The clinical pattern of metastases may provide clues to the route of metastasis. For example, metastases to extremities suggest intra-arterial embolic spread, widespread skin metastases suggest that tumour cells are present in the general circulation, whilst metastases to the skin in the vicinity of the affected organ (for example, prostatic tumour metastases are often on the lower abdomen, Fig. 62.11) is more suggestive of dissemination by lymphatic vessels or by veins. Retrograde lymphatic spread may occur from pelvic tumours, causing metastases in the perineal area or on the legs. In general, the head, neck and upper trunk are disproportionately commonly affected by tumours that metastasize to the skin [2,7–9,11], possibly because of the high vascularity of this area. Some of the tumour and host factors involved in metastasis, both generally and organ-specific, are reviewed in [13–17]; in particular, chemokine receptors on tumour cells may influence the organs involved in metastatic spread [18,19].

Other than the scalp, notable sites for skin metastasis include the umbilicus (Sister Mary Joseph's nodule, related to bowel tumours most commonly) [11,20,21] and recent operative scars. Scar metastasis is most often related to surgery for the primary tumour, and, in view of the low frequency of 'tumour spillage' documented previously, presumably represents spread by local lymphatic or venous drainage; however, recent but distant scars (for example, skin graft donor sites [22,23]) may be a site for metastases, suggesting a role of adhesion molecules, metalloproteinases or cytokines related to angiogenesis and tissue repair. Metastases have also been reported that are localized to a site of irradiation of the skin [24]. An additional, unusual phenomenon is 'tumour-to-tumour metastasis', in which metastases localize to another (usually benign) tumour [25]. A postulated mechanism is the trapping effect of fibrin in the vessels of recipient tumour; most such metastases occur within quite vascular neoplasms, such as thyroid or adrenal adenomas, but metastasis to lipoma and to basal cell carcinoma [26] have both been reported and are relevant to dermatologists.

Metastases to the scalp may give rise to focal alopecia, carcinomas of breast, lung and kidney being the commonest tumours to metastasize to the scalp. Renal and thyroid cancer metastases may be quite vascular in appearance, both clinically and pathologically [27], and are occasionally misdiagnosed as benign haemangiomas or pyogenic granulomas; hypernephroma metastases may even be pulsatile. Generally, cutaneous metastases may be mistaken for cysts or inflammatory lesions, although alopecia over a scalp 'cyst' should give rise to suspicion regarding the true nature of the lesion.

Histopathology and investigations

Biopsy of skin metastases is generally helpful in confirming a metastatic tumour, but is not always useful in determining the organ of origin if the tumour cells are poorly differentiated. Occasionally, it may be difficult, even with use of immunohistochemical tumour markers, to confidently distinguish between primary skin tumours and metastatic disease. Although, in general, the cells of a metastasis resemble the cells of the primary tumour, some patterns may prove diagnostically difficult. Spindle cell tumours, and tumours comprising 'small blue cells', cause particular difficulty and may need a panel of immunohistochemical markers to aid in diagnosis both between primary skin lesions and metastases, or between different origins of an internal tumour. For example, small cell neoplasms may occur in primary skin tumours (Merkel cell tumour), in skin or systemic lymphomas, and in metastases from small cell carcinoma of lung, from carcinoid or visceral neuroendocrine tumours, and in rarer metastatic tumours such as neuroblastoma or retinoblastoma. Immunohistochemistry may help in determining the diagnosis of the primary tumour, especially in the case of prostatic metastases (prostate-specific antigen) or thyroid metastases (thyroglobulin); where a specific site of origin cannot be determined, cytokeratin stains may help to distinguish between squamous cell carcinomas (e.g. from lung) and adenocarcinomas. Melanoma metastases may mimic many cell types, and melanoma markers such as MART-1 are not always expressed. Pathological diagnosis of specific metastases and immunohistochemical markers are discussed in [11,28]. In some instances, there may be marked oedema or dilated lymphatic vessels, which may make diagnosis difficult. In some specific tumours such as hypernephroma, or in some clinical patterns such as carcinoma telangiectoides, the tumour cells may either be scanty or the vascular proliferation may dominate the histopathological appearance. Lymphatic spread of tumour cells may lead to an 'Indian filing' appearance in some cases, sometimes with fibrosis.

Implications and prognosis

Cutaneous metastases usually occur in subjects with a known cancer, but may be the first indication of an internal neoplasm, especially in the case of lung cancers. They are usually indicative of disseminated disease and indicate a correspondingly poor prognosis; survival is typically only about 3 months in patients with disseminated skin metastases [4]. Patients with solitary metastases without other evidence of dissemination may have a better survival [29]. Infrequent cases of tumour regression after primary tumour removal are documented [30]. It is noteworthy that cutaneous metastases do not necessarily relate to a prior, documented tumour; the histological pattern, localization and

temporal relationship may occasionally point to a second primary [31]. Treatment options, depending on the primary tumour, may include excision or other destructive therapy (e.g. laser destruction, radiotherapy, photodynamic therapy) for limited numbers of lesions, and chemotherapy or other systemic treatment for disseminated lesions.

Genodermatoses associated with internal malignancies [1–10]

Most cutaneous signs of neoplasia do not involve direct spread of tumour to the skin but are paraneoplastic. Genodermatoses account for a significant minority of paraneoplastic skin lesions; some including both cutaneous and internal neoplasms as part of the syndrome, both benign and malignant. The most important are listed in Table 62.8; non-cancer aspects of these disorders are discussed more fully in earlier chapters. A number of mechanisms underlie the association of genodermatoses with internal malignancy; these include chromosomal instability, faulty DNA repair mechanisms, abnormal lymphocyte function and immunosurveillance, and in some cases a combination of these. More precise genetic diagnosis, understanding of mechanisms, awareness of the benefits and ability to focus screening of family members for genetic abnormalities or for cancers, is a constantly evolving area within dermatology and paediatric medicine in particular.

Genodermatoses that predispose to skin but not to internal cancers are not discussed here; examples include disorders such as albinism, epidermodysplasia verruciformis, dystrophic epidermolysis bullosa, porokeratosis of Mibelli and KID syndrome.

Table 62.8 Examples of genodermatoses associated with internal malignancies.

Main organ affected or usual mode of presentation (many are multisystem disorders)	Genodermatosis	Main neoplasms (may be limited to some families in some of the disorders listed)
Gastrointestinal tract	Gardner's syndrome	Gastrointestinal polyposis and carcinomas (p. 62.56), central nervous system tumours
	Bannayan–Riley–Ruvalcaba syndrome	
	Turcot syndrome (mismatch repair cancer syndrome)	
	Peutz–Jeghers syndrome	Gastrointestinal polyposis and carcinomas (p. 62.56), pancreatic carcinoma, genital tumours (especially Sertoli cell, sex cord and cervix), breast cancers, lung cancers
Neurological	Ataxia–telangiectasia	Lymphomas, leukaemias
	Neurofibromatosis	Neurological tumours, sarcomas, phaeochromocytoma
Skin	Xeroderma pigmentosum	Skin cancers, sarcomas, central nervous system tumours, leukaemia, various solid organ tumours
	Naevoid basal cell carcinoma syndrome (Gorlin)	Basal cell carcinomas of skin, medulloblastoma
	Basex–Dupré–Christol syndrome	Basal cell carcinomas of skin, possible leukaemia
	Porphyria cutanea tarda	Hepatocellular carcinoma
	Tylosis	Oesophageal carcinoma
	Sclerotylosis (Huriez syndrome)	Squamous cell carcinoma of skin; oral and bowel cancers also reported
	Muir–Torre syndrome	Colorectal tumours, sebaceous carcinoma
	Birt–Hogg–Dube syndrome and Hornstein–Knickenberg syndrome	Medullary carcinoma of thyroid, renal cell carcinoma
	Familial leiomyomas (also uterine)	Renal cell carcinoma, others (see text)
	Incontinentia pigmenti	Wilms' tumour, rhabdomyosarcomas (renal, paratesticular), retinoblastoma, leukaemias
	Familial atypical naevi and melanoma	Pancreatic carcinoma, cutaneous and ocular melanoma
	Melanoma–astrocytoma syndrome	Melanomas, astrocytomas and other central nervous system tumours
	Supernumerary nipples	Genitourinary tumours—renal cell carcinoma, Wilms' tumour, bladder, testicular, prostate
	Ichthyoses (autosomal dominant and X-linked)	Testicular carcinoma
Endocrine	Multiple endocrine neoplasia syndromes	Medullary carcinoma of thyroid, phaeochromocytoma
Growth/skeletal	Werner's syndrome	Many, especially sarcomas
	Rothmund–Thomson syndrome	Skin, osteosarcoma
	Bloom's syndrome	As general population but early onset
	Maffucci syndrome	Chondrosarcomas, gliomas, ovarian cancers
	Goltz syndrome	Chondrosarcomas, giant cell tumour of bone
	Fanconi's anaemia (usually presents due to congenital malformations)	Myelodysplastic syndrome, acute myelogenous leukaemia, hepatic carcinoma
Haemopoietic	Dyskeratosis congenita	Mucosal squamous cell carcinoma, haemopoietic malignancy, and others
Immunological	Wiskott–Aldrich syndrome	Lymphoreticular malignancies
	Chediak–Higashi syndrome	Lymphoreticular malignancies
Multisystem	Cowden's (multiple hamartoma and neoplasia) syndrome	Breast, thyroid, gastrointestinal, cerebellum, endometrial and renal carcinomas
	Carney complex	Myxomas, Schwannomas, testicular Sertoli cell tumour, pituitary adenomas, thyroid cancer
	Von Hippel–Lindau disease	Phaeochromocytoma, renal carcinoma, haemangioblastoma, pancreatic carcinoma
	Beckwith–Wiedermann syndrome (EMG syndrome)	Wilms' tumour, adrenal carcinoma, hepatoblastoma, pancreatoblastoma, others (especially in patients with hemihypertrophy)

Focal palmoplantar keratoderma (Howel-Evans syndrome; tylosis; MIM 148500) and other palmoplantar keratodermas (Chapter 19)

Howel-Evans syndrome is the association of autosomal dominantly inherited focal palmoplantar keratoderma (tylosis) with the eventual development of oesophageal carcinoma in most cases [1]. Since the original description, other families linked with inherited tylosis and carcinoma of the oesophagus have been described [2,3]. The genetic locus is at chromosome 17q25. However, in diffuse familial palmoplantar kerato-

derma starting in infancy, there is no genetic susceptibility to neoplasia.

A possible familial association has been described between palmoplantar keratoderma and gastrointestinal malignancy [4], diffuse epidermolytic palmoplantar keratoderma has been linked with increased risk of breast and ovarian cancer [5] and punctate porokeratotic keratoderma has been tentatively associated with internal neoplasia [6,7]. However, it is likely that such cases represent a separate, inherited tendency as most such reports relate to one specific family [8].

Acquired palmar hyperkeratosis may also occur as a marker of carcinogen ingestion (pp. 62.46–62.47), principally linked with arsenic. The relationship between arsenic-induced keratosis or punctate keratoderma and internal malignancy is controversial.

Palmoplantar punctate keratoses may be present in Cowden's disease (p. 62.25), in which there is a predisposition to several malignancies.

Naevoid basal cell carcinoma syndrome (NBCCS; Gorlin's syndrome, MIM #109400) (Chapter 52)

This is an autosomal dominant condition with prevalence of about 1/100 000 (about half being due to *de novo* mutations), the main features being multiple basal cell carcinomas (BCCs), mandibular odontogenic keratocysts, skeletal anomalies, abnormal calcification and dyskeratotic pits of palms and soles [1–6]. Diagnostic criteria are documented in [5,6]. The most commonly reported internal malignancies are medulloblastoma [7] and ovarian tumours (mainly benign fibromas, but also desmoids and sarcomas); astrocytomas, meningiomas, craniopharyngiomas, fibrosarcomas and ameloblastomas have occasionally been reported [2]. It is important to note that individuals may have only the family history, without themselves having developed BCC. However, neoplasia may also commence early in life, with a median age of onset of BCC by 20 years; most patients will have at least one BCC before age 30 years. The BCCs may present as small, subtle, tan-coloured or brown papules or acrochordon-like lesions on the face, neck, back, chest and upper limbs. They may become more aggressive as the patient ages, with both deep local invasion and metastases being possible. Facial milia also occur, and multiple skin cysts (some with a corrugated internal surface similar to odontogenic keratinocysts) have been reported. An acral distribution of skin cysts may be suggestive of NBCCS [8].

The gene for NBCCS has been mapped to chromosome 9q22.3, with a high percentage (about 60% of pedigrees) having germ-line mutations in the *PTCH* gene [5,6,9], part of the Sonic Hedgehog (SHH) signalling pathway which is involved in transcription and cell cycle regulation.

Familial melanoma and internal malignancy syndromes

Familial melanoma, and metastases from melanoma, are discussed in more detail in Chapter 54, but links between melanoma and other internal neoplasms are detailed here [1–6].

Familial melanoma syndrome (B-K mole syndrome, familial atypical multiple-mole and melanoma, dysplastic naevus syndrome; MIM 155600)

This is a variable group of disorders, probably polygenic in inheritance, in which multiple melanomas are the main feature. Typically, there is one or more of a family history of melanoma, a personal or family background of multiple atypical ('dysplastic') melanocytic naevi, or all of these. Large multiple and irregular naevi are the norm, with an early onset of melanoma, potentially multiple primary melanomas, and in some pedigrees an increase in non-cutaneous malignancies such as pancreatic, gastrointestinal, lung, breast and laryngeal cancers, as well as ocular melanoma and cutaneous SCC of the head and neck. The *CDKN2A* germline mutation in the 9p21 gene region has been implicated in most cases [1,2]. The molecular genetics of *CDKN2A* has been extensively studied [2]; it encodes proteins that are involved in regulation of cell cycle progression (p16 and p14ARF). Those mutations that impair p16 function are linked with increased risk (22-fold) in pancreatic cancer, and specific mutations have been linked with breast cancer in some populations [2]. However, other gene mutations are also involved in familial melanoma, and external factors such as sunlight may alter the likelihood of cutaneous melanoma.

Melanoma–astrocytoma syndrome (melanoma–nervous system tumours syndrome, melanoma-NST syndrome; MIM 155755)

This syndrome comprises an association of melanomas with astrocytomas specifically, or with astrocytomas, other central nervous system tumours, meningiomas, ependymomas and peripheral nerve tumours such as malignant schwannoma [3–6]. Deletions of chromosome 9p21, which includes tumour suppressor and cell cycle regulating genes, are implicated. Several genetic loci have been implicated in different families, including all or parts of the p16, p19 and p15 gene cluster (*INK4* locus) which includes *CDKN2A* and *CDKN2B* (suggesting contiguous suppressor gene deletion) [3–5], and more recently a specific deletion of p14(ARF) [6]. In one study, a kindred with melanomas and nervous system tumours (melanoma/NST syndrome) had a large germline deletion of the *INK4* locus, whilst a more circumscribed gene disruption was associated with a melanoma–astrocytoma family [5].

Xeroderma pigmentosum (XP; MIM 194400, 133510, 278700–278800) [1–4]

This group of disorders with autosomal recessive inheritance are discussed in more detail in Chapter 15. XP characteristically presents at an early age with severe photosensitivity, marked reduction in threshold for sunburn and myriads of lentigines, principally in a sun-exposed distribution. Early onset of photoageing is found in infants, followed by sun-induced dysplasias, BCC, SCC and malignant melanomas, commencing in the first decade of life, which occur with a 2000-fold increased risk; SCC of the tip of the tongue has a 10 000-fold increased risk compared with individuals of the same age [3]. Ocular neoplasms, both melanoma and non-melanoma, occur in 10–20%. However, it is not only neoplasms linked with solar exposure that are increased in frequency; there is also a 10- to 20-fold increased incidence of internal malignancy, including central nervous system (CNS) sarcomas, leukaemia, and carcinomas of lung, breast, pancreas, stomach and testes [4]. The mutations causing XP cause abnormal fibroblast sensitivity to ultraviolet radiation, in most cases (complementation groups A–G) resulting from a defective DNA nucleotide excision repair process; the eighth form, termed XP variant, codes for a post-replication repair polymerase. Inactivation of tumour suppressors and activation of oncogenes due to these mutations results in development of multiple tumours [2].

Von Hippel–Lindau disease (VHL; MIM *193300)

A rare, autosomal dominantly inherited condition, characterized by benign and malignant tumours of various systems, particularly haemangioblastomas of the CNS, angiomatosis of the retinae, phaeochromocytoma [1] (which may be bilateral), renal carcinoma [2], pancreatic adenoma, carcinoma and cysts [3], and epididymal cystadenomas. Endolymphatic sac tumours are rarely found other than in von Hippel–Lindau disease [4]. The non-specific cutaneous manifestations include haemangiomas and café-au-lait spots [5]. The VHL gene has been located on chromosome 3p26-p25; although different mutations have been found to be causative, the gene is a tumour-suppressor gene following the Knudson two-hit model. Families may be characterized by the presence (type 2, missense mutations) or absence (type 1, deletions/protein-truncating mutations) of phaeochromocytoma; in those with a predominance of familial phaeochromocytoma, analysis of VHL mutations may be useful to identify asymptomatic subjects at risk of von Hippel–Lindau disease. Type 2b has, in addition to an association with phaeochromocytoma, a high incidence of renal cell carcinoma and haemangioblastomas, whereas in type 2a there is a lower incidence of renal cell carcinoma and in type 2c an exclusive association with phaeochromocytoma [6]. However, genetic investigation of patients with apparently sporadic phaeochromocytoma rarely identifies subjects with mutations in *VHL* or in the *RET* proto-oncogene (mutations in which cause multiple endocrine neoplasia type 2, another cause of familial phaeochromocytoma) and is not routinely indicated [7].

Neurofibromatosis types 1 and 2 (NF1, von Recklinghausen's disease, MIM *162200; NF2, MIM *101000) (Chapter 15) [1–5]

There are two main forms of neurofibromatosis, type 1 (NF1) and type 2 (NF2). Both have an autosomal dominant inheritance but in a large proportion of affected individuals the condition is due to a *de novo* mutation (which may be mosaic). The abnormal neural crest cell function in NF1 leads to development of multiple peripheral neurofibromas, as well as CNS tumours (notably optic glioma, which is one of the diagnostic criteria for NF1 [4]) and café-au-lait macules [1–5]. Patients with a deletion of the whole gene have earlier development of neurofibromas and an apparent higher frequency of malignant peripheral nerve sheath tumours [5].

NF1 is the commonest form of neurofibromatosis, with a prevalence of approximately 1/3000, about tenfold that of NF2. There are several different clinical presentations, depending on the localization of the lesions. Clinical overlap between NF1 and NF2 occurs particularly in children, who may have café-au-lait macules and peripheral nerve tumours; flexural freckling is indicative of NF1. Café-au-lait macules occur in NF2, but only in half of affected subjects and usually fewer than six in number (six or more being one of the diagnostic criteria for NF1).

Lisch nodules (pigmented iris hamartomas) are found with slit-lamp analysis in 90% of adult patients with NF1 and are fairly specific for NF1; two or more such lesions are one of the diagnostic criteria. Around 80% of patients with NF2 have posterior subcapsular cataracts, including about a third of affected children.

The associations with benign tumours, malignancy and systemic manifestations are varied but patients with NF1 have an overall 2.5-fold increase in risk of developing a malignancy [4]. In general, NF2 patients have fewer skin lesions than in those with NF1, and the lesions that occur are mainly schwannomas, but more severe disease in NF2 is linked with greater prevalence of skin tumours [3,4].

NF2 patients develop vestibular and peripheral nerve schwannomas (the vestibular schwannomas characteristically being bilateral), together with CNS tumours such as meningiomas. Spinal schwannomas (mainly), astrocytomas or ependymomas eventually occur in about three-quarters of patients with NF2. If meningiomas occur in children, NF2 should be suspected. Perhaps the commonest neoplasm developing in patients with neurofibromatosis is a malignant neurofibrosarcoma [6]. Most superficial neurofibromas have a low malignant potential, change occurring more often in the deep plexiform neurofibromas and those more in continuity with nerves, designated schwannomas. Benign tumours such as acoustic neuromas, dumb-bell tumours and optic gliomas can result in disastrous sequelae when occurring in confined, pressure-sensitive sites. The commonest CNS malignancy is an astrocytoma. Other malignancies include nephroblastoma (Wilms' tumour), fibrosarcoma, rhabdomyosarcoma and leukaemia, especially in children [3–8]; there is an association between NF1, juvenile myelomonocytic leukaemia and juvenile xanthogranulomas [9]. Monosomy 7 myelodysplastic syndrome may also occur [10]. There is an increased frequency of phaeochromocytomas and carcinoid tumours [4], and ocular melanoma has been reported [11].

The *NF1* gene, located on chromosome 17q11.2, has a role as a tumour-suppressor gene; its protein product, neurofibromin, regulates cell growth, including an effect of accelerating inactivation of the p21 *ras* proto-oncogene [4,12]. Transformation of benign neurofibromas to malignant peripheral nerve sheath tumours involves the loss of other tumour-suppressor genes such as p53 and p16.

The *NF2* gene locus is on chromosome 22q12.2; the product of this gene, termed merlin, has an uncertain effect on tumour suppression [3,4].

Tuberous sclerosis complex (TSC; Bourneville's disease; TSC1, MIM #191100 and TSC2, MIM *191092) (Chapter 15) [1–5]

An autosomal dominant condition of angiokeratomas, epilepsy and mental retardation; a high spontaneous mutation rate accounts for over half of cases. It may be associated with multisystem tumour involvement, mostly hamartomatous. There are two known causative genes—*TSC1* on chromosome 9q34, encoding hamartin, and *TSC2* on chromosome 16p13.3, encoding tuberin; both genes function as tumour suppressor genes. There are large numbers of different mutations, *TSC2* mutations being more common, and causing more severe disease, than *TSC1* mutations.

Other than skin lesions (Chapter 15), the CNS, renal and cardiopulmonary systems are most significantly affected [1–3]. Angiomyolipomas (of vessels, fat and smooth muscle) all show the same loss of heterozygosity at the *TSC1* or *TSC2* loci, with hyperphosphorylation of ribosomal protein S6; the smooth muscle component of these lesions is identical to that of the smooth muscle in lymphangiomyomatosis, which is also a feature of tuberous sclerosis [5]. Malignant sarcomatous change can occur, particularly with angiomyolipomas and rhabdomyomas, but is uncommon,

and metastases are unusual [4]. Renal cell carcinoma is a recognized, infrequent complication [3,6].

Multiple endocrine neoplasia syndrome (multiple endocrine adenomatosis, MEA)

This section actually includes three conditions, MEN1, MEN2A and MEN2B (previously termed MEN3).

Multiple endocrine neoplasia type 1 (MEN1; Wermer syndrome; MIM *131100). This is an autosomal dominant familial cancer syndrome, with parathyroid, pancreatic islet cell and pituitary gland tumours, as well as cutaneous findings. It is caused by mutations in the *MEN1* gene, located on chromosome 11q12-13, which codes for the production of a protein named menin. The cutaneous findings in MEN1 are mostly multiple facial angiofibromas and collagenomas. Café-au-lait macules and lipomas are also encountered [1,2].

MEN1 is, at least in part, a tumour-suppressor gene. MEN1 is characterized by tumours of the parathyroid, anterior pituitary, pancreatic islet cells, neuroendocrine origin, foregut carcinoid and adrenal cortex. It is associated with 20–25% of cases of Zollinger–Ellison syndrome (ZES). In MEN1, 60–100% of cases have gastroenteropancreatic (GEP) lesions, especially pancreatic islet endocrine tumours (pancreatic polypeptidomas or non-functional 80–100%, ZES 54%, insulinoma 21%, glucagonoma 3% and vasoactive intestinal peptide (VIP)oma 1%). Glucagonoma may be difficult to diagnose as even subjects with MEN1 without a pancreatic endocrine tumour may have glucagon levels above the normal basal level. Associated endocrine disease consists of parathyroid hyperplasia >95%, anterior pituitary adenomas around 60% (range 14–100%), adrenal adenomas about 30%, lung carcinoids 7% and gastric carcinoids 13–30%. The pituitary adenomas are prolactinomas in 14–76% and cause acromegaly in 11–33% and Cushing's syndrome in 5–19%. The commonest tumours in MEN1 secrete PTH or gastrin; hyperparathyroidism is present in 95–100% of affected individuals. However, screening patients with sporadic pituitary adenomas for other features of MEN1 yields few cases of MEN1, the greatest number being in patients with prolactinoma. Screening patients with hyperparathyroidism yields 1–16% with MEN1, whilst screening those with GEP tumours identifies 10–50% as having other features of MEN1.

Metastases from malignant neuroendocrine tumours (carcinoid) may be one of the commonest causes of mortality in MEN1; most of these, unlike non-MEN1 cases, arise from the embryological foregut (bronchi, thyroid, stomach, duodenum and pancreas) [3–5].

Multiple endocrine neoplasia type 2A (MEN2A, Sipple syndrome; MIM #171400—mucosal neuromas, medullary thyroid carcinoma and phaeochromocytoma) [5–7]. This shares some features with MEN2B. Both principally involve the thyroid and parathyroid glands, and the adrenal medulla, and are linked with familial medullary thyroid carcinoma (FMTC) [8,9]. They are caused by mutations of the *RET* proto-oncogene locus (10q11.2) [10–12]. Both are autosomal dominant, but 50% of cases with MEN2B are due to spontaneous mutations. In the same vicinity, near the centromere of chromosome 10, are the genes for Hirschprung disease (which may occur in both MEN2A and 2B) and for FMTC. Thickened corneal nerves occur in both MEN2 syndromes.

Type 2A is linked to a mutation of the *RET* oncogene, located on chromosome 10, compared to a sporadic *RET* oncogene in 2B; *RET* testing has replaced calcitonin screening to diagnose *MEN2* carrier status. The specific *RET* codon mutation will delineate the course of the disease and degree of aggression; details of the genetic aspects underlying MEN2 are provided in [3,4,6,11,12].

MEN2A lacks the mucosal neuromas and skin lipomas of MEN1 and MEN2B, and café-au-lait macules are only present in those with a combined phenotype of MEN2A with neurofibromatosis type 1. By contrast, symmetrical, bilateral pruritic skin lesions are found overlying the scapular area, with hyperpigmentation and hyperkeratosis clinically suggestive of macular amyloidosis; deposits of keratin-derived amyloid are typically found histologically [3,5,7]. Lesions suggestive of notalgia paraesthetica have been reported prior to recognition of the syndrome. Reflecting the genetic background, lichen amyloidosis also occurs in FMTC.

The main internal disorders in MEN2A, described as the triad of cardinal manifestations, are medullary thyroid carcinoma (MTC), phaeochromocytoma and hyperparathyroidism (due to either hyperplasia or adenomas). Other hamartomas and tumours include cerebellar haemangioblastomas, cervical neuroblastoma, pituitary adenomas and pinealomas [7]; Cushing's syndrome also occurs.

Multiple endocrine neoplasia type 2B (MEN type 2B or 3, MIM #162300). This is characterized by mucosal neuromas that are apparent at birth or in the first years of life. Neuromas manifest as asymptomatic, soft, flesh-coloured papules or nodules. They cause a characteristic facial appearance with soft, lumpy ('blubbery'), protuberant lips; everted, thickened, bumpy eyelids; and prominent eyebrows. Neuromas typically affect mucosal surfaces, especially the anterior border of the tongue and the buccal mucosa inside the commissures of the lips; gingival, palatal and pharyngeal surfaces may occasionally be affected. Medullated corneal nerve fibres are seen on slit lamp examination, and there may be conjunctival and, rarely, corneal neuromas. Perioral lentiginosis, pigmentation of hands and feet, and café-au-lait macules may occur and, rarely, a progressive striated pigmentary change of hyperplastic dermal nerves on the trunk [13]. Prognathism or retrognathism can be evident, and there may be a high-arched palate. About 75% of patients have a marfanoid appearance; muscle

weakness and musculoskeletal anomalies (especially kyphoscoliosis, pes cavus and (often bilateral) slipped upper femoral epiphysis) may also be present [10].

MEN2B is also associated with MTC (in 75%) and phaeochromocytoma (in almost 50%), the MTC in type 2B presenting earlier and more aggressively than in type 2A. The MTC is often multicentric and bilateral, occurring in a background of calcitonin-producing cell hyperplasia; it may be found in children as young as 3 years. Diarrhoea is a common symptom. Early lymphatic spread may occur, 75% having metastases at presentation [10]. Prophylactic thyroidectomy may be indicated. Phaeochromocytomas are often bilateral, but the mortality is greater from MTC than from phaeochromocytoma. Hyperparathyroidism due to parathyroid hyperplasia or adenomatosis is much less common than in MEN types 1 and 2A. Intestinal ganglioneuromatosis is more common in type 2B than 2A, occurring in 30% and often presenting early in life due to constipation or abdominal pain.

Carney complex (CNC; Carney syndrome; NAME syndrome; LAMB syndrome; myxoma syndrome. Type I MIM #160980, type II MIM *605244) [1–5] (see also p. 62.78)

This is a group of disorders in which there are cutaneous pigmented lesions associated with cutaneous, subcutaneous and internal myxomas at various sites, and associated endocrinopathy (mainly tumours) which typically includes involvement of one or more of the adrenal cortex, thyroid, pituitary, and gonads. NAME syndrome consists of *n*aevi (congenital melanocytic), *a*trial myxomas, *m*yxoid neurofibromas and *e*phelides. LAMB syndrome consists of *l*entigines, *a*trial myxomas, *m*ucocutaneous myxomas and *b*lue naevi. The association with myxomas has led to many other names; some prefer to use '*myxoma syndrome*', or the combined term *Carney complex/myxoma syndrome* [5]. Cardiac myxomas occur in 61% [1] and are the most important internal myxomas, due to the causation of cardiac symptoms and potentially life-threatening effects (see also the section on cardiac disease later in this chapter). Likewise with endocrine involvement, adrenal-linked Cushing's syndrome can have critical, life-threatening effects; the adrenal tumours in Carney complex are typically of primary pigmented nodular type, an otherwise rare condition. Various other gonadal and endocrine hormone-secreting tumours, including pituitary tumours producing GH, prolactin or ACTH, occur; ovarian tumours are associated, and both benign and malignant thyroid tumours (usually of follicular type) also occur [2,3]. Testicular tumours, often large-cell calcifying Sertoli cell tumours, occur in about 30% of males, and are often bilateral and multicentric. Psammomatous melanotic schwannoma, usually of the upper gastrointestinal tract or of paravertebral sympathetic nerves, is very suggestive of this syndrome. Myxoid fibroadenomas of the breast, and mammary ductal adenomas, may be found [5], and myxoid leiomyomas and uterine tumours are described. Lentiginosis and blue naevi occur in two-thirds, typically on the face, lips and conjunctivae [5], and skin myxomas occur in over a third of cases [1].

Over half of patients with Carney complex have mutations in genes coding for a regulatory subunit type 1A of protein kinase A. CNC is clinically and probably genetically heterogeneous. At least two gene locations have been proposed, one on chromosome 2p16 (type 2) and another on 17q23-24 (type 1) [3,4].

PTEN hamartoma tumour syndrome (Cowden's disease, multiple hamartoma and neoplasia syndrome; MIM #158350) [1–6]

This rare, cancer-associated genodermatosis was first described by Lloyd and Dennis and named after their patient Rachel Cowden [1]. Inheritance is as an autosomal dominant trait with incomplete penetrance. It is due to germline mutations in the *PTEN* (protein tyrosine phosphatase with homology to tensin; *MMAC1*) gene on chromosome 10q23.3. *PTEN* is a tumour suppressor gene; mutations may produce their effects in Cowden's disease and allied hamartomatous disorders due to a failure to regulate cell death [2–4]. The spectrum of the disorder has increased with understanding of the genetic aspects [5], and has not only led to development of diagnostic criteria by the International Cowden Disease Consortium [3,5,6] but also to inclusion within the PTEN hamartoma neoplasia syndrome of several other hamartomatous

disorders including Bannayan–Riley–Ruvalcaba syndrome (Bannayan–Zonana syndrome; MIM 153480) and Lhermitte–Duclos disease [5], in which hamartomatous outgrowths of the cerebellum occur. Bannayan–Riley–Ruvalcaba syndrome, as originally described, has many features in common with Cowden's disease, but lacks the extent of the malignant lesions of the latter; it is characterized by microcephaly, vascular anomalies, lipomas, thyroid disease, gastrointestinal polyposis and speckled genital pigmentation; it is discussed further with other gastrointestinal polyposis syndromes (p. 62.56). A family history of features of Bannayan–Riley–Ruvalcaba syndrome is typical in patients with Cowden's disease, the latter having a stronger association with internal malignancy. Also of dermatological importance is an overlap with Proteus syndrome (MIM 176920); up to 20% of patients with Proteus syndrome have *PTEN* mutations, and 50% of patients with Proteus-like syndrome (in which some features of Proteus syndrome are present, but not sufficient to meet formal diagnostic criteria) [5].

Pathognomonic criteria for Cowden's disease are mucocutaneous lesions, facial trichilemmomas (at least three), acral keratosis (at least six palmar lesions), papillomatous lesions and mucosal lesions. These are found in over 90% of patients. The mucosal lesions (Fig. 62.12) comprise a warty, 'cobblestone' hyperplasia of the mucosal surfaces, particularly affecting the tongue and buccal mucosa; periorificial facial papules, acral warty keratoses and palmoplantar semitranslucent, punctate keratosis are characteristic. The lesions, which are grouped especially around the mouth, nose and ears, have a hyperkeratotic, flat-topped, wart-like appearance, as do many lesions elsewhere; these are mostly trichilemmomas or related benign tumours of the follicular infundibulum [3–7]. Multiple hamartomatous lesions of ectodermal, endodermal and mesodermal origin occur. The other cutaneous lesions include ganglioneuromas, lipomas, fibromas, angiomas, angiolipomas, epidermoid cysts and a variety of pigmentary changes. Craniomegaly is common; there may be an adenoid facies, kyphoscoliosis and a high-arched palate.

Benign internal anomalies are numerous, most commonly affecting the breast (severe fibrocystic disease occurs in the majority of women) and the thyroid (mainly multinodular goitres and adenomas). Gastrointestinal polyposis and cysts or polyps of the female genitourinary system are also frequent. Seizures and mental retardation occur (the latter is a minor diagnostic criterion) and there may be an association with meningioma.

The predisposition to neoplasia includes almost any internal malignancy, but particularly cancers of the breast [8], colon and thyroid (especially follicular thyroid carcinoma). Adenocarcinoma of the breast occurs in about 50% of women. Fibrocystic breast disease and cancers may have an early onset, and screening of at-risk family members is therefore recommended. Even prophylactic mastectomy has been suggested [8]. Benign gynaecomastia has been reported in the male, but malignancy of the breast or thyroid is exceptional. Breast, endometrial and thyroid cancers all contribute to a higher mortality in females. Renal carcinomas have more recently been linked with this syndrome, and an increased likelihood of melanoma has been suggested.

Sebaceous tumours, keratoacanthomas and visceral malignancy (Muir–Torre syndrome, MTS, Torre syndrome; MIM 158320) [1–6]

This is a cancer-associated genodermatosis in which there is an association between sebaceous lesions and, to a lesser extent, keratoacanthomas and internal malignancy. Inheritance is autosomal dominant with variable expression, males being affected more commonly than females. MTS has been considered to be a variant of the 'cancer family syndrome' [3]; it is currently viewed as a phenotypic variant of the hereditary non-polyposis colon cancer syndrome (HNPCC; Lynch syndrome). Both syndromes are due to mutations at the same region of chromosome 2p22-p21 in the genes *MLH1* and *MSH2*, which are DNA mismatch repair enzymes. Defects result in microsatellite instability, a finding in HNPCC which has also been documented in many MTS-associated keratoacanthomas and sebaceous tumours [6]. About 1% of patients with HNPCC have features of MTS, although this may be an underestimate as the cutaneous features may occur after the development of internal malignancy, or may go unrecognized.

Sebaceous tumours are usually multiple, but occasionally solitary. Although sebaceous adenoma is the commonest, sebaceous carcinoma and epithelioma frequently occur, and within the same patient a variety of different pilosebaceous-derived skin lesions

including keratoacanthomas may arise. Most skin tumours occur in middle age, keratoacanthomas occurring in a quarter of affected subjects. Multiple or early onset of keratoacanthomas are suggestive of this diagnosis, as are multiple (especially eyelid) sebaceous tumours. Multiple or solitary keratoacanthomas associated with SCC of the larynx and lower gastrointestinal tract [7,8] probably represent a variant of MTS in which expression of sebaceous tumours and adenocarcinomas is not exhibited. The cutaneous manifestations of MTS have been reported to be exacerbated by immunosuppression.

The most important internal malignancy is colonic adenocarcinoma, which occurs in almost 50%, often at a relatively young age—around 10 years earlier than in the normal population—and most commonly in the region of the splenic flexure; rectal adenocarcinomas also occur but only in about 5% [4,5]. Urogenital malignancies are also common, occurring in 25% [4]; bladder, renal pelvis and endometrial cancers each account for about 5% of cancers in MTS. The proband in the first family described with HNPCC died of endometrial carcinoma, and gynaecological cancers of various types occur both in HNPCC patients [9] and in those with MTS [4]. Nearly half of affected patients have two or more internal malignancies [10]; other notable malignancies are breast cancers and haematological malignancies (each in about 5% of subjects) [4]. Despite the high risk of malignancy, both the malignant cutaneous sebaceous tumours and the colonic tumours tend to have relatively indolent behaviour (the 50% survival time for colonic cancers is about 12 years [2]) and the incidence of metastases is relatively low. Criteria for diagnosis (Amsterdam and Bethesda criteria), and recommendations for screening of patients and relatives, have been reviewed [11].

Bloom's, Rothmund–Thomson's and Werner's syndromes

These conditions are considered together as they are all caused by RecQ helicase gene mutations, and they all predispose to abnormal growth, premature ageing and increased incidence of site-specific malignancies [1].

Reference

1 Lindor NM, Furuichi Y, Kitao S *et al.* Rothmund–Thomson syndrome due to RECQ4 helicase mutations: report and clinical and molecular comparisons with Bloom syndrome and Werner syndrome. *Am J Med Genet* 2000; **90**: 223–8.

Bloom's syndrome (MIM *210900) (Chapter 15) [1–4]. This is an autosomal recessive disorder that affects principally the Ashkenazi Jewish ethnic group, nearly 1% of whom are carriers. Affected subjects have small stature and slight build, a sun-sensitive telangiectatic facial rash and café-au-lait macules. Minor congenital anatomical abnormalities commonly occur. Levels of IgA and IgM are low and bacterial infections frequent. Mutations of the gene designated *BLM* on chromosome 15q26.1 lead to inhibition of the function of the protein product, a DNA helicase enzyme. This loss of function allows genomic instability with the occurrence of significantly increased exchanges between DNA strands during the S phase of mitosis, including a tenfold increase in sister chromatid exchanges, such that mutations occur throughout the genome.

The occurrence of lymphoproliferative neoplasia (approximately equally divided between leukaemias and lymphomas) and epithelial tissue cancers, particularly of the aerodigestive tract and lower gastrointestinal tumours, is very high; they typically occur at an early age, and the mean age of death is 23 years [3]. Cervical cancer and Wilms' tumour are additional risks. There is a predisposition to malignancy through mutations in other target genes [4].

Rothmund–Thomson syndrome (RTS; poikiloderma congenitale; MIM #268400) (Chapter 15) [1–3]. This is a rare autosomal recessive genetic disease, characterized by developmental abnormalities in the skin and skeletal systems, with photosensitivity, poikiloderma, small stature and juvenile cataracts. Premature ageing and a predisposition to certain malignancies occur, notably an approximate 30% incidence of osteosarcoma. Fibrosarcoma, myelodysplasia and non-melanoma skin cancer also occur. A mutation of genes for RecQ helicase is thought to be responsible for at least some, if not all, cases of RTS.

Werner's syndrome (adult progeria; MIM #277700) [1–4]. This is an autosomal-recessive condition of premature ageing, with onset in the second to third decade of life. It is due to mutation of the *WRN* gene on chromosome 8p12-p11.2. The normal gene product

is a DNA helicase belonging to the RecQ family which unwinds double-stranded DNA and is able to resolve aberrant DNA structures, so that aberrations occurring during repair, recombination and replication are made good, together with those that result from direct DNA damage [1–4]. Neoplasms develop in about 10% of cases, although the commonest cause of death is arteriosclerosis. Sarcomas, melanomas, leukaemia and a variety of epithelial-derived carcinomas have been reported [1–6]. Meningiomas are a recognized association, and an astrocytoma has been documented [7]. Werner's syndrome is a chromosome-instability syndrome and, as with XP, ataxia–telangiectasia, Bloom's syndrome and Fanconi's anaemia, is associated with a high incidence of neoplasia [2,3].

Immunodeficiency and neoplasia syndromes: Wiskott–Aldrich syndrome, Chediak–Higashi syndrome, ataxia–telangiectasia, dyskeratosis congenita, Fanconi's anaemia

Wiskott–Aldrich syndrome (MIM #301000) (Chapter 15) [1]. This is an X-linked recessive immunodeficiency syndrome due to mutations at Xp11.23-p11.22; the Wiskott–Aldrich syndrome protein (WASP) is expressed in all haemopoietic cells, and mutations cause defective T-cell function and thrombocytopenia. Infections are the commonest cause of death but lymphoreticular malignancy occurs in 18% and is the cause of death in about 10% [1,2]. Non-Hodgkin's lymphoma occurs in almost all subjects who survive infections or bleeding due to thrombocytopenia, usually by the age of 30 years. Lymphoma (especially large cell or immunoblastic) and leukaemia occur; the small intestine is a particular site for lymphomatous involvement. Cerebral tumours such as astrocytoma, and various sarcomas, have also been reported [1–4].

Chediak–Higashi syndrome (MIM #214500) (Chapter 15) [1,2]. This is a fatal autosomal recessive illness, with features of partial albinism, photophobia, neurological abnormalities and severe, recurrent bacterial infections. About 85% of patients develop a terminal, accelerated 'lymphomatous' phase, which may be triggered by viral infections, especially due to Epstein–Barr virus [2]. There is extensive organ infiltration with lymphoid and histiocytic cells; patients develop fever, jaundice, hepatosplenomegaly, lymphadenopathy, leukaemia-like gingival lesions and sloughing of the oral mucosa, pancytopenia and a deterioration of neurological changes. Death may result from bleeding due to thrombocytopenia and reduced synthesis of clotting factors, or from infection due to neutropenia. Although strongly suggestive of lymphoma, the infiltrate of affected organs is reported to be of a reactive, diffuse, mononuclear cell type, rather than neoplastic [1].

Ataxia–telangiectasia syndrome (AT; Louis–Bar syndrome; MIM *208900) (Chapter 15) [3–9]. This is a condition with autosomal recessive inheritance, characterized by progressive cerebellar ataxia and oculocutaneous telangiectasia. Like XP, the condition has different complementation groups defined by fibroblast fusion and irradiation studies. Most families have one of many different germ-line mutations in the large *ATM* gene at chromosome 11q22.3; the product, ATM protein (phosphatidylinositol-3-kinase p53 checkpoint regulation), is involved in the handling of chromosome strand breaks and activation of the p53 oncogene [6], and has been considered to be a 'caretaker' of the genome and tumour suppressor. Mutations are mainly inactivating in type but may be missense [9]; they allow unregulated DNA synthesis, with DNA that is predisposed to instability and hypersensitive to ionizing radiation [6]. Peripheral blood lymphocytes are abnormal, having translocations mainly involving chromosomes 7 and 14, and abnormal function, and there is a variable but progressive immune deficiency of both the cell-mediated and humoral types, which results in frequent infections and a reduction in immune surveillance [3]. As a result, there is a high incidence of neoplasia, approximately 30% lifetime risk, usually in or before the teenage years, and being the cause of death in 15% of affected individuals [3–8].

The majority (around 80%) of tumours are lymphoproliferative or leukaemic, although carcinomas of various sites also occur, the latter usually in older subjects [5,7,8]. Most haematological malignancies are B-cell lymphomas but 25% are leukaemias, notably chronic T-cell leukaemia with chromosome 14 translocations, occurring in older patients. However, T-cell leukaemias do occur in younger patients, and both T-cell lymphomas and B-cell leukaemias are also encountered. Most tumours have early onset, and may precede diagnosis of AT from the cutaneous features; this is of considerable importance as standard radiotherapy doses are contraindicated. Heterozygotes (carriers) have a five to tenfold increased risk of tumours, usually not lymphoid, including a fivefold increase in risk of breast malignancy in females [4,6]. Atm-deficient mice also develop lymphomas.

Dyskeratosis congenita (Zinsser–Cole–Engman syndrome; MIM #305000) (Chapter 15) [10]. This is a multisystem ectodermal dysplasia, in which a triad of cutaneous abnormalities are the most consistent and diagnostic feature, comprising reticulate hyperpigmentation of the skin, nail dystrophy and leukokeratosis of mucous

membranes. Dental, skeletal, ocular and gastrointestinal abnormalities are common; mental retardation, short stature and premature ageing also occur. Most cases have X-linked recessive inheritance (linked to Xq28) but autosomal recessive and autosomal dominant forms also occur [10].

Aplastic anaemia occurs in 50%, typically in early teens. Oropharyngeal carcinomas secondary to the mucous membrane lesions are the commonest form of malignancy; there is also increased incidence of internal malignancy, particularly gastrointestinal, including pancreatic adenocarcinoma and other haematological disorders, similar to those found in Fanconi's anaemia and Hodgkin's disease, which may evolve into leukaemia [11,12]. A defect in cell-mediated immunity involving suppressor T cells may be linked to the premature ageing sometimes associated with this syndrome [13].

Fanconi's anaemia (MIM #227650 and others). This is an autosomal recessive disorder characterized dermatologically by pigmentary abnormalities which may be diffuse (with accentuation around the neck and over joints), mottled, often with scattered darker macules, and sometimes just exhibiting localized café-au-lait macules. Scattered areas of hypopigmentation are a common finding. The main abnormality is progressive pancytopenia, which may lead eventually to development of leukaemia. Multiple skeletal abnormalities occur, including digital hypoplasias, scoliosis and short stature. The underlying defect is one of increased DNA cross-linkage (especially radiation-induced) and defective DNA repair.

Follicular atrophoderma (Bazex–Dupré–Christol syndrome; MIM *301845)** [1]

A rare, X-linked, dominant condition of follicular atrophoderma, milia, epidermoid cysts, hypotrichosis, basal cell epitheliomas and occasional generalized or localized hypohidrosis, which appears to have an association with leukaemia. Pigmented, perioral, follicular atrophoderma is characteristic [2].

Hereditary leiomyomatosis and renal cell carcinoma (HLRCC) syndrome (MIM #605839)

A syndrome comprising multiple cutaneous leiomyomas with uterine leiomyomas (Reed syndrome, MIM #150800); in some cases (2% in one series [1]) there is also an association with aggressive renal cell carcinoma, mainly of papillary cell type. Numerous different fumarate hydratase (FH) mutations on chromosome 1q 42.1 have been identified; patients who have renal cell carcinomas are usually female and have truncating or frameshift mutations [1]. One study of 40 such renal carcinomas found that the presence of a large nucleus, with a prominent orangiophilic or eosinophilic nucleolus surrounded by a clear halo, appeared to be characteristic and was seen even in the renal carcinomas that were not papillary or tubulopapillary in type [2]. Most women with HLRCC develop uterine leiomyomas ('fibroids'). Benign ovarian mucinous cystadenomas, renal cysts and adrenal gland adenomas, as well as uterine leiomyosarcomas, have also been linked with FH mutations; there is also some evidence for an association with breast and bladder cancers [3] and a suggested association with Leydig cell carcinoma of testis.

Paraneoplastic disorders [1–14]

Paraneoplastic dermatoses are skin conditions that have an association with internal malignancy but are not themselves malignant. They may be classified in a variety of ways; some authors include genodermatoses within the spectrum of paraneoplastic disorders [1] whilst others view these as a separate group [2,3], or distinguish between paraneoplastic dermatoses [4], hereditary paraneoplastic syndromes [5] and hormonally mediated paraneoplastic syndromes [6]. They may be classified according to strength of association with malignancy, association with certain types of malignancy [13,14], by the type of eruption that occurs (papulosquamous, vascular, etc.) or by the apparent mechanism (hormone

secretion, autoimmune, cytokine/growth factor, etc.). Paraneoplastic conditions occur in other organ systems as well, but whatever system is affected there are general principles that can be applied to determine a relationship.

Helen Ollendorff Curth proposed criteria for diagnosis of a paraneoplastic dermatosis (discussed in [7]):

1 Both conditions start at approximately the same time
2 Both conditions follow a parallel course
3 In syndromes, neither the onset nor the course of either condition is dependent on the other
4 A specific tumour occurs with a specific skin manifestation
5 The dermatosis is not common in the general population
6 A high percentage of association between the two conditions is noted

These criteria were quite specific and some conditions that would now be viewed as potentially paraneoplastic, such as acquired ichthyosis, would fail to meet several of the above criteria.

A less rigid definition that has been in common use is as follows [1]:

1 The malignancy and the cutaneous disorder may occur concurrently
2 The two disorders may follow a parallel course
3 There can be a specific tumour site or cell type associated with the cutaneous disease
4 There may be a statistical association between the two processes
5 There may be a genetic association between the two processes

Those disorders with a genetic link between the dermatological features and internal malignancy are discussed above; this section discusses other paraneoplastic dermatoses. Specific tumour sites are discussed in the following sections although this text is arranged in categories of types of presentation. In terms of the intensity of investigation required, it is also helpful to divide paraneoplastic disorders into groups depending on the likelihood of an underlying neoplasm being discovered. Thus, the likelihood of finding a neoplasm may be graded as high, intermediate or low for some of the better known paraneoplastic disorders (Table 62.9), as derived from several reviews [1–15].

Table 62.9 Strength of correlation of some potentially paraneoplastic dermatoses with internal malignancy.

Strength of correlation	Type of reaction pattern	Examples
Strong	Papulosquamous and figurate eruptions	Bazex syndrome
		Erythema gyratum repens
		Necrolytic migratory erythema
	Deposition disorders	Primary amyloidosis
		Scleromyxedema
		Necrobiotic xanthogranuloma
		POEMS syndrome
	Others	Acquired hypertrichosis lanuginosa
		Paraneoplastic pemphigus
		Tripe palms
		Carcinoid syndrome
		Trousseau's syndrome
Moderate	Papulosquamous and neutrophilic eruptions	Sweet's syndrome
		Pyoderma gangrenosum
		Dermatomyositis
	Others	Multicentric reticulohistiocytosis
		Pityriasis rotunda
Weak	Epidermal conditions	Acanthosis nigricans in isolation
		Acquired ichthyosis (unless widespread, deeply fissured, truncal pattern)
		Eruptive seborrhoeic keratoses (sign of Leser–Trélat)
	Deposition disorders	Scleredema
		Calcinosis cutis
	Others	Vasculitis, Raynaud's phenomenon, digital ischaemia
		Erythromelalgia
		Relapsing polychondritis
		Erythroderma/exfoliative dermatitis
		Digital clubbing (unless with hypertrophic osteoarthropathy)
		Pruritus
		Erythema annulare centrifugum
		Cushing's syndrome

Acanthotic, epidermal and ichthyotic conditions

Acanthosis nigricans [1–5]

Acanthosis nigricans may be simply divided into two important categories, benign (see also Chapter 19) and malignant, although Schwartz [1] described eight types of acanthosis nigricans: benign, obesity-associated, syndromic, malignant, acral, unilateral, medication-induced (especially nicotinic acid) and mixed types. Benign acanthosis nigricans is actually fairly common, especially in obesity or in individuals with insulin resistance, and is usually relatively mild; it has been documented in up to 7% of children, mainly in teenage years, and virtually all childhood cases are of benign type.

Malignancy-associated acanthosis nigricans is much less common than the non-malignancy-associated types. It may have a rapid onset and progression to produce symmetrical, hyperpigmented, rugose velvety plaques [1–5]. The axillae and other flexures are particularly affected, along with the areolar area, and the nape of the neck. There may be prominent acrochordon-like papillomatosis arising from the plaques; the sign of Leser–Trélat, and acanthosis palmaris (tripe palms) may coexist [5]. *De novo* development of acanthosis nigricans in adults, especially if progressive and associated with weight loss (most patients with insulin resistance having a rather stocky build), is strongly suspicious that there is an underlying neoplasm, although cases have been described in which acanthosis nigricans has preceded a malignancy by 10 years or more [2]. If there is also generalized pruritus or the skin changes of tripe palms (see below), then a malignancy is even more likely; mucosal involvement is a useful pointer to the diagnosis of paraneoplastic acanthosis nigricans as it occurs in over half of cases [6]. Production by tumour cells of either transforming growth factor-alpha, or cytokines that activate insulin-like growth factors or their cutaneous receptors, have been suggested as the pathogenetic mechanism.

By far the commonest site of underlying neoplasm is the gastrointestinal tract (70–90%); gastric adenocarcinoma is most frequent [1–5]. A number of different malignancies have been reported, nearly all being adenocarcinomas, at sites including other parts of the intestine, liver or bile duct; other tumour sites include lung, breast, endometrium, kidney, bladder, prostate, testis, cervix, thyroid and adrenal. Most are solid organ tumours but lymphoma has been recorded [7]. Sarcomas occur rarely. The prognosis with malignant acanthosis nigricans is generally poor, which at least in part is related to the low survival rate from the neoplasia concerned. However, the changes may resolve with eradication of the cancer [8]. Malignancy-associated acanthosis nigricans has rarely been associated with other paraneoplastic conditions including pachydermoperiostosis, paraneoplastic pemphigus and acquired hypertrichosis lanuginosa.

An additional, indirect link between acanthosis nigricans and internal malignancy is that it may be associated with ataxia–telangiectasia (p. 62.28).

Acanthosis palmaris (Tripe palms, pachydermatoglyphy) [1–4]

Tripe palms describes thickened skin of the palms and occasionally the soles, with an enhanced dermatoglyphic change, causing a velvety or, less commonly, a pitted honeycombed pattern of the hand. It is associated with neoplasia in about 90% of cases; it may be the only paraneoplastic manifestation in 30–40% or it may occur with one or both of malignant acanthosis nigricans or the sign of Leser–Trélat [1–3]. It occurs particularly in men, especially when it occurs in isolation or when the underlying tumour is a lung cancer [2]. However, it can occur in isolation without neoplasia, or as a pattern of exfoliative psoriasis or eczema [1,2], and has been reported with bullous pemphigoid.

As the condition is usually associated with an internal neoplasm, usually of solid organ type (but rarely lymphoma), it requires appropriate evaluation and investigation. Most commonly the underlying tumour is bronchial or gastric, together accounting for over half of associated malignancy, but many sites are reported including tumours of genitourinary tract, breast and others [2]. One study found that acanthosis palmaris occurring alone was more often associated with bronchial carcinoma (53%) compared with combined acanthosis nigricans and acanthosis

palmaris, in which 35% had gastric carcinoma and only 11% had bronchial neoplasia [4]. If nail clubbing is also present (18% of patients [2]), then bronchial carcinoma is very likely. Thus, tripe palms alone, especially if the patient is male and also has clubbing, very strongly suggests an underlying lung cancer, whilst tripe palms with acanthosis nigricans is more suggestive of an underlying gastric carcinoma. Resolution of the palmar changes has been described with resection of the tumour [4].

The sign of Leser–Trélat [1–4]

This is the sudden development of numerous seborrhoeic keratoses, in an eruptive fashion, with or without pruritus, as an indicator of internal malignancy. However, the significance of eruptive seborrhoeic keratoses remains unclear, with strong proponents and opponents of its importance [2,3]. Multiple seborrhoeic keratoses are extremely common, especially in elderly people, and may be pruritic or rapidly erupting, without any apparent cause; they may also occur in other situations [4] such as HIV infection, acromegaly, and in the resolving phase of erythrodermic dermatoses [5].

Of the cases reported with a neoplasm, half of the tumours are adenocarcinomas, most of which (one-third of the associated tumours) arise in the gastrointestinal tract; this is similar to the distribution of tumours in acanthosis nigricans, which may coexist. Carcinomas of the breast are also frequent, although this may just reflect the incidence of these tumours in an age group who are also likely to have seborrhoeic keratoses. Rare associations have been documented with a variety of other neoplasms, including malignant haemangiopericytoma [6], malignant melanoma [7], renal carcinoma [4] and transitional cell carcinoma of the bladder [8]. Lymphoproliferative disorders, which are rarely associated with acanthosis nigricans, have been more commonly reported with the sign of Leser–Trélat, accounting for about 20% of associated tumours [4].

Truly sudden development of multiple seborrhoeic keratosis, especially in younger patients, and especially if associated with pruritus or with acanthosis nigricans, does warrant investigation, but the mere presence of many seborrhoeic keratoses is unlikely to be linked with malignancy and the strength of this sign as a marker of internal malignancy must be viewed as uncertain.

Acquired ichthyosis [1–5] *and pityriasis rotunda*

Acquired ichthyosis usually has gradual onset, consists of a mild dryness or asteatosis pattern, and is not associated with underlying malignancy. Other systemic diseases associated with acquired ichthyosis include nutritional deficiencies, sarcoidosis, leprosy, HIV infection, hypothyroidism, lupus erythematosus, graft-versus-host disease and drug reactions [2]. Some of these cause particular problems in differential diagnosis as well, especially sarcoidosis which may itself have an association with lymphoma (p. 62.40). Asteatosis is a common problem cause, especially in elderly people, and does not warrant an extensive search for malignancy unless there are other suggestive features such as weight loss or focal symptoms.

However, more sudden onset of ichthyosis similar to the pattern of ichthyosis vulgaris in adult life, or with a generalized eczema craquelé appearance, does suggest the possibility of internal malignancy, particularly if it occurs in a younger age group. The strongest association is with Hodgkin's disease (accounting for over 70% of cases) and other lymphoreticular tumours, including T-cell lymphomas, leukaemias, myelodysplastic syndrome, multiple myeloma and polycythaemia rubra vera [1–4], although cases linked with solid tumours are also well documented [4], including cancers of ovary, kidney, liver and breast [5] as well as leiomyosarcoma [2]. Paraneoplastic ichthyosis is typically very extensive, affecting the trunk and having quite prominent fissuring; a parallel course with the underlying lymphoma (including resolution related to treatment) is also usual. Other paraneoplastic signs have been reported to be present in conjunction with acquired ichthyosis, including erythema gyratum repens, Bazex syndrome and dermatomyositis [4].

Pityriasis rotunda [4,6] is a fixed, annular, scaling, dry-skin change more often seen in the African and Asian races—it has been associated with neoplasia, particularly hepatocellular carcinoma. However, it may also be seen in other systemic diseases and in leprosy [4,6].

Other epidermal conditions

Transient acantholytic dermatosis has been linked with internal malignancy, particularly with myelogenous leukaemia and carcinoma of the genitourinary tract. However, this may be linked in part with therapy, or simply because it may go unrecognized unless it is specifically considered [1].

Seed-like keratoses of the palms and soles, an acquired pattern of punctate keratoses of the palms and soles, are a common normal finding in healthy subjects (36%) over 50 years old, but are apparently more common in individuals with carcinoma of the bladder (87%) and bronchus (71%) [2]. Punctate keratoderma occurring in Cowden's syndrome (Chapter 12 and p. 62.25) and seed-like keratoses with arsenic ingestion may also be associated with internal malignancy (p. 62.47). Inherited palmoplantar keratodermas were discussed on p. 62.20.

Café-au-lait macules (spots) [3] **and lentigines** (see also Table 62.10). Café-au-lait macules are common, but increased numbers of such lesions are a component of many disorders, some of which are associated with internal malignancy.

Some of these have been discussed above (Genodermatoses associated with internal malignancies); these include neurofibromatosis, Bloom's syndrome, Fanconi's anaemia, Cowden's disease and (variably) ataxia–telangiectasia. An association between café-au-lait macules and early-onset colorectal neoplasia has been proposed to represent a variant of the HNPCC (Lynch) syndrome [4].

Lentiginosis is a feature of the Carney complex (pp. 62.25 and 62.78). Lentigines of the palms and/or soles have recently been described as a paraneoplastic syndrome in four patients, two with previously undiagnosed tumours (one small bowel lymphoma and one carcinoma of stomach) and the other two with known breast cancer [5].

Pigmentation

Many aspects of generalized or localized pigmentation that can be associated with internal malignancy have been discussed in relation to specific disorders. However, it is potentially useful to summarize the most important or characteristic types here, and to comment on those that are not discussed elsewhere in this chapter. A summary is provided in Table 62.10; the mechanisms of pigmentation are discussed in more detail in Chapter 58.

The *ectopic ACTH syndrome* (extracutaneous neuroendocrine melanoderma) occurs due to production of an ACTH-like hormone from tumours; small cell bronchial carcinoma is the cause in over 50%, other reports have described the same condition resulting from gastric, pancreatic, oesophageal and ovarian cancers, as well as in thymoma, phaeochromocytoma, carcinoid syndrome and in various APUD (amine precursor uptake and decarboxylation) tumours. Pituitary and adrenal ACTH production and its effects are discussed in the section describing Cushing's syndrome (p. 62.3). The pigmentation in ectopic ACTH syndrome is addisonian in distribution, diffuse but with photoaccentuation and more prominent over pressure points and in flexures, genital skin, scars and the oral mucosa [1].

Hyperpigmentation with scleromyxoedema and gammopathy [2] has been reported. One patient had pigmentation of the face and V of the neck; the other had generalized pigmentation with accentuation in thickened skin, at acral sites and of genitalia. A similar picture has been seen by one of the authors in a patient without gammopathy.

In Carney complex (p. 62.25), lentiginosis is typically centrofacial but may be widespread at almost any body site; the buccal mucosa is only affected in 5%, rarer sites include the conjunctivae and labia minora, but palms, soles and penis are rarely affected. Blue naevi, usually few in number, occur on the face, trunk or limbs but rarely on the extremities.

Pruritus [1]

Internal carcinoma is a non-specific, rare, but important cause of pruritus. Many mechanisms may be involved, including secondary metabolic effects such as uraemia or cholestasis, or itch related to iron-deficiency anaemia, acquired ichthyosis or xerosis. Other mechanisms, such as that linking brain tumours with pruritus, are less well understood. Unfortunately, senile pruritus and asteatosis are not uncommonly encountered in elderly patients, a group who are more at risk from malignancy. It is therefore difficult to dissociate chance from true association, which can lead to difficulties in deciding whether screening is indicated on a cost-effective basis [2].

Generalized pruritus

In a 6-year study of 125 patients with generalized pruritus, Paul *et al*. [2] found no significant increase in malignancy, although of the eight patients with malignancy detected, two had lymphoma—a higher than expected incidence.

Other studies support the likelihood of a genuine association of haematological disorders and lymphoma with generalized pruritus; in particular, itch may be a severe problem in patients with Hodgkin's disease and may indicate a poorer prognosis [3]. Other haematological disorders, including Sézary syndrome, mycosis fungoides, myelomatosis and leukaemia, may also cause generalized pruritus [4,5]; the mechanisms in these conditions are poorly understood. In polycythaemia rubra vera (PRV), the initiating factor appears to be rapid cooling of the skin, as encountered after bathing. This is thought to be due to the release of pruritogens by

Table 62.10 Pigmentary abnormalities associated with internal malignancy.

Pigmentary change	Pattern	Examples
Hyperpigmentation	Diffuse, or diffuse with localized accentuation (addisonian pattern of pigmentation)	Melanoma (rarely causes diffuse slate grey pigmentation) Phaeochromocytoma (addisonian pattern) Ectopic ACTH syndrome (addisonian pattern) POEMS syndrome (p. 62.94) (diffuse or semiconfluent speckled pattern) Hyperpigmentation with scleromyxoedema and gammopathy Diffuse mastocytosis Lymphomas (uncommon) Ependymoma (mild increase in pigmentation) Werner's syndrome (localized or diffuse pigmentation; p. 62.24) Cachexia due to neoplasia
	Patchy or reticulated	Fanconi's anaemia (various pigmentary changes, p. 62.28) Dyskeratosis congenita (reticulate pigmentation; p. 62.28)
	Other distributions	Carcinoid syndrome (photodistributed) Pancreatic, gastric and renal tumours (erythema ab igne due to local application of heat)
	Lentigines and freckles	Peutz–Jeghers syndrome (p. 62.56) (lentigines) Carney complex (pp. 62.25 and 62.78) (lentiginosis is characteristic, freckles also occur) Xeroderma pigmentosum (Chapter 15) (freckles) Neurofibromatosis (Chapter 15 and p. 62.23) (flexural freckle-like macules) Cowden's disease and Bannayan–Riley–Ruvalcaba syndrome (genital lentigines) Gardner's syndrome (p. 62.56) (freckles) Paraneoplastic acral lentiginosis (p. 62.33)
	Café-au-lait macules	Neurofibromatosis (p. 62.23) Bloom's syndrome (p. 62.27) Multiple endocrine neoplasia types 1 and 2B Fanconi's anaemia von Hippel–Lindau disease
	With epidermal hyperplasia	Acanthosis nigricans (p. 62.31)
	Melanocytic naevi and melanoma	Associated with pancreatic neoplasia, astrocytomas and other cerebral neoplasms in some families Blue naevi and ordinary naevi occur in Carney complex
Mixed hyper- and hypopigmentation	Poikiloderma	Dermatomyositis (speckled pigmentation on hypopigmented background) Rothmund–Thomson syndrome (photodistributed poikiloderma)
Hypopigmentation	Generalized	Chediak–Higashi syndrome (p. 62.28)
	Localized, multiple	Tuberous sclerosis complex (ash leaf macules) Mycosis fungoides (hypopigmented variant)
	Melanoma-associated (other than regression within the primary lesion)	Halo depigmentation around primary tumour or metastases Distant leukoderma, usually with centrifugal spread starting on the trunk

POEMS, polyneuropathy, organomegaly, endocrinopathy, M protein, skin changes.

degranulated mast cells [6]. However, patients with PRV can also develop intractable itching unrelated to bathing.

Many other visceral carcinomas can cause pruritus, including breast and gastrointestinal cancers, and carcinoid syndrome [7]; again, the mechanisms are frequently poorly understood.

Localized pruritus

Nerve damage by a tumour at any site can cause neuropathic pain or pruritus. The patterns that are most likely to present to a dermatologist are brachioradial pruritus and localized facial or nasal pruritus.

Brachioradial pruritus [8] most commonly affects the lateral upper arm or dorsum of the forearm. Although solar damage has been implicated as a cause, most cases appear to be due to neuropathic damage between C5 and C8. Most of these cases are mechanical due to bony abnormalities but a case due to a spinal tumour has been reported, with rapid resolution of symptoms after treatment [9].

Brain tumours are an uncommon cause of pruritus localized to the face [8,10]. Variations that have been recorded include unilateral pruritus and pruritus limited to the nostril. The latter is particularly linked with tumours invading the floor of the fourth ventricle but tumours elsewhere in the brain, and other cerebral lesions (e.g. abscesses) as well as trigeminal neuralgia can also produce this distribution of pruritus. Generalized itching can also sometimes occur with intracranial neoplasia [10].

Hair, nails and skin appendages

Paraneoplastic hypertrichosis lanuginosa acquisita [1–4]

This is a rare but important condition; cases reported in the medical literature up to 2007 have recently been reviewed [1]. About 70% of cases occur in women, usually aged 40–70 years, and most patients have metastatic tumours at presentation, with correspondingly poor prognosis. The commonest tumour sites in men are lung, followed by colorectal, and in women are colorectal, followed by lung and breast. Other reported sites or tumour types include endometrium (about 7–8% of cases), ovary, cervix, renal, prostate, bladder, adrenal gland, stomach, gallbladder, skin (including melanoma), parotid gland, sarcoma, lymphoma and leukaemia [1,3].

There may be associated acanthosis nigricans, hypertrophy of papillae of the tongue, and glossitis [2]; disturbances of taste or smell also occur [3]. However, the glossitis in at least some patients may be a manifestation of vitamin deficiency rather than a specifically related condition [4]. Development of paraneoplastic hypertrichosis lanuginosa acquisita tends to affect the face initially, extending down the body with time. The mechanism is unclear but the hair is of fine, downy, lanugo type; prolongation of the anagen growth phase has been proposed to explain this. Resolution of hypertrichosis lanuginosa occurs after treatment of the underlying tumour, and regrowth related to recurrence of the neoplasm.

Clubbing of nails

This nail abnormality is discussed in more detail in Chapter 65. Both clubbing and associated hypertrophic osteoarthropathy (HOA) have been documented with many neoplasms, the commonest being carcinoma of the bronchus. In patients with lung cancer, clubbing has been reported to be present in 29%, especially in females; most lung tumours are squamous cell carcinoma or adenocarcinoma [1]. A high incidence of HOA occurs particularly with mesothelioma, but it may also occur with malignancies of the pulmonary, cardiovascular, gastrointestinal and hepatobiliary systems [2]; it is much less common than clubbing, occurring in perhaps 5% of patients with clubbing.

Sebaceous neoplasms

Sebaceous neoplasms of various types are strongly linked with Muir–Torre syndrome (p. 62.26).

Hyperhidrosis [1]

Generalized hyperhidrosis may rarely be associated with malignant disease. It is an almost consistent finding in phaeochromocytoma (PCC; see below), in which it may be limited to night-time or occur at any time. Nocturnal hyperhidrosis ('night sweats') may occur in PCC, lymphoma and carcinoid syndrome, as well as in non-neoplastic conditions such as thyrotoxicosis, chronic infections and others. Localized hyperhidrosis may occur in POEMS syndrome.

Specific distributions of localized hyperhidrosis may also be important. Hyperhidrosis with autonomic dysreflexia is associated with spinal cord lesions above T6, and is characterized by episodic sweating of the face, neck and upper trunk with vasodilatation in the same distribution, headache, hypertension and piloerection; most cases are due to injury or cord compression but intracranial posterior fossa neoplasms can produce similar symptoms. Paroxysmal unilateral hyperhidrosis of the face and neck, usually severe and unrelated to stimuli such as eating, may be due to an ipsilateral thoracic tumour (adenocarcinoma, squamous cell carcinoma or mesothelioma) compressing or infiltrating the sympathetic trunk; associated features may include Horner's syndrome, facial weakness, sensory disturbance, and other features of the primary tumour.

Phaeochromocytomas (PCCs) may be present in 0.3–1.9% of individuals, based on post-mortem studies and biochemical screening, but only 10% are malignant in nature [2]. Standard teaching is that 10% of PCC are familial, including those occurring in MEN syndromes (p. 62.24), neurofibromatosis, von Hippel–Lindau disease, hereditary paragangliomatosis and tuberous sclerosis; however, screening PCCs for germline mutations demonstrated that 24% of apparently sporadic PCC had mutations of *VHL*, *RET*, *SDHD* or *SDHB* genes [3]. Patients with PCC that have *SDHD* or *SDHB* mutations have a 20–30% risk of developing glomus tumours (these genes confer susceptibility to both extra-adrenal PCC (paragangliomas) and glomus tumours, as both have a common neural crest origin) [4]. Genetic aspects of PCC and other adrenal tumours are reviewed in [5].

Presentation of PCC is often incidental due to discovery of labile hypertension, but the classical triad of features in PCC is episodic

headache with palpitations (tachycardia) and hyperhidrosis due to release of catecholamines [2,4]. Numerous other symptoms may occur, including hyper- and hypoglycaemia, pallor with rebound flushing, diarrhoea, fatigue, dyspnoea, chest pain, abdominal pain and malaise.

Dermatoses

Several dermatoses have a significant association with internal malignancy; in other conditions there is just a minor statistical link documented, as discussed below.

Acrokeratosis paraneoplastica (Bazex syndrome) [1–5]

This is a rare condition, much commoner in males than females [3–5], which is associated particularly with squamous cell carcinoma of the upper respiratory or gastrointestinal tracts, particularly when there are metastases in the cervical lymph nodes. An underlying malignancy is a required criterion for the diagnosis; the cutaneous features are predominantly acral in distribution and papulosquamous lesions, hyperpigmentation, keratoderma, paronychia and nail dystrophy (at least one of which is also required for diagnosis) [3]. More than 60% of tumours arise in the oropharynx, larynx or are cervical squamous cell carcinoma metastases with an unknown primary site; lung, oesophageal and other primary or metastatic lesions above the diaphragm make up most of the remainder [5]. Rare associations, such as metastatic adenocarcinoma of the prostate and transitional cell carcinoma of the bladder, have been reported [6,7]. The cutaneous changes develop gradually, often in several phases, initially with violaceous erythema and scaling on the peripheries, especially helices of the ears, tip of the nose, hands and feet (especially the distal portion of digits). The eruption then becomes more hyperkeratotic, with a keratoderma on hands and feet. Subsequently, the eruption may become more generalized. Nail dystrophy and paronychia are often present. Changes on the face may appear more eczematous or lupus erythematosus-like, whereas acral changes are often psoriasiform. The differential diagnosis can include dermatitis, especially seborrhoeic or contact-allergic types. Alternatively, acral psoriasis with the possibility of Reiter's syndrome may be considered. The course mostly parallels the underlying neoplasm; resolution may occur with successful tumour resection, and recurrence may develop on relapse of malignancy. When resection is felt inappropriate or impracticable, systemic retinoids may improve the cutaneous changes [8]. The histological changes are non-diagnostic, but essentially reflect the clinical appearance with hyperkeratosis, parakeratosis, focal spongiosis and a mixed, inflammatory cell infiltrate [4,5,9].

Dermatomyositis (Chapter 51) [1–5]

Both dermatomyositis (Fig. 62.13) and polymyositis in adults may be associated with internal malignancy. The reported likelihood of finding a neoplasm varies between 6% (in polymyositis) [6] and 50% [7]; overall, about 25–30% is probably a representative proportion for the various reported studies of dermatomyositis, making this a condition with a significant association with underlying malignancy. The association with neoplasia is much stronger for dermatomyositis than for polymyositis or dermatomyositis/autoimmune disease overlap conditions. Conventional teaching has been that malignancy is an uncommon cause of dermatomyositis in subjects less than 40 years of age; however, paediatric cases with neoplasia are reported [8]. As there is a lower incidence of malignancy in the younger age group, and there are no age-matched comparative studies against a control population in children, it is difficult to judge the strength of the association in this age group [3].

Fig. 62.13 Dermatomyositis in a patient with ovarian carcinoma.

The temporal association of dermatomyositis with neoplasia varies; in one report approximately equal proportions had a known malignancy at the time that dermatomyositis presented, had a malignancy found due to investigation when dermatomyositis was diagnosed, or had a malignancy found during follow-up (usually in the first 6 months after diagnosis of dermatomyositis) [4]. Others report a four to five times increased incidence of malignancy in the first 2 years [9] or even 5 years [5] after diagnosis. Accounts of specific malignant associations may be subject to bias by rare-case reporting, and in larger series the malignancies identified generally reflect tumour prevalence in the general population; lung cancer in men, breast and gynaecological tumours in women, and colorectal cancers in both sexes. In South-East Asia, there is a higher frequency of nasopharyngeal carcinoma, that probably also reflects the background risk of this type of neoplasm. The one exception to this generalization is ovarian carcinoma, which appears to be significantly overrepresented and potentially overlooked [2,4,5,10].

The value of extensive screening for neoplasia in dermatomyositis is questionable. Several authors have stressed that the emphasis should be attached to thorough clinical evaluation, simple investigations and then specific investigations as indicated [1,4,10]. However, all of these studies were performed before easy availability of CT or MRI scanning, and the quality of such imaging has increased hugely in recent years, so radiological screening should be included in the investigation of patients with dermatomyositis. 'Blind' (i.e. not symptom-directed) CT scanning of chest, abdomen and pelvis increased the yield of malignancies in one study, although the number of patients in whom a tumour might have been missed was small, and one was an ovarian tumour which has been documented above as worthy of greater suspicion. There should certainly be a low threshold for further or repeated investigations at the time of diagnosis or during follow-up if previous neoplasia has been present, when the therapeutic response is poor, or if new symptoms develop; there is also an argument for ongoing screening for ovarian cancers throughout follow-up of female patients without any initial screening test abnormalities, using clinical examination, trans-vaginal ultrasound and tumour markers (CA125) [2].

In general, subjects with dermatomyositis who truly have amyopathic dermatomyositis (dermatomyositis sine myositis) [12], or who have a connective tissue overlap syndrome, appear less likely to have an underlying malignancy; however, some patients with amyopathic dermatomyositis do actually develop myositis, some studies document similar tumour rates in those with or without myositis [13], and tumours have been reported in all such variants, so screening investigations should still be performed [14]. In one study, patients with malignancy were found to have a more rapid onset of dermatomyositis, higher mean creatine kinase and erythrocyte sedimentation rates, and a lower frequency of Raynaud's phenomenon compared with patients without an underlying malignancy [11]. However, a low creatine kinase has also been linked with a higher frequency of malignancy. Vasculitis or necrosis, manifest clinically or in histopathology specimens, has also been associated with an increased risk of an associated neoplasm [13,15–17].

Whilst no clinical pattern reliably excludes the possibility of an underlying malignancy, a greater understanding of the immunopathogenesis of paraneoplastic dermatomyositis may be instructive [18–20]. A recent report documented that subjects with a myositis-specific autoantibody reactive with 155-kDa and 140-kDa nuclear antigens (anti-155/140 Ab) had a much higher risk of malignancy (71%) than those without this antibody (11%) [19]. Patients with this antibody had a higher frequency of heliotrope rash, Gottron's papules and flagellate erythema than those with negative results, but none with anti-155/140 Ab had interstitial lung disease. No patients with systemic lupus erythematosus, systemic sclerosus or healthy controls had this antibody. A novel myositis-specific antibody (anti-CADM 140) has recently been demonstrated in amyopathic dermatomyositis, and some myositis-specific antibodies are expressed both in regenerating muscle cells and in some cancers [20]. Such insights may in the future help to determine which patients require investigation for malignancy.

Migratory erythemas

This descriptive term is applied to a variety of annular and figurate eruptions, which are discussed in more detail on pp. 62.106–62.113. Two variants, erythema gyratum repens and necrolytic migratory erythema, have a clear association with internal neoplasia. Others, such as erythema annulare centrifugum and some unspecified figurate erythemas, also have a very variable association with neoplasia. There are also reports of subacute lupus erythematosus-like annular and figurate rashes, linked with myeloproliferative disorders and carcinoma of lung, liver, breast, larynx and oesophagus in individual cases.

Erythema gyratum repens (see also p. 62.107) is a rare, bizarre cutaneous eruption consisting of mobile concentric, often palpable, erythematous, wave-like bands, which give a 'wood-grain' appearance to the skin (Fig. 62.14). A peripheral scale or collarette may be present. The complete torso is frequently affected. There is often associated severe pruritus, sometimes ichthyosis, and sometimes bullae within the erythema. The lesions migrate from day to day, usually changing position by about 1 cm daily. It has a strong association with internal malignancy (over 80% of cases), particularly lung cancer [1,2] which is present in about a third of cases; other cancer sites include oesophagus, breast, bowel, uterus, cervix, kidney, pancreas and haematological neoplasia [2]. Occasional cases without associated malignancy have been reported [3] but it is important to be aware that 6% are found to have a tumour of unknown primary origin [2]. Identification and resection of the tumour often results in resolution of the eruption.

Necrolytic migratory erythema (glucagonoma syndrome) is the characteristic eruption associated with an α-cell tumour of the pancreas. It is discussed in the section on pancreatic disease later in this chapter (p. 62.66).

Erythema annulare centrifugum [4,5] is the term used to describe one of the commoner annular erythemas, which is usually not associated with neoplasia (p. 62.110). If an underlying malignancy is found, it is usually a myeloproliferative disorder [5]. Clinical examination and routine screening tests are the only investigation required, rather than an exhaustive search for malignancy, unless there are additional clinical pointers.

Other dermatological disorders

Lichen planus may rarely be induced by neoplasia [1]. There is also an increased risk, particularly in males, of oral squamous cell carcinoma (SCC); this may be due to a combined direct effect and co-factors such as smoking [2]. The strength of the association may however have been overestimated, as some of the reports are those that have collected patients presenting with oral SCC and have then looked for histological evidence of lichen planus as a background factor.

Urticaria; with the exception of cold urticaria and peripheral gangrene as a result of circulating cryoglobulins, where there is a possible, but uncommon, link with myeloma and lymphoma [3], associations of urticaria and neoplasia are difficult to evaluate. Certainly it cannot be regarded as an established paraneoplastic phenomenon, other than in Schnitzler's syndrome (a distinct disorder of chronic urticaria, bone pain, hyperostosis, high erythrocyte sedimentation rate and monoclonal IgM gammopathy, usually IgMκ; see Chapter 22). Histologically, there is neutrophilic inflammation within dermal venules with some perivascular involvement, rarely extending to a leukocytoclastic vasculitis. Although the overall prognosis is reasonable, around 10–15% of patients develop lymphoplasmacytic lymphoma [4].

Erythroderma (Chapter 23) and exfoliative dermatitis have both been linked with malignancy [5,6]. In most such cases (around 10% in most reported series), the neoplasm is mycosis fungoides or its leukaemic variant, Sézary syndrome; these are really a representation of a systemic neoplasm rather than a truly paraneoplastic disorder. However, there are a small number of patients who have neither condition, but present with erythroderma and eventually develop lymphoma or leukaemia. The incidence is uncertain and rare; a report in an Asian population failed to demonstrate one association in 80 patients [7]. Immunophenotypic studies do not appear to help distinguish benign from malignant cases. There are additionally reported cases of erythroderma with cancers of liver, lung, colon, stomach, pancreas, thyroid, prostate and cervix [5,6,8]. *Ofuji papuloerythroderma* has also been associated with peripheral T-cell non-epidermotrophic cutaneous lymphoma [9].

Granuloma annulare has been reported in association with lymphomas, other haematological malignancies, and uncommonly

with solid tumours [10]; however, a causal relationship in such cases is uncertain. It has been suggested that the subcutaneous pattern of granuloma annulare may carry a greater risk of malignancy, but this may reflect the more extensive investigation that is usually performed to establish the diagnosis in such cases by comparison with more typical granuloma annulare.

'*Insect bite-like' reactions* are reported in haematological malignancy, usually chronic lymphocytic leukaemia [11].

Cutis verticis gyrata may occasionally occur as a paraneoplastic phenomenon [12].

Mental neuropathy ('numb chin syndrome') has several benign causes, but may occur as a feature of metastatic disease and is considered an indicator of poor prognosis [13]. Relevant tumours include breast, thyroid, renal, lung, prostate, lymphomas and melanoma.

Non-melanoma skin cancer has been linked with increased risk and poor prognosis of non-Hodgkin's lymphoma [14].

Connective tissue and rheumatological disorders

Malignancies have been reported in association with many disorders that overlap between dermatology and rheumatology. Those that fall into the collagen vascular group are discussed here; dermal deposition disorders, neutrophilic infiltrates, paraneoplastic vasculitis and other vascular conditions are discussed later.

Systemic lupus erythematosus

The possibility of an increased risk of internal malignancy in systemic (SLE) and subacute cutaneous lupus erythematosus has been debated for many years, and still remains controversial. There are individual cases in which a close temporal relationship has been documented [1], and large cohort and population studies have mainly produced results in favour of an increased risk [2,3]. Studies that have supported an association with malignancy have suggested increases in lymphomas, monoclonal gammopathy, cervical, lung, hepatobiliary and breast cancer [3–6], although the latter is disputed [4]. The majority of large studies suggest an increase in non-Hodgkin's lymphoma [3], particularly diffuse large B-cell lymphoma (DLBCL) [5]. The mechanism may be a T-cell defect in SLE, or may be a result of immunosuppressive medication used in treatment (especially implicated in the increased risk of haematological malignancies [7]). The evidence for an association between autoimmune conditions and lymphoma is supported by a large study of 3055 patients with non-Hodgkin's lymphoma and matched controls; significant associations were found with rheumatoid arthritis, primary Sjögren's syndrome, and SLE, again documenting the specific association with DLBCL [8]. The increased tumour risk in patients with Sjögren's syndrome has been noted in other reviews [9]. Treatment with antimalarials has been suggested to have a protective effect against development of cancers in SLE [10].

Rare patterns of lupus erythematosus, such as lupus erythematosus gyratum repens, may carry a higher risk of internal malignancy [11], although this condition is generally reported as isolated cases, so this conclusion is uncertain. Individual reports suggest an association of a subacute cutaneous lupus erythematosus (SCLE)-like eruption with tumours of various organs (including myeloproliferative disorders causing a neutrophilic lupus-like figurate erythema, and SCLE-like rash associated with tumours of lung, liver, larynx, breast and oesophagus [12,13]. Potential clues to this association are an SCLE-like rash in males, in an older age-group than usual, and with resistance to therapy.

Scleroderma, fasciitis, panniculitis and similar sclerodermoid conditions

Like SLE, scleroderma/systemic sclerosis has been linked with occurrence of internal malignancy [1,2], and a possible role of fibrogenic peptides has been proposed [3], although overall the association is probably not strong [4]. Likewise, eosinophilic fasciitis has occasionally been linked with contemporaneous diagnosis of a neoplasm [5]. Many of the cases described are not entirely classical of 'usual' scleroderma, some cases having a more aggressive course of fibrosis than anticipated, an unusual distribution, extensive fibrotic changes in the subcutaneous fat, or progressive arthritis. To reflect these features, more recent cases have been described under the terms palmar fibrosis/arthritis [6,7] or cancer-associated fasciitis–panniculitis syndrome [8,9]. The commonest tumour types documented are ovarian and lung; breast, prostate and pancreatic tumours have also been reported.

A more typical panniculitis process resembling Weber–Christian disease may occur in patients with acinar cell carcinoma of the pancreas, in whom a syndrome of panniculitis, polyarthritis and eosinophilia can occur. Eosinophilic panniculitis has also been reported in association with other solid tumours or pre-leukaemia [10,11].

Scleroderma-like skin changes may also be a cutaneous manifestation of carcinoid syndrome, the differential diagnosis from collagen vascular scleroderma processes being suggested by the presence of flushing and the absence of Raynaud's phenomenon.

Post-irradiation morphoea is a phenomenon seen after treatment of breast cancer [12]; its importance is not as a marker of underlying malignancy, but in the differential diagnosis of carcinoma en cuirasse (or occasionally carcinoma erysipeloides), discussed above.

Relapsing polychondritis

It is increasingly recognized that relapsing polychondritis may be linked with malignancy. Myelodysplastic syndrome and other haematological malignancies are much the commonest association [1,2], but a variety of solid tumours have also been reported including lung, breast, colorectal, pancreas, prostate and others [1]. Concurrence with malignancy-associated Sweet's syndrome is discussed in Chapter 50.

Sarcoidosis

Several studies document an association of sarcoidosis with malignant disease [1–4]; the suggested mechanism relates to abnormal immune function in sarcoidosis [1,4]. The strongest link reported is with lymphomas, to the extent that the term 'sarcoidosis–lymphoma syndrome' is used by some authors [1,3]. In most such cases, lymphoma has followed sarcoidosis, but the rationale for any association is less clear in cases in which sarcoidosis has developed after a cutaneous lymphoma. An apparent aetiological relationship is suggested in a quarter of cases [4]. Testicular tumours, carcinomas of skin (including melanoma), multiple myeloma, lung cancer, female genitourinary tract and other tumours have also been reported. However, large studies have found no evidence to support any significant association between sarcoidosis and malignant disease (or lymphoma specifically) [5,6].

Fig. 62.15 Pyoderma gangrenosum of the lower leg in a patient with myelodysplastic syndrome.

Pyoderma gangrenosum and neutrophilic dermatoses. These are discussed in greater depth in Chapter 50 and are only briefly noted here. Pyoderma gangrenosum, particularly in a superficial and bullous form, has been associated with myeloproliferative diseases, including acute and chronic myeloid leukaemia, acute lymphocytic leukaemia, myeloid metaplasia, PRV, multiple myeloma, lymphoma and myelofibrosis (Fig. 62.15) [1]. The association of pyoderma gangrenosum with monoclonal gammopathy is uncertain, but it does occur at a frequency higher than expected in the general population and is usually of IgA type, whereas IgG gammopathy is the commonest type overall. Solid tumours reported include carcinoid, colon, bladder, prostate, breast, bronchus, ovary and adrenocortical carcinoma.

Sweet's syndrome has likewise been associated with several malignancies, especially haemopoietic. Chronic recurrent Sweet's syndrome [2] appears to have a particularly strong link with myelodysplastic disorders.

***Multicentric reticulohistiocytosis* (lipoid dermatoarthritis; reticulocytoma cutis)** [1,2]

This is a rare condition, usually occurring in adult life, and characterized by papulonodular lesions of the fingers or other extremities, the face, and sometimes mucous membranes. Papules around the nail fold have been termed the 'coral bead sign'. A severe symmetrical polyarthritis, especially affecting the hands, is frequently associated [3]. Approximately 25% of cases are associated with internal neoplasia, virtually always solid tumours such as those of the breast, lung, colon, pancreas, stomach, ovary or cervix [1–3], although haematological malignancies have also been reported [4].

Vascular disorders

Raynaud's phenomenon and digital ischaemia (paraneoplastic acral vascular syndrome) [1–3]

Persistent, painful digital ischaemia, with an unusual Raynaud's syndrome-type appearance but often progressing to gangrene, has been linked to a variety of solid tumours and reticuloendothelial neoplasms [1–3]. The process may have a vasculitic element [4] (see below).

Hyperviscosity syndromes such as polycythaemia rubra vera, leukaemias or myeloma-linked cryoglobulinaemia may give rise to cutaneous ischaemia and phlebitis by microvascular occlusion; cancer-associated coagulopathy may also cause vascular occlusion [5].

Hypereosinophilic syndrome, for which there is increasing evidence of a malignant clonal proliferation, has also been associated with acrocyanosis, cutaneous microthrombi, digital infarction and gangrene [6–8]. In some instances, there is a clonal T-cell production of interleukin-5, a major controlling cytokine in production release and differentiation of eosinophils. In other cases, there is clonal expansion of eosinophils with hepatosplenomegaly and thrombocytopenia; this condition appears to be due to a cytogenetic defect t(9;22)(q34;q11) in which there is chromosomal breakage and reciprocal exchange of chromosomal fragments that leads to formation of a fusion tyrosine kinase FIP1L1–PDGFRα.

Erythromelalgia

This condition is linked with myeloproliferative disorders, most commonly polycythaemia rubra vera or essential thrombocythaemia, in over a third of adult cases. In a large series of patients with erythromelalgia linked with haematological malignancy, the feet were most commonly affected, with severe burning pain and erythema; symptoms may occur 2 years or more before the haematological disorder is documented [9]. The mechanism involves microvascular occlusion (typically with platelet aggregates, termed 'white thrombi'); Raynaud's phenomenon may also occur.

Palmar erythema

This is rarely linked with malignancy, but an interesting association was observed in a series of patients with cerebral malignancies, in whom nearly 20% had palmar and (to a lesser extent) plantar erythema, either diffuse or mottled. This occurrence seemed to be linked with the vascularity of the tumour, and was particularly seen with high-grade astrocytomas and glioblastomas; a role for vascular endothelial growth factor was proposed [10].

Vasculitis and malignancy [4,11]

There appears to be an association of cutaneous vasculitis with neoplasia, particularly in myeloproliferative disorders [11–13] and

myeloma [14,15], although solid tumours have also been reported [4,16,17]. Hairy cell leukaemia appears to be especially associated with vasculitis, which may be of leukocytoclastic or polyarteritis nodosa pattern. Of the solid tumours reported with malignancy, the most common would appear to be approximately the sites expected in an average population, including breast, lung, colon, oesophageal, renal, prostatatic and head and neck tumours. As noted above, there is overlap with paraneoplastic digital ischaemia. In a study of 200 patients with ANCA-positive vasculitis (Wegener's granulomatosis or microscopic polyangiitis), the relative risk of malignancy preceding or concurrent with vasculitis was sixfold greater than that for the local population; patients with Henoch–Schönlein purpura (n = 129) had a fivefold relative risk, but only five of 333 patients with SLE had a malignancy [18].

The dermatological manifestations include palpable purpura, maculopapular, urticarial and petechial lesions; these presumably reflect a small-vessel vasculitis or even, when ulceration occurs, a necrotizing vasculitis [4,11]. When linked with a haematological malignancy, vasculitis often antedates bone marrow involvement, as opposed to the more predictable purpura due to thrombocythaemia, which reflects bone marrow infiltration by myeloproliferative disease or carcinoma. It is difficult in some reports to distinguish between microvascular occlusion (for example, by a monoclonal type I cryoglobulin) versus primary vasculitis or therapy-related vessel injury.

Chilblain-like lesions

Lesions resembling perniosis may be a manifestation of leukaemias and myeloproliferative disorders (Fig. 62.16; see also p. 62.88) [19,20]. They are persistent rather than episodic, which would be expected in idiopathic perniosis, refractory to treatments for perniosis, such as calcium channel blockers, and biopsies may show blast cells. Metastasis from breast carcinoma has also been documented as resembling chilblains [21].

Cancer-associated thrombosis

Three main patterns need to be considered: migratory thrombophlebitis, deep venous thrombosis, and Mondor's disease (a specific pattern of thrombophlebitis, but sufficiently distinctive that it is described separately). Arterial thrombosis may also occur as a paraneoplastic entity but is much less common. The aetiology of cancer-associated thrombosis is multifactorial. Interaction of macrophages with cancer cells causes release of tumour necrosis factor and interleukin-6 which damage endothelium, creating a pro-thrombotic situation; the same interaction causes activation of platelets, and of clotting factors X and XII [1]. Some tumour proteases are also procoagulant, especially 'tissue factor' which activates factor VII, and sialic acid moieties of mucin (released from adenocarcinomas) which activate factor X [1].

Migratory thrombophlebitis (Trousseau's sign) [2–7]. Unlike superficial thrombophlebitis confined to the lower limbs, thrombophlebitis associated with neoplasia is often recurrent and migra-

tory. A variety of sites, especially the upper extremities and trunk, can be involved, and lesions are usually multiple. Migratory thrombophlebitis is associated with malignancy in 50% of cases. The mechanism in most cases is an intravascular, low-grade hypercoagulation, which responds poorly to anticoagulant therapy; heparin is usually more effective than warfarin [8]. As well as altered level or function of prothrombotic and anticoagulant proteins, the coagulation and thrombotic process may involve cytokines, angiogenic factors or mucin secretion by tumours, altered blood viscosity, vascular endothelial changes and production of small tumour emboli. Migratory thrombophlebitis can be associated with any cancer, but particularly occurs with carcinomas of the pancreas, stomach, colon and lung; pancreatic carcinoma accounts for about half of all cases. Leukaemias and lymphomas are less commonly associated with migratory thrombophlebitis. Causative tumours are often highly malignant and metastatic with a poor prognosis.

Deep vein thrombosis (DVT). This is not commonly the presenting feature of malignancy [4,7], although cancers have a significant risk of causing thrombosis. The likelihood of finding a malignancy is increased by about fourfold in patients with a deep venous thrombosis of the leg compared with expected population rates, the overall risk of such an association is about 10%. By contrast, DVT of the upper limb is more commonly linked with neoplasia (in some cases, the reason is obstruction by an apical lung tumour), and DVT is identified post-mortem in half of patients who have died due to cancer. Tumours associated with DVT are usually adenocarcinomas in the gastrointestinal tract, urogenital tract, breast or lung; mucin secretion, as noted above, causes non-enzymatic activation of factor X to factor Xa, initiating the thrombotic cascade. Older age of patients with a DVT has been proposed as a factor that should be associated with a lower threshold for malignancy screening.

Mondor's disease. This is a rare condition in which a cord-like lesion is palpable in the subcutaneous tissue of the anterior or lateral thorax, or sometimes abdomen. The underlying lesion is a thrombophlebitis of thoracic or epigastric veins, usually unilateral but occasionally bilateral, which may occur as a result of trauma, inflammation or post-surgery. However, 10–15% of patients may have an associated breast carcinoma [4,7,9] so careful examination and mammography are indicated unless an alternative cause is obvious.

Flushing

This is a normal physiological response and may be a problematic menopausal symptom. However, it may be a feature of carcinoid syndrome, mastocytosis, phaeochromocytoma, medullary carcinoma of thyroid, hypogonadism in males, pancreatic tumours producing vasoactive intestinal peptide (VIPomas), basophilic leukaemia, horseshoe kidney (Rovsing's syndrome) and renal cell carcinoma [1,2]; it is also a feature of POEMS syndrome which is associated with myeloma (discussed on pp. 62.92 and 62.94). Plethora, but not flushing, may be apparent in polycythaemia rubra vera.

Carcinoid syndrome may be difficult to diagnose at an early stage, as flushing is typically provoked by common triggers of physiological flushing, such as emotional stress or alcohol ingestion. Only about 10% of patients with a carcinoid tumour have a malignant carcinoid syndrome, and paroxysmal flushing is present in virtually all cases; episodes typically last a few minutes and may be more widespread than emotional flushing, sometimes involving the whole body. Nearly 75% of carcinoid tumours are gastrointestinal (especially involving the appendix and ileum), 25% are bronchial, and a small number arise at other sites including the larynx, pancreas, gallbladder and ovary [3]. Flushing is described as varying according to the site of the neoplasm; the most common midgut tumours (appendix and ileum) are associated with gradual development of fixed cyanotic erythema in the flushing distribution, whereas foregut tumours (stomach, pancreas, lung) are associated with a brighter pink flush. This may reflect production of different mediators; gastric carcinoids typically cause flushing by production of histamine, whereas midgut carcinoids produce serotonin, bradykinin and prostaglandins. Other symptoms, such as diarrhoea, abdominal pain, dyspnoea, wheezing and occasionally syncope, may occur with progression of the tumour, usually not occurring until liver metastases have developed. Persistent erythema with or without telangiectasia, scleroderma-like change, pigmentary anomalies and a pellagra-like dermatitis eventually develop.

Mastocytosis [1,4,5] is discussed in more detail in Chapter 22. It is most commonly limited to the skin but may be systemic, in which event it can be classified into four groups: indolent, associated with a clonal haematological non-mast cell lineage disease (myeloproliferative or myelodysplastic disorders), aggressive (lymphadenopathic with eosinophilia), and mast cell leukaemia. It may be associated with mutations in the gene for c-kit. The more aggressive forms tend not to be associated with cutaneous mast cell lesions but flushing, dyspnoea, chest pain, abdominal cramps, palpitations, syncope and other systemic reactions due to mast cell degranulation may occur. Serum tryptase is a useful screening test that may suggest systemic disease. However, the proportion of bone marrow mast cells, eosinophilia (especially in bone marrow) and alkaline phosphatase level are of greater prognostic importance than levels of mast cell mediators [6].

Phaeochromocytomas (PCC) may cause pallor with rebound flushing [1,2], but the more typical dermatological feature is

hyperhidrosis, discussed above. *Medullary carcinoma of thyroid*, like PCC, may occur as part of a MEN syndrome (p. 62.24) but may occur in isolation. They may produce several other hormones such as ACTH, as well as prostaglandins and amines, which may cause other symptoms such as diarrhoea.

Venous or lymphatic obstruction

In addition to vasculitis and the thrombotic intravascular occlusion described above, vessels of different types may become occluded by intravascular tumour cells, or may be compressed by an adjacent tumour. The facial and upper limb suffusion of superior vena caval obstruction is well known. Obstruction of venous flow from the head and neck may also occur due to benign retrosternal thyroid gland enlargement and is typically seen when the arms are elevated (Pemberton sign). Lymphatic obstruction typically occurs at the main lymph node sites, such as in the axilla due to a breast carcinoma, lymphoma or limb melanoma. Apical lung neoplasms may also cause damage to sympathetic nerves, leading to anhidrosis and sometimes hyperhidrosis and flushing of the contralateral, unaffected side. Arterial obstruction by tumours is much less common, although tumour emboli may occur.

Other vascular disorders

Various other angiomatous lesions have been linked with internal malignancy, including *eruptive angiomas* [1] and *telangiectasia* [2]. The latter may occur as a direct tumour infiltration of vessels (carcinoma telangiectoides, p. 62.16) but has also been described secondary to lung cancer. Painful telangiectatic plaques are a feature of malignancy angioendotheliomatosis. *Glomeruloid angiomas* are a feature of POEMS syndrome, in which a monoclonal paraprotein is a feature. Telangiectasia occurs in several genodermatoses described earlier, such as Bloom's syndrome and Rothmund–Thomson syndrome, and is a feature of more advanced cases of carcinoid syndrome.

Deposition disorders: mucinoses, xanthomas, amyloidosis and calcification

Dermal deposition disorders may be linked with internal malignancy [1]; in particular, there are a number of diverse cutaneous manifestations of paraproteinaemia and myeloma (p. 62.92) [2]. Some of these are rare conditions, and their occurrence should prompt a search for an underlying internal cause. Some of the most important deposition disorders, and their potentially associated internal malignancy, are listed in Table 62.11; all listed are discussed in detail in other chapters.

Paraproteinaemia is associated with many of the deposition disorders listed in Table 62.11. Other manifestations of paraproteinaemia are discussed in more detail in the section on haematological disorders (pp. 62.92–62.94). Pathology of disorders such as sclero-myxoedema and necrobiotic xanthogranuloma is discussed in [2–4].

Calcinoisis cutis is a rare complication of internal carcinoma. However, it should be noted that many cancers cause hypercalcaemia, and that metastatic calcification may occur in other organs, such as the lung or kidney, even if not in the skin. The commonest underlying tumours are carcinoma of oesophagus, myeloma, breast cancer, lymphoma and osteolytic metastases; mechanisms include production of parathyroid hormone, parathyroid hormone-related peptide, vitamin D, cytokines, up-regulation of NFκB ligand (RANKL) or down-regulation of RANKL antagonist (osteoprotegerin) [2].

Bullous disorders

Paraneoplastic pemphigus (PNP; neoplasia-associated pemphigus) [1–6]

This is a heterogeneous, multiorgan, autoimmune syndrome in which patients may display a spectrum of mucocutaneous manifestations including pemphigus-like, pemphigoid-like, erythema multiforme-like, graft-versus-host disease-like or lichen planus-like patterns, characteristically with oral involvement; in addition, there is an association with small-airways occlusion [5] and deposition of autoantibody complexes in different organs. The mucosal disease is often severe and progressive.

Associated neoplasms in one large review series were mainly B-cell proliferations and thymoma or thymoma-like neoplasms; specific neoplasms included Hodgkin's lymphoma (42%), chronic lymphocytic leukaemia (29%), Castleman's tumour (10%), thymoma (6%), spindle cell neoplasms (6%) and Waldenström's macroglobulinaemia (6%) [1]. PNP is distinguished from pemphigus by its clinical features and by the presence of serum autoantibodies to a range of antigens of 250, 230, 210, 190 and 170 kDa (which include bullous pemphigoid antigen, as well as desmosomal and hemidesmosomal proteins including desmoglein 1, desmoglein 3, envoplakin and periplakin); direct immunofluorescence of skin biopsies is usually positive for IgG and C3 but may be negative in some cases. High sensitivity and specificity for this differential diagnosis has recently been reported by taking account

Table 62.11 Some deposition disorders that are linked with internal malignancy.

Material deposited	Disorder	Associated internal malignancies	Comments
Amyloid proteins [1] (see Chapter 59)	Primary and myeloma-associated systemic amyloidosis (AL protein deposition)	Paraproteinaemia, myeloma	Amyloidosis occurs in about 15% of patients with myelomatosis
	Secondary amyloidosis (AA protein deposition)	Lymphomas, especially Hodgkin's lymphoma Hypernephroma Other solid tumours	
Mucin/proteoglycans and fibromucinoses	Scleromyxedema/lichen myxoedematosus	Paraproteinaemia, typically a 'slow gamma region'	Paraprotein is present in most cases
	Papular mucinosis	Paraproteinaemia	Uncommon
	Scleredema	Paraproteinaemia	More commonly associated with diabetes or streptococcal infection
	POEMS syndrome	Paraproteinaemia	Features are polyneuropathy, organomegaly, endocrinopathy, M-protein, skin changes
Lipids (as foamy macrophages)	Necrobiotic xanthogranuloma	Paraproteinaemia, usually monoclonal IgGκ, present in about 70% of cases	Also associated with cryoglobulinaemia, myeloma, marrow dyscrasias and rarely leukaemia; some cases apparently occur in isolation
	Normolipaemic plane xanthomatosis	Myeloma	Usually IgG paraprotein
	Xanthoma disseminatum	Gammopathy, bone marrow dyscrasias	Usually IgG paraprotein
Calcium	Metastatic calcification	Lung and other squamous carcinomas Due to primary hyperparathyroidism; may be associated with multiple endocrine neoplasia syndromes	Due to ectopic parathyroid-like hormone secretion See p. 62.24
	Dystrophic calcification	Pancreatic carcinoma	Calcification of fat

of the association with a lymphoproliferative disorder, indirect immunofluorescence of rat bladder urothelium (antibodies to desmoplakin), and envoplakin and/or periplakin bands on immunoblotting [6].

Bullous pemphigoid

Isolated reports have suggested an association between bullous pemphigoid and underlying neoplasia [1–3]. However, larger series do not support a significant association with malignant disease [4,5]. Despite this, the issue remains controversial, and more selective studies have shown there may be a correlation when immunofluorescent findings are negative and mucosal involvement is present [4,6]. Historical reports are difficult to evaluate with certainty, as some cases may actually have been epidermolysis bullosa acquisita, or even bullous pemphigoid-like PNP, which can now be separated from bullous pemphigoid by current immunological techniques. Malignancies have been reported from breast, lung, thyroid, larynx, skin, soft tissue, stomach, colon, lymphoreticular system, prostate, cervix, bladder, kidney and uterus.

Pemphigus

Historically, pemphigus has been linked with various tumours; some cases, such as those associated with thymoma and Castleman's tumour, would probably now be found to have the features of PNP. Pemphigus foliaceus has been associated with acanthosis nigricans-like lesions and hepatocellular carcinoma [7], and pemphigus in Japanese subjects has been associated with lung cancer. The concurrence of internal malignancy and pemphigus, as with bullous pemphigoid, may be a true association [8], although some suggest this to be coincidence [9].

Other blistering disorders

Dermatitis herpetiformis (DH) has been documented in some studies to have a link with internal malignancy of various types, especially lymphoma [1–4], although some studies suggest that the risk is actually quite low and confined to a small increase in likelihood of lymphoma [3]. Review of a single-institution large cohort of patients with DH documented a low frequency of lymphoproliferative disorders (seven of 270 patients, including two with small bowel and one with gastric lymphoma) and although 10.4% of the series had some form of documented malignant disease at some time, there was no apparent tumour type that was overrepresented, no control population to know whether this represented an increased risk, and the interval between DH and lymphoma varied widely [5]. There is logic for an indirect link with lymphoma; DH is always associated with some degree of gluten-sensitive enteropathy, and the latter has a well documented association with small bowel lymphoma. One group of authors who initially found an increased risk of lymphoma in DH [4] later, in a larger study, documented that the overall risk of mortality in DH was lower than in the general population [6], although the risk of non-Hodgkin's lymphoma was increased with a standardized incidence ratio of 6.0. In this study, one of seven lymphomas in DH was an enteropathy-associated T-cell lymphoma, associated with inadequate dietary compliance [6], supporting the earlier documentation that a gluten-free diet (GFD) reduces the risk of small bowel lymphoma in patients with DH [7].

It therefore appears that there is an increased risk of lymphoma in DH but that the overall risk is small; additionally, the lymphoma risk, particularly of bowel lymphoma, is decreased by adherence to a GFD.

Linear IgA disease also appears to have a higher-than-predicted association with lymphoproliferative malignancy although this is much less well documented [8].

Epidermolysis bullosa acquisita (EBA) is commonly linked with autoimmune diseases but has also been reported to occur in association with neoplasia (Fig. 62.17), particularly myeloma and lymphoma [9–11]. An interesting possible explanation is partial homology of a 105-kDa basement membrane antigen with a 90-kDa tumour antigen [12]. The difficulties in separating EBA from other subepidermal blistering disorders such as cicatricial pemphigoid and bullous pemphigoid have already been alluded to, and make evaluation of earlier reports uncertain.

Porphyria cutanea tarda and *variegate porphyrias* have been associated with hepatocellular carcinoma [13]. Myeloma and visceral carcinoma have also been reported [14].

Erythema multiforme is most commonly related to herpes simplex or other infections, or to medications; if it occurs in the context of neoplasia it can be difficult to prove an association. The association is certainly weak and does not warrant investigation routinely.

Fig. 62.17 Paraneoplastic epidermolysis bullosa acquisita in a patient with metastatic breast carcinoma; irregular erosions on the abdomen resulting from fragile blisters.

Indirect cutaneous markers of internal malignancy

Exposure to carcinogens [1]

Nicotine staining of the fingers is one of the commonest signs that a patient may be predisposed to bronchial carcinoma, together with other tobacco-linked neoplasia.

Fig. 62.18 Arsenical keratoses on the hand.

Radiotherapy damage to the skin may indicate that underlying tissues are at increased risk of neoplasia; this is particularly relevant for neck and thyroid carcinoma. Radiotherapy damage and/or multiple BCCs over the spine following radiotherapy for ankylosing spondylitis may indicate the patient is predisposed to leukaemia.

Arsenic-induced pigmentation, keratoses (Fig. 62.18), Bowen's disease, superficial BCCs and multiple sebaceous tumours can be linked to an increased risk of internal neoplasia (especially bronchial). The relationship between Bowen's disease of non-sun-exposed skin and an increased risk of internal neoplasia has been a long-standing controversy; a meta-analysis of published studies did not confirm a significant association [2], and if the link with arsenic is excluded, the association appears unsubstantiated [3,4]. A further study of 1147 patients found the overall incidence of internal cancers in patients with Bowen's disease to be slightly increased (115 cancers versus 103 expected, standardized incidence ratio (SIR) 1.1) but not significant [5]. However, there was an SIR of 3.2 for leukaemia in men and of 4.6 for lung cancer in men with Bowen's disease before age 60 years (the overall lung cancer SIR for both sexes and all ages was 1.3). There are various sources of potential bias in many studies of this type, and available evidence would still suggest that routine investigation for internal malignancy in patients with Bowen's disease is not justified [6].

Vinyl chloride-related acrosclerosis, acro-osteolysis and papular skin changes are variable markers of heavy industrial exposure in polyvinyl chloride manufacture. A link with angiosarcoma of the liver has been noted [7].

Immunosuppression

Patients on immunosuppressive therapy have an increased risk of internal malignancy. Some such patients have no specific cutaneous features but some may have a combination of features of their underlying disease (e.g. signs of renal failure), side effects of their treatment (e.g. hypertrichosis and gingival changes due to ciclosporin; frequent, severe or unusual infections), and other features linked with immunosuppression (e.g. sebaceous hyperplasia, viral warts, skin cancers or precursors). These issues are discussed in the section on organ transplantation (p. 62.74).

Several inherited immunodeficiency syndromes also carry an increased risk of internal neoplasia, the most important of which are discussed above.

A variety of viral, bacterial and fungal infections may occur as a result of compromised immune response as a consequence of internal malignancy, particularly in haematological malignancies or in those with a large tumour burden. Occasionally, such infection may be the presenting feature—in particular, herpes zoster occurs more severely, with higher incidence and wider dissemination, in patients with reticuloendothelial or myeloproliferative neoplasia [8]. More than 20 disseminated (chickenpox-like) lesions, or involvement of two or more dermatomes, are suggestive of immune compromise and possible underlying malignancy, although involvement of adjacent sacral dermatomes is not uncommon and does not warrant extensive investigation. Chronic herpes-virus infections may also be a feature of immunosuppression and therefore indirectly linked with neoplasia (such as Kaposi's sarcoma in AIDS).

The gastrointestinal tract

This section concentrates on bowel, hepatic and pancreatic diseases in which cutaneous associations or consequences are prominent [1–4]. Skin changes related to more general effects of gastrointestinal diseases, such as nutritional defects, are discussed in Chapter 59; oral disease is described in Chapter 69. Links between skin disorders and abdominal pain are not specifically considered, but many of the disorders in this section may cause this symptom; other causes of skin eruption with abdominal pain include disorders such as hereditary angio-oedema (Chapter 22), vasculitides (Chapter 50), porphyrias (Chapter 59), and autoinflammatory diseases (periodic fevers; see the section on bone and joint disease later). Cutaneous metastases and paraneoplastic eruptions due to gastrointestinal malignancy are discussed in the preceding section of this chapter.

Oesophagus and stomach

Bleeding from the oesophagus or stomach may be associated with skin and nail changes of iron deficiency, such as koilonychia, smooth tongue and angular cheilitis (Chapter 59). Iron deficiency is associated with dysphagia and development of a postcricoid web as in the Paterson–Brown–Kelly (Plummer–Vinson) syndrome. Skin disorders that are associated with gastrointestinal bleeding, or with polyps, are discussed later. Cutaneous metastases may occur from tumours of the oesophagus or stomach. Paraneoplastic eruptions linked to the upper gastrointestinal tract, such as tylosis with oesophageal carcinoma (Howell–Evans syndrome), acrodermatitis and nail dystrophy with upper gastrointestinal carcinoma (Bazex syndrome), or acanthosis nigricans with gastric carcinoma, are discussed earlier in this chapter.

Bullous diseases may affect the pharynx, oesophagus or stomach. Epidermolysis bullosa (EB) is of particular relevance; dystrophic EB may cause oesophageal scarring [1], with a risk of SCC, and gastric outflow is affected in junctional EB, resulting in pyloric atresia [2,3]. Several inflammatory disorders such as lichen planus may affect the mouth, pharynx or oesophagus [4,5]. Immunobullous diseases, particularly those with an IgA basement membrane zone immunoreactant, may cause mucosal blistering and erosions—examples include cicatricial pemphigoid, linear IgA disease and the IgA variant of epidermolysis bullosa acquisita. Cicatricial pemphigoid may also cause oesophageal scarring and stenosis.

Sclerodermatous processes also affect the oesophagus, in particular CREST (*c*alcinosis, *R*aynaud's phenomenon, *o*esophagus, *s*clerodactyly, *t*elangiectasia). This disorder is discussed more fully in Chapter 51. The oesophageal abnormality consists of decreased and disordered peristalsis. Scleroderma is also associated with decreased peristalsis throughout the bowel, leading to malabsorption, constipation and diverticulae. Sjögren's syndrome may also cause dysphagia, as may dermatomyositis in cases in which there is involvement of the pharyngeal musculature.

Helicobacter pylori has been implicated as an aetiological factor in some cases of urticaria, rosacea, vasculitis, Sweet's syndrome, erythema multiforme, alopecia areata, chronic itch and prurigo nodularis, and atopic and nummular dermatitis [6–8]. Although there are some individuals in whom eradication therapy coincides with resolution of a dermatosis, most larger studies in which there is adequate control for confounding factors such as age and social class have failed to demonstrate either a higher prevalence of *H. pylori* infection, higher titres on ^{13}C urea breath test, or a higher rate of response to eradication therapy in infected individuals compared with controls [9–12].

Crohn's disease (regional ileitis)

Crohn's disease is now known to be one of a group of diseases caused by mutations in the caspase recruitment domain 15 gene (*CARD15*), also termed *NOD2* [1]. Other disorders in which *CARD15* mutations are involved include several with dermatological aspects, including Muckle–Wells syndrome, IPEX (immunodysregulation, polyendocrinopathy, enteropathy, X-linked syndrome), and PAPA (pyogenic arthritis, pyoderma gangrenosum and acne).

Skin lesions are frequently seen in Crohn's disease [2–5]. These include:

- Crohn's disease occurring as direct extension from the bowel
- Cutaneous lesions of Crohn's disease at other skin sites
- Reactive lesions that are associated with Crohn's disease, but which do not have granulomatous histology
- Skin lesions related to malabsorption (Chapter 59)
- Skin lesions related to treatment: drug reactions, stoma dermatoses, etc.
- Psoriasis
- Other associated dermatoses.

Direct skin and mucosal involvement in continuity with the bowel

Cutaneous Crohn's disease may occur at sites in continuity with the bowel, such as the lip, stoma sites (see later section) or, commonly, the perineal skin including the vulva in females. Orofacial granulomatosis and the overlap with Crohn's disease is discussed in Chapter 69. The umbilicus, a site connected to the bowel by a vestigial tract, may also be involved [6]. Rarely, there may be frank enterocutaneous fistulae due to underlying Crohn's disease, sometimes with multiple lesions.

Perineal abscesses and multiple fissures and fistulae occur in about a quarter of patients ('watering-can perineum'). This is more frequent in individuals with colonic disease [7] and may affect

about 60% of patients, although symptoms may be absent. By contrast, such lesions are rare in ulcerative colitis. Anal tags, which may be oedematous or have granulomatous histology, are common.

Oral Crohn's disease is manifest as a thickened, corrugated appearance of the oral mucosa and lips. Granulomatous cheilitis may precede other features of Crohn's disease (Chapter 69).

Cutaneous Crohn's disease at other sites ('metastatic Crohn's disease')

Cutaneous Crohn's disease may also occur at sites separated from the bowel by normal tissues—a situation that is termed 'metastatic Crohn's disease', although not technically correct [8–11]. Lesions may parallel gastrointestinal disease activity, or may occur with a totally separate temporal pattern.

Lesions of cutaneous Crohn's disease may be solitary or multiple, and may have varied morphology, including intact or eroded plaques and nodules, or sinus formation. The lower legs are involved in half of the cases, with lesions sometimes mimicking erythema nodosum, but cutaneous Crohn's disease may affect the abdominal wall, groin and inframammary flexures, face and other sites. Genital involvement may be a presenting feature, affecting the perineum [11], vulva [12], scrotum or penis [4,13]. Unusual patterns include perifollicular papules [14], erysipelas-like lesions [15] and necrobiotic lesions [16]. In any of these morphological variants, there is a granulomatous histology in the dermis and subcutis. Lymphoedema, typically of the genital area, perineum or face, are also well documented and presumably related to local lymphatic obstruction by granulomatous inflammation.

Treatments for both contiguous and 'metastatic' Crohn's disease include topical and intralesional corticosteroids, agents used to treat the bowel disease (oral corticosteroids, sulphasalazine and split products such as mesalamine, immunosuppressive agents), oral metronidazole, and hyperbaric oxygen. Antitumour necrosis factor-α (anti-TNF) monoclonal antibodies, specifically infliximab and adalimumab, have been increasingly used for Crohn's disease, in which they may heal fistulae, both bowel–bowel and bowel–skin or bowel–vagina. A particular problem in such cases is being certain that infection is not playing a part in fistulation or sinuses, as this may worsen. Anti-TNF therapy is also effective for cutaneous associations, especially psoriasis and pyoderma gangrenosum but also hidradenitis suppurativa, so may have dual benefit in Crohn's disease. The benefit in ulcerative colitis is less clear. This and other cytokine treatments are discussed in [17,18]. Serum sickness-like reactions have been reported with infliximab.

Reactive dermatoses associated with Crohn's disease

These include oral aphthae, erythema nodosum and a variety of neutrophilic dermatoses. As most of the reactive processes can occur with either type of inflammatory bowel disease, but most are more commonly associated with ulcerative colitis than with Crohn's disease, they are discussed later in this section.

Other dermatoses that have been associated with Crohn's disease

Epidermolysis bullosa acquisita (EBA) has been associated with both Crohn's disease and ulcerative colitis, mainly the former [19] (see also Chapter 40 and Fig. 62.19). In most instances, Crohn's disease had been established for several years prior to development of EBA, although EBA may precede diagnosis of the bowel disease [20]. This condition may be very refractory to treatment; drugs that may improve both the bowel disease and the cutaneous lesions of EBA include corticosteroids, azathioprine and ciclosporin.

Fig. 62.19 Epidermolysis bullosa acquisita associated with a flare of inflammatory bowel disease.

Other bullous disorders that have been linked with Crohn's disease include *oral intraepidermal IgA pustulosis* [21] and *subcorneal pustular dermatosis* [22]; it has been suggested that the latter eruption was actually pustular pyoderma gangrenosum [23].

Polyarteritis nodosa (PAN) has been associated with Crohn's disease, but not specifically with ulcerative colitis [24,25]. It may be difficult to distinguish PAN from 'metastatic' Crohn's disease in patients with both disorders, as the histological features include a granulomatous component with the arteritis [26]; PAN may also resemble erythema nodosum or early pyoderma gangrenosum. The presence of livedo may suggest the diagnosis, but this can also occur due to cryoglobulinaemia. Other patterns of vasculitis associated with inflammatory bowel disease are discussed in the section on ulcerative colitis.

Psoriasis has been associated with Crohn's disease in several studies [27], and involvement of TNF in the pathogenesis of the two disorders has strengthened the view that they are linked. *Vitiligo* may also be associated.

In patients with Crohn's disease, apparently unrelated skin disorders may develop granulomas, for example hidradenitis suppurativa [28]. The presence of granulomas within predominantly neutrophilic infiltrates may cause diagnostic difficulty [29]; distinguishing between perineal sinuses of either disorder can be very difficult.

Disorders of keratinization that have been linked to Crohn's disease include *porokeratosis* [30] and *parakeratotic horns* [31].

Acrodermatitis enteropathica due to secondary zinc deficiency is a well-documented consequence of Crohn's disease [32] (Chapter 59).

Ulcerative colitis [1–4]

Skin lesions are reported in up to a third of patients with ulcerative colitis [2], although the cited frequency is usually in the region of 10–15%. As with Crohn's disease, these fall into several categories:

- Reactive lesions (a similar spectrum, but commoner in ulcerative colitis than in Crohn's disease)
- Direct involvement contiguous with the bowel (fissures and fistulae; rare)
- Skin lesions related to malabsorption (Chapter 59)
- Skin lesions related to treatment: drug reactions, stoma dermatoses, etc.
- Other associated dermatoses.

Reactive lesions associated with ulcerative colitis and Crohn's disease

A variety of non-specific eruptions may occur with either ulcerative colitis or Crohn's disease, usually paralleling the activity of inflammatory bowel disease [5]. However, all of these may occur for other reasons or in isolation. They include:

- Erythema nodosum—this occurs in about 5% of patients with ulcerative colitis (usually extensive rather than of limited extent) and in about 2% with Crohn's disease. It is the predominant pattern of reactive skin lesions in children, and in adults is most common in women. It is frequently associated with articular and other extragastrointestinal manifestations of the underlying bowel disease [6].
- Aphthous ulceration [1]—this occurs in about 5–8% of patients with ulcerative colitis and a rather smaller proportion with Crohn's disease. In some instances, the mechanism may be malabsorption, leading to iron and vitamin deficiency. Oral aphthae also occur in isolation, in association with numerous medications and in other medical disorders (including other bowel disorders, such as coeliac disease).
- Erythema multiforme [7,8]—this may occur in either disorder, usually associated with active disease (or as a side effect of treatment).
- Urticaria and angio-oedema.
- Neutrophilic dermatoses—these also occur in association with other disorders, but pyoderma gangrenosum and pyostomatitis vegetans in particular are strongly associated with inflammatory bowel disease. These disorders are discussed in more detail below.
- Vasculitis and intravascular coagulation disorders—these also occur as a consequence of inflammatory bowel disease, most commonly active ulcerative colitis, and are discussed separately below.

Neutrophilic dermatoses

Pyoderma gangrenosum [9–12]. Pyoderma gangrenosum occurs as a complication of inflammatory bowel disease, haematological disorders, inflammatory arthritides and other medical conditions [9] (it is discussed more fully in Chapter 50). It is estimated to occur in about 2–5% of patients with ulcerative colitis, this disor-

der being the single commonest cause of pyoderma gangrenosum; it is three to five times commoner in patients with ulcerative colitis than in those with Crohn's disease. The ulcerative and pustular variants in particular are associated with inflammatory bowel disease. It may also occur in other bowel diseases, such as the bowel-associated dermatosis–arthritis syndrome (see below) and diverticular disease [13], as a peristomal dermatosis [14] and in patients with hepatitis. The characteristic lesions are rapidly progressive necrotic skin ulcers with a bluish-coloured undermined border, but nodular and pustular lesions may occur, especially in early disease. Trauma is sometimes a predisposing factor. Pyoderma gangrenosum generally parallels the activity of the colitis [1–4], but may precede the diagnosis [15] or occur many years after complete removal of the diseased bowel [16]. Treatments for pyoderma gangrenosum include corticosteroids (topical, oral, intralesional), dapsone, azathioprine, ciclosporin, mycophenolate mofetil, tacrolimus (topical, oral), chlorambucil, intravenous immunoglobulin, and antitumour necrosis factor-α monoclonal antibodies such as infliximab [10,17–19].

Pyodermatitis–pyostomatitis vegetans [20,21] is a rare disorder of the oral mucosa and skin; the skin lesions were previously termed pyodermite végétante. The oral lesions consist of multiple pustules, plaques and erosions, which may have a 'snail's-track' appearance. The skin lesions are crusted papules and plaques, which coalesce into annular lesions, mainly affecting the major flexures and the scalp. There are similarities to pemphigus vegetans, but this is associated with strongly positive direct immunofluorescence of lesional skin, which is either negative or weak in pyodermatitis–pyostomatitis vegetans. Oral and skin lesions show the same histological features, having intraepidermal and superficial dermal microabscesses containing neutrophil and eosinophil polymorphs, and a more mixed, deeper dermal inflammatory infiltrate. Acanthosis, acantholysis and pseudoepitheliomatous hyperplasia occur, especially in the oral lesions. Most cases of pyodermatitis–pyostomatitis vegetans are associated with inflammatory bowel disease, usually ulcerative colitis, although the condition has also been reported with sclerosing cholangitis and in isolation. It is difficult to control; high-dose, systemic corticosteroids are the first-line therapy, but dapsone or azathioprine may be of benefit. Remission may occur following colectomy.

Acute febrile neutrophilic dermatosis (Sweet's syndrome). This has been associated with inflammatory bowel disease, especially ulcerative colitis [22–25]. It may coexist with pyoderma gangrenosum [22,24], and may also occur after colectomy in patients with inflammatory bowel disease. It is discussed more fully in Chapter 50. Treatment options include corticosteroids, dapsone, non-steroidal anti-inflammatory drugs, colchicine, tetracyclines, ciclosporin and other immunosuppressive agents and, in the context of inflammatory bowel disease, metronidazole [25]. A neutrophilic colitis in a patient with Sweet's syndrome and acute myeloid leukaemia, and with previous Crohn's disease, was felt to be histologically distinct from Crohn's disease or ulcerative colitis [26].

Vesicopustular eruption and other neutrophilic dermatoses. A vesicopustular eruption may occur in ulcerative colitis [1,2,27,28], or less commonly in Crohn's disease [29]. The lesions consist of a dense neutrophilic infiltrate similar to that of pyoderma gangrenosum or Sweet's syndrome, and may be a variation of these [2,9]. In practice, many of the group of neutrophilic dermatoses may overlap, coexist or evolve from smaller papular or pustular lesions. Morphologically similar lesions in the bowel-associated dermatosis–arthritis syndrome may have vasculitic histology; features of this syndrome may also occur in patients with inflammatory bowel disease [30]. Treatment is similar to that of the other neutrophilic dermatoses.

Erythema elevatum diutinum has been reported with both Crohn's disease and with ulcerative colitis [31,32], as has oral intraepidermal IgA pustulosis [33,34].

An important recent issue in the field of neutrophilic dermatoses has been a general view that the spectrum of conditions in this category is greater than previously thought. Some of the internal manifestations of neutrophilic dermatoses may cause diagnostic difficulties in patients with Crohn's disease, particularly features such as mesenteric lymphadenitis or aseptic abscesses [35,36]. Most such abscesses are internal but vulval and other cutaneous lesions have occurred.

Vasculitis and intravascular coagulation disorders

Vasculitis and purpura [1,2,37–39] may occur in either ulcerative colitis or Crohn's disease, most commonly in ulcerative colitis. The clinical picture is of a leukocytoclastic vasculitis with palpable purpura, typically affecting the lower legs and sometimes causing nodules or ulceration. Pustular lesions may have vasculitic histology. Joint pain and malaise may be prominent. Polyarteritis nodosa in Crohn's disease is discussed above.

Antineutrophil cytoplasm antibodies (ANCA) are present in 60–70% of patients with ulcerative colitis and 5–10% with Crohn's disease [40].

Cutaneous gangrene and focal thrombosis [41–43] is a rare complication. Patients with ulcerative colitis have significant coagulation defects; in one large early series, this was sufficient to complicate the clinical course in more than 1% of patients [41]. Thrombosis of internal vessels affects younger patients, unusual vascular sites, is associated with active inflammatory Crohn's disease but apparently quiescent ulcerative colitis, and has significant mortality of 5–10%. Abnormalities underlying this tendency are unclear—some reports implicate thrombocythaemia, elevated levels of fibrinogen, factor VIII and factor V, and decreased levels of antithrombin III whilst others have excluded common thrombophilic states such as factor V Leiden, deficiencies of protein C, protein S or antithrombin III, or presence of anticardiolipin antibodies. Microvascular thrombosis of the skin may result in cutaneous gangrene. High-dose systemic steroids have no effect on the thrombotic complications, which should be treated with anticoagulant therapy. Similar features have been reported due to cryoglobulinaemia associated with inflammatory bowel disease.

Other cutaneous disorders associated with ulcerative colitis

Linear IgA disease. Linear IgA disease may be relatively common in patients with ulcerative colitis, which usually precedes the dermatosis by several years [44]. Linear IgA disease may resolve after

colectomy has been performed for ulcerative colitis [45]. Whether these patients actually have ulcerative colitis or a specific colitis associated with linear IgA disease is uncertain; two recent patients with preceding bowel symptoms developed oral ulceration and were found to have linear IgA deposition in mouth and colon. The bowel histology was that of a lymphocytic colitis or Crohn's disease [46]. Linear IgA disease has also been associated with Crohn's disease [47].

Epidermolysis bullosa acquisita, discussed above in relation to Crohn's disease, also occurs in some patients with ulcerative colitis; an erythema gyratum repens-like pattern has been described in such a case [48].

Hermansky–Pudlak syndrome (MIM #203300) (Chapter 39). This may be associated with an inflammatory colitis that resembles ulcerative colitis but has a granulomatous infiltrate histologically; this appears to be distinct from either ulcerative colitis or Crohn's disease [1,49].

Ulcerative colitis has been linked with a variety of autoimmune disorders and with sarcoidosis [50,51], although the strength of this association is not clear. Finger clubbing may be associated with inflammatory bowel disease, particularly ulcerative colitis [52], as well as with several other gastrointestinal diseases, including tumours, chronic infections, protein-losing enteropathy and laxative abuse [53]. Acne fulminans has also been reported in association with inflammatory bowel disease [54].

Collagenous colitis

This, with lymphocytic colitis, is a type of microscopic colitis characterized clinically by diarrhoea and histologically by a thickened subepithelial collagen layer. Cases have been described that have evolved to, or from, ulcerative colitis; it has also been reported to have evolved to Crohn's disease and, of dermatological relevance, to have coexisted with systemic sclerosis and to have possibly been triggered by isotretinoin. There are now several reports of associated pyoderma gangrenosum [1,2], including peristomal and vulval involvement; lymphocytic venulitis of adjacent bowel, but not of the skin, has also been reported.

Bowel-associated dermatosis–arthritis syndrome [1–6]

Synonyms
- Blind loop syndrome
- Bowel bypass syndrome
- Intestinal bypass arthritis–dermatitis syndrome

This is a serum sickness-like illness which is related to bacterial overgrowth in the bowel. Bacterial antigens in the form of peptidoglycans are probably released from the intestinal flora, particularly *Escherichia coli* [2]. Circulating immune complexes can be demonstrated in most patients actively developing skin lesions [3].

It was originally linked with bowel bypass surgery for obesity [1–4], which created a 'blind loop' of bowel. Most cases now are related to other causes of a blind loop, or simply to areas of stasis, and the condition has attracted the name 'bowel bypass syndrome without bowel bypass' [6]. Causes include achalasia [7], strictures and inflammatory bowel disease [5], as well as surgical procedures that create a defunctioning segment of bowel [8]. Pyoderma gangrenosum secondary to diverticular disease [9] is probably in the same spectrum of disease.

The characteristic skin lesions are crops of erythematous papules, sterile vesicopustules similar to those associated with ulcerative colitis, or overtly indurated or necrotic vasculitic lesions. Erythema nodosum-like and panniculitis-like lesions may occur. Associated constitutional symptoms include fever, polyarthritis, tenosynovitis, myalgia and nephritis. Raynaud's phenomenon has been described, as has Sweet's syndrome. The joint involvement is variable and similar to the type of arthritis recognized in regional ileitis and ulcerative colitis. The bypass enteropathy may manifest itself as acute massive abdominal distension resembling intestinal obstruction, but milder and chronic forms have been described.

Histological examination shows dilated dermal venules and capillaries with a marked perivascular neutrophilic infiltrate. This is most pronounced in vesicopustular lesions, in which the resulting dermal oedema may lead to dermal–epidermal separation. Epidermal necrosis may be found. Treatments include oral corticosteroids, antibiotics such as metronidazole, a variety of immunosuppressive medications and restorative surgery.

Skin complications of stomas [1,2]

Dermatoses associated with a stoma include those related to its function (irritation from faecal leakage, infections, contact dermatitis), Koebner reaction of existing or new dermatoses (psoriasis, lichen sclerosus) and disorders related to bowel disease (peristomal pyoderma gangrenosum, cutaneous Crohn's disease) [1,2].

The skin around a gastrointestinal or urinary tract stoma is liable to irritation from the effluent, the wafer and pouch, and substances applied as barriers, adhesives and cleaners. The collection pouch is either attached to a wafer or directly to the skin; a barrier/sealant may be applied before adhesion. The sealant is either a gelatine–pectin formulation, karaya (a hygroscopic partially acetylated polysaccharide), or a flexible plastic, applied in liquid form. The adhesives are usually acrylic, silicone or latex. Ideally, the wafer should adhere perfectly to the skin, with a rim of skin 1–2 mm between the stoma and the appliance. If this rim is too narrow, chafing against the stomal mucosa will occur, and if it is too wide there is a higher risk of dermatitis. Any surface

irregularities beneath the attachment surface will allow effluent to track beneath. This may occur if there are changes in body weight, or if there is incorrect or unavoidable siting of the stoma in body folds or adjacent to scars.

Enzyme-degradation dermatitis, caused by proteolytic enzymes in an alkaline fluid medium, is commonest with ileostomies [3], and presents with maceration, erythema and erosions. Because of the tracking of the fluid downwards, the pattern of dermatitis depends on the patient's predominant position. Diversion of the urinary stream also causes problems because of stagnation and ammonia production.

Treatment. Most peristomal skin disease is irritant and is treated by judicious use of topical corticosteroids together with soothing and barrier preparations. Infections such as *Candida* or pyogenic bacterial infection should be treated with an appropriate specific antimicrobial agent. Many types of protective wafer and protective powders are available. These contain gelatine, pectin, polyisobutylene and sodium carboxy-methylcellulose. They adhere to moist skin and allow healing to take place if they are left for about 3 days. Creases and crevices around a stoma or fistula can be filled using pastes, which generally consist of gelatine, sodium carboxy-methylcellulose, triacetin, fixin and ethanol. They are applied in layers, moulded into the creases with a moist finger and built up to the required level. If the drainage application can then remain in position for several days, this will usually allow the damaged skin to heal. Other topical treatments for irritant peristomal dermatoses include soothing compresses (for example, saline or 1:40 aluminium acetate), karaya and sucralfate [3]. In the case of very painful conditions such as pyoderma gangrenosum, instillation of a suitable topical local anaesthetic under the appliance 40–60 min before changing it can make a great difference to patient comfort.

Allergic contact dermatitis can occur to the adhesive [4], the barrier or any part of the appliance. Epoxy resins have been a problem in pouch materials, even though they are often present in small amounts only [5]. It has been suggested that patch testing should be carried out on the symmetrically opposite part of the abdomen [1]. It is usually possible to provide substitutes for materials causing the allergic reaction.

