which may occur in the absence of joint symptoms. Serology for lupus is evident with a positive antinuclear antibody (ANA), along with positive perinuclear antineutrophilic cytoplasmic antibodies (pANCA), and raised C-reactive protein. Severely deranged hepatic enzymes are also a feature and rarely liver damage is devastating resulting in death or needing liver transplantation [46,47]. Positive antihistone antibodies are rarely identified. The lupus-like reaction is reversible if the drug is withdrawn but the abnormal serology may persist for many months. It is therefore advisable to avoid minocycline in patients with a personal or family history of systemic lupus erythematosus. Before embarking on long-term minocycline it is advisable to check hepatic function and ANA at baseline and to repeat hepatic function, ANA and pANCA every 3–6 months, regardless of whether the patient has signs or symptoms of this condition. Absolute certainty about potential cross-reactivity to tetracyclines is not evident; it is therefore advisable for a patient with any of these iatrogenic side effects to avoid all classes of tetracycline antibiotics.

Pseudomembranous colitis is an exceedingly rare consequence of oral antibiotic therapy, and was a particular problem with long-term oral clindamycin treatment, but oral clindamycin is rarely used in acne management.

Trimethoprim may produce some rare but serious adverse effects [48]. DHS has been discussed previously. Haematological reactions, including agranulocytosis, thromobocytopenia and pancytopenia, have all been reported and the risk of these developing correlates with the use of higher dose regimens and those with folic acid deficiency and/or megaloblastic haematopoiesis characterized with elevated mean corpuscular volume or hypersegmented neutrophils [48,49].

Toxic epidermal necrolysis and Stevens–Johnson syndrome have been reported in the first 2 months of treatment and are associated with significant morbidity and mortality [48].

The possible interaction between oral antibiotics and the contraceptive pill leading to contraceptive failure is reported as a small risk [50,51]. Although a recent review identified rifampicin as the only antibiotic implicated in this problem [52], it is important to discuss this with all sexually active females.

Should therapy be required in pregnancy, oral erythromycin is thought to be safe although there are no data available evaluating chronic use over prolonged periods in pregnancy [53]. The safest therapies in pregnancy are therefore topical benzoyl peroxide and/or topical erythromycin [52].

Hormonal treatments

Various systemic hormone preparations are available for acne in female patients. These may be indicated when:

1 Standard antibiotic regimens have failed
2 Menstrual control and/or contraception are required alongside acne therapy
3 Oral isotretinoin is inappropriate or not available.

Topical therapy can and should be prescribed in conjunction with hormonal regimens. Table 42.11 outlines the relative sebosuppressive effects of systemic acne therapy.

Potential hormonal treatments for acne include inhibitors of androgen production by the ovary (oral contraceptives) or adrenal gland (low-dose corticosteroids), androgen receptor blockers, and antiandrogens that block the effect of androgens on the sebaceous gland.

Inhibitors of adrenal androgen production

Low-dose glucocorticoids are used most commonly to manage late-onset congenital adrenal hyperplasia, an inherent defect in the 11-hydroxylase or the 21-hydroxylase enzyme. Low-dose prednisolone 2.5–5 mg/day at bedtime is usually used. Dexamethasone may also be employed but the risk of adrenal suppression is greater with dexamethasone. Low-dose glucocorticosteroids (i.e. 2.5 mg prednisolone on waking and 5 mg on retiring) to suppress adrenal androgens, with or without a contraceptive pill, will reduce sebum production by up to 50% with a concomitant improvement in acne [1]. Cyclical oestrogen (30 μg) with medroxyprogesterone acetate (5 mg for 7 days) is also of benefit [2].

Inhibition of ovarian androgen production

Gonadotrophin releasing agonists block ovulation by interrupting cyclic release of LH and FSH from the pituitary. These products, such as leuprolide, nafarelin and buserelin, are available in nasal spray and injectable forms. However, as well as reducing ovarian androgen production, they will also block the ovarian production of oestrogens, potentially leading to reduced bone mass and menopausal symptoms. As a result, the potential benefit in acne is far outweighed by the potential adverse effects which negate their usage.

Oral contraceptives generally contain oestrogen (most commonly ethinyl oestradiol) and a progestin. Oestrogens act on the liver to increase synthesis of sex hormone binding globulin (SHBG), which binds testosterone and reduces the level of free circulating testosterone, hence all oral contraceptives will potentially improve acne. In addition, oral contraceptives suppress ovulation by inhibiting the production of ovarian androgens which results in reduced serum androgens and lower sebum production. The dosage of oestrogen in oral contraceptives has been reduced over the years and many third-generation combined contraceptives contain 20 μg of ethinyl oestradiol. Progestins in combined oral contraceptives include estranes and gonanes, which are derivatives of 19-nortestosterone, cyproterone acetate and drosperinone. The third-generation progestins (gestodene, desogestrel, norgestimate) are less selective for the androgen and more selective for the progesterone receptor. Drosperinone is a novel progestin derived from 17α-spironolactone and as with the parent compound has antimineralocorticoid and antiandrogenic activity, making it potentially helpful in acne. Yasmin® contains drospirenone 3 mg combined with ethinyl oestradiol 30 μg and Yaz® contains the same dose of drospirenone with 20 μg of ethinyl oestradiol.

The use of oral contraceptives as treatment for acne has been studied extensively. A Cochrane systematic review to determine the effectiveness of combined oral contraceptives (COCs) for the treatment of facial acne compared to placebo or other active therapies confirmed that COCs reduced acne lesion counts, severity grades and self-assessed acne compared to placebo. Limited data suggested that chlormadinone or cyproterone acetate (CPA) achieved better efficacy than levonogestrel, and a COC containing CPA may produce better outcomes than one containing desogestrel, although results from three studies were conflicting. Likewise one study showed slight superiority with levonorgestrel compared to desogestrel but this was not consistent with results from a second comparative study. Limited data were available comparing COCs with other therapies [3]. One company-supported comparative study [4] has shown that Yasmin® is similar to co-cyprindiol in its efficacy against acne.

Androgen receptor blockers

These include CPA, spironolactone and flutamide. Antiandrogens are a logical approach to the treatment of acne, as they suppress sebum production to an extent that depends on the drug and dose prescribed (Table 42.11) [5–9].

The antiandrogen CPA is licensed for acne in most European countries, but not in the USA. It directly inhibits the androgen receptor and serves as a progestogen in oral contraceptives. Co-cyprindiol (Dianette® and Estelle 35®) is an oral contraceptive that ameliorates acne [5–9]. It is as effective as oral tetracycline 1 g/day given over a 6-month period, although it is slower in action [10]. It is also of potential benefit in women with acne resistant to other therapies [7]. In males, 25 mg CPA has been used with success, but it reduces libido and produces gynaecomastia and possible azoospermia. In women, it has been suggested that the side effects of CPA 2 mg with ethinyl oestradiol (35 μg) oestrogen are different from those of conventional contraceptive pills that contain lower amounts of oestrogen. In particular, it has been suggested that there is a greater risk of deep venous thrombosis embolism (VTE) [11] and as a result current recommendation suggests that once the acne is brought under control co-cyprindiol formulations should be replaced by a combined oral contraceptive containing a lower dose of oestrogen. However, a recent article reviewing the evidence for efficacy and adverse effects with co-cyprindiol concluded that the risk of VTE was no greater than with third-generation combined oral contraceptives [12]. Co-cyprindiol reduces sebum production by no more than 30%; it is likely that it also acts by an additional mechanism, such as a direct effect on comedogenesis, which is also androgen-mediated [13]. The clinical efficacy of this combination can be enhanced by giving an extra 50 mg or 100 mg CPA from the fifth to 14th day of the cycle [14]. At this dosage, the reduction in sebum production is 50–67%.

Spironolactone is an effective treatment (it is not a contraceptive) and reduces sebum excretion by 30–75% depending on the dosage used. Its effects are dose dependent, and it is usually prescribed at a dose of 50–100 mg daily with meals, but many women with sporadic outbreaks do well with doses as low as 25 mg daily [15–18]. Although spironolactone is used in this context with clinical success there are a paucity of studies to confirm its effectiveness due to very small sample populations [19]. The main side effects are menstrual irregularity, breast tenderness, occasional fluid retention and, rarely, melasma. A question mark remains over its long-term use because of a theoretical increase in breast cancer, which has been shown in animal but not human studies [20]. Pregnancy should be avoided due to potential abnormalities to the male fetus and serum electrolytes should be monitored in

older females who might have other medical problems due to potential risk of hyperkalaemia. All hormonal regimens should be combined with appropriate topical therapies. Effective hormonal regimens seem to have a dual mechanism of action, suppressing gonadotrophin release and having an additional peripheral effect on the sebaceous gland [21]. A recent study, albeit small, confirmed efficacy and good tolerability in 27 women with severe papular and nodulocystic acne treated with a combination of ethinyl oestradiol 30 μg and drospirenone 3 mg as well as 100 mg spironolactone [22].

Flutamide is a potent antagonist of the androgen steroid. Although most commonly used in the treatments of prostatic conditions flutamide has been shown to be efficacious in a number of androgen-mediated problems, including acne, administered at a dose of 250 mg daily. Fatal hepatotoxicity has been reported and therefore use in acne is not generally advocated [23]. One single randomized, controlled trial showed significant reductions in acne score and hirsutism in 119 women with PCOS treated with three different doses of flutamide plus COC compared to placebo at 6 and 12 months [24]. There are a paucity of good studies comparing hormonal approaches to antibiotics and isotretinoin. Isotretinoin has been shown to be more effective than co-cyprindiol for acne patients [5]. One systematic review of this subject assessed mean weighted effects across different reported variables. Isotretinoin scored 85 ± 10% improvement compared with baseline, whereas tetracyclines and hormonal treatments were less effective, scoring 54 ± 3%, and CPA plus ethinyl oestradiol 65 ± 4% improvement compared with baseline levels [25]. There is concern about the potential reduction in efficacy of oral contraceptives as a result of systemic antibiotics used in conjunction with COCs. The risk is theoretical, based on the hypothesis that broad-spectrum antibiotics reduce bacterial flora in the gut and thus interfere with oestrogen absorption. Pharmacokinetic studies have demonstrated that serum levels of oestrogen are unaffected by tetracycline, doxycycline and others and there have been very few reports in the literature associating pregnancy with the combined use of COCs and antibiotics. The failure rate of COCs when used with tetracycline resulting in pregnancy is reported as 1.2–1.4 pregnancies per 100 woman-years of oral contraceptive use which is no greater than background failure rate of COCs. The only antibiotic which has been shown to reduce COC efficacy is rifampicin [26–29].

Hormonal therapy provides an excellent alternative for women whose acne is not responding to conventional therapy. Signs of hyperandrogenism require investigation and are an indication for hormonal treatment but it is clear that women with normal serum androgen levels also respond well to hormonal therapy. For female patients with intractable moderate or severe acne, and/or in whom antiandrogen therapy is not appropriate, isotretinoin is the treatment of choice.

Table 42.12 Reasons for poor response to treatment in acne.

Reason for poor response to therapy	Comments
Poor education of the doctor or patient	Understanding of how to use therapies is mandatory for successful treatment
Poor compliance to therapy	Steadily diminishing compliance may lead to relapse
Presence of relevant antibiotic resistant *P. acnes* in patient complying to therapy	Colonization with resistant isolates from the start results in poor response, subsequent colonization leads to relapse
Development of Gram-negative folliculitis	
Incorrect diagnosis	See section on differential diagnosis
Refractory subtypes of acne	See section on unusual cases
Intolerance to or side effects of treatment	See section on adverse effects
Inadequate dose of antibiotics	Patients of high body weight or marked seborrhoea may require a higher dose

Table 42.13 Factors implicated in affecting medical adherence to acne therapy.

	Improved adherence	Reduced adherence
Demographics of the patient	Older more mature patients Female gender Being married (vs. single)	Smoking Alcohol Unemployment
Patient preferences	Good doctor–patient relationship Shame, embarrassment Satisfaction with treatment	Psychosocial morbidity (anxiety and depression)
Characteristics of medication		
Systemic treatments	Oral isotretinoin (better than other systemics) Once daily formulations (better than divided doses)	Increasing costs (regardless of treatment type)
Topical treatments	Gel formulations Once daily formulations	

The patient with slow or failed response to treatment

There are several reasons why some acne patients show slow, minimal or no response to therapy as outlined in Table 42.12.

Poor medical compliance

Acne represents a chronic disease frequently requiring treatment over many years [1]. It is well recognized that chronic diseases *per se* are associated with poor compliance to treatments and acne is no exception [2]. Medication adherence is integral to therapeutic success as illustrated by a number of studies examining a variety of chronic diseases in which predictable and disappointing responses to treatment frequently resulted from poor adherence [3,4]. These same studies confirmed that adherence is influenced by many variables. One study in students with acne treated with over-the-counter benzoyl peroxide (BPO) demonstrated that compliance to treatment was only 48% despite implementing educational strategies to improve this outcome [5]. A further study confirmed that 44% of dermatological patients did not follow their prescription instructions [6]. In one study utilizing direct (pill count) and indirect (interview) methods, a 65% adherence rate was recorded [2]. As well as not taking therapy acne patients may miss appointments, as demonstrated in a study that determined 19% of patients did not return after their first visit and only 28% kept all four scheduled appointments. The likelihood of keeping appointments related to demographics, including age and race as well as financial aspects [7]. The frequency of medication has been shown to influence adherence such that an orally administered therapy once daily was adhered to in 87% of patients but only 39% of patients treated with a four-times daily regimen complied. In addition, the number of medications and costs of treatment can affect adherence [4]. Demographics have not been shown to be good indicators of medical adherence in many studies but one has linked poor adherence in acne subjects to young age, sex of the patient (females being more adherent than males), and marital status (single persons being less adherent than those that are married). Some social aspects were also linked to poor adherence in this study, including smoking, alcohol and unemployment [2]. Patient satisfaction with therapy as well as with the manner of the prescribing physician both strongly correlate with treatment adherence. Shame and embarrassment also link to better adherence, possibly as these motivate the patient to take their therapy [6]. Psychiatric morbidity correlates negatively with adherence and worse scores on the DQLI have been shown to be associated with poor adherence [2]. Degree of disability of disease in acne but not clinical rating can influence adherence to therapy [6,8]. It is important to recognize that patients with severe disease may not be as motivated to adhere to therapy as the prescribing clinician or parents would expect (Table 42.13) [9].

Education of patients and doctors is paramount to achieve good medical compliance. This should include explanation that acne is a chronic disease which responds slowly and requires a strategic approach to therapy. Utilization of simple therapies that take into account patient preferences and lifestyle are important issues to consider. Support over the treatment period is vital, particularly if patients have had disappointing results to treatment in the past. Assessment of treatments used and how patients have used them is important during the follow-up period. Impact of acne on quality of life and psychosocial morbidity should be routinely assessed as this may impact on adherence [10]. The patient–physician relationship is one of the most important factors influencing adherence in any chronic disease and acne is no exception. Clinicians should be adept in counselling patients regarding their condition and therapy and should provide realistic expectations with written educational material, medication reminders and information on available resources that might help to support the consultation and management of their patients [11].

Propionibacterium acnes resistance

Resistant isolates of *Propionibacterium acnes* to commonly used antibiotics can contribute to inadequate response to therapy in acne patients.

The outcome of antibiotic treatment for acne patients whose skin is colonized by *P. acnes* with reduced susceptibility to a

particular antibiotic depends on many factors, most of which act at the follicular level. Colonization of some follicles by resistant *P. acnes* is likely to produce a diminished response to treatment rather than complete failure, as it is unlikely that all follicles will harbour resistant organisms at any one time. However, it is likely that the more follicles that contain resistant organisms or acquire them during therapy the fewer will respond to treatment [12].

Clinical resistance will occur if the MIC of the resistant isolates of *P. acnes in vitro* exceeds the concentration of the antibiotic in the pilosebaceous duct. The concentration of ductal antibiotics varies considerably [13]. There are several factors that contribute to a less than optimal concentration of the drug in and around the pilosebaceous duct. Poor compliance will reduce drug availability, and a high sebum excretion is likely to dilute an effective drug concentration [14]. A low tissue drug concentration will encourage the acquisition of antibiotic resistant *P. acnes.* Tables 42.8 & 42.9 summarize possible factors that might indicate the presence of antibiotic-resistant *P. acnes* and strategies that might avoid resistance emerging.

Antibiotic-resistant isolates of *P. acnes* have now been identified in Europe, the USA, the Far East and Australasia [12,14–19]. In one UK study, resistance rose dramatically between 1990 and 1997 but has not increased significantly in subsequent years [12]. In 2003, the prevalence rates in a pan-European study [15] were lowest in Hungary (50.8%) and highest in Spain (93.6%). Resistance is seen to tetracycline and doxycycline in 20% of subjects in Europe and 30% in the USA. When present, tetracycline and doxycycline resistance is frequently associated with resistance to erythromycin and clindamycin [12]. One in two acne patients are colonized by strains resistant to erythromycin and clindamycin in European centres.

The incidence of erythromycin- and clindamycin-resistant *P. acnes* in non-antibiotic-treated close contacts is 50% and this may account for the apparent difficulty in treating some of our younger acne patients who have older siblings who have received antibiotic therapy for their acne. Colonization with tetracycline-resistant strains is rare in these contacts [19].

Isolates resistant to trimethoprim have been demonstrated in 12% of cases sampled and isolates resistant to more than one antibiotic are found in 24% of patients. Resistance to minocycline is said to be relatively uncommon [15]. However, there is now some doubt as to which minocycline MICs indicate clinical resistance and it is very likely that isolates of *P. acnes* from the USA which require 16 mg/L of minocycline to inhibit their growth *in vitro* [18] will not be inhibited *in vivo*, as this concentration far exceeds serum levels that can be achieved even using high-dose minocycline at 200 mg daily. It is well recognized that the correlation between microbiological resistance and clinical response is complex. However, there is clinical evidence to suggest that the presence of antibiotic-resistant *P. acnes* will correlate with poor clinical response to antibiotics in some patients. This was originally observed over 20 years ago by Leyden *et al.* who found that the mean MIC of the therapeutic antibiotic for propionibacteria obtained from acne patients receiving long-term therapy with tetracyclines or oral erythromycin exceeded the mean MIC for isolates from untreated patients and controls without acne. This same study confirmed that patients harbouring resistant strains had higher propionibacterial counts and responded less well than their counterparts with susceptible strains [20]. In 1989, one UK study showed that acne outpatients colonized with erythromycin-resistant propionibacteria were significantly less likely to respond adequately than those with fully susceptible strains [21]. A further study has demonstrated that acne patients colonized with tetracycline-resistant propionibacteria respond less well to both tetracycline and minocycline [22]. This suggests that combinations of antibiotics of dissimilar chemical groups should be avoided in an attempt to avoid promotion of multiple resistances.

Molecular studies have demonstrated that the resistance of *P. acnes* to erythromycin and clindamycin is due to a mutation [23]. The same is likely to be the situation with tetracycline [24]. This suggests that resistance will persist even after the selective pressure of any specific antibiotic has been removed and it is clear with mutational resistance that the harder the organisms are hit the more they will retaliate, resulting in higher and higher MICs.

Several studies have confirmed that the therapeutic use of antibiotics for acne drives resistance [16,22]. Hence, clinicians should adhere to treatment strategies that aim to prevent antibiotic resistance emerging and utilize therapies that reduce resistant organisms when present (Table 42.9).

High-dose antibiotics (such as minocycline 200 mg/day or trimethoprim 600 mg/day) have been shown to be successful in overcoming apparent resistance [25]. This may be due to the balance between the antimicrobial and anti-inflammatory activity. High-dose antibiotics will inevitably increase the drug concentration in the intrafollicular duct, where they may act as better antimicrobial agents, but in the dermis the higher dose may enhance the drug's anti-inflammatory action. Oral isotretinoin has also been shown to have a profound effect on *P. acnes* reducing numbers significantly, regardless of whether they are antibiotic sensitive or resistant [26,27].

Gram-negative folliculitis (GNF) can result as a consequence of any long-term topical or oral antibiotic therapy. It results from an overgrowth of Gram-negative organisms including *Klebsiella*, *Escherichia coli*, *Proteus*, *Serratia* or *Pseudomonas* organisms [28]. Clinically two forms of GNF have been described [29]. Type 1 may present with an acute flare of many pustules, predominantly around the nose and chin. Alternatively, an apparent deterioration of ordinary acne may occur and this is characterized by more painful, deep pustules and nodules, some of which may coalesce to form sinus tracts. *Proteus mirabilis* is frequently isolated from this second form. Bacterial swabs should be sampled from the skin and nose of these patients to identify the offending organism. The current antibiotic should be stopped. Alternative antibiotic treatment options include ampicillin 250 mg three times per day or oral trimethoprim 200–300 mg twice a day. However, systemic isotretinoin 0.5–1.0 mg/kg/day is the treatment of choice as relapse after antibiotic therapy is much more frequent.

Certain subtypes of acne are more frequently associated with clinical failure. As discussed above, some patients have specific types of comedones. Patients with sandpaper comedones respond poorly to the more standard antibiotic/topical retinoid therapy and frequently require oral isotretinoin (0.5 mg/kg/day for 4–6 months). Patients with macrocomedones (Fig. 42.57) require physical treatment with gentle cautery under a local anaesthetic (EMLA®) [30,31]. Ill-advised prescription of isotretinoin to patients

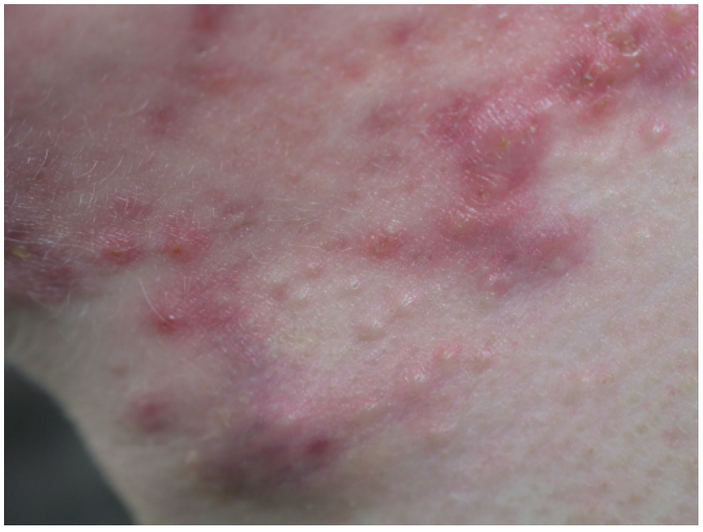

Fig. 42.57 Multiple macrocomedones: a frequent cause of persistent inflammatory acne. (Courtesy of Dr A. Yung, Auckland, New Zealand.)

with multiple macrocomedones may precipitate a bad flare of acne, which may produce significant scarring. This disease flare probably relates to the release of large quantities of inflammatory mediators due to death of *P. acnes* organisms within the duct system. Similar treatment with gentle cautery is also required for patients with submarine comedones, but in contrast to those patients with macrocomedones who respond very well to this physical treatment, only about 50% of patients with submarine comedones show a satisfactory response.

Patients with severe inflammatory acne, such as acne fulminans, acne conglobata and sinus tract disease, also respond badly to standard therapy. Most other non-responding patients will respond successfully to isotretinoin.

Oral isotretinoin

Oral isotretinoin (13-*cis*-retinoic acid) is a synthetic vitamin A analogue which was first approved by the US Food and Drug Administration (FDA) in 1982 for the treatment of severe recalcitrant acne. Since this introduction, the management of acne has been revolutionized and, over two decades later, isotretinoin remains the most clinically effective antiacne therapy, producing long-term remission or significant improvement in many patients.

Mechanism of action

Isotretinoin is the only treatment that has an effect on all of the major aetiological factors involved in acne, by influencing

cell-cycle progression, cellular differentiation, cell survival and apoptosis [1–6]. It lowers sebum production significantly although the exact mechanism is poorly understood; it reduces comedogenesis as well as surface and ductal *P. acnes* and has anti-inflammatory properties.

Oral isotretinoin is the only oral retinoid known to have a profound effect on sebaceous gland activity. A dose of 0.5–1.0 mg/kg/day dramatically reduces sebum excretion by the order of 90% within 6 weeks. Unlike tretinoin (all-*trans* retinoic acid), isotretinoin has little or no ability to bind to cellular retinol-binding proteins or retinoic acid nuclear receptors (RARs and RXRs) but may act as a pro-drug that is converted intracellularly to metabolites that are agonists for RAR and RXR nuclear receptors [1–4].

Isotretinoin has at least five biologically important metabolites: 4-*oxo*-13-*cis*-retinoic acid (4-*oxo*-isotretinoin), all-*trans*-RA (tretinoin), all-*trans*-4-*oxo*-retinoic acid (4-*oxo*-tretinoin), 9-*cis*-retinoic acid and 4-*oxo*-9-*cis*-retinoic acid (see Fig. 42.12). Studies of SER in sufferers of severe acne have shown that, within 4 weeks, 4-*oxo*-isotretinoin (30–60 mg/day orally) produces a mean reduction of 70% of that achieved by 30–60 mg/day of oral isotretinoin and that isotretinoin is superior to either 9-*cis*-retinoic acid or all-*trans*-retinoic acid for suppression of sebum production and sebaceous gland activity [4,5].