Urostomy encrustations and acanthotic chronic papillomatous dermatitis (pseudoverrucous lesions). The encrustations are crystals of phosphates and sometimes uric acid that form on the stoma and can damage the mucosa and even the bag. Pseudoverrucous lesions are grey or reddish-brown, warty papules at the mucocutaneous junction. They are more common around urostomies than around gastrointestinal stomas, occurring in about 20% of urostomy patients. There may be a non-specific erythematous and erosive change [6]. Stagnation and urinary infection are important in the aetiology of both encrustations and pseudoverrucous lesions and, as well as treating infection, acidification of the urine is helpful—for example, with cranberry juice or vitamin C in large doses [1]. Peristomal viral warts are a particular differential-diagnostic problem.

Parastomal fistulae and ulcers [7]. These are particularly associated with ileostomy for Crohn's disease and may represent or herald recurrent disease. Fistulae are often preceded by abscesses, and may be multiple. The parastomal ulcer is defined as a defect in the surface 1.5 cm or more across. It is typically accompanied by severe burning pain and erythema, and often associated with induration and erythema of the stoma [8]. Low-grade infection should be considered as a possible cause in parastomal ulcers that occur early after formation of the stoma, but in late-appearing ulcers, recurrent Crohn's disease is probably the most important underlying cause. Treatment of both parastomal ulcers and fistulae is usually surgical.

Dermatoses. Psoriasis and pemphigus have been described as a result of the Koebner reaction around 'ostomies' [9], and pyoderma gangrenosum can localize to the peristomal skin after colectomy for inflammatory bowel disease [10,11], and much less commonly in relation to urostomies. A papular, erythematous condition similar to granuloma inguinale infantum has been described following intensive use of a potent fluorinated steroid around a colostomy site [12].

Neoplasms. Basal cell carcinoma has been described as a long-term complication of colostomy [13]. Metastatic carcinoma at the stoma site, sometimes invading the surrounding skin, has been reported following ureterosigmoidostomy [14] and in patients who have had colectomy for ulcerative colitis [15–18].

Coeliac disease [1]

Coeliac disease usually presents with malabsorption and diarrhoea. The pathogenesis is discussed in detail elsewhere [1,2]; a digestion-resistant peptide in gliadin (mer-33) may be the initiator of the disease [3].

There are associations with numerous other autoimmune diseases, notably type 1 diabetes and thyroid disease [1], and strong HLA associations; 95% of patients have the HLA-DQ(α1*501,β1*02) heterodimer (HLA-DQ2) and almost all the remainder have HLA DQ8. A significant increase in the frequency of coeliac disease in patients with inflammatory bowel disease has been suggested recently, and it has been reported following interferon treatment for hepatitis C and other disorders [4].

Diagnosis of coeliac disease can be made by serological tests for IgA antiendomysial antibodies (sensitivity is 85–98% and specificity 97–100%) or IgA tissue transglutaminase (sensitivity 91–95% and negative predictive value nearly 100%) [1,2]. Tissue transglutaminase acts as an autoantigen—it deaminates glutamine residues in gliadin to create negatively charged glutamic acid residues that activate T cells. IgA antigliadin antibodies are less specific but are useful in younger children. Antigliadin, antiendomysial and tissue transglutaminase antibody levels all become undetectable after a period of 3–6 months on a strict gluten-free diet (GFD). Other tests include documentation of malabsorption and small-bowel biopsy.

Dermatological features of coeliac disease include cutaneous features of malabsorption of nutrients (Chapter 59), and features of associated autoimmune conditions. Darkening of previously white hair has been reported after starting GFD to treat coeliac disease [5]. Other documented dermatological features include follicular keratosis and alopecia. The most important dermatological association is with dermatitis herpetiformis (DH) which occurs in 25% of subjects (Chapter 40); the enteropathy of DH seems to be the same as that of coeliac disease, and some degree of abnormality of small-bowel mucosa is present, even if minimal and asymptomatic, in all patients with DH. However, it is unclear why DH only occurs in some subjects, often with mild enteropathy; there may be factors that alter disease expression. A recent study showed a significant linkage of coeliac disease chromosome 19p13, but investigation of a candidate gene, myosin IXB, showed no association with coeliac disease but a weak association with DH. The precise genetic aspects of coeliac disease and DH may therefore not be identical [6]. There is an association between DH and internal malignancies, the most important being lymphoma of the small bowel (enteropathy-associated lymphoma) [7,8], as in coeliac disease. GFD exerts a protective effect [8].

Improvement of psoriasis in a small number of patients who were treated with GFD suggested the possibility that coeliac disease and psoriasis might be associated. Patients with psoriasis have a high frequency of positive IgA antigliadin antibodies, which correlate with lymphocytic infiltration of the duodenal mucosa, but do not have an increased incidence of coeliac disease, and there is no increase in either antireticulin or antiendomysial antibodies [9,10].

Vasculitis, sometimes with cryoglobulinaemia, may occur in association with coeliac disease [11].

Whipple's disease

This disorder, another cause of malabsorption and diarrhoea, may be accompanied by skin manifestations. Diffuse pigmentation is frequent, and may resemble Addison's disease, but buccal pigmentation is not a feature. Subcutaneous nodules may occur, resembling rheumatoid nodules or sarcoidosis [1–3]. The disorder usually presents with arthralgia and general malaise; abdominal features (pain, diarrhoea and malabsorption leading to weight loss) occur in most individuals with more advanced disease. Cardiac, pleural, ophthalmological or neurological symptoms also occur, and there may be generalized lymphadenopathy. The diagnosis has historically been confirmed by demonstration of periodic acid–Schiff-positive particles in biopsies from infected tissue (usually bowel mucosa). The diagnosis can now be made using polymerase chain reaction (PCR) amplification of sequences from the causative organism, *Tropheryma whippelii*, in infected tissue [4,5] and the organism has been cultured [6].

Skin disorders associated with gastrointestinal bleeding

These are listed in Table 62.12. Most are discussed elsewhere in this section, or in other chapters. In addition, gastrointestinal tumours may metastasize to skin (see earlier in this chapter), some

Table 62.12 Skin lesions associated with gastrointestinal disorders that may present with bleeding.

Disease	Gastrointestinal lesion	Skin symptom
Vascular defects and inherited		
Osler–Weber–Rendu disease (Chapter 47)	Telangiectasia	Telangiectasia
Blue rubber bleb naevus (Chapter 18)	Haemangiomas	Haemangiomas
Pseudoxanthoma elasticum (Chapter 45)	Involvement of visceral arteries	Yellowish papules and plaques
Ehlers–Danlos syndrome (type IV) (Chapter 45)	Fragility of visceral arteries	Hyperelasticity of skin and joints
Polyposis (see text in this chapter)		
Neurofibromatosis (von Recklinghausen)	Neurofibromas	Café-au-lait spots, neurofibromas
Cronkhite–Canada syndrome	Gastrointestinal polyposis	Diffuse hyperpigmentation, alopecia, nail defects
Gardner's syndrome	Polyposis of colon (cancer)	Lipomas, epidermoid cysts
Peutz–Jeghers syndrome	Polyposis, especially small intestine	Hyperpigmentation on lips, circumoral area and fingertips
Cowden's disease	Polyposis	Papules, lipomas, angiomas
Inflammatory bowel disease		
Crohn's disease, ulcerative colitis	Inflammatory changes of the intestinal wall	Erythema nodosum Aphthous stomatitis Pyoderma gangrenosum, other neutrophilic dermatoses Necrotizing vasculitis Epidermolysis bullosa acquisita Erythema multiforme
Vasculitis and systemic disease		
Henoch–Schönlein purpura and other vasculitides (Chapter 50)	Mesenteric vasculitis, gastric ulcers (polyarteritis nodosa)	Purpura, livedo, nodules, necrosis
Cholesterol emboli (Chapter 49)	Intestinal arterial occlusion	Vasculitis, necrosis, livedo
Degos' disease (Chapter 49)	Intestinal perforation	White atrophic lesions
Amyloidosis (Chapter 59)	Vascular fragility	Purpuric lesions
Neoplasia		
Primary gastrointestinal cancers	Neoplasm	Metastases, paraneoplastic eruptions, features of polyposis syndromes
Kaposi's sarcoma (Chapter 35)	Kaposi's sarcoma of bowel	Kaposi's sarcoma of skin

tumours may affect the skin and gastrointestinal tract (e.g. Kaposi's sarcoma), and skin tumours may rarely metastasize to the gastrointestinal tract (e.g. melanoma).

Several patterns of cutaneous vasculitis or collagen vascular disease may be associated with mesenteric vasculitis and/or thrombosis, leading to bleeding or ulceration. Various radiological signs of mesenteric vasculitis seen on computed tomography (CT) have been reviewed in relation to systemic lupus erythematosus, and include a palisade and comb-like pattern of vessels, peritoneal enhancement of ascitic fluid, thickening of the bowel wall, and a 'double-halo' or 'target sign' [1,2].

Intestinal polyposis [1,2]

A number of, usually inherited, gastrointestinal polyposis disorders also have cutaneous features. The most important are:

- Peutz–Jeghers syndrome
- Gardner's syndrome
- Cowden's disease (multiple hamartoma and neoplasia syndrome, p. 62.25)
- Bannayan–Riley–Ruvalcaba syndrome (Ruvalcaba–Myhre–Smith syndrome, Bannayan–Zonana syndrome)
- Cronkhite–Canada syndrome (non-inherited)
- Birt–Hogg–Dubé syndrome
- Naevoid basal cell carcinoma syndrome (p. 62.21) [3]
- Neurofibromatosis (Chapter 15).

Additionally, ganglioneuromas of the gastrointestinal tract and oral mucosal neuromas may be associated with Hirschsprung's disease, and colonic diverticula as features of MEN type 2B syndrome.

Peutz–Jeghers syndrome (MIM #175200) [4]. This is an autosomal-dominant or sporadic condition due to mutations in the serine/threonine kinase *STK11* (*LKB1*) gene on chromosome 19p13.3 [5–7]. This appears to be a tumour suppressor gene—loss of heterozygosity at this site has been shown to be associated with malignant transformation of polyps. Polyps occur mainly in the small intestine, but also in the stomach and colon. The usual presentation is with intussusception or melaena. Polyps can also be found in the genitourinary and respiratory tracts, and occasionally in the gallbladder.

The cutaneous feature is lentiginosis, with a predominantly perioral, periorbital and intraoral distribution; perianal and acral lentiginosis (occasionally causing longitudinal melanonychia) also occurs. The pigmented macules appear in early childhood and may fade with increasing age, although the mucosal lesions persist [4]. The pigmented lip lesions may be confused with those of Laugier–Hunziker syndrome (a benign, non-polyposis, disorder with onset in later years).

Cancers may occur in the gastrointestinal tract, but the frequency is relatively low, as the polyps are hamartomatous; additional mutations of the β-catenin gene or the p53 gene appear to be needed to convert them into adenomas or carcinomas. However, there is an increased risk of non-gastrointestinal cancers, with an overall risk estimated at 18-fold greater than that of the general population [8]. Other associated neoplasias include pancreatic adenocarcinoma (100-fold more common than expected [8]), and less commonly breast and pulmonary adenocarcinoma. Multiple myeloma may occur more frequently than expected. Precocious puberty may occur in either sex, and a variety of genital cancers have been associated with Peutz–Jeghers syndrome, including Sertoli cell tumours; there is a particular link with multifocal sex-cord tumours and an aggressive variant of adenocarcinoma of the cervix [1]. Finger clubbing may occur in conjunction with the ovarian sex-cord tumours.

Gardner's syndrome (MIM +175100) [6,7,9]. This condition is allelic with adenomatous polyposis of the colon. Both are caused by mutations in the *APC* gene, which has an important role as part of a signalling pathway involving β-catenin and E-cadherin, thereby influencing cell division, migration, adhesion and apoptosis; the wild-type gene also antagonizes a tumour suppressor gene *WNT1*. There is very high penetrance but marked variation in expression.

The syndrome is the association of adenomatous colonic polyposis with large numbers of subcutaneous fibromas, epidermoid cysts (both mainly on the upper trunk and head), desmoid tumours (mainly abdominal wall), retinal pigmentary changes, osteomas (especially of the facial bones), odontomas and other dental abnormalities, including supernumerary teeth [9]. The onset of cysts is generally prepubertal. Multiple pilomatricomas, or pilomatricoma-like areas within the epidermoid cysts, have also been recorded. The occurrence of fibromas may involve a general tendency to fibromatosis, including desmoid tumours, mesenteric and retroperitoneal fibrosis. Nuchal-type fibromas [10], especially if multiple or at unusual sites [11], may be an early sign of the syndrome. Leiomyomas, lipomas, neurofibromas and BCCs may also occur [9].

It is an autosomal dominant condition with variable expression, and is caused by mutations in the same APC gene on chromosome 5q21 that also causes familial polyposis coli without associated cutaneous abnormalities [1,6,7]. The phenotype is not simply determined by different mutations of the gene, as exactly the same mutation may on occasions give rise to a phenotype with or without skin lesions—suggesting that other genes influence the disease expression. There are also subsets of this condition in which skin lesions may be limited in type; for example, epidermoid cysts and colonic polyposis without the other features has been termed Oldfield's syndrome [12]. Skin lesions are usually the earliest manifestation of this group of diseases, although the retinal pigmented lesions (hypertrophy of the pigment epithelium) occur in 90% and are probably congenital. The latter are dark, roughly oval-shaped lesions, at the periphery of the retina; they are generally multiple, bilateral, and also occur in first-degree relatives [13].

The bowel polyps are premalignant, and virtually all untreated cases will eventually develop colonic cancer, even in childhood occasionally, so regular colonoscopy and early colectomy is advised for affected individuals. The colon and rectum are the main cancer sites, but gastric and small-bowel polyps may occur. There is also an increased incidence of other neoplasia, which may be gastrointestinal (especially duodenal), bony (osteosarcoma and chondrosarcoma), hepatic (hepatoblastoma), neurological (medulloblastoma), endocrine (thyroid and adrenal) or soft tissue (liposarcoma) [8]. The diagnosis is usually suspected from the family history, can be supported by funduscopy and dental radiological studies and is confirmed by genetic testing.

Cowden's disease (multiple hamartoma and neoplasia syndrome; MIM #158350) [1,2,14–17]. Gastrointestinal polyposis and less commonly malignant change occur. However, the main neoplastic condition in Cowden's disease is breast cancer, and numerous other sites of cancer may be associated; this condition is therefore discussed in more detail in the section on genodermatoses associated with neoplasia (p. 62.25). A Cowden-like syndrome has also been reported in which the mutation is in the *BMPR1A* gene rather than in *PTEN1* as in Cowden's syndrome.

Bannayan–Riley–Ruvalcaba syndrome (Ruvalcaba–Myhre–Smith syndrome; Bannayan–Zonana syndrome, MIM #153480). This multiply named syndrome comprises gastrointestinal polyposis with vascular malformations, lipomas, penile café-au-lait spots, macrocephaly and thyroid disease. There is considerable overlap with Cowden's disease; both conditions involve mutations in *PTEN1* [18,19], and it has been suggested that they may be best grouped together as the *PTEN* hamartoma tumour syndrome.

Birt–Hogg–Dubé syndrome (Hornstein–Knickenberg syndrome; MIM #135150) [20–22]. These two conditions probably represent the same entity, in which there is autosomal-dominant inheritance. The gene locus is on chromosome 17p11.2, coding a presumed tumour suppressor 64-kDa protein, folliculin. Birt–Hogg–Dubé syndrome consists of multiple fibrofolliculomas, trichodiscomas and acrochordons; several cases have also had intestinal polyposis. Hornstein–Knickenberg syndrome is the association of perifollicular fibromas with intestinal polyposis. Lipomas (which may be large), angiolipomas, oral fibromas, parathyroid adenomas, renal tumours (especially oncocytomas), lung cysts and flecked choroidoretinopathy have also been linked with these conditions. Individual cases with meningioma and neurothekeoma have also been described. The odds ratio of renal tumours has been calculated at 6.9, and of pneumothorax (due to the lung cysts) at 50.3 [23].

Cronkhite–Canada syndrome (MIM 175500) [24–26]. This rare syndrome is characterized by skin pigmentation, alopecia,

nail-plate defects and polyposis of the gastrointestinal tract, from oesophagus to anus. The cause is unknown, and only sporadic cases have been reported. Affected patients are middle-aged or elderly, with a male/female incidence ratio of 3:2.

Chronic diarrhoea due to protein-losing enteropathy associated with the intestinal polyposis is the usual presenting feature, leading to hypoalbuminaemia, hypokalaemia and hypocalcaemia. There is diffuse macular pigmentation of the skin (but not intraorally) with accentuation over the face, neck and extremities; histologically, there is an increased number of melanin granules in keratinocytes and an increased number of melanosomes in melanocytes, with marked hyperkeratosis and a perivascular inflammatory infiltrate in the dermis. The palms and volar aspects of the fingers are also involved. The scalp hair becomes thin and sparse, initially resembling alopecia areata; later, total loss of hair occurs. All fingernails and toenails are dystrophic, undergoing onycholysis, onychoschizia and onychomadesis with a peculiar, triangular, residual nail plate. The course is usually slowly progressive; therapy is symptomatic and non-specific.

Acrochordons (fibroepithelial polyps, 'skin tags'). Several studies have suggested a link between acrochordons and colonic polyposis [1,2]. However, most of these studies were either small or examined only a population who were being investigated for bowel disease. A meta-analysis that divided patients into those with colonic symptoms and those who were asymptomatic demonstrated that the association was only sustained in the former group, and that this was therefore an artefact of patient selection [27].

Liver disease

Hepatobiliary diseases are frequently associated with abnormalities of the skin, nails and hair. However, most are non-specific, as they may be present in other diseases and absent even in patients with advanced liver dysfunction—jaundice, for example, may occur due to haemolysis rather than due to liver damage. Additionally, many diseases may share the same cutaneous features (for example, most causes of cirrhosis have a commonality of clinical signs), and there is no clear correlation between the degree of the skin changes and the severity of liver dysfunction. However, there may be constellations of features that suggest specific diagnoses (e.g. pigmentation, jaundice and xanthomas in primary biliary cirrhosis). The overall picture of the patient may therefore be as useful as the presence of particular cutaneous signs.

This section will discuss some of the main groups of hepatobiliary disease, followed by some of the more important symptoms and signs.

Hepatitis and acute liver disease

Acute hepatic damage is most often due to viral hepatitis, alcohol or other drugs. Cutaneous features may be absent, or there may be jaundice. Other features may occur, depending on the cause. Most of the cutaneous features of alcohol excess are related to chronic abuse and are considered later; flushing and, uncommonly, urticaria may occur as short-term effects. This section considers the dermatological associations of infective hepatitis.

Hepatitis A virus infection is usually asymptomatic and transient. Dermatological features, if present, are jaundice, urticaria (less than 2%) and exanthema [1]. Chronic liver disease is not a feature, but a relapsing variant has been described in which itch, purpura and urticarial lesions occur [2]. Histology in such cases demonstrates a small-vessel vasculitis. More severe vasculitis or panniculitis is rare.

Hepatitis B virus (HBV) infection [1,3–5] is of major relevance to health-care workers, as it may be transmitted parenterally. It is also transmitted sexually, and HBV infection may be associated with other sexually transmitted diseases. HBV screening and vaccination are recommended for all health-care workers; routine HBV screening may be recommended for patients attending genitourinary medicine clinics, but at present is usually targeted to high-risk groups (human immunodeficiency virus (HIV)-positive individuals and parenteral drug abusers). Vaccination is not without dermatological side effects—provocation of granuloma annulare, lichen planus, Gianotti–Crosti syndrome, urticaria and contact reactions to excipients have all been reported [6–9].

Dermatological features of acute HBV infection include:

- Urticaria, non-specific erythema or a serum sickness-like picture (generalized malaise, fever and arthralgia)—this occurs in 20–30% of patients with hepatitis [3]. Angio-oedema, erythema multiforme or erythema nodosum-like lesions may occur. Circulating immune complexes are probably involved [10], and skin biopsy shows small vessel vasculitis with positive direct immunofluorescence for IgG, IgM, complement C3 and hepatitis B surface antigen (HB_sAg). This eruption may precede other features of infection, or may occur as recurrent urticaria after infection.
- Gianotti–Crosti syndrome (papular acrodermatitis of childhood, papulovesicular acrolocated syndrome)—this eruption was originally linked with HBV infection, although accumulated knowledge documents that it is a feature of numerous viral infections. Lesions consist of small, umbilicated papules, often affecting the knees, buttocks, cheeks and extremities; the lesions usually last about 6–8 weeks and are associated with non-specific malaise in the early phase.
- Polyarteritis nodosa (PAN)—about 20% of patients with PAN may have positive HBV serology, but the frequency has decreased considerably over the last 20 years, some units that previously expected HBV positivity in 30–50% of cases only finding this in less than 5% now. PAN is discussed in Chapter 50. In relation to the link with hepatitis, it is of interest that cases have been reported after vaccination. Additionally, cases are described in which PAN has resolved after treatment of the HBV infection with lamivudine (and interferon in one case), although the patients concerned had also received corticosteroids or other immunosuppressive therapy. Hepatitis viruses do not seem to provoke larger vessel vasculitides, and one study of patients with Behçet's disease demonstrated a lower frequency of antibodies to HBV than in controls.
- Cryoglobulinaemic vasculitis—about 15% of patients with HBV have detectable cryoglobulins, although most have no symptoms. The association is more important in hepatitis C.
- Other skin lesions—pyoderma gangrenosum, lichen planus and dermatomyositis have been reported with HBV infection. However, at least in the case of lichen planus, this may reflect high geographical prevalence rather than being a true association.

Hepatitis C virus (HCV) infection is usually transmitted parenterally. Acute HCV infection is usually only mildly symptomatic; chronic hepatitis occurs in about 75%, but progression varies considerably [11,12]. Its importance in dermatology is increasingly recognized; dermatological features [13–20] include mixed cryoglobulinaemia, PAN, acral necrolytic erythema, red fingers syndrome, porphyria cutanea tarda, pruritus, lichen planus, features of chronic liver disease in some cases, and various treatment-related eruptions. Some of these warrant more detailed discussion:

- Mixed cryoglobulinaemia, usually type II (polyclonal IgG and monoclonal IgM rheumatoid factor) and less commonly type III (polyclonal IgG and polyclonal IgM rheumatoid factor) is strongly linked with HCV infection; 70%–90% of type II cryoglobulinaemia is HCV-associated. Features include small vessel vasculitis, livedo reticularis, acrocyanosis, arthralgia, glomerulonephritis, peripheral neuropathy, hepatosplenomegaly and hypocomplementaemia [17,18]. Other patterns of vasculitis may also occur. A high frequency of autoimmune thyroid disorders and antibody tests has been reported in patients with HCV-related mixed cryoglobulinaemia. Treatment is discussed in detail in references [11,12].
- Necrolytic acral erythema is a relatively recently described and apparently specific, if rare, feature of acute HCV infection [19–21]. Well demarcated, acral (mainly hands and feet but can affect forearms, knees, lower legs), dusky discoloration with peripheral blister formation progresses to form keratotic erythrokeratoderma-like chronic inflammation. Histology is that of a necrolytic process but the distribution and laboratory tests (positive HCV, normal glucagon) confirm the diagnosis. The relationship to zinc deficiency has been debated—typically, zinc deficiency has been excluded by the lack of periorificial rash and by normal serum zinc levels. However, some cases improve with empirical administration of zinc supplements, including two treated with zinc alone—one of these had a baseline zinc level that was only just in the normal range [21], but the other had frank deficiency and improvement in the necrolytic acral erythema correlated with restoration of serum zinc levels [22]. More commonly, treatment has usually been with interferon, usually combined with ribavirin [23].
- Red fingers syndrome—an earlier description of red fingers syndrome in patients with HIV and HCV infection [24] may have represented the same entity, and was felt to be due to the HCV infection, although skin histology (only obtained in one of nine cases) just showed capillary dilatation.
- PAN—in patients with 'classic' PAN in whom hepatitis virus is of relevance, the association is usually with HBV rather than HCV infection, but preceding HCV infection has been reported in up to 30% of patients with the cutaneous variant of PAN [25]. Hypocomplementaemia seems to be more common in patients with cutaneous PAN who also have HCV infection, but the numbers of patients studied is small.
- Porphyria cutanea tarda (PCT)—the most important risk factors for PCT are alcoholic liver disease and hereditary

haemochromatosis (see later). However, in some countries where there is a low prevalence of the gene mutations that cause haemochromatosis, chronic HCV infection may assume greater importance in the aetiology of PCT; the prevalence of positive HCV serology in PCT varies from about 10% to 90%, depending on geography [26]. HCV has also been linked to variegate porphyria. A case–control study in the USA found that 16 of 17 patients with PCT were HCV-positive (94%), compared with 0.17% of nearly 150 000 volunteer blood donors (although these may not be fully representative of the general population) [26]. HCV is therefore best viewed as an important independent risk factor in development of PCT [27,28]. Overall, PCT appears to be uncommon as a manifestation of HCV positivity. A large study of patients with HCV or HIV infection, or both, only found one of 177 patients to have a PCT porphyrin excretion pattern and did not support a direct role of HCV in provoking PCT. However, the mean coproporphyrin level was significantly raised in HCV-positive patients and especially in those who were also HIV-positive [29].

- Autoimmune disorders. There are associations between HCV infection and lichen planus, autoimmune thrombocytopenic purpura, Behçet's disease, vitiligo and a Sjögren's syndrome-like sialadenitis. However, as with HBV, the association with lichen planus is questionable as there is marked geographical variation; in an area of low HCV prevalence, no association could be demonstrated [30].
- Other dermatological symptoms. Pruritus may be a presenting symptom of HCV infection, and persistent itch may occur [16]. Urticaria, erythema multiforme, erythema nodosum and papuloerythroderma [31] have been reported.
- Treatment related dermatoses—interferon and antiviral agents have many potential side effects, including urticaria and exanthematous reactions. Discoid eczema and Meyerson's phenomenon (halo eczema around naevi) have been reported. Potentially more severe or less apparent reactions include a thrombotic microangiopathy reported due to pegylated-interferon-α-2b [32], and sarcoidosis (which may self-resolve, or may be treated with judicious oral corticocosteroid) associated with use of pegylated-interferon-α plus ribavirin [33].

Hepatitis D causes cutaneous features similar to those of HBV. *Hepatitis E* is generally mild, but may cause disseminated intravascular coagulation [1]. *Hepatitis F* is disputed, and *hepatitis G* is usually transmitted parenterally.

Cirrhosis of the liver

Assessing the degree of liver disease is not the remit of dermatologists, but measurement of hepatic fibrosis warrants discussion as this has importance with regard to monitoring of methotrexate therapy (see 'Drugs and the liver' below, and Chapters 20 and 74).

Progression to cirrhosis, whatever the cause, is often avoided if fibrosis is detected at an early stage. Increasingly, measurement of serum levels of the amino-terminal propeptide of collagen III (PIIINP) is being used as a substitute for liver biopsy in methotrexate monitoring [1–3], and, if performed three or four times annually, a consistently normal result appears to indicate a negligible risk of significant fibrosis. It does however have limitations—it can only detect active fibrosis, and can be elevated in other situations (notably psoriatic arthritis). Biopsy also has limitations—one study showed that, in 25% of cases where each liver lobe was biopsied, there was at least one fibrosis stage difference between the samples. Algorithms based on an increased number of parameters may help to improve non-invasive accuracy—a study that used biopsy as the gold standard in 1021 subjects and analysed nine other factors determined that four of these (age, hyaluronic acid, PIIINP and tissue inhibitor of matrix metalloproteinase I) had 90% sensitivity and a negative predictive value of 92% for significant fibrosis [4].

Cutaneous features of chronic liver disease

Cutaneous features of chronic liver disease are listed in Table 62.13 [1,2]. Causes include chronic hepatitis (above), alcohol abuse and others—some of the idiopathic causes are discussed below, as each has some specific features in addition to those that occur in liver failure of any cause.

Table 62.13 Skin lesions associated with chronic liver disease.

Spider angiomas, telangiectasia
Palmar erythema
Dilated abdominal/chest veins (including periumbilical caput medusae)
Jaundice
Increased melanin pigmentation
Thin 'paper-money' skin, striae
Excoriations
Loss of secondary sexual hair in males
Bruising, purpura
Nail changes: clubbing, pallor, Muehrcke's bands, Terry's nail
Features of malnutrition (see Chapter 59)
Associated lesions
Xanthomas (primary biliary cirrhosis)
Porphyria cutanea tarda (alcoholic liver disease)
Vasculitis/capillaritis/pyoderma gangrenosum (chronic active hepatitis)
Lichen planus (primary biliary cirrhosis)

Haemochromatosis

There are at least five hereditary (idiopathic) types of haemochromatosis ('bronze diabetes') [1–7], a disorder in which iron overload is associated with arthropathy, endocrine failure, cardiovascular disease and some infections. By far the commonest is 'classic' autosomal recessive haemochromatosis, which is due to mutations of the *HFE* gene (chromosome 6p21.3); mutations C282Y (cysteine 282 tyrosine) and H63D (histidine 63 asparagine) account for about 80% of cases, and mutations in S65C for perhaps 10% (all vary considerably between populations). The genotype combinations that may occur influence the risk of some associated disorders such as PCT (below). The 'classic' haemochromatosis phenotype also occurs due to mutations in the hemojuvulin gene (chromosome 1q21, also autosomal recessive). Haemochromatosis type 2 (HFE2, juvenile haemochromatosis) also occurs as a result of mutations in two different genes, HFE2A is due to hemojuvulin gene mutations and HFE2B due to mutation in *HAMP* (was *LEAP1*) which encodes hepcidin antimicrobial peptide (hepcidin). Other genes in which mutations cause haemochromatosis include *TFR2*, the gene for transferrin receptor-2 (causing haemochromatosis type 3, usually mutation Y250X) and *SCL40A1*, the gene for ferroportin (causing hemochromatosis type 4, HFE4). Classic idiopathic haemochromatosis usually presents in males over the age of 40 years. An acquired form also occurs, secondary to haemosiderosis or alcohol abuse.

There is increased iron absorption leading to iron deposition in various organs, including the liver, pancreas, heart, pituitary and endocrine organs. Skin pigmentation, diabetes, hepatic cirrhosis and cardiac failure are prominent features [8–10]. Dryness of the skin and koilonychia may have been underestimated in the past [11]; stigmata of chronic hepatic failure may also be present. Deposition of iron in the skin has been used as a surrogate for deposition in other organs [12,13]; in idiopathic haemochromatosis, iron deposition includes deposition in eccrine sweat glands [11]. However, the pigmentation of haemochromatosis is due to melanin rather than to haemosiderin [8–10]. It typically has a grey hue, and is most prominent on exposed skin, similar to addisonian pigmentation. Keratin cysts with a black colour [14], and black stasis dermatitis [15], have also been reported.

There is a 200-fold increase in the risk of hepatocellular carcinoma compared with the general population [8].

Porphyria cutanea tarda has been linked with haemochromatosis [10,16,17]. It has subsequently been shown that homozygosity for the C282Y mutation and seropositivity for HCV are the greatest risk factors for expression of PCT [18] and that they appear to act as independent co-factors [19]. In patients with mutations in uroporphyrinogen decarboxylase, which leads to PCT, coinheritance of C282Y homozygosity is associated with earlier age of onset of the porphyria [20].

Primary biliary cirrhosis and biliary tract disease

From the dermatological standpoint, primary biliary cirrhosis (PBC) is the most important biliary tract disease. The cutaneous features of significance are marked itch (discussed in more detail below), excoriation, hyperpigmentation and various xanthomatous lesions due to secondary hyperlipidaemia [1,2]. Xanthelasma, palmar crease, tuberous and tendinous xanthomas may all occur. PBC occurs mainly in middle-aged women as an autoimmune disease, is strongly associated with the presence of antimitochondrial antibodies (AMA), and has been associated with numerous other autoimmune conditions, including CREST, morphoea and other scleroderma spectrum disorders, lichen planus and lichen sclerosus [1–7]. The constellation of CREST with PBC is also known as Reynolds' syndrome, and is usually associated with M2 antibodies. Sarcoidosis [8] and other patterns of granulomatous disease such as granuloma annulare are also reported. There is a strong link with Sjögren's syndrome—about 10% of patients with Sjögren's syndrome have AMA, sometimes with abnormal liver function tests or liver histology, and over half of patients with PBC have some evidence of Sjögren's syndrome [9]. Itch is often the first symptom of PBC, so serology to detect AMA is a useful screening test in women with unexplained pruritus; AMA-negative PBC causes particular diagnostic difficulty.

Cholestasis and bile stones may cause acute or chronic jaundice and other features of liver disease. Pigment bile stones may occur due to erythropoietic protoporphyria.

Congenital biliary tract hypoplasia is a feature of Alagille's syndrome (MIM #118450) [10], a dominantly inherited disorder due to a gene mutation on chromosome 20p12. Affected individuals have a characteristic facies, jaundice, pruritus and retardation of growth and mental development. Various skeletal, ocular and vascular defects are associated. A report of 38 children documented firm xanthomas in 28%, mainly flexural but also affecting palms and ears; the xanthomas resolved in those individuals treated by liver transplantation [11].

Biliary tract abnormalities are also common in hereditary haemorrhagic telangiectasia, resembling either a congenital malformation of the ductal plate, or appearing similar to the changes seen in sclerosing cholangitis [12].

Drugs and the liver

Drug-related links between the skin and the liver include the following:

- Drugs used to treat the skin, whose hepatic metabolism is altered by liver disease or by other drugs that are also metabolized in the liver, e.g. ciclosporin
- Drugs used to treat skin disease that may cause hepatitis or other liver damage, e.g. azathioprine, methotrexate
- Drugs used to treat liver disease that may have cutaneous side effects, e.g. local reactions to vitamin K (Texier's syndrome),

elastosis perforans serpiginosa due to penicillamine for Wilson's disease
- Drugs used to prevent liver disease that may have cutaneous side effects, e.g. local reactions due to thimerosal or other preservatives in hepatitis vaccines
- Drugs that cause liver changes with secondary cutaneous signs, e.g. oestrogens leading to PCT
- Drugs that may cause concurrent hepatitis and rash, e.g. phenytoin and other anticonvulsants.

Systemic diseases and the liver

A large number of systemic diseases may affect the liver, many with cutaneous features. Most are discussed in other chapters. For example, sarcoidosis is associated with subclinical hepatic involvement in over 50% of patients, but may cause overt hepatomegaly or abnormalities of liver function in conjunction with skin lesions.

Porphyrias, especially PCT, may occur as a consequence of liver disease (see Chapter 59 and the discussion of PCT below); severe liver disease is also a feature in some patients with erythropoietic protoporphyria.

Hereditary haemorrhagic telangiectasia, mentioned earlier as a cause of gastrointestinal bleeding, is associated with portal hypertension due mainly to portosystemic shunting, so bleeding in such patients may be from varices.

Dermatological features and dermatoses associated with liver disease

Pruritus

Pruritus is the most common skin symptom associated with liver disease. It may precede the onset of jaundice of any cause, and may be a feature of hepatitis, as discussed above. Liver diseases in which itch is most prominent are PBC, sclerosing cholangitis and any other biliary tract obstruction, and disorders causing cholestasis; itch is less prominent in haemochromatosis, alcoholic cirrhosis and autoimmune chronic active hepatitis [1]. The symptoms are generally most severe at acral sites and at areas of tight clothing, and are more prominent nocturnally. Disappearance of pruritus may accompany severe deterioration in hepatic function [2].

The precise mechanism of itch in obstructive liver disease remains unclear. It was believed to be due to the presence of bile salts in the skin [3,4], but the intensity of itch does not reliably correlate with bilirubin or bile acid levels in chronic liver failure, and this theory is not supported by more recent research [1,5]. Other proposed mediators of cholestatic itch include alternative liver metabolites, histamine or other mast cell mediators, and endogenous opiates. Although patients with cholestasis may have elevated plasma histamine levels, the therapeutic response to antihistamines is limited, and it is unlikely that release of histamine plays an important role in the pathogenesis of hepatobiliary itch [1]. Improvement in hepatic itch after administration of drugs that block the action of endogenous opiates suggests that the latter may have an important role in cholestatic itch [6–8].

Treatment, where possible, is for the underlying cause—for example, drug withdrawal in drug-induced cholestasis, surgery for mechanical biliary obstruction, interferon and ribavirin for chronic HCV infection, etc. Less specific options include ursodeoxycholic acid, cholestyramine, phenobarbital, anabolic steroids such as stanozolol, rifampicin, antihistamines and dietary manipulation to supplement polyunsaturated fatty acids [1,9,10]. Phototherapy of various types—daylight, ultraviolet A (UVA), ultraviolet B (UVB), photoirradiation of plasma and extracorporeal photophoresis—can be effective, but ongoing treatment is generally required [1,11,12]. Other treatments that have been used with success include haemoperfusion or plasma perfusion through charcoal-coated beads (which can produce benefit lasting several weeks), plasmapheresis, infusions of albumin (benefit for a few days) and slow injection of intravenous lidocaine (lignocaine) (which produces short-term benefit only). On the basis that endogenous opiates play a role in this symptom, and that these have a circadian rhythm regulated by light, bright-light therapy to the eyes was studied and found to reduce cholestatic itch in a short-term study [13]. Oral opiate antagonists are effective but may cause opioid withdrawal-like reactions—this may be reduced by use of very low dose naloxone infusions prior to gradual increase in dose of an oral opiate antagonist [14]. Gabapentin was ineffective in a double-blind, controlled trial [15].

Skin pigment changes in liver disease [1–3]

Jaundice (icterus) is first visible as a yellowish hue of the sclerae and soft palate before it becomes generalized. It is due to

hyperbilirubinaemia. Carotenaemia may have a similar appearance but does not affect sclerae; skin discoloration following mepacrine or busulphan therapy may simulate jaundice, but these usually also cause subungual pigmented bands.

Green-coloured sweat [4] and green discoloration of the gingivae may occur due to jaundice.

A muddy-grey coloured hyperpigmentation occurs in chronic liver disease of any cause. It is due to hypermelanosis with normal numbers of melanocytes, but the precise mechanism is uncertain. There may be a yellowish tinge due to associated jaundice. Usually, pigmentation is more prominent in sun-exposed areas. It may be blotchy or diffuse, and may be exaggerated in the perioral and periorbital areas (resembling chloasma); in other cases it may resemble freckling and it can also localize to palmar creases. Males frequently show increased pigmentation of the areola in association with gynaecomastia and testicular atrophy.

Spotty hypomelanosis may occur on the back, buttocks and thighs, often in relation to spider angiomas.

Associated dietary deficiency may cause the pigmentary changes of pellagra (Chapter 59).

Vascular changes

Spider angiomas are a characteristic feature in patients with severe chronic liver disease (Fig. 62.20). Contributory factors [5] include decreased hepatic metabolism of oestrogen leading to hyperoestrogenaemia (which also accounts for loss of secondary male-pattern hair, gynaecomastia and testicular atrophy); alcohol-induced vasodilatation and altered central vasomotor control may also be involved. The same factors lead to palmar erythema ('liver palms'), which is most pronounced on the thenar and hypothenar regions and may also affect the soles of the feet, and also to facial plethora. None of these vascular features are specific for liver disease. Diffusely scattered tiny telangiectatic vessels are referred to as 'paper money skin'. Increased peripheral blood flow with dilatation of digital pulp arteriovenous anastomoses is thought to be the cause of finger clubbing, which occurs in about 15% of patients with hepatic cirrhosis.

Fig. 62.20 Telangiectasia in alcoholic liver cirrhosis.

Purpuric lesions including scurvy may occur as a result of poor nutrition, especially in alcoholic liver disease (see Chapter 59). Altered production of prothrombin and deficiency of vitamin K may lead to frank ecchymoses.

In progressive liver disease with portal hypertension, collateral blood flow creates visible coiled varicose veins on the abdominal wall. When these are in a pattern radiating from the umbilicus, the appearance is termed 'caput Medusae'.

Hair, nail and collagen changes [1–3]

The body hair is often thinned or partially lost, and males tend to develop a female pubic-hair pattern. There is both increased production and decreased metabolism of oestrogens, as well as decreased production and increased metabolism of testosterone. When there is severe loss of scalp hair, zinc deficiency should be suspected (Chapter 59).

Nail changes include a diffuse white colour with an invisible lunula, proximal white colour with distal pink colour (Terry's nails) and white bands (Muehrke's bands [6]). Altered digital blood flow, soft-tissue overgrowth and hypoalbuminaemia may all contribute. Lunulae may be red in patients with hepatic cirrhosis, and occasionally an azure-blue colour in hepatolenticular degeneration (Wilson's disease). Nail-plate changes include clubbing (see above) and its milder variant, the 'watch-glass' deformity; flattened nails or koilonychia may occur if there is poor nutrition or altered iron metabolism (e.g. haemochromatosis).

Striae occur in both sexes, especially on the lower abdomen, thighs and buttocks. Chronic alcoholism also alters metabolism of corticosteroids, leading to 'pseudo-Cushing's syndrome'.

Porphyria cutanea tarda

Chronic liver disease is involved in the skin changes of porphyria cutanea tarda. Lesions consist of bullae, scarring and hyperpigmentation of sun-exposed skin areas and hypertrichosis of the face. This is discussed in more detail in Chapter 59.

Other cutaneous lesions associated with liver disease

Lichen planus has been reported in a number of diseases with abnormal immune function. The association of erosive oral lesions in PBC [7] and chronic active hepatitis [8] may be related to a common immunological pathogenesis. Most reported patients have received penicillamine therapy which is believed by some to trigger the eruption [9–11]. HCV infection is associated with lichen planus [12].

In chronic active hepatitis (juvenile cirrhosis, lupoid hepatitis) and in PBC, firm reddish papules resembling pityriasis lichenoides chronica or lymphomatoid papulosis have been reported [8,13]. The lesions erupt on the trunk and extremities and may heal leaving slightly depressed atrophic scars. Histological examination reveals a capillaritis of the skin. Pityriasis lichenoides has also been reported in association with HCV seropositivity.

Pyoderma gangrenosum has also been reported in chronic active hepatitis [14]. The Gianotti–Crosti syndrome has been discussed in relation to hepatitis. Skin changes simulating classical glucagonoma syndrome have been reported in cirrhosis and termed the 'pseudoglucagonoma syndrome' [15].

Fig. 62.21 Scaling rash on the trunk in chronic zinc deficiency.

Acquired zinc deficiency (Fig. 62.21) may occur in chronic alcoholic liver disease due to increased loss of urinary zinc in cirrhosis and poor nutrition [16,17]. Clinical features are a crackled and reticulate eczema on the trunk and extensor aspects of the limbs, erosive crusted changes in the perianal and genital areas, cheilitis, hair loss and multiple Beau's lines on the nails. Increased hair growth, often with a deeper pigmentation, may occur. Beer, wine and spirits are practically free of zinc, but most beer brands contain vitamin B in significant amounts and the typical zinc-deficient beer-drinker does not show additional clinical signs of vitamin B depletion [17].

Pancreatic disease

Apart from jaundice and panniculitis, skin changes associated with pancreatic disease are uncommon. As with other causes of chronic, localized pain, erythema ab igne has been described in the skin overlying the pancreas in cases of chronic pancreatitis. The glucagonoma syndrome is a rare but highly characteristic skin disorder, which is discussed below. The pancreas is often involved in haemochromatosis (see the section on liver disease, above). Skin disorders associated with diabetes mellitus are discussed in Chapter 59.

Acute pancreatitis [1–3]

Jaundice and fat necrosis (see below) may both be prominent. Purpura or bruising may occur in about 5% of patients with acute pancreatitis; note however that neither are specific for this cause, they may occur due to retroperitoneal haemorrhage, or bleeding from sources such as splenic rupture, ectopic pregnancy, metastatic tumour or aortic aneurysm. Four eponymous signs occur with retroperitoneal bleeding, the tracking of haemorrhagic fluid being:

1 Grey Turner sign (Turner sign)—tracks from the pararenal space to the edge of the quadratus lumborum muscle then through a defect in the fascia to the subcutaneous tissues of the flank (left sided in pancreatitis)
2 Cullen's sign—tracks into the falciparum ligament then through the connective tissues of the round ligament to the periumbilical area
3 Fox's sign—tracks along the fascia of the psoas and iliac muscles to the subcutaneous tissues of the upper thigh
4 Bryant's sign—tracks to the scrotum to produce the 'blue scrotum' sign.

Features of causative factors of pancreatitis may also be present, such as signs of alcohol abuse or hepatic cirrhosis, or xanthomas due to hypertriglyceridaemia.

Subcutaneous fat necrosis [1–7]

Synonym
- Nodular panniculitis

Systemic nodular fat necrosis is a rare condition that affects 2–3% of patients with pancreatic disease [6]. It may be associated with acute or chronic pancreatitis, post-traumatic pancreatitis or pancreatic carcinoma [1–3]. Pancreatitis accounts for about two-thirds and carcinoma one-third of reported cases [4]. Most of the reported

pancreatic neoplasms are acinous adenocarcinoma, which is rare. Subcutaneous fat necrosis associated with acute pancreatitis in a newborn has been reported [5].

The mechanism of fat necrosis is not fully understood, but the condition is probably due to the effect of enzymes released from damaged pancreatic tissue. However, the condition does not simply relate to release of amylase or lipase from the pancreas. Not only is fat necrosis relatively uncommon in pancreatitis, but the eruption does not correlate with enzyme levels—it may occur in patients with normal lipase levels, or fail to occur in subjects with grossly elevated levels. Furthermore, incubation of skin with lipase or with patient's serum *in vitro* fails to demonstrate fat necrosis [4]. Thus, other enzymes are presumably involved.

Clinical features. Pancreatic nodular fat necrosis is accompanied by fever, abdominal pain (less common in those with underlying carcinoma), blood eosinophilia and synovitis of the small joints. Either the nodules or the arthralgia may predominate. Nodular lesions are usually 1–3 cm in diameter and tender or symptomless. The areas of predilection are the trunk and the lower extremities, especially the anterior shins, but lesions may occur anywhere. Lesions persist for 2–3 weeks and usually heal without scar formation, leaving slightly depressed, hyperpigmented spots. More severe changes due to periarticular fat necrosis may occur. Polyserositis may be part of the syndrome [7]. Increased serum amylase or lipase levels can be demonstrated in most cases, but may be normal in cases due to carcinoma.

Histopathology. There are foci of subcutaneous fat necrosis, with ghost cells and a surrounding inflammatory infiltrate of neutrophils and eosinophils. At the periphery of the lesion histiocytes, foam cells and foreign-body giant cells are seen. Secondary calcification may be observed in necrotic areas.

Migratory thrombophlebitis [1–3,8–11]

Pancreatic cancer is one of the classical associations with Trousseau's sign, in which multiple, migratory, superficial thromboses occur. Recent studies indicate that lung cancer is the most common associated neoplasm in men aged over 40 years, but pancreatic cancer is still an important cause; historically, pancreatic cancer accounts for about 25–30% of cases of migratory thrombophlebitis. Cancers elsewhere in the gastrointestinal tract may also cause this condition. The usual interval to diagnosis is about 4 months from onset, but pancreatic neoplasia may present later than this [9]. The phlebitis is distributed on the trunk, neck and extremities and is usually limited to a short segment of the vein. A significantly increased frequency of deep venous thrombosis is also found. The cause is unknown, but probably related to increased levels of clotting factors and disordered fibrinolysis, a form of disseminated intravascular coagulopathy. The combination of thrombotic change with haemorrhage (purpura fulminans) may also occur as a paraneoplastic phenomenon. Thrombotic change may coexist with other paraneoplastic features; it was demonstrated in the skin of a patient with malignancy-associated fasciitis due to a pancreatic carcinoma [11]. Other signs of pancreatic carcinoma include cutaneous metastasis; about 10% of cases of Sister Mary Joseph's nodule (metastasis to the umbilicus) are due to pancreatic carcinoma [2].

Other dermatological features of pancreatitis

The main dermatological features of acute and chronic pancreatitis have been described above, or are the result of malabsorption in the chronic disease (Chapter 59). Livedo reticularis has also been described in both acute and chronic pancreatitis as 'Walzel's sign' [12,13].

Necrolytic migratory erythema, pancreatic islet cell tumours and glucagonoma syndrome [1–6]

Necrolytic migratory erythema

Aetiology. Necrolytic migratory erythema is a cutaneous reaction that occurs in the context of hyperglucagonaemia. The syndrome was described in 1941 [1] and there have been several subsequent reviews [2–7]. The same condition occurs in dogs and other animals. It is usually due to a glucagonoma, an α-cell tumour, which is usually in the tail of the pancreas [4,8], and which secretes excessive amounts of proglucagon-like material [7]. However, it may also occur due to other causes such as pancreatic insufficiency [9], intestinal causes of malabsorption [6,9,10], intestinal protein loss (for example, secondary to lymphatic disease—Waldmann's syndrome [11]), hepatic cirrhosis [12,13], and aberrant glucagon-secreting tumours such as bronchial or nasopharyngeal carcinoma [14,15]. It has also been documented as an iatrogenic condition after administration of glucagon [6] and in a heroin abuser [16]. MEN (discussed below) is associated with glucagonoma, which occurs in about 3% of cases and accounts for about 20% of glucagonomas.

Hyperglucagonaemia also causes diabetes; the 'diabetico-dermatogenic syndrome' occurs in almost 60% of patients with glucagonoma [4], but when only some of the features are present this may lead to delay in diagnosis. Glucagon production and metabolism are discussed in [7].

The pathogenetic mechanism of the skin eruption is not certain, but the condition is probably due to hypoaminoacidaemia caused by high glucagon levels [5] or by intestinal protein loss or malabsorption. There may be a contributory role of essential fatty acid and zinc deficiencies, but abnormal zinc levels or response to zinc supplementation are not consistent, and correction of amino acid levels does not reliably lead to resolution of the skin eruption [16]. It is characteristic that all skin changes disappear after complete surgical removal of the tumour in cases in which this is the cause [17].

Clinical features. The typical patient with glucagonoma is a woman 45–65 years of age. The usual features are weight loss (67%), anaemia (33%), glucose intolerance (56%) and necrolytic migratory erythema (72%) [8]. The rash is itchy or burning and particularly affects flexural sites on the lower abdomen, groin, buttocks and thighs (Fig. 62.22). It is initially macular, extending to form superficially eroding areas of erythema that progress to fragile vesicle and bullae formation. Irregular centrifugal extension of the annular lesions causes a marginated, often crusted, polycyclic or geographical pattern. It has a prolonged, fluctuating course or cyclical pattern; the central part heals over 7–14 days, leaving postinflammatory pigmentation, while the erythematous periphery becomes crusted. Perianal and genital lesions are common. Angular cheilitis and a painful, beefy-coloured glossitis occur in about one-third of patients with glucagonoma [8].

Fig. 62.22 Glucagonoma syndrome. (Courtesy of Dr Kristian Thomsen, Finsen Institute, Copenhagen, Denmark.)

The clinical spectrum also includes diarrhoea (20%), weakness, venous thromboses (10%) and psychiatric disturbances. The plasma glucagon level is generally elevated several-fold above the upper limit of the normal range, but may show only minor elevation. The systemic features, such as weight loss, anaemia and hypoaminoacidaemia, are all more frequent in patients with glucagonoma with the diabetico-dermatogenic syndrome than in those without [4]. The same pattern of eruption has been described due to zinc deficiency with normal glucagon levels, usually in the context of liver disease.

Histopathology [2,3]. Biopsy should be taken from the edge of early lesions. The characteristic histological feature is well-demarcated necrolysis of the outer cell layers in the Malpighian stratum. Early lesions may present as a 'dyskeratotic dermatitis' with superficial perivascular inflammation in the dermis, and minor spongiosis and dyskeratotic or vacuolated epidermal cells [3,18]. Clefts and separation occur, associated with necrotic keratinocytes and cellular debris surrounding the cleft. In the dermis, a mild perivascular lymphocytic and histiocytic infiltrate is seen. Older lesions show various degrees of dyskeratosis, acanthosis and a lymphocytic infiltrate in the dermis. The histological changes are similar to those observed in acute zinc deficiency, in which cell degeneration and the formation of clefts and vesicles are predominant at the level of the basal cells.

Diagnosis. Pancreatic and hepatic scans and arteriography are helpful in locating a primary pancreatic tumour and its metastases if present. Serum amino acid, glucose, zinc and plasma glucagon levels should be determined. In cases with an elevated plasma glucagon level and a clinical and histological picture suggestive of the disease, surgical exploration should be performed.

Treatment. Where there is a glucagonoma, surgical resection is indicated, with embolization of hepatic metastases, which are present in the majority at the time of diagnosis. Various forms of chemotherapy have been used [2,5,19–21], such as streptozocin (a nitrosourea compound used for the ablation of β-cell adenoma) with 5-fluorouracil. Somatostatin is an inhibitor of glucagons but has a half life of just a few minutes, so analogues such as lanreotide, which is active for up to 2 weeks after intramuscular injection, are used therapeutically. Octreotide, a somatostatin analogue, rapidly improves symptoms, especially the rash, by altering glucagon metabolism, but it does not influence tumour growth [7,21]; dacarbazine is also useful [22]. Parenteral amino-acid infusions and correction of any essential fatty acid deficiency may be helpful [19], although the benefit of amino-acid infusions does not appear to be sustained long term [17]. In the rare cases related to malabsorption, correction of this (for example, GFD in coeliac disease) is usually effective [4,10].

Other non-insulin-secreting pancreatic endocrine tumours

Although glucagonoma is more important dermatologically, the most common islet cell tumours are insulinoma of β-cells and gastrinoma of δ-cells (Zollinger–Ellison syndrome, ZES). These do not have specific skin changes, but they may occur together with other tumours that secrete ACTH, MSH and serotonin; severe

diarrhoea in ZES may cause secondary hypovitaminosis and other nutritional deficiencies, giving rise to skin and hair changes. Both of these tumours occur sporadically or as part of the autosomal-dominant MEN type 1 syndrome (Wermer syndrome, MIM *131100), which is due to a mutation in the *MEN1* gene on chromosome 11q13. In this condition, as well as the endocrine tumours, other cutaneous features include angiofibromas, collagenomas, café-au-lait macules, lipomas and gingival macules [21]. MEN1 was associated with 13% of glucagonomas in one large series [4], and glucagonoma has also been reported in MEN2.

Tumours that produce vasoactive intestinal polypeptide (VIPomas) cause flushing (discussed in Chapter 43) with watery diarrhoea, hypokalaemia and achlorhydria [23]. A macular rash that resolved after tumour resection was reported in a patient with a pancreatic polypeptide-producing tumour of the pancreas (PPoma) [24].

Renal disease [1–4]

The skin and renal systems may be affected not uncommonly by the same disease processes. The more important of these renocutaneous syndromes are listed in Table 62.14.

Hereditary syndromes and malformations

Angiokeratoma corporis diffusum (Fabry's disease; MIM *301500; Chapter 59). Affected individuals often show proteinuria, microscopic haematuria and lipiduria. Renal disease eventually develops in most male patients, and as lipid deposition in the form of glycosphingolipids occurs, renal function deteriorates. The premature mortality in the condition is often a result of renal failure. Renal transplantation can supply a source of the deficient enzyme lysosomal hydrolase, α-galactosidase A, and results in an improvement in the condition; commercial preparations of this enzyme are

Table 62.14 Renocutaneous syndromes.

also now available (see Chapter 59). Other enzyme defects may give rise to the same clinical phenotype.

Neurofibromatosis (NF1, MIM *162200; NF2, MIM *101000; von Recklinghausen's disease) (Chapter 15). Urinary outflow obstruction may develop secondary to an impinging neurofibroma. Vascular lesions can result in renal artery thrombosis and subsequent hypertension. In patients with hypertension, normal plasma and urine catecholamine levels—especially those under the age of 20 years—renal artery stenosis should be suspected [5]. Raised blood pressure may also develop as a result of an associated phaeochromocytoma. Causes of hypertension in neurofibromatosis should be fully investigated [5]. Nephroblastoma is a recognized association in neurofibromatosis [6] and renal polycystic disease.

Tuberous sclerosis complex (TSC1, MIM #191100; TSC2, MIM *191092; Bourneville's disease; Chapter 15). An increased incidence of rhabdomyomas and carcinoma may occur in this condition [7]. Malignant renal tumours may include renal cell carcinoma, malignant angiomyolipoma and Wilms' tumour [8]. The classical renal lesion associated with tuberous sclerosis is an angiomyolipoma. Renal cysts also occur in conjunction with these, or as isolated findings [9].

Nail–patella syndrome (Fong's syndrome; hereditary osteo-onychodysplasia; MIM #161200; Chapters 15, 65). The defective gene *LMX1B* is located on the long arm of chromosome 9 (9q34.1); this gene regulates type IV and VI collagen expression, which in turn affects skeletal and basement membrane structure and function [10]. *LMXIB* is expressed in the kidney, primarily in podocytes, and regulates many crucial podocyte proteins. Renal dysplasia presenting as chronic glomerulonephritis occurs in some cases, and characteristic electron-microscopic glomerular abnormalities are present in most cases of nail–patella syndrome. The ultrastructural features consist of thickening and splitting of the glomerular basement membrane and fibrillar α3(IV) and α4(IV) collagen deposits. Renal lesions are asymptomatic; patients show proteinuria, haematuria and reduced creatinine clearance. Although there is often a progressive course to renal failure, many patients with the complication do surprisingly well. Helpful diagnostic signs include small, defective nails that do not reach the free nail border, triangular lunulae, the thumbnails being the most frequently and severely affected nails and the severity of the defect reducing from the index to little finger nails. There is absence of the skin creases on the dorsal interphalyngeal joints [11]. The patellae are less well developed, potentially giving stability problems for the knee and there is instability of the radial head; other indicators include (radiologically) posterior iliac horns and (ophthalmically) irregular hyperpigmented pupillary borders. There is a tendency to glaucoma.

Birt–Hogge–Dubé syndrome (BHD; Hornstein–Knickenberg syndrome; MIM #135150). Hereditary renal cell cancer syndromes include BHD, von Hippel–Lindau disease, as well as hereditary papillary renal cell carcinoma, familial oncocytoma and hereditary renal cell carcinoma of various types [12].

The cutaneous features of BHD include trichofolliculomas, trichidiscomas and skin tags. Pulmonary cysts, predominantly basilar, may cause spontaneous pneumothorax. A variety of coding sequence mutations have been linked to the 17p11.2 chromosome [12].

Hereditary leiomyomatosis and renal cell carcinoma (HLRCC) syndrome (MIM #605839). Multiple cutaneous leiomyomas, which have an inherited predisposition, are linked to uterine leiomyoma (Reed syndrome, MIM #150800) and also appear to be associated with an increased incidence of renal cell carcinoma, usually aggressive and of papillary cell type. Numerous different fumarate hydratase mutations have been identified, but the patients who have renal cell carcinomas associated (only 2% in one series) are more likely to have truncating or frameshift mutations and be female [13]; see also the section 'Cutaneous markers of internal malignancy' above, p. 62.29.

Multiple hamartoma and neoplasia syndrome (Cowden's disease; MIM #158350). This is associated with an increased incidence of renal cell carcinoma, liposarcoma and transitional cell carcinoma of the bladder [8]. It is discussed earlier in this chapter.

von Hippel–Lindau syndrome (VHL; MIM *193300; see earlier in this chapter and Chapter 15). Renal lesions in VHL are either simple cysts or adenocarcinomas; usually they are a late manifestation. Renal carcinoma may present with cutaneous metastases several years in advance of the systemic malignancy; alternatively, cutaneous deposits may indicate a recurrence of previously treated neoplasia [3]. von Hippel–Lindau syndrome represents one of the hereditary kidney cancer syndromes in which a two-hit model of tumour genesis occurs, explaining the often late development of this complication.

The other tumours linked to VHL are dealt with in Chapter 15, but phaeochromocytomas and pancreatic tumours can occur with increased frequency in close anatomical association with each other.

Familial Mediterranean fever with urticaria (FMFU), Muckle–Wells syndrome (MWS) and tumour necrosis receptor associated periodic syndrome (TRAPS) [14,15]. These 'autoinflammatory syndromes' are all associated with a significant risk of renal failure secondary to amyloidosis, frequently resulting in premature death (see also later in this chapter).

Oral–facial–digital syndrome [16]. Oral–facial–digital syndrome type I (OFD1) is characterized by the following abnormalities: oral (lobed tongue, hamartomas or lipomas of the tongue, cleft of the hard or soft palate, accessory gingival frenulae, hypodontia and other dental abnormalities); facial (ocular hypertelorism or telecanthus, hypoplasia of the alae nasi, median cleft or pseudocleft upper lip, micrognathia); digital (brachydactyly, syndactyly of varying degrees, and clinodactyly of the fifth finger; duplicated hallux [great toe]; preaxial or postaxial polydactyly of the hands) and brain (intracerebral cysts, corpus callosum agenesis, cerebellar agenesis with or without Dandy–Walker malformation). Polycystic disease of the kidneys and liver occurs commonly in this

condition. As many as 50% of individuals with OFD1 have some degree of mental retardation, which is usually mild. Almost all affected individuals are female. However, males with OFD1 have been described, mostly as malformed fetuses born to women with OFD1.

Metabolic and systemic disorders

Partial lipodystrophy

Renal disorders occur frequently in this condition (25%), usually as a membranoproliferative glomerulonephritis; subsequent renal failure is common at an early age. There is a circulating C3 nephritic factor and reduced levels of complement (C3) [1]. An association with hereditary angio-oedema (C1 inhibitor deficiency) has been reported [2].

Primary and myeloma-associated systemic amyloidosis (Chapter 59)

Up to 40% of patients have waxy, purpuric cutaneous or mucosal changes, periocular lesions are the most recognizable [3] and diagnostically useful. Typically, patients may also have macroglossia, hepatomegaly, oedema and carpal tunnel syndrome. Cutis laxa-like clinical changes have also been reported [4]. Without dialysis, renal failure is often fulminant and fatal; peritoneal dialysis may be the most appropriate approach. Although renal amyloid may recur after transplantation, this is not completely contraindicated [5]. Primary cutaneous amyloid does not appear to have renal associations. Nodular or tumid amyloidosis was said to represent an early phase of systemic amyloid, but recent studies have reported only a 7% progression to systemic disease after long follow up [6].

Calcification and calcific uraemic arteriolopathy (calciphylaxis) (see also Chapter 49)

Calcifying panniculitis has been reported occasionally in renal failure, a disorder now termed calcific uraemic arteriolopathy [7–9]. It is usually, but not invariably, associated with a high serum calcium phosphate product. Metastatic skin calcification is a rare phenomenon in uraemic patients; it usually presents as papular or nodular cutaneous lesions around large joints or flexural sites. Non-cutaneous metastatic calcification is, by comparison, much commoner. Metastatic calcification in blood vessel walls associated with hyperparathyroidism and renal failure (calcific uraemic vasculopathy, calciphlaxis) may lead to cutaneous necrosis or gangrene as a result of thrombosed vessels (Fig. 62.23); however, calcification does not always need to be present, and vascular damage may be triggering a premature haemostatic cascade. This carries a poor prognosis, in one series, only 40% of patients survived a year after diagnosis. Risk factors included obesity, liver disease, systemic steroid use, and a high calcium phosphate product and high serum aluminium [9]. Treatments include low phosphate dialysate fluids, non-calcium phosphate binders, parathyroidectomy, and more recently drugs such as sodium thiosulphate or cinacalcet which alter calcium metabolism.

Sarcoidosis and the kidney [1,2]

Nephrolithiasis and nephrocalcinosis occur in patients with sarcoidosis with a 20% higher frequency than in the normal population. Hypercalcaemia which occurs in sarcoidosis may cause polyuria and polydipsia, and may even precipitate acute renal failure. Renal sarcoidosis can give rise to diffuse interstitial nephritis, but it is seldom that there are identifiable granulomas or direct renal involvement. Rarely, cases of outflow obstruction from retroperitoneal sarcoidal masses and sarcoid of the urethra have been reported [3].

Vasculitis (Chapter 50)

Renal involvement commonly occurs in various types of vasculitis that present with cutaneous changes and is the main cause of mortality in many of these syndromes. This should be considered particularly in classical Henoch–Schönlein purpura (anaphylactoid purpura), especially in adults, where IgA nephropathy has become recognized as a fairly common form of glomerulonephritis [1]. An association between anaphylactoid purpura and familial IgA nephropathy has also been described [2]. Patients labelled as having allergic vasculitis and arteritis with livedo reticularis [3] should also be regarded as being at risk of kidney damage.

Renal failure is a recognized, but rare, complication of Behçet's syndrome, usually with immune-complex deposition [4]. Concomitant or delayed renal involvement is common in Wegener's granulomatosis, usually as a focal necrotizing glomerulitis. Deposits of IgM and IgG are present in renal vessels and circulating immune complexes are also frequently detected [5]. Renal changes that occur in these conditions, and in collagen vascular disorders such as polyarteritis nodosa, systemic lupus erythematosus and scleroderma, are considered in Chapters 50 and 51.

Renal disease in bullous disorders

Bullous pemphigoid. Renal disease, including membranous glomerulopathy, diffuse proliferative and mesangioproliferative glomerulonephritis, has been infrequently reported in patients with pemphigoid [1].

Toxic epidermal necrolysis (TEN) [2]. Deteriorating renal function is a poor prognostic factor in TEN, and is one of the parameters used in the SCORTEN prognostic score.

Epidermolysis bullosa (EB). Renal failure was the second most common cause of death (with a mean age of 35) in 12% of adults with recessive dystrophic EB of the Hallepeau–Siemens type [3]. It was surpassed as a cause of death only by metastatic squamous cell carcinoma. Renal failure due to IgA nephropathy, and post-infectious membranoproliferative glomerulonephritis, has complicated recessive dystrophic EB. Obstructive uropathy has been seen in junctional EB. Surveillance for early renal involvement should become part of the routine evaluation of all adults with RDEB and JEB [4].

Infective dermatoses causing renal disease

Streptococcal impetigo. An acknowledged cause of acute glomerulonephritis, particularly when streptococcal infection occurs secondary to scabies [1], but most cases of acute nephritis are not the sequel of streptococcal infection.

Secondary syphilis. A rare cause of the nephrotic syndrome.

Herpes zoster. If affecting the appropriate dermatomes, herpes zoster cause neurogenic bladder dysfunction and pain [2], leading to acute urinary retention.

Renal failure and dialysis [1–3]

Cutaneous signs of renal failure are mainly related to chronicity of disease. Urea frosting, in which crystalline urea is deposited on the skin, is now very rare, but dry, pigmented skin with excoriations is typical.

Uraemic patients tend to have a dry skin, sometimes with fine scaling. A reduction in the size of eccrine sweat glands in uraemia may contribute to this effect [4], although high-dose diuretic regimens are a co-factor [5].

Pigmentation. Anaemia presenting as pallor is an early and common sign in renal failure, resulting from reduced erythropoiesis and increased haemolysis.

A muddy brown hyperpigmentation develops in many cases, attributed to retention of chromogens and deposition of melanin, possibly due to impaired renal processing of melanocyte-stimulating hormone [6]. Increased nail pigmentation, usually confined to the distal aspect, occurs in a proportion of patients [7]. This distal brown or more normal red colour, combined with a proximal white appearance gives rise to the 'half-and-half' nails, a distinctive pattern seen in about 10% of patients with renal failure [8].

Purpura due to a mild thrombocytopenia or more marked platelet dysfunction is common and may be partly corrected by dialysis [9]. Wound healing is prolonged and patients may be more susceptible to pressure sores.

Pruritus. Generalized, severe pruritus occurs in about one-third of renal failure cases, less troublesome involvement occurs in many more. Unfortunately, haemodialysis can initiate the symptom as well as improve it. Up to 85% of patients on haemodialysis suffered from itching in one study [10], one-third before dialysis, the others after; 12% had reduced pruritus after 6 months' dialysis. There seems to be an association with predialysis blood urea levels, and a less clear correlation with dry skin and secondary hyperparathyroidism [11]. Subtotal parathyroidectomy may be very helpful [12], but the problem can subsequently recur, and many cases are not related to secondary hyperparathyroidism. Moreover, many patients with this finding do not itch. A complete explanation for pruritus in renal failure is obscure, as pruritus is unusual in acute renal failure and a reduction in uraemia often does not improve the symptom. Slowly accumulated or deposited pruritogen(s), of as yet uncertain nature, are the likely cause. In dialysis, lowering the magnesium concentration of the dialysate has been reported as helpful [13]. In intractable itching, UVB radiation is an effective therapy [14], benefit being associated with a reduction of skin phosphorus to normal values. Ultraviolet A (without psoralen) has been reported nearly as effective [15]; oral cholestyramine and activated charcoal are alternatives [16,17]. Erythropoietin therapy can alleviate pruritus in some cases of renal failure. Naltrexone (and other opioids such as nalmefene) and odansetron have also been reported to help uraemic pruritus [11]. Gabapentin has recently been demonstrated to be effective in uraemic pruritus [18].

Perforating disorders. A perforating disorder variously described as acquired reactive perforating collagenosis, Kyrle's disease or perforating folliculitis occurs in renal failure; often there is diabetes, diabetic nephropathy and/or retinopathy. Pruritus is nearly always present, and up to 10% of dialysis patients may be affected. The condition seems to have a higher incidence in Afro-Caribbeans. The cutaneous lesions consist of hyperpigmented papules up to 1 cm in diameter with a central keratinous plug (Fig. 62.24). The extensor surfaces of the limbs are more commonly affected but the trunk and face may be involved. The pathogenesis is uncertain, but there is some histological evidence that it is a perforating collagenosis [19,20].

Fig. 62.24 Reactive perforating collagenosis in end-stage renal failure.

Other cutaneous features. Uraemic neuropathy affects some 60% of patients with renal failure or on long-term haemodialysis. This appears to be a predominantly sensorimotor neuropathy [20].

Up to 40% of patients with renal failure may develop gynaecomastia while receiving dialysis [21]. Calcinosis cutis may occur in 1% of patients with end-stage renal disease [22]. It may be reversed by a low phosphorus diet and aluminium hydroxide gel.

Features related to treatment. Premature ageing of the skin and actinic keratoses have been described, a reason for avoiding excessive ultraviolet therapy for pruritus. This should be distinguished from the numerous viral, dysplastic and frankly malignant skin lesions which may develop in immunosuppressed renal allograft recipients.

Cutaneous complications affecting the limb of patients in which their haemodialysis arteriovenous shunt is situated include infection, phlebitis and haematoma. However, both irritant and allergic contact eczema may also develop [23]. Vascular complications of arteriovenous fistula construction are relatively uncommon, but include digital ischaemia and aneurysm formation. The venous hypertension syndrome with or without ulceration may occur; pseudo-Kaposi's sarcoma [24], and pyoderma gangrenosum [25], are both rare developments.

Bullous eruptions mimicking PCT (pseudoporphyria of haemodialysis) are well recognized, with an incidence reported at between 2 and 18%. True porphyria cutanea tarda due to defi-

ciency of uroporphyrin decarboxylase is reported but uncommon. Distinguishing these two conditions can be difficult as many patients on haemodialysis have elevated blood porphyrin levels slightly above what is regarded as the normal range due to their reduced excretion; the importance of accurate assays is emphasized [26,27]. Photosensitizing drugs such as furosemide, oestrogens and non-steroidal anti-inflammatory agents may also induce a pseudoporphyria picture. In all cases, UV protection is important. *N*-acetylcysteine, which acts as an antioxidant, may help reduce the blistering [28]. Treatment of true PCT in patients with end-stage renal failure is limited as antimalarials work by binding porphyrins and renal excretion of the complexes formed (which will not occur in many patients with renal failure, as the complexes will not be excreted by anuric subjects and will not cross dialysis membranes), and venesection is limited by anaemia; treatment with erythropoietin to increase conversion of porphyrin to haem is the usual approach.

Nephrogenic systemic fibrosis. A condition termed nephrogenic fibrosing dermopathy, or, more recently, nephrogenic systemic fibrosis, was initially linked with haemodialysis but occurs in other patients with renal failure [29–31]. Clinical features include indurated plaques, sometimes with finger-like projections, that may be erythematous, yellowish or skin-coloured. Nodules and contractures occur in more advanced disease. Scleral plaques may also occur, although the face is usually spared (by contrast with scleromyxoedema). There may be internal organ involvement (hence the more modern term nephrogenic systemic fibrosis), and death and severe disability can ensue. Involvement of the diaphragm is frequently the event that leads to death and 10% of patients have a fulminant course. Histology shows increased mucin deposition and spindle cells and compact collagen bundles. There has been a strong association with the use of radio-contrast agents that contain gadolinium, such as gadodiamide, which are used to enhance magnetic resonance imaging of vessels [32,33]. Such contrast media are now not recommended for use in patients with a GFR less than 30 ml/min [32,33] as they are renally excreted and have a tissue half-life about 10-fold longer in those with severe renal impairment compared to normal subjects. The resulting prolonged high tissue levels may be pro-fibrotic. A recent study using quantitative scanning electron microscopy/energy-dispersive X-ray spectroscopy demonstrated the presence of gadolinium in the skin of 20 patients with nephrogenic systemic fibrosis but not in the skin of a gadodiamide-exposed patient with renal failure but without fibrosis; importantly, where repeat biopsies were examined, gadolinium levels increased for almost 2 years in 60% of subjects [34]. On the basis that the toxic Gd^{3+} ion is retained in apatite-like structures, the findings suggested that there might be gradual mobilization of gadolinium from bone stores, explaining the variability in timing and extent of fibrosis.

Skin changes in renal transplant recipients

To prevent graft rejection after renal transplantation, immunosuppressive therapy with corticosteroids, and either azathioprine, ciclosporin, tacrolimus or sirolimus will be required for the duration of the graft survival. The long-term consequences of this are best documented after kidney transplant, but similar problems arise after other organ transplants; the degree of immunosuppression needed after liver transplants is not so great, whilst that required after cardiac or heart–lung transplantation is greater. The effects of these drugs on the skin include:

Corticosteroid effects. These include skin atrophy, fragility and purpura; see Cushing's syndrome (p. 62.3) for details.

Infections [1]. Some infections, such as candidal infection, herpes simplex infection, and impetigo are prominent during the first post-transplant year. Dermatomycoses, herpes zoster and folliculitis are more common after the first post-transplant year [2]; infections with unusual organisms (e.g. cutaneous alternariosis) should always be considered, as discussed below. The incidence of warts increased steadily after transplant, such that of patients transplanted for more than 5 years, 92% were found to have warts and 65% had more than five each [3]. Warts may become unusually florid (Fig. 62.25) [4], and recalcitrant to therapy [5].

Exotic and aggressive opportunistic infections are a challenge to both diagnose and treat, and may be caused by virus (disseminated herpes simplex and varicella zoster infection, cytomegalovirus [6]), bacteria (tuberculosis and atypical acid-fast infections [7]), fungi, yeasts and moulds (aspergillus [8], altenaria [9], nocardia [10], invasive candidiasis, cryptococcus [11], sporotrichosis [12], histoplasmosis [13], mucormycosis [14]) and protozoa (leishmaniasis [15] and acanthamoebiasis [16]). Abscesses, nodules or cellulitic lesions need biopsy, with appropriate culture as well as histological examination, and close microbiological liaison.

Skin tumours. Transplant recipients are at greatly increased risk of developing skin cancers, particularly squamous cell carcinoma (SCC; Fig. 62.26) [17–19]. The pathogenesis of post-transplant skin cancer is reviewed in detail in [19]; SCC is discussed in Chapter 52. Renal recipients are at particular risk as the survival period is now so prolonged. Liver transplant recipients may not be as susceptible due to the less profound immunosuppression they require [20]. In a series of nearly a thousand recipients from the south of England followed for over 20 years, 61% of patients developed a skin cancer, and SCC was the most frequent. The cancer may behave aggressively, particularly on the ear and scalp, and have a spindle cell morphology. The mean time to first cancer development post transplant was 8 years, and 60% of patients had multiple cancers, with as many as 50 lesions recorded. The risk of BCC was also increased [20]. The same group has reported melanomas occurring at approximately eight times the rate in the general population [21]. Due to regular surveillance of their skin, melanomas were identified with relatively thin Breslow thickness, so prognosis was good.

An important issue in post-transplantation skin cancers is the reversal of the expected ratio of BCCs compared with SCCs. Whilst the incidence of BCC may be increased 10-fold compared to the normal population, that of SCC is increased 65- to 250-fold. Thus SCC is at least four times as common as BCC in post-transplant patients [22]. The risk of tumours is multifactorial—as well as skin type, sun exposure history and degree of immunosuppression, genetic factors may play a part. These include polymorphisms in genes coding for glutathione-S-transferase, interleukin-10, p53,

Fig. 62.25 Viral warts and multiple dysplastic lesions on the arms in a renal transplant recipient.

Fig. 62.26 Squamous cell carcinoma and semi-confluent dysplastic lesions on the trunk of a patient immunosuppressed after organ transplantation.

retinoblastoma, folate metabolism, melanocortin-1 receptor and vitamin D receptor [23]. Human papilloma virus (HPV) may also be co-oncogenic; HPV DNA can be detected in 65–90% of SCCs in immunosuppressed subjects, often several types of HPV are within a single tumour [22].

Kaposi's sarcoma affecting the skin as well as other organs is well recognized after transplantation; it was reported in 3% of kidney recipients in one series [24], and has been documented as being between 84- and 500-fold commoner in subjects with a transplant compared to the normal population [22]. Some series report Kaposi's sarcoma confined to the skin [25]—this is possibly as a result of surveillance and early detection in at-risk individuals, as earlier series suggested internal involvement in 50%. Merkel cell tumours also seem to be more frequent and carry a poor prognosis [22,26]; increased risk up to 80-fold greater than the normal population has been suggested. Appendageal tumours are common, as is sebaceous gland hyperplasia. Sebaceous carcinomas are overrepresented in organ recipients [27]. Lymphomas of both B (associated with Epstein–Barr virus) and T–cell lineage (often $CD30^+$) are reported [28]. Sirolimus (rapamycin) may be less likely to provoke skin cancers [19], and a change from immunosuppression with ciclosporin and mycophenolate mofetil to sirolimus has been described to cause regression of Kaposi's sarcoma [25]. Oral retinoids (notably acitretin) appear to reduce the rate at which skin cancers develop [29,30]; some renal physicians have reservations as the manufacturer's product information states that renal disease is a contraindication to use of acitretin, but, although there is a possible increased tendency to mucocutaneous side effects, none of the studies reported have shown any unexpected renal adverse effect. Topical imiquimod is useful in reducing skin dysplasia in patients at high risk of developing skin neoplasms [31].

Cardiac disease

There are several diseases in which both cardiac and skin involvement may be found (Table 62.15). Most of these are part of a syndrome or are systemic disorders affecting other organs as well [1,2]; most are discussed in other chapters, but some are briefly described below. Disorders of blood vessels are not included here. The effects of skin disease on the heart (e.g. cardiac failure due to erythroderma) and indirect effects, such as anaemia due to immunosuppressive agents used to treat the skin, are not discussed. Numerous infections may occasionally cause myocardial disease

Table 62.15 Conditions that affect the heart and skin.

Disease	Main cardiac feature, or comment
Congenital/inherited	
Ehlers–Danlos syndrome	Dilated main vessels, mitral or tricuspid insufficiency, cardiac/vascular rupture (type IV)
Cutis laxa	Early CAD, aortic aneurysm, mitral valve prolapse
Marfan syndrome	Aortic aneurysm, aortic regurgitation, mitral valve prolapse or regurgitation
Pseudoxanthoma elasticum	Arterial calcification, CAD, mitral valve prolapse
Werner's disease	Early CAD
Progeria	Early CAD
Cockayne's syndrome	Early CAD
Cornelia de Lange's syndrome	Septal defects, persistent ductus arteriosus, pulmonary stenosis
Fabry's disease	Conduction defects, arrhythmias, hypertension, left ventricular hypertrophy, mitral valve prolapse
Noonan's syndrome	Pulmonary stenosis, septal defects, hypertrophic cardiomyopathy, aortic abnormalities, others
Rubinstein–Taybi syndrome	Aortic coarctation, persistent ductus arteriosus, pulmonary stenosis, septal defects
LEOPARD syndrome	E, ECG abnormalities (various forms of heart block); P, pulmonary stenosis; also subaortic stenosis and hypertrophic cardiomyopathy
Tuberous sclerosis	Cardiac rhabdomyomas
Neurofibromatosis	Hypertension (renovascular or phaeochromocytoma)
Incontinentia pigmenti	Patent ductus arteriosus, tricuspid insufficiency
Alagille's syndrome	Pulmonary artery hypoplasia/stenosis
Di George's syndrome	Tetralogy of Fallot, aortic arch defects
Lymphoedema–distichiasis syndrome	Tetralogy of Fallot, patent ductus arteriosus
Naxos disease	Arrhythmogenic right ventricular cardiomyopathy
Chromosomal syndromes	Various—includes Down's syndrome, Turner's syndrome, trisomy 13, trisomy 18
Inflammatory diseases, connective tissue disease, vasculitis	
Systemic lupus erythematosus	Vegetations (especially mitral, Libman–Sacks endocarditis), pericarditis, myocarditis, aortic/mitral regurgitation
Neonatal lupus erythematosus	Neonatal heart block (various patterns), septal defects, persistent ductus arteriosus, tricuspid/mitral insufficiency
Systemic sclerosis	Pericarditis and effusion, conduction defects, myocardial fibrosis, cardiomyopathy, cor pulmonale
CREST	Pulmonary hypertension
Polyarteritis nodosa	Coronary artery vasculitis, ECG abnormalities, hypertension
Behçet's disease	Pericarditis, pulmonary and coronary artery aneurysm
Antiphospholipid syndrome	Vegetations, valvular heart disease, coronary artery thrombosis, pericardial effusion, CCF
Degos's disease	Pericarditis, pericardial effusion
Churg–Strauss disease	Pericarditis, cardiac fibrosis, pericardial effusion
Wegener's granulomatosis	Cardiomyopathy
Cholesterol emboli	Coronary artery occlusion
Other vasculitides	Coronary artery vasculitis
Dermatomyositis	Conduction defects, arrhythmias, cardiomyopathy, CCF, (rarely) pulmonary hypertension
Relapsing polychondritis	Mitral or aortic insufficiency, dissecting aortic aneurysm, pericarditis, myocardial ischaemia, heart block, aortitis
Rheumatic fever	Mitral and aortic valve disease
Kawasaki disease	Conduction defects, coronary artery aneurysms, pericardial effusion, cardiomegaly
Multicentric reticulohistiocytosis	Pericarditis, cardiomegaly, CAD, CCF
Hypereosinophilic syndrome	Eosinophilic endomyocarditis, valvular scarring, CCF, restrictive cardiomyopathy
Sarcoidosis	Conduction defects, arrhythmias, CCF
Reiter's disease	Conduction defects, aortic regurgitation
Deposition, metabolic and endocrine disorders	
Amyloidosis	Conduction defects, cardiomegaly, CCF
Haemochromatosis	Arrhythmias, cardiomyopathy, CCF
Wilson's disease	Arrhythmias, cardiomyopathy
Mucinoses: scleromyxoedema	Cardiomyopathy, CCF
Atrial myxoma syndromes	See text
Hyperlipidaemias	CAD
Diabetes mellitus	CAD, cardiomyopathy
Hyperthyroidism	Tachycardia, atrial fibrillation, mitral regurgitation
Hypothyroidism	Bradycardia, CAD, pericardial effusion
Acromegaly	Left ventricular hypertrophy, CCF
Carcinoid syndrome	Tricuspid or pulmonary stenosis, right heart failure
Phaeochromocytoma	Variable heart rate, hypertension/hypotension
Mastocytosis	Tachycardia, hypotension, arrhythmia, angina
Homocystinuria	Atherosclerosis

(Continued)

Table 62.15 *Continued*

Disease	Main cardiac feature, or comment
Embolic diseases	
Subacute bacterial endocarditis	Vegetations, valvular incompetence
Cholesterol emboli	Usually from proximal arteries rather than cardiac
Atrial myxomas	See text
Infections	
Lyme disease	Myocarditis, heart block
Syphilis	Aortitis, aortic aneurysm, aortic and mitral regurgitation, obstructed coronary arteries
Varicella	Myocarditis
Septicaemia	Pustules, infarcts, disseminated intravascular coagulopathy
Congenital rubella	Pulmonary artery and valve stenosis, patent ductus arteriosus
Whipple's disease	Pericarditis, myocarditis, valve deformity (especially mitral valve endocarditis)
Drugs	
Used in cardiology, causing rash	e.g. amiodarone (photosensitivity, pigmentation)
Cardiotoxic and cause skin eruptions	e.g. doxorubicin (cardiotoxic, anagen effluvium, pigmentation)
Used for skin disease, cardiovascular side effects	e.g. ciclosporin (hypertension)
Teratogenic, causing both skin and cardiac defects	e.g. alcohol, phenytoin, retinoids
Miscellaneous	
Earlobe crease	CAD
POEMS syndrome	Cardiac failure
Mycosis fungoides, Sézary syndrome	Heart is infiltrated in advanced disease
Kaposi's sarcoma	Heart is commonly involved
Diffuse neonatal haemangiomatosis	High output cardiac failure
Erythroderma, any cause	High output cardiac failure
Pacemaker reactions	Infection, contact dermatitis, mechanical issues
Clubbing of nails	Cyanotic congenital heart defects
Red lunulae	Occur in CCF

CAD, coronary artery disease; CCF, congestive cardiac failure; CREST, calcinosis, *R*aynaud's phenomenon, *e*sophageal disease, *s*clerodactyly, *t*elangiectasia; ECG, electrocardiogram; LEOPARD, *l*entigines, *E*CG abnormalities, *o*cular hypertelorism, *p*ulmonary stenosis, *a*bnormalities of genitalia, *r*etardation of growth, and *d*eafness (syndrome); POEMS, *p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M* protein, *s*kin changes (syndrome).

and may have an exanthem (for example, parvovirus B19), but these are not discussed individually. Drug reactions due to cardiac medications are described in Chapter 75.

Consequences of cardiac disease

Dermatological consequences of cardiac disease include skin colour changes such as cyanosis, erythema due to secondary polycythaemia, and a combination of the two that may occur in congenital heart disease (and which has been termed erythremia). Finger clubbing is a consequence of congenital cyanotic heart disease, but occurs in other situations as well. Applying pressure on the tip of the nail in subjects with aortic regurgitation reveals visible flushing of the nail bed in time with the pulse, due to the wide pulse pressure in this disorder (Quincke pulsation) [2].

Congenital and inherited disorders

Cardiac involvement occurs in several congenital and inherited conditions, such as the LEOPARD syndrome, Anderson–Fabry disease, Alagille's syndrome and the cardiofaciocutaneous and Noonan's syndromes [1–8], as well as in chromosomal abnormalities such as Turner's syndrome and trisomy 13 or 18 [1]. The lymphoedema–distichiasis syndrome, due to mutations in *FOXC2* (*MFH-1*) on chromosome 16q24.3, has been linked to cardiac anomalies such as tetralogy of Fallot and patent ductus arteriosus [9,10]; spinal arachnoid cysts also occur. Cardiac rhabdomyomas occur in about 50% of patients with tuberous sclerosis (see Chapter 15).

In the LEOPARD syndrome (multiple lentigines syndrome; MIM *151100) [3] there are widespread *l*entigines, *e*lectrocardiographic abnormalities, *o*cular hypertelorism, *p*ulmonary stenosis, *a*bnormal genitals, *r*etardation of growth and *d*eafness. The cardiac involvement includes left-axis deviation on the electrocardiogram (ECG), ventricular hypertrophy and arrhythmia.

In angiokeratoma corporis diffusum (Anderson–Fabry disease; MIM *301500) [4], cardiac involvement may be manifest as arrhythmias, an abnormal P–R interval on ECG and left-ventricular hypertrophy. ECG abnormalities may also be found in heterozygotes. Manufactured α-galactosidase is now available to treat this condition [4] and appears to be more beneficial for the renal and cardiac lesions than for the cutaneous angiokeratomas, although accumulated globotriaosylceramide in the skin decreases during treatment.

Coronary artery disease

Coronary artery disease and ischaemic heart disease may occur in premature ageing syndromes such as progeria and Werner's syndrome, and premature myocardial ischaemia has also been reported in pseudoxanthoma elasticum, although it seems to be less common than the presence of a calcifying vascular pathology might suggest [2,11]. Coronary artery disease may be associated with xanthelasma or xanthomas due to hyperlipidaemia [2]. Both all-cause and cardiac-specific morbidity and mortality have been linked with the presence of a unilateral or bilateral diagonal earlobe skin crease [12,13], although others suggest that the association is with older age rather than with coronary artery disease *per se*. Both antinuclear [14] and high-titre anticardiolipin antibodies [15] have been demonstrated in a high proportion of patients with coronary artery disease; the significance of these is uncertain.

Connective tissue and systemic diseases

Cardiac involvement is common in systemic disorders such as sarcoidosis [16], connective tissue diseases [17–19], vasculitides (Chapter 50) [20,21], dermatomyositis (Chapter 51), relapsing polychondritis (Chapter 68) [22] and the hypereosinophilic syndrome [23,24], although it may be underestimated if symptoms are absent. Sudden death due to conduction defects and ventricular arrhythmias is the most important complication, and is particularly well recognized in sarcoidosis [16]; cardiomyopathy may also occur. The major vasculitides that affect the heart are Wegener's granulomatosis, polyarteritis nodosa, Churg–Strauss syndrome, temporal arteritis and Takayasu arteritis. Cardiac involvement is commoner in Churg–Strauss syndrome than in Wegener's granulomatosis, but has low discriminatory value—this is discussed in more detail in Chapter 50 and in the section on respiratory disease and the skin, below.

A number of cardiac complications occur in systemic lupus erythematosus (SLE), especially pericarditis, which may be present in 60–80% of patients at autopsy (Chapter 51) [2,25]. Neonatal LE is a particularly important entity, as about two-thirds of affected children have congenital heart block, although the frequency of this manifestation varies between countries [18,19]. Mothers of affected children generally express the 52-kDa and 60-kDa anti-SS-A (Ro) antibodies, even if they have no other features of LE. This antibody group is particularly associated with subacute cutaneous LE, but also with systemic LE. Mothers of children with neonatal LE with heart block tend to have higher titres of anti-SS-A but lower titres of anti-SS-B (La) antibody than mothers of children with neonatal LE rash alone [19].

Cardiac involvement occurs in 80% of patients with systemic sclerosis, but is not always clinically apparent; pericarditis, pericardial effusion, myocardial fibrosis, endothelial damage to coronary arteries and heart failure due to pulmonary arterial hypertension all occur [2,26,27]. Symptoms include heart failure, palpitations and myocardial infarction. Vasospasm may occur due to Raynaud's phenomenon. Pulmonary hypertension is particularly associated with CREST.

In the antiphospholipid syndrome (APLS) [28], about 50% of patients have valvular heart disease, either vegetations or thickening. The mitral valve is most frequently affected. About 5% require cardiac valve surgery, but many have no symptoms. There is also an increased incidence of coronary artery disease. Intracardiac thrombus is a rare complication. Unrecognized APLS may explain some cases of valvular heart disease in SLE.

Cardiac involvement is frequent in primary and in familial amyloidosis [29], causing features of cardiomyopathy such as congestive heart failure, low voltage on the ECG and conduction disturbances. Cardiomegaly is present in about one-third of the patients. Cutaneous signs, macroglossia and demonstration of amyloid deposition on skin histology support the diagnosis.

Kawasaki disease (mucocutaneous lymph-node syndrome) is an acute febrile disease of unknown aetiology, with accepted diagnostic criteria [30]. Coronary artery aneurysms may develop in up to 25% of patients, more commonly in children; conduction defects, pericardial effusion and cardiomegaly also occur. Symptoms and signs may include murmurs, gallop rhythm, angina and myocardial infarction [25,30]. Echocardiography and ECG are indicated. Treatment consists of acetylsalicylates and high doses of intravenous gammaglobulin.

Infections

Subacute bacterial endocarditis (SBE) [31–33] typically occurs in patients with a past history of heart disease (rheumatic fever, congenital heart disease, heart valve operation) or of parenteral drug addiction. About 75–80% of cases are caused by *Staphylococcus aureus* or streptococcal species, predominantly *Streptococcus viridans*. Cutaneous lesions may represent either septic emboli or immune complex disease due to the bacterial focus [31]; organisms can occasionally be cultured from skin lesions [32]. The skin lesions may be purpuric, pustular or erythematous, and various patterns are described. A non-specific small vessel vasculitis with splinter haemorrhages of the nail fold or nail bed occurs in about half of affected individuals. Similar small haemorrhages occur on the conjunctivae and retina (Roth spots). Osler's nodes are small, tender, red papules situated mainly on the distal finger and toe pads; Janeway lesions are faint, red, macular lesions on the thenar and hypothenar eminences. Both rheumatoid factor and cANCA can be demonstrated in some patients with SBE; these are of uncertain significance, but may erroneously suggest that the diagnosis is of systemic ANCA-associated vasculitis rather than of infective aetiology [33].

Rheumatic fever is a complication of streptococcal infection [34]. It causes arthritis, carditis, neuromuscular disease (Sydenham's chorea, dysphagia, dysarthria, distal weakness) and cutaneous lesions. The latter include erythema marginatum and papular lesions on the extensor surface of the extremities, particularly near the joints—both of these manifestations are usually transient, typically resolving after a few weeks. Erythema marginatum is a transitory gyrate erythema situated mainly on the trunk and proximal parts of the extremities. Urticaria, erythema nodosum and purpura are described in about 2% of patients. Cardiac features include valvular disease, pericarditis, myocarditis and congestive cardiac failure.

Cardiac myxoma syndromes

Carney complex (type I, MIM #160980; type II, MIM *605244). A number of atrial myxoma syndromes have been described, with various eponyms and acronyms and overlapping features [35–39].

These include LAMB syndrome, NAME syndrome, Danoff syndrome and the Carney complex. LAMB is an acronym for *l*entigines, *a*trial myxoma, *m*ucocutaneous myxoma and *b*lue naevi. The NAME syndrome indicates blue *n*aevi, *a*trial myxoma, *m*yxoid neurofibromas and *e*phelides. The inheritance is autosomal-dominant. In the Danoff syndrome there are, apart from atrial myxomas, adrenocortical dysplasia, lentigines and spindle cell tumours.

About 50% of cases of bilateral, pigmented, micronodular adrenal hyperplasia—a rare cause of ACTH-independent Cushing's syndrome—are associated with the Carney complex; anti-ACTH receptor antibodies are present and stimulate adrenal growth and secretion. Other features include cardiac myxomas (in one-third of patients), skin myxomas (two-thirds), skin pigmentation (96%), myxoid fibroadenomas of the breast (in one-third of women, uncommon in men), GH-secreting pituitary tumours (acromegaly occurs in 8% of patients), Sertoli cell (in 10%) and Leydig cell testicular tumours (which cause male precocious puberty), thyroid cysts, hyperplasia and tumours (10%), and ovarian cysts and tumours (which are felt to be underestimated in frequency) [37–39]. Psammomatous melanotic schwannoma is rare, but is usually part of this syndrome when it occurs [40].

The genetic background of these disorders has been extensively investigated. Carney complex type 1 (CNC1) is linked to a susceptibility gene for the protein kinase A type 1α regulatory subunit gene (*PRKAR1A*) and has loci on chromosomes 2p16 and 17q23–24, whilst CNC2 links to a currently unknown gene on chromosome 2p. Genetic evaluation has demonstrated that this disorder is related to PJS. Any patient with multiple melanocytic and myxomatous tumours of the skin and mucosa (including vulval melanotic macules) should have a cardiac evaluation.

From a dermatological aspect, atrial myxomas may present due to embolic infarction of the skin. They may mechanically interfere with cardiac function and can also lead to pericarditis. Systemic malaise, pleurisy, Raynaud's phenomenon and the occasional occurrence of ANCA [41] may suggest other forms of vasculitis as the cause of skin lesions.

Miscellaneous

Cardiac pacemaker and implantable defibrillator dermatoses. Cutaneous reactions over the site of implanted cardiac pacemakers have been reported [42–45]. Most of these are either infections or mechanical issues (erosions, extrusions, capsular contracture, exposed generator or electrodes, bronchopleural cutaneous fistulae) and may respond to antibiotics or altered positioning of the pacemaker [42,43]. However, contact dermatitis to epoxy resins, nickel or chromium may occur, in which event removal of the implanted material and use of titanium pacemaker casings may be appropriate [44,45]. A reticular telangiectatic pattern of erythema overlying pacemaker or defibrillator sites may occur [46,47]. Cardiac pacemakers also have dermatological surgical relevance, as they may malfunction during the use of electrosurgery [48].

Respiratory system

Pulmonary disease rarely occurs as a direct consequence of a primary skin disease, except for instances such as metastasis from a primary skin tumour (e.g. melanoma). Similarly, there are relatively few instances in which skin abnormalities occur as a direct consequence of respiratory pathology. Examples include cyanosis due to severe pulmonary disease or intrapulmonary right-to-left shunts, and finger clubbing due to chronic cyanotic lung disease or neoplasm. Dermatomyositis may occur as a paraneoplastic phenomenon due to lung cancer (but, as discussed below, lung disease also occurs as a consequence of dermatomyositis). Amyloidosis may occur secondary to chronic respiratory diseases such as bronchiectasis or cystic fibrosis, but cutaneous signs in secondary amyloidosis are generally few, even though aspiration of subcutaneous fat for histological examination can be diagnostic. Tumours may cause direct nerve damage and abnormalities of sweating [1,2].

However, in most instances in which the skin and respiratory tract exhibit the same disease process, this is as part of a multisystem disorder. This section on the respiratory system concentrates on this diverse group of disorders (Table 62.16).

Congenital and inherited disorders

Examples are listed in Table 62.16. NF1 (Chapter 15) is not uncommonly associated with the development of restrictive lung disease if there is severe scoliosis. Intrathoracic, intra-abdominal or retroperitoneal diffuse plexiform neurofibromas can also compromise pulmonary function [3]. Fibrosis is found in around 10% of patients with NF1, mainly in the lower lobes, and bullous changes may occur in the upper lobes [4]. Pleural effusions have been reported in tuberous sclerosis [5] (Chapter 12). Pulmonary involvement is uncommon but, especially in adult female patients, there may be numerous small cysts which represent lymphangioleiomyomatosis [6]. These may be mistaken for tuberculosis or sarcoidosis radiologically. Diffuse lower lobe fibrosis and laryngeal involvement has been reported in Darier's disease [7] (Chapter 19). α_1-Antitrypsin deficiency, particularly the ZZ genotype, links cutaneous panniculitis with emphysema and hepatic cirrhosis [8]. In familial dysautonomia (Riley–Day syndrome), there are acute episodes of bronchopneumonia, with profuse mucous secretion causing dyspnoea. Skin changes include multiple excoriations, and erythematous mottling associated with fever and sweating [9]. Radiological features of lung disease [10] may be accompanied by abdominal distension as the 'chest–abdomen' sign [11]. Ataxia–telangiectasia (Louis–Bar syndrome) may be associated with pulmonary problems, including recurrent pneumonia, bronchiectasis and pulmonary fibrosis [12].

Infections

Numerous infections may be associated with both respiratory and skin disease, and only a selection of these have been listed. Many viral infections, for example, may cause upper and sometimes lower respiratory tract symptoms in association with either a non-specific exanthem or with erythema multiforme. *Mycoplasma* infection is particularly associated with erythema multiforme with mucosal involvement (Stevens–Johnson syndrome). *Psittacosis (ornithosis)* may be accompanied by erythema nodosum and erythema multiforme (Bateman's syndrome).

Associations between *tuberculosis* and the skin include non-specific reactions such as erythema nodosum or erythema multiforme, as well as several patterns of specific skin lesion such as lichen scrofulosorum, Bazin's disease or papulonecrotic tuberculide (Chapter 31). Several *systemic mycoses* are caused by inhalation but may subsequently cause skin lesions (Table 62.16)—either non-specific reactions such as erythema multiforme or erythema nodosum, or specific lesions caused by haematogenous dissemination. Other mycoses may have primary cutaneous lesions with occasional spread to internal organs, including the lung (e.g. sporotrichosis). *Pulmonary melioidosis* may run a subacute course and last for one to several weeks. It may be contracted by inhalation, causing early pneumonic symptoms, or via skin defects, in which case abscess formation precedes the septic stage. Urticaria may occur in chronic melioidosis [13].

Connective tissue diseases

This group of disorders has a variety of respiratory features.

Respiratory disease is frequent in the various forms of *scleroderma* [14,15]. Systemic sclerosis is associated with fibrosing alveolitis and interstitial fibrosis, causing a restrictive defect. This occurs

Table 62.16 Conditions that affect the skin and respiratory system.

Disease	Respiratory tract features or comment
Congenital/inherited	
Atopic disease	Asthma, hay fever
Cutis laxa	Emphysema, cor pulmonale
Tuberous sclerosis	Rhabdomyomas
Neurofibromatosis	Kyphoscoliosis, intrathoracic neuromas, lung fibrosis, bullae
Ataxia–telangiectasia	Pneumonia, bronchiectasis, pulmonary fibrosis
Hereditary haemorrhagic telangiectasia	Haemoptysis, dyspnoea, cyanosis due to arteriovenous shunting
α_1-antitrypsin deficiency	Emphysema
Darier's disease	Lower lobe fibrosis, laryngeal involvement
Dyskeratosis congenital	Interstitional pneumonia, fibrosis
Lipoid proteinosis	Laryngeal involvement
Riley–Day syndrome	Lung infiltrate, pneumonia
Birt–Hogg–Dubé syndrome	Lung cysts, pneumothorax
Hyper-IgE syndrome	Abscesses, pneumonia
Infections and infestations	
Tuberculosis	Specific skin lesions, erythema nodosum
Mycobacterium avium–intracellulare infection	May disseminate to skin (usually in HIV infection)
Leprosy	Laryngeal involvement
Mycoplasma infection	Causes erythema multiforme (often mucosal)
Dissemination of pulmonary fungal infections	Blastomycosis, coccidioidomycosis, cryptococcosis, aspergillosis, histoplasmosis, melioidosis
Scrub typhus	Pneumonia (common)
Varicella	Pneumonia
Measles	Pneumonia
Larva migrans	Asthma/bronchitis with eosinophilia
Chronic mucocutaneous candidiasis	Bronchiectasis
Whipple's disease	Cough, pleural effusion, pulmonary infiltrate, hilar lymphadenopathy
Infiltrations and metabolic	
Histiocytoses (Langerhans' cell histiocytosis, Rosai–Dorfman disease, haematophagocytic syndrome, necrobiotic xanthogranuloma, sea-blue histiocytosis, others)	Pulmonary nodules and fibrosis, upper respiratory tract infiltration disease, xanthoma disseminatum
Amyloidosis	Cutaneous amyloid deposition secondary to chronic lung disease, lung infiltration in primary amyloidosis
POEMS	Pleural effusion, bronchospasm
Carcinoid syndrome	Bronchospasm
Hypothyroidism	Laryngeal involvement
Myxoma	Pleurisy
Inflammatory	
Sarcoidosis	Pulmonary fibrosis, hilar lymphadenopathy, laryngeal involvement, necrotizing sarcoid granulomatosis
Pulmonary vasculitides	See text (this section)
Systemic sclerosis	Interstitial fibrosis, pneumothorax, pulmonary hypertension (especially in CREST)
Sjögren's syndrome	Decreased secretions, sinusitis, bronchoalveolitis, interstitial lung disease
Lupus erythematosus	Pleuritis, pleural effusion, shrinking lungs syndrome
Mixed connective tissue disease	Fibrosing alveolitis (especially U_1 ribonucleoprotein antibody-positive)
Antiphospholipid syndrome	Pulmonary embolism, infarction, thrombosis, haemorrhage
Dermatomyositis	Muscular weakness, pharyngeal dysfunction (aspiration pneumonia), interstitial lung disease, bronchiolitis obliterans
Relapsing polychondritis	Tracheal collapse
Multicentric reticulohistiocytosis	May be associated with bronchial neoplasia, also lung infiltration, pleural effusion
Bullous diseases (epidermolysis bullosa, pemphigus, erythema multiforme/Stevens–Johnson syndrome/toxic epidermal necrolysis)	Upper respiratory tract involvement; paraneoplastic pemphigus is associated with intrathoracic disease, especially Castleman's disease, thymoma
Graft-versus-host disease	Restrictive defect, fibrosis
Pyoderma gangrenosum	Neutrophilic nodules in lung, tracheal pyoderma
Familial Mediterranean fever	Pleuritis

(*Continued p. 62.82*)

Table 62.16 *Continued*

Disease	Respiratory tract features or comment
Drugs	
Used in respiratory disease, causing rash	e.g. co-trimoxazole (drug eruptions)
May cause skin eruptions and respiratory tract disease	e.g. antibiotic-induced toxic epidermal necrolysis, cisplatin (bronchospasm, pigmentation)
Used for skin disease, respiratory side effects	e.g. isotretinoin (bronchospasm)
Miscellaneous	
Angio-oedema	Upper airway obstruction
Anaphylaxis	Bronchospasm
Pancreatitis	May cause basal pleural reaction, and cutaneous fat necrosis
Yellow nail syndrome	Pleural effusion, bronchiectasis
Mastocytosis	Rhinorrhoea, laryngeal oedema, bronchospasm
Tumours	Metastatic disease, Kaposi's sarcoma, lymphomatoid granulomatosis, extensive mycosis fungoides/Sézary syndrome, others

HIV, human immunodeficiency virus; POEMS, *p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M* protein, *s*kin changes (syndrome).

in at least 50% of patients. Symptoms (exertional dyspnoea and cough) may be relatively late in presenting—pulmonary function tests including transfer factor should be measured. Pneumothorax, pleural effusion, respiratory muscle involvement and 'splinting' of the chest by sclerotic skin may all occur. Pulmonary vascular disease leading to pulmonary hypertension is a particular concern in CREST syndrome; this may be identified by transoesophageal echocardiography and treated with bosanten.

Over 50% of anti-U1RNP-positive patients with *systemic lupus erythematosus* (SLE) and about a quarter of those with *mixed connective tissue disease* may have pleurisy [16]. Involvement of the respiratory muscles may lead to diaphragmatic elevation and the *'shrinking lungs' syndrome* [17]. These conditions are discussed in more detail in Chapter 51. Pulmonary embolism, haemorrhage, infarction and hypertension may occur in patients with the *antiphospholipid syndrome* [18].

Relapsing polychondritis [19] is due to autoantibodies against type II collagen, and is a potentially fatal disease. Dyspnoea and inspiratory stridor occur due to swelling of the respiratory tract, and collapse of cartilages of the larynx and trachea, in over 50%. Costal cartilage is involved in one-third of cases. Inflamed nasal and auricular cartilages are present in most patients, with nasal obstruction, arthropathy and high erythrocyte sedimentation rate (ESR). The disorder may therefore mimic one of the vasculitides, such as Wegener's granulomatosis. The non-cartilaginous lobe of the ear is classically spared in relapsing polychondritis.

In *dermatomyositis,* there are three main mechanisms that provide a link with respiratory disease [20–22]. Firstly, dermatomyositis may occur as a consequence of bronchial carcinoma, the commonest malignancy associated with dermatomyositis in males [20]. Muscular weakness due to myositis may affect either the intercostal and thoracic musculature, or the larynx and pharynx—the latter may lead to aspiration pneumonia as a complication. Finally, interstitial lung disease or bronchiolitis obliterans may occur due to dermatomyositis. The lung disease is typically associated with the presence of antiaminoacyl-tRNA synthetase antibodies, notably anti-Jo-1, and with anti-tRNA antibodies such as anti-$tRNA^{his}$. Patients with these antibodies only comprise 15–20% of individuals with dermatomyositis, but most patients with lung disease have one of these antibodies. The antisynthetase syndrome consists of dermatomyositis (or polymyositis) with interstitial lung disease, arthritis and Raynaud's phenomenon [22]. Presence of antisynthetase antibodies is also associated with the clinical entity of 'mechanic's hands' in dermatomyositis, but they are not usually a feature of paraneoplastic dermatomyositis. Dermatomyositis may also indirectly be associated with lung disease as a consequence of treatment—either infection due to immunosuppression, or rarely drug-induced pneumonitis (methotrexate).

In *Sjögren's syndrome,* alveolitis can be demonstrated in about 50% of patients, but is often asymptomatic. Inspissated secretions may predispose to pneumonia; obstructive and interstitial lung disease may occur [23].

Vasculitis and neutrophilic dermatoses (see also Chapter 50)

Vasculitis of many types may affect the lung. The major pulmonary vasculitides are Wegener's granulomatosis, Churg–Strauss disease, polyarteritis nodosa and Behçet's disease [24].

Behçet's disease (Chapter 50). The frequency of lung involvement in Behçet's disease may be as high as 19%, although 5–10% is a more frequent estimate. Pleurisy or perihilar radiological opacities may be found [23], and pulmonary arterial aneurysm is an important feature, which can be fatal [25]. About 90% of patients with Behçet's disease complicated by pulmonary artery aneurysm also have thrombophlebitis.

Small-vessel vasculitis (Chapter 50). Any form of small-vessel vasculitis can also affect the lung, even urticarial vasculitis. In one large series, over 20% of patients with urticarial vasculitis had pulmonary disease, either chronic obstructive pulmonary disease or asthma. Although it is not clear that these were always causally related to the vasculitis, obstructive pulmonary disease was more frequent in the group of patients with hypocomplementaemia [26], and lung vasculitis or serological evidence of LE was demonstrated in over 50% of patients with lung disease.

Wegener's granulomatosis [27,28]. This is an uncommon disease. The 'classic' syndrome is characterized by necrotizing granulomatous vasculitis of the upper and lower respiratory tracts, necrotizing glomerulonephritis and disseminated vasculitis of various organs. Skin lesions are frequent, including vasculitis with purpura, subcutaneous nodules and ulcers (see also Chapter 50). Upper airway disease causes nasal discharge, ulceration and bleeding, and oral ulceration. Pulmonary changes are typical with bilateral infiltrate, nodules or cavities. Subglottic or tracheobronchostenosis may also occur. There is no hilar or mediastinal lymphadenopathy. Prognosis is poor in patients with lung or renal disease; chronic nasal staphylococcal carriage is also associated with a poorer prognosis. Treatment consists of immunosuppressive agents (cyclophosphamide, azathioprine, chlorambucil and methotrexate). Trimethoprim–sulfamethoxazole (co-trimoxazole) also appears to be of benefit in induction of remission [29]. Diffuse alveolar haemorrhage, due to extensive pulmonary capillaritis, is a life-threatening complication of Wegener's granulomatosis—it also occurs in microscopic polyangiitis, and more rarely in SLE, antiphospholipid syndrome, Behçet's disease and secondary to drugs such as D-penicillamine [30].

Churg–Strauss syndrome (allergic granulomatous angiitis) [27,28]. This rare condition comprises rhinitis, asthma, pneumonitis, fever, malaise, eosinophilia (usually over 10%) and widespread vasculitis, which may cause skin lesions, neuropathy and cardiac or less commonly renal disease. Cutaneous lesions include palpable purpura and nodular lesions. Distinction from Wegener's granulomatosis or microscopic polyangiitis may be difficult in the early stages—peripheral eosinophilia is the most useful discriminatory feature [31], but eosinophils in inflammatory infiltrates may occur in all three disorders (also in SLE and Sjögren's syndrome), as may mononeuritis multiplex. Cardiac disease is more frequent in Churg–Strauss syndrome than in Wegener's granulomatosis, but is not specific; a history of asthma and other allergies with the other features suggest Churg–Strauss syndrome [24,27]. There is some concern that leukotriene receptor antagonists may provoke Churg–Strauss syndrome in patients with asthma, although an alternative explanation is simply that disease progression or altered corticosteroid therapy allowed additional clinical features to become apparent [32,33]. Therapy consists of high-dose corticosteroids, if necessary with other immunosuppressive agents such as cyclophosphamide, azathioprine or chlorambucil.

PAN and microscopic polyangiitis (microscopic polyarteritis) [27]. These conditions are distinguished by the size of vessels affected and by the usual absence of antineutrophil cytoplasm antibodies against myeloperoxidase (MPO-ANCA) in 'classic' PAN. The term 'polyangiitis' is preferred to polyarteritis for the microscopic disease, as arterioles, venules and capillaries may all be affected. Lung disease is not a particular feature of classic PAN, although bronchial arteries can be affected. By contrast, microscopic polyangiitis has many similarities to Wegener's granulomatosis, including nasopharyngeal involvement, renal vasculitis and tendency to cause alveolar haemorrhage [27,30]. However, the presence of granulomas and proteinase 3-ANCA (which suggest the diagnosis of Wegener's granulomatosis) help to distinguish these disorders.

Neutrophilic dermatoses (Chapter 50). Pulmonary and major airway involvement have been described with pyoderma gangrenosum and neutrophilic dermatoses [34–38], usually comprising focal, dense neutrophilic infiltrates with scattered radiological opacities. Tracheal lesions may occur. Endobronchial involvement may also occur in eosinophilic states such as the hypereosinophilic syndrome, although cardiac disease is more important in this condition.

Other systemic diseases

Sarcoidosis [39] is discussed in Chapter 61. Hilar lymphadenopathy occurs with erythema nodosum in acute sarcoidosis. Pulmonary involvement is the major feature in chronic sarcoidosis, about 30% of such patients also having skin lesions. *Necrotizing sarcoid granulomatosis* (also termed necrotizing sarcoid angiitis and granulomatosis) is a rare disorder that is in the differential diagnosis of Wegener's granulomatosis but is currently felt to be an arteritic variant of sarcoidosis [40]. In the respiratory system, a nodular pulmonary infiltrate is typical; extrapulmonary involvement is most commonly ophthalmological (uveitis or ophthalmoplegia) but other organs including the skin [41] may be involved and necrosis due to arteritic vascular occlusion may be a feature.

Multicentric reticulohistiocytosis is associated with pleural effusion and hilar lymphadenopathy [42]; it may also occur as a paraneoplastic phenomenon.

Scleromyxoedema has been associated with lung disease, causing dyspnoea, in a sixth of reported cases [43]. Pulmonary hypertension has been reported.

Amyloidosis (Chapter 59); involvement of the respiratory tract is common in primary amyloidosis. It may cause dyspnoea, but is often asymptomatic.

Lymphomatoid granulomatosis [44,45] is a rare lymphoproliferative disease which primarily affects the lung; radiology shows multiple, small nodules that predominantly affect the periphery of the lower lung fields. Cutaneous lesions are present in about 50% of cases, typically on the face, and consist of infiltrated flat or nodular lesions that may become necrotic and ulcerated. Histologically, there are necrotizing angiocentric lesions of various organs, with an infiltrate of atypical lymphocytes. Epstein–Barr virus infection has been demonstrated [46]. The condition behaves as a lymphoma with poor prognosis; corticosteroids and cyclophosphamide may help in some cases.

Miscellaneous

Yellow nail syndrome (MIM #153300). Associated respiratory features include recurrent pleural effusion, bronchiectasis and chronic infections such as empyema [47,48].

Paraneoplastic pemphigus (PNP). Respiratory failure in PNP is particularly important as it is frequently the cause of death in patients with this disorder. Pathologically, there is a diffuse segmental constrictive bronchiolitis of small bronchioles causing a bronchiolitis obliterans clinical picture. The mechanism may be due to autoantibody-mediated damage as direct immunofluorescence

of bronchial mucosal biopsies may demonstrate linear deposition of IgG and complement in the lamina propria [49], although $CD8^+$ T lymphocytes may have a key role in this process [50], and underlying neoplasms, toxic effects of immunosuppressive therapy, and secondary infections may all be involved in some cases.

Hoarseness as a sign of systemic disease [51]. Hoarseness from laryngeal or tracheal involvement is an important audible sign of certain systemic diseases with skin involvement. Examples are pachyonychia congenita, de Lange's syndrome, Farber's disease, lipoid proteinosis, sarcoidosis, secondary syphilis, epidemic typhus, hypothyroidism, relapsing polychondritis, LE and dermatomyositis. Several inherited or acquired bullous diseases may affect the pharyngeal or laryngeal mucosa. Carcinoma of the larynx may complicate chronic inflammation.

Haematology [1]

Disorders of the blood components and the coagulation system may have striking cutaneous and mucosal signs and symptoms and sometimes are the presenting features of haematological disease, and these will be elaborated in this section.

Erythrocyte disorders

Anaemia

Anaemia from any cause will result eventually in pallor of the skin and mucous membranes, traditionally appreciated in the palmar creases of the hand and mucous membranes of the palpebral conjunctivae and mouth. Constitutional symptoms such as fatigue, breathlessness, dizziness and postural hypotension are more likely to occur the more acutely that the anaemia has developed. Many nutritional anaemias (see also Chapter 59) develop slowly, and physiological adaptation may account for the relatively minor symptoms despite marked reduction in the haemoglobin concentration in some instances. Palmar crease erythema will be evident until the haemoglobin concentration is around 7 g/dl.

Iron deficiency. This results from an inability to absorb sufficient iron to match bodily iron losses. Many cases result from both increased losses, either overtly, as in heavy menstrual blood loss or frequent and heavy nose bleeds, or covertly, such as with intestinal blood loss from hook worm infestation, tumours or other vessel abnormalities such as angiodyspasia, coupled with inadequate dietary iron intake. Intestinal malabsorbtion due to coeliac disease (coeliac sprue) often produces a mixed iron and folic acid deficiency.

The mucocutaneous signs [2,3] of iron deficiency include pallor, koilonychia or spooning of the nail plate, diffuse hair thinning and pruritus. A burning sensation of the tongue (glossodynia) and cravings for eating unpalatable substances (pica) are described in iron deficiency.

Iron deficiency is particularly liable to develop in hereditary haemorrhagic telangiectasia and the blue rubber bleb naevus syndrome due to either nasal or gastrointestinal blood loss from vascular abnormalities in these conditions. Chronic blood loss from vascular abnormalities in the gut in pseudoxanthoma elasticum results in iron deficiency, though blood loss may be more acute and present with melaena [4]. Anaemia may occur in dermatitis herpetiformis due to both iron and folic acid malabsorbtion complicating the associated gluten sensitive enteropathy, compounded also by dapsone-induced haemolysis [5].

Megaloblastic anaemias. These are due to impaired DNA synthesis, and the most common causes are either vitamin B_{12} or folic acid deficiency. Antimetabolite drugs are a potential cause, macrocytosis due to hydroxcarbamide being the most familiar to the dermatologist; drugs such as folate antagonists (trimethoprim) and anticonvulsants are less common causes.

As the onset of megaloblastic anaemias is insidious, symptoms may only be evident when anaemia is marked. A mild haemolysis resulting in a type of jaundice may give the patient a lemon yellow hue. Hyperpigmentation of the feet, hands and face is reported. Megaloblastic anaemia due to vitamin B_{12} deficiency has been reported to produce a partially reversible poikiloderma. Premature greying of the hair (canities) is associated with pernicious anaemia [6]. Loss of lingual filiform papillae and cheilitis are common. Neurological symptoms, leading ultimately to subacute combined degeneration of the spinal cord, may prompt cutaneous symptoms such as paraesthesiae and loss of sensation in the skin.

Vitamin B_{12} deficiency usually results from pernicious anaemia; antiparietal cell antibodies (present in 70% of cases) destroy the cells that produce intrinsic factor needed to absorb the vitamin. There is an association between other autoimmune disorders, such as vitiligo and Addison's disease, and dermatological manifestations; these diseases, and testing for their relevant antibodies, should always be considered. Rarely, vitamin B_{12} deficiency is the result of terminal ileal disease, such as Crohn's disease, fish tape worm or ileal resection.

Folic acid deficiency is usually the result of inadequate dietary intake due to poor nutrition, but may occur in times of increased metabolic requirement, such as pregnancy. Dermatological causes of folate deficiency include erythroderma, particularly due to psoriasis [7], and in such situations it is prudent to check folate levels prior to administering folate antagonists such as methotrexate (discussed further in Chapters 20 and 74).

Haemoglobinopathies and haemolytic anaemias

Both sickle cell disease and thalassaemia have important cutaneous manifestations due to the underlying diseases and their therapies. Lower leg ulceration, which may start in childhood and be both recalcitrant and recurrent, is a major burden; ulcers may be the first manifestation of milder disease [8,9]. Ulceration occurs with a prevalence of 2.5% in sickle disease, being more common in sickle and sickle thalassaemia, but does not occur in sickle C disease. Ulcers are more common in men and prevalence increases with age. In sickle disease there is a strong association with venous incompetence; leg elevation and compression hosiery are thus important aspects of treatment. Spherocytosis may also be complicated by leg ulcers [10].

Thalassaemia requires multiple blood transfusions and haemosiderosis with slate-grey skin pigmentation may be a consequence.

Both chronic sickle cell anaemia and thalassaemia can be associated with a condition similar to familial pseudoxanthoma elasticum (PXE) [11]. As well as the characteristic features of PXE, including yellow papular and plaque lesions on the neck (the 'plucked chicken skin'), axillae and antecubital fossae, retinal angioid streaks may be present. Associated mitral valve prolapse indicates the general and widespread nature of the elastin disorder seen in haemoglobinopathy-associated PXE-like disease.

Hydroxcarbamide has become an important therapy for sickle disease. Its chronic use has numerous dermatological complications, including a dermatomyositis-like eruption affecting the dorsal hands and face (hydroxycarbamide dermopathy), painful ulcers on feet and ankles, nail pigmentation and cutaneous malignancies [12].

Polycythaemia

Defined as an increase in the red cell mass, polycythaemia can be a primary disorder (polycythaemia vera; PV) or secondary. The secondary form is usually due to chronic hypoxaemia, but rarely may be due to erythropoietin production by renal tumours or exogenous administration of erythropoietin (such as illicit use by athletes). Polycythaemia vera is believed to be a stem cell disorder due to mutation of the Janus kinase 2 gene (*JAK2*). Splenomegaly and an elevation of both the total white cell and platelet counts usually develop; this, and an elevated leukocyte alkaline phosphatase, help distinguish PV from other causes of polycythaemia. As *JAK2* mutations occur in 95% of cases, and can now be readily identified, genotyping has replaced more complex tests previously used to estimate total red cell mass. *JAK2* mutations are also found in about 50% of cases of essential thrombocythaemia and chronic myeloid leukaemia.

The most important consequences of PV are an increased tendency to thrombosis (resulting in stroke and hepatic vein thrombosis) or bleeding. Hyperhomocysteinaemia is a risk factor for thrombosis. Dermatological features may include skin changes due to peripheral vascular disease and deep vein thrombosis, leg ulcers, digital gangrene and erythromelalgia (burning erythema of the extremities, usually the feet, on warming).

Pruritus is common in PV [13], and aquagenic pruritus, an intense disabling itching after water exposure, may antedate the onset of polycythaemia by several years [14]. Itching may persist even after restoration of the red cell mass to normal. Venesection is used to reduce the red cell mass followed by the use of hydroxycarbamide to maintain blood parameters. However this drug may induce dermopathy. Therapy with either radioactive phosphorus, or alkylating agents, is used less than previously, as both treatments are associated with the development of leukaemia. Aquagenic and spontaneous pruritus may improve with emollients, topical antipruritics, oral antihistamines, UVB or PUVA phototherapy, recombinant interferon-α or opioid antagonists such as naltrexone. Repeated venesection may lead to iron deficiency, and this should be excluded as a cause of itch. A superficial pustular dermatosis, nosologically thought to be a superficial variant of Sweet's syndrome, has been described in PV [15].

Leukocyte disorders

Neutrophils

Neutrophilia commonly occurs with infections and as a response to a variety of skin disorders including erythroderma, pustular psoriasis and erythema multiforme, and as a result of systemic corticosteroid administration.

Acute febrile neutrophilic dermatosis (Sweets's syndrome; Chapter 50) [1] has neutrophilia as one of its diagnostic criteria, and may be associated with infection, myelodysplasia, polycythaemia, leukaemia, lymphomas, myeloma and paraproteinaemia as well as solid cancers. Superficial pustular variants have been reported in chronic myeloid leukaemia, and the dorsal hand variety in polycythaemia vera. Sweet's syndrome, subcorneal pustular dermatosis, superficial bullous pyoderma gangrenosum, conventional pyoderma gangrenosum and erythema elevatum diutinum are felt to be a continuum of neutrophilic disorders that may be associated with a neutrophilia or with myelodysplasia, myelofibrosis and myeloid leukaemia.

Eosinophils

Eosinophilia of the blood is a frequent finding in parasitic helminth infestation of the gut and the skin (for example, in larva migrans or onchocerciasis) and in non-helminth infestations such as scabies. Worldwide, infestations are the commonest cause of eosinophilia. In developed areas of the world, allergic causes predominate. Severe atopic dermatitis is often accompanied by a marked eosinophilia; immunobullous diseases such as pemphigoid and pemphigus, even in their prebullous phase, may be accompanied by an eosinophilia, as may allergic drug reactions. Conditions of particular dermatological interest associated with eosinophilia are listed in Table 62.17, and are discussed below.

Churg–Strauss syndrome (Chapter 50) [2]. Asthma and rhinitis, haemorrhagic palpable purpuric lesions and granulomatous

Table 62.17 Some dermatologically relevant causes of peripheral blood eosinophilia.

Category	Examples
Infestation and infection	Scabies Strongyloides Helminths Other parasitic infections Insect bites, reactions to stings HIV/AIDS (especially if late stage)
Allergic/atopic	Atopic dermatitis Allergic reactions Episodic angioedema with eosinophilia Other urticaria and angioedema
Immunobullous	Bullous pemphigoid Pemphigoid gestationis
Vasculitis (Chapter 50)	Churg-Strauss syndrome Wegener's granulomatosis (some) Polyarteritis nodosa (some) Eosinophilic vasculitis Drug-induced vasculitis Granuloma faciale (some)
Other inflammatory conditions	Eosinophilic cellulitis (Wells' syndrome) Eosinophilic fasciitis (Shulman syndrome) Eosinophilic panniculitis Eosinophilic mastitis Eosinophilia myalgia syndrome Toxic oil syndrome Chronic graft-versus-host disease Eosinophilic pustular folliculitis (Ofuji disease) Eosinophilic folliculitis of HIV infection Connective tissue disorders (some) Sarcoidosis (rarely) Erythema annulare centrifugum and annular erythema of infancy (some cases) Incontinentia pigmenti Pyoderma vegetans
Medications	Many cutaneous drug reactions (Chapter 75) Granulocyte-monocyte colony stimulating factor Other cytokine infusions Capillary leak syndrome
Neoplastic/clonal/proliferative	Hypereosinophilic syndrome (Gleich syndrome) Cutaneous T cell lymphoma Hodgkin's lymphoma Myeloproliferative disorders/leukaemias Systemic mastocytosis
Idiopathic/miscellaneous	Cholesterol emolization syndrome Angiolymphoid hyperplasia with eosinophilia Addison's disease (some)

plaques on the elbows and knees, weight loss, arthralgias and pulmonary infiltrates are the characteristic findings. p-ANCA is frequently but not always positive; eosinophilia in excess of 10% is a diagnostic criterion.

Eosinophilic fasciitis (Chapter 51) [3]. A fibrosing condition usually affecting the limbs, due to inflammation and fibrosis of the fascia, associated with an eosinophilic infiltration of the fascia and a circulating eosinophilia. The absence of Raynaud's phenomenon differentiates it from scleroderma.

Fig. 62.27 Eosinophilic cellulitis. Lesions may be bullous and often resolve to leave a green discoloration of the skin.

Eosinophilia myalgia syndrome [4]. A fibrotic condition similar to eosinophilic fasciitis, but induced by ingestion of tryptophan.

Eosinophilic cellulitis (Wells' syndrome; Fig. 62.27) [5]. This typically presents as an indurated erythematous plaque, which sometimes blisters, mimicking bacterial cellulitis; histologically, it is characterized by a dense, eosinophilic dermal infiltrate and eosinophilic flame figures. Eosinophilia is usual during episodic exacerbations of the cellulitis, and usually resolves to the normal range between attacks.

Hypereosinophilic syndrome (HES; Gleich syndrome) [6,7]. This condition is characterized by an eosinophilia in excess of 1500/μl (but usually greatly in excess of this), with no apparent cause, for greater than 6 months, and with presumptive signs of multiple organ involvement. Although traditionally viewed as idiopathic, recent evidence suggests that the entity may include more than one form of haematological malignancy [8]. In some instances, there is a clonal T-cell production of interleukin (IL)-5, a major controlling cytokine in production, release and differentiation of eosinophils. In other cases, there is clonal expansion of eosinophils with hepatosplenomegaly and thrombocytopenia; this condition appears to be due to a cytogenetic defect t(9;22)(q34;q11) in which there is chromosomal breakage and reciprocal exchange of chromosomal fragments that leads to formation of a fusion tyrosine kinase FIP1L1–PDGFRα.

The disease most commonly affects middle-aged men and the morbidity and mortality is related to endomyocardial fibrosis, eosinophilic vasculitis, thrombosis and embolic phenomena [9–12]. Skin lesions are varied and include vesicles, petechiae, papules and papulonodules, angio-oedema, livedo reticularis, erythema annulare, Raynaud's phenomenon, digital ischaemia, acrocyanosis, cutaneous microthrombi and gangrene. The pathology of the skin lesions may be non-specific with variable eosinophilic infiltration; cutaneous microthrombi may be a clue to the disease.

Eosinophilic cellulitis with florid eosinophilic infiltration and flame figures has been reported.

Newer treatments combined with identification of the causative abnormality may allow targeted therapy; imatinib mesylate, used mainly in treatment of chronic myelogenous leukaemia, targets the platelet-derived growth factor receptor (PDGFR) in the fusion tyrosine kinase of HES [13], described above, and mepolizumab, an anti-IL-5 monoclonal antibody, has also been used recently to treat HES [14].

Haematological malignancies

Leukaemia

Leukaemias can cause a huge array of cutaneous symptoms and signs, some of which are common and non-specific (e.g. purpura due to thrombocytopenia), some of which are relatively uncommon but specific (e.g. leukaemia cutis), and some of which are both rare and non-specific (e.g. numb chin due to acute lymphoblastic leukaemic cells infiltrating the mental nerve). Some of the dermatologically relevant features of leukaemia are listed in Table 62.18.

Leukaemia can infiltrate the skin, where it is termed leukaemia cutis [15]. This is uncommon, and although it may occur in any leukaemia, it is commoner in acute monocytic and myelomonocytic disease. Skin infiltration can occur in any chronic leukaemia, including chronic myeloid, chronic lymphocytic, hairy cell and the leukaemic phase of non-Hodgkin's lymphoma. It tends to be a late manifestation of acute leukaemias, and may herald a blast transformation of chronic leukaemia. There is a strong association of leukaemia cutis with other extramedullary disease. Lesions are usually painless, evolving from patches to plaques and nodules and may ulcerate (see Fig. 62.6).

Aleukaemic leukaemia cutis, where there is evidence of leukaemic skin infiltration before evidence of leukaemia in the peripheral blood, is reported, and lesions may be mistaken initially for a high-grade lymphoma. Congenital leukaemia cutis is more common in congenital myeloid leukaemia where purple 'blueberry muffin' lesions may mimic congenital infection [16]. An important differential diagnosis occurs in neonates with Down's syndrome, who may develop a leukaemic blood picture and vesicopustular skin eruption as a transient myeloproliferative disorder (leukaemoid reaction) [17,18]. Vasculitis has been noted in some lesions of leukaemia cutis with vascular injury being mediated by blast cells [19]. Leukaemia cutis due to juvenile myelomonocytic leukaemia has been reported to mimic chilblains [20], and chilblain-like lesions have been reported in various forms of adult leukaemia [21]. Non-specific skin lesions and reactions (such as erythroderma) can occur as a paraneoplastic phenomenon in leukaemia; a variety of paraneoplastic syndromes associated with haematological malignancy are summarized in [22].

Table 62.18 Skin lesions in leukaemia.

Category	Examples
Specific lesions	Leukaemia cutis Chloroma Granulocytic sarcoma
Paraneoplastic phenomena	Sweet's syndrome (including GCSF-induced and ATRA-induced) [23,24] Neutrophilic dermatosis of the dorsal hands (Fig. 62.28) [25] Pyoderma gangrenosum [23] Subcorneal pustular dermatosis [22] Erythema elevatum diutinum [26] Neutrophilic eccrine hidradenitis [27] Vasculitis [19,28] Eosinophilic pustular folliculitis [29] Erythroderma [22]
Secondary to disordered immune or white cell function	Infections: bacterial e.g. echthyma gangrenosum viral e.g. herpetic infections (especially chronic herpes simplex or disseminated herpes zoster) fungal e.g. candidosis, zygomycosis
Due to other haematological parameters	Bruising, purpura
Conditions associated with leukaemias	Increased incidence of basal cell carcinoma and squamous cell carcinoma in chronic lymphocytic leukaemia [29] Association of juvenile chronic myelomonocytic leukaemia with juvenile xanthogranuloma and neurofibromatosis type 1 (pp. 62.23 and 62.96)
Due to treatment	Drug eruptions Neutrophilic eccrine hidradenitis Graft-versus-host disease (p. 62.96) Effects of cytopenia, infections etc as above

Myelodysplastic syndrome (MDS)

This refers to a closely related group of disorders characterized by ineffective blood cell production that may affect either erythrocytic, granulocytic or megakaryocytic cell lines. Myelodysplastic syndrome can occur at any age but is more common in older men. It represents a clonal haematopoietic disorder and after a variable time may progress to an acute myelogenous leukaemia.

A variety of skin disorders are associated with MDS, neutrophilic dermatoses (Fig. 62.28) being the best known [22,23]

Fig. 62.28 Neutrophilic dermatosis of the dorsal hands in a patient with myelodysplastic syndrome.

Fig. 62.29 Cutaneous extramedullary haematopoiesis in myelofibrosis. (Courtesy of Dr C. Blasdale, Sunderland Royal Infirmary, UK.)

(Chapter 50). Vasculitis [30], extramedullary haemopoiesis (Fig. 62.29) [31], reactive angioendotheliomatosis [32] and prurigo [33] have been reported. A significant proportion of patients with relapsing polychondritis have MDS [34]. Erythroderma [22] and erythromelalgia [22] may both occur.

Lymphoma

After the gastrointestinal tract, the skin is the commonest organ to be affected by malignant lymphomas. Most lymphomas are of the cutaneous T-cell variety, but the cutaneous B cell form constitutes up to a third of primary skin lymphomas.

The skin may be infiltrated by metastatic nodal lymphoma; in Hodgkin's disease direct infiltration from underlying nodes may produce a scrofuloderma-like appearance [1,2].

Lymphoma may produce a number of paraneoplastic phenomena; itch, which may be intractable and severe, was found in 8% of a large series of patients with Hodgkin's disease and it purported a relatively poor prognosis. Mild itch was present in almost a quarter of the patients at diagnosis [3]. Eczema, excoriations, prurigo and reactive perforating collagenosis have also been reported [4]. Cutaneous T-cell lymphoma appears to be more common in Hodgkin's disease [5]. Acrokeratosis paraneoplastic (Bazex syndrome), more commonly associated with solid respiratory tract neoplasia, may occur with Hodgkin's disease [6].

Fig. 62.30 Paraneoplastic pemphigus of the mouth and lips in Castleman's disease.

The development of acquired ichthyosis is most strongly associated with either Hodgkin's disease [7], non-Hodgkin's lymphoma [8] or anaplastic large cell lymphoma [9]. It is important to distinguish this from the increasingly well recognized ichthyotic variant of cutaneous T-cell lymphoma [10].

Paraneoplastic pemphigus (Chapter 40) is most associated with B cell malignancies (lymphoma, chronic lymphatic leukaemia and Castleman's disease; Fig. 62.30) and may manifest as a severe mucositis with an acral lichenoid eruption, ranging to a more widespread eruption, even mimicking toxic epidermal necrolysis. An associated obliterative pneumonitis is a major cause of mortality [11,12].

Other reported associated dermatological conditions or paraneoplastic phenomena in lymphomas include Sweet's syndrome, subcorneal pustular dermatosis, pemphigus foliaceous and vulgaris (some of these in retrospect possibly representing paraneoplastic pemphigus), pemphigoid, erythroderma, exfoliative dermatitis, acanthosis nigricans, dermatomyositis, dermatitis herpetiformis and vasculitis [13].

Platelet and clotting disorders

Purpura and bruising

Purpura is discussed in more detail in Chapter 49. A brief overview and details of some specific disorders of platelet numbers or function, and of impaired blood clotting, are listed here.

Non-palpable purpura or macular haemorrhages are suggestive of low platelet count or abnormal platelet function (Fig. 62.31). Petechiae are red-purple lesions less than 4 mm in diameter, and are usually due to a significant reduction in absolute platelet numbers (less than 50 000/microlitre), or abnormal platelet function (hereditary, salicylates, renal and hepatic disease). Less commonly, petechiae are the result of intermittent, severe elevation of intravascular pressure due to paroxysmal coughing, straining, stasis or strangulation. Viral exanthems, often enteroviral, may be purpuric. Macular haemorrhage is a term applied to larger lesions, between 4 and 10 mm. Causes include many of the same conditions that cause petechiae, although lesions of this size are uncommonly due to vascular leakage. Larger, non-palpable macules may recur in crops on the lower legs in Waldenstrom's hyperglobulinaemic purpura. This occurs most commonly in women, and may be associated with the sicca syndrome, SLE and rheumatoid arthritis.

Ecchymoses (bruises) are lesions larger than 10 mm in diameter. They are less likely to be due to platelet disorders, but can result from procoagulant defects, such as anticoagulant use, vitamin K deficiency, diffuse intravascular coagulopathy, or from inadequate dermal vasculature support, as occurs in severe actinic disease, corticosteroid use, scurvy, systemic amyloidosis, and ecchymotic (type IV) Ehlers–Danlos syndrome (Fig. 62.32).

Fig. 62.32 Bruising in type IV Ehlers–Danlos syndrome; the hyperextensibility of skin and joints is also apparent.

Fig. 62.33 Palpable purpura with haemorrhagic bullae in small vessel vasculitis.

Palpable or reticulate purpura

Palpable purpura is usually the result of vasculitis, most commonly of the small vessel leukocytoclastic type (Fig. 62.33). Inflammatory vascular changes produce an early erythematous change so that lesions remain red–pink when compressed. They are usually discrete macules or plaques rather than reticulate (compare with microvascular occlusive disorders, below) and they may progress to produce haemorrhagic blisters. Causes include ANCA-positive diseases (Wegener's granulomatosis, microscopic polyangiitis and Churg–Strauss disease) and non-ANCA syndromes (benign cutaneous polyarteritis nodosum) and small vessel vasculitis (Chapter 50).

This may be contrasted with the palpable purpura that is associated with non-inflammatory processes which result in occlusion of small dermal vessels (microvascular occlusion, Chapter 49), for example following platelet or crystal plugging, embolization (due to cholesterol, atrial myxoma, or endocarditis), cold-related gelling or agglutination, or abnormal coagulation control (coumarin necrosis, thrombophilic disorders). In these disorders, initial erythema is minimal (early lesions may fade on compression) and development of a reticulate morphology is common.

Essential thrombocythaemia shares many of the cutaneous signs seen with PV, with livedo reticularis and erythromelalgia being the best recognized.

Table 62.19 The thrombophilic disorders.

Lupus anticoagulant/antiphospholipid disease
Protein S and protein C deficiency
Factor V Leiden mutation
Antithrombin III deficiency
Hyperhomocysteinaemia
Plasminogen activator inhibitor-1 level elevation

Deep venous thrombosis and post phlebitic syndrome
Leg ulcers, cutaneous infarcts [7,8]
Cutaneous nodules and plaques with histological evidence of intravascular thrombosis [9]
Purpura fulminans [10]
Anetoderma [11]

Thrombophilic disorders

The thrombophilic disorders (Tables 62.19 and 62.20; also discussed in more detail in Chapter 49) cause a tendency for blood to clot; they are due to deficiencies of, or resistance to, anticoagulant factors, either inherited or acquired, and may present as a single factor disorder or due to several deficiencies coexisting in the same individual (Table 62.19). Many such factors have now been identified. Thrombophilias may present in the neonate (homozygous factor S or C deficiency) with neonatal purpura fulminans, during infection (heterozygous protein S or C deficiency), or in later childhood or adult life with an increased

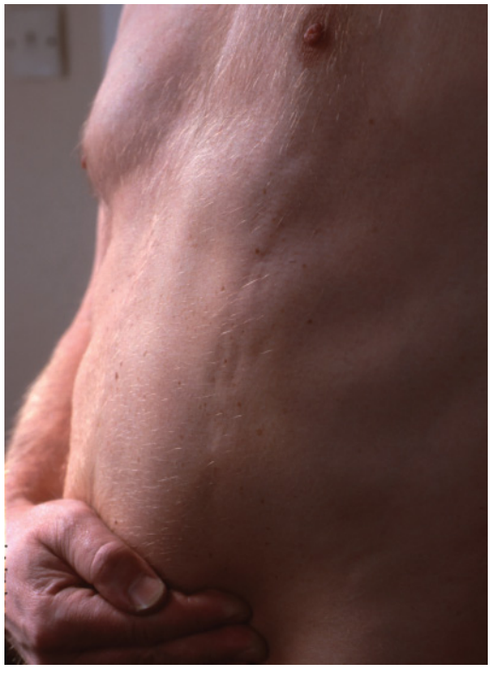

Fig. 62.34 Mondor's disease (thrombophlebitis of the superficial chest wall veins) associated with protein S deficiency.

Fig. 62.35 Cutaneous necrosis after initiation of warfarin treatment in protein C deficiency.

tendency to superficial (Fig. 62.34) and deep venous thrombosis, pulmonary embolism, and less commonly arterial thrombosis. Some disorders, particularly the presence of antiphospholipid antibodies/lupus anticoagulant, may be identified due to recurrent spontaneous abortions. Table 62.20 outlines the range of dermatological disorders with which they may manifest. Most can be explained as arising as a result of intravascular thrombosis in cutaneous vessels of different sizes.

Coumarin necrosis

This is an uncommon but serious complication arising within the first week of coumarin anticoagulation. Well-circumscribed, haemorrhagic necrosis of the skin, usually of the breasts, buttocks, abdomen or thighs develops (Fig. 62.35). Histologically, fibrin occlusion of the small veins and postcapillary venules in the skin and fat is seen. The condition is more common in women, and occurs in 0.1 to 0.01% of individuals anticoagulated. Coumarin necrosis arises as a result of temporary reduction in levels of the vitamin K-dependent natural anticoagulants such as proteins C and S, prior to reduction in the levels of the procoagulant factors in the clotting cascade; this results in a temporary state of thrombophilia when coumarins are commenced. In a minority of patients it is a manifestation of familial protein S or C deficiency. Heparin-induced skin necrosis is rarer, appears to be immunologically mediated and often associated with heparin-induced thrombocytopenia.

Paraproteins and multiple myeloma [1–6]

There are numerous cutaneous associations with monoclonal gammopathy of uncertain significance and multiple myeloma. Several of these are discussed in more detail in other chapters and are listed in Tables 62.21 and 62.22, without additional discussion; selected disorders that are not discussed elsewhere are noted below. A classification according to mechanisms has suggested

Table 62.21 Categories of paraprotein-related disorders by mechanism (adapted from text of [6]).

Category/mechanism	Examples
Cutaneous extravascular deposition of paraproteins	Nodular and other cutaneous amyloidosis (Chapter 59) Plasmacytoma Papules of macroglobulinaemia (IgM) Hyperkeratotic spicules Acquired cutis laxa Cutaneous light chain deposition
Intravascular paraproteinaemia	Vascular occlusion/cutaneous necrosis (Chapter 49) Type I cryoglobulinaemia (Chapter 49) Reactive angiomas, glomeruloid angiomas in POEMS syndrome (reactive post-thrombosis)
Cutaneous lesions due to biological activity of the paraprotein	Normolipaemic plane xanthoma (anti-LDL activity) Acquired C1 esterase deficiency Bullous lesions of Waldenström's macroglobulinaemia (dermo-epidermal deposition) Schnitzler syndrome (Chapter 22) Mucinoses associated with gammopathy (e.g. scleromyxoedema, acral papuar mucinosis) may also belong in this category
Conditions resulting from abnormal cytokine secretion	AESOP syndrome POEMS syndrome
Unknown mechanism	Telangiectasia, oedema, capillary leak syndrome (may be due to capillary deposition of monoclonal protein) Necrobiotic xanthogranuloma Neutrophilic dermatoses (Chapter 50)

AESOP, *a*denopathy and *e*xtensive *s*kin patch *o*verlying a *p*lasmacytoma; LDL, low density lipoprotein; POEMS, *p*olyneuropathy, *o*rganomegaly, *e*ndocrine disorders, *m*onoclonal gammopathy, *s*kin changes.

Table 62.22 Skin lesions and conditions associated with paraproteinaemias and multiple myeloma [1–6].

Amyloidosis AL type (Chapter 59; Fig. 62.36)
Cryoglobulinaemias, especially Type 1 cryoglobulinaemia (Fig. 62.37) [4,7]
Crystalglobulinaemia [8]
POEMS syndrome [9,10]
AESOP [11,12]
Livedo reticularis [7]
Small vessel vasculitis [13]
Neutrophilic disorders [3]—pyoderma gangrenosum, subcorneal pustular dermatosis [14], Sweet's syndrome, erythema elevatum diutinum (Chapter 50)
Mucinoses—scleredema, papular mucinosis and scleromyxoedema [15]
Xanthomatous disorders [3]—necrobiotic xanthogranuloma, normolipaemic plane xanthoma, and xanthoma disseminatum
Immunobullous disorders [5,16]—IgA pemphigus, linear IgA disease, epidermolysis bullosa aquisita (Chapter 40)
Schnitzler syndrome [17]
Nasal spicules [18]
Acquired cutis laxa [19]
Acquired ichthyosis, acanthosis nigricans, pityriasis rotunda [20]
Calcinosis cutis [3]
Plasmacytomas, myeloma skin metastases (Fig. 62.39) [21]
Systemic lupus erythematosus [22]
Dermatomyositis [5]

AESOP, *a*denopathy, *e*xtensive *s*kin patch *o*verlying a *p*lasmacytoma; POEMS, *p*olyneuropathy, *o*rganomegaly, *e*ndocrine disorders, *m*onoclonal gammopathy, *s*kin changes.

Fig. 62.36 Waxy plaques and periorbital purpura in paraprotein-associated systemic amyloidosis.

five categories (Table 62.21) [6]. A fuller list, including consequences of paraproteinaemia and selected references, is provided in Table 62.22.

The manifestations of systemic amyloid are discussed in Chapter 59. Waxy yellow plaques into which bruising easily occurs are typical, particularly on the eyelids (Fig. 62.36).

Cryoproteinaemias are associated with multiple myeloma. Monoclonal gammopathy-associated cryoglobulinaemia (type 1 cryoglobulinaemia; Chapter 49) may produce haemorrhagic, vasculitis-like lesions, often in a livedo distribution on the limbs.

(a) (b)

Fig. 62.37 (a,b) Reticulate purpura and small infarcts in type I cryoglobulinaemia, shown on the knees and ear (a cold site).

Although types II and III cryoglobulinaemia damage vessels in part by immune complex deposition and ensuing vasculitis, type I monoclonal cryoglobulinaemia causes physical obstruction of blood vessels (Figs 62.37 & 62.38) [4,7]. Areas sensitive to the cold, such as the ear lobe and nasal tip, are particularly affected. Livedo reticularis and leg ulcers may be seen in both cryoglobulinaemia and cryofibrinogenaemia (Chapter 49). Crystalglobulinaemia [8] has similar features.

POEMS syndrome [9,10] is a rare multisystem disorder characterized by *p*olyneuropathy, *o*rganomegaly of liver, spleen and lymph nodes, *e*ndocrine disorders, *m*onoclonal gammopathy and a variety of *s*kin changes. It has also been associated with the multicentric variant of Castleman's disease. Raynaud's phenomenon, scleroderma, oedema, generalized pigmentation and hypertrichosis are the most common skin changes. Angiomas and angioendotheliomatosis (particularly glomeruloid haemangiomas), alopecia, flushing reactions, whitening of the proximal nail, Sweet's syndrome-like lesions and vasculitis have all been reported in POEMS syndrome. The associated paraprotein is usually of the IgG or A type.

AESOP syndrome (*a*denopathy and *e*xtensive *s*kin patch *o*verlying a *p*lasmacytoma) [11,12] is a rarely described disorder in which mucinosis and angiomatosis occur over a bony or other plasmacytoma, with or without associated regional lymphadenopathy. Several of the few reported cases have also had, or have developed, concurrent POEMS syndrome [11].

Nasal spicules (small follicular keratin horns) and anetodermas are rare pointers to paraproteins, but can also occur in other haematological disorders.

Schnitzler's syndrome (Chapter 22) is an urticarial eruption associated with fever, and there is an underlying IgM paraproteinaemia; it has recently been incorporated into the group of 'autoinflammatory syndromes'.

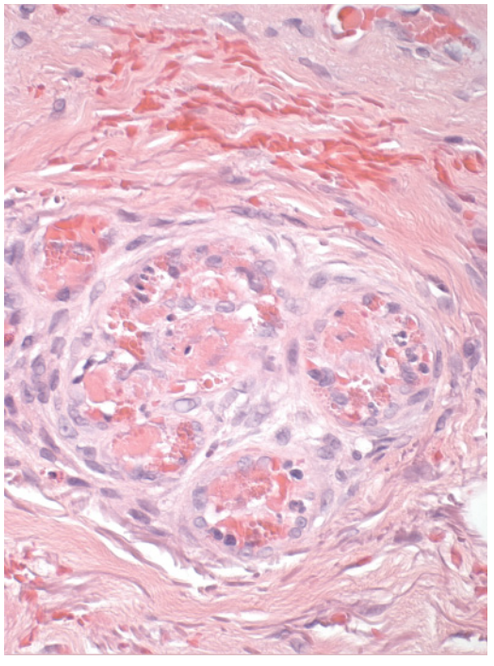

Fig. 62.38 Histological features of type I cryoglobulinaemia showing deposition of immunoglobulin obstructing small vessels.

Miscellaneous haematological diseases with cutaneous manifestations

Dyskeratosis congenita [1]

A genetically heterogeneous disorder with recessive, X-linked and dominant heredity, thought to be due to telomerase dysfunction. The skin changes are a mottled or reticulate macular hyperpigmentation, hypopigmentation or a mixture of both in a light-exposed distribution. Alopecia, premature hair greying, hyperhidrosis and adermatoglyphia are less common. A progressive nail dystrophy starts with ridging and splitting, and ends with atrophic rudimentary nails. There is leukoplakia of the tongue and buccal mucosa, and malignancy may develop within these sites. Bone marrow failure develops at a mean age of 10 years and is the major cause of mortality.

Fanconi's anaemia [2]

This rare disorder presents in early childhood with generalized increased pigmentation, particularly on the lower trunk, flexures and neck; more discrete café-au-lait type lesions are associated. A progressive hypoplastic marrow failure develops within 2 to 5 years of the onset; the disease often terminates with leukaemia or other neoplasia, or with infection resulting from leukopenia.

Chediak–Higashi syndrome [3]

This syndrome includes vitiligo-like depigmentation, blond or silvery grey hair and blue eyes, due to melanosome autophagocytosis. Polymorphonuclear cell dysfunction leads to oral and cutaneous infections, abscesses and pyodermas, usually due to staphylococcal infection. A lymphoma-like process is a frequent cause of early mortality.

Hermansky–Pudlak syndrome [4]

An autosomal recessive disorder characterized by oculocutaneous albinism, bleeding due to platelet dysfunction and ceroid accumulation in lysosomes. The skin is pale and the hair blond. Freckles and lentigines are common, as are atypical naevi. Trichomegaly and acanthosis nigricans-like flexural pigmentation has been described. Lack of melanin increases the risk of non-melanoma skin cancer as well as of melanoma. It is common in Puerto Rico, but rare elsewhere. Pulmonary fibrosis at the age of 40–50 years is the most common cause of death.

Griscelli syndrome [5]

Partial albinism is associated with immunodeficiency (a variety of defects are reported, including deficiency or dysfunction of T and B cells, natural killer cells, cell mediated immunity and hypogammaglobulinaemia). Silver or grey hair in infancy may be the clue to the diagnosis.

Wiskott–Aldrich syndrome [6]

An X-linked recessive disorder characterized by thrombocytopenia, an atopic eczema-like dermatitis and recurrent infections due to an inherited defect of T-cell function caused by the WASP gene

mutation. Purpura and eccymoses may occur in the eczematous areas and be a diagnostic clue.

Neurofibromatosis, juvenile xanthogranuloma and juvenile chronic myeloid leukaemia [7]

The finding of juvenile xanthogranuloma and NF1 type neurofibromatosis is estimated to be associated with a 30 to 40-fold increased risk of juvenile chronic myeloid leukaemia.

Graft-versus-host disease [1–5]

Graft-versus-host disease (GVHD) occurs when T lymphocytes from an allograft exert immunological activity against cells of the graft recipient (host). Historically, it was the advent of bone marrow transplantation 50 years ago that brought GVHD to prominence, but it also occurs in the settings of solid organ allografting (renal, liver, etc.), non-irradiated blood or blood product transfusion and maternofetal transfusion (typically in an immunodeficient fetus).

Haemopoietic stem cell transplantation (HSCT) is now used rather than bone marrow transplantation; the main indication is haematological malignancies (leukaemias, lymphoproliferative disorders, aplastic anaemia, etc.) but HSCT is also used in the treatment of various immunological deficiency disorders, metabolic disorders (e.g. congenital erythropoietic porphyria, some mucopolysaccharidoses) and increasingly as a treatment for some solid tumours [2]. A major issue in haematological transplantation has been how to separate the beneficial graft-versus-tumour effects from the deleterious graft-versus-host effects of transplantation [6].

The conditioning regimen used for myeloablation in leukaemias, the type of transplantation performed, treatments used in preparation of the cells to be grafted (e.g. depletion of T cells using antithymocyte globulin) and a number of host factors (e.g. HLA disparity of host and donor, age, previous episodes of GVHD) all influence the likelihood that GVHD will occur [4]. Stem cells are now usually derived from peripheral blood treated with granulocyte colony-stimulating factor, rather than from bone marrow; some reports suggest that this may have increased the risk of chronic GVHD, but this may in part be due to better survival such that patients survive long enough to develop GVHD, coupled with an increased use of transplantation in older subjects in whom GVHD is more likely to occur.

All organs are affected, but are not discussed here although they are important in diagnosis and scoring of GVHD [3]. From a dermatological perspective, there are three main manifestations [1,2,4,5]; early GVHD causes acute rashes (which may have infections or drug eruptions in the differential diagnosis), later eruptions are often lichenoid (see also Chapter 4), and finally there is a sclerodermoid phase in which several morphologies occur (see also Chapter 51). The lichenoid and sclerodermoid manifestations may occur together.

Acute GVHD

Acute GVHD occurs in 60% of HLA-identical sibling HSCT and in 80% of unrelated HSCT, with a mortality of 50% if graded moderate or severe [2]. It develops in three phases—epithelial cell injury and cytokine release due to the conditioning regimen is followed by antigen presentation (by host dendritic cells) to donor T lymphocytes, resulting in cell death caused by activated cytotoxic T cells and cytokines [5–8]. Tumour necrosis factor (TNF) plays a key role in this process [2,8], activating dendritic cells, recruiting effector cells, and directly causing apoptosis and cell death; the interaction of Fas with its ligand FasL is also critical. Experimental blocking of TNF inhibits both GVHD and graft-versus-leukaemia (GVL) reactions, whilst blocking Fas inhibits GVHD but not GVL [8].

The cutaneous features of acute GVHD usually occur 2–6 weeks after transplant, typically at 4 weeks but a severe 'hyperacute' form with high mortality can occur within a week of HSCT. There may be early pain, itch or folliculocentric lesions; generally the rash of acute GVHD is rather morbilliform in distribution, affecting mainly the face and upper trunk, as well as palms and soles (Fig. 62.40). More extensive erythroderma, blistering and necrosis resembling toxic epidermal necrolysis (TEN) characterize the more severe forms of acute GVHD, and are associated with diarrhoea and abnormal liver function; in the hyperacute form there is erythroderma, hepatitis, fever and shock [1,2,4,5]. Mucositis also

Fig. 62.40 Acute GVHD; (a) morbilliform exanthem-like rash , and peeling on the neck, and (b) acute palmar erythema and desquamation. (Courtesy of Dr C. Kennedy, Bristol Royal Infirmary, UK.)

occurs, but is difficult to differentiate from the effects of chemotherapy and irradiation used for conditioning regimens for marrow ablation. The differential diagnosis includes drug eruptions (chemotherapeutic drugs, antimicrobials, etc.) and infections, especially viral. A TEN-like pattern, and palmoplantar disease, are particularly problematic as both can occur due to drugs; the morbilliform rash may be difficult to distinguish from potentially important viral infections. Other patterns of acute GVHD skin eruption include ichthyosis, scarlatiniform rash, varicelliform rash and pustular acral chemotherapy rash. Purpura and haemorrhagic conjunctivitis may occur due to thrombocytopenia in association with capillary leak syndrome.

Reactivation of human herpesviruses (HHV) is a difficult diagnostic issue, as it occurs in both GVHD and in severe drug-induced hypersensitivity syndrome. HHV-6 is commonly reactivated, but cytomegalovirus, Epstein–Barr virus and HHV-7 reactivation may all occur; the sequence in GVHD is the same as that in severe drug hypersensitivity [9].

Skin biopsy is important in diagnosis of GVHD. Both acute and chronic GVHD cause an interface dermatitis which may be a lichenoid lymphocytic infiltrate or predominantly vacuolar damage of basal cells. Lymphocytic 'satellitosis' (lymphocytes encircling necrotic keratinocytes) is particularly suggestive of GVHD, although no single histological feature is pathognomonic. For many years, a system of four histological grades has been used where grade I is characterized by basal cell vacuolation; grade II by keratinocyte dyskeratosis or eosinophilic degeneration; grade III by more frank keratinocyte necrosis leading to basal epidermal clefts; and grade IV by frank epidermal loss [2,4]. Recent criteria have emphasized that keratinocyte necrosis also occurs in the outer root sheath of the hair follicle and in the acrosyringium, and used the degree of apoptotic activity as a marker of severity [10]. However, in situations where the risk of acute GVHD is high (over 30%, as in HSCT), it has been shown that treatment on suspicion gives a better outcome than performing a biopsy; by contrast, if acute GVHD is unlikely, basing treatment on the results of a skin biopsy is preferable [11]. Documentation of macrochimerism (determining the presence of donor cells in the host) has been performed on blood and in skin biopsies [12,13] and may be helpful in identifying or predicting GVHD.

Chronic GVHD

Chronic GVHD may develop without a preceding acute GVHD phase, after acute GVHD with an intervening symptom-free period, or as a continuum from prior acute GVHD. The pathophysiology is different from that of acute GVHD, and is reminiscent of that seen in autoimmune disorders; indeed, several autoantibodies (antinuclear, anti-dsDNA, antinucleolar, anti-smooth muscle and others) may be found in up to 60% of subjects, vitiligo has been reported in several cases, and the hepatic disease of chronic GVHD is very similar to primary biliary cirrhosis. Donor alloreactive T lymphocytes, with a predominance of cytotoxic $CD8^+$ cells, and autoreactive $CD4^+$ T lymphocytes arising due to defective thymic deletion, damage tissues directly, lead to disordered cytokine synthesis and regulation. Chronic GVHD is usually a multisystem disease in which the skin is affected in 90–100% of subjects; localized chronic GVHD also occurs, in which individual organs (usually skin or liver) are affected. The multiorgan involvement has allowed development of 'organ scoring' from which severity grades (mild, moderate or severe) can be derived [3,4]; the percentage of skin involved is part of this scoring system [3,4]. Chronic GVHD of the skin is sometimes provoked by trauma, sunlight or infections such as herpes zoster.

The lichenoid form of chronic GVHD typically occurs as an earlier form of the disorder, and is conventionally defined as occurring more than 100 days after transplantation although the timing varies considerably; it is unlikely before day 80 but may occur after many months. Papules or plaques resembling lichen planus develop, usually less well defined and more scaly than true lichen planus; initially they affect acral sites (distal limbs, including palms and soles), ears and the periorbital area, before becoming generalized. Oral mucosa and oesophagus may also be affected. In some cases, the eruption may be more lupus erythematosus-like [1,2,4]. Like drug-induced lichenoid eruptions, the lymphocytic infiltrate of this form of chronic GVHD is usually rather less tightly band-like than that of standard lichen planus, and may contain eosinophils.

The sclerodermoid spectrum of chronic GVHD may follow the lichenoid form, or may develop without preceding rash—it usually presents between days 150 and 300. Profibrotic cytokines (IL-4 and transforming growth factor-β) are increased, as well as IL-5, which may cause tissue and blood eosinophilia [4]. Early sclerodermoid chronic GVHD is usually lichen sclerosus-like or morphoeaform, later becoming deeper with involvement of fascia and resemblance to eosinophilic fasciitis. The lichen sclerosus lesions frequently occur at areas of trauma (a predilection for sites of central venous lines has been reported), and typically involve the neck, upper trunk and genitalia. The morphoeaform lesions tend to involve the lower trunk; histologically, fibrosis is more superficial than in sporadic morphoea although lesions may progress and coalesce to form a deeper and firmer scleroderma-like picture (Fig. 62.41).

The scleroderma-like and eosinophilic fasciitis-like fibrotic reactions tend to affect the limbs [14]. Septal panniculitis and fibrosis may lead to a puckered ('ripply' [1]) appearance of the skin [15], and blisters, erosions, ulceration and scarring (including scarring alopecia and nail dystrophy) occur [1,4]. Other features include eczema craquelé, eczematoid reactions [16], nodular fibromas, cutaneous mucinosis, eruptive angiomas, dermatomyositis-like rash [17], cicatricial pemphigoid-like conjunctival involvement, poikiloderma, vitiligo, leukotrichia and other pigmentary disturbance (increased, decreased or both; sometimes termed 'leopard-skin' eruption) [1,2,4,5]. Skin changes associated with GVHD affecting other organs also need to be considered, for example plane xanthomas due to cholestasis [18].

Treatment [1,2,4,5,13]

Management of GVHD typically involves treatments that might be used in autoimmune conditions, such as prednisolone, ciclosporin, mycophenolate mofetil, azathioprine, hydroxychloroquine, methotrexate, cyclophosphamide, clofazimine, cladribine, tacrolimus, sirolimus, dacluzimab and thalidomide; the most common regimen is corticosteroid with ciclosporin, thalidomide is generally too toxic and azathioprine may contribute to further malignancies. Antithymocyte globulin has been used in acute GVHD

(a)

(b)

Fig. 62.41 (a,b) Chronic GVHD showing extensive sclerodermoid changes. (Courtesy of Dr C. Kennedy, Bristol Royal Infirmary, UK.)

but has no benefit in the chronic form. Prophylaxis for acute GVHD typically consists of ciclosporin, tacrolimus or mycophenolate mofetil for about 6 months post-transplantation. Photochemotherapy (PUVA) and UVB have been used for both the acute and the lichenoid lesions, and PUVA, UVA1 and extracorporeal photopheresis (ECP) for deeper sclerodermoid lesions [19]. Acitretin appears to be beneficial for sclerodermoid lesions, as does denileukin diftitox. Biological agents such as dacluzimab have been disappointing but rituximab appears to be helpful in treatment of sclerodermoid lesions; aletuzumab, infliximab and etanercept have also been used. Recent guidance on the use of extracorporeal photopheresis (ECP) in the UK [20] suggests that it should be reserved for those who have GVHD refractory to corticosteroids (prednisolone 1 mg kg^{-1} daily for at least 4 weeks, or prednisolone dosed consistently at >10 mg daily), and achieves best results for skin, mucous membrane and hepatic GVHD; however, its best effects in improving survival are seen if treatment is started early, and there is no easy way to predict which patients will require ECP.

Other aspects of transplantation

Dermatologists have an important role in the management of skin cancers arising due to immunosuppression following solid organ transplantation [21]. Such concerns are most prominent after cardiac transplantation, and least after liver transplants, but are discussed in this chapter in the context of renal disease and the skin on the basis that renal transplantation is the commonest such procedure, this post-transplant complication is discussed on p. 62.74.

Hypothyroidism occurs in about 25% of stem cell transplant recipients in whom whole body radiotherapy has been part of the conditioning regimen [22]. As discussed in the section on renal disease, ongoing immunosuppression increases the risk of many infections after HSCT [1,22]; herpes zoster is of particular importance dermatologically as lichen sclerosus-like sclerodermoid GVHD reactions may localize to sites of recent zoster.

The transfer of donor diseases to a recipient of a solid organ transplant or of an SCT is a potential disaster. Transfer of viral infections such as cytomegalovirus is well recognized; transfer of tumours can also occur. Of dermatological relevance, peanut allergy [23], psoriasis [24] and psoriatic arthritis [25] have also been documented post-transplant. There is also evidence of donor stem cells causing a skin cancer in a female recipient of a renal transplant from a male donor, in whom most epithelial (cytokeratin-positive) cells within a basal cell carcinoma were demonstrated to be XY and thus of male origin [26].

Bone and joint diseases

There are several diseases in which bone or joint abnormalities occur together with skin changes (Tables 62.23 & 62.24) [1–3]. In some instances, as occurs in several inflammatory diseases (for example, gout or psoriatic arthropathy), or due to localized tumours (such as glomus tumour), the bone or joint disease may be obvious; in other conditions, skeletal changes may be asymptomatic but demonstrated radiologically. For example, more than half of adults with *mastocytosis* may have diffuse bone disease detected radiologically [4], and the osteopoikilosis of *Buschke–Ollendorf syndrome* (Fig. 62.42) is asymptomatic and usually only demonstrated as an incidental finding or if the patient presents with cutaneous elastomas.

Bony changes may be an important factor in diagnosis of several *genodermatoses* (Chapter 15) [1,2] and underlying bony or neural defects should always be considered in midline *congenital lesions* such as faun tail or on the head and neck (e.g. facial or scalp nodules and pits) [5,6]. The genetic and metabolic basis for some of these are now well understood—for example, the role of G proteins in *McCune–Albright syndrome* [7]. Vascular or lymphatic proliferations or malformations of limbs should also generate suspicion of possible associated bony abnormality, such as asymmetry of growth in *Klippel–Trenaunay* syndrome, or osteolysis due to lymphatic proliferation in *Gorham–Stout* disease [8,9].

Soft-tissue calcification, and less commonly ossification, occurs in numerous disorders [10]. It is particularly prominent in *childhood dermatomyositis* and is discussed in more detail in Chapter 51. *Progressive systemic sclerosis* and *CREST* (Chapter 51) are characterized by atrophy and dystrophic calcifications in the soft tissues, ultimately leading to joint deformities and resorption of the terminal tufts of the phalanges. Resorption of bone occurs at other sites as well in these individuals, and marginal erosions may develop in the metacarpophalangeal and interphalangeal joints of the hands [11]. Calcification of cerebral blood vessels may be associated with facial haemangiomas (Chapter 18). Both calcification and ossification of the cartilage of the ear can occur following repeated cold injury, and may present with symptoms of chrondrodermatitis nodularis helicis (Fig. 62.43). Osteoma cutis affecting the face can occur spontaneously, but may follow acne.

Skin lesions may also occur as a direct consequence of bone disease. Neuropathic ulcers, an important cause of morbidity in type I diabetes, have a strong association with bony deformity of the foot and typically occur at bony pressure points. Bone infection, in the form of osteomyelitis, is closely linked with chronic skin ulceration and has a risk of development of squamous cell carcinoma. Less obviously, as there is no obvious local body site correlation, *fat emboli*, particularly caused by fractures of the long bones, may present cutaneously with petechiae, usually 2 or 3 days after trauma; other symptoms may include respiratory distress and cerebral impairment. The intensity of the petechiae may indicate the severity of other organ involvement. Fat globules may be observed histologically in affected tissue, including the skin, when suitably processed. The distribution of skin petechiae is principally on the anterior trunk; they are seldom found on the back or face [12].

Table 62.23 Skin disorders that are commonly associated with bony abnormalities.

Disorder	Skin lesions	Bony change
Congenital/inherited		
Ectodermal dysplasias and keratodermas	Various	Chapter 19
Conradi–Hünermann syndrome	Chapter 19	Chondrodysplasia punctata
Neurofibromatosis	Neurofibromas, café-au-lait patches	Kyphoscoliosis, vertebral erosions, partial absence of sphenoid bone, cystic lesions, pseudarthroses
Tuberous sclerosis	Angiofibromas, ash leaf macules, collagenomas	Intracerebral calcification, bony sclerosis (especially skull), cortical thickening, bone cysts (especially phalanges)
Klippel–Trenaunay syndrome	Port-wine stains, other vascular lesions, lymphangioma	Bony hypertrophy, macrocephaly, polydactyly/syndactyly
Proteus syndrome	Soft-tissue overgrowth, epidermal naevi	Partial gigantism (usually hand/foot), scoliosis and vertebral abnormalities, exostoses, osteochondromas
Maffucci's syndrome	Haemangiomas, lymphangiomas	Enchondromas (especially hands), chondrosarcoma
Sturge–Weber syndrome	Port-wine stain	Calcification of meningeal vessels, hemiatrophy
Gorham (Gorham–Stout) syndrome (osteovascular dysplasia)	Lymphatic vascular proliferations	Lytic lesions, 'disappearing bones'—usually unilateral
Gardner's syndrome	Cysts, lipomas, fibromas	Osteomas, exostoses
Ehlers–Danlos syndrome	Skin laxity, atrophic scars, molluscoid pseudotumours	Kyphoscoliosis (especially type IV), abnormalities of long bones, short clavicles, occipital exostoses (all in type IX)
Osteogenesis imperfecta	Atrophic skin	Brittle bones, otosclerosis
Marfan syndrome	Arachnodactyly	Increased limb length, arachnodactyly, chest deformities, joint laxity
Focal dermal hypoplasia (Goltz's syndrome)	Dermal atrophy, telangiectasia, fatty herniation	Syndactyly, scoliosis, skeletal asymmetry, osteopathia striata, bony tumours, dental abnormalities
Rothmund–Thomson syndrome	Poikiloderma	Hypoplasia of thumbs or forearm bones, dental abnormalities, osteosarcoma
Linear naevus sebaceus syndrome	Sebaceous naevi (often facial or widespread)	Asymmetry (especially skull), spinal abnormalities, hypophosphataemic rickets
Linear epidermal naevus syndrome	Epidermal naevi	Asymmetry, kyphoscoliosis, bone cysts, equinovarus deformity
Incontinentia pigmenti	Atrophic streaks, fatty herniations	Dental abnormalities (conical teeth), spina bifida occulta, skeletal asymmetry, vertebral/rib abnormalities, phalangeal lytic lesions
Hypomelanosis of Ito	Pale, whorled streaks	Kyphoscoliosis, spina bifida occulta, skeletal asymmetry, various digital anomalies
Buschke–Ollendorf syndrome	Elastomas	Osteopoikilosis
McCune–Albright syndrome	Pigmented macules	Fibrous dysplasia, asymmetry, scoliosis, sclerosis of base of skull, fractures, rickets, osteomas
Lipoid proteinosis	Confluent waxy papules, alopecia	Intracranial calcification
Disseminated lipogranulomatosis	Nodules on digits	Destructive arthropathy
Pseudoxanthoma elasticum	'Plucked chicken' appearance of neck, flexures	Calcification of soft tissues, falx cerebri, dura, choroid plexus
Nail–patella syndrome	Hypoplastic nails	Absent or small patellae, iliac horns, scoliosis, hypoplasia of first rib, absent fibulae
Fabry disease	Angiokeratomas	Necrosis of femoral head, arthritis of distal interphalangeal joints
Werner's syndrome	Premature ageing	Osteoporosis, sclerodactyly, joint contractures, sarcomas
Progeria	Aged appearance	Skeletal dysplasia, osteolysis, osteoporosis, dislocation or avascular necrosis of hip, non-union of fractures
Gaucher disease	Pigmentation	Bone pain, fractures, cortical destruction
Naevus of Ota	Facial naevus	Posterior cranial fossa defects
Midline lesions	Various, includes scalp nodules/cysts, nasal gliomas, pits and sinuses, faun tail	Various; connections between skin and CNS may be associated with bony defects, e.g. spina bifida
Infection		
Local		
Dental sinus	Localized nodule, may discharge	Usually periapical abscess, may be retained root, cyst
Chronic ulcer	Skin ulcer	Underlying osteomyelitis
Systemic		
Syphilis	Various; see Chapter 34	Periostitis, osteitis, focal osteolysis or sclerosis
Leprosy	Various; see Chapter 32	Acral bone resorption, osteitis leprosa multiplex cystica
Cryptococcosis	Skin nodules	Osteolytic lesions
Blastomycosis	Skin nodules	Osteomyelitis
Hyper-IgE syndrome with recurrent infections	Abscesses, eczema-like rash	Fractures, scoliosis, abnormal facies

(Continued)

Table 62.23 *Continued*

Disorder	Skin lesions	Bony change
Inflammatory and systemic diseases		
Psoriasis and Reiter's syndrome	See Chapter 20	Erosive arthritis, sacroiliitis
Palmoplantar pustulosis	Palm and sole pustules	See text (this section)
Sarcoidosis	See Chapter 61	Honeycomb change and bone cysts (especially hands), acrosclerosis
Scleroderma	See Chapter 51	Resorption of terminal phalanges (acronecrosis), soft-tissue calcification, erosive arthritis Linear scleroderma may show underlying linear hyperostosis Acro-osteolysis is typical of vinyl chloride disease
Scleromyxoedema	Mucinosis	Arthralgia, carpal tunnel syndrome, acro-osteolysis
Granuloma annulare	Aggressive nodular/subcutaneous type	Subperiostial involvement, 'vanishing bones'
Acne fulminans/ conglobata	See Chapter 42	Lytic lesions, especially clavicles; clavicular hyperostosis
SAPHO	Acne, pustules	Hyperostosis, osteomyelitis
Neutrophilic dermatoses	See Chapter 49	Periosteal reaction adjacent to pyoderma gangrenosum, osteomyelitis-like lesions (chronic recurrent multifocal osteomyelitis)
Gout	Tophi	Erosive arthritis
Multicentric reticulohistiocytosis	Skin and subcutaneous nodules	Destructive polyarthritis, especially terminal interphalangeal joints (similar to rheumatoid disease), atlantoaxial disease
POEMS syndrome	Pigmentation, sclerosis, hypertrichosis	Sclerotic lesions, may have central lucency
Neoplastic		
Naevoid basal cell carcinoma syndrome (Gorlin syndrome, Gorlin-Goltz syndrome)	Basal cell carcinomas	Cysts of jaw and other bones, frontal bossing, calcification of falx cerebri, bifid ribs, spina bifida and other spinal abnormalities, polydactyly/syndactyly, shortened metacarpals
Histiocytoses (Langerhans' cell histiocytosis, Rosai–Dorfman disease, Erdheim–Chester disease, juvenile xanthogranuloma, others)	See Chapter 55	Lytic lesions, defects of skull and mandible, vertebral lesions
Mastocytosis	See Chapter 22	Diffuse or focal osteoporosis or sclerosis
Fibromatoses	See Chapter 56	Various; most characteristic are cystic lesions of skull and long bones in infantile myofibromatosis
Subungual tumours	Glomus, squamous cell carcinoma, others	Osteolysis
Other		
Subungual exostosis	Hard subungual nodule	Underlying exostosis
Osteoma cutis	Hard plaque(s)	Focal bone formation, possibly primary or within a preceding lesion
Becker's naevus	Pigmented hairy lesion	Scoliosis, spina bifida
Thyroid acropachy	Finger clubbing	Expanded distal phalangeal tuft
Acromegaly	(See p. 62.2)	Increased periosteal bone growth
Pachydermoperostosis	Clubbing, thickened digits, cutis verticis gyrata	Periosteal new bone affecting all segments of bone, acro-osteolysis
Complex regional pain syndrome (reflex sympathetic dystrophy, Sudek's atrophy)	Soft tissue swelling (usually limb or acral), hyperhidrosis/hypohidrosis, vasomotor changes	Patchy osteoporosis, bone atrophy
Scurvy	Ecchymosis, 'corkscrew' hairs, gingival lesions	Increased bone density ('white line' of scurvy, Wimberger's sign), lucent bands, metaphyseal corner breaks, pseudo-double epiphysis, periosteal new bone due to haemorrhages
Fat embolism	Petechial rash on anterior trunk	Causative fracture(s)

POEMS, *p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M* protein, *s*kin changes (syndrome); SAPHO, synovitis, *a*cne, *p*ustulosis, *h*yperostosis, *o*steomyelitis.

Inflammatory conditions [1,2]

Arthralgia and/or arthritis is frequent in a number of inflammatory and metabolic conditions which also affect the skin, such as psoriasis and sarcoidosis (Table 62.24). Most of these individual diseases are discussed in more detail elsewhere in this text; some of the multisystem disorders are briefly described here.

Palmoplantar pustulosis (Chapter 20). A group of overlapping joint diseases occur in conjunction with palmoplantar pustulosis, and less frequently with psoriasis, acne and non-dermatological conditions such as inflammatory bowel disease. The various patterns have been brought together under the acronym SAPHO (*s*ynovitis, *a*cne, *p*ustulosis, *h*yperostosis and *o*steitis). Individual components include predominant sternoclavicular disease (variously termed intersternocostoclavicular osteitis, sternoclavicular pustulotic osteitis, sternocostoclavicular hyperostosis, pustulotic arthro-osteitis or anterior chest wall syndrome; Fig. 62.44) and a more widespread non-purulent chronic recurrent multifocal osteo-

Table 62.24 Some inflammatory and metabolic disorders that affect skin and joints.

Dermatoses
Psoriasis, Reiter's syndrome, palmoplantar pustulosis
Acne fulminans and conglobata, SAPHO
Connective tissue diseases
Lupus erythematosus (especially systemic and subacute cutaneous)
Mixed connective tissue disease
Sclerodermas
Still's disease
Rheumatic fever
Rheumatoid disease
Relapsing polychondritis
Granulomatous disorders
Sarcoidosis
Interstitial granulomatous dermatitis with plaques and cords
Blau syndrome (granulomatous arthritis, uveitis, campylodactyly)
Vasculitis and neutrophilic vascular reactions (see Chapter 50)
Vasculitis (any; notably Henoch–Schönlein purpura)
Behçet's disease and related disorders
Neutrophilic dermatoses (notably Sweet's syndrome)
Bowel-associated dermatosis–arthritis syndrome
Metabolic, endocrine and deposition disorders
Gout
Pancreatic panniculitis
Amyloidosis
Scleromyxoedema, cardiac myxoma
Ochronosis
Haemochromatosis
Acromegaly
Fabry's disease
Infections
Whipple's disease
Lyme disease
Disseminated gonococcal infection, chronic meningococcal infection, others
Miscellaneous
Ehlers–Danlos syndrome
Hyper-IgE syndrome
Multicentric reticulohistiocytosis
Autoinflammatory disorders (periodic fevers), e.g. familial Mediterranean fever, PAPA

PAPA, *p*yogenic *a*rthritis, *p*yoderma gangrenosum, *a*cne; SAPHO, *s*ynovitis, *a*cne, *p*ustulosis, *h*yperostosis, *o*steomyelitis.

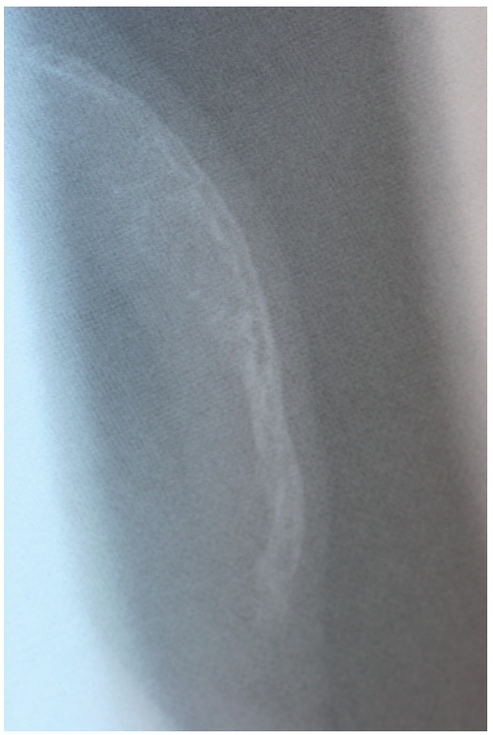

Fig. 62.43 Calcification of the ear due to cold injury.

myelitis [1–5]. Diagnostically, scintigraphy is more sensitive than radiographic examination. Hidradenitis suppurativa and pyoderma gangrenosum have been linked with similar bone and joint changes. Therapeutic options include non-steroidal anti-inflammatory drugs and doxycycline; if infection has been excluded then oral or intra-articular corticosteroids, methotrexate and infliximab may also be considered.

Acne. In addition to the SAPHO pattern described above, arthritis of larger joints occurs in about a third of patients with acne fulminans—most have arthralgia. This is associated with fever, systemic malaise and weight loss, and can usually be controlled with short-term oral corticosteroids. Other skeletal manifestations linked to acne are those secondary to therapeutic agents (skeletal hyperostosis due to isotretinoin, usually only if given long term, and arthralgia in the lupus-like syndrome caused by minocycline); infectious arthritis due to *Propionibacterium acnes* may also occur [6].

Vasculitides (Chapter 50). Arthralgia or arthritis is a common feature of many disorders in this spectrum, occurring for example in about 90% of patients with systemic lupus erythematosus, two-thirds of those with Henoch–Schönlein purpura and about 40% of those with Behçet's disease.

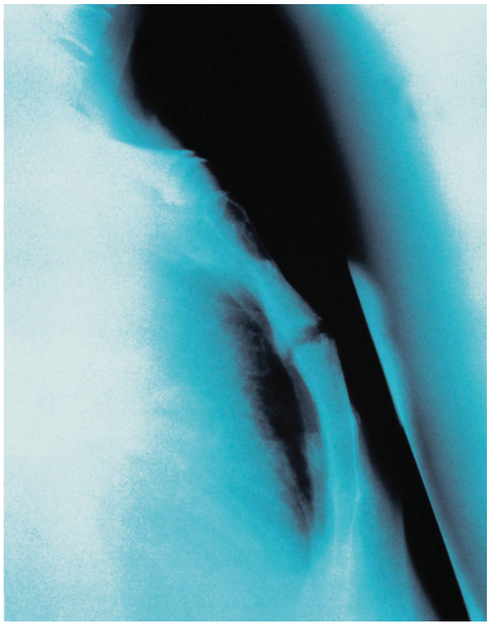

Fig. 62.44 Tomogram showing inflammatory changes of the sternal synchondrosis with widening and 'woolly' appearance in a patient with palmoplantar pustulosis.

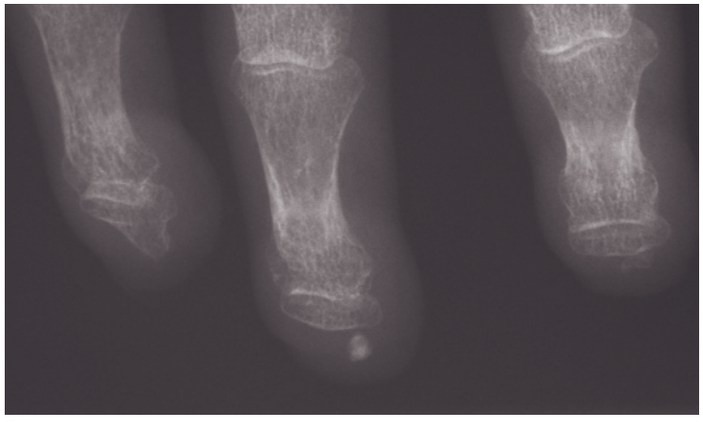

Neutrophilic dermatoses. This group of disorders is discussed in relation to gastrointestinal and haematological disease in this chapter, and in more detail in Chapter 50. Sweet's syndrome may be associated with arthralgia, with a frequency of around one-third to over 60%. Patterns include a seronegative polyarthritis, a chronic axial and peripheral destructive polyarthritis, and acute aseptic monoarthritis [7,8]. Multifocal osteomyelitis, which may be chronic or recurrent, is increasingly recognized as one of the systemic manifestations of this syndrome, and localized osteitis may occur in association with pyoderma gangrenosum [9,10].

Connective tissue diseases (Chapter 51) **and rheumatological disorders.** Arthralgia is a major feature in many conditions in this category, such as lupus erythematosus, progressive systemic sclerosis (PSS) and localized acral variants, mixed connective tissue disease and dermatomyositis. Interstitial calcinosis in these disorders has already been briefly discussed. In most cases, radiological studies show no major changes as the arthritis is typically non-erosive, but acral or periarticular osteoporosis may be apparent. In PSS, resorption of distal phalanges may be apparent (Fig. 62.45), as well as osteolytic foci and 'cysts' in bones such as ribs, spinous processes and in the wrists [1]. Melorrheostosis is also linked with scleroderma, usually localized in type.

Rheumatoid arthritis (RA) is associated with potentially severe bone changes, as is psoriatic arthropathy (Chapter 20). Rheumatoid disease is also associated with several skin disorders, including vasculitis, pyoderma gangrenosum and other potentially severe complications. *Fibroblastic rheumatism*, a less well known condition, causes polyarthritis of medium-size joints, together with skin nodules that typically affect the hands and areas adjacent to joints [1]. An unusual but distinctive feature in RA is marked skin redness around the elbows, associated with joint

(a)

(b)

Fig. 62.45 Progressive systemic sclerosis; (a) tight skin, dyspigmentation, shortening and distortion of phalanges, and (b) X-ray image of the same patient showing bony resorption and some soft tissue calcium deposition.

swelling and raised inflammatory markers—skin histology shows massive aggregates of histiocytes in dilated vessels, with a mixed dermal inflammatory infiltrate [11]. This has been termed *intravascular or intralymphatic histiocytosis associated with RA*.

Interstitial granulomatous dermatitis. This histological pattern may occur in many situations including infections (such as borreliosis or hepatitis C infection), lymphoreticular malignancies, drug eruptions and autoimmune disease. Various skin lesions have been described in *palisading neutrophilic and granulomatous dermatitis (PNGD) of immune complex disease*, including papulonodules, urticaria, vasculitis and granuloma annulare-like lesions. Arthralgia may occur due to systemic vasculitis, and PNGD may occur in rheumatoid arthritis [12]. There are also several reports of a related disorder in which arthritis occurs together with cutaneous lesions that may be plaques or subcutaneous cords ('rope

sign'), which are linear or arciform and typically on the trunk or proximal limbs; this disorder is usually termed *interstitial granulomatous dermatitis with plaques* [13,14].

Relapsing polychondritis (Chapter 68). Migratory arthritis of small and large joints, usually sparing the hands, is a frequent feature [1,15]. It probably occurs in about two-thirds of patients. Chondritis affecting spinal vertebra may cause chronic back pain.

Still's disease. Evanescent rash (typically erythema marginatum pattern, occurring in about 80%), spiking high fever and arthralgia/arthritis are seen. It is often reasonably characteristic in children, but frequently a less easy diagnosis in the rarer cases in older individuals. Different diagnostic criteria have been proposed for adult-onset Still's disease (AOSD), of which the most sensitive are those of Yamaguchi [16]. Additional cutaneous findings in AOSD are persistent widespread papules and plaques in up to two-thirds of patients, in some cases forming confluent sheets [17] or with a lichenoid or linear patterning [18], vesicopustules and post-inflammatory pigmentation. Marked elevation of ferritin levels is a helpful diagnostic clue in active AOSD.

Multicentric reticulohistiocytosis (Chapter 55). Polyarthritis, especially affecting the interphalangeal joints of the hands, occurs as the first manifestation of the disorder in half to two-thirds of patients. It is typically rapidly progressive, and all of the synovium-lined joints may become affected, with arthritis mutilans the end result in one-third to half of cases. The erosions are strikingly symmetrical and well circumscribed, and accompanying osteoporosis is disproportionately mild. The arthritis may burn out, but residual hypertrophic osteoarthropathy may persist [1,19]. A disorder reported as familial histiocytic dermatoarthritis [20] has been described in which there is early onset of a papulonodular eruption, a symmetrical destructive arthritis and ocular lesions such as cataract and glaucoma. Subsequent cases and electron microscopy studies [21] suggest that this may be part of the spectrum of multicentric reticulohistiocytosis.

Autoinflammatory syndromes (periodic fevers). The most important 'classical' periodic fevers are familial Mediterranean fever (FMF; MIM *249100), FMF with amyloidosis (MIM *134610), Hibernian fever—now redesignated as *t*umour necrosis factor (TNF) *r*eceptor–*a*ssociated *p*eriodic *s*yndrome, TRAPS, MIM #142680—and the hyperimmunoglobulin D and periodic fever syndrome (HIDS; MIM #260920). All are characterized by recurrent fever with serositis (peritonitis-like abdominal pain, pleurisy, pericarditis), headache and arthralgia or arthritis [22–26]. In FMF, there may be urticarial lesions, subcutaneous nodules, purpura, leukocytoclastic vasculitis (described, probably incorrectly, as Henoch–Schönlein purpura), or transient cellulitis-like erythematous plaques [22–25]. Both the articular symptoms [26], and erysipelas-like skin lesions predominantly affect the lower leg [23]. Erythematous macules and nodules, but not the erysipelas-like lesions, may occur in HIDS [22]. In TRAPS, the cutaneous features include migratory patches, oedematous plaques and periorbital oedema [23]. FMF is due to a variety of mutations in the *MEFV* gene [27]; classic-type HIDS is due to mutations in the *MVK* gene leading to deficient activity of mevalonate kinase [28,29]; and TRAPS is due to mutations in *TNFRSF1A,* which codes for the 55-kDa TNF receptor [26].

This spectrum has recently been expanded by the addition of some hereditary syndromes that may not include fever, but which have related mutations in genes that regulate innate immunity. Dermatologically, this includes several 'connective tissue' diseases, as well as a number of syndromes that include both skin and bone components [30]. Some of these have already been discussed above or are discussed in other chapters, including sarcoidosis, PAPA (pyogenic arthritis, pyoderma gangrenosum, acne) syndrome (now known to be due to a mutation of *PSTPIP1*), chronic recurrent multifocal osteomyelitis (linked with acne and hidradenitis suppurativa) and psoriatic arthropathy. *Blau syndrome* is also included with the above conditions. It is a familial condition in which there is granulomatous arthritis, granulomatous skin rash and uveitis, with synovial cysts and camptodactyly [31]; the underlying defect is a mutation in *NOD2* which is an intracellular toll-like receptor. Increasingly, defects of handling microbial agents are being demonstrated in these conditions.

Sarcoidosis is discussed in detail in Chapter 61. The classical constellation of features in acute sarcoidosis includes erythema nodosum, arthralgia of medium sized joints and hilar lymphadenopathy [32]. The main differential diagnoses for the joint symptoms include Lyme disease, gonococcal infection and Reiter's syndrome. Less recognized is an acute periarticular ankle inflammation [32], which may occur alone or with erythema nodosum, is more common in men, and in which skin biopsy from the periarticular subcutis shows a non-specific inflammation or panniculitis. Chronic sarcoidosis is associated with both articular symptoms and bone cysts [33], often affecting the hands and occasionally presenting to dermatologists initially [34].

Inherited conditions associated with hypermobility of joints include Ehlers–Danlos syndrome, of which there are several types, and hyper-IgE syndrome in which two-thirds of patients have hyperextensible joints together with a triad of abscesses, pneumonia and elevated IgE levels [35].

Metabolic conditions

Gout may present to dermatologists due to tophi, but is generally diagnosed due to acute arthropathy or chronic erosive joint disease [1,2]. Tophi may be small and occurring in clusters, but may be large and deforming, and may be associated with lytic bone lesions. They may be detected within the carpal tunnel using CT or MRI. Medullary tophi cause subchondral osteolytic areas [1].

Haemochromatosis—arthropathy is a frequent complication, probably due to abnormal accumulation of metal ions [3,4]; other aspects are discussed elsewhere in this chapter.

Ochronosis is discussed in Chapter 68. Calcium crystal deposition accompanies the cartilage degradation characteristic of this disease [4].

Amyloidosis (Chapter 59) is closely linked to joint disease, as rheumatoid arthritis is the commonest cause of secondary amyloidosis [5]. Amyloid A has cytokine-like properties and may be actively involved in inflammatory processes.

Scleromyxoedema causes arthralgia or arthritis in 10% of patients, and is also associated with rheumatoid arthritis and sicca syndrome. Carpal tunnel syndrome and acroosteolysis may also occur [6].

Other metabolic disorders that may have skin and bony or joint symptoms include Fabry's disease, Gaucher's disease and Farber's disease [4]. Bone symptoms are an important part of *Gaucher's disease* [4,7]. Bone crises may be related in part to haemorrhage; they may be treated with prednisolone, bisphosphonates or with prophylactic enzyme replacement therapy. Avascular necrosis, pathological fractures and cortical destruction of bones with extraosseous extension also occur.

Xanthomas at acral sites can be associated with prominent defects in underlying phalanges.

Scurvy is discussed in Chapter 59; bony features are listed in Table 62.23.

Infections

Numerous infective conditions may affect both the skin and joints. Arthralgia is associated with the exanthem of viral infections such as parvovirus, hepatitis B or rubella. *Reiter's syndrome* may be provoked by genital infections such as *Chlamydia*, or by various enteritic organisms such as *Yersinia*, *Shigella* or *Campylobacter*. Arthralgia is frequent, with constitutional symptoms and a non-specific exanthem, in brucellosis. Other bacterial causes of arthritis with pustular or vasculitis skin lesions include disseminated *gonococcal infection* and *chronic meningococcal septicaemia*. Arthralgia may be prominent in spirochaetal diseases such as *Lyme disease* or *secondary syphilis*. In the latter, the flat bones of the skull are frequently involved, causing headache. Osteomyelitis is a feature of tertiary syphilis. Arthralgia is the presenting feature in two-thirds of patients in the early stage of *Whipple's disease* [8,9].

Annular and figurate reactive erythemas

Numerous dermatoses produce annular lesions, in some cases leading to a specific diagnosis (for example, tinea corporis or granuloma annulare). The aim of this section is not to discuss all annular eruptions that may be part of a systemic disease (such as annular sarcoidosis). However, there are a group of, often chronic, annular and figurate eruptions that do not easily lead to a specific diagnosis. This rather vague group, collectively termed 'annular erythemas', and some of their more important differential diagnoses, may have systemic causes and may pose diagnostic and therapeutic problems. The nomenclature of this group of disorders has been discussed in detail elsewhere [1] but most of the descriptive and eponymous terms that are applied do not help greatly in management of the patient. Equally, although the pathological features can be divided into those cases with superficial or deep perivascular lymphohistiocytic infiltrate ('superficial or deep gyrate erythema' [2], clinically corresponding to annular erythema with scaling or with smooth surface respectively), the clinical relevance of this is not clear. Some of these annular erythemas that have a specific clinical pattern or clinical course related to their aetiology are discussed separately; the remainder are conveniently grouped with erythema annulare centrifugum (EAC) although it should be appreciated that this latter group are undoubtedly a heterogeneous mixture.

For the purposes of this section, the following will be discussed:

1 Erythema (chronicum) migrans
2 Erythema marginatum (rheumaticum)
3 Erythema gyratum repens
4 Annular erythema of infancy
5 Annular erythema associated with extractable nuclear antigens
6 Erythema annulare centrifugum and other 'annular erythemas'
7 Neutrophilic and vasculitic annular eruptions.

Erythema migrans (Chapter 30)

Synonym
- Erythema chronicum migrans

Erythema (chronicum) migrans is the term applied to the commonest skin lesion of Lyme borreliosis. This condition is caused by infection with *Borrelia burgdorferi sensu lato*, *B. afzellii* or *B. garinii*, which are spirochaetes transmitted by bites from *Ixodes* ticks [1]. The primary lesion of erythema migrans at the site of a tick bite is usually solitary and usually essentially flat with mild inflammation, but may be urticated or haemorrhagic (lesions of *B. burgdorferi* are usually more inflammatory and more rapid in evolution than those caused by the other species). The shape may be an expanding annular morphology, a homogeneous macule, or less often may consist of concentric target-like rings. Non-annular erythema migrans is more frequent in infections with *B. afzellii* or *B. garinii* in parts of Europe. Malaise, flu-like symptoms and lymphadenopathy are common at this stage. The lesion expands slowly over a period of weeks to a median size of about 15 cm with central clearing (the early-localized, or first, stage) [2–6]. Although erythema migrans accounts for 85% of skin lesions of Lyme disease, a 'borrelial lymphocytoma' is another manifestation of this stage, consisting of a small (up to 5 mm) plaque, usually on the earlobe, nose, areola, scrotum or over bony prominences. The two disorders together are pathognomic for Lyme borreliosis.

In the early disseminated (or second) stage, which occurs within one to a few weeks, additional, usually multiple, annular plaques may develop in up to half of patients. These are usually smaller than the first stage lesion, and may have a polycyclic pattern that resembles erythema annulare centrifugum or an annular erythema multiforme-like appearance. The term 'erythema migrans chronicum' is something of a misnomer as the early stages are of quite short duration, although Lyme disease itself may become chronic if untreated, and a chronic (third, or late disseminated, stage) skin lesion termed acrodermatitis chronicum atrophicans may occur in such cases. Rarely, lesions typical of erythema migrans may occur in the third stage [7]; there may also be lesions clinically resembling morphoea and having histological features of an interstitial granulomatous dermatitis with histiocytic pseudorosettes [7].

Histology of early localized or disseminated stage erythema migrans shows a superficial perivascular lymphocytic infiltrate, which may contain plasma cells, and which may extend more deeply around vessels or appendages. The diagnosis can be confirmed serologically, but serology after treatment is not useful for predicting the clinical course—persistence of IgG antibody is linked with size and duration of erythema migrans, rather than with other clinical variables [8].

Treatment is usually with tetracyclines (generally doxycycline 100 mg b.d. for 2–3 weeks, although a single dose has been reported as being effective in 87%) or ampicillin; third-generation cephalosporins such as ceftiaxone are the alternative. Vaccination was also available in the USA but, due to high cost and uncertainty about safety and efficacy, was withdrawn from the market. It should be noted that coinfection with the organism of human granulocytic anaplasmosis (was human granulocytotropic ehrlichiosis) has been reported in up to 20% of cases, both organisms being carried by deer ticks [9].

Associated systemic manifestations in the disseminated stages include arthralgia and arthritis, myalgia, cardiac involvement (especially atrioventricular block or pericarditis) and a variety of neurological manifestations (cranial nerve palsies, peripheral neuropathy, meningitis, encephalitis). These same features are seen in canine infection. Treatments for Lyme disease with heart block, facial palsy or meningitis have recently been reviewed [10].

Erythema marginatum (rheumaticum)

Synonym
- Erythema annulare rheumaticum

Rashes of various morphologies can occur in rheumatic fever and Still's disease, erythema marginatum being the most classical and distinctive, but now rare, pattern. Along with carditis, migratory polyarthritis, chorea and subcutaneous nodules, it is one of the Duckett Jones major criteria for the diagnosis of rheumatic fever, and is probably specific for this diagnosis (two major, or one major and two minor, criteria are strictly required for the diagnosis but newer echocardiography techniques and Doppler colour flow mapping may extend the diagnostic criteria). However, erythema marginatum may be subtle, and only occurs in about 10% of patients (especially in children) with active rheumatic fever [1–3]; one study of 126 children (80 first attacks and 46 recurrences) did not identify any with erythema marginatum [4].

The eruption consists of rings or segments of rings, pale or dull red in colour, flat or palpably thickened. The rings may be discrete, or may enlarge and merge to produce a polycyclic or reticular pattern.

Characteristically, the lesions fade in a few hours or at most in 2–3 days, and tend to be more prominent in the afternoon. Recurrent crops, often in different sites, may appear at intervals for many weeks. The lesions occur most frequently on the trunk, especially on the abdomen, but are occasionally seen on the limbs. They are asymptomatic.

Histologically, an infiltrate of polymorphs can help to distinguish this disease from other annular erythemas [5], but is not always found.

A similar eruption has been reported with psittacosis [6], and erythema marginatum has been reported preceding attacks of hereditary angioneurotic oedema [7,8].

Erythema gyratum repens [1–8]

The first description of this condition in 1953 is attributed to Gammel, who reported a case associated with breast carcinoma [1]. It is exceptionally rare but clinically distinctive (see Fig. 62.14). It is more common in men than in women, and usually occurs in or after the seventh decade of life.

Clinical features [1–8]. Regular waves of erythema spread over the body to produce a series of concentric, figurate bands in a pattern resembling the grain of wood (see Fig. 62.14). The characteristic feature is the way rings, swirls or waves appear within existing lesions to form a concentric pattern of sequential eruptions, with day-to-day migration of the leading edge by about 1 cm. Scaling, usually at the trailing edge, and itch are usually prominent. This is by contrast to the more common 'annular erythemas' of erythema annulare centrifugum pattern, in which each lesion is usually a distinct ring or arc with variable but usually without prominent scale, and not in a concentric arrangement. Hyperkeratosis of palms occurs in about 10% and has been reported in both paraneoplastic and idiopathic cases.

Aetiology. This eruption has been briefly discussed earlier (p. 62.38) as a paraneoplastic eruption; about 80% of reported cases are associated with an internal tumour [4,6–9], most commonly of the lung. Other tumour sites include bowel, oesophagus, urogenital tract, breast, pancreas and haematological neoplasia.

However, not all cases are paraneoplastic. Since the report of a case associated with tuberculosis [10], several cases have been reported in apparently well patients or associated with other disorders such as CREST syndrome (reviewed in [4,7]). Drug hypersensitivity has also been implicated. Some of these non-paraneoplastic cases are questionable in the absence of photographic documentation, but some cases appear very convincing, such as a patient with recurrent pregnancy-associated episodes [11]. An infant was reported in whom lesions were controlled by long-term systemic ketoconazole [12].

Pathology [13]. There is a superficial, and occasionally deep, perivascular lymphocytic infiltrate associated with acanthosis, spongiosis and parakeratosis. Deposition of C3 or IgG in the sublamina densa region supports the concept that the eruption is

immunologically mediated, possibly by immune complex deposition [5,14].

Investigation. The paramount issue is a detailed search for underlying malignancy. Fungal infection should be excluded, especially tinea imbricata in relevant populations. Skin biopsy is important as a similar gyrate eruption may be a prodromal manifestation of pemphigoid [15], and similar but rather localized lesions have been reported due to vasculitis, especially in lupus erythematosus [16] and in neutrophilic dermatoses; a morphologically similar disorder termed lupus erythematosus gyratum repens has been reported, related to either medications or internal malignancy [17,18]. Necrolytic migratory erythema (p. 62.66) and erythrokeratoderma variabilis (Chapter 19) may produce very similar lesions, as may the subacute annular (Lapière) variant of psoriasis, although none of these typically have multiple concentric lesions. Cases of apparent idiopathic erythema gyratum repens have also been suggested to represent a stage in the evolution of pityriasis rubra pilaris [19,20]. A patient with EBA associated with ulcerative colitis has been reported due to occurrence of erythema gyratum repens-like lesions, but PCT-like erosions and milia on the dorsum of hands and feet were also present [21].

Annular erythema of infancy

This term was first applied by Peterson and Jarratt [1] although infantile onset of a similar eruption had been reported previously [2]; numerous cases have been reported subsequently [3–8]. Although the age group does not define a category that can be distinguished from other cases of EAC, and probably also represents a range of disorders, the implications for investigation are somewhat different. For example, cutaneous fungal infection and malignant diseases are unlikely causes, whereas other (systemic) infections and lupus erythematosus-related antibodies (see below) are important to exclude. However, the fact that some cases started in teenage years and others in infancy in a family with autosomal dominantly inherited annular erythema [9] argues against there being a specific infantile variant.

Clinical features. The clinical morphology of lesions is generally as described for EAC.

Pathology. Histological appearances are typically the same as in cases of EAC. However, some authors have reported eosinophils to be prominent [7,8] and they may be the predominant cell type and associated with peripheral eosinophilia [10]. A neutrophilic variant has also been reported [6,11,12].

Aetiology. As in EAC (below), no cause can be identified in many patients, often despite extensive investigation. Some childhood cases may be discovered to have lupus erythematosus or have had transplacental transfer of maternal antibodies against extractable nuclear antigens, as discussed below; a clinical pattern described as erythema gyratum atrophicans transiens neonatale is now felt to be a variant of neonatal lupus erythematosus [13]. Heavy intestinal colonization with *Candida albicans* has been documented as a cause [14], and concurrent Epstein–Barr virus infection has been reported in an infant [15]. *Pityrosporum* infection in an infant has been reported as a mimic of EAC [16]; other differential diagnoses that may apply in children are listed in the section on EAC. A recently described 'annular lichenoid dermatitis of youth' [17] appears to be distinct, although it may include lesions resembling annular erythema; 'lymphomatoid annular erythema' [18] has also been described as a childhood presentation of mycosis fungoides.

Treatment. Any associated infection should be treated as discussed in the section on aetiology. Treatments are otherwise symptomatic, as for EAC. In one case, lesions resolved during febrile episodes but reappeared 2 weeks later [12]. Responses to sodium cromoglycate and to IFN-α have been reported, but in many cases new lesions continue to erupt over many years.

Annular erythema associated with extractable nuclear antigens

It has been recognized for many years that annular lesions in neonatal lupus erythematosus are related to maternal antibodies against SSA(Ro) [1]. Neonatal lupus erythematosus with annular lesions but without anti-SSA antibodies may be explained by the demonstration that some patients have anti-U1RNP antibodies instead [2].

More recently, it has been recognized that annular lesions may occur in anti-SSA(Ro)-positive patients with Sjögren's syndrome, lupus erythematosus (or both together), and less commonly in otherwise well patients who do not fit criteria for either of these diagnoses [3–6]. In a group of 15 patients with anti-SSA antibodies and annular erythema, all sera were positive for the anti-60kDa-SSA and 11 for the anti-52-kDa-SSA [7]. It has been suggested that patients with annular lesions in Sjögren's syndrome actually have lupus erythematosus, although a more recent review of 93 patients with Sjögren's syndrome demonstrated that annular erythema was a more common feature in primary Sjögren's syndrome (6.5%) than in secondary Sjögren's syndrome (3.2%) [8], and was associated with anti-SSA and anti-SSB(La) antibodies in 75%. A role for anti-SSB(La) antibodies has also been proposed in patients with a rather more tumid-appearing pattern of annular erythema [9]. Further investigation has shown that patients with Sjögren's syndrome and/or lupus erythematosus who have anti-tRNA antibodies as well as anti-SSA or anti-SSB antibodies are more likely to have recurrent papulosquamous annular erythema than are those with anti-SSA or anti-SSB alone [10]. Conversely, anti-alpha-fodrin antibodies (which are most common in primary Sjögren's syndrome) do not appear to be linked with annular erythema [11].

Affected patients are usually young adults, although childhood onset occurs [12], and they are usually female; individuals of Japanese origin seem to be particularly likely to develop annular lesions. Although the edge of the lesions is often broader than in many cases of EAC, and the distribution is often photosensitive and limited to the face, it is likely that some cases previously classified as EAC may be explained by this mechanism.

In some cases, there may be residual central atrophy or telangiectasia. Such cases usually have granular IgG deposition at the dermoepidermal junction. This pattern is felt to be a variant of neonatal lupus erythematosus, termed erythema gyratum atrophicans transiens neonatale [13].

Treatment is usually determined by the underlying disease; topical treatments such as corticosteroids have limited benefit. Phototherapy, used for some patients with EAC, is probably not advisable as anti-SSA antibodies are linked with photosensitivity. However, as has been demonstrated in discoid lupus erythematosus, topical tacrolimus may be beneficial in annular erythema associated with Sjögren's syndrome [14].

Erythema annulare centrifugum (EAC) and other 'annular erythemas'

The term EAC was originally used by Darier [1], who delineated EAC from a more scaly and itchy eruption described earlier by Colcott Fox as erythema gyratum perstans. The term EAC is conveniently applied to the annular erythemas that do not obviously fall into one of the more specific categories discussed previously, although the 'diagnostic' term EAC probably identifies a mixed group of disorders with similar clinical appearance and histological features. Annular erythema of infancy is discussed separately, as it can be defined by the age group, and annular erythemas associated with anti-SSA (anti-Ro) and anti-SSB (anti-La) antibodies are viewed as a separate group as their aetiology is more defined; EAC usually has no identifiable cause, although many anecdotal triggers are reported.

Clinical features. EAC has been reviewed by several authors [2–6]. It is commonest in young and middle-aged adults, although onset may occur in infancy (discussed previously). Some authors suggest a female preponderance [5]. A small, pink, infiltrated papule slowly enlarges and forms a ring, as the central area flattens and fades (Figs 62.46 & 62.47). The rate of extension is variable; although a diameter of 6–8 cm may be achieved in less than 2 weeks, extension is usually much slower (typically 2–3 mm/day), especially in the cases with epidermal involvement. Extension may be irregular, to leave arciform segments. Lesions may be solitary or, more often, multiple. The edge may be quite flat or easily palpable with a superficial cord-like quality, and lesions may be smooth or show slight scaling behind the advancing edge. Rarely, vesiculation occurs. Itching is variable, but seldom intense. The commonest sites are the buttocks, thighs and upper arms, but any areas may be involved. Sometimes lesions are mainly on the extremities, but the face is seldom affected.

Individual lesions last for a few days, more often a few weeks, or slowly extend for a few months. Further lesions usually occur, and the disease is usually chronic with periodic fluctuations over many years. Purpura and pigmentation may rarely occur within the lesions [7].

Pathology. The characteristic feature in EAC is a perivascular 'sleeve-like' lymphohistiocytic infiltrate, referred to as a 'gyrate erythema', which may be mainly superficial, mainly deep, or mixed. The pathological changes may be entirely within the dermis, whereas in other cases there is much more obvious epidermal change (spongiosis and parakeratosis) [8,9]. There is dispute about whether these represent two separate diseases or a continuous range.

A study of 82 biopsies from 73 patients suggested that EAC with a superficially situated infiltrate is different to that with a deeper dermal infiltrate [10]. The superficial pattern was associated clinically with a collarette of scale, that was not seen in the deeper pattern. Histologically, the superficial pattern was more likely to have spongiosis, parakeratosis, epidermal hyperplasia and papillary dermal oedema, whilst the deeper pattern more commonly had a sleeve-like infiltrate, melanophages and individual necrotic keratinocytes. However, neither pattern appeared to have any consistent systemic disease association, so the clinical utility of this histological distinction is unclear.

Eosinophils may occasionally be seen around superficial vessels. Significant peripheral eosinophilia raises the possibility of parasitic infection as the underlying cause. A very rare eruption that has clinical features of EAC but with a frankly eosinophilic infiltrate has been described under the name 'eosinophilic annular erythema' [11,12]. It has been suggested that this may actually be a variant of Wells' syndrome (eosinophilic cellulitis).

Aetiology. A broad range of associations has been described as causes of EAC (Table 62.25) [13–31]; however, some 'associations' that have been described may be coincidental, and some may be more properly categorized as unusual presentations of diseases mimicking EAC. A seasonally recurrent form has been reported and described as having received little attention [28], although the image of seasonally recurrent EAC in this textbook (Fig. 62.46) had already been published in the previous edition. Drug- and infection-induced cases are well documented although only in a small minority of cases. Underlying malignancy is an important

Fig. 62.46 Erythema annulare centrifugum; an expanding lesion with central clearing and scaling at the 'trailing edge'. This case was seasonally recurrent.

Fig. 62.47 Erythema annulare centrifugum; cases with deeply situated inflammation feel more tumid and exhibit less scaling.

Table 62.25 Possible causes and associations of erythema annulare centrifugum.

Category	Examples
Idiopathic	Including annually recurrent forms [13]
Familial	Dominant inheritance [14], twins [15]
Infantile onset	(see p. 62.108)
Fungi	Cutaneous tinea [5], intestinal *Candida* [16,17], ingested fungi (cheese) [16]
Other infections [2–6]	Molluscum contagiosum, Epstein–Barr virus, genital herpes, herpes zoster, Q fever, recurrent appendicitis, *E. coli* urinary tract infection, tuberculosis, *Ascaris* infection, trypanosomiasis, *Phthirus pubis* infestation, *Borrelia* spp.
Drugs [2–6]	Aldactone, amitryptiline, ampicillin, cimetidine, etizolam, granulocyte colony-stimulating factor, gold, hydrochlorthiazide, hydroxychloroquine, penicillin, piroxicam, salicylates, thiacetazone, vitamin K, finasteride
Endocrine	Hyperthyroidism [18], Hashimoto's thyroiditis, autoimmune progesterone dermatitis, oestrogen dermatitis, pregnancy, polyglandular autoimmune syndrome type I (the latter possibly mediated by *Candida* infection)
Haematological disorders	Lymphomas (various) [4,5,19,20], leukaemias [21,29–31], thrombocythaemia [22], polycythaemia rubra vera, myelodysplastic syndrome, hypereosinophilic syndrome [23], myeloma, dysproteinaemia, cryoglobulinaemia
Other neoplastic conditions [4,5,24]	Carcinomas of bronchus, prostate, nasopharynx, ovary, rectum and liver; carcinoid tumour
Immunological	Relapsing polychondritis [25,26], sarcoidosis [27], autoimmune hepatitis, linear IgA disease, lupus erythematosus
Miscellaneous	Liver disease, following biliary surgery, localized at pacemaker site, seasonal

consideration—for example, both 'standard' and eosinophilic variants of EAC have recently been reported in association with underlying chronic lymphocytic leukaemia [29–31]. In the large majority of cases the aetiology remains obscure, even after prolonged observation and investigation.

One study of 66 cases identified cutaneous fungal infection as the most important aetiological factor (in 72%), other causes being internal neoplasm in 13%, other skin diseases in 18% and other internal diseases in 21% [5]. However, a causal association could not always be proven, and the high frequency of fungal infection may have been influenced by the geographical location of the study in Korea.

A retrospective study of 90 cases suggested alternative diagnoses (urticaria, vasculitis, psoriasis) in 22%; the others were felt to be LE tumidus (32%), spongiotic dermatitides (28%) and pseudolymphoma (18%); in the latter group, 81% had *Borrelia* sequences detected [32].

Investigations. These are aimed at excluding alternative diagnoses, and search for an underlying cause (see section on Aetiology, above).

Fungal infections are the commonest differential diagnosis and should be excluded by microscopy and culture of skin scrapings. Other skin infections are less likely to mimic EAC but leprosy and leishmaniasis have both been reported to cause similar lesions, and an annular presentation of cutaneous *Pseudomonas* infection has been described in an immunosuppressed child. Granuloma annulare can usually be distinguished on clinical and/or histological features, and has slower evolution of individual lesions, but can cause diagnostic difficulty in some cases. Lymphomas, especially mycosis fungoides (MF), may produce annular lesions very similar to those of annular erythemas; these usually have a broader edge, but a very EAC-like appearance over 10 years prior to diagnosis has been reported [20] as well as a case of juvenile MF resembling EAC and termed 'lymphomatoid annular erythema' [33]. Pseudolymphomas also pose a diagnostic dilemma, as they may be both clinically and histologically similar to EAC—especially a disorder termed palpable migratory arciform erythema of Clark, which may be a variant of Jessner's lymphocytic infiltrate [34]. Genodermatoses such as erythrokeratoderma variabilis and erythrokeratoderma en cocardes should be considered in children, and similar lesions may be seen in carriers of chronic granulomatous disease. Several immunobullous diseases have been reported to have EAC-like lesions, especially in the prodromal phase, including bullous pemphigoid, pemphigus, dermatitis herpetiformis and linear IgA disease. Sarcoidosis, Still's disease, necrolytic migratory erythema, subacute annular psoriasis, pityriasiform seborrhoeic dermatitis, neutrophilic dermatoses, vasculitides, acute haemorrhagic oedema of childhood, leprosy, leishmaniasis and trypanosomiasis may all cause clinical confusion at times, but should be identifiable by histology and evolution of the eruption. Cases of pityriasis rosea in which there are few and large lesions may cause confusion but are self-limiting. Lupus erythematosus and Sjögren's syndrome need to be excluded, particularly cases with a dermatosis mediated by extractable nuclear antigens (see above).

Otherwise, it is seldom possible to establish an underlying cause. A search for a neoplasm should be made, especially in those with older age of onset, but exhaustive investigations are not recommended in the absence of other clues. Tinea pedis, *Candida* infection of the gut and other underlying infections are always worth excluding.

Treatment. Discovery and elimination of the cause are seldom possible. Numerous other treatments have been used including antihistamines, oral or topical corticosteroids, vitamin D analogues such as calcipotriol [35] or calcitriol, narrow-band UVB, various types of allergen avoidance, and systemic immunosuppressive therapies. Two patients with topical corticosteroid-resistant annular erythema responded promptly to use of topical tacrolimus [36]. Cases that have responded to antimicrobials such as sulphonamides or metronidazole may suggest that there was in fact an underlying infective cause. However, most empirical treatments appear to be relatively unsuccessful. The eosinophilic variant of annular erythema has been reported to respond to chloroquine [12] or hydroxychloroquine.

Neutrophilic and vasculitic annular eruptions

A variety of vasculitides or neutrophilic dermatoses have been documented as causing annular or figurate lesions, sometimes consistently in some individuals. These include acute haemorrhagic oedema of infancy, erythema elevatum diutinum and chronic recurrent annular neutrophilic dermatosis, which may clinically resemble the annular erythemas described above.

Examples of annular vasculitis were summarized by Nousari and colleagues [1], and included acute haemorrhagic oedema of infancy, erythema elevatum diutinum, urticarial vasculitis, Henoch–Schönlein purpura, and some cases of leukocytoclastic vasculitis associated with myeloma, inflammatory bowel disease or pregnancy. These are discussed in Chapter 50. A disorder described as recurrent annular erythema with purpura is noted here rather than within the spectrum of EAC, as it has vasculitic histology and response to dapsone, consistent with a form of leukocytoclastic vascultis [2]; the three cases included one each with ulcerative colitis and a benign IgA monoclonal gammopathy, all had monthly episodes of multiple, purpuric, centrifugally-spreading lesions. Subsequent similar cases have been reported [3], as well as annular purpuric lesions in a patient with lymphoma [4]. Large, annular purpuric lesions with histology of leukocytoclastic vasculitis have been reported in a patient with Sjögren's syndrome and carcinoma of the cervix [5]. Eosinophilic vasculitis may present with annular lesions [6], and both drugs [7] and infections [8] may cause annular leukocytoclastic vasculitis. Sarcoidosis itself can present as vascular lesions, but there are also reports of annular leukocytoclastic vasculitis in patients with sarcoidosis, distinct from cutaneous sarcoid lesions [9,10]. Figurate erythema with an erythema gyratum repens clinical morphology but leukocytoclastic vasculitis on histology has been reported in a patient with lupus erythematosus [11].

Sweet's syndrome often includes some annular lesions [12,13] but these seem to be a particular feature of a chronic variant of Sweet's syndrome [14–16]; in one series of nine cases of recurrent Sweet's syndrome characterized by erythematosus and annular plaques, with an initially lymphocytic histology, all developed myelodysplastic syndrome [16]. Annular lesions have also been reported in neutrophilic eccrine hidradenitis [17] (Chapter 50).

Introduction

The relationship between the nervous system and the skin is complex, and the aim of this chapter is to outline the physiology and pathophysiology of the interactions. Nervous system disorders may be divided broadly into those associated with sensory abnormalities and those associated with autonomic abnormalities, although there is overlap between these two groups. Skin manifestations may occur when the pathology is predominantly located either in the central nervous system (CNS), such as the spinal cord, or in the peripheral nervous system.

The sensory innervation of the skin allows the detection of a number of stimuli from the surrounding environment and the transmission of this information to the CNS (Chapter 4).

Groups of disorders affecting the skin and nervous system simultaneously might include genetic conditions (e.g. neurofibromatosis and tuberous sclerosis, Chapter 15), metabolic abnormalities (e.g. the mucopolysaccharidoses and Tangier disease, Chapter 59), Refsum's disease (Chapter 19), vitamin deficiency states (e.g. pellagra, Chapter 59) and exposure to toxins (e.g. arsenic poisoning) or infective agents (e.g. *Meningococcus*).

Skin innervation

The skin is innervated by a dense, three-dimensional network of highly specialized afferent sensory and efferent autonomic nerve branches. The sensory system contains receptors for touch, temperature, pain, itch and various other physical and chemical stimuli [1,2]. The autonomic system comprises post-ganglionic cholinergic parasympathetic nerves and adrenergic and cholinergic sympathetic nerves. It plays a crucial role in maintaining cutaneous homeostasis by regulating vasomotor function, pilomotor activity and eccrine gland secretion. As many as 1000 such afferent neurones may innervate 1 cm^2 of skin. The afferent sensory neurones are unipolar and branch off with a single axon travelling towards the skin. The autonomic nerves innervate the skin in a different pattern. Post-ganglionic fibres originate in the sympathetic chain and are co-distributed with the sensory neurones until they arborize into plexuses around sweat glands, blood vessels and arrector pili muscles [1,2]. Skin nerves may contain myelinated and/or unmyelinated fibres: subgroups of sensory neurones are myelinated A fibres, whereas unmyelinated C fibres contain sensory and autonomic fibres. The sensory myelinated fibres can be further subdivided, on the basis of diameter, into rapidly conducting Aα and slowly conducting Aδ nerves, which transmit tactile sensitivity or temperature, noxious sensation and itch, respectively [2–4]. In the upper dermis, small myelinated nerves lose their nerve sheaths and, together with the unmyelinated nerves, end in either free nerve endings or in association with receptors, such as Merkel cells or nerve ending organs [2,3].

Sensory innervation

Sensory innervation follows well-defined dermatomes with some overlap between adjacent dermatomes. Sensory nerves not only function as an afferent system to conduct stimuli back from the skin to the CNS, but also act in an efferent neurosecretory fashion,

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

releasing neuropeptides with important visceromotor, inflammatory and trophic effects on skin (see below). Unmyelinated type C fibres terminate as either free nerve receptor endings or in association with receptors such as the pacinian or Meissner's corpuscles. Pacinian corpuscles, innervated by a single myelinated sensory axon, are most densely located on the palms and soles, where they act as mechanoreceptors. Meissner's corpuscles also occur in greatest density on the palms and soles; being innervated by one or more sensory nerve endings, they also act as mechanoreceptors, and in addition transmit touch sensation. Merkel cells, which occur at low density generally, with an increased density around hair follicles and at the palms, nail beds and lips, are innervated by synaptic nerve endings. Merkel cells produce and contain a wide range of neuropeptides, which may be important in the local regulation of inflammation [2].

Afferent sensory nerves, either unmyelinated C fibres or myelinated Aδ fibres, derive from the dorsal root ganglion and are capable of the release of a variety of neuropeptides in response to noxious stimuli [2–4]. Sensory impulses are conducted in the peripheral and central axon of the spinal ganglion cell in the dorsal root ganglion, and pass via the lateral spinothalamic tract and the lemniscus spinalis to the thalamus [4]. From the thalamus the information reaches consciousness via the thalamic radiation to the post-central gyrus of the parietal lobe.

C and Aδ fibres not only conduct nociceptive information to the dorsal root ganglion but also have an important efferent function, in that they stimulate target tissues by releasing a range of neuropeptides in response to noxious stimuli, such as chemical, electrical, thermal and mechanical injury, or UV radiation. Over 20 neuropeptides have been identified and more or less characterized in the skin of various species [5]. Neuropeptides with an important neurotransmitter function contained in primary sensory neurones include three tachykinins, substance P, (SP), neurokinin A (NKA) and calcitonin gene-related peptide (CGRP) [6]. These neuropeptides most frequently coexist in the same subpopulation of primary sensory neurones, the Aδ and C fibres, and are involved in the nerve transmission of impulses initiated by noxious stimuli. They usually occur in free nerve endings in the upper dermis (Fig. 63.1) and epidermis throughout the body, but are at greatest density on the palms and soles, where some end in a plexus around Meissner's corpuscles (Fig. 63.2) [6].

Capsaicin, a vanilloid alkaloid found in red pepper fruit [7], functions in nociception by binding to a specific receptor called the vanilloid receptor, the name referring to a homovanillyl group found in ligands of the receptor. Vanilloid receptors have been found on the unmyelinated C and thinly myelinated Aδ fibre types, which transmit painful stimuli. When capsacin stimulates the transient receptor potential vanilloid receptor 1 (TRP-V1), one of the vanilloid receptors particularly implicated in neurogenic inflammation [7], this causes cation influx which is rapidly followed by receptor desensitization. If calcium overload is sufficient, this can lead to cell death [7,8].

Release of neuropeptides often leads to neurogenic inflammation. The key components of neurogenic inflammation are precapillary vasodilation, plasma protein extravasation and leukocyte infiltration, which follow antidromic stimulation of peripheral nerves. Neuropeptides can regulate both acute and chronic

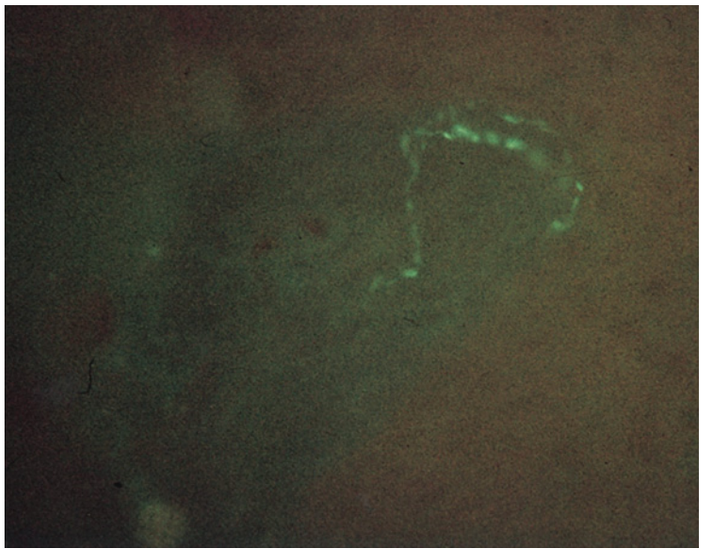

Fig. 63.1 Substance P immunoreactive nerve endings in the epidermis of human skin.

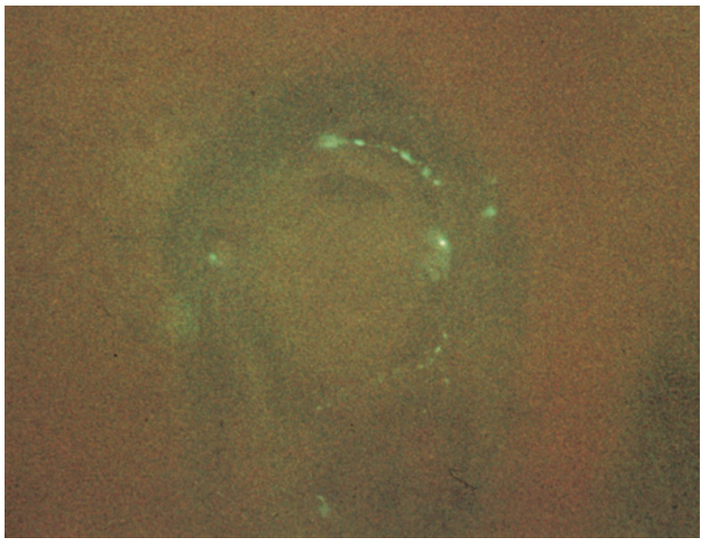

Fig. 63.2 Substance P fibres ending in Meissner's corpuscles of skin.

inflammation by influencing vascular motility and cellular trafficking. After release, neuropeptides are metabolized by membrane-bound endopeptidases that occur on target structures such as blood vessels and eccrine sweat glands in skin [9]. Neutral endopeptidase (NEP) and angiotensin converting enzyme (ACE) in particular seem to play an important role in terminating the action of neuropeptide agonists [5].

A key receptor on sensory nerves which is involved in neurogenic inflammation is the proteinase-activated receptor 2 (PAR-2). PAR-2, bound to G-protein, occurs on keratinocytes (especially in the stratum granulosum), endothelial cells, hair follicles, and in the myoepithelial cells of the sweat glands [7]. Tryptase released from degranulated mast cells cleaves PAR-2 in the sensory nerve endings. This leads to its activation and stimulates the release of

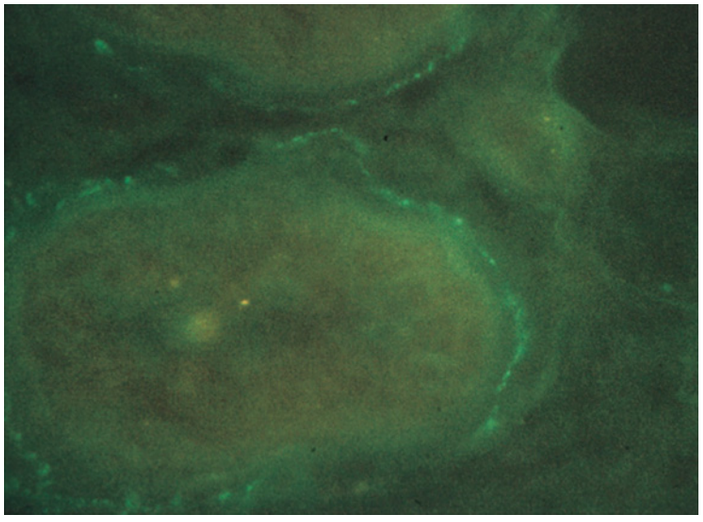

Fig. 63.3 Vasoactive intestinal peptide immunoreactive fibres surround secretory cells of eccrine sweat gland.

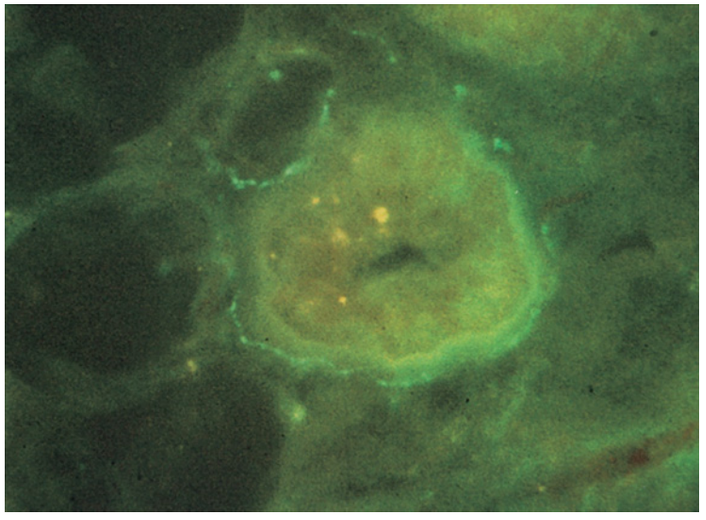

Fig. 63.4 Peptide histidine methionine immunoreactive fibres surround eccrine sweat glands.

CGRP and neurokinin—SP and NKA from sensory nerve endings. CGRP interacts with CGRP-1 receptor to induce arteriolar dilation and hyperaemia; SP interacts with NKA-1 receptor on the endothelial cells of postcapillary venules, to induce plasma extravasation; the overall result is tissue oedema. SP may also stimulate degranulation of mast cells, leading to release of tryptase, which produces positive feedback. Tryptase degrades CGRP and reduces its effects, CGRP inhibits SP degradation by neutral endopeptidase and enhances SP release. Other mediators from mast cells and other inflammatory cells stimulate the release of vasoactive peptides from sensory nerves [5,7].

It can be seen that close interaction between the different neuromediators, target cells and neuropeptide-degrading enzymes is critical for the control of cutaneous neurogenic inflammation [5].

Autonomic nervous system

The autonomic nervous system innervates the skin through post-ganglionic fibres originating in sympathetic ganglia, and terminating in autonomic plexuses that supply sweat glands, blood vessels and arrector pili muscles [1]. Histochemically there are two main groups of post-ganglionic nerve fibre in the skin. Firstly, adrenergic fibres synthesize and store catecholamines and norepinephrine (noradrenaline). The second major group consists of the cholinergic fibres containing acetylcholine. Co-localizing with acetylcholine are 'secretory' neuropeptides such as vasoactive intestinal peptide (VIP) and peptide histidine methionine (PHM). Nerves containing these should be regarded, at least physiologically, as parasympathetic. The secretory portion of the eccrine sweat glands, myoepithelial cells and nearby blood vessels are innervated by a basket-weave pattern of nerves, containing predominantly acetylcholine but also significant numbers of fibres containing 'secretory neuropeptides' including VIP (Fig. 63.3), PHM (Fig. 63.4), neuropeptide Y (NPY), CGRP, galanin, atrial natriuretic peptide (ANP) and norepinephrine. Secretory neuropeptides, mainly VIP and ANP, together with norepinephrine, are not as effective as acetylcholine at sweat production, and probably synergistically amplify acetylcholine-induced adenosine 3′,5′-cyclic monophosphate (cAMP) accumulation, which is the most important secondary messenger in sweat production. ANP may be responsible, at least in part, for regulation of sodium and other electrolytes released in sweat [6]. NPY has been identified in the periarteriolar nerve fibres of the deep and superficial vascular plexus, and in eccrine sweat glands, and is likely to play a role in regulation of skin blood flow and eccrine sweating [6]. Pituitary adenylate cyclase-activating polypeptide (PACAP) also plays a significant role in modulating cutaneous inflammation. It belongs to the VIP family and is capable of binding identical receptors to VIP in the same tissue but with different affinities. Therefore it is possible that there is some differential, fine-tuned interaction between these two peptides [5]. PACAP leads to mast cell degranulation and dilatation of small blood vessels [10]. PACAP may have a proinflammatory effect on endothelial cells during acute inflammation, yet it exerts anti-inflammatory effects under chronic inflammatory conditions [5].

Blood vessels in the skin are innervated by adrenergic fibres, which are vasoconstrictor, while acetylcholine and neuropeptides, such as VIP and PHM, act as vasodilators and increase vascular permeability [6,11]. Thus, by increasing release of acetylcholine and secretory neuropeptide, the body has a mechanism of increasing blood flow to the skin and increasing sweating, both of which act to reduce body temperature. If body temperature falls, this is detected in the preoptic region of the hypothalamus, which activates the sympathetic nervous system, which in turn reduces skin blood flow and sweating. Conversely, if warmer blood is detected in the hypothalamus, inhibition of sympathetic response allows skin sweating and blood flow to increase, thereby reducing core temperature [12,13].

Adrenergic fibres mediate strong vasoconstriction and arrector pili muscle activity, thus diverting blood from the skin, and pulling hairs into the upright position, in the classical 'fight or flight' reaction [1].

The digital nerves in patients with Raynaud's phenomenon and with systemic sclerosis are deficient in CGRP fibres [14], and intravenous infusions of CGRP increase digital blood flow in such patients. A similar depletion of CGRP fibres has been described in digital nerves of patients with vibration white finger, and this may be responsible for both the vasoconstriction and sensory abnormalities characteristic of this condition [15].

Wound healing and trophic effects

Impaired wound healing is often found in patients suffering from peripheral neuropathies, spinal cord lesions or after peripheral nerve trauma. Depletion of neuropeptides in animal models using capsaicin, and *in vitro* studies demonstrating that certain neuropeptides such as substance P, neurokinin A, CGRP and VIP stimulate DNA synthesis in fibroblasts, keratinocytes, melanocytes and endothelial cells, suggest that they are likely to act as mitogens, stimulating proliferation of tissue cells and thereby aiding the healing process [6,15–18]. The sprouting of sensory nerve endings, containing large amounts of substance P, occurs in wounds during the first 3 weeks, and is probably important in wound healing. Substance P has also been shown to up-regulate the synthesis of interleukin-1 (IL-1), IL-6 and transforming growth factor-α (TGF-α) in keratinocytes [18]. Nerve growth factor (NGF) is a neurotrophic factor released from sensory neurones, as well as fibroblasts, mast cells, lymphocytes and keratinocytes, which may act as a major controller of cutaneous wound healing and inflammation [18].

CGRP has a trophic effect in the regeneration of UV-damaged skin, and synthesis of CGRP increases after nerve injury, suggesting that this peptide may have a role in nerve regeneration [19].

Neuroimmunology

There is significant evidence of a close interaction between the nervous system and the immune system. Substance P, neurokinin A and CGRP predominantly function as pro-inflammatory mediators, whereas VIP, somatostatin and α-melanocyte-stimulating hormone (α-MSH) largely have anti-inflammatory properties [20].

Substance P *in vivo* and *in vitro* enhances the proliferation and function of B and T cells and induces cytokine secretion from monocytes, including IL-1, IL-6, tumour necrosis factor-α (TNF-α) and interferon-γ (IFN-γ) [21]. Substance P influences inflammatory responses by enhancing macrophage and leukocyte activity, and acts to release histamine, prostaglandin and leukotriene from mast cells [22]. Furthermore, it activates human dermal microvascular endothelial cells to express vascular adhesion molecule 1 [23].

While VIP is a potent releaser of histamine for mast cells, a mechanism that is independent of IgE activation, it also has anti-inflammatory effects, suppressing delayed hypersensitivity *in vitro* and inhibiting phospholipase A2 [24]. VIP inhibits natural killer cell activity and may have an inhibitory effect in inflammatory processes, such as contact dermatitis, an effect which may be mediated through an increased production of IFN-γ in peripheral blood monocytes [24].

Neuropeptides can activate a number of target cells, including keratinocytes, Langerhans' cells, mast cells, epithelial cells, granulocytes, eosinophils, macrophages and lymphocytes, all of which have been shown to have receptors for neuropeptides. Recent evidence shows that many of these cells may also synthesize these neuropeptides. In addition cytokines, including IL-1, TNF-α and NGF are potent stimulators of neuropeptide production [20]. The release of substance P, CGRP and other neuropeptides may ultimately hold the link between psychological stress and the flaring of inflammatory skin diseases [25–27]. Substance P, neurokinin A and CGRP are all up-regulated by UV light exposure of human skin, and may contribute to the inflammation of acute UV exposure, while in the longer term CGRP inhibits Langerhans' cell activity, thus leading to immunosuppression as a result of UV exposure [28]. Similarly, α-MSH is produced in the skin as a result of UV irradiation, and has been shown to induce the production of IL-10 and inhibit the production of IL-1 and IL-12, thereby inhibiting the chemokine-mediated migration of antigen-presenting cells [29].

In addition to their role as neurotransmitters, neuropeptides can modulate immune responses, leading to the concept of the neuro-immuno-cutaneous system, representing an interrelationship between the nervous system, immunity and skin. This may explain the link between the flare up of inflammatory diseases, such as atopic dermatitis [30] and psoriasis [25,26,31], during periods of emotional stress.

Neurophysiological testing for skin innervation

Sympathetic skin response

Sympathetic skin response (SSR) is a safe, simple and non-invasive electrophysiological test used to evaluate sudomotor function in a variety of clinical settings [32–34]. It can be used to assess autonomic function in patients with suspected sympathetic nerve dysfunction. The SSR is a polysynaptic reflex associated with the activation of sweat glands. It is usually performed by electrical stimulation of the median, ulnar, peroneal or sural nerves and measuring the change in galvanic resistance on glabrous skin brought about by sweating using a conventional electromyograph apparatus. The afferent component may be activated by non-specific sensory stimuli or repeated electrical stimulation; the efferent component depends on the functioning of the sympathetic-cholinergic fibres from the sympathetic chain to the sweat glands. In autonomic failure the SSR cannot be elicited.

Cold-induced vasodilation

Hand cooling is a cold pressor test in which an extremity is placed in cold water, leading to a rapid decrease in skin temperature, accompanied by initial strong vasoconstriction aimed at limiting heat transfer to the environment [35–39]. After a few minutes, skin temperature starts increasing as a consequence of cold-induced vasodilation. The precise mechanism of this reflex is unknown, but it is thought to be mediated through an increase in sympathetic stimulation, although factors independent of the sympathetic nervous system may also play a role. Exposure of the human body to cold stress elicits generalized cutaneous vasoconstriction. This is a response mediated by a sympathetic control process, triggered partly by stimulation of cutaneous cold receptors and partly by cold blood returning to the general circulation and stimulating the temperature-regulating centre in the hypothalamus. The tone of cutaneous vessels is controlled mainly by

vasoconstrictor skin sympathetic nerve activity. A reduction in this response has been reported in diabetic and neuropathic patients, and in the immature and elderly, probably resulting from reduced skin sympathetic nerve vasoconstriction [38,39].

Triple response of Lewis

Lewis described the capacity of the cutaneous microcirculation to vasodilate in response to direct stimulation with a firm mechanical stroke or with a dermographometer (the axon reflex) [39–41]. The amount of vasodilation can be measured by Doppler flow meter. The axon reflex, known as 'antidromic vasodilation', does not occur in chronically denervated skin or skin in which neuropeptides have been depleted by capsaicin. The antidromic vasodilation and plasma extravasation, which occurs in the skin following stimulation of the dorsal nerve roots or peripheral sensory nerves, can be mimicked by intra-arterial infusion of substance P.

Histamine is known to be a principal mediator of the triple response of Lewis, and to act via H_1 and H_2 receptors to produce vasodilation and increased vascular permeability. However, it is known that substance P, neurokinin A and CGRP from primary sensory fibres are also mediators in the skin flares of the triple response of Lewis [42,43].

Laser evoked potentials (LEPs)

Sensory evoked potentials (SEPs) are used for standard clinical neurophysiological assessment of somatosensory pathways, and can detect dysfunction in the tactile and proprioceptive systems, consisting of large fibres in the peripheral nerve, the dorsal columns of the spinal cord and the medial lemniscus in the brainstem. However, lesions in the nociceptive and thermoreceptive pathways of the somatosensory system are not detectable by these means. In recent years, studies have confirmed the usefulness of laser evoked potentials (LEPs), which can be produced by rapid heating of the skin with infrared laser pulses. These latter specifically activate such pathways, which consist of small fibres in the peripheral nerves and the anterolateral spinothalamic tract in the spinal cord and brainstem. Unlike standard SEPs, the LEP technique can be applied to non-glabrous skin in any dermatome. The late components of the LEPs allow the assessment of the functional status of nociceptive Aδ-fibre afferents and so provide complementary information to the standard SEPs, which assess the functional status of tactile Aβ-fibre afferents [44].

Thus this technique, performed carefully, allows the assessment of the functional status of the nociceptive pathways within the somatosensory system. Additional information beyond that obtainable with standard SEPs may be expected particularly in those patients who present with a dissociated sensory loss of pain and temperature sensitivity and preserved tactile and proprioceptive sensitivity. Its potential usefulness lies in documenting clinically relevant sensory deficits, detecting subclinical lesions, and differentiating axonal and demyelinating lesions [44].

Post-herpetic neuralgia

Herpes zoster (Chapter 33) is itself painful, and is sometimes followed by neuralgia. The risk of developing post-herpetic neuralgia (PHN) rises with age, which influences both the duration and the severity of the neuralgia once it appears [1]. Post-herpetic neuralgia, defined as pain persisting beyond 4 weeks, occurred in 16% of patients younger than 60 years but in 47% of those older than 60 years [2]. Only about one-quarter of those with pain 4 weeks after the vesicles have healed still have pain a year later, but this pain, which is chronic and debilitating, especially in the elderly, can be so severe that it interferes with sleep, and causes depression or even suicidal tendencies.

Patients may report a variety of painful sensations with different components, including spontaneous and continuous deep aching and throbbing pain, burning, lancinating pain, or paroxysms of burning pain, sometimes provoked by non-noxious stimuli, such as contact with clothing or changes in temperature [3]. The pain is accompanied by autonomic instability and its intensity is exacerbated by physical and emotional stress and alleviated by relaxation. Some patients with PHN have profound sensory loss in the area of maximum pain (anaesthesia dolorosa), while others have pronounced allodynia with minimal sensory loss. Another group of patients has areas of sensory loss surrounded by a 'transition zone', within which a noxious stimulus can elicit a particularly unpleasant pain that radiates widely [3]. The patient may go to extraordinary lengths to protect the area from innocuous stimuli, while firm compression of the skin may actually produce pain relief.

Why some patients develop PHN is incompletely understood. There is, for example, no consistent relationship between this type of pain and a loss of large fibres in the damaged nerves, but *in vitro* studies [4] suggest that the virus itself may cause normally silent neurones to produce spontaneous action potentials. In only 70% of PHN patients is it possible to demonstrate loss of function within punch biopsies of the affected tissues, with degeneration of small fibre afferents in the affected dermatome [5].

Pathophysiology of pain

Post-herpetic neuralgia may be caused by neurological lesions at all levels of the nervous system including peripheral, central and autonomic components.

In pain associated with peripheral damage in the dorsal root ganglion, spinal cord and afferent neurones, ectopic impulse generation may occur at the site of damage, and these impulses can be evoked by mechanical or thermal stimuli in the local environment (tactile allodynia) [3]. For this type of disorder, membrane-stabilizing drugs are likely to work best. There is also some evidence that nociceptors in painful skin of post-herpetic neuralgia patients have enhanced adrenergic sensitivity [3].

When sensory deficits are present, suggesting destruction of dorsal root ganglion cells, the pain is primarily sustained by processes in the CNS, resulting in what is known as 'deafferentation pain' [3].

With the realization that several pain mechanisms may be operating in any one individual, it is unrealistic to expect any one drug to completely alleviate the pain in all neuropathic pain disorders, or to significantly reduce the pain in all patients suffering from the same neuropathic condition.

Prevention of post-herpetic neuralgia

Two controlled studies [6,7] suggested that the use of systemic corticosteroids during the acute episode of herpes zoster might reduce the risk of developing post-herpetic neuralgia, and in neither was generalized herpes zoster a problem. However, a systematic review [8] concluded that corticosteroids are not of proven efficacy, and this was borne out in a randomized, open trial [9]. Given its immunosuppressive effects, and potential for serious complications, systemic corticosteroids are not recommended.

In older adults with localized herpes zoster, oral aciclovir (800 mg five times daily for 7 days) reduces acute pain and healing times if treatment is initiated within 72 h of the onset of the eruption [10]. A reduction in ocular complications, particularly keratitis and anterior uveitis, occurs with treatment of herpes zoster ophthalmicus [11]. A systematic review of four placebo-controlled trials of oral aciclovir showed only marginal evidence for pain reduction after herpes zoster. Famciclovir and valaciclovir significantly reduced the duration but not the incidence of post-herpetic neuralgia, in one placebo-controlled trial for each agent. Famciclovir (500 mg three times daily for 7 days) or valaciclovir (1000 mg three times daily for 7 days) may provide more prompt relief of zoster-associated pain than aciclovir in acute herpes zoster in older adults (over 50 years of age) [12].

In immunocompromised patients with herpes zoster, intravenous aciclovir (500 mg/m^2/8 h for 7 days) reduces viral shedding, healing times, the risks of cutaneous dissemination and visceral

complications, as well as the length of hospital stay in disseminated zoster [13].

A vaccine has been developed which decreases the incidence both of herpes zoster reactivation and post-herpetic neuralgia. In a placebo-controlled primary prevention study of the vaccine, men and women age 60 and over had a significant reduction in the burden of illness due to both clinical herpes zoster and of post-herpetic neuralgia [14].

Management of established post-herpetic neuralgia [15]

In mild and moderate cases of established post-herpetic neuralgia, simple analgesics help, but in severe cases they may have little effect. Opioids should probably be prescribed for resistant pain not coming under control with other drugs (below). Controlled-release oxycodone at a dose of 10–30 mg 12-hourly was shown to be effective in a randomized, placebo-controlled study for steady-state, paroxysmal spontaneous pain and allodynia [16]. Tramadol, a centrally acting analgesic with both opioid and non-opioid activities, seemed to work well in a pilot study up to a maximum dose of 600 mg daily [17].

The most effective drugs include antidepressants and anticonvulsants (membrane-stabilizing drugs). In a placebo-controlled trial, amitriptyline was shown to be superior to placebo, with about 60% of patients experiencing a good response to the active drug [18]. Pain relief was achieved with a relatively low dose. At a dose of around 70 mg/day, some 60% of patients experienced a good result with reduction of pain from severe to mild, and 14% had no pain. Most patients complained of side effects including dry mouth, drowsiness, constipation or urinary hesitancy. Other antidepressants recommended for post-herpetic neuralgia include desipramine, nortriptyline and maprotiline. Of these, nortriptyline [19] and desipramine [20] were shown to be effective in randomized controlled trials, whereas a controlled trial showed no advantage of maprotiline over amitriptyline [21]. While anticonvulsants such as sodium valproate, phenytoin, carbamazepine and clonazepam are frequently advocated for shooting or lancinating pain, others have claimed that these drugs are unproven and relatively ineffective [22]. The new anticonvulsant drug, gabapentin, has been shown in a randomized, double-blind placebo-controlled trial to reduce post-herpetic neuralgia pain [22], and has recently been licensed for the treatment of peripheral neuropathic pain such as painful diabetic neuropathy and PHN. Gabapentin, an analogue of γ-aminobutyric acid (GABA), does not interact with any known neurotransmitter receptors and specifically it is not a GABA agonist, unlike its close relative, baclofen. Data suggest that it exerts an effect on the presynaptic calcium channels of primary nociceptive endings and it is now widely used in neuropathic pain [5]. To date, there are no studies directly comparing gabapentin with antidepressants, but it is considered at least as effective and safe as the antidepressants but with fewer side effects [3]. The results of these studies support the use of gabapentin as a first-line medication in the treatment of chronic neuropathic pain syndromes such as post-herpetic neuralgia. A successor drug, pregabalin, has also been shown to be efficacious but with superior bioavailability, making it easier to use without the need for long titration periods [5,23]. Other drugs reported to be of help are clonidine and lamotrigine, although, as yet, no controlled trials have been carried out on these drugs [3]. Randomized, controlled trials of capsaicin, at either 0.025 or 0.077% applied three to four times per day, have been shown to be effective [24]. The use of topical 5% lidocaine (lignocaine) patches either worn for around 12 h/day [25], or applied up to four times per day [26], has been shown to be efficacious, well tolerated and associated with low systemic absorption. Surprisingly, clinical response to topical lidocaine was seen in the group of patients shown by Quantitative Sensory Testing to have predominant degeneration of nociceptive neurones rather than in those with sensitized nociceptors. It may be appropriate to consider topical lidocaine before capsacin since the latter produces burning pain and hyperalgesia, which often leads to discontinuation [5]. Other treatments that have been reported to produce benefit in some patients include baclofen [27] and weekly lumbar intrathecal injections of methylprednisolone [28].

Surgical treatments have been tried in the past, including division of the dorsal root or tractotomy, or ablation by injection of the ganglion or sensory root, but these are not advocated due to limited efficacy and the high rate of morbidity [3]. Spinal cord stimulators have been used with variable results, and transcutaneous stimulation (TENS) may be helpful, but proper trials are lacking [29]. There seems to be no good evidence to support a role for acupuncture in treating post-herpetic neuralgia [30].

Neuropathic ulcers

Neuropathic ulcer is a form of chronic ulceration, also known as 'perforating ulcer', which develops in anaesthetic skin. Characteristically neuropathic ulcers are painless, persistent and uninflamed, appearing on areas subject to trauma or pressure.

Aetiology. While a number of neurological disorders may cause neurotrophic ulcers, the vast majority occur in patients with type II diabetes [1,2]. Other causes include leprosy, peripheral neuropathy, alcoholism, vitamin deficiencies, pernicious anaemia, syringomyelia, tabes dorsalis, spinal dysraphism, spinal cord injury and hereditary sensory and autonomic neuropathies [3,4].

Neuropathic ulcers result from a distal polyneuropathy encompassing motor, sensory and autonomic components.

Motor involvement leads to weakness of the intrinsic muscles of the feet and an imbalance between the long flexor and extensor tendons, leading to a typical cavus or high arched foot along with clawing of the toes (Fig. 63.5) [5]. This, combined with arch collapse, leads to the 'rocker-bottom foot', which is prone to tissue breakdown and ulceration. The plantar aspect of the foot is protected by fat pads, which anticipate weight-bearing forces in all directions. Increased pressure under the metatarsal heads and heel, the sites of around 90% of such ulcers, results in high pressure with initial callosity leading to ulceration. In the majority of patients, a palpable pulse in the affected foot is an indication of good vascular supply. However, the presence of rest pain, diminished or absent pulses, pallor on elevation and sluggish refilling of toe capillaries, together with trophic signs in the skin, are highly indicative of ischaemic ulcers. The associated sensory neuropathy allows the patient to injure the foot, either suddenly by standing on sharp objects such as pins or glass, or gradually, for example from pressure within a poorly fitting shoe, without the patient being aware of the damage. Autonomic neuropathy leads to a foot with loss of sweating, leading to dryness with fissuring and cracking and changes in the normal microcirculation autoregulation. Such cracks or fissures allow a portal of entry of infection. In the diabetic foot there is an impairment of the neurogenic vasodilator response, or flare, which correlates with the clinical diminution in pain sensation. It is likely that loss of both components of the nociceptive C-fibre function, both neurological inflammation and pain sensation, is an important factor in the development of foot complications in diabetes. Diabetics have been demonstrated as having a defect of unmyelinated nociceptive C fibres on the soles of their feet, leading to loss of nociceptive function and the development of both neuropathic plantar ulcers and neuroarthropathy. As sympathetic tone is lost, increased peripheral blood flow leads to arterial venous shunting, with blood bypassing the capillary bed, thereby reducing nutritive skin blood flow [6].

Fig. 63.5 Clawing of feet occurring in neuropathic foot with painless damage to skin on great toe.

Clinical features. Primary neuropathic limbs tend to be warm, insensitive and prone to ulceration on the sole of the foot, while neuroischaemic limbs are usually cool, discoloured and prone to ulceration on the foot margins [2]. Neuropathic ulcers typically occur under the metatarsal heads or heel, surrounded by thick hyperkeratosis, and have a pink punched out base that bleeds easily and is painless (Figs 63.6 & 63.7). The foot is warm with palpable pulses and the changes include pes cavus, warm, dry and insensitive foot with dilated veins, clawed toes and hyperkeratosis under the forefoot and heel [2]. In diabetic patients, there may be

Fig. 63.6 Typical neuropathic ulcers with surrounding hyperkeratosis under metatarsal heads.

Fig. 63.7 Neuropathic ulcer with hyperkeratosis removed.

a complex interplay of neuropathy and ischaemia, and when the latter is present, the foot may be cold with absent pulses, hyperkeratosis and a dark fibrotic base that does not bleed easily and is painful to touch. Continuing mechanical overload on established callus can result in fissures and increases the risk of future ulcer formation [7]. In the neuropathic ulcer, the sensations of light touch and vibration and sharp–blunt discrimination are reduced, which can be demonstrated using a Bailey® nylon monofilament (Fig. 63.8), which buckles in response to 10 g force, neurotheissometer and Neurotip® [8], respectively. Absent pulses suggest ischaemia. Falsely high ankle–brachial pressure indices may occur, especially in diabetics, as a result of non-compressible calcified vessels.

A frequent complication is the presence of cellulitis or deep infection with abscess formation or osteomyelitis. One study found that Gram-positive, aerobic bacterial colonization predominates (84%), with *Staphylococcus aureus* being the commonest organism (79%). Methicillin-resistant *S. aureus* (MRSA) was isolated in 30% of patients, which was almost double the proportion of MRSA-infected patients 3 years previously [9]. Bacterial colonization of the ulcer does not necessarily indicate infection. By contrast, infection may be present, especially in diabetics, without a very apparent pyrexia; leukocytosis, elevation of erythrocyte sedimentation rate and local signs may be less than expected. Cellulitis should alert one to the possibility of underlying osteomyelitis; plain X-rays may exhibit periosteal reactions or osteolysis. Probing a wound to find palpable bone at the base of an ulcer is an excellent predictor of osteomyelitis [10] (Fig. 63.9). A plain X-ray of the foot should be done to check for foreign bodies, tissue gas or bony abnormalities. A sinogram may be required to show communication of the sinus with a joint or a subfascial plantar abscess. A radioisotope bone scan, or magnetic resonance imaging (MRI) scan, may help to establish the diagnosis [11].

Fig. 63.8 Bailey® nylon monofilament assessing sensory loss on neuropathic foot.

Treatment. The prevention of ulceration in neuropathic patients is of the utmost importance [11]. Persons at risk should receive instruction on basic foot care, preferably from a podiatrist, with education on regular self-inspection of feet and correct nail-cutting techniques. Shoes should accommodate any deformity, have broad rounded or square toes, adequate toe depth and a low heel to avoid excessive pressure on the forefoot [12,13]. They should fasten securely to prevent movement within the shoe. Orthotic devices such as cushioned insoles may also be beneficial in preventing ulceration. Management with urea-based products may be helpful in managing callus [7]. Patients should be discouraged from removing callus themselves; this should be done by a podiatrist. Control of hypertension, cessation of smoking, prescription of aspirin in patients with atherosclerosis and meticulous control

(a)

(b)

Fig. 63.9 Probing a neuropathic wound. (a) Probe in position. (b) With probe removed.

of hyperglycaemia can slow or even reverse the signs of peripheral neuropathy [14].

In the treatment of a neuropathic foot ulcer, a multidisciplinary approach is most effective, and has been shown to significantly reduce amputation [15]. Typically, the ulcer is debrided surgically or treated using a hydrogel followed by the application of a hydrocolloid dressing. Randomized, controlled trials have shown benefit from the use of the platelet-derived growth factor becaplermin [16], cultured dermis (Dermograft®) [17] and hyaluronic acid dressings (Hyalofill®) [17,18] in promoting wound healing in clean wounds.

An essential part of treatment is the offloading of areas of abnormal pressure on the foot [15]. Contact casting is useful for healing ulceration over metatarsal heads but requires expertise in application and should not be used in patients whose ulcers are infected, or where there is a significant ischaemic component [15]. An example of such a casting is the Aircast Walkers® foam boot (Fig. 63.10). A modified non-weight-bearing boot made out of layers of adhesive foam padding may achieve complete removal of pressure points [19]. Boots made of plaster of Paris (with a rocker base) seem popular in some centres, especially with orthopaedic practitioners. The plaster boot is applied, initially weekly, and every 3 weeks, until ulceration is healed [20].

Peripheral neuropathy

Peripheral neuropathy may be sensory, motor or mixed [1]. In most types of peripheral neuropathy, the involvement is symmetrical and symptoms begin in the extremities with sensory loss in a glove and stocking distribution. In contrast to this, is the patchy involvement of peripheral nerves in mononeuritis multiplex seen, for example, in polyarteritis nodosa, or sarcoidosis (Chapter 61). The causes of peripheral neuropathy are numerous and include diabetes mellitus, carcinomatous neuropathy, vitamin B group deficiency and drugs or chemicals (Table 63.1).

The typical picture of polyneuropathy occurs with acquired, toxic or metabolic neuropathic states, and it is these that will usually be seen by a dermatologist. The first symptoms tend to be sensory, consisting of tingling, prickling, burning or band-like dysaesthesia in the balls of the feet or tips of the toes, or in a general distribution over the soles. Symptoms and findings are usually symmetrical and graded distally. If the polyneuropathy remains mild, objective motor or sensory signs may not be detectable. With progression, the dysaesthesia spreads up the legs, pan-sensory loss is found over the feet and the ankle reflexes are lost. Sensory loss moves centripetally in a graded 'stocking' fashion. The patient may complain that the feet have a numb or 'wooden' feeling. Neuropathy is usually less severe in the arms, and spreads in a centripetal, symmetrically graded manner with palmar sensory loss and areflexia. Overall, nerve fibres are affected according to axon length, without regard to the root or nerve trunk distribution, giving rise to the term 'stocking and glove' distribution to describe the pattern of the sensory deficit. Mononeuritis multiplex refers to sequential involvement of individual non-contiguous nerve trunks. This leads to a patchy, multifocal neurological defect, and is often caused by an immunological or toxin-mediated disease process. Lightning pains may be a feature of tabes dorsalis and angiokeratoma corporis diffusum (Fabry's disease).

Autonomic neuropathies can be a manifestation of a more generalized polyneuropathy, but may also occur in isolation, when structural changes in the pre- and post-ganglionic neurones occur. Autonomic neuropathy is characterized by symptoms of postural hypotension, anhidrosis, hypothermia, bladder atonia, constipation, dry mouth and eyes, failure of salivary and lacrimal glands to secrete, blurring of vision from lack of pupillary and ciliary regulation, and sexual impotence in males [1].

Carpal tunnel syndrome is caused by an entrapment mononeuropathy of the median nerve at the wrist. It may be secondary to excessive use of the wrist, tenosynovitis, or local infiltration with connective tissue such as in acromegaly, amyloid or mucopolysaccharidosis. The main symptoms are nocturnal paraesthesiae of the thumb, index and middle fingers.

Table 63.1 List of causes of peripheral neuropathy.

Metabolic	Diabetes mellitus, alcohol, porphyria, myxoedema, acromegaly, uraemia, POEMS syndrome, hypoglycaemia
Neoplastic	Paraneoplastic neuropathy, lymphoma, Hodgkin's disease, multiple myeloma
Nutritional	Deficiencies of vitamins B_1, B_{12} or E and malabsorption syndromes including coeliac disease
Toxic	Alcohol, heavy metals (e.g. lead, mercury, gold, thallium), drugs (e.g. amiodarone, cisplatin, hydralazine isoniazid, dapsone, nitrofurantoin, disulfiram, phenytoin, vincristine, metronidazole, antiretroviral nucleoside analogues), other toxic agents (e.g. organophosphates, acrylamide)
Trauma	Pressure neuropathy, ischaemia, pressure from tumours, electrical shock
Infective	Diphtheria, leprosy, mumps, Guillain–Barré syndrome, HIV infection, Lyme disease
Inflammatory	Rheumatoid arthritis, polyarteritis nodosa, sarcoidosis, systemic lupus erythematosus, primary biliary cirrhosis, primary systemic amyloidosis, chronic obstructive airways disease, Churg–Strauss syndrome, critical illness
Genetic	Charcot–Marie–Tooth disease, Refsum's disease, HSANs, Fabry's disease, Roussy–Levy syndrome, metachromatic leukodystrophy

HIV, human immunodeficiency virus; HSANs, hereditary sensory autonomic neuropathies; POEMS, polyneuropathy, organomegaly, endocrinopathy, M-protein, skin changes.

Investigations. The investigations variably appropriate in peripheral neuropathy are shown in Table 63.2 [1].

Despite the complaints of pain and burning due to degeneration of thin myelinated Aδ fibres and unmyelinated C fibres, neurological examination, including sensory nerve conduction studies, may be normal in small-fibre neuropathy. In such cases, skin biopsy

Table 63.2 Investigation of peripheral neuropathy [1].

Urine	Glucose, protein, Bence Jones protein
Haematology	Full blood count, erythrocyte sedimentation rate, vitamin B_{12} and folate
Biochemistry	Fasting blood glucose, renal function, liver function, thyroid function, glucose tolerance test, serum protein electrophoresis, serum angiotensin-converting enzyme, prostate-specific antigen
Radiology	Chest X-ray, abdominal or pelvic ultrasound, chest and abdominal computed tomography, mammography, PET
Immunology	Antinuclear factor, antibodies to extractable nuclear antigen (Ro, La), neutrophilic cytoplasmic antigen, HIV, gliadin, neuronal (Hu, Yo)
Neurophysiology	Proximal and distal nerve conduction studies
Cerebrospinal fluid	Cells, protein, immunoglobulin oligoclonal bands

HIV, human immunodeficiency virus; PET, positron emission tomography.

may prove helpful. The technique is safe, almost painless, cheap and repeatable. In centres trained in the technique, the density of small fibres can be measured easily using bright field microscopy in sections cut from the specimen and appropriately immunostained with antibodies against markers expressed by peripheral nerve fibres, such as protein gene product 9.5, microtubules and neuropeptides. Location of these fibres either in the epidermis or around sweat glands, arrector pili muscles and blood vessels, helps distinguish somatic from autonomic neuropathies [2].

Treatment. Treatment of neuropathic pain and neuropathic foot, sexual dysfunction and bowel or bladder control are dealt with in the relevant sections in this chapter.

Human immunodeficiency (HIV) neuropathy

With the effectiveness of antiretroviral treatment and the decline in opportunistic infections and HIV-induced dementia, HIV-associated neuropathies have become the most common neurological disorder associated with acquired immune deficiency syndrome (AIDS). They present as acute or chronic demyelinating neuropathies, mononeuritis multiplex, cytomegalovirus (CMV)-related polyradiculoneuropathy, autonomic neuropathy or distal painful sensory neuropathy [3–5]. They are multifactorial in aetiology, occurring in all stages of the illness, and take a variety of courses. Early in the course of HIV infection, acute inflammatory demyelinating polyneuropathy resembles Guillan–Barré syndrome. In other patients, a progressive or relapsing inflammatory neuropathy, resembling chronic inflammatory demyelinating polyneuropathy and mononeuritis multiplex, occurs. The most common peripheral neuropathy in patients with HIV infection is distal sensory polyneuropathy (DSP), which may be either a direct consequence of HIV infection, or a side effect of antiretroviral therapy, antiretroviral toxic neuropathy (ATN), or both [3,5].

Aetiology. DSP is characterized by axonal degeneration of long nerves in the extremities. The virus, which is not found within ganglionic neurones or Schwann cells but only within the endoneurial macrophages, may generate a tissue-specific autoimmune attack by secretion of cytokines that promote trafficking of activated T cells and macrophages within the endoneurial parenchyma [6–8].

Studies of skin biopsies of patients with HIV-associated sensory neuropathy, developing during treatment with didanosine or zalcitabine, have shown a reduction in the density of epidermal fibres in distal lower extremities, with an inverse correlation between reduced nerve density and neuropathic pain [8,9]. Mononeuritis multiplex in AIDS may be due to immune complex necrotizing vasculitis, resulting from associated hepatitis B or C infection or cryoglobulinaemia [10,11]. In patients with opportunistic infection and AIDS, extension of CMV cytopathic effects may involve endothelial cells and Schwann cells in the nerve roots, dorsal root ganglia or spinal cord [3].

Clinical features. Distal sensory neuropathy and ATN lead to sensory loss and neuropathic pain in the extremities. Presenting symptoms are usually painful burning sensations in the feet and lower extremities. When due to antiretroviral therapy, patients may complain of a sensation that they are walking on ice. Findings on examination would include a stocking type sensory loss of pin prick, temperature and touch sensation and loss of ankle reflexes. Patients may develop a progressive weakness in the distal muscle groups in limbs [3–5]. Two-thirds of patients with AIDS may have electrophysiological studies showing some evidence of peripheral nerve disease. Progressive, relapsing inflammatory neuropathy, mononeuritis multiplex and CMV-related neuronal damage give rise to sensorimotor neuropathies. Xerosis is common in HIV infection, occurring in around 20% of seropositive patients. This may be related to a decrease in immunoreactive substance P and CGRP fibres occurring around the tubules of the eccrine sweat glands [12].

Treatment. In the acute stage of demyelination, plasma exchange or intravenous immunoglobulins may have been tried with variable success. Gabapentin [13], carbamazepine [14], tricyclic antidepressants or analgesics may be effective for dysaesthesia [3–5].

A multicentre, placebo-controlled, randomized trial has been carried out using recombinant human NGF, which is trophic for small sensory neurones and stimulates the regeneration of damaged nerve fibres [15,16]. The treatment was shown to be efficacious in reduction of neuropathic pain and increase in pin prick sensitivity. Side effects of treatment included pain at the site of injection and transient myalgic pain.

Trigeminal trophic syndrome

This is an uncommon disorder in which trophic ulceration follows minor, repetitive trauma to anaesthetic skin within the trigeminal area. Neurotrophic changes in the trigeminal area may follow the destruction of fibres conveying pain and temperature sensation [1]. Causes of this disorder include central sensory neuronal damage (post-encephalitic parkinsonism, syringobulbia, posterior fossa tumour or occlusion of the posterior inferior cerebellar artery [2,3], leprous neuritis and brain stem infarcts [4]) or damage to the trigeminal nerve by attempts to relieve intractable trigeminal neuralgia (by surgery or alcohol injections into the gasserian ganglion [5]) or herpes zoster [6] or simplex-related neuritis [7]. Trigeminal trophic syndrome is usually a disease of adults, although recently a case has been described in a 14-year-old child secondary to herpes simplex trigeminal neuritis [8].

Clinical features. The patient complains of paraesthesiae or a sensation of itch on the ala nasi. This is then picked, rubbed or scratched and, because the trauma is painless, the erosion increases in size and may extend to destroy the nasal cartilage [1,9]. The patients freely admit to traumatizing the area in an attempt to relieve the uncomfortable sensation. A clinical similarity to a basal cell carcinoma may be striking, often requiring a biopsy, which in trigeminal trophic syndrome simply shows inflammatory reaction [9] (Fig. 63.11). The pattern of ulceration may be sufficiently bizarre to suggest dermatitis artefacta. The ulcer spreads towards the cheek and the upper lip and, apart from the problems of control of secondary infection, subsequent scar formation in the area of the ala can result in the elevation of the lip resulting in a disfiguring sneer [9]. Characteristically, the alar rim is involved and the tip of the nose spared. Sites less frequently involved include the forehead, scalp and cheeks. Neurological examination should reveal decreased perception of light touch and pain over the area, and sometimes an absent corneal reflex on the same side [9].

Fig. 63.11 Trigeminal trophic syndrome resembling basal cell carcinoma of the right ala nasi.

Treatment. Surgical approaches in the past have included cervical sympathectomy [10], transcutaneous electrical stimulation [11] and grafting or the use of innervated transposition flaps [12], although these can fail if trauma to the area continues. Wearing gloves can be of some help, but the ulceration commonly persists, particularly in the elderly or in confused patients who compulsively pick at the skin. Protection through dressings such as Aquaplast thermoplastic dressing has been shown to promote ulcer healing [13]. Medical treatments which have resulted in improvement have included amitriptyline [5], diazepam [5], chlorpromazine [1] and pimozide, presumably through influencing the paraesthesiae and behavioural factors involved in the syndrome. Carbamazepine was found to be very effective in one reported case [9], although less so in others [1].

Peripheral nerve injury

Lesions of the peripheral nerve may cause permanent denervation with paralysis and disability, and represent a challenging problem in neurosurgery. The slow rate of nerve regeneration conspires together with atrophy and degeneration of the denervated organs

to increase the risk of permanent disability after peripheral nerve injury, emphasizing the importance of rapid and timely intervention [1,2]. Neurotrophic factors are secreted polypeptides that control the survival, differentiation and maintenance of neurones. Sectioning of peripheral nerves results in the almost total loss of immunoreactivity for both low- (p75) and high-affinity (TrkA-like) receptors for NGF [3]. Meissner's and Pacinian corpuscles, after nerve section, lose immunohistochemical antigens such as S100 protein, epithelial membrane antigen and vimentin, strongly suggesting that the structure and integrity of the nerve axis is essential in maintaining some immunohistochemical characteristics of the human sensory corpuscles [4].

Section or severe contusion of a peripheral nerve has been held responsible for a variety of cutaneous changes. Skin manifestations are found in some 20% of patients with the carpal tunnel syndrome [5], and include a reddish discoloration of the fingers with bullae, small foci of necrosis and nail dystrophy [6]. Nail dystrophy and other trophic changes are also sometimes caused by a cervical rib [7]. In one report, injury to the lateral femoral cutaneous nerve during appendicectomy [8] was followed 6 days later by the development of bullae on the outer aspect of the right lower leg, with subsequent ulceration and scarring.

Cooling also affects conduction in peripheral nerves. Loss of sensation in the feet has been reported after prolonged immersion in cold seawater [9]. Areas of skin looking like partial-thickness burns and blistering were found on the feet of 25 out of 160 participants in a barefoot run: a temporary cold-induced neuropathy of the feet had allowed subjects to continue running despite these injuries [10]. Neuropathy may be induced by cryotherapy, and in one series of 183 lesions treated in this way, some subsequent sensory loss was demonstrated in 28%. This was usually mild and transient, although rarely long lasting [11].

Syringomyelia

This is a rare disorder characterized by a longitudinal cyst in the cervical cord and/or medulla (syringobulbia) immediately anterior to the central canal, which spreads, usually asymmetrically, to each side. The majority of lesions occur in association with type 1 Chiari's syndrome where there is a congenital extension of the cerebellar tonsils below the foramen magnum [1]. Other causes include trauma and tumours [1]. MRI scanning of the hindbrain and upper spinal cord is best for delineation of the syrinx [1–3]. An association with other abnormalities, such as a short neck and a low hairline, suggests a developmental origin. Symptoms usually appear in young adults and the disease is generally slowly progressive over 20–30 years, although limited resolution of symptoms has occurred in adults [1] and children [2,3].