In vitro studies of human sebocyte proliferation in cell culture, keratin 7 induction in pig sebocytes, HL-60 cell differentiation, the limb bud assay and the production of hypervitaminosis A in rats, have shown that isotretinoin and its three main metabolites, tretinoin, 4-*oxo*-isotretinoin and 4-*oxo*-tretinoin, have comparable but not identical activities. In the human sebocyte proliferation assay, all three isotretinoin metabolites inhibit sebocyte proliferation at slightly lower concentrations than isotretinoin. All three metabolites have similar activity in the limb bud assay, which defines teratogenic potential, and in the hypervitaminosis A assay, which predicts the overall side-effect potential. It is reasonable, therefore, to conclude that all three metabolites may contribute to the overall efficacy and safety, and side effects, of isotretinoin. These four compounds activate retinoid receptors RAR-α, RAR-β and RAR-γ in SZ 95 sebocytes, but only tretinoin and 4-*oxo*-tretinoin bind to RAR-γ, which is the receptor that is thought to be important in retinoid treatment of acne. Incubation of SZ 95 human sebocytes with isotretinoin led to significantly higher intracellular concentrations of tretinoin than isotretinoin [6]. The incubation with tretinoin generated very high intracellular concentrations of tretinoin and negligible concentrations of isotretinoin. These data suggest that tretinoin may be the active intracellular form of isotretinoin and prompted Tsukada *et al.* [6] to conclude that isotretinoin should be considered as a pro-drug. Differences in the plasma concentrations of these metabolites could therefore explain the differences in the intensity of the therapeutic response and the severity and/or occurrence of side effects in individual patients. Isotretinoin has been found to induce apoptosis in sebocytes and this effect is independent of RAR receptor activation [7], suggesting that it is sebaceous gland involution resulting from oral isotretinoin which leads to reduced sebum production.

Just how oral isotretinoin influences a significant reduction in comedogenesis by decreasing hyperkeratinization by 50% is uncertain [8–11]. However, research demonstrates that isotretinoin does not affect the metabolic activity of the keratinocytes [12].

Oral isotretinoin has no direct antimicrobial action, but by dramatically reducing SER and the size of the pilosebaceous duct it markedly alters the microenvironment within the duct. The result is a $\log_3$ reduction in *P. acnes*—a suppression much greater than that seen with oral and topical antibiotics. It has also been suggested that like all-*trans*-retinoic acid, isotretinoin might increase host defence mechanisms [13].

Oral isotretinoin also modifies monocyte chemotaxis, which in part explains the anti-inflammatory effects of the drug [14]. The significant reduction in the *P. acnes* population also contributes to the reduction in acne inflammation.

Clinical benefit of oral isotretinoin

Most patients who receive oral isotretinoin will be free of acne by the end of 4–6 months of treatment depending on the dose used. Recent clinical experience suggests that the long-term cure rate may be lower than was initially thought by dermatologists when isotretinoin became prescribable in the mid 1980s [15–20]. One explanation is that isotretinoin is being used to treat patients with less severe acne, who then have high expectations of a totally acne-free life, whereas the initial cohorts of patients had severe disease and were less concerned by the resurgence of a few spots. Furthermore, some of the early reported 'cures' may have been due to the fact that patients had eventually grown out of their acne as they may well have received initial treatments much later on in the course of their disease. There is evidence to suggest that younger patients relapse more readily than older ones [21]. Isotretinoin currently has a licence for treatment of severe acne unresponsive to other combination therapies including antibiotics used for acne (Figs 42.58–42.60) [9–15]. However, over the years

Fig. 42.58 A patient with severe acne before treatment with oral isotretinoin.

Fig. 42.59 The same patient at 3 months of treatment with isotretinoin.

Fig. 42.60 The same patient 3 years after treatment with isotretinoin.

isotretinoin has been used to treat other cases of acne with poor prognostic factors and a number of other clinical conditions with varying degrees of success, as outlined in Table 42.14.

A European directive on prescribing of isotretinoin has recently been introduced [22]. The aims of the directive are to ensure generic prescribing is harmonized and delivered appropriately throughout the European Union and to minimize the risk of adverse effects including pregnancy. Table 42.15 summarizes the recommendations. The regulatory authority in each country has approved a Pregnancy Prevention Programme (PPP). This programme includes advice on education, therapy management and control of distribution of the drug. Education suggests that both patients and prescribers must be fully aware of teratogenicity. The patient should acknowledge the problem by signing a consent form and should accept detailed counselling by the clinician prior to and during treatment. Therapy management includes medically supervised pregnancy testing before, during and 5 weeks after a course of therapy and provides advice on contraception. Distribution control suggests that only 30 days of oral isotretinoin can be supplied at one time to a female patient and the prescription will only be valid for 7 days.

The scope of the PPP suggests that it should include all females of childbearing potential. Clinicians can exercise clinical judgment if they establish that the patient is not currently sexually active, but it is mandatory that clinicians check carefully at each 4-week follow-up visit and record as well as act on any change in circumstance. Pregnancy testing is mandatory pre- and 5 weeks post-therapy. It has been suggested that the initial test can be done up to 2 weeks prior to the start of treatment providing contraception is used in those who require it. In addition, monthly pregnancy testing is recommended throughout the treatment period. The treatment should ideally start on day 3 of the menstrual cycle. The programme suggests that where possible patients should agree to at least one, and preferably two, complementary methods of effective contraception, including a barrier method, before therapy is

Table 42.15 Recommendations from the European Directive on Isotretinoin Prescribing.

	Pre Directive	Post Directive
Dosage	0.5–1.0 mg/kg/day	Start 0.5 mg/kg/day
Indications for use	Isotretinoin recommended as first-line therapy for severe acne (nodular and conglobata) as well as acne not responding to 3 months' systemic antibiotics in combination with topical therapy	The new recommendations suggest isotretinoin should only be used in severe acne (nodular, conglobata) that has or is not responding to appropriate antibiotics and topical therapy; the inference of this being that it should now not be used at all as first-line therapy
Age	Previously no age limit	Not indicated in children <12 years
Monitoring	Liver enzymes and lipids should be checked before treatment and 1 month after the maximum dosage has been used	Baseline investigations as before but at 1 month and 3 monthly throughout the course of treatment
Physical treatments	It was recommended that chemical and physical peeling should be avoided during treatment and for 6 months afterwards and that wax depilation should be avoided during and 6 weeks post-therapy.	All forms of peeling and wax depilation should be avoided during therapy and for 6 months afterwards
Pregnancy prevention programme		See text

initiated. The dispensing restrictions do not apply to males as the process is aimed at ensuring that females do not get extended periods of treatment without pregnancy tests being performed. The responsibility for the assessment of pregnancy tests and the administration of further prescriptions lies with the clinician. Clinical problems relating to the implementation of this approach include difficulties in females with irregular menses, potential lack of continuity of treatment due to potential unavailability of patient and/or health-care workers as well as forgotten tests. These factors may all contribute to early cessation and/or partial treatment, resulting in ineffective management and associated financial burden on health-care systems [22]. Given potential side effects of oral contraceptives, it may not always be appropriate to insist on all patients regardless of pregnancy risk using specific contraceptives.

The recommendations suggest that isotretinoin should no longer be used as first-line therapy and/or should not be used below the age of 12 years. There are many publications advocating the use of isotretinoin for severe acne and scarring acne in the literature, hence delaying this effective therapy in certain cases may go against best and evidence-based practice. With increasing clinical experience, use of the drug has been expanded worldwide to include less severely affected patients who have responded unsatisfactorily to what have been called conventional treatments, including long-term antibiotics and/or appropriate topical antimicrobial or retinoid-like therapies [16–18,23–25].

Failure of conventional treatment may occur for many reasons, including resistance of *P. acnes* to antibiotics [26]. A European review outlines when isotretinoin might be considered in light of the new European directive and identifies poor prognostic factors, as summarized in Table 42.15 [27]. The recommendations to start at 0.5 mg/kg/day and to titrate the dose as tolerated are well received when using isotretinoin for conventional acne. However, some patients with persistent acne, especially in the mature age group, as well as cases where side effects are not tolerated at these recommended doses, will require low-dose and possibly intermittent treatment. This has been advocated for some of these specific cases in the literature [28,29].

The USA has adopted a more rigid programme for pregnancy prevention and monitoring. In 2005, the Food and Drug Administration (FDA) announced that both male and female users of Accutane® (oral isotretinoin) would have to enrol into the National Registry 'iPLEDGE'. If this is not achieved, patients will no longer be able to receive the drug. Women of childbearing age now have to provide two negative pregnancy tests before their initial prescription, show proof of another negative pregnancy test before each monthly repeat prescription, and use two forms of contraception throughout therapy and for 30 days after treatment. They must enter these forms of contraception into the registry. All patients sign a document confirming that they are aware of potential adverse effects including depression and suicidal thoughts. One unfortunate consequence of this strict regimen may be a reduction in the usage of isotretinoin, which could potentially disadvantage patients who require this effective treatment. In addition, the restriction of isotretinoin as a second-line therapy may have consequences on the evolution of acne scarring, and on the quality of life in many acne patients. Expert opinion based on clinical data [17,23,24,27] supports the use of isotretinoin for patients with moderate acne who are failing to respond to conventional therapy, for whatever reason. Acne may produce scars in 30% of patients with moderate disease, and significant psychological morbidity in 12–13%.

The definition of poor response should be made against objective or semiobjective criteria. The use of a clinical acne scoring system [30], as well as quality-of-life and psychosocial assessments [31], should be used when evaluating acne. Physical and psychological severity of acne and local financial pressures will all play a role in the decision whether to prescribe isotretinoin. There is strong evidence to show that isotretinoin significantly reduces the psychological problems associated with acne [32,33].

A small number of patients with mild acne have psychological problems disproportionate to their degree of acne. These patients may have body dysmorphophobic syndrome. There is evidence to suggest these patients respond to isotretinoin but withdrawing the drug may be difficult [34].

Although the European directive suggests isotretinoin should not be used below 12 years of age, up to 0.5 mg/kg/day has been used successfully in a number of neonates or juveniles with acne that have not responded to all appropriate topical or oral therapy [35]. Some pre-adolescent youngsters, even under 10 years of age,

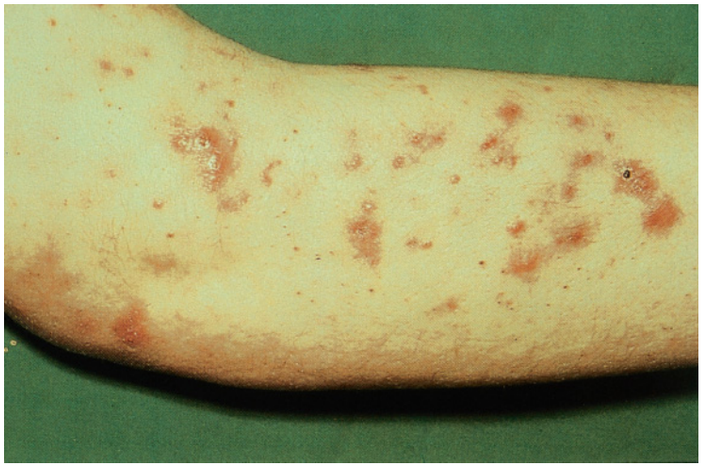

Fig. 42.61 The unusual extent of acne in a patient with Apert's syndrome.

Fig. 42.62 The typical appearance of the fingers of a patient with Apert's syndrome.

develop troublesome acne with scarring. Oral isotretinoin should be considered for paediatric acne patients if there are sufficient clinical indications [36]. Apert's syndrome is a rare disorder associated with a hyperresponse of the epiphyses (Figs 42.61 & 42.62) and sebaceous glands to androgens, which results in premature epiphyseal fusion, particularly of the long bones and skull, and in acne, respectively. These patients, presumably because of the hypersensitivity of the sebaceous glands to androgens, respond poorly to conventional therapy, and are therefore often treated successfully by oral isotretinoin [37].

Most dermatologists are treating increasing numbers of patients with acne that has persisted beyond the age of 25 years. The reasons for this change in the age-referral pattern are unclear, but may reflect increased expectations for cure based on the widely known clinical effectiveness of isotretinoin. Although the acne severity in these cases is not usually as great as when they were 15–25 years old, the persistence of the disease results in an increased risk of scarring and disproportionate psychological distress [38]. Isotretinoin can play an important role in the treatment of this age group. Data from a clinic in Leeds, UK, show that an adult with acne persisting at the age of 30 years is likely to have acne for at least a further 10 years. Small, intermittent-dose isotretinoin therapy (see below) may be appropriate for this subgroup of patients, but relapse often occurs quickly following a successful acne-free interval while on therapy.

Table 42.16 Isotretinoin dose schedules that may be most appropriate for patients with significant systemic disease.

1 Protocol A: standard regimen	2 Protocol B: initially half the standard regimen	3 Protocol C: once-a-week regimen with gradual dose increase
Crohn's disease	Chronic renal failure	Behçet's syndrome
Diabetes mellitus	Renal dialysis	Cerebellar spongiform encephalopathy
Epilepsy	Hypertriglyceridaemia	Idiopathic thrombocytopenic purpura
Spina bifida	Immunosuppression	Leukaemia
Ulcerative colitis	Manic depressive psychosis	Mitochondrial degeneration
	Myalgic encephalopathy	Paroxysmal nocturnal haemoglobinuria
	Motor neurone disease	Polymyalgia rheumatica
	Multiple sclerosis	

Isotretinoin for patients with significant systemic disease

Patients with significant systemic disease have been successfully treated with oral isotretinoin. It has been suggested that these patients fall into three subgroups and therefore three appropriate protocols have been recommended (Table 42.16) aimed at minimizing adverse effects in the associated disorder. In all instances it is necessary that a careful check be made by the dermatologist and/or the relevant physician at monthly intervals to ensure that there are no significant clinical or laboratory changes in the systemic disease [39,40].

1 Patients in Group 1 are those patients for whom there is evidence to show that the full dose of isotretinoin can be safely given.
2 Patients in Group 2 are those patients for whom there is limited information but, on balance, the drug probably does not cause any change in the associated disorder. These patients usually can start on a dose regimen of 0.25–0.5 mg/kg/day. If all is well, the dose can be increased at 2-monthly intervals to 0.5 mg/kg/day, and beyond if required, and therapy usually maintained for 24 weeks.
3 Group 3 includes patients who have rare diseases, or where not much information exists. In these uncommon circumstances, it is recommended that therapy begins at 20 mg isotretinoin/week. The dose is increased by 20 mg each week so that at the end of 7 weeks patients are taking 20 mg/day. The cycle can then be repeated to achieve a higher dose, so that by the end of a further 7 weeks they are taking 20 mg twice a day. In this group of diseases, it is particularly important that the dermatologist links with the appropriate physician so that a very careful clinical and, where appropriate, laboratory measurement is made of the associated disease. The authors recommend publication of these cases to help other similarly affected patients.

Isotretinoin in the treatment of acne variants

These diseases are very rare, and represent a small but essential indication for oral isotretinoin. This group includes patients with acne fulminans, rosacea fulminans, Gram-negative folliculitis, dissecting cellulitis of the scalp, hidradenitis suppurativa and acne conglobata.

Patients with acne fulminans and rosacea fulminans respond to oral isotretinoin [41,42]. The best response in these conditions is obtained by starting with a course of prednisolone 0.5–1.0 mg/kg for 4–6 weeks [41,42]. The steroids can usually be reduced gradually over the following 2 weeks, and isotretinoin can be introduced at a dosage of 0.5 mg/kg body weight/day and this can be increased gradually to 1 mg/kg/day according to the response.

Patients with acne conglobata and Gram-negative folliculitis usually do not require oral steroids, and can be started immediately on oral isotretinoin at a dose of 0.2–0.5 mg/kg/day [43]. Hidradenitis suppurativa is a distressing disease that is difficult to treat. The response to isotretinoin is variable [44,45]. However, oral isotretinoin may achieve some improvement in patients who have not responded to hormonal regimens or long-term high-dose antibiotics such as minocycline. Dissecting cellulitis of the scalp also responds variably to oral isotretinoin, but a 4-month course should be tried [46].

Steatocystoma multiplex does not respond well to isotretinoin and although the inflammatory component of this disease may improve, it may respond equally well to long-term oral antibiotics [47]. Other uncommon diseases related to acne that may respond to isotretinoin are oil acne [48], especially where there is an inflammatory component, and extensive Fordyce's disease [49]. Table 42.14 summarizes the acne-related conditions that have been treated successfully with isotretinoin in the literature.

Recommended doses and duration of therapy

Most physicians to date have prescribed a dose within the range 0.5–1.0 mg/kg body weight/day. There are variations in the way treatment is started [50–53]. According to the European Directive treatment regimens should start with 0.5 mg/kg/day and may be increased to 1.0 mg/kg/day according to tolerance and response. The half life is 22 h and the bioavailability is 25%. Absorption of isotretinoin is markedly affected by the presence of fat and pharmacokinetic studies show that absorption can be doubled by taking isotretinoin with, or after, a meal compared with the fasting state [52]. It is therefore advisable to take the capsules with food at the same time of day. The dose can then be adjusted according to clinical response and presence or absence of side effects.

The duration of therapy varies according to the dose administered over the course of the treatment period. The range is usually 16–30 weeks, and the mean between 16 and 20 weeks, with patients receiving 0.5 mg/kg/day requiring a longer course of therapy to achieve appropriate results. Studies to derive a cumulative dose for maximum benefit and reduced relapse rate [51] have confirmed that there is a definite effect of both dose and duration of therapy but that there is not an *a priori* pharmacokinetic reason to support the concept of accumulation of drug or a cumulative dose effect. Post-therapy relapse is minimized by treatment courses that amount to a total of at least 120 mg/kg, but there is not necessarily any added benefit when 150 mg/kg is exceeded [51]. Typically, this total dose can be achieved by 4–6 months at 0.5–1.0 mg/kg/day. The duration of therapy should be adjusted to give at least 90% clearance of acne based upon initial clinical acne grade scoring techniques followed by 4–8 weeks of consolidation.

Demographic factors, such as age, sex and duration of acne, may also govern the rate of response and relapse. Males with extensive truncal acne, more severe acne, and/or suffering from acne for less than 7 years, fail to respond as well as, and relapse more quickly than, female patients with predominantly facial acne of a less severe grade.

Eighty-five per cent of patients who receive a dose of 0.5–1.0 mg/kg/day are virtually clear of their acne by 16 weeks. Thirteen per cent require 5 or 6 months to clear, and 3% require a longer course. Less than 1% of patients may need up to 12 months of continuous therapy. Low-dose courses of isotretinoin have been used successfully in mature adults with persistent and late-onset acne [28,29]. A typical approach consists of 0.5 mg/kg/day taken 1 week out of 4 for a period of 6 months. Ninety-one per cent will be clear of acne using this regimen [54] but relapse is disappointingly frequent. Furthermore, some patients will not accept even minimal disease and become very dependent on these small doses, expecting to stay on the drug for many years at this lower dosage. It is not clear whether this approach will result in long-term adverse effects and it is important to clarify with the patient that although nothing untoward has been reported to date this is clearly using the drug outside recommended guidelines and is not deemed appropriate for a female of reproductive potential.

What are the reasons for a slow response to isotretinoin?

Analysis of slow responders to isotretinoin shows that the cause is due to the presence of macrocomedones (see Fig. 42.63) in the majority of cases 70% [55], although hyperandrogenism may also play a part in resistance to isotretinoin therapy [56]. An early post-isotretinoin flare, poor absorption, possibly differences in receptor

Fig. 42.63 Macrocomedones may be a reason for acne flare when treated with isotretinoin.

sensitivity, colonization with *Staphylococcus aureus*, severe acne and unusual variants account for 25% of poor responders, and the cause of poor response is unknown in about 5%.

Macrocomedones may be subtle and should be detected under a suitable lamp with the skin stretched. They should be identified before systemic isotretinoin is started as an acute flare of acne may ensue if left untreated before embarking on isotretinoin [57]. Treatment requires light cautery or hyfrecation. A local anaesthetic cream should be applied to the lesions for the requisite time beneath an occlusive dressing and then the lesions touched gently with light cautery [58] or hyfrecation. This procedure should initially be performed on a test area of 10 cm^2, to ensure that the patient does not develop scarring or hypo- or hyperpigmentation.

When macrocomedones are not the cause of poor response, the dosage of isotretinoin should be carefully considered as some patients will suffer a deterioration in their acne at the start of a course of isotretinoin [57]. If the poor response or worsening acne is thought to be due to an early post-isotretinoin flare which is well reported an antibiotic can be used in combination with isotretinoin such as erythromycin 1 g daily or trimethoprim 200–300 mg twice daily. Tetracyclines should be avoided in combination with isotretinoin due to a possible increased risk of benign intracranial hypertension [59,60].

If the acne is very inflammatory, then a significant reduction in the dose of isotretinoin and addition of oral steroids may be required (e.g. 0.5–1.0 mg/kg/day for 2–3 weeks). In other patients it may be appropriate to increase the dose of isotretinoin providing that the side effects are tolerated.

Some patients do not appear to metabolize isotretinoin as well as others and therefore may require higher doses. Adherence to therapy must also be considered. Mucocutaneous side effects, particularly cheilitis, are usually a good measure of absorption.

Unusual variants as discussed elsewhere may lead to slow response and some female patients with hormonal dysfunction, due, for example, to polycystic ovarian syndrome, may need additional treatment with a hormonal preparation such as co-cyprindiol.

Persistent deep pustules in about 1% of patients may be due to *Staphylococcal aureus*, and bacterial swabs should always be examined and appropriate antistaphylococcal therapy prescribed. Some patients have multiple reasons for the slow response.

Further courses of therapy are usually successful when required. There are no reports of cumulative toxicity from using repeat courses and tachyphylaxis has not been noted.

Side effects

Isotretinoin has many side effects but most are predictable and rarely interfere with the patient management [16–18,23,25,47]. The common mucocutaneous side effects are dose dependent and rendered tolerable by modification of the dose and/or additional symptomatic therapy.

Teratogenicity is well recognized and regarded as one of the most serious potential adverse effects [61]. Fifty per cent of pregnancies spontaneously abort, and of the remainder about half of the infants are born with cardiovascular or skeletal deformities. The recently introduced European Directive and iPLEDGE in the USA have addressed the importance of pregnancy prevention as discussed previously. Discussion about the teratogenicity and recognized side effects should be recorded in the notes at each visit, and patients should be given appropriate written information.

Mood changes including depression are common among adolescents and have been reported in acne patients treated with isotretinoin. Two studies that looked at spontaneous reports of side effects for the Food and Drug Administration (FDA) in the USA [62,63] found little or no increase in psychiatric disease including depression and suicide over the background prevalence in the adolescent population. A further study of general practice databases in Canada and the UK showed similar findings [64] as have subsequent studies [65]. A more recent controlled case crossover study demonstrated a relative risk for depression of 2.68 (95% CI = 1.03 to 3.89) for acne patients exposed to oral isotretinoin [66]. This is the first controlled study to find a statistically significant association between isotretinoin and depression. Despite contradictory reports, clinicians have been advised of a potential rare idiosyncratic reaction in some young vulnerable patients which could lead to mood changes and clinical depression during treatment with isotretinoin. It is therefore advisable to specifically enquire about related symptoms at each clinic visit.

A suggested short questionnaire with good stringency is:

Over the past 2 weeks have you consistently . . .

1 Been feeling unusually sad or fed up?
2 Lost interest in things that used to interest you?
3 Felt any more short tempered or irritable than you used to?

If significant depression is identified, then a psychiatric referral may be indicated. Increased aggression has been identified in some male patients and the FDA in the USA has advised clinicians to warn potential patients about this side effect. If there is any doubt, the drug must be stopped.

The mucocutaneous side effects are dose dependent and can usually be controlled with regular use of moisturizers and lip salves. Occasionally retinoid dermatitis, a severe retinoid cheilitis or conjunctivitis occur (Figs 42.64 & 42.65), often complicated by secondary infection with *S. aureus* (Fig. 42.66).

Fig. 42.64 Patient with troublesome cheilitis due to oral isotretinoin.

Fig. 42.65 Patient with troublesome discoid eczema due to oral isotretinoin.

Fig. 42.66 Patient with troublesome facial crusting (and *Staphylococcus aureus* infection) due to oral isotretinoin.

These patients may need treatment with an intermediate-strength steroid ointment combined with an antiseptic. If there is impetiginization, oral antistaphylococcal therapy such as flucloxacillin and/or topical mupirocin 2% ointment may be required [67]. A nasal preparation of mupirocin can be used to eradicate nasal carriage of staphylococci.

Table 42.17 and Table 42.18 outline common and rarer side effects reported with isotretinoin.

Significant systemic effects are uncommon; headaches may uncommonly be an early feature of benign intracranial hypertension and arthralgia is seen most frequently in those patients participating in regular and heavy exercise. Tetracyclines, including doxycycline and minocycline, must not be prescribed with isotretinoin, as both drugs may produce benign intracranial hypertension [60]. Systemic side effects are usually well controlled by dose reduction and concomitant use of non-steroidal anti-inflammatory drugs or aspirin. There is a long list of very uncommon, systemic side effects (Chapter 75); a detailed review of these is beyond the scope of this chapter.

Table 42.17 The most common mucocutaneous problems that may arise from isotretinoin use.

Adverse effect	Incidence (maximum %)
Cheilitis	98
Conjunctivitis/blepharitis	35
Dermatitis	65
Desquamation	20
Facial erythema	65
Epidermal atrophy	25
Epistaxis	35
Fragility of skin	20
Itching	25
Mucositis	40
Vestibulitis	50
Xerosis	50

Table 42.18 Less common but recognized side effects of isotretinoin.

Achilles tendonitis
Acne fulminans
Depression
Diarrhoea/colitis
Elkonyxis
Hair loss
Headaches/benign intracranial hypertension
High-tone deafness
Mood changes
Night blindness
Paronychia
Pyogenic granulomas
Sticky palms
Urticaria
Vasculitis

An acute flare of acne early in a course of isotretinoin is a recognized problem in about 6% cases and is clinically significant in half of these [57]. The physician should inform patients accordingly and provide a fast track follow-up should this problem occur as these flares can be very aggressive producing physical and psychological difficulties. Predisposing risk factors for a flare include the presence of macrocomedones and nodules [57]. If a severe flare occurs oral prednisolone should be given in a dose of 0.5–1.0 mg/kg/day over a period of 2–3 weeks, and the dose slowly decreased over the next 6 weeks. The isotretinoin should either be stopped or reduced to a dosage of 0.25 mg/kg/day depending on the severity of the problem. If stopped, the drug can be slowly reintroduced at a dose of 0.25 mg/kg/day, and then increased or decreased as response dictates.

There has been much debate as to whether liver function tests and lipids should be monitored while on therapy. Elevations in these tests occur in almost all patients and rapidly return to pretreatment levels after therapy has been stopped [15,21,68]. It is,

however, essential to carry out these tests before starting therapy. Published evidence suggests that the laboratory tests need not be repeated except in groups at risk, such as diabetics and patients with known familial hypertriglyceridaemia [24,68]. However, the EU directive is prescriptive in suggesting these investigations should be performed at baseline, 1 month into therapy and 3-monthly throughout treatment. Amichai and Grunwald have published an excellent overview on the many side effects of oral isotretinoin [69].

Cost-effectiveness

Oral isotretinoin is clearly more effective than oral antibiotics in acne of all grades of severity. However, its relative expense and side effects have deterred some physicians from prescribing it. Cost-effectiveness comparisons, prior to the EU directive and iPLEDGE, in the UK [70,71], France [72], New Zealand [73] and Australia [74] have shown that a 4–6-month course of isotretinoin is significantly cheaper than a 3-year therapeutic regimen of rotational courses of antibiotics and topical treatment. In fact, only patients treated with isotretinoin achieved complete clearance of acne when assessed 3–5 years post-treatment [60]. Generic isotretinoin has made the cost-effectiveness more apparent. However, the extra investigations, monitoring and prescription control introduced with the European Directive and iPLEDGE have negatively impacted on this cost-effectiveness.

Drug interactions

Reduced efficacy has been noted when isotretinoin is taken with heavy alcohol intake [75]. Isotretinoin is metabolized by cytochrome P450 enzymes, inducible by ethanol and inhibited by some drugs, for example ketoconazole. Hence, increased drug levels of isotretinoin may occur if combined with imidazole fungistatics. Salicylic acid and indometacin represent acidic drugs with a high affinity for albumin. If present in the blood in high therapeutic concentrations they may displace isotretinoin from protein binding sites, so resulting in an increase in the unbound concentration of the drug [76]. Carbamazepine plasma levels decrease when concurrent isotretinoin is taken, hence careful monitoring should be considered in epileptics on carbamazepine if requiring isotretinoin [77]. Oral tetracyclines in combination with isotretinoin should be avoided, as both can lead to benign intracranial hypertension. These are likely to be rare idiosyncratic reactions attributable to each drug in its own right, but there are reports in the literature suggesting there could theoretically be an additive effect by combining the two [60]. Vitamin supplements containing vitamin A should be avoided alongside isotretinoin, as additive toxic effects could ensue.

Other oral treatments

Several other oral treatments may occasionally be adopted for management of difficult acne if the newer drugs are contraindicated, unobtainable or ineffective. Oral zinc is of some value [1–6]. Two double-blind studies showed a significant benefit, particularly with zinc gluconate (200 mg/day). Comparison with minocycline 100 mg/day demonstrated the antibiotic improved acne by 63% in contrast to 32% with 30 mg/day of elemental zinc after 3 months, no placebo was included in the study. Certain non-steroidal anti-inflammatory drugs, such as ibuprofen and benoxaprofen, have been shown to reduce inflamed lesions [7]. More recently, a small pilot study using a 5-lipoxygenase inhibitor elicited a reduction in inflamed lesions and seborrhoea but had little effect on comedones [8]. Clofazimine (200 mg three times a week) has been shown to improve acne fulminans [9]. Dapsone (100–300 mg/day for 6 months) has also been tried with varied success [10,11]; it is much less effective than isotretinoin [11].

Oral vitamin A has been used [12,13] but doses of less than 40 mg/day are not effective and in our experience, oral vitamin A proved considerably less effective than 1 g/day of either tetracycline or erythromycin. The side effects of oral vitamin A are similar to oral isotretinoin.

Oral prednisolone (0.5–1.0 mg/kg body weight/day) should be prescribed in patients with severe inflammatory acne vulgaris and in acne fulminans and pyoderma faciale [14]. Oral steroids are also indicated in patients whose acne flares badly while taking oral isotretinoin [14]. If these patients have many macrocomedones,

they should be urgently treated with light cautery under a local anaesthetic cream such as EMLA® [15].

Physical modalities for treating active acne

Some of the physical modalities used as an adjunct to treatment require considerable skill. The many abrasive materials, usually based on polyethylene and aluminium oxide, are of little or no value. Facial saunas, heat and massage probably worsen the condition by precipitating the development of inflamed lesions. Removal of comedones can be aided by hot compresses. Comedone removal can be surprisingly uncomfortable, and a variety of specially shaped tools, particularly for blackhead removal, are available. Some patients have very visible closed comedones, which often become inflamed. For these lesions, the eccentrically placed pore may be widened with a small blade under a good light, which allows enucleation of the cornified plug with the comedo remover. The limitations of comedonal extraction include incomplete extraction, refilling and the risk of tissue damage. Light cautery or hyfrecation after the application of a local anaesthetic (EMLA®) [1] has been shown to help patients with multiple macrocomedones; these are usually whiteheads but occasionally blackheads (up to 1.5 mm diameter), and chloracne can be improved [1,2]. A topical anaesthetic preparation is applied for the requisite time beneath an occlusive dressing. The cautery or hyfrecation should be set as low as possible to produce little or no pain. The tip of the instrument should be just sufficiently warm to char paper towelling. The aim is to produce very low-grade thermal damage so as to stimulate the body's own defence mechanisms to eradicate the comedo. The actual treatment of each lesion takes seconds and is associated with very little scarring or post-inflammatory pigmentation. This therapy is more effective than topical tretinoin for macrocomedones [3].

Until recently, there has been little objective assessment of treatment by UV radiation. Broad-spectrum sunlamp therapy is probably not as good as natural sunlight; both provide only short-term benefits in acne. Lasers and light-based devices have been available over the last few years, and there has been increasing interest in their use in acne. The mode of action for light therapy relates to destruction of propionibacteria via targeting porphyrins produced by these bacteria. There is a differential cytotoxic effect, in that cutaneous bacteria, including *P. acnes*, are more susceptible to short-term damage from, for example, photodynamic therapy, than keratinocytes [4]. These regimens also significantly suppress a range of comedonal and pro-inflammatory cytokines [5,6].

To date, the evidence in support of the use of lasers and light devices is poor. A significant number of randomized controlled trials (RCTs) embracing light of diverse wavelengths have been conducted, but results from these studies have been contradictory. Many of the studies include small numbers and short follow-up periods, and have not compared these therapies to conventional treatments used for acne. Outcome measures have also been very variable, making comparison between trials and meta-analysis difficult. A systematic review assessing lasers, light sources and photodynamic therapy (PDT) for acne in 16 randomized controlled and three controlled studies confirmed most light sources do help in the short term, with PDT showing the most consistent results (up to 68% improvement, aminolaevulinic acid, methyl aminolaevulinic acid and red light) [7]. One single-blinded RCT of red light in Asian women showed a 66% improvement in acne at 8 weeks [8]. However, the light was self-administered to the randomized side of the face with no treatment given to the other side (not even a conventional topical treatment) and the results were reported as percentage improvements, with no actual figures, so it is difficult to judge whether improvements were clinically significant. A well-conducted RCT of infrared laser therapy versus placebo treatment showed no difference between the laser and placebo for acne, but there was a transient improvement in open comedones or blackheads [9]. An RCT comparing intense pulsed light (IPL) versus benzoyl peroxide in Asian women found that both treatments improved acne, but there was no statistically significant difference between the two treatments [10]. One controlled study demonstrated that blue light improved inflammatory lesions by 76% compared with benzoyl peroxide, which resulted in a 60% improvement, suggesting the benefits of light therapy were only marginal [11]. A small randomized controlled trial of IPL-PDT versus IPL versus control [12], with all subjects using adapalene 0.1% gel at night, showed no significant difference in improvements in acne lesions between the groups, but a statistically significant improvement in comedones in the light treatment groups. However, the confidence intervals for the results were large, reflecting the small numbers of subjects. Laser therapy with the NLite laser, which emits light at 585 nm, has been reported in a small randomized controlled trial to produce a 50% improvement

in acne grade and lesion counts by 12 weeks after a single treatment [13].

Light therapy may cause pain, erythema, crusting, oedema, pigmentary changes and pustular eruptions. The intensity of these problems is more likely when aminolaevulinic acid or methyl-aminolaevulinic acid are employed in the treatment, and frequently leads to the patient not pursuing further therapy. The other concern relates to long-term safety, as sebocytes are necessary for the immune function of the skin and may be permanently damaged by PDT. Topical amino laevulinic acid (ALA) plus broad-band light (550–700 nm) has been shown to produce acute damage to the sebaceous glands, resulting in significant sebum suppression for up to 20 weeks post-therapy; this was associated with a significant decrease in *P. acnes* for many weeks [12].

Patients should be informed of the existing evidence, which indicates that optical treatments today are not included among first-line treatments.

Superficial freezing with liquid nitrogen will hasten the resolution of chronic fluctuant nodular lesions and is comparatively painless [14]. Two freeze–thaw cycles of 15–30 seconds each are recommended, depending on the size of the nodule. It is uncertain how this treatment works, but it probably invokes an inflammatory reaction, so breaking down the indolent tissue surrounding the lesion. Cryotherapy is probably preferred to intralesional steroid injections in the treatment of older (7 or more days) nodular lesions, whereas intralesional steroid is preferred in lesions less than 7 days old [15]. Triamcinolone, 2.5 mg/mL, may be administered from a syringe with a 30-gauge needle [15,16]. Placement too superficially or too deeply may cause atrophy; 0.025–0.1 mL should be injected into the middle of the lesion, causing slight distension. Aspiration before the steroid injection is desirable but not always possible because of the nature of the fluctuant nodular lesions, which are not true cysts. Deep X-ray treatment must not be prescribed because of its carcinogenic risk. Superficial X-ray therapy (no more than 8.1 Gray given in fractionated doses to any one area of skin in a lifetime) has been advocated, but is of questionable benefit.

Chemical peels [17,18]. Some dermatologists in certain countries use light chemical peels to help remove comedones as well as possibly helping superficial scarring and hyperpigmentation. Peeling agents include α-hydroxy acids (glycolic acid), salicylic acid and trichloroacetic acid. A small split-face, double blind randomized controlled trial comparing α-hydroxy and β-hydroxy acid peels in the treatment of mild to moderate acne demonstrated that the glycolic acid and salicyclic acid peels were of similar efficacy. The salicylic acid peel had sustained effectiveness and fewer side effects in this study [19]. Chemical peels are said to promote desquamation which reduces corneocyte cohesion and keratinocyte plugging, so enabling the extrusion of inflammatory contents. There is still limited scientific evidence to support the use of chemical peels, but guidelines and evidence for use have been considered in a recent Japanese review [20].

Treatment of scars

There is no good evidence available to promote one therapeutic measure over another in the treatment of acne scars. Response to treatment is variable and sometimes not that successful. Some scars will become less conspicuous over time and where possible it is worthwhile adopting a wait and see policy. Recent interest in the pathogenesis of wound healing and scars may pave the way for new oral and topical therapies. The expansion of dermatological surgery and new lasers hold some promise. Surgical/laser therapies for scars should be reserved for patients whose acne is under good control. Treatment of facial scars associated with loss of tissue may include excision, planing and filling techniques. Such techniques are rarely used for scars on the trunk.

Treatment of atrophic scars

Excision of scars. Small, well-defined scars can sometimes be satisfactorily excised via punch excision, sub-cision or punch elevation [1].

Dermabrasion and laser resurfacing [2–7]. These may be of value for depressed scars of even depth, but multiple ice-pick scars of irregular depth respond badly. Dermabrasion involves the use of a high-speed wire brush or diamond fraise to plane the skin under local or general anaesthesia. It is best avoided in summer because of the risk of post-inflammatory hyperpigmentation. Hypopigmentation can also occur in some patients. Postoperative care is very important, and should include the use of a topical sunscreen and in some cases prophylaxis with oral aciclovir to prevent herpes simplex infection. In the past 5 years, laser resurfacing has taken over from dermabrasion [6,7].

A recent review on laser resurfacing for acne scars confirmed that there is lack of good-quality evidence for any conclusions to be drawn about the effectiveness of lasers for treating atrophic or ice-pick acne scars. No randomized, controlled trials where laser treatment was compared to either placebo or a different type of laser were found. Most of the 27 studies uncovered were poor-quality case series with small numbers of acne-scarred patients. The authors therefore concluded that well-designed, randomized controlled comparisons of carbon dioxide versus Erbium:YAG laser are urgently needed [8].

Filling materials. Injections of purified bovine dermal collagen to augment tissue defects are of limited benefit, but have been shown to help soft scars that are easily stretched [9–11]. Deep ice-pick and fibrotic scars show little improvement. Degradable, biosynthetic implants such as hyaluronic acid (Restylane, Perlane) are now being used in preference to collagen as the potential risks of sensitization and foreign body reactions are much lower with these agents.

Recollagenation of acne scars refers to a technique in which an implant of freeze-dried, irradiated human cadaver fascia lata is placed in an intradermal pocket at the site of each scar through a needle hole to elevate the depressed epidermis [12]. A further alternative is the injection of autologous fat into atrophic scars.

Gelatine matrix implant. One or two injections of this preparation have been shown to help scars and the improvement was maintained over 2 years [13].

Chemical peeling. Chemical peeling has been used in the treatment of atrophic acne scars. Expertise is required for such a procedure. Several chemical agents are used, including α-hydroxy acids, glycolic acids and resorcinol. The reader is referred to detailed texts on how, when and why to use chemical peels [14–17].

Multiple treatments. If several approaches are required, it is probably best to excise the larger scars and then re-plane the skin surface using lasers. Filling agents may then be necessary. In older patients with significant loss of tissue, face-lifts may help.

Treatment of hypertrophic and keloids scars

Keloids and hypertrophic scars (Fig. 42.67) also vary in their response to therapy, but several options are worth trying. These include steroids, either potent topical steroid creams or triamcinolone depot injections, excision, cryotherapy or topical application

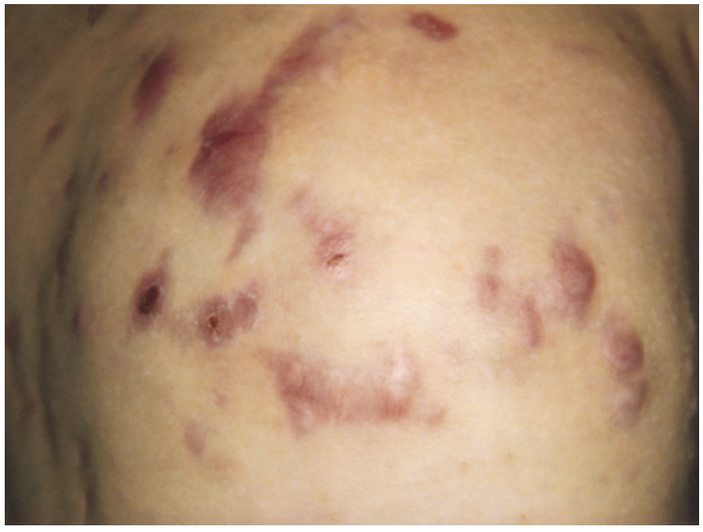

Fig. 42.67 Hypertrophic and keloid scars over the upper trunk.

of silicone gels. There are several papers that testify to both the benefit and pitfalls of such therapy [18,19]. Potent steroids such as clobetasol propionate need to be applied carefully to the scar, usually twice daily, avoiding adjacent skin to prevent atrophy of the perilesional skin. Each treatment should be used initially for 2 months. Intralesional triamcinolone (2.5 mg/mL; 0.05–0.1 mL) injections into the scars can be tried at monthly intervals for a few months and the decision about subsequent therapy based on the response. Excision is frequently followed by recurrence, which may be larger than the original lesion. Double-blind studies are needed to confirm the optimum therapy for hypertrophic and keloid scars. It is important to remember that some scars improve with time and without treatment. Vascular keloids may benefit from therapy with the pulsed tuneable dye laser [20]. Silicone gel sheeting applied for 12/24 h per day for at least 2 months to young hypertrophic and keloid scars has been reported to be of benefit [21]. Such sheets are available without prescription in many countries but adequate trials are lacking.

Many patients have multiple scars, and since multiple treatments are available then different treatments could be used for different scars—perhaps with some not being treated to act as an internal control. This approach might determine the natural resolution of the patient's scars.

Cosmetic camouflage. Although certain cosmetics may induce acne, it is often psychologically necessary for female patients to use some form of cosmetic camouflage. Patients can be advised that they can wear light, non-greasy make-up. In certain countries, professional advice is available, and in the UK these cosmetics are available on prescription. Make-up is often needed for persistent post-inflammatory pigmentation seen most frequently in darker skins. Topical all-*trans*-RA and azaleic acid may be of possible therapeutic benefit in reducing post-inflammatory pigmentation, but therapy has to be continued for many months.

Uncommon associations with acne

A miscellaneous group of either distinct diseases or unusual physical features which may coexist with acne are included in this section. In some, the association is unquestionable, but in others the association is debatable. In many of these clinical situations much more research is required to provide clarity.

Acne excoriée

Synonym
- Acne des jeunes filles

Acne excoriée is considered a subset of neurotic excoriations. It is seen predominantly in adolescent girls and young women (Fig. 42.68) and is regarded as a self-inflicted skin condition in which the sufferer compulsively picks real or imagined acne lesions. The disease can emerge into dermatitis artefacta. There is frequently some personality or psychological problem underlying the condition including obsessive compulsive disorder [1,2]. Evidence of linear erosions is suggestive of self-mutilation, and underlying psychiatric disease should be suspected [3]. An atopic background may be evident and the patient often complains of significant pruritus in the lesions. A contact dermatitis should be considered and excluded [4]. The persistent trauma to lesions can result in significant scarring.

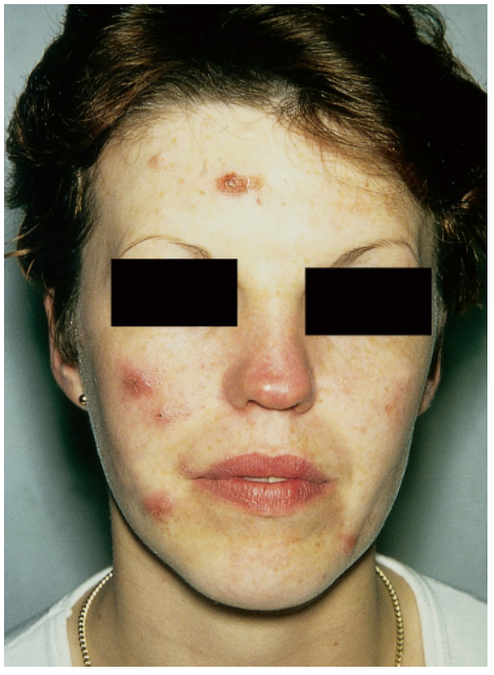

Fig. 42.68 A patient with acne excoriée.

Treatment can be difficult. The importance of not picking needs to be emphasized. If active acne is evident, an aggressive approach to treatment should be utilized. By reducing the number of inflammatory lesions, the regimen leaves the patient with fewer spots to tamper with. Topical treatment has a tendency to irritate the skin and aggravate the problem.

In those with virtually no acne spots, trifluoperazine hydrochloride (5–30 mg/day), pimozide (2 mg twice a day) and olanzapine 2.5–5 mg daily have all been used with some success [5,6] along with psychotherapeutic support. In addition, doxepin as well as selective serotonin re-uptake inhibitors such as fluoxetine have been used, as has sertraline. Hypnosis and habit reversal techniques have also been utilized [7,8]. Treatment for facial scarring and ulceration resulting from acne excoriée has been improved using the 585-nm pulsed dye laser along with cognitive psychotherapy [9].

Apert's syndrome

Synonym
- Acrocephalosyndactyly

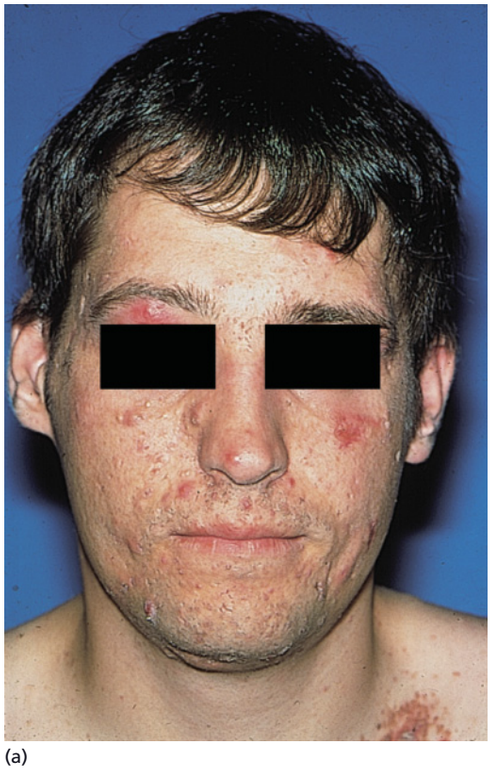
Apert's syndrome is a rare congenital type I acrocephalosyndactyly, characterized by craniosynstosis and early epiphyseal closure which results in deformities of the skull, hands and feet. The characteristic facial abnormalities are: hypertelorism, a flattened occiput, proptosis due to shallow orbits, prognathism, a parrot-beaked nose and fused shortened digits. Severely delayed tooth eruption, shovel shaped incisors and malocclusion of teeth occurs.

Abnormalities of the upper and lower respiratory tracts include cleft soft palate and bifid uvula [10]. There is an association between acne and Apert's syndrome [11–12] and most adolescents with this disorder are prone to the development of severe pustular acne which can extend from the usual sites on the trunk and face to forearms and buttocks (see Figs 42.61 & 42.62) [13]. Early epiphyseal closure, like acne, is an androgen-mediated event. No difference in the androgen receptor expression has been demonstrated between patients with Apert's cases compared to controls, suggesting that the underlying problem in Apert's relates to abnormal sensitivity to normal circulating levels of androgens rather than excess numbers of androgen receptors [14–16].

Other cutaneous changes reported in Apert's include seborrhoea, hyperhidrosis, nail dystrophy, hyperkeratosis of plantar surfaces and ocular and cutaneous hypopigmenatation [17]. Apert's syndrome may be inherited as an autosomal dominant, but most mutations are new and of paternal origin, with a 1% risk of a second child being affected. The genetic defect is a missense mutation of the amino acid substitution of serine–proline dipetide in exon 7 of chromosome 10, the fibroblast growth receptor (*FGFR-2*) [18].

The acne responds less well to topical preparations and oral antibiotics in Apert's syndrome and patients frequently require oral isotretinoin [19,20]. Etretinate has also been reported to be beneficial in refractory cases [21].

Body dysmorphic disorder and acne



A small number of patients with body dysmorphic disorder have acne as their prime symptom [22]. The acne is usually very mild, and the patient's complaint is out of all proportion to the physical signs. These patients require much support; they are often depressed or obsessional and have a significant risk of suicide [23]. Unfortunately, they usually tolerate psychiatric treatment badly, and the dermatologist must treat the acne aggressively with effective treatment. Isotretinoin given for 4 months is the preferred therapy. The authors consider that 'relapse', either real or perceived, is common and requests for further isotretinoin are also common [24]. This subject is dealt with in greater detail in Chapter 64.

Darier's disease

This disease is discussed in detail in Chapter 19, but it is possibly associated with acne; some patients with Darier's disease have significant nodular acne that can be very difficult to treat with antibiotics, oral isotretinoin or acitretin. The variable penetrance of Darier's disease means that sometimes the clinical features are relatively inconspicuous, such that Darier's disease may be initially missed in patients with severe nodular acne (Fig. 42.69). Two patients with prominent nodular and comedonal lesions on the face and scalp showed histological features of Darier's disease on examination of a comedone [25].