Early involvement of pain and temperature fibres, where they cross the midline anteriorly, leads to a characteristic dissociated sensory loss, in which pain and temperature sensation is lost early in the upper limbs, while other sensory modalities carried in the posterior columns (e.g. touch, vibration and position sense) may remain relatively intact. These changes are responsible for the earliest manifestation of the disease, a tendency to sustain painless burns and cuts on the hands and forearms. Later, upper motor neurone signs in the legs may accompany weakness, wasting and loss of reflexes in the arms. Occasionally a combination of progressive pain loss, resultant skin ulceration, loss of soft tissue, resorption of the phalanges and muscular atrophy (Morvan's syndrome) occurs.

Body asymmetry or hemi-hypertrophy is known to occur in syringomyelia and can occur on the head and face. Hypertrophy of the hands and feet, together with hypertrophy of the bones and muscles in the same limb (especially in the upper limbs), has been described with syringomyelia [4].

Many of the skin changes accompanying syringomyelia are the result of repeated burns or other injuries, particularly of the hands, where the skin over the fingers and knuckles may become thickened, swollen, cyanotic and keratotic. Analgesia renders the patient liable to minor injuries, which heal slowly. Gangrene rarely occurs, but damage to, or loss of, terminal phalanges or nails is not uncommon. The French term '*la main succulente*' refers to the swollen and oedematous hands of syringomyelia sufferers. Syringomyelia is responsible for dyshidrosis with hyperhidrosis or hypohidrosis, this being more common than previously recognized, with one series showing dyshidrosis in 60% of patients [5]. The dyshidrosis, usually occurring over the face and upper arms, may be spontaneous or occur reflexly, when the patient consumes hot or highly seasoned food. Its distribution, which can be studied by thermography, correlates with the location of the syrinx and other neurological manifestations [5]. Hyperhidrosis is probably caused by stimulation of the sympathetic preganglionic neurones and, as the disease progresses, hyper-reactivity gradually decreases and is replaced by hypoactivity. This may be important, as focal hyperhidrosis can be regarded as a hallmark of a relatively intact, even though slightly damaged, spinal cord [5]. Asymmetry of scalp hair can also occur in syringomyelia, with the denervated areas having less abundant hair, which grows more slowly [6].

Extension of the syrinx into the medulla may disrupt the vestibular pathways, the descending root of the trigeminal nerve, the sympathetic and taste pathways, and the hypoglossal nerve. The symptoms and signs may then include vertigo with nystagmus, dissociated sensory loss over the face, loss of taste, a wasted tongue, Horner's syndrome and sometimes paralysis of the vocal cords. Facial oedema confined to areas of sensory loss has been described [7].

Tabes dorsalis

This is still the most common form of neurosyphilis and is the one with the longest incubation period (usually 10–20 years: range 5–50 years), affecting men more often than women. The main symptoms are due to degeneration of the afferent fibres of the dorsal roots. It is characterized by a triad of symptoms (lightning pains, dysuria and ataxia) and a triad of signs (Argyll Robertson pupils, areflexia and loss of proprioceptive sense) [1].

Usually, sensory symptoms precede ataxia by months or years. Lightning pains are the most characteristic early symptom, and occur in 90% of cases at some stage, most often affecting the legs. Pain sensibility is also impaired early, the deep tissues becoming insensitive before the skin does. This may be demonstrated by squeezing the Achilles tendon. Argyll Robertson pupils, miotic pupils that fail to react to direct light, are found in about half of the patients. Originally associated with tabes dorsalis, the sign is now recognized as being common to a number of conditions causing lesions in the area of the nucleus of Edinger–Westphal. Thus, MRI studies have localized lesions to this region in patients with sarcoidosis and multiple sclerosis [2]. With the declining incidence of neurosyphilis, the sign is increasingly likely to indicate another cause, although an assiduous search for syphilis should also be undertaken.

Later features may include ataxia, with a wide-based gait, made worse by the elimination of visual clues, dribbling overflow incontinence, visceral crises, optic atrophy and a painless distortion of the hips, knees or ankles (Charcot's joints).

The commonest trophic change in the skin is a neuropathic ulcer. Symptomatic herpes zoster may occur, as in other conditions affecting dorsal roots.

The clinical features and laboratory findings may be modified by the widespread use of antibiotics and corticosteroids for treating unrelated diseases [3]. This sometimes leads to difficulty in deciding whether tabes dorsalis is active or 'burned-out', with a neurological deficit due to fixed structural damage. Penicillin treatment will arrest the course of the disease, but residual lightning pains, gastric crises and urinary incontinence are likely to persist.

Spinal dysraphism

Spinal cord development occurs between weeks 2 and 6 of embryonic life. A raphe is a line of junction between symmetrical embryological structures: dysraphism is a failure of this type of fusion [1]. Spinal dysraphism leads to malformations of midline dorsal structures [2]. Defects in the early embryonic stages produce spinal dysraphisms, which can be categorized clinically into two subsets. Open spinal dysraphisms are exposed to the environment (e.g. spina bifida, myelomeningocoele), while closed spinal dysraphisms are covered by intact skin.

A review of 200 published cases of spinal dysraphism [3] included 102 with cutaneous abnormalities, often in combination. A dermatologist may be the first physician to see such patients, and should be aware of possible associations with underlying neurological abnormalities. Spinal sonography is a useful screening method in newborns in the presence of a suggestive cutaneous lesion, while progressive ossification makes spinal ultrasound less relevant after 4 months of age. Indications for referral for ultrasound or MRI have recently been reviewed [4]. While lumbosacral dimples are indications for further investigation, a clinical dilemma relates to cutaneous dimples. Coccygeal dimples may represent a normal variation unrelated to spinal dysraphism and may not need as aggressive an investigation, whereas the presence of lumbosacral dimples is higher risk for underlying problems [4,5].

Patients with giant congenital melanocytic naevi overlying the scalp or dorsal spine can, on MRI, have abnormalities of the leptomeninges, the amygdala, cerebellum and pons [6].

Many skin abnormalities overlying the lumbosacral region have been reported to be associated with spinal dysraphism and cord tethering, including lipomas [7], port-wine stains, haemangiomas [8,9], 'faun tail' (hypertrichosis) [10], pigmented macules and pits or dimples. Because tethered spinal cord is a treatable condition and, if left untreated, can lead to progressive neurological degeneration, spinal MRI scanning of infants with giant melanocytic naevi involving the lumbosacral area is advocated [11,12]. Approximately 20% of patients with large congenital naevi in this region will have associated neurological or developmental abnormalities on MRI scanning [13].

Spina bifida

Several varieties of spina bifida are described, differing in the nature and severity of the spinal defect. In the severe form, a sac

Fig. 63.12 Tuft of hair in association with spina bifida.

protrudes through the vertebral opening and transmits an impulse on crying or coughing. In the least severe cases (spina bifida occulta) there is no such protrusion, but a defect in the vertebral lamina may be felt as a depression, and is sometimes covered by a tuft of hair or a dimple (Fig. 63.12). The likelihood of a mid-line fusion defect is increased when the cutaneous findings are associated with a subcutaneous lesion such as a lipoma [4]. Spina bifida occulta may give rise to no symptoms, and be a chance finding in the course of a routine examination. However, lesions preventing the ascent of the spinal cord, which occurs during normal growth, can lead to undue traction on the lower end of the cord and cauda equina.

The neurological changes will then be those of a chronic lesion of the cauda equina. Such patients may have been slow to learn to walk. Sensation may be impaired over the areas innervated by the lowest sacral segments, leading to a characteristic saddle-shaped area of analgesia over the buttocks and dorsa of the thighs. Trophic changes are conspicuous in some cases, and are rarely lacking altogether. In milder cases, the feet are usually cold and cyanosed: cutaneous injuries are slow to heal and tend to ulcerate, not only on the feet but also in the analgesic skin of the buttocks and thighs. The most severe neurological abnormality is a flaccid paraparesis with sphincter paralysis.

The diagnosis is confirmed by radiography [14], showing defective fusion of the laminae in the affected region, usually the first sacral and fifth lumbar vertebrae. An MRI scan or myelography may be helpful. Estimation of α-fetoprotein in the amniotic fluid or in the maternal serum may successfully identify a fetus with a severe malformation of the CNS such as spina bifida cystica or anencephaly.

Patients with spina bifida are at risk of latex sensitivity [15] due to exposure to latex products, both at the time of surgery and also with indwelling catheters, etc. Such patients should be assessed using latex-specific serum IgE, radioallergosorbent test (RAST), skin prick testing to latex suspension and latex glove usage test [15,16]. Patients allergic to latex may display urticaria, conjunctivitis, angio-oedema, rhinitis and bronchial asthma. They are at risk of anaphylaxis during procedures when healthcare workers are using latex gloves during bladder catheterization and, because of cross-sensitivity to food allergens, can be allergic to fresh foods including kiwi, pear, orange, pineapple, tomato and banana.

The treatment of spina bifida lies in the domain of the paediatrician or neurologist, but the dermatologist may be asked for advice on the trophic ulcers.

Congenital dermal sinuses

These lie close to the midline and may be no more than 1 or 2 mm in diameter [1]. Hairs may protrude from the opening, but these sinuses differ from pilonidal sinuses in that they connect directly to the contents of the spinal canal and so serve as a portal of entry for infection. Probing is therefore unwise. Such sinuses may expand into cysts deeply, and these may press on the spinal cord. The outcome over a 30-year period in a cohort of children with congenital dermal sinuses was reviewed. Cutaneous markers, such as sinus ostea, pigmentation changes, erythema, skin tags and subcutaneous masses, were seen in 15 of 28 cases. Patients over 1 year old at presentation were more likely to have a neurological deficit than younger patients, and delay in diagnosis was identified as a risk factor for developing neurological damage [17].

Spinal cord injury

The spinal cord may be injured directly by penetrating wounds or, more frequently, it suffers indirectly as a result of dislocations or fracture dislocations of the vertebral column. Damage may not necessarily be as a result of direct trauma but because of surrounding tissue damage, causing the spinal cord to swell and occupy the entire diameter of the spinal cord at the level of the injury. Causes include motor vehicle accidents (36–48%), violence (5–29%), falls (17–21%) and recreational activities (7–16%) [1]. Conventional radiography on its own should not be depended on to define the damage, and dynamic views in flexion–extension movement may provide additional information; where these are not deemed safe, MRI is necessary [1]. Rare dermatological causes of spinal cord injury have included a neglected basal cell carcinoma on the back [2], an adenocystic carcinoma in overlying skin [3] and multiple myeloma in a man presenting with primary cutaneous plasmacytomas, resulting in spinal cord compression [4].

Seborrhoea and seborrhoeic dermatitis have been reported in quadriplegia patients [5,6]. In one study [6] of 20 patients with spinal injury but no seborrhoeic dermatitis on admission, 13 developed the condition on the face and trunk within a few weeks. Nummular eczema may also occur below the level of the lesion [5]. Twenty-one patients with complete paralysis below levels varying from C5 to T12 were investigated for sebum excretion rate, skin temperature and the presence of acne [7]. An increased incidence of acne was found on the back and buttocks, often occurring for the first time after the onset of paralysis. Sebum excretion on the forehead did not differ from that of normal, but was significantly increased below the neurological lesion. This could not be explained by changes in skin temperature.

The changes in eccrine sweating after spinal cord injuries are complex [8]. Episodes of profuse sweating on the face, neck and upper trunk in patients with lesions at or above T6 may occur as an exaggerated response to stimuli such as bowel or bladder distension (autonomic dysreflexia). Facial flushing and headache may be associated with these episodes. Other patients develop sweating of the face and arms after dizziness due to postural hypotension. Finally, post-traumatic syringomyelia can lead to hyperhidrosis [9]. Dryness of the skin, particularly noticeable on the soles, is an effect of anhidrosis.

Chronic decubitus ulceration can be a problem, and local osteomyelitis rarely leads to secondary amyloidosis. Excellent nursing, prevention of pressure and attention to the patient's general health are essential. There should be frequent review of pressure ulcer prevention and management strategies, and patients should be supplied with aids such as ripple mattresses to help reduce localized pressure. Pressure sore closure is frequently a reconstructive challenge and in itself can be deforming. The use of an inferiorly based vertical rectus abdominis myocutaneous flap for both recalcitrant ischial and trochanteric pressure sores has been shown to be useful [10].

Early decompression and high-dose methylprednisolone may reduce further spinal cord damage following injury. Small gains in neurological regeneration can lead to a disproportionate gain in function, since, for example, fewer than 10% functional long-tract connections are needed to enable good locomotor action. Adequate rehabilitation will prevent many complications and improve outcome [1]. Tendon transfer can improve hand grip and transcutaneous electrical stimulation can help muscles, including the diaphragm, facilitate erection and ejaculation and control pain. Bladder and bowel control may be helped with implantable electrical stimulators or botulinum toxin [11]. Sexual dysfunction can be treated by mechanical (vacuum pumps, penile implants, electrical stimulation) or pharmacological interventions (sildenafil, intracavernosus injection) [1,12], the latter depending on the sparing of either the sacral (S2–S4) or thoraco–lumbar (T10–L2) spinal segments. Exciting new treatment opportunities have emerged through the use of NGFs, creation of neuronal 'bridges' using peripheral nerves and the use of stem cells [1], and future development is likely through collaboration between scientists and clinical specialists [1].

Disorders associated with autonomic abnormalities

Hereditary sensory and autonomic neuropathies (HSANs)

The classification of HSAN was modified by Dyck [1] into five main groups of syndromes with common clinical, pathophysiological and genetic phenotypes. The considerable advances made in identifying the specific loci and genes implicated in the different types of HSANs [2] and the resulting mechanisms of disease [3] are reviewed below.

Hereditary sensory and autonomic neuropathy type I (HSAN I)

HSAN type I differs from all other HSANs in that its symptoms appear late, rather than congenitally. It is an autosomal dominant disorder, mapping to chromosome 9q22.1–q22.3 [4,5], and the affected gene has been identified as serine palmitoyltransferase long-chain base subunit-1 (SPTLC1) [2], leading to an impact on enzyme systems critical for sphingolipid synthesis [6]. It is the most common HSAN, resulting in progressive degeneration of sensory dorsal root ganglia, with loss of both small myelinated and unmyelinated nerves leading to a distal sensory and motor loss, particularly in the lower limbs [4,7]. HSAN type I presents in late childhood or adolescence with progressive loss of all modalities of sensation in the lower extremities, particularly pain and temperature. This often results in chronic trophic ulceration on weight-bearing areas of the feet, associated osteomyelitis and mutilating deformity [7,8]. Later manifestations include muscle wasting, weakness and lancinating pain in the lower limbs and extension of sensory symptoms to the upper limbs. Neural deafness is frequent, and congenital cataracts and mental retardation have been reported [7].

Treatment is supportive, with good fitting shoes and alleviation of weight bearing if ulcers form [8].

Hereditary sensory and autonomic neuropathy type II (HSAN II)

HSAN type II is an autosomal recessive disorder with a congenital or early onset, with marked loss of sensory, motor and autonomic motor neurones and marked loss of unmyelinated nerves [1,9–11]. Linkage analysis has identified a locus mapping to 12p13.33 with subsequent isolation of a possible HSN2 gene, although as yet the biological activity of its gene product is not clear [12]. A high urinary excretion of sphingomyelin and lecithin suggest that the primary mechanism may be a disorder of phospholipid metabolism [7].

Infantile hypotonia is common. Unlike HSAN I, which primarily affects the feet, HSAN II results in loss of sensation equally in hands and feet, leading to ulceration at sites such as the forehead, trunk, tongue and lips as a result of repeated injury. Fingers can show ainhum-like constriction bands and spontaneous amputations. Loss of deep sensation results in deep ulceration, osteomyelitis, stress fractures and injury to long bones [9–11]. Tendon reflexes and anhidrosis occur in areas of decreased sensation, although anhidrosis is less prominent than in HSAN IV.

Associated features include mental retardation, neural deafness, impaired taste and smell, retinitis pigmentosa and cataracts.

Hereditary sensory and autonomic neuropathy type III (HSAN III) (familial dysautonomia)

HSAN type III (previously familial dysautonomia; Riley–Day syndrome) is the most common of the sensory and autonomic neuropathies [13–17]. The disorder is transmitted as an autosomal recessive trait, mapping to 9q31–q33 [18–20], involving the gene inhibitor of kappa light polypeptide gene enhancer in B-cells, kinase complex-associated protein (IKBKAP) [2], and is prevalent in Ashkenazi Jews, in whom the frequency is 1:10 000. Scattered cases in non-Jewish patients have been reported. Prenatal diagnosis is now possible [19].

Onset is congenital, and hypotonia, sucking difficulties, a poor cry and vomiting are present at birth. Autonomic features are prominent, with impaired production of tears, unstable temperature control, postural hypotension and excessive sweating, especially during infection, all being major features. Impaired oesophageal motility, with resultant pneumonia, together with bouts of apnoea, are causes of death in childhood. Blotchy erythema occurs during overheating, and erythematous macules 2–5 cm in diameter may occur on the trunk and limbs in response to emotional upsets [17].

A diagnosis is sometimes made in infancy because the child cries without producing tears. Other diagnostic criteria include absent fungiform papillae on the tongue, absent tendon and corneal reflexes, lack of axon flare after intradermal histamine, and miosis following instillation of methacholine. Later, the child may show delayed growth and invariably displays postural hypotension. Intelligence remains normal, but emotional lability is common. Progressive abnormalities of cutaneous temperature discrimination and nociception are found in most patients [15]. Mortality rates remain high but have improved with better supportive measures, and 50% of patients now survive to adulthood [21]. Death may follow inhalation during attacks of vomiting, and hypotension and cardiac arrest are risks with a general anaesthetic [22].

Treatment is symptomatic. Attention to feeding must be meticulous and gastrostomy may be required. Diazepam and chlorpromazine can be used to treat acute autonomic crises and intranasal midazolam can be used for patients at home [23].

Hereditary sensory and autonomic neuropathy type IV (HSAN IV)

HSAN type IV probably comprises a heterogeneous group of patients and is transmitted by autosomal dominant inheritance [24]. Defects in the human neurotrophic tyrosine kinase receptor type 1 (*NTRK1*) gene (previously known as *TRKA*) located on chromosome 1 (1q21–q22), which encodes a receptor tyrosine kinase (RTK), have been shown [25]. The action of nerve growth factor on RTK seems to be crucial for the correct development of nociceptive neurones and sweating as a means of thermal regulation [2]. Clinically, the boundary between HSAN II and IV can be difficult to delineate. HSAN IV is an autosomal recessive disorder characterized by recurrent episodic fevers, anhidrosis, absence of reaction to noxious stimuli, self-mutilating behaviour and mental

retardation [24,25]. Infants are hypotonic and areflexic. High fever related to an inability to sweat, especially in the summer, can be associated with seizures [24–26]. Insensitivity to pain with self-inflicted injury results in multiple scars and bone fractures, autoextraction of teeth and ulceration of tongue, lips and buccal mucosa.

The anomalous pain and temperature sensation and anhidrosis in HSAN IV are due to the absence of afferent neurones activated by tissue-damaging stimuli and a loss of innervation of eccrine sweat glands, respectively [27]. These patients have recently been shown to have a decrease in skin nerve fibres positive for PGP 9.5, CGRP, substance P, NPY, nitric oxide and VIP [26,27], and innervation is almost completely absent around eccrine sweat glands [27].

Treatment is limited; oral shields may prevent damage to the oral tissues [28].

Hereditary sensory and autonomic neuropathy type V (HSAN V)

Synonym

- Congenital insensitivity to pain

HSAN type V is a rare, autosomal, recessive, hereditary sensory autonomic neuropathy characterized by insensitivity to pain, self-mutilating behaviour, anhidrosis with recurrent hyperpyrexia and mental retardation [29,30].

This autosomal recessive condition results in a defect in the development of sensory and autonomic peripheral nerves [30]. It has been reported as being caused by mutations of the human *TRKA* (*NTRK1*) gene located on chromosome 1q21–q22, which codes for the receptor for NGF and tyrosine kinase [31–34], although the locus 1;13.1 and the associated gene *NGFB* have also been implicated [2,3]. Nociceptive and sympathetic Aδ-fibre and C-fibre nerve activity is reduced or absent in the skin, S100 protein and neurone-specific enolase are reduced or absent in the vicinity of eccrine sweat glands, and substance P receptors are absent from nerve fibres and the epidermis [35]. This is consistent with the loss of unmyelinated and small myelinated fibres, as seen in sural nerve biopsies [36].

Patients present in early childhood when they start to crawl; they fail to learn the consequences of injury and do not cry with soft-tissue injury. There is associated heat intolerance due to anhidrosis, with episodes of hyperpyrexia. Death from hyperpyrexia has been recorded in up to 10% of patients in the first 3 years of life. Sunburn and frostbite may occur. There is a striking absence of the SSR. Congenital insensitivity to pain with anhidrosis is characterized by multisystem involvement. Skin ulcerations on the fingers and toes are common from self-biting, and neurological examination often reveals complete analgesia, although tactile discrimination, sensation of cold, heat and vibration may be normal. Corneal reflexes are usually present but deep tendon reflexes are abolished. Neonatal hypotonia and psychomotor retardation are common, as are slow healing fractures, joint deformities, osteomyelitis, avascular necrosis and acro-osteolysis of fingers [37].

Sympathetic nerve injury [1]

When the sympathetic supply of the skin is interrupted, loss of vasoconstrictor impulses leads to erythema. There is passive vasodilation and the denervated area is anhidrotic. The skin may become noticeably dry with scaliness and fine fissures. The affected area heals only slowly following minor trauma, and some patients complain that it is hyperaesthetic. It has been shown that after sympathetic ganglionectomy there can be dissociation of sudomotor and pilomotor activity [2]. In the denervated areas, there is no loss of cutaneous sensation, and the phenomenon may be due to the regeneration of post-ganglionic cholinergic fibres. In general, the areas of vasodilation correspond to the areas of anhidrosis, suggesting a close correspondence of sudomotor and vasoconstrictor fibres [3]. Measurements of sweating and vasomotor responses can help to determine the extent of autonomic denervation [4].

As discussed earlier in this chapter, when sympathetic denervation is combined with a loss of somatic sensation, as, for instance, in peripheral nerve injury or severe peripheral neuropathy, neurotrophic ulcers may be encountered. These result from local minor trauma and are characteristically painless and slow to heal. Sympathetic denervation may also slow or prevent the normal greying of hair that takes place with increasing age [5,6], and in one case it seemed to cause hyperpigmentation of the skin in the affected area [7].

Complex regional pain syndrome (CRPS)

Complex regional pain syndrome (CRPS Type I, previously known as reflex sympathetic dystrophy, or Type II, previously known as causalgia) is a heterogeneous group of conditions resulting in neuropathic pain that is characterized by pain and dysfunction of the sympathetic nervous system [1–3]. CRPS is a painful disorder typically involving the distal portion of a limb, represented by spontaneous and evoked pain as well as autonomic, motor and trophic abnormalities. It commonly occurs in the 30–50 age group and women predominate with a ratio of 4:1, with upper limbs being twice as frequently involved as lower limbs; fractures are the most common initiating triggering factor, occurring in nearly half of patients. CRPS I is much more prevalent and typically develops after minor trauma with either no obvious or only a small nerve lesion, while CRPS II is usually associated with an identifiable nerve injury [4]. It has been recommended that the diagnostic criteria include at least one event from each of four groups: (i) a syndrome that develops after a noxious event; (ii) spontaneous pain or allodynia/hyperalgesia not limited to the territory of a single nerve and disproportionate to the initiating stimulus; (iii) past or present oedema, abnormal skin blood flow or sudomotor activity; and (iv) absence of conditions that might otherwise account for pain and dysfunction [1,2].

Aetiology. Complex regional pain syndrome commonly develops after trauma, with at least 50% of cases involving a fracture (most often a Colles' fracture), but it can be induced by sprains, contusion or lacerations. It usually involves a distal limb site. Other antecedent factors have included injury to the central or peripheral nervous system, stroke, myocardial infarction, tuberculosis and certain drugs [1]. Dermatologically associated causes of CRPS are listed in Table 63.3 [1,5–8].

The pathogenesis of CRPS is not well understood, although pathologies in peripheral nerves and abnormalities in the CNS have been described in patients with both CRPS I and II [4]. Hypotheses include release from peripheral unmyelinated fibres of neuropeptides, including substance P, CGRP and neurokinins which cause pain and vasodilation, enhanced α-adrenergic receptor activity, and up-regulation of afferent nocioreceptors in response to norepinephrine release from sympathetic efferents. Other theories suggest excessive inflammation at the site of injury and involvement of the immune system or the CNS [1].

Table 63.3 Dermatologically associated causes of complex regional pain syndrome (CRPS) [1,4–7].

Acrodermatitis continua of Hallopeau
Chronic venous ulceration
Dupuytren's contracture
Epithelioid haemangioendothelioma
Herpes zoster
Human parvovirus B19
Minor surgery (nail, skin biopsy)
Osteogenesis imperfecta
Psoriatic arthritis
Systemic lupus erythematosus
Vasculitis
Weber–Christian panniculitis

Table 63.4 Dermatological manifestations of complex regional pain syndrome (CRPS) [1].

Sudomotor changes and oedema
Erythema and warmth
Pallor or cyanosis
Hypertrichosis or hypotrichosis
Hypohidrosis or hyperhidrosis
Beau's lines or nail notching, leukonychia, onychodystrophy
Factitious ulcers
Bullae

Symptoms. It is common to divide the symptoms of CRPS into three stages [1].

The first stage begins several days or weeks after the injury and lasts about a month. During this first stage, the symptoms are those of spontaneous burning and stinging pain, tearing or shooting pain precipitated by mechanical stimuli such as bathing, clothing resting on the skin or draughts blowing on a limb [2]. The second stage occurs from 1 to 7 months after injury and lasts 3–6 months. The symptoms relate to sympathetic hyperactivity and include cool, oedematous skin, hyperhidrosis and cyanosis or livedo-like changes. Hair may show decreased growth and nails become brittle. Pain is variable and the neuralgia may either spread or decrease.

In the third stage, starting some 8 months after injury, there is progressive tissue damage, which can become permanent. The skin becomes shiny, atrophic and dry and fingertips may diminish in size. When pain is made worse by a variety of stimuli, the patient may protect the limb, leading to trophic changes in bone, muscle and skin (Sudeck's atrophy).

Dermatological manifestations of CRPS are listed in Table 63.4 [1].

Diagnosis. By definition, electrodiagnostic studies (needle electromyography and nerve conduction studies) are normal in CRPS type I, but demonstrate a peripheral nerve lesion in CRPS II [9]. While patchy osteoporosis may be seen on plain radiographs in CRPS I, some patients may have no changes. CT scan or MRI may show signs of atrophy or swelling of soft tissues and changes in bone mineralization. Bone scintigraphy using three-phase bone scans may be of more value in picking up changes early in the disease process. Other tests include: pain relief on α_1-adrenergic blockade with intravenous phentolamine; pain exacerbation on α_2 stimulation by clonidine; and elicitation of severe pain on cold stimulation, induced by evaporation of a drop of acetone or ethyl chloride on the skin. These tests help identify those patients with sympathetically maintained pain (SMP). Despite having similar clinical signs and symptoms, only a proportion of patients with CRPS type I show alleviation of the pain by selective blockage of the sympathetic nervous system or of α-adrenoreceptors. SMP can also be shown in patients with CRPS II, although the mechanism subsequent to trauma with a nerve lesion is unlikely to be identical [4].

Treatment. While many CRPS patients improve spontaneously, for others the syndrome may deteriorate and become devastating. Interdisciplinary pain management techniques should include the use of occupational therapy and physiotherapy to aid active movement and allow graded increase in activity. Early mobilization of 'at risk' extremities or joints, for example the wrist after Colles' fracture or surgery, can be preventative. This can be accomplished by a series of exercises using devices; for example, in the case of Colles' fracture a rubber ball progressing to spring grip strengtheners and mat exercises [2,10]. Desensitization techniques, such as rubbing the skin with silk, then cotton, then towelling, or baths of contrasting temperature, can be particularly useful [2,10].

Drug treatment may include tricyclic antidepressants, or newer antidepressants such as venlafaxine and mirtazapine, especially in the setting of associated depression [2]. Gabapentin [11], lamotrigine and carbamazepine have proved useful, although randomized control trials in CRPS are lacking [2]. Both α- (phentolamine) and β- (propranolol) blockers have been found useful in some patients [1]. A eutectic mixture of local anaesthetics (EMLA) or capsaicin creams have not generally proved beneficial [2,12]. Where inflammation is considered to have an aetiological role, ketoprofen or even a short course of oral steroids may be of help [2]. Interestingly, calcitonin is one of the best-studied drugs in the management of CRPS and produced significant pain relief in almost 60% of patients in a randomized clinical trial [13].

There has been a recent report of resolution of CRPS with thalidomide therapy [14]. Although sympathectomy has been a traditional first line of treatment in CRPS, there is little evidence to support its use, and it does not seem to have a long-term effect [15,16]. Intravenous regional sympathetic blockade using guanethidine [2] or bretylium [2,17], use of a spinal cord stimulator [18] and subcutaneous lidocaine infusions [19] may be helpful.

Psychological interventions, including biofeedback, cognitive-behavioural and relaxation techniques are of crucial importance, although are often overlooked.

Horner's syndrome [1]

This follows partial or complete interruption of the sympathetic pathways of the face. It is characterized by ptosis, miosis and anhidrosis.

Aetiology. The fibres responsible for the sympathetic nerve supply to the skin of the face travel from the hypothalamus via the spinal cord, to relay at the level of the first and second thoracic segments in the lateral column of the spinal grey matter. The preganglionic fibres emerge from the cord in the anterior rami of the first and second thoracic spinal nerves, and pass up the cervical sympathetic chain to relay in the superior cervical ganglion. From here, post-ganglionic fibres pass to supply the eye and the skin of a small central area of the face via the internal carotid sympathetic plexus. Other fibres pass along the external carotid artery and its branches to innervate the greater part of the facial skin with vasomotor and sudomotor fibres.

This pathway can be interrupted centrally in the spinal cord; for example, by medullary infarction, syringomyelia, multiple sclerosis or intraspinal tumours. The peripheral fibres can be damaged by an aortic aneurysm, cervical lymphadenopathy, surgery, regional anaesthetic procedures or tumours. Horner's syndrome may follow sympathectomy for the treatment of palmar and axillary hyperhidrosis, and occurs in up to 40% of patients having cervical sympathectomy by conventional open surgery and in up to 8% of those having transthoracic endoscopic sympathectomy [2]. In such cases, there may be resolution of long-standing pompholyx-type hand eczema on the ipsilateral side, suggesting a neurological pathogenesis for endogenous pompholyx in some patients [3,4].

Clinical features. An irritative phase is described, but rarely seen, in which there is transient unilateral hyperhidrosis and vasoconstriction. The paralytic phase is characterized by drooping of the eyelid (ptosis) with narrowing of the palpebral fissure. The pupil is small, but shows normal reflex constriction to light and accommodation, and sweating is absent on the ipsilateral side of the face. There may be slight retraction of the globe of the eye into the orbit (enophthalmos). Cases of bilateral Horner's syndrome are rarely encountered. Sweat glands on the medial and lateral parts of the forehead are innervated separately, with the medial forehead being supplied by nerve fibres from the sympathetic plexus of the internal carotid artery, while the lateral forehead derives its sympathetic nerve supply from the plexus surrounding the external carotid artery [5]. This accounts for the findings in Raeder's syndrome, where damage involving the perivascular plexus of the internal carotid artery leads to anhidrosis medially but not laterally on the forehead [6].

Treatment. This should be directed to the underlying cause; usually, however, this is not amenable to therapy.

Gustatory hyperhidrosis

The autonomic nervous system has a propensity for regrowth [1]. Damage to adjacent preganglionic parasympathetic fibres and post-ganglionic sympathetic fibres may be followed by parasympathetic fibres regrowing into the sympathetic nerves, thereby directly controlling sweat gland function. In the neck, for example, following damage to the sympathetic cervical trunk and the vagus (parasympathetic) at the time of thyroidectomy or after trauma, such reinnervation may result in gustatory hyperhidrosis even after eating bland foods [2]. A similar event may occur on the cheeks or chin following surgery to the parotid or submandibular glands—the so-called auriculotemporal syndrome (Frey's syndrome) [3]. Secretory sweating is now more frequently seen after endoscopic trans-thoracic sympathectomy [4,5]. A recent review of 918 procedures in 458 patients reports a rate of gustatory hyperhidrosis of 1.1% [6].

Treatment. Fortunately, topical preparations such as those containing aluminium chloride hexahydrate often control these

symptoms well, but may themselves produce an irritant dermatitis. Botulinum toxin has been shown to be effective and safe in gustatory sweating [7]. A further option is the use of a 0.5% aqueous solution of glycopyrronium bromide topically, which has been shown to be effective, safe, well tolerated and convenient in diabetes-associated gustatory sweating [8].

Chronic skin pain

The diagnosis of dysmorphophobia or dermatological non-disease [1,2] should always be considered when patients present with chronic skin pain, especially when areas important to body image are involved. These include the burning vulva syndrome (vulvodynia) and the burning scrotum syndrome (Chapter 71) as well as orodynia (Chapter 69). However, one should keep an open mind about other entities including notalgia paraesthetica, brachioradial pruritus (BRP) and skin–ache syndrome. Postherpetic neuralgia is discussed earlier in this chapter.

Scalp dysaesthesia

Cutaneous dysaesthesia syndrome is a disorder characterized by chronic cutaneous symptoms without objective findings. Patients complain of burning, stinging or itching, which is often triggered or exacerbated by psychological or physical stress. These symptoms may be manifestations of an underlying psychiatric disorder or may represent a type of chronic pain syndrome. Patients are typically middle-aged or older women who experience debilitating scalp pain and/or pruritus. The sensations of both pain and itch are carried on the same unmyelinated (slow), afferent, group C nerve fibres. Treatment is low-dose antidepressants but it has been noted that patients with only pruritus were less responsive or unresponsive to such therapy [3].

Notalgia paraesthetica

Notalgia paraesthetica was first described in 1934 by Astwazaturow [4]. It is characterized by episodes of itch and skin pain, usually close to the medial border of the scapula, corresponding to the posterior primary rami of the thoracic nerves T2–T6. The condition may be caused by entrapment of the posterior rami of these spinal nerves as they pass through muscle, and may be predisposed to by back injury or back trauma from prolonged sitting [5]. Patients present with localized discomfort or pruritus on the back; the condition runs a chronic course, and is probably more frequent than previously thought. Examination often reveals a speckled or uniform area of pigmentation, which may be associated with lichenification. There may be hypoaesthesia or hyperaesthesia to pin prick, often localized to the centre of the area [6]. Histopathology characteristically shows intraepithelial necrotic keratinocytes with melanin and macrophages in the papillary dermis [7]. One study found increased substance P immunoreactive fibres in the skin [8].

The relationship of this condition to primary localized cutaneous amyloidosis of macular type [6] is unclear; but in most cases amyloid has been found to be absent, although it may have been missed because deposits were sparse [4,9]. Cases with classical features of notalgia paraesthetica have been reported in which macular amyloid was present on skin biopsy [4]. It is well known that prolonged scratching and rubbing can give rise to friction-related amyloid deposits (Chapter 59); the intractable pruritus characteristic of notalgia paraesthetica may thus explain the association with localized cutaneous amyloidosis.

In one study, 70% of patients treated with topical capsaicin and 30% of patients receiving vehicle, reported some degree of improvement, but it was difficult to maintain the double-blind design of the study because of the symptoms produced by capsaicin itself [10]. In a series of three patients, all patients were reported as improved by application of topical EMLA (2.5% lidocaine and 2.5% prilocaine) [6]. A small open study has also found useful results with oral oxcarbazepine 300–600 mg twice daily for a minimum of 6 months in three of five patients, although one patient discontinued early due to side effects [11]. Recently, case reports on two subjects pointed to the possibility of long-lasting relief after only one or two injections with botulinum toxin A [12].

In addition to pharmacological approaches, Wallengren and Sundler [13] explored cutaneous field stimulation (CFS) in patients with a variety of pruritic conditions, using a 0.8-mA current applied locally to the point of maximal itch for 20 min each day for 5 weeks. Some symptom improvement was noted in patients with notalgia paraesthetica and brachioradial pruritus (see below). This was accompanied by structural changes shown by immunostaining of baseline and post-treatment biopsy material for calcitonin gene related peptide and protein gene product 9.5. After treatment a decrease in epidermal nerve fibres was noted, and the appearance of thick bundles of protein gene product immunoreactive nerve fibres just beneath the epidermis was taken potentially to indicate nerve regeneration. The effect did not, however, persist indefinitely after discontinuing CFS, and over time the itch gradually reappeared [13].

Brachioradial pruritus

Brachioradial pruritus (BRP) is a localized itch in a dermatomal distribution, which usually occurs on the lateral aspect of the arm and elbow, or less commonly on the shoulders, neck or upper thorax [14]. It was originally described in patients from Florida, USA, and the Transvaal, South Africa. A strong seasonal variation, with symptoms being worse in summer months, improvement

with photoprotection and the fact that case reports have come mainly from tropical areas, have all been cited as evidence that BRP is a photodermatosis [14–18]. In other cases, cervical root damage (C5–C8) from degenerative arthropathy, cervical rib or spinal tumours may have been important aetiological factors [19]. It is likely that both cervical spine disease and sunlight-induced damage to cutaneous nerve endings are important underlying contributors and triggering factors [17]. Specific staining with neuronal markers has shown brachioradial pruritus to be associated with a reduction in epidermal and dermal nerve fibres, which normalizes during the symptom-free period [20]. Dermal pin prick hyperaesthesia may be present in a cervical nerve distribution [18]. MRI scanning should be performed to define cervical nerve-root compression [21].

Unlike normal itch, which tends to be relieved by scratching, in BRP scratching seems to potentiate the sensation of itch transmitted by the C fibres [14,22]. BRP is often refractory to topical or oral steroids and antihistamines [19]. Reports of response to topical capsaicin have been variable [10,22,23]. Gabapentin may be useful for BRP [24] and its use in a number of chronic skin syndromes has recently been reviewed [25] A small open study suggested a possible long-lasting beneficial effect from the use of deep intramuscular stimulation acupuncture to the para-vertebral muscles in the dermatomal segments of the body affected by the pruritus [26].

Skin-ache syndrome

Bassoe [27] suggested the term 'skin-ache syndrome' for a situation in which patients experience pain of unknown aetiology characterized by cutaneous trigger points, although this is not widely used. Relief of symptoms was reported after injection of lidocaine or surgical removal of the skin trigger point. This is in contrast to fibromyalgia, from which it must be distinguished, and where pain is more refractory.

Restless legs syndrome (RLS)

RLS is a common sleep and movement disorder. A large population based study in over 15 000 subjects estimated 7.2% to have had RLS symptoms during the preceding year: in 5.0% this was at least weekly and 2.7% reported moderately or severely distressing RLS symptoms at least two times per week [1]. RLS is a clinically pleomorphic syndrome, probably reflecting multiple genetic and acquired factors. A significant linkage was established to chromosome 12q [2], and it has long been felt that it represented a subclinical sensory neuropathy [3]. Others have related it to a dopamine imbalance, due to the presence of dyskinetic movements and response to levodopa [4]. Studies of the basal ganglia using positron emission tomography (PET) scanning techniques have shown a decreased binding of dopamine to its receptor [1]. More recently, involvement of the endogenous opioid system has been implicated in the pathogenesis of RLS [5]. Up to 30% of patients have iron deficiency, with consequent reduced levels in brain tissue and cerebrospinal fluid [1]. RLS is a common disorder in haemodialysis patients [6] and associations have also been noted with pregnancy, fibromyalgia, rheumatoid arthritis and multiple sclerosis [5].

Clinical features. Two subtypes are recognized. The first, with an early onset, accounts for some 25% of cases, is more commonly familial and is associated with a history of 'growing pains' in childhood [7]. Those with a late onset (idiopathic RLS) have less painful paraesthesiae or dysaesthesiase, insomnia and lack a family history of the condition. RLS is characterized by leg paraesthesiae, associated with an irresistible urge, occurring at rest, to move the

legs, which is relieved by movement [3,8,9]. These symptoms are worse at night, with both circadian rhythms and recumbency being shown to play a role [5], and often lead to disruption of life and chronic sleep deprivation. Children may struggle at school and present with symptoms of attention deficit hyperactivity disorder [5]. Sensory symptoms include painful legs and arms, and pain at 'internal' sites. Many patients will have a previous diagnosis of a musculoskeletal disorder, such as joint and back pains, and there is a significant association with depression and other neuropsychiatric symptoms [7,8]. Headache on awakening and daytime headache occurs frequently, while in men, hypertension and heart problems have been reported [9].

Treatment. Some believe the first choice of treatment for RLS should be dopaminergic agents such as levodopa [3] or the longer-acting cabergoline [3]. However, a recent evidence-based review including newer treatment options suggested a greater rate of augmentation with levodopa compared to other dopaminergics. Non-ergot dopaminergic derivatives, such as pramipexole, ropinirole or rotigotine, were preferable to ergot derivatives with their risk of heart or lung fibrosis [10], for patients where side effects such as nausea and daytime somnolence could be tolerated [11]. In recent randomized, double-blind studies of gabapentin, significant improvement occurred in both idiopathic RLS [12] and haemodialysis patients [6]. Other second-line options suggested included opioids such as oxycodone, codeine and methadone, and benzodiazepines such as clonazepam or diazepam [5]. Ferrous sulphate, which had been felt to be effective as an empirical treatment, was not shown to have an effect in a randomized, double-blind, placebo-controlled trial [13]. It penetrates the blood–brain barrier poorly and is not suitable as monotherapy. It should only be given in the presence of relative iron deficiency (serum ferritin <50 ug/L) [5].

Burning feet syndrome (BFS)

BFS is a poorly recognized and often underdiagnosed condition [14,15]. It may occur as a result of diabetic neuropathy, but in most cases it is idiopathic. Families with an autosomal dominant inheritance for BFS have been described [16]. A kindred of 21 patients with familial BFS has been described; BFS was often associated with minor foot abnormalities such as high arches or reduced toe fanning [16]. Loss of small fibre sensory nerves has been found both in type 2 diabetics [14] and idiopathic cases. Tests on the autonomic system have shown predominantly cholinergic defects, unlike other autonomic neuropathies. There is a close correlation between quantitative abnormalities in the sudomotor axon reflex test and the loss of small nerve fibres in the skin [14].

Clinical features. The main clinical features are of a burning sensation on the feet with accentuation by heat or cold. Other autonomic associated features may include dry skin, eyes and mouth, vasomotor symptoms with peripheral coldness, burning or flushing, hypertension and impotence. Orthostatic hypotension does not appear to be an association [14,15].

Treatment. Treatment options for BFS appear less defined than for RLS, but treatments efficacious for the latter would probably also help in the BFS.

The psychological and symbolic importance of skin [1,2]

We call our emotions our feelings. The metaphors of everyday language emphasize the ingrained influence that touch [3,4] has in our experience and psyche. We talk about 'getting in touch', our feelings are 'hurt', we are 'touched' when an unexpected kindness is given, we 'handle' a problem 'with kid gloves'. Madness is described as being 'touched'. *Noli me tangere* translates literally as 'don't touch me', but it is legal Latin, meaning 'do not interfere' and, significantly, was the original term for ulcerated cutaneous lupus vulgaris.

The significance of the skin as a substance, as a vehicle and in descriptive language gives it a unique position in human life. Beliefs, true or erroneous, attitudes and responses are commonly based upon mythological and cultural values which have persisted despite the rise of science and reason. This unique position has emphasized the inviolability of the skin, the need to remain whole and to guarantee this by maintaining it in a smooth and immaculate state. The flayed or abstracted skin was the bearer of special powers; Hercules dressing in the hide of the slain lion to assume the mantle of peerless courage or the Aztecs honouring the spirit of vanquished enemies by wearing their inverted flayed skin. The ancient Greeks, the Syrians and later, medieval anatomists regarded the skin as a dried form of the excrescence of impurities and as such an indicator of inner impurities, both physical and sinful. The use of the term complexion changed from being an indicator of the interaction of the four humours (blood, phlegm, black and yellow bile), to that signifying colour, texture and condition of the skin but retaining the meanings and relationship to dirt and sin. This concept of the 'complexion' related to all of an individual's body and character until the mid 16th century when the skin came to be taken as the most direct and readable indicator of a person's physical and emotional state. The secretions of the pores, the colour, and texture of skin were signifiers of disease of the body and by implication of the moral and virtuous standing of an individual. The aesthetic immaculateness of the 18th century, with smooth white complexion of the ladies, pure neo-classical sculpture and portraiture, was in direct contrast to the rotting, eruptive, crusty skin of syphilis, plague and smallpox. The skin would be the first sign of contagion and usually eventual death, and thus the simplistic belief that a clear skin would ward off the dangers was paramount, particularly to the ruling classes. This thinking continues in cosmetic advertising where the culture

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

of skincare [5] means not only an indication of health and vigour but particularly sexual attractiveness, the largely unspoken issue in most dermatological consultations.

Closely allied to the visual disgust of rashes is the fear of those who itch. Intrinsic to our responses is the reaction to scratch when we see others itch and indeed to scratch ourselves when we read or think about itch. Again the implication is of contagion and transferable disease, not only mites but also worms and in the case of those with delusions (see below) the unique products of their own distorted imagination. To scratch brings distress and pain and in psychoanalytic terms the guilt and pleasure of self touching.

Touch is the oldest sense because it is the first sensation of the newborn [6]. It is their introduction to the world and continues to be essential for development, both physically and emotionally. The nocioceptors are capable of recognizing an enormous variety of sensations through a combination of responses to produce sensations as diverse as intense pain, erotic pleasure or the minute differentiations of texture and structure. Massaged babies gain weight appreciably quicker than non-massaged ones. In some cultures it is the norm for any family member, not necessarily solely the mother, to take turns massaging the newborn and infant. Emotionally deprived children are more likely to suffer psychosocial dwarfism with lack of growth, delayed milestones and emotional blunting. Furthermore, a beneficial change in social circumstances alone produced an acceleration of growth if applied soon enough. Deprivation of social touch affects the bonding process between individuals. Distorted sensation, either because of sensory loss or disease of the skin, may significantly affect the intended response in both toucher and touched. The diseased child has a relative sensory deprivation if, for example, they are enclosed in a curasse of ichthyosis. The family may feel a reluctance and repulsion to touch a child who feels unpleasant as well as being physically changed. The maturing child with widespread skin disease develops an awareness of stigmatization and a disinclination to be invited into peer group contact play. Emotional stunting and isolation can be a permanent consequence unless this is recognized and active interventions initiated.

For young and old adults alike the violation of tactile memories by disease may impair the continuation of relationships within family, the forging of new alliances especially sexual, and the corruption of tactile skills in work or leisure. There is a human need for touch and to be touched, to feel safe and supported and the unwelcome touch of a person with visible skin disease is treated as a boundary violation by the touched and as personal rejection by the diseased. Professional touchers are given permission to engage in an intimacy reserved usually for only those close to a patient. This 'laying on of hands' is not confined to the qualified doctor or nurse but equally to any healer, legitimate or not. The success of alternative medicine practitioners such as aromatherapists, reflexologists or shiatsu massage may, in part, be due to the element of touch rather than any other elaborate quasi scientific explanations. Reduction in experimental stress-induced blood cortisol levels was found to be greater in those who had forms of relaxation massage than a control group who were not touched.

Disfigurement has always been associated with rejection of the afflicted, guilt and stigma. Guilt for a birthmark has been traditionally visited upon the mother for some misdemeanour that is implied by others or ruminated upon by the woman herself. Positively assuaging this reaction should be standard advice for all families who seek the reasons for the imperfections, not only in scientific terms but also to dispel these arcane beliefs. It may seem paradoxical that the decorated body with tattoos and piercings, which are in themselves violations of the body, should continue to flourish [7]. They are regarded as marks of enhancement and tokens of bonding in groups, and only rarely as forms of concealment, for example over a birthmark, or as self-mutilation, for example found particularly in those with hundreds of metal piercings.

It is impossible to manage a patient's distress about skin disease without in some part addressing the metaphors and myths surrounding it. These myths remain a part of every culture, no matter how ancient their origins, but need demystifying to manage the disease which is neither curse, nor punishment but usually treatable [8].

Psychodermatology

Psychodermatology covers all aspects of how the mind and body interact in relation to the onset, form and progression of skin disease. The subject is best regarded as a global term, used to encompass the wide and diverse relationships that have been recognized to exist between the two disciplines, psychology and dermatology.

Historically, clinicians [1,2] have noted the apparent influence of the emotions on skin disease. Eminent dermatologists of the past have related clinical associations of the nervous system with dermatological disease but it is important to realize that what were described as dermatological neuroses was to define some dysfunction of the nervous system which subserves those affections of sense and emotion, some of which are prominent symptoms in skin disease. Thus, for example, Erasmus Wilson [2] ascribed leukoderma to a physical weakening of the innervation of the skin. To quote Hunter and Macalpine [3,4], 'The term neurosis retained its essential meaning of a disordered nerve function without a structural pathology until, 100 years later, the prefix "psycho" was added for nervous disease caused psychologically'.

This is not to undermine the observations that rosacea, urticaria or eczema were sometimes the result of 'affections of the nervous system as mental emotions especially of the depressive kind'. The diagnostic problem for dermatologists was clear since mental

illness was mainly classified as the major organic and functional psychosis. There are pertinent, if cautious, references to the influence of melancholia and depression but not the psychoneuroses until late in the 19th century. Hebra [5] (1866) was sceptical of a relationship saying that 'I have neither seen myself or read nor heard from physicians who have charge of lunatics that cutaneous affections are particularly common in such cases'.

When Brocq described localized and disseminated neurodermatitis he also proposed a deep disorder he called nervosism. Later, in association with Besnier and Jacquet [6] they referred to the neurasthenia of eczema more as a result of the distress of the disease than as a significant cause. By this time (1901) they were still of the belief that 'particularities of a nervous pathological state that would make eczema more likely must be taken into account'.

This time was a significant one for medicine with the twin rise of scientific medicine and an excitement of observable physiological, microbiological and pathological knowledge. The emergence of the concepts of neurasthenia and hysteria, and redefinitions of psychiatric illness were hampered by a lack of objective scientific evidence and charges of quackery based on the disreputable practitioners such as Mesmer and his followers. In psychiatry, there were two significant developments relevant to assessment of illness in general. Firstly, the concepts of psychosomatic medicine and, secondly, the development of psychoanalysis.

The term psychosomatic disorder refers to a physical condition caused or aggravated by psychological factors. At this time, medicine was passing through a descriptive era where morbid pathology had identified changes in organs and tissues and which were recorded in great detail. Unfortunately, certain long-term diseases defied resolution by these methods and alternative explanations based on early psychosomatic research influenced medical thinking.

Clinicians who suggested that they had no doubt that in some cases the patient's mind operates through the endocrine system and in others via the vasomotor system were denounced as unscientific and discreditable [7]. Dunbar [8] (1954) catalogued the psychosomatic dermatology research during the first 50 years of the 20th century from 1910 to 1953, during which it became clearer that the contribution of the understanding of 'functional diseases' of the World Wars in particular could be extended to understanding the effects of stress and deprivation in specific disease states of organ systems such as the skin.

At this time, controlled studies from psychiatrists and psychoanalytically trained researchers attempted to apply some stringency to a field fraught with difficulties [9,10]. Psychophysiological measurements of parameters in certain skin disorders continued to establish the credibility of psychosomatic relationships in skin disease [11], but the history of development has been phasic, marked by advances punctuated by lulls in activity. Dermatology moves from its original exemplary, clinical expertise with limited aetiological understanding into new scientific clarity where disease complexity is more understandable. At these times the alleged role of psychogenesis in disease is undervalued and there is a contemporary dismissal of skin–psyche relationships. This was not helped by an apparent failure of psychological therapies in psychosomatic dermatoses. Whitlock wrote that 'it is worth noting that improved biochemical and immunological understanding does not rule out contributory psychological factors whose importance will vary from time to time and case to case' [11]. This astute observation ushered in further developments for psychodermatology.

The term 'psychoimmunology' was introduced in 1964 by Solomon and Moses [12], but the real expansion of psychoneuroimmunology did not begin until the demonstration of behaviourally conditioned immunosuppression in 1975 by Adler and Cohen [13]. For further consideration of psychoneuroimmunology, see below.

It is encouraging that the development of a multidisciplinary approach to psychodermatology continues to validate the relationships between skin disease and psychological mechanisms.

Skin–psyche interactions

An essential component of dermatological illness is the relationship that somatic dermatology has to psychological status of the sufferer at the time. The influence that these psychological, psychosocial and sometimes psychiatric factors play can be conveniently assessed as:

1 Multifactorial dermatological disorders which can be substantially influenced by psychological factors, e.g. psoriasis
2 Dermatological disorders as a result of psychiatric illness, e.g. factitious dermatoses, body dysmorphic disorder
3 Psychiatric illness developing as a result of skin disease, e.g. depression, adjustment disorder
4 Co-morbidity with another psychiatric disorder, e.g. alcoholism.

In large centres, this work can be refined and developed in specific clinics for psychosomatic dermatology [1]. Ideally, liaison psychiatry should be available together with help from clinical psychologists and social workers [2]. Research and dissemination of further knowledge in psychosomatic dermatology is supported in Europe by the European Society for Investigative

Dermatology and Psychiatry (ESDaP) and in North America by the Association for Psychodermatological Medicine of North America (APMNA).

The dermatological consultation is substantially different from the psychiatric one. However, for those who feel intimidated, the consultation process and descriptive psychopathology of psychological medicine is well described for non-psychiatrists [3,4].

Psychosomatics

A common folk belief is that there is an influence of 'mind over matter' and this can influence the onset, progression and resolution of disease. In other words, that the state of mind can, to some extent, have a significant bearing not only upon how an illness is perceived but also on its severity and content. The narrative of clinical anecdote and experience held for a long time that emotional stress could be counted as an integral cause of skin disease or at least an exacerbating factor leading to increased disease morbidity.

The concept of 'well being' is common to all cultures and associated with declarations of 'life forces', 'vital life energies', chi in Chinese, ki in Japanese and prana in Sanskrit. In the presence of physical symptoms and disease, psychosomatic theories have given insight into the effects of stress on the onset of disease, for example: psoriasis, on the persistence of symptoms; glossodynia, and the effects of anxiety and depression on the rate of disease recovery; and atopic dermatitis. The therapeutic value of the 'talking therapies' and the effect they have on physical recovery in skin disease are well established [1,2]. Chronic illness requires a series of psychological adjustments and these can differ depending on the patterns of illness. Thus an acute relapsing illness with full recovery between episodes, such as recurrent genital herpes, will produce different stress influences than a chronic illness with gradual linear decline, for example peripheral vascular disease or the stepwise decline of psoriatic arthritis with increasing disability after each episode. The effectiveness of coping strategies relates directly to the degree of psychological morbidity experienced and thereafter the stress effect on disease expression [3]. Those patients who use problem-focused coping strategies are better at seeking information, learning new skills and participating in treatment. Disease control is better with fewer exacerbations and less anxiety and depression. Emotion-focused coping strategies help patients to share their feelings, express anger and become realistic about prognosis. Adverse psychological responses to illness are related to chronicity, to increasing disability and poorer prognosis. Examples of this form of thinking are the vain belief that the condition will cure itself spontaneously, denial of the disease (and thus poor treatment acceptance) and seeking to blame others.

Atopic dermatitis

The complex psychological issues have been admirably summarized by Koblenzer [4]. The child is distressed from an early age, uncomfortable, exhausted and restless. The comfort from parental touching is limited, either by the irritation produced or the reluctance of parents to cuddle the imperfect infant. The parents' anxiety is transferred to the child and this leads to increased itching and scratching. Some children may become the sole focus of parental attention, resulting in elaborate regimens which prolong the infantilization of the child, promote sibling rivalry and even marital disharmony and divorce. Atopic children and adolescents show more anxiety, handle situations less well and are provoked to anger more readily. In school and college, the psychosocial issues of mixing in peer groups and making personal relationships may be blighted by feelings of stigmatization and disfigurement (see below). Regression and/or paradoxical aggressive behaviour are related to increased psychological morbidity, which has been shown to be commoner in boys than girls [5]. Stress makes atopic dermatitis worse [6]. Psychometric and immunological measures of change (see below) have emphasized that this is no longer an arcane clinical whim. Furthermore, psychotherapies have a part to play in the treatment plan [1,7]. Analysis of the effect of psychological interventions in atopic dermatitis is encouraging rather than conclusive because of the different types of approach employed. These therapies had a significant ameliorating effect on clinical severity, itching intensity and scratching in adults [8] and to a lesser extent in children [9] where correction of psychosocial and educational factors were more helpful.

Psoriasis

There have been many reviews of the psychosomatic aspects of psoriasis [10,11]. The imposition of a disfiguring, scaly and obvious disease in young adults has a profound effect upon body image and self-esteem at the very time when the independence of the personality is being established. The physical limitations introduced by widespread involvement as well as the stigma of visible disease make team games less likely. Sexual relationships are stunted by facial and flexural psoriasis because of shame and fear. Anxiety, depression and suicidal ideation (see below) are commoner than in eczema, acne or alopecia [11]. Depression is particularly significant and may remain undetected but is important because untreated it may contribute to therapy resistant disease and increased pruritus [12]. Patients with significant stress in the previous 6 months were found to be at increased risk for acute guttate psoriasis [13], as were those with diffuse plaque psoriasis [12]. The latent period between a significant life stress and the onset of an exacerbation of psoriasis has been difficult to assess. One study [10] suggested a 3-month delay was significant but this could not be confirmed by others. The response to PUVA therapy in highly worried individuals was almost half that of those who were deemed low worry and was constant for disease severity, gender, age, duration and skin type [14].

Chronic urticaria

The urticarias are a heterogeneous group of conditions. Chronic urticaria which is largely 'idiopathic' has a significant effect on quality of life [15,16]. It is significantly associated with depression,

dysthymia and anxiety [16,17]. Psychological factors may be prominent at onset, and contribute to disease progression [18] and negative coping may be associated with exacerbations. Psychotherapies are not well developed for chronic urticaria and are not as effective as for atopic dermatitis.

Alopecia areata

There has always been a strong anecdotal belief that the onset and recurrence of alopecia areata is related to stress and major life events; the few major controlled studies have failed to produce conclusive evidence [19]. First episodes of alopecia areata tended to be associated with avoidance of personal binding relationships, poor social support and high alexithymic personality characteristics. That is, a difficulty identifying and expressing internal emotions. Recurrent attacks were more frequent in these personality types and also those with trait anxiety and high stress perception [20]. Although the finding of stress mediators such as substance P and nerve growth factor (NGF) in the immunoreactivity of alopecia areata are suggestive of a remedial mechanism of therapy [21], large controlled studies of psychotherapy or psychoactive drugs are absent. Individual case reports continue to record success with individual psychotherapy, or antidepressants, either imipramine or SSRIs, not always in the presence of clinical depression [4].

Self-esteem [1]

Self-esteem is a widely used concept both in popular language and in psychology. It refers to an individual's sense of his or her value or worth, or the extent to which a person values, approves of, appreciates, prizes, or likes him or herself [2]. The most broad and frequently cited definition of self-esteem within psychology is Rosenberg's [3], who described it as a favourable or unfavourable attitude toward the self.

Self-esteem is generally considered the evaluative component of the self-concept, a broader representation of the self that includes cognitive and behavioural aspects as well as evaluative or affective ones [2]. While the construct is most often used to refer to a global sense of self-worth, narrower concepts such as self-confidence or body-esteem are used to imply a sense of self-esteem in more specific domains. It is also widely assumed that self-esteem functions as a trait—that is, it is stable across time within individuals. Self-esteem is an extremely popular construct within psychology, and has been related to virtually every other psychological concept or domain, including personality (e.g. shyness), behavioural (e.g. task performance), cognitive (e.g. attributional bias) and clinical concepts (e.g. anxiety and depression). While some researchers have been particularly concerned with understanding the nuances of the self-esteem construct, others have focused on the adaptive and self-protective functions of self-esteem (for a review of conceptual and methodological issues see [3]).

The concept of self-esteem has expanded and therefore the previous understanding should be clarified. The expanded definition [1] states that there are many different concepts of self-esteem, some primarily psychological and others sociological, all dealing with different dimensions of the phenomenon. Various perspectives on self-esteem lead us to emphasize one or other policy direction. Self-esteem has been related both to socioeconomic status and to various aspects of health and health-related behaviour, as has a related construct, self-efficacy. Self-efficacy refers to an individual's sense of competence or ability in general or in particular domains. The sociological perspective leads us to support policies which will increase self-esteem by reducing environmental pressures on vulnerable persons. The psychological perspective tends to support policies which will increase self-esteem by changing individuals within themselves, for example counselling and psychotherapy.

Each perspective involves a different vision of what the self means in self-esteem and how to understand it. The psychological approach to the self and self-esteem focuses largely on the individual developmental intrapsychic processes, the role of the individual in the creation of the self through decision making, and

specific behaviours, particularly those involving success, mastery of tasks and achievement. This defines self-esteem as a component of competence within the self, the family and the workplace. The more sociological approach to self began to emphasize how others react to us, how we respond to these reactions and how these reactions lead to the development of self and one's worth or value in a social context. This sociological view was developed by Rosenberg [3] and others who emphasized the worthiness component of self-esteem.

Self-esteem was assumed to be a relatively stable characteristic akin to intelligence or personality type which gave it the form of a *trait*, measurable in unidimensional terms of degrees high or low. The scales of worthiness generally function in this way. Self-esteem functions appear to work in a more multidimensional way [4], involving the stability or instability of the self-esteem, defined as the *self-esteem state*. Measures of this component are essential because it is more dynamic than trait self-esteem. That is, it assesses the quality of self-esteem at a particular time relevant to, perhaps, treatment or other influences. The measurement of self-esteem is therefore more complex than originally assumed and thus multidimensional tools are now used to measure the changing dynamic situation presented by treatment and patient responses [1].

Stigma [1,2]

The word *stigma* referred originally to a mark or brand on Greek slaves, distinguishing them from free men. The term describes the situation of an individual who is disqualified from full social acceptance. It is a social state initiated by others but with extensive and possibly long-lasting repercussions. The routines of social intercourse when meeting new people are the anticipation that we have an expected and normal response. These anticipations are shaped by the extended views and models of our experience of an accepted norm. The stigmatized individual is normal until abnormalized by the societal views around him or her. These events may occur early, for example in those afflicted by congenital deformities, or later with an acquired deformation, for example following trauma.

Stigma is not just confined to the alterations in the visible body. There are implications of character such as stigmatization in those who have deficiencies of will, passions or beliefs inferred from mental disorder, alcoholism, drug addiction, unemployment and imprisonment. In addition there are the population prejudices of ethnicity and religion.

For dermatologists the commonest situations where stigma is encountered may be:

1 Physical deformities
- i Congenital naevae, e.g. port-wine stain [3]
- ii Acquired deformities from developmental disorders, e.g. tuberose sclerosis
- iii Widespread inflammatory skin disease [4]
- iv Surgical or post-traumatic deformities

2 Implications of inferred character deficiencies
- i Psychiatric disorder, i.e. their views on the skin disease are disqualified because they also have a psychiatric diagnosis
- ii Learning disability, i.e. they have limited emotional capacity to respond to their dermatosis, e.g. Down's syndrome
- iii Persistent treatment non–compliance, i.e. an assumption of a fickleness of character, e.g. depressive illness
- iv Alcoholism and drug addiction, e.g. the cutaneous signs of substance abuse are a labelling of character weakness
- v Unemployment
- vi Imprisonment
- vii HIV status

3 Stigma of
- i Race, e.g. implications of vitiligo for marriage [5]
- ii Religion, e.g. allowing the naked body to be seen by a stranger.

Stigma is therefore an undesired difference from what was anticipated. Thus society constructs a theory based on, amongst other things, sociocultural beliefs to account for that difference. Cultural beliefs abound, relating a physical difference to an assumed association with an inferior or degenerate form or action.

The commonest are those of dirt and contagiousness whose roots are based on arcane skin beliefs related to leprosy, disfiguring and deadly dermatoses such as smallpox and morally reprehensible dermatoses of syphilis. The further beliefs are imported on the visible and represent an assumption of inferior and degenerate action and behaviour upon the visible imperfection. Thus 'dirty thoughts' are a prelude to dirty skin, acne is occasioned by self abuse and chronic ulcers (especially leg ulceration in men) are a sign of a dissolute past. There is the perception that all skin conditions are contagious, with imputations of an unclean house, and rashes are described as 'poxy', 'scabby', 'plecky' or 'wormy' in everyday conversation.

The stigmatized person may be victimized or exploited because of their vulnerable status. The stigmatized person becomes exposed to fraudulent merchandisers offering youth restoration, skin lightening, blemish removal etc, of an ever more sophisticated and allegedly technically advanced variety. Dermatologists are regularly assailed by desperate patients with a new therapy they have found. This is not because they are particularly gullible but is a reflection of a deeper unhappiness.

After a time, stigma can be used by patients for secondary gain. It is used as a hook to hang the failures and inadequacies of life after the effect on self-esteem has been made concrete over time. There is a danger that these patients accommodate to a subachievement status that develops into a compensatory hypochondriasis, anxiety state or illness complication syndrome, for example chronic somatic pain. The stigmatized patient is uncertain what category he/she will be placed in. A sense of insecurity exists, a feeling of not knowing what people really think. It is important in

children, especially, that they are encouraged to be open about their positive qualities and not focusing on the defect or the bad skin whilst being open about it to others. There is a small risk of inducing the bravado approach to the stigma which is counterproductive and may be seen as aggressive behaviour. The advice of a child psychologist in these situations is invaluable.

Help for the stigmatized begins with information control from both physician and family. Thus the child is protected from the derogatory and the hurtful by association with children of informed friends. Information about new therapies can be sifted to sort the real from the quack. Self help or disease clubs can be invaluable. A tolerant and informed grouping allows the expression of the normal developmental skills of the individual. The very act of offering treatment for birthmarks increases self-esteem in children even though treatment is not perfect [3].

The emergence of the patient into a more unprotected life means anticipating and neutralizing expected reactions such as teasing, taunting and bullying. One such response is that of naming and overtness techniques [2]. A particular difficulty arises from both congenital and acquired skin stigmata with the trauma of sports teams (and changing rooms) and the first experience of partner relationships [6]. Disfiguring conditions have significant effects upon depression, anxiety and self-esteem. There is a weak relationship between the severity of a condition and its social and personal effects. In clinic, this is one of the reasons for the patient with minimal lesions who is particularly distressed and insistent on aggressive therapy. In addition, whilst treatment can reduce and improve quality of life, social improvements and adjustments are not closely related to clinical improvement [6]. There is a significant difference between those who develop skin disease whilst in a relationship and those with stigma who attempt to make a new relationship.

Stigmatization in later life presents a different perspective because the patient has become a physical stranger to themselves. This is most striking and obvious in those who have developed disfiguring facial scarring but is also as valid for the patient with a late-onset dermatosis or those who suffer the odour of hidradenitis suppurativa. These patients have the unease not only of meeting and explaining their disease to new associates but how to relate to old associates.

The ordinary, the routine and the normal generate social anticipations which are then transformed into 'normative expectations, into righteously presented demands' [1]. There is the transformation into moral claims on others not to upset the reliable smooth running of life. There is the imposition of a shame morality upon the afflicted which relates to what you are and physically appear to be rather than, as in guilt morality, to what you may have done. The minimal demand on the stigmatized is not to make undue claims on people's fears or trigger their embarrassment or disgust. Thus, not to attempt to hide a significant facial scar, to expose widespread skin disease in a public place or to present with extensive acne in an intimate crowd leaves the individual open to claims of shame and disgust from others who are 'normal'. A form of attribution theory would suggest that the sufferer has brought retribution upon themselves [2].The stigmatized patient has an imposition from others to make themselves as unobtrusive as possible. This has been described as being *civilly disattendable*. To disregard this social rule is to be judged as being shamed for being unaware of the sensitivity of others and guilty for taking no action to minimize the effect on the observer. A distinction has been drawn within the broad term of stigma between felt stigma and enacted stigma. Felt stigma refers to the shame and expectation of discrimination, that is internal self-stigmatization that prevents people from talking about their experience and inhibits them from seeking help. Enacted stigma refers to unfair treatment by others, that is external stigma [7].

In the past, there would have been little guilt on the observer's part for the emotions the stigmatized provoke. Nowadays, in most societies the guilt of the observer is mollified by the respect given to the stigmatized. However, one of the mechanisms proposed for the continued avoidance of the stigmatized is that there is still a feeling that good deeds may be motivated by an uneasy self-congratulation rather than open respect for patients [8].

Stigma in psychiatry [9]

Many people hold negative stereotypes of those with mental illness. As with skin disease there is a traditional stereotyping from historical attitudes towards psychiatric patients. They are portrayed traditionally as unpredictable, unreliable and uneconomic. In addition there is a 'perceived dangerousness' that sets them apart from the normal social intercourse of everyday interactions. These concerns are modern. Images of mental illness on television focused on violence in 66% of items and 50% of patients with psychiatric problems reported that negative media coverage had a significant adverse effect on recovery. Health professionals who do not work with psychiatric patients have difficulty in accommodating to the needs of this group and tend to hold a range of attitudes towards individuals similar to the general public. With increasing education and contact, medical practitioners become less stigmatizing. The problem with all non-psychiatric specialisms, including dermatology, is that the demands of the consultation in terms of time, knowledge and therapy place unique demands for them on the doctor–patient relationship.

The importance in reducing the impact of stigmatization [10] is better understood in relation to Social Exclusion Theory (SET) which holds that:

1. Humans possess a fundamental motive to avoid exclusion from social groupings
2. Much social behaviour attempts to improve the chances of inclusion
3. Negative effect (including loneliness and depression) results when a person does not or cannot achieve a desired level of social inclusion.

The experience of involvement in groups, not necessarily 'Disease Clubs', helps to improve a sense of well-being and to determine physical and psychological fitness.

Measurement of stigma in dermatology and psychiatry has tended to rely on general measures of mental health with depression and anxiety scores but also with psychometric measures of self-esteem such as the Rosenberg Self-esteem Scale. This has been used to assess stigmatization in psoriasis and eczema as well as mental illness. Further the Stigma Scale for mental illness [11], developed to examine discrimination, disclosure and potential positive reactions to mental illness, demonstrated that Stigma

Scale scores were negatively correlated with global self-esteem. Interventions in dermatological physical visual stigmata are concentrated on firstly the reduction in visibility and secondly the psychologically based approaches to forestall stigmatization. Skilful cosmetic camouflage [2] and the use of cosmetic surgery and laser therapy [12] have all shown that patients gain a better self-image and sense of well-being.

Psychological therapies using social skills training, cognitive behavioural therapy and an interventional method to directly challenge staring and rejection behaviour increased self-esteem and reduced automatic negative thinking [2].

Methods to change entrenched reactions within society to physical and psychological difference are more difficult to evaluate. Frances studied children with visible differences at school and developed programmes of community inclusiveness to reduce discrimination [13].

Psychoneuroimmunology [1]

It has been consistently recorded that patients with depression suffer more physical illness and conversely patients with chronic physical illness more often suffer major depressive illness [2]. Much recent research reflects the potential shared mechanisms of inflammation mediated by the known immune mechanisms.

The anatomy of the structures in brain, nerve and skin are embryologically derived from the ectoderm. They show their origins from the neural plate where both the CNS and peripheral nerves develop from the neural crest as do the cutaneous structures, melanocytes and Merkel cells [3]. The functional relationships between brain and immune system are linked by the autonomic nervous system and the neuroendocrine outflow via the hypothalamus and the pituitary gland. Communication between the immune system and the brain is bi-directional and probably largely mediated by neuropeptides released within nerves and also locally at tissue sites, in this case the skin. This neuro-immuno-cutaneous-endocrine system (NICE) [4] seems to form part of an integrated system, relating behaviour to neuroendocrine and immune function.

The skin has a critical immune function, employing a large number of cell populations in a coordinated manner to respond to both extrinsic and intrinsic challenge (see Chapter 13).

The clinical links between psychosomatic factors and skin disease are amply demonstrated by the fluctuations of remission and relapse which are seen in dermatological disorders as a result of stress and psychological events in patients' lives. There is a substantial body of evidence detailing the neural innervation of the skin with nerve fibres extending from the subcuticular tissue through the dermis and into the epidermis. The contact between nerve cells and epidermal cells, as first recorded by Langerhans and Merckel, is well documented.

Interactions between the immune and the neuroendocrine systems: bidirectional communication pathways [5,6]

Sickness behaviour is a common and not trivial experience, accompanying infectious or inflammatory illnesses. Individuals are lethargic, lose interest in surroundings and have depressed mood. This apathy is accompanied by hyperalgesia. Peripheral inflammation results in the production of various inflammatory mediators including cytokines, which signal to the brain by various routes. Peripherally generated cytokines, for example by infections, induce monocytes and macrophages to secrete pro-inflammatory cytokines centrally, which modulate brain function and can produce fever and sickness behaviour (malaise, lethargy, depressed mood). Because of the large size of cytokines, those produced in peripheral inflammation do not readily cross the blood–brain barrier. However, three mechanisms have been suggested by which cytokines may have access to the brain [7,8]: firstly, via the circumventricular organs; secondly, by binding to specific binding proteins on brain endothelium; and, thirdly, activation of vagal afferent fibres which transmit cytokine signals to specific brain nuclei [9]. The CNS cytokine networks have an effect on neurotransmitter and corticotrophin-releasing hormone (CRH) functions to produce a sickness behaviour syndrome of lethargy, anorexia and impaired sleep patterns [5].

The symptoms of sickness can be reproduced experimentally by induction of pro-inflammatory cytokines or measured from activated monocytes and macrophages during illness. Cytokine receptors are present in the brain and are activated by cytokines produced locally in response to peripheral cytokines. These brain cytokines are produced in macrophage-like cells in the meninges and microglial cells in the brain parenchyma. This sickness response is both physically and psychologically apparent and is reversible in acute illness by potent endogenous factors such as the glucocorticoid system and the production of anti-inflammatory cytokines. However, with disease chronicity there is a blunting of the HP axis response (see below) and the pro-inflammatory cytokine activity leads to the symptoms of sickness becoming chronic. This results in cognitive changes and

depression of chronic disease. Structural changes can occur in the brain as astrogliosis and degeneration of the oligodendrocytes in the myelin sheath, leading to neuronal death. Experimentally, the parenteral injection of the pro-inflammatory cytokines interleukin-1 (IL-1) and tumour necrosis factor (TNF) α resulted in depressed social and feeding activity in rats; this did not occur with IL-6 [8].

CNS stress response: effects on the immune system

The nervous system regulates the immune system through hormonal effects, regionally via immune organ secretion and locally at sites of inflammation [6,8]. Endogenous glucocorticoids are essential in the regulation of the immune response and resultant degree and type of inflammation. The hypothalamic–pituitary–adrenal (HPA) axis activates CRH which activates CRH type 1 receptors in the anterior pituitary to release propiomelanocortin (POMC)-derived peptides adrencorticotropin, α-melanocyte stimulating hormone and β endorphin. It has been proposed that the physiological levels of glucocorticoids secreted via the HPA axis feedback mechanism have a significant immunomodulatory role and result in a shift of cytokine production from a primarily pro- to an anti-inflammatory pattern.

The activation of stress responses results in increased neural output to peripheral tissues. The sympathetic and parasympathetic nervous systems modulate inflammatory responses through regional innervation of organs including spleen, thymus and lymph nodes.

The parasympathetic nerves modulate inflammatory responses at the regional level via efferent fibres of the vagus nerve. The afferent fibres signal the presence of peripheral inflammation to the brain via cytokines such as IL-1, which bind to paraganglial cells to increase activity in vagal brain stem centres. This increased vagal tone results in increased acetylcholine release, which suppresses cytokine release; this is known as the cholinergic inflammatory reflex [9]. The peripheral nervous system affects inflammation through neuropeptides such as substance P (SP) and vasoactive intestinal peptide (VIP) released from peripheral sensory neurones. These neuropeptides may be pro-inflammatory, particularly SP, or anti-inflammatory, particularly VIP.

Stress and immunity [5,6,8]

The mechanisms by which stress can influence the progress, continuity and severity of skin disease can usefully be grouped into three areas: firstly, as mentioned previously, the effect on the immune system of steroid hormones and catecholamines; secondly, the induced alterations in the normal feedback mechanisms of the HPA axis; and, thirdly, the peripheral influence of neuropeptides and inflammatory mediators on skin function. Stress, whether it be emotional, physical or an infective challenge, induces cortisol secretion via corticotrophin-releasing factor from the hypothalamus to adrenocorticotrophin hormone from the pituitary and stimulation of the adrenal cortex. The sympathetic system is activated via the limbic system to release norepinephrine and peripheral neuropeptides. These act on the immune system by influencing the expression of T helper cells and tissue macrophages. Norepinephrine can stimulate Th2 cells through induction of IL-10 and suppression of macrophage IL-12.

Influences on skin disease [5,10–14]

The many influences on the immune system, both known and unknown, cannot give a wholly predictable picture of response of skin disease to stress and adverse psychological influences. The balance between Th1 and Th2 responses can vary enormously and may account for the fluctuations seen in the commoner chronic inflammatory disease such as atopic dermatitis and psoriasis [14]. Endocrine and immune responses to experimental stress showed that there was significant attenuated responsiveness of the HPA axis and increased sympathetic activity in atopic dermatitis patients, leading to increased eosinophil numbers, increased IgE levels and elevation of pro-inflammatory cytokines, particularly IFN-γ. Similar studies in psoriasis demonstrated a significant rise in monocytes and $CD4^+$ cells. Pro-inflammatory IFN-γ and IL-2 levels were elevated whilst IL-10, an anti-inflammatory cytokine, decreased. This mimics the changes found in active psoriasis.

There are many anecdotal reports of stress-induced exacerbations in other dermatoses, but fuller immunological evidence is not available. However, many studies support the role of stress in the pathogenesis of chronic urticaria, recurrent herpes simplex and delayed wound healing [15,16].

Disability and quality of life [1]

This aspect of dermatology is covered in more detail in Chapter 72.

Quality of life (QOL) is defined as an individual's perception of their position in life in the context of the culture and value system in which they live and in relation to their goals, expectations standards and concerns. It is a broad-ranging concept, affected in a complex way by the person's physical heath, psychological state, level of independence, social relationships and their relationship to salient features of their environment.

Established dermatological medicine describes skin disorders in tightly defined diagnostic criteria, which takes little account of the individual patient's responses. The patient with disease needs to be understood not only in terms of objective outcomes of the kind usually assessed in clinical practice but also those composed of the psychosocial structures that are assessed from the patient's self-reports. It is important to try and determine these disparate degrees of disability that a particular skin disease confers because their recognition leads to greater patient compliance and a more positive response.

The effect on QOL induced by psoriasis, eczema and acne have been assessed using disability indices which are readily accessible [2]. These scales can also be used to quantify reduction in disability before and after treatment. The newer indices of disability have successfully combined the physical and psychological measures to produce a more holistic assessment of disease, as exemplified by the Salford Psoriasis Index [3]. For instance the presence of relatively trivial amounts of psoriasis on an individual's face may induce disparate depression. The concept of a person's QOL includes measures of the psychological impact of the disease including stigma and its corollary self-esteem. Questions clarifying the contributions of embarrassment, helplessness, anger and depression are reflected in social, sexual and occupational life. The further development of these instruments has indicated that at similar objective levels of clinical severity QOL may differ significantly between individuals because of the psychological impact. In acne the QOL measures indicated that neither clinical severity scores nor the presence of scarring correlated with psychological morbidity [4]. The use of specific instruction in skin care make up in acne improved the psychological components of the World Health Authority QOL 26 questionnaire in patients compared to controls [5]. The same groups showed no significant differences with the Dermatology Life Quality Index (DLQI). In a study of 936 patients using the Skindex-29, the DLQI and Psoriasis Disability Index, the authors concluded that the Skindex-29 showed higher scores, and was more sensitive to psychological distress in women over 65 years of age. Further work in childhood atopic eczema [6] suggested that the three measuring instruments SCORAD (scoring atopic dermatitis), NESS (Nottingham Eczema Severity Scores) and CDLQI (Children's DLQI) measured differing elements of disease activity and should be regarded as intercalated and not mutually exclusive measurements. This may be related to the different scoring, which can be objective by the physician or subjective by the patient. Patient reported outcome (PRO) measures are increasingly used both for present state assessment and also as a measure of treatment response. Comparisons of DLQI, the Short Form SF-36 and EuroQOL 5D in psoriasis demonstrated that the SF-36 was more valuable in measuring bodily pain and impairments in psychosocial functioning [7]. This sensitivity to mental health issues was true also for different types of psoriasis. Nevertheless, the DLQI identified the significant psychosocial distress in women with vitiligo compared to men [8] when used as the sole measure and specifically for Muslim women compared to men comparing psychological health and sexual activity.

The assessment of the effect of the disease on the family of the patient has been a new use of QOL measures [9,10] in atopic eczema and psoriasis [11]. The demonstration that significant emotional distress occurs in parents and partners is not new but allows the evidence to be used to negotiate for increased resources for family care. It is clear that the different QOL instruments may be general measures of disability; other disease-specific instruments may also vary in the emphasis they bring to assess disability, be it physical or psychological. They may also help to identify gender and ethnic differences in disease and response to therapy [2]. Measurements of psychosocial predictors of disease activity have been used, particularly in management of cancer. The baseline psychosocial predictors of survival in localized melanoma have been estimated with QOL measures and showed shorter survival with anger repression, hopelessness and depression. A better prognosis was associated with reality recognition and minimizing response [12].

QOL assessments are not related to health but to disease and are usually specific to a particular diagnosis. This is very different from the non-medical connotation of the meaning of the phrase which is accepted to relate to a non-ill state of contentedness of 'having a good time'. It has been proposed that in future the QOL of ill people may need to take account of this difference because the patient's abnormal physiological state (cytokines and other mediators) may affect the psychological state and responses to questionnaires [13].

Classification

The classification of diseases serves to describe the speciality and place the categories within the speciality such that they are inclusive and relate to each other to facilitate diagnosis and treatment. The difficulties inherent in a joint classification of diseases within dermatology and psychiatry have been fully explored [1,2]. There are fundamental differences in nosology, morphology, phenomenology and thus diagnostic clustering. Consequently, the psychiatry in psychodermatology has been classified by dermatologists in generalizations because they have limited familiarity with the diagnostic and classification difficulties in psychiatry, for example the nuances of disorders of belief which stretch from an episodic rumination through to a fixed psychotic delusion. For psychiatrists the dermatological lesion such as excoriation may represent a consistent physical sign of self-harm but which for dermatologists may be on the spectrum from pure itchy dermatosis to fabricated and induced disease.

There are two main internationally recognized classifications of psychiatric disorders. The first is produced by the American Psychiatric Association, with disorders defined by diagnostic criteria which describe their essential features. The Diagnostic and Statistical Manual of Mental Disorders (DSM) is modified regularly, the current revision DSM-IV dating from 2000 with DSM-V due for publication in 2012 [3]. The text revision version of DSM-IV gives extra information on diagnostic categories. The second is the current International Statistical Classification and nomenclature system for medical and psychiatric disorder (ICD-10), published by the World Health Organization [4] and in many respects is similar to DSM. However, these classifications are probably not particularly easy for dermatologists to use in everyday practice. There are very good textbooks which are much more user friendly [5]. These classifications are part of the essential practice of psychiatry where the language and symptoms of disease, and thus its subsequent treatment, is to identify, for example, organic syndromes, schizophrenia, bipolar disorders, somatic and personality disorders. But whatever the presenting features to dermatologists it is important to remember that the symptoms are not a diagnosis and therefore should not be assumed to be treatable in the same way. Therefore, for example, dermatitis factitia may be a symptom of depression, personality disorder or an abnormal psychosocial situation. Each requires a different treatment.

The diagnosis in psychiatry has become more dynamic to encompass the present state of a patient's vulnerability according to the type and intensity of stress factors. These dimensional diagnostics [1,6] are no different in concept from assessing an atopic and their eczema activity at any one time.

The classification is necessarily psychiatrically based because the treatment is primarily directed to the mental disorder and not the dermatological one. However, the classification crosses the borderlines of those divisions between the psychoses, thought and mood disorders, and the classical neuroses representing the ultimately inappropriate reactions to stress in emotion and behaviour.

This classification is therefore pragmatic with an emphasis on usefulness for dermatologists and modified from the Vienna Diagnoses Schedule for Psychodermatological Disorders [1].

1 Psychiatric disorders without significant dermatological disease
- **1.1** Delusional syndromes
  - Parasitosis
  - Smell
  - Impregnation and contamination
  - *Folie à deux*
  - Other hypochondriasis, e.g. so-called Morgellons
- **1.2** Disorders of awareness of the body
  - Phobias and obsessive compulsive disorders
    - Disorders of body image: body dysmorphic disorder (BDD) (synonyms dysmorphophobia, dermatological non-disease)
    - Disturbance of body size and eating, e.g. anorexia nervosa, bulimia
    - Phobias, e.g. mole phobia, venereophobia, wart phobia, erythrophobia, electrophobia and steroid phobia
    - Obsessive–compulsive behaviours, e.g. hand washing, hair plucking
    - Atypical pain disorders, e.g. glossodynia, vulvodynia and scrotodynia, anodynia
    - Pruritis sine materia
    - Other dermatologic hypochondriases: botoxophilia, tanorexia, cyberchondria

2 Mental disorders and dermatological disorders
- **2.1** Classical psychosomatic disorders
  - Dermatoses in which emotional precipitating or perpetuating factors may be important
    - Vesicular eczema of the palms and soles
    - Atopic dermatitis
    - Seborrhoeic dermatitis
    - Psoriasis
    - Some cases of localized or generalized pruritus
    - Alopecia areata
    - Aphthosis
    - Flushing reactions and rosacea
    - Hyperhidrosis
    - Urticarias
- **2.2** Dermatoses primarily factitious in origin
  - Dermatitis factitia
  - Artefact by proxy
  - Witchcraft syndrome
  - Dermatological pathomimicry
  - Dermatitis simulata
  - Malingering
  - Compensation neurosis
  - Münchausen's syndrome
  - Fabricated and induced illness (Münchausen's syndrome by proxy)
  - Deliberate self-cutting
  - Self-mutilation

2.3 Dermatoses in association with harmful habits and compulsions
- Lichen simplex
- Neurotic excoriations
- Prurigo nodularis
- Acne excoriée
- Hair plucking
- Trichotillomania
- Trichophagia
- Nail destruction
- Onychotillomania
- Lip-licking cheilitis
- Knuckle biting

2.4 The psychogenic purpura syndromes
- Autoerythrocyte sensitization (Gardner–Diamond syndrome)
- Autosensitivity to DNA
- Psychogenic purpura (idiopathic)
- Stigmata

2.5 Disorders of neglect of self-care (synonym Diogenes syndrome)

2.6 Drug-dependence syndromes
- Alcohol-related syndromes
- Substance abuse

2.7 Mental disorders due to dermatological treatment
- Cortisone psychosis
- Interferon depression

2.8 Dermatological disorders due to psychopharmacological treatment
- Lithium-induced psoriasis
- Tranquillizer hyperpigmentation
- Anti-depressant hyperhidrosis

2.9 Dual non-associated disease, dermatological and psychiatric disorders
- Skin cancer in patients with major psychosis

3 Dermatological patients with psychic symptoms not amounting to a disorder
- 'Troublesome patients'
- Dysthymic responses to illness
- Cosmetology associated worries

4 Group and mass population reactions
- Sick building syndrome
- Epidemic hysteria

Disorders of dermatological beliefs [1–10]

The classical reports of patients who erroneously believed that they were infested by parasites were first reported by Thibierge in 1894 [11] and reiterated by Perrin in 1896 [12]. The 'Nervodermies Parasitophobiques' as they were called perhaps led to the misnomer that these patients suffered from a phobia which is an irrational fear and anxiety reaction when what they really suffer from is a disorder of thought and belief.

The many reports and reviews since Ekbom series in 1938 [10] have emphasized the psychiatric heterogeneous nature of the cases [2–8]. The heterogeneity of the group was recognized by Lyell [13] who commented that it is hard to know where eccentricity ends and psychiatric illness begins. Musalek [3,4] and others [5,6] stressed the importance of the nosology and classification which is critical when most of these patients are presenting to dermatologists.

The content of this form of hypochondriasis (or excessive preoccupation with health) is usually a preoccupation with infestation, especially parasites, but may take the form of a belief about smell, halitosis, or impregnation. In so-called Morgellon's syndrome (see below) fibres are extruded from the skin. The intensity of the belief depends on the psychopathology of the hypochondriasis. The expressed belief is a symptom and needs to be positioned within a diagnostic psychiatric classification to make a judgement about treatment and prognosis.

A true primary delusion is a judgement made by others about a false unshakeable belief which arises from internal morbid processes in a patient and which are not amenable to logic and are out of keeping with the person's educational and cultural background. Primary delusions can be an isolated phenomenon as in a monosymptomatic hypochondriacal psychosis as described by Munro in the cases of delusions of parasitosis [9] or as part of a broader psychosis for example schizophrenia which has other features such as paranoia. A secondary delusion more commonly occurs with affective disorder such that the belief is understood in terms of the underlying depressed mood. The nihilistic delusions may influence the patient to believe that her skin is rotting and infested.

Depressive thinking to a lesser degree may take the form of depressive ruminations which are insistent recurring thoughts which the patient may try to resist because of its compulsive nature. Patients may therefore say that they 'keep thinking they (might) have parasites'. To some extent the belief is shakeable and amenable to reason. Similarly obsessional ruminations about infestations arise as recurrent thoughts but without depressive moods.

Ideas of infestation, smell or impregnation may arise as an overvalued idea. This is more commonly seen as an extension of an acceptable comprehensible thought pursued by the patient beyond the bounds of reason [1]. It is distinguishable from an obsessional belief and a delusion because the former is subjectively felt to be 'senseless' and the latter qualitatively different with irrational meanings given to events. An overvalued idea is an isolated notion, in this case ideas of infestation associated with strong affect and an abnormal personality. These patients with beliefs of infestation have a degree of conviction similar in quality to politi-

cal or religious zealotry. They assert that their ideas 'stand to reason'.

Some anxious mildly depressed patients with psychosocial isolation may form the notion they have an infestation as a way of interpreting patients' symptoms provoked by an itchy dermatosis. These ideas are usually shakeable and the patients persuadable about the error of their belief.

Delusions of parasitosis [4–8]

Synonyms
- Beliefs of infestation
- Delusions of infestation
- Psychogenic parasitosis

Definition. The patient with delusions of parasitosis (DP) has an unshakeable conviction that his or her skin is infested by parasites (this must be differentiated from parasitophobia—the *fear* of becoming infested).

Table 64.1 summarizes the secondary organic causes of DP [14]. Delusions of perception may follow disease in the non-dominant hemisphere, thus DP are sometimes seen in patients after a cerebrovascular accident involving that side of the brain. Similarly, DP may be part of the picture of dementia and should be considered when examining the elderly patient. DP have also been described in pellagra, vitamin B_{12} deficiency, following coronary bypass surgery, as a side-effect of phenelzine and in severe renal disease. Delusions of parasitosis in a young adult suggest illicit exposure to recreational drugs, in particular amphetamine, cannabis (skunk) or cocaine [15].

Table 64.1 Organic medical disorders associated with delusional parasitosis.

Neurological
Cerebrovascular disease
Dementia and neurodegenerative diseases
Parkinson's disease
Huntingdon's disease
CNS tumours
Head injury
Encephalitis
Meningitis
Multiple sclerosis
Learning disability

Cardiovascular disorders
Arrhythmias
Heart failure
Coronary artery bypass

Renal disease
Chronic renal failure
Dialysis

Liver disease
Hepatitis

Endocrine disease
Diabetes mellitus
Hyperthyroidism
Hypothyroidism
Panhypopituitarism
Hypoparathyroidism
Acromegaly

Nutritional disorders
Pellagra
Folate deficiency
Vitamin B_{12} deficiency
Anorexia nervosa

Infectious diseases
Syphilis
AIDS
Tuberculosis (pulmonary)
Leprosy

Malignancy
Breast cancer
Colon cancer
Lung cancer
Lymphoma
Chronic lymphatic leukaemia

Substance abuse
Amphetamines
Cannabis
Cocaine
Ecstasy
Opiates

Medicines
Corticosteroids
Ciprofloxacin
Mefloquine
Pemoline
Phenelzine
Pargyline

Detailed analysis of these cases cannot always determine whether the aetiology is primary delusional, secondary to depression or a toxic effect. Huber [16] has proposed that decreased striatal dopamine transportation (DAT) corresponding with an increased level of extracellular dopamine would account for the aetiology in primary DAT inhibitors such as cocaine, pemoline and amphetamine. Several other associated causes of secondary DAT dysfunction, for example Parkinson's disease, brain injury and HIV/AIDS may also be relevant.

It is particularly important to exclude the possibility of a real infestation. In 6% of one series, patients developed DP following real infestation [13] and 3% had been in contact with an infestation, usually scabies, at some time in their life. For 12% this was part of a delusion shared with another member of the family (*folie à deux*), see below.

Pseudodelusory syndromes have been recorded with thrips infestation [17], bird mites and fir tree pollen (personal observations).

Incidence. Patients with DP are rare but the true prevalence is unknown. The condition affects both sexes equally below the age of 50 years, but after that age three times as many women are affected as men [3,8,18]. Although patients with delusions of parasitosis are relatively easily recognized, it is possible to spend a lifetime as a dermatologist and never see a new case. The average age of onset varies from 55 to 68 years; at this age the patient is more likely to be female. The age group 20 to 40 years with DP should be regarded with the utmost concern for they may be regular users of recreational drugs especially cocaine and/or amphetamines, particularly crystal meth and ecstasy (methylenedioxymethylamphetamine). The symptom may be the earliest sign of a major psychotic illness in young patients [15].

Clinical features. The presenting episode of DP to the dermatologist may be extremely variable. It can be as an urgent appeal from the primary care practitioner to see a patient with an established delusion of infestation because they are disrupting everyone's life with their constant demands. Patient and relatives may be regular and vociferous visitors to the emergency room refusing to leave until 'something is done'. Colleagues in other specialities, such as infectious diseases, public health and tropical medicine, call in despair and exasperation to take over the patient's care. Fellow dermatologists in public and private practice are relieved if they can refer on to a psychodermatology team. By contrast, the patient can present with an ill-defined, persistent itching with no immediate, obvious delusional thoughts. These may only become apparent on closer questioning.

In the most established case the patient has consulted a series of specialist services to eradicate the imagined infestation. The family doctor is consulted repeatedly for even 'stronger' medicines to treat the 'bugs', the public health authorities called on many occasions to disinfest the home, and the veterinary services recruited to scrutinize and treat pets as a *proxy folie* [19]. Eminent university personnel may have been consulted—both medical, in infectious disease departments, and scientific, in zoology specialities. Specimens are sent to international institutions such as the British Museum for the ultimate examination. By the time the patient reaches the clinic there is always an inevitable degree of frustration, anger and impatience which makes the first consultation both difficult and vital. The situation can be complicated by previous consultations where unwittingly various complexities have been added. In the pressure of the situation some physicians and scientists claim to see an offending organism, others give a 'new treatment' to get the patient out of the consulting room, and some collude with the patient and suggest they can see the parasite in the skin and then refer to 'someone who is more expert'.

The patient, usually female, is tense, expectant and beneath the simmering frustration has a certainty of demeanour. The presenting symptoms are variable and not consistent amongst patients. It may be a feeling of creeping, crawling, burrowing, biting, burning and stinging. Some speak of a sensation in their skin as though an insect or worm is crawling around, followed by a prolonged and elaborate description of the pathway the organism is taking. In addition, elaborate life cycles are constructed involving the different 'stages' of maturity. This agent may not be confined to the skin but also involve the genital, oral [20] or ocular [21] areas. They may describe and draw the insect or worm concerned but can describe the infestation as invisible or dissolved in orificial secretions.

No obvious skin disease may be present, but excoriations are usual and can be both extensive and very destructive (Fig. 64.1).

These are produced in an attempt to extricate the organism using fingernails to produce deep excoriations and resultant scarring. Most resort to instrumentation with nail files, scissors, needles, penknives, tweezers and nail clippers. Significantly, the most disturbed patients use surgical implements, handicraft knives and chemical corrosives which inflict significant damage, occasionally endangering their eyesight [22]. These follow attempts by the patient to extract the 'parasites' and are therefore not fabricated lesions but produced in an apparently legitimate attempt at cure. Usually, the patient will bring samples to the clinic but not always offer them unless asked directly. Commonly they reveal a small container, such as a matchbox or pill container enclosing their insects. More often they produce a sealed plastic bag or Ziplock (Fig. 64.2). Other samples which have been brought are collections of scales and crust, sellotape strippings of skin, folded elastoplast impregnated with debris and liquid samples collected from orifices. Debris collected as it 'falls' from the body or clothes, collected in the bath or shower tray and gathered at the hairdresser can amount to bags of detritus. On microscopy these offerings are usually found to be fragments of skin and hair, samples of fabric, and coagulated elements of serum, dust and dirt. The samples may include actual organisms such as ants, flies and sundry isolated fleas.

The purification rituals become rapidly established and are more frequent and elaborate. Patients are compelled to cleanse the skin and their environment with ever-increasing zeal. Their skin may smell of organic solvents such as benzyl benzoate or horticultural insecticide spray and the hands of bleach and disinfectant. A secondary general or localized, chemically induced insult dermatitis is a feature. This itchy dermatitis is a further reinforcement of the delusional belief. Clothes and soft furnishings are jettisoned, rooms cleared and mothballed, daily clothing and towels limited to two sets, one of which is used, the other in a sealed bag, after stringent cleaning, ready for use. These details are usually kept

secret but as an important indicator of disease severity discreet enquires need to be made.

In 12% of cases delusions are shared with another individual [2,9,23], so-called *folie à deux*. This is defined in DSM-IV as a delusion developing in an individual in the context of a close relationship with another person, who has an established delusion. This does not refer to a close partner or friend who believes the patient's account but who crucially does not imagine they too have the infestation. The separate phenomenon of induced pruritus is a common sympathetic accompaniment in those close to the patient but does not mean induced secondary delusion. Again, this phenomenon is reported more often in women [23] and therefore the relationship between subjects is more often between sisters (34%), wife and husband (20%) and mother and child (20%). This contrasts with that reported between brothers (9%) and fathers and sons (2%). The disorder may rarely involve most or even whole families.

Diagnosis. Although it is unlikely the first task is to exclude scabies, bed bugs, insect mites, fabric or fibreglass impregnation. Rarely, onchocerciasis may confuse the unwary although the rash is usually prominent. In most cases the history, clinic behaviour, physical examination and presentation of specimens makes the diagnosis of DP obvious. It is also important to rule out underlying secondary organic disease, although this is rare. A clinical examination will exclude most organic disease but full biochemical investigation is advisable and most patients are happy to have 'tests'. Musalek *et al*. [3] have emphasized the importance of establishing the psychiatric diagnosis before instituting treatment. However, presentations in patients with secondary delusions as part of a depression or dementia may present in a more subtle fashion. The nature of depression may make the patient less communicative, and more guilt ridden. A short inquiry about features of depression can clarify this element of the diagnosis. Questions about widowhood, the empty nest syndrome, social isolation because of physical disability or retirement can be folded into the history. There may be a need to actively enquire about beliefs of infestation in a patient who complains of itching alone. Clinically, there may be a need to distinguish between a true delusion and an overvalued idea [3,4]. This latter is an acceptable comprehensible idea carried on beyond the bounds of reason.

Management. It should be remembered that suicide is an ever-attendant risk in these patients [1,4]. The management of patients with delusional parasitosis is always difficult. The basis of the consultation is to change the agenda from one of dermatological infestation as seen by the patient to one of psychiatric intervention. The shakeability of the belief depends on the psychiatric assessment. It is therefore essential to maintain a cohesive doctor–patient relationship. The first consultation is crucial. It is important to look, listen and be empathetic; to defuse the anger and tension but never to collude with the belief, nor to mention the parasites directly. It is preferable to mention 'the problem', 'the itch', 'the discomfort'. The full consultation process should be pursued, with adequate time given for the history, and proper care taken in the physical examination. All samples should be examined at the time and under the microscope. If none are volunteered encourage them to bring or send examples. Report truthfully what you see and invite the patient to look also. If you are perfunctory about this the patient will be less likely to continue with the same cooperation. Neither is it helpful to say directly on the first visit that he or she has a mental problem.

Listen politely without interruption and resist the temptation to question the singular interpretation of events. This non-judgemental acceptance of events does much to reduce the often fevered nature of the first consultation and reduce the isolation and fervency of the patient's feelings. Do not get drawn into the criticism of past consultations of others. This is an opportunity to reassure them that the consultation is 'new' with no strings but also gives the time when an assessment of the psychiatric state can be made (see above), particularly the presence of features of depression.

If the patient has been told previously that they are 'imagining it' they need to be reassured that to them the symptoms are real and that you recognize this. This does not imply an alliance on thought content. It is necessary to say that you have seen this problem before, that sometimes the reason for the symptoms is not always clear. After two to three visits and examination of more samples both in the consulting room and the laboratory there comes an opportunity to discuss further the 'whole illness', meaning the skin symptoms and the distress, anxiety and depression. If there is a history of using recreational drugs this needs mentioning also. At this time it is also useful to remind the patient of the dominance this illness plays in their life and the need to treat them even though there are differences in interpretation of the sensations. Some psychodermatologists have suggested that perhaps the sensations remain in the skin in very sensitive and aware individuals even though the precipitating event has receded. These feelings can be more intense and sometimes out of control the more the illness 'gets you down' and makes you depressed. Explain that this is an illness that torments otherwise sane individuals and that this does not make them 'irredeemably crazy'.

It is at this stage that there are indications as to the shakeability or not of the belief. For those with a recognized anxiety, social isolation or depression it is possible to discuss the next stage of psychotherapy, or antidepressants such as doxepin, citalopram or venlafaxine. Referral to a psychiatrist can be offered for consideration either then or in the immediate future. The very difficult problem of the truly deluded patient with an unshakeable belief needs the help of a psychiatrist, ideally as part of a psychodermatology team or failing that a liaison psychiatrist who is familiar with the work in the dermatology department and can see the patient on site. The failure and non-attendance rate for paper and distant referrals to psychiatry is enormous and it is better to continue attendance at the skin department in the expectation that the situation may change under the influence of relatives and input of a primary care physician [4,5].

A surprising number of patients will accept medication to help their distress even though it is not directed at the eradication of the 'parasites'. If broached in terms of using a medication which 'has helped others before' and 'getting started to help in some way' you can suggest an antidepressant if there are significant signs of depression but it is mandatory to refer to a psychiatrist if there is any indication of risk of suicide [24]. Initially, it is often best to admit the patient to hospital. This reduces pressure at

home on other family members and ensures compliance with medication. A psychiatric colleague can more easily be asked to see the patient in the dermatology ward. The further management is ideally a joint consultation with liaison psychiatry but the inevitable difficulty is to convince the patient that this is a psychiatric problem.

The response to pimozide is often good in these patients and the initial dose, 2 mg, is increased weekly by 2 mg increments as necessary to a maximum of 12 mg daily. On higher doses, patients may develop extrapyramidal symptoms which requires addition of benztropine 1– 2 mg up to four times per day. In addition, with higher doses of pimozide there is a definite risk of ventricular arrhythmias and other electrocardiogram (ECG) abnormalities such as prolongation of the Q–T interval and T-wave changes. An ECG should be performed before pimozide therapy, and the drug should not be given to patients with a prolonged Q–T interval or to patients with a history of cardiac arrhythmia. Patients taking long-term pimozide should have an ECG at least once a year and if the Q–T interval is prolonged, treatment should be reviewed or withdrawn [18]. Moreover, concurrent treatment with other antipsychotics, tricyclic antidepressants and drugs that prolong the Q–T interval, such as the antihistamines terfenadine and astemizole, antimalarials, or drugs such as diuretics that alter the electrolyte status, should be avoided. Hypokalaemia may predispose to the cardiotoxic effects of pimozide and care should be taken in patients with hepatic or renal dysfunction.

Many physicians, including the authors, have found that the usefulness of pimozide is outweighed by the possible complications. Other equally effective treatments exist with the availability of other antipsychotics. The so-called atypical antipsychotics have a better side-effect profile and in case reports are effective. Alternative effective therapy with a better side-effect profile includes sulpiride 200–400 mg per day and amisulpride [6], which are selective dopamine antagonists. Extrapyramidal side effects are rare with no risk of arrhythmias. The antipsychotic respiridone is both a dopamine blocker and a serotonin antagonist and has proved of further use in doses of 1–8 mg per day [24]. Olanzapine has a higher affinity as a serotonin blocker than a dopamine antagonist and can be effective in surprisingly small doses. The side-effect profile is significant in high doses, including weight gain and disturbed glucose tolerance. When compliance is a problem, depot neuroleptics such as haloperidol may be used [6], but these are best reserved for specialist psychiatric use.

Patients frequently defect from follow-up clinics with the consequent risk of relapse. Therefore strenuous efforts should be made to maintain contact either via the general practitioner or community psychiatric services.

Olfactory delusions [1–3]

Synonyms

- Delusions of smell
- Olfactory delusional syndrome
- Olfactory reference syndrome
- Bromidrosiphobia

This complaint is important for dermatologists because they are more likely than any other speciality to see patients who complain of unpleasant body odour. This is usually assumed to be related to either sweating or sebum excretion. The cultural significance of body odour varies with ethnic group but an excessive or unpleasant body smell carries with it social and psychological significance and judgements.

Patients who do have intense body odour because of self-neglect, beliefs of natural existence without washing or phobias about washing are easily identified. There are patients who smell because of disease [4]. Nevertheless those who emit a strong smell, whether it be for the reasons above or from wounds, exfoliative skin or contaminated dressings, will suffer from the self-righteous opprobrium of a section of society such that they will feel guilty and be stigmatized.

As with patients with erroneous beliefs of infestation, the false belief about body smell can represent various psychiatric aetiologies [3,5,6]. As a monosymptomatic hypochondriacal delusion it may be difficult to differentiate an olfactory hallucination from a delusion as this is also a symptom of a schizophrenic illness. Men are more likely than women to develop this belief in a ratio of 4–5:1 [3–6]. Schizophrenic patients are more likely to be young men with severe, disabling beliefs accompanied by personality deterioration and paranoid features [6]. Others with beliefs of delusional intensity have compensatory, excessive cleansing rituals and associated social avoidance patterns which may be a monosymptomatic delusion or body dysmorphic disorder (see below) of delusional intensity. In depression the symptom is an expression of feelings of worthlessness and negative self-evaluation and accompanied by the other vegetative signs of sleep, appetite and behaviour alterations. Patients may voice an association between the unpleasant odours and disgust or guilt, especially of a sexual nature.

The patient 'knows' that they are emitting a foul odour. They believe that the origin of the smell is usually flatus and may have seen a gastroenterologist. Occasionally, they believe that foul sweat is produced in excess from body folds and orifices. Most patients complain that the smell comes from the groin or sometimes the armpit. Those with paranoid features believe that other people avoid them and talk about them with evident disgust [1,6]. A subgroup of patients complain of unbearable halitosis and plague dentists. This delusion is commonly related to a chronic avoidant paranoid personality trait [7].

Organic syndromes should be noted. Delusions of smell have been associated with cerebral tumours, epilepsy, alcoholism and substance abuse [8,9]. Konuk [10] also showed that frontotemporal hypoperfusion could be a feature. Psychotherapy may occasionally be successful but antidepressants and antipsychotics are indicated, as for delusions of parasitosis.

Morgellons syndrome [1,2]

In 2002, a biologist whose 2-year-old child developed sores on the skin 'discovered' that the multicoloured fibres coming from her child's lesions were undiagnosable by the multitude of physicians she consulted. The Morgellons were described by Sir Thomas Browne in 1674 as a population in the Languedoc, one of whose characteristics was the development of a hairy back. Nevertheless this misnomer was coined to name a syndrome, set up a research foundation, raise funding and generate vast media and Internet interest.

The phenomenon comprises:

- Sensations of crawling, stinging and biting under the skin
- Sores that do not heal
- Fibre-like filaments, granules and crystals that appear on or under the skin lesions
- Joint and muscle pain and fibromyalgia
- Debilitating fatigue
- Cognitive dysfunction, poor concentration and memory.

Most dermatologists recognize the familiarity between this constellation of symptoms and patients with delusions of parasitosis but more particularly of delusions of impregnation and extrusions who have presented more rarely. An examination of the Internet website shows the disparate and heterogeneous nature of the respondents, similar to the websites dedicated to the treatment of non-identifiable parasites. It has been described as a rapport-enhancing term for delusions of parasitosis [2]. Researchers at the Morgellons Foundation have suggested Lyme disease is to blame as well as agricultural filamentous yeasts [3]. The US Center for Disease Control has set up an independent study to evaluate the phenomenon. Treatment responses to pimozide and risperidone have been recorded [4].

Disorders of body awareness

Body dysmorphic disorder [1–3]

Synonyms

- Dermatological non-disease
- Dysmorphophobia

In 1886, Morselli [4] described dysmophophobia as a distortion of psychological body image and more recently 'dermatological non-disease' [5] has been used to describe patients who are rich in symptoms (especially in areas important in the body image) but poor in signs of organic skin disease [1,2]. All dermatology clinics contain these distressed patients whose chronic attendance is a reflection of their impaired family, social and occupational functioning. This disorder is defined in DSM-IV as body dysmorphic disorder (BDD) a preoccupation with an imagined defect in appearance; if a slight defect is present the person's concern is markedly excessive. In DSM-IV (TR) the revision separates the

distress caused by the apparent physical defect (B1) from the impairment in social, occupational and domestic functioning. Although BDD is classified as a somatoform disorder, there is a variant in which the belief is of delusional intensity and as such is regarded as a psychotic disorder and may have been included as another manifestation of monosymptomatic hypochondriacal psychosis [6]. There is significant evidence to classify BDD as one of the obsessive–compulsive disorders [2,7] based on similarities between OCD and BDD, the increased rates of OCD-related disorders in BDD [8], and OCD samples which show increased rates of BDD [9]. Those who disagree would point to the fact that insight is poor in BDD not only among the delusional type but also the non-delusional [10] whereas insight is usually good in OCD.

Prevalence. This condition was originally thought to be uncommon, but it is now clear that concern about the body image and some particular facet of self is remarkably common. The prevalence in the general population has been difficult to measure and therefore results vary from 12% [2] in a community, whilst a study of German students revealed a prevalence of 5.3% [11]. A point-prevalence study of a community sample of women in the USA showed a frequency of 0.75% [12]. A very thorough, large point-prevalence study found a prevalence of 1.7% of the population conforming to BDD criteria [11]. Previous studies with estimates of 0.7% were confounded by selective populations, for example students or geography. This is more often a female disorder, though marginally so with a female:male ratio of 3:2 to 2:1 [1,2,10,11]. Studies of body dissatisfaction not amounting to BDD suggest that 27% of men and 40% of women are unhappy about at least one part of their body [2,9,11]. In dermatology clinics, 8.5–12% have diagnosable BDD [13,14] and 9% of mild acne patients fulfil the criteria for BDD. Aesthetic clinics show a prevalence of 6% [9,15] for BDD with 18% at a subthreshold level. In a plastic surgery clinic those who conform to BDD criteria vary from 3.2 to 20% [2,9]. These rates may be underestimates because BDD is often a secret illness, revealed only to relatives or to physicians when under severe duress. Grant *et al*. [16] reported that 13% of psychiatry in-patients had BDD symptoms but these were only demonstrable on direct inquiry.

Aetiology. Theories on the aetiology of BDD reflect the knowledge of disease characteristics and treatment response. The cognitive behavioural theory suggests that sufferers from BDD have self-defeating thoughts, cognitive distortions and aberration and destructive beliefs about themselves and their appearance [17]. The development of selective processing of emotional information about body image, physical appearance and interpersonal contact may be related to anxiety disorders and social phobias. BDD patients exhibit more perfectionist thinking and maladaptive attractiveness beliefs [18] and it is assumed that these are aetiological rather than symptomatic [18]. In support, it has been suggested that childhood abusive experiences may result in body dissatisfaction, bodily shame, low self-esteem and body image distortion [19–21].

Neurobiological theories relate BDD to acquired brain abnormalities and parietal lobe function. Neurochemical and psychopharmacological evidence suggests that abnormal serotonin metabolism also contributes to BDD [22]. By contrast, social and cultural influences are assuming an increasing importance of personal bodily appearance because of the pressures that the perceived concepts of beauty and the quest for perfection play at present in public and media-driven societies. These pressures shape the attitudes of both women and men. Women are socially driven to view and treat themselves as objects [19] whilst men are pushed towards an often unattainable body image, the Adonis complex [23] of muscular perfection even though they use illegal oral steroid supplements. This sociocultural model opens up further therapeutic pathways, particularly postmodern narrative therapy [19].

BDD is often co-morbid with other mental disorders. For instance depression may occur in 60% and a lifetime rate of up to 80% has been reported [1,24]. The depressive symptoms may be subclinical but are revealed on direct questioning. An obsessional premorbid personality is not unusual [2,8] and co-morbidity with obsessional compulsive disorder may be found in 30% [2,9]. Dysmorphophobic symptoms in a teenager or adult may be the presentation of schizophrenia, while in an elderly patient dementia should be considered. Co-morbid psychiatric conditions have also included social phobia, that is fear of a negative impact (37%), substance abuse (40%), and avoidant personality disorder [10,25]. In a study of patients with anorexia nervosa, 39% were diagnosed with co-morbid BDD unrelated to concerns about weight. These individuals had higher levels of delusionality and lower levels of social functioning than those with eating disorders alone [26]. There is usually no evidence of any underlying organic disease.

Clinical features. The problem of BDD is disturbing for dermatologists because their clinical expectations are confounded and they are disenfranchized from participation because there is little or nothing to see. For the patient there exists a state of stigmatization and all the personal dread, loathing and discontent that goes with these insistent compulsive thoughts.

Affected individuals are more often solitary, unmarried or divorced. As a whole they socialize poorly and do not like contact with other people [1,2,10]. Those with severe symptoms are more likely to be unemployed. Their symptoms may appear after severe emotional, especially marital, or sexual problems.

Most patients are in their third decade although reported ages are from 5 to 80 years. The duration of symptoms is long, from 11 to 18 years [8,10]. Women are affected slightly more often than men [2,11] although referral sources may affect the statistics. Dermatological non-disease presents with symptoms that appear to have gender differences. For women the sites of dominance were skin, mainly face, breasts, hair, nose and stomach, whereas men presented with concerns about hair (usually thinning), nose, ears, genitals and body build [27]. Facial symptoms include complaints of excessive redness, blushing, a burning feeling, scarring, large pores, excessive facial hair and facial greasiness. Scalp symptoms include a feeling of intense burning, unremitting by day or night, and excessive hair loss. Those patients with facial and scalp problems are more often female than male, but those with perineal

symptoms are more likely to be male than female. Perineal symptoms in males include complaints of an excessively red scrotum, discomfort in the genital area, often spreading to the anterior thighs making the wearing of clothes uncomfortable. This is described rather cumbersomely as the dysthaesic penoscrotal syndrome [28]. Women had more concerns about perceived flaws than men, sometimes up to four areas in 40%, the effect being additive with time. Women develop BDD earlier than men, although men more often show severe delusional forms [29].

A consultation with a patient with dermatological non-disease always takes much longer than with a patient with organic disease. The content of the consultation is dominated by complaints of ugliness, unattractiveness and irreconcilable deformity. It is important to remember that this long consultation can consume vast amounts of time to no great purpose unless it is used to assess, firstly, the effect of personal behaviours induced by the illness on life quality and, secondly, the impaired functioning of the patient's daily social, family and work life. Their thoughts are dominated by the abnormality for up to 8 h per day, the distress is intense, self-esteem poor and insight minimal. They perform repetitive, almost compulsive, behaviours with excessive grooming, repeatedly applying makeup to hide the 'defect', changing hairstyles and altering clothes to disguise the problem. Inappropriate dress such as veils, or coats with high collars or long gloves on hot days are not unusual. Dark glasses, huge wigs and excessive tans are other devices used to hide the defect; 'mirror gazing' is irresistible and time-consuming as part of continual checking behaviours [3]. Patients are driven by the desire to know what they look like, a desire that is made worse if they resist the urge. BDD patients invariably feel worse after mirror watching but cannot resist looking in other reflective surfaces such as shop windows, chromed surfaces, cutlery and shiny CDs. This continual mirror watching may be to show the 'best face' to the public and avoiding the feared adverse attention. Other activities and behaviour may be stimulated by these beliefs with diet regimes, the purchase of enormous quantities of beauty products and the seeking of unending aesthetic treatments. Muscle dysmorphia describes men who use illicit anabolic steroids and obsessive weight training to develop their body, so called 'bigorexia'.

Patients with BDD touch, tease, adjust, squeeze and pick their skin. The picking may become pathological, intense and time consuming. The episodes begin as a minor peel and pick at a small lesion and progress to a prolonged 'binge'. Some confess to eating the scabs. After hours the damage done is so appalling that the patient can no longer go out, and is more distressed than before. When picking reaches this stage the effect on family, social and work life is significant. At first, the patient arrives late for work, has significant absences for toilet room breaks, and then eventually misses days at work. They may become unemployed. An increasing reclusiveness curtails social life and family, friends and partners become estranged. Alcoholism and drug abuse may follow.

Patients with dermatological non-disease are 'doctor shoppers' and will have often seen many doctors about their many problems over the years. An individual patient is likely to return to the clinic within a few minutes of being seen and may repeatedly telephone the doctor asking questions that have already been answered many times in the immediate past. Uncommonly, the delusional type of BDD gives rise to familial BDD where a parent imposes a delusional idea upon a child who in turn develops BDD [30] or even more rarely the patient believes that their child has a bodily defect, BDD by proxy [31].

There is a definite risk of suicide in patients with BDD [1,8–11]. High rates of suicidal ideation (78%) and suicide attempts (27.5%) in some series may have been because of co-morbid factors such as lifetime depression or eating disorder [8,29]. Significant but lower estimates of ideation (20%) and attempts (7%) were found by Reif *et al*. [11]. They also found that a group with subthreshold BDD features, that is body concerns not reaching BDD criteria, had a 1% rate of attempted suicide. A prospective study [32] over 4 years in 185 subjects with BDD showed 58.7% reported suicide ideation, 2.6% attempted suicide per year and 0.3% completed suicide per year. The risk is very real. A transcultural study of BDD [33] showed no significant variations in features between Brazilian, North-American and European populations.

Dermatological and plastic-surgical treatment [9]. Most patients with dysmorphophobia perceive the solution to their problems as dermatological, aesthetic or plastic-surgical treatment. They 'shop' between doctors to find one who will perform the procedure which is the answer to their problem, and so come to haunt dermatologists and plastic surgeons rather than psychiatrists. Some patients demand repeated medical cosmetic treatments such as botulinum toxin, so called botulophilia, and repeated face peels. In a series of 130 patients, it was found that 30% had received previous cosmetic surgery, with a mean of 2.0 ± 1.3 procedures and as many as six procedures had occurred in individual patients. Two international studies reported rates of 6.3 and 9% BDD amongst cosmetic surgery patients [9,15]. A perfect cosmetic result may be perceived by a depressed, dysmorphophobic patient as worse than the situation before surgery. In a large study 91% of patients reported no improvement in symptoms [9] and furthermore, 81% of patients with body dysmorphic disorder were either dissatisfied or very dissatisfied with their consultation and results of surgery [8]. A study of patients who had either BDD or sub-BDD concerns showed that after 5 years most were dissatisfied with the operative result despite earlier, immediate postoperative satisfaction. In addition, half of those with sub-BDD concerns developed full BDD criteria despite operative intervention [34]. If aesthetic or plastic surgery is planned in this group of patients it is very important to have careful preoperative psychiatric assessment. Those contemplating surgery should remember that some patients with body dysmorphic disorder are angry and easily progress to litigation. One-third of aesthetic surgeons [35] had threats of legal action from BDD patients. More crucially, 2% of BDD patients threaten their physicians and surgeons physically and at least two cosmetic surgeons have been murdered by patients with BDD. Photography before and after surgery is important to refute legal claims objectively. However, plastic surgery in carefully selected cases may be deemed helpful, assessment with preoperative questionnaires may temper the surgical decision. There is always a risk that the patients may then move their preoccupation to another part of the body.

Diagnosis [1–3]. BDD is often diagnosed late, up to 11 years after initial symptoms. This is possibly because patients are reluctant to disclose their distress, shame and embarrassment. The clinical clue for dermatologists may be a persistent return to the clinic for a harmless, small lesion or presentation as a persistent picker. These patients make up a large proportion of the querulous and disenchanted complainers. Most experienced dermatologists have a well developed 'BDD radar' but the trainee will always be vulnerable to the demands of these patients. BDD should be asked about; brief questionnaires to expose BDD-related thoughts and behaviours [2,3] and a longer structured instrument, the BDD Examination [35], which includes measures of severity, are available.

Management. The management of patients with dermatological delusional disease is always difficult and should not be done by the inexperienced. The most difficult task is to make the transfer from a primary dermatological illness of perceived flaws to one which requires psychiatric care. This is not unlike the management of primary skin delusions. There is nothing to be gained by talking about either the non-existence or minimal nature of the lesions. The way forward is to talk about the presentation of *illness* about which both patient and physician are agreed. Demonstration of the distress, disability and impairment of function as a consequence of the illness will show an empathetic response. The next step is to talk about differences in interpretation which does not invalidate any of the profound distress and dysfunction this has caused. It is valid to explain that nobody knows why the patient, their partners and friends and physicians see the problem differently, but the aim is to use treatment which has been proven to help. There are a number of useful texts and websites which can serve as 'homework' for patients between consultations [3].

Treatments that have been shown to be successful are pharmacotherapy with specific serotonin reuptake inhibitors (SSRIs) [1], or psychological treatments such as cognitive behavioural therapy, or a combination of both [21].

Treatment with SSRIs. Early open studies showed that nearly 50% of patients may respond completely or partially to fluoxetine or clomipramine, whereas there was only a 5% response to all other medications. A systematic review of trials [36] confirmed that over 60% of patients have a significant improvement in symptoms. It is important that the medication be continued long term, as discontinuation precipitates relapse in 80%. All SSRIs are equally effective and the choice depends on tolerability. Those most studied have been fluoxetine, fluvoxamine and citalopram. A randomized, controlled trial of fluoxetine showed it was superior to placebo [1]. In many patients there is a significant improvement in the social prognosis evidenced by an ability to return to school or work, and this is accompanied by a reduction in ritualistic behaviour, such as mirror checking and skin picking. Only a small proportion of patients responding to SSRI drugs experience any change in insight. A review of the addition of anti-psychotic drugs such as pimozide or olanzepine demonstrated inconclusive benefits [9].

It is important to note that sometimes the effective dosage of SSRI drugs is higher than the dosage conventionally used to treat depression, for fluoxetine 50 mg/day and for fluvoxamine 260 mg/day. The dose of SSRI needs to be high and the duration of treatment is also long term, with response taking, on average, 2–4 months. The duration of treatment is usually at least a year. Venlafaxine 37.5 mg/day can be substituted for the SSRI. The help of the liaison psychiatry services should be used at this stage.

Cognitive behavioural therapy [2,21]. Simple behavioural treatment, such as encouraging patients to avoid ritualistic behaviour and mirror checking, and urging them to give up unnecessary cosmetic camouflage, while gradually exposing them to the most feared social situations, can be helpful. This is especially true if combined with a cognitive approach involving self-esteem building and modification of distorted thinking, coupled with coping strategies. All these techniques are more likely to be effective when combined with SSRI treatment, and initially some patients may be too ill to benefit from a cognitive behavioural approach. This needs the help of a skilled clinical psychologist but has the advantage that it is often more acceptable to the patient. Stress and symptom reduction may be as much as 77%.

Supportive psychotherapy can be helpful in patients with overvalued ideas and who are not truly deluded, but it is very time consuming and emotionally demanding. Patients with body dysmorphic disorder are poor communicators and difficulty with interpersonal relationships may be one of the central, crucial and earliest features of this disorder. The physician undertaking supportive psychotherapy has to be patient and realize that further skilled directive intervention will eventually be needed from psychiatrists or clinical psychologists. Body dysmorphic patients are poor attenders at clinics, but the consultation may in some cases be the only opportunity that a patient has to talk to another human being, a reflection of the isolated life these patients often lead. The dermatologist's essential role is to recognize the problem and sympathetically steer the patient on the correct path to help.

Narrative therapy [19]. Narrative therapy addresses the sociocultural causes which may establish beliefs, in this case about the body. The change process in narrative therapy involves helping patients replace these influences by more preferred stories about their problems and lives. Single case studies have been encouraging.

Anorexia nervosa and bulimia [1–5]

Eating disorders are considered primarily psychiatric illnesses which have significant physical complications. Anorexia nervosa (AN), bulimia nervosa (BN) and a third group classified as eating disorders not classified (EDNOS) are particularly common among young women and are increasing in incidence. Anorexia nervosa now has an incidence of up to 1% and bulimia up to 5% [1]. Reviews [6–8] suggest a lifetime prevalence of 2.2% with over half the cases not detected initially in the health care system. The annual prevalence is about 0.3% for AN and 1% for BN, although this may be higher in women aged 15–24 years. The incidence is 270 per 100 000 person years in this group of younger women compared to 8 per 100 000 person years in the group of women as a whole.

Definitions. Anorexia nervosa must satisfy the criteria for:

1 An inability to maintain the normal or minimum weight for age and height coupled with an intense fear of gaining weight; the BMI is less than 17.5 kg/m^2
2 A distorted perception of weight, size and body configuration
3 Amenorrhoea

Bulimia nervosa [9] is defined by the following:

1 Recurrent and compulsive overeating episodes (binge eating)
2 Recurrent and inappropriate compensatory behaviour in order to avoid gaining weight; these include induced vomiting and abuse of diuretics and laxatives
3 Binge eating and weight reduction behaviours occurring at least twice per week for 3 months
4 Self-esteem affected by weight and body configuration.

In the definition in ICD-10, body image distortion is one of the essential features. There is a dread of fatness as an intrusive, overvalued idea and the patient imposes a low weight threshold upon herself or himself. Anorexia occurs earlier in life, usually adolescence, whilst bulimia has its peak in later teens and early twenties. The majority are young women, the proportion of men being 1 in 20. White races predominate in published studies. The prevalence in Afro-Caribbean and Asian women is rare [6,10]. It is commoner in industrialized societies and much more frequent in those of high social class. There is a clear association between body image disturbance and eating disorder. The lower the weight the greater the degree of body image abnormality. There are descriptions of 'nervous consumption' in the 18th century as fashion dictated women wear wire bodices and bustles which emphasized the fashionable tiny waist. Fashion models are particularly newsworthy as a group suffering eating disorders, sometimes aggravated by substance abuse. Illness and death are not uncommon. Gymnasts, athletes and jockeys are other vulnerable groups. 'Fashionable' thinness is one of the precipitating factors for the disease.

There are associations with other psychodermatoses, body dysmorphic disorder and self-injurious behaviours, trichotillomania, severe onychophagia and fabricated dermatitis. Self-cutting, excoriations and bruising occurred in 44% of 134 female patients [11]. The suicide risk is higher than in the normal population [12].

The significant metabolic effects of these eating disorders have a marked effect upon all major body systems but particularly the skin. Signs are detectable earlier in the skin and the astute physician may well detect disease long before severe medical complications supervene, particularly in anorexia nervosa where illness from inanition is a real risk.

Table 64.2 Cutaneous manifestations of eating disorders.

Cutaneous manifestations	Frequency (%)
Xerosis	60–70
Hair loss	25–50
Angular cheilitis	42–75
Nail fragility and dystrophy	45
Acneform eruption	40
Gingivitis aphthae	35
Diffuse hypertrichosis	25–60
Acrocyanosis	30
Knuckle abrasions and calluses, Russell's sign (bulimia only)	4–60
Carotenoderma	20
Hyperpigmentation	12
Generalized pruritus	15
Seborrhoeic dermatitis	8
Follicular hyperkeratosis	5
Striae, scurvy, pellagra, peripheral oedema, pili torti, acquired acrodermatitis enteropathica	Rarely

Fig. 64.3 Russell's sign: callosities of the knuckles from manual forced vomiting in bulimia.

The nutritional and physical consequences of anorexia nervosa and bulimia are frequent with many dermatological sequelae. Gupta and Gupta [13] showed that patients with eating disorders were more concerned with dermatological problems than the normal population and thus would be more likely to attend for consultation (Table 64.2). Although reviews show some variation in the frequency of cutaneous signs in eating disorders [1–5], in general they are consistent.

The most frequent skin manifestation is xerosis with a particular form of branny scaling developing on the extensor surfaces of the limbs and flexures, often described as 'dirty skin'. Hair effluvium occurred in 50% and is slow to recover, even on weight gain. Nails are fragile, discoloured and patchily white. Angular cheilitis reflects iron and vitamin deficiency in half the patients. Diffuse lanugo hypertrichosis has been related to a reduction in 5α-reductase secondary to thyroid hypofunction. The abrasions and callosities of the knuckles (Russell's sign; Fig. 64.3), caused by the forcible contact with the incisor teeth during self-induced vomiting, may be present as an early sign.

As the bulimia becomes more chronic, vomiting may be provoked by manual abdominal pressure. An acneform eruption is frequent and may be pruritic, resembling acne excoriée. Paradoxically, food fads are common in anorexia and can cause carotenaemia following dietary loading with green vegetables and yellow/orange discoloration of carotenoderma. Poor wound healing and striae distensae were more common in the restrictive type of anorexia as opposed to the bulimic type, where hair and nail changes, seborrhoeic dermatitis and generalized pruritus were more prominent. Severe perniosis is also seen in individuals with anorexia nervosa [14]. Drenching night sweats during weight recovery, possibly due to secondary changes in thermoregulation which occur with rapid refeeding, have also recently been described in patients with eating disorders [15].

Russell's sign, hand dermatitis, interdigital intertrigo and brittle nails with dystrophy are highly suggestive of bulimia. In the mouth, there may be dental enamel erosion, caries and gingivitis. Some patients develop a Sjögren-like syndrome.

Other cutaneous features may result from the use of laxatives, such as phenolphthalein, producing a fixed drug reaction, and thiazide diuretics, producing photosensitivity, while the use of the emetic ipecac can be associated with a dermatomyositis-like syndrome. Compulsive hand washing and trichotillomania may result from accompanying psychiatric illness.

The alert dermatologist should suspect anorexia nervosa when presented with these suggestive signs, particularly hair loss, angular cheilitis and xerosis in an underweight girl. A simple screening questionnaire (SCOFF) [16] is helpful for detecting eating disorders. Eating disorders are largely undetected in the community. Patients are not resistant to the suggestion of specialist care and should be referred to a psychiatrist.

Psychogenic pruritus [1,2]

Psychogenic pruritus is a poorly defined disorder. In the past it has commonly been applied to a subgroup of the psychopruritic disorders, representing those with intractable or persistent itch for which no pruritic physical illness or dermatological illness can be found [1]. The definition cannot solely be confined to this simple group since itch can be a major debilitating symptom, both psychologically and physically.

The psychological parameters of itch should be considered as:

1 Predominant psychological pruritus classified as a somatoform or dissociative disorder
2 Pruritus in dermatological illness for which psychological factors play a role in the development or course
3 Problems in coping with chronic pruritus in the sense of an adjustment disorder, so called helpless/hopelessness reactions
4 Co-morbidity with other psychiatric conditions, particularly substance abuse, anxiety reactions and depression.

It is a *sine qua non* that pruritus is a multifactorial symptom. Dermatological, neurological, iatrogenic illness and internal disease are well-recognized causes [1,2]. These must be taken into account in any evaluation of persistent itch. A proposed clinical classification of itch has been produced to serve as a diagnostic pathway for better evaluation of patients [2]. However, the propensity for normal subjects to sense itch after psychological provocation by pictures of insects, rashes and watching other subjects scratching demonstrates the ready ability of simple measures to induce psychosomatic pruritus. Histamine release in skin may be influenced by psychiatric factors and in normal subjects the sensation of itch and cutaneous sensory symptoms was correlated with major life events [3]. Musaph [4] pointed out that one mechanism for relieving everyday irritations is to scratch a little. The motorist stopped at a red traffic light almost invariably scratches some accessible site such as the neck, arms or scalp. Grooming behaviours such as adjustments of hair, clothing or makeup may be associated with an accompanying scratch for transient itch.

Functional itch disorder has been studied by Misery and colleagues who have proposed diagnostic criteria for psychogenic pruritus. There are three compulsory criteria: (i) localized or generalized pruritus *sine materia*; (ii) chronic pruritus (>6 weeks); and (iii) the absence of a somatic cause. Three additional criteria from the following seven should be present: a chronological relationship of pruritus with one or several life events that could have psychological repercussions; variations of intensity associated with stress; nocturnal variation; predominance during rest or inaction; associated psychological disorders; pruritus that is improved by psychogenic drugs; pruritus that is improved by psychotherapy [5].

In individuals who develop localized or generalized neurodermatitis it may begin as a stress response. Patterns of itching and scratching may predominantly occur during periods of relaxation or non-occupied time. Pruritic episodes may be unpredictable in onset and present with abrupt and sudden termination. The quality of itch may be unusual, described as crawling, stinging or burning. Sites of predilection in two-thirds of subjects were legs, arms and back. Furthermore, localized itching may lead to generalized body itch within a short time. The activity may mimic the chronology of depressive symptoms as a depression equivalent with early morning waking and exacerbations at times of agitation [6]. In some individuals, intense scratching can induce an ultimate feeling of pleasure and this may be related to the release of opioids centrally. Enkephalins and endorphins are important as neurotransmitters in the CNS in mediating the sensation of itch because itch and pain are thought to share common neurological pathways. The central elicitation of itch by morphine may result from binding to opioid receptors and this may mimic the normal physiological binding of endorphins and enkephalins at these receptor sites [7]. Paroxysmal intense scratching to produce pain instead of itch has been described as 'orgasm cutanee'. Patients with generalized pruritus who had responded well to placebo reported greater itching after naloxone, probably due to the abolition of the placebo response. Conversely, the placebo non-responders reported less itch after naloxone than the placebo responders, suggesting that naloxone may be competing with an endorphin system, thus modulating the individual perception of itch.

Patients with psychogenic itch tend to be introverted and there may be a history of recent major psychological stress [8]. A psychiatric and psychodynamic investigation of patients with prurigo nodularis demonstrated an extraordinary propensity for these patients to suffer from psychological trauma, and a distinct correlation was claimed between the outbreak of the disease and the preceding loss of a human relationship detrimental to self-esteem [9]. A significant proportion of patients with generalized pruritus may be suffering from depression. Using the Beck Depression Inventory, significantly more patients with generalized pruritus (32.4%) had depressive symptomatology than did controls [10]. Recent studies of psychosomatic co-factors and psychiatric co-morbidity have confirmed these earlier observations with psychosomatic stress factors exhibiting a marked influence on severity of pruritus in skin disease. Severity of itch was related to the failure of psychosocial coping, with 39% suffering from feelings of helplessness and lack of control [11]. In most studies the prevalence of anxiety and depression is 10% for outpatients and 20% for inpatients [12].

Treatment with antihistamines is disappointing although those which have phenothiazine activity, such as hydroxyzine 50 to 75 mg daily, may produce more relief. However, even those patients with proven depression may respond disappointingly to antidepressants. Doxepin, used in doses up to 125 mg/day, is more effective probably because of the combined effect of both antipruritic and antidepressant actions. Selective serotonin reuptake inhibitors can also afford relief, used for up to 1 year. Typical doses are paroxetine 20–40 mg/day, fluvoximine 100–200 mg/

day or citalopram 20–40 mg/day [13]. Psychiatric referral is indicated in non-responders for the expertise in the use of higher doses of these antidepressants and the use of alternative antidepressants such as trazadone or duloxetine. Behaviour-orientated therapy is useful for those with high psychosocial morbidity. The benefit depends upon the availability of therapists and does rely upon a receptive patient. Success may be limited and disappointing in those with significant mood shift or personality disorder [14].