Drug-induced acne/acneiform eruptions

Many drugs have been implicated as possible aggravators or inducers of acne [26–51]. Much of the evidence consists of isolated case reports, and many of the reported reactions are idiosyncratic.

(a)

(b)

Fig. 42.69 (a) A patient with acne conglobata, which can coexist with Darier's disease (b).

Acneiform eruptions account for about 1% of all drug-induced skin eruptions (Table 42.19). Clinically the acne presents as monomorphic inflammatory papules and pustules with little evidence of comedones, contrasting with the heterogeneous morphology usually seen in normal acne. The face and upper trunk are most frequently affected. The interval between the onset of the acneiform eruption and the start of the drug implicated depends very much on the agent provoking the response. Only those substances that definitely induce acne or acneiform eruptions will be discussed.

Table 42.19 Drug classes and types of medication that may exacerbate or cause acne.

Drug class or type	Examples
Corticosteroid:	
topical	Betamethasone
oral	Prednisolone
inhaled	Budesonide
ACTH	ACTH, synthetic ACTH
Anabolic steroid/synthetic androgen	Danazol, nandrolone, stanozolol
Anticonvulsant	Carbamazepine, phenytoin, phenobarbitone, troxidone, gabapentin, topiramate
Antidepressant	Lithium, sertraline
Other neuroleptic/antipsychotic	Pimozide, risperidone
Antitubercular	Isoniazid, pyrazinamid
Antineoplastic/EGFR-antagonists	Dactinomycin, pentostatin, cetuximab
Antiviral	Ritonavir, ganciclovir
Calcium antagonist	Nilvadipine, nimodipine
Halogen	Sodium fluoride, potassium iodine
Human growth hormone	Genetically engineered human growth hormone
Vitamins	Vitamin B_{12}, possibly other B vitamins
Miscellaneous	Buserelin, cabergoline, ciclosporin, clofazimine, dantrolene, disulfuram, famotidine, follitropin alfa, isosorbide mononitrate, medroxyprogesterone, mesalazine, quinine, ramipril, sulphur, thiouracil, thiourea

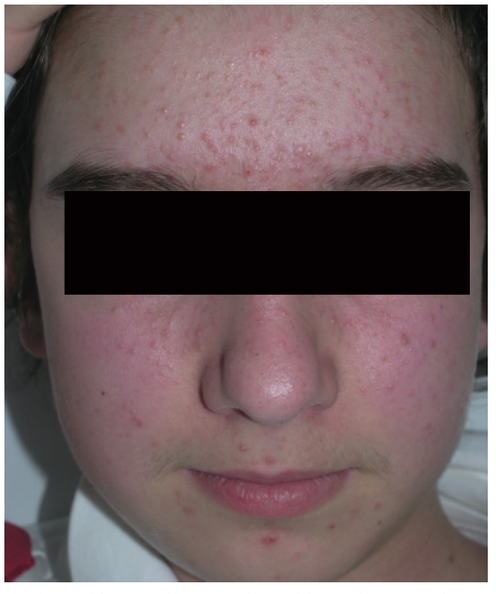


Fig. 42.70 A patient with acne due to oral steroids used to treat dermatomyositis. (Courtesy of Dr V. Bettoli, University of Ferrara, Italy.)

Corticosteroids may provoke an acneiform reaction regardless of their route of administration (Fig. 42.70) [31–36]. The precise mechanism is uncertain. Corticosteroids induce cornification in the upper part of the pilosebaceous duct, but do not affect the number of surface bacteria [31,33]. Steroid acne is usually, but not invariably, more monomorphic than true acne vulgaris; however,

Fig. 42.71 Acneiform rash in a gentleman receiving cetuximab for colonic cancer.

both inflammatory and non-inflammatory lesions may be present on the face, back and chest [50].

Androgens including anabolic steroids and gonadotrophins may precipitate acne, especially in athletes who take performance-enhancing drugs [37–41]. In the former group, both testosterone and stanazolol have been shown to increase sebum excretion and the surface population of *P. acnes* [40]. Acne is said to occur in up to 50% of athletes and body builders that abuse anabolic–androgenic steroids, especially in young men 18–26 years old. Both acne conglobata and acne fulminans may result [41].

Antiepileptic drugs, especially phenytoin, have been incriminated in case reports in the past, but a study of severe epileptics taking several different anticonvulsants showed that they were at no more risk of acne than the normal population, although some patients with severe epilepsy showed features of hypogonadism [42].

Isoniazid, especially in patients who slowly inactivate the drug, provokes an acneiform rash [43]. A small number of patients receiving PUVA treatment have been reported to develop a perioral dermatitis and/or an acneiform eruption on the face [44,45].

An acneiform eruption has also been described in patients taking amineptine [29,46]. Most reported cases have involved adult females. Comedonal lesions are the most prevalent and inflammatory lesions are usually absent or few in number. The causal mechanism is unknown; the drug contains no halogenated substances. The drug should be withdrawn, but the response is variable and oral isotretinoin (0.5–1.0 mg/kg/day) plus physical treatment of the comedones appears to be the most appropriate treatment.

A follicular acneiform eruption (Fig. 42.71) has been reported in cancer patients treated with the anti-EGF receptor inhibitors [47,48]. The consistency of lesion morphology and timing following monotherapy with this antibody suggest a direct biological effect of the antibody. Histological examination of the lesions, which occur within a few weeks of receiving the antibody, has demonstrated a superficial dermal inflammatory cell infiltrate surrounding a dilated follicular infundibulum. A direct correlation

Fig. 42.72 A patient with acne due to lithium. (Courtesy of Dr V.M. Yates, Royal Bolton Hospital, Bolton, UK.)

Fig. 42.73 A patient with pomade acne.

between efficacy to cancer therapy and severity of acneiform reaction has been reported [48].

Iodides and bromides used to be a common cause of follicular pustules that were marked by the rapidity of onset after starting these preparations [49,50]. In contrast to acne vulgaris, all people and all ages were affected. Lithium is currently still an occasional cause of iatrogenic acne (Fig. 42.72).

In all cases, the risks and benefits must be assessed, and the causative drug should be stopped if possible. Clinicians should enquire about use of over-the-counter products, as well as treatments prescribed, when trying to elicit a drug-related cause for acne.

Endocrine acne

The role of the endocrine system in the aetiology of acne is discussed elsewhere in this chapter. Most patients suffering from acne have no underlying endocrinological abnormalities. The term 'endocrine' acne should be reserved for cases associated with clear signs and symptoms of endocrine disease such as Cushing's disease, late-onset congenital adrenogenital syndrome and polycystic ovarian syndrome. The latter is the commonest cause of 'endocrine' acne. The acne is generally more severe, associated with marked seborrhoea, may present abruptly and is frequently more refractory to therapy. Insulin resistance and acanthosis nigricans can occur in the context of hyperandrogenism in the HAIR-AN syndrome. These patients should be monitored carefully as they have an increased risk of cardiovascular disease and type II diabetes. Also reported is the so-called SAHA syndrome (*s*eborrhoea, *a*cne, *h*irsutism and *a*lopecia), which can be associated with polycystic ovarian syndrome, cystic mastitis, obesity and infertility (Orfanos CE *et al*. data presented at Third Teupitzer Colloquium, Berlin 2000). The association of these clinical features should also alert the physician to exclude an androgen-producing tumour.

Externally induced acne

Cosmetic acne

Cosmetics are cited as a cause for acne particularly in adolescent girls and young women. This variant is reported more commonly in the USA [51]. The lesions characteristically occur in the perioral area, and are seen more frequently in those who had acne as an adolescent and in those who have used cosmetics for a long time. The rabbit-ear model, which is oversensitive for humans, has shown that some cosmetics, especially those containing lanolin, petrolatum, certain vegetable oils, butylstearate, lauryl alcohol and oleic acid, are comedogenic. Many cosmetics, especially in the USA, are now screened by the rabbit-ear test and appropriate cosmetics are labelled as being non-comedogenic [52]. Patients should be warned that switching to a non-comedogenic cosmetic does not bring rapid clinical improvement in cosmetic acne. Treatment with topical retinoids or benzoyl peroxide is usually successful.

Pomade acne

Pomades are greasy preparations used to defrizz curly hair used most frequently in Afro-Caribbeans. The rash is similar to cosmetic acne and consists predominantly of many non-inflamed lesions around the forehead and other areas, where greasy pomades may extend onto the hairless skin (Fig. 42.73) [53]. It may also coexist with true acne vulgaris. The rabbit-ear model has shown that certain pomades are comedogenic. Restriction of the

use of pomades is essential, and the treatment of choice is with topical retinoids.

Detergent acne

This uncommon form of acne develops in patients who wash many times each day, in the mistaken hope of improving their existing acne. Trauma and the alkalinity of soap are likely to be involved in the mechanism. Pustular and papular lesions are most noticeable [54]. Several bacteriostatic soaps contain weak acnegenic compounds, such as hexachlorophene.

Folliculitis on the scalp (dissecting cellulitis of the scalp/folliculitis decalvans) and acne

Scalp folliculitis

About 1% of acne patients will complain of, or are found on examination to have, small papules or pustules in the scalp. In patients with moderate and severe acne, it is not unusual to see inflammatory papules, pustules and nodules in and around the hairline in the occipital area. Despite the frequent occurrence of this association, there have been few clinical and research studies.

Follicular pustules in treated acne patients are also seen in subjects with Gram-negative folliculitis. Patients receiving treatment with oral isotretinoin may develop a pustular scalp folliculitis, which is either due to *S. aureus* infection or may arise for unknown reasons and may persist for several weeks after stopping therapy. If due to a *S. aureus* infection, response to therapies such as oral flucloxacillin is very successful. Significant, very persistent scalp folliculitis associated with an acneiform eruption has been recorded in patients with cyclical neutropenia [55].

Folliculitis decalvans

Folliculitis decalvans is a chronically progressive disorder of the hair-bearing areas on the scalp that leads to scarring, alopecia and atrophy [56–58]. The aetiology is unknown, but in some cases *S. aureus* may be identified from lesions, and it has been suggested that folliculitis decalvans may be the result of an abnormal host response to toxins released from *S. aureus*. If *S. aureus* is identified systemic antibiotics are required; oral clindamycin or rifampicin may help by offering better tissue penetration, one case report suggests added benefit by also using topical mupirocin acid [59]. An isolated case report advocates the use of oral clindamycin in combination with oral isotretinoin and steroids [60]. Topical fusidic acid and oral zinc have also been used with some success in one series [61] but the response to any therapy is frequently poor. Radiation therapy and treatment with dapsone have also been reported in isolated cases [62,63]. Areas of tufted folliculitis have been identified in cases of folliculitis decalvans and the histological features embrace hyperkeratosis, follicular plugging and perifollicular inflammation.

Dissecting folliculitis of the scalp

Synonym

- Perifolliculitis capitis abscedens et suffodiens

This condition is more frequently seen in Afro-Caribbean males. It is an uncommon chronic suppurative disorder of the scalp [64–68]. Together with acne conglobata, hidradenitis suppurativa and pilonidal cysts it is a component of the 'follicular occlusion tetrad'. Patients present with multiple, tender, inflammatory nodules and abscesses most commonly on the vertex and occiput of the scalp. Lesions frequently coalesce into sinus tracts. Scarring alopecia frequently results from the chronic suppurative changes.

Follicular hyperkeratosis appears to be the primary feature in pathogenesis but secondary bacterial superinfection frequently occurs. Histology demonstrates a neutrophilic perifolliculitis with follicular destruction, granulomas and fibrosis.

Lesions characteristically last years and are cosmetically disfiguring, painful and foul smelling. It has been reported to occur with marginal keratitis [64]. Response to therapy is poor. Options include high-dose systemic antibiotics used for acne (such as minocycline 100 mg twice daily, trimethoprim 300 mg twice daily). Success has also been reported with oral zinc sulphate, 135 mg three times a day [65] and topical isotretinoin [66]. A prolonged course of oral isotretinoin has been advocated as one of the most effective treatments [67]. Other treatment options include potent topical, intralesional and systemic steroids and widespread surgical excision with skin grafting [68].

Solid facial oedema

This is a rare and disfiguring complication of acne [69] that has been reported in twins [70]. It is also reported as a consequence of rosacea [71] and in Melkersson–Rosenthal syndrome. The solid symmetrical or asymmetrical facial oedema leads to significant distortion of the midline face and cheeks due to soft tissue swelling most likely due to pre-existing hypoplastic lymphatics. The thickened woody changes are often associated with erythema. The disorder is frequently progressive, and the associated acne must be treated aggressively to minimize the swelling, which can become permanent. Successful treatment with oral isotretinoin alone or in combination with clofazamine or ketotifen has been reported [72–74]. Short or intermittent courses of oral steroids may also help the inflammatory component.

Granulomatous acne

Extensive, localized acne may also be due to an extensive granulomatous reaction (Fig. 42.74) to the mediators of acne inflammation. The precise mechanism producing localized granulomatous acne is not known. The clinical picture is usually that of deep, very well-demarcated lesion(s), especially on the cheeks. Response to therapy is slow and sometimes unsatisfactory, and antibiotics and isotretinoin are of limited benefit; oral steroids are also often required.

These patients often have recurrent relapses and therefore long-term follow-up is recommended.

Hidradenitis suppurativa

This entity is described in more detail in Chapter 30. However, given its occasional association with severe nodular acne, often of the conglobate type, a brief note is necessary. There is often a family history and the onset is usually in late adolescence; the disease may persist up to the age of 40 or 50 years [75–78]. There are very occasional reports of early- or late-onset disease. It is a persistent disease that affects the axillae, breasts, and the genital

Fig. 42.74 A patient with granulomatous acne.

and perianal areas, and may sometimes spread extensively on to the buttocks and lower back. There is clinical evidence of comedones (often polyporous), papules, pustules, deep nodules, large abscesses, sinus track formation and scarring. The inflammatory lesions are frequently deep seated, exudative, painful, and malodorous, which often results in significant compromise of daily activities. Thus, the disease produces a high degree of morbidity [76].

It is primarily a disorder of follicular occlusion. It is not a primary disease of the apocrine gland. Aetiological factors such as hyperandrogenism, obesity, smoking and local irritation (e.g. from excessive sitting) are not consistently associated with the disease, but in some patients may be relevant aggravating factors.

Treatment is usually very disappointing. Therapeutic options include long-term antibiotics as used in acne but in high doses, such as minocycline at 100 mg twice daily, trimethoprim 300 mg twice daily; co-cyprindiol plus additional CPA (100 mg/day taken from the fifth to the 14th day of the cycle); topical retinoids; topical antiseptic washes; oral isotretinoin; oral zinc; and potent topical, intralesional and intermittent pulsed oral steroids (the dose of steroid prescribed depending upon the severity of the inflammation). Combinations of such therapy may also be tried. At the moment, there are no good clinical data to indicate which therapy should be prescribed first and in what order. Finasteride 5 mg/day has been reported to be successful [79] and, more recently, infliximab [80].

Childhood acne

Acne can present in the first year of life and early childhood as well as in the classic prepubertal and adolescent age groups [81]. It is usually mild and transient in the neonatal period but can be more severe and persistent in the infant.

Neonatal acne and neonatal cephalic pustulosis

In the neonatal period, acne may present at birth or shortly afterwards as predominantly comedonal lesions of the cheeks with a paucity of inflammatory lesions. The acne usually settles spontaneously and leaves little in the way of scars. The underlying pathogenesis is thought to relate to hyperactivity of the sebaceous glands stimulated by neonatal androgens from the testes in boys and adrenals in girls [82].

Neonatal cephalic pustulosis (NCP) was historically referred to as neonatal acne [83]. This disorder usually presents in the first 3 weeks of life, and affects about 20% of newborns. It is characterized by erythematous papular/pustular lesions especially on the cheeks but also on the chin, eyelids, neck and upper chest. Comedonal lesions are not usually seen. It has been postulated that NCP develops in association with *Malassezia sympodialis* and *Malassezia globosa*; however, the exact aetiological role of *Malassezia* is uncertain, as the organism is part of the normal flora of neonatal skin, and up to 38% of cases had negative smears in one study [84]. Another explanation is that NCP relates to an overgrowth of lipophilic yeasts at birth that results in an inflammatory reaction leading to monomorphic papules and pustules in predisposed neonates with more sebum production. Treatment is often not required for this self-limiting disorder which usually heals without scarring in 1–3 months. If the condition does persist beyond this time and/or is widespread and unsightly, topical ketoconazole cream helps to shorten the duration of lesions [85,86].

Differential diagnosis should include infections, milia, miliaria, transient neonatal pustular melanosis, sebaceous hyperplasia, erythema toxicum neonatorum, bilateral naevus comedonicus, acneiform eruptions relating to topical applications (acne venenata) or systemic maternal medications (steroids, phenytoin, lithium) or a virilizing luteoma in pregnancy [87].

Infantile acne

Infantile acne is much less common and usually presents later than neonatal acne/NCP at 3–6 months of age but has been reported as late as 16 months [86–98]. Male infants are affected more commonly than females and there may be a history of severe acne in one or more parents. Patients present with facial acne between 3 and 24 months, and the acne may persist up to 5 years of age (Fig. 42.75) [86,87,90–97]. The lesions are generally localized to the cheeks. Clinically, comedonal acne is prominent but inflammatory papules, pustules and nodules can occur and may result in scarring (Fig. 42.76). Rarely, conglobate acne can be seen associated with deep-seated, inflammatory nodules and sinus tracts [86–89].

A study of 29 patients with infantile/juvenile acne over a period of 25 years [88] showed that the median age of onset was 9 months; the disease was mild in 24%, moderate in 62% and severe in 14%. In 59% the acne was predominantly inflammatory. Five patients (17%) were left with scarring. It is important to note that this single study was from a specialist acne centre, and therefore the data may not reflect completely the overall clinical pattern of patients with infantile acne. It is thought that infantile/juvenile

Fig. 42.75 A patient with infantile acne.

Fig. 42.76 A patient who has scarring as a consequence of infantile acne.

acne initially results from transplacental stimulation of the adrenal gland, as most sufferers have elevated plasma adrenal androgens [92]. Sebaceous glands are unique, in skin, in having enzymes capable of converting the adrenal androgen dehydroepiandrosterone to androstenedione and testosterone. It is uncertain why the acne should sometimes last for several years. Infantile acne is very rarely associated with other clinical features of androgen excess such as hirsutism or premature closure of epiphyses; very occasionally, there may be transient or more persistent high plasma levels of testosterone, LH and FSH. An associated virilizing tumour or underlying congenital adrenal hyperplasia is extremely rare. If the child is otherwise well and there are no other abnormal features, no endocrine investigations are required. However, such investigations may be appropriate in a patient who develops acne between 5 and 8 years of age. Occasionally, a drug such as phenytoin has been incriminated, but the evidence is weak [93].

The principles of treatment are the same as for patients with adult acne, except that the tetracycline group of drugs is not prescribed because of the risk of damage to developing bones and permanent discoloration of dentition. For mild disease, topical therapies such as topical retinoids and/or topical antimicrobials (not containing tetracycline) are recommended. For moderate disease, a topical retinoid and/or benzoyl peroxide combined with a systemic antibiotic such as erythromycin (as ethyl succinate, 125 mg three times a day) for 6 months is essential until lesions have totally disappeared. Alternatives include oral trimethoprim (100 mg twice daily) [88].

Deep nodules can be injected with a low concentration of intralesional triamcinolone acetonide (2.5 mg/ml). Infantile acne may take several months to resolve—the more severe the disease the longer the disease lasts [88]. Isotretinoin is rarely needed, and only for severe non-responding cases. Successful treatment with isotretinoin has been reported in the literature using doses of 0.36–2 mg/kg/day for 4–6 months in children younger than 5 years [89,99,100]. Patients with infantile acne may develop significant acne as teenagers [86,88,95–98]. Topical retinoids may provide prophylaxis following systemic therapy [98].

Mechanical acne

Synonym
- Acne mechanica

This term reflects acne that occurs at the site of physical trauma due to repeated mechanical and/or frictional obstruction of the pilosebaceous outlet [101–103]. Comedo formation is the result of the trauma or friction. Examples include ‘fiddler’s neck’, which may occur on the neck of violin players, and is characterized by well-defined plaques with the presence of comedones, lichenification and pigmentation. Headbands, tight bra straps, suspenders and collars as well as turtleneck sweaters may cause localized acne in the frictional sites [102]. The mechanism involved in the development of mechanical acne is unclear. Most patients have a tendency to develop acne, and its localization may be caused by an irritant dermatitis of the upper part of the pilosebaceous duct or excessive hydration at that site. Adolescent patients lying in bed for a long time, for example following a fractured femur in the orthopaedic ward, may develop a flare of acne—so-called ‘immobility acne’. Linear areas and geometrically distributed areas of involvement should raise the suspicion of acne mechanica. This is probably due to a change in the environment of the skin, which may enhance bacterial colonization of the duct [103]. Treatment of

these conditions should include elimination of the causative forces and treatments aimed at reducing non-inflammatory and inflammatory lesions as in other forms of acne.

Occupational acne

Oil and tar acne

This acneiform eruption occurs in areas of skin that are in contact with oils and crude tars [104–107]. It is now much less common because of improved working practices. However, outbreaks do still occur. In a controlled study of 55 workers in a tar distillation plant, 18% in the study group, and 4% of the control group, had periorbital comedones [105].

Not surprisingly, men are more often affected than women. The skin may show conspicuous comedones with just the occasional superficial inflammatory lesion. Occupational acne can occur within 6 weeks of exposure on almost any site, but the thighs and lower arms are especially prone. It has been suspected, but not proven, that individuals with acne vulgaris are more likely to develop oil acne. The commonest oils involved are the impure paraffin mixtures used in the engineering industry. Petroleum products can affect oilfield and refinery workers; workers exposed to heavy coal-tar distillates, especially pitch and creosote, may also develop acne. Dichlorodiphenyltrichloroethane (DDT), asbestos and heavy water distillate has caused acne in some patients.

The treatment is removal from the source of the disease and the use of topical retinoids. If significant inflammatory lesions are present, then topical and oral antimicrobials may help. Very infrequently, oral isotretinoin has been successfully prescribed [107].

Chloracne

This term is used to describe occupational acne caused by exposure to chlorinated aromatic hydrocarbons. Chloracne lesions develop after prolonged exposure to the hydrocarbons and consist of multiple comedones; inflammatory lesions are not always evident [108–123]. Lesions are usually located on both sides of the head and neck (Fig. 42.77), especially the temporal retroauricular and mandibular regions but in more severe cases the chloracne may occur on other parts of the body including the axillae, scrotum, extremities, trunk and buttocks. Inflammatory lesions may be evident as cystic papules and nodules. These may heal with significant scarring and outbreaks may persist for many years after exposure to the causal agent.

Other skin lesions may also occur, including pigmentation, hypertrichosis and palmar and plantar hyperhidrosis. Ophthalmic chloracne may occur, due to the Meibomian gland involvement. Systemic abnormalities are less frequent but when present include fatigue, anorexia, neuropathy, impotence, disturbed liver function and hyperlipidaemia. The chloracne and systemic disturbances may last for many years following exposure [113,116,118,124]. Persistent chloracne, goitre, headache, broken teeth, anaemia and arthritis were more prevalent in patients compared to controls in a 14-year follow-up study following exposure to polychlorinated biphenyls and polychlorinated dibenzofurans [124].

Chloracne has been reported following exposure to a number of chemicals (Table 42.20) linked to electrical conductors and insulators, fungicides, pesticides, wood preservatives and herbicides.

Fig. 42.77 A patient with multiple blackheads typical of chloracne.

Table 42.20 Chemicals resulting in chloracne.

Polychlornaphthalenes
Polychlorinated and polybrominated biphenyls:
Polychlorinated dibenzofurans
Polychlorinated dibenzodioxins
Tetrachloroazobenzenes/tetrachloroazoxybenzenes
Chlorophenol contaminants
Trifluoromethyls
Pyrazole derivatives

Contamination may follow an explosion resulting in the uncontrolled liberation of the chemical [110,116,120]. The chloracnegens have been identified in the blood in some cases [117,121,123]. They have not been identified in the pilosebaceous apparatus, but in one instance exposure to dioxin was reported to produce a hyperproliferative reaction of the cutaneous epithelium with squamous metaplasia of the pilosebaceous duct, with subsequent atrophy of the sebaceous gland [121].

The skin lesions are relatively persistent and resistant to treatment. Topical therapy with retinoids such as adapalene and tretinoin are worthy of a therapeutic trial; long-term oral antibiotic therapy may be needed for the inflammatory lesions. Oral isotretinoin does not help. This is not surprising, since the sebaceous gland has already undergone atrophy [121]. Gentle cautery under local anaesthetic cream (EMLA® applied for 60–75 min under polythene occlusion) produces excellent results [124]. Litigation is frequent when the contamination follows an industrial accident.

Osteoma cutis

This term denotes the development of focal ossifications in the subcutaneous and dermal tissue. This uncommon complication of acne is described more commonly in women with long-standing inflammatory acne and usually needs no treatment [125–127]. The calcification presents as small, 2–4 mm persistent papules, which are slightly firm to touch and usually skin or ivory coloured, mimicking macrocomedones and cysts [128]. They are occasionally associated with hyperpigmentation, especially after therapy with minocycline and tetracyclines [129]. A biopsy will reveal calcified trabecular bone formation surrounded by a perivascular proliferation, sometimes with increased fibrous tissue formation.

Treatment modalities are limited. Topical tretinoin has improved some cases by promoting transepidermal elimination of osteomas and is probably only successful in small superficial lesions [130,131]. Surgical ablative therapy is the most effective and reports describe techniques of combined dermabrasion and punch biopsy, scalpel incisions and curettage, extirpation of the small bone fragments after microdissection using a needle followed by a primary closure using steristrip application, as well as laser therapies. The Erbium:YAG laser is said to be associated with minimal thermal injury with better cosmetic results than the carbon dioxide laser [132–136].

Pilosebaceous naevoid disorders

Some of these disorders are only tenuously linked with the pilosebaceous system; they are described in more detail in Chapter 18.

Acne and non-acne naevi

Patients have been described with symmetrical areas of normal skin set in the midst of severe acne on the back [137], or with acne localized to one side of the back [138]. A reduced rate of sebum excretion with a reduction in surface bacteria has been demonstrated in the normal (non-acne) areas.

Comedo naevus

Synonyms
- Naevus comedonicus
- Naevus follicularis
- Naevus unilateralis comedonicus

This uncommon naevus is usually a developmental defect of the hair follicles [139–145]. The associated sebaceous glands may be normal, hypoplastic or hyperplastic. In one case, however, the sweat duct was the origin of the lesions [141]. Lesions usually occur on the scalp, face and trunk, and occasionally at unusual sites such as the penis. The individual lesions consist of keratin-filled pits, often grouped or linear in arrangement (Fig. 42.78). Occasionally, inflammatory acne lesions may be found. Although usually present at birth they often become more prominent at puberty [145]. *FGFR2* mutations have been identified in a comedonal naevus but not in the adjacent normal skin [146]. The symptoms are mainly cosmetic, but at times can be psychologically and physically devastating. An association with epidermolytic hyperkeratosis has been reported [144]. Treatment is usually of only limited success. Topical retinoids are a logical treatment. Twelve per cent aqueous ammonium lactate solution has been reported to be of benefit. Gentle cautery can help the less severe cases [145].

Fig. 42.78 A patient with a comedo naevus (predominantly consisting of blackheads) on the lower abdomen.

Familial comedones

This uncommon genetic disorder shows autosomal inheritance. The earliest lesions are monoporous, but later the face may be extensively involved with polyporous comedones and cysts, and scarring may follow. New lesions may continue into middle age.

Sebaceous naevus

Synonym
- Naevus sebaceus of Jadassohn

This is an organoid naevus, consisting of a mixture of relatively normal-looking epidermis, dermis, sweat and sebaceous glands. It usually presents on the scalp as an area of alopecia associated with a pinkish yellow, fleshy swelling [147–151]. At puberty, the sebaceous glands enlarge and the epidermis becomes verrucous. Co-occurrence with aplasia cutis has been reported [148]. Trichoepithelioma and eccrine syringoadenoma has been reported to develop in naevus sebaceus [150]. Unusual haematopoietic proliferation at birth that spontaneously resolved at 4 months has been documented [151]. Lesions occurring in the midline are often associated with mental subnormality and epilepsy. Excision is usually recommended because of malignant change into a squamous or basal cell carcinoma in later life [149].

Pyogenic granulomas in acne

Pyogenic granulomas are a rare complication of healing severe nodular lesions [152], and this occurs more frequently following isotretinoin therapy [153]. The lesions can either be left alone or, if single, treated with cautery; if multiple, they will usually respond to clobetasol priopionate (Dermovate®) cream topically twice daily applied carefully to the lesions over a 2–3-week period.

Seborrhoea

Excessive grease production is an uncommon reason for referral, but some patients complain bitterly of seborrhoea. Excess sebum can persist after the acne has regressed [154]. Patients with acromegaly or Parkinsonism, especially the post-encephalitic type, often have seborrhoea. Antibiotic and desquamating agents used in the treatment of acne do not influence the seborrhoea, but oral isotretinoin, CPA combined with oestrogen (co-cyprindiol) and spironolactone all significantly reduce the seborrhoea. Physicians have to decide whether the patient's distress justifies the use of these systemic drugs.

(Acne with) solar comedones

Synonyms
- Senile comedones
- Favre–Racouchot syndrome

These are seen in elderly people, especially in the periorbital areas (Fig. 42.79). Most patients have had high exposure to UV radiation, and the solar damage to the supporting dermis allows the pilosebaceous duct to become more easily distended with impacted corneocytes. The clinical presentation is that of multiple, open, and sometimes closed, comedones superimposed on a sun-damaged skin, usually symmetrically affecting the periorbital areas and the cheeks; occasionally the lesions are unilateral [155]. Similar lesions may be seen in pseudoxanthoma elasticum and after radiotherapy. In patients with isolated lesions, the edge of the adjacent skin may be mistaken for the pearly edge of a basal cell carcinoma. The lesions are easily removed with a comedo extractor, but they slowly recur. A topical retinoid to suppress the formation of future comedones may help. Gentle electrocautery can eliminate the smaller comedones [126].

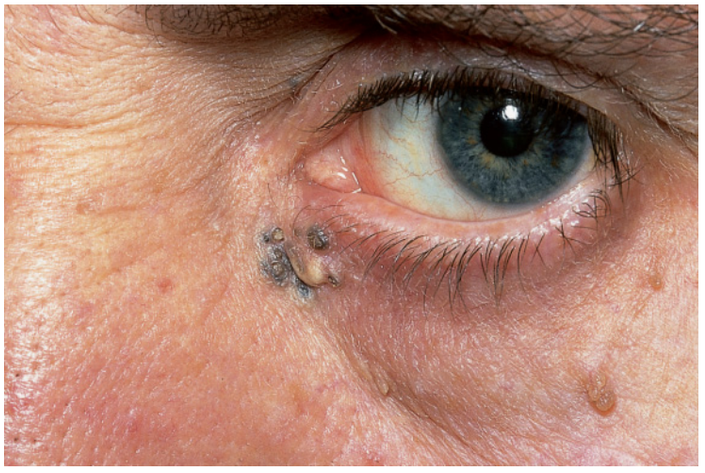

Fig. 42.79 Typical senile comedone seen in a light-exposed area in an elderly patient.

'Tropical' acne (hydration acne)

Troops in the Second World War suffered badly when posted to the Far East, but US Marines in Vietnam were relatively spared, possibly because acne-prone individuals were not selected for service [156]. Certain occupations may aggravate pre-existing acne; for example, workers in a hot, humid environment, such as cooks and pressers, are at risk. It is thought that hydration of the pilosebaceous duct pores may accentuate blockage of the duct and so precipitate inflamed lesions [157]. A similar explanation may apply to 'Mallorca acne', Norwegian acne (Fig. 42.80a & b) in which small, follicular papules appear, especially on the upper trunk, during or after a holiday in a hot, humid environment. Comedogenic sunscreens may also be an exacerbating factor in these patients [158]. Prolonged conventional treatment is often required as the event often precipitates or exacerbates troublesome pre-existing acne.

'Virally' induced acne

Acne can occur at unusual sites and at unusual ages with little involvement of the commonly affected sites. An acneiform rash has been reported at the site of previous herpes zoster infection. Histology revealed follicular occlusion and the disease was quite persistent [159].

A very small number of patients with severe acne and significant glandular fever responded poorly to oral antibiotics and oral isotretinoin. It was proposed that the viral illness in some way played an important role in the poor response [160].

Severe acne variants

Six severe acne variants will be discussed in this section. For ease of reference, they are discussed alphabetically.

Acne conglobata

This is a rare but severe form of acne found most commonly in adult males with no or little systemic upset. Familial cases have been reported. Lesions usually occur on the trunk and upper limbs and frequently extend to the buttocks. In contrast to ordinary acne, facial lesions are not common. The condition often presents in the second to third decade and may persist into the 40s and 50s. Acne conglobata is characterized by multiple inflammatory papules, tender nodules and abscesses which commonly coalesce to form draining sinuses (Figs 42.81 & 42.82). Multiple grouped comedones and extensive disfiguring scarring are also features [1]. Malignancy has been reported in chronic scars [2]. Acne conglobata may occur in the context of hidradenitis suppurativa, folliculitis decalvans—a rare chronic progressive scalp disorder that produces scarring alopecia and atrophy [3]—and pilonidal cysts. An association of severe acne with sterile pyogenic arthritis and pyoderma gangrenosum has been reported (PAPA syndrome) as part of a

Fig. 42.81 A patient with extensive acne conglobata.

Fig. 42.82 Sinus formation in a patient with acne conglobata.

related group of inflammatory disorders including psoriasis, uveitis and inflammatory bowel disease [4]. Familial transmission has been reported with linkage to chromosome 15q24-26 in the region of IL-16 and *CRABPI* genes [5].

Therapy is notoriously difficult; options include long-term high-dose antibiotics, dapsone, ciclosporin and/or colchicine in conjunction with topical retinoids and antimicrobial therapy [6]. Oral isotretinoin (1 mg/kg/day) for 4–6 months is the treatment of choice. Isotretinoin may need to be combined with oral antibiotics such as erythromycin or trimethoprim. Concomitant short, intermittent courses of oral steroids may relieve inflammation during acute exacerbations. Surgery may well be required to lay open abscesses and sinus tracts [1,6,7]. One report has demonstrated the benefit of the carbon dioxide laser in combination with tretinoin to open up cysts and to prevent the emergence of new lesions [8]. In addition, infliximab, an anti-TNF inhibitor, has proved helpful in an isolated case report [9].

Fig. 42.83 A patient with severe truncal acne who had acne fulminans.

Acne fulminans

Acne fulminans represents a rare form of acne presenting in adolescent males, most commonly on the trunk. It was originally described as an acute form of febrile ulcerative acne conglobata. It presents very suddenly, usually in the context of previous mild to moderate acne (Fig. 42.83) [10–37]. Associated features are fever, polyarthropathy, marked leukocytosis (even a leukaemoid reaction), weight loss, anorexia and general malaise. Painful splenomegaly [23], erythema nodosum [24] and bone pain due to aseptic osteolysis have also been reported [21,25]. Bone involvement is common [26]; in a series of 24 patients, 48% had lytic bone lesions on X-ray and 67% showed increased radiolabel uptake; 25% showed destructive lesions resembling osteomyelitis [25,26]. The prognosis for bone lesions is good, and chronic sequelae, if any, are mild, leading to sclerosis and hyperostosis [26]. Blood cultures from the pustular lesions are universally sterile. The aetiology of acne fulminans is uncertain but the presence in some patients of microscopic haematuria, erythema nodosum, increased response to *P. acnes* antigen on skin tests and depressed response to intradermal purified protein derivatives are in favour of an abnormal immunological response. Skin tests with *P. acnes* demonstrate a very extensive, immediate and delayed reaction, the immunohistology of which reveals a type III or type IV hypersensitivity reaction [27]. One case has been reported in a young man with late-onset congenital adrenal hyperplasia [34]. A number of case reports have cited anabolic steroids, testosterone or oral isotretinoin as a trigger for acne fulminans [20,28,29,31]. An acne fulminans-like picture has been reported in association with Epstein–Barr virus infection. Thus, patients with a sudden

Fig. 42.84 A patient with the typical multiple pustules of Gram-negative folliculitis.

exacerbation of previously relatively mild acne should be checked for infectious mononucleosis [30].

Oral prednisolone therapy should be commenced first line (0.5–1.0 mg/kg/day) and decreased slowly over 2–3 months. The acute myalgia, arthralgia and fever can also be helped with oral salicylates or non-steroidal anti-inflammatory drugs and graduated physical exercise. Low-dose oral isotretinoin (0.25–0.5 mg/kg/day) should be cautiously introduced after 3–4 weeks of steroids [32,33,36] and gradually increased as tolerated, according to clinical response. Oral isotretinoin should be used with caution as paradoxically it has been reported to induce acne fulminans in some patients [37]. Topically, crusts need to be removed by soaking the skin with emollient oil, followed by the use of a potent steroid/antimicrobial cream for 2–3 weeks. Isotretinoin in combination with dapsone has been used successfully to treat acne fulminans associated with erythema nodosum [37].

Gram-negative folliculitis

Gram-negative folliculitis can occur as a complication of long-term oral or, less frequently, topical antibiotic therapy used to treat acne [38–40]. Clinical features include a sudden eruption of multiple, small follicular pustules (Fig. 42.84) or occasionally nodular lesions, most frequently localized around the perioral or perinasal regions. This results from overgrowth of Gram-negative organisms including *Klebsiella*, *Escherichia coli*, *Serratia marescens*, *Proteus mirabilis* or *Pseudomonas aeruginosa*. These organisms replace the Gram-positive flora of the facial skin and mucous membranes. As sampling for Gram-negative folliculitis is not routine the incidence of this problem in acne patients is probably underestimated.

Discontinuation of the current antibiotic is required; replacing it with either ampicillin (250 mg four times a day) or trimethoprim (600 mg/day) may effect improvement. However, the response may be slow and relapse is almost inevitable. Isotretinoin is now considered the treatment of choice, relapse following oral isotretinoin being much less likely [41–43].

It has been shown that 1% of treated acne cases with pustular lesions have significantly high counts of *S. epidermidis*, and very occasionally this may cause folliculitis [44]. Therapy usually requires stopping all antibiotics and using topical benzoyl peroxide, which is particularly helpful.

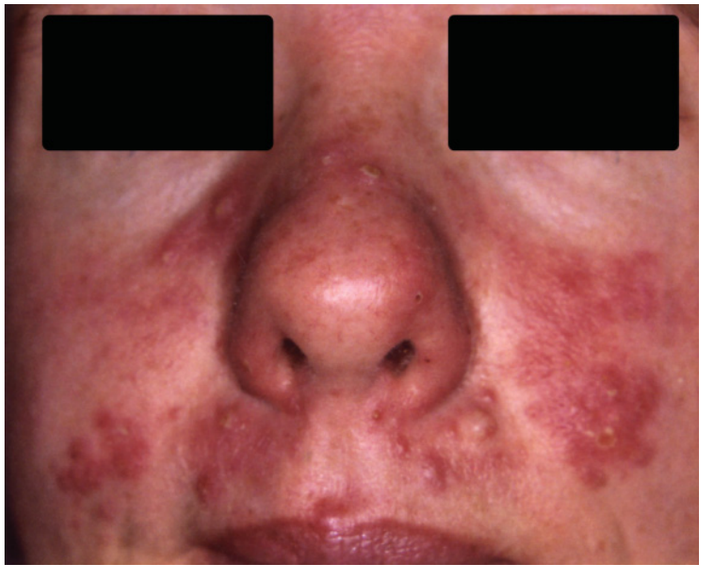

Fig. 42.85 A patient with rosacea fulminans.

Pyoderma faciale

Synonym
- Rosacea fulminans

This was initially believed to be a variant of acne but there has been subsequent debate that it represents rosacea (Chapter 43) [45,46]. Further clinical and basic science research is required to evaluate the underlying pathogenesis of this devastating facial dermatosis. It is rare and seen more commonly in postadolescent women of 20–40 years of age. It is reported to occur in the context of emotional distress and suddenly erupts producing numerous inflammatory pustules and nodules, predominantly on the face, making it particularly visible and distressing (Fig. 42.85). Comedonal lesions are rare. Facial flushing frequently precedes the exacerbation. In contrast to acne fulminans, there are usually no systemic symptoms. The reason for the sudden acute flare is unknown. Rosacea fulminans has been reported in association with Crohn's disease—the significance of which is unclear [47]. The daily ingestion of high-dose vitamin B supplements has also been reported to be associated with the sudden onset of rosacea fulminans [48].

Treatment options include the use of oral tetracyclines plus intralesional steroids or liquid nitrogen to the nodules aimed at reducing inflammation and reducing the nodular component, respectively. However, progress is generally slow with systemic antibiotics and the inflammation can be controlled more quickly using potent topical corticosteroids for a week along with systemic prednisolone (1 mg/kg/day), decreasing slowly over a 4- to 6-week period. Reports recommend the early use of isotretinoin (within a week of starting the steroids) at a dose of 0.5 mg/kg/day gradually increasing to 1 mg/kg/day, for at least 4–6 months

[39–42]. Dapsone has also been used successfully in this condition [49].

The prognosis is difficult to assess, but scarring is infrequent. Recurrence occurs more frequently than was believed some 5 years ago.

SAPHO syndrome

This acronym, first described in 1987, represents a syndrome of pustular dermatoses together with aseptic osteoarticular lesions in the form of *s*ynovitis, *a*cne, *p*ustulosis, *h*yperostosis and *o*steitis [50,51]. In the classic syndrome patients present with sudden-onset haemorrhagic and ulcerative acne on the face and trunk, sterile pustular lesions on the palms and soles with slowly evolving pain, especially on the anterior chest wall. However, the acne and palmoplantar pustulosis may be quite mild and it is believed the condition is under-diagnosed in these cases. The disease may represent an immune reaction to a particular skin or bacterial antigen. *Propionibacteria acnes* have been isolated in a few osteitic bone lesions but this is by no means universal and the bony lesions fail to respond to antibiotics suggesting that the bacteria are not necessarily the primary trigger [52]. Treatment remains empiric as only small groups of patients have been studied in any one series and results are conflicting. Recent reports have suggested that biphosphonates will aid the bony lesions as a result of their osteoclastic activity but they have no impact on the cutaneous manifestations of the syndrome [53].

There is documented evidence of incremented TNF-α in SAPHO, hence TNF-α blockers may be helpful. An isolated case report has demonstrated that prolonged benefit, up to 10 months, can be achieved by using infliximab [54]. However, other authors have suggested that whereas amelioration of the osteoarticular effects may occur the cutaneous manifestations may be exacerbated [55]. Isotretinoin has been used very successfully for the acne but concerns of possible provocation of the articular symptoms have been suggested.

Vasculitic/pyoderma gangrenosum acne

A few patients, who previously had very mild acne, have developed the sudden onset of severe vasculitic, pyoderma gangrenosum-like lesions (Fig. 42.86). Significant scarring is the inevitable consequence (Fig. 42.87). The mechanism of this devastating acne is probably an immunological reaction to *P. acnes*. Such patients appear to be unresponsive to oral isotretinoin alone, but settle to some extent with oral steroids and azathioprine (200 mg/day) over a 3- to 4-month period [56].

Fig. 42.86 A patient with very significant vasculitic acne.

Fig. 42.87 Pyoderma gangrenosum-type scarring in a patient who had suffered from vasculitic acne.

Ectopic sebaceous glands

Synonym
- Fordyce spots

Fordyce spots are heterotopic sebaceous glands that can occur around the vermilion border of the lips or within the oral mucosa. They are commonly multiple, and appear as symmetrical, barely elevated, discrete yellow papules [1]. They are present in 25% of the population over the age of 35 years and are usually asymptomatic. When extensive they can be quite disfiguring, especially if evident on the lips. Oral isotretinoin has been used with some success to treat extensive lesions [2]. However, there are no adequate data that indicate whether or not relapse occurs post-therapy. Carbon dioxide ablative laser therapy has also been used with good effect to treat Fordyce spots [3]. Lesions may also occur on the penile shaft, especially on the ventral surface, and these may become inflamed and can be cause for concern. Other sites occasionally affected include the areolar area of the breast [4].

Sebaceous gland hyperplasia, adenoma and carcinoma

Sebaceous gland hyperplasia

This represents a benign proliferation of the sebaceous gland (Fig. 42.88). The sebaceous glands sometimes become prominent in middle-aged or elderly people. In white people they produce numerous yellowish pink papules, each 1–3 mm in diameter. They

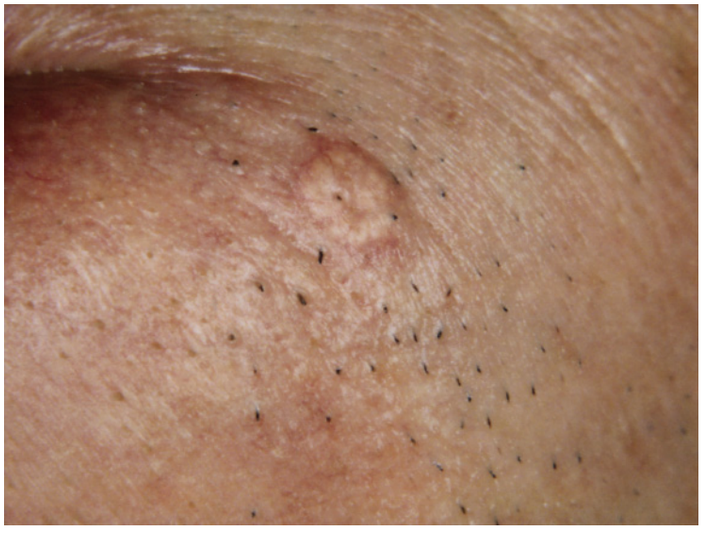

Fig. 42.88 A localized area of sebaceous hyperplasia.

are seen especially on the forehead and temples, and are of no clinical significance. They also are present occasionally on the light-exposed skin of renal transplant patients who are receiving ciclosporin [1]. Treatment is rarely requested, but cosmetic camouflage may be used. If requested and appropriate, some physical treatments such as gentle cautery, cryotherapy, trichloroacetic acid, and carbon dioxide and pulsed dye laser may be used [2,3]. Sometimes, but very uncommonly, the lesions are diffuse, producing a yellowish hue to the skin. In such patients, oral isotretinoin has been reported to be of considerable benefit [4]. Co-cyprindiol (Dianette® and Estelle 35®), with or without additional oral CPA, will also produce regression of sebaceous hyperplasia whilst on therapy. A therapeutic trial of oral isotretinoin may help to differentiate between sebaceous hyperplasia and multiple early basal cell carcinomas in transplant recipients, and may avoid multiple biopsies if there are many lesions. More recently photodynamic therapy using aminolevulinic acid has been used successfully [5].

Sebaceous gland tumours

These are very uncommon. The adenomas in particular may be associated with an internal malignancy and systemic disease.

Sebaceous adenoma

This is a benign tumour composed of incompletely differentiated sebaceous cells. It occurs in both sexes and is seen mainly in elderly patients on the face or scalp [1]. The pink or waxy yellow tumours are round, raised, sessile or pedunculated; they are usually 10 mm or less in size, but may form plaques and ulcerate. Excision is the best treatment, but they are radiosensitive. Very infrequently, sebaceous gland adenomas can be associated with multiple visceral carcinomas. The internal tumours are usually of relatively early onset (45 years). This association is referred to as the Muir–Torré syndrome (MTS). MTS is a rare genodermatosis defined clinically by the occurrence of a sebaceous neoplasm (adenoma, epithelioma or carcinoma) and at least one internal malignancy in the absence of other predisposing factors. Most patients present with sebaceous adenomas but cystic sebaceous neoplasms have been reported as specific markers of MTS. Gastrointestinal and genitourinary malignancies are the most commonly reported with colorectal cancers presenting at or proximal to the splenic flexure contrary to most sporadic colorectal cancers [2,3]. MTS is most frequently found as a variant of the autosomal dominant hereditary disorder non-polyposis colorectal cancer (HNPCC) [4] with tumours demonstrating microsatellite instability and germline mutations in the DNA mismatch repair genes Muts homolog *MSH-2* and *MLH1*. However, the distribution of gene mutations in patients with MTS is slightly different from that seen in all patients with HNPCC and some cases of MTS arise spontaneously [5].

Clinicians should consider a diagnosis of MTS in patients presenting with sebaceous neoplasms and immunohistochemical examination of tumours for MSH2 and MLH1 protein can be used as a screening test for MTS. The neoplasms of MTS tend to follow a more indolent course than the sporadic cases which can be quite aggressive. The role of microsatellite instability in sporadic sebaceous carcinoma has until recently not been demonstrated. Of the nine tumours recently reported, five tumours were from four renal transplant recipients and four were from otherwise healthy individuals [6].

Careful follow-up and active treatment are required for both familial and sporadic cases. Evidence suggests that patients with MTS and HNPCC should undergo colonoscopy every 1–2 years from the age of 25 years or at an age 10 years younger than the family member who originally presented with the disease. Others recommend annual history, physical examination including thorough review of the skin, and urinalysis as well as endometrial sampling and transvaginal ultrasound for females.

Sebaceous carcinoma

This is a very uncommon malignant tumour arising from sebaceous glands. It is commoner in men over the age of 40 years and presents as a solitary, firm tumour, yellow–orange in colour, especially on the face and scalp. Sebaceous carcinomas have a well-recognized association with the Muir–Torré syndrome. The tumour grows slowly, but those arising in the eyelid (from the Meibomian glands) have a greater predilection for metastasizing [7]. Treatment is by excision or radiotherapy [8]. A tumour diameter of 10 mm or greater and/or tumours classified as T4 on the

T classification of the tumour, node, mestastasis staging system are linked to a poor prognosis [9].