Cutaneous phobias

Phobias are irrational fears which cause anxiety. These fears are unreasonable and inappropriate. The fear is out of proportion to the demands of the situation and cannot be explained or reasoned away. Phobias are overwhelming and compelling and tend to distort the conduct of everyday life. They can be regarded as *obsessional fears* whereas not all obsessions, thoughts or actions are associated with these anxieties. There is a loss of voluntary control and the feared situation leads to avoidance behaviour. Dermatology patients may present with focused anxieties about the development of a variety of cutaneous diseases. These are usually based upon either a fear of contamination and infection, or of impending malignancy and cancer. Occasionally, there is a fear of showing emotion or embarrassment. Predominant cutaneous phobias can be divided into:

1 Fear of contamination, e.g. dirt phobia, germ phobia, wart phobia
2 Fear of malignancy, e.g. cancer phobia, mole phobia
3 Fear of emotional display, e.g. blushing, sweating.

Dirt, infection and wart phobias

Studies of obsessive–compulsive behaviour in dermatology outpatients [1,2] estimate that OCD is present in up to 25% but this may include some with body dysmorphic disorder. However, excluding this group there were still up to 15% who had *fears* of contamination or malignancy half of whom showed compulsive washing behaviours. Hand washing leading to dermatitis is common but up to 10% will admit to compulsive body washing also. The precipitating factors are fears of dirt and contamination from others who have been infected with real organisms, for example MRSA, or those who might have been, that is those recently discharged from hospital. Situational exposure in work to dirt and waste may initiate the fear. Hand washing may occur up to 100 times per day and compulsive showering and bathing 10–20 times daily. Irritant dermatitis which does not resolve with adequate advice should prompt inquiry, not only about washing compulsions but also checking behaviours.

Wart phobia is a specific contamination fear and usually follows an index case in family or acquaintances, often children. Patients with imagined wart infection are sent with real lesions such as milia, normal anatomical variations, for example pearly papules or milia, or even no lesions at all. Fear and guilt is associated with genital wart phobia. Avoidance behaviours such as cleaning of door handles, chairs and toilet seats are associated with carriage and excess usage of boxes of antiseptic wipes. Underwear, socks and gloves may be discarded to avoid the possibility of contamination in the wash. Parents who are unwilling to wait for natural resolution of viral warts may insist on aggressive treatment to prevent other members becoming infected and complain to managers and the media if it is not forthcoming.

Mole phobia and cancer phobia

For dermatologists these are usually related. Occasionally, a dislike of moles and freckles may be a manifestation of BDD but for most patients who repeatedly demand mole examinations, and sometimes excision, there is an underlying cancer phobia. This is in response to various stimuli. They may have had a malignant lesion removed and need constant reassurances. This is a 'normal' response to disease. There may have been malignancy or unfortunately death from melanoma in the family or friends, or concern repeatedly triggered by media or commercial pressure. These patients present regularly and acutely to screening clinic or primary physicians. They may demand removal of some or all their moles [3,4] or even attempt to multiple self-surgery. Mole phobia by proxy is not uncommon in parents who worry about their children and their moles to such an extent that normal play activities are curtailed because of the sun, and family holidays are compromised also. Screening programmes *per se* are not shown consistently to increase cancer anxiety, nor to attract a disproportionate number of phobic patients although the vulnerable attendees are the young, those with low education and social class and high doctor dissatisfaction [5]. The management of these patients is difficult because they usually present with an instant demand to be seen and the consultation is a form of crisis management. It is preferable to organize regular reassuring appointments, gradually extending the period between visits to a reasonable interval. Nor is it reasonable to regularly take off normal naevi to 'reassure'

the patient who will see this as a form of definitive therapy. Many of these patients are seen in private clinics where their fears are reinforced by repeated, expensive operations.

Topical steroid phobia

Topical corticosteriod preparations were introduced in the 1960s and by the 1970s most dermatologists were familiar with patients who expressed fears about the use of these drugs. A few examples of gross abuse were published in the media, fuelling a continuing irrational concern, predominantly about skin thinning [6] and to a lesser extent stunting of growth in children. These families present in the clinic as angry resentful parents suspicious of conventional therapy, significantly disillusioned and poorer from repeated expensive, useless alternative therapy. Their child is miserable, undertreated and suspicious of all therapists, riven by discord between parents and physicians. Management is extremely difficult because the fears are so dominant. However, cognitive assessment of needs, rational explanation of effects of safe therapy and frequent, regular, open review of progress with interactive discussion does much to alleviate anxieties. It may take many months to reach a state of equanimity with parents in particular, whose fears may remain to some degree.

Group and mass population reactions [1,2]

Synonyms

- Epidemic hysteria syndrome
- Mass psychogenic illness
- Mass sociogenic illness
- Occupational mass psychogenic illness (OMPI)

The modern nomenclature for hysteria is conversion or dissociation disorder. This disorder has been defined as a constellation of symptoms suggestive of organic illness, but without an identifiable cause, that occurs between two or more people who share beliefs related to those symptoms [2]. The implications from this classification are that the symptoms are psychogenic, that the causation is unconscious, and that symptoms may carry some advantage either primary, such as debilitating symptoms, or secondary, by being exempted from community responsibility or gaining public attention. It can be seen as a social phenomenon or cultural and ethnic stress reaction occurring in otherwise normal populations. Conversion implies the behaviour of physical illness without evidence of organic pathology, the patient being unaware of the psychopathology. The prime examples of this group response are epidemics occurring in the closed communities of the workplace or in schools. It has been called a culture bound stress reaction with two recognizable variants. Firstly, those associated with anxiety, namely headache, nausea, dizziness, flushing, fainting, abdominal pain and hyperventilation. Secondly, the motor variant, mainly tics, pseudoseizures and convulsions.

Two large reviews of epidemic hysteria, one covering 78 outbreaks between 1872 and 1972 [3], and another the 70 incidents between 1973 and 1993 [2], found limited cutaneous symptoms. The earlier reports emphasize the motor symptoms whilst the latter lists more widespread symtomatology including a 9% incidence of a rash. These occurred usually in factories or schools with a minority within a family group. Skin-related symptoms have been reported in widespread reaction to contamination of a community water supply where there was anxiety but no long-term effects on health [4]. In the 1981 food poisoning outbreak caused by adulterated rapeseed oil, where 20 000 people were affected by well-defined symptoms, some cutaneous, more than 6000 people with symptoms of 'reactive psychological disaster syndrome' were allowed compensation in the absence of specific physical illness [5]. The fear of skin illness or contagion led to two separate outbreaks of skin disorders among factory workers in a small northern English town. In each outbreak a central female figure with non-industrial dermatological problems fuelled an epidemic of what was thought to be dermatitis among several employees in a ceramics factory and a second epidemic in a textile factory. In the first outbreak, 10 employees were affected and 17 in the second. No significant dermatological pathology of industrial origin was found [6]. A similar outbreak occurred in a warehouse, triggered by two severe cases of non-occupational dermatitis, combined with the idea that incoming aircraft parts to the warehouse from foreign countries might be 'dirty' in some way. This caused a heightened perception of the risk of skin disease with increased frequency of hand washing. Over-frequent hand washing in a few employees resulted in a dermatitis with a false reinforcement of the fear of industrial dermatitis [7]. The presence of proven dermatitis may stimulate a response from the remainder of the workforce. An outbreak in the pottery industry which began as isolated gum arabic sensitivity developed into a more widespread epidemic described as 'epidemic hysteria dermatologica' in eight female workers [8]. There was also a female preponderance in the outbreak at a textile factory where the skin problems were common dermatoses unrelated to work [9].

Most of these mass reactions involve female workers in stressful situations with boring, low-paid, repetitive jobs. Women are more likely to externalize their discontent as a conversion symptom than a direct complaint which may jeopardize their job [2]. Surveys of OMPI episodes stress that many outbreaks occur in dehumanizing jobs with poor management communication. Secondary compensation neurosis may follow to prolong the epidemic from those who feel particularly injured. It is clearly important, if possible, to visit a factory very early and examine all the complainants in an outbreak of alleged 'epidemic' industrial dermatitis.

The other common closed communities are schools, where epidemic complaints of itch, dry skin and transient rash were predominant [2,10–12]. These outbreaks involved 50 to 100 children aged 7 to 12 years. The symptoms lasted 2 weeks and no cause

was found. Girls outnumbered boys by 3 to 1. It has been suggested that the precipitating factors may be illness in a favourite teacher or student, rigid teaching regimes and parental pressure for academic success.

Sick building syndrome and building-related illness [1–4]

The concept of sick building syndrome (SBS) and building-related illness (BRI) [1] is used to define a group of symptoms that appear to be due to a range of apparent allergic, toxic, irritant and possibly infectious causes within non-industrial and non-residential buildings [5]. Both SBS and BRI refer to illnesses related particularly to non-industrial premises such as large blocks of flats or offices where people spend a large quantity of time in close association. In a minority of cases these syndromes consist of a specific homogeneous illness caused by identifiable vapours, for example formaldehyde, or identifiable allergens, such as pollens. A series of heterogeneous complaints, such as irritable dry skin, facial flushing, pruritus, dryness and cracking of mucous membranes of mouth, nose and eyes, recurrent sore throat, headache, fatigue and loss of concentration exist, for which no cause can be found. In over half the patients the symptoms are dermatological but the lack of demonstrable biological correlates together with vague aetiological attributes makes precise definition of the problem difficult [2]. Patch testing was negative. In large reviews [2,6,7] symptoms were significantly associated with signs of dampness, condensation, water leakage, high humidity, and mouldy odour. Furthermore, the symptomatology could be related more to mechanical ventilation systems and internal air conditioning than in buildings where there was efficient natural ventilation [6]. In addition, changing from artificial ventilation to a natural one reduced skin symptoms by one-third [8].

Workers may feel ill when exposed to odours from xenobiotic sources (cacosmia) [9]. The presence of a strange smell at work may precipitate symptoms in a significant number of previously healthy individuals. Patients develop headaches, itchy eyes, transient rash, and congested nose or throat followed by sweating, faintness and tachycardia. In most cases the odour is chemically harmless. The medical and social prognosis of SBS in a long-term follow-up study showed that fatigue, irritation of the eyes and facial erythema were the most common persistent symptoms [10]. Personal factors such as atopy and photosensitive skin, psychosocial conditions and physical factors prolong symptomatology. A significant psychological component was postulated when 24 workers reported sensitivity to electricity in the workplace causing itchy wealing of face and limbs [11]. The patients reported increased symptoms not only when they were exposed to an experimental electromagnetic field but also when they believed they were exposed even though the field was turned off. Patients with visual display-related skin symptoms and hypersensitivity to electricity who complained of continuing problems were female, had poor self-image and limited capacity for coping [12].

Not surprisingly therefore, work stress, manifested by role conflict, work overload, managerial difficulties and workplace building renovations have all been significantly associated with perceptions of poor workplace air quality and increased dermatological symptoms of SBS [8].

Symptoms were more common in those lower down the office hierarchy than in managers because they had no authority or power to tackle the perceived stresses but women had more symptoms than men, irrespective of their status [2,12,13].

Harmful cutaneous habits

There are certain everyday habits which are non-destructive and can be regarded as an extension of grooming behaviours. These are seen in the general population as autocontact and displacement activities. These are commonly seen as hair adjustments,

non-excoriative scratching of face, neck or genital areas, nose touching and clearing and ear cleaning [1].

In past editions of this text a number of skin conditions have been defined as harmful habits, for example knuckle biting, or considered in isolation as a primary destructive condition, for example acne excoriée. It is clear that a redefinition of these is overdue because they represent a continuum of disease from a simple harmless stress-induced (and therefore relieving) habit with no other psychiatric overtones, for example nail biting, to a severe self-destructive process, for example trigeminal trophic syndrome which can result in massive tissue destruction as part of a depressive disorder, OCD or dementia [2,3].

Pathological rubbing and picking behaviours producing visible change represents a more informative grouping for the following activities:

1 Repeated, localized skin rubbing: lichen simplex, knuckle biting, neurodermatitis
2 Pathological excoriation and picking producing scarring, previously called neurotic excoriations, acne excoriée
3 Nail sucking, picking, biting, eating and instrumentation onychotillomania
4 Pathological picking of a localized area of skin, e.g. acne excoriée des jeunes filles
5 Trichotillomania of one or more areas of hair-bearing skin
6 Pathological picking representing a psychiatric disorder, e.g. 'corrective picking' in BDD or investigative picking in delusional disorder
7 Fabricated disease.

Lichen simplex and neurodermatitis

(see also Chapter 23)

Lichenification describes the characteristic pattern of response of the predisposed skin to repeated rubbing. In some instances, a minor initiating event, such as trauma, infection or insect bite, precipitates episodic insistent scratching and rubbing. Irresistible itching is the major complaint, scratching the chronic accompaniment. This behaviour takes the form of rubbing with either the hands, back of nails or knuckles and in extreme cases sometimes with the use of a convenient instrument such as hairbrush, pen or some other domestic implement. The actions may be subconscious. However, in some cases patients subject themselves to frenetic, prolonged spasms of uncontrollable self-damage which proceeds with increasing rapidity until the pruritus is relieved, to be replaced by soreness and pain. The change from itch to pain is quite sudden and this abrupt cessation has been described as 'orgasm cutanée'. Nodular pruriginous lesions probably represent two populations: an early-onset atopic group with mean age 19 years, and a later, non-atopic group with mean age 48 years [1]. The early-onset group was associated with hypersensitivity reactions whereas the later group, predominantly female, show more habit-induced responses. Lichen simplex and neurodermatitis are much rarer in the elderly and may be related to a reduced capacity to lichenification.

Regular rubbing and pressure on the skin produces characteristic thickened, coarsely grained papules and nodules with hyperpigmentation. The classic sites of involvement are within easy reach, particularly on the nape and sides of the neck, elbows, thighs, knees and ankles. It is unknown why these areas remain so discrete. These areas may be in varying stages of evolution, from early small violaceous papules with surface excoriations to chronic areas that present as hyperkeratotic plaques with pigment changes, described as 'dermatological worry beads'. Localized patches of lichen simplex presenting as pruritus ani and vulvae are more often found in females and occur predominantly after puberty. They are found, very rarely, as isolated phenomena in children, even in atopics. It is more often seen in Afro-Caribbean and oriental races.

Most authors have commented on the relationship of emotional tension to bouts of scratching [2]. Patients are usually described as stable but anxious individuals, whose reactions to stress are relieved by ritualized behaviour such as rubbing [3]. Aggression and hostility related to anxiety caused by emotional disturbance may lead to itching. This maladaptive response has been treated successfully with behaviour therapy [4–6] to break the itch–scratch cycle.

Treatment with antihistamines is helpful, but antidepressants, particularly tricyclic compounds such as doxepin in doses as low as 25–50 mg/day, may be more effective. Non-psychotropic medication is also sometimes effective, using thalidomide 50–100 mg daily for up to 2 months at a time [7].

Pathological skin picking [1,2]

Synonyms

- Psychogenic excoriations
- Neurotic excoriations
- Compulsive skin picking
- Dermatotillomania
- Acne excoriée

Epidemiology and pathogenesis. Pathological skin picking is defined as recurrent picking accompanied by visible tissue damage and functional impairment [1]. The DSM-IV classification does not

include a category for skin picking, which has been previously described as an impulse control disorder, stereotypic movement disorder or obsessive compulsive disorder. Body dysmorphic disorder and delusional skin disease are separated by the primary psychiatric pathology. The commonest of the self-inflicted dermatoses have previously been called neurotic excoriations, psychogenic excoriations or compulsive skin picking. The lesions differ from other artefactual disorders as those who suffer admit to an urge to pick and gouge at their skin. Not uncommonly, there may be an initial reluctance to confess to the self-damage but patients are willing to discuss the 'response to itch' or the 'relief of tension' as a mechanism of guilt dissociation. There may be an associated involvement of the face and neck as acne excoriée. It is unknown why particular areas are involved but may relate to the occurrence of the site of the initial lesion, for example acne trauma or an insect bite. Picking occurs in 2% of dermatology clinic patients [3] and 4.6% of college students [1,4]. Pathological picking can be seen before 10 years of age through to middle age. Curiously, the elderly are spared. Childhood onset [5] may progress into adulthood in up to 47%. This group had similar characteristics to those who begin primarily in their late 30s [3]. All of these clinical syndromes are characterized by the preponderance of females, even in childhood and adolescence. Destructive excoriations are seen most frequently in middle-aged women, the average age of onset being between 30 and 50 years [2,6], but significantly the average duration of disease before presentation can be up to 10 years. This group makes up the most severe cases, where the problem tends to be persistent and unremitting. Picking intensity coincided with menstruation in 44% [7], although it is common for activity to wax and wane. On average patients spend up to 3 h per day picking, thinking about picking or resisting the urge to pick [1,2,7]. These bouts can be ritualized to a set time and place, often the bathroom, frequently at bedtime. These activities are done in full consciousness although in children, particularly, a fugue or trance state can be apparent [5].

These patients are described as rather rigid and obsessional individuals with repressed emotions [5]. They have difficulty in verbalizing their problems and are aggressive but also insecure [6]. Depression is a very common feature [1,2,6,7]. There is a compulsive quality about the need to continue until pain is produced. Psychosocial stresses have been reported to precede exacerbations of excoriations in 30–90% of patients [1–4]. Studies indicate that increasingly severe skin picking is related to greater levels of anxiety, depression and experiential avoidance, defined simply as the tendency of an individual to avoid or escape negative events or emotions [1,8].

Clinical features. Lesions can be seen in all stages of development, the appearance depending on chronicity and degree of instrumentation. Clinically, the lesions are polymorphic, the newer lesions are angular excoriated erosions with a serosanguineous crust found predominantly on the face, hair margins, sides of the neck, chin, upper chest, shoulders, upper arms and thighs. The healing lesions are erythematous, eventually becoming white and atrophic centrally and commonly hypertrophic and hyperpigmented at the periphery. They may be quite deep, extending into dermis, and are distributed symmetrically within reach of the hands. Significant bouts of cellulitis and ulceration are common, leading to hospitalization [9]. Older lesions show pink or red scars, some of which may be hypertrophic. Chronic lesions may also show atrophic scars, which merge and are eventually seen as linear, coalescent areas. Lesions appear at all stages of development and may number from a few to several hundred (Fig. 64.4).

Fig. 64.4 Acute excoriations and chronic, scarred, atrophic lesions due to pathological picking on face, neck and shoulders.

Characteristically, these lesions appear as discrete islands in a sea of normal skin. Concealment behaviour, for example by make-up and clothing, was present in 65% of chronic cases and active avoidance of social situations in 40%. Up to one-quarter of patients may increase alcohol, tobacco or recreational substance habits to counter the burden of disease [1].

Differential diagnosis. It is important to exclude excoriations caused by generalized pruritus, bullous disorders, such as pemphigus, and linear excoriated lesions, which may be the presenting signs of lichen planus or lupus erythematosus. Rarities such as self-healing keratoacanthomas or mucinoses which cause scarring are usually distinguishable entities.

Treatment. Simple, empathetic, supportive psychotherapy can produce significant improvement, particularly in children. Crucially, the parents need to be convinced they are part of the therapeutic team. Cognitive behavioural therapy alone has improved some patients, although the management of underlying personality difficulties may require the specific skills of a psychotherapist [1,8–10]. Habit reversal programmes may also help [11]. The compulsive nature of this disorder responds well to antidepressants and in particular to serotonin re-uptake inhibitor drugs, such as fluoxetine, fuvoxamine and citalopram [2,12]. Clomipramine and doxepin [13] have been reported to work well. The A-B-C model of habit disorders, that is Affect regulation, Behavioural regulation and Cognitive control [14], makes use of all modalities to help patients conceptualize and manage skin picking behaviours. An open study of lamotrigine used as a mood stabilizer improved two-thirds of patients, mean age 3 years, over a period of 3 months [15]. Whilst the condition eventually resolves, the most difficult

cases are middle-aged women with established patterns of excoriation, which may have been continuing for decades. It may be necessary to continue antidepressants in these patients for some years.

Acne excoriée (see Chapter 42) [1,2]

There is not one patient with acne who can resist squeezing and pinching the lesions. Brocq in 1891 [3] described acne excoriée particularly in adolescent girls under emotional stress who picked and squeezed acne lesions. Although some patients develop these lesions after picking acne, most had no acne at all [2]. The condition should be considered a variant of psychogenic (neurotic) excoriation [2], with the lesions largely confined to the face. Acne excoriée is commoner in women [1–4] and seen in an older age group than acne vulgaris, with a mean age of about 30 years [1,2,4]. Psychological studies have shown no diagnosable DSM-IV-R disorder such as body dysmorphic disorder or obsessive compulsive disorder [4,5]. An immature personality or narcissistic personality disorder were commented upon. Sneddon and Sneddon described associated phobic states [1] and specifically excluded monosymptomatic hypochondriasis as a diagnostic category. However, the depressive and delusional disorders [6,7], which have been described in the past in association with acne excoriée, may have represented patients with excoriations as a result of pathological picking in BDD.

The clinical lesions resemble those of chronic excoriations. They are found predominantly around the hairline, forehead, preauricular cheek and chin areas (Fig. 64.5). Extension to the neck and occipital hairline is common. Chronic lesions characteristically show white, atrophic scarring with peripheral hyperpigmentation. Lesions are picked as a ritual, apparently as a response to itch or throbbing. The lesions are excoriated until 'emptied' [1].

Fig. 64.5 Acne excoriée; habitual scarring lesions of cheek and chin.

Although patients with acne excoriée sometimes respond to simple acne therapy, most require systemic antibiotics and isotretinoin. The tetracyclines, in particular doxycycline, are better than the other antibiotics [1] and topically the patients prefer antibiotic roll-on preparations to the benzoyl peroxide creams, which are too irritant. Whilst this may modify the development of new lesions and scarring, the course of the disease is poor without psychological support [1]. These patients tend to be psychologically dependent on the effects of the disfigurement to provide them with an excuse not to go out. The benefits of simple supportive consultation and psychotherapy should not be underestimated [8]. Habit-reversal therapy and hypnosis has worked well [9,10] but combined laser resurfacing and cognitive psychotherapy had prolonged success [11].

Trichotillomania [1–3]

Definition. The term was first used by Hallopeau in 1889 and is derived from the Greek *thrix* hair, *tillein* pull out and *mania* madness. Literally it means a morbid craving to pull out hair. Originally DSM-IV [4] lists trichotillomania under impulse-control disorders in company with compulsive gambling. It is now clear that the definition must encompass the probability of a broader spectrum of additional psychopathologies [1] such as OCD, BDD and mood disorders. The revised DSM-IV [5] diagnostic criteria for trichotillomania are:

A Recurrent pulling out of one's own hair resulting in hair loss
B An increasing sense of tension immediately before pulling out the hair or when attempting to resist the behaviour
C Pleasure, gratification or relief when pulling out the hair
D The disturbance is not better accounted for by another mental disorder and
E The disturbance provokes clinically marked distress and/or impairment in occupational, social or other areas of functioning.

The ICD-10 definition [6] is consistent with this but does not mention either distress or loss of functioning.

Aetiology and pathogenesis [1,2]. The epidemiology of this complaint is not absolutely clear, probably for the reason that this physical sign and response is a product of various complex psychopathologies. The grouping includes both paediatric and adult patients and the latter in particular may have additional classifiable psychiatric illnesses, which contaminate any attempt to make this a homogeneous entity as has been attempted previously. Studies of frequency show a wide variation. There is an estimated lifetime prevalence of 0.6% in college students [7] with equal sex incidence. If the criteria are based on ICD-10 then the prevalence increased to 3.4% in females and 1.5% in men. Another study, again in students, found that 11% plucked their hair for other than cosmetic reasons and that 1% satisfied DSM criteria [8]. There is great difficulty in assessing the true incidence. Firstly, adult patients have been reluctant to present themselves for treatment because of shame and exposure, preferring instead to disguise the problem with hats and wigs and makeup. Secondly, the diagnosis may have been missed. Thirdly, any apparent increase in frequency may be the product of media attention, particularly when patients die of complications of trichobezoar. Lastly, infants and children with hair loss are more likely to be seen because of parental concern.

In a study of unselected populations, the incidence varied from below 1 per 1000 to more than 1 in 200 below the age of 18 years [6]. However, there appear to be two distinct populations: those who present in childhood [2,9] mainly between the ages of 5 and 12 years and more chronic cases who present as adults who have continued hair-pulling activity from adolescence or developed the disorder in early adult life [2]. One study has suggested that over 40% of adult cases have continued from adolescence. Nevertheless, the number of affected children may be seven times that of adults [8] and there is evidence of a bimodal distribution with peaks in the preschool years and in adolescence. The preschool children are more likely to be boys (62%) although after this older boys and adolescents are only 30% of the group [9]. There is some difficulty in meeting the diagnostic criteria for DSM-IV in young children because of the need to satisfy criteria B (a pattern of rising tension prior to pulling) and C (relief after pulling). This early-onset group, usually between the ages of 2 and 10 years, show benign, self-limiting behaviour and most are probably suffering a habit disorder, perhaps as an extension of hair twirling activity and childhood stress [8,10]. The association with nail biting and thumb sucking, skin picking, nose picking, lip biting and cheek chewing is well documented [11,12]. In children, there is an association with anxiety and dysthymia [13], learning disability and iron deficiency [14]. Emotional problems in the pre-adolescent group tend to be less severe, more a reflection of a stressful life event rather than serious psychopathology [15].

The adolescent group are much more likely to be female, with ratios of up to 3.5:1 [3]. The psychopathology may be related to parent relationships, school difficulties (commonly bullying), body image changes and, increasingly, parental and sexual abuse [16]. It is more likely that there is an accompanying anxiety disorder, although depression in children may be missed because the features are of somatic complaints and irritability.

In adults, there is greater psychopathology and a distinct female preponderance [1,2,9,16], usually 4:1, but 15:1 being most evident in the oldest group [17]. These statistics may be skewed because women are more likely to seek treatment and comprise the majority of those in clinical trial data. This remains true for different racial groups [18–20]. Adult patients show more diverse psychopathology with depression, anxiety disorder and obsessive–compulsive disorder (OCD). Depression was present in 14% and anxiety in 15% [21]. Substance abuse (6%) and eating disorders may also be evident [2,3]. There is a significant debate about the relationship of trichotillomania to obsessive–compulsive disorder [1,16]. An extensive review discusses the similarities between trichotillomania and OCD, in particular the compulsive urges and ritualistic behaviours. Whilst it has been proposed that adult chronic trichotillomania is a variant of obsessive–compulsive disorder, with positive correlation in family studies [22], this definition is too narrow for many patients [2], and has not been supported by psychometric testing [11]. OCD compulsions are ego dystonic, that is are performed to avoid increased anxiety, are not pleasurable and are performed in full awareness. That is they have the compulsion to perform an act to prevent something which they feel may happen. Whereas for those with trichotillomania the act is performed to release tension, may be pleasurable and not always performed in full awareness. Patients with OCD have an explanation for their responses whereas those with trichotillomania rarely justify their actions. In addition, the activity relieves stress for those with trichotillomania although a small subset may have the typical disabling compulsive conscious behaviours [23]. A family history of trichotillomania is present in 5–8% of cases and also higher rates of OCD, which may represent either a genetic predisposition or, more likely, a continuing family psychosocial response [22].

Clinical features [1]. The hair pulling activity is usually not as a response to any skin symptoms but is either a conscious deliberate

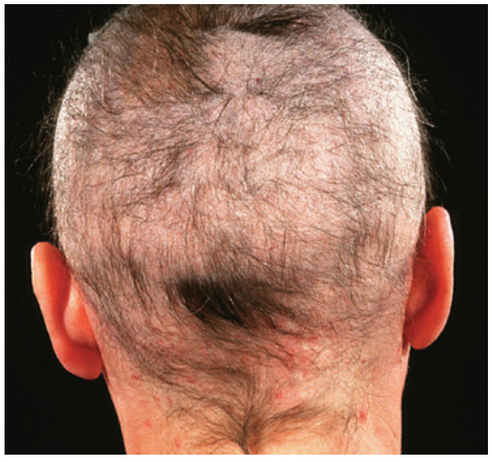

Fig. 64.6 Adult trichotillomania; extensive hair loss with a preserved tuft over the occiput.

Fig. 64.7 Childhood trichotillomania showing eyelash involvement with hair loss and broken-off hairs. This child also had scalp involvement.

act or more often a subconscious act, almost in some children being part of a hypnogogic (dreamlike) state. Some patients may have incomplete awareness until the pattern has been established [24].

Hair pulling and plucking is commonest from the scalp, but is only occasionally as a response to scalp symptoms. Some patients select an apparently abnormal hair by feel or texture and extend into an adjacent area. Most pull hair from the vertex, but temporal, occipital and frontal hair loss in children may be more obvious on the side of manual dominance. The hair loss may be minimal, commonly a solitary patch but visible hair thinning may progress to virtual total depilation, significantly so in adult women (Fig. 64.6).

Typically, the hairs are short, irregular, broken and distorted. The hair feels like stubble because of the broken, fractured hair shafts by contrast to alopecia areata which is much smoother. The patterns of plucking activity are centrifugal from a single starting point or linear, in wave-like activity. In extreme cases, the centrifugal pattern removes all hair except the most difficult to access namely the occiput. This shows as a 'tonsure pattern' [25] or 'Friar Tuck' [26] distribution. The eyelashes, eyebrows [27], facial and pubic hair may also be primarily affected. Children will also pluck eyebrows and eyelashes but adults almost exclusively pluck hair on the torso. Two-thirds of adults pulled hair from two or more sites and one-third from three areas [2,3]. Involvement of a second area began after an average of 8 years [1]. Body and pubic hair plucking, commoner in males [28], may become a ritualized activity either alone or as a conjugal activity and can indicate a personality or psychotic disorder. Hair is plucked from the scalp on average two to three times per day and daily from other areas. The duration and frequency of activity is variable but adults in general have longer and more frequent activity.

Children tend to manipulate hair at times of leisure for example watching TV, when tired and in the evening (Fig. 64.7). Adults have a more conscious structured activity initially seeking thicker or distorted hair and then progressing to larger areas, taking more and more time over the activity. This may become similar to a compulsion with elaboration of the rituals using instruments such as tweezers. The more frequent the plucking episodes, the greater the body image dissatisfaction and the more likely the patient will suffer depression and anxiety. There are similarities and overlap with body dysmorphic disorder in some cases.

Patients use wigs, hair weaving, false eyelashes and semipermanent use of hats and scarves to disguise the defects. The psychosocial effects of hair loss, for example reluctance to swim, date and participate in sports, cause significant disability. Chronic folliculitis of the neck, chin, chest, pubic areas or thighs as a result of plucking activity may also be the presenting complaint.

Once removed the hair may be licked or stroked against the cheeks and lips. The children may pluck the hair, stroke or suck the hair root before chewing and swallowing the remainder. The hair root alone may be eaten (trichorhizophagia) as a secretive activity and in a few patients the whole hair is eaten (trichophagia). Occasionally, hair may be seen stuck between the teeth. Patients who eat more hair tend to swallow the longer strands and a small percentage develops gastrointestinal bezoars.

Trichobezoar and the Rapunzel syndrome

Bezoar is derived from the Arabic word *badzahr*, meaning an antidote or counter poison. It also relates to the hardened contents of the fourth stomach of the Syrian goat, much prized as a cure for many diseases. Bezoars are ball-like aggregations of vegetable or fibre-like materials in the stomach and small intestine. The true incidence of trichobezoar is unknown. It is seen almost exclusively in girls and young women. It is rare but its importance is that morbidity is high with chronicity and severe complications which can lead to death. The aetiology has been linked to iron deficiency and pica where the tendency to swallow non-organic materials is reduced by iron replacement. Swallowed hair is retained within the folds of the gastric mucosa. The longer the hair, the more likely the action of peristalsis to stimulate the hair to become enmeshed into a ball which then becomes too large to easily leave the stomach

via the pylorus. The larger the ball becomes, the more likely it is that gastric atony will develop, leading to symptoms of nausea, indigestion, bloating and pain. The hair ball may eventually completely fill the stomach. Gastric erosions are common in chronic cases leading to anorexia and weight loss. The hair ball is decomposed to a degree by gastric acidity and fermentation of fats and food in the interstices of the hair gives a putrid smell and significant halitosis. These effects darken the hair in the bezoar no matter what the original hair colour. Children with trichotillomania who present with a combination of any of the following: abdominal pain; weight loss; nausea; vomiting; anorexia; and foul breath should be investigated [9,14]. Gastric trichobezoars may cause intestinal bleeding, pancreatitis or obstructive symptoms [1,18], particularly if the hair bolus extends down the small intestine. The Rapunzel syndrome [29] described this particular group after the character in the Grimm Brothers fairy tales. The syndrome is now defined as those with a trichobezoar with a tail that extends at least to the jejunum and in whom gastrointestinal obstructive symptoms are highly likely [30]. In a review of 27 cases which included only one male, the mean age at presentation was 10.8 years. Most patients ingested their own long hair although cases have been recorded of *Bezoar by proxy* where another person's hair has been eaten by the patient, one a hairdresser (personal observation) and another a nit picker [31]. The sole male in this study ate his sister's hair. In this group 37% had abdominal pain, 33% nausea and vomiting, 26% obstruction and 18.5% developed peritonitis. The hair ball can have a tail as long as 195 cm. The tail may also be broken up into numerous segments distributed throughout the small bowel. Recurrent Rapunzel syndrome has been reported. Life-threatening intestinal obstruction necessitates surgical intervention.

Investigations. Scalp biopsy has been shown to be the most useful investigation [1,8,9]. There are normally growing hairs amongst empty hair follicles in a non-inflamed dermis. This is the product of mechanical traction of hairs. Follicular plugging with keratin debris is evident. Many of the empty hair follicles show evidence of changing into the catagen phase with transformation of the lower follicular epithelium into a cord of undifferentiated basiloid cells. The hair shafts are often broken or reduced to little dark bodies. Trichomalacia is seen as deep distortion and curling of the hair bulb. In severe damage there is intraepithelial and perifollicular damage.

Clinically, gastrointestinal bezoars may be palpated as a non-tender, mobile mass in the upper abdomen. Barium contrast shows a filling defect in a lace-like, mottled pattern (Fig. 64.8).

The most accurate diagnostic tool is CT scan which in one study diagnosed at least 65% of cases in both stomach and small intestine [32]. Conventional X-ray was least helpful. Gastric endoscopy is confirmatory and laparoscopic endoscopy has been successfully used for removal [12].

Treatment. Clinical assessment scales are helpful in the fuller evaluation of treatments but remain largely research tools. Treatment is based on either some form of behavioural therapy or pharmacotherapy with tricyclic or SSRI antidepressants [33–35]. For many adolescents and children, identification of stressful episodes with accompanying support and parent education is usually all that is necessary. Teaching awareness and relaxation training and the introduction of coping strategies needs the expertise of a clinical psychologist. It is essential to present the harmful habit in an atmosphere of non-blame or fault but to change the agenda to a positive one to negotiate change. Habit reversal is effective as is behaviour therapy. Systematic reviews [33,34] showed that cognitive behavioural therapy (CBT) was effective alone and combined CBT and SSRIs were possibly more effective. Clomipramine was more useful than SSRI alone. One study showed that tricyclic antidepressants were effective and that clomipramine was more effective than desipramine [17] although relapse may be common unless treatment is continued for at least a year. All therapy is time consuming and needs expert clinical psychology support to maintain progress.

Fig. 64.8 Gastric trichobezoar on barium contrast examination showing a lace-like pattern of the mass of hairs.

Onychotillomania and onychophagia [1]

(see also Chapter 65)

The compulsive habits of nail picking and nail biting have been shown to be common in children and adolescents [2,3]. The aetiologies suggested include stress, imitation of family members and transference from the thumb sucking habit. Nail biting is usually confined to the fingernails, but nail picking, especially in adults, may involve all digits. Damage to cuticles and nails causes paronychia, nail dystrophy and longitudinal melanonychia [4]. In chronic cases, there is an association with trichotillomania [1]. Compulsive biting, tearing or picking with instruments such as scissors, knives or razorblades may lead to permanent destruction [5].

Onychotillomania may be a feature of developmental problems in children and is a component of self-destructive behaviours in Tourette's and Prader–Willi syndromes. In adults, chronic nail biting is most commonly an isolated self-destructive habit which may respond to cognitive behavioural training [6]. The other common problem is a compulsive action as a part of OCD, not always at times of stress. Rarely, onychotillomania is a manifestation of a major depressive disorder which has a suicide risk [7]. Self-induced anonychia of the toenails was produced by one man who plucked out the nails with pliers rather than suffer recurrent paronychia from previously crushed toes [8]. Delusions of parasitosis may provoke self-destruction of the nails [9] as can a *folie à deux* in the confused elderly [10]. Successful drug response to treatment has been shown with clomipramine [9] and pimozide [10].

Psychogenic purpuras and painful bruising syndrome

This group of disorders continues to present an enigma. The common features are the presence of purpura, bruising or frank bleeding in patients who often have a history of psychological disturbance. Patients are almost always female. Reports of male involvement are extremely rare since the original description of the syndrome over 50 years ago. For clarification it is helpful to consider the following separate categories, although some overlap is apparent:

1 Autoerythrocyte sensitization syndromes (Gardner–Diamond syndrome)
2 Purpura factitia.

Autoerythrocyte sensitization syndromes [1–3]

In this rare but well-recognized condition, exquisitely tender bruises arise after minimal trauma with or without a history of emotional disorders. In the original cases, it was noted there was a preceding history of an injury involving extensive bruising or major surgery. These bizarre, tender lesions are most commonly located on the arms and legs [4,5]. Bruising is heralded by a burning or stinging sensation followed after a few hours by

oedema, and erythema and appears a day or so later. There are reports of severe, deep bruising mimicking cellulitis of the leg [6] and also resembling compartment syndrome [7]. Magnetic resonance imaging shows subcutaneous swelling and histology oedema and erythrocyte extravasation [8]. Abdominal pain, bleeding from internal organs and neurological symptoms may occur [1]. The characteristics of the clinical picture have remained consistent in young adolescents [9] and in the few men reported [10]. However, the pathognomonic autosensitivity testing by injection of autologous red cells is not consistently positive. Other abnormalities may be found [3,11,12] including abnormalities of platelet aggregation. Typical ecchymoses can be reproduced by the intradermal injection of the patient's own erythrocytes and in some cases red-cell phosphatidyl-L-serine [13]. Gomi and Miura [14] described a case with associated thrombocytosis where busulphan therapy induced a reduction in attacks. Increased fibrinolytic activity has also been noted at the onset of fresh lesions in some patients [11,15]. One case seemed to have been made worse by a copper-containing intrauterine contraceptive [16].

Psychiatric symptoms were present in 21 of 30 cases reported [17]. All reported cases emphasize the severe emotional disturbances as a constant feature. Anxiety, depression and psychosocial isolation are consistent findings. The possible relationship of stress to altered fibrinolysis is conjectural but measurable effects have been found [18] and the relationship to religious stigmatization has been discussed [1,14,18,19]. Psychotherapy [1,4,8] is a more successful treatment than psychotropic drugs and should be offered early in the course of the disease.

Purpura factitia

Bleeding, bruising and purpura have all been reported as factitious disease. A case of autoerythrocyte sensitivity associated with dermatitis artefacta has been recorded [20]. Anticoagulant malingerers, dicoumarol eaters and superwarfarin ingesters [21,22] misuse anticoagulants to produce bruising and bleeding. Child abuse has also been induced by surreptitious warfarin ingestion [23]. High-dose aspirin has also been taken by adults and given to children to produce similar but milder effects. Mechanical suction purpuras are ingenious and usually found on the chin in children as a result of sucking on a cup or glass. Adults may produce the purpura using machinery [24,25].

Factitious skin disease [1,2]

Doctors are trained to believe what the patient says. The unwritten contract of the consultation process is that the patient will relate the details of the illness as truthfully as they see it and respond to the physician's questions as openly as possible, neither deliberately hiding nor distorting the facts. The physician makes these assumptions in assessing the combination of signs and symptoms of the illness. It is also assumed that the patient will not do anything to hinder or interfere with the course of treatment and recovery. The anxious and apprehensive patient will commonly exaggerate or occasionally minimize symptoms in order to press their case in the alien and unique atmosphere of the consulting room. 'My skin was literally on fire and I had to throw myself into the bath' is the dramatic expression of the effects of skin disease on a patient driven to hyperbolic and dramatic language rather than by any real belief she had to convince her dermatologist that she had suffered spontaneous combustion of the skin. Patients may mis-attribute causation on the basis of experience, culture and a need to place the illness in a context. They may have mistaken beliefs because of other advice from other medical or increasingly media- or Internet-inspired sources. These consultation behaviours are common and do not really constitute a fabrication, although as persistent conduct can alienate a clinician's objectivity.

The clinician can be deceived by somatizing illness which has an unconscious basis, for example pain syndromes, the dynias, psychogenic itch or rarely for a dermatologist a conversion phenomenon which has a wholly psychogenic cause. These were previously grouped as hysteria.

Clinical deception refers to a spectrum of illness that lies in a continuum depending on the level of intention to deceive at the time of the act and the motivation for the induced illness. The definition of factitious behaviour is not completely clear since the level of intention may vary but for the dermatologist the definition by DSM-IV-TR [3] criteria maintains the difference from malingering. The DSM-IV-TR criteria for factitious disorder include:

A Intentional feigning of physical or psychological signs or symptoms

B The motivation is to assume the sick role

C External incentives for the behaviour (such as economic gain, avoiding legal responsibility, or improving physical well-being, as in malingering) are absent.

Criterion A supposedly excludes disorders characterized by unintentional production of symptoms, thereby marking a distinction between factitious disorders and somatoform, conversion and dissociative disorders. Criterion B assumes an internal incentive but a conscious one and criterion C excludes the intentional production of symptoms for external gain, thereby marking a distinction with malingering. There is much debate about this imperfect definition but it serves to helpfully distinguish most categories of factitious illness found in dermatology.

Dermatologists will encounter the DSM-IV subtype 300.19 presenting with predominantly physical signs and symptoms.

The nomenclature for dermatological lesions produced by patients as defined above is multifarious. Artifice is a noun meaning the use of cunning plans or devices in order to trick or deceive whilst an artefact is defined as man-made and artistic or decorative. A fabrication is an invention often in certain contexts meaning with deceitful intent, whilst factitious is an adjective meaning artificial or contrived. The term factitious dermatitis will be used preferentially here in keeping also with the revised definition of Münchausen's syndrome by proxy as factitious or induced illness (FII) [4].

Most physicians will maintain an endearing and undiscerning naïvety even in the face of strong evidence of simulated or fraudulent illness. The dilemma for the clinician is to determine the degree of intention present in the patient for the consciousness of the action which may not equate with the consciousness of the motive.

Factitious falsification of information, that is lying, is a consequence of the manufacture of skin lesions, the occult use of others (proxy disease) and disease produced for material profit or retribution. The lying may have a different quality in these cases such that the psychosocial lies of the impulsive, immature, young girl are mainly used to avoid the shame and denigration of exposure whereas the pathological lies (pseudologica fantastica) of the accomplished malingerer are used to embellish his performance.

There are a series of recognized skin diseases characterized by the essential features that, firstly, they are caused by the fully aware patient and, secondly, there is a desire to hide the cause from their doctors. This definition includes dermatitis factitia, dermatological pathomimicry, dermatitis simulata and dermatitis passivata. These syndromes are additionally distinguishable from others where there is overt secondary gain, such as Münchausen's syndrome, Münchausen by proxy and malingering.

Dermatitis factitia

Definition. Dermatitis factitia is a skin disease caused entirely by the actions of the fully aware (i.e. not consciously impaired) patient on the skin, hair, nails or mucosae. These patients hide the responsibility for their actions from their doctors.

Epidemiology and aetiology. In adults all studies have shown a female preponderance, the ratio of female to male varying from 20:1 to 4:1 [1–5]. Lesions have been found in children from the age of 8 years [5], pre-pubertal children having an equal sex ratio, rising to 3:1 female predominance by early teenage years [5,6]. These series confirm that the majority of cases begin in adolescence and in adults under 30 years of age, although there is an important subgroup whose age of onset is significantly older. This subgroup is distinguished by being more likely to be male (male to female ratio 2:1), to produce more subtle skin lesions [1,2] and to have a past history of somatizing illness [1,5,7]. These complaints may take the form of pseudoseizures, abdominal pain, syncope, chronic fatigue and backache. Previous work has suggested that factitious dermatitis is more common in health-care workers and their families [8,9] because this environment provides not only a ready 'model to copy' but also a social structure where illness is always sympathetic and allowed for. However, this bias may now be less obvious [2–4] in a well-informed society whose medical symptoms, pathology and disease are more available via the media and the Internet.

The motivation to assume the sick role [10] depends on understanding the lexicon of medical anthropology. There is a distinction between disease, illness and sickness. Disease refers to primarily biological forms of pathology, illness to the subjective experience of being diseased and sickness involves the *process* of being ill. People differ in the way that they perceive, assess, act or fail to act upon the symptoms that they experience. This is recognized as a personal 'illness behaviour' [11] and shapes the role, firstly, within the family and, secondly, with professional health advisors. Those who assume the sick role [10] are exempted from responsibility for their illness but should do all in their power to get better. The psychopathology underlying the production of factitious lesions [1,2,12,13] suggests that the patient *wants* the *sickness role* as the essential pathology since the primary gain of *being a patient* is usually to be suspected of all illness. It is suggested that these patients have strong masochistic needs, for

example self-hate and guilt, and an illness which allows inappropriate regression and avoidance of adult (especially sexual) responsibilities, for example marital trauma. Factitious illness symbolizes both anger at, or conflict with, authority figures, for example school phobia and attempts at mastery of past trauma. Psychiatric or medical care fulfils massive dependency needs, for example inadequate coping strategies.

In many cases, the psychosocial stress of a major life event may be apparent. Children and adolescents commonly show anxiety and immaturity of coping styles in response to a dysfunctional parent–child relationship, bullying, physical body changes, or sexual and substance abuse. Adults may be neurotic and react to adverse situations in an immature, impulsive manner [3,12]. However, there may also be significant depression [2,3]. The more chronic patients tend to have a demonstrable personality disorder, more particularly borderline or hysterical in females and paranoid in males [2,12,14]. There is a significant literature on the relationship between factitious disorder and illness falsification in both children and adults and previous factitious and induced illness (FII; see below).

The development of factitious illness is commoner in those with memorable early (and sometimes continuing) experience of illness. There is a frequent association with medicine and these patients may have a grudge against medicine because of perceived mismanagement to them or their family. Alternatively, there may have been a close relationship to a physician in the past which is now loosened. It is part of the doctor–patient relationship that as an acute, active illness passes into a more chronic, enduring phase, some patients perceive that they are less important to both family and physician and a sort of 'emotional fatigue' is apparent in their responses to them.

Fig. 64.9 Factitious dermatitis; symmetrical and predominantly monomorphic.

Fig. 64.10 Factitious disease of skin on the chin and 'Mona Lisa smile'.

Clinical features. The two characteristics of the illness are, firstly, the physical signs and, secondly, the fabricated story that accompanies it. Because this story is essentially a compendium of lies, the nature of the clinical symptomatology in factitious dermatitis is the 'hollow history' [15]. The patient often describes the sudden appearance of complete lesions with little or no prodrome. There is no complete description of the genesis of individual skin lesions. The signs appear or are 'discovered' on waking, or in a lunch break, or on the way home from school or work. Lesions appear at an identical stage in development, in crops or groups, more often symmetrically but rarely scattered apparently at random (Fig. 64.9).

There is a significant lack of a history of progression of each lesion from its initial appearance to its fully developed state. By contrast there is a prolonged and elaborate description of complications and the failure to heal. Characteristically, established lesions may undergo sudden deterioration at the same time as new areas appear. Only rarely do patients use more than one method to produce lesions. It has been suggested that the patients show a 'belle indifference' to their predicament as part of a dissociative state and that, in the presence of visible disease, manifest a nonchalance and innocence transmitted through an enigmatic 'Mona Lisa smile' (Fig. 64.10).

This is more likely to represent a characteristic gesture of liars under questioning [15]. It is probably truer to say that the patients are more often passive than aggressive, even though they have a widespread disfigurement. However, considerable anger is commonplace from parents, carers, husbands or partners, who complain at the incompetence of a succession of doctors. This may extend further to recruiting other doctors, university academics, nurses and social workers to support their case [2]. More than one person may be involved, as in the *folie à deux* of two patients with factitious ulcers [16]. Official complaints to hospital management and to local government officials may follow.

Clinical signs [4,9,17]. For all age groups the commonest site of involvement is the face, particularly cheeks, representing over half the presentation in children [2,5,6]. The dorsa of the hands rather than the palms are the next commonest site, then the forearms,

Fig. 64.11 Crude, linear, angulated and destructive factitious dermatitis.

Fig. 64.12 Persistent ulceration of the breast from covert injections of milk and talcum powder.

most frequently of the non-dominant limb. There is a particular covert pattern on covered skin where the clothes hide significant mutilation of the breasts, abdominal areas and sometimes the genitalia. These areas of damage in young girls should prompt inquiry about sexual abuse. Involvement of the back, axillae and external ear is uncommon.

Cutaneous lesions have been produced by every known means of damaging the skin and are thus polymorphic, bizarre and mimic any of the known inflammatory reactions in the skin. Factitial dermatitis should enter the differential diagnosis of every chronic, puzzling and recurrent dermatosis. Most patients have simple 'models to copy', mainly acute inflammatory, traumatic or infective. The lesions are crude, angulated, destructive processes with a tendency to a linear configuration, as the result of thermal, chemical or instrumental injury (Fig. 64.11).

Circular erosions or blisters of a uniform size can be manufactured by cigarette burns or cryodamage from a closely applied pressurized aerosol such as an antiperspirant or asthma inhaler [18]. Perfume may remain detectable in the lesions for some days (personal observations). Less commonly, dermal lesions from blunt trauma presenting as odd haemorrhages or dramatic dermal indurations and necrosis are found from foreign body injections of milk, cosmetic oil or industrial grease. These are found more often in the breasts (Fig. 64.12), thighs or penis, the latter as covert body augmentation.

Oedema of limbs from constricting bands and hysterical dependent posture has been described [19] (Secretan's syndrome). It is characteristic that one digit, usually a toe, will be constricted at a time whilst all others are healthy. A repeated series of single, different ischaemic toes, whilst all others are healthy, should raise suspicion of external banding. Embolic disease can be excluded by vascular scan.

Excoriations may be made with nail files, sanding boards, cheese graters or wire brushes to produce raw, crusty, linear or arciform lesions with characteristic geometrical edges (Fig. 64.13). Punched-out necrotic areas, sometimes with blisters developing into indurated scars, are typical of thermal burns from cigarettes, soldering irons or ovens. These lesions are usually uniform in size and scattered haphazardly. Urticarial lesions are initially produced by chemical damage and progress subsequently to blistering, crusting and scarring.

Fig. 64.13 Dermatitis factitia: note the straight edges and sharp angulation of some of the lesions.

Characteristically, these areas may show the 'drip-sign', where corrosive liquids have been uncontrolled and allowed to run over

Fig. 64.14 Dermatitis factitia showing the drip sign.

the skin (Fig. 64.14). Bleaches, soaps and household cleaners are most commonly employed by women; industrial acids and automotive fluids by men. These chemicals may produce a persistent, detectable smell on the skin. Purpura and bruising are seen after suction, friction or blunt trauma. Children produce purpura on the chin by sucking on cups and on limbs by direct mouth suction or with the use of a toy or tool. Shearing stress also produces purpura, tending to present as linear limb lesions. Extensive bruising and bleeding in a child means that factitious and induced illness (see below) should be excluded, caused not only by trauma but also drug-induced by anticoagulants (see above, factitious purpura).

Subtle factitious skin lesions [2] are seen as fixed urticaria, vasculitic dermal nodules, panniculitis-type lesions and boggy fluctuant swellings. Considerable atrophy and pigment change occur with resolution. Careful examination of an acute lesion may reveal the presence of a needle track where milk, air, faeces, urine, cooking oil, silicone, grease or engine oil has been injected [20,21]. Access to needles and syringes may be via medical or paramedical family and friends. In other medical specialities, such as ophthalmology, oral medicine and otolaryngology, factitious disease presents as non-healing, infected wounds and excoriations [22–24].

There is a group that presents with a non-healing, post-surgical wound. This may follow a small operation after minor skin trauma, breast biopsy or instrumentation such as a laparoscopy (Fig. 64.15).

Wounds 'burst' after the sutures are removed, become recurrently infected and real organisms such as MRSA appear. Unfortunately, further 'wound repairs' exacerbate and legitimize the continuing wound. It is not unusual to see patients who have had up to eight operative revisions before a further referral is made to a dermatologist. Real complications arise, such as osteomyelitis or fistulae, provoking the need for further intervention [25]. There may be unexpected complications to the induced damage, leading to severe infection such as cerebral abscess [26], osteomyelitis and peritonitis, which may be life threatening [25,27].

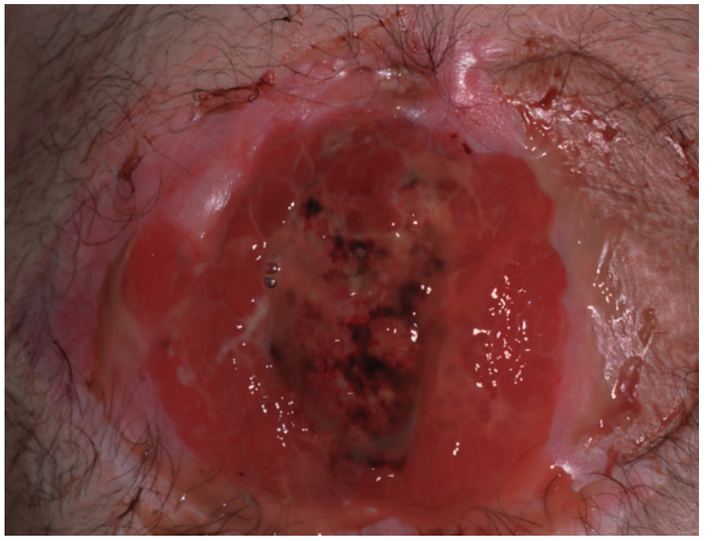

Fig. 64.15 Non-healing wound after surgery with characteristic central 'interference haemorrhage'.

Fabricated skin disease in children can begin from the age of 5 years (personal cases), is significantly more common in girls [5,6] and has an additional emphasis on certain imaginative presentations. Makeup, skin painting and application of glue have been skilfully used to simulate port-wine stains, other naevi, scaly dermatoses and even religious stigmata (personal series) (Fig. 64.16). Widespread, destructive eroded lesions can be an indicator of past or present sexual abuse [28].

The disease becomes self-generating as a perpetual circle of laboratory tests and investigations compounded by the voluble distress of the patient about the effect of the wound and the complaints of the relatives about medical incompetence. The primary reason for the appearance of the wound is obscured. The reason for the medical journey becomes lost because the accompanying emotional and investigative luggage has become so heavy and obstructive.

Differential diagnosis. The distribution and physical characteristics of the crude dermatitis are almost diagnostic. However, blistering, crusty lesions may simulate ecthyma, herpes simplex and bullous disorders. More subtle facial blisters may simulate porphyria cutanea tarda. Rare disorders, such as epidermolysis bullosa acquisita or amyloid, are a trap for the unwary. The collagen–vascular diseases including vasculitis and pyoderma gangrenosum must be excluded in non-healing wounds as must atypical mycobacterial infections and imported tropical infections. The curious linear dermatoses such as Nékam's syndrome, cuta-

Fig. 64.16 Glue applied to look like herpes zoster.

neous lymphomas, epidermolysis bullosa pruriginosa and linear drug eruptions [29] must be excluded. The diverse hereditary sensory neuropathies can show chronic non-healing ulcers and be mistaken for factitious wounds as can the cutaneous changes of reflex sympathetic dystrophy [30,31]. Drug addicts develop extensive ulceration and scarring at injection sites after extravasation of drug 'cocktails' into the skin. The purpuras and tissue purpuric reactions such as cutaneous amyloid can be perplexing and should be excluded [32].

Factitious cheilitis

Synonym
- *Le tic des levres*

The production of artefactual lesions of the lips is not common. Studies are small but a personal review of cases reported over the last 10 years shows that it is commonest in girls and young women but the incidence is equal in older groups [1,2]. Simulation of cheilitis has been produced by applying a crust of paper, glue and colorant. There is a significant debate about the role of factitious behaviour in the pathogenesis of exfoliative cheilitis. Reactions of the lips are limited and appear particularly as persistent inflammation with crusting and variable haemorrhage. The crusts may be very thick with a succession of layers of congealed haemorrhagic exudates resembling a carapace or oyster shell. The haemorrhage can also be impressive with coagulated blood and serum extruding over the lips. This is caused by picking, biting, rubbing and licking [3,4]. Occasionally, young adolescents will develop a disuse crusting of the lips because they become dysmorphic about cleaning and washing their mouth [5]. Removal of the crusts leaves a relatively normal lip although with time there is some superficial erosion.

Differential diagnosis includes contact dermatitis, actinic damage, chronic lip-licking habit and causes of granulomatous cheilitis.

Secondary candidiasis is not uncommon and treatment containing an antifungal is helpful as well as addressing the problem of self-trauma (see below).

Factitious nail disease

Traumatic and chemical damage to both the nail and nail fold have been seen in children and adults [1]. The paediatric cases show chronic paronychia caused by the insertion of nails, pins or splinters [2]. Soldiers avoiding duty have habitually used caustics to damage their fingers. The characteristic lesions show purpura and haemorrhage around the nail fold but also subungual haemorrhage and pustules. Similarly, Lyell [3] described a patient who induced haemorrhagic nail loss using a nail file. A significant sign is repeated traumatic nail loss occurring singly or multiply on one hand only. The differential diagnosis is described in Chapter 65.

Hair artefact

A distinctive pattern of hair loss may occur after cutting or shaving. It differs from the plucked appearance of trichotillomania with obvious gross changes such as rough, cropped areas of hair loss or unnatural, patterned shaved alopecia of scalp or eyebrows.

Differential diagnosis. See Chapter 66.

Witchcraft syndrome [1,2]

Artefact dermatitis can be provoked on an unknowing and unsuspecting victim by proxy. As an act of revenge, the daughter of a hairdresser applied benzyl ether of nicotinic acid to a customer's skin. This induced hyperaemia with some oedema within 10 min but not on the perpetrator since absorption of the agent is very low on the palm of the hand so she could easily apply it to the customer's skin without harm to herself.

Dermatitis artefacta with artefact of patch tests

Bullous dermatitis artefacta in a female veterinary assistant healed with occlusive dressings [1]. New bullae on the other arm prompted the parents to demand 'allergy' tests. Ten patch tests to yellow petrolatum were applied to the back, which provoked a non-inflammatory bulla on one of the sites 2 days later. In another case the patch test reaction was mimicked by scarification in an attempt to claim compensation [2].

Investigations. The primary suspicion of factitious dermatitis is clinical. The diagnosis is on the weight of evidence, both clinical and investigational, over a period of time. The clinical evidence is as much a finding of fact as the finding of, for instance, talc injected in a wound, provided that this has demonstrable objectivity. Clinical evidence is based on the physical appearance, distribution and evolution of lesions. Other clinical diagnostic clues may be seen such as the sparing of decorative marks and the areas of skin on the back [1]. Suspicions are aroused by the presence of physiologically impossible symptoms, observably incompatible lesions, contradictory objective evidence and non-response to reasonable treatment. However, certain investigations may produce supportive information. Dressings or underlying skin lesions may test unusually acid or alkaline with litmus [2]. Odd discoloured areas, brown, red or green, may dissolve with alcohol swabs and the pigment analysed by chromatography [3].

A skin biopsy will provide essential supportive information [4] but may not be necessary in all cases such as suction purpura (see above) on the chin. Trunk and limb lesions are easier to biopsy than facial areas but if there is a solitary lesion a diagnostic biopsy is indicated. Indurated areas need a deep incisional section to include deep tissues down to subcutaneous fat [4]. The epidermis is most damaged by friction or chemicals with a vacuolar dermatitis and lymphocyte around degenerating keratinocytes. The superficial acute and dramatic epidermal necrosis from physical and chemical damage is characteristic of crude damage to the skin. Additional subepidermal blistering can be produced by thermal and cryodamage. In contrast, the subjacent deeper dermal tissues can appear spared. Some chemicals, for example toothpaste, can induce unusual inflammatory reactions suggestive of cutaneous lymphoma [5] simply as a response to continuous rubbing and a foreign body reaction. Lesions produced by injections into subcutaneous tissues produce deeper lesions which show as vasculitis or an odd panniculitis. Careful examination may show injection tracks and foreign material [6–8]. Ink shows as pigment with limited inflammation, and talc excites a macrophage reaction with giant cells. Injected oils and greases produce deep continuing panniculitis. An alarming form of squamous syringometaplasia was seen after covert injections [9]. Special stains can reveal silver from silver nitrate caustic damage. Examination under polarized light can identify foreign material and further refinement can be found with energy dispersive X-ray analysis and infrared spectrometry [10]. Unlike disease states, the histopathology of factitious disease may vary with time and it has been shown that serial biopsy may be diagnostically helpful in sophisticated artefact [4] because

differing patterns of change may be present on each occasion. Occasionally, patients will bury needles completely into their skin to produce recurrent abscesses. A straight X-ray will visualize these. Some patients have inserted hundreds of these throughout the skin. Identification in one area needs X-rays of other body areas also. Wooden skewers may also be inserted, these are best seen via MRI scanning (personal cases).

There are psychometric tests which can be used for the assessment of factitial disorders, but these are essentially research tools [11,12].

Co-morbidity. Twenty per cent of patients have a somatization disorder and hypochondriasis [1,2]. These are co-morbid with anxiety, depression and substance abuse [3]. Borderline personality disorder is a factor for chronicity in both sexes [4]. True hysteria where there is dissociation between the act of self-damage and the awareness of performing the action is debated at length based on the premise that the patient may be performing a conscious act for unconscious reasons [5].

Treatment. The management of factitious dermatitis is not an interrogation. There are three therapeutic aims. First, the skin damage may be extensive, disfiguring and infected. It is a mistake to assume that the perpetrator, that is the patient, does not wish treatment. There is always significant skin damage which will be both inflamed and infected with the potential for scarring and residual pigmentation. The process of tissue repair may take time but allows the opportunity for patient contact and relationship building. Topical and systemic antibiotics, analgesics and anti-inflammatories establish the doctor–patient relationship and underline to the patient that the physician has a helpful, non-aggressive, sympathetic approach. Efficient occlusive bandaging will allow most lesions to heal except for those of the most devious and determined.

Secondly, time should be taken to identify the nature and extent of the psychological problem. The dilemma has always been whether patients should be confronted or not [1–7]. In most cases the urge to confrontation is stimulated by the aggression the physician feels because the doctor–patient relationship has apparently been betrayed. The doctor must avoid personalizing the episode and needs to consider the approach which is likely to change the patient's behaviour.

For many years a non-confrontational and non-punitive approach has been favoured. This passive acceptance of 'a cry for help' has the merit of a non-aggressive interview in the short term. The psychological problems should be approached in a non-intrusive manner [5–9], allowing the patient freedom to express their difficulties in a passive, confidential environment. Children usually respond well to this approach, particularly if a cause of psychosocial pressure is identifiable. However, chronic persistent self-damage is predictive of long-term emotional illness and referral to a child psychiatrist is imperative [4]. Paradoxically, too passive an approach gives the patient consent to continue in the abnormal sickness role [4,10]. Although this approach has been unsuccessful, for a dermatologist it is the most comfortable since there is no confrontation.

Thirdly, adult patients may respond to a different type of non-confrontational approach which also displays surprising robustness. This is the 'narrow escape', 'quasi-confession', 'recovery', 'face-saving' or 'escape with honour' strategy. This mechanism works by suggesting that the patient does some 'personal homework' to find a solution to their illness by offering a rationale for recovery. The patient may claim that alternative medicine such as hypnosis, homeopathy or fringe methods such as manipulation and aromatherapy has 'cured' them. It is important to follow up the patient to establish that psychological and social factors were intrinsic to the remission.

One additional technique is the double-blind strategy where the physician explains that the treatment carries an expectation for recovery. If this does not occur then they will be forced to conclude that failure to improve constituted conclusive evidence that the problem is psychological or factitious [10]. A study of behavioural interventions of this type in acute and chronic non-organic (conversion/factitious) motor disorders showed that this produced positive resolution in chronic cases resistant to more passive techniques. This strategy worked particularly well where members of the family were angry or sceptical about the nature of the symptoms.

In addition, the physician can reformulate the physical problem as a synthesis of both the physical and the psychological effects of

discovered stressful events. This deliberate change of agenda provides a basis for an 'inexact explanation', relating the stress to the appearance of physical lesions without direct confrontation. This is a form of *indirect* confrontation.

Direct confrontation is a highly charged strategy and should only be used if the deliberate act is certain (e.g. if the self-damage has been witnessed) and there is sufficient support and advice available at the consultation. In certain paediatric cases early intervention with confrontation has been advised [11]. This will need the assistance of psychiatric advice and to effect a transference to psychiatric care if necessary. This catharsis can be achieved in a manner which allows the patient to express a positive decision to change without dwelling on the deception and precipitating an aggressive defensive response [1,4,10–12]. Not surprisingly, other workers disagree with this approach citing the high failure rate and the risk that the patient may strive even harder to legitimize the illness and himself by consulting other doctors [2,7].

The management and prognosis in adults is that of the primary psychological disorder [8]. Acute stress reaction can be addressed in a series of short consultations at the time when the dressings are changed. Depression responded well in two series to tricyclics, or SSRI antidepressants [7,8] even when no precipitating event was identifiable. Tacit acceptance that the cause of the rash has been identified, without further challenge, helps to make the transfer to formal psychiatric care easier if needed [10]. Between one-third and a half of patients continue to develop chronic lesions [6,7–9]. Such cases usually have a personality disorder, commonly hysterical, paranoid or borderline [10], and need psychiatric assessment [13]. Unfortunately, this is frequently unacceptable to the patients who default the clinic or are referred elsewhere.

Dermatological pathomimicry [1]

Some patients may intentionally aggravate an existing dermatosis using the explanation of its genesis given by their dermatologist. It is distinguishable from dermatitis factitia because the disease appears like an exacerbation of established skin disease with none of the bizarre physical signs typical of mechanical, chemical or thermal interference. This is also to be differentiated from self-inflicted delayed healing of surgical and traumatic wounds which is achieved by external damage. The clinical suspicion should arise when patients suffer unexplained exacerbations of disease or are particularly unresponsive to adequate supervised therapy. A group of 13 patients who had deliberately caused recurrence of their existing skin disease by reintroducing the precipitating factor and invoking the original pathogenic mechanism have also been described [1,2]. Atopic patients reintroduced allergens, for example animal danders, and patients with proven allergic contact dermatitis used the allergen on their skin, for example lanolin, local anaesthetics. Those patients with systemic drug sensitivities were found to have the drug detectable in their blood or urine on representation. Known past irritants were applied to chronic leg disorders and a married couple swapped contaminated dressings to continue mutual skin sepsis. Since the original description there have been numerous reports of contrived exacerbations of common dermatoses. A patient with psoriasis covertly retook atenolol which previously had caused problems (personal communication). Other reports have described irritant contact dermatitis [3], allergic perianal dermatitis [4] and artificial oedema of an arm or leg [5]. The largest group were young women who had lost support from within their family group. A smaller sample were elderly who had lost social contact and felt isolated.

More direct confrontational discussion without recrimination proved helpful and follow-up showed only minor recurrence in two patients 5 years later [2].

Dermatitis simulata

Apparent skin disease can be represented by patients who are ingenious enough to use external disguise to simulate disease. These patients do not significantly damage their skin. Makeup has been used to paint on a rash [1] or simulate a birthmark. This is most common in children. Glue and crystallized sugar can produce a coagulum to simulate a desquamating rash or chronic cheilitis, drugs to induce skin discoloration [2] and topical printing dyes to produce discoloured sweat [3]. These discolorations can be removed by aqueous or alcohol swabs and analysed if necessary [3]. Sugar crusts dissolve easily in water, keratin ones

do not. Red makeup has been used to simulate a port-wine stain on the face. Localized red facial rashes seen on two young girls disappeared after treatment with erythromycin but no analysis of the pigment or skin biopsy was possible to confirm the source of the pigment in this bizarre distribution [4]. An acute blue patch on the arm of a diabetic in an injection site was diagnosed on biopsy as self-injected printer ink rather than an injection haematoma [5].

These deceptions were clever enough to confuse their doctors for months. Most of these patients were young and immature, but a somatizing illness was recorded in one older patient and previous treated depression in another. The main differential diagnosis is from apocrine and eccrine chromhidrosis or pseudochromhidrosis after accidental absorption of dyes through the skin.

Dermatitis passivata

The cessation of normal skin cleansing will produce an accumulation of keratinous crusts. This is commonly seen in geriatric or demented patients who suffer from self-neglect and in its extreme form has been called the Diogenes syndrome [1,2]. The lesions are the result of self-neglect and comprise cumulative accretions of keratin and dirty debris which forms a thick carapace with time. Lesions are usually found on the upper central chest, over the back and accumulated as coagulated debris in the groins. These elderly patients may be paranoid, have mood disorders or have temporofrontal dementia. Alcohol abuse is a co-factor. Characteristically, they are hoarders and live in extreme squalor. However, a group of younger patients have been described [3] who showed lesions on the scalp, face or arms. They were young adults who were invariably accompanied by parents or family (Fig. 64.17).

Significant psychopathology was schizoid thought disorder and social withdrawal. Occasionally, patients with a dissociative hysterical limb palsy will present with mild but significant hyperkeratosis on the affected limb. Specialist psychological therapy was usually necessary either as day care or community psychiatric support [2,4].

Malingering

Asher [1] defined malingering as the imitation, production or encouragement of illness for a deliberate end. The American Psychiatric Association DSM-IV definition states that the 'essential feature of malingering is the intentional production of false or grossly exaggerated physical or psychological symptoms, motivated by external incentives such as avoiding military duty, avoiding work, seeking financial compensation, evading criminal prosecution, or obtaining drugs'. However, the taxonomy of malingering is difficult because of the moralistic overtones of criminality and false compensation litigation [2–5].

Malingering may be co-morbid with conversion disorders, personality disorders and other factitial behaviour. However, usually it differs from most factitial disease in being short-term and opportunistic whereas other illness falsification is chronic and persistent. Fear, desire and escape are the three main motives to produce false or grossly exaggerated physical or psychological symptoms. Soldiers feigning disease and disability hope to avoid duty, suspend transfer or be discharged from the service [6,7]. Workers can prolong sick leave, delay corporate change of job or seek to obtain early retirement with an apparently extended illness [8]. Some patients may seek compensation for some contrived illness, for example alleged burns, or aggravate and continue an existing disease, for example industrial dermatitis, out of a sense of grievance or retribution. Active intervention to introduce policies and procedures to reduce the risk of illness deception at work are recommended [9]. Prolonged legal cases of supposed medical negligence are common in those with manufactured illness whose dissatisfaction with their doctors or the care they have been given may lead to a financial settlement as a reward [10].

Chronic, non-healing, post-operative scars are manipulated with instruments, or even faecal injection to maintain sepsis [11,12]. Hand dermatitis, both irritant and allergic contact, may be perpetuated to seek higher compensation awards [13,14].

Treatment depends on the underlying psychiatric illness if significant psychopathology can be found but the opportunist

response in patients with an underlying personality disorder is poor.

Pseudologica fantastica and Münchausen's syndrome [1–4]

Asher used this term to describe the notorious hospital hopper who presents with a dramatic and untruthful story of illness. This is a chronic, severe and dramatic subtype of factitious disease [1]. The essential elements are the recurrent nature of the illness, and the frequency and similarity of the repetitive pattern of the complaint in different hospitals (peregrination). The simulated illnesses may be esoteric and rare with the patient often presenting a dossier to the doctors. Whilst dermatological complaints are uncommon in Münchausen's syndrome, simulated porphyria and connective tissue disease, for example, may present to the dermatologist. The last element in the syndrome is pseudologica fantastica (pathological lying) [3]. This describes the telling of lies about past social history and connections, exploits, wealth and invention of an alias. The patients are usually male, over 30 years of age and travel widely from hospital to hospital. They complain of abdominal pain, haemorrhage or some neurological incapacity. Skin lesions are rare. The commonest signs are non-healing wounds, widespread blistering or multiple excoriations associated with other somatic complaints [5]. Serious consequences such as septicaemia and paraplegia have occurred [6] from induced cutaneous ulceration. Characteristically, patients take their own discharge if they sense their deception has been discovered. The Internet provides access to those interested in health and medicine and is a rich resource for the expansive personality of the Münchausen patient. Because the Internet offers 'virtual support groups' these individuals may offer 'virtual' factitious disorders. Four cases have been reported showing the facility with which they can attract attention, mobilize sympathy and control others [7].

Fabricated and induced illness (Münchausen's syndrome by proxy) [1,2]

In 1977, Meadow [1] had the clinical acuity and personal courage to describe the syndrome of Münchausen by proxy where the illness in the child is fabricated by the parent, usually mother, or someone *in loco parentis*. This phenomenon has been redefined as fabricated and induced illness (FII). Other carers may be involved and that may include health professionals. Doctors and others may not only fail to understand the origins of a child's symptoms but also institute further harm by inappropriate investigations, treatment and surgery [2]. The guidelines to identifying cases [3] mirror many of those discussed for factitious dermatitis. The history is 'hollow' with a lack of detail. Most parents and carers can give a clear account of an accident. Risk factors include single parent, previous abuse, frequent visits to GP or Accident and Emergency departments, poverty, overcrowding and young parents. The victims have a persistent or recurrent illness that cannot be readily explained. The previous diagnoses remain descriptive and not stringent. Symptoms do not respond and laboratory tests are incongruous. The reported symptoms are inconsistent with presenting health and the symptoms fail to appear in the absence of a certain parent (usually the mother). The perpetrator is reluctant to leave the child even for a few minutes, but remains oddly impassive even in an emergency. They refuse treatments and hospital admission and may become hostile and abusive. Characteristically, these carers attempt to make close relationships with some medical staff, usually nurses, with a blurring of the professional–parent objective relationship. There may be fabrication of family details and a disturbed marital and social structure. Rarely, the parent exhibits the syndrome herself and produces proxy lesions on the child [4].

The victims are usually infants or toddlers with a mean age at diagnosis of 40 months [5,6,7]. The mean delay between presentation and diagnosis was 15 months. The most common presentations in a literature review were bleeding and bruising (44%), CNS depression (19%), apnoea (15%), diarrhoea (11%), vomiting (10%), fever (10%) and rash (9%) [6]. A list of 105 symptom presentations showed dermatological lesions were amongst the five commonest signs [7]. Skin lesions are very commonly bruising, often blistering

and burns. Bruises in children are common on the lower legs and arms but certain sites should raise concern. These are the face and head of a child less than 1 year old, sides of the face and ears, black eyes, and bruising on buttocks/lower back and outer thighs. These are the 'punishment' sites. The pattern of bruising may show fingertip marks, striate finger stripe effect from slapping, or pinch marks as opposing crescent shaped lesions. Kicks to the lower body show as irregular, large, deep bruises. Belt and strap damage appears on the trunk as parallel curved marks. The other skin lesions are usually crude forms of factitious dermatitis [6,8] produced by thermal burns or caustic corrosives on the skin [9]. On one occasion the rash was the result of drug poisoning. A large review of countries outside English speaking industrialized populations produced similar results in rather older children [10]. The long-term consequences of childhood victimization might contribute to the development of factitious disease in adult life. Elements of the child victim experience, including feelings of powerlessness, lack of control and disappointment in the physician, are the suggested dynamics for the development of independent illness falsification [11]. A full discussion of the issues in these cases with the paediatric services is essential [12–14].

Münchausen by proxy may also rarely be seen in the elderly, mentally handicapped or other dependent persons [14,15] perpetrated by relatives, nurses and care-home personnel.

Medicolegal issues in suspected factitious dermatitis [1]

The most important action for the physician who suspects factitious disease is to share the suspicion with colleagues at a very early stage. Case conference discussion and involvement of the institution's management and legal services after these group discussions help to avoid isolation and persecution of the physician. Structures will differ according to health providers in each country but the solitary physician may find disappointing support if an acrimonious dispute arises and legal action has been taken.

Self-mutilation

Self-mutilation of the skin, sometimes termed self-injury or self-harm, may present with a wide range of lesions. Cutting and scratching are frequent, but other methods, such as grazing, burning with fire or chemicals or insertion of foreign bodies under the skin are also seen. The damage can be to a wide range of body parts, including face and genitals. Cases of self-mutilation may present to accident departments with acute damage in need of treatment, or present with chronic lesions or scarring in clinic (Fig. 64.18).

The relationship between such self-harming behaviours and suicide is complex and varies widely amongst cases [1]. Authors have made a distinction between repetitive cases of self-mutilation that occur in the context of suicidal ideation, or ambivalence towards suicide, and those cases that clearly occur outside the context of suicidal ideation [2–4]. It should be noted, however, that there is a potential for overlap between the two, both due to the difficulty in measuring or categorizing 'intent' [5] and cases of repetitive self-mutilation, apparently without suicidal intent, progressing to completed suicide [3].

Self-mutilation with suicidal ideation

Self-mutilating behaviour is often grouped with other behaviours, such as self-poisoning, attempted hanging or jumping from heights, as 'parasuicide' or 'deliberate self-harm'. The patient describes suicidal ideation, or ambivalence about continuing to live, at mental state examination. The most frequent lesions are caused by self-cutting, often to the wrists. Burns and ligature marks, and their scars, may also be seen.

The predisposing and precipitating factors for this behaviour are numerous [1,6]. The act may be in response to the symptoms of an underlying psychiatric illness, such as depression, substance misuse or schizophrenia. Vulnerable individuals may respond with parasuicidal behaviour to social or interpersonal stressors. Often a combination of the psychiatric and social is elicited from history.

Patients often present to Accident and Emergency departments with acute lesions. In many areas, psychiatric screening of such cases by specialist services is standard. Some patients, however, commit these acts and do not present for emergency medical treatment. Patients may present with chronic lesions or scarring when this behaviour has become a frequent response to stressors, and such stressors are chronic, such as untreated illness or continuing social problems.

Referral for treatment of underlying psychiatric illnesses is indicated where one is present. There is evidence that social intervention is of benefit in improving outcome where these factors are precipitants [7].

Repetitive self-mutilation without suicidal intent

A number of authors have made the case for a distinct syndrome of self-injurious behaviour, or self-mutilation, occurring outside the context of conscious suicidal ideation [2,4,5,8]. Currently, a disorder of self-mutilation does not occur in either the ICD-10 or DSM-IV classifications of mental disorders, although ICD-10 contains the category 'Other habit and impulse disorder' (F63.8) and DSM-IV 'Impulse control disorder, not otherwise specified' (312.30) and it has been suggested that repetitive self-mutilation meets the criteria for these categories [2,3].

A further attempt has been made to classify the syndrome into categories based on degree of tissue damage and rate and pattern of the destructive behaviour, yielding the categories Major, Stereotypic and Superficial/Moderate [3,8]. When described as a syndrome, onset is reported as typically in early life, below the age of 30 years. Increased prevalence in women is reported by the same authors. The mean duration of the syndrome is 12 years [2]. Recent work has demonstrated a potential genetic link [9].The syndrome has been associated with numerous other psychiatric conditions. Personality disorders, especially borderline type, are found in numerous studies and reviews. There is an association with childhood trauma, including abuse. Eating disorders, depressive and bipolar affective disorders, anxiety disorders, somatoform disorders, OCD, substance misuse disorders and schizophrenia have also been described in association with the syndrome. Another major group of patients who self-mutilate is found in those with learning disability [3,8,10,11].

Psychological symptoms described by repetitive self-mutilators include dysphoria, anxiety, depersonalization and aggression. The patient may experience and describe a strong compulsion to self-harm, similar to compulsion in OCD. The act of self-mutilation may provide relief from the unpleasant emotions or compulsion to self-mutilate, and may also induce feelings of self-control, power or euphoria. Relief may last from several hours to several weeks. In addition, a marked reduction in pain sensation, or increase in pain tolerance, is described in self mutilators, although is not uniform. The act is often performed in private [4,8].

Reviews of biological correlates of self-injurious behaviour have suggested changes in opiate, dopaminergic and serotonin systems. One study found reduced imipramine binding sites at platelets, a marker for serotinergic dysfunction, associated with self-mutilation [10]. Other proposed biological mechanisms are reinforcement of self-mutilating behaviour due to dysregulation of the dopamine system.

Treatment should include appropriate referral where the syndrome is associated with another psychiatric diagnosis. There are no clear guidelines for pharmacological treatment of self-mutilation syndrome itself, and a lack of randomized trials. Indeed some authors do not feel there are any general recommendations for the use of psychotropic medication [8]. Where suggestions have been made, SSRIs have been used, in line with the serotonergic hypofunction hypothesis. Dopamine antagonists and opiate antagonists have also been suggested. Mood stabilizers, β-blockers and analgesics have all been used [3].

Psychological approaches to treatment are varied. Behavioural and psychodynamic techniques are used, in group and individual settings. Dialectical behaviour therapy (DBT) has been described as successful, but access to this therapy varies regionally. Authors make the point that therapy can be long term, difficult and, in serious cases, involve periods of in-patient care.

Patients presenting with self-mutilation are a heterogeneous group, and likely to have complex problems in any of the biological, psychological and social domains. An understanding of the aetiological factors behind an individual's presentation is a key first step to deciding upon a programme of treatment. This may include pharmacological strategies, but there is as yet no clear core medication recommendation for these cases, and treatment is often complex and specialized.

Cutaneous disease and alcohol misuse [1,2]

Alcohol dependence and alcohol abuse are on the increase. They rank among the three commonest psychiatric disorders in the

Table 64.3 CAGE questionnaire.

1. Have you ever felt you should Cut down on your drinking?
2. Have people Annoyed you by criticizing your drinking?
3. Have you ever felt bad or Guilty about your drinking?
4. Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover (Eye opener)?
Item responses are scored 0 or 1 with a higher score over 2 clinically significant

community. The prevalence of DSM-IV alcohol abuse and dependence rose to 4.65% and 3.8% respectively [3]. There are significant medical and economic consequences because of differing effects of alcohol on metabolism, health, treatment behaviour and motivation [4]. Alcohol abuse can be missed as a diagnosis by experienced physicians even though the problem is common. Mechanisms for screening and brief interventions are well established and show robust stringency. The four-question CAGE questionnaire used as part of a general health enquiry is a consistent indicator of alcohol problems (Table 64.3). A two-question screen consisting of, firstly, enquiry about past alcohol problems and, secondly, significant drinking within the last 24 h is also a sensitive index. The combined sensitivity shows a 90% accuracy [5]. Up to 15% of admissions to hospital are directly or partially related to alcohol intake. Alcohol abuse is also co-morbid with psychiatric disorders such as depression, OCD and anxiety states.

The cutaneous manifestations of alcohol abuse are reviewed elsewhere [1,2]. Other studies show small variations in common manifestations with a different emphasis such as the prominence of seborrhoeic dermatitis and nail and oral changes according to race [6,7].

The psychosocial effects of chronic and disfiguring skin disease commonly produce feelings of stigma and rejection. Recreational substances such as alcohol are commonly used by affected patients [8]. Discoid dermatitis appears to be more frequent in alcohol abusers and is a more reliable indicator of alcohol dependence with significantly abnormal biochemistry and immunology related to alcohol excess. Atopic dermatitis appears to be unaffected by alcohol to the same degree. Seborrhoeic dermatitis is twice as common with alcohol abuse and this may be related to immunosuppression and the effect on cutaneous microflora.

A study of a large urban population suggested that male as well as female psoriatics showed an excess rate of alcoholism [9,10]. However, further studies suggested that, whilst alcohol abuse was not a factor in the onset of psoriasis, it became significant in women after the disease was present and was associated with the area of skin surface involvement [11] and severity particularly in men [12]. Up to 30% of patients thought they had difficulties with alcohol and 13% a current drinking problem [13]. Furthermore, a prospective study [14] showed that a daily intake of alcohol of more than 80 g was more frequently associated with less treatment-induced in-patient improvement in the percentage of the total body surface area affected by psoriasis. It also appears that the changed character and distribution of psoriasis make it more difficult to treat [1,2]. In studies of patients with psoriasis, alcohol abuse was not marked by elevated liver function tests. Alcohol abstinence helped to induce remission and relapse was induced by re-consumption. The effects of alcohol on immune function and skin vasculature are thought to precipitate exacerbations of rosacea and post-adolescent acne.

Infestations of the skin and superficial skin infections were found more often in alcoholic vagrants than in non-alcoholics and those with other psychiatric disorders. This also suggests that more specific alcohol-related immune factors were active [15].

Depression in dermatological patients

The concept of depression is frequently used loosely to mean disillusion, disenchantment, helplessness, frustration or mental fatigue. Depression has also been called 'melancholia without its charms'. For all its public profile, true depressive illness is one of the most frequently missed diagnoses for non-specialist psychiatrically trained physicians. Up to one-third of medically ill patients have depressive symptoms and depression has a greater impact on mean health scores than angina, asthma or diabetes and more so when combined with chronic physical illness [1]. This is also true for dermatology [2]. Depression, and to a lesser extent all forms of substance abuse, were the most overlooked diagnoses by dermatologists in 500 unselected dermatology patients examined by Musalek [3]. Screening for depressive diseases in patients with skin disease showed a prevalence of major depressive disorder in 8.4% and dysthymic disorder in 6.3% [4].

DSM-IV criteria for major depressive disorders are:

1 Depressed mood most of the day every day, subjective feelings of sadness, objective evidence of tearfulness; in children irritability may predominate
2 Diminished pleasure or interest in the activities of the day (anhedonia)

3 >5% change in weight
4 Insomnia or hypersomnia every day
5 Psychomotor retardation or agitation every day
6 Fatigue or loss of energy every day
7 Feelings of worthlessness or inappropriate guilt (which may be delusional)
8 Diminished ability to think or concentrate nearly every day
9 Recurrent thoughts of death, recurrent suicidal ideation without a specific plan, or a suicide attempt or a suicide plan.

Five or more symptoms must be present in the same 2 weeks with one of the symptoms being depressed mood.

Dysthymia is a chronic state of depression that may not be severe enough to meet the criteria for major depression. Depressed mood must be present for most of the day for at least 2 years. The patient must not have gone more than 2 months without experiencing at least two of the following symptoms:

1 Poor appetite or overeating
2 Insomnia or hypersomnia
3 Low energy or fatigue
4 Low self-esteem
5 Poor concentration
6 Feelings of hopelessness.

Such chronic forms of depression are at risk of subsequent major depression, considerable social disability and unhealthy lifestyle choices such as poor diet, alcohol abuse and smoking.

Depression in the elderly may be more manifested by irritability, self-neglect, somatic complaints or forgetfulness than conventional symptoms. In children, depression may be insidious and present as disruptive behaviour, irritability, truancy or somatic complaints [5].

A number of robust screening instruments have been developed and validated to detect depression either administered by the physician, for example Beck Depression Inventory, Hospital Anxiety and Depression Scale [6], or self-reported [7]. One- and two-question screening tools have the merit of speed but a high false positivity. The Patient Health Questionnaire-9 for depression appears well validated as a diagnostic and treatment outcome measure [7].

Suicide in dermatological patients

Suicide refers to a range of self-destructive behaviours ranging from non-lethal acts, which have been called suicidal gestures, attempted suicide, parasuicide and more recently self-injury, to a lethal action in which a patient dies, defined as a completed suicide. The rates of completed suicide in the UK are 8–10 per 100 000 people and in the US a little higher. The rate is rising in young men particularly in those with behavioural disturbance, substance misuse (25%) and persistent psychosocial difficulties. Suicide is an essential feature of depressive disease and 15% of patients with major depression kill themselves. It is therefore one of the 10 most common causes of death in Great Britain [1]. Psychiatric disorders are the main risk factors but numerous studies have also identified physical illness as an important contributory factor [1,2].

Chronic illness is a risk factor in suicidal ideation and 50% of patients who attempt suicide have a physical illness, especially chronic debility and pain. Not surprisingly, disfiguring chronic dermatoses have been shown to put patients at risk.

In a study of 217 patients with psoriasis, 10% of patients reported a death wish and 6% reported active suicidal ideation at the time of the study [3]. In another group, 2.5% of outpatients and 7.2% of in-patients with psoriasis expressed suicidal ideas. The severity of the psoriasis was reflected in the frequency of suicidal ideation and also measurable clinical depression [4]. Facial acne was also associated with significant risk (5.6%) of suicidal ideation, which is also higher than the levels reported in general medical patients [1]. Suicidal ideation was found in seven of 11 patients with Darier's disease related to the disfigurement, the intractability, social exclusion and smell of the dermatosis [5].

Some dermatological patients become so disturbed that they commit suicide successfully [6–8]. A group of 16 patients—seven males and nine females—who committed suicide successfully after presenting with dermatological problems to two dermatologists working in the same skin department, have been described [6]. The majority of these patients had either body-image disorders (dysmorphophobia, body dysmorphic disorder) or acne. It is important to recognize that patients with dermatological non-disease, and particularly females with facial complaints, may be extremely depressed and at risk of suicide. Even more strikingly, body dysmorphic disorder in children and adolescents carries a much larger risk, 67% experiencing suicidal ideation and 21% had attempted suicide [7]. Acne scarring can have just as profound an effect, or even a more profound effect, on body image, self-esteem and confidence as inflammatory acne. The positive therapeutic role of isotretinoin was emphasized [1,8].

Assessment of risk

Dermatologists are not accustomed to asking patients about their intentions for self-harm. However, it is essential in some circumstances where the indications are such that a depressed patient has opened up and confided their distress that they should be asked about suicidal thoughts. It is appropriate to ask 'How difficult have things become? Do you wonder whether you can go on?', gradually pressing to 'Have you ever thought you can't go on, or even don't want to go on?', and eventually 'Have you ever thought about harming yourself, or even ending your life?' It is important not to try and persuade the patient out of their suicidality by false reassurance but to assess whether they just have suicidal thoughts, have an intention to act, have plans and have the

means to implement the plan. Record the interview and seek permission to call a psychiatrist.

Isotretinoin and mood changes [1–3]

Since the introduction of oral isotretinoin for the systemic treatment of acne in 1982 there has been increasing controversy over the relationship of this treatment to the apparent development of depression and suicidality. Shortly after the introduction of oral isotretinoin there were isolated case reports of mood change and depression. Large doses of vitamin A have well-recognized toxic effects including fatigue, confusion, headache and diplopia. Psychological effects include aggression, personality changes, poor concentration, tearfulness, depression, ruminations of guilt and psychosis [3]. These neuropsychological adverse effects have been suggested as a general model for retinoid side effects. The relationship between the drug and depressive illness was made more acute by reports of suicide in isolated rare cases. Many case reports have described depression developing during treatment, some with resolution during the discontinuation of the drug, so-called positive dechallenge, and a few with the recurrence of symptoms on rechallenging with the drug. In addition, there have been descriptions of an increase in frequency and/or severity with increased dosage, simulating a dose–response relationship [2].

Grouped case reports showed some patients who developed depression whilst on isotretinoin who recovered whilst off the medication and further groups who tolerated re-exposure without depression. A very small minority redeveloped mood change on retaking the drug. Secondary analysis of large data sets did not support any association between isotretinoin and mood change but was criticized for being industry based and for methological inaccuracies. A systematic literature search [4] for studies reporting primary data on depression and suicidal behaviour in patients treated with isotretinoin for acne could only analyse nine studies which met the inclusion criteria of 214 examined [3]. Rates of depression varied from 1% to 11%. A period prevalence of 11% was found in a 4-month treatment period in one study and monthly prevalence of 4% in another. These rates are similar to those seen in 12-month prevalence rates of 10% in the US, of 6% in Canada and 9% in Europe. The incidence of newly diagnosed depression whilst taking isotretinoin was 1.5% over 20 weeks [4]. The annual incidence rate of depression varies from 1.6% to 7.5% by country [5]. In other controlled studies the low self-esteem and measurable depression were improved by therapy with isotretinoin and comparisons of mood changes before and after in matched groups of patients receiving either antibiotics or isotretinoin also showed no difference in mood change.

The data on suicidality is hampered by the need for a large population study to examine the statistics and accuracy of the rarity of attempted and completed suicide in patients with acne. No difference was found in one study [6] but methodological criticisms were cited particularly as attempted suicide and completed suicide are fundamentally different behaviours. The frequency of mood change in a normal population of this age is probably more than would be identified by a dermatologist in routine practice. However, monitoring an individual patient represents a different clinical scenario from assessment of the risk in a group. There still remains enough doubt about the validity of a relationship between isotretinoin and mood changes to suggest that clinicians need specifically to enquire about depression at each outpatient visit. Most national dermatology associations have produced guidelines to assess this risk of mood change in patients on isotretinoin. Most dermatologists will now routinely ask about mood change at each clinic visit and if indicated use a depression inventory, for example Beck Depression Inventory (BDI) or Hospital Anxiety and Depression Scale (HAD). Positive scores (BDI > 10) should prompt withdrawal of the drug and referral to the psychiatry team.

Psychiatric treatments

Psychiatric treatments are traditionally divided into physical and psychological. Physical treatments now most often refer to medication, but also include some other infrequently used modalities, such as electroconvulsive therapy, light box treatment and even psychosurgery. Psychological treatments cover a wide range of interventions, including anxiety management techniques, cognitive behavioural therapies and psychoanalytic therapies.

It should also be noted that the treatment of psychiatric conditions often involves social interventions, such as attention to housing, occupational or educational interventions and arranging appropriate access to benefits or resources.

The synthesis of the three approaches is often termed the bio-psycho-social approach.

Clearly, the specialist dermatologist who is presented with a psychiatric case in the dermatology clinic would not be expected to have knowledge of or access to a full range of specialist interventions. However, if a diagnosis can be made in dermatological clinic, and there is a working therapeutic rapport with the dermatologist, there is clearly an opportunity for both the initialization of appropriate prescribing, and also recommendation and referral for further treatments if indicated. Useful guidance to this is found in the NICE recommendations so far published for psychiatric interventions that cover primary care and secondary care. At the time of writing, such guidelines have been produced for anxiety, bipolar affective disorder, dementia, depression (both in adults and children), drug misuse, eating disorders, obsessive compulsive disorder (which contains specific guidelines for body dysmorphic disorder), post-traumatic stress disorder, pre- and post-natal mental health disorders, schizophrenia and self-harm.

These guidelines provide information about recommended treatments across the biological, psychological and social domains.

Drug treatments

Antidepressants

Antidepressants are widely used, not only in depression [1,2] but also anxiety [3], obsessive–compulsive disorder and body dysmorphic disorder [4], post-traumatic stress disorder [5] and also in bulimia nervosa [6]. They are also occasionally used cautiously in depression in the context of bipolar affective disorder [7]. The introduction of antidepressants with a better safety profile in over-dosage has led to an increase in their prescription in recent years. Arguments have been made both that there is now over-prescription [8], especially with concerns about associations with suicide and certain agents [9] particularly in adolescents. These concerns have been contested [10] but guidelines for treatment now reflect an increased caution in the prescribing of antidepressants.

The precise mechanism of action of antidepressants is not yet fully established, nor is it yet fully understood why antidepressant action takes a number of weeks to take effect. Most theories postulate effects through the monoamine system.

When starting an antidepressant, it is necessary, due to the delay in therapeutic action, to counsel the patient that side effects may appear before response. Otherwise, the patient can discontinue medication in the early stages. A particular caution is the use of potentially toxic medications in patients who have suicidal ideation, who may be at risk of over-dosage in the window before therapeutic effects are noticed. In addition, patients are often concerned that reports of withdrawal reactions from antidepressants indicate that they are addictive, causing tolerance or craving, and it can be helpful to pre-empt this by discussing this fully. Antidepressants do need to be withdrawn gradually, but are not associated with tolerance or craving.

Caution is advised when starting antidepressants, with review after 1 week of starting for those felt to be at high risk of self-harm, or those under 30 years of age, and review after 2 weeks for others. It is also recommended that antidepressants be continued for at least 6 months past the remission of symptoms, as this helps reduce the risk of relapse.

Table 64.4 Use of SSRI antidepressants.

Name	Dose (adult under 65 years)	Indications [1,2]	Notes
Fluoxetine	20–60 mg/day	Depression OCD Bulimia nervosa	Long half-life SSRI with most experience of use in pregnancy
Paroxetine	10–60 mg/day	Depression OCD Panic disorder PTSD Social anxiety disorder Generalized anxiety disorder	Marked withdrawal syndrome Associated with extrapyramidal side effects Recommended as good choice in liver impairment [13] Recommended as good choice in breast feeding [11]
Sertraline	50–200 mg/day	Depression OCD PTSD (women)	Recommended as good choice in hepatic impairment [11] Recommended as good choice in breastfeeding
Fluvoxamine	50–300 mg/day	Depression OCD	Split dosing if above 150 mg/day
Citalopram	10–60 mg/day	Depression Panic disorder	Recommended as good choice in hepatic impairment [11]
Escitalopram	5–20 mg/day	Depression Panic disorder Social anxiety disorder	Isomer of citalopram

All antidepressants have been associated with hyponatraemia, especially in the elderly [11].

Serotonin reuptake inhibitors (SRIs, SSRIs) (Table 64.4) are now recommended as first-choice use in depression [1], obsessive–compulsive disorder, specifically including body dysmorphic disorder [4] and anxiety disorders [3], due to their relatively low side-effect profile and lower toxicity in over-dosage when compared with the older tricyclic antidepressants.

They are not entirely free from side-effects, the most common of which include nausea, dyspepsia and gastrointestinal upset, headache, agitation and anxiety, sweating and rashes, insomnia, and sexual dysfunction. In some cases, purpura occur. In the under-18-years age group, the association with agitation leading to increased suicidal behaviour and hostility has led to the recommendation that SSRIs be only used by specialists [2].

Tricyclic antidepressants

The tricyclic antidepressants are no longer recommended for first-line use in depression (Table 64.5) [1]. They are still useful when sedation is required, as this can provide some immediate relief from the insomnia of depressive states, and aid concordance. Their usefulness has been limited by their toxicity in over-dosage, and by side effects. They are most often now used by specialists in treatment-resistant cases.

Side-effects can be marked, and include dry mouth, blurred vision, constipation, sedation, urinary retention and postural

Table 64.5 Use of tricyclic antidepressants.

Name	Dose (adult under 65 years)	Uses [12]	Notes
Amitriptyline	10–200 mg/day	Depression Neuropathic pain	Noted cardiotoxicity
Clomipramine	10–250 mg/day	Depression Phobic states Obsessional states	
Dosulepin	75–225 mg/day	Depression	Previous name dothiepin
Imipramine	75–300 mg/day	Depression	Less sedating Split dose twice daily above 150 mg/day
Lofepramine	140–210 mg/day	Depression	Split dose twice daily Less toxic in overdose Occasionally hepatotoxic
Nortriptyline	10–150 mg/day	Depression Neuropathic pain	Plasma level monitoring often available
Trimipramine	50–300 mg/day	Depression	Regarded as most sedating

hypotension. Cardiac effects, including heart block, are known, and also reduction of the seizure threshold and an association with convulsions. They can precipitate angle-closure glaucoma.

They are often used in low doses for treatment of anxiety or insomnia. Some tricyclics are also used adjunctively for the management of pain, and have also been used in pruritus.

Other antidepressants

A number of other antidepressant drugs are available, they are also believed to act through changes in monoamine activity (Table 64.6). None are recommended for first-line use, although all have a role in specialist treatment of resistant cases. Mirtazipine has been suggested as a second choice of drug if the first choice is unsuccessful.

Switching antidepressant drugs

The need to switch between antidepressant drugs is common, not only because response rates to the first drug are around 60%, but also due to intolerance of side effects or troublesome interactions. When switching from drug to drug, it is necessary both to consider the potential for withdrawal reactions from the first drug, and also the possibility of interactions between the old and new agent. It has been recommended that antidepressants be withdrawn gradually if prescribed for longer than 6 weeks, and that doses of new drugs are cross-tapered upwards if possible [11]. Interactions described on switching include serotonin syndrome, cholinergic rebound, elevated levels of drugs due to pharmacokinetic interactions and excessive side effects due to pharmacodynamic interactions. Tabulated guides to switching antidepressants have been produced [11,13].

Certain drugs are particularly troublesome in switches, such as monoamineoxidase inhibitors (due to their mechanism of action) and fluoxetine (due to a long half-life).

Table 64.6 Other antidepressants in use.

Name	Dose (adult under 65 years)	Uses	Notes
Mirtazipine	15–45 mg/day	Depression	Relatively free of anticholinergic side effects, but appetite increase and weight gain Sedating, often used if sleep poor
Venlafaxine	75–375 mg/day	Depression Generalized anxiety disorder	Serotonin and norepinephrine reuptake inhibitor Previously quite widely prescribed; now recommended if two other drugs unsuccessful Split dosing, or up to 225 mg/day can be given as a modified release form
Duloxetine	60 mg/day	Depression (also diabetic neuropathy and stress incontinence)	Serotonin and norepinephrine reuptake inhibitor
Trazadone	150–600 mg/day	Depression Anxiety	Sedating, often used if sleep poor Fewer antimuscarinic effects than tricyclics; can cause nausea Doses above 300 mg/day in hospitalized patients Split dosing above 300 mg/day
Mianserin	30–90 mg/day	Depression	Tetracyclic Fewer antimuscarinic effects than tricyclics Associated with blood dyscrasias and blood count monitoring recommended
Reboxetine	8–12 mg/day	Depression	Not sedating Split dosing

Antipsychotic medication

Dermatologists may occasionally find themselves in a position where the prescribing of antipsychotic drugs is indicated, such as psychoses presenting with cutaneous symptoms. There may be a delay before the patient can see a psychiatrist or, in some cases, the patient may be reluctant to see a psychiatrist at all. Although the British National Formulary indications for antipsychotic drugs often list schizophrenia solely, their use in the related conditions such as delusional disorder and acute and transient psychotic disorders, including those related to stimulant drug use, is recognized. NICE guidelines suggest the consideration of early treatment of symptoms with antipsychotic medication by general medical practitioners and the dermatologist may find themselves in a similar position [14]. Early referral to and advice from psychiatry is recommended if possible.

Table 64.7 Use of atypical antipsychotics.

Name	Dose (adult under 65 years)	Uses [12]	Notes
Amisulpiride	400–1200 mg/day	Schizophrenia	Potent raiser of prolactin Split dosing
Aripiprazole	10–30 mg/day	Schizophrenia	Can cause nausea
Olanzapine	5–20 mg/day	Schizophrenia Mania	Weight gain Sedating Avoid in stroke disease in elderly
Quetiepine	25–800 mg/day	Schizophrenia Mania	Split dosing or available in MR form
Risperidone	2–16 mg/day	Acute and chronic psychoses Mania	Avoid in stroke disease in elderly
Sertindole	4–24 mg/day	Schizophrenia	Low EPSE Associated with arrhythmias Limited use in many countries including UK
Zotepine	75–300 mg/day	Schizophrenia	Three times per day split dosing

Atypical antipsychotics [15]

The agents of choice are the 'atypical antipsychotics', the more recently developed agents, which have a lower incidence of extrapyramidal side-effects (Table 64.7). These side effects, which include parkinsonian symptoms, dystonia and tardive dyskinsia, are less common than in the older 'typical' antipsychotics.

Other side-effects are frequent with antipsychotics, such as drowsiness and weight gain, hyperprolactinaemia and QT interval prolongation. There is an association with impaired glucose tolerance with antipsychotics, especially the atypical.

Clozapine, although atypical, is reserved for specialist use due to the association with severe agranulocytosis which requires close monitoring of the full blood count.

Typical antipsychotics

A wide number of typical antipsychotics are still available, although are unlikely to be prescribed by a dermatologist. Chlorpromazine, the first of the antipsychotics, is still available. It can cause a contact sensitivity rash in patients and health-care workers who handle the tablets. Haloperidol has a wide range of uses, not only in psychoses, but also in tic disorders, hiccup and nausea. Many dermatologists may have used it in the early part of their medical career to treat agitation in the elderly in-patient. Sulpiride is very similar in structure to amisulpiride, and is less expensive.

Flupentixol, in low doses, has a licence for adjunctive treatment in depression.

Some dermatologists may be familiar with pimozide, which is listed in the British National Formulary for treatment of monosymptomatic hypochondriacal psychosis, and was often used in Ekbom's syndrome [16]. Increasing concerns about cardiotoxicity and sudden death related to lengthened QTc have limited its use, and use of atypicals has been suggested [17].

Anxiolytics

The benzodiazepine anxiolytics can appear initially very effective in alleviating anxiety symptoms and states, but problems with tolerance and dependence rapidly develop, and they are frequently misused. They should be avoided.

Buspirone has low dependence potential and is rarely misused, and is licensed for short-term use in anxiety. β-blockers are used for autonomic anxiety symptoms but do not affect psychic symptoms or muscle tension. As mentioned before, the use of low-dose antipsychotics or tricyclic antidepressants is widespread.

Mood stabilizers

Few dermatologists would expect to prescribe a mood-stabilizing drug, although they may be familiar with some of the agents from other indications.

Lithium is the oldest of the mood stabilizers, but still widely used and effective in acute mania, prophylaxis of bipolar disorder and augmentation of treatment in refractory depression. It has a narrow therapeutic index and a wide array of side effects, especially on the kidneys and thyroid, and requires careful monitoring through blood tests. It is also known for causing exacerbations of psoriasis.

Valproate in various forms is very frequently used. Semisodium valproate has a licence for treatment of acute mania. Modified-release forms of valproate are frequently used off licence for prophylaxis.

Carbamazepine is licensed for the prophylaxis of bipolar disorder, and is also used in augmentation strategies for refractory depression.

Other antiepileptic drugs have been used off licence for treatment and for prophylaxis. Use of lamotrigine has become widespread, and topiramate and gabapentin have also been used.

Psychological therapies

The use of psychotherapies in disorders that combine somatic and psychological factors is widespread, but there is often confusion about how these conditions are defined, and the evidence base is incomplete [18]. An example of the difficulties in this area is given by a recent Cochrane review of conversion disorder [19] in which all but three of only 43 identified references were excluded on grounds of quality.

There is more evidence for specific therapies in certain psychiatric illnesses, and recommendations for use of therapies have been included in clinical guidelines [1–4].

The therapeutic relationship

The relationship between clinician and patient has a potentially powerful therapeutic (or sometimes counter therapeutic) effect, even before formal psychological techniques are considered.

The effect of an empathic and patient approach can be very powerful in those cases presenting with emotional distress related to dermatological presentation. Although efforts are constantly made to reduce stigma, some patients may feel stigmatized by both their skin and psychiatric symptoms. The opportunity to

express their anxieties and fears may provide significant relief. It may be necessary for the clinician to gently question defensive explanations that patients use for their symptoms, which at first may appear spurious and even obstructive. The effect of touch during examination has been described as relieving the anxiety of patients who feel stigmatized by their skin lesions. The effect of actively listening within a therapeutic relationship in allowing patients to express their feelings has been described as helpful in allowing patients to address their own problems, and is the basis of client-centred counselling, described by Rogers [20]. Of course, the dermatologist will need to give clinical advice, but a confident, authoritative rather than authoritarian approach, where the clinician offers explanation and clinical advice when indicated, but is able to tolerate this advice initially being partially taken or prevaricated on, will aid sustained engagement.

It should also be noted that a small, but significantly morbid, population of patients can have a marked negative effect through the therapeutic relationship. With such patients, who usually have severe neurotic or personality pathologies, the clinician can find themselves feeling pressed into making unusual decisions, ordering unusual investigations and going to extreme lengths to manage the patient's anxiety, anger or demands. It is not unusual for such patients to initially present with the impression that the clinician is 'the best they have seen' or 'the only one who has understood', a relationship that can rapidly change to one of dissatisfaction, complaint or litigation. In such patients, although presenting as seeking 'a cure', there may be an unspoken or unconscious need to remain in the sick role, and the clinician has an apparently impossible task. It is important for the clinician to recognize when such dynamics are potentially distorting practice, and seek appropriate advice if severe neurosis or personality disorder are suspected.

Cognitive behavioural therapy (CBT)

Increasingly, CBT has become the first line psychological therapy in depression and anxiety disorders, including BDD [1–4]. Randomized trials have shown its efficacy in BDD [21] and it is recommended in national guidelines for treatment of BDD.

CBT was developed by Beck [22] for the treatment of depression. The theory of CBT is that the patient automatically responds to certain situations and stimuli with ingrained negative thoughts. These thoughts in turn lead to negative emotions such as fear or depression, and behavioural consequences such as avoidance or rituals. Treatment in CBT is based around the process of sympathetically, through the development of a treatment alliance, challenging these negative automatic thoughts and exploring alternative responses that may not lead to behavioural and emotional pathology. The therapeutic process may include exposure and response prevention, wherein the patient is exposed to a troubling thought or stimulus (often, initially, in imagination or abstract) and encouraged to explore alternative thoughts and responses to their ingrained pathological reaction. Often, adjunctive relaxation and anxiety management techniques are an integral part of the therapy. CBT techniques are very widely used, and have been published in 'self-help' formats, for example *Mind Over Mood* [23] and *Overcoming Depression and Low Mood* [24]. The clinician can incorporate CBT principles and techniques in their clinical practice, for example when working with BDD [25]. Computer packages have been developed to deliver CBT, although guidelines state the evidence is better in depression and anxiety than in OCD [26]. Formal CBT treatment, when provided by a trained therapist, can consist of from six to 20 or more hour-long sessions, depending on severity of the case, complexity, co-morbidities and response. The main concern for many health-care providers is insufficient therapist hours to meet demand, resulting in lengthy waiting lists. The therapy can be provided in group as well as individual settings. Group therapy in a cognitive behavioural model has been used in eczema [27]. Although widely researched with good efficacy, and now most often considered, CBT is not suitable for all cases, and alternate modalities of therapy still need to be considered.

Interpersonal psychotherapy (IPT) and interpersonal counselling (IPC)

These forms of therapy are based on the work of Klerman and associates [28]. The focus of IPT is on the relationships of the patient and how they affect mood states. Problems in relationships are categorized as one of dispute, change in role, grief or deficit. The therapist then assists the patient in working through the problems using techniques such as role play and analysis of communications within relationships. Like CBT, the therapy takes place over a number of hour-long sessions, usually 12 to 16.

IPC is a modification of IPT, of a simpler form that can be integrated into the work of health professionals. It was designed for primary care, but can be used in other health settings. IPT has been shown to be effective, and equivalent to CBT in depression and also eating disorders. Unlike CBT, it has not yet been shown to be effective in OCD or BDD. It has been suggested that IPT be offered as an alternative to CBT for patients who prefer the approach. However, provision, especially outside the US, is often limited by a shortage of trained practitioners.

Dynamic psychotherapies and psychoanalysis

There is not scope here to fully describe the range of varieties of these psychotherapies available. Some awareness of, or even familiarity with, the concepts first described by Freud are common in Western and European cultures. There have been numerous therapist, theorists and writings on the subject. Psychodynamic concepts such as transference, counter transference, projection and identification can help the clinical interview, and good descriptions can be found for the interested in textbooks such as *Introduction to Psychotherapy* [29].

Short-term forms of dynamic therapies (defined as fewer than 40 sessions) have been shown to have efficacy in a wide range of common mental health disorders [30]. Many forms of dynamic therapies and psychoanalytic therapy are long lasting and intensive, with three or more sessions weekly. Due to the complexity of the longer forms of therapy, especially around conducting controlled studies and defining outcomes, there are difficulties with an evidence-based approach to demonstrating efficacy [31,32]. Whilst this is acknowledged by practitioners writing in this field, the point is often made that these forms of therapy are complex, and used in complex conditions where the 'drug paradigm' or

'single intervention for single condition' approach may not be strictly relevant. Others have proposed the view that such long-term therapies can be shown to have better outcomes [33].

Varieties of psychiatric syndrome presenting to the dermatologist, either as part of or alongside a cutaneous presentation, can be effectively treated by the clinician familiar with the stratagems used in primary care. Although specialist knowledge and training is required to deliver formal psychotherapy, techniques from psychotherapy, especially the commonalities of empathy, understanding, patience and reflection can be used to augment safe prescribing where indicated [27]. Specialist referral is indicated where symptoms are severe or specialist drugs or therapies needed.

Alternative therapies

There has been a long tradition of the use of complementary therapies in dermatology but especially for those diseases where there is a psychological component. Most reports of therapy are anecdotal, often single cases with no randomized controlled trials. Therapies with a neurogenic basis are claimed to work by the neuroimmune mechanisms although no hard evidence is available. Acupuncture, biofeedback and hypnosis in skin disease are summarized by Shenefelt [1] and Freid [2]. The mechanisms of action may be related to the beneficial effects of supportive psychotherapy and relaxation rather than any specific therapeutic component measurable for each treatment type. Hypnotherapy has been the most frequently studied in Western literature. Despite the lack of trials there are strong advocates for the use of hypnosis as an adjunct to control itch [3] and pain [4]. Hypnotherapy for warts in children showed a 53% success at 3 months compared to none in the control group [5]. The practicality and cost was not assessed.

Alternative herbal medications are used both topically and systemically. In an evidence-based review of the literature [6] there was no compelling evidence for the efficacy of diet, herbal medicine or dietary supplements in atopic eczema. The authors suggested promising data for treatments with a psychological component such as hypnosis, autogenic training and biofeedback. For chronic venous insufficiency oral horse chestnut seed extract appeared to have a real effect as opposed to topical aloe vera gel or tea tree oil. Two fuller reviews of phytopharmaceutical agents explored not only the therapeutic uses of herbs but also the toxic and allergic skin reactions [7,8].

Introduction

The epithelial part of the nail apparatus develops *in utero* from the primitive epidermis. In generalized integumentary diseases, such as psoriasis, the nail apparatus, hair follicle and epidermis may all be structurally and functionally affected, presumably because of their common tissue of origin.

The main function of the nail apparatus is to produce a strong, relatively inflexible, keratinous nail plate over the dorsal surface of the end of each digit. The nail plate acts as a protective covering for the fingertip. By exerting counter-pressure over the volar skin and pulp, the flat nail plate allows precision and delicacy when picking up small objects and in many other subtle finger functions [1–3]. Fingernails typically cover approximately one-fifth of the dorsal surface, whereas on the great toe the nail may cover up to 50% of the dorsum of the digit.

The nail apparatus develops and matures from the primitive epidermis between the ninth and 20th weeks of intrauterine growth. At 20 weeks, the matrix cells show postnatal-type cell division, differentiation and keratinization, and the nail plate begins to form and move distally [4,5]; the nail bed loses its granular layer at this stage [6]. By 36 weeks, the complete nail plate reaches the tip of the digit and is surrounded by prominent lateral nail folds and a well-formed cuticle.

Anatomy and biology of the nail unit

Structure

Gross anatomy [1–5]

The component parts of the nail apparatus are shown diagrammatically in Fig. 65.1. The rectangular nail is firmly attached to the nail bed; it is less adherent proximally, apart from the posterolateral corners. Approximately one-quarter of the nail is covered by the proximal nail fold, and a narrow margin of the sides of the nail plate is often occluded by the lateral nail folds. Underlying the proximal part of the nail is the white lunula (half-moon, lunule); this area represents the most distal region of the matrix [6]. It is most prominent on the thumb and great toe and may be partly or completely concealed by the proximal nail fold in other digits. The reason for the white colour is not known [7–9]. The natural shape of the free margin of the nail is the same as the contour of the distal border of the lunula. The nail plate distal to the lunula usually appears pink, due to its translucency, which allows the redness of the vascular nail bed to be seen through it. The proximal nail fold has two epithelial surfaces, dorsal and ventral; at the junction of the two, the cuticle projects distally onto the nail surface. The lateral nail folds are in continuity with the skin on the sides of the digit laterally, and medially they are joined by the nail bed. Some authorities term the lateral nail fold and adjacent tissue lateral to the nail fold the 'nail wall'.

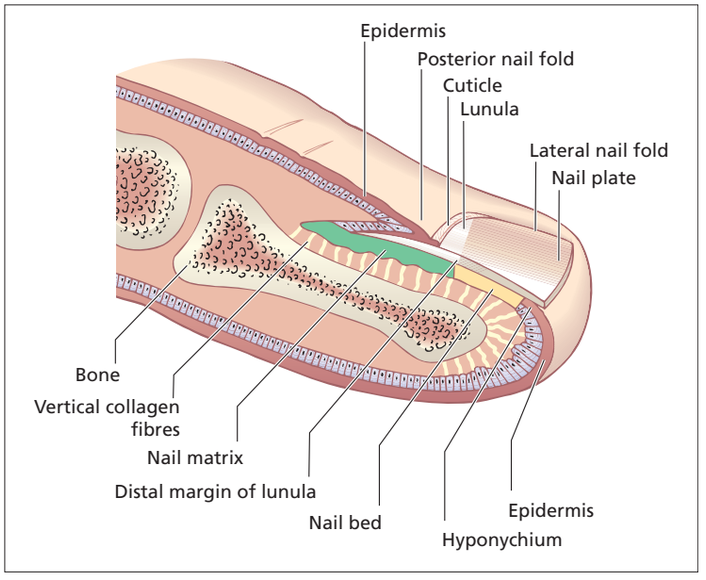

Fig. 65.1 Longitudinal section of a digit showing the dorsal nail apparatus.

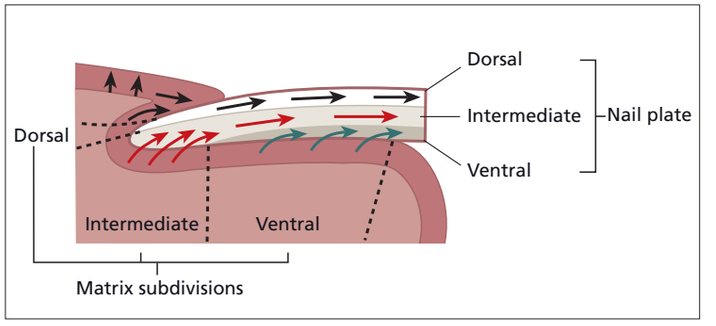

Fig. 65.2 Direction of differentiation and cell movement within the nail apparatus.

The definition of nail matrix is controversial [10]. There is common acceptance that there is a localized region beneath proximal nail which produces the major part of the normal nail plate. For those who consider this the sole source of nail it is termed simply the matrix, or germinal matrix. However, there is some evidence that other epithelial parts of the nail unit also contribute to the nail plate, and these are then also attributed matrix status (Fig. 65.2). The matrix can be subdivided into dorsal (ventral aspect of the proximal nail fold), intermediate (germinal matrix or matrix) and ventral (nail bed) sections. The nail bed is also termed the sterile matrix and its role in the production of nail is unclear. Although it appears that the nail plate may thicken by up to 30% as it passes from the distal margin of the lunula to the end of the nail bed [3], this is not associated with an increase in cell numbers and may represent compaction of the nail from distal tip trauma rather than nail bed or nail plate production [11]. The situation may change in disease, where the nail bed changes its histological appearance to gain a granular layer [12] and may contribute a false nail of cornified epithelium to the undersurface of the nail [5]. The gap beneath the free edge is known as the hyponychium.

When the attached nail plate is viewed from above, two distinct areas may be visible: the proximal lunula and the larger pink zone. On close examination, two further distal zones can often be identified: the distal yellowish-white margin and immediately proximal to this the onychodermal band [13]. Histologically, it is defined as the most distal attachment of cornified epithelium to the undersurface of the nail. As such, it is structurally significant for the adherence of nail plate to the nail bed. Once breached, as in conditions such as psoriasis, separation of the nail bed from the nail plate can be progressive.

Microscopic anatomy [14]

Nail folds

The proximal nail folds are similar in structure to the adjacent skin but are normally devoid of dermatoglyphic markings and pilosebaceous glands. There is a normal granular layer. From the distal area of the proximal nail fold the cuticle adheres to the upper surface of the nail plate; it is composed of modified stratum corneum and serves to protect the structures at the base of the nail, particularly the germinal matrix, from environmental insults such as irritants, allergens, and bacterial and fungal pathogens.

Nail matrix (intermediate matrix)

Nail matrix produces the nail plate in the absence of disease (Fig. 65.2). The basal compartment of the matrix is broader than the same region in normal epithelium or in other parts of the nail unit, such as the nail bed [10]. There is no granular layer, and cells differentiate with the expression of trichocyte 'hard' keratin as they become incorporated into the nail plate, alongside normal epithelial keratins [15,16]. During this process, they may retain their nuclei until more distal in the nail plate. These retained nuclei are called *pertinax bodies*. Apart from this, the detailed cytological changes seen in the matrix epithelium under the electron microscope are essentially the same as in the epidermis [17,18].

The nail matrix contains melanocytes in the lowest three cell layers and these donate pigment to the keratinocytes. The presence of 6.5 melanocytes per millimetre of matrix basement membrane can be used as a guide to a normal matrix melanocyte population [19]. The appearance of melanocytes separate from the basement membrane distinguishes them from those found in the nail folds, which are primarily basal [20]. Unlike melanocytes in the proximal nail fold and most other sites, nail matrix melanocytes do not express HLA-A/B/C antigens [21]. Matrix melanocytes are further distinguished from those elsewhere by their failure to produce melanin in normal circumstances in white people. This can change, with melanotic streaks presenting in local inflammatory, naevoid or neoplastic disease. In non-white people, brown streaks are common and are almost universal in Afro-Caribbeans by the age of 60 years.

Langerhans' cells are detectable in the matrix by CD1a staining, and the matrix appears to contain basement membrane components indistinguishable from normal skin [22].

Nail bed

Nail bed consists of epidermis with underlying connective tissue closely apposed to the periosteum of the distal phalanx. There is no subcutaneous fat in the nail bed, although scattered dermal fat cells may be visible microscopically.

The nail bed epidermis is usually no more than two or three cells thick, although there may be tongues of epithelium that extend obliquely down. The transitional zone from living keratinocyte to dead ventral nail plate cell is abrupt, occurring in the space of one horizontal cell layer; in this regard it closely resembles the Henle layer of the internal root sheath of the epidermis [23]. Nail bed cells do not have any independent movement, and it is yet to be clearly demonstrated whether they are incorporated into an overlying nail plate as it grows distally [24]. The process of nail bed keratinization has been likened to that seen in rat-tail epidermis, possibly being affected by pressure changes. The loss of the overlying nail results in the development of a granular layer, which is otherwise present only in disease states [11,25,26].

The nail bed dermal collagen is mainly orientated vertically, being directly attached to the phalangeal periosteum and the epidermal basal lamina. Within the connective tissue network lie blood vessels, lymphatics, a fine network of elastic fibres and scattered fat cells; at the distal margin, eccrine sweat glands have been seen [1].

Nail plate

The nail plate comprises three horizontal layers: a thin dorsal lamina, the thicker intermediate lamina and a ventral layer from the nail bed [4]. This is not always apparent with normal light microscopy using routine stains, where the nail demonstrates a transition between flattened cells dorsally and thicker cells on the ventral aspect. Electron microscopy shows squamous cells with tortuous interlocking plasma membranes [18,19]. At high magnification, the contents of each cell show a uniform fine granularity similar to the hair cuticle [23]. Nail plate thickness can be measured in health and disease using ultrasound or optical coherence tomography [27].

The nail plate contains significant amounts of phospholipid, mainly in the dorsal and intermediate layers, which contributes to its flexibility. The detectable free fats and long-chain fatty acids may be of extrinsic origin. For further details of these and other histochemical changes in the components of the nail apparatus, the reader is referred to more detailed texts [8].

The nail plate is rich in calcium, found as the phosphate in hydroxyapatite crystals; it is bound to phospholipids intracellularly [28]. The relevance of other metals (copper, manganese, zinc, iron and others), which are present in smaller amounts, is not known [25]. Calcium is present in a concentration of 0.1% by weight, 10 times greater than its concentration in hair. It is possible that calcium is not an intrinsic part of the nail but is incorporated from extrinsic sources. Calcium does not significantly contribute to the hardness of the nail [6].

Nail keratin

Nail keratin analysis shows essentially the same fractions as in hair, but amino acid analysis shows higher cysteine, glutamic acid and serine, and less tyrosine in nail compared with hair and wool [17,29].

One classification of keratins is to divide them into 'soft' epithelial keratins or 'hard' trichocyte keratins. The latter are characteristic of hair and nail differentiation, where their high sulphur content is responsible for their rugged physical qualities. This is matched by the resistance of trichocyte keratins to dissolution in strong solvent.

Trichocyte and epithelial keratins are intermediate filaments representing the major cytoskeletal protein of epithelial cells. They share the normal classification into type I or type II based on gene hybridization, which reflects segregation on two-dimensional electrophoresis into acidic and basic proteins. Each acidic keratin is expressed in a tissue with a corresponding basic keratin to form specific heterodimers, which are assembled into higher-order protofibrils and protofilaments.

Keratin distribution in the nail and associated epithelium has been studied in adult [16,30], infant [17] and embryonic [31,32] digits. Immunohistochemistry of the epithelial structures of normal nail demonstrates that the suprabasal keratin pair K1/K10 is found on both aspects of the proximal nail fold and to a lesser degree in the matrix. However, it is absent from the nail bed. This is reversed when there is nail bed disease, such as onychomycosis or psoriasis, where a granular layer develops and K1/K10 becomes expressed at corresponding sites [23]. The nail bed contains keratin synthesized in normal basal layer epithelium, K5/K14, which is also found in nail matrix. An antibody marking the epitope characteristically associated with keratin expressed in the basal layer is found throughout the thickness of the nail bed, but only basally in the matrix [26].

Recent examination of the nail bed using monospecific monoclonal antibodies to the keratin pair K6/K16 demonstrates these proteins in the nail bed but not the germinal matrix [16]. This is paradoxical given our understanding that K6/K16 is characteristic of psoriasis and wound healing, where proliferation is a prominent feature. It has been shown that the nail bed has very low rates of proliferation [10,33], and it may be that K6/K16 more precisely illustrates a loss of differentiation, often associated with proliferation in skin but representing the resting state of nail bed epithelium.

The location of K6/K16 is reflected in the localization of the features of pachyonychia congenita. In this group of autosomal dominant disorders, there is thickening of the nail plate attributed to disease of the nail bed. In some forms of pachyonychia congenita, there is a missense mutation of the initiation peptide of K16 [34].

Trichocyte keratins can also be detected immunohistochemically within the epithelial structures of the nail unit. A monospecific antibody to Ha-1 has been created and characterized on nail, hair and skin. In the nail, it demonstrates a well-demarcated suprabasal region corresponding to the matrix [16]. Proximally, it does not extend onto the ventral aspect of the proximal nail fold, sometimes described as the dorsal matrix. Distally, the keratin expression is limited to a margin taken as corresponding to the lunula. Ha-1 is only one of at least 10 trichocyte keratins, but quantitatively it probably represents a large fraction of nail keratin. According to its distribution it appears to define a matrix consistent with the classic description of the germinal matrix.

Improved understanding of the distribution of keratins in the nail bed and matrix has accompanied further understanding of the molecular basis of pachyonychia congenita, where the various nail manifestations correlate with mutations within the keratin genes and corresponding phenotypes [35].

Blood supply [1]

There is a rich arterial blood supply to the nail bed and matrix derived from paired digital arteries, a large palmar and small dorsal digital artery on either side. The palmar arteries are supplied from the large superficial and deep palmar arcades [2]. The main supply passes into the pulp space of the distal phalanx before reaching the dorsum of the digit (Fig. 65.3). Distally, the arteries are extremely tortuous and coiled, which allows them to be distorted without occluding supply by kinking. There are two main arterial arches (proximal and distal) supplying the nail bed and matrix, formed from anastomoses of the branches of the digital arteries. In the event of damage to the main supply in the pulp space, such as may occur with infection or scleroderma, there may be sufficient blood from the accessory vessels to permit normal growth of the nail. At a microvascular level, there are three patterns. Within the matrix, vessels are longitudinal with a helicoidal twisting. This becomes more definably longitudinal in the nail bed without the tortuosity—a pattern that is also seen in the distal proximal nail fold. This orientation is reflected in the appearance of splinter haemorrhages. In the digit pulp, vessels follow the pattern of the dermatoglyphics [3–5].

There are many arteriovenous anastomoses beneath the nail—glomus bodies—which are concerned with heat regulation. Glomus bodies are important in maintaining acral circulation under cold conditions: arterioles constrict with cold but glomus bodies dilate [6]. These occupy the subdermal tissues and increase in number in a gradient towards the distal nail bed [7].

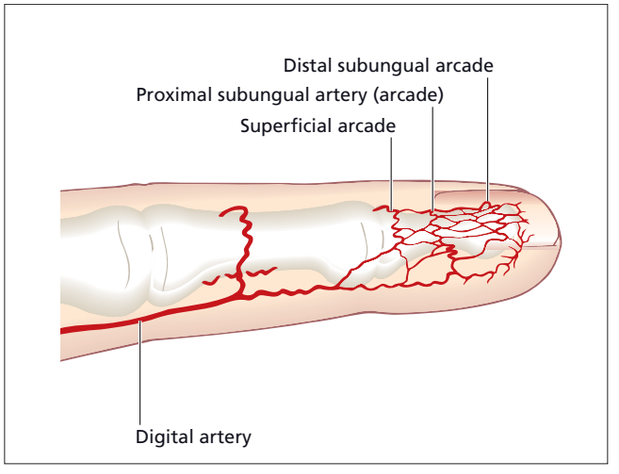

Fig. 65.3 Arterial supply of the distal finger.

Nail growth and morphology

Clinicians used to observing the slow rate of growth of diseased or damaged nails are apt to view the nail apparatus as inert, although it is biochemically and kinetically active throughout life. In this respect, it differs from the hair follicle, which undergoes periods of quiescence as part of the follicular cycle.

Cell kinetics

The kinetic activity of the matrix has been examined using many techniques. These include immunohistochemistry, autoradiography and direct measurement of matrix product (i.e. nail plate) by ultrasound [1], micrometer or histology.

There is a broad basal compartment of proliferating cells in the matrix, which can be detected immunohistochemically with antibodies to proliferating cell nuclear antigen and Ki-67 (Fig. 65.4); both antigens are associated with proliferating cells [2]. The matrix is also the site of maximal inclusion of tritiated thymidine if injected into the peritoneum of squirrel monkeys and followed subsequently by autoradiography [3]. Although there was some inclusion of thymidine into the nail bed, Zaias and Alvarez interpreted the findings as indicating that the nail bed had no role in creation of the nail plate. Norton [4] drew a similar conclusion from work with live human subjects where labelled thymidine and glycine were injected locally to act as markers of proliferating and metabolically active keratinocytes, and both primarily labelled the matrix.

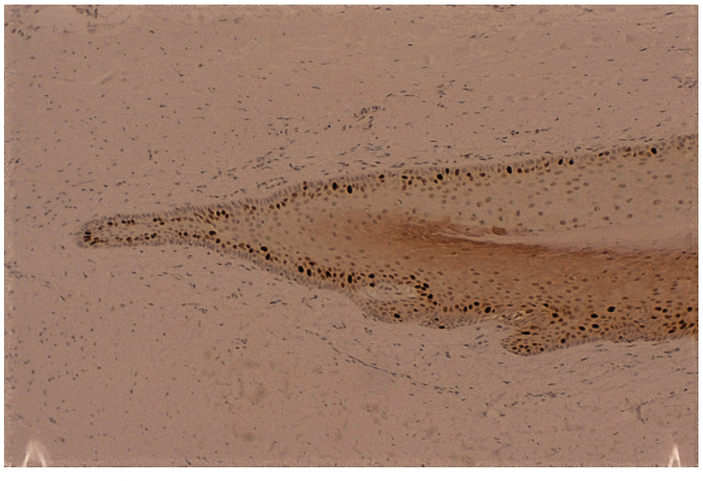

Fig. 65.4 Proliferating epithelial cells of the matrix and ventral aspect of the proximal nail fold, staining with the antibody MIB-1.

However, the earlier work of Lewis [5] suggested on histological grounds that the nail plate is a trilaminar structure originating from three separate matrix zones: the dorsal matrix (ventral aspect of proximal nail fold), intermediate matrix (germinal matrix) and ventral matrix (nail bed). In support of this, Johnson *et al*. [6,7] demonstrated that 21% of the nail thickness is gained as it passes over the nail bed, implying that the nail bed is generating this fraction of the nail plate. De Berker *et al*. [2] noted that the increase in nail thickness did not coincide with corresponding increases of nail plate cells. This challenges the interpretation that nail thickens over the nail bed because of a contribution from underlying structures. An alternative explanation may be appropriate, such as compaction arising from repetitive distal trauma. Others have also debated this issue [8] and, although the nail bed may have a significant contribution to make in disease [9], the evidence for its contribution at other times is conflicting.

Nail morphology

Why the nail grows flat, rather than as a heaped-up keratinous mass, has generated much thought and discussion [10–14]. Several factors probably combine to produce a relatively flat nail plate: the orientation of the matrix rete pegs and papillae; the direction of cell differentiation [15]; and moulding of the direction of nail growth between the proximal nail fold and distal phalanx [16]. Containment laterally within the lateral nail folds assists this orientation, and the adherent nature of the nail bed is likely to be important. In diseases such as psoriasis, the nail bed can lose its adherent properties, exhibiting onycholysis. In addition, there may be subungual hyperkeratosis. These combined factors make psoriasis the most common pathology in which up-growing nails are seen. Onychogryphosis is characterized by upward growth of thickened nail. In this condition, the nail matrix may become bucket-shaped and the effect of the overlying proximal nail fold is lost.

Linear nail growth [17–19]

Over the last century, many studies have been carried out on the linear growth of the nail plate in health and disease; these have been reviewed [20,21] and are listed in Tables 65.1 and 65.2 [22]. Most of these studies have been performed by observing the distal movement of a reference mark etched on the nail plate over a fixed

Table 65.1 Physiological and environmental factors affecting the rate of nail growth.

Faster	Slower
Daytime	Night
Pregnancy [25]	First day of life [14]
Right-hand nails	Left-hand nails [28,29]
Youth, increasing age	Old age [18,23,30]
Fingers	Toes [31]
Summer [18]	Winter or cold environment [32,33]
Middle, ring and index fingers	Thumb and little finger [28,31,34,35]
Male gender	Female gender [27,35]
Minor trauma/nail biting [26,27]	

Table 65.2 Pathological factors affecting the rate of nail growth.

Faster	Slower
Psoriasis [36] Normal nails [23] Pitting Onycholysis [37]	Finger immobilization [41]
Pityriasis rubra pilaris [21,38]	Fever [42] Beau's lines [43]
Etretinate, rarely [39]	Methotrexate [24], azathioprine [24], etretinate [39]
Idiopathic onycholysis of women [37]	Denervation [44]
Bullous ichthyosiform erythroderma [13]	Poor nutrition Kwashiorkor [45]
Hyperthyroidism [28]	Hypothyroidism [28]
Levodopa [40]	Yellow nail syndrome [13]
Arteriovenous shunts [28]	Relapsing polychondritis [46]

period of time; this may well correlate with matrix germinative cell kinetics but there is no direct proof that it does. However, studies on nail growth in psoriasis, and its inhibition by cytostatic drugs [23,24], suggest that cell kinetics and linear growth rate do have a direct correlation.

Fingernails grow approximately 1 cm every 3 months and toenails at one-third of this rate.

Nails in childhood and old age

Childhood [1]

In early childhood, the nail plate is relatively thin and may show temporary koilonychia. This is particularly prominent on the great toes. Under the age of 5 years, nails are also prone to terminal onychoschizia (lamellar splitting). This can be most prominent on the sucked thumb, but is also seen on the toes. Sucking may also lead to paronychia, which can be a troublesome condition in childhood, with pain and nail dystrophy. Ingrowing can also cause pain

and may present in different forms. At birth, there is often a degree of distal ingrowing, particularly in the great toe, as the nail has not surmounted the tip of the digit in its development [2]. In a more gross form, this may present as congenital hypertrophic lip of the hallux, where soft tissue overgrowth may resemble fibrous tumours of the digit before spontaneously disappearing [3]. Painful distal embedding can lead to infection, but as long as the toenail is properly orientated with respect to the underlying phalanx, the condition usually subsides. In one series of seven children, two needed surgery due to painful persistence of the problem [4]. The changes associated with congenital malalignment of the great toe may also subside within 5–10 years in about 50% of children. In this condition, there is deviation of the tip of the great toe nail laterally, rotating on the distal phalanx. The nail is yellow, triangular, thickened and has transverse ridges [5].

Fungal infection is relatively uncommon in children, with a prevalence of 0.3% [6] to 0.44% [7]. Terbinafine is not licensed for use in children in most countries, although there is evidence of its efficacy and it is sometimes used [7].

Beau's lines can be seen in up to 92% of normal infants between 8 and 9 weeks of age [8]. Normal surface markings of the nail can differ in children from those seen in adults. A herringbone pattern is common and gradually diminishes with time [9], which may reflect a gradual change in the pattern of matrix maturation.

Old age

With age, altered arterial and venous supply and cumulative trauma affect the feet more than most other body sites [10]. Elastic tissue changes diffusely affecting the nail bed epidermis are often seen histologically. The whole subungual area in old age may show thickening of blood vessel walls with vascular elastic tissue fragmentation [11]. Nail growth is inversely proportional to age [12].

The nail plate becomes paler, dull and opaque with advancing years, and white nails similar to those seen in cirrhosis, uraemia and hypoalbuminaemia may be seen in normal subjects. Longitudinal ridging is present to some degree in most people after 50 years of age and this may give a 'sausage links' or beaded appearance.

For details of the common traumatic abnormalities and changes due to inadequate pedicure or neglect, detailed texts should be consulted [1,12]. Nail problems in the elderly are often associated with more widespread mechanical changes of the foot, and it is often more important to direct treatment at maintaining mobility rather than the restoration of normal nails [13,14].

Onychomycosis is one of the most common nail diseases of the elderly, and is often combined with an element of traumatic dystrophy that will predispose to relapse after treatment. There are concerns that drug interactions in this group might make systemic therapy a poor choice [15]. This is not borne out by one large study designed to examine the effects of terbinafine. But the study also revealed that complete cure at the conclusion of the trial occurred in only 28% of cases, which should be considered before instigating therapy [16].

Nail signs and systemic disease

It is important for clinicians to understand and accurately describe nail findings if they are to communicate accurately with their colleagues and avoid the vagueness that often surrounds nail pathology. Signs fall into categories of shape, surface and colour.

Abnormalities of shape

Clubbing

In clubbing there is increased transverse and longitudinal nail curvature with hypertrophy of the soft-tissue components of the digit pulp. Hyperplasia of the fibrovascular tissue at the base of the nail allows the nail to be 'rocked', and in causes associated with cardiopulmonary disease there may be local cyanosis.

There are three forms of geometric assessment that can be performed. *Lovibond's angle* is found at the junction between the nail plate and the proximal nail fold, and is normally less than 160°. This is altered to over 180° in clubbing (Fig. 65.5). *Curth's angle* at the distal interphalangeal joint is normally about 180°. This is diminished to less than 160° in clubbing (Fig. 65.6). *Schamroth's window* is seen when the dorsal aspects of two fingers from opposite hands are apposed, revealing a window of light, bordered laterally by the Lovibond angles. As this angle is obliterated in clubbing, the window closes [1]. Assessment of clubbing at the bedside shows poor agreement between examiners [2] in milder cases and there are problems in firm morphometric analysis that do not lend themselves to routine clinical solutions [3].

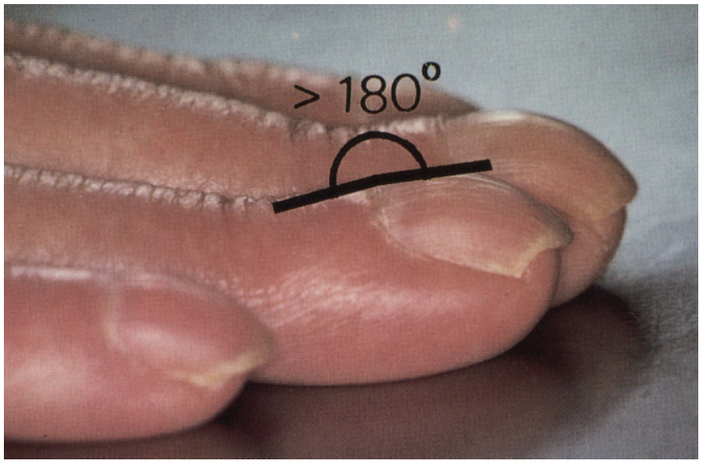

Fig. 65.5 Clubbing: Lovibond's profile sign. The angle is normally less than 160° but exceeds 180° in clubbing.

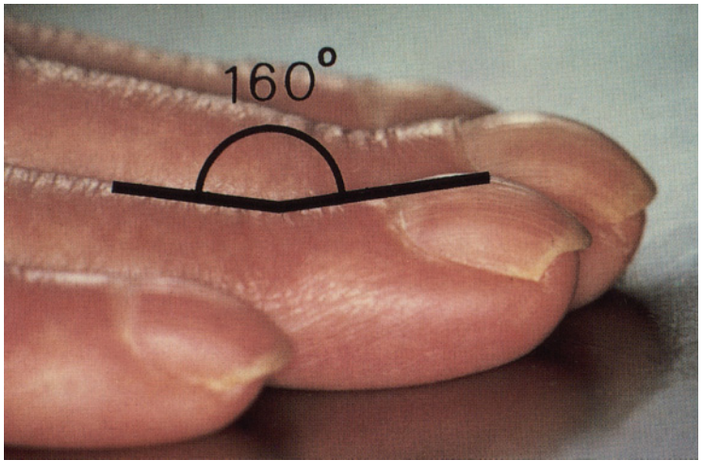

Fig. 65.6 Clubbing: Curth's modified profile sign.

Clubbing appears to be related more to increased blood flow through the vasodilated plexus of nail unit vasculature than to vessel hyperplasia. Altered vagal tone and microvascular infarcts have been implicated [4,5].

Pathological associations of clubbing include inflammatory bowel disease, carcinoma of the bronchus and cirrhosis. In forms associated with bronchiectasis or neoplasm, prominent inflammatory joint signs may also be seen, resulting in hypertrophic pulmonary osteoarthropathy. It has also been reported as a common finding in hemiplegic limbs [6] and can be a presenting feature of a subungual tumour when in a single digit [7]. In some cases of bronchiectasis, a variant of clubbing, *shell nail syndrome*, can be seen. This is distinguished from clubbing by the presence of atrophy of underlying bone and nail bed [8] and may have more in common with yellow nail syndrome than with clubbing. Rare cases of association with medication leave the matter open to doubt [9].

Koilonychia

In koilonychia (Greek: *koilos*, hollow; *onyx*, nail), there is reverse curvature in the transverse and longitudinal axes giving a concave dorsal aspect to the nail [1]. Fingers and toes may be affected, with signs most prominent in the thumb or great toe. The nail may be thickened, thinned, softened or unchanged in quality. Koilonychia is common in infancy as a benign feature of the great toenail, although in some infants its persistence may be associated with a deficiency of cysteine-rich keratin [2] in trichothiodystrophy. The most common systemic association is with iron deficiency [3] and haemochromatosis, although the majority of adults with koilonychia demonstrate a familial pattern which may be autosomal dominant [4]. In dermatoses such as psoriasis and dermatophyte infection, nail bed hyperkeratosis may push the nail up distally to produce a spoon-shaped nail. In mechanics, softening of the nail with oil may be a factor [5], and in hairdressers, permanent wave solutions may be causal [6].

Pincer nail

Synonyms
- Involuted nail
- Trumpet nail

Pincer nail describes a dystrophy where nail growth is pitched towards the midline, combined with increased transverse curvature. It presents in three patterns [1–3]. Probably the most common is in association with psoriasis, where the thumbs and big toes are the most likely to be affected, although the pattern is not as orga-

nized and symmetrical as that seen in the inherited version. In the latter there is often a gradient of involvement, radiating from the thumbs and big toes outwards, which progresses with time. The third variant is the individual nail which develops a pincer deformity. In this instance careful imaging and surgical exploration should be undertaken to exclude an isolated space-occupying lesion beneath the matrix [4–6]. Although the changes in matrix geometry may only be slight, their effect is amplified by longitudinal growth of the nail such that the free edge may take on the shape of the apex of a cone in extreme cases. Pain may arise due to embedding of the pincer nail in the lateral nail folds and nail bed, which becomes most pronounced distally. It is seen as an isolated familial abnormality that usually becomes manifest in adulthood.

Imaging can be helpful in all variants. Treatment is usually by surgery to relieve the pain. In toes it is usually best to perform a lateral ablation of the most embedded margin. This will sometimes lead to a shift of the nail such that the other side no longer embeds. If both sides require ablation, the dimensions of the toenail may mean that it is better to ablate the entire matrix rather than to leave a central zone of nail. The alternative of corrective surgery in toes has less chance of success, although successful case series are reported. Ablation may ultimately be required as a definitive procedure. When treating the thumbs or fingers, the chance of success with corrective surgery is higher and the cosmetic and functional handicap of ablation may not be acceptable. Again, a lateral ablation may be adequate, but more complex procedures entail altering the alignment of the matrix [2,7,8], level of the nail bed [9], and addressing any midline hypertrophy of the distal phalanx. Some surgeons advocate a combination of reconstruction and ablation [10]. Nail braces rarely produce long-term benefit, although promising outcomes have been reported [11].

Macronychia and micronychia

Macronychia and micronychia are conditions where a nail is considered too large or too small in comparison with other nails on nearby digits. The nail disorder is usually associated with an abnormal digit, arising from underlying bony abnormalities such as local gigantism causing macronychia or megadactyly [1]. This is also the basis of racket thumb (Fig. 65.7), the most common form of benign, dominantly inherited macronychia. Plexiform neurofibromas may cause nail changes, and duplication of the terminal phalanges may cause bifid or small nails [2].

Fig. 65.7 Racket nail associated with clubbing.

Anonychia

Anonychia is absence of all or part of one or several nails [1]. It may be congenital, acquired or transient. The underlying genetic abnormality of the congenital form has recently been identified as a mutation in the R-spondin 4 gene, which plays a part in Wnt signalling within the cell [2]. There may be a biological interaction with the underlying phalanx in embryogenesis [3]. Acquired forms are due to scarring of the nail matrix. This can arise as a result of burns, surgery or trauma, or be due to inflammatory dermatoses such as lichen planus where the entire nail matrix is scarred and lost [4]. Similar scarring can occur in variants of epidermolysis bullosa, with irreversible nail loss. The transient variant is due to nail shedding. This can occur due to an intense physiological or local inflammatory process, in the absence of scarring.

Abnormalities of nail attachment

Nail shedding

Nails can be lost through different mechanisms:

1 Complete loss of the nail plate due to proximal nail separation extending distally [1] is called onychomadesis and is a progression of profound Beau's lines. This may reflect local or systemic disease and in the latter may result in temporary loss of all nails.
2 Local dermatoses, such as the bullous disorders and paronychia, may cause nail loss. Generalized dermatoses may be manifest, for example toxic epidermal necrolysis (TEN) and severe/rapid onset of pustular psoriasis. Scarring of the nail unit is seen in lichen planus and following TEN, which may both provoke nail loss.
3 Trauma is a common cause of recurrent loss and may reflect the nature of the activity, such as football, or some underlying abnormality of footwear [2] or pedal mechanics. It is often associated with subungual haemorrhage [3]. In the long term, athletes often develop thickened dystrophic nails matching a history of recurrent shedding.
4 Temporary loss has also been described due to retinoids [4], and large doses of cloxacillin and cephaloridine during the treatment of two anephric patients [5].
5 Onychoptosis defluvium or alopecia unguium describes atraumatic, familial, non-inflammatory nail loss [6]. It may be periodic and associated with dental amelogenesis imperfecta.
6 Nail shedding can be part of an inherited structural defect, most obviously in epidermolysis bullosa [7], although at times the diagnosis may be occult [8].
7 Nail degloving [9]: this refers to partial or total avulsion of the nail and surrounding tissue (perionychium). Typically, it appears as thimble-shaped nail shedding or total loss of the nail organ with soft tissue. Nail degloving represents the end result of a variety of insults to the nail apparatus, including trauma, dermatological diseases and drug reactions.

Onycholysis

Onycholysis is the distal and/or lateral separation of the nail from the nail bed [1] and can be graded for the purposes of clinical documentation or therapeutic trials [2]. Psoriatic onycholysis can be considered the reference point for other forms of onycholysis where it is typically distal, with variable lateral involvement. Areas of separation appear white or yellow due to air beneath the nail and sequestered debris, shed squames and glycoprotein exudate. Isolated islands of onycholysis present as 'oily spots' or 'salmon patches' in the nail bed. At the border of onycholysis, the nail bed is usually reddish-brown, reflecting the underlying psoriatic inflammatory changes. All the common causes are associated with diminished adherence of nail to nail bed as a primary (idiopathic) or secondary event and include trauma, fungal infection, eczema, drug reactions and photo-onycholysis [3].

Fig. 65.8 Onycholysis: idiopathic type.

Idiopathic onycholysis

This is a painless separation of the nail from its bed, which occurs without apparent cause. Overzealous manicure, frequent wetting and cosmetic 'solvents' may be the cause but may not be admitted by the patient. There may, however, be a minor traumatic element, as the condition occurs rather more often in persons who keep their nails abnormally long. Maceration with water may also be a factor [3]. It must be distinguished from other causes of onycholysis (see below). The affected nails grow very quickly [4].

The condition usually starts at the tip of one or more nails and extends to involve the distal third of the nail bed (Fig. 65.8). Persistent manicure is attempted to remove the debris which accumulates within the onycholytic space, and this can result in a crescentic margin of onycholysis matching the onychocorneal band and appearing similar in all involved digits. Pain occurs only if there is further extension as a result of trauma or if active infection supervenes. More often there is microbial colonization of a mixed nature, including *Candida albicans* and several bacteria, of which *Pseudomonas pyocyanea* is the most common. If the condition persists for several months, the nail bed becomes dark and irregularly thickened. The condition is mostly seen in women and many cases return to normal after a few months. The longer it lasts, the less likely is the nail to become reattached, due to keratinization of the exposed nail bed.

Treatment [5]. The patient should be advised to cut away as much as possible of the loosened nail and to apply a topical steroid preparation containing broad-spectrum antimicrobials, effective against both yeasts and bacteria. Reattachment is slow, and the loosened nail should be recut several times if necessary. The object

Fig. 65.9 Photo-onycholysis with a uniform pattern of discoloured onycholysis in the midline.

of treatment is to prevent infection becoming established beneath the loosened nail, because this leads to thickening of the nail bed and prevents reattachment. Some authorities still recommend 4% thymol in chloroform (not available in the USA) as a means of preventing infection and further maceration of the nail bed; however, 2% thymol is often as strong as the patient can tolerate and is usually effective. Where antimicrobial therapy is needed for *Pseudomonas*, gentamicin eye drops can be useful. Drying under the onycholytic nails with a hair dryer has been advocated in order to desiccate the environment in which *Pseudomonas* would otherwise grow. Soaking the finger tips several nights a week in vinegar or sodium hypochlorite solution (Milton™) for 5 minutes can be useful to prevent recurrence.

Secondary onycholysis

There are many causes of secondary onycholysis [5,7–8]. Psoriasis, fungal infections, dermatitis and trauma are among the most common. Onycholysis occurs in general medical conditions, including impaired peripheral circulation, hypothyroidism [8], hyperthyroidism [9], hyperhidrosis, yellow nail syndrome and shell nail syndrome. Minor trauma is a common cause, and many occupational cases are due to trauma [10]. Immersion of the hands in soap and water may be considered traumatic, as also may the use of certain nail cosmetics. It has also been described after the application of 5% 5-fluorouracil to the fingertips [11]. There is a condition of hereditary partial onycholysis associated with hard nails [12]. Photo-onycholysis (Fig. 65.9) may occur during treatment with psoralens, demethylchlortetracycline and doxycycline [13,14], and rarely other antibiotics. This is sometimes associated with cutaneous photosensitivity (see Chapter 29). Drugs such as retinoids [15] and cancer chemotherapy can also be implicated, with taxanes eliciting nail changes in between 19 and 44% of patients, depending on the chemotherapy regimen [16]. Cooling the hand with a specialized glove has been demonstrated to help diminish or delay onset of the side effects [17].

Pterygium [1]

The term 'pterygium' describes the winged appearance achieved when a central fibrotic band divides a nail proximally in two. However, the fibrotic tissue may not always grossly alter the nail, and can extend from the lateral nail fold as well as the more typical proximal nail fold origin. A large pterygium may destroy the whole nail.

An inflammatory destructive process precedes pterygium formation. There is fusion between the nail fold and underlying nail bed and matrix. The fibrotic band then obstructs normal nail growth. Superficial abnormal vessels may be seen and there are no skin markings. It most typically develops in trauma or lichen planus and its variants, including idiopathic atrophy of the nail [2] and graft-versus-host disease [3]. It can also occur in leprosy, where it may represent scarring secondary to neuropathic damage and secondary purulent infection [4].

Ventral pterygium [1]

Ventral pterygium or pterygium inversum unguis [2] occurs on the distal undersurface of the nail, with forward extension of the

nail bed epithelium dislocating the hyponychium and obscuring the distal groove. Causes include trauma, systemic sclerosis [2,3], Raynaud's phenomenon, lupus erythematosus, familial [4] and infective [5]. The overlying nail may be normal, but adjacent soft tissues can be painful.

Subungual hyperkeratosis

Subungual hyperkeratosis entails hyperkeratosis of the nail bed and hyponychium and may occur in a range of conditions, including those where the primary diagnosis is not clear. Nail plate changes are variable, but thickening is common. Dry, white or yellow hyperkeratosis may crumble away from the overhanging nail. Hyperkeratosis may extend onto the digit pulp. Features of onychomycosis and wart virus infection (mainly toes) or psoriasis, pityriasis rubra pilaris and eczema (mainly fingers) may be found elsewhere to indicate the aetiology.

The nail bed is an epithelium of low proliferative turnover. Any disease process that affects it is likely to result in an excess of squamous debris. The overlying nail prevents simple loss. The initial outcome is compaction of debris into layers of subungual hyperkeratosis. The only route of loss is by emerging distally with the growing nail.

Focal subungual keratoses are seen with Darier's disease, and keratotic debris beneath the nail in Norwegian (crusted) scabies may contain mites and eggs.

Nail thickening

Isolated thickening of the nail is associated with yellow discoloration as the nail bed vasculature is obscured. Common causes include psoriasis, eczema, trauma and onychomycosis, some of which may be associated with subungual hyperkeratosis. The shape of the nail may alter depending on the underlying cause, such as in yellow nail syndrome, where there is increased curvature in the longitudinal and transverse axes.

In the elderly and in yellow nail syndrome, retarded longitudinal growth of the toenail is compensated for by increased thickness [1]. Yellow nail may also develop where the nail bed produces abnormal nail [2]. Onychogryphosis describes thickened nails, usually the great toenails, which commonly grow upwards in a spiral. It is attributed to chronic distorting trauma and can be treated surgically or by conservative methods. These include trimming with an electric drill, chemical destruction with 40% urea paste, phenolization of the matrix to achieve total ablation (phenol time reduced to 2 min) or carbon dioxide laser.

Changes in nail surface

Longitudinal grooves

Longitudinal grooves may run all or part of the length of the nail in the longitudinal axis, and need to be distinguished from ridges that are proud of the nail surface [1]. Grooves may be full or partial thickness.

The median canaliform dystrophy of Heller [2] is the most distinctive form [3]. The nail is split, usually in the midline, with a fir-tree-like appearance of ridges angled backwards. The thumbs are most commonly affected and the involvement may be symmetrical. The cuticle may be normal, as distinct from the cuticle in habit tic deformity (washboard nails). After a period of months or years the nails often return to normal, but relapse may occur [4] and a ridge may replace the original defect. Some patients give a definite history of trauma [1], or the disorder can be attributed to oral retinoids [5]. Familial cases have been recorded. Sutton [6] described involvement of a toenail in which a flabby filament of fleshy tissue was present in the canal. Treatment is unnecessary, although the patient should be advised to apply an emollient cream to the nail fold.

Physiological furrows and ridges are accentuated in lichen planus, rheumatoid arthritis, peripheral vascular disease, old age and Darier's disease. *Onychorrhexis* may occur where there are superficial grooves in the nail that lead to a distal split.

Tumours (warts, myxoid cysts) pressing on the matrix, or a proximal nail fold pterygium, may produce a longitudinal groove.

Transverse grooves and Beau's lines [1,2]

Transverse grooves may be full or partial thickness through the nail. When they are endogenous they have an arcuate margin matching the lunula. If exogenous, such as those due to manicure, the margin may match the proximal nail fold and the grooves may be multiple as in washboard nails associated with a habit tic [3]. When multiple, it may be difficult to distinguish a habit tic from psoriasis. Transverse grooves may occur on isolated diseased digits (trauma, inflammation or neurological events) [4] or may be generalized, reflecting a systemic event such as drug reaction [5], coronary thrombosis, measles, mumps or pneumonia. If endogenous, they are usually referred to as *Beau's lines* [2]. They arise through temporary interference with nail formation and become visible on the nail surface (Fig. 65.10) some weeks after the precipitant. The distance of the groove from the nail fold is related to the time since the onset of growth disturbance. The depth and

Fig. 65.10 Beau's lines present as transverse grooves in the nail, matching the proximal margin of the nail matrix and lunula.

width of the groove may be related to the severity and duration of disturbance, respectively. In many cases, grooves are seen on all 20 nails but are most prominent on the thumb and great toenail, and are deeper in the midline of the nail. Full-thickness grooves can be associated with distal extension of the plane of separation of the nail plate. This can lead to nail loss, termed *onychomadesis*.

Pitting

Pitting presents as punctate erosions in the nail surface. Individual pits may be shallow or deep, with a regular or irregular outline. The individual pits of psoriasis are said to be less regular in form and in overall pattern than those of alopecia areata, but this is not always the case. When numerous, they appear randomly distributed upon the nail surface or have a geometric pattern. The latter may cause rippling or create a grid of pits. Extensive pitting combined with other surface irregularities results in the appearance of *trachyonychia*. An isolated large pit may produce a localized full-thickness defect in the nail plate termed *elkonyxis*, which is found in Reiter's disease, psoriasis and following trauma.

Fig. 65.11 Trachyonychia: roughened surface of up to 20 nails.

Histologically, pits represent foci of parakeratosis, reflecting isolated nail malformation [1].

Trachyonychia

Trachyonychia presents as a rough surface affecting all of the nail plate and up to 20 nails (20-nail dystrophy) [1]. The original French term was 'sand-blasted nails', which evokes the main clinical feature of a grey, roughened surface (Fig. 65.11). It is mainly associated with alopecia areata [2], psoriasis and lichen planus, although the most common presentation is as an isolated nail abnormality. In the isolated form, histology shows spongiosis and a lymphocytic infiltrate of the nail matrix [3]. It may present as a self-limiting condition in childhood or as a more chronic problem in adulthood. There is some response to potent topical, locally injected and systemic steroids, but this may be temporary. Topical 5-fluorouracil has also been used to good effect [4], although it is important to be wary of associated onycholysis where the diagnosis is psoriasis, as onycholysis can be exacerbated by 5-fluorouracil. Childhood forms normally resolve spontaneously.

Onychoschizia

Onychoschizia is also known as lamellar dystrophy and is characterized by transverse splitting into layers at or near the free edge (Fig. 65.12) in fingers and toes, especially in infants [1]. There is a subtle distinction between the static features, such as types of split, and the subjective experience of having brittle nails. Usually these characteristics coincide, although clinicians and patients may

Fig. 65.12 Onychoschizia (lamellar dystrophy).

prefer to use one term in preference to the other. The different features can be assessed within a scoring system [2]. Variants include splitting at the lateral margins alone and multiple crenellated splits at the free edge. It is seldom associated with any systemic disorder, although it has been reported with polycythaemia [3], human immuno-deficiency virus (HIV) infection [4] and glucagonoma [5], and recently it has been referred to as a 'syndrome' [2].

Scanning electron microscopy illustrates the tendency of the lamellar structure of nail to separate after repeated immersion in water [6], although case–control studies show that occupation is not a major determinant of the condition [7]. However, efforts at retaining hydration (gloves, emollient and base coat with nail varnish) may help reverse clinical changes. Biotin has been used as systemic therapy, but the evidence for its efficacy is weak [8].

Beading and ridging

Beading and ridging have been described as occurring more often than normal in patients with rheumatoid arthritis [1]. More recently, increased beading has been examined using optical profilometry in patients taking itraconazole for onychomycosis [2]. Itraconazole is known to increase the rate of nail growth, and it was proposed that beading may be a feature of this increase. As beading is more commonly a feature of old age, when nail growth rate slows down, one would not expect beading to correspond directly to faster linear nail growth. Both beading and ridging are common signs in normal ageing patients and at present their significance remains unclear.

Changes in colour [1–7]

Alteration in nail colour may occur because of changes affecting the dorsal nail surface, the substance of the nail plate, the undersurface of the nail or the nail bed.

Exogenous pigment

Exogenous pigment on the upper surface is easy to demonstrate by scraping the nail. If the proximal margin of the pigment is an arc matching the proximal nail fold, this is a further clue confirming an exogenous source. Often, the cuticle is less absorbent than nail and there will be a narrow proximal margin of unstained nail. This margin will broaden as the period since exposure lengthens. Hence the 'quitters' nail, which demonstrates the cessation of smoking and nicotine-free fingers for 2 months.

Exogenous pigment on the undersurface of the nail is less easy to demonstrate and may mean that part or all of the nail needs to be avulsed in order to scrape the undersurface and examine it separately from the nail bed. The green pigment of *Pseudomonas* infection [6] in association with onycholysis is a typical situation where partial avulsion is the best way to demonstrate the site of pigmentation, although it may not always be the best treatment.

Nail plate changes

The nail plate can be changed by the addition of pigment or the alteration of the normal cellular and intercellular organization such that there is loss of normal lucency. Pigment is typically added in the form of melanin produced by matrix melanocytes during nail formation. This produces a brown longitudinal streak the entire length of the nail. In white people this is abnormal and requires thorough assessment and, in some instances, biopsy. In darker-skinned people it is a common variant. The incorporation of heavy metals and some drugs into the nail via the matrix can also produce altered nail plate colour, such as the grey colour associated with silver. The disruption of normal nail plate formation by disease, chemotherapy, poisons or trauma can result in waves of parakeratotic nail cells or small splits between cells within the nail. Both make the nail less lucent and produce the white marks of true *leukonychia.* Transmission electron microscopy suggests that there is a change in collagen fibre organization, which might provide an intracellular basis for altered diffractive properties. This disruption can be achieved at nail formation or subsequently in the case of fungal nail infection, where discoloration may start distolaterally rather than via the matrix.

Dermoscopy can be very helpful in the assessment of nail plate pigmentation and underlying nail bed changes [7].

Nail bed changes

In addition to generalized vascular changes in the nail bed, there can be localized changes, as seen with nail bed tumours. In the instance of a glomus tumour, this may be the sole method of localization and arises because of the differential blood supply in the tumour and surrounding nail bed. Subungual hyperkeratosis or the incorporation of drugs (antimalarials, phenothiazines) may also change the apparent colour of the nail. Splinter haemorrhages, representing ruptured nail bed vessels, deposit haemoglobin on the undersurface of the nail, which grows out. Cyanosis makes the nail bed blue and carbon monoxide poisoning makes it bright red.

True leukonychia

White discoloration of the nail attributable to matrix dysfunction occurs in a variety of patterns [1,2]. There is the rare, inherited form called total leukonychia, in which all nails are milky porcelain white [3]. In subtotal leukonychia, the proximal two-thirds are white, becoming pink distally. This is attributed to a delay in keratin maturation, and the nail may still appear white at the distal overhang (Fig. 65.13).

Transverse leukonychia (Mees' line) reflects a systemic disorder, such as chemotherapy or poisoning [4], or systemic infection [5] affecting matrix function. The 1- to 2-mm-wide transverse band is in the arcuate form of the lunula and is analogous to a Beau's line, with which it is occasionally found. Punctate leukonychia comprises white spots of 1–3 mm diameter attributed to minor matrix trauma (e.g. manicure) and is also seen in alopecia areata. The pattern and number of spots may change as the nail grows. With longitudinal leukonychia, there is a parakeratotic focus in the matrix, sometimes attributable to Darier's disease or a small tumour.

Fig. 65.13 True leukonychia with white nail in the distal free edge.

Apparent leukonychia

In apparent leukonychia, changes in the nail bed are responsible for the white appearance [1,2]. Nail bed pallor may be a non-specific sign of anaemia, oedema or vascular impairment. It may occur in particular patterns that have become associated with certain conditions.

Terry's nail

This is white proximally and normal distally and is attributed to cirrhosis, congestive cardiac failure and adult-onset diabetes mellitus [3]. Nail bed biopsy reveals only mild changes of increased vascularity. This is similar to *half-and-half nails*, where there is a proximal white zone and distal (20–60%) brownish sharp demarcation, the histology of which suggests an increase of vessel wall thickness and melanin deposition. It is seen in 9–50% of patients with chronic renal failure and after chemotherapy. It is unclear whether the variant *Neapolitan nails*, where there are bands of white, brown and red, is a version of half-and-half or Terry's nails, or a feature of old age.

Muehrcke's paired white bands

These bands are parallel to the lunula in the nail bed, with pink between two white lines. They are commonly associated with hypoalbuminaemia, the correction of which by albumin infusion can reverse the sign. They have also been reported following placement of a left ventricular assist device in a patient with congestive heart failure [4].

Colour changes due to drugs [1]

There are a number of colour changes due to drugs. Yellowing of the nail is a rare occurrence in prolonged tetracycline therapy, which can also produce a pattern of dark distal photo-onycholysis associated with photosensitivity [2]. The whole nail is affected and returns to normal when the drug is discontinued. A similar effect, but of a bluish colour, is seen with mepacrine [3], the nails fluorescing yellow–green or white when viewed under Wood's light. Normal nails show slight fluorescence of violet–blue colour. Hydroxyurea has been reported to result in blue lunulae [4].

Chloroquine may produce blue–black pigmentation of the nail bed [5]. Other antimalarials may produce longitudinal or vertical bands of pigmentation on the nail bed or in the nail [6]. A fixed drug eruption of the nail bed can be dark blue [7]. Argyria may discolour the nails slate blue [8], and inorganic arsenic may produce longitudinal bands of pigment or transverse white stripes (*Mees' stripes*) across the nail.

Hyperpigmentation due to increased melanin in the nail and nail bed has been noted in children after 6 weeks of treatment with doxorubicin (Adriamycin) [9,10]. Other, similar cytotoxic drugs may cause a variety of patterns of increased pigmentation [1]. However, in acquired immune deficiency syndrome (AIDS), longitudinal melanonychia may be seen in untreated cases [11,12] as well as in those receiving zidovudine [9,13].

Yellow nail syndrome

The nails in yellow nail syndrome are yellow due to thickening, sometimes with a tinge of green possibly due to secondary infection. The lunula is obscured and there is increased transverse and longitudinal curvature and loss of cuticle (Fig. 65.14). Occasionally, there is chronic paronychia with onycholysis and transverse ridging [1]. The condition usually presents in adults, but may occur as early as the age of 8 years [2]. Although an autosomal dominant inheritance was initially suggested, detailed modern family trees suggest that it is not heritable [3]. Some of the clinical features may overlap with lichen planus [4], although the latter does not have the other systemic features normally seen in this syndrome. The features are usually accompanied by lymphoedema [5] at one or more sites and respiratory or nasal sinus disease. The nails grow at a greatly reduced rate: 0.1–0.25 mm/week for fingernails compared with the lowest normal rate of 0.5 mm/week. All 20 nails may be involved, although often a few are spared. Histologically, in the nail bed and matrix, dense fibrous tissue is found replacing subungual stroma, with numerous ectatic endothelium-lined vessels [6]. A foreign-body reaction has been noted [7]. It has been suggested that obstruction of lymphatics by this dense stroma leads to the abnormal lymphatic function found in the affected digits in some [8] but not all [9] cases.

Fig. 65.14 Yellow nail syndrome.

The oedema most frequently affects the legs, and may not be seen for some months after the nail change has been noted. Less often it affects the face or hands, and occasionally it is universal. In some instances the oedema has been shown to be due to abnormalities of the lymphatics, either atresia or, in some cases, varicosity [10]. Other cases have normal lymphatics, suggesting that a functional rather than an anatomical defect may be present [11], or perhaps only the smallest lymph vessels are defective. Although the nail changes may draw attention to the underlying lymphatic abnormality, they are found only in a minority of patients with congenital abnormality of the lymphatics. Recurrent pleural effusions have been noted in a few cases [12,13]. Chronic bronchitis and bronchiectasis may also occur [12]. The condition may be associated with an increased incidence of malignant neoplasms [10,14,15]. Other associations include D-penicillamine therapy [5] and nephrotic syndrome [16]. In hypothyroidism and AIDS [17] there may be yellow nails, but it is debatable whether these represent yellow nail syndrome or simply the discoloration of nail associated with retarded growth [18].

Although the nail changes, once established, are usually permanent, complete reversion to normal may occur spontaneously. Attempted treatments include oral [19] and topical [20] vitamin E, oral zinc [21] and treatment of chronic infection at other sites [22]. There is debate as to whether itraconazole is of value as treatment. The drug has been demonstrated to increase the rate of longitudi-

nal growth, but an open trial in eight patients demonstrated that half gained no benefit with respect to nail changes [23]. It is reported that results are better when itraconazole or fluconazole is combined with oral vitamin E [24].

Red lunulae

Erythema of all or part of the lunula may affect all digits, but most prominently the thumb. Erythema is less intense in the distal lunula, where it can merge with the nail bed or be demarcated by a pale line, and can be obliterated by pressure on the nail plate. The appearance can fade over a few days. A single report of histological features did not reveal any vascular or epidermal changes [1]. Dotted red lunulae have been reported in psoriasis and alopecia areata, but otherwise the list of associations is so broad that it is unconvincing [2].

The exception to this is a red lunula seen in a single digit. In this setting, it often indicates a local disturbance of vascular flow, which is most likely to be a benign tumour. Glomus tumours and subungual myxoid cysts are the most common [3] and the colour may vary between blue and red.

Longitudinal erythronychia (Fig. 65.15)

A longitudinal red streak in the nail can have several causes [1,2]. All will have a corresponding band of thinned nail plate as part of the defect. The effect of this is a strip where the nail bed is less compressed by the overlying nail so that blood pools and is more apparent. Equally, the colour is more easily seen because the nail is thinner in this line. Splinter haemorrhages may lie longitudinally within the erythronychia.

A strip of thinned nail arises because of focal reduction of matrix function. This can be due to direct matrix disease, such as an epidermal pathology, or as a result of pressure on the matrix with secondary loss of function. This second category contains the full range of dermal tumours as well as tumours of bone and cartilage that arise from the distal phalanx.

Matrix epidermal disease covers a spectrum of pathologies. The most common are lichen planus and Darier's disease, where thin longitudinal red streaks may terminate at the free edge with a split. In Darier's disease there may be a small subungual keratosis

(a) (b)

Fig. 65.15 (a) Longitudinal erythronychia. (b) The longitudinal ridge in the nail bed corresponds to the groove on the undersurface of the nail plate.

[3]. Acantholytic dyskeratotic naevus and warty subungual dyskeratoma [4] may both represent localized forms of Darier's disease. Acrokeratosis verruciformis of Hopf has a greater focus on nail fold disease, but also demonstrates longitudinal erythronychia and both clinical and pathological overlap with Darier's disease. In some instances there does not appear to be any primary disease to provide an explanation for multiple areas of erythronychia and in this setting the term 'idiopathic polydactylous erythronychia' has been suggested [5].

Baran has coined the term 'onychopapilloma' to describe the isolated, benign warty distal nail bed lesions found in association with longitudinal erythronychia where the diagnosis lies outside those described above [6]. The papilloma is a secondary element, given that it is found distally in the nail bed while the cause lies proximally within the matrix. However, there is a category of this disease where the matrix disease remains unclear and the distal papilloma represents the identifiable entity. At other times, despite a similar clinical presentation with erythronychia and splinter haemorrhages, the matrix pathology may reveal a specific alternative diagnosis such as Bowen's disease [6] or basal cell carcinoma [7]. This means that isolated longitudinal erythronychia needs careful assessment, and biopsy may be warranted if there is evolution.

Not all causes of longitudinal erythronychia conform to these rules. This is particularly the case where there are multiple red streaks associated with a dermatosis and additional nail changes. It can be a feature of lichenoid diseases of the nail unit, discoid lupus erythematosus, psoriasis, Langerhans' cell histiocytosis and a number of other diseases where there is patchy nail atrophy.

Splinter haemorrhages

Splinter haemorrhages represent longitudinal haemorrhages in the nail bed conforming to the pattern of subungual vessels [1–4]. They are most frequently seen in the distal nail bed and on the fingers of the dominant hand, reflecting trauma as the cause. In dermatological practice, they are often found in association with psoriasis, dermatitis and fungal infection of the nails. As they occur under so many conditions, their importance as a sign of disease is often exaggerated. Focal pathology may also represent a cause, as in longitudinal erythronychia and onychomatricoma (see pp. 65.17 and 65.32).

Large numbers of proximal haemorrhages with no obvious traumatic origin may indicate a systemic cause [5], such as bacterial endocarditis or antiphospholipid syndrome [6]. Unilateral splinter haemorrhages may arise after arterial catheterization on the involved side. Examination under oil or gel with a dermatoscope may reveal greater detail.

Developmental abnormalities of the nails [1,2]

Congenital anonychia

Absence of the nails from birth is a rare congenital anomaly. It may occur as an isolated sign or be accompanied by other defects of the digits and other structures. In many of the affected families there is a mix of anonychia with hyponychia. In several pedigrees, mutations in the gene for R-spondin 4 have been identified, which play a part in the Wnt signalling pathway [3]. This has been shown to have significance in the early stages of nail embryogenesis, with expression of the signalling protein in the distal dorsal digit ridge which acts as a landmark for early nail unit formation. This is deficient in those with the mutation—with the implication that loss of signalling results in a failure of nail unit formation.

Anonychia with ectrodactylia [4] has been shown to be inherited as a dominant trait without sex linkage. In this condition, there is usually complete absence of the nails on the index and middle fingers, and when there is any nail on the thumb it is often present on the proximal lateral corners of the nail fold. On the ring fingers, the radial half of the nail is often absent, and the nail bed is also missing. In a minority of affected individuals there are striking and bizarre defects of the digits, sometimes restricted to one hand or foot. The defects usually take the form of absence of one or more digits. Two sisters in a sibship of five, whose parents were first cousins, are recorded as having rudimentary nails associated with congenital deafness. The parents showed neither abnormality [5]. Bart *et al*. [6] described a family with congenital absence of areas of skin, blistering of skin and mucous membranes, and absence or deformity of the nails, inherited as an autosomal dominant trait. It is now classified as a subtype of dominantly inherited dystrophic epidermolysis bullosa, with the responsible gene mapped to chromosome 3p [7]. Verbov [8] described a case with bizarre flexural pigmentation and anonychia, thought to be an autosomal dominant condition.

Nail–patella syndrome

This uncommon condition is of special interest because it involves abnormalities of ectodermal and mesodermal structure. It is inherited as an autosomal dominant trait. The disorder is caused by mutations in the LIM-homeodomain transcription factor β1 protein (LMX1B). This protein plays an important role in dorsoventral limb patterning during embryogenesis [1]. Gradients of expression of the protein determine the dominance of dorsal or ventral axon growth with concomitant trophic effects on mesoderm and ectoderm [2]. The gene maps to chromosome 9q34.1, with affected families showing a wide range of deletions and mutations [3]. In a typical case, the nails are grossly defective, being only one-third or half the normal size and never reaching the free edge of the finger [4]. In other cases, the thumbnails alone may be defective or only the ulnar half of each may be missing [5]. In every case, the thumbnails are most affected [6] and the remaining nails, if involved, are progressively less damaged from index to little finger. The lunulae may be triangular, with a distal peak (Fig. 65.16) in the midline [7]. Missing dorsal creases of distal finger joints is also a diagnostic clue of nail–patella syndrome [8]. Even when the nail is completely missing, the nail bed is present. In addition to the nail changes, the patellae are smaller than normal and may be rudimentary, so that the knees are unstable. There are also bony spines arising from the posterior aspect of the iliac bones, visible on X-ray examination.

Other recorded features include hyperextension of the joints, skin laxity, hyperhidrosis [9], renal abnormalities [10,11], and open angle glaucoma. LMX1B is known to influence transcription of genes affecting collagen IV in the glomerular basement membrane [12].

In 1965, there were 255 patients with this syndrome known to be living in the UK. The mutation rate is estimated at 1 per 1.9 million alleles per generation [13].

Screening entails examination of knee, hip and elbow X-rays for characteristic changes, renal assessment and measurement of intraocular pressures in case of glaucoma. Once the diagnosis is established, the last two aspects should be reviewed annually. The condition must be distinguished from congenital ectodermal defects and pachyonychia congenita.

Congenital onychodysplasia of the index fingers [1,2]

Synonym
- Iso-Kikuchi syndrome

In this condition, the nail of the index finger is absent, small or represented by two nails of unequal size. There may be a family history suggestive of autosomal dominant inheritance, although there is frequently no clear genetic pattern, and involvement of other digits has been reported [1,3,4]. Underlying changes in the distal phalanx can usually be demonstrated by lateral radiography, where bifurcation of the distal phalanx is the norm [4]. Syndactyly is an associated hand anomaly in some cases [2].

Variants include a similar form of onychodysplasia affecting other digits, including toes [5].

Pachyonychia congenita (Fig. 65.17)

Pachyonychia congenita (PC) is a rare, autosomal dominant genodermatosis in which hypertrophy of the nails occurs, in some cases associated with nail bed and hyponychial hyperkeratosis [1,2]. A recessive form has been reported [3].

The two variants of PC arise through mutations affecting the genes encoding keratins 6a and 16 in PC-1 [4,5] and 6b and 17 in PC-2 [6,7]. In some instances, onset can be delayed into adult life and be more subtle in appearance. This is designated PC tarda [8].

Fig. 65.17 Pachyonychia congenita.

PC-1 (Jadassohn–Lewandosky type). The nails are normal at birth but within months they become discoloured and progressively thicken, more so on the hands than feet. Typical associated findings include palmar and plantar hyperkeratosis and warty skin lesions at various sites: knees, elbows, buttocks, legs, ankles and popliteal region. Acral bullae may be crippling and hyperhidrosis may be severe. Mouth and corneal dyskeratosis are less common findings.

PC-2 (Jackson–Lawler type). In this type, with less severe nail thickening and keratoses than type 1, many associations have been described: teeth may be present at birth; multiple epidermal cysts; sebocystomatosis; dry, lustreless and kinky scalp hair; eyebrows that stand straight out; and hamartomas.

The thickened nails can be treated surgically in some instances [9]. This is most likely to be warranted in PC-1. The localization of the four implicated keratins to the nail bed underlines that this is the main site of pathology [10]. Affected nails viewed end-on can appear almost normal, but with a dense wedge of subungual keratin, representing the focus of nail bed disease.

A range of associated features have been reported, including amyloidosis in one pedigree [11] and a case where PC coincided with tuberous sclerosis [12]. Treatments are based on focal complaints such as ingrowing or paronychia. There are no established therapies [13].

Infections of the nail and nail folds

Fungal nail infections

See Chapter 36.

Paronychia

Bacterial paronychia

Acute paronychia is a common complaint usually due to staphylococcal infection. It may result from local injuries, splits, splinters or nail biting. It also occurs frequently as a complication of chronic paronychia, when other organisms may be involved, including streptococci, *Pseudomonas pyocyanea*, coliform organisms and *Proteus vulgaris*.

The condition presents as a painful swelling of the nail fold. If superficial it may point close to the nail and can easily be drained by incision with a size 11 scalpel, without anaesthesia [1]. Deeper lesions are best treated by antibiotics initially, but if they do not improve within 2 days, incision under local anaesthesia is required, particularly in childhood. A broad-spectrum antibiotic is preferred because it is unlikely that the organisms can be identified in advance. Some authorities recommend removing the proximal one-third of the nail plate without initial incisional drainage. This gives more rapid relief and more sustained drainage. There may be a place for treatment with topical steroid at the same time as antibiotic therapy [2].

Chronic paronychia

This is an inflammatory dermatosis of the nail folds, with secondary effects on the nail matrix, nail growth and soft-tissue attachments. It may be associated with infection on the background of the dermatosis. The dermatosis may be directly due to an irritant associated with wet work or caustic materials. Alternatively, it may be on the background of atopy or psoriasis, where minor provocation can result in active disease.

Wet, cold hands are predisposed to chronic paronychia [1,2]. Wet foods are a combined source of factors, where the food may be an irritant [3]. It is predominantly a disease of domestic workers, bar staff, canteen workers and fishmongers [4]. The majority of cases are in patients between 30 and 60 years of age [1], although chronic paronychia is also seen in children, especially as a result of finger- or thumb-sucking [5].

Any finger may be involved, most often the index and middle fingers of the right hand and the middle finger of the left [4]. These fingers may be more subject to minor trauma than the remainder. The condition begins as a slight swelling at the base of one or more nails (Fig. 65.18), which is tender but much less so than in acute paronychia. The cuticle is soon lost and pus may form below the nail fold. Inflammation adjacent to the matrix disturbs nail growth, resulting in irregular transverse ridges and other surface irregularities, which may be combined with discoloration (Fig. 65.18).

Fig. 65.18 Chronic paronychia with nail plate discoloration due to *Pseudomonas pyocyanea*.

There is some evidence that the darkening is due to the pigment from *Pseudomonas* infection of the nail [6]. In long-standing cases, the size of the nail may be reduced, and this reduction is exaggerated by bolstering of the fold all around the nail. Most of the nail deformity is due to the inflammation interfering with the formation of the nail, but a true *Candida* infection of the nail plate is occasionally seen.

There is a complex relationship with *Candida*, usually *Candida albicans* [7], which may be identified by swabs or scraping. Stone and Mullins [8] showed that chronic paronychia can be produced by non-viable *C. albicans* introduced into a relatively sterile nail fold. Much of the chronic inflammation seen in this disorder probably arises from an irritant reaction to material sequestered beneath the proximal nail fold. The loss of the cuticle means that detergent and other solvents may gain access to this tight space and act like a prolonged irritant patch test. This chronic, non-infective, inflammatory component is why topical steroids are useful in addition to antimicrobials as part of the treatment [9]. Acute exacerbations occur from time to time and are due to secondary bacterial infection. Various organisms may be found, including *Staphylococcus aureus* or *albus*, *Proteus vulgaris*, *Escherichia coli* and *Pseudomonas pyocyanea*. Barlow *et al*. [9] consider that *S. aureus* plays a more active part in initiating the process by penetrating the keratin at the base of the nail and opening up the nail fold. The role of *S. aureus* as a superantigen may also be relevant. Ingested allergens may also play a part [10].

Pemphigus [11] and squamous cell carcinoma [12] can present as chronic paronychia. The latter usually involves a single digit, and underlines the need for biopsy in isolated periungual

conditions where the diagnosis is unclear. Cancer chemotherapy, antiretroviral medication and retinoids can provoke acute paronychia with features of pyogenic granuloma, which may become chronic.

Treatment. Treatment is a combination of avoidance of precipitants, hand care and medication. Perhaps the most important part of the treatment, but the one most difficult to achieve, is to keep the hands dry. For all wet work the patient should be advised to wear cotton gloves under rubber or plastic gloves and avoid manicure of the proximal nail folds. Covering the affected fingers with porous surgical tape may afford some protection, but normal occlusion aggravates the problem. General hand care with emollient and protection during rough work is useful. If this stage of the therapy is not adequately pursued, the condition is likely to fail to settle whatever medical treatment is provided.

Topical therapy requires a combination of steroid [13] and antimicrobial. A potent steroid may be used for short periods when there is adequate antimicrobial cover. Injected triamcinolone (2.5 mg/mL) is useful in some instances. Topical imidazoles are usually sufficient to treat *Candida* and may provide a modest therapy against some bacteria. More potent topical antibacterials may be needed. Barlow *et al*. [9] suggest using gentamicin ointment during the day and nystatin ointment at night. When features are marked, oral antibiotics appropriate for *S. aureus* should be used. Because of the 'mixed' aetiology of the inflammation, many clinicians use antiseptic or antibiotic/anti-*Candida*/steroid creams in the chronic phase.

Incision is not indicated unless the condition enters an acute tender purulent phase, where removal of the proximal third of the nail may help. Attempting to clean out the nail fold with a sharp instrument is not recommended. If there is obvious candidal infection elsewhere, or *Candida* onychomycosis, this should be treated. Surgical removal of the proximal nail fold and adjacent part of the lateral nail folds may cure recalcitrant cases [14].

In societies in which mechanical dishwashers and washing machines have become common household appliances, chronic paronychia is now rarely encountered.

Pseudomonas infection

This is almost always a complication of onycholysis or chronic paronychia and is usually restricted to one or two nails (see Fig. 65.18). The nail plate has a characteristic bluish-black or green colour [1–3] due to accumulation of debris beneath the nail and the pigment pyocyanin adhering to the undersurface of the nail plate. Pigment may remain after the organism has been removed. In some cases, the nail plate appears to be invaded by the bacillus [2]. Subjects with nail extensions and nail wraps are susceptible to *Pseudomonas* colonization beneath the extensions. This has been documented as a risk factor for passing infection to patients in the medical setting [4]. Treatment [5] is as described for onycholysis or paronychia, whichever appears to be the prominent predisposing state. In addition, it is possible to treat with gentamicin or sulfacetamide (sulphacetamide) eye drops to eradicate the colonization where onycholysis is resistant to therapy. Once treated, if the onycholysis persists, prevention of further *Pseudomonas* infection can be achieved with nightly soaks of the finger tips in dilute hypochorite solution (Milton™) or vinegar.

Herpetic paronychia [1,2]

Synonym
- Herpetic whitlow

This uncommon condition is due to primary inoculation of the herpes simplex virus and presents as single or grouped blisters close to the nail; it may give a honeycomb appearance. Clear at first, the blisters soon become purulent and may break and be replaced by crusts. It is usually very painful and takes about 3 weeks to resolve, with pain settling in half that time. Lymphangitis sometimes occurs and may precede vesiculation. Diagnosis may be established by recovering the virus from a recent blister and by cytological examination of the blister floor. Contact cases may occur.

Treatment probably does little to shorten the course of the disorder, but cleaning with 1/6000 potassium permanganate followed by application of a bland cream is recommended. Relapse may occur as with other primary herpetic infections. The value of

thymidine analogues, such as oral aciclovir, famciclovir and valaciclovir, is unproven, but use for other forms of recurrent herpes suggests that they might be useful in shortening the duration and severity of an episode.

Numbness of the finger has been reported following infection [1], and persistent lymphoedema may occur. Persistent cases may have an atypical presentation in patients with HIV infection [3].

HIV infection

The most common nail changes in individuals with HIV infection are clubbing, transverse lines, onychoschizia, leukonychia and longitudinal melanonychia [1]. In addition, there is a lower threshold for infection with dermatophytes, yeasts, human papillomavirus and herpesvirus [1]. Severe scabies infection, in the form of crusted scabies, is more common in HIV infection, with chronic paronychia and subungual hyperkeratosis [2]. Proximal subungual white fungal infection is said to be a pointer to HIV infection [3]. There may be erythema of the proximal nail folds [4], and paronychia may occur during antiretroviral therapy [5]. The nail can also manifest various patterns of melanonychia, which is usually ascribed to zidovudine therapy [6] but has also been attributed to hydroxycarbamide (hydroxyurea) [7].

Terbinafine is effective for most dermatophyte onychomycosis in HIV infection [8].

Dermatoses affecting the nails

Psoriasis

Psoriatic dystrophy is probably the most common disorder affecting fingernails. Between 1.5 and 3% of the population have psoriasis, and up to 50% of psoriatics have nail involvement [1]. Over a lifetime, this may cumulatively increase to 80–90% [2]. In children, nail involvement ranges from 7% [3] to 39% [4], and pitting has been observed in the first week of life in the offspring of a mother severely affected with psoriasis [5]. Psoriatic nail changes are prominent in the childhood nail disease of parakeratosis pustulosa. Approximately one-third of these children will develop other features of psoriasis in time, a smaller fraction will have variants of eczema and half of the total will get better [6]. De Jong *et al*. [7] reported that 93% of those with nail psoriasis considered it a significant cosmetic handicap, 58% found that it interfered with their job and 52% described pain as a symptom.

Clinical features. In order of reducing frequency, nail signs of psoriasis include pits, onycholysis, subungual hyperkeratosis, nail plate discoloration, uneven nail surface, splinter haemorrhages, acute and chronic paronychia, and transverse midline depressions in the thumbnails. These features can be recorded using a Nail Psoriasis Severity Index (NAPSI), which can be of value in trials of drug treatment [8]. Baran's nail psoriasis severity index has also been validated by a Polish team [9,10].

Pits. Pits more commonly affect fingers than toes (Fig. 65.19). They represent punctate surface depressions arising from proximal matrix disease (Table 65.3). Zaias [1,11] has demonstrated small columns of pathological parakeratotic nail falling off the upper surface of the nail plate to produce a pit. Some authorities advocate nail plate histology as a means of diagnosing nail psoriasis [12]. This can be useful for exclusion of fungal infection, although the specificity of nail plate changes in psoriasis is yet to be established. The origin of pits means that they can be influenced by disease in the proximal nail fold and it is thought that injection of triamcinolone into the nail fold alone can suppress this

Table 65.3 Relationship between clinical features and site of disease activity in psoriasis of the nail. (From Zaias [1].)

Clinical feature	Area of disease	Duration of disease
Changes in nail plate	*Matrix*	
Pits	Proximal matrix	Episodic: short
Transverse furrows	Proximal matrix; distal extension depends on depth of furrow	1–2 weeks
Crumbling nail plate	Entire matrix	Prolonged
Leukonychia with rough surface	Proximal matrix; leukonychia may involve distal matrix	Variable
Changes in nail bed and hyponychium	*Nail bed*	
Splinter haemorrhages	Nail bed dermal ridge haemorrhage	Short
Oily spot/onycholysis	Nail bed psoriasis	Prolonged
False nail following onychomadesis	Nail bed psoriasis	Prolonged
Subungual hyperkeratosis	Nail bed psoriasis	Prolonged
Yellow/ green discoloration of nail bed	Secondary infection by yeasts or *Pseudomonas*	Prolonged

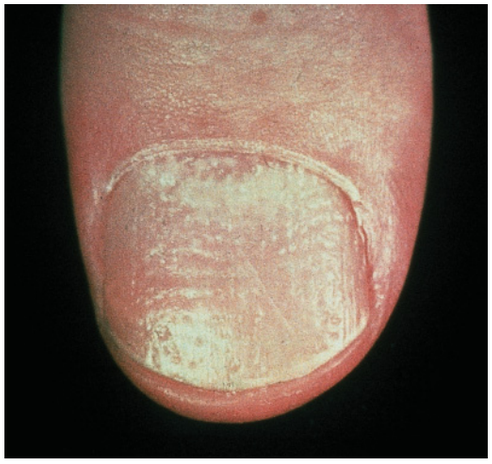

Fig. 65.19 Psoriasis: diffuse pitting.

Fig. 65.20 Psoriasis: onycholysis.

clinical feature. The pattern of pitting may be disorganized or occur in transverse/ longitudinal rows as seen in alopecia areata [2]. Pits may be shallow or large [11], to the point of leaving a punched-out hole in the nail plate (elkonyxis).

Onycholysis. Focal nail bed parakeratosis produces an 'oily spot' or 'salmon patch'. Extension of this area to the free edge produces onycholysis, which typically has a reddish-brown margin. Alternatively, onycholysis may commence at the distal edge (Fig. 65.20), representing disruption of the onychocorneal band [13]. Once this band of firm attachment has been breached, the condition is often progressive. Minor manicure, wet work and leverage from long nails exacerbate the condition.

Discoloration. Discoloration in psoriasis is multifactorial. The major factors are nail thickening and subungual hyperkeratosis. Both of these contribute to a yellow appearance, particularly common in the toes. It is possible that at this site repeated trauma elicits the isomorphic reaction (Köbner phenomenon), with local exacerbation of psoriasis. The coincidence of onychomycosis and psoriasis is also seen in the toenails [14] and can add to the pathological appearance. *Candida* spp. and *Pseudomonas* infection can result in green discoloration. While non-dermatophytes and bacteria are common, dermatophytes are rare [1].

Fig. 65.21 Psoriasis: subungual hyperkeratosis.

Subungual hyperkeratosis. Subungual hyperkeratosis represents nail bed disease (Fig. 65.21). Substantial nail plate thickening may result from subungual hyperkeratosis, which is most marked distally and extends proximally. The fingertip may become very tender where there is gross subungual hyperkeratosis, as the nail plate attachment is greatly reduced and the nail can easily be caught and tug on the matrix attachment. Subungual hyperkeratosis is a prominent feature when pityriasis rubra pilaris affects the nail and is often accompanied by splinter haemorrhages [14,15].

Nail plate abnormalities. Splits, atrophy and fragility may be seen. The nail may also thicken, independent of subungual hyperkeratosis. Transverse midline depressions resembling the nail changes seen in 'washboard nails' [16] are also seen. Usually, these are a consequence of the habit tic of picking the cuticle (Fig. 65.22) and, although this may play a part in psoriasis, it appears that there is a lower threshold for the development of this midline feature in the presence of psoriasis.

Splinter haemorrhages. Splinter haemorrhages are seen in the nail bed of 42% of fingernails and 6% of toenails [17]. This may be due to the increased capillary prominence and fragility in nail bed dermis in psoriasis and the presence of dystrophy. Where trans-

Fig. 65.22 Multiple transverse grooves of the thumbnails.

verse overcurvature occurs for reasons other than psoriasis, splinter haemorrhages are also common, suggesting that mechanical factors may contribute to splinter haemorrhage formation.

Subacute and chronic paronychia. Periungual involvement may be dramatic and inflammatory, giving rise to gross disruption of nail matrix. Loss of the nail may follow, with scaling of the nail bed or a deep transverse furrow.

Chronic psoriatic paronychia causes loss of the cuticle. The nail plate can become thin [18], although this may be offset by matrix disease, which can result in thickened nail. The nail fold may be scaly, in the form of psoriasis seen elsewhere.

Acropustulosis. This form of psoriasis involves destructive pustulation of the nail unit. It may present as part of pustular psoriasis, palmoplantar pustulosis [19], acrodermatitis continua of Hallopeau [20] or parakeratosis pustulosa (typically in young girls) on isolated digits. The nail plate may be lifted off by sterile pustules in the nail bed and matrix. There is associated erythema and discomfort of the end of the digit. There may be long-term nail loss, except in parakeratosis pustulosa, which usually resolves spontaneously. Parakeratosis pustulosa may affect only part of one digit—there is pitting and ridging combined with fine scaling erythema of the periunguium and only very rarely pustules. It is usually interpreted as a form of psoriasis [6], although it shares histological features with eczema [21], and some consider it a variant of eczema [22].

Acrodermatitis continua of Hallopeau can be very aggressive and result in resorptive osteolysis [23] or loss of toes and distal parts of fingers [24]. In a study of 20 patients with the condition, seven were male and 13 female, with a mean age of 46 years, and all had involvement of only one digit, with no features of psoriasis elsewhere [25].

Differential diagnosis. When the diagnosis of psoriatic nail dystrophy is in doubt, the main differential diagnoses are onychomycosis and lichen planus. In onychomycosis, the features usually present in the toes, whereas the fingernails are more commonly affected in psoriasis. Equally, there are often changes on the nail surface alone in psoriasis, whereas in onychomycosis features are usually within or beneath the nail plate. If there is fingernail involvement in onychomycosis, it is usually of only one or a minority of digits, in contrast with psoriasis where there are usually several digits affected.

Some forms of fingernail lichen planus and psoriasis are very difficult to distinguish. Both may result in roughened nails (trachyonychia) with subungual hyperkeratosis. If pits are prominent the diagnosis of psoriasis can be made, but if they are subtle and difficult to distinguish from other surface changes, they may be part of lichen planus. The nails in Reiter's disease and pityriasis rubra pilaris can also be difficult to distinguish from psoriasis [26,27], where distal subungual hyperkeratosis and splinter haemorrhages are common [8]. Aggressive forms of atypical nail psoriasis presenting in later life may represent acrokeratosis paraneoplastica. The patient is usually male, with subungual hyperkeratosis and scaling of the periunguium, ears and nose associated with malignancies of the upper gastrointestinal or respiratory tract [28–30].

Arthritis of the distal interphalangeal joint suggests a psoriatic cause of any associated dystrophy [31], with the exception of changes due to a myxoid pseudocyst associated with adjacent osteoarthritis. Baker *et al*. [32] found that there was no strict relationship between which joints are arthritic and which nails are dystrophic, although Jones *et al*. [33] noted that in a group of 100 psoriatics with arthritis, where there was nail involvement there was a significantly greater chance of joint disease in the adjacent distal interphalangeal joint. There was also a significant correlation between PASI (Psoriasis Area and Severity Index) score and scoring of nail disease, and nail disease increased with the duration of psoriasis. A variant of nail psoriasis presents with pain and soft-tissue swelling of the distal part of the digit associated with psoriatic nail changes, and underlying bone erosion and periosteal reaction. This can be in the absence of joint involvement and has been termed 'psoriatic onycho-pachydermo-periostitis' [34].

Histopathology. Histopathology varies according to the clinical focus of the disease [1,35]. The matrix and nail bed develop a granular layer, whereas the hyponychium, where a granular layer is normally present, no longer has one [1]. Where there is subungual hyperkeratosis, there are mounds of parakeratotic keratinocytes beneath the nail plate. Neutrophils may be found throughout these mounds and Munro microabscesses may form. Similar features are seen in acrodermatitis continua of Hallopeau [25]. Amorphous material, interpreted as glycoprotein, may accumulate within the keratotic mass [1]. Acanthosis and elongation of the rete ridges are present, with dilatation and tortuosity of the capillaries of the dermal papillae. Where the nail is lost, the nail bed may form a false nail of compacted hyperkeratosis [36]. The matrix can become quiescent, which can be demonstrated immunohistochemically by the absence of synthesis of the hard keratin Ha-1, which is normally a major constituent of nail [37].

The nail plate may show faults, clinically manifest as transverse splits and pits, which are lined with parakeratotic cells. These probably originate from the most proximal part of the matrix, or the ventral aspect of the proximal nail fold [1].

Treatment [38–40]. General hand care is important to avoid provocation of the isomorphic (Köbner) response, whereby minor trauma may elicit psoriasis. These measures include avoiding manicure, keeping the nails short, wearing gloves for wet work and heavy or greasy manual work, avoiding direct exposure to solvents and encouraging emollient usage. Concealment with nail lacquer is a reasonable approach to milder forms of psoriasis, and surface irregularities can be smoothed by the use of nail gel. This is a polymer, applied by a beautician and hardened by exposure to a table-top UVA source. The gel can then be shaped and buffed. Gel or other forms of sculptured or adherent artificial nails have the potential for aggravating onycholysis and are not usually recommended if this is a prominent feature.

Active treatments are mainly directed at the more dystrophic forms of nail involvement and may sometimes help with onycholysis. Often the focus of therapy is the proximal nail fold, where active psoriasis is disturbing the underlying matrix and lack of cuticle is promoting chronic paronychia. Medical treatments include the following.

Local steroids. Clobetasol propionate ointment may be used without occlusion, rubbed into the nail fold. Duration of treatment is limited by local atrophy. It is useful for psoriatic paronychia where there are secondary nail plate changes. Onycholysis may benefit if the nail is clipped back to the point of nail plate attachment and the nail bed treated topically. *Candida* is a frequent colonizer of this space and warrants treatment at the same time. Triamcinolone acetonide may be used by injection into the nail fold or nail bed with regional or digital ring block. Using 0.1-mL injections of 10 mg/mL triamcinolone acetonide at matrix and nail bed sites, on no more than two or three occasions, de Berker and Lawrence [41] report a good response in subungual hyperkeratosis, nail plate thickening and ridging. However, onycholysis and pitting improved in only 50% of nails. Alternative regimens employ more dilute triamcinolone (2.5–5 mg/mL) and are routinely used more than two or three times per digit, infiltrating the proximal nail fold alone, and making a ring block optional. The Dermojet™ is rarely used in nail fold injections now due to the risk of blood splashback and an account of bone damage.

Topical vitamin D analogues. Calcipotriol can be useful where there is subungual hyperkeratosis and nail thickening [42]. It has also been used in combination with topical steroid on an alternating basis (AM/PM) [43] and it is now possible to use it as a combined steroid and calcipotriol ointment. Calcipotriol has the advantage of avoiding the risk of atrophy with long-term use, but it is not as beneficial in treating the nail fold inflammation and consequent changes in proximal matrix function, which manifest as ridging and pitting.

Maintenance treatment with calcipotriol may also be one of the most effective topical therapies for pustular nail psoriasis [44].

Photochemotherapy. Subjects may improve as part of their general psoralen and UVA (PUVA) therapy or may have local PUVA to the nail unit. This can be done with topical or systemic psoralen. Specific high-dose handsets of UVA lamps have been advocated. As part of whole-body PUVA, 18 of 26 patients showed a greater than 50% improvement in nail changes, although pitting was unresponsive [45]. With local therapy, four of five patients improved: onycholysis was more responsive than pitting, but one patient with severe pitting showed improvement [46].

Retinoids. The nail plate is made thin by acitretin and etretinate. This reduces subungual hyperkeratosis. Pitting or onycholysis may be exacerbated [47,48]. Pustulation may be improved. Topical tazarotene 0.1% can be helpful for the treatment of onycholysis and pitting when applied under occlusion [49].

Others. Systemic methotrexate and ciclosporin (cyclosporin) may both help the nail unit but would not usually be advocated as therapy for disease affecting this area alone. Biological agents can also be effective, whilst usually being given in the context of severe disease elsewhere [50], although there are additional reports of psoriasis precipitated by them when given for rheumatological diseases [51]. Acrodermatitis continua of Hallopeau and psoriatic onychopachydermo-periostitis [52] are exceptions, and may respond to methotrexate.

Topical ciclosporin has been reported as useful in a single case report [53]. 5-Fluorouracil 1% has been used topically in 20% urea [54] and also in propylene glycol [55]. Pitting and subungual hyperkeratosis were thought to respond well to the former. Both are contraindicated in onycholysis.

Superficial radiotherapy [56] and electron-beam therapy [57] have been shown to be only of temporary benefit and are not usually recommended.

Treatment of coincident fungal infection may provide clinical benefit, although it is seldom a dermatophyte and positive cultures may only represent colonization.

Darier's disease [1–5]

Nail involvement is common in Darier's disease; 96% of patients are reported to have acral changes, of which nail changes are the most common [2]. These include red and/or white longitudinal streaks in the nail, often terminating in a V-shaped notch (Fig. 65.23). The streak may represent a zone of fragile or thinned nail, which makes it prone to fragmentation at the tip, with the consequent notch at the free edge. In severe cases, the nails are almost lost by extension of the fragmentation process to involve the entire matrix. Subungual hyperkeratotic papules can be found in the hyponychium. Histologically, matrix and nail bed changes resemble the acantholysis seen in involved skin, with the addition of multinucleate giant cells and epithelial hyperplasia in the nail bed

Fig. 65.23 Darier's disease: white and red longitudinal lines and distal notching.

[5]. These histological features make it possible to diagnose Darier's disease when it is confined to the nail [1]. Excess ridging and a rough nail surface may also be found, as may total leukonychia. Occasionally, marked thickening of the nail plate occurs. It is probable that the nail is sometimes affected in the absence of disease elsewhere [1].

Hailey–Hailey disease has some histological similarities and may also present with longitudinal white streaks [2]. However, the disease does not have the same destructive effect and is not associated with hyperkeratoses or symptoms of the nail apparatus.

A case of squamous cell carcinoma developing in a nail bed with chronic changes of Darier's disease has been reported [6]. Pain or conspicuous, uncharacteristic features in a nail apparatus affected by Darier's disease may therefore be indications for biopsy.

Eczema

Nail changes may accompany eczema elsewhere or occur as an isolated finding. Endogenous and exogenous factors may contribute. The nail changes may reflect this division, in that they may be in response to a systemic atopic disposition, with pitting in the absence of inflammation, or may demonstrate the effects of local eczema in the nail unit influencing nail formation.

The common allergens, such as nickel, fragrance and medicaments, rarely have particular bearing on nail abnormalities. However, allergic contact sensitivity to rubber and chromate, and irritant dermatitis are significant factors in hand dermatitis. These materials, and hand dermatitis in general, are associated with particular occupations. Selective exposure to such allergens or strong irritants is as important as chronic low-grade irritation from milder agents, such as water, seen in catering workers.

Cyanoacrylates used in prosthetic nails can provoke local and distant allergic reactions. Formaldehyde, occasionally used as a nail hardener, can provoke painful onycholysis if the patient becomes sensitized, or sometimes when acting solely as an irritant. Some allergens may cause nail dystrophy without associated inflammation.

A combination of atopy and an exogenous irritant or allergic contact reaction is common.

Clinical features. Nail matrix disturbance is reflected in thickening, pits, nail loss, transverse ridges and furrows in a pattern similar to psoriatic nail disease (Table 65.4).

Nail bed disease can produce subungual hyperkeratosis, splinter haemorrhages, onycholysis and pain. Allergens and irritants can be sequestered beneath the free edge of the nail to achieve high concentrations and prolonged exposure.

Nail changes may betray eczema elsewhere and the nails may be buffed smooth and shiny, indicating their use as a tool for rubbing itchy skin.

Associated hand dermatitis may show vesicles, scaling, erythema, cracks and swollen fingers, although the presence of vesicles will not always distinguish the condition from psoriasis, which should be sought at other sites. The distribution on the hand or foot may give some clues as to possible local causes, such as gloves, shoes, prosthetic nails or nail varnish. Hands and feet should always be examined together, as the presence of disease in both diminishes the likelihood of a contact dermatitis.

Defining the presence of atopy, or patch testing, can be useful even in the absence of active eczema, as subungual hyperkeratosis and discomfort may be disproportionate to the cutaneous features [1].

Treatment. General hand care is important, with the avoidance of soap, irritants, wet work and any identified cause. Protective gloves should be used, with copious emollient application. Barrier creams are not usually adequate protection once features have developed. Potent topical steroids may be needed, sometimes with additional topical or systemic antimicrobial therapy. These should be rubbed in around the nail folds. In the young, steroids may precipitate premature closure of the phalangeal epiphyses if too potent or used for too long [2]. Osteomyelitis has also been reported in children using potent topical steroids in this area. Hand or foot PUVA can help.

Table 65.4 Differential diagnosis between four common nail disorders: fungal infections, psoriasis, chronic paronychia and dermatitis.

	Fungal infections	Psoriasis	Chronic paronychia	Dermatitis
Colour	Often yellow or brown; part or whole of nail	May be normal or yellow or brown	Edge of nail often discoloured brown or black	May be normal
Onycholysis	Frequent	Frequent	Usually absent	Confined to tip or absent
Pitting	Infrequent	Often present and fine	Uncommon	Coarse pits frequent
Filaments or spores in potash preparations	Filaments, usually abundant	Absent	May be spores in edge of nail; filaments and spores in scrapings from nail fold	Absent
Cross-ridging	Absent	Uncommon	Frequent	Frequent
Other	Associated fungal infections elsewhere	Associated psoriasis elsewhere or family history of psoriasis	Predominantly women; wet work and cold hands cause predisposition	Recent history of dermatitis on hands

Lichen planus

Nails are involved in about 10% of cases of disseminated lichen planus [1]. In a study of 24 adults with nail lichen planus, nail changes were the sole manifestation of the disease in 75% [2,3], and the figure may be higher in children [4,5], in whom lichen planus of all types is rare. This suggests only a modest degree of overlap between the disease process in the nail unit and at other sites. Although the skin lesions may itch intensely, nail disease may be relatively asymptomatic except when nails are shed.

Clinical features. The disease can involve the proximal nail folds with bluish-red discoloration. Nail plate changes include thinning, onychorrhexis, brittleness, crumbling or fragmentation, and accentuation of surface longitudinal ridging. All these features are secondary to disease affecting the matrix, which can also produce transient or permanent longitudinal melanonychia [6] or leukonychia as a post-inflammatory phenomenon (Fig. 65.24). When inflammation is intense and widespread within the nail apparatus, nails may be shed. Single longitudinal depressions in the nail, with a distal notch or entire split, may arise from a pterygium. This is a fibrotic band of tissue fusing the proximal nail fold with the nail bed and matrix, following destructive local inflammation. Surviving proximal matrix is unable to push growing nail through the scar tissue, with a consequent split. Thickening, with features resembling yellow nail syndrome, is a less common pattern of presentation [7]. Where this occurs there is usually little difficulty in making the distinction in the fingernails as the prominent surface changes and/or atrophy of lichen planus are seen. However, these changes are less obvious in the toes, where yellow discoloration due to thickening can be marked [8].

Nail bed disease can produce subungual hyperkeratosis and onycholysis. Bullous lichen planus may affect the soles of the feet and in particular the toenails. Permanent anonychia may follow [9] (Fig. 65.25).

Twenty-nail dystrophy, with stippling of the nail plate (see Fig. 65.11) in up to 20 nails, is seen in a range of autoimmune diseases [10], alopecia areata [3], primary biliary cirrhosis and possibly in pemphigus [11]. In itself, it does not indicate the diagnosis of lichen planus, but is one of the recognized forms of the disease. It is one of the more common childhood patterns of presentation in which the nails feel rough and lose their lustre [12]. It has a reasonably good prognosis, in contrast with idiopathic atrophy of the nails, which may also occur in children. In the latter, the surface change is less marked and the change in overall nail morphology greater, with thinning and disintegration of the nail plate. Although nail biopsy is seldom undertaken in children, it may be warranted when lichen planus is suspected, because if destructive lichen planus is not treated in childhood, there will be lifelong loss of nails.

In the related disorder, lichen nitidus, numerous pits giving a fine rippling effect have been reported [13]. Longitudinal ridging, beads and thickening may occur and nails become brittle.

In keratosis lichenoides chronica, although the skin condition may resemble hyperkeratotic lichen planus the nail changes may mimic psoriasis; 30% have nail involvement, with hyperkeratotic hypertrophy of periungual tissues.

Lichen planus nail changes are seen in graft-versus-host disease [14] and in the disseminated lichenoid papular dermatosis of AIDS. There can be an overlap between lichen planus and discoid lupus erythematosus, in both the skin and the nails. Coexistence of skin and nail lichen sclerosus has been reported [15]. Lichen striatus may extend down a limb to the nails [16].

Fig. 65.24 Lichen planus with longitudinal melanonychia.

Fig. 65.25 Anonychia following lichen planus.

The differential diagnosis for the range of appearances of lichen planus in the nail unit includes Stevens–Johnson syndrome, infection, peripheral vascular disease, trauma and radiodermatitis.

Histology. In 20-nail dystrophy, there is a granular layer in the nail bed and matrix, with marked spongiosis [3]. The hypergranulosis is believed to reflect the disordered keratinization that causes both subungual hyperkeratosis and the poor nail plate formation. In other forms of nail lichen planus, in addition to hypergranulosis, there is occasionally saw-toothing of the rete pattern, and colloid bodies are rarely seen [2,17,18].

In 20-nail dystrophy it may be useful to perform a screen for organ-specific antibodies because of the association with alopecia areata and the related autoimmune diathesis [3].

Treatment. Potent topical steroids may help when rubbed into the nail folds in the active stage. Triamcinolone acetonide may be instilled into the proximal nail fold under local anaesthetic. In children, potent steroid therapy puts them at risk of premature closure of the phalangeal epiphyses. Oral steroids at up to 60 mg/day have been used to arrest severe scarring nail lichen planus [2]. Triamcinolone acetonide can be given intramuscularly at a dose of 0.5–1 mg/kg per month for 3–6 months [12]. Failure to deliver effective treatment in progressive disease may result in permanent nail loss or dystrophy. Ciclosporin can also be of benefit and azathioprine has been used to good effect in erosive disease [19]. Ulcerative lichen planus of the nail unit may benefit from grafting the nail bed.

Tumours under or adjacent to the nail

Tumours of the nail apparatus and adjacent structures are relatively common. Neoplasms of the nail area can be divided into benign, benign but aggressive lesions (e.g. keratoacanthoma, recurring digital fibrous tumours of childhood and some warts) and malignant tumours [1].

Clinical diagnosis is often difficult because of traumatic factors, infection and pigmentation, and because the translucent nail plate masks physical signs in the nail bed. Also, common tumours, easily recognized at other sites, may behave differently in the nail apparatus. An X-ray investigation should be carried out on all swellings in or around the nail apparatus, particularly those affecting a single digit, to exclude osteoma. Where changes are primarily in soft tissues, magnetic resonance imaging (MRI) may be preferable [2].

Benign tumours

Viral warts

This is the most common tumour involving the nail, usually found in one of the nail folds but also seen in the digit pulp and less commonly on the nail bed. In the lateral nail folds, there may be no nail plate changes, although proximal nail fold warts can result in longitudinal ridging and nail plate distortion (Fig. 65.26), and nail bed warts may cause onycholysis (Fig. 65.27). Erosion of underlying bone has also been reported.

Fig. 65.26 The entire periunguium is affected by wart, with secondary nail changes.

Fig. 65.27 Nail bed warts can cause onycholysis and nail plate disruption.

Fig. 65.28 Garlic clove fibroma.

The causal human papillomavirus is usually type 1, 2 or 4. Nail biting and certain occupations, such as butcher, may predispose to warts and complicate therapy. Warts are more common and difficult to eradicate in the immunosuppressed, particularly in organ-transplant recipients.

The most significant lesion from which warts need to be distinguished is squamous cell (epidermoid) carcinoma. However, this malignancy often destroys part of the matrix and nail bed and is usually painful; both features are uncommon in benign viral warts, unless aggressive cryosurgery has been used or there has been bacterial infection. Other disorders, such as syringometaplasia, amyloid, subungual corn and verrucous epidermal naevus, may mimic viral warts.

Although most warts remit spontaneously, a wide range of therapies is available [3], including topical salicylic acid (paste, on plaster or in collodion), salicylic acid combined with abrasion [4], cryosurgery [4–7], bleomycin [8,9], cantharidin [10], imiquimod [11], curettage and carbon dioxide laser therapy [12,13], pulsed dye laser [14] and interferon [15]. Immunotherapy can be successful using sensitization to diphencyprone [16], or relying on naturally acquired immune sensitivity to pathogens such as mumps or *Candida* [17].

Fibrous tumours

There are several types of fibrous tumours of the nail apparatus, which can be differentiated on clinical and histological grounds [1,2]. Koenen tumours are associated with tuberous sclerosis and present at puberty as periungual fibromas. They are often multiple, large or small, elongated or nodular, and may produce a longitudinal groove in the nail plate due to matrix compression. Histologically, they show loose collagen with numerous small vessels distally, but with dense collagen and few vessels proximally.

Acquired periungual fibrokeratoma [3] is probably the same as acquired digital fibrokeratoma and garlic clove fibroma (Fig. 65.28). They are all benign asymptomatic fibromas with a hyperkeratotic tip and narrow base arising in the periunguium, especially at the proximal aspect of the matrix. They grow out along the nail, resulting in a longitudinal groove. There are three histological variants:

1 thick, dense, closely packed collagen bundles
2 similar to type 1, but with increased fibroblasts in the cutis
3 oedematous and loose dermis.

Fibrous dermatofibroma is a true fibroma presenting as a smooth-edged tumour, commonly in the periungual tissues rather than within the nail unit. There is no collar of elevated skin as is often seen in acquired fibrokeratomas and it lacks the hyperkeratotic tip. It is hypocellular but with prominent collagen bundles, and rarely has a histiocytic dermal component. Occasionally, fibromas can be confused with other lesions, such as Bowen's disease, exostosis, keloid, dermatofibrosarcoma, eccrine poroma, neurofibroma and verruca. Multiple soft fibromas presenting on the dorsal aspect of digits in childhood may be infantile digital fibromatosis. These are benign and resolve with age [4,5]. Periungual fibromas may act as a diagnostic clue for tuberous sclerosis, although they normally occur in association with at least one other feature such as hypomelanotic macules that allows corroboration [6]. They are rarely seen before the age of 5 years, but are present in 23% of subjects with tuberous sclerosis at 14 years, rising to 88% over 30 [6]. Presentation with a single periungual fibroma should lead to a full history and examination to establish whether it is a feature of undiagnosed tuberous sclerosis. However, if nothing else is found, it is unlikely that the tumour has broader significance [7].

Treatment is by excision. In acquired periungual fibrokeratoma arising in the proximal matrix, great care is needed to remove the origin of the tumour without damaging the matrix: there is a fine balance between allowing recurrence and producing long-term nail dystrophy. Koenen tumours are particularly prone to relapse, probably because of their dermal origin.

Onychomatricoma

Onychomatricoma [1] may be considered a form of fibroma of the proximal nail fold [2,3], closely associated with the matrix. Its location means that the main features are those of altered nail, which becomes thickened, with increased longitudinal ridging (Fig. 65.29). There may be increased transverse and longitudinal curvature in larger tumours. Splinter haemorrhages within the zone of altered nail are common. When the onychomatricoma is small it may occupy only a narrow band of altered nail which is thickened and grey or yellow. As it enlarges, the band broadens and thickens. When avulsed, the proximal aspect of the nail reveals multiple, honeycomb channels corresponding to the digitations of the matrix, which has changed shape in response to the dermal matrix tumour. The tumour has normal immunohistochemical markers for a benign fibroma [3,4]. The matrix epithelium is normal in cytology and differentiation with respect to keratins [4].

(a)

(b)

Fig. 65.29 (a) Subtle longitudinal thickening and opacity of the nail plate due to an onychomatricoma. (b) Onychomatricoma on MRI.

Electron microscopy demonstrates decreased amounts of tonofilaments and desmosomes in basal epithelial cells [5]. It is the marked change in shape that leads to the altered nail and characteristic clinical presentation.

Less classical presentations of the tumour may have nail features of melanonychia and onychomycosis [6].

Treatment is by excision. The margins need to include a proximal element of the proximal nail fold, and extend down to bone and into proximal nail bed to obtain the whole tumour. This typically sacrifices a significant fraction of the matrix and may mean that total matrix excision is the best option.

Subungual exostosis

A subungual exostosis is a benign bony outgrowth of the terminal phalanx. It is usually found on the great toe [1] or rarely a finger [2] in subjects between the ages of 10 and 35 years (Fig. 65.30). It is not clear whether trauma is causal or contributory. Where there are hereditary multiple exostoses, the problem is inherited in a dominant pattern and attributable to mutations of the *EXT1* and *EXT2* genes on chromosomes 8q and 11p, respectively. These genes encode the proteins exostosin 1 and 2, which are part of a family of glycosyltransferases required for the synthesis of heparan sulphate chains. Heparan sulphate is integral to the expression of proteoglycans on the cell surface and in the extracellular matrix [3]. Mutations of *EXT1* and *EXT2* are also found in specimens of solitary exostoses [3]. This corresponds to the absence of heparan sulphate in the chondrocyte zones of exostosis growth plates [4], consistent with the proposal that such changes in chondrocyte biology are associated with abnormal cell signalling.

Fig. 65.30 Subungual exostosis.

Pain as a presenting feature is common. It is usually associated with trauma, but is also caused by ingrowing of the nail plate as it is displaced by the tumour [5]. The nail plate is elevated laterally but rarely damaged by the tumour. Radiography reveals an outgrowth of trabeculated bone [6], which may seem modest in comparison with the clinical complaint because of the large radiolucent cartilaginous cap. The X-ray examination should include a lateral view, as typically a view from above will miss the pathology.

Distinction from a subungual osteochondroma may be possible histologically because fibrous cartilage caps the bony outgrowth in exostosis and hyaline cartilage in osteochondroma [7]. Although this rule is often stated, it is not clear whether an absolute distinction can be made between the two lesions.

Where multiple exostoses exist, autosomal dominant multiple exostosis syndrome must be considered. The tumours in this condition are 'near the knee and far from the elbow' and can be destructive to nail [8]. The importance of making the diagnosis lies in the remote possibility of transformation of individual tumours to chondrosarcoma—an estimated figure for malignant change is 0.5% [9]. Older patients may have a different variety of exostosis, which represents hyperostosis of the distal tuft. This can cause elevation of the nail and pincer deformity, whereby the distal and lateral borders of the nail curve downward and inward to act as a pincer upon the nail bed.

Treatment. Treatment of subungual exostosis is by partial nail avulsion or fish-mouth elevation of nail bed and plate and removal of the tumour using bone nibblers or a chisel [7]. A margin of normal bone should be removed at the base to prevent recurrence. There is a 10% relapse rate following surgery, and children are more prone to relapse than adults [5]. Permanent matrix damage may follow surgery if tumours undermine the matrix. Rates of postoperative nail deformity or loss as high as 56% have been reported, but our experience suggests a figure in the order of 15% with residual abnormality.

Other bone tumours

Enchondroma

An enchondroma is a cartilage tumour, which may present as a painful solitary tumour of the distal phalanx with clubbing, paronychia, nail thickening, discoloration, ridging and elevation of the nail, and pathological fractures [1]. In Ollier's disease, multiple digits are usually affected. In Maffuci's syndrome there are multiple subcutaneous angiomas and hard cartilaginous nodules of the epiphyseal line, which may distort the entire hand or foot [2].

X-ray shows lucent expansion of distal phalanges alone, with spotty calcification in simple enchondromas. In Maffuci's syndrome there is widespread lucency in many phalanges of all the digits. Treatment is by enucleation of the tumour and autologous cancellous bone grafting. All these tumours can be associated with chondrosarcoma, angiosarcoma being an additional risk in Maffuci's syndrome [3].

Osteoid osteoma [4–6]

Osteoid osteomas of the distal phalanx present with enlargement of the entire digit tip in a young adult, with thickening of the nail, clubbing, increased local sweating and violaceous skin changes. A tender tumour may be palpated within the diffuse swelling, and the tumour may cause a nagging pain, characteristically relieved by non-steroidal anti-inflammatory drugs.

X-ray reveals a small area of rarefaction surrounded by sclerosis, although symptoms may precede this appearance and an isotope bone scan or MRI may show the focus earlier. Arteriography and thermography demonstrate the hypervascularity. Surgical treatment of this benign condition is by *en bloc* resection through a fish-mouth incision.

Implantation epidermoid cyst

Implantation epidermoid cyst may produce gradual enlargement of the tip of the digit, with the appearance of clubbing, or pincer nail. Pain may arise due to disturbance of the underlying bone where there is erosion, with distortion of cortical bone seen on X-ray, or a cyst may be demarcated on MRI. There is sometimes a history of previous trauma or surgery. Surgery is generally curative [7,8].

Metastases

Metastatic tumours present as inflamed swellings at the tip of a digit, with relatively few symptoms. X-ray reveals an osteolytic lesion, and systemic examination and investigation may reveal the primary focus; 50% will be from carcinoma of the lung [9,10].

Vascular tumours

Glomus tumour

Glomus tumours are the most characteristic of vascular nail bed tumours. There is pain, which may be spontaneous or evoked by mild trauma or temperature change. Nail plate changes depend on the location of the tumour. Matrix tumours cause splitting and distortion of the nail plate. Nail bed lesions are most likely to appear as bluish or red foci, 1–5 mm in diameter, beneath the nail [1]. On X-ray, 36% show a depression in the underlying phalanx [1]; MRI can reveal the exact site of the tumour, but can miss tumours of less than 3 mm across. Such cases will still need surgical exploration on the basis of signs and symptoms, which undermines its value as a baseline investigation [2]. However, it can be of value when there is pain after excision in order to help determine whether the pain is a complication of surgery or due to recurrent tumour [3]. High-resolution ultrasound has also been used with some success [4].

Histology is the definitive investigation and reveals vascular channels lined with endothelium and cuboidal glomus cells. These have dark nuclei and pale cytoplasm. Myelinated and non-myelinated nerves are found, which may account for the associated symptoms; neuromas must be considered in the differential diagnosis [5].

Treatment. Excision is the treatment of choice. Some surgeons advocate approaching the pathology by a fish-mouth incision, expecially when the tumour is in the nail bed [6]. However, this assumes a clear knowledge as to the location and nature of the tumour before surgery. Often it is necessary to remove the nail for preliminary assessment and this also facilitates matrix repair [5,7]. Where there is persistent pain after treatment, it may be due to the earlier surgery or further tumour. MRI can help in assessing this [2]. Residual scarring of the nail may remain, depending on the nature of the surgery and the extent of preoperative damage.

Pyogenic granuloma and periungual vascular lesions

Pyogenic granulomas are benign eruptive haemangiomas. They may involve the nail fold, with a prominent collar of epithelium, or be subungual and penetrate the nail plate (Fig. 65.31). In this location, they almost invariably arise from the matrix and produce a localized deformity of the nail plate, visible as the nail grows distally. Mild penetrating injury, friction [1] and immobilization of the limb in a cast [2] are physical causes. Medication can also be relevant. Retinoids [3], ciclosporin [4], cancer chemotherapy and antiretroviral treatment for HIV infection are all potential initiating factors. With these medications, the presentation is often of excessive granulation tissue on more than one digit as part of an ingrowing nail, rather than the classic isolated lesion puncturing the matrix and emerging from beneath the proximal nail fold. There may be features that blur the distinction between focal lesions and areas of hyperaemia with inflammation [5] and onycholysis [5–7]. Pain can be a significant feature [7] and docetaxel, used in breast and prostate cancer, has been implicated in such cases. Where antiretroviral medication is implicated, it is usually in association with nucleoside reverse transcriptase inhibitors [8,9].

Fig. 65.31 Pyogenic granuloma penetrating the nail plate.

A pyogenic granuloma bleeds easily and must be distinguished from an amelanotic malignant melanoma, histiocytoid haemangioma [10], granulation tissue reaction to ingrowing nail and cavernous angioma. Where the clinical evolution is slow, the differential diagnosis includes squamous cell carcinoma and a range of benign tumours [11]. The possibility of malignancy and other progressive tumours makes histological examination important. Bacteriology is also required and may help with the diagnosis of coccal nail fold angiomatosis, which may resemble a pyogenic granuloma arising from the matrix. This can relapse locally and on other digits [12].

Treatment. Once histology is available, if the lesion persists, destructive therapy such as carbon dioxide laser or suppressive therapy such as a potent topical steroid can be used. The latter is preferable and adequate for matrix lesions where infection has been adequately treated. Potassium permanganate soaks, or local or systemic antibiotics, may be needed if there is secondary infection with excessive oozing.

Arteriovenous abnormalities

Periungual and subungual arteriovenous tumours (cirsoid aneurysms) are firm, bluish, non-pulsatile nodules in a nail fold or penetrating the nail [1]. Following excision, histology shows thick-walled vascular channels with fibrous tissue boundaries and no internal elastic lamina. In the presence of a digital arteriovenous malformation, the digit and nail bed are purple, with gradual shrinkage and overcurvature of the nail plate [2]. Growth may be rapid in young people, in whom the digit may become bulbous and painful. X-ray may reveal aneurysmal destruction of the terminal phalanx, and more precise detail may be gained by MRI.

Myxoid cyst

Synonym

- Myxoid or mucoid pseudocyst

This benign cystic swelling has many names and is often termed a pseudocyst because a cellular cyst wall can seldom be demonstrated. It is usually located between the crease of the distal interphalangeal joint on the dorsal surface and the proximal nail fold. Less commonly it is found between the proximal nail fold and the nail plate, beneath the nail matrix or in the digit pulp. Pressure on the matrix results in a longitudinal groove or gutter in the nail plate (Fig. 65.32), which may have transverse ridges within it, reflecting episodes of decreased matrix pressure when the cyst is decompressed as a result of discharge of its contents. When it occupies the space between the nail and proximal nail fold, it may protrude from beneath the nail fold with what appears to be a keratotic tip, mimicking a fibrokeratoma. When located beneath the matrix, the nail becomes misshapen, with increased transverse curvature, and the lunula appears red [1].

Myxoid cysts are more common in the fingers than the toes. They contain a clear gelatinous fluid that may discharge spontaneously or on minor trauma. This fluid may be the product of mucoid degeneration of connective tissue or be derived directly from the adjacent distal interphalangeal joint with which a communication is usually demonstrable by injection of methylene blue into the joint [2,3]. The condition of the joint is a major factor in the origin of the cyst, with osteoarthritic osteophytes damaging the joint capsule and provoking the flaw through which synovial fluid escapes. Infection of the ruptured pseudocyst may cause septic arthritis or local paronychia, although this is uncommon.

Fig. 65.32 Nail plate groove due to proximal myxoid cyst.

High-resolution ultrasound or MRI provides non-invasive visualization to confirm the diagnosis or to localize the pedicle in recurrent cases. However, it may be more practical to attempt transillumination with a pen torch. This will distinguish it from a giant cell tendon sheath tumour, which is usually found overlying the dorsal distal interphalangeal crease in women with osteoarthritis [4,5]. Giant cell tendon sheath tumours are often rubbery and fail to transilluminate. Alternatively, a myxoid cyst will easily puncture using a size 11 scalpel, with sterile technique, revealing the diagnostic gelatinous contents.

Histology usually reveals a pseudocyst cavity within a fibrous capsule containing a myxomatous stroma with scattered fibroblasts. Areas of myxomatous change may merge to form a multilobular pseudocyst. Some workers report a mesothelial lining to the pseudocyst, consistent with continuity with the synovial joint space. This is not always confirmed and may mean that there are different histological forms of myxoid pseudocysts.

Treatment. There are many conservative approaches to cure [6,7], none of which is definitive. These include incision and drainage (pricking with a sterile blade or needle) and which may be repeated by the patient [8], injected sclerosant [9] or steroid [10,11], cryosurgery [12,13], laser [14] and infrared photocoagulation [15].

Surgical therapy may entail removal of osteophytes involving the distal interphalangeal joint [16–19], excising the distal margin of the proximal nail fold if the lesion is located there [20], or tracing the communication between the joint and cyst with methylene blue and tying it off [3,21].

There is a high relapse rate after single treatments with less invasive therapies. More detailed surgical therapies are more effective [19,21].

Squamous cell carcinoma

Synonym
- Epidermoid carcinoma

Squamous cell carcinoma of the nail unit includes *in situ* (Bowen's disease) and invasive forms (Fig. 65.33). A single biopsy may fail to make a distinction between them. A tumour that appears *in situ* at one site may be invasive elsewhere [1]. Periungual features include hyperkeratotic warty changes, erosions and fissuring, macerated cuticle, periungual swelling, erythema and occasional secondary infection. Subungual changes include onycholysis with a friable or warty nail bed, longitudinal melanonychia, nail dystrophy, ingrowing or loss. Some cases may be as subtle as a single, red longitudinal streak [2] (see p. 65.18). Nodular change with ulceration and bleeding is a late development. The condition may affect many digits [3]. Common misdiagnoses include onychomycosis, periungual warts, recurrent paronychia, pyogenic granuloma and subungual exostosis. As some of these conditions do not warrant biopsy and clinicians seldom think of squamous cell carcinoma at this site, the diagnosis is frequently delayed. Mean periods of 52 months [4], 9 years [5] and 5 years [6] have been reported. This slow progression may mean that the diagnosis is never made on older people, with the consequent impression that the disease is less common than is the case [7].

Fig. 65.33 Bowen's disease with melanonychia.

Predisposing factors include radiation exposure [3,8], human papillomaviruses 16, 18 and 34 [4,5,8–10], and possibly ectodermal dysplasias and chronic trauma. Features of chronic radiation damage to the periunguium may precede the onset of malignancy [11]. History and examination should include a note of genital wart infection or cervical dysplasia in the patient or partner [8]. Appropriate investigation includes X-ray and biopsy of a large and representative area. Prognosis is good, with few cases of metastatic disease in the literature [9], two of which were in patients with ectodermal dysplasia [12,13].

Treatment. Mohs' micrographic surgery is the treatment of choice for ill-defined lesions, as long as there is no evidence of bone involvement [1,6,14]. The technique allows the digit to be preserved in most instances. Horizontal sections in the context of the complex three-dimensional anatomy and histology of the nail unit require careful and experienced interpretation [15]. Alternative treatments include local excision, digit amputation and radiotherapy [16].

Epithelioma cuniculatum [1,2]

Epithelioma cuniculatum is a slow-growing, locally destructive, low-grade tumour, histologically related to squamous cell carcinoma [1,2]. It is typically found on the sole of the foot, but may involve the periunguium, mucosal surfaces and other locations [3]. It is warty, with discharge of foul-smelling yellow material from nail bed sinuses. The overlying nail is disrupted by onycholysis or destruction at the matrix, and there may be paronychia. The underlying bone is usually affected and X-ray reveals destruction of the terminal phalanx in most cases. Biopsy confirms the diagnosis. A system of epithelium-lined channels within the tumour forms fistulae extruding keratinous debris. Mitoses and dyskeratotic cells are rare and the benign appearance may lead to the misdiagnosis of pseudoepitheliomatous hyperplasia. Mohs' micrographic surgery is a useful treatment.

Keratoacanthoma

Subungual or periungual keratoacanthomas are typically painful, rapidly enlarging lesions that are usually solitary [1,2]. They are often referred to by the acronym SUKA. Keratoacanthoma is a misleading term as it is very uncommon for the tumour to involute [3] as seen in keratoacanthomas elsewhere. There is no apparent relationship to sun exposure. Although trauma and wire wool have been implicated [4], in most cases there is no obvious precipitating factor. Erosion of bone is seen on X-ray, which is an essential preliminary investigation [3,5–7]. This feature is likely to represent a reversible pressure effect of rapid subungual expansion, rather than bone invasion [3]. The diagnosis is made partly on the history but largely from the histology, which closely resembles that of a keratoacanthoma seen elsewhere, but showing little or no squamous dysplasia [5]. Subungual wart, squamous cell carcinoma and subungual exostosis are among the differential diagnoses. Clinically, subungual keratotic incontinentia pigmenti tumours fall between the appearance of fibroma and keratoacanthoma [8,9]. They resemble the latter in often being painful and causing underlying bone changes. They are commonly multiple and seen with the other features of incontinentia pigmenti, which is usually lethal in males. These tumours can be treated with oral retinoids [10], but may eventually require surgery.

Treatment. Treatment of subungual keratoacanthoma can be by Mohs' micrographic surgery or curettage. More aggressive treatments, including amputation of the digit, have been employed in the past, but are rarely warranted [11]. Given the concern that the tumour may represent a form of squamous cell carcinoma, confirmation of excision margins is important.

Melanocytic lesions

Benign and malignant melanocytic lesions present as longitudinal melanonychia (LM). This means that a careful approach needs to be take to the evaluation of a pigmented nail streak [1]. An understanding of the causes of benign nail pigmentation is important in order to judge when biopsy is indicated to exclude melanoma. Dermoscopy can be useful in assessment [2], although different patterns of melanin deposition within the nail may not allow confident clinical distinction between melanocytic lesions. The presence of blood droplets can enable distinction between melanocytic lesions and haemorrhage, usually related to trauma.

Benign causes of LM

Laugier–Hunziker syndrome

Laugier–Hunziker syndrome features pale-brown LM on one or more digits [3]. There may be periungual involvement resembling Hutchinson's sign, and the oral and genital mucosae may be affected with pigmented macules. The macules are amenable to laser treatment [4].

Subungual naevi

Subungual naevi may present in adulthood or early in life with LM or with naevoid melanosis of the nail plate [5] (Fig. 65.34). This has been described in European [6,7] and Japanese [8] adults and children.

Drug therapy

Drug therapy with hydroxyurea, minocycline, zidovudine [9] and antimalarials may produce brown streaks in the nail (see p. 65.16), as may dermatoses such as lichen planus [10] and onychomycosis [11], trauma [12] and non-melanocytic tumours such as squamous

Fig. 65.34 Benign longitudinal melanonychia due to a subungual naevus.

Fig. 65.35 Malignant melanoma arising in the nail matrix and invading the nail bed.

cell carcinoma *in situ* [13] (see Fig. 65.33). Subungual blood pigment may resemble melanin, but associated features in the history, dermoscopy and gross appearance usually make it possible to distinguish between the two.

Benign racial pigmentation

The most common cause of LM is racial variation; 77% of Afro-Caribbeans over 20 years of age have LM and this prevalence rises to almost 100% by the age of 50 years [14]. It is present in 10–20% of Japanese [15] and is more common in Mediterranean races than in northern Europeans. However, in this context, the percentage of malignant melanomas presenting in the nail unit is higher in Afro-Caribbeans (15–20%) [14] than in any other group (3% in white populations [16]). This contrasts with the low incidence of malignant melanoma at other skin sites in Afro-Caribbeans.

Malignant melanoma [17–20]

There are many features of LM that should suggest the possibility of malignant melanoma. Trauma may be described early in the evolution of the pathology, although a definite association with melanoma is difficult to establish [18]. Variation within the melanonychia and a darker range of pigments can be significant. This is of particular note if the pigment spreads onto the adjacent nail fold or digit pulp (Hutchinson's sign) [21], especially in a single digit in adult life, with a clear history of evolution. Hutchinson's sign is a risk factor, but does not necessarily carry a bad prognosis [2,22]. Dermatoscopic examination through the nail, and end on at the free edge, may help with diagnosis [1,2, 23,24]. The suspicion of melanoma is raised further if the individual has any other risk factors for melanoma, if the involved digit is a thumb, great toe or index finger, and if the nail has become dystrophic.

Despite the importance of LM as a warning sign, 30% of subungual melanomas present as amelanotic tumours. This exceeds the percentage of melanomas presenting as an amelanotic tumour elsewhere. It is difficult to determine whether these tumours were always amelanotic [25] or whether loss of pigment is due to development of the disease process (Fig. 65.35). This form of melanoma usually has associated nail plate damage and easily bleeds. With this appearance, the differential diagnosis includes pyogenic granuloma, chronic paronychia and vascular tumour.

The assessment of pigmented streaks in children is complex. The earlier dictum that they were all benign and could be left has some ramifications. Indeed they are almost all benign [7], although very rare cases of melanoma are reported [26]. This alone may make diagnostic biopsy warranted in some. In addition, it is documented that pigmented streaks arising in childhood can evolve into melanoma, even after an initial biopsy with benign histology (S. Goettmann-Bonvallot, personal communication). The implication of this is that repeated biopsies may be needed as a pigmented streak evolves, and lifelong monitoring is required for children with such signs. Faced with this, complete excision of the matrix origin can sometimes be the best option, even when there is permanent loss of all or part of the nail.

The significance of preceding trauma is unclear [25]. Such a history is present in a large number of cases. It is thought that primary malignant melanoma of the nail unit arises only from within the matrix and not from the nail bed. This is consistent with the absence of antigenically identifiable melanocytes in the nail bed [27,28] and can provide some reassurance when assessing pigmented lesions not arising from the matrix. However, such lesions may arise from the nail folds, or be secondary malignant melanomas.

Biopsy of LM

Given the potential gravity of isolated longitudinal melanonychia, there should be a low threshold for biopsy. The type of biopsy can be determined by a range of factors [1].

1 Periungual pigmentation present. This indicates high risk of malignancy. If there are no other factors to account for this pigmentation, the whole area of affected nail unit should be removed *en bloc* down to bone with a 1-mm margin of normal tissue. Cosmetic considerations are secondary.
2 Lateral third of nail plate involved. This indicates lateral longitudinal biopsy. The cosmetic outcome is reasonable and the assurance provided by complete removal of the affected area is usually worthwhile.
3 Mid-portion of the nail plate involved. The cosmetic outcome of complete excision at this site is potentially bad. This is particularly so if the origin of melanocytes is proximal in the matrix. This may be determined by sampling the free edge of the nail plate and performing a Masson–Fontana stain, or undertaking end-on nail dermoscopy at the free edge. Pigment in the lower part of the nail reflects a distal matrix origin, compared with ventral nail pigment reflecting an origin in the proximal matrix. The latter carries a high risk of scarring following excision.

For lesions less than 3 mm wide. It is usually possible to undertake a full excision and repair of a longitudinal ellipse extending into the nail bed.

For lesions 3–6 mm wide. If the pigment arises from distal matrix, a transverse matrix biopsy can be performed. Proximal matrix pigment requires an en bloc removal and repair using a Schernberg and Amiel flap.

For lesions greater than 6 mm wide. Matrix punch or transverse biopsy is usually adequate as the preliminary investigation. Where the clinical suspicion of a melanocytic lesion is high, it is reasonable to undertake complete matrix and nail bed excision as a single procedure. A benign histology on sampling a band of this size will not provide total reassurance in the long term, and it may therefore be preferable to undertake a curative and preventive excision at the outset.

Treatment and prognosis. Nail unit melanoma has a record of delayed treatment and poor prognosis [29]. It affects light- and dark-skinned people, with those of African origin representing 12% of patients in one North American series [30]. The most common pattern is of acral lentiginous melanoma [17], although one series reported the superficial spreading type as being marginally more common [31]. In the acral lentiginous form, there is lentiginous spread of pleomorphic, often dendritic, atypical melanocytes in the basal and suprabasal layers of the epidermis. Epidermal melanoma cells may be incorporated into the nail plate and seen on stained clippings of nail taken from the free edge. Dermal melanoma cells are pleomorphic, with spindle, epithelioid, polygonal, dendritic and bizarre shapes.

Hutchinson's sign is represented histologically by atypical melanocytes mainly in the basal layer, with a few higher in the epidermis. *In situ* subungual melanoma has junctional nests of melanoma cells. Nodular patterns of melanoma are rare.

Amputation of the digit is the routine treatment, although local excision is occasionally practised for small shallow lesions and is an accepted mode of treatment for *in situ* melanoma [1]. Mohs' micrographic surgery is used in some centres, but is still at a relatively early stage of evaluation [32]. In one series of 14 patients, three had recurrence at the margins of treatment. Adjuvant isolated limb perfusion has failed to show benefit in stage 1 subungual melanoma [33], although use of a more aggressive regimen has possibly been associated with improved survival [34].

British surveys [31,35,36] suggest that the poor prognosis of subungual melanoma is related to the depth of invasion at diagnosis (4.7 mm). This reflects late diagnosis (3 months to 12 years). The mean 5-year survival was 41% compared with 61% for a control group of primary cutaneous malignant melanomas in the same study [35]. In comparison, in a French study of 146 patients with acral lentiginous melanoma there was a mean Breslow thickness of 2.51 mm and 76% 5-year survival [20]. Japanese evidence supports the idea that diagnosing subungual melanoma early, with a lower Breslow thickness, improves prognosis, with an 87% 5-year survival rate [34].

Nail surgery [1,2]

Nail surgery is delicate and requires attention to detail. It is important that anyone performing a nail biopsy appreciates the principles outlined in the preliminary section of this chapter on anatomy and physiology, and that they obtain tuition in detailed technique. Once in this position, the outcome of nail unit surgery is usually excellent and provides useful and definitive diagnostic material [3].

For many procedures, the routine skin surgery pack needs to be supplemented by specialized instruments. These include a Freer septum elevator for finger work and a larger elevator for the great toenail. English nail splitters are essential for performing partial avulsion. They have a flat undersurface, which can be introduced beneath the nail to act as an anvil and a sharp upper part that cuts down upon the nail to meet the other half of the instrument. For bone surgery, such as removal of exostoses, bone rongeurs and McKindoes are needed.

Indications

A nail biopsy may perform several functions. It can provide useful positive diagnostic information or help exclude a malignant condition, such as squamous cell carcinoma of the nail bed. Painful conditions may be relieved by the drainage of pus with proximal hemi-avulsion, or ablation of an ingrowing toenail. Focal pathology, such as a glomus tumour or the origin of melanonychia, can be completely excised and provide the diagnosis. If a positive diagnostic and therapeutic attitude is taken to the nail disorder, a good outcome can be expected.

Diagnostic nail biopsy may be undertaken as part of the investigation of nail dystrophy of unknown cause in the presence of more than one negative mycology sample.

Biopsy of the nail plate alone, or with associated nail bed and occasionally matrix biopsy, may be needed to confirm fungal infection in atypical cases, although biopsies are more commonly directed at distinguishing between dermatoses affecting the nail, such as lichen planus, psoriasis or infiltrative disease. In instances of nail dystrophy of a single digit, it is appropriate to biopsy to exclude a neoplasm once necessary imaging has been performed.

Caution is needed in patients with relevant medical and circulatory problems. The latter are subject to poor reperfusion following the tourniquet and it may be necessary to abbreviate the procedure to ensure no inadvertent damage is done. The wound must be seen to bleed and the digit colour return before the dressing is applied in these cases, and this can take several minutes. This contrasts with the usual pace at which dressings are applied to prevent bleeding in a healthy digit. Diabetics may have ischaemia combined with immune impairment and frequently need attention to toenail problems. Paradoxically, they are cited as a group in whom cold steel surgery for nail problems is preferable to other techniques such as phenolic ablation or cryosurgery. This is because the course of healing in these wounds is predictable and often shorter than wounds produced by other therapies.

Preoperatively

It is advisable to prepare the patient for the procedure by a discussion on a day other than that on which the surgery is performed. In this discussion, the patient must appreciate the potential benefits and problems of the biopsy. It is useful to make it clear that it will be painful and that they will have a degree of disability postoperatively for which they must make provision at home and at work. The best surgical technique can be utterly confounded by a patient who goes back to a dirty workplace the next day. Much of the information concerning scarring, the need for elevation, dressings and analgesia has to be repeated on the day of the procedure. The patient should have a means of transport home that does not involve them driving or standing for prolonged periods.

The affected digit should be soaked in warm antiseptic and scrubbed in a manner similar to that used by the surgeon prior to gloving. This will diminish the bacterial load beneath the free edge of the nail, which is a source of potential pathogens. Soaking for 10 min softens the nail and facilitates removal of parts of the nail plate, so avoiding complete avulsion. During this period, the local anaesthetic can take effect.

Anaesthetic (Fig. 65.36)

Lidocaine (lignocaine) 2% or equivalent can be used [4]. Bupivacaine can be used to provide prolonged analgesia. The use of

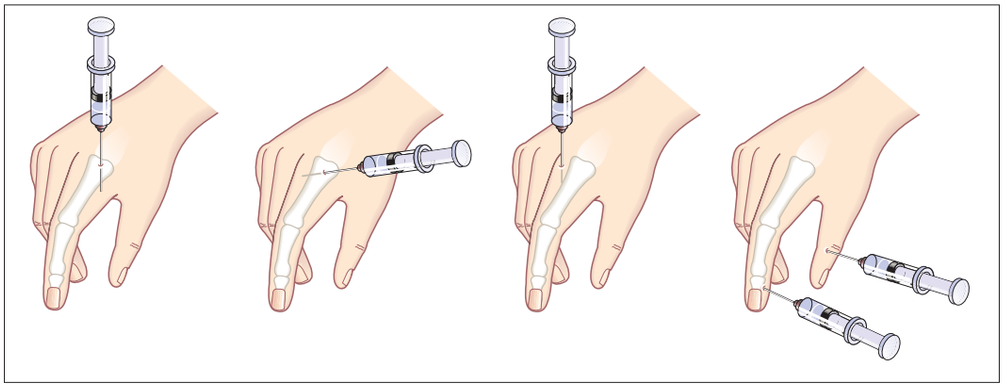

Fig. 65.36 Digital sites of injection for a ring block.

epinephrine (adrenaline) in anaesthetic remains controversial. There are several publications illustrating how anaesthetic containing 1 in 200 000 epinephrine has been used safely [5]. The ischaemia and prolongation of anaesthesia is a potential advantage. If subjects with peripheral ischaemic or vasospastic disease are avoided, anaesthetic with 1 in 200 000 epinephrine appears safe. An alternative is to use ropivacaine. This local anaesthetic has physiological and pharmacological properties somewhere between bupivacaine and lidocaine. It has a moderately quick onset of action and can produce anaesthesia for over 12 h, combined with a modest short-term vasoconstrictive effect [6]. We use ropivacaine 7.5 mg/mL in the same way as lidocaine, with very good results. A 30-gauge needle causes less discomfort during injection than larger needles, and minimizes the risk of damage to digital nerves when inserting a ring block. Risk of nerve trauma may be reduced further by the use of nerve-block needles, which have less traumatic tips.

The most common form of anaesthesia is a ring block (digital nerve block), which is delivered by injection of anaesthetic into the dorsolateral aspect of the digit at the base, with about 1–2 mL on each side of the phalanx. Greater than 5 mL may impair circulation, but this can be assessed visually during the procedure and is very variable according to the bulk of individual digits. Anaesthesia may take 10–20 min to become total. In the great toe, additional anaesthetic should be placed ventrally. After 10 min, efficacy of the block can be assessed at the digit tip with the same needle; if the anaesthesia is incomplete, it can be supplemented by a small local injection at the site of surgery. However, this can increase tissue turgor and render fine manipulation difficult.

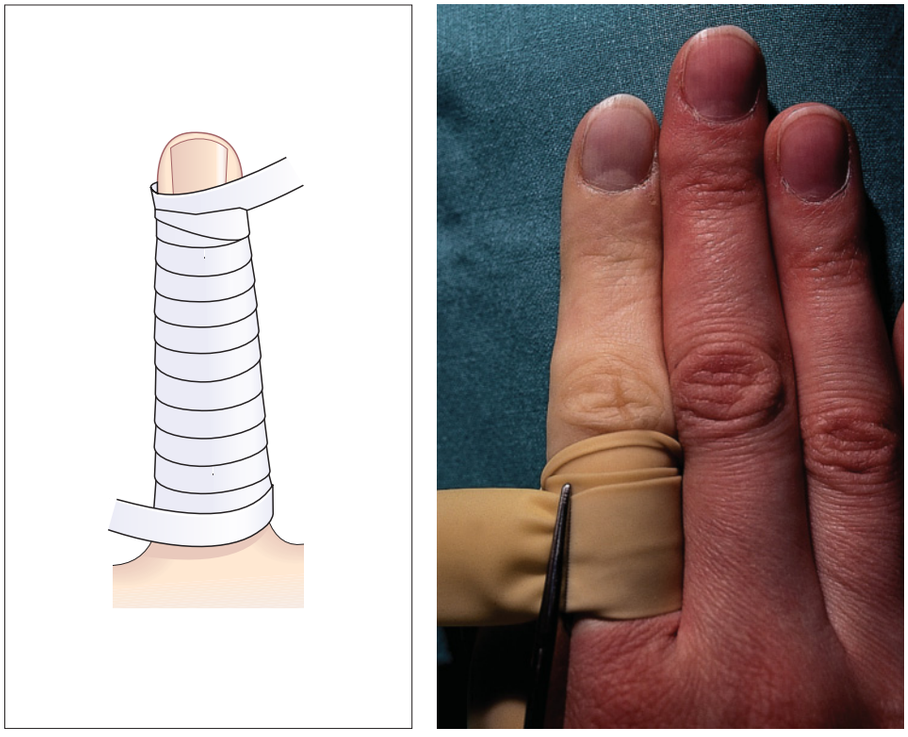
Other ring block techniques can be employed, including a method that aims to infiltrate the anaesthetic via the flexor tendon as a transthecal block [7,8]. An alternative is the distal 'wing' block given 2–3 mm proximal to the junction of the proximal and lateral nail folds. The injection is first directed distally into the lateral nail fold. After partial withdrawal, it is redirected over the proximal nail fold. Sufficient is used to produce blanching in both nail folds. The procedure is repeated on the other side to achieve complete block. The digit is more sensitive distally than proximally and it is often more comfortable to provide the traditional proximal digital nerve block.

For invasive procedures on many digits concurrently, more proximal or regional blocks can be employed [9]. In children it can be worthwhile to use a topical anaesthetic as a preliminary measure before ring block. Evidence of its efficacy in adults is mixed [10,11].

Tourniquet

It is important that the area of applied pressure beneath the tourniquet is as broad as possible to avoid pressure damage to underlying structures. In particular, neuritis may be a long-term complication of prolonged application of a narrow, tight tourniquet. This effect can be exacerbated by topping up anaesthetic near the tourniquet after it is in place. Ischaemia can be tolerated in a normal digit for 20 min and possibly longer, with no complications as long as there is no local trauma from the tourniquet.

The standard tourniquet for local anaesthetic is the Penrose drain (Fig. 65.37), which may be wound around the digit from the tip proximally. This exsanguinates the digit and provides a tourniquet effect that can be maintained with a pair of artery forceps. A sterile glove is an alternative. It is worn by the patient and the tip of the glove digit at the site of surgery is snipped off. It is then rolled back to the base of the digit, exsanguinating it, providing a tourniquet and avoiding contamination from adjacent digits peroperatively. With general anaesthetic, an exsanguinating cuff can be used on the forearm or calf.



It is our practice to remove the tourniquet before sutured repairs, to detect bleeding points and achieve haemostasis with electrocautery. For some reconstructions it may be necessary to re-apply the tourniquet.

Specimen

The specimen must be delivered to the pathologist undistorted and with the maximum of clinical and operative information. It is useful to allow the specimen to adhere lightly to a piece of paper before immersion in fixative, or to enclose it in a small plastic mesh cassette. This should be matched with a detailed drawing on the histopathology request form. It is helpful to work regularly with the same pathologist for nail specimens, as processing requires specialized understanding of specimen preparation and histological interpretation.

Postoperatively

Dressings should be ready before removal of the tourniquet. They must be firm and moderately bulky. An acceptable dressing

(a) (b)

Fig. 65.37 (a) A Penrose drain is applied from the tip and wound down the digit achieving exsanguination. (b) The drain is then unwound from the top, with the base maintained secure with artery forceps.

includes an antimicrobial ointment under a greasy tulle, padding and a small bandage. Calcium alginate dressings can also be useful if there is an area that needs to heal by secondary intention. Dressings should be held in place with oblique or longitudinal sticky tape to avoid a tourniquet effect if the digit swells. A sling or plastic overshoe should be provided.

The frequency of change of dressings is determined by the nature of the procedure and the patient. An antiseptic soak is normally needed to remove the dressing and clean the wound. Infection should be treated vigorously with systemic antibiotics combined with daily antiseptic soaks.

It is good practice to provide a moderately strong analgesic and to recommend taking it regularly in the first 48 h. It may prove unnecessary, but the distress of unrelieved pain in the few who suffer warrants caution. Some patients need night-time sedation.

In most cases, it is wise to arrange review within 2 days of surgery to change the dressing, assess the wound and answer any questions that have arisen.

Complications

Pain can sometimes be disproportionate to the wound [12]. When it is severe, the patient is at risk of reflex sympathetic dystrophy [13]. They should receive regular potent analgesics, including non-steroidal anti-inflammatory agents, amitriptyline and sometimes an anxiolytic such as diazepam.

Bleeding is common and should be accommodated by firm, bulky dressings. Once blood has clotted in these dressings they can be rock-like and represent an infection risk—good reasons for an early dressing change.

Infection is a potential problem and can be devastating to the matrix. Prophylactic antibiotics are a reasonable precaution when the surgical site is likely to be heavily colonized due to skin changes or a dystrophic nail. Surgery to the toenail matrix, children or patients with poor hygiene may also warrant antibiotics.

Longer term, complications are mainly related to scarring dystrophy and loss of function. The former is always a potential risk of any surgery involving the matrix and should be discussed preoperatively as part of the risk assessment with the patient. Loss of function can be modest, with a tendency for the nail to catch, or more significant if associated with pain or marked paraesthesia. Mild paraesthesia is quite common in the short term and is sometimes seen with cold sensitivity. Complications involving the tendons of the distal interphalangeal joint are very rare and usually related to more proximal surgery.

Patterns of nail biopsy

Nail avulsion [1,2]

Nail avulsion can be performed in order to examine underlying tissues or to provide temporary relief in cases of soft-tissue trauma. In isolation, it is not a treatment for ingrowing toenails. The procedure requires a distal or ring block, and an elevator in addition to the routine instrument pack. For a partial avulsion, nail splitters are also needed.

To minimize the trauma of the procedure, soft-tissue nail attachments should be loosened at all sites prior to removal. This minimizes tearing damage to the nail folds. The cuticle may need disrupting with fine scissors or a blade, but all other detachments can be performed with a septum elevator. Once this is done, the nail is gripped with a pair of rugged artery forceps and removed by a mixed twisting and lifting action (Fig. 65.38).

With a lateral partial avulsion, the nail splitter is used to define the medial margin and only the attachments of the piece of nail to be removed need to be interrupted. Proximal hemi-avulsion of the nail plate entails the following technique.

1 The origin of the nail and its proximal lateral aspects are undermined with a septum elevator.
2 In nails with a shallow lateral nail fold, a nail splitter may be inserted and the nail transversely bisected.
3 In nails with a deep lateral nail fold, a deep transverse score is placed with a scalpel across the nail halfway along its length.
4 The septum elevator is then fully inserted through the transverse score to loosen and elevate the proximal nail.

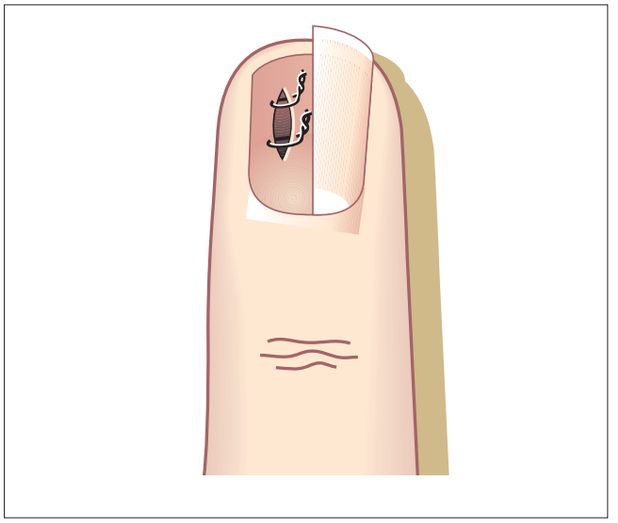

Fig. 65.39 After partial nail avulsion, the nail bed can be seen and biopsied along the longitudinal access.

Nail bed biopsy [1–4]

Biopsy of the nail bed is usually performed to investigate a focal abnormality of the nail bed or changes in the nail plate arising distally. Occasionally, it may be appropriate to biopsy through the nail plate where the histological relationship between nail bed and plate is under investigation. More commonly, the nail bed is visualized first, following complete or partial avulsion. A thin ellipse is taken down to bone in the long axis of the digit (Fig. 65.39). An alternative is to employ a double punch technique, where a 6-mm hole can be made in the nail plate with a biopsy punch over the area of nail bed to be examined, and the nail bed sampled using a smaller punch.

If there has been nail avulsion, it is possible to close the wound, which may require gentle undermining. In small biopsies this may be unnecessary, and the wound will heal well by secondary inten-

tion. When the nail is left *in situ* or if the double punch technique is used, closure is not possible. After a double punch, as long as there is complete haemostasis, the original disc of nail plate can be returned after soaking in antiseptic; it may reattach or at least provide a natural dressing during the early healing phase.

No scarring is anticipated from this biopsy if it is small and does not extend into the nail matrix.

Matrix biopsy

Lateral longitudinal nail biopsy [1,2]

Lateral longitudinal nail biopsy is the definitive method for sampling all the tissues of the nail unit. It is most commonly required when there is dystrophy affecting the whole nail or for the excision of a melanonychia. If focal matrix pathology occurs laterally, longitudinal biopsy may be warranted to preserve the shape of the nail, which can otherwise be altered by local matrix surgery. Early literature suggested that longitudinal biopsies of less than 3 mm in width could be taken from the midline of the nail without scarring [3] but it is now accepted that this may produce long-term nail dystrophy.

The first incision starts in the lateral nail sulcus, between the nail and nail fold. The distal limit is just beneath the distal groove, in the tip of the digit. Proximally, the incision extends almost to the first of the transverse skin markings of the distal interphalangeal joint. The medial margin of the ellipse is formed by an incision through the nail plate, which has been softened by an antiseptic soak. Both incisions are down to bone and separated by 3 mm at the widest point. The specimen is released from its deep attachment from the distal point proximally. The nail can be lifted at the free edge with forceps, allowing the bottom of the specimen to be released with curved iris scissors. Particular care is needed at the proximal end to ensure that the matrix is fully sampled without damage.

A 3/0 or 4/0 monofilament suture is used for closure. One suture closes the wound through the proximal nail fold. One or two further sutures are needed through the nail plate and lateral nail fold. The suture is designed to elevate the lateral nail fold and enhance the embedding of the new nail edge in the nail fold (Fig. 65.40).

The nail will be permanently narrowed following this procedure and the contour of the lateral and proximal nail fold intersection is altered to provide a more acute angle. In spite of the specialized suture to elevate the lateral nail fold, the nail is seldom fully embedded in a new lateral sulcus. Where biopsies of greater than 3 mm width are taken, the nail may develop malalignment, with distal deviation towards the side of the biopsy [4].

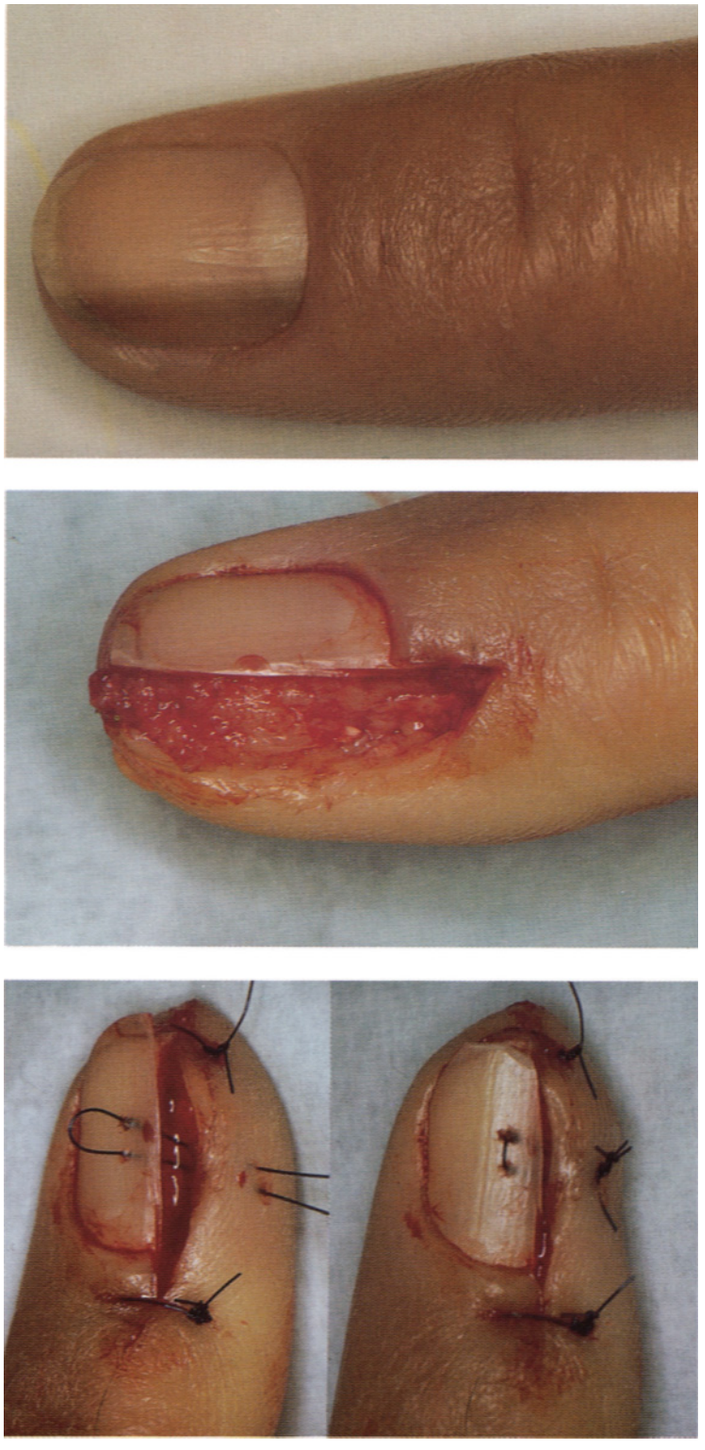

Fig. 65.40 A large, lateral, longitudinal nail biopsy is closed with sutures designed to reconstruct the lateral nail fold.

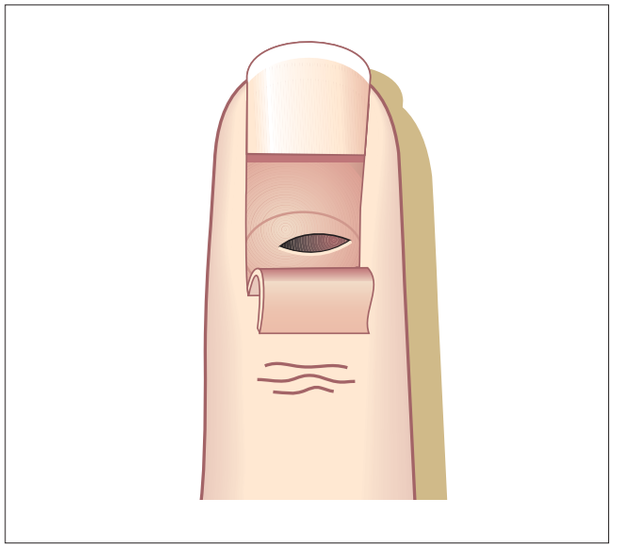

Fig. 65.41 Crescentic or narrow elliptical transverse matrix biopsy, which can be performed after removal of the proximal half of the nail plate alone.

Transverse matrix biopsy (Fig. 65.41)
A transverse matrix biopsy may be performed to investigate focal abnormality of a nail dystrophy arising from the matrix.

The proximal nail fold is reflected following an oblique incision at the junction with the lateral nail folds and gentle separation of the proximal nail fold from the dorsal aspect of the nail plate. The matrix is then visualized by performing a proximal hemi-avulsion. A thin ellipse is taken from the distal matrix with the distal margin of the excision matching the shape of the lunula.

The wound may be gently undermined, taking care with the extremely fragile matrix epithelium and undermining most on the distal nail bed margin. Loose sutures with resorbable 6/0 monofilament can be used.

Once healed, a blemish may remain in the margin of the lunula. The nail plate will show changes in thickness proportional to the extent of the biopsy.

Matrix shave or tangential biopsy
Haneke has described a technique of obtaining a diagnostic shave biopsy from nail matrix in longitudinal melanonychia [1,2]. When successful, it can also represent an excision specimen. The matrix needs to be exposed, with clear identification of the origin of the melanonychia. The origin is then scored with a scalpel, 1 mm beyond the edge of the pathology. This score mark is then used as a guide for a shave sample to be obtained, extending the excision into the dermis so as to avoid leaving a remnant of the matrix epidermis rete pattern or superficial melanocytic naevus. Incomplete excision may occur with deeper naevi or biopsies of irregular depth. The nail plate is replaced to prevent contact between the wound and ventral aspect of the nail fold, and suture repair is not required. Secondary intention healing can result in normal or only slightly abnormal nail, but there are insufficient published cases to give clear guidance.

Nail fold biopsy [1–4]

Proximal nail fold biopsy
It may be necessary to biopsy the proximal nail fold to investigate a local dermatosis, connective tissue disease or focal tumour. The biopsy can be taken in different axes, but preservation of the symmetry and curvature of the proximal nail fold is a priority. If sutures are to be used, a distal wing block should be avoided, as the tissues will become turgid and difficult to manipulate.

Transverse nail fold biopsy
A transverse ellipse (for connective tissue disease), a 2-mm punch (far from the free edge) or a shave biopsy are simple nail fold procedures. The transverse ellipse and punch biopsies are down to the dorsal aspect of the nail plate. The matrix may require protection from cutting trauma and this can be achieved by inserting a septum elevator between the nail fold and the nail.

The transverse biopsy requires 4/0 monofilament suture. Wounds from other biopsy methods can be left to heal by secondary intention. Postoperatively, a thin line may remain in the nail fold after the transverse biopsy; otherwise, these techniques leave little or no scarring. There is no nail plate change.

Crescentic nail fold biopsy (Fig. 65.42)
A larger nail fold biopsy can be taken as a distal crescentic wedge. A crescentic incision is performed just proximal to the cuticle with the blade angled to direct trauma away from the proximal matrix if the nail is penetrated. Additional matrix protection may be provided by inserting a septum elevator beneath the proximal nail fold. The distal fraction of the proximal nail fold (including the cuticle) can be removed, although the width of the specimen should not exceed 4–5 mm in the midline. The contour is aimed at recreating a new edge to the entire nail fold. The wound heals by secondary intention and a new cuticle usually reforms, depending upon the original problem. The amount of exposed nail is permanently enlarged, but the nail surface is unchanged unless ridging or grooves produced by the original pathology are reversed.

This technique can be used for the excision of chronic paronychia resistant to routine therapy. It has also been recommended for the excision of digital mucus cysts occupying the most distal margin of the nail fold. At this site, it is argued that the lesions are solely degenerative and do not communicate with the joint space [3,4].

Focal nail fold biopsy
Focal pathology in the nail fold can be excised by a V-shaped incision into the nail fold. The excision is through the entire thickness of the nail fold, but should not penetrate underlying nail. Relaxing incisions are made at one or both of the lateral margins of the proximal nail fold (Fig. 65.43). The primary defect is closed with 4/0 monofilament suture and the relaxing incisions heal by sec-

Fig. 65.42 Crescentic shave of the distal proximal nail fold and cuticle as treatment for chronic paronychia. Also provides histological specimen where biopsy relevant.

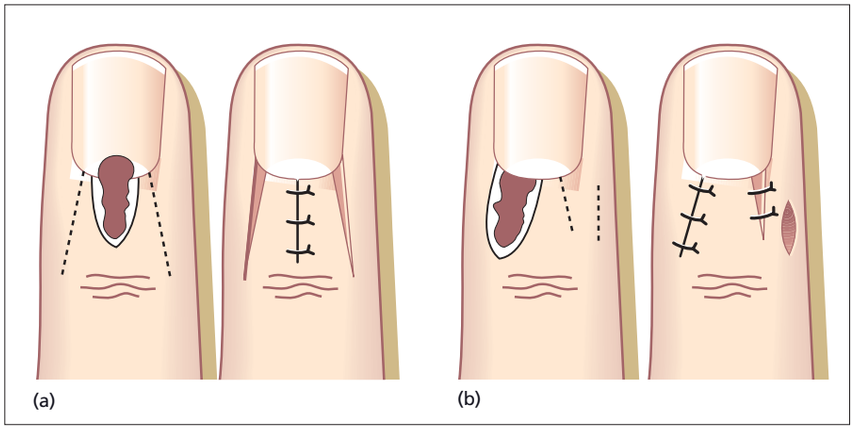

Fig. 65.43 Method for removing a small lesion from the proximal nail fold.

ondary intention. Wounds in the midline of the nail fold can leave some scarring, but the nail plate is usually unaffected.

Nail plate biopsy [1,2]

It is sometimes useful to biopsy the nail plate, with or without a small piece of the hyponychium. This may help differentiate between onychomycosis and psoriasis. If hyponychium is included, a small bleb of anaesthetic will be needed or a distal wing block can be performed. A chunk of distal nail plate of at least 3 mm width is then removed with large nail clippers. Subungual debris should also be obtained and a scalpel may be needed if hyponychium is attached. Hyponychial wounds heal by secondary intention after cautery haemostasis, and leave no scarring.

Lateral matrix phenolization [1,2]

Ingrowing nails, particularly toenails, can be treated in many different ways [1–4]. However, phenolization is quick, relatively painless and has a high success rate [5]. Any area of matrix may be phenolized, including total ablation. In some centres sodium hydroxide is used in place of phenol. This is reported to produce good results and possibly a shorter period of postoperative ooze [6].