‘Sebaceous’ (epidermoid) cysts and steatocystoma multiplex

The classical ‘sebaceous’ cyst is an epidermal structure; strictly, it should be referred to as an epidermoid cyst, and it is discussed in Chapter 52. However, true sebaceous cysts occur as so-called steatocystoma multiplex, a naevoid condition that histologically shows a mixture of a keratinizing epithelium and sebaceous lobules attached to the epidermis by a thin epidermal strand [1–3]. A recent clinical and histological study examined 64 sporadic cases with an average age of onset of 26 years. They confirmed the presence of multiple, smooth, elastic, yellow dermal swellings varying from a few millimetres to 20 mm in size (Fig. 42.89) distributed on the arms, chest, neck and axillae and appearing and/or enlarging at puberty. Lesions are known to last indefinitely, and whether they resolve with old age is uncertain. Inflamed lesions due to rupture of the cysts are common and, when extensive, can produce the so-called steatocystoma multiplex suppurativa, which mimics acne conglobata. Steatocystoma multiplex (SM) shares many clinical features and may show overlapping histopathological features with eruptive vellus hair cyst (EVHC). In this series of 64, all cases exhibited eosinophilic cuticle and lack of granular layer, and 17–42% displayed vellus hair, hair follicles, keratin, and smooth muscle components within the cavity, in the wall, or adjacent to it. The results of this study suggest that SM is a hamartomatous condition and that SM and EVHC are variants which originate in the pilosebaceous duct [4].

Steatocystoma multiplex is uncommon, and in some patients is associated with type 2 pachyonychia congenita (PC-2 or Jackson–Lawler syndrome), in which natal teeth are also a feature [5–9]. Histologically, the cysts in PC-2 may be true steatocysts, eruptive vellus hair cysts or keratinous cysts, even in the same family or individual [10–12]. To date, mutations in the Ia domain of keratin 17 (K17) have been found in all cases [12,13]. In some families with clinically and histologically typical steatocystoma multiplex,

Fig. 42.89 A patient with extensive steatocystoma multiplex. (Courtesy of Dr N.K. Veien, Dermatology Clinic, Aalborg, Denmark.)

mutations in the K17 gene are also found [14]. In these families, close inspection shows that some but not all members have nail changes, which are usually but not always milder than those of PC. Familial steatocystoma multiplex has also been associated with natal teeth in the absence of nail dystrophy [14], and it seems likely that these cases are also due to keratin gene mutations. However, in a case of steatocystoma multiplex/eruptive vellus hair cyst (EVHC) and in another of EVHC, mutations in K17 were not found along the Ia domain [13], and hence it is likely that steatocystoma multiplex is genetically heterogeneous.

Treatment is very difficult [1]; excision of the larger cysts is possible, but total removal of all cysts is impractical because of their number. Successful treatment employing a vein hook to locally extract cysts has been reported [15]. One study has also utilized the carbon dioxide laser with some improvement [16]. Topical therapy is of limited benefit. Systemic antibiotics may reduce inflammation and/or suppuration and oral isotretinoin is of some help in reducing inflammation, but does not affect the primary disease process.

This chapter brings together a range of dermatoses presenting with facial eruptions and/or flushing. It includes rosacea, the rosacea-like eruptions and carcinoid syndrome.

Rosacea

Definition. Rosacea is a disease lacking an entirely satisfactory definition. It is a chronic disorder affecting the facial convexities, characterized by frequent flushing, persistent erythema and telangiectasia, interspersed by episodes of inflammation during which swelling, papules and pustules are evident [1]. However, not all cases fit this description since not all features are always present. A recent attempt to define diagnostic criteria [2] concluded that the presence of one or more of the following signs with a central face distribution is indicative of rosacea: flushing, non-transient erythema, papules and pustules, and telangiectasia. Clearly, if all individuals with one or more of these features are to be included, rosacea is a highly heterogeneous entity.

Many authorities have expressed the view that vascular changes, particularly flushing, are the initial and constant feature, followed by progression to inflammatory changes (papulation and pustulation) and that the development of chronic lymphoedema, thickening of affected skin and rhinophyma are late complications. However, many cases do not demonstrate this pattern of evolution.

Nomenclature. The term 'acne rosacea' is used synonymously with rosacea but is better avoided. It reflects the occurrence in both diseases of facial papules and pustules. However, the epidemiology, aetiology and pathology of rosacea are quite distinct from acne vulgaris. The latter is primarily a disorder of pilosebaceous units but it is not clear to what extent the same is true of rosacea.

Epidemiology. Rosacea is a very common disease. It is considered more common in fair-skinned than darker-skinned individuals, although it does occur in all skin types including black people [3] and may just be more noticeable in those with pale skin. Meaningful figures on prevalence are scarce, but in Swedish 'white-collar' workers the figure is probably about one in ten [4], representing about 1–3% of dermatological consultations. In a study from Greece, rosacea accounted for 1.2% of dermatological consultations [5]. Women are more commonly affected than men, especially within the age range 36–50 years [5]. The development of rhinophyma is much more common in men. Rosacea is predominantly a disease of young to middle-aged adults but is seen in patients of all ages, including occasionally in children [6].

Pathogenesis. The cause, or causes, of rosacea remain uncertain. In contrast to acne vulgaris, rosacea is not associated with seborrhoea [7]. Marks [1] has proposed that damage to dermal connective tissue, often caused by solar irradiation, may be the initiating event. This may result in dysfunction of the unsupported facial blood vessels with consequent endothelial damage, leakage, oedema and inflammation.

Others have argued for the central role of abnormal vascular reactivity [8]. The association of rosacea with migraine seems to support this hypothesis [9]. When assessed by laser Doppler studies cutaneous blood flow is increased markedly in papulopustular disease and, perhaps surprisingly, to a lesser degree in erythematotelangiectatic rosacea [10]. Capillaroscopy demonstrates the presence of telangiectasia and neoangiogenesis in erythematotelangiectatic rosacea. These findings are not present in nailfold capillaries, suggesting that the vascular abnormalities associated with rosacea may be confined to the face [11]. Vascular endothelial

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

growth factor (VEGF) receptor expression appears to be increased in the vascular endothelium of the skin in rosacea, suggesting a possible role for VEGF in mediating the vascular and inflammatory changes [12].

Sensitivity to noxious stimuli including heat is increased in involved skin, regardless of whether vascular or inflammatory features predominate [10]. This may explain the burning sensation characteristic of rosacea and lends support to a neurogenic aetiology. It is possible that lowered neural thresholds for reaction to noxious stimuli may result in neurogenic inflammation [10].

Changes in redox status, with reduced levels of superoxide dismutase have been observed in the skin in cases of inflammatory rosacea [13], although it is not clear whether this is the cause or the effect of the inflammation. A role for oxidative stress is further supported by a report of increased malondialdehyde (an indicator of reactive oxygen species activity) and reduced antioxidant potential in peripheral blood of rosacea patients [14]. The therapeutic effect of antibiotics, including tetracyclines, metronidazole and azithromycin, may be explained by their antioxidant properties.

Abnormally high levels of cathelicidin have been demonstrated in the facial skin of patients with rosacea [15]. Cathelicidin is an endogenous antimicrobial peptide which constitutes a component of the innate immune system. In addition to their ability to kill microorganisms, cathelicidin and related peptides trigger inflammation by promoting leukocyte chemotaxis and angiogenesis. The active antimicrobial component of cathelicidin, LL-37, is cleaved off a precursor molecule by serine proteases, including stratum corneum tryptic enzyme. Interestingly, activity of this protease also appears elevated in rosacea. This could potentially result in production of a specific pattern of cathelicidin isoforms which are pro-inflammatory and which may play a central role in the pathogenesis of rosacea.

Because there is usually no associated sweating, it has been argued that flushing in rosacea is mediated by released vasoactive substances rather than a neural reflex mechanism [16] but this cannot yet be taken as established and both mechanisms may play a role. Proposed mediators included serotonin, bradykinin, prostaglandins [17], substance P, opioid peptides and gastrin. Blood levels of substance P were raised in some patients but not consistently [18]. Involvement of opioid peptides has been proposed on the basis of the suppressive action of the opioid antagonist naloxone [19].

It is often stated that rosacea is associated with gastrointestinal symptomatology although there is little evidence to support this [20–22]. No consistent evidence of gastritis was obtained in a controlled endoscopic study [23]. An association between jejunal mucosal atrophy and rosacea has also been proposed [24] but has not been confirmed.

A possible role for *Helicobacter pylori* infection of the gastric mucosa has been the subject of particular controversy. A high prevalence of this infection has been reported in patients with rosacea, reaching up to 100% in one uncontrolled series [25,26]. In controlled studies, prevalence rates have sometimes been similar to controls [27–30] and sometimes higher than controls [22,31–33]. The infection may be more prevalent in patients with papulopustular rosacea than those with erythematotelangiectatic disease [34]. It has been suggested that the prevalence of seropositivity in patients with rosacea might be artificially reduced as a result of antibiotic treatment [22], increasing the difficulty in drawing conclusions from these data.

The role of *H. pylori* in rosacea might be clarified if it could be established that eradication of the organism cured the disease, but the available data are inconclusive in this regard. There are anecdotal reports of impressive responses. A patient who had suffered from rosacea for 9 years cleared and remained free of the disease 2 years later [35]. A case of granulomatous rosacea of 4 years' duration resolved after eradication of *H. pylori* and remained clear 3 years later [36]. Significant improvement was seen in an uncontrolled trial of *H. pylori* eradication studying 22 patients with rosacea and evidence of *H. pylori* infection [30]. In a placebo-controlled trial of *H. pylori* eradication on 44 *H. pylori* infected patients with rosacea, the disease abated in almost all the patients in both treatment groups, although none were cured [37]. There was no significant difference between placebo and active treatment at the 60-day end point, although improvement was somewhat greater in the active limb. In an open-label study comparing the response of rosacea to a helicobacter eradication regimen in groups of patients with and without evidence of helicobacter infection, both groups were improved when assessed at 3 and 6 weeks with a somewhat larger response being seen in those with *H. pylori* [32]. Szlachcic *et al*. [33] treated 53 *H. pylori* infected patients with rosacea with an eradication regimen and reported clearing of rosacea within 2 to 4 weeks in 51 cases. The clinical improvement was accompanied by resolution of gastritis and reduction in serum levels of gastrin, IL-8 and TNF-α, possible mediators of the vascular changes in rosacea.

A range of different eradication regimens were used in these studies but all contained antibiotics known to be effective in rosacea. Antibiotics used in treatment of rosacea are all potentially effective in treatment of *H. pylori*. Whilst these do have anti-inflammatory properties and may therefore work by other mechanisms, it remains an interesting and plausible hypothesis that suppression of *H. pylori* might partially explain their efficacy.

A potential role has often been proposed for the follicle mites *Demodex folliculorum* and *Demodex brevis* in the pathogenesis of rosacea. Infestation with these mites is extremely common in the general population, reaching up to 100% of subjects in some studies [38]. These organisms have traditionally been considered harmless commensals but there is increasing evidence that they are potentially pathogenic, especially when present in very high numbers. Eruptions strongly resembling rosacea and associated with the presence of large numbers of *Demodex folliculorum* have been reported under the title of rosacea-like demodicosis [39,40]. These cases have improved following treatment to eradicate the mite.

Several investigators have reported increased numbers of *Demodex folliculorum* in the facial skin of patients with rosacea relative to controls [38,41–45]. Demodex mites have also been demonstrated in the dermis associated with an inflammatory response and undergoing phagocytosis by multinucleate giant cells. This phenomenon has been observed both in localized and more widespread facial eruptions resembling rosacea [46,47]. Furthermore, *Demodex brevis* is often present in the eyelid in hair

follicles, eyelash follicles and meibomian glands [48,49] and is often reported in association with periocular pathology including blepharitis and meibomianitis [50–52]. These observations would suggest that the presence of *Demodex* mites might also play a role in some of the ophthalmic complications of rosacea. Against a central role for *Demodex* is the relatively infrequent observation of the mites (in 19% or less of the biopsies) in some of the larger histological studies of rosacea [53–55]. However, in a histological study specifically examining the prevalence of mites, these were observed in 51% of patients with rosacea and perifollicular inflammation was observed around infested hair follicles [56].

Further insight into the role of *Demodex* in the pathogenesis of rosacea might be gained by investigating the effects of eradication of this organism but there has been limited formal study of this. A combination of oral ivermectin with topical permethrin has proved helpful in isolated cases [57]. In a small left/right comparative study permethrin cream and topical metronidazole both yielded similar results [58]. In a parallel group study, permethrin was superior to placebo and equivalent to metronidazole in reducing papules and erythema [59]. Some improvement has been reported in an uncontrolled study using crotamiton [44]. Benzyl benzoate reduces mite numbers but seems to be irritant in patients with rosacea [60]. A florid rosacea-like facial eruption associated with *Demodex* and accompanied by dermal inflammatory response and phagocytosis of the mites responded to metronidazole [47]. This is not easy to explain as metronidazole is not considered to be mitocidal. However the mites are associated with bacteria, both in their gut and on their skin [44]. One bacterium found in association with *Demodex* is *Bacillus oleronius*, and proteins from this organism have the potential to induce an immune response in patients with rosacea [61]. These microorganisms therefore provide a potential microbial target for antibiotics.

Recently, rosacea has been reported as a manifestation in the skin of human immunodeficiency virus (HIV) infection [62], and the same is true of rosacea-like demodicosis [40,63].

An important question relating to the pathogenesis of rosacea has been how to link the vascular features and the inflammatory lesions. A possible link is provided by the theory that the inflammatory lesions may develop as a result of the increased skin temperature associated with the vascular features. This may be explained by different behaviour of bacteria [64] or perhaps follicle mites, at a higher skin temperature. Improvement of inflammatory lesions has been reported after effective ablation of telangiectasia and would support this hypothesis [65], although this has not been consistently reported and others have commented on the failure of laser therapy to improve inflammatory lesions [66].

Clinical features. Rosacea is a polymorphic disease with several variants, each of which may require a different approach to treatment. The areas characteristically affected are the central convex areas of the face (nose, forehead, cheeks and chin) (Fig. 43.1). Occasionally, the scalp, upper chest, back and even the limbs may be involved [67]. In cases of rosacea showing the classical pattern of progression, the onset is most often marked by vascular changes, notably episodic flushing usually unaccompanied by sweating. Erythema, which is often accompanied by a burning sensation [10], gradually becomes more persistent, is easily triggered by minor irritants, and is associated with increasingly prominent telangiectasia. More advanced cases show follicular and non-follicular papules and pustules, without comedones, followed by persisting tissue thickening due to oedema, fibrosis and glandular hyperplasia, leading ultimately to a *peau d'orange* appearance and phymas.

Fig. 43.1 Predominantly erythematotelangiectatic rosacea affecting the cheeks and nose. Note conjunctival injection.

Table 43.1 Rosacea: classical pattern of progression.

Early	Episodic flushing
	Mild telangiectasia
	Transient oedema
Progressive	Papules
	Pustules
	Sustained oedema
	Extensive telangiectasia
Late	Induration
	Rhinophyma

Factors which trigger flushing include emotion and stress [68], hot drinks [69], alcohol [19] and other vasodilating drugs, and spicy food. Despite traditional beliefs to the contrary it is the heat, not the caffeine content of hot drinks, which causes flushing [69]. Aggravating factors include the use of topical steroids on those occasions when they are used (usually in error) to treat rosacea. Sun exposure may worsen or improve rosacea [70].

The classical progression of rosacea is summarized in Table 43.1. Many cases do not follow this pattern. Some show predominantly the vascular features (erythematotelangiectatic rosacea, Fig. 43.2), others develop mainly inflammatory lesions (papulopustular rosacea, Fig. 43.3), others develop mainly chronic thickening and induration and still others develop only rhinophyma. Each of these patterns, and also ocular rosacea, may occur in isolation or in any combination.

Complications. Rosacea, usually of long duration, is associated with several important complications.

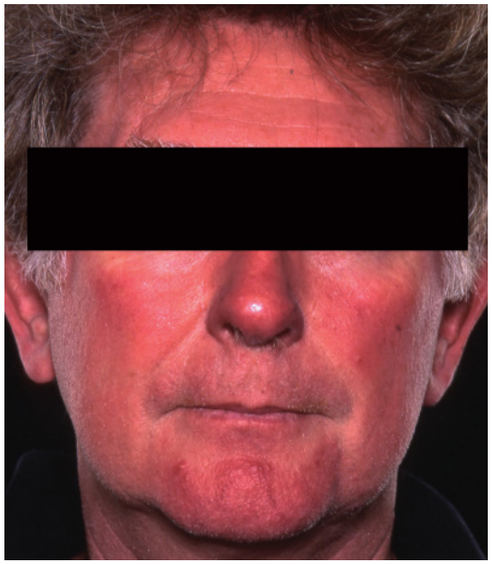

Fig. 43.2 Erythema mainly involving the convex areas of the face in a patient with rosacea.

Fig. 43.3 Inflammatory papulopustular rosacea. (Courtesy of Professor M. Greaves.)

Lymphoedema. This is a relatively rare complication of rosacea which can affect any part of the face and the ears (Fig. 43.4). In time this may develop into a coarsening of the features known as leonine facies. A characteristic pattern of lymphoedema of the upper half of the face developing as a complication of chronic rosacea has been termed chronic upper facial erythematous oedema or Morbihan's disease [71]. The orbital skin is often affected resulting in severe eyelid swelling and sometimes ectropion [72,73]. Histological examination reveals features of lymphoedema and inflammatory cell infiltration of variable intensity.

Eye involvement. Ophthalmological complications are common, although estimates of prevalence vary widely from 6% [74] to over 50% of patients with rosacea [75] although the pathogenesis is still not well understood. These include a sensation of grittiness or irritability of the eyes, often accompanied by visible reddening of the conjunctiva. Blepharitis, episcleritis, chalazion and hordeolum are also common. Rosacea keratitis is a more serious and quite common complication, occurring in 5% of patients including children [76,77]. The conjunctivitis, keratitis and other complications seem likely to be at least partly secondary to reduced tear secretion and Meibomian gland dysfunction, resulting in an unstable tear film [78,79]. Ocular rosacea may be seen in isolation or occur before the onset of cutaneous features, especially in children [80]. The condition may be unilateral or asymmetrical [80]. Interestingly, childhood sty may be indicative of increased risk of developing rosacea in adulthood [81].

Fig. 43.4 Chronic lymphoedema in a patient with a long history of rosacea. (Courtesy of Professor M. Greaves.)

Salivary gland involvement. The well documented reduction in tear secretion associated with ocular rosacea would suggest that involvement of the lacrimal glands is not infrequent. The involvement of salivary glands appears to be a rare event [82].

Histopathology [53,54,56,83,84]. The histological features are predominantly dermal. These tend to reflect the clinical features. Thus telangiectasia is indicated by the presence of dilated superficial capillaries. Lymphatic channels may also be dilated but tend to be located rather deeper in the mid-dermis. Solar elastosis is commonly present and often prominent. The intensity and pattern of inflammation is variable, ranging from a mild perivascular lymphohistiocytic infiltrate in erythematotelangiectatic cases, to more intense infiltration which may be perifollicular, interfollicular and perivascular in papular rosacea (Fig. 43.5). Mast cell density is reported to be increased [85]. Some lesions contain granulomas (Fig. 43.6) which can be epithelioid, elastolytic or pallisaded around altered collagen. Foreign-body type giant cells may be observed. Pustules are evidenced by polymorph accumulation in

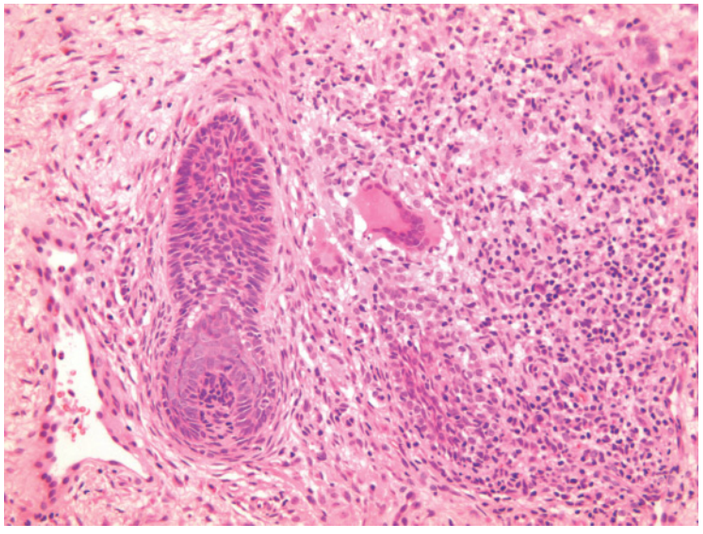

Fig. 43.6 Histological appearance of granulomatous rosacea (H & E × 400). (Courtesy of Dr R.A. Carr.)

the upper parts of hair follicles. Areas of necrosis are occasionally conspicuous, sometimes marking the remnants of inflamed hair follicles. *Demodex folliculorum* has been observed in up to 51% of cases in one series [56] and may densely populate the pilosebaceous follicles. However, the mites have not consistently been associated with inflammation.

Differential diagnosis. Important differential diagnoses include acne vulgaris, lupus erythematosus, perioral dermatitis, seborrhoeic dermatitis and nasal sarcoidosis. Although acne vulgaris and rosacea are quite distinct diseases, there are occasional patients in whom the distinction is difficult. Since both conditions are very common, it is to be expected that, by chance, both will often occur in the same patient. Acne vulgaris affects a younger age group and often has an extensive distribution over the face, neck and trunk whereas extra-facial rosacea is rare. Typical acne vulgaris lacks the redness, telangiectasia and flushing of rosacea whilst rosacea lacks the comedones and seborrhoea characteristic of acne vulgaris [86].

Scarring, scaling and follicular plugging are not features of rosacea and therefore readily distinguish it from facial discoid lupus erythematosus. However, patients are often referred to the dermatology clinic with a 'butterfly' erythema and a tentative diagnosis of systemic lupus erythematosus (SLE). The latter is not pustular and is usually associated with systemic symptoms. In some cases, lupus serology and a skin biopsy for histological and immunofluorescent examination may be necessary.

The pattern of the rash in seborrhoeic dermatitis differs markedly from that of rosacea. The former, but not the latter, characteristically involves the scalp, retroauricular area, eyelids and nasolabial folds. That scaling is not normally a feature of rosacea but is the rule in seborrhoeic dermatitis may also be helpful. However, rosacea and seborrhoeic dermatitis often seem to occur concurrently.

Nasal sarcoidosis (lupus pernio) superficially resembles rhinophymatous rosacea and both are granulomatous. However, sarcoidosis often affects the nasal septum (causing nasal obstruction) and the surface of the thickened nose in lupus pernio, although telangiectatic, is smooth and lacks the rugose *peau d'orange* surface which characterizes rhinophyma. Patients with lupus pernio almost invariably have evidence of multisystem disease.

Demodex folliculitis can clearly mimic rosacea but is generally considered to be a separate entity.

Rosacea may occasionally be induced by carcinoid syndrome [87]. The possibility of carcinoid syndrome should be considered particularly when the symptoms are predominantly vascular and unusually severe (see p. 43.17).

Prognosis. The duration of the disease and eventual outcome are highly variable and difficult to predict. In a follow-up study on 70 patients after 6 months' treatment with tetracycline, two-thirds had relapsed after a mean follow-up period of 2.6 years [88]. In a survey of 92 patients 10 or more years after a diagnosis of rosacea, 48 responded and 25 still had active disease, whilst 23 had cleared [89]. In those patients in whom the rosacea had resolved, the duration of the disease had ranged from 1 to 25 years. There is no evidence that treatment affects the likelihood of resolution. When it persists, rosacea usually follows a fluctuating course. In males and less often females, the persistence of rosacea may result in chronic thickening and induration of the face (leonine facies) and rhinophyma. Eye involvement is usually mild and reversible, though occasionally ocular keratitis can lead to severe scarring and even corneal perforation [90]. Most symptoms of rosacea can usually be successfully controlled (see below) but the flushing is often impossible to suppress.

Treatment. Papulopustular rosacea responds well to treatment in the majority of cases but improvement may be gradual so perseverance is sometimes required. Relapse is often prompt when treatment is discontinued [88]. It is important to avoid irritants such as strong soaps and cosmetic alcohol-based cleansers. Emollients are soothing in some cases. Although many patients say that their rosacea improves in the sun, solar exposure should probably

not be encouraged in view of the marked photodamage often seen in these patients and the possible role of this elastotic change in the pathogenesis.

Papulopustular rosacea. Both topical and systemic modalities can be highly effective and patients often have a particular preference for one route or the other. Effective oral agents include tetracyclines (e.g. tetracycline or oxytetracycline 250 mg twice daily) and erythromycin 250 mg twice daily. Higher doses are often prescribed in the belief that they are more effective although there is little evidence that this is true. More recently developed tetracyclines, such as minocycline, lymecycline and doxycycline, are often used and offer the advantages of once daily administration and lower potential for interaction with dietary calcium, enabling them to be taken with food. Doxycycline appears to be effective at doses as low as 40 mg daily [91]. Ampicillin appears superior to placebo but less effective than tetracycline [92]. Oral metronidazole can also be effective [93], although this can cause peripheral neuropathy if used for more than 3 months. Series of patients and open-label trials have shown efficacy of azithromycin [94]. In one series this drug proved beneficial after 4 weeks at 250 mg/day, for 3 days each week (Monday, Wednesday and Friday) [95]. Ocular symptoms also improved. Development of Gram-negative folliculitis has been reported as a rare complication of broad-spectrum antibiotic treatment of rosacea [96].