After anaesthetic, antiseptic soak and tourniquet, the margin of lateral ingrowing nail is avulsed using nail splitters to separate it from the rest of the nail plate. The nail folds are then protected with a layer of yellow soft paraffin, and 85% aqueous phenol is applied on the end of an orange stick to the exposed matrix. This is done for 3 min (one stick per min), before douching with 70% alcohol to neutralize the chemical cautery. Although 3 min is common practice [1], in one series of 537 ingrowing nails, phenol was applied for 5–6 min and a 99% 1-year cure rate was achieved, with a mean healing period of 20 days [2]. As a result of the chemical burn, there is some ooze from the wound, which can occasionally last several weeks, but it is seldom infected and is often pain-free. If the ooze is prominent, the toe should receive daily potassium permanganate or povidone–iodine soaks, or be irrigated directly to remove debris. It is advisable to culture for specific microbes. The nail is permanently narrowed.

There is occasionally a small element of lateral nail regrowth, although further surgery is indicated only if there is repeated symptomatic ingrowing. Complete nail ablation can be achieved using the same technique applied to the entire matrix.

Other surgical modalities

Mohs micrographic surgery

This technique applied to the nail unit exploits the principle of maximum conservation of healthy tissue while ensuring tissue clearance of tumour. It is particularly useful in squamous cell carcinoma of the nail unit (see p. 65.37), where it should be offered as an alternative to digit amputation when there is no evidence of invasion of bone by tumour [1,2]. At this site, the conservation of normal tissue is of considerable functional significance. The place of Mohs' surgery in treatment of pigmented lesions of the nail apparatus remains to be fully explored. There is limited experience of its use in nail melanoma [3].

Cryosurgery

Cryosurgery is widely used for the treatment of periungual warts. There is a small risk of damage to the tendons in the finger with aggressive freezing techniques. It is also used for myxoid cysts [4,5]. The cysts should be evacuated of their mucoid contents before a double 20-s freeze–thaw cycle. EMLA (eutectic mixture of local anaesthetics) or injected local anaesthetic may sometimes be needed. This regimen produces cure in approximately 25% of cases [5], although more aggressive freezing can produce better results [4].

Infrared photocoagulation

This has been used as a treatment for myxoid cysts of the proximal nail fold [6,7]. The contents are evacuated through a puncture wound before treatment.

Carbon dioxide laser

There is a range of indications for carbon dioxide laser [8–10], and its virtue may be in provision of a bloodless wound which allows a good view of the surgical procedure. This can normally be provided only in cold-steel surgery by an effective tourniquet.

The bulk of laser work on the nail unit is for subungual and periungual warts. This uses the defocused mode with a 1–2 mm spot at 5–10 W output and can be intermittent, in 0.05-s bursts, or continuous. Haemostasis may not be complete, and both anaesthetic and tourniquet are usually used with the laser.

It is also used in the treatment of myxoid cysts [11] and ablation of abnormal nail in irreversible nail disorders. This includes partial destruction of the matrix in ingrowing nails [12–14] and in pachyonychia congenita to reduce nail thickness.

Table 65.5 Classification of acute trauma. (From Van Beek *et al.* [1].)

Type	Effect	Therapy
I	Small haematoma associated with a small break in the nail bed	Fenestration of nail over the haematoma
II	Large haematoma with significant nail bed injury	Remove nail in order to identify site and nature of subungual damage
III	Large haematoma, nail plate displaced	X-ray may reveal fracture of terminal phalanx, usually in association with nail bed laceration which requires resorbable 6/0 suture
IV	Severe crush injury	Avulsion needed to reveal matrix, with multiple lacerations requiring careful reconstruction
V	Amputation of tip of digit, may include parts of matrix	If tip can be retrieved, it should be used as a graft. Otherwise nail bed from other sites may provide autologous grafts

Traumatic nail disorders

Nails may show signs of acute trauma, scars following acute trauma or chronic repetitive trauma.

Acute trauma

Acute trauma is classified with respect to severity, ranging from a small haematoma to digit amputation (Table 65.5).

Nail bed laceration

The nail bed may be lacerated by different forms of trauma, including incisions, and crush and avulsion injuries. In simple injuries there is displacement of the nail plate, which may be found proximally avulsed but retaining distal attachment to the nail bed. In this form of trauma, and in many others, the nail plate can be employed as a useful splint [2]. Initially, the nail bed damage should be assessed by avulsion, and then the nail can be replaced after any necessary nail bed repair has been performed; a small window for drainage of blood and exudate is made in the nail [3]. More complicated injuries may require flap or graft reconstructions and, in some instances, vascularized composite nail grafts are used with microvascular anastomoses. When the wounds arise from crush injury, fracture is relatively common. If the distal tuft has been fractured to leave fragments of bone dispersed in the soft tissues, it may prevent long-term morbidity if these are removed [4].

Delayed trauma

The most common kind of chronic deformity following an acute injury is a split nail or reduction in the length of the nail bed with consequent overcurvature of the tip of the nail. Cure of a split-nail deformity is difficult, with only a modest chance of success [1]. Sometimes, there is an associated pterygium. Treatment entails excision of the nail bed and matrix scar and, in the case of a pterygium, a split-skin graft may be placed on the ventral aspect of the proximal nail fold to help prevent recurrence of the pterygium. It is important to keep the wounded aspects of nail bed or matrix separate from the overlying nail fold after surgery, and this is often best done by returning the nail plate after soaking it in antiseptic during the procedure.

If treatment is required for a shortened distal phalanx with nail bed changes, there are two choices [2]: the entire nail can be phenolized, or a V–Y advancement flap can be performed based on two neurovascular pedicles.

Haematoma [1,2]

Subungual bleeding is a common sign. It may present as a feature of acute trauma, with pain due to the recent event in combination with pain arising from the pressure exerted by the subungual accumulation of blood. A haematoma arising within the matrix will be incorporated into the nail plate [3]. Where the haematoma is associated with acute trauma, there is usually pain and the diagnosis is obvious. However, with less extreme trauma, a haematoma may not develop immediately and may be painless. This is most common in the toes and may give rise to clinical uncertainty as to whether it represents early subungual melanoma. A history of traumatic sporting hobbies is useful, and signs of symmetrical nail trauma and inappropriate footwear all point towards trauma as the cause of the appearance. Dermoscopy will nearly always resolve the situation [2], but if it does not, making a small punch in the surface of the nail may reveal old blood as the source of pigment. Malignancies can bleed and so confirmation of blood does not refute the possibility of a tumour; however, as an isolated finding in the absence of other clues, this test should be sufficient to obviate the need for surgical exploration. An alternative is to score a transverse groove in the nail at the proximal margin of the pigment and observe over a few weeks as the discoloration grows out. If pigment continues to spread proximal to the groove, surgical exploration is needed.

The only treatment that can be offered is to relieve the pressure, and if seen soon after the injury this can be done by puncturing the nail, for instance with a hot pointed implement, cautery or a small drill. This procedure will relieve pain and may save the nail.

The possibility of an underlying fracture must be considered for larger haematomas [1].

It is stated that if more than 50% of the visible nail is affected, the nail plate should be removed. However, there is evidence to challenge this rule. A comparison between two groups of children having exploration and repair or trephination alone showed fewer complications in the latter group and considerably less investment in medical time [4]. A literature review failed to find clear evidence for avulsion [5].

Chronic repetitive trauma

Chronic repetitive trauma may take several forms. Some have been considered in other sections detailing transverse ridges produced by a habit tic (Fig. 65.22; p. 65.25), the canaliform dystrophy of Heller (Fig. 65.44; p. 65.50) and chronic paronychia (Fig. 65.18; p. 65.21).

Nail biting

The nail plate, periunguium and nail bed are all subject to biting and picking. Although fingers are most commonly involved, rarely toenails are also bitten [1]. This produces distinctive features, which are found in 60% of children, 45% of adolescents and 10% of adults [2]. The majority of moderate nail biters have no associated psychiatric disorder [3,4]. Focal abnormalities, such as viral warts, are often a complication, whether as a cause or as a result of the Koebner effect after biting. Severe damage may be associated with self-mutilating disorders such as Lesch–Nyhan syndrome.

The nails are typically short, with up to 50% of the nail bed exposed. The free edge may be even or ragged. Surface change may include splitting of the nail into layers or a sand-papered effect, and the nail may acquire a brown longitudinal streak [5]. The most aggressive nail biting (onychotillomania/onychophagia) can produce subungual haemorrhage, strips of nail loss with residual spurs, or loss of the entire nail (Fig. 65.45). Onychotillomania may be allied to delusions of parasitosis when the patient picks off pieces claiming that they contain parasites [6]. A rough and irregular nail and nail fold may result. Many fingernails are involved. Oral pimozide may be beneficial [7].

Direct damage and secondary infection may make nail loss permanent or result in pterygium formation. The nail folds are sometimes bitten in addition to, or as a substitute for, the nail. This can lead to bleeding and chronic paronychia, with acute infective exacerbations. This in turn may lead to nail plate damage or ridging and nail fold scarring. In cases associated with infection, osteomyelitis of the terminal phalanx can develop [8,9]. Subjects will sometimes deny nail biting and attribute the appearance to a disease that stops nail growth. Transverse grooves scored proximally in the nail plate will confirm that the nail is growing by moving distally with time. In aggressive nail biting, the groove may be eroded from the surface.

Fig. 65.44 Median canaliform dystrophy of Heller.

Fig. 65.45 Nail biting can be extensive, with damage to the nail folds and nail plate causing subungual haemorrhage.

Trauma is sometimes inflicted by other nails, with pushing back of the proximal nail fold as part of a habit tic (see p. 65.24 and Fig. 65.22). This results in serial transverse ridges and depressions running up the midline of the nail, associated with loss of the cuticle. In more conscious forms of self-damage, sharp instruments are used to produce dermatitis artefacta of the nail unit, and the nail fold is commonly preserved [10].

Treatment. Treatment is often unsuccessful and cure relies largely on the motivation of the patient. Local antiseptics and antimicrobial ointments may help settle infection secondary to nail unit damage. Those with the most bitter taste are often prescribed in the belief that this will discourage biting. This is seldom the case. Antidepressants [11] and behavioural therapy [12] have been used with some success in limited studies.

Hang nails

These are due to hard pieces of epidermis breaking away from the lateral nail folds. Although often due to nail biting, they may result from many other minor injuries. The splits may be painful when they penetrate to the underlying dermis. They should be removed with sharp pointed scissors.

Nutcracker nails

Under this heading, Cohen [1] described splitting and onycholysis caused by the habit of separating the two halves of cracked walnuts over a period of 10 years.

Damage from nail manicure instruments

Metal instruments, such as a nail file or scissors, wooden or plastic orange sticks, or nail whitener pencils may create acute or chronic injuries in the nail area. Onycholysis may result from using the sharp point for cleaning under the nail plate. Nails, however, are best cleaned with a nail brush and soap, because overzealous manicure, pushing back the cuticles, may result in white streaks across several nails. Cleaning around the nail with contaminated instruments may lead to acute or chronic paronychia. According to Brauer and Baran [1], it is not advisable to cut or clip the nail plate, as this produces a shearing action that weakens the natural layered structure and promotes fracturing and splitting. An emery board is preferred for shaping the fingernail by filing from the sides of the nail towards the centre.

Trauma from footwear

Onychogryphosis and nail hypertrophy [1–5]

Onychogryphosis is an acquired dystrophy usually affecting the great toenail, which is thickened, yellow and twisted. It is most commonly seen in the elderly [1,2,4], although trauma and biomechanical foot problems may precipitate similar changes in middle age or earlier.

At one time, onychogryphosis was known as ostlers' nail, owing to the fact that some cases could be traced to injury caused by a horse trampling on the foot of the ostler. Competitive sport is a more contemporary cause. The injury, once sustained, is aggravated by footwear. As the nail becomes longer and thicker, the damage from the footwear becomes progressively more important. Nail hypertrophy implies thickening and increase in length, whereas onychogryphosis implies curvature also.

Some cases of nail hypertrophy are intrinsic, and this applies especially to toenails other than the nail of the great toe. The nail becomes thick and circular in cross-section instead of flat, and thus comes to resemble a claw. There are two possible explanations for this formation.

1 There is insufficient matrix under cover of the posterior fold to exert a flattening effect. The altered relationship between matrix and proximal nail fold in postmortem specimens supports this.
2 The nail bed is contributing a greater quantity of keratin to the nail than usual. It is usually possible to exclude this on clinical grounds as there is often an element of onycholysis that separates the dystrophic nail from the nail bed.

Hypertrophy of fingernails is usually traumatic in origin and is often the result of a single injury.

In onychogryphosis, one or more nails become greatly thickened (Fig. 65.46) and, with neglect, increase in length, becoming curved like a ram's horn. The nails of the great toes are most often involved, but no toenail is exempt. It is possible that the nail plate distortion produced by chronic untreated onychomycosis may be partly responsible for onychogryphosis at a later stage. In extreme cases, the free edge may press on or even re-enter the soft tissues of the foot.

Treatment of onychogryphosis and nail hypertrophy is either radical or palliative. Radical treatment consists of surgical removal of the nail and matrix and is recommended in those with good circulation (Fig. 65.47). Palliative treatment requires regular paring

(a)

(b)

(c)

Fig. 65.47 (a–c) Onychogryphosis is often best treated by ablation of the nail matrix.

and trimming of the affected nails, usually by a podiatrist using nail clippers and a file or mechanical burr. The thickened nails are extremely hard and trimming is difficult. Not infrequently, the nail is invaded by granulation tissue from the nail bed, and incision of this during trimming will result in pain and haemorrhage.

Other causes of thickened nails are psoriasis, pityriasis rubra pilaris, Darier's disease, fungal infections, pachyonychia congenita, congenital ectodermal defects and congenital malalignment of the great toenails [6].

Ingrowing toenail [1–3]

Synonym
- Onychocryptosis

The soft tissue at the side of the nail (lateral nail fold) is penetrated by the edge of the nail plate, resulting in pain, sepsis and, later, the formation of granulation tissue [4]. Penetration is often caused by spicules of nail at the edge of the nail plate, which have been separated from the main portion of the nail. The great toes are those most often affected. The main cause of the deformity is compression of the toe from the side due to ill-fitting footwear, and the main contributory cause is cutting the toenails in a half-circle instead of straight across. Anatomical features, such as an abnormally long great toe and prominent lateral nail folds, are important in some cases. Sport, with the toe impacting on the inside of the shoe through kicking or other movements, can also be contributory.

In infancy, ingrowing toenail most commonly occurs before shoes are worn, associated with crawling, 'pedalling' or wearing undersized 'jumpsuits' [5]; acute paronychia may be associated [6]. Rarely, it is congenital [7] and even familial [2]. In children, ingrowing is commonly distal rather than lateral. Management is conservative in most instances, with topical steroid and antiseptic preparations. Surgery is occasionally required [8].

The first features are pain and redness, shortly followed by swelling and pus formation. Granulation tissue then forms and adds to the swelling and discharge. More severe infection may follow. There is seldom any difficulty with diagnosis. Excess nail fold granulation tissue can also be a feature of amelanotic melanoma and reactions to medications such as retinoids, ciclosporin, antiretroviral drugs and chemotherapy [9–15].

Treatment. Treatment may be difficult and prolonged. The first essential is to insist on the patient wearing shoes that are sufficiently wide, high and pliable to remove lateral pressure [16]. Any abnormality of foot/toe function should be corrected. The patient must also be instructed to cut the nail straight across instead of in a semicircle. The nail must be allowed to grow until its edges are clear of the end of the toe before it is cut; this prevents the further formation of marginal spicules. In the early stages, the infection may be overcome by the application of antiseptics and by inserting a pledget of cotton-wool under the edge of the nail. Taping the toe or applying plastic gutters between nail edge and nail fold are alternatives [17]. These can be supplemented with acrylic nail to build up a smooth surface able to push the nail fold away and relieve ingrowing [18]. Twice-daily warm-water baths followed by careful drying and powdering are helpful. Potent topical steroid can be useful to diminish inflammation and suppress granulation tissue – but can only be used when infection is ruled out or being actively managed. If the infection is more severe and there is local cellulitis, an appropriate systemic antibiotic should be administered. When granulation tissue forms this should be destroyed by cauterization with a silver nitrate stick. It is important that an amelanotic melanoma is not missed [19], and if there are atypical features a biopsy should be performed.

If conservative measures fail, operative intervention will be necessary. Removing the nail alone is likely to result in recurrence of ingrowing when the nail returns [20] and so should be combined with a curative procedure such as phenolization of the relevant part of the matrix [4,21]. Although surgical excision of matrix can provide an excellent result, it is more dependent than phenolization on the skill of the practitioner. In large studies, phenol treatment results in a greater cure rate and less morbidity [21]. The prolonged period of ooze from the wound after phenolic ablation leads to suspicion of infection, but this has not been confirmed by formal research [22]. Recent reports of the use of 10% sodium hydroxide suggest that it may be equally effective but with a shorter period of postoperative ooze [23]. Where there is diabetes or impaired peripheral circulation, surgery may require avoidance of prolonged or tight tourniquet application, and close follow-up. Phenolization can be undertaken safely in diabetics [24]. Carbon dioxide laser has been used, although it lacks the analgesic properties intrinsic to phenol [25].

The nail and cosmetics

The main areas of medical involvement with nail cosmetics are:

1 where nail cosmetics cause alteration or damage to the nails and periunguium [1,2]
2 where nail cosmetics cause allergic contact dermatitis locally and ectopically, such as of the eyelids [1,2]
3 where nail disease has limited therapeutic options and nail cosmetics can provide an important supplement to dermatological management [3].

To understand these areas it is helpful to have some knowledge of the agents and techniques used in cosmetic nail care. Nail coatings represent an attractive nail enhancement. They may harden upon evaporation (nail polish) or polymerize (sculptured nails, gels, preformed artificial nails).

Coatings that harden upon evaporation

Nail polish

The term 'nail lacquer' is sometimes used to include enamels, top coats and base coats, either as separate entities or combined in one product. Although chemically similar, they contain different ratios of the same constituents to lend different characteristics. The base coat is used to improve the adhesion or bonding of enamel to the nail. A top coat improves the depth and lustre of the enamel and increases its resistance to chipping and abrasion. Nail polishes consist of solids and solvent ingredients, the former representing about 30%, the latter 70% of the product. The ingredients can be divided into six principal groups.

1 cellulose film formers (e.g. nitrocellulose): provide gloss, body and gel structure
2 resins (e.g. tosylamide formaldehyde resin [previously known as toluene sulphonamide formaldehyde resin]): improve the gloss and adhesion of the film
3 plasticizers (e.g. dibutylphthalate): give the film pliability, minimize shrinkage, and soften and plasticize the cellulose
4 thixotropic suspending agents (e.g. bentonite) for non-settling and flow: keep pigments in suspension on shaking
5 solvents and diluents (e.g. toluene): keep nitrocellulose, resin and plasticizer in the liquid state and control the application and drying time
6 colour substances: these are either inorganic (iron oxides) or a variety of certified organic colours (D and C yellow A1 lakes).

Recently, there has been a move away from toluene and formaldehyde resin, and most recently avoidance of dibutylphthalate due to potential health risk.

'Pearls' or 'frosts' are produced by bismuth oxychloride and titanium dioxide coated with mica and guanine (obtained from fish scales). 'Clears' contain a small tint.

The base coat is formulated in a manner similar to standard lacquer, but it has a lower non-volatile content (less nitrocellulose) and lower viscosity, because a thinner film is desirable; it may also contain hydrolysed gelatine. In the top coat the nitrocellulose content is increased and the resin is reduced. A slight increase in plasticizer content improves elasticity of the film. There is no pigment. The top coat often has an added sunscreen.

Reactions such as an allergic contact dermatitis to nail polish frequently appear on any part of the body accessible to the nails, with paradoxically no signs in or around the nail apparatus [4]. The commonest areas involved are the eyelids, the lower half of the face, the sides of the neck and the upper chest. Generalized dermatitis may rarely occur. Sometimes the use of nail polish on stockings to stop 'runs' or on nickel-plated costume jewellery to prevent nickel dermatitis may induce nail-polish dermatitis on the legs or at the site of metal contact. Nail-polish dermatitis may occur in the user's partner or other close contacts. Although any ingredient may account for distant allergic contact dermatitis, tosylamide formaldehyde resin is the most common culprit. After the nail polish is removed, the dermatitis usually clears rapidly unless secondary infection or lichenification has occurred. Metal pellets present in some bottles to maintain a liquid state may cause nickel reactions and onycholysis.

Nail plate staining from the use of polish is most commonly yellow/ orange in colour. It typically starts near the cuticle, extends to the nail tip and becomes progressively darker from base to tip. With time, the dyes penetrate the nail too deeply to be removed. Injury to the nail plate from nail lacquers is rare. However, 'granulation' of nail keratin, a superficial friability, can be observed in some instances where individuals leave nail lacquer on for many weeks or where there is poor formulation of the product. For patch testing, several nail lacquers should be used and tested 'as is'; they should be allowed to dry for 15 min because the solvents and diluents may cause false-positive reactions. The following substances should be included in the test battery.

- tosylamide formaldehyde resin (10% in petrolatum)
- nickel (5% in petrolatum); dimethylglyoxime spot test for nickel
- glyceryl phthalate resin (polymer resin) (10% in petrolatum)
- pearly material: guanine powder (pure)
- formaldehyde (1% aqueous)
- colophony (20% in petrolatum); drometrizole (Tinuvin P) (1–5% in petrolatum).

The resin contains no free formaldehyde. Formaldehyde is merely the chemical moiety on which the resin is formed. Usually, formaldehyde-sensitive individuals do not cross-react with this resin. However, it has been suggested that there is always a small amount of free formaldehyde present in many preparations. Various cosmetic companies now make varnishes that are formulated without the sensitizing resin.

Nail polish removers. These are composed of various solvents such as acetone. Occasionally, nail polish removers cause trouble by excessive drying of the nail plate, and may be responsible for some inflammation of nail folds.

Coatings that polymerize [5]

Sculptured nails

The basic kit of sculptured nails is sold as a set containing a template, a liquid monomer and a powdered polymer. Self-curing acrylic resins are created by polymerization of methyl methacrylate monomer and polymethyl methacrylate powder with an organic peroxide and an accelerator. They harden at room temperature. The compound has to be moulded on the natural nail. The acrylic compound is applied to the nail, which has been roughened on the surface. When hardened, the compound produces a prosthetic nail that is enlarged and elongated by repeated applications. The prosthesis can be filed and manicured to shape; as the plate grows out, further applications of acrylic can be made to maintain a regular contour.

Technicians who sculpt nails should be instructed to wash their hands before touching the face or eye area. Usually, the area involved is the chin, which technicians tend to rest in their hands. Additionally, they should be warned to avoid contact with the dust of freshly applied product and to avoid using the wet product.

Allergic reactions. Allergic reactions due to sculptured nails may occur 2–4 months, and even as long as 16 months, after the first application. The first indication is an itch in the nail bed. Paronychia, which is usually present in allergic reactions, is associated with excruciating pain in the nail area, and sometimes with paraesthesia. The nail bed is dry and thickened, and there is usually onycholysis. The natural nail plate becomes thinner, split and sometimes discoloured. It takes several months for the nails to return to normal. Permanent nail loss is exceptional, as is intractable prolonged paraesthesia [6].

Patch tests most commonly show reactions to the acrylic liquid monomer and not to the polymer; this is similar to denture allergy (see Chapter 26).

Improper application and maintenance. With continued wear, the edges of the sculptured nails become loose. These must be clipped and then rebuilt to prevent the development of an environment prone to bacterial and, beneath the nail plate, candidal infection. In fact, this is a result of improper application and maintenance. Failure to file the prosthetic nail every 2 weeks will result in the creation of a lever arm that predisposes to traumatic onycholysis or damage to the natural nail. Onycholysis is very common with nail extensions that are too long.

Irritant reactions. Irritant reactions to monomers are possible. These manifest as a thickening of the nail bed's keratin layer, which can sometimes cause the entire nail bed to thicken with or without onycholysis. Nonetheless, the overwhelming majority of cases result from physical trauma or abuse.

Damage to the natural nail is not unusual after 2–4 months of wear of a sculptured nail. If it becomes yellow or crumbly, this means that the product was applied and maintained incorrectly. The patient should find a better-qualified nail technician. The problem may well not be the acrylic nail materials but rather the thinning of the nail due to excessive filing with heavy abrasives.

Primer (methacrylic acid) is a strong irritant, which may produce third-degree burns. It is hazardous if the cuticles are flooded or spills are not washed out immediately. Primer can permeate the plate and soak into the nail bed if the nails are too thin. Soap or baking soda, used with water, are excellent neutralizers. If primer gets into the eye, it should be flushed with water for at least 15 min, and a Poisons Information Centre should be contacted.

Premixed acrylic gels

Gel system products are premixed and either acrylic-based (14% of the market) or cyanoacrylate-based (1% or less of the market). Their virtual lack of odour makes gels popular in full-service beauty salons. UV light-cured gels are the best known of the different gel technologies. These gels contain urethanes and (meth)acrylate compounds, a photoinitiator and cellulose, which necessitates antiyellowing agents and a UV light unit. The gel remains in a semiliquid form until cured in a photobonding box. The proportion of resins to monomers determines the gel consistency. When the gel is exposed to light of an appropriate wavelength, polymerization occurs, resulting in hardening of the gel. UV gels never involve catalysts and often do not employ primers.

Gel enhancement products shrink by up to 20%, which may result in lifting and tip cracking. As an effect of excessive shrinkage, clients may comment that the enhancement feels tight on the nail bed. Other symptoms include throbbing or warmth below the nail plate. This may lead to tender, sore fingertips. Photobonded acrylate has been observed to cause nail reactions, sometimes with nail loss and paraesthesia. Hemmer *et al*. [7] have patch tested 'hypoallergenic' commercial products in patients wearing photobonded acrylic nails who had perionychial and subungual eczema. Triethyleneglycol dimethacrylate, hydroxyfunctional methacrylates, and (meth)-acrylated urethanes proved to be relevant allergens in photobonded nail preparations. Meth-acrylated epoxy resin sensitization was not observed. The omission of irritant methacrylic acid in UV-curable gels does not reduce the high sensitizing potential of new acrylates. Contrary to the manufacturers' declarations, all 'hypoallergenic' products continue to include

acrylate functional monomers and therefore continue to cause allergic sensitization. Gels and acrylics, being chemically distinct entities, will not necessarily cross-react.

Unreacted UV gel in the dusts and filings may produce distant allergic reactions. Although sensitization to butyl-hydroxytoluene is possible, gels usually contain acrylated oligomers and monomers. Acrylates are far more likely to cause sensitization than methacrylates or stabilizers.

Finally, thick ornately painted gel false nails that may be difficult to remove present a real challenge to pulse oximetry. It appears to be the polish more than the sculpted nail that interferes with the readings [8,9].

Preformed plastic nails

Preformed plastic nails are packaged in several shapes and sizes to conform to the normal nail plate configuration. Such nails are trimmed to fit the fingertip and are fixed with cyanoacrylate adhesive supplied with the kit. The usefulness of these prosthetic nails is limited by the need for some normal nail to be present for attachment. Normal physical and chemical insults to the nails cause the preformed plastic nails to loosen. If the preformed nails remain in place for more than 3 or 4 days, they may cause onycholysis and nail-surface damage. Eczematous, painful paronychia due to cyanoacrylate nail preparations may be observed after about 3 months. Dystrophy and discoloration of the nails may become apparent and last for several months. In some cases, distant contact dermatitis of the face and eyelids occurs. On patch testing, the patients react far more often to the adhesive than to the prosthetic nails. Suggested test substances are *p*-tertiary-butylphenol resin (1% in petrolatum), tricresyl ethyl phthalate (5% in petrolatum), cyanoacrylates and other glues (5% in methylethylketone).

Nail-mending kits

These include paper strips of a basic film-forming product to create a 'splint' for the partially fractured nail plate. The split is first bonded with cyanoacrylate glue, then the nail is painted with fibred clear nail polish. A piece of wrap fabric is cut and shaped to fit over the nail surface. This is then embedded in polish of high solid content, and several coats are applied.

Nail wrapping

In nail wrapping, the free edge of the nail should be long enough to be splinted with paper, silk, linen, plastic film or fibreglass, and fixed with cyanoacrylate glue. After drying, the edge is shaped, and the nail is coated with enamel.

Removal of nail coatings that polymerize. The most commonly used solvent for removal of nail products is acetone. Warming the solvent with great care can cut product removal time in half. However, most gels are difficult to remove because they are highly cross-linked and resistant to many solvents. Therefore, if gel enhancements have to be removed, slowly file (not drill) the enhancement with a medium-grit file, leaving a very thin layer of product. Soak in warm product remover and, once softened, scrape the remaining product away with a wooden pusher stick.

Cuticle removers

These are lotions or gels containing approximately 0.4% sodium or potassium hydroxide. The lotion is left in place for 1–3 min and then washed off. Creams containing 1–5% lactic acid (pH 3–3.7) are also used.

Nail hardeners

Nail keratin can be hardened by tissue fixatives such as formaldehyde. These are not commercially available in the USA because of their toxic effects. Nail changes caused by such nail hardeners may include pain, subungual haemorrhage and bluish discoloration of the nail. The nail returns to normal when the offending agent is discontinued. Formaldehyde nail hardeners have been reported as causing onycholysis and allergic contact dermatitis; they may also act as irritants. Patch testing should be with formaldehyde (1% aqueous). Because of its irritant qualities, reactions should be interpreted with caution.

Silicone rubber nail prosthesis [10]

In a wide variety of cases, ranging from deformed nail to complete loss of the terminal phalanx, a silicone rubber, thimble-shaped finger cover may be indicated. This prosthesis is easily fitted on the finger stump, encasing the entire distal phalanx; it must be fine and flexible to maintain pulp sensitivity and must have the same marking and colouring as the finger. The fixation is excellent and the nail form takes nail varnish well.

Nail cream

This is an ordinary water-in-oil moisturizing cream, with low water (30%) and high lipid content. It is applied, after cleaning the hands, to prevent or diminish brittleness.

Nail buffing

Weekly buffing may be indicated for removing small particles of nail debris, thus enhancing the lustre and smoothness of the nail plate. Buffing creams, which contain waxes and finely ground pumice, and buffing powders are abrasive and should not be overused on thin nails.

Nail whitener

This is a pencil-like device with a white clay (kaolin) core used to deposit colour on the undersurface of the free edge of the nail.

Infection risks

Secondary infection with *Candida* or bacteria is a hazard for anyone with an irritant or allergic contact dermatitis of the periunguium. Where this is associated with artificial nails, the prosthetic nails may be longer than usual and so reduce the ability to keep the area clean. Prosthetic nails are sometimes worn because there are underlying problems with the natural nails, such as cracks or onycholysis. These features may also lower the threshold to certain types of infection.

Medical staff with artificial nails or nail extensions may put patients at risk through carriage of pathogens [11]. Guidelines in the UK now require medical staff not to wear such embellishments [12]. Nail varnish is also thought to be associated with bacterial

carriage when it becomes chipped, although the evidence for this is less strong [13]. Infection through nail salons and the manicuring process is a further factor that adds to the risks for those with artificial nails [14].

Conclusion

Nail beauty therapy may certainly produce an attractive enhancement and disguise unsightly nail conditions but it may also represent a potential hazard due to instrument damage, and is not recommended for psoriatic nails as it may provoke the Koebner phenomenon.

Anatomy and physiology

A.G. Messenger, pp. 66.1–66.16

Introduction

Hair has no vital function in humans, yet its psychological functions are extremely important, as any clinical dermatologist or cosmetician can readily attest from routine daily practice. If the inevitability of scalp baldness makes it reluctantly tolerable to genetically disposed men, in women, loss of hair from the scalp is distressing as is the growth of body or facial hair in excess of the culturally accepted norm.

The evolutionary history of hair is no less enigmatic. Mammals probably evolved from Therapsid reptiles during the Late Triassic period over 200 million years ago (MyA). The earliest direct evidence of hair in mammals comes from fossilized casts and impressions in coprolites and pellets from the Late Paleocene beds of Inner Mongolia [1]. Hairs from at least four extinct mammalian taxa were identified, notably the multituberculate *Lambdopsalis bulla*, all showing striking preservation of the cuticular scale pattern. The three extant mammalian groups—monotremes, marsupials and placental mammals—all possess hair, indicating its presence prior to the divergence of therian mammals from monotremes, which probably took place between 170 and 230 MyA [2,3]. The multituberculate lineage extends back into the Triassic, suggesting that hair is a very ancient and possibly defining feature of mammals. Whatever its origin, it is clear that the warm-blooded mammals owe much of their evolutionary success to the properties of the hairy pelage as a heat insulator. Paradoxically, Man's movement from the ancestral forest home to populate the globe is linked with a reversion to relative nudity and an ability to keep cool. Moreover, hair serves other purposes: in particular, it is concerned with sexual and social communication by constructing adornments such as the mane of the lion or the beard of the human male, or assisting in the dispersal of scents secreted by complexes of sebaceous or apocrine glands.

For these evolutionary reasons, hair follicles are not all under identical control mechanisms. To match the animal coat to seasonal changes in ambient temperature or environmental background requires moulting and replacement of the hairs. The process appears to involve an inherent follicular rhythm, modified by circulating hormones such as melatonin, prolactin, androgens or thyroxine, whose secretion is geared to environmental cues through the pineal gland, hypothalamus and pituitary.

The control of sexual hair growth must be clearly differentiated from that of the moult cycle. The development of pubic, axillary and other body hair is delayed until puberty because it is dependent upon androgens in both sexes; that 'male' hormones are, in contrast, also a prerequisite for the manifestation of androgenetic alopecia still defies adequate explanation.

In all mammals, including humans, but with the possible exception of the merino sheep and the poodle dog, hair follicles show intermittent activity. Thus, each hair grows to a maximum length, is retained for a time without further growth, and is eventually shed and replaced.

Types of hair

Different types of hair may be produced by different kinds of follicle, and the type of hair produced in any particular follicle can change with age or under the influence of hormones. Animals characteristically have both an overcoat of stiff guard hairs and an undercoat of fine hairs [4], but many kinds of follicle and fibre have been described. Many species also have large vibrissae or sinus hairs, which are sensory and are produced from special follicles containing erectile tissue, but there are no strictly comparable follicles in humans. In humans, a prenatal coat of fine, soft, unmedullated and usually unpigmented hair, known as *lanugo*, is normally shed *in utero* in the eighth to ninth month of gestation. Postnatal hair may be divided at the extreme into two kinds: vellus, which is soft, unmedullated, occasionally pigmented and seldom more than 2 cm long; and terminal hair, which is longer, coarser and often medullated and pigmented. However, there is a range of intermediate kinds. Before puberty, terminal hair is normally limited to the scalp, eyebrows and eyelashes. After puberty, secondary sexual 'terminal' hair is developed from vellus hair in response to androgens.

Development and distribution of hair follicles

Human hair follicles appear first in the regions of the eyebrows, upper lip and chin at about 9 weeks of embryonic development, and in other regions in the fourth month [5]. Hair over most of the scalp passes through a complete cycle and is shed *in utero*, and follicles in these regions have re-entered anagen by the time of birth. In the occipital scalp, telogen is delayed until after birth and this may give rise to a patch of hair loss in this region in the neonatal period. A fuller account of embryonic development is given in Chapter 3.

In humans, the full complement of hair follicles is probably established by the time of birth. Follicle density is highest in the fetus, when it may be similar across the skin surface. With growth there is a progressive reduction in follicle density, which continues until adult life, as skin surface area increases (Table 66.1). This occurs to a greater degree over the trunk and limbs than over the head so that the reduction in follicle density is less marked on the head than elsewhere [6]. The highest hair follicle densities, in the region of 800/cm^2, are found on the forehead and cheeks, with rather lower values for visible vellus hairs on the forehead in young adults of both sexes, and on the cheeks in women (400–450/cm^2) [7]. Lower hair densities of 50–100/cm^2 are found on the chest and back in both sexes [7,8], and follicle densities of approximately 50/cm^2 on the thigh and leg [6]. Published values for the average scalp hair density in white people vary between 250 and 320 hairs/cm^2 [9–12]. Scalp hair density shows a normal distribution in the population, with a wide range [12]. There is also racial variation in scalp hair density: average hair density in Africans (187/cm^2) [13] and African Americans (171/cm^2) [14] is lower than in white people, and it is lower still in Koreans (128/cm^2) [15].

Table 66.1 Hair follicle density in human fetal and adult skin. In adults, hair follicle density is highest on the head and much lower on the trunk and limbs. At 24 weeks' gestational age hair follicle density is similar in forehead and thigh skin. There is a pronounced reduction in thigh hair follicle density by adult life but only a small fall on the forehead. (Adapted from Szabo [6].)

	Fetal skin				Adult	
	24 weeks		Full term

Anatomy of the hair follicle (Fig. 66.1)

Hair is the keratinized product of the hair follicle, a tube-like structure continuous with the epidermis at its upper end. The follicles are sloped in the dermis, and longer follicles extend into the subcutaneous layer. An oblique muscle, the arrector pili, runs from the mid-region of the follicle wall to a point in the papillary dermis close to the dermal–epidermal junction. Above the muscle, one or more sebaceous glands, and in some regions of the body an apocrine gland also, open into the follicle. The hair fibre is made up of three cell layers: an outer cuticle, the cortex (which forms the bulk of the fibre in most hair types) and a variable central medulla, all of which derive from highly proliferative cells in the hair bulb

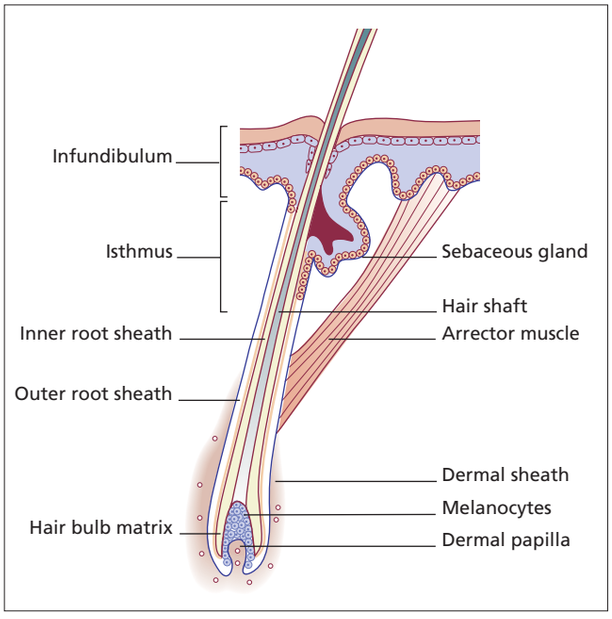

Fig. 66.1 Diagram of an anagen hair follicle.

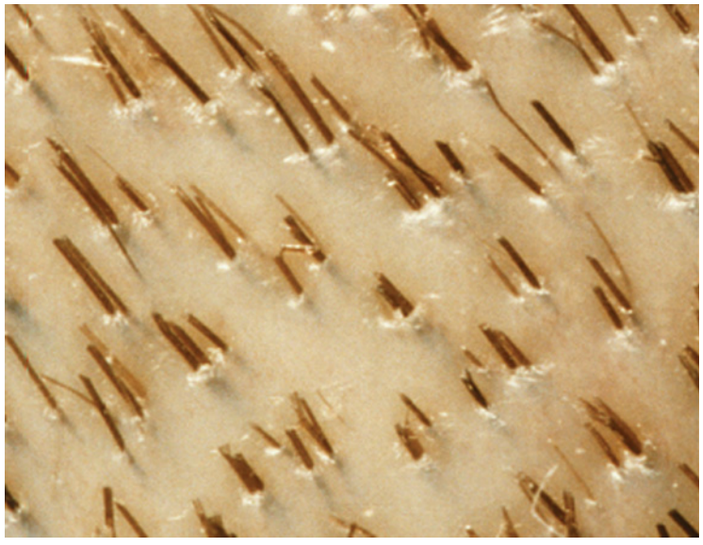

Fig. 66.2 Grouping of hairs in follicular units on human scalp. In some groups, multiple hairs emerge from a single follicular opening.

at the base of the follicle. Cells in the hair bulb also give rise to the inner root sheath which surrounds the hair fibre and which disintegrates before the hair emerges from the skin. The inner root sheath is itself enclosed by the outer root sheath, which forms a continuous structure extending from the hair bulb to the epidermis, although the functions and microscopic structure of the outer root sheath vary along the length of the follicle. The hair follicle also has a specialized dermal component, which includes the dermal or connective tissue sheath surrounding the follicle, and the dermal papilla which invaginates the hair bulb.

The hair follicle is conventionally divided into two regions: the upper part consisting of the infundibulum and isthmus and the lower part comprising the hair bulb and suprabulbar region. The upper follicle is a relatively constant structure, whereas the lower follicle undergoes repeated episodes of regression and regeneration during the hair cycle. On the scalp, and some other regions of the skin, hair follicles are arranged in groups of three or more follicles known as follicular units (Fig. 66.2). Several follicles within a follicular unit may coalesce so that hairs emerge through a common infundibulum.

The infundibulum

The infundibulum extends from the skin surface, where it merges with the epidermis, to the opening of the sebaceous duct at the junction with the isthmus. Infundibular epithelium differentiates in a similar manner to epidermis, producing a granular layer and stratum corneum which desquamates into the follicular lumen.

The isthmus

The isthmus extends from the opening of the sebaceous gland duct to the insertion of the arrector pili muscle. It consists of a multilayered outer root sheath that is continuous with the infundibulum but differs in its structure. The innermost cells lack a granular layer and undergo a pattern of differentiation known as trichilemmal keratinization. The keratinized inner root sheath, which lies within the outer root sheath, disintegrates at or about the level of the sebaceous duct. The arrector muscle loops around the follicle in the manner of a sling [1]. Each follicular unit is supplied by a single arrector muscle, which splits to encircle each follicle within the follicular unit [2].

Hair follicle stem cells reside in the lower part of the isthmus close to the insertion of the arrector muscle [3]. During embryogenesis, and in adult follicles in other species, this region shows a distinctive bulge, although a clearly defined bulge is often not seen in human adult hair follicles. Hair follicle stem cells show distinctive biochemical properties, they are slow cycling and proliferate only during the onset of anagen. Daughter cells, known as transient amplifying cells, input into the outer root sheath of the lower part of the hair follicle whence they migrate in a downward direction. On entering the hair bulb matrix, they proliferate and undergo terminal differentiation to form the hair shaft and inner root sheath [4]. The progeny of hair follicle stem cells may also migrate distally to form the sebaceous gland and, under certain circumstances such as wound healing, the epidermis.

The suprabulbar region (Fig. 66.3)

The suprabulbar region of the follicle, below the isthmus and above the hair bulb, is comprised of three layers from outermost to innermost: outer root sheath, inner root sheath and hair shaft. The outer root sheath is a multilayered epithelium enclosing the inner root sheath which, at this level, is a fully keratinized structure. Cells of the hair shaft, at the centre of the follicle, undergo terminal differentiation within the keratogenous zone in the middle part of the suprabulbar region. Keratinization of the inner root sheath precedes that of the hair shaft, suggesting that the inner root sheath has a role in 'moulding' the shape of the hair fibre.

The hair bulb (Fig. 66.4)

In large terminal follicles, the deepest part of the follicle, the hair bulb, is situated in the subcutaneous fat. The hair bulb is

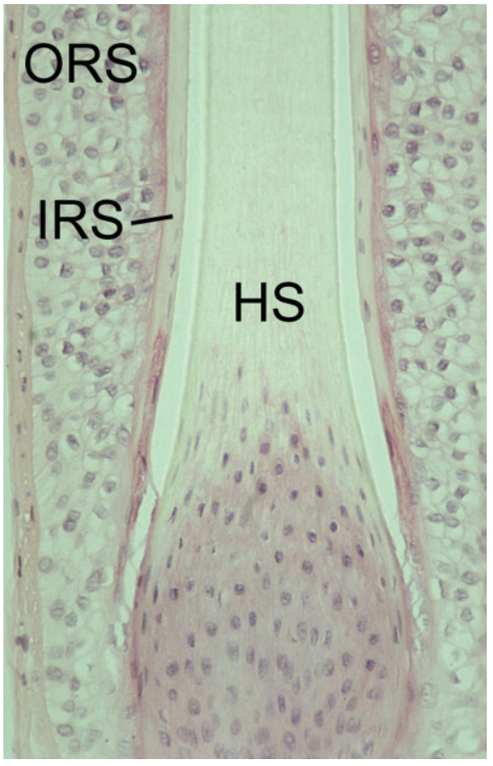

Fig. 66.3 Longitudinal section through the suprabulbar region of an anagen follicle showing the keratogenous region of the hair shaft (HS). The inner root sheath (IRS) is keratinized at this level. ORS, outer root sheath.

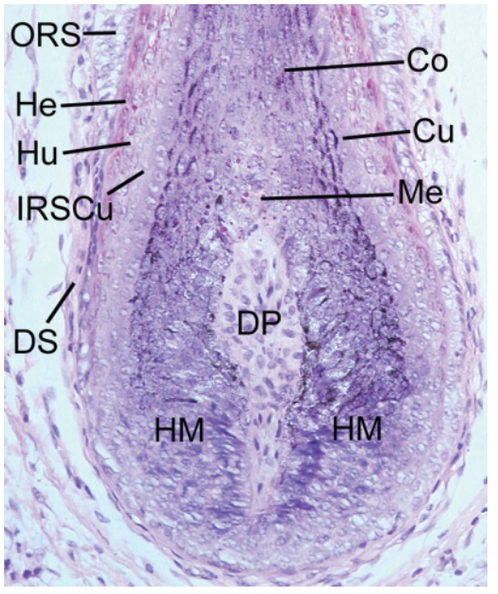

Fig. 66.4 Anagen hair bulb. Co, hair cortex; Cu, hair cuticle; DP, dermal papilla; DS, dermal sheath; He, Henle's layer; HM, hair matrix; Hu, Huxley's layer; IRSCu, inner root sheath cuticle; ORS, outer root sheath.

invaginated at its base by the dermal papilla, which is connected to the perifollicular dermal sheath by a narrow stalk. The hair shaft and the inner root sheath are derived from epithelial cells surrounding the dermal papilla, a region known as the hair bulb matrix or germinative epithelium. These cells have a high mitotic rate, with a rate of cell turnover similar to that in the bone marrow. Daughter cells migrate in an upward direction and differentiate in a highly ordered fashion to form the concentric layers of the inner root sheath and the hair shaft. The inner root sheath derives from cells in the lower, more lateral part of the matrix, whereas the hair shaft is formed from the upper, centrally situated cells. In pigmented hair follicles, highly melanized melanocytes are situated amongst cells destined to form the hair cortex. Occasional Langerhans' cells may also be found in the matrix region. The outer root sheath surrounds the inner root sheath. At the level of the hair bulb it consists of a single layer of cells, which can be followed almost to the lower tip of the hair follicle.

The dermal papilla

In anagen follicles, the dermal papilla is a flask-shaped structure that invaginates the base of the hair follicle. It is made up of specialized fibroblast-like cells embedded in an extracellular matrix rich in basement-membrane proteins and proteoglycans, and in large follicles the dermal papilla often contains a loop of capillary blood vessels. It is connected to the dermal sheath surrounding the follicle by a narrow stalk. Both the dermal papilla and the dermal sheath are derived from a condensation of mesenchymal cells, which appear at an early stage in follicular embryogenesis. Tissue recombinant studies have shown that the dermal papilla plays an essential part in the induction and maintenance of follicular epithelial differentiation [5–8]. It is responsible for determining the follicle type, so that cultured dermal papilla cells derived from the rat vibrissae follicle induce the formation of a vibrissa-like follicle when implanted into ear skin [9]. The volume of the dermal papilla may also be responsible for controlling the size of the hair follicle, and that of the hair fibre [10,11]. This is of particular relevance to androgen-dependent changes in human hair growth, as the dermal papilla is probably the primary target of androgen action in the hair follicle.

The dermal sheath

The lower part of the hair follicle is enveloped by a collagenous layer known as the dermal or connective tissue sheath. Like dermal papilla cells, fibroblasts of the dermal sheath are specialized. In experimental circumstances, these cells can reconstitute the dermal papilla and induce the formation of new hair follicles in adult human skin [12]. As we move distally along the hair follicle, above the level of the arrector insertion, the dermal sheath becomes less distinct, both structurally and functionally, as it merges with the interfollicular dermis.

The inner root sheath

The inner root sheath consists of three layers (from outermost to innermost): Henle's layer, Huxley's layer and the inner root sheath cuticle. Inner root sheath cells accumulate filaments approximately 7 nm thick and, in contrast with the hair cortex, amorphous trichohyalin granules appear in the cytoplasm. As the cells move up the follicle towards the surface, the filaments become more abundant and the number and size of the granules increase. Each of the three layers of the inner root sheath undergoes abrupt keratinization.

This occurs at different levels in each layer, although the patterns of change are identical. In the hardened cytoplasm, however, only filaments can be seen. The changes occur first in the outermost Henle's layer, then in the innermost cuticle and lastly in Huxley's layer, which is situated between them. Cells of the inner root sheath cuticle become flattened and overlap, with their free edges pointing downwards to interdigitate with the upwards-pointing cells of hair shaft cuticle, thus anchoring the hair shaft within the hair follicle. The inner root sheath hardens before the presumptive hair within it, and it is consequently thought to control the definitive shape of the hair shaft.

The outer root sheath

The outer root sheath forms the most peripheral layer of hair follicle epithelium, enclosing the inner root sheath. At the lower tip of the hair bulb it consists of a single layer of cuboidal cells, becoming multilayered in the region of the upper hair bulb. The cytoplasm of outer root sheath cells is rich in glycogen, giving a clear appearance with routine histological stains. In some follicles, particularly large beard follicles, there is a distinct single cell layer interposed between the outer and inner root sheaths, known as the companion layer [13]. Companion layer cells are flattened along the axis of the follicle and are relatively devoid of glycogen. They show numerous intercellular connections to the inner root sheath and are thought to migrate distally along with the inner root sheath to be lost in the isthmus region. The direction of movement of outer root sheath cells is unclear but they may migrate downwards towards the hair bulb, the companion layer forming the plane of slippage between the inner and outer root sheaths. The outer root sheath of the suprabulbar region merges imperceptibly with the isthmus where the innermost cells undergo tricholemmal keratinization.

The cuticle

The hair cuticle is formed initially as a single cell layer, but the cells become progressively imbricated (tile-like) as they move peripherally. The cells become flattened, first in a direction at right angles to the plane of the follicle, and then becoming progressively angulated so that the outer edges of the cells point in an upward direction. The flattened cells overlap, their free edges directed towards the tip (Fig. 66.5) and interlocking with the cuticle of the surrounding inner root sheath. In the fully formed hair shaft, the cuticle consists of 5–10 overlapping cell layers, each 350–450 nm thick (Fig. 66.6). The mature cells are thin scales consisting of compact cuticular keratin, associated with ultra-high sulphur proteins, which show three distinct layers by transmission electron microscopy: the outer A-layer, which is particularly rich in cystine; the exocuticle (also cystine-rich); and the inner endocuticle, which is virtually devoid of sulphur. The endocuticle has an irregular substructure of membrane-like elements which are probably the remnants of cytoplasmic structures [14]. The outer surface of the cuticle is thought to be coated with long-chain (straight and branched) fatty acids linked to an underlying lipid–protein matrix [15]. This layer is 2–7 nm thick and is known as the fibre cuticle surface membrane or epicuticle. The cuticle has important protective properties. It acts as a barrier to physical and chemical insults, and also maintains the integrity of the hair shaft. Wear and tear

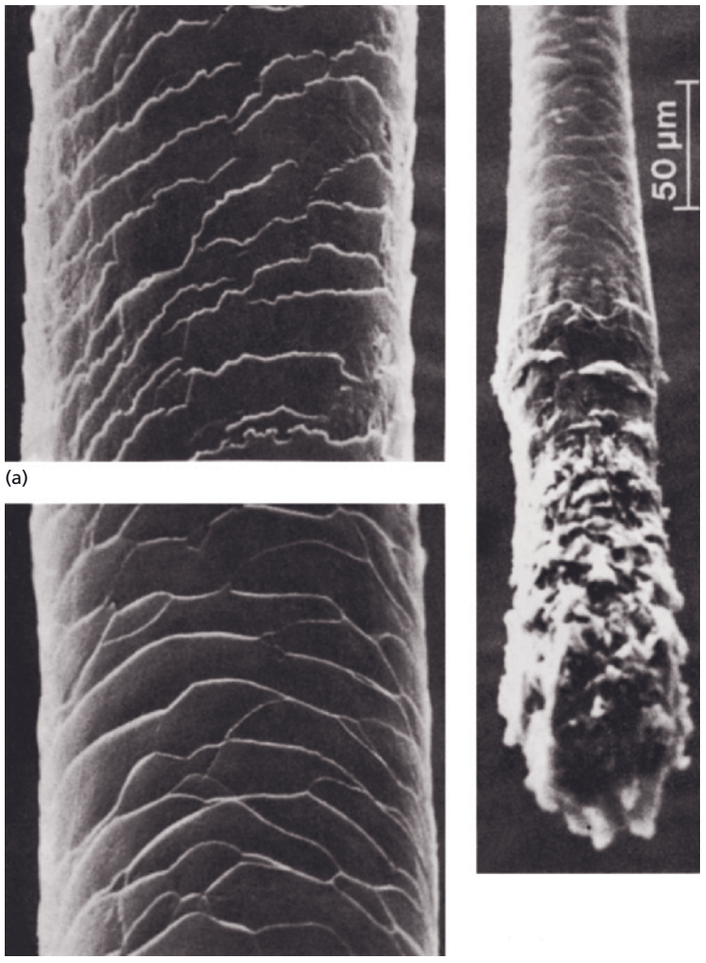

Fig. 66.5 (a) Surface view of weathered cuticular scales in the distal portion of the hair shaft. (b) Surface view of undamaged cuticular scales in proximal part of hair shaft. (Courtesy of Dr D. Jackson, University of Sheffield, Sheffield, UK.)

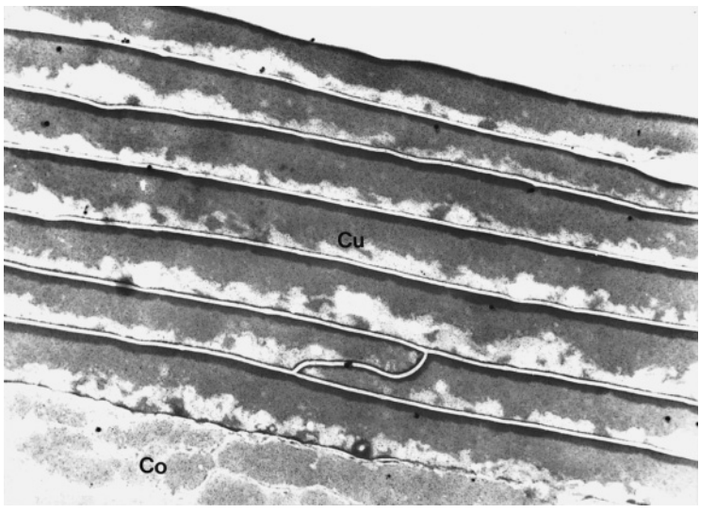

Fig. 66.6 Cross-section through hair shaft showing cuticle layers (Cu) surrounding the central cortex (Co). (Transmission electron micrograph, silver methenamine stain.)

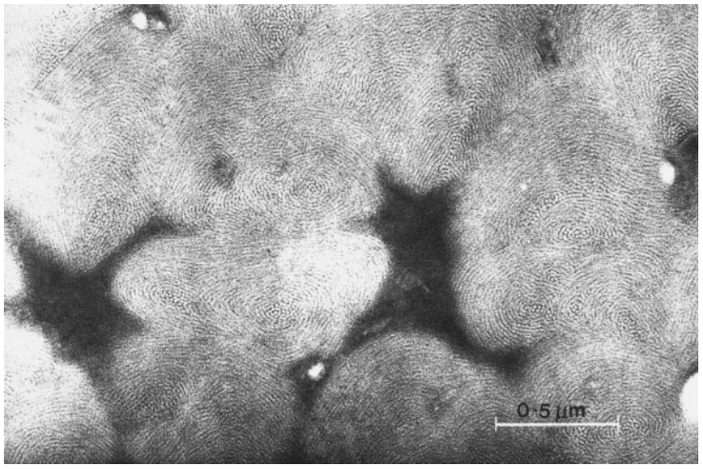

Fig. 66.7 Cross-section of transformed cortical cells of human hair. The relatively translucent filaments, set in a more dense sulphur-rich matrix, appear as concentric lamellae (macrofibrils), giving a characteristic fingerprint pattern.

(e.g. from cosmetic procedures) leads to gradual degradation of the cuticle ('weathering'), with breaking and lifting of the free margins of cuticular cells. Eventually this process may lead to exposure of the cortex and fracture of the hair shaft.

The cortex

Cells destined to form the cortex gradually become more fusiform in shape as they migrate upwards from the hair bulb. They develop a dense filamentous cytoskeleton in the upper hair bulb to become fully hyalinized in the suprabulbar region (the keratogenous zone) (Fig. 66.7). The hard α-keratin intermediate filaments (α-KIF) are the major structural component of the mammalian hair cortex. The molecule in α-KIF is an obligate heteropolymer containing a type I and a type II polypeptide chain [16–18], in which right-handed α-helices coil round one another in a left-handed manner to form a rod-like dimeric structure (a 'coiled coil') (Fig. 66.8). The 8-nm keratin filaments (microfibrils) are formed from multiple α-KIF molecules, on average 16 molecules or 32 chains in cross-section [19]. Keratin filaments are cross-linked to keratin-associated proteins, which form a matrix between the filaments. More than 60 hair keratin-associated proteins have been found in various species. They are classified into three major families: high sulphur, ultra-high sulphur and high glycine–tyrosine proteins [20]. In some species, notably the sheep, the cortex can be divided into two regions: the orthocortex and paracortex, which differ in the arrangement of KIFs and the proportion of keratin-associated proteins. In humans, the hair cortex appears to contain mixtures of KIF arrangements within each cell.

The medulla

The medulla is a variable structure in human hairs, where it may be continuous, discontinuous or absent. Large-diameter hairs are more likely to contain a medulla, although the relationship between hair diameter and medullation is not clear-cut. The medulla develops quite abruptly around the upper pole of the dermal papilla, without any obvious precursor cell population. Medullary cells contain distinctive eosinophilic granules that eventually form internal coatings within the membranes of mature cells. As these

cells develop, arginine residues are converted to citrulline, and isopeptide bonds are formed to yield a highly insoluble protein complex [21]. Mature medulla cells have a spongy structure, with amorphous material bounding air spaces of varying sizes.

Hair follicle innervation

A plexus of longitudinally aligned sensory nerve fibres surrounds the isthmus region. Small nerve fibres may also be arranged in a circular fashion outside the longitudinal fibres. Several different types of nerve endings are found around human hair follicles, including free nerve endings, pilo-Ruffini nerve endings and Merkel nerve endings [22,23]. In other species, lamellated nerve endings are found in richly innervated sinus hair follicles (e.g. vibrissae follicles), which have specialized sensory function [23]. Merkel cells, with or without associated nerve endings, may be found within the bulge region epithelium and the surrounding connective tissue sheath, and it has been postulated that their secretions are involved in regulating the hair cycle [24].

The hair cycle (Fig. 66.9)

Hair follicles undergo a repetitive sequence of growth and rest known as the hair cycle. The timing of the phases of the hair cycle and its overall duration varies between species, between follicles in different regions of the skin in the same species and, in some animals, between different follicle types, such as guard hairs and underhairs, in the same region of the skin.

The period of active hair growth is known as *anagen* and the duration of this phase is responsible for determining the final length of the hair. In most hair follicles in most animals, anagen

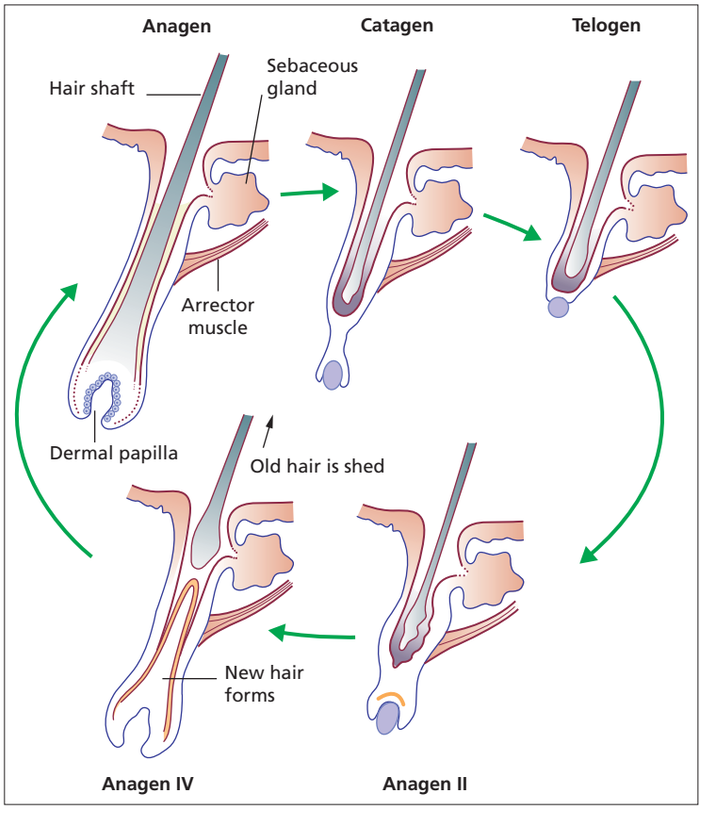

Fig. 66.9 The hair cycle. (From *Disorders of Hair Growth*, McGraw-Hill.)

is relatively brief, lasting a few weeks at most. In some hair follicles, such as those on human scalp, the horse's tail and wool follicles in the merino sheep, anagen may continue for several years, so that very long hairs are produced. Under normal circumstances, 80–90% of hair follicles on the human scalp are in anagen at any one time.

The entry of a resting hair follicle into anagen is heralded by the onset of mitotic activity in epithelial cells overlying the dermal papilla at the base of the follicle (the secondary epithelial germ). In most follicle types (vibrissa follicles are an exception), the lower part of the follicle elongates downwards along a preformed dermal tract (the stele). The developing hair bulb partly envelops the dermal papilla, and epithelial cells start to differentiate to form the inner root sheath and the hair shaft (Fig. 66.10). The dermal papilla expands from a tightly packed ball of cells into a flask-shaped structure where the cells become separated by an extracellular matrix rich in proteoglycans and basement-membrane proteins. A network of capillary blood vessels develops around the lengthening follicle, extending into the dermal papilla in larger follicles. In the fully developed anagen follicle, epithelial cells in the hair bulb undergo vigorous proliferative activity. Their progeny move distally and differentiate in an ordered fashion to form the layers of the inner root sheath and the hair shaft. At the end of anagen, epithelial cell division declines and ceases, and the follicle enters an involutionary phase known as *catagen*. During catagen, the proximal end of the hair shaft keratinizes to form a club-shaped structure and the lower part of the follicle involutes by apoptosis (Fig. 66.11). The basement membrane surrounding the follicle

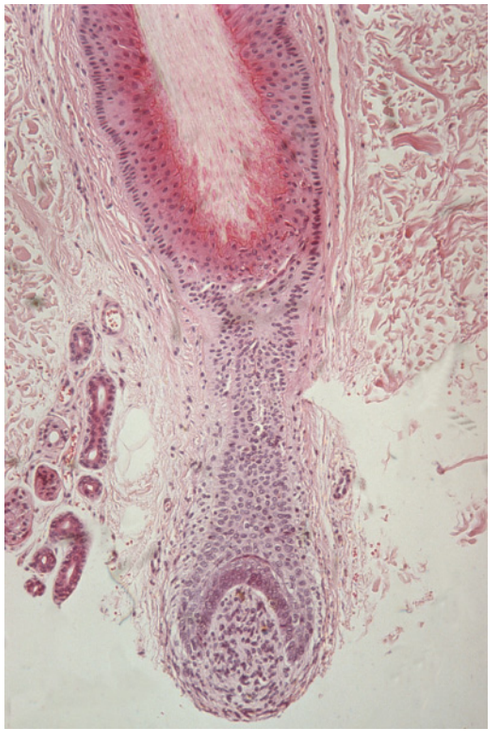

Fig. 66.10 Scalp hair follicle in Anagen 2 stage of development. The club hair from the previous cycle is still present within the follicle. (Courtesy of Dr A.J.G. McDonagh, Royal Hallamshire Hospital, Sheffield, UK.)

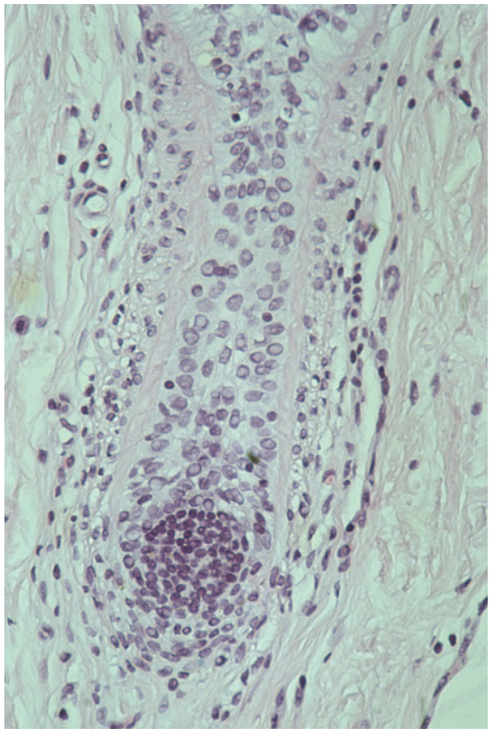

Fig. 66.11 Human hair follicle in mid-catagen. There is a prominent glassy membrane surrounding the regressing epithelial column. The dermal papilla has rounded and condensed. (Courtesy of McGraw-Hill.)

becomes thickened and corrugated to form the 'glassy membrane'. The base of the follicle, together with its dermal papilla, moves upwards, eventually to lie just below the level of the arrector insertion. The period between the completion of follicular regression and the onset of the next anagen phase is termed *telogen*. The club hair lies within an epithelial sac to which it is attached by tricholemmal keratin. The club hair is eventually shed through an active process termed *exogen*. In many species, follicles re-enter anagen prior to shedding of the club hair so that the old hair is not shed until the follicle is well into its next growth phase. This may also be seen in human follicles although it is unusual for a club hair to be retained much beyond the mid-stage of anagen development. In human scalp, hair follicles may remain in a state of latency, also known as *kenogen*, for a prolonged period after the club hair is shed [1].

Control of the hair cycle

It is thought that hair cycling is controlled primarily within individual hair follicles but that this intrinsic rhythmic behaviour may be modulated by both local and systemic factors. In most mammals, including humans, hair cycles are coordinated in a wave-like fashion (moult waves) across regions of the skin in the neonatal period. Moult waves are regulated within the skin and are accompanied by changes in other skin structures, such as epidermal and dermal thickness. In many mammals, living in their natural environment in temperate and higher latitudes, moult waves continue into adult life and occur on a seasonal basis. This allows adaptation of the thickness of the coat, and sometimes its colour, to different climatic conditions in summer and winter (Fig. 66.12). In humans, synchronous hair cycling is lost rapidly with increasing age so that, beyond the neonatal period, hair follicles cycle independently of their neighbours. In these circumstances, hair cycling must be regulated by mechanisms intrinsic to the hair follicle.

Seasonal hair growth

Seasonal moulting is regulated by the endocrine system under the influence of environmental signals. The most important of these

Fig. 66.12 Bactrian camel in spring moult.

is change in day length (the photoperiod) [2,3]. Temperature may act as a modifying factor in some species. Changing levels of melatonin production by the pineal gland have a key role in orchestrating endocrine control of seasonal hair growth [4–6]; pinealectomy prevents seasonal moulting, whereas administration of melatonin advances onset of the growth of the winter coat and prevents growth of the summer coat. Prolactin production by the pituitary correlates inversely with melatonin levels, being raised during the summer and falling during the winter. Pinealectomy abolishes the fall in prolactin level in animals kept in short day length conditions and prevents the development of the winter coat [7]. The same response is seen in animals treated with prolactin. Prolactin receptors have been identified in the hair follicle, suggesting that prolactin can affect hair growth directly [8]. Pineal and pituitary hormones may also act indirectly by modulating the activity of peripheral endocrine glands. In rats, oestradiol, testosterone and adrenal steroids delay the onset of anagen, whereas gonadectomy and adrenalectomy have the opposite effect [9]. Conversely, thyroid hormones accelerate the onset of follicular activity, whereas thyroidectomy or treatment with propylthiouracil delays it. Seasonal moults are also delayed by testosterone and accelerated by thyroxine in other species [10]. Hormones also act on the anagen phase of hair growth [9]. Oestradiol and thyroxine both reduce the duration of anagen in rats, but oestradiol decreases the rate of hair growth, whereas thyroxine has the opposite effect, suggesting these hormones have different points of action. In the mouse, oestrogen receptors are expressed in the dermal papilla and the inhibitory effect of exogenous oestrogen on hair growth is prevented by topical treatment with an oestrogen receptor antagonist [11].

Vestiges of seasonal variation in hair growth are present in humans [12], although the magnitude is seldom sufficient to be noticeable. The best example of a systemic influence on the human hair growth cycle is pregnancy (Fig. 66.13) [13]. During pregnancy,

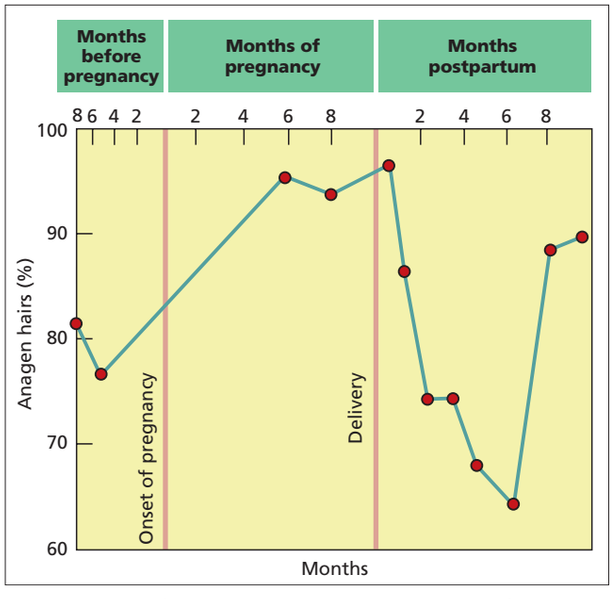

Fig. 66.13 Percentage of anagen hairs in a 25-year-old woman before, during and after pregnancy. (From Lynfield [13].)

there is an increase in the proportion of follicles in anagen, although it is not clear whether this is caused by prolongation of anagen or more rapid shedding of telogen hairs, as there is also a reduction in hair density during the second and third trimesters [14]. Following childbirth, large numbers of follicles enter telogen, leading to increased shedding from about 3 months postpartum (postpartum telogen effluvium). Telogen shedding may also be caused by a number of drugs and by febrile and other catabolic illnesses [15].

Intrinsic control of the hair growth cycle

Although local and systemic factors modulate the hair cycle in some species, in humans and some other mammals hair cycling is asynchronous. Hair follicles in different regions of the skin may also cycle differently. In humans, for example, the duration of anagen on the scalp may last several years, whereas on the eyebrows anagen is very brief. Even in animals showing seasonal hair growth, hair cycles in different follicle types in the same skin region are not necessarily in phase. When scalp hair follicles are transplanted into other regions of the skin they retain the cyclical behaviour of the donor site, indicating that cycle control is determined within the follicle or its immediate tissue environment. Interactions between two key cell populations in the hair follicle, epithelial stem cells in the outer root sheath and mesenchymal cells in the dermal papilla and dermal sheath, are thought to underlie intrinsic control of hair cycling, and a large number of molecules have been implicated in this process. However, the location and the nature of the 'switch' that initiates and terminates anagen growth are unknown.

It has been known for many years that plucking of resting hairs from telogen follicles advances the onset of anagen. This led to the idea that the hair cycle is controlled by a locally active inhibitor which accumulates during anagen causing entry into catagen when present in sufficient concentration (the chalone hypothesis) [16]. The putative inhibitor would disperse during telogen, and plucking resting hairs could accelerate this process. The chalone hypothesis has been disputed because the plucking of resting hairs from follicles that have already entered anagen does not prolong the anagen in progress, although it does advance the onset of the next anagen cycle [9]. There is one report that murine skin contains a factor that inhibits hair growth *in vivo* and *in vitro* [17]. This inhibitory factor appeared to be derived from the epidermis and was present in telogen skin but not in anagen skin.

Cotsarelis *et al.* [18] suggested that anagen is initiated by signals from the dermal papilla which stimulate mitosis in stem cells in the bulge region of the outer root sheath (the bulge activation hypothesis). As transient amplifying cells, daughter cells have a limited mitotic potential. When this is exhausted, hair growth ceases and the follicle enters catagen, thus determining the duration of anagen and the onset of catagen.

Molecular control of hair cycling [19]

A large number of molecular signals are involved in controlling the hair cycle (Table 66.2). These include developmental genes, several families of growth factors and their receptors, transcription factors, nuclear receptors, neurotrophins, cytokines and intracellular signalling pathways. These factors interact to form

Table 66.2 Molecular mediators of hair cycle control.

Growth factor	Location	Function
FGF5	ORS	Terminates anagen [21]
FGF7 (KGF)	DP	Induces hair growth in athymic nude mice [32]
		Hair shaft defect in KGF-deficient mice [33]
EGF/TGF-α		Inhibits hair development and growth [34,35]
		Stimulates ORS proliferation *in vitro* [36]
EGF-R	Hair bulb and ORS	Wavy hair in EGF-R deficient mice [37]
TGF-α		Wavy hair in TGF-α deficient mice [38]
TGF-β1, 2, 3		Inhibits hair growth *in vitro* [39]
		TGF-β mRNA expressed in skin during anagen/catagen transition [24]
TGF-β receptors		TGF-β receptors expressed in hair follicle—maximal during anagen/catagen transition [40]
		Delayed catagen in TGF-β1 null mice [41]
IGF-1	DP, hair bulb	Maintains hair follicle growth *in vitro* [42]
IGF-1 receptors	DP, pre-cortex, ORS	Down-regulated in catagen [43]
IGF BP-3, -4, -5	DP and DS [44]	
HGF		Stimulates hair growth when injected into mouse skin [45]
		Expression in skin varies during hair cycle: high in anagen, low in telogen [46]
VEGF	DP, ORS	Probably regulates perifollicular angiogenesis; increased follicle size in transgenic mice which overexpress VEGF in ORS; systemic VEGF antibody retards hair growth in mice [47]
IL-1α, IL-1β		Inhibits hair growth *in vitro* [48]
TNF-α		Inhibits hair growth *in vitro* [48]; TNF-α receptor mRNA expression increased in late anagen [43]
Sonic hedgehog (SHH)		Overexpression in skin accelerates entry into anagen [49]
		SHH antibody inhibits pelage (but not vibrissae) follicle development in mice; inhibits anagen in postnatal cycles [50]
Hairless		Required for normal catagen [25]
PTHrp	Follicle epithelium	Inhibits initiation and maintenance of anagen; PTHrp antagonist induces and prolongs anagen [51]
RXR		Required for normal catagen? [29]
Vitamin D receptor	DP, ORS	Variable expression during hair cycle [52]
		Alopecia in vitamin D receptor knockout mice [28] and in human vitamin D-resistant rickets [53]
Oestrogen receptor	DP	Oestrogen inhibits hair growth in mice [11]
		ER-beta expressed in human hair follicles [54]
Neurotrophins	Follicle epithelium	NGF, brain-derived neurotrophic factor, neurotrophin-3, neurotrophin-4, and p75 neurotrophin receptor, TrkB receptors promote progression of catagen [55]
Mast cells		Increased degranulation at end of anagen and fall in number during telogen; may be involved in control of catagen [56]

DP, dermal papilla; DS, dermal sheath; EGF, epidermal growth factor; FGF, fibroblast growth factor; HGF, hepatocyte growth factor; IGF, insulin-like growth factor; IGF BP, IGF binding proteins; IL-1, interleukin-1; KGF, keratinocyte growth factor; ORS, outer root sheath; PTHrp, parathyroid hormone-related peptide; RXR, retinoid X receptor; TGF, transforming growth factor; TNF, tumour necrosis factor; VEGF, vascular endothelial growth factor.

signalling networks and their activity may also be modulated by interactions with extracellular matrix molecules that serve to increase or reduce the biological response.

Telogen. The growth factor bone morphogenetic protein-4 (BMP-4) appears to play an important role in suppressing follicular growth and differentiation during telogen, and it may be the inhibitor identified by Paus [17]. BMP-4 is produced in the dermal papilla and may interact with the receptor BMPR-IA, which is expressed by keratinocytes in the secondary epithelial germ. BMP-4 treatment prevents entry into anagen of murine follicles induced by plucking, whereas administration of the BMP-4 antagonist noggin accelerates the onset of anagen [20]. In the mouse, there is also increased expression of oestrogen receptors in the dermal papilla during telogen, and topical administration of an oestrogen receptor antagonist causes premature entry of resting follicles into anagen [11], suggesting that oestrogen is involved in maintaining telogen, presumably acting by a paracrine or autocrine mechanism.

Anagen. The transition of telogen follicles into anagen is associated with activation of Wnt/beta-catenin/Lef1, Sonic Hedgehog (Shh) and STAT3 pathways, and down-regulation of BMP signalling [19]. Other growth factors involved in promoting anagen include insulin-like growth factor 1 (IGF-1), hepatocyte growth factor, keratinocyte growth factor and vascular endothelial growth factor. Anagen development is a time of extensive remodelling of the follicle and its tissue environment. Follicles grown *in vitro* synthesize a variety of metalloproteinases, suggesting that this process involves degradation of the surrounding extracellular matrix. Hair follicles also express tissue inhibitor of matrix metalloproteinase 3 (TIMP-3) in the outer root sheath during anagen, implying that remodelling involves a carefully controlled sequence of positive and negative influences.

Catagen. The end of anagen and transition into catagen is a key period in the hair cycle, as its timing determines the final length of the hair. Catagen may be initiated as a passive process through exhaustion of the mitotic potential of transient amplifying cells in the hair bulb or the loss of action of growth promoting agents. Also, several growth factors and cytokines, including transforming growth factor-β (TGF-β), interleukin-1α (IL-1α) and tumour necrosis factor-α (TNF-α) have an inhibitory effect on hair growth and may be actively involved in triggering catagen. Transgenic mice with a null mutation in the gene for fibroblast growth factor 5 (*FGF5*) show a delay in the onset of catagen and grow abnormally long hair. The phenotype is identical to the naturally occurring *angora* mouse which has a mutation in the *FGF5* gene, suggesting that this growth factor has an active role in terminating anagen [21]. *FGF5* is expressed in the outer root sheath towards the end of anagen, in keeping with this idea. However, although anagen is delayed in *FGF5*-deficient mice, it is not delayed indefinitely, indicating that other factors must also be involved. The ectodysplasin signalling pathway is involved in regulating apoptosis during catagen, in addition to its role in hair follicle development [22].

Catagen proceeds in an orderly fashion as cells are deleted from the regressing epithelial column by apoptosis. The expression levels of several proto-oncogenes associated with apoptosis, including c-*myc*, c-*jun* and c-*myb*, change immediately prior to or coincident with the onset of catagen [23]. The apoptosis-inhibitory proto-oncogene *bcl*-2 is expressed in cycling follicular epithelium during anagen, disappears during catagen and is absent in telogen. *Bcl*-2 is expressed in the dermal papilla throughout the hair cycle, suggesting a possible protective role in this site [24]. For the follicle to maintain the ability to cycle, it must maintain its integrity during catagen regression. In the *hairless* mouse, the first coat develops normally but the pelage is then lost. Towards the end of the first anagen phase, cells in the hair bulb undergo extensive premature apoptosis, and formation of the epithelial column is disrupted during catagen. The dermal papilla loses contact with the base of the hair follicle epithelium and the follicle is unable to re-enter anagen. Follicular remnants subsequently undergo cystic degeneration [25]. A similar pattern of hair loss is seen in the human disorder atrichia with papular lesions, in which there is a mutation in the human homologue of the mouse *hairless* gene [26]. The function of *hairless* in the hair follicle is not fully established but there is some evidence that it acts as a co-repressor of the thyroid receptor (TR) [27]. Atrichia with papules also occurs in some families with vitamin D-resistant rickets [28], which is caused by a mutation in the vitamin D receptor (VDR) gene. Like the TR, the VDR is a transcription factor and a member of the nuclear hormone receptor superfamily. Both TR and VDR bind to response elements in target genes as heterodimers with the retinoid X receptor (RXR), another nuclear hormone receptor. Transgenic mice with a null mutation in the RXR gene also show a *hairless* phenotype [29], suggesting there is a common pathway involving nuclear hormone receptors that regulates entry into catagen.

Exogen. Release of the club hair from the follicle, a process that has been termed *exogen* [30], does not necessarily coincide with re-entry of the follicle into anagen, and this has led to the idea that shedding is controlled separately from the hair cycle. The club root lies embedded in tricholemmal keratin and its release presumably requires local proteolysis. The cells surrounding the club root are also rich in desmosomes. Transgenic mice with a null mutation in the gene for the desmosomal protein desmoglein 3 show defective anchorage of the club hair [31].

Role of the immune system in hair cycling

Cells in the lower part of the hair follicle, below the arrector insertion, show reduced or absent expression of class I major histocompatibility complex (MHC) molecules [57]. In rat skin the expression of class I MHC in follicular epithelium increases during catagen, and this is associated with a perifollicular accumulation of activated macrophages and loss of the proteoglycan-rich extracellular matrix [58]. These observations led to the suggestion that an immune process mediated by macrophages contributes to control of the hair cycle, but other studies have failed to confirm these findings [59]. However, there is experimental support for the idea that the lower part of the hair follicle is an immunologically 'privileged' site not subject to classic immune surveillance [60,61]. This is relevant to disease states, such as alopecia areata, which may be explained by a breakdown of putative immune privilege.

Rate of hair growth

The rate of hair growth varies from species to species, and within one species from region to region, as well as with sex and age. For example, in the rat it can be more than 1 mm/24 h [62] and in the guinea pig up to 0.6 mm/24 h, whereas in humans it is much less. The rate has been determined by direct measurement of marked hairs *in situ* [63], by shaving and clipping at selected intervals [64,65] or by pulse labelling with ^{35}S-cysteine [66,67]. Most investigators now use macrophotographic methods (phototrichography), which may be analysed using computerized systems. Comparable measurements are obtained by all methods. The average rate of growth of human hair has been stated to be approximately 0.03 mm/24 h for the vellus on the male forehead [68], 0.21 mm/24 h on the female thigh and 0.38 mm/24 h on the chin of a young male. On the crown of the scalp it averaged approximately 0.5 mm/24 h, being slightly less on the margins. In another study in which graduated capillary tubes were fitted around the growing hairs, the average growth in males was as follows: vertex 0.44 mm/24 h; temple 0.39 mm/24 h; chest 0.44 mm/24 h; beard 0.27 mm/24 h [69]. The average rate on the vertex of women was 0.45 mm/24 h, and there were no variations diurnally or during the menstrual cycle. Although scalp hair grows faster in women than in men [69,70], the rate before puberty is greater in boys than in girls [71].

There is agreement that shaving has no effect on the rate of growth [69,72]. Various endocrine factors have been shown to influence the rate of hair growth in animals; for example, oestrogens reduce it [62,73] and thyroxine increases it [74].

Androgens and hair growth

Androgens influence hair growth in several ways. Firstly, they participate in the endocrine control of moulting in animals that show seasonal hair growth [1]. Secondly, in some mammals, androgens stimulate the growth of hair follicles in certain regions of the skin following sexual maturity. Thirdly, in humans and some other primates, androgens are necessary for the development of balding on the scalp.

Androgen-stimulated hair growth

The growth of obvious facial, trunk and extremity hair in the male, and of pubic and axillary hair in both sexes, is dependent on androgens. The development of such hair at puberty is, in broad terms and at least initially, in parallel with the rise in levels of androgen from testicular, adrenocortical and ovarian sources, which occurs in both sexes and is somewhat steeper in males. That testosterone from the interstitial cells of the testis is responsible for growth of beard and body hair in male adolescence and that testicular activity is itself initiated by gonadotrophic hormones of the pituitary is unquestioned. However, the findings that growth-hormone-deficient boys and girls are less than normally responsive to androgens, and that growth hormone is necessary as a synergistic factor to allow testosterone to be fully effective with respect to hair growth [2], as well as protein anabolism and growth promotion, suggest that hypophysial hormones also have a more direct role. Direct evidence of the role of testicular androgen is that castration reduces growth of the human beard [3], whereas testosterone stimulates it in eunuchs and elderly men. The role of androgen is further demonstrated in the treatment of hirsute women with the antiandrogen cyproterone acetate [4], which reduces the definitive length, rate of growth, diameter and extent of medullation of the thigh hairs [5].

At puberty, terminal hair gradually replaces vellus, starting in the pubic regions. In both sexes the first pubic hair is sparse, long, downy, slightly pigmented and almost straight. It later becomes darker, coarser, more curled and extends in area to form an inverse triangle. A British study showed that boys had the first recognizable pubic hair at an average age of 13.4 years, and the full adult 'male' pattern at 15.2 years, approximately 3.5 years after the start of development of the genitalia [6]. The corresponding mean ages for girls were considerably earlier, namely 11.7 years and 13.5 years [7]. In approximately 80% of men and 10% of women the pubic hair continues spreading until the mid-twenties or later; there is no absolute distinction between male and female patterns, only one of degree.

Axillary hair first appears approximately 2 years after the start of pubic hair growth. The amount, as measured by the weight of the fully grown mass, continues to increase until the late twenties in males as well as in females, in whom, however, it is less at any age [3]. The mean amounts grown per day increase from late puberty until the mid-twenties and thereafter decrease steadily.

Facial hair in boys first appears at about the same time as the axillary hair, starting at the corners of the upper lip, and spreading medially to complete the moustache and then the cheeks and beard.

Terminal hair development is continued in regular sequence on the legs, thighs, forearms, abdomen, buttocks, back, arms and shoulders [8]. The extent of terminal hair tends to increase throughout the years of sexual maturity, but most patterns occur over a wide age range. The adult pattern is not achieved until the fourth decade, when the androgen levels are already somewhat lower than in early adult life. Moreover, aural hairs do not appear until late middle age, and a study of coarse sternal hair in men showed that the hairs continue to increase in length and number from puberty to the fifth or sixth decade.

There is considerable racial variability in androgen-dependent hair growth. The growth of facial and body hair is greater in European men than in Chinese men [3] and there is also variation within these broad racial categories—southern European men tend to be hairier than men from northern Europe [9].

Androgenetic alopecia

It has been known since ancient times that eunuchs do not go bald. Hippocrates noted that 'eunuchs are not subject to gout nor do they become bald' (Aphorisms VI, 28). The role of testosterone in male balding was first recognized by James Hamilton, an American anatomist [10]. He observed that men castrated before puberty

retain a prepubertal hairline and do not go bald. Of 12 such men who were treated with testosterone, four developed typical male hair loss. Castration later in life halted the progression of hair loss but did not result in regrowth of hair.

The prevalence and severity of male balding increase with age. All races are affected but the prevalence is higher in white males, reaching at least 80% in men aged over 70 years, than in African American [11] and in Japanese men [12]. Chinese and Korean men are also less likely to show frontal recession [13,14].

It has long been recognized that male balding runs in families. Twin studies confirm there is a strong genetic element to male balding with concordance rates of 80–90% in monozygotic twins and consistently lower rates in dizygotic twins [15–17]. There is an association between male balding and a variant region in the androgen receptor gene (AR) [18,19], but this does not explain the strong paternal influence on balding [20] as the AR gene is on the X chromosome and inherited from the mother.

The loss of hair in male balding is the result of a gradual reduction in the duration of anagen and a prolongation of the latent period of the hair cycle [21], and miniaturization of terminal hair follicles [22].

Androgen synthesis and metabolism

The initial stages in the synthesis of steroid hormones from cholesterol occur exclusively in the gonads and the adrenal glands. Circulating androgens are also derived from the peripheral conversion of weak precursor hormones into potent androgens, a process that takes place in many tissues including the skin and hair follicles. The majority of androgens in the circulation are bound to plasma proteins, principally sex hormone-binding globulin (SHBG), with approximately 20% bound to albumin. The remaining 1–2% circulates in a free unbound form and this comprises the biologically active pool. Androgen bound to albumin dissociates readily and can replenish the free pool. SHBG binds androgen with high affinity and its plasma concentration therefore has an important effect on the free and albumin-bound pools. High levels of SHBG reduce the biologically active androgen level and low levels of SHBG have the reverse effect. Free androgen is thought to enter cells by passive diffusion, where it binds to a specific intracellular androgen receptor.

Testosterone is the major circulating androgen, but in most body sites the effect of testosterone on hair growth is mediated by its more potent metabolite 5α-dihydrotestosterone (DHT). The conversion of testosterone to DHT is catalysed by the enzyme 5α-reductase. There are two isoforms of 5α-reductase, which are encoded by different genes [23]. Although both enzymes catalyse the conversion of testosterone to DHT they differ in their pH optima, substrate affinities and tissue distributions. Type 1 5α-reductase is widely distributed in the skin, but expression of the type 2 isoform is restricted to androgen target tissues such as the prostate and the epididymis. Much of our knowledge of the biological role of DHT in hair growth comes from studies of men with 5α-reductase deficiency (type II pseudohermaphroditism, pseudovaginal perineoscrotal hypospadias) [18,19], which is caused by mutations in the 5α-reductase 2 gene [24]. In this autosomal recessive disorder, genetic males (46XY) are born with normally differentiated but usually undescended testes. The external genitalia are ambiguous, with a small hypospadic phallus, a bifid scrotum and a blind vagina. Partial virilization of the genitalia occurs at puberty, the voice deepens and the musculature assumes a typical male distribution. Circulating testosterone levels are within or above the normal male range but DHT levels remain low, with testosterone : DHT ratios 3.5–5 times higher than normal. Subjects show a female pattern of androgen-dependent hair growth, with terminal hair largely restricted to the axillae and the lower pubic triangle, suggesting that hair growth in these sites responds to less potent androgens. In the large group of subjects studied in the Dominican Republic, beard growth was absent or sparse. More facial hair has been observed in affected men from other parts of the world, perhaps reflecting underlying racial differences in normal androgen-dependent hair growth, although this was reduced compared with normal males in the same communities. None of the cases studied has shown temporal recession of the hairline or balding. A role for DHT in balding is supported by studies in macaques in which treatment with 5α-reductase inhibitors prevented the development of balding [25] or increased scalp hair growth in balding animals [26], and a large clinical trial of the 5α-reductase type 2 inhibitor finasteride in balding men. This latter study showed that the progression of balding was prevented in almost all men taking finasteride orally, and about two-thirds showed an increase in hair growth [27].

Hair follicles possess 5α-reductase activity, suggesting that DHT acts as a paracrine or intracrine hormone (it is synthesized within or close to the target cell). It is possible that circulating DHT also contributes to androgen effects on hair growth. Other steroid-metabolizing enzymes, including 3β- and 17β-hydroxysteroid dehydrogenase which interconvert weak and potent androgens, and aromatase which converts androgens to oestrogens, are also expressed in the hair follicle [28,29], but their role in hair growth is not currently known.

The androgen receptor

The tissue effects of androgens are mediated through binding to the intracellular androgen receptor. The androgen receptor is a nuclear hormone receptor [30], and like other members of the nuclear hormone receptor superfamily it acts as a gene transcription factor following ligand binding. Mutations in the androgen receptor gene are responsible for the androgen insensitivity syndrome [31]. Individuals with the complete form of the syndrome, in which there is failure of functional androgen receptor expression, have intra-abdominal testes but female external genitalia, breast development and psychosocial development. After puberty, circulating testosterone is in the normal or elevated male range but pubic and axillary hair fail to develop, there is no beard growth and no balding.

Mechanism of androgen action on the hair follicle

Hamilton [10] reported that balding did not progress following castration in older men but neither did it promote regrowth of hair. Similarly, although beard growth was prevented by castration before puberty and stimulated by subsequent treatment with testosterone, there was only partial regression of the beard in postpubertal men castrated before the age of 20 years and no effect in older men [3]. Hamilton's observations were relatively crude

by modern standards and it is now clear from clinical trials of 5α-reductase inhibitors that some reversal of male balding is possible. However, the response is far from complete, indicating that androgens induce changes in gene expression in hair follicles that are only partially reversible in the absence of androgen and probably not at all once these changes are fully expressed.

The specificity of the response of hair follicles to androgens is determined within the skin. Hair follicles in occipital skin, a site that shows little or no response to androgens, retain their site-specific behaviour when transplanted into balding areas on the frontal scalp [32]. Conversely, hair follicles from balding scalp continue to regress when transplanted into skin of the forearm [33]. The success of micrografting techniques, in which individual follicles are transplanted, shows that androgen responsiveness is determined at the level of the follicle or its immediate tissue environment. Three lines of evidence suggest that the dermal papilla is the primary target of androgen action in the hair follicle.

1 Androgen receptor expression in the lower part of the follicle is restricted to dermal papilla cells [34,35].
2 The size of the hair follicle is probably determined by the volume of the dermal papilla [36,37].
3 Dermal papillae express 5α-reductase type 2 whereas hair follicle epithelium expresses only 5α-reductase type 1 [38].

Androgens may act on hair growth by altering the number of cells in the dermal papilla and its extracellular matrix [37]. Cells cultured from dermal papillae of human beard hair follicles also release growth factors in response to androgens that stimulate proliferation of keratinocytes [35,39], and the pattern of androgen metabolism by cultured and intact dermal papilla cells is consistent with that expected from their site of origin [40,41]. There is one report that dermal papilla cells grown from balding scalp follicles secrete TGF-β in the presence of testosterone [42]. TGF-β is a growth factor known to inhibit hair growth [43]. Hence the variable response of hair growth to androgens may reflect site-dependent differences in the types of growth factors produced by the dermal papilla.

Alopecia

Introduction

When assessing a patient for alopecia it is important to establish whether the hair loss is due to loss of hair follicles, alteration in hair cycling or fracture of the hair shaft.

Fractured hair shafts are usually visible as a short stubble of hair on the surface of the scalp. It may be patchy or generalized. Most hair shaft disorders are congenital, but may not be clinically apparent until the second or third post-natal moult wave when the child is around 12 months old. Tinea capitis is an acquired form of hair shaft fracture.

Alterations in the hair cycle with premature termination of anagen growth is a feature of alopecia areata, androgenetic alopecia, telogen effluvium and anagen effluvium. Follicular ostia remain visible on close inspection of the scalp and are best seen with a hand-held epiluminescent microscope. In alopecia areata there are patches of hair loss where the scalp is completely bald with the exception of the occasional exclamation mark hair. In androgenetic alopecia hairs shorten and ultimately disappear in a characteristic pattern across the scalp. Telogen effluvium leads to generalized hair shedding and a diffuse reduction in hair volume, but the shedding is never so severe as to render the scalp bald. In contrast, the shedding associated with anagen effluvium commonly leads to total alopecia.

Complete loss of hair follicles is a feature of scar tissue following wounding, primary cicatricial alopecias and congenital follicular agenesis. Follicullar ostia are lost and the scalp is smooth and shiny. Most acquired cicatricial alopecias produce patches of baldness.

Common baldness and androgenetic alopecia

R.D. Sinclair, pp. 66.16–66.31

Synonyms
- Male pattern hair loss
- Female pattern hair loss
- Patterned or premature baldness

Nomenclature. Common baldness is the result of a progressive, patterned hair loss that occurs when genetically predisposed individuals are exposed to androgens. The lack of balding in eunuchs, pseudohermaphrodites and individuals with androgen insensitivity syndrome confirms that androgens are a prerequisite for common baldness. As the pattern of hair loss differs between men and women, the terms male pattern hair loss and female pattern hair loss are also commonly used [1]. Whether someone is considered bald, and in particular prematurely bald, is in part a subjective assessment. The process by which common baldness occurs is androgen-mediated conversion of susceptible terminal hairs into vellus hairs, and has been termed androgenetic alopecia (AGA).

Aetiology. Four separate but interrelated factors determine whether an individual will become bald: susceptibility to AGA, age of onset, rate of progression and pattern of hair loss. Among men, susceptibility to AGA is near universal, and variations in baldness are largely explained by the other three factors.

Hamilton [2] defined the progressive pattern of male baldness and produced the first useful grading scale. This classification was modified by Norwood [3], who added grades IIIa, III vertex, IVa and Va (Fig. 66.14). Although the grades are imprecise measures of the continuum of hair patterns that are seen in adult males, they are useful as diagnostic aids and in the classification of extent of hair loss in clinical investigations.

Prepubertal boys universally have a straight frontal hairline. By the age of 20 over 90% of men demonstrate some degree of frontoparietal recession of the hairline [2]. As the histology of this hair loss shows increased vellus hairs, and as Hamilton observed that three males castrated at the age of 15 and 16 years failed to develop even minimal recession along the frontal hairline, it is likely that this hair loss occurs by androgen-mediated miniaturization of terminal follicles, and by definition is AGA [4]. However, 6% of 80-year-old men still have stage I hair density. Therefore, limited frontoparietal AGA does not always progress, and may be a benign manifestation of sexual maturity rather than a precursor of male pattern baldness (MPB).

The lifetime risk of MPB (as opposed to AGA) can be defined by studying hair patterns in men aged 80 years and above. In Norwood's cohort [3], 16% had a type I hair pattern, and by definition are not bald despite many demonstrating at least some degree of bitemporal AGA. Fourteen per cent had a type 2 hair pattern, with a moderate degree of bitemporal AGA, but would not be considered bald. The remaining 70% had a type III (16%), IV (12%), V (12%), VI (13%) or VII (17%) pattern of hair loss and would be considered to be balding.

The age of onset of MPB is highly variable. If early MPB is defined as stage II hair pattern, then 40% begin to develop MPB

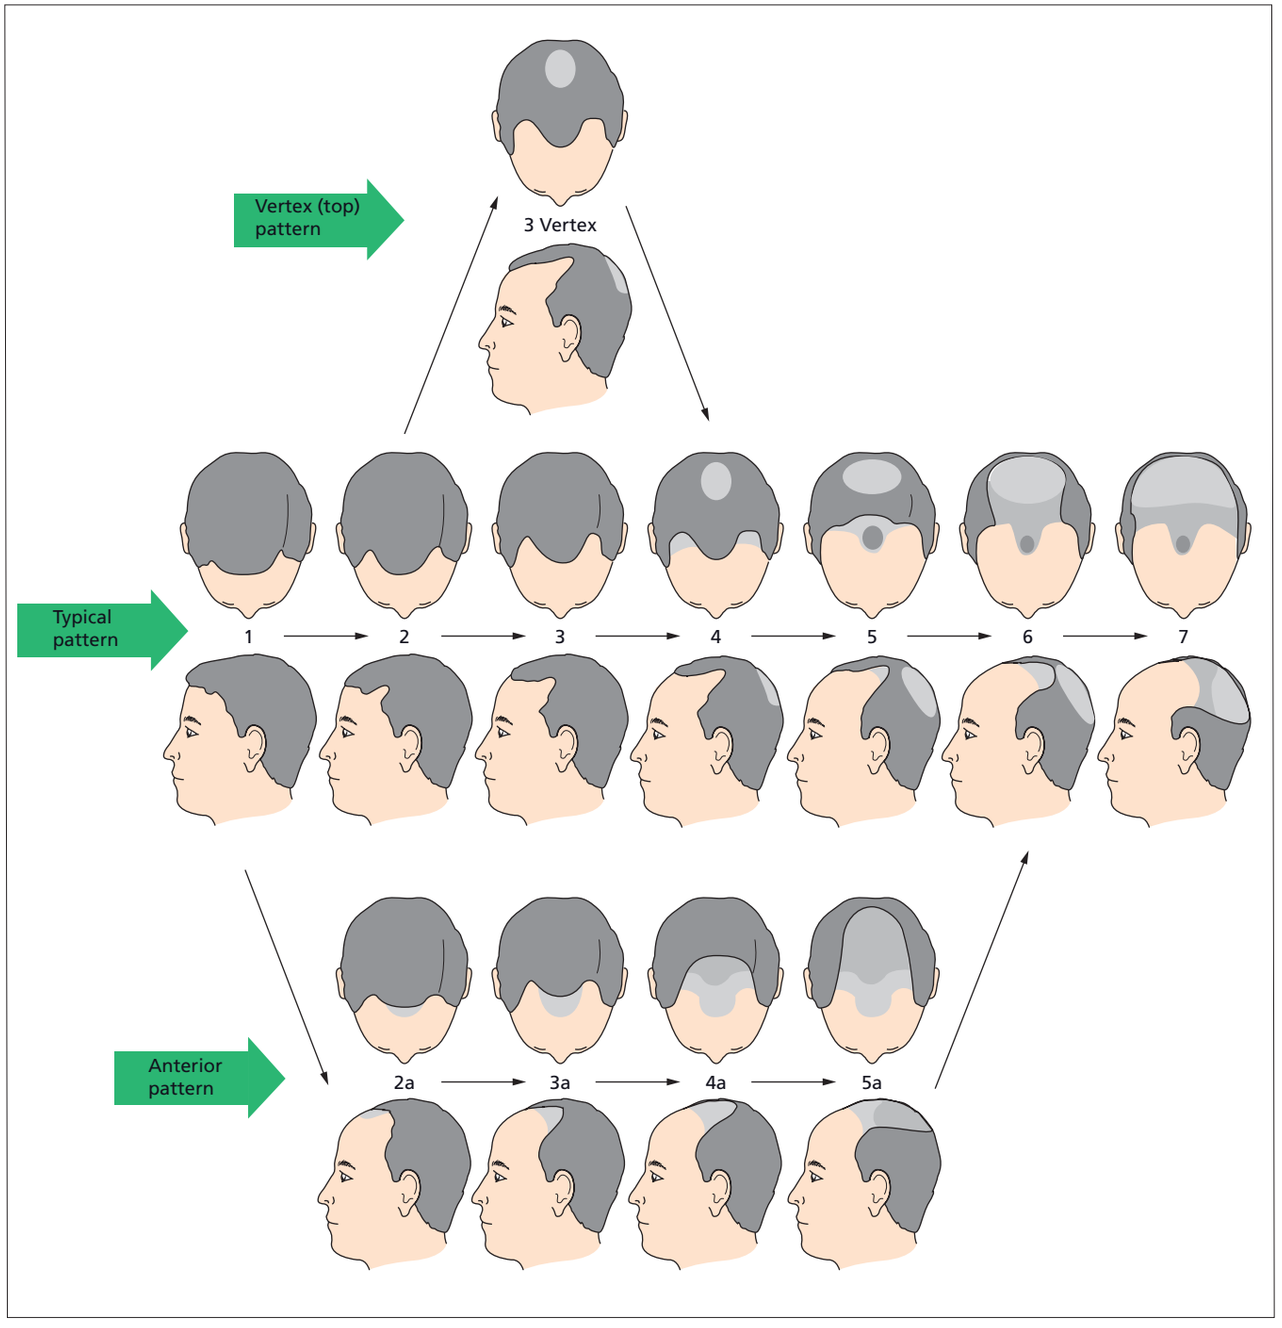

Fig. 66.14 Hamilton–Norwood scale for grading male pattern hair loss [3].

between the ages of 18 and 29, a further 24% first develop MPB in their thirties, 3% in their forties, 5% in their fifties, 9% in their sixties, 2% in their seventies and 1% at or beyond the age of 80 years [3].

There is wide individual variation in the rate of progression of hair loss in MPB. A small number of men achieve type V or VI hair loss in their twenties, indicating a very rapid rate of progression. In contrast, approximately 25% of men with MPB show no visible hair loss on standardized clinical photographs over a 5-year period [5]. Early-onset MPB progresses more rapidly. Men who develop MPB in their twenties tend to advance one to two stages per decade, whereas men with late-onset MPB may take two decades to progress a single stage [3]. Not every man with AGA goes bald. Although 40% of men start losing their hair in their twenties, only 30% ever reach stage VI or VII. Hence, even for those with early-onset AGA complete baldness is not inevitable.

Twin studies in males indicate that susceptibility, age of onset, pattern and rate of progression of MPB are all under genetic influence [6,7]. The lower age-related prevalence of MPB and higher proportion of men with a Ludwig pattern hair loss among Koreans also confirms the profound influence of genes on susceptibility, age of onset and pattern of hair loss [8].

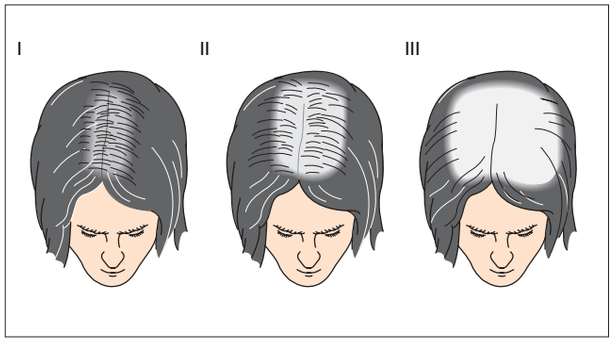

Fig. 66.15 Ludwig scale for grading female pattern hair loss [11].

Patterned balding occurs in women, but the susceptibility, age of onset, rate of progression and pattern are different from men. Thirty-two per cent of women aged 80 years and above show no visible evidence of female pattern hair loss (FPHL). The age of onset of FPHL is later than that seen in men. Only 3% first develop clinically detectable FPHL by age 29 years, a further 13% first develop it by age 49 years, a further 8% by age 69 years and a further 6% after the age of 70 years [9,10].

As many women wear their hair long, they are more aware of fluctuations in daily hair shedding. Women with AGA-related hair shedding often present prior to the development of reduction in hair volume over the crown (FPHL), making early diagnosis problematic.

Fewer than 1% of women progress to Hamilton–Norwood stage IV or above (equivalent to Ludwig stage III). Severe bitemporal recession (Hamilton–Norwood III) is uncommon and, as Ludwig pointed out, the most common pattern of hair loss seen in women is diffuse reduction of hair density over the crown, with complete or near complete preservation of the frontal hairline [11]. Olsen observed the so-called Christmas-tree pattern, with widening of the central parting line most noticeably in the mid-frontal scalp. She also pointed out that the hair loss in women is often not confined to the crown but may extend ear to ear (Figs 66.15 & 66.16) [12].

The histology of FPHL is indistinguishable from MPB. The process of FPHL involves androgen-mediated miniaturization of terminal hair follicles and therefore is AGA. Miniaturization of terminal hair follicles is also seen in alopecia areata, traction alopecia and secondary syphilis. In contrast with the uniform miniaturization of alopecia areata, miniaturization in FPHL spares one or two hairs within each follicular unit. The net result is that follicular units that normally have three to five terminal hairs only have one to two terminal hairs. Hair follicle miniaturization together with diffuse hair loss over the frontal scalp has also been observed in a female without androgens, indicating that other non-androgen-dependent mechanisms can miniaturize terminal hairs in a pattern that mimics AGA [13].

Minor bitemporal recession also occurs in more than 25% of women in their twenties and, as in men, is not necessarily a precursor of frontal baldness, even though biopsy from these areas reveals AGA [14].

Inheritance. Twin studies confirm the long-held belief that there is a genetic predisposition to MPB [7]. Of the 54 father–son relationships in the Victorian Family Heart Study, 81.5% of balding sons had fathers who had cosmetically significant balding. The

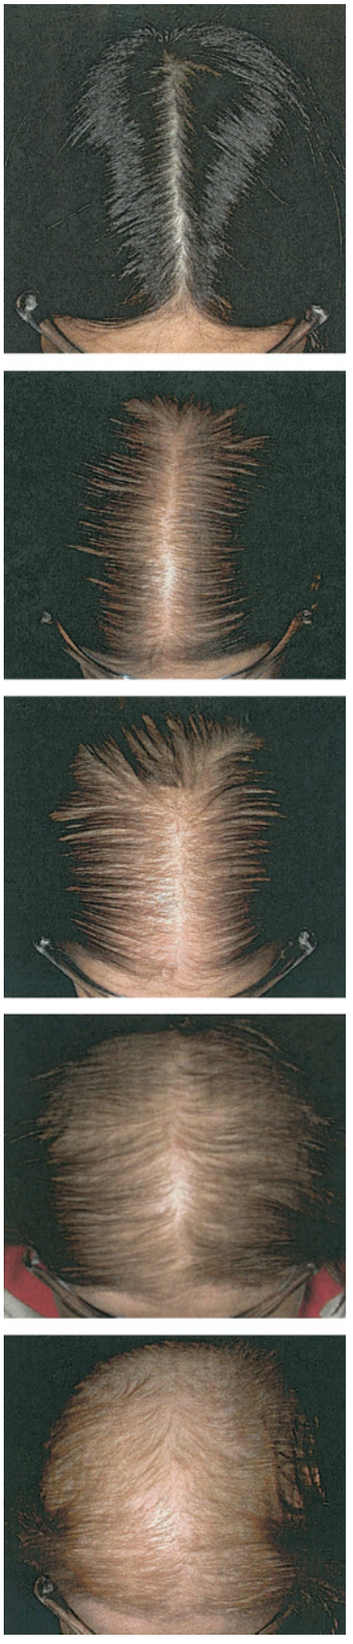

Fig. 66.16 Pattern of frontal hair loss in women with androgenetic alopecia. Stage 1 is normal.

high prevalence of MPB in the population, racial variation in the age-related prevalence of balding, the finding that baldness risk increases with the number of affected family members and the high frequency of baldness in the fathers of balding men can all be explained by polygenic inheritance [15].

Gene association studies comparing DNA from young bald men with that of old non-bald men have identified an association of MPB with a polymorphism of the androgen receptor gene on the X chromosome [16]. The androgen receptor gene *Stu1* restriction fragment length polymorphism (RFLP) was found in almost all (98.1%) young bald men, and most older bald men (92.3%), but only in 77% of non-bald men. This polymorphism appears to be necessary for the development of AGA, but its presence in non-bald men indicates that it is not sufficient for the development of AGA. This association has been confirmed by other groups in different patient cohorts [17,18]. However, other genes must be involved as the androgen receptor gene is located on the X chromosome and is inherited exclusively from the mother.

Current modelling suggests the involvement of at least four genes that combine to modify the age of onset, pattern of loss and rate of progression of MPB [19]. Other candidate gene and chromosomal regions have been examined. They include *SRDA1* and *SRDA5*, coding for the two variants of the 5α-reductase enzymes [20], the insulin gene [21], the aromatase gene, the gene for the ER-α oestrogen receptor, the non-recombinant area of the Y chromosome and the type II IGF genes [19]. Thus far, no association has been found between any of the above-mentioned genetic areas and MPB. Recently, Hillmer and colleagues, in a genome-wide linkage study of 95 families, have identified an additional gene locus for androgenetic alopecia on chromosome 3q26. The putative gene has not yet been disclosed [22].

Although a positive association between vertex balding and prostate cancer [23] has been identified, there is no clear association between MPB and dense hair patterns on the trunk [24] or number of children [25]. Several studies have reported an association between male balding and coronary artery disease [26–28]. In the largest of these, a retrospective study conducted amongst 22 071 US male physicians, there was a weak association between coronary heart disease and vertex balding [27].

To date there are no comparable genetic studies in female pattern hair loss.

Pathogenesis. Any unifying hypothesis for AGA has to explain the following: the occurrence in humans and simian species; strong familial tendency; the involvement of both sexes; geographical patterning of hair loss on the scalp; the diffuse nature of initial hair loss; the paradoxical effect of circulating and local androgens on scalp and body hairs; the phenomenon of donor dominance in hair transplantation; the alteration of hair cycle dynamics; follicular miniaturization; perifollicular inflammation; and the coexistence of greasy skin, acne and hirsutism in some women.

Hormonal influences

Systemic hormonal effects (see p. 66.13)

The key role of androgens in the pathogenesis of male AGA was revealed by the observations of the American anatomist James Hamilton. He noted that men castrated before puberty did not develop balding unless treated with testosterone [1]. A number of studies have tried to determine whether balding males have

increased circulating androgens, but no differences between patients and controls have been consistently found. Absolute levels of serum dihydroepiandrosterone sulphate (DHEA) and testosterone [2], free testosterone [3,4], the ratio of DHT : testosterone [5], and IGF-1 [6] have all been measured in bald men. All these studies suffer from a lack of reproducibility, and although differences in mean levels have been variously detected, the substantial overlap in the absolute levels of all androgens between cases and controls demonstrates that normal male levels of androgen are sufficient to make manifest the degree of baldness determined genetically for the individual.

While the role of androgens is well established in the pathogenesis of male pattern hair loss, their role in female pattern hair loss has been recently questioned. On the one hand, scalp hair loss and hirsutism are undoubtedly features of hyperandrogenism in women; indeed, loss of hair was reported in women with androgen-secreting tumours prior to Hamilton's observations in men [7,8]. Several investigators have noted that women with hair loss are more likely to have elevated androgen levels, although usually of minor degree, or show an increased frequency of other features of androgen excess than women without hair loss [9–11]. However, on the other hand, several investigators have failed to find evidence of raised androgen levels in women with FPHL [12], and in all studies there is a variable proportion of women with hair loss who do not show clinical or biochemical signs of androgen excess. It is not yet known whether hair loss in this latter group relates to a high level of sensitivity of scalp hair follicles to normal female levels of androgens or is due to another, non-androgenic mechanism.

It would seem that for women, androgens in the normal female range are sufficient to induce early baldness in women with a strong genetic predisposition. In women without a strong predisposition, balding will not occur until later in life unless endogenous androgen production is increased or drugs with androgen-like activity are taken. Some women with even grossly abnormal levels of androgen do not develop clinically significant baldness, although such patients are generally hirsute.

Local hormonal effects

Androgens do not affect all hairs equally. Body hair grows, scalp hair is lost whereas the eyebrows remain essentially unchanged at puberty. On the scalp there is a hierarchy of sensitivity, with the most anterior of the hairs at the temples being lost first, and subsequent hairs miniaturizing in a highly ordered fashion to produce patterned baldness. Similarly on the male beard, hairs first appear on the upper lip at the lateral corners and then over the rest of the face in a highly ordered fashion. On the chest, hairs first appear centrally and then around the areolae before migrating across the rest of the torso.

In men, where circulating androgens are surplus to the requirements of the hair follicles for maximal stimulation, local factors determine individual susceptibility and severity of baldness. This intrinsic regulation is best demonstrated in hair transplantation experiments; occipital hairs maintain their resistance to AGA when transplanted to the vertex [13], and scalp hairs from the vertex transplanted to the forearm miniaturize at the same pace as hairs neighbouring the donor site [14]. In females, where circulating androgens are not sufficient to maximally stimulate hair follicles, local factors still determine susceptibility, but severity is influenced by both local factors and levels of systemic hormone.

Beard dermal papilla cells are known to secrete growth-inducing autocrine growth factors including IGF-1 in response to testosterone, leading to an increase in dermal papilla size and enlargement of the hair follicle and hair cortex [15–17]. Similar investigations performed on dermal papilla cells from the balding scalp of the stump-tailed macaque showed that testosterone inhibited the growth and proliferation of keratinocytes [18]. TGF-β1 has been identified as a major component of the secreted cytokines in the vertex scalp and neutralizing anti-TGF-β1 antibody reversed the androgen-induced inhibition of keratinocyte proliferation. It has been postulated that the androgen-induced anti-TGF-β1 derived from the dermal papilla cells mediates hair growth suppression in androgenetic alopecia [19]. Studies examining distribution and expression of androgen receptors have shown varying results. Two studies showed that androgen receptors are only found in the nuclei of dermal papilla cells [15,20]. However, another study found more extensive follicular distribution of receptors, including the hair bulb [21]. Comparing different anatomical sites, there appear to be higher numbers of androgen receptors in the pubic hair follicles and beard dermal papilla cells, with occipital scalp follicles expressing lower levels [22].

Hair cycle dynamics

In AGA, the duration of anagen decreases with each successive cycle, whereas the length of telogen remains constant or is prolonged. Prolongation of telogen occurs particularly in the latent phase of telogen (also known as kenogen) that follows release of the club hair (exogen). This leads to a reduction of the anagen : telogen ratio and corresponds to periods of excessive hair shedding, most noticeable while combing or washing. Prolongation of the latent phase increases the proportion of empty hair follicles on the scalp, further contributing to the balding process [23].

As the hair growth rate remains relatively constant, the duration of anagen growth determines hair length. Thus, with each successively foreshortened hair cycle, the length of each hair shaft is reduced. Ultimately, anagen duration becomes so short that the growing hair fails to achieve sufficient length to reach the surface of the skin, leaving an empty follicular pore.

Hair follicle miniaturization

The population density of hair follicles per unit area of the scalp does not change with balding. Rather there is a gradual diminution in the size of follicles that results from the transformation of terminal follicles into vellus-type follicles.

Hair follicle miniaturization leads to finer hair that is often lighter in colour. On the balding scalp, transitional indeterminate hairs represent the bridge between full-sized and miniaturized terminal hairs [24].

Although smaller follicles tend to cycle more quickly there is no absolute correlation between hair follicle size and anagen duration. Eyebrow, eyelash and nasal follicles are large but the hair is relatively short. It is likely that separate factors control the miniaturization and hair cycle changes. Consequently, baldness and increased hair shedding do not necessarily go hand in hand. Many balding men and women are never aware of increased hair shed-

ding, and increased hair shedding occurs without associated follicular miniaturization in chronic telogen effluvium.

The dermal papilla is central to the maintenance and control of hair growth and is likely to be the target of androgen-mediated events leading to follicle miniaturization and hair cycle changes [18,25,26]. The constant geometric relationship between the dermal papilla size and the size of the hair matrix [27] suggests that the size of the dermal papilla determines the size of the hair bulb and ultimately the hair shaft produced.

The cross-sectional area of individual hair shafts remains constant throughout fully developed anagen [28], indicating that the hair follicle, and its dermal papilla, remain the same size through each individual anagen stage of the cycle. Thus, miniaturization occurs between rather than within cycles. Follicular miniaturization has been traditionally thought to occur in a stepwise fashion although there have been suggestions that it occurs rapidly, possibly in the space of a single hair cycle [29].

Follicular miniaturization leaves behind stellae as dermal remnants of the full-sized follicle. These stellae, also known as fibrous tracts or streamers, extend from the subcutaneous tissue up the old follicular tract to the miniaturized hair and mark the formal position of the original terminal follicle. Arao–Perkins bodies may be seen with elastic stains within the follicular stellae. An Arao–Perkins body begins as a small cluster of elastic fibres in the neck of the dermal papilla. These clump in catagen and remain situated at the lowest point of origin of the follicular stellae. With the progressive shortening of anagen hair seen in AGA, multiple elastic clumps may be found in stellae, like the rungs of a ladder [30].

Clinical features. The essential clinical feature of balding in both sexes is patterned hair loss over the crown. Pigmented terminal hairs are progressively replaced by finer hairs, which are short and virtually non-pigmented. This process may begin at any age after the onset of adrenarche and may precede pubarche.

Males. The clinical appearance of male androgenetic alopecia is instantly recognizable in most cases. The progression of the hair loss occurs in an orderly manner and has been well documented by Hamilton [1] and Norwood [2] (Fig. 66.14). The posterior and lateral scalp margins are relatively spared, and only affected in the most advanced cases and with old age. Twin concordance studies indicate that variations in the pattern are governed, at least in part, by genetic factors, as is the rate of progression [3].

The main significance of hair relates to socialization, and hair is an essential part of an individual's self-image. Thus, the consequences of AGA are predominantly psychological. Despite an identical libido, bald men are likely to have fewer lifetime sexual

partners than non-bald men, reflecting reduced physical attractiveness to potential partners [4]. In Germany, where it is customary to include a photograph in job applications, otherwise identical applications accompanied by a photograph that had been digitally altered to make the applicant bald were less likely to lead to interview. Several studies have shown that the negative self-perception of balding patients appears to be consistent between Western [5,6] and Asian cultures [7]. The negative impact of AGA is often trivialized or ignored by the non-bald [8]. However, there is evidence that perception by others may compound the psychological problems suffered by balding men. A Korean study of the perception of balding men by women and non-balding men found that their negative perception of men with AGA was similar to the psychosocial effects reported by the patients themselves [7]. Of note was that a perception of bald men looking less attractive was found in more than 90% of subjects surveyed. Importantly, this view was more common in women than non-balding men. Such negative perceptions may further impair the social functioning of balding men.

However, it is important to note that most affected men cope well with AGA, and it does not have significant impact on their psychosocial function. Thus, those who do seek help are likely to be in greater emotional distress and to have been dissatisfied with any treatment they have received. The most distressed balding men are those with more extensive hair loss, those who have very early onset, and those who regard their balding as progressive (often arising from observation of their father) and socially noticeable [5].

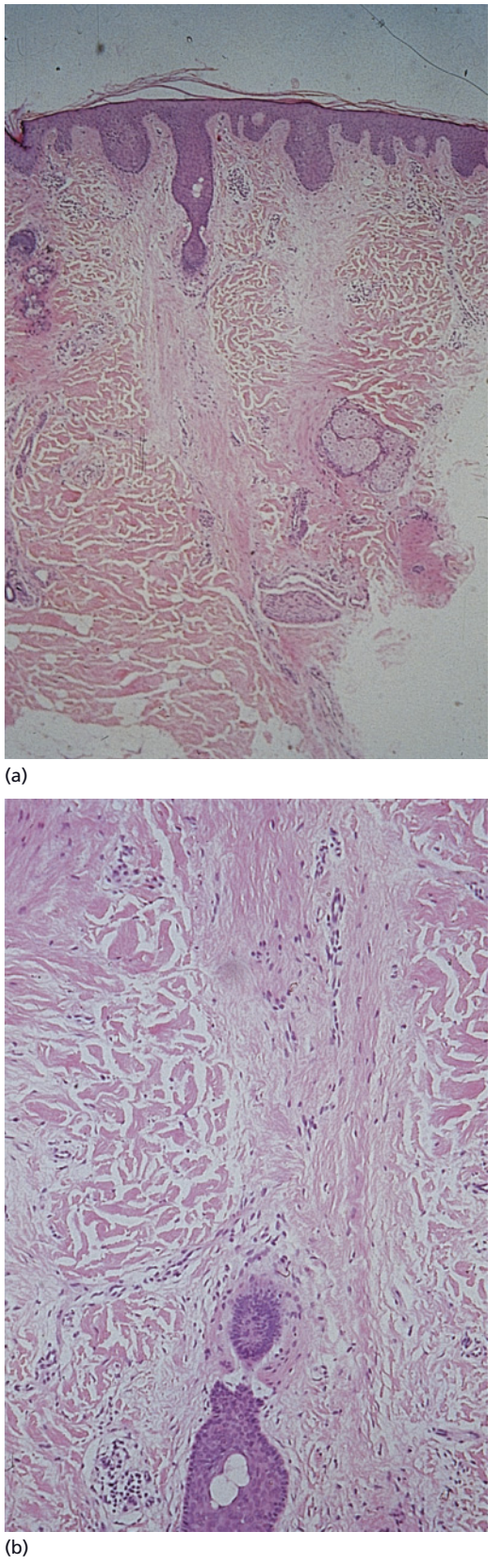
Females. The pattern of hair loss and the clinical presentation of AGA in women differ from men. Women may present with either an episodic or continuous increase in hair shedding without any noticeable reduction in hair volume, increased hair shedding with loss of hair volume over the crown, or diffuse thinning over the crown with no history of hair shedding [9]. The most informative question to ask balding women is about change in the thickness of their ponytail. This enables women to estimate their degree of hair loss. Loss of volume or thinning over the crown is best detected when the hair is parted centrally. Widening of the central parting may follow a 'Christmas tree' pattern and is used to score the hair loss [10].

Ludwig described the earliest change (Ludwig grade I) as rarefaction of the hair on the crown [11]. This produces an oval area of alopecia encircled by a band of variable breadth with normal hair density. Frontally the fringe is narrow (1–3 cm) and at the sides the margin is 4–5 cm wide. Progression to Ludwig grade II results in further rarefaction of the crown, with preservation of the fringe. Grade III is near-complete baldness of the crown. As Ludwig only produced three illustrations (Fig. 66.15), other validated scales with more images have proved to be more useful for patient grading (Fig. 66.16) [12].

Not all women who develop FPHL maintain their frontal hair line. Bitemporal recession occurs in 13% of premenopausal women and 37% of postmenopausal women [13].

In many women the hair loss is confined to the vertex scalp, but in a significant proportion hair loss also occurs diffusely over the parietal scalp. Generalized hair loss often precludes women from hair transplantation procedures because of a diminished donor population.

Most women who present with hair loss have no other evidence of virilization. However, if the hair loss is of sudden onset, rapidly progressive and advanced, a full medical history and examination, and endocrinological investigation are desirable to exclude virilization, which can rarely be caused by a virilizing tumour. Investigation is also indicated in women with AGA of gradual onset accompanied by menstrual disturbance, hirsutism or recrudescence of acne [14].



The principal differential diagnosis of early AGA is chronic telogen effluvium (CTE) [15]. Women with CTE present with chronic diffuse hair shedding without noticeable widening of the central parting. They may describe a loss in volume of the ponytail of up to one-third, and there is commonly mild bitemporal recession. Scalp biopsy of women who present in this fashion reveals AGA in approximately 60% of cases and CTE in 40% [12]. Scalp biopsy is not required in women who present with loss of hair volume either alone or associated with increased hair shedding.

Pathology. The key elements of the histology of AGA are a reduction in terminal hairs, an increase in secondary vellus hair with associated angiofibrotic streamers, a variable increase in telogen and catagen hairs, and a mild or moderate perifollicular lymphohistiocytic infiltrate, with or without concentric layers of perifollicular collagen deposition (Fig. 66.17) [1].

A mild lymphohistiocytic inflammation is found in approximately one-third of cases of AGA and a similar number of controls, and is non-specific. In contrast, a moderate lymphohistiocytic inflammation is found in another one-third of cases of AGA, but

(a)

(b)

Fig. 66.17 Histology of androgenetic alopecia on a vertically sectioned scalp biopsy. (a) The low-power photomicrograph shows a reduction in follicle number and size. (b) The high-power photomicrograph shows the follicular streamer and a light perifollicular inflammatory infiltrate.

in only 10% of controls [2]. Occasional eosinophils and mast cells can be seen. The cellular inflammatory changes also occur around lower follicles in some cases and occasionally involve follicular stellae. The diagnostic and prognostic significance of the degree of the inflammation is not known.

Many of these changes are best seen on horizontally sectioned scalp biopsies. Horizontal sections reveal numerous pseudovellus hair follicles in the papillary dermis, reflecting a miniaturization process. In the vast majority of cases there is no genuine reduction in the number of follicles, and follicular fibrosis is seen in less than 10% of cases. The presence of arrector pili muscles and angiofibrotic streamers distinguishes them from true vellus hairs. There is a change in the ratio of terminal : vellus hairs from greater than 8 : 1 to less than 4 : 1. Also, the anagen : telogen hair ratio reduces from 12 : 1 to 5 : 1 [3]. The increased proportion of catagen and telogen hairs reflects the shortened duration of anagen and the relative increase in telogen hairs.

As the balding scalp loses its protective covering of hair, solar degenerative changes may be seen. A reduction of blood supply has been observed [4], but whether it follows or precedes the hair loss is unknown.

Treatment. There are now a number of effective treatments to arrest the progression of the hair loss, that will also stimulate partial regrowth. Complete regrowth of a bald scalp is not yet feasible. Although epithelial stem cells in the bulge region contribute to wound healing they generally do not stimulate new hair follicle formation in adult mammals in any meaningful way. However, transgenic mice overexpressing certain WNT molecules do generate large numbers of new hair follicles following wounding [1].

As baldness is not life-threatening and the morbidity is variable, most people do not seek treatment. Some patients simply attend for a diagnosis, and when the currently available therapies are discussed, decline treatment. Without therapy baldness is progressive, although the rate of progression is extremely variable. Twenty-five per cent of men will have no visible progression after 5 years. Some will achieve Hamilton stage VII within 5 years, whereas others may take 50 years.

Before a patient embarks on therapy they should be counselled carefully and made aware of the requirement for maintenance therapy for sustained effect. It is preferable that advice is given by qualified medical practitioners who are fully aware of all the treatment options so that vulnerable individuals are protected from dubious Internet sites and profit-driven hair loss clinics.

Surgery. All surgical procedures involve the redistribution of terminal hair follicles from hairy into balding regions of the scalp.

Hair can be redistributed using autografts or flaps. Either procedure can be performed alone or in combination with reduction of the bald area by excision and closure. Grafts may be as large as 4 mm in diameter, but better results are achieved with much smaller 'mini' and 'micrografts', which can be manipulated to produce a natural-looking frontal hairline. Maintaining hair follicle unit groupings enhances graft survival and is the favoured approach. Reduction of the bald area by removal of an ellipse from the vault or repeated such operations may cover the top of the head by stretching the remaining parietal scalp. Expansion techniques have been used successfully to restore post-traumatic alopecia [2]. The implantation of artificial fibres may be complicated by foreign body reactions and infection [3,4] and its use has been banned in a number of countries.

Surgery is often performed long before the ultimate pattern of hair loss is clear. Without adjunctive medical therapy to prevent progression of the balding process, an unnatural appearance can evolve over time that may require further surgery to correct.

Hair transplantation techniques are constantly undergoing revision and improvement; they have been reviewed [5].

Camouflage and wigs. Camouflage is the simplest, easiest and cheapest way of dealing with mild AGA. Balding becomes most noticeable when the scalp can be seen through the hair. Camouflage treatments involve either adding small fibres held in place electrostatically or dyeing the scalp the same colour as the hair to create the illusion of thicker hair. Numerous brands are available, each in a range of colours. Although many of the newer agents are water-resistant, if the hair becomes wet in the rain the dye may still run.

Wigs are an alternative to scalp surgery. For many women, an alternative to a full wig is a smaller hair piece that can either be interwoven with existing hair or worn over the top of existing hair. Because interwoven wigs lift as the hair beneath grows, they require periodic adjustment.

Wig hair is composed of either a synthetic acrylic fibre that withstands wear and tear very well, or natural fibre (usually Asian or European human hair). Natural fibre wigs look better, are easier to style and last longer, but are considerably more expensive. Wigs can be styled and washed, and modern wigs provide excellent coverage that looks natural. A drawback of wigs is that the head may be hot in the summer, and some patients find them difficult to wear for this reason.

Advice on wigs is available from alopecia patient support groups in the UK, USA and Australia. In the UK, the National Health Service subsidizes wigs for 'medical hair loss'.

Medical management. Medical management for women consists of oral antiandrogens, topical minoxidil or a combination of both. Antiandrogens feminize males and are therefore not appropriate for men. They are also potential teratogens, and women should be advised to avoid pregnancy while taking these medications. Pharmacological therapy for men includes topical minoxidil and the 5α-reductase inhibitors finasteride and dutasteride. Finasteride and dutasteride are both teratogens with very long biological half-lives. Finasteride should be ceased at least 6 months prior to a woman contemplating pregnancy, and dutasteride should be avoided completely in women of childbearing age as its teratogenic potential might persist for years.

Although improvement may be seen after as soon as 4 months, 1 year of treatment may be required before a clinical response is observed. Maintenance therapy is required to sustain the effect. Monitoring of clinical response can be problematic. Patients are often anxious about their hair and inspect it frequently. Subtle fluctuations are often overinterpreted, and patients' subjective assessment of hair density is commonly unreliable. Serial photography at 6- to 12-monthly intervals helps to encourage patient adherence to treatment in the medium and long term [6].

Management of male pattern baldness

Minoxidil lotion. Minoxidil is a piperidinopyrimidine derivative and a potent vasodilator that is effective orally for severe hypertension. When applied topically in a lotion or foam vehicle, minoxidil increases terminal hair density in up to 30% of individuals [7,8]. Terminal hair appeared to regrow at the margins, but complete covering of the bald areas was seen in less than 10% of responders. De Villez [9] suggested that men who responded best to minoxidil were those in whom the balding process was at an early stage, with a maximum diameter of the bald area of less than 10 cm, and in whom the pre-treatment hair density was in excess of 20 hairs/cm^2. There is a slight increase in benefit if the concentration is increased to 5%. The benefit is most pronounced in the first 6 months of therapy and thereafter is marginal.

Topical minoxidil appears to be a safe therapy with side effects only of local irritation and hypertrichosis of the temples, and there is a low incidence of contact dermatitis [10]. If treatment is stopped, clinical regression occurs within 6 months, to the state of baldness that would have existed if treatment had not been applied [11]. Patients should be warned that in order to maintain any beneficial effect, applications must continue twice daily for the rest of their lives.

Finasteride. Finasteride is a synthetic aza-steroid that is a potent and highly selective antagonist of 5α-reductase type 2. It inhibits the conversion of testosterone to DHT. A scalp biopsy study of patients with AGA found that after 12 months of finasteride treatment, terminal hair counts increase and vellus hair counts decrease, demonstrating the ability of finasteride to reverse the miniaturization process and to encourage the growth of terminal hairs [12].

An oral dosage of 1 mg/day reduces scalp DHT by 64% and serum DHT by 68% [13]. Clinical trial data showed that, after 1 year, patients on finasteride have a 10% increase in the mean number of terminal hairs compared with baseline counts [14]. After 5 years of continuous therapy, hair counts remained close to the 1-year level, whereas the counts in the placebo patients had dropped by 30%. Using global photography to assess scalp coverage, 48% of patients taking finasteride had increased hair density, compared with 7% of the placebo group at the end of 1 year. At 2 years, coverage continued to improve in the finasteride group, with 66% having increased density, whereas only 7% of the placebo subjects had increased coverage. By 5 years [15], 10% of treated patients had a lowered hair density, 42% had no change, and 22%, 21% and 5% were assessed as moderately, markedly and greatly improved, respectively. In contrast, 19%, 31% and 25% of patients

in the placebo group were greatly, markedly or moderately worse. Nevertheless, 25% of the patients in the placebo group showed no deterioration over the 5-year period, reflecting the variable rate of progression of balding among males.

These data suggest that the maximal number of finasteride-responsive follicles are recruited by the end of 1 year, and further improvement in scalp coverage results from increase in hair length, diameter and pigmentation [15]. At the end of the first year, some finasteride patients were changed to placebo, resulting in a decrease in their hair counts after 12 months. Some in the placebo group were also crossed over, receiving finasteride for the second year; these subjects had an increase in their hair counts, although the average increase was less than that seen in the original group, indicating the potential for regrowth diminishes as the AGA progresses.

Studies using hair weight as the objective measure of outcome indicate that men on placebo had a reduction in hair weight of 9.2% at 48 weeks and 15.4% at 96 weeks, compared with the men on active treatment who had an increase of 25.6% at 48 weeks and 35.8% at 96 weeks. Factors that affect hair weight include the number of hairs, hair growth rate and hair thickness [16]. Work examining the effect of finasteride on frontal hair loss also confirmed efficacy here, although the magnitude of regrowth appears less [17].

Few adverse effects were reported in the phase III studies [14,15]. In the finasteride group, loss of libido was reported in 1.8% and erectile dysfunction in 1.3%. The placebo groups reported these same events, with frequencies of 1.3% and 0.7%, respectively. These events appeared to resolve on cessation of the drug and, in some cases, with continued treatment. It has been suggested that even these figures overstate the true incidence of sexual dysfunction [18].

Of note is that older men on finasteride experienced a 50% reduction in serum prostate-specific antigen (PSA) levels, which could result in an underestimation of prostatic cancer risk. It has been shown in the urology literature that PSA levels remain valid while patients are taking finasteride, but the value should be doubled to correct for the finasteride effect [19,20]. Men between 18 and 41 years of age have a negligible decrease in measured PSA [21].