Oral isotretinoin (10–60 mg/day) is an alternative in resistant rosacea [97]; it not only reduces inflammatory lesions, but also improves quality of life [98]. This treatment can even improve rhinophyma [99]. This is most often used in relatively low dosage in rosacea, partly due to concern about worsening ocular disease. Treatment may need to continue for several months and particular caution is required with this teratogenic drug in fertile female patients. Isotretinoin may not be suitable for patients with ocular involvement (see below).

Topical treatment with metronidazole 1% cream is effective [100]. A 0.75% gel formulation is also available and is preferred by some patients. Tetracycline and erythromycin are also available in topical formulations although these are lotions developed for treatment of acne vulgaris and they can prove irritant on skin affected by rosacea. Clindamycin gel, also developed for treatment of acne, may be better tolerated. A combined formulation containing 5% benzoyl peroxide and 1% clindamycin has proved effective and well tolerated in a placebo-controlled trial [101].

Topical tacrolimus has been reported to improve erythema, but not inflammatory lesions, in an open-label series of 20 patients [102]. Pimecrolimus cream has been reported to improve erythema and papulopustular lesions in an open study with 12 subjects [103]. In a controlled trial, topical pimecrolimus was no more effective than placebo [104]. Topical tacrolimus and pimecrolimus have both been reported to induce rosacea-like eruptions [105,106].

Additional topical therapies reported as effective include azelaic acid 20% cream and 15% gel, 0.025% retinoic acid, 0.1% adapalene gel, 10% sulphur cream, NADH, methylnicotinamide and 5–10% benzoyl peroxide gel.

Combinations of topical and systemic treatment are often used and may be more effective than either used alone. The addition of low-dose (20 mg) doxycycline has been shown to improve the response to topical metronidazole [107].

There is little point in discontinuing treatment before 3 months and in many cases it is necessary to continue for several years.

Treatments directed at eradication of *Helicobacter pylori* or *Demodex* are discussed above. The final place of these modalities will be determined when the pathogenic role of these organisms has been established or excluded. On current evidence, the author would suggest that these treatments may prove helpful in individual cases where there is reason to believe that these organisms may be playing a role.

A novel approach is the use of photodynamic therapy [108]. A series of 17 patients with rosacea refractory to previous therapy were treated with PDT using 16% methyl aminolevulinic acid (Metvix®) cream applied for 3 h followed by 37 J/cm^2 of red light. Initially, patients received one or two treatments at an interval of 1 week, and up to four treatments were used on each treated area if required. A good response was reported in 10 cases.

Flushing. It is important to explain to patients with papulopustular rosacea that none of the above measures will significantly suppress the troublesome flushing or the burning discomfort which often accompanies this. Flushing and burning are the most difficult features of rosacea to treat. Non-cardioselective β-blockers, such as propranolol 40 mg twice daily or nadolol 40 mg daily [109], are often used but generally provide rather limited benefit. Clonidine 50 μg twice daily and the related but less sedative drug rilmenidine 1 mg daily may also provide some modest improvement, perhaps due to a non-specific vasoconstrictor effect [110]. Two cases of erythematotelangiectatic rosacea have recently been reported to respond to topical oxymetazoline 0.05% applied daily [111]. Both redness and flushing were improved. Treatment of erythema and telangiectasia with vascular lasers or intense pulse light can also be beneficial in reducing flushing and burning.

Cosmetic camouflage may also be helpful for patients with persistent facial redness. The British Red Cross provide cosmetic camouflage clinics free-of-charge throughout the UK in association with hospital dermatology departments (British Red Cross Beauty Care and Camouflage Service, 9 Grosvenor Crescent, London SW1X 7EJ).

Telangiectasia and erythema. Vascular lasers and intense pulsed light sources provide a range of highly effective treatments for ablation of telangiectasia and can also improve erythema [112–114].

Lymphoedema of rosacea. Treatment is far from satisfactory. Reduction of the inflammatory component of rosacea by broad-spectrum antibiotics may slow down progression. Jansen and Plewig have suggested the use of low-dose isotretinoin 0.1–0.2 mg/kg/day over a period of 2–4 months, which may be combined with ketotifen 1–2 mg daily and a potent H_1 antihistamine [71]. Marked reduction in facial swelling was reported in one case from a reducing course of prednisolone, starting at 30 mg daily and metronidazole 400 mg/day over a 4-month period, followed by metronidazole 200 mg/day [115]. For established leonine facies, regular facial massage may help. In cases of severe eyelid oedema

surgical debulking of the tissue [116] and CO_2 laser blepharoplasty [117] have proved helpful.

Ocular rosacea. The keratitis associated with rosacea can be severe and specialist ophthalmological supervision is frequently required.

Symptomatic benefit is often achieved with use of a wide range of 'artificial tears'. These include ophthalmic formulations of liquid paraffin, carbomers (polyacrylic acid), hydroxyethylcellulose, hypromellose, povidone and others.

Systemic tetracyclines are helpful. A comparison of doxycycline 100 mg/day and tetracycline 1 g/day showed improvement in both treatment groups. Tetracycline was significantly more effective at 6 weeks, but the difference between groups was not significant at 3 months [118]. Tetracyclines are thought to act as anti-inflammatory agents and can suppress cytokine secretion [119]. A study on the actions of minocycline has demonstrated changes in the composition of Meibomian gland lipids, suggesting that the treatment reduced lipase activity, which may have been secondary to changes in microbial flora [120]. In another trial, a topical ophthalmic formulation of fusidic acid appeared more effective than systemic oxytetracycline [121]. Retinoids are probably best avoided in patients with eye involvement as they may further impair Meibomian function, exacerbating the sensation of grittiness and the dryness of the eyes.

Eradication of *H. pylori* is reported to improve ocular rosacea [122].

Rhinophyma and other phymas

The phymas are localized swellings of facial soft tissues due to variable combinations of fibrosis, sebaceous hyperplasia and lymphoedema [1]. They develop predominantly in males. The commonest is rhinophyma, a swelling of the nose which may become grossly distorted in contour (Fig. 43.7). Other areas which may be affected include the forehead (metophyma) (Fig. 43.8), chin (gnathophyma) (Fig. 43.9), eyelids (blepharophyma) and ears (otophyma) [2]. In many cases rhinophyma develops in patients with a long history of other features of rosacea and it is often regarded as a complication or 'end stage' of the disease. However, rhinophyma is sometimes also seen in patients who do not have any history of other manifestations of rosacea. Occasionally, rhinophyma is complicated by the development of a malignancy and this can be difficult to recognize [3]. There have also been examples of various malignancies being misdiagnosed as rhinophyma.

It is likely, but not proved, that active treatment of rosacea may inhibit the development of rhinophyma. Unfortunately, neither systemic nor topical treatments for rosacea have any useful impact on established rhinophyma. One exception is systemic isotretinoin, which can significantly reduce the bulk of rhinophyma although it does not restore normal skin contours [4]. Treatment of rhinophyma and other phymas therefore usually involves surgical removal of excess tissue or other means of physical ablation. Remodelling can often be successfully achieved simply by paring

Fig. 43.7 Rhinophyma. (Courtesy of Dr I. Ahmed, Coventry.)

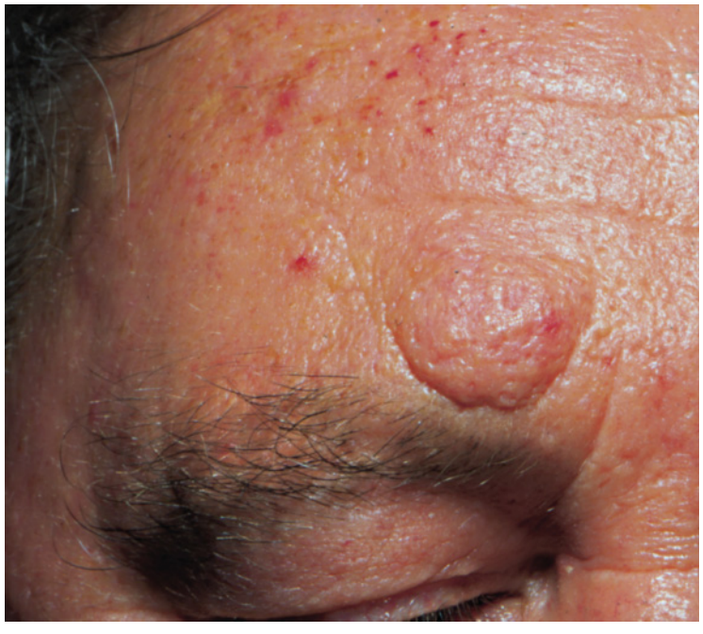

Fig. 43.8 Metophyma.

off the excess tissue with a scalpel. Electrosurgery is an inexpensive alternative method. Excision and vaporization with argon, carbon dioxide or Nd : Yag lasers is effective. Other treatments have included cryotherapy and ionizing radiation [5]. The latter approach is probably most useful in cases with coexisting malignancy.

Corticosteroid-induced rosacea

The use of potent topical corticosteroids on the face often results in a papulopustular eruption accompanied by erythema which may closely resemble rosacea (Fig. 43.10) [1,2]. Patients of all age groups and either gender are susceptible although this seems to happen rather more often in females. It is usually necessary to continue treatment for 8 weeks or more before steroid rosacea develops. If application of the steroid continues, fixed erythema and telangiectasia develop, further increasing the similarity to idiopathic rosacea. Patients experience exquisite sensitivity of the involved skin to the slightest irritant; itching, burning and intense redness being major complaints. Whenever the treatment is discontinued, the eruption flares, leading to a state of dependence. Patients affected by steroid rosacea often fail to recognize the causal link between the treatment and the rash. On the contrary, the application of the steroid usually produces prompt, if transient, improvement in the symptoms, creating the illusion of significant benefit.

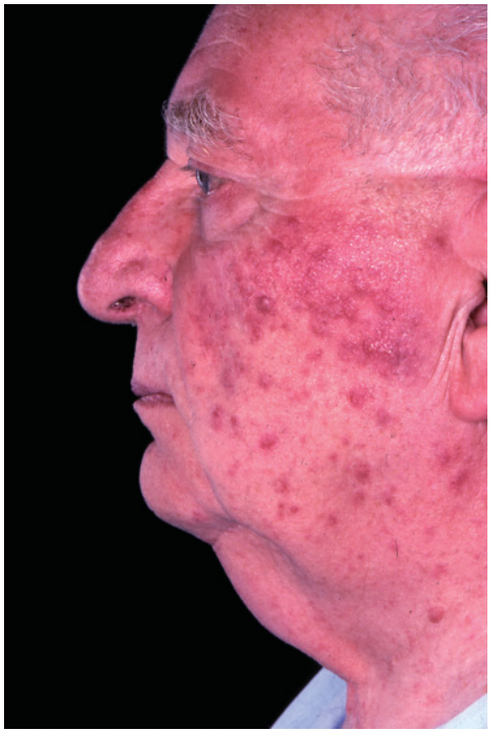

Fig. 43.10 Corticosteroid-induced rosacea.

On occasions, even 1% hydrocortisone may provoke steroid rosacea in children [3]. The use of steroid nasal spray may also be responsible [4]. A granulomatous eruption described as resembling rosacea developed 9 months into therapy with topical tacrolimus 0.1% ointment [5]. This resolved on treatment with doxycycline and did not recur when the tacrolimus was reintroduced.

Treatment. The first and most important step is withdrawal of the causative topical corticosteroid. Patients must be advised to anticipate a flare of the rosacea at this stage. In order to reduce the severity of this flare it is often necessary initially to introduce a less potent steroid. The author has found that a topical or systemic antibiotic, used in the same way as in idiopathic rosacea, can also be very useful in the early stages of steroid withdrawal. Topical application of tacrolimus ointment [6] or pimecrolimus cream [7,8] has proved helpful, although a rosacea-like eruption has also been reported to arise or worsen as a side effect of topical tacrolimus and pimecrolimus therapy (see above). Steroid rosacea may take several weeks or even months to subside but eventually complete resolution can be anticipated.

Perioral dermatitis

Definition. Perioral dermatitis is a persistent erythematous eruption, consisting of tiny papules and papulopustules with a distribution primarily around the mouth [1]. A similar eruption involving the eyelids and periorbital skin has been termed periocular dermatitis [2,3].

Epidemiology. First described in the late 1950s and 1960s, it became a commonplace diagnosis in the 1970s [1]. Over the past decade there has been an apparent fall in new cases—possibly attributable to a decline in the use of potent topical steroids on the face. It almost entirely affects young adult females, the age range tending to be somewhat younger than that of rosacea and occurrence in childhood more frequent. It has a worldwide distribution.

Aetiology. Although infectious agents and infestations including *Candida* spp. [4], *Demodex* [5] and fusiform bacteria [6] have been incriminated, none is established as playing a causative role. A variety of primary irritant and allergic contact factors have been proposed but not substantiated, including toothpaste and intimate contact with a partner's beard stubble [2]. A high prevalence of atopy has been reported in patients suffering from perioral dermatitis [7] and these patients were also found to have impaired barrier function of facial skin assessed by measurement of transepidermal water loss. Despite the prevalence among young female adults, there is no evidence to incriminate the oral contraceptive pill. Cosmetic products, especially foundation, may play a role, possibly resulting from an occlusive effect [8]. Topical steroid therapy is known to be an important aetiological factor. Prescribed initially for trivial facial eruptions, regular application of potent topical steroids leads to papulation and pustulation in the 'muzzle' area of the face [9,10]. Even brief exposure may occasionally cause the disease [9]. The more potent the steroid the more likely it is to cause perioral dermatitis although even hydrocortisone may very occasionally be sufficient [11]. The use of inhaled steroids for treating asthma, particularly from nebulizers, may also cause perioral dermatitis [12]. Systemic steroids may be an additional triggering factor [13]. Periocular dermatitis may be caused by steroid eye ointment [3].

Clinical features. Characteristically, the eruption begins abruptly in the nasolabial areas spreading rapidly to the perioral zone but sparing the lip margins (Fig. 43.11). The course of the condition may be continuous, intermittent or remittent. Occasionally it may spread to the forehead, eyelids and glabella, and rarely the lesions may be only periocular. Pruritus, burning and soreness are prominent symptoms. The lesions consist of monomorphic small papules and pustules occurring against a background of redness and variable scaling. The papules may occur in recurrent crops and are usually less substantial than those of rosacea. Strong soaps, sunlight and even contact with water may cause discomfort.

Fig. 43.11 Perioral dermatitis.

Histopathology. There is not a large amount of data published on the histology of perioral dermatitis, probably because of concern over the risk of scarring from facial biopsies. One study of 26 cases [14] showed a perivascular and perifollicular mononuclear cell infiltrate with mild eczematous changes. In another study of 36 patients similar features were observed but in addition to epidermal spongiosis, oedema of the papillary dermis was prominent. There was often perifollicular inflammation and some follicular pustules were observed. Granulomatous infiltration was observed in only two cases and *Demodex* mites were also rarely present [15].

Differential diagnosis. The clinical picture of perioral dermatitis is distinctive. The important differential diagnoses include rosacea, seborrhoeic dermatitis, contact allergic dermatitis, late-onset acne vulgaris, acne agminata and granulomatous perioral dermatitis in children (see below). Unlike rosacea, there is usually no telangiectasia or flushing in perioral dermatitis. Seborrhoeic dermatitis like perioral dermatitis affects the nasolabial area, but is not usually circumoral, and the scalp, ears and eyebrows are commonly involved. Contact dermatitis does not usually spare the immediate perioral area, but may present a problem which can only be resolved by patch testing. Acne vulgaris usually shows evidence of comedones, large papules and cysts in a wider distribution and responds more slowly to treatment than perioral dermatitis. Acne agminata may be difficult to distinguish if confined to the perioral area but can be differentiated histologically, if

necessary, as the lesions are more consistently granulomatous. Similarly, granulomatous perioral dermatitis in children (facial Afro-Caribbean childhood eruption) may be difficult to distinguish when the lesions are predominantly perioral although they do not spare the perilabial skin as in perioral dermatitis and pustules do not occur. This occurs especially in Afro-Caribbean children and unlike perioral dermatitis, seems to occur often in males.

Prognosis. Most patients experience permanent remission after a fairly short course of broad-spectrum antibiotics [16]. Relapses occur in a small minority [17]. However, if untreated and especially if the provoking topical steroids are continued, perioral dermatitis can persist for years [18].

Treatment. The most important measure is usually to discontinue the application of topical corticosteroids. Other applications, including cosmetics, should also be stopped. The patient must be warned that an initial flare may develop after withdrawal of a topical steroid. A 4-week course of oral tetracycline is usually all that is required. Topical tetracycline is also effective [19] as is topical metronidazole cream 1% [20] and topical erythromycin [21]. Response to pimecrolimus 1% cream has been demonstrated in recent clinical trials [22,23]. Photodynamic therapy performed weekly for 4 weeks proved somewhat more effective than clindamycin in a left/right comparative trial with 14 evaluable subjects [24]. Adapalene proved useful in one case [25].

Acne agminata

Synonyms
- Lupus miliaris disseminatus faciei
- Acnitis
- Facial idiopathic granulomas with regressive evolution

Acne agminata is seen mainly in young adults and adolescents of either gender although a case has been reported in a 71-year-old Japanese woman [1]. It presents as multiple, monomorphic, symmetrical, reddish-brown papules on the chin, forehead, cheeks and eyelids (Fig. 43.12). The lesions may cluster around the mouth or on the eyelids or eyebrows so that the term 'agminata' is appropriate, although paradoxically, in many cases, the lesions are widely disseminated around the face and the term 'disseminatus' seems more applicable. Diascopy of larger lesions often reveals an apple-jelly nodule-like appearance indicating their granulomatous histology, which also shows central caseation. The lesions are not consistently related to hair follicles [2]. This eruption tends to be self-limiting, resolving completely over a few months or up to 2 years. In some cases there is scarring. There are reports of similar eruptions having an extra-facial distribution but this seems to be very rare [3].

Fig. 43.12 Acne agminata. (Courtesy of Dr S. Charles-Holmes, Nuneaton.)

The clinical picture in classical cases of acne agminata is quite distinctive and does not closely resemble rosacea or acne vulgaris since the other features of these diseases are not present. The synonym 'lupus miliaris dissseminatus' results from a historical classification of this condition as a presentation of tuberculosis. It now seems most unlikely to be tuberculous in aetiology and more likely that this condition is a distinct entity. The recently proposed acronym 'FIGURE' (facial idiopathic granulomas with regressive evolution) is perhaps more appropriate as it avoids linking the condition to acne or tuberculosis [4].

The aetiology remains unknown. It has been considered by some to be a variant of rosacea and may represent a self-limiting variant of the granulomatous form of this disease. Whilst the distribution of lesions is similar, the natural history and the tendency to affect males and females approximately equally argue against this being a form of rosacea. It can be difficult to distinguish from micropapular sarcoidosis.

The response of acne agminata to tetracyclines has been variable as has the response to isotretinoin. Dapsone may be effective [5], and a good response to low-dose prednisolone has been reported [6]. In one case the use of clofazimine 100 mg three times weekly was followed by complete resolution within 8 weeks [7].

Granulomatous perioral dermatitis in children

Synonyms

- Facial Afro-Caribbean childhood eruption (FACE)
- Gianotti-type perioral dermatitis
- Granulomatous periorificial dermatitis
- Sarcoid-like granulomatous dermatitis

This eruption, which is seen in prepubertal children, may represent a juvenile form of perioral dermatitis or of acne agminata. It is considered relatively common in Afro-Caribbean children, giving rise to the acronym FACE (Fig. 43.13) [1] (see also Chapter 9).

This is a papular eruption generally confined to the face with lesions clustering around the mouth, eyes and ears [1–4]. In contrast to perioral dermatitis it does not spare the narrow zone bordering the lips and pustules are not seen. The histology has been variously described as showing non-specific inflammation with hyperkeratosis or, more often, as granulomatous, with the inflammatory changes often, but not invariably, being perifollicular. Blepharitis has occasionally been present. A series of cases with typical facial lesions accompanied by more disseminated lesions involving the trunk, limbs and labia majora has been described [5].

Fig. 43.13 Facial Afro-Caribbean childhood eruption. (Courtesy of Professor H.C. Williams.)

Complete resolution usually occurs after a few months, either spontaneously or in response to treatment. In some cases small pitted scars have been reported. Treatment with systemic erythromycin or topical metronidazole seems to have hastened resolution in several cases. A good response has been reported to treatment with minocycline and topical tacrolimus [6].

Pyoderma faciale

Synonym

- Rosacea fulminans

Although pyoderma faciale is also known as rosacea fulminans it is not yet clear whether this condition is a variant of rosacea or acne vulgaris or a separate entity.

Pyoderma faciale affects mainly adult females. This is a sudden, severe eruption of pustules and cystic swellings, which may be interconnected by sinuses (Fig. 43.14). Marked erythema and

Fig. 43.14 Pyoderma faciale.

oedema are usually present. Comedones are usually absent or inconspicuous, as are other features of acne vulgaris or rosacea [1,2]. There is often no preceding history of acne. Some cases have developed during pregnancy, suggesting that hormonal factors may play a role. Occasional cases may arise as a side effect of medication, for example interferon α-2B and ribavirin therapy for hepatitis C [3]. As the name implies, the eruption is usually confined to the face, involving the cheeks, chin, nose and forehead. Localized forms may be confined to the cheeks, jaw line or chin. Culture of the purulent discharge or needle aspiration may be sterile or may yield growth of commensal organisms including *Staphylococcus epidermidis* and *Propionibacterium acnes*. This investigation can be helpful in excluding Gram-negative infection. Significant scarring develops in many cases.

In view of the distressing nature of this disease and the risk of severe scarring it is usually treated initially with systemic corticosteroids. In one series, 10 of the 20 cases were hospitalized to commence treatment with prednisolone at 1 mg/kg/day, before adding isotretinoin 0.2–0.5 mg/kg/day. The steroid was tapered off over 2–3 weeks and the isotretinoin continued for 3–4 months [2]. Others have used moderately potent topical corticosteroids combined with systemic isotretinoin [4], application of Vleminckx packs (containing sulphur, calcium polysulphide and calcium thosulphate), UVB, benzoyl peroxide, systemic antibiotics [1] or dapsone [5].

Idiopathic facial aseptic granuloma

This recently described entity manifests as a benign, painless, inflammatory nodule on the face in children aged 8 months to 13 years [1]. Most cases seem to occur on the cheek and many are solitary, although two or three lesions are sometimes present. Histology shows a dermal lymphohistiocytic granuloma with numerous foreign body type giant cells. The lesions typically persist for 11 months or more.

Flushing and flushing syndromes

Synonyms
- Blushing
- Hot flushes
- Hot flashes

Flushing is intermittent redness, often accompanied by a sensation of warmth or burning due to cutaneous vasodilation. This is usually most evident on the face and neck but less conspicuous changes may occur over the entire body. Flushing may arise from the action of a circulatory vasodilator substance, for example histamine, or it may be caused by changes in the neurological control of the cutaneous vasculature in the affected areas. In the face, neck and upper trunk, where flushing is most apparent, vascular tone is predominantly influenced by autonomic vasodilator nerve fibres rather than by relaxation of vasoconstrictor tone [1]. These fibres are found in somatic nerves supplying the affected skin, including the trigeminal nerve [2]. Since autonomic nerve fibres also supply sweat glands, neurally activated flushing is frequently associated with sweating ('wet flushing') whereas flushing due to circulating vasodilator mediators usually does not involve sweating ('dry flushing'). The presence or absence of sweating has therefore been proposed as a clinical guide to the mechanisms of flushing [3]. This is not entirely reliable in practice and it should be noted, in particular, that severe sweating occurs in some cases of carcinoid syndrome. Causes of flushing are summarized in Table 43.2.

Table 43.2 Causes of flushing.

Cause	Proposed mediator(s)
Physiological	Autonomic
Menopausal	Autonomic
Drug-induced	Various
Alcohol	Acetaldehyde
Chlorpropamide and alcohol	Acetaldehyde
Food	Autonomic
Scombroid fish poisoning	Histamine
Carcinoid syndrome	Serotonin
	Prostaglandins
	Bradykinin
	Histamine
Mastocytosis	Histamine
Thyrotoxicosis	Thyroxine
Medullary carcinoma of the thyroid	Prostaglandins
	Calcitonin
Pancreatic tumours	Vasoactive intestinal peptide
Insulinoma	?
POEMS syndrome	?

Table 43.3 Drugs that cause flushing.

5-HT3 receptor antagonists: ondansetron, ramosetron, tropisetron
ACE inhibitors: captopril, enalapril, lisinopril, perindopril, ramipril
β-3 adrenoceptor agonists: fluvoxamine, mirtazapine
Calcium channel blockers: nifedipine, verapamil

Pilocarpine
Prostacyclin
Prostaglandin E
Sildenafil, tadalafil and vardenafil
Venlafaxine

* With ethanol.

Physiological flushing

Flushing develops as part of the normal thermoregulatory response in a hot environment or following exercise. A similar mechanism is responsible for facial flushing due to hot drinks, which cause a rise in temperature of blood in the oral cavity which in turn leads, by a counter-current heat-exchange process involving the internal jugular vein and internal carotid artery, to a rise in temperature of blood perfusing the hypothalamus [4].

Emotionally triggered flushing due to embarrassment or anger may be a problem in some patients in whom the threshold for this response may be low or the reaction itself unusually intense or extensive. It is often associated with telangiectasia and with sweating and can be a significant social handicap. Such patients are occasionally referred for investigation to exclude an underlying carcinoid tumour.

Explanation, accompanied if necessary by the β-blocker propranolol, may alleviate the symptom, which is essentially due to exaggeration of a normal response. Transthoracic endoscopic sympathectomy can be effective but seems justifiable only in the most severe cases and perhaps those with concurrent severe palmar hyperhidrosis [5,6]. This procedure can result in compensatory hyperhidrosis at other sites, Horner's syndrome and other complications.

Menopausal flushing

About 80% of menopausal women develop troublesome flushing, often associated with sweating. Attacks, which are often preceded by a feeling of heat, may be provoked by emotion, exertion and hot food or drink. The mechanism remains imperfectly understood but it is likely that the endocrine changes associated with the menopause result in a disturbance of thermoregulation and the flushing and sweating represent a hypothalamic response reducing body temperature [7]. A similar syndrome may also occur in men with prostatic cancer receiving treatment by gonadotrophin-releasing hormone analogues such as buserelin [8].

Menopausal flushing usually improves with oral or transdermal oestrogen replacement therapy. Combined oral contraceptives are effective and even the use of progestagens alone may be beneficial. Non-hormonal approaches to management include the use of clonidine 0.05 mg twice daily or selective serotonin reuptake inhibitors (SSRIs) [9].

Flushing caused by drugs

Numerous drugs cause flushing as an unwanted side effect, most frequently those listed in Table 43.3. There seems to be considerable variation between individuals in susceptibility to this side effect. It is not surprising that vasodilating drugs, such as calcium antagonists and sildenafil, may do this. Flushing occurs in an estimated 12% of patients taking sildenafil and may be accompanied by headache [10].

Fumaric acid esters, used in treatment of psoriasis, produce flushing in about one-third of patients [11]. Some state that this regularly occurs 20–60 min after each dose but in others the timing is not consistent. Flushing episodes may be quite severe but are usually very evanescent, lasting for only a couple of minutes. They may be accompanied by headache. Some patients do not notice this flushing at all whilst occasionally it is so severe that they cannot tolerate the drug. The flushing may sometimes be reduced by addition of oxypentifylline, perhaps due to antagonism of TNF-α by the latter drug [12].

Flushing is observed as part of generalized vasodilatation in reactions to gold therapy for rheumatoid disease, which have been termed 'nitritoid reactions' [13]. These occur most commonly with gold sodium aurothiomalate but have also been reported with other formulations. The reaction may develop after several years of regular treatment and may be more severe if angiotensin-converting enzyme (ACE) inhibitors are used simultaneously.

This phenomenon may be accompanied by hypotension and has occasionally been complicated by stroke or myocardial infarction. It is usually quite benign.

A reduction in the normal flushing response induced by systemic or topical nicotinic acid has been proposed as the basis of a diagnostic test for schizophrenia [14].

Flushing associated with alcohol intake

Most information on alcohol-evoked flushing in otherwise healthy individuals has been acquired by study of Japanese, Chinese and Korean volunteers since a majority of these oriental genotypes show extensive flushing in response to low doses of alcohol [15]. This difference with occidentals is associated with higher plasma levels of acetaldehyde, the initial metabolite of ethanol. Acetaldehyde may act partly by causing histamine release from mast cells [16]. Harada *et al*. [17] demonstrated deficiency of an isoenzyme of liver aldehyde dehydrogenase (low Km aldehyde dehydrogenase ALDH-1) in 50% of Japanese and that these, but not other, Japanese developed flushing after alcohol intake. This population can be detected using an ethanol patch test, which shows erythema due to accumulation of acetaldehyde in the ethanol-treated skin [18]. In a Caucasian population, patch testing with acetaldehyde proved more reliable [19]. Symptoms can be alleviated by aspirin [20] and also by antihistamines, H_1 and H_2 antagonists being most effective used in combination [21].

The chlorpropamide–alcohol flush is a special type of alcohol-induced flushing occurring in patients receiving this oral antidiabetic sulphonylurea drug. Even small amounts of alcohol provoke intense flushing within a few minutes of ingestion [22]. There is no associated sweating, and no systemic symptoms. The abnormality is dominantly inherited, associated with familial non-insulin-dependent diabetes and with a low frequency of diabetic complications. The flush is mediated by elevated acetaldehyde plasma levels, but release of prostaglandins is also involved since aspirin and other non-steroidal anti-inflammatory agents block the flush [23].

Flushing associated with food

It is a matter of common experience that eating spicy foods causes facial flushing, usually associated with sweating. This type of flushing, termed gustatory, is due to a nerve reflex involving autonomic neurones carried by the branches of the trigeminal nerve. Sour foods may also cause a similar response which, curiously, may be unilateral, as demonstrated by a child in whom the right (but not the left) side of the face manifested a 'slapped cheek' appearance (without sweating) a few seconds after sucking an acid drop (Fig. 43.15).

Monosodium glutamate has a reputation for causing flushing associated with sweating and faintness ('Chinese restaurant syndrome'). Although first described by Kwok [24], his account did not include flushing which was added to the symptom complex by later authors [25]. A more recent study involving oral challenge of volunteers with and without a history of previous monosodium glutamate reactions, by both monosodium l-glutamate and its cyclized derivate monosodium l-pyroglutamate, failed to provoke flushing over a range of doses although burning and tightness of the skin was noted in some volunteers [26]. Similar negative results have subsequently been reported [27]. Flushing due to monosodium glutamate, if it exists at all, must be an extremely rare occurrence.

Fig. 43.15 Unilateral gustatory flushing. (Courtesy of Professor M. Greaves.)

Scombroid fish poisoning

The scombroid families of edible fish include tuna and mackerel. Non-scombroid fish including dolphin and herring have also occasionally been reported to cause this syndrome [28]. Scombroid fish poisoning, which is the commonest form of ichthyotoxicosis worldwide, is due to ingestion of fish which has 'gone off', usually due to having been left on the fishmonger's counter in a warm atmosphere for several hours. Ingestion of the affected fish causes flushing, heat, sweating, vomiting and diarrhoea. That the symptoms are due to histamine intoxication is indicated by recent studies of the histamine content of affected fish and measurement of urinary histamine excretion in affected individuals [29]. Bacterial biosynthesis (by histidine decarboxylation) is thought to be the source of histamine in the spoiled fish.

Patients poisoned in this way should be treated with a combination of H_1 and H_2 antihistamines. Adrenaline and corticosteroids may be required in severe cases.

Other causes of flushing

Persistent flushing is sometimes observed in thyrotoxicosis as part of a picture of generalized vasodilatation. Mastocytosis is discussed elsewhere (Chapter 22). Medullary carcinoma of the thyroid [30] and certain pancreatic tumours [31] have been found to cause attacks of flushing. There are also single case reports of the association of flushing with an insulinoma [32] and the POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal proteinaemia and skin changes) [33]. These may therefore cause confusion with the carcinoid syndrome, which may also present with flushing (see below).

Carcinoid syndrome

The carcinoid syndrome results from secretion of a variable and diverse range of endocrinologically active substances by a malignant carcinoid tumour and its metastases. It may present with cutaneous features alone so it is of particular importance that dermatologists remain alert to this disease.

The term 'Karzinoid' was first used in 1907 to denote an intestinal tumour which behaved less aggressively than the more common adenocarcinoma [1]. A variety of other terms have been used to describe these tumours, which are probably derived from a primitive endocrine stem cell. Some of these reflect staining characteristics (argentaffinoma, enterochromaffinoma), others reflect their functional capacity to secrete a range of hormonally active substances (neuroendocrine tumours, Amine Precursor Uptake and Decarboxylation tumours (APUDomas)).

The tumours are variable in their degree of malignancy and in the pattern of hormones they secrete. Clinical manifestations are also highly dependent on the anatomical situation in which they arise, as their secretory products are substantially metabolized during passage through the liver and lungs when these organs lie downstream of the circulation from the tumour.

Carcinoid tumours are found most commonly in the embryological midgut (appendix, small bowel), especially in the appendix, where they may cause appendicitis. Estimates of the prevalence of appendiceal carcinoids range between 0.03 and 0.69% [2]. Most are asymptomatic and only a minority metastasize. Small bowel carcinoids are also common, whereas foregut (stomach, pancreas, biliary tract) and hindgut (colon and rectum) tumours are relatively rare. Occasionally, carcinoid tumours arise outside the intestinal tract (lung, ovary, testis).

The low levels of endocrine activity associated with most carcinoid tumours are asymptomatic, probably as a result of rapid hepatic metabolism of endocrine products in portal blood. The symptoms of the carcinoid syndrome normally develop as a consequence of liver metastases, although pulmonary carcinoids release hormonal products directly into the systemic circulation and can therefore cause symptoms without metastases. The considerable range of products with potential for endocrine activity known to be produced by carcinoid tumours includes 5-hydroxytryptamine (5-HT, serotonin), 5-hydroxytryptophan, histamine, dopamine, kallikrein, prostaglandins, tachykinins (neuropeptide K, substance P), gastrin, motilin, somatostatin, calcitonin and pancreatic polypeptide [2,3].

Clinical features. The cardinal features of carcinoid syndrome are flushing, diarrhoea, asthma and right sided cardiac dysfunction.

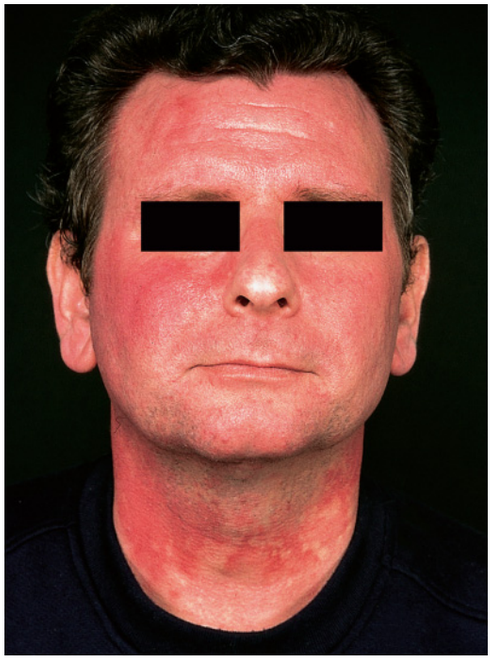

Fig. 43.16 Histamine-evoked 'geographical' pattern of flushing due to foregut carcinoid tumour. (Courtesy of Professor M. Greaves.)

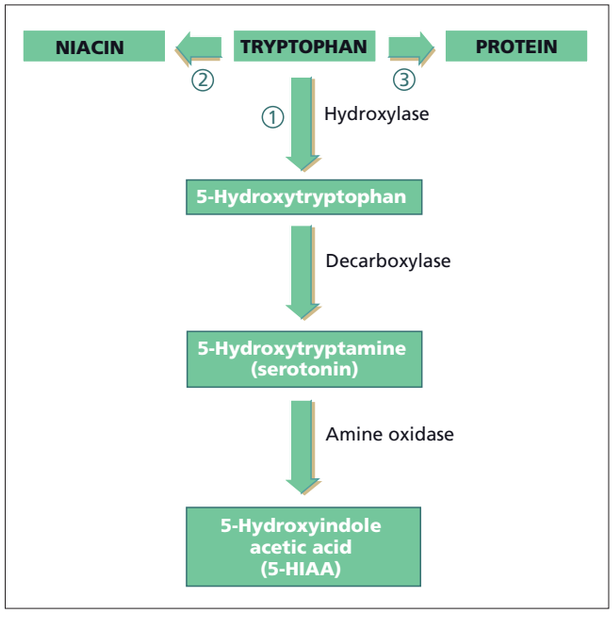

Fig. 43.17 Pathways for transformation of tryptophan to 5-hydroxytryptamine (pathway 1); niacin (pathway 2); and protein (pathway 3).

The relative prominence of these varies considerably between patients. Flushing and diarrhoea are the most common symptoms.

Flushing is observed in 80% of cases and may develop long before other symptoms. This is usually episodic and may be spontaneous or precipitated by exercise, alcohol, stress or meals. Certain foods, especially those containing tyramine or catecholamines (red wine, chocolate, blue cheese) are especially likely to induce flushing.

The character of the flush can vary considerably and seems to depend particularly upon the site of origin of the tumour. Midgut tumours usually produce diffuse, transient flushes of pink to red colour, lasting 2 to 10 min, affecting the face, neck, arms and upper chest. The flush is often mingled with areas of pallor, especially as it resolves [4]. Foregut carcinoids tend to produce slightly more prolonged and violaceous flushes, sometimes associated with a permanent cyanotic hue, facial telangiectasia, watery eyes, and injected conjunctivae [2]. Gastric carcinoids are often associated with increased histamine secretion and bright red, patchy 'geographic' flushing (Fig. 43.16) [5]. Bronchial carcinoids may result in particularly severe episodes of fiery violaceous-red flushing lasting up to 2 weeks and associated with profuse lacrimation, salivation and sweating, nasal congestion, swelling of the salivary glands, facial oedema, tachycardia, increased cardiac output and hypotension [6]. In contrast, rectal carcinoid tumours very rarely result in the carcinoid syndrome, tending to present with local symptoms such as bleeding, pain, constipation or pruritus ani.

The pathophysiology of the flushing is not fully understood. It is likely that histamine plays a major role in the distinctive bright red, geographical flushing associated with foregut (especially stomach) carcinoids [5]. The cause of the more classical flushing of midgut carcinoids is less clear. Serotonin, the major product of these tumours, seems unlikely to be the primary mediator. Serotonin infusions do not consistently induce flushing and flushing is not consistently associated with a rise in serotonin [7]. Serotonin antagonists inhibit the diarrhoea associated with the carcinoid syndrome but not the flushing. It seems more likely that carcinoid tumours may release kallikrein, which may produce flushing by acting on kininogen to release bradykinin [8]. Other proposed mediators of flushing include prostaglandins [9] and substance P [7].

A photosensitive eruption resembling pellagra may occur as part of the carcinoid syndrome and is believed to result from diversion of tryptophan metabolism away from synthesis of niacin (Fig. 43.17). Additional cutaneous manifestations reported in association with carcinoid tumours have included scleroderma [10], pyoderma gangrenosum [11] and pruritus [9]. Fixed facial erythema, telangiectasia and lymphoedema may give rise to an incorrect diagnosis of rosacea [12], and rosacea may develop as a feature of carcinoid syndrome [13].

Gastrointestinal symptoms are common. An estimated 76% of patients develop watery (secretory) diarrhoea [2]. This seems likely to be mediated substantially by serotonin. Abdominal pain is often reported and arises from a range of causes including altered motility, bowel obstruction, intussusception or appendicitis. Cardiac involvement results from the development of right-sided endocardial fibrosis, which may lead to pulmonary stenosis, tricuspid incompetence and congestive cardiac failure. The pathogenesis of the fibrotic changes is unknown. The asthma associated with carcinoid syndrome is a less constant feature than the flushing and the diarrhoea, occurring in about 25% of cases [2]. The episodes of wheezing often coincide with flushing and/or diarrhoea.

Diagnosis. The clinical diagnosis is not difficult in patients with advanced disease who present with flushing, diarrhoea, wheezing, weight loss and a large liver. Early recognition of the carcinoid syndrome is not so easy and some cases have been misdiagnosed for years as suffering from benign causes of flushing. These symptoms may even be dismissed as psychogenic in origin.

The diagnosis is usually confirmed by determining the urinary excretion of 5-hydroxyindole acetic acid (5-HIAA), the major metabolite of serotonin. The normal excretion rate is up to 10 mg (150 µmol) in 24 hours. In carcinoid syndrome, the level often exceeds 40 mg daily and may be much higher, especially after flushing episodes. However, levels can vary considerably from day to day. If attacks are infrequent, it may be helpful to wait until a flushing episode occurs before performing the urine collection. Foods containing serotonin, such as avocados, aubergine, bananas, pineapples, plums, tomatoes and walnuts should be avoided for 3 days before the urine collection is made, in order to avoid false-positive results. The elevation of 5-HIAA due to these is usually only marginal. Various drugs, including bromocriptine, caffeine, L-dopa, paracetamol, phenothiazines and salicylates, may also cause marginal changes in 5-HIAA excretion or interfere with the assay, so the laboratory should be advised about the patient's drug intake.

Further confirmation of the diagnosis may be obtained by induction of the flushing which can usually be provoked by alcohol ingestion (4 ml of 45% ethanol) or the infusion of norepinephrine (noradrenaline) 6 µg. This response to norepinephrine can be blocked by phentolamine (5–15 mg i.v.) [14].

If hepatic involvement is evident by abdominal palpation there is little point in elaborate attempts to locate the primary tumour, unless it is suspected to be causing obstruction. Many imaging techniques have been employed to investigate the extent of liver and lymph node metastases including angiography, ultrasound, endoscopic ultrasound, CT scanning and positron emission tomography [2]. Octreotide receptor imaging using radiolabelled octreotide can be used to localize both primary and secondary tumours [15].

In some cases, further investigation may be indicated to exclude additional neuroendocrine tumours. Carcinoid tumours, especially those of foregut origin, may occur in association with multiple tumours of the pancreas, parathyroid and pituitary as a feature of type I multiple endocrine neoplasia [16]. This condition is inherited as an autosomal dominant trait.

Prognosis. About one-fifth of patients with the carcinoid syndrome undergo a protracted course. In the remainder, deterioration can be rapid. The mean survival in one series was 8 years, the longest survivor living for 20 years [17].

Treatment. Alcohol and foods that may exacerbate symptoms (listed in Table 43.4) should be avoided as should exercise and stress. Nicotinamide supplements are often provided to reduce the risk of pellagra.

A range of pharmacological agents have been employed with variable degrees of success in providing control of symptoms.

Table 43.4 Food items that may cause flushing in carcinoid syndrome.

Alcohol	Pecan nuts
Aubergine	Pineapples
Avocado	Plums
Bananas	Red wine
Chocolate	Spicy foods
Hickory nuts	Tomatoes
Kiwi fruit	Walnuts

Serotonin antagonists such as cyproheptadine, ketanserin and methysergide, and the inhibitor of serotonin synthesis parachlorophenylalanine, can help control the diarrhoea but these are less effective against flushing [18]. Codeine phosphate and loperamide can also be useful for reducing diarrhoea. Clonidine has been reported to suppress flushing at low doses (0.05 mg twice daily) [19] and higher (antihypertensive) doses (0.4 mg/day) [20]. Antihistamines, both H_1 and H_2 [21], are effective in blocking the flush of foregut, especially gastric carcinoids, due to the dominant role of histamine in carcinoids at this location. Corticosteroids can be highly effective in controlling prolonged flushing associated with bronchial carcinoids [6]. α-Adrenoceptor blockers such as phentolamine and phenoxybenzamine have been helpful in improving flushing, diarrhoea and wheezing in some cases [22].

Octreotide, a somatostatin analogue given by subcutaneous injection at total daily dosage of 50–600 µg, lowers plasma levels of serotonin and tachykinins and relieves both flushing and diarrhoea [23]. The requirement for subcutaneous injections two or three times daily has been a disadvantage but a long-acting depot injection is now available and can be used at the dose of 20 mg intramuscularly every 28 days. In some cases, treatment for 6–12 months has resulted in partial or complete tumour regression [24]. Another somatostatin analogue, lanreotide, is also now available in depot formulation.

Surgical excision of carcinoid tumours is performed when possible. In metastatic disease, reduction of tumour mass can be useful in reducing symptoms; a similar effect can often be achieved by hepatic artery ligation or embolization [25]. Some patients have had multiple embolizations over a number of years. This treatment is based upon the dependence of metastatic malignant tissue, but not healthy liver parenchyma, on an intact hepatic arterial blood supply. Chemotherapy with agents such as streptozotocin, dacarbazine, adriamycin and 5-fluorouracil has also been employed [2]. All these 'tumour ablative' interventions run the risk of provoking an acute carcinoid crisis (profound flushing, bronchospasm and shock), due to massive release of mediators. This can be prevented or treated with intravenous octreotide [26]. Interferon-α has also proved helpful in reduction of symptoms and 5-hydroxyindole acetic acid levels in some cases, but side effects include flu-like symptoms and bone-marrow suppression [27].

Comparative anatomy and physiology

Sweat glands are described as merocrine; unlike the holocrine sebaceous glands, their cells are not destroyed in the process of secretion. Merocrine glands have been further subdivided into two major types, usually known as apocrine and eccrine. The nomenclature is attributed to Schiefferdecker [1,2], who believed that secretion by apocrine glands involved decapitation of the apical cytoplasm, in contrast with eccrine glands, in which no breakdown of any cellular material occurs. Such a distinction between modes of secretion has been denied [3–5]. However, in the rabbit chin gland [6] and the lemur antebrachial organ [7], large portions of secretory epithelium do appear to be sloughed during secretion. In the axillary organ of humans, although some authors have claimed that decapitation of apical cells can sometimes occur [8], most believe this to be abnormal. The favoured view is that secretion occurs by small portions of apical cytoplasm becoming pinched off [9].

Even though the mechanisms of secretion may be debatable, there are a number of characteristic differences between the two types of gland (Fig. 44.1). The alternative designations of 'epitrichial' (where the sweat duct opens into the hair follicle) for 'apocrine', and 'atrichial' (where the duct does not enter the hair follicle) for 'eccrine', are not entirely satisfactory, because glands that on developmental and histochemical grounds must be classed as apocrine do not invariably open into the hair ducts. On balance, therefore, there is no strong case for abandoning the well-established terms.

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

The terminology has become further complicated by the use of 'apoeccrine' to describe a distinct type of tubule present in the human axilla. The axilla contains not only typical eccrine and apocrine elements, but numbers of large, irregularly shaped glands which cannot be assigned to either category, although they have some characteristics of each [10]. Such glands consistently occur in adults, but not in children, and become apparent between the ages of 8 and 14 years. Whether their precursors are apocrine or eccrine is unclear, but their ducts do not open into hair canals.

Apocrine glands occur in all known orders of mammals except whales, elephants, sea cows and scaly ant-eaters, although in some species only as part of specialized aggregates [11]. When dispersed, their density varies widely, ranging from 20 to 30/cm^2 in the pig to over 2000/cm^2 in Zebu cattle [5].

Eccrine glands occur in the footpads of many mammals; the exceptions again include whales, sea cows, elephants and scaly ant-eaters, with the addition of bats. Such glands probably serve to moisten the surface of the skin to improve grip.

In hairy skin, however, eccrine glands are found only in tree shrews, Old World monkeys, apes and humans. They appear to replace, but not to evolve from, apocrine glands. Only in humans do eccrine glands completely replace apocrine glands over the major areas of hairy skin. In the human embryo, such glands develop later than those on the friction surfaces, and thus should probably be placed in a different category and distinguished from mammalian footpad glands in general.

Specialized glands, that is aggregations of secreting units, are not only widespread among mammalian orders but, in different species, can be found in almost every area of the body, from the head to the rump and the extremities [11]. Some—for example, the chin and anal glands of the rabbit—contain only tubular units [12,13]; others—for example, the supracaudal gland of the guinea

pig, the flank organ of the golden hamster, the abdominal gland of the gerbil and the preputial glands of rodents—are purely sebaceous. Both types of unit may be associated, as in the muzzle glands of certain bats [14], the side glands of shrews, in which batteries of tubular glands underlie the sebaceous elements [15], and the inguinal glands of the rabbit, which consist of a discrete pair of each type [16]. Similar glandular aggregations occur in primates [17]. In humans, rudiments of apocrine glands attached to each follicle appear during development, but survive to become functional only in the axillae, the genital area and the areolae.

In animals, two main functions, thermoregulation and odour production, are performed by apocrine glands. The first is carried out by glands dispersed over the general body surface or, in some species, limited to areas such as the scrotum. Odour production is a property of specialized aggregates, although possibly not exclusive to them.

The extent to which the glands respond to environmental heat loads, and the exact nature of the control mechanisms, have been studied mainly in domestic animals. They vary widely. In horses, oxen and camels, the glands secrete in response to a rise in ambient temperature, but in pigs, dogs and deer they do not [18]. Apart from the primates, Equidae and some Bovidae, sweat glands appear to play a minor role in the control of body temperature in warm conditions [5,19], although they may cool local areas, such as the scrotum in sheep [20]. By sympathetic denervation of the skin, it has been shown that sweating is under adrenergic nervous control, even in species that lack a demonstrable nerve supply. In addition, in most species studied, the glands also respond to administration of epinephrine (adrenaline), although in contrast with human eccrine glands they are much less sensitive to acetylcholine. Although various interpretations have been made of the experimental results, it is now accepted that apocrine sweating is, in general, controlled by adrenergic nerves, and that in some species—for example the horse—epinephrine from the adrenal medulla supplements the sweating caused by exercise, although not that caused by heat exposure [18,19].

Odour production is known to occur in 15 out of 29 mammalian orders, but has received detailed study in only a few species. Chemical signals serve a number of social purposes, of which the marking of territory, the maintenance of social hierarchy, alarm signals and individual, group or species recognition are only a few [13,21–23]. They are also concerned with sexual attraction, either of the female by the male, as has been well established, for example, in the boar [24], or of the male by the female, as in the hamster [25] and the rhesus monkey [26,27].