Finasteride is a teratogen. Male rats exposed to finasteride *in utero* develop hypospadias with cleft prepuce, decreased anogenital distance, reduced prostate weight and altered nipple formation [22]. As the drug is secreted in the semen and can be absorbed through the vagina during intercourse, it was originally advocated that men taking finasteride should avoid unprotected intercourse with pregnant women. In practice, the concentration of finasteride in the semen is well below the minimum effect dosage, and no recommendations regarding the use of condoms are made in the product information leaflet. There are no reports of adverse pregnancy outcomes among women exposed to finasteride taken by their partners [23]. Finasteride has no effect on spermatogenesis or semen production [24].

Finasteride has now been in widespread use for over 10 years. Many recipients are elderly men taking 5 mg/day for prostate hyperplasia. Very few side effects have been observed [25]. There is no effect of long-term use on bone mineral density [15,26]. Reversible painful gynaecomastia has been reported [27] and the incidence is thought to be approximately 0.001% [28]. The prostate cancer prevention trial has demonstrated that 5 mg daily of finasteride will reduce the incidence of prostate cancer by 25% among men aged 55 and over. More of the reduction occurred in low-grade prostate cancers (Gleason stage 2–6), whereas the incidence of high-grade cancers (Gleason stage 7–10) was increased [29]. As this increase in Gleason score has not yet been shown to adversely affect patient survival it is not known whether it accurately reflects the biology of the tumour or is an artefact of the scoring system [30].

Dutasteride is a combined type 1 and 2 5α-reductase inhibitor. It produces a dose-dependent reduction in serum and scalp DHT levels to a greater degree than that seen with finasteride, and is more effective than finasteride in stimulating hair regrowth in MPB [31]. Dutasteride is currently marketed at a 0.5 mg dosage for benign prostatic hypertrophy and it is not licensed for treatment of MPB. Sexual side effects are more common with dutasteride than with finasteride, and are also dose related, but appear to be reversible on cessation.

Management of female pattern hair loss

Minoxidil. Topical minoxidil has been shown to arrest hair loss or to induce mild to moderate hair regrowth in approximately 60% of women with FPHL [32]. A clinical trial comparing 5% and 2% formulations of minoxidil found a mean increase in non-vellus hair counts after 48 weeks of 18% and 14%, respectively [33].

Antiandrogens. Oral antiandrogen therapy with cyproterone acetate, spironolactone or flutamide is widely used in the treatment of FPHL although there is a dearth of clinical trial data.

Spironolactone is a synthetic steroid, structurally related to aldosterone, which acts by competitively blocking androgen receptors. It also weakly inhibits androgen biosynthesis. Its primary use is as a diuretic and antihypertensive, and many of its side effects and numerous drug interactions relate to this. Several studies have demonstrated the efficacy of spironolactone in the treatment of hirsutism [34]. There are no controlled trials in FPHL. There is one report that women treated for 1 year with spironolactone showed less hair loss than in an untreated group [35]. Dosage ranges from 100 to 300 mg/day. Side effects are dose related and include menstrual irregularities, postmenopausal bleeding, breast tenderness or enlargement, and fatigue [36]. Spironolactone has the potential to feminize a male fetus and women should not become pregnant while taking spironolactone. Concomitant use of oral contraceptives will reduce the hormonal side effects. The antialdosterone effect can result in an elevation of serum potassium and a slight reduction in blood pressure, although this is rarely significant in the absence of renal impairment. Rare cases of hepatocellular carcinoma and hepatitis have been reported, but with substantially higher doses [37,38].

Cyproterone acetate is an androgen receptor blocker and potent progestin [39]. It also has an antigonadotrophic effect. It has been in common usage for over 40 years in the treatment of hirsutism but the limited controlled trial evidence has shown little evidence of efficacy in FPHL. In a study comparing cyproterone acetate with topical minoxidil lotion hair density had declined after 1 year

in the cyproterone acetate group but had improved in those using minoxidil [40]. However, subset analysis showed some increase in hair density in women with clinical evidence of androgen excess taking cyproterone acetate, suggesting that antiandrogens may be more effective in women with hyperandrogenism. There are no dose-ranging studies, but most practitioners use cyproterone acetate 50–100 mg/day for the first 10 days of each menstrual cycle. For postmenopausal women, cyproterone acetate may be used continuously, with or without oestrogens.

The side effects of cyproterone acetate are dose dependent and include lassitude, weight gain, breast tenderness, loss of libido, depression and nausea [41]. Shortness of breath is an uncommon side effect [42]. Feminization of a male fetus may occur and so patients should be advised to cease the medication before conception. The combination of cyproterone acetate and oral oestrogen therapy provides effective contraception and stabilizes menstrual irregularities.

Flutamide is a non-steroidal antiandrogen that acts by inhibiting androgen uptake and by inhibiting nuclear binding of androgen within the target tissue. One study suggested that flutamide is superior to cyproterone acetate and finasteride in the treatment of androgenetic alopecia [43]. However, rare but potentially fatal hepatotoxicity limits the use of flutamide for this condition [34].

In a double-blind, placebo-controlled study involving almost 100 postmenopausal women with FPHL, 1 mg finasteride was found to be no better than placebo [44]. Subsequent case reports and a case series have reported benefits in both pre- and postmenopausal women, but teratogenicity remains a relative contraindication to use in premenopausal women [45,46].

Disturbances of hair cycle

Telogen effluvium

Synonym
- Telogen defluvium

Definition. The term telogen effluvium, first coined by Kligman in 1961 [1], refers to the loss of club (telogen) hair in disease states of the follicle. Kligman's hypothesis was that whatever the cause of the hair loss, the follicle tends to behave in a similar way—the premature termination of anagen. 'The follicle is precipitated into catagen and transforms into a resting stage that mimics telogen.' The observation of increased telogen hair shedding does not infer a cause. To establish a cause, one requires a history to identify known triggers, biochemical investigation to exclude endocrine, nutritional or autoimmune aetiologies and, in persistent cases, histology to identify the earliest stages of AGA. The duration of the hair shedding at presentation helps predict those patients in whom further investigation will have the greatest yield.

Follicular cycling within anatomical regions is synchronous in infancy, in that all neighbouring hairs grow together, involute together and are shed together, producing a moult wave. Whereas the moult wave persists indefinitely in many animals, in humans synchronous hair growth disappears in childhood. Rather than periodically shedding all 100 000 scalp hairs over the course of a few months, adult humans tend to lose a few hairs each day [2].

Scalp trichography reveals that an average of 86% of plucked hairs are in anagen, 1% in catagen and 13% are in telogen, whereas data from analysis of horizontal scalp biopsies puts these figures at 93% of follicles in anagen and 7% in telogen [3]. Based on biopsy data, if the average number of scalp hairs is 100 000, then 7000 hairs should be in telogen at any one time. As the approximate duration of telogen is 100 days, 77 hairs should be shed each day, but most people are not aware of shedding anywhere near this amount. Although this number is likely to correspond to the absolute number of hairs that are shed each day, it still remains to be defined what amount is normally noticed and how introspection heightens one's powers of detection [4]. When people are concerned they are losing hair, they look harder and find more.

Pathogenesis. Headington [5] described five functional types of telogen effluvium, based on different phases of the follicular cycle: immediate anagen release, delayed anagen release, short anagen syndrome, immediate telogen release and delayed telogen release. Immediate anagen release is a short-onset effluvium where follicles are stimulated to leave anagen and enter telogen prematurely, resulting in increased hair shedding at the end of telogen, approximately 2–3 months later. It is common after a physiological stress such as severe illness, and with drug-induced hair loss. Reversal is associated with resumption of the normal cycle. Delayed anagen release is the cause of postpartum hair loss. During pregnancy, hairs remain in prolonged anagen rather than cycling into telogen. If a large number of follicles are involved, postpartum telogen conversion will be accompanied by increased shedding some months later. Short anagen syndrome is caused by an idiopathic shortening of the duration of anagen and can cause a persistent telogen hair shedding in some individuals [5].

It is not known precisely how long a telogen hair remains in the follicle, but it is believed that club hairs are released 4–6 weeks after the onset of anagen. This may explain the different anagen : telogen rates seen on trichogram versus biopsy. Immediate telogen release results from a shortening of normal telogen, with release of club hairs as the follicles are stimulated to re-enter anagen. Drugs such as minoxidil can precipitate immediate telogen release. Delayed telogen release occurs after a prolonged telogen followed by transition to anagen. It occurs in animals with synchronous hair cycles during shedding of their winter coats. It may occur seasonally in some humans.

Acute telogen effluvium. Acute telogen effluvium is an acute-onset scalp hair loss that occurs 2–3 months after a triggering event such as a high fever, surgical trauma, sudden starvation or haemorrhage [1,4–6]. In approximately a third of cases of acute telogen effluvium, no trigger can be identified. Acute telogen effluvium is commonly attributed to emotional stress, but the evidence for this is weak and there is no evidence that suggests the stresses of everyday life are sufficient to induce diffuse hair loss. The functional mechanism of shedding is immediate anagen release.

The patient may be particularly aware of increased loss on the brush or comb, or during shampooing. The daily loss ranges from under 100 to over 1000. If the lower rates of shedding are continued for only a short period there may be no obvious baldness, but if shedding occurs at higher rates, diffuse reduction in hair density is produced (Fig. 66.18). It may be severe but is never total. Unless the trigger is repeated, spontaneous complete regrowth occurs within 3–6 months. The proportion of follicles affected, and hence the severity of the subsequent alopecia, depends partly on the duration and severity of the precipitating cause and partly on unexplained individual variations in susceptibility.

Telogen gravidarum refers to the telogen hair loss seen 2–3 months after childbirth [7,8]. It is an example of delayed anagen

Fig. 66.18 Acute telogen effluvium.

release. It is universal to some degree, but is often subclinical. Most cases of telogen gravidarum resolve; however, a small proportion of women may experience persistent episodic shedding that may be diffuse or localized. It has been suggested that after pregnancy some hairs may not revert to an asynchronous growth pattern seen in normal adult hair follicles [5]. A similar state of affairs prevails when the contraceptive pill is discontinued after it has been taken continuously for some time [8,9].

Diagnosis. The diagnosis is usually simple. Abrupt-onset telogen effluvium is likely to be related to a specific event or trigger 6–16 weeks earlier. The hair pull test is positive, with normal club hairs. The hair loss is always diffuse and never total. Gradual onset or prolonged hair loss is more difficult to assess. Increased shedding of club hairs is a variable but often very obvious symptom of early AGA. Other differential diagnoses are discussed below under the heading of chronic diffuse telogen hair loss.

The hair pull test is notoriously difficult to interpret. In acute telogen effluvium, it is usually strongly positive for telogen hairs at the vertex and the scalp margins. However, a negative hair pull test does not exclude the diagnosis of telogen effluvium. The trichogram from a hair pluck sample usually shows more than 25% of telogen hairs in acute telogen effluvium [1]. When an obvious explanation exists for a recent-onset telogen effluvium, expectant management and observation is appropriate. Shedding can be expected to cease within 3–6 months and thereafter recovery should be complete. Histological examination shows no abnormality other than an increase in the proportion of follicles in telogen.

Chronic diffuse telogen hair loss. A short-lived insult usually produces a sudden-onset diffuse shedding. If the insult is prolonged or repeated, shedding can develop insidiously. Chronic diffuse telogen hair loss refers to telogen hair shedding persisting for longer than 6 months. It can be a result of a primary chronic telogen effluvium or be secondary to a variety of causes including FPHL. To be a true cause of chronic diffuse telogen hair loss, the relationship between the trigger and the hair loss must be reversible and reproducible. The requirements of proof include exclusion of other known causes of shedding, in particular AGA, reversal of the hair loss following correction of the causative factor, and relapse on rechallenge.

Accepted causes of chronic diffuse telogen hair loss are thyroid disorders (Fig. 66.19), profound iron deficiency anaemia, acrodermatitis enteropathica and malnutrition [1]. Both hyperthyroidism and hypothyroidism (including drug-induced hypothyroidism) may cause a diffuse telogen hair loss [2,3]. The mechanism of telogen hair shedding in thyroid disorders is unclear [4]. Hair loss is reversible when the euthyroid state is restored, except in long-standing cases. If replacement therapy fails to correct the hair loss, alternate causes should be sought [5].

Profound iron-deficiency anaemia can cause a diffuse telogen hair loss that is corrected by iron replacement. The relationship between iron deficiency with no anaemia or only mild anaemia and chronic diffuse hair loss is, however, more complex and controversial [6–8]. Depending on how it is defined, low iron stores are a common finding in women of child-bearing age. AGA is also common in this age group and the shedding in the early stages of female AGA can be diffuse and episodic, and mimic a telogen effluvium. It is important not to focus on the treatment of a subclinical iron deficiency while neglecting the underlying AGA, especially when therapy for female AGA is more reliable in arresting hair loss than stimulating regrowth. It is not uncommon for women presenting with increased telogen hair shedding caused by AGA to coincidentally have low iron stores. As the telogen hair loss in AGA can be episodic, it may even appear to abate with iron replacement. However, in patients with AGA the shedding tends to be chronic and relapsing, and recovery is generally incomplete. A punch biopsy can usually clarify the diagnosis.

Acrodermatitis enteropathica and acquired zinc deficiency (Fig. 66.20) brought about by long-standing parenteral nutrition can lead to a severe telogen effluvium [1,9]. However, low zinc levels

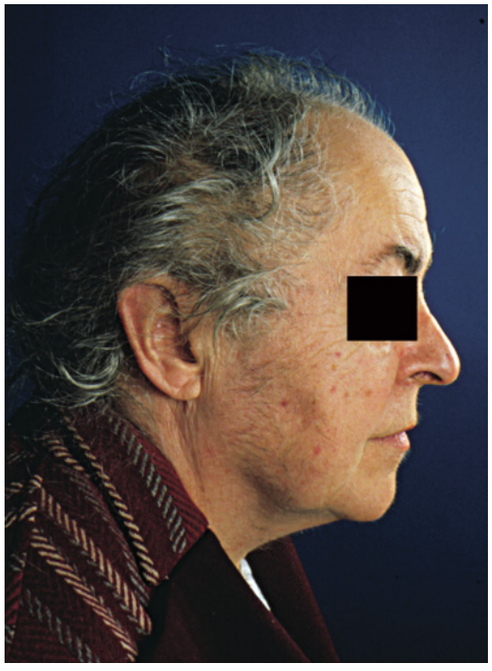

Fig. 66.19 Diffuse alopecia in association with hypothyroidism.

Fig. 66.20 Acquired zinc deficiency resulting from prolonged parenteral feeding and inadequate zinc supplementation.

found on routine blood biochemistry screening in patients being investigated for diffuse telogen hair loss are probably an incidental finding. Diffuse hair loss alone, with no other symptoms or signs, is never a result of dietary zinc deficiency [8].

Crash dieting with severe protein–calorie restriction can precipitate hair loss [10,11]. Chronic starvation, especially marasmus, causes a diffuse telogen hair loss often accompanied by hair shaft abnormalities [12]. Hypoproteinaemia of metabolic as well as dietary origin can cause hair loss [1]. Pancreatic disease and other forms of malabsorption also cause a diffuse telogen hair loss [13], as do the essential fatty acid deficiencies seen in prolonged parenteral nutrition and hypervitaminosis A [14,15]. Metabolic disturbances such as liver disorders [1,16] and chronic renal failure can produce sparse scalp hair [17]. Hair loss in advanced malignant disease may be a result of hypoproteinaemia rather than the malignancy itself, but alopecia has occurred as an early sign of Hodgkin's disease [18]. Systemic lupus erythematosus (Fig. 66.21) and dermatomyositis can also cause telogen hair loss [19]. Diffuse hair loss may occur in secondary syphilis, but the characteristic moth-eaten appearance is not always present [20].

Drug-induced diffuse telogen hair loss usually starts 6–12 weeks after instigation of treatment and is progressive while the drug is continued [21,22]. It is most commonly a result of immediate anagen release [23]. The diagnosis of drug-induced telogen hair loss is made by demonstrating compatible chronology of drug exposure and the onset of the hair loss, and exclusion of the other causes of alopecia. Shedding can recur with drugs that are chemically unrelated, suggesting that true cross-reactivity is rare, and individual susceptibility exists to drug-induced telogen effluvium. Chronic telogen effluvium and AGA are important differential diagnoses. If a particular drug is suspected, testing involves stopping it for at least 3 months. Regrowth following discontinuation and recurrence on re-exposure to the drug supports the conclusion that the drug caused the alopecia. Many drugs have been said to cause a diffuse telogen hair loss but few have fulfilled the above criteria. A dose-related diffuse telogen hair loss is common with etretinate [24] and acitretin, but less common with isotretinoin. The retinoids appear to cause a telogen anchorage defect and reduce the duration of anagen. Occasionally, continued shedding

Fig. 66.21 Hair loss and photosensitivity caused by systemic lupus erythematosus.

is noted after retinoid-induced telogen effluvium, but such cases may be caused by coincidental AGA. Minoxidil has been reported to cause a short-lived telogen shedding by immediate telogen release [23,25].

Chronic telogen effluvium. Chronic telogen effluvium (CTE) is a primary, idiopathic and often self-limiting condition affecting middle-aged women that is distinct from androgenetic hair loss and chronic diffuse telogen effluvium secondary to organic causes [1]. Women describe a sudden onset of increased hair shedding persisting for at least 6 months. There is no associated visible widening of the central parting line, and no miniaturization of hair follicles on scalp biopsy. CTE contrasts with acute telogen effluvium by its prolonged fluctuating course and much less frequent occurrence. It occurs mainly in females between 30 and 50 years of age. Hair shedding is much less obvious in males with short hair, and for unknown reasons few males with long hair present with increased hair shedding [2]. Although some cases of CTE follow an acute telogen effluvium with an identified trigger, such as pregnancy or systemic illness, in most cases no trigger can be identified. Any of the functional types of telogen effluvium could account for CTE, but it is believed to be related to shortening of the anagen phase of the hair cycle [3].

The diagnosis of CTE is made by exclusion of other causes of diffuse telogen hair loss. A thorough history is required, including a detailed drug and dietary history. A full clinical examination should be performed, including scalp examination and hair pull testing. The routine work-up includes full blood count and thyroid function tests. Syphilis serology, antinuclear antibody titre, serum zinc levels and other investigations of nutritional status should be performed if clinically warranted.

Affected women present with persistent severe shedding that runs a fluctuating course over several years [3] (Fig. 66.22). They often give a history of the ability to grow their hair very long in childhood, suggestive of a long anagen phase, and report a high hair density prior to the onset of hair loss [4,5]. They usually have a negative family history of AGA. Clinical examination reveals bitemporal recession, but no widening of the central hair parting, which if present would support the diagnosis of AGA. However, these criteria are not absolute, and AGA can mimic this presentation. A positive hair pull test is common over the vertex and occipital scalp, and patients may describe a reduction in the thickness of their ponytail volume, stating it has decreased by up to 50% [3]. A negative hair pull test on any one given day does not exclude the diagnosis of CTE.

Fig. 66.22 Idiopathic chronic telogen effluvium.

CTE has to be distinguished clinically from AGA, as women with early AGA may present with periods of increased hair shedding without a discernible pattern to the loss. In an evaluation of 600 women presenting with chronic diffuse telogen hair shedding with little or no reduction of visible hair density, 60% were found on scalp biopsy to have hair miniaturization consistent with a diagnosis of AGA and 40% had CTE [6].

The diagnosis of CTE can usually be suspected from the history and examination, but scalp biopsy may be required to differentiate it from early AGA [1]. The optimal scalp biopsy is a 4-mm punch biopsy taken from the vertex of the scalp for horizontal embedding. A terminal : vellus ratio below 8 : 1 is suggestive of AGA [1].

Despite the assertion that CTE is a self-limiting process that does not evolve into AGA, its natural history remains poorly characterized, with only one published longitudinal study [7].

Alopecia areata

A.G. Messenger, pp. 66.31–66.38

Alopecia areata is a chronic inflammatory disease that involves the hair follicle and sometimes the nails. Current evidence indicates that hair follicle inflammation in alopecia areata is caused by a T-cell-mediated autoimmune mechanism occurring in genetically predisposed individuals. Environmental factors may be responsible for triggering the disease.

In the only formal population study of alopecia areata, from Olmsted County, Minnesota, USA, the incidence rate was 0.1–0.2% with a projected lifetime risk of 1.7% [1]. Several large case series of alopecia areata have been reported from Europe [2], North America [3,4] and Asia [5,6], but these have generally been drawn from hospital clinic attenders and no accurate indication of variation in disease rates between populations is available.

Aetiology.

Genetic factors

The importance of genetic factors in alopecia areata is underlined by the high frequency of a positive family history in affected individuals [7]. In most reports, this ranges from 10 to 20% of cases, but mild cases are often overlooked or concealed and the true figure may be greater. The lifetime risk of alopecia areata in the children of a proband is approximately 6% [8,9]. Price and Colombe [10] found a family history of alopecia areata was more common in those with disease onset before the age of 30 years (37% compared with 7.1% in patients with onset after 30 years). There are several case reports of alopecia areata in twins [11–13]. A study in monozygotic and dizygotic pairs found a concordance rate of 55% for alopecia amongst monozygotic twins with no concordance among the dizygotic pairs [14]. The numbers studied were insufficient to allow a precise estimate of the genetic contribution in alopecia areata. Except in occasional families, alopecia areata is not inherited in a simple Mendelian fashion and the genetic basis appears to be multifactorial.

Gene associations. Case–control studies have reported associations between alopecia areata and a variety of genes involved in regulating immune and inflammatory responses (reviewed in [15]). The strongest associations to date have been with genes of the major histocompatibility complex (MHC), particularly the Class II alleles *HLA-DQB1*0301* [16–18] and *HLA-DRB1*1104* [18,19]. A genome-wide scan performed on 20 families confirmed the linkage between alopecia areata and the MHC region on chromosome 6p [20]. This study also showed susceptibility loci on chromosomes 10, 16 and 18. The loci on 16 and 18 are also associated with psoriasis.

Atopy. Several studies have reported an association between alopecia areata and atopic disease [4,5,21,22], and have suggested that alopecia areata in atopic subjects tends to have an earlier age of onset and be more severe than in non-atopic subjects. However, none of these studies has used a control group to which the same criteria for defining atopy have been applied, and the association has been disputed in a study from India [23].

Autoimmunity

The idea that alopecia areata is an autoimmune disease was first suggested by Rothman following a paper presented by Van Scott [24]. Alopecia areata is associated with other autoimmune diseases, such as myxoedema and pernicious anaemia [4,25].

The frequency of type 1 diabetes mellitus is increased in the relatives of patients with alopecia areata but not in the patients themselves [26], suggesting that the predisposition to alopecia areata protects against the development of diabetes. In most published series, patients with alopecia areata have had an increased frequency of circulating organ-specific and non-organ-specific autoantibodies compared with normal subjects, and a variety of non-specific abnormalities in peripheral T-cell numbers and function have also been reported (reviewed in [7]). Circulating autoantibodies to hair follicle tissue have been found in patients with alopecia areata [27] but their pathogenic role is uncertain. Passive immunization with alopecia areata serum failed to induce hair loss in human skin grafted on to nude mice [28].

The most convincing evidence implicating circulating immune factors in the pathogenesis of alopecia areata comes from the transplantation experiments carried out by Gilhar *et al.* They first showed that hair growth recovered in alopecic skin transplanted on to athymic nude mice [29]. In their later experiments alopecia was induced in grafted skin by the injection of autologous T lymphocytes incubated with hair follicle extracts and antigen-presenting cells [30]. T cells not incubated with hair follicle extracts failed to cause hair loss.

Immune privilege

The low or absent expression of MHC proteins by cells in the lower part of the hair follicle has led to the concept that the hair follicle is an immunologically privileged site, an idea that has some experimental support [31]. It has been suggested that the development of a hair follicle-targeted immune response in alopecia areata is the consequence of impairment in this putative immune privilege status, but this has yet to be confirmed [15].

Environmental factors

The idea that alopecia areata is caused by infection, either directly or as a consequence of a remote 'focus of infection', has a long history and still cannot be ruled out. It was the predominant aetiological theory until well into the 20th century, and sporadic reports connecting alopecia areata with infective agents continue to appear. Skinner *et al.* [32] reported finding mRNA for cytomegalovirus in alopecic lesions, but this was not confirmed in a subsequent study from Italy [33]. There are also reports of alopecia areata in husband and wife, although this may be coincidence [34,35]. The 'external' factor most frequently implicated in triggering alopecia areata is psychological stress [36–38]. The significance of such an association is difficult to establish because of the problems in performing a controlled investigation. The published evidence is also conflicting, with some studies failing to show any relationship between stressful events and onset of hair loss [39,40], to the extent that no firm conclusion can be reached.

Despite the anecdotal nature of much of the evidence it is possible that environmental factors are responsible for triggering alopecia areata in some patients. If so, it seems likely that a diversity of factors can operate in this way.

Pathology. Anagen follicles at the margins of expanding patches of alopecia areata characteristically show a perifollicular and intrafollicular inflammatory cell infiltrate, concentrated in and around the hair bulb (Fig. 66.23). The inflammatory infiltrate is composed mainly of activated T lymphocytes, with a preponderance of CD4 cells, and an admixture of macrophages and Langerhans' cells [1,2]. In contrast to the inflammatory scarring alopecias, little or none of the inflammatory infiltrate is seen around the isthmus of the hair follicle, the site of hair follicle stem cells [3]. This may explain why follicles are not destroyed in alopecia areata. Lymphocytic infiltration of the dermal papilla and bulbar epithelium may be accompanied by increased expression of HLA class I and II antigens and of intercellular adhesion molecule-1 (ICAM-1) [4–6], which are thought to be secondary to the local release of T-cell cytokines. Normal numbers of follicles are found in established bald patches and in alopecia universalis. Both anagen and telogen follicles are found in these sites, with a higher proportion in telogen than in normal scalp. Follicles are smaller than normal and anagen follicles do not develop beyond the Anagen 3–4 stage, when the hair shaft starts to be formed [7]. The inflammatory infiltrate tends to be less pronounced than in early lesions and is associated mainly with anagen follicles.

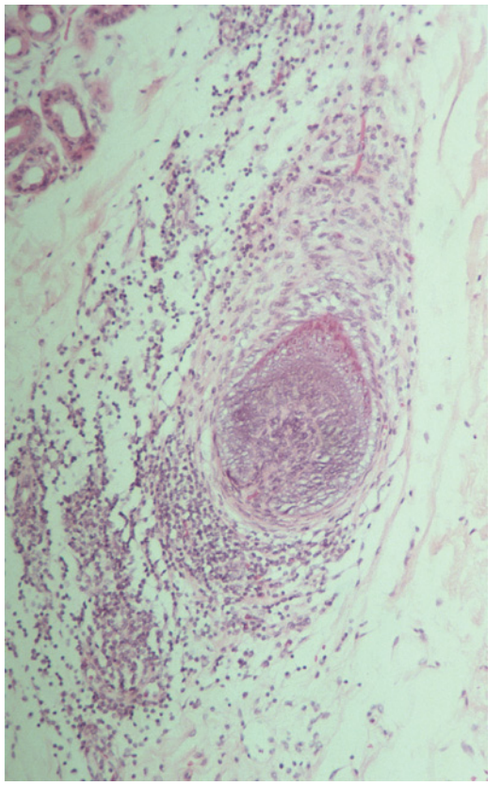

Fig. 66.23 Lymphocytic inflammatory infiltrate surrounding an anagen hair bulb in alopecia areata.

Alopecia areata causes a disturbance in the normal dynamics of the hair cycle. Anagen follicles are precipitated into telogen. This may occur as a centrifugal wave, reminiscent of a moult wave [8]. Follicles are able to re-enter anagen but, whilst the disease is active, are unable to progress beyond the Anagen 3–4 stage [7]. It has been suggested that they then return prematurely to telogen and that these truncated cycles continue until disease activity wanes [9] (Fig. 66.24).

The inflammatory infiltrate in alopecia areata is concentrated in and around the bulbar region of anagen hair follicles. Cells of several different types and differentiation pathways are found in the hair bulb, but which of these is the primary focus of the pathology is unknown. Trichocytes in the hair bulb matrix undergoing early cortical differentiation may show vacuolar degeneration (Fig. 66.25) [10,11] and are also the predominant cell type showing aberrant class I and II MHC expression. However, it is possible that changes in the epithelial compartment of the hair follicle are secondary to dysfunction of the dermal papilla. The sparing of white hair sometimes seen in alopecia areata has also raised the possibility that alopecia areata is primarily a disease of hair bulb melanocytes. Alopecia areata may show other pigmentary features, including reduced pigmentation in regrowing hairs and an association with vitiligo. However, the melanocyte hypothesis does not explain why sparing of white hair is often a relative phenomenon and is sometimes absent.

Alopecia areata in other species

Alopecia areata occurs in mammals other than humans, including chimps, dogs, horses, rats and mice. Two rodent strains, in which alopecia areata is common, the Dundee experimental bald rat (DEBR) and the CH3/HeJ mouse, have been used as experimental models of the disease. Extensive studies using the CH3/HeJ mouse have demonstrated a central role for T cells in mediating the follicular pathology in alopecia areata (reviewed in [12]).

Clinical features. The onset of alopecia areata may be at any age, peaking between the second and fourth decades. The sex incidence is probably equal. The characteristic initial lesion is a circumscribed, totally bald, smooth patch (Fig. 66.26). It is often noticed by chance by a parent, hairdresser or friend. The skin within the bald patch appears normal or slightly reddened. Short, easily extractable broken hairs, known as exclamation mark hairs, are often seen at the margins of the bald patches during active phases of the disease (Fig. 66.27). Subsequent progress is very varied; the initial patch may regrow within a few months, or further patches may appear after an interval of 3–6 weeks and then in a cyclical fashion. These intervals are of varying duration. A succession of discrete patches may rapidly become confluent by the diffuse loss of remaining hair. In some cases the initial hair loss is diffuse, and total denudation of the scalp has been reported within 48 h. However, diffuse hair loss may occur over part or the whole of the scalp without the development of bald areas.

Fig. 66.27 Exclamation mark hairs.

Fig. 66.28 Alopecia areata affecting the beard.

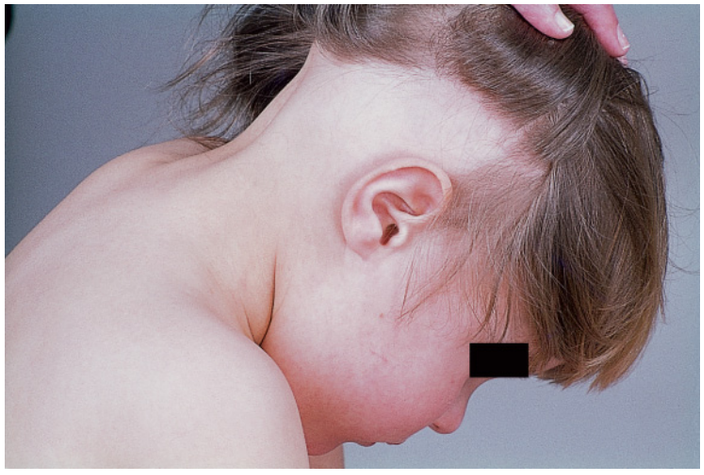

Fig. 66.29 The ophiasis pattern of alopecia areata.

Fig. 66.30 Regrowth of hypopigmented hair in alopecia areata.

Regrowth is often at first fine and unpigmented, but usually the hairs gradually resume their normal calibre and colour. Regrowth in one region of the scalp may occur while the alopecia is extending in others.

The scalp is the first affected site in most cases, but any hair-bearing skin can be affected. In dark-haired men, patches in the beard are conspicuous and in such individuals are often the first to be noticed (Fig. 66.28). The eyebrows and eyelashes are lost in many cases of alopecia areata and may be the only sites affected. The term alopecia totalis is applied to total or almost total loss of scalp hair, and alopecia universalis is the loss of all body hair. The extension of alopecia along the scalp margin is known as ophiasis (Fig. 66.29).

An intriguing feature of alopecia areata is the sparing of white hairs. In patients with grey hair, which is an admixture of pigmented and non-pigmented hair, the disease process appears preferentially to affect pigmented hair, so that non-pigmented or white hair is spared. This may result in a dramatic change in hair colour if the alopecia progresses rapidly, and is probably the explanation for historical accounts of people 'going white overnight'. Sparing of white hair is a relative phenomenon and it is clear that the white hairs, although less susceptible to the disease, are not immune. During the regrowth phase hairs may be non- or hypopigmented (Fig. 66.30) but hair pigmentation usually recovers completely. In exceptional cases where regrowing hairs remain non-pigmented the possibility of concurrent vitiligo should be considered.

In 10–15% of cases referred for specialist opinion alopecia areata also involves the nails, usually in the context of severe hair loss. Classically, alopecia areata causes fine, stippled pitting of the nails (Fig. 66.31), but some cases show less well-defined roughening of the nail plate (trachyonychia) or a non-specific atrophic dystrophy. For some patients, the latter problem is the most troublesome aspect of the disease.

Differential diagnosis. In children the main sources of diagnostic difficulty are tinea capitis and trichotillomania. Tinea capitis should always be considered in children presenting with patchy hair loss. There is usually evidence of scalp inflammation but this may be limited to mild scaling. The hair loss in trichotillomania may be asymmetrical or occur in artificial shapes. Broken hairs are usually present across the areas of hair loss, giving a bristly texture and, unlike exclamation mark hairs, are firmly anchored in the

Fig. 66.31 An organized pattern of pitting present on all fingernails 8 months prior to the onset of alopecia areata. Pits are highlighted with mascara.

scalp. In most cases the true diagnosis will become evident with time; a biopsy is useful when doubt remains. Occasionally, the early stages of scarring alopecia can resemble alopecia areata. The diffuse form of alopecia areata is perhaps the most difficult to identify. A history of previous episodes of hair loss, nail dystrophy and the usually rapid progression may provide clues, but other causes of diffuse hair loss, such as SLE, may need to be excluded by appropriate serological tests and a scalp biopsy. Secondary syphilis sometimes presents with diffuse or patchy hair loss.

Prognosis. Alopecia areata does not destroy hair follicles, and the potential for regrowth of hair is retained for many years, and is possibly lifelong. In some patients, patches of hair loss occur at infrequent intervals interspersed with long periods of normal hair growth. In others, alopecia areata is more persistent, so that new patches of hair loss continue to develop at the same time as regrowth occurs elsewhere. In a relatively small number of patients, hair loss progresses to involve all of the scalp (alopecia totalis) or the entire skin surface (alopecia universalis); in these cases, spontaneous recovery is the exception rather than the rule.

Data from secondary and tertiary referral centres indicate that 34–50% of patients will recover within 1 year, although almost all will experience more than one episode of the disease, and 14–25% progress to alopecia totalis or alopecia universalis, from which full recovery is unusual (less than 10%) [1–3]. One study from Japan reported that spontaneous remission within 1 year occurred in 80% of patients with a small number of circumscribed patches of hair loss [4]. The prognosis is less favourable when onset occurs during childhood [3,5] and in ophiasis [5]. The concurrence of atopic disease has been reported to be associated with a poor prognosis [4,5], but this was not found in a study from India [6].

Management. A number of treatments can induce hair growth in alopecia areata, but none has been shown to alter the course of the disease, and the response rate in patients with extensive hair loss is low. Few treatments have been subjected to randomized controlled trials and, except for contact immunotherapy, there are few published data on long-term outcomes. These difficulties mean that counselling of the patient and, where relevant, of their family, are of paramount importance. This should include discussion of the nature of the disease and its natural history, the treatments available and their chances of success. Some patients have great difficulty coping with alopecia areata and require considerable support. Sources of support may include the physician, other patients, formal patient support groups and, in some circumstances, professional counselling services.

Treatment. Leaving alopecia areata untreated is a legitimate option for many patients. Spontaneous remission occurs in up to 80% of patients with limited patchy hair loss of short duration (less than 1 year) [1]. Such patients may be managed by reassurance alone, with advice that regrowth cannot be expected within 3 months of the development of any individual patch. The prognosis in long-standing extensive alopecia is less favourable. However, all treatments have a high failure rate in this group and some patients prefer not to be treated, other than wearing a wig if appropriate.

Corticosteroids. Potent topical steroids are widely used to treat alopecia areata. Two controlled trials have demonstrated modest benefit in limited disease, one using the steroid under occlusion [2] and the other using a foam formulation [3]. Topical steroids are not effective in alopecia totalis/universalis.

Intralesional depot corticosteroids can be used to accelerate regrowth in a circumscribed patch of alopecia areata that is cosmetically disfiguring or difficult to conceal [4,5]. They can also be useful to stimulate regrowth of the eyebrows, but care must be exercised to avoid steroid side effects in the eye. Hydrocortisone acetate (25 mg/mL) and triamcinolone acetonide (5–10 mg/mL) are commonly used, either by needle injection or jet injection; 1–3 ml can be injected in a session, each injection of 0.05–0.1 ml,

and repeated at intervals as necessary. Localized atrophy is a common complication, particularly if triamcinolone is used, but this is temporary and recovers within a few months. Repeated injections into the same site should be avoided.

Long-term daily treatment with oral corticosteroids will produce regrowth of hair in some patients. One small, partly controlled study reported that 30–47% of patients treated with a 6-week tapering course of oral prednisolone (starting at 40 mg/day) showed more than 25% hair regrowth [6]. Unfortunately, in most patients, continued treatment is needed to maintain hair growth and the response is usually insufficient to justify the risks. There are several case series reporting a favourable response to high-dose pulsed corticosteroid treatment using different oral and intravenous regimens [7–9]. In the only controlled trial, patients receiving prednisolone 200 mg once a week for 3 months showed better hair regrowth at 6 months than those taking placebo [10], but this was not statistically significant [11].

Contact immunotherapy. Contact immunotherapy is the most effective and best-documented treatment for alopecia areata, but problems associated with its use mean that it is available in only a few centres. The patient is sensitized to a potent allergen and the same allergen is then applied to the scalp, usually at weekly intervals, in a concentration sufficient to induce a mild contact dermatitis. The contact allergens that have been used in the treatment of alopecia areata include dinitrochlorobenzene (DNCB), squaric acid dibutylester (SADBE) and diphenylcyclopropenone (DPCP). Most centres now use DPCP [12]. A review of all the published studies of contact immunotherapy concluded that 50–60% of patients achieve a worthwhile response, but the range of response rates was very wide (9–87%) [13]. Patients with extensive hair loss are less likely to respond [14,15]. Other reported adverse prognostic features include the presence of nail changes, early onset and a positive family history [13]. In most studies treatment was discontinued after 6 months if no response was obtained. In one case series from Canada, clinically significant regrowth occurred in approximately 30% of patients after 6 months' treatment, but this increased to 78% after 32 months of treatment, suggesting that more prolonged treatment is worthwhile [16]. The response in patients with alopecia totalis and universalis was less favourable at 17% and this was not improved by treatment beyond 9 months. Relapses may occur following or during treatment. In the Canadian series, relapse following successful treatment occurred in 62% of patients. Two case report series of contact immunotherapy in children with alopecia areata reported response rates of 33% [17] and 32% [18]. A third study found a similar short-term response in children with severe alopecia areata, but less than 10% experienced sustained benefit [19].

Most patients will develop occipital and/or cervical lymphadenopathy during contact immunotherapy. This is usually temporary but may persist throughout the treatment period. Severe dermatitis is the most common adverse event, but the risk can be minimized by careful titration of the concentration. Uncommon adverse effects include urticaria [20] and vitiligo [21]. Cosmetically disabling pigmentary complications, both hyper- and hypopigmentation (including vitiligo), may occur if contact immunotherapy is used in patients with racially pigmented skin. Contact immunotherapy has been in use for 20 years and no long-term side effects have been reported.

The mode of action of contact immunotherapy is unknown. Happle [22] suggested that the contact allergen competes for CD4 cells, attracting them away from the perifollicular region ('antigenic competition'). Other suggested mechanisms include the non-specific stimulation of a local T-suppressor-cell response [23] and increased expression of TGF-β in the skin, which acts to suppress the immune response [24].

Photochemotherapy. There are several uncontrolled studies of photochemotherapy (PUVA) for alopecia areata, using all types of PUVA (oral or topical psoralen, local or whole body UVA irradiation) [25–27], claiming success rates of up to 60–65%. Two retrospective reviews have reported low response rates [28] or suggested that the response was no better than the natural course of the disease [29], although these observations were also uncontrolled. The relapse rate following treatment is high and continued treatment is usually needed to maintain hair growth, which may lead to an unacceptably high cumulative UVA dose.

Minoxidil. An early double-blind study reported a significantly greater frequency of hair regrowth in patchy alopecia areata in patients treated with topical 1% minoxidil compared with placebo [30]. Subsequent controlled trials in patients with extensive alopecia areata using 1% or 3% minoxidil failed to confirm these results [31–33]. Two of these studies reported a treatment response during an extended but uncontrolled part of the trial [32,33]. In one study comparing 5% and 1% minoxidil in extensive alopecia areata, regrowth of hair occurred more frequently in those receiving 5% minoxidil, but few subjects obtained a cosmetically worthwhile result [34]. Topical minoxidil is ineffective in alopecia totalis and universalis.

Dithranol. There are a small number of case report series of the use of dithranol (anthralin) or other irritants in the treatment of alopecia areata. The lack of controls makes the response rates difficult to evaluate, but only a small proportion of patients seem to achieve cosmetically worthwhile results. In one open study, 18% of patients with extensive alopecia areata achieved cosmetically worthwhile hair regrowth [35]. The published data indicate that dithranol needs to be applied sufficiently frequently and in a high enough concentration to produce a brisk irritant reaction in order to be effective.

Summary

Alopecia areata is difficult to treat and few treatments have been tested in randomized, controlled trials. The tendency to spontaneous remission and the lack of adverse effects on general health are important considerations in management, and counselling, with no treatment, is the best option in many cases. Topical and intralesional corticosteroids can be helpful in disease of limited extent. Minoxidil lotion and dithranol are widely used but there is little convincing evidence of efficacy. Contact immunotherapy is the most effective treatment for extensive alopecia areata, although it is not widely available, and the response rate in alopecia totalis

and universalis is low. The place of systemic corticosteroids is controversial.

Alopecia areata may cause considerable psychological and social disability and, in some cases, particularly those seen in secondary care, it may be a chronic and persistent disease causing extensive or universal hair loss. If the prognosis is poor (e.g. in a prepubertal atopic child with total alopecia), a full explanation and help in adjusting to the problems of hair loss will be of far greater value than the raising of unwarranted hopes.

Acquired cicatricial alopecia

R.D. Sinclair, pp. 66.38–66.52

Cicatricial alopecia is the generic term applied to permanent areas of hair loss that are associated with destruction of hair follicles. Following recovery from the initial injury or inflammatory insult, there is little if any potential for hair regrowth. Histologically, the follicles are replaced by fibrous stellae.

One of the earliest descriptions of cicatricial alopecia was by Brocq in 1885 [1]. He described what later became known eponymously as pseudopelade of Brocq [2], which is now regarded as a syndrome in which destruction of follicles leading to permanent patchy baldness is not accompanied by any clinically evident inflammatory pathology. Quainquad [3] described folliculitis decalvans, a form of scarring alopecia in which pustular folliculitis of the advancing margin was a conspicuous feature.

Cicatricial alopecia may result from a disease that affects the follicles primarily or a disease process external to the follicle that damages them secondarily. Secondary causes include trauma, as in burns or radiodermatitis, infections such as favus, tuberculosis or syphilis, or benign or malignant tumours. Chemicals used to straighten or curl hair may also cause a secondary cicatricial alopecia in susceptible persons.

Once the preliminary diagnosis of cicatricial alopecia has been made, the scalp should be examined for other clues as to the cause of the hair loss such as folliculitis, follicular plugging or broken hairs. These signs may help to establish the cause of a cicatricial alopecia, but no single sign is pathognomonic for a particular disease, and clinico-pathological correlation is usually needed to make a specific diagnosis. An occasional sterile pustule can even be seen in some cases of lichen planopilaris and chronic cutaneous lupus. Hairs, even if grossly normal in appearance, should be extracted from the edge of the bald area for microscopy and culture. Any pustule should be swabbed and the fluid cultured.

If no firm diagnosis is achieved, general examination of the skin, nails and oral mucosa should be carried out. Up to 40% of patients with scalp lichen planus and 30% of patients with discoid lupus of the scalp will have cutaneous disease elsewhere either at presentation or during follow-up.

In most cases, a diagnostic biopsy is indicated. The site for biopsy must be carefully selected and an early lesion is preferable. Several punch biopsies are preferable to a single elliptical biopsy; in this way, the biopsies can be orientated along follicles, and different stages of the disease process can be investigated. Ideally, at least one 4-mm biopsy should be taken from a clinically active area, prepared for horizontal section and stained with haematoxylin and eosin. If vertical sections or immunofluorescence are desired, a second 4-mm biopsy specimen from an area of similar clinical activity should be obtained. Additional biopsies from the centre of a patch of alopecia to establish whether follicular loss has occurred or to assess potential regrowth are optional, as are further biopsies for special stains (e.g. elastin, mucin, periodic acid–Schiff [PAS]) [4].

Classification of the primary causes of cicatricial alopecia is difficult because of changing clinical and histological features as these conditions evolve. The most common identifiable causes among white people are lichen planopilaris (LPP), folliculitis decalvans and discoid lupus erythematosus. Among black people, especially in North America and Europe, the most common cause is central centrifugal alopecia (see p. 66.46). Tumours, in particular metastatic nodules from renal, breast and lung carcinomas, should not be forgotten as a rare but important cause of cicatricial alopecia.

Despite multiple investigations a specific diagnosis is not always possible and a generic diagnosis of cicatricial alopecia is the best that can be offered. In such cases, a trial of oral steroids or antimalarials may be considered to assess the potential for regrowth. Surgical correction of small areas can be considered once the underlying disorder has burned out. This can be done either by follicle transplantation or excision of the area. Larger areas may require the prior use of tissue expanders [5].

Classification [4]. The causes of cicatricial alopecia are classified here into broad groups, and the individual causes then considered in greater detail (Table 66.3). Many of the causes are discussed in other chapters where appropriate.

Non-specific cicatricial alopecia

Aetiology. This is by far the most common diagnosis made among patients presenting with cicatricial alopecia. In Whiting's series of 358 patients who were biopsied because of cicatricial alopecia this was the diagnosis made in 32% of cases [1]. Although often called pseudopelade, this term is best avoided because of confusion with pseudopelade of Brocq, a specific and distinct clinical disease. This entity of non-specific cicatricial alopecia encompasses a range of idiopathic, non-inflammatory, irregular, permanent alopecias that are often slowly progressive. Many primary cicatricial alopecias ultimately burn out and the final common pathway is an irregular area of cicatricial hair loss of the scalp with no distinguishing clinical or histological features. Various authorities have estimated that between 15% and 90% of cases of non-specific cicatricial alopecia result from LPP, but there is no way of confirming this. That a small minority of patients initially diagnosed as having non-specific cicatricial alopecia later develop associated cutaneous lichen planus confirms significant overlap between this condition and LPP.

Pathology. The histology is variable and non-specific. Scalp biopsies taken from hairy skin at the edge of a scarred patch may be either completely normal or show a non-specific lymphocytic infiltrate around follicular infundibulum and mid-follicle, with or without a light, superficial perivascular infiltrate. Follicles may be depleted and replaced by fibrous tracts, and sebaceous glands and follicular units may be disrupted. In the centre of areas of alopecia, follicles are absent or dramatically diminished in number and the epidermis is atrophic. Concentric lamellar fibrosis and follicular atrophy is seen around residual follicles. The adjacent dermis is sclerotic. Follicle rupture can produce hair granulomas or pustules that may lead to an erroneous diagnosis of folliculitis decalvans.

Clinical features. The initial patch often occurs over the crown, but may occur anywhere on the scalp. The lesions tend to be oval, and several foci may coalesce to form irregular bald areas. There is usually no erythema and the patches are smooth, shiny and slightly depressed. Within any patch, a small number of terminal hairs may persist. These are often irregularly twisted and sometimes easily extracted. Folliculitis is rarely seen. The hairs at the edge of the patch of alopecia are also often irregularly twisted and easily extracted, even when in anagen, which indicates active extension of the alopecia.

Prognosis. The prognosis is extremely variable and unpredictable. Some patches extend almost imperceptibly over many years, whereas others enlarge rapidly. Whether this condition ever truly burns out, or merely extends too slowly to be noticed, is uncertain.

Treatment. Much has been tried empirically, but nothing has been shown to be effective.

Lichen planus (see Chapter 41)

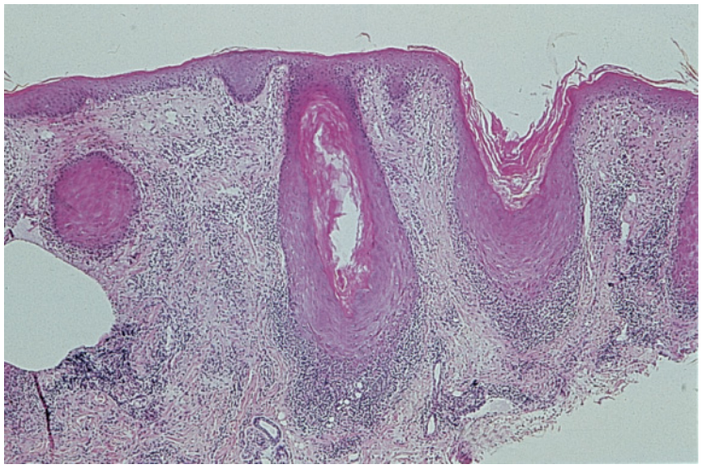

Fig. 66.32 Low-power photomicrograph showing lichen planopilaris. There is follicular plugging and a periappendageal inflammatory infiltrate.

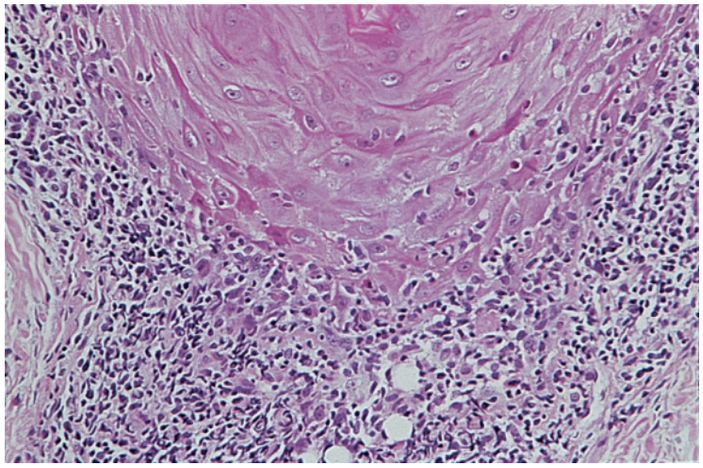

Fig. 66.33 Base of the hair follicle shows hydropic degeneration of the basal layer and a lichenoid mononuclear cell infiltrate.

Aetiology. Lichen planus is an idiopathic inflammatory disease that may affect the skin, hair and nails. There are numerous cutaneous variants of lichen planus. On the scalp it tends to produce a cicatricial alopecia. Three variants of cicatricial alopecia resulting from lichen planus are recognized: LPP, Graham-Little syndrome and frontal fibrosing alopecia. In each of these conditions the scalp may be affected alone or in conjunction with lichen planus elsewhere.

Lichen planus occurs throughout the world, although there are no data on its frequency in different ethnic groups.

Pathology [2]. The initial abnormality is in the epidermis; fibrillar changes in the basal cells lead to the formation of colloid bodies and at an early stage these, and macrophages containing pigment, may be seen in the dermis. By immunofluorescence, fibrin and immunoglobulin M (IgM) may be detected in the upper dermis, and various components of complement in the basement-membrane zone. The damaged basal cells are continually replaced by the migration of cells from neighbouring normal epidermis. In the established lesion, the horny layer and granular layer are thickened and there is irregular acanthosis. Flattening of the rete pegs gives rise to a saw-tooth configuration. There is liquefaction degeneration of the basal cells. Close up against the epidermis is a dense infiltrate of lymphocytes and some histiocytes. In many sections, colloid bodies can be seen. If the process involves hair follicles, the infiltrate extends around them and the hairs are replaced by keratin plugs. The follicles may ultimately be totally destroyed (Figs 66.32 & 66.33).

AGA with associated fibrosis may be confused with patterned LPP, especially as mild to moderate lymphohistiocytic inflammation is commonly seen in AGA [3].

Clinical features [4]. Lichen planus occurs at any age, but in over 80% of cases the onset is between 30 and 70 years [5]. Significant involvement of the scalp is relatively infrequent—only 10 of 807 patients in one series [5]—but the incidence is probably rather higher than such figures suggest, because they tend to exclude those patients in whom alopecia, classified as pseudopelade, was the only manifestation of the disease. Scalp involvement occurs in over 40% of patients with either of two unusual variants of lichen planus: the bullous or erosive form and LPP.

Fig. 66.34 Scarring alopecia caused by lichen planus, showing active lesions.

Recent scalp lesions may show violaceous papules, erythema and scaling (Fig. 66.34). These papules are replaced quickly by follicular plugs and scarring (Fig. 66.35). Eventually, the plugs are shed from the scarred area, which remains white, smooth and atrophic. Follicular orifices are absent within the area of alopecia. If the patch is extending, horny plugs may still be present in follicles around its margins, and the hair pull will be positive at the margins, with twisted anagen hairs being easily extracted by gentle traction.

Patients commonly present with pseudopelade-like patches of scarring that are non-specific. The diagnosis of lichen planus can be made only in the presence of unquestionable lesions elsewhere and lichen planus histology. These may take the form of bullous lichen planus with shedding of nails [6], of bullous lesions associated with typical lichen planus of the skin and mucous membranes, or of lichen planus of very limited extent involving, for example, the nails only.

Fig. 66.35 More advanced lichen planus, showing follicular plugs and scarring.

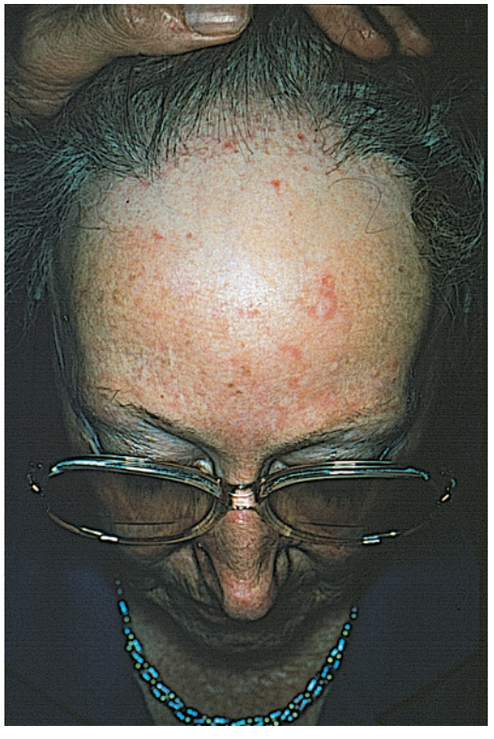

Fig. 66.36 Frontal fibrosing alopecia of Kossard.

One clinical variant of LPP is frontal fibrosing alopecia (Fig. 66.36) [7]. This condition superficially resembles AGA with frontal recession, but on close inspection there is loss of follicular orifices, and perifollicular erythema and hyperkeratosis at the marginal hairline. It typically occurs in postmenopausal women, although it can occur earlier. In contrast with AGA, the frontal hairline recedes in a straight line rather than bitemporally.

The natural history of frontal fibrosing alopecia is slow progression over many years. There is no effective treatment [7].

Prognosis. In some patients, the course of lichen planus of the scalp is slow and only a few inconspicuous patches are present after many years. However, particularly if the skin lesions are of bullous or planopilaris type, they may rapidly result in extensive and permanent baldness.

Treatment. In some cases, a short course of systemic treatment with a corticosteroid may be desirable. In other cases, intralesional corticosteroids are helpful, but only at a stage when active inflammatory changes are still present. Potent topical steroids such as clobetasol propionate ointment twice daily usually relieve associated symptoms such as itch or pain, and may slightly inhibit the process [8]. Hydroxychloroquine and acitretin have been tried with variable success. Ciclosporin is very effective for cutaneous lichen planus, and has been reported as useful in Graham-Little syndrome [9], as has thalidomide [10,11].

The lack of a clearly defined natural history, the permanency of the hair loss, the absence of any proven effective treatment to arrest disease progression, and the difficulty in monitoring clinical response, conspire to make treatment of this condition particularly frustrating for both patient and doctor.

Graham-Little syndrome

In 1915, Graham-Little reported the case of a woman aged 55 years who had suffered for 10 years from slowly progressive cicatricial alopecia and for 5 months from groups of horny papules [1]. Since then many further cases have been reported. Whether this syndrome is or is not a form of lichen planus is still unresolved, although the immunofluorescence in typical cases strongly suggests lichen planus [2]. However, whatever its cause or causes, the syndrome is distinctive. It is known eponymously and variously as the Graham-Little, Lassueur–Graham-Little or Piccardi–Lassueur–Little syndrome.

Pathology. In the scalp, the mouths of affected follicles are filled by horny plugs. The underlying follicle is progressively destroyed and eventually an atrophic epidermis covers sclerotic dermis. In

the axillae and pubic region, the follicles are likewise destroyed, although the skin does not appear clinically to be atrophic.

Clinical features. Most patients are women between the ages of 30 and 70 years. The essential features of the syndrome are progressive cicatricial alopecia of the scalp, loss of pubic and axillary hair without clinically evident scarring, and the rapid development of keratosis pilaris [3].

In most patients, the earliest change has been patchy cicatricial alopecia of the scalp. In general, the scalp alopecia precedes the widespread keratosis pilaris by months or years [4]. In some patients, the alopecia and the keratosis pilaris appear to have developed more or less simultaneously, or the keratosis pilaris has preceded the discovery of the alopecia [5].

The scalp changes are commonly described simply as patches of cicatricial alopecia. Some authors specifically mention associated follicular plugging of the scalp [6]; others refer to 'scaly red patches'.

The keratosis pilaris is referred to in early case reports as lichen spinulosus, which emphasizes that the horny papules are prolonged into conspicuous spines. In most cases they have developed aggressively over a period of weeks or months and have been grouped into plaques, often on the trunk, or the trunk and limbs, but occasionally involving the eyebrows and the sides of the face. Pruritus is an inconstant symptom; it was noted in several reported cases [7]. Thinning and ultimately total loss of pubic and axillary hair has been noted in many cases.

Treatment. None is universally effective. Ciclosporin was reported as useful in a single case [6].

Discoid lupus erythematosus [1]

Lupus erythematosus (LE) is an autoimmune connective tissue disease characterized by the presence of circulating non-organ-specific autoantibodies to cell nuclear antigens. Three different forms of LE are described: systemic (SLE), subacute and discoid (DLE) lupus. However, only DLE regularly produces cicatricial alopecia. Inflammation of the infundibular region of the hair follicle that contains the stem cells is thought to be the basis of the scarring alopecia that occurs in DLE, but this does not explain why the identical pattern of inflammation seen in SLE does not scar.

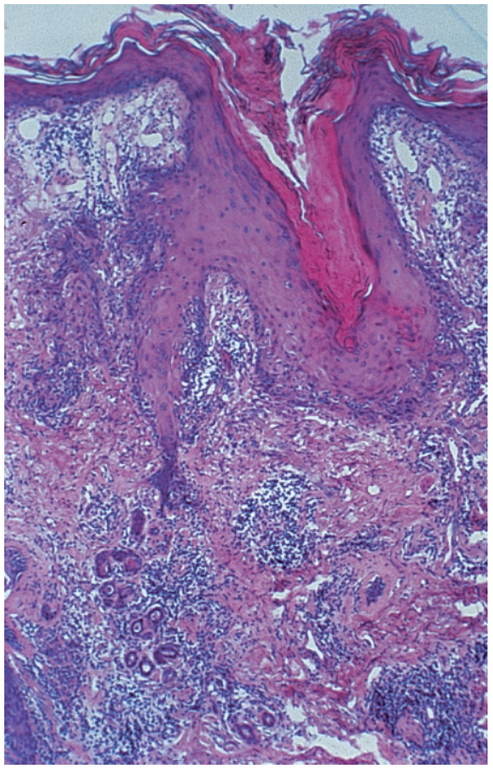

Fig. 66.37 Discoid lupus erythematosus. Low-power photomicrograph showing follicular plugging, superficial and deep perivascular and periappendageal lymphocytic infiltrate. (Courtesy of Dr G. Mason, Melbourne, Australia.)

The diffuse hair shedding that accompanies SLE is believed to be an acute telogen effluvium.

Pathology [2]. The histology of DLE, in common with SLE, shows hyperkeratosis with follicular plugging, a perivascular and periadnexal lymphoid infiltrate, which may be sparse, moderate or heavy, and the essential feature of focal basal layer vacuolar degeneration (Figs 66.37–66.39). This may be associated with colloid body formation, pigmentary incontinence, papillary dermal oedema, thickening of the basement-membrane zone and exocytosis of lymphocytes into the epidermis and follicular epithelium. Mucin can be seen in the dermis as a faint blue tinge between widely separated collagen bundles. Scarring only occurs in DLE and manifests as homogenized collagen fibres running parallel to the surface, a loss of appendages and lone arrector pili muscles. Staining for elastin shows that elastic fibres are absent from the scar.

Hypergranulosis, saw-toothed rete ridges, perifollicular fibrosis and clefts are not seen in lupus, and this helps to distinguish it from lichen planus. However, frequently it is not possible to separate these two conditions on routine histological examination and in such cases immunofluorescence may be decisive. There is linear staining of deposits of complement (C3), IgM and IgG on the basement membrane in more than 80% of cases of LE, but not in lichen planus. Direct immunofluorescence is also positive in non-lesional skin in approximately 50–75% of cases of SLE, depending on

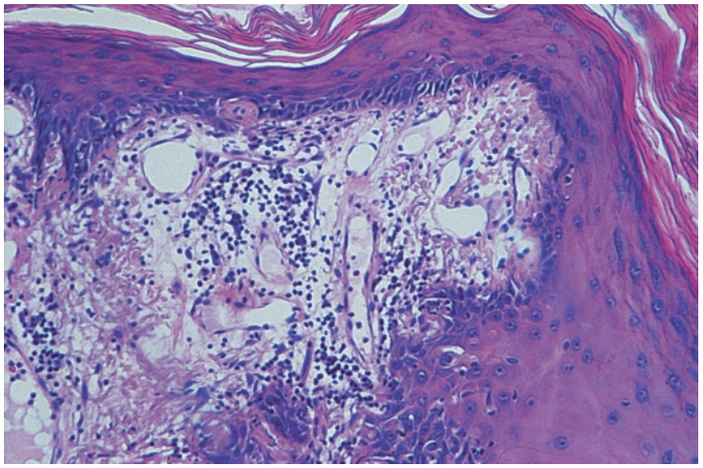

Fig. 66.38 Discoid lupus erythematosus. High-power photomicrograph showing the hydropic degeneration of the basal layer and the mononuclear cell infiltrate. (Courtesy of Dr G. Mason, Melbourne, Australia.)

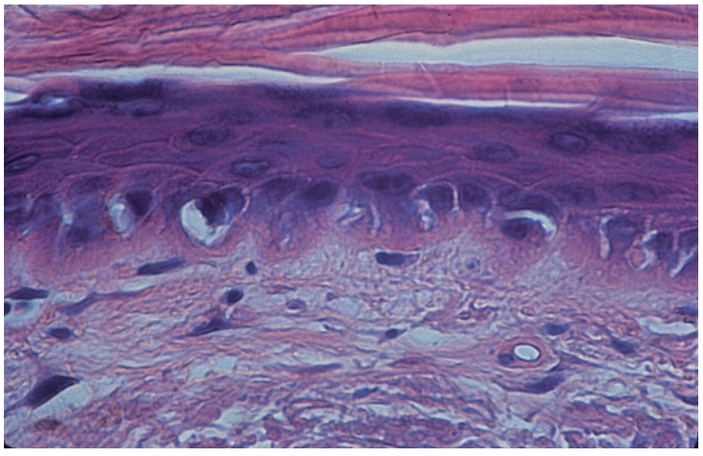

Fig. 66.39 Discoid lupus erythematosus. High-power photomicrograph showing the hydropic degeneration of the basal layer. (Courtesy of Dr G. Mason, Melbourne, Australia.)

whether sun-exposed or non-exposed skin is chosen. Only approximately 20% of cases of DLE will have positive immunofluorescence of uninvolved skin. A weak false-positive immunofluorescence to IgM can occur on the head and neck and is a source of confusion. Only positivity to IgG or very strong positivity to IgM (Fig. 66.40) should be used as supportive evidence of lupus on the scalp, as this only rarely occurs in the absence of lupus.

In old, burnt-out lesions, the histology and immunofluorescence may be inconclusive, and in such cases a non-specific diagnosis such as scarring alopecia is all that can be made.

Clinical features [2]. DLE occurs most commonly in women (8:1 for SLE and 2:1 for DLE), and is about three times more common in African Americans than in white people. The incidence is approximately 1 in 2000. Familial cases occur in approximately 10%. The peak age of onset is around 40 years.

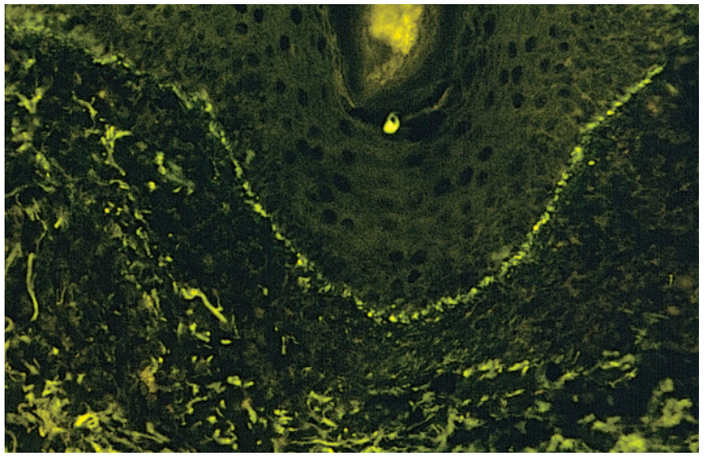

Fig. 66.40 Positive linear immunofluorescence to IgG: the lupus band test. (Courtesy of Dr G. Mason, Melbourne, Australia.)

Fig. 66.41 Discoid lupus erythematosus producing cicatricial alopecia.

Scarring alopecia occurs in 20% of men and 50% of women affected with DLE, and the scalp is the only area affected in a significant number of patients. Patches on the scalp are often itchy. Areas of erythema and scaling with follicular plugging extend irregularly across the scalp and produce scarring (Fig. 66.41). Sometimes patches of scarring alopecia develop with little in the way of preceding inflammation, and then resemble pseudopelade of Brocq. Ultimately, large areas of alopecia may form. Some cases burn out after 1–2 years, but others continue to progress for many years.

Pigmentary disturbance, particularly in dark-skinned people, is common. Rarely, calcification occurs in the patches. Squamous

cell carcinoma has been reported in chronic cicatricial LE of the scalp [3].

Antinuclear antibody (ANA) is positive in approximately 35% of patients with DLE. Anti-Ro antibodies are found in 10%. DLE may occur on its own or associated with SLE. If the initial DLE is confined to the head and neck, the risk is 1–2%, whereas if the lesions are generalized the risk is 22%. SLE first presents with DLE in 10% of cases and DLE can be found at some stage during the course of SLE in 33%.

Treatment [4]. Potent topical corticosteroids, intralesional triamcinolone and systemic prednisolone (1 mg/kg) may halt progression of active DLE. Antimalarials form the mainstay of treatment in chronic cases refractory to topical steroids. Hydroxychloroquine in a regimen of 200–400 mg/day produces a remission within 3 months in the majority and the dosage can then be tapered gradually. Scarring is permanent, but early treatment may produce a surprising amount of regrowth. Chloroquine, acitretin, dapsone, thalidomide or a combination of these medications may be useful in refractory cases. Cyclophosphamide, methotrexate and ciclosporin have also been used in severe, rapidly progressive cases where all other treatments have failed.

Pseudopelade of Brocq [1]

Pseudopelade of Brocq is an idiopathic, chronic, slowly progressive, patchy cicatricial alopecia that occurs without any evidence of inflammation. It is primarily an atrophy rather than an inflammatory folliculitis. The term pseudopelade was first used by Brocq to distinguish this condition from the 'pelade' of alopecia areata. The French term pelade had been in use at that time for more than 200 years and is derived from *pelage*—the fur, hair, wool, etc. of a mammal. In recent times, the term pseudopelade has been used to describe a generic scarring alopecia, the end result of any number of different pathological processes, and the interchangeable use by some of 'pseudopelade' and 'pseudopelade of Brocq' has led to confusion in the literature.

Pathology [2]. Early lesions may have a light lymphocytic infiltrate around the upper two-thirds of the hair follicle (including the hair bulge) that spares the epidermis and eccrine glands [3]. This infiltrate invades the walls of the follicles and sebaceous glands and eventually destroys the entire pilosebaceous unit. Single hairs may survive within a patch for many years.

Later patches are smooth, soft and slightly depressed, and histological examination reveals only a thin atrophic epidermis overlying a sclerotic dermis containing fibrotic streams extending into the subcutis. There are no inflammatory changes at this stage. These fibrotic streams are follicular 'ghosts'. Arrector pili muscles may be seen inserting into these fibrous remnants of hair follicles. Elastic stains are important in differentiating pseudopelade of Brocq from lichen planus, DLE and other scarring alopecias. With an acid–alcohol orcein stain, elastic fibres are seen around the lower part of the follicle, whereas in all the other scarring alopecias the scar tissue consists of collagen devoid of elastin.

Fig. 66.42 Pseudopelade of Brocq.

Clinical features [1]. Pseudopelade of Brocq may occur in both sexes at any age. Most commonly, women over 40 years are affected. Childhood cases are rare. The aetiology and pathogenesis are unknown. The condition is almost always sporadic, but the occurrence in two brothers suggests a genetic factor may be important. There is no doubt that lichen planus can produce a very similar clinical picture and there are some authorities who maintain, on the basis of associated skin lesions and histopathological findings, that 90% of cases of 'pseudopelade' are caused by lichen planus [4].

The alopecia is asymptomatic and is often discovered by chance. It always remains confined to the scalp. The initial patch is often on the vertex but may occur anywhere (Fig. 66.42). On examination, the affected patches are smooth, soft and slightly depressed. At an early stage in the development of any individual patch there may be some erythema. The patches tend to be small and round or oval, but irregular bald patches may be formed by the confluence of many lesions. The hair in uninvolved scalp is normal, but if the process is active the hairs at the edges of each patch are very easily extracted.

The course is extremely variable. Most often there is slow development over many years of small round patches of alopecia that ultimately converge to produce larger irregular areas of hair loss. The hair in the uninvolved scalp is normal and the progression is sufficiently slow that even after 15–20 years patients may still be able to arrange their hair in such a way as to conceal the bald areas. The entire process can burn out spontaneously at any stage, leaving behind only relatively small areas of alopecia.

Table 66.4 Diagnostic criteria for pseudopelade of Brocq. (After Braun-Falco *et al.* [1]).

Clinical criteria
Irregularly defined and confluent patches of alopecia
Moderate atrophy (late stage)
Mild perifollicular erythema (early stage)
Female : male ratio 3 : 1
Long course (more than 2 years)
Slow progression with spontaneous termination possible
Direct immunofluorescence
Negative (or only weak IgM on sun-exposed skin)
Histological criteria
Absence of marked inflammation
Absence of widespread scarring (best seen with elastin stain)
Absence of significant follicular plugging
Absence, or at least a decrease, of sebaceous glands
Presence of normal epidermis (only occasional atrophy)
Fibrotic streams into the dermis

The diagnostic criteria of Braun-Falco *et al.* [1] shown in Table 66.4, and based on the histological criteria of Pinkus [5], should be fulfilled before this specific diagnosis is made. Cases that do not fulfil these criteria should be diagnosed generically as scarring alopecia.

Treatment. The alopecia is irreversible and does not respond to topical or intralesional corticosteroids. No treatment is known to arrest progression. If the disfigurement is considerable and no active inflammatory changes are present, autografting from unaffected to scarred scalp may be considered [6], or surgical 'expansion' techniques in severe cases.

Follicular degeneration syndrome [1]

This condition begins as a single focus of cicatricial alopecia over the vertex scalp in black women that gradually spreads outwards in a centrifugal pattern, but remains unifocal. It was originally called hot comb alopecia, but many patients have no preceding history of hot comb usage. A possible relationship to other hair-straightening procedures is postulated, but not conclusively proven. The name 'central centrifugal alopecia' has also been proposed, and this focuses attention on the clinical appearance of the hair loss rather than the histological identification of premature degeneration of the inner root sheath, which is variable and not entirely specific [2].

Pathology. A superficial perivascular and perifollicular lymphocytic infiltrate is seen in active areas. There is no associated interface change. Sebaceous glands are lost early, but eccrine glands are spared. Premature disintegration of the inner root sheath epithelium has been emphasized, but is not always found. Hair follicle destruction is severe and widespread and leaves prominent concentric lamellar fibrosis. Release of hair fragments into the dermis results in granulomatous inflammation.

Clinical features. Most patients are middle-aged black females who chemically straighten their hair. The alopecia is slowly progressive and the symmetrical forward progression follows a pattern similar to female pattern hair loss.

Treatment. Minimal hair grooming is recommended, but many patients find this difficult. No treatment has been found to help. Many patients resort to wearing a suitable hair piece.

Folliculitis decalvans and tufted folliculitis [1]

Under the general term folliculitis decalvans we group the various syndromes in which clinically evident chronic folliculitis leads to progressive scarring. This is probably a heterogeneous group.

Aetiology. The cause of folliculitis decalvans is still uncertain. *Staphylococcus aureus* may be grown from the pustules. In the vast majority of people who develop a bacterial pustular folliculitis of the scalp it is transient, resolves with antibiotics and heals without scarring. In some, the folliculitis is more persistent, penetrates more deeply within the hair follicle, tends to recur in the same site after apparently successful treatment with antibiotics and produces a scarring alopecia. Spread tends to only occur to neighbouring follicles so that the condition presents as a slowly enlarging solitary area of cicatricial alopecia. It is rarely multifocal.

Failure to confine the *Staph. aureus* to the infundibulum of the hair follicle and to completely eradicate it from the isthmus is postulated, which may be due to disruption by bacterial proteases of the protective barrier provided by the inner root sheath. No consistent defect in cell-mediated immunity or inner root sheath keratinization has been identified in patients with folliculitis decalvans.

Douwes *et al.* [2] reported simultaneous occurrence in identical twins, with no identifiable immune abnormality [2].

Pathology [1,3,4]. Histology reveals follicular abscesses, with a dense perifollicular polymorphonuclear infiltrate, and scattered eosinophils and plasma cells. Foreign-body granulomas occur in response to follicular disruption, which is succeeded by scarring. Eventually all that remains of the follicle is extensive fibrosis.

Clinical features [1]. Men may be affected from adolescence onwards, whereas women tend not to develop this condition until

Fig. 66.43 Folliculitis decalvans, showing active pustulation and scarring.

their thirties. Following a pustular folliculitis of the scalp, usually one, but occasionally more, rounded patches of alopecia develop, each surrounded by crusting and a few follicular pustules. Successive crops of pustules appear and are followed by progressive destruction of the affected follicles (Fig. 66.43). In some cases the folliculitis spreads along the scalp margin in a coronal pattern, or along the edge of an AGA. The severity of the inflammatory changes fluctuates, but the course is prolonged.

Tufted folliculitis is a variant of folliculitis decalvans where circumscribed areas of scalp inflammation heal with scarring characterized by tufts of up to 15 hairs emerging from a single orifice (Fig. 66.44) [5–7]. The tufts consist of a central anagen hair surrounded by telogen hairs, each arising from independent follicles, converging towards a common dilated follicular infundibulum. Cases in which the tufts were comprised of only anagen hairs have also been described. Based on an animal model, it is suggested that erythema and scaling are the initial events and the tufting is a consequence of the emergence of hairs from beneath the free edge of the scales.

A scalp biopsy is required to confirm the diagnosis and swabs should be taken of any pustules. Investigation for an underlying defect in cell-mediated immunity is generally unrewarding, and only indicated when there is additional evidence of impaired immunity. As fungal kerion may mimic folliculitis decalvans, hairs should be plucked for fungal culture and a PAS stain should be performed on the scalp biopsy.

Treatment [1]. Essentially, treatment consists of attempts to eradicate *Staph. aureus* from the scalp. Prolonged courses of flucloxacillin induce remission, but relapse occurs when the antibiotics are stopped. For localized areas, topical clindamycin is useful. Tetracyclines are also commonly effective. Isotretinoin has been used to alter the follicular environment to make it less suitable for *Staph. aureus* colonization, but it may increase cutaneous carriage of this organism and make the condition worse. The only treatment shown to induce prolonged remission is rifampicin in a dosage of 300 mg twice daily. This should be given in combination with other antibiotics to prevent the emergence of resistant organisms. Drugs commonly used in combination include clindamycin 300 mg twice daily, fucidic acid 150 mg three times daily, ciprofloxacin, doxycycline and clarithromycin.

Fig. 66.44 Tufted folliculitis.

Tufting may be reduced by measures directed at reducing the scale, such as the use of tar shampoos and topical keratolytics.

Dissecting cellulitis of the scalp [1]

Synonyms
- Dissecting folliculitis
- Perifolliculitis capitis abscedens et suffodiens

This rare condition manifests with a perifolliculitis of the scalp, deep and superficial abscesses in the dermis, sinus tract formation and extensive scarring. It occurs predominantly in black males aged between 18 and 40 years. Familial cases are exceptional, as is childhood onset.

Fig. 66.45 Dissecting cellulitis of the scalp. (Courtesy of Dr D. Dyall-Smith and the *Australasian Journal of Dermatology* [4].)

Aetiology. The aetiology of this inflammatory condition is unknown. Although staphylococci, streptococci and *Pseudomonas* may be cultured from various lesions, no specific causative organism has been isolated. Dissecting cellulitis associates with hidradenitis suppurativa and acne conglobata in the follicular occlusion triad [2]. Other reported associations include pilonidal sinus and spondyloarthropathy. The activity of the arthritis parallels the activity of the skin.

Clinical features. Painful, firm, skin-coloured nodules develop near the vertex of the scalp and later become softer and fluctuant (Fig. 66.45). Confluent nodules form tubular ridges with an irregular cerebriform pattern, on a red and oedematous background. Thin blood-stained pus exudes from crusted sinuses, and pressure on one region of the scalp may cause discharge of pus from a neighbouring intercommunicating ridge. Cervical adenitis is present in some cases, but is more remarkable for its absence in many others. Progressive scarring and permanent alopecia occur. Characteristically, hair is lost from the summits of these inflammatory lesions and retained in the valleys. The condition is chronic, with frequent acute exacerbations. Fatal squamous cell carcinoma has developed within the areas of scarring after many years [3].

Pathology [5]. Histology shows a perifolliculitis with a heavy infiltrate of lymphocytes, histiocytes and polymorphonuclear cells. Abscess formation results, and leads to destruction of the pilosebaceous follicles initially, and eventually the other cutaneous appendages. Keratin fragments induce a granulomatous reaction, with foreign-body giant cells, lymphoid and plasma cells. Special stains for bacteria, fungi and mycobacteria are negative.

Investigations. Culture from affected areas often grows bacterial organisms. Fungal cultures and a scalp biopsy for routine histology and direct immunofluorescence will exclude other causes of scarring alopecia.

Treatment. Although systemic antibiotics and topical or intralesional corticosteroids are sometimes helpful, relapses are frequent and the course is usually protracted. Isotretinoin in full dosage (1 mg/kg), in combination with prednisolone (1 mg/kg) and erythromycin 500 mg four times daily, may induce a rapid remission and significant hair regrowth in areas not yet irreversibly damaged [4]. Because the inflammation is predominantly perifollicular, a surprising amount of regrowth may occur. The antibiotics can be stopped after 4 weeks and the prednisolone gradually tailed off and replaced by topical steroids. The isotretinoin should be continued for at least 6 months, and reintroduced if the condition relapses. In recalcitrant cases, widespread excision and grafting may be considered, or alternatively in an older patient, X-ray epilation has been used with success [6]. Improvement has also been noted following laser-assisted hair removal [7].

The benefit of isotretinoin in this condition contrasts with the frequent worsening seen with oral isotretinoin in folliculitis decalvans and suggests that these two conditions are distinct entities rather than different points along a spectrum of the same disease.

Circumscribed scleroderma and linear morphoea

Circumscribed scleroderma is rare in the scalp, but may occur there as single or multiple lesions. The hair is shed at an early stage to leave a cicatricial alopecia. The diagnosis must be confirmed histologically. Linear circumscribed morphoea in the frontal region—'en coup de sabre' morphoea (Fig. 66.46)—is slightly more common (see Chapter 51). It has been suggested that lesions may follow the lines of Blaschko [1]. Histological examination of both conditions shows chronic inflammation of the upper and mid-follicle, and prominent fibrosis [2]. Linear morphoea has been associated with hereditary deficiency of complement C2 [3].

Cicatricial pemphigoid

Synonym
- Benign mucosal pemphigoid

Cicatricial pemphigoid affects predominantly the elderly, and women more than men [1,2]. It is associated with autoantibodies to the basement-membrane-zone adhesion complex (see Chapter 40).

Bullae are formed at the dermal–epidermal junction. Direct immunocytochemical studies show that linear deposits of IgG, IgA, C3 and C4 may be found in the basement-membrane zone, but circulating basement-membrane-zone antibodies (IgG or IgA) are not always demonstrable [3,4].

Although the disease predominantly affects the ocular and/or genital mucous membrane, the skin is involved in 40–50% of cases, and skin lesions may precede the mucosal lesions by months or years [5]. The skin lesions repeatedly recur and leave scars. The favoured sites are the face and upper trunk, the scalp being involved in approximately 10% of cases [6]. Skin lesions, predominantly on the head and neck, are the major feature of the Brunsting–Perry variant.

Management is often dictated by the need to control mucosal lesions. If recurrent bullae in a localized area of skin are troublesome, excision and grafting may be successful [6]. Whether to prescribe oral corticosteroids or immunosuppressive drugs for skin lesions alone is controversial, but topical clobetasol propionate cream may inhibit the process to some degree.

Erosive pustular dermatosis of the scalp

This clinical entity particularly affects the elderly [1,2]. Its cause is unknown but Grattan *et al*. [3], in their study of 12 cases, suggested that local trauma and sun damage are important. Surgery, cryosurgery, skin grafting and radiation therapy may all precipitate this condition [4].

Pathology. Histological examination shows areas of epidermal erosion, a chronic inflammatory cell infiltration in the dermis consisting predominantly of lymphocytes and plasma cells, and sometimes small foci of foreign-body giant cells where hair follicles have been destroyed.

Clinical features. This condition almost always occurs in association with AGA. Initially, a small area of scalp becomes red, crusted and irritable; crusting and superficial pustulation overlie a moist, eroded surface (Fig. 66.47). As the condition extends, areas of activity coexist with areas of scarring. Squamous carcinoma has developed in the scars [5].

Differential diagnosis. Pyogenic and yeast infection is excluded by bacteriological examination and the lack of response to antibacterial or antifungal agents. Biopsy may be necessary to exclude pustular psoriasis, cicatricial pemphigoid, 'irritated' solar keratosis or squamous cell carcinoma.

Treatment. The stronger topical corticosteroids (e.g. 0.05% clobetasol propionate) will suppress the inflammatory changes. Gradual reduction in the potency of topical steroid over a 6-month period may result in cure. Maintenance therapy with sun protection and intermittent moderate potency steroid can provide

long-term relief. Ikeda *et al.* [6] suggested oral zinc sulphate, and Boffa [7] suggested topical calcipotriol can be curative in some cases.

Necrobiosis lipoidica, granuloma annulare and sarcoidosis

Necrobiosis lipoidica occurs in 0.2–0.3% of cases of diabetes mellitus, and approximately 70% of patients with necrobiosis have diabetes. The diabetic cases begin in childhood or early adult life, and the non-diabetic cases rather later and usually in women.

The oval atrophic plaques classically occur on the shins but may be seen on other parts of the body, including the scalp. The patches are glazed and yellowish, often with conspicuous telangiectases. Scarring may be dense. The clinical features in the scalp vary from large plaques of cicatricial alopecia to multiple small areas of scarring [1].

An atrophic form affecting predominantly the forehead and the scalp has been described [2]. In general, the differential diagnosis is from sarcoidosis and granuloma annulare [3,4].

Cutaneous sarcoidosis may produce plaques or nodules on the scalp as well as both cicatricial and non-cicatricial alopecia (Fig. 66.48) [5]. Affected areas may itch. There is a marked preponderance of females amongst reported cases. The histology is distinctive, with non-caseating granulomatous inflammation [3].

Lichen sclerosus

Lichen sclerosus of the scalp is rare (Fig. 66.49). It may cause an extensive cicatricial alopecia that is relatively nondescript clinically, but which has all the characteristic histological features. Associated lesions are usually found on the trunk and vulva [1,2].

Developmental defects and hereditary disorders

Scarring follicular keratosis

Numerous syndromes have been described and elaborately named, all of them characterized by keratosis pilaris associated with some degree of inflammatory change leading to destruction of the affected follicles [1].

Only detailed clinical and genetic studies can provide the essential facts to allow reliable differentiation of syndromes that some authorities regard as forms or degrees of a single state and others accept as distinct entities. For the time being, the reported cases can be conveniently classified in three groups; in addition, certain apparently well-defined entities can be recognized.

1 *Atrophoderma vermiculata* (acne vermiculata, folliculitis ulerythematosa reticulata). There is honeycomb atrophy of the cheeks. Scarring alopecia may occur, but rarely.
2 *Keratosis pilaris atrophicans faciei* (ulerythema oophryogenes). The process is more or less confined to the eyebrow region.
3 *Keratosis follicularis spinulosa decalvans*. Keratosis pilaris of variable extent is associated with cicatricial alopecia [2].

All these conditions are assumed to be genetically determined, although many cases occur sporadically. Such genetic data as are available are considered under the individual forms.

Clinical features. Atrophoderma vermiculata usually begins in childhood. Follicular plugs, often in the pre-auricular regions, are gradually shed to leave reticulate atrophy. On the face, the extent of the process is variable. Exceptionally, cicatricial alopecia of the scalp may be associated [3].

Keratosis pilaris atrophicans faciei (ulerythema oophryogenes) is present from early infancy. Erythema and horny plugs begin in the outer halves of the eyebrows, which they eventually destroy, and then advance medially and to a variable extent on the cheeks. Involvement of the scalp has apparently not been reported in cases in which the eyebrows are predominantly involved. However, there are reports of cases to which this diagnosis has been applied, but which appear to be more rationally classified in one of the other categories, in which alopecia has occurred. Such cases emphasize the need for improved diagnostic criteria.

Keratosis follicularis spinulosa decalvans is also a genetically heterogeneous syndrome. In some families it is inherited in an X-linked fashion with a mutation in the spermidine/spermine N(1)acetyltransferase gene (*SSAT*) at Xp22.1 [4,5]. In other families it appears to follow autosomal dominant inheritance [6]. The clinical presentation includes extensive keratosis pilaris and progressive cicatricial alopecia. Keratosis pilaris begins in infancy or childhood, often on the face. Ultimately, it may be confined to the face or to face and limbs, or may be more or less universal. The cicatricial alopecia may occur from early childhood or later, and may be localized or extensive, involving eyebrows and eyelashes as well as the scalp. Other features may include facial erythema, photophobia and ophthalmitis, and palmar–plantar keratoderma [2,7,8].

Treatment. Only symptomatic measures are available. Topical and systemic retinoids, topical steroids, antibiotics and methotrexate have been tried but without notable success. Retinoic acid deserves a trial. The status of oral retinoids remains controversial, although anecdotal response has been noted.

Porokeratosis of Mibelli

Porokeratosis of Mibelli commonly begins in childhood but may first appear at any age. It is most frequent on the limbs, particularly the hands and feet, the neck, the shoulders and the face, but may occur anywhere, including the scalp [1]. The initial lesion is a crateriform horny papule that gradually extends to form a circinate or irregular atrophic plaque with a raised horny margin, which may be surmounted by a furrow from which the lamina of horn projects. In the scalp there is loss of hair in the atrophic phase.

Incontinentia pigmenti

Cicatricial alopecia has been present in at least 25% of reported cases of incontinentia pigmenti; it appears in early infancy and ceases to extend after a variable period of up to 2 years, but the loss of hair is permanent. Other hair defects present in some cases have been hypoplasia of the eyebrows and eyelashes, and woolly hair naevus of the scalp [1].

Generalized follicular hamartoma

Cicatricial alopecia beginning in childhood was a feature of a syndrome described by Mehregan and Hardin [1]. Their patient was a woman aged 23 years. From infancy, she had widespread horny plugs over the trunk and limbs and small pits on the palms and soles. She later developed cicatricial alopecia, in which, from the age of 8 years, appeared follicular tumours. The tumours of the scalp were proliferating trichilemmal cysts. The lesions of palms and soles showed funnel-shaped dilatation of sweat ducts, which were plugged with parakeratotic material containing acid mucopolysaccharide. Ridley and Smith [2] described this entity with alopecia and myasthenia gravis.

Epidermolysis bullosa

The term epidermolysis bullosa is applied to a group of distinct, genetically determined disorders characterized by the formation of bullae of skin, and often also of mucous membranes, in response to trauma, or spontaneously (see Chapter 39). Atrophic alopecia is a feature of generalized atrophic benign epidermolysis bullosa (GABEB) [1,2], a group of non-lethal hemidesmosomal forms. Mutations in several genes may cause GABEB including *COL17A1*, *LAMA3*, *LAMB3* and *LAMC2* (MIM #226650). Cicatricial alopecia may also occur in recessive dystrophic epidermolysis bullosa.

Cleft lip-palate, ectodermal dysplasia and syndactyly

This rare or rarely recognized syndrome is probably hereditary, and determined by an autosomal recessive gene. The constant features of the syndrome are mental retardation, cleft palate, genital hypoplasia, cicatricial alopecia, defective teeth and syndactyly [1].

Reference

1 Bowen P, Armstrong HB. Ectodermal dysplasia, mental retardation, cleft lip/palate and other anomalies in three sibs. *Clin Genet* 1976; **9**: 35–42.

Polyostotic fibrous dysplasia

The progressive enlargement over a period of 10 years of a bald patch present since childhood was shown histologically to be caused by the replacement of the follicles by coils of fibrous tissue. The patient had polyostotic fibrous dysplasia [1].

Infestations

See Chapter 38.

Syphilis

Hair loss occurs in approximately 10% of cases of secondary syphilis and may be the presenting feature [1,2]. The hair loss typically has a 'moth-eaten' appearance but may be diffuse in nature [3]. Other features of secondary syphilis are present in most cases, particularly lymph node enlargement and hepatomegaly, but hair loss has been reported as the only sign of the disease [4]. Histological features include an increase in catagen and telogen forms, and a peribulbar lymphocytic infiltrate, similar to the changes seen in alopecia areata [3]. Additional features in syphilis include lymphocytic infiltration of the isthmus region, parabulbar lymphoid aggregates and the presence of plasma cells within the infiltrate.

The serpiginous nodulo-squamous syphilide of tertiary syphilis may affect the scalp, and the syphilitic gumma is a cause of scarring alopecia.

Human immunodeficiency virus (see Chapter 35)

A variety of alterations in hair growth have been described in patients with HIV infection. Telogen effluvium is a common cause of hair loss [5]. Causes include chronic HIV-1 infection itself, secondary infections, nutritional deficiencies and drugs. Hair loss on the body as well as the scalp has been reported with several antiretroviral drugs, particularly indinavir [6] and other protease inhibitors. There are also reports of alopecia areata occurring in patients with HIV infection [7–9].

There are several reports of hypertrichosis of the eyelashes (eyelash trichomegaly) in HIV infection [9–11]. The cause of this striking and unusual feature is not known. It is usually associated with advanced disease and has been noted to regress with antiretroviral treatment [11].

Straightening of the hair is a common feature of HIV infection in black patients [12].

Various forms of folliculitis are seen in HIV infection, including acneiform eruptions, staphylococcal folliculitis and eosinophilic pustular folliculitis.

Leprosy

Loss of eyebrow and body hair may occur in lepromatous leprosy but the scalp is rarely involved.

Artefactual alopecia

D.A.R. de Berker, pp. 66.53–66.54

Cosmetic alopecia

Cosmetic practices can result in damage to the hair shaft or the scalp. The application of heat (e.g. from heated tongs) to damp hair may cause breakage due to the formation of bubbles in the hair shaft ('bubble hair') [1]. Fracture of hair shafts, which can be extensive, may also be caused by overuse of chemical treatments such as permanent waves and relaxers.

Traction alopecia

Traction alopecia is brought about by hair styles that impose sustained pulling on the hair roots. The clinical features in the many variants of this syndrome include folliculitis, hair casts [2], reduction in hair density with vellus hairs and sometimes broken hairs in the affected areas, and eventually scarring alopecia. It can be associated with headache, relieved when the hair is loosened [3]. The pattern of the hair loss is often distinctive and reflects the distribution of the traction.

Traction alopecia is seen most commonly in Afro-Caribbean hair styles where the hair is tightly braided. The hair loss commonly begins in the temporal regions and in front of and above the ears, but may involve other parts of the scalp (Fig. 66.50), particularly where 'corn row' patterns are adopted. Problems typically start in childhood, where they may initially be reversible [4]. A degree of temporal thinning may also be part of a genetic hair pattern seen in those with no traction.

Pony tails, hair twisting in Sikh boys [5], and tight scarf styles can all result in hair loss [6].

Treatment. The patient, or parents of affected children, need to be educated to adopt hair styles that do not pull the hair tight [7]. Where there is inflammation, a mild topical steroid can be helpful, but is not a substitute for a non-traction hair style.

Fig. 66.50 Traction alopecia from braiding.

Medical trauma

There are instances where medical intervention may result in scalp trauma and be implicated in scarring alopecia. Scalp electrodes or infusion [1] or forceps delivery in the neonate can result in trauma. Uterine rings have also been reported as a cause of infant scalp problems [2]. Marks from such interventions need to be distinguished from aplasia cutis which can sometimes be the underlying diagnosis [3].

Interventions in adulthood, directly through scalp and brain surgery or indirectly through local embolization procedures, can result in scarring. Adler *et al.* [4] described a case in which ischaemic necrosis of the occipital scalp occurred following embolization and surgery for a large convexity meningioma.

Pressure ischaemia can occur during intensive care or gynaecological surgery in the Trendelenburg position [5]. In one large clinic, over a period of 3 years, 60 cases of occipital pressure alopecia were observed after open-heart surgery [6]. In 29 of these cases, the hair loss was permanent. Temporary alopecia followed prolonged pressure on the scalp by a foam rubber ring used to prevent such an occurrence [7].

Chronic radiodermatitis [1,2]

Roentgen discovered X-rays in 1895. X-ray epilation of the face for hirsutism was frequently employed during the first two decades of the 20th century and, although Schultz [3] condemned this treatment, it continued to be so widely used that Cipollaro and Einhorn [4] entitled their paper: 'The use of X-rays for the treatment of hypertrichosis is dangerous'.

X-ray epilation for the treatment of scalp ringworm was introduced in Paris in 1904. The discovery of griseofulvin in 1958 gradually made X-ray epilation unnecessary, but it has been estimated that between 1904 and 1959 some 300 000 children throughout the

world were treated with X-rays for ringworm of the scalp. Correct dosage did not cause toxicity; however, technical errors were frequent, from inadequate and poorly calibrated apparatus. The treatment produced complete epilation in approximately 3 weeks and regrowth after 2 months. The follow-up of 2043 patients treated in childhood showed a higher incidence of cancer in the patients than in a control group [1]. Radiodermatitis of the scalp may occur also as an unavoidable consequence of skin damage during the treatment of both internal malignant disease and malignant disease of the skin.

In chronic radiodermatitis, the epidermis is generally atrophic, with loss of hair follicles and sebaceous glands, but there are also irregular areas of acanthosis. Degenerative changes and nuclear abnormalities are frequent in the epidermis. Dermal collagen stains irregularly. Superficial small vessels are telangiectatic, but deeper vessels are partially or completely occluded by fibrosis.

Clinical features. The development of a basal cell carcinoma in middle age or later in an area of the scalp should lead the dermatologist to enquire about X-ray epilation for ringworm in childhood [5]. In other cases, the patient complains of hair loss, which is apparently accentuated in certain areas, and these areas are found to show both AGA and reduction of follicle population as a result of the earlier radiation.

Chronic radiodermatitis produced by radiation therapy of a malignant tumour of the scalp presents a circumscribed area of cicatricial alopecia. Radiation necrosis may simulate a recurrence of carcinoma, but the edges of the necrotic ulcer are not raised. The diagnosis should be confirmed by a biopsy. Superficial X-ray of Grenz ray type does not penetrate deeply enough to damage scalp follicles. Malignant tumours arising in radiodermatitis should be excised [6].

Trichotillomania (see also Chapter 64)

A.G. Messenger, pp. 66.54–66.57

Trichotillomania is a behavioural disorder characterized by compulsive hair pulling. It presents as a pattern of hair loss, often bizarre, with no clear biological or overt traumatic explanation [1]. Compulsive hair rubbing (trichoteiromania [2]) and hair cutting (trichotemnomania [3]) fall into the same general category.

Pathology. Microscopy may be undertaken of the hair or of a scalp biopsy. Hairs may be of different length in an affected area.

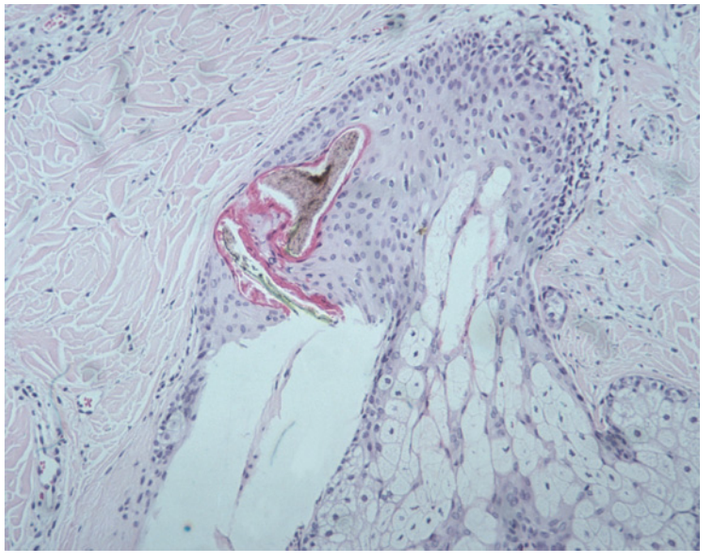

Fig. 66.51 Histology of trichotillomania, showing fragmentation of the hair shaft.

They may be broken, where trauma has snapped the shaft, or be tapered, where trauma is in the form of plucking. The scalp itself is usually clinically normal except in the instances where the trauma is rubbing or scratching. In these instances there are often scalp signs and the problem may present primarily as a scalp dermatosis—even if it is wholly artefactual. Rubbing can also lead to hair breakage or interfere with the normal anagen cycle without specifically altering the hair shaft.

Dermoscopy of the scalp may help differentiate between trichotillomania and alopecia areata, where follicular orifices may appear as yellow dots [4].

Scalp histology varies according to the severity and duration of the hair plucking. Numerous empty canals are the most consistent feature. Some follicles are severely damaged; there are clefts in the hair matrix, the follicular epithelium is separated from the connective tissue sheath, and there are intraepithelial and perifollicular haemorrhages and intrafollicular pigment casts (Fig. 66.51) [5]. Injured follicles may form only soft, twisted hairs—a process that has been described as a separate entity under the name of trichomalacia [6]. Many follicles are in catagen, with very few or no follicles in telogen. Some dilated follicular infundibula contain horny plugs [7].

Aetiology and psychopathology. Trichotillomania occurs in two main forms. In infants and young children it is usually a habit akin to thumb-sucking and nail biting. It seems slightly more common in boys and usually resolves spontaneously or with minimal treatment. Parents who have not noticed hair-pulling behaviour in their offspring may deny the diagnosis. In older age groups, adolescents and adults, trichotillomania is seen predominantly in females, with women outnumbering men by up to 7:1, and evidence of some form of psychological or behavioural stress is often apparent [8]. The American Psychiatric Association classifies trichotillomania as an impulse control disorder, in which there is an irresistible desire to pull out the hair. This process results in an

Table 66.5 DSM-IV criteria for trichotillomania.

Recurrent pulling out of one's hair resulting in noticeable hair loss
An increasing sense of tension immediately before pulling out the hair or when attempting to resist the behaviour
Pleasure, gratification or relief when pulling out the hair
The disturbance is not better accounted for by another mental disorder and is not due to a general medical condition (e.g. a dermatological condition)
The disturbance causes clinically significant distress or impairment in social, occupational or other important areas of functioning

instant release of tension and sense of relief. The diagnostic criteria are given in the fourth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV), and are listed in Table 66.5, although not all patients with trichotillomania fit these criteria.

Trichotillomania shares some features of obsessive–compulsive disorder (OCD), but some authorities consider it may be the result of a number of psychopathologies including OCD, personality disorders, body dysmorphophobic disorders, mental retardation and psychosis. There is an extensive psychiatric literature on trichotillomania, but this may be biased because psychiatric help is likely to be sought only in those patients who accept that it is a self-inflicted problem. This is not true of all patients presenting to dermatologists.

Clinical features. In young children, the hair-pulling tic develops gradually and unconsciously. Hair is plucked most frequently from one frontoparietal region. This results in a patch of hair loss, often in a bizarre or angular pattern, in which the hairs are twisted and broken at various distances from the clinically normal scalp. Older patients present with an area of scalp on which the hair has been reduced to coarse stubble uniformly 2.5–3 mm long. The plucked area may be asymmetrical or cover the entire scalp apart from the margin (Fig. 66.52). It is unusual for hair to be lost completely within the affected area (in contrast with alopecia areata). The scalp skin appears normal. Over time the extent of hair loss can vary, and hair growth may recover temporarily.

Hair in sites other than the scalp can also be affected, such as eyelashes, eyebrows and beard. Exceptionally, the patient may pluck hair also, or only, from other regions of the body, such as the mons pubis and perianal region.

A hairball (trichobezoar) is a rare accompaniment of trichotillomania in those who also eat the plucked hair (trichophagia) [9].

Differential diagnosis. The minor form in young children can be confused with ringworm or with alopecia areata. In ringworm, the texture of the infected hairs is abnormal and the scalp surface may be scaly. Alopecia areata may be difficult to exclude with certainty at the first examination, but the course of the condition usually establishes the correct diagnosis. Unlike alopecia areata, it is unusual for hair to be lost completely in trichotillomania and, in contrast with exclamation mark hairs, the broken hairs of trichotillomania are firmly anchored in the scalp. Where doubt remains, dermoscopy [4] or a skin biopsy will usually establish the correct diagnosis. However, there are reports of the coexistence of alopecia areata and trichotillomania [8,10]. In rare cases, genetic disorders characterized by increased hair fragility, such as monilethrix, may resemble trichotillomania and should be excluded by hair microscopy.

Fig. 66.52 Trichotillomania. Characteristic 'tonsure' pattern with scalp margin hair spared.

Treatment. The establishment of a relationship between the physician and the patient, or with the parents of an affected child, is an important step in management of trichotillomania. A confident diagnosis is essential, but this is not always easy and may require observation over time and sometimes a scalp biopsy. The habit tic in young children is often self-limiting, but input from a paediatric psychologist can be very helpful. Trichotillomania in adolescents and adults is a different proposition, and can be intractable [11]. Patients with insight should be referred to a psychiatrist or clinical psychologist. A number of psychotherapeutic approaches have been used, particularly behavioural therapy aimed at habit reversal, and pharmacotherapy using clomipramine or selective serotonin-reuptake inhibitors (SSRIs), but none is uniformly successful. A systematic review of published studies found that habit-reversal therapy is superior to drug treatment [12]. Clomipramine is more effective than placebo but there was no convincing benefit from treatment with SSRIs.

Some patients are helped by contact with fellow sufferers, and there are several patient support groups and Internet websites devoted to trichotillomania. Patients who fail to admit the self-inflicted nature of the hair loss present particular difficulties, as they are unlikely to accept psychiatric referral and, like dermatitis artefacta, a confrontational approach will probably be unsuccessful. Management should be aimed at helping the patient recognize the cause for themselves. This can be a long and slow process requiring skill and empathy on the part of the physician.

Scaling disorders of the scalp

Scaling of the scalp is a feature of a number of clinical disorders, including dandruff (pityriasis capitis), seborrhoeic dermatitis, psoriasis and pityriasis amiantacea. These disorders show overlapping clinical and histological features and, when confined to the scalp, it can be difficult to distinguish between them. Scalp scaling is also seen in other inflammatory dermatoses such as atopic dermatitis, tinea capitis, discoid lupus erythematosus and cutaneous T-cell lymphoma.

Pityriasis capitis

Pityriasis capitis, or dandruff, and seborrhoeic dermatitis confined to the scalp are generally regarded as the same entity, with dandruff representing the mild non-inflammatory end of a spectrum of scalp scaling. Its peak incidence and severity are reached at the age of approximately 20 years, and it becomes less frequent after 50 years of age. At age 20 years, some 50% of white people are affected to some degree. Although previously thought to be uncommon in children, an epidemiological study from Australia found that approximately 40% of children under the age of 6 years showed at least mild pityriasis capitis, and 10% of neonates had seborrhoeic dermatitis of the scalp [1].

Aetiology [2]. It is reasonably well established that pityriasis capitis and seborrhoeic dermatitis are related, in some way, to the presence on the skin of lipophilic yeasts of the genus *Malassezia*, previously known as *Pityrosporum*. This idea, which evolved in the 19th century when these organisms were first identified [3–5], is based largely on the clinical observations of improvement with antifungal treatment. For a time during the 1960s and 1970s the microbial hypothesis was disputed [6], but it became re-established with the advent of azole antifungal agents [7–9]. Although there is no numerical relationship between colonization of the scalp by *Malasezzia* and seborrhoeic dermatitis the treatment of patients with seborrhoeic dermatitis with azole antifungal agents such as ketoconazole is associated with improvement of the rash, a reduction in *Malassezia*, and relapse as the skin is recolonized following treatment [10]. As *Malassezia* is present on normal skin there must be other factors involved that lead to scalp scaling. Possible explanations have included a direct inflammatory effect of free fatty acids released by the organisms from metabolism of sebaceous triglycerides and individual susceptibility [10].

Clinical features. Small, white or grey scales accumulate on the surface of the scalp in localized, more or less segmental patches or more diffusely. After removal with an effective shampoo, the scales form again within 4–7 days. The condition first becomes a cosmetic problem during the second and third decades, but there are long- and short-term variations in its severity, without obvious cause. There are also variations in the ease with which the scales become detached and drift unaesthetically among the hair shafts or fall on the collar and shoulders. Although pityriasis usually clears spontaneously during the fifth or sixth decade, it may persist in old age. Pityriasis merges, almost imperceptibly, into seborrhoeic dermatitis where signs of inflammation and itching are also present, and other skin sites may be involved. Pruritus is not a feature of simple pityriasis.

Diagnosis. Asymptomatic scalp scaling in children also occurs in pediculosis and in tinea capitis. The latter is typically associated with broken hair shafts and patchy hair loss, but these features may be absent in carriers of anthropophilic dermatophyte infections. Pediculosis should also be considered in adults with scalp scaling. Other than in the neonatal period, seborrhoeic dermatitis is uncommon in children, and psoriasis should be considered in the presence of significant scalp inflammation. Differentiation between seborrhoeic dermatitis and scalp psoriasis can be difficult at any age. Psoriasis is suggested by more demarcated plaques, extension of lesions beyond the hairline and the silvery character of the scaling. Occasionally, atopic dermatitis is confined to the scalp, when pruritus is usually a major feature. Profuse, adherent silvery scale should suggest pityriasis amiantacea.

Treatment. Pityriasis in its milder forms is a physiological process. The object of treatment is to control it at the lowest possible cost and inconvenience to the patient, appreciating that any procedure found to be effective will need to be repeated at regular intervals.

Shampoos containing the antiyeast agents ketoconazole or zinc pyrithione are effective in most cases of pityriasis capitis. One controlled trial reported an excellent response in 88% of subjects using ketoconazole [11]. Another study showed a 71% reduction in the dandruff score after 4 weeks of treatment with ketoconazole shampoo and a 67% reduction in subjects using a shampoo containing zinc pyrithione [12]. The scaling will return if treatment is discontinued, but the frequency of relapse can be reduced by prophylactic treatment (e.g. once-weekly treatment with ketoconazole shampoo [11]). Shampoos containing selenium sulphide or

tar have also been widely used to treat pityriasis capitis. Topical steroids may be used in patients with seborrhoeic dermatitis who do not respond to a shampoo. Salicylic acid-containing preparations (e.g. sulphur and salicylic acid cream) can be helpful for heavy scaling.

Pityriasis amiantacea

Pityriasis amiantacea is an inflammatory scaling reaction of the scalp, often without evident cause. One Scandinavian follow-up study reported that psoriasis occurred in 15% of patients with pityriasis amiantacea [1]. Another study failed to show an association with psoriasis but suggested that seborrhoeic dermatitis was more common [2]. In Knight's study of 71 patients, two had associated psoriasis and nine had eczema [3]; he pointed out that pityriasis amiantacea may occur at any age, but the average age was 25 years (range 5–40 years).

Pathology. Biopsies from 18 patients were examined by Knight [3]. The most consistent findings were spongiosis, parakeratosis, migration of lymphocytes into the epidermis and a variable degree of acanthosis. The essential features responsible for the asbestos-like scaling are diffuse hyperkeratosis and parakeratosis together with follicular keratosis, which surrounds each hair with a sheath of horn.

Clinical features. Masses of adherent silvery scales, overlapping like the tiles on a roof, adhere to the scalp and are attached in layers to the shafts of the hairs, which they surround (Fig. 66.53). The underlying scalp is usually reddened. The disease may be confined to discrete areas of the scalp, or may be very extensive, either involving a large area diffusely or affecting a number of small patches. The majority of patients notice some hair loss in areas of severe scaling. The hair regrows when the scaling is effectively treated, although scarring alopecia has been reported following pityriasis amiantacea [4].

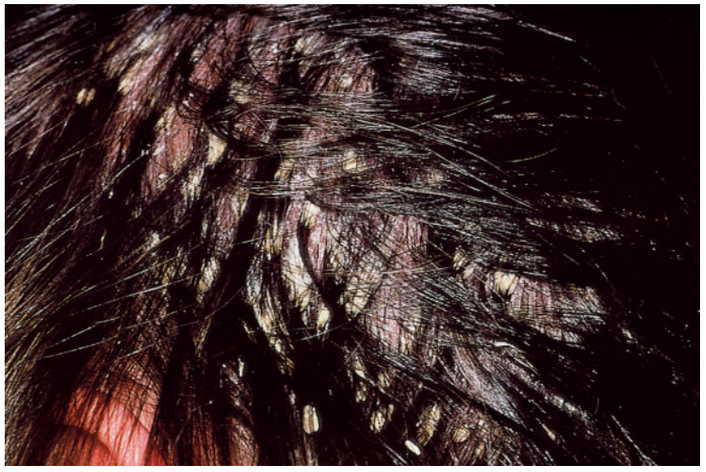

Fig. 66.53 Pityriasis amiantacea.

Diagnosis. The distinctive clinical appearance usually makes the diagnosis easy, but the identification of the underlying disease may not be straightforward; indeed, none may be established.

Treatment. Generous applications of an oil-based product are needed to remove the scales. Tar or salicylic acid ointments are commonly used. The preparation is left on the scalp for several hours and then washed out. The scales may be gently removed using a metal-toothed comb. Once the scaling is controlled an antidandruff or tar-based shampoo may help to maintain remission, but most patients will need to re-treat with an ointment from time to time. Potent topical corticosteroid lotions are beneficial in some cases, but are not effective in removing thick scales.

Cutis verticis gyrata

The term cutis verticis gyrata (CVG) describes a morphological syndrome in which there is hypertrophy and folding of the skin of the scalp to present a gyrate or cerebriform appearance. Polan and Butterworth established the classification of CVG, dividing it into primary and secondary forms [1]. The classification was later modified by Garden and Robinson [2], who subdivided the primary form into primary essential CVG, in which there are no associated features, and primary non-essential CVG, which is associated with a wide range of mental, cerebral and ophthalmological abnormalities.

Primary CVG. The aetiology of primary CVG is not known. Most cases appear to be sporadic although familial forms have been reported in the context of complex syndromes [3,4]. The skin changes typically develop after puberty and usually before 30 years of age. It is more common in men, with a male : female ratio of 5 : 1 or 6 : 1. There is a strong association with mental retardation. Akesson [5] found 47 cases (3.4%) of CVG in institutionalized mentally retarded subjects in Sweden, and CVG was observed in 22 out of 494 (4.5%) patients in an Italian psychiatric institution [6]. Cytogenetic analyses in the latter study showed chromosome fragile sites in nine subjects (chromosomes 9, 12 and X).

Secondary CVG. This has been described with a wide range of underlying causes. Congenital melanocytic naevi appear to be the most common but other naevoid abnormalities, such as naevus lipomatosus and connective tissue naevi, and acquired lesions such as neurofibroma, may also cause CVG [7–9]. CVG has been described in association with a variety of endocrine and genetic disorders, including acromegaly [10,11], myxoedema [12], insulin resistance [13], Turner's syndrome [14,15] and eczema [16]. The age of onset is more variable than in primary CVG and, in the naevoid forms, it may be present at birth.

The differential diagnosis includes pachydermoperiostosis and 'lumpy scalp syndrome'. The former is genetically determined and occurs mainly in men. It differs from CVG in several particulars. The scalp is folded but the skin of the face is also affected, as is that of the hands and feet. The cutaneous changes, which are accompanied by thickening of the phalanges and of the long bones of the limbs, progress for 10–15 years, then become static.

Pathology. The essential abnormality appears to be overgrowth of the scalp in relation to the underlying skull. In primary CVG, the histology appears normal in most cases. The histopathology in the secondary form depends on the nature of the underlying pathology.

Clinical features. CVG typically affects the vertex and occipital scalp but it may involve the entire scalp. The folds are usually arranged in an anteroposterior direction but may be transverse over the occiput. Hair density may be reduced over the convexities of the folds.

Treatment. Investigations are aimed at identifying underlying causes. These may include neurological, endocrine, ophthalmological and cytogenetic studies. In early-onset CVG, a biopsy is advisable to identify those cases caused by a structural lesion, such as a melanocytic naevus. In the majority of cases treatment is symptomatic. Patients should be educated in scalp hygiene to avoid accumulation of skin debris and secretions in the furrows. Surgical correction can be helpful in selected cases [17,18], and may be indicated in cerebriform naevi.

Lipedematous alopecia

Lipedematous alopecia is a rare condition of unknown aetiology. It is characterized by a thick, boggy scalp with varying degrees of hair loss [1,2]. Although originally reported in black women, lipedematous alopecia also occurs in white women [3,4] and in men [5]. There is slowly progressive, diffuse alopecia and boggy thickening of the scalp. There are no associated medical or physiological conditions. The fundamental pathological finding consists of an approximate doubling in scalp thickness resulting from expansion of the subcutaneous fat layer in the absence of adipose tissue hypertrophy or hyperplasia. There is associated atrophy and fibrous replacement of many hair follicles. Light and electron

microscopy suggests that the increase in scalp thickness is caused by localized oedema, with disruption and degeneration of adipose tissue. Mucin is not seen [6].

Congenital alopecia and hypotrichosis

R.D. Sinclair, pp. 66.59–66.61

Total or partial absence of hair of developmental origin occurs in a bewildering variety of clinical forms, either as an apparently isolated defect or in association with a wide range of other anomalies. A logical classification must be based on detailed histological and genetic investigations and these, unfortunately, are seldom carried out. Provisionally, a purely clinical classification is useful to enable the clinician at least to understand the clearly defined types [1].

Total alopecia

Synonym
- Atrichia congenita

As an isolated abnormality

Aetiology. Total alopecia as an apparently isolated defect is usually determined by an autosomal recessive gene. Some pedigrees have been traced back to the early 19th century [1]. Dominant or irregular dominant inheritance has occurred in some families [2,3]. The two genotypes seem to be phenotypically indistinguishable, but detailed investigation would probably reveal differences. The term 'total' is relative, but if any hairs are present they are extremely few. Many isolated cases and families reported under the diagnosis of congenital alopecia are found on review of the original reports to be unquestionably examples of other syndromes; many were hidrotic ectodermal dysplasia.

Pathology. The hair follicles are absent in adult life, even when the fetal hair coat has been normal. Sebaceous glands are smaller than normal. When a few stray hairs have survived, the structure of the shaft appears to be normal.

Clinical features [3,4]. The scalp hair is often normal at birth but is shed between the first and sixth months, after which no further growth occurs. In some cases the scalp has been totally hairless at birth and has remained so [4]. Eyebrows, eyelashes and body hair may also be absent [5], but more often there are a few straggling pubic and axillary hairs and scanty eyebrows and eyelashes. Teeth and nails are normal, and general health, intelligence and life expectancy are unimpaired.

With associated defects

Total or almost total alopecia is unusual in hereditary syndromes.

Papular atrichia [6]. This rare, autosomal recessive syndrome is associated with mutations in the zinc finger domain of the hairless gene [7]. Patients are born with hair that falls out and is not replaced. They are completely devoid of eyebrows, eyelashes, and axillary and pubic hair. Histological studies show the presence of the infundibular portion of the hair follicles, but the middle and lower portions of the follicle are replaced by small, keratinizing epithelial cysts. No hair shafts are formed. At any age between 1 and 10 years, numerous small, horny papules appear, first on the face, neck and scalp, and then gradually over the greater part of the limbs and trunk. Histologically, the papules are thick-walled keratin cysts [6]. Whitish, hypopigmented streaks can be found on the scalp. Nails, teeth, sweating, growth and development are normal.

The underlying disorder in papular atrichia appears to be that towards the end of the first anagen phase the hair bulb, proximal inner root sheath and outer root sheath all undergo premature and massive apoptosis and disintegrate into separate cell clusters that lose contact with the dermal papilla. As a result, the dermal papilla fibroblasts fail to migrate upward, and break up into clusters of shrunken cells stranded in the reticular dermis as dermal cyst precursors, and the follicle loses the ability to cycle [8].

The genetics are complex. Apart from cases of pseudodominant inheritance [9], there is phenotypic and genetic heterogeneity in inherited atrichias caused by mutations in the *hr* gene, suggesting different roles for the regions mutated in atrichia with papular lesions and in other forms of congenital atrichia during hair development [10]. Furthermore, mutations in the gene for the vitamin D receptor, causing vitamin D-dependent rickets, Type II, cause a similar clinical and histological phenotype in some families [11,12].

Progeria. There is progressive loss of scalp and body hair in this rare, premature ageing disorder, which is caused by mutation in the lamin A gene [13].

Hidrotic ectodermal dysplasia. Total or almost total alopecia is associated with palmoplantar keratoderma and thickened, discolored nails. Any hairs that are present are structurally normal but are often finer than the average. Mutations in the *GJB6* gene encoding the gap junction protein connexin 30 have been shown to cause this disorder [14].

Moynahan's syndrome. This autosomal recessive syndrome is associated with mental retardation, epilepsy and total baldness of the scalp; the hair may regrow in childhood between 2 and 4 years of age [15]. A similar clinical presentation in an inbred family was reported by Baraitser and colleagues [16]. In a large

consanguineous Pakistani family with alopecia and mental retardation the disease locus was mapped to 3q26.33-q27.3 [17].

Hypotrichosis [1,2]

Hypotrichosis is also a relatively common feature of many hereditary syndromes, usually in association with other ectodermal defects. In the majority, the hair is not only sparse but is structurally abnormal. Where hypotrichosis is the most prominent manifestation and the structural defect is distinctive and well characterized, it has given its name to the syndrome, as in monilethrix and pili torti. In other syndromes, the scanty scalp hair is a minor and sometimes inconstant manifestation, and the shaft defect is usually less specific.

Hypotrichosis simplex. In this autosomal dominant condition hair is usually normal at birth but thins progressively during childhood to become very sparse or absent by the third decade. Hair loss may be confined to the scalp (hypotrichosis simplex of scalp) with normal growth of facial and body hair [3]. This disorder is associated with mutations in the *CDSN* gene located on 6p21.3 [4]. *CDSN* encodes a protein called corneodesmosin that is exclusively expressed in cornified squamous epithelia. A second form of hypotrichosis simplex, in which there is reduced hair growth on the scalp and body, although eyelashes, eyebrows and male beards are normal, maps to 18p11.32-p11.23 [5].

Marie–Unna hereditary hypotrichosis [6–8]. In this rare but distinctive syndrome the hair in affected individuals is typically coarse and wiry in early childhood and is then progressively lost during childhood and early adulthood. Unna described two patterns of alopecia. In the more severe form, the child's hair is always sparse and is progressively lost, so that alopecia is advanced by puberty. In the other, milder form, the hair is initially thick and the hair loss only commences in the second or third decade. The hair loss predominantly affects the frontal, mid-scalp and vertex regions and ultimately may resemble Hamilton stage VIII androgenetic alopecia. There is usually also a subtle, simultaneous loss from around the scalp margins. Scattered, coarse, twisted hairs may remain within the alopecic regions.

The eyelashes, eyebrows and body hair are typically absent from birth, and after puberty any axillary or pubic hair that develops is also sparse. General physical and mental development is normal. Scanning electron microscopy shows that the hair shafts are coarse, irregularly twisted and fluted [6].

Marie–Unna hypotrichosis maps to chromosome 8p, close to the *hairless* locus, but the gene has not yet been identified [9]. Other disorders clinically very similar to Marie–Unna hypotrichosis, but genetically distinct, are now recognized and indicate that more than one form of progressive patterned alopecia with wiry hair exists [10].

Hypohidrotic ectodermal dysplasia [11]. Affected males show hypotrichosis, abnormal teeth and absent sweat glands. The hair is fine and silky but thin and short. Both X-linked and autosomal dominant forms exist. The X-linked condition is caused by mutations in the ectodysplasin gene; the autosomal dominant form is due to mutation of the gene encoding the ectodysplasin receptor. Mutations in either the ectodysplasin gene or its receptor disrupt ectodysplasin-mediated cell–cell signalling, which regulates the morphogenesis of ectodermal appendages.

Hypotrichosis resulting from short anagen [12]. This autosomal dominant condition is characterized by hair that is fine and short from birth. While the growth rate is normal, shortening of the duration of the anagen phase limits hair length to a few centimetres.

Hypotrichosis with keratosis pilaris [13]. The hair is apparently normal at birth, but after the birth coat has been shed, between the second and sixth months, it fails to grow satisfactorily and remains sparse, short, brittle and poorly pigmented. Eyebrows and eyelashes may be normal or sparse. Keratosis pilaris is present on the occipital region and neck, and sometimes on the trunk and limbs. Nails, teeth and general physical development are normal. The hairs show no beading or other distinctive abnormality.

Hypotrichosis with keratosis pilaris and lentiginosis [13]. Seven females in three generations in a family of three males and 13

females developed hypotrichosis at or just after puberty, which progressed until the menopause. Axillary and pubic hair was completely lost. There was keratosis pilaris of the scalp and axillae, brittleness and longitudinal striation of the nails, and centrofacial lentiginosis.

Eyelid cysts, hypodontia and hypotrichosis. See [14].

Hypomelia, hypotrichosis, facial haemangioma syndrome [15]. This 'pseudothalidomide' syndrome, which is probably determined by an autosomal recessive gene, associates gross reduction defects of the limbs, a mid-facial capillary naevus and sparse silver–blonde hair.

Hypotrichosis in disorders of amino acid metabolism. In many disorders with aminoaciduria, the hair is hypopigmented and is often also fine, friable and sometimes sparse. Fine, sparse hair has been reported in phenylketonuria, arginosuccinic aciduria and hyperlysinaemia.

A number of case reports associate hypotrichosis with a variety of ectodermal defects. Some such cases may represent partial forms of recognized syndromes but it is probable that many additional distinct syndromes remain to be identified and characterized.

Differential diagnosis. Microscopy of plucked hairs will exclude the more distinctive structural defects (pili torti, monilethrix and pili annulati). Other ectodermal defects should be carefully sought and relatives should be examined.

Abnormalities of the hair shaft

D.A.R. de Berker, pp. 66.61–66.100

Structural defects of the hair shaft may be sufficient in degree to cause significant cosmetic disability, or they may render the hair abnormally susceptible to injury by minor degrees of trauma (excessive weathering). Hair microscopy can be a useful part of clinical assessment in some situations [1], including a range of hereditary or acquired metabolic disorders, where the hair shaft can sometimes provide clues to the diagnosis [2,3] (Table 66.6).

Price [4] classified anomalies of the shaft into those that are associated with increased fragility, and those that are not. This distinction is useful because only the former present clinically as patchy or diffuse alopecia. Price's classification will be followed throughout the present section.

Structural defects with increased fragility

Monilethrix (beading of hair)

Smith initially called this condition 'a rare nodose condition of the hair' [1]. Radcliffe Crocker subsequently suggested the term monilethrix. Nevertheless, some early reports, and even some more recent ones, confuse monilethrix with other shaft defects (e.g. trichorrhexis nodosa) when 'weathering' is severe.

Aetiology. Autosomal dominant transmission has been demonstrated in numerous large pedigrees [2]. The alleged occurrence of normal carriers of the dominant gene has not been proven, as a parent with only 5% of abnormal follicles is easily passed as normal [3]. The abnormality is attributable to mutations in the genes coding for the human hair keratins hHb1 and hHb6 [4]. There is no clear correlation between the severity of the phenotype and the mutation responsible [5]. A variant of monilethrix, with scalp erosions and the appearance of congenital alopecia, is attributed to a mutation in the gene for desmoglein 4, which can be recessively inherited [6].

Pathology. The hair shaft is beaded and breaks easily (Fig. 66.54). Elliptical nodes 0.7–1 mm apart, are separated by narrower

Table 66.6 Terms used to define hair shaft pathology.

Term	Meaning	Associations
Trichorrhexis nodosa (Fig. 66.63)	A circumferential break in the hair cuticle, with cortical fibres extruding through the fracture	Physical and chemical trauma to the hair elicits this appearance at a threshold dependent upon the age and fragility of the hair; seen in normal hair
Brush end	When a trichorrhexis node breaks it leaves the proximal end looking like a chimney sweep's brush	As above
Trichoclasis	A 'greenstick' fracture of the hair, where the cuticle is partly stripped in continuity with the fracture	Trauma and moderate fragility
Trichoptilosis	Split ends—in continuity with the tip	Common outcome of cumulative brushing and chemical trauma
Circle hairs	Circle and spiral hairs on the thigh and abdomen; usually trapped beneath the stratum corneum; in males	Normal in more hirsute males; not the same as scurvy
Trichomalacia	Softened hair residue with keratin in open scalp follicular orifice	Trichotillomania
Trichoschisis	Clean transverse fracture across hair	Typically associated with sulphur-deficient hair of trichothiodystrophy
Pohl-Pinkus constriction	Zone of constriction within the hair shaft, possibly due to transient physiological compromise of hair growth; comparable with a Beau's line	Period of ill health or cytotoxic medication, where not sufficient to precipitate telogen effluvium or anagen effluvium
Tapered hairs	The tip of a hair that has been generated *de novo* at the commencement of anagen will be tapered	Characteristic of hair that is regrowing after shedding or of hair with a short anagen phase, e.g. eyebrow
Bayonet hair	Slight kink in hair within 1–2 mm of tapered tip	Variant of normal
Trichonodosis	Knots in hair	Usually a simple reef knot, seen where hair is rubbed or where the hair is markedly curly and predisposed to knotting; can contribute to fragility; most common in African hair
Bubble hair (Fig. 66.74)	Bubbles within hair shaft	Arises due to extreme heat or singeing of hair; attributed to leaning over a fire, or hot hair treatments where thermostatic controls are faulty
Hair casts (Fig. 66.75)	Keratin cylinders moving freely on the proximal hair shaft and arising from the upper part of the internal root sheath	May be associated with scaling scalp conditions or hair styling where there is tension on the hair; sometimes referred to as 'pseudonits'
Tiger tail (Fig. 66.65)	Light and dark transverse stripes on a hair shaft when viewed with cross-polarization, preferably in histological medium	Sulphur deficient hair has a weakened cortex which loses its longitudinal rigidity and tends to become wavy; this alters light polarization characteristics
Nit	The egg case of a head louse adherent to the shaft	The egg case may be empty or still contain the louse nymph; only nits proximal on the shaft are likely to represent active infestation, which needs to be confirmed by identification of a live head louse
Pili torti (Figs 66.56–66.58)	Twisting of hair through 180° within the long axis of the hair	Although this is a sign, it is sometimes used as a diagnosis; it is associated with the specific diagnosis of Menkes' syndrome, but also presents as an isolated autosomal dominant condition

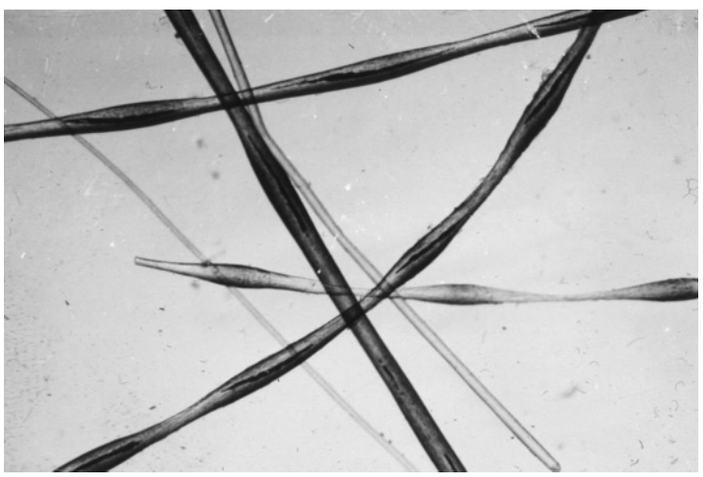

Fig. 66.54 Monilethrix with the swollen (node) and narrow (internode) fluctuations in hair bore.

internodes with a form resembling the body and neck of a skittle. The widths of the nodes and the distances between them vary between the hairs of an individual and between members of the same family. The nodes and some of the internodes show a normal imbricated scale pattern, but most internodes show longitudinal ridging [7,8]. True monilethrix must be distinguished from pseudomonilethrix, an artefact produced by tweezers or compressing overlapping hairs between two glass slides.

Histologically, the follicle shows wide and narrow zones corresponding to the nodes and internodes [9]. Attempts have been made to investigate the mechanism of node formation and to relate it to the diurnal rate of hair growth, but with no overall conclusion [7,10,11]. Intermittent administration of an antimitotic agent can give rise to zones of constriction alternating with zones of normal diameter [12].

Clinical features. Monilethrix shows considerable variation in age of onset, severity and course [13]. Hair loss or broken hair is accompanied by follicular keratoses most commonly on the nape

Fig. 66.55 Monilethrix. Nape of the neck, showing follicular keratoses and short, broken hairs.

and occiput (Fig. 66.55). In some cases, the eyebrows and eyelashes, pubic and axillary hair and general body hair may be affected.

In many patients, the condition persists with little change throughout life [2]. Spontaneous improvement or complete recovery has occurred [1] and has been reported during pregnancy [14].

Treatment. Three reports support the use of oral retinoids, providing a reversible benefit [15–17]. This may result from a therapeutic effect on the keratosis pilaris, which lessens in combination with a reduction of shaft beading and modest increase in overall hair length [17]. Improvement has been attributed to the hormone changes of menarche in one report [18]; male and female cases may both improve at puberty. Griseofulvin also has temporarily restored normal hair growth [19]. Iron supplementation has been reported to be of value in the presence of iron deficiency [20]. Reduction of hairdressing trauma may be followed by some improvement, by lessening the 'weathering' from chemical and physical insults.

Pili torti (twisting of hair)

In pili torti, the hairs are flattened and at irregular intervals completely rotated through 180° around their long axis (Fig. 66.56). This rotation runs for three to five twists before the shaft normalizes [1]. True pili torti of Menkes' syndrome and the isolated expression of the abnormality in an otherwise unaffected person, demonstrate the same distinct twisting (Figs 66.57 & 66.58). Scanning electron microscopy has made it clear that twisted hairs occur in many different forms, and that not all twisted hairs are pili torti.

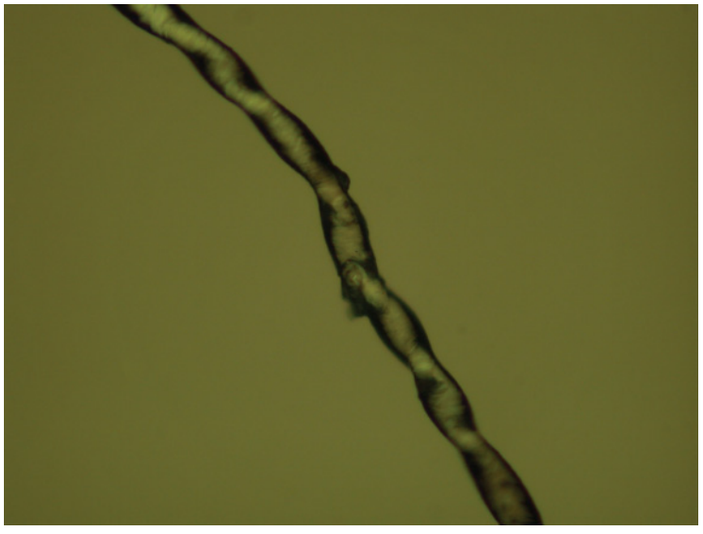

Fig. 66.57 Pili torti in a 6-month-old boy with Menkes' syndrome.

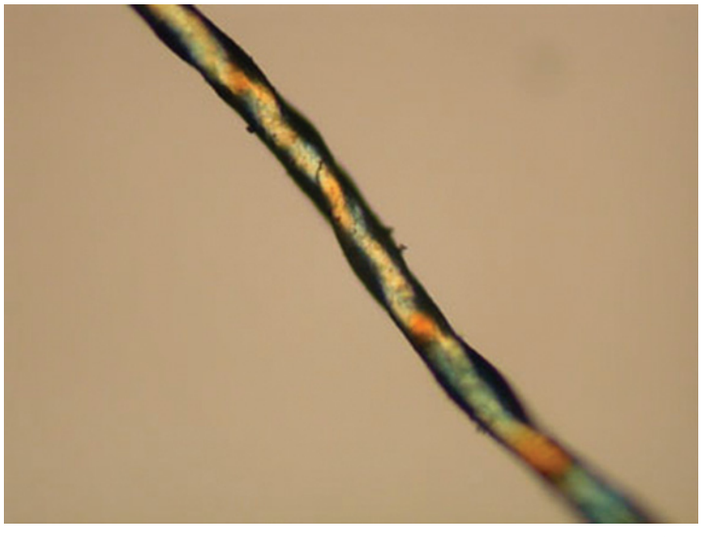

Fig. 66.58 Pili torti in a 27-year-old woman with no personal or family history of associated disorders.

Occasional twists of varying angle should not be taken to be this distinctive genetically 'fixed' abnormality of pili torti—many dystrophies and distortions of the follicular zone of keratinization will vary the hair shaft 'bore', sometimes showing less than 180° irregular twists.

Syndromes in which twisted hair is a feature

Menkes' syndrome. Light-coloured, twisted hair is a manifestation of a hereditary defect of intestinal copper transport; the inheritance is of sex-linked recessive type. Accumulation of copper in the neonatal period leads to brain damage, mental retardation and fitting. Fits may be the presenting complaint, with the diagnosis made later on hair microscopy. The twisting of the hair microscopically is generally exactly the same as in pili torti [2,3]. The disorder is caused by a mutation in the gene encoding Cu^2 transporting ATPase, α-polypeptide. The occipital horn syndrome is caused by mutation in the same gene.

Differential diagnosis (Table 66.7). The main differential is Björnstad's syndrome with sensorineural deafness. Other diagnoses found in the literature are probably erroneous and based on a loose interpretation of the term pili torti. The spiral is either too low-pitched or it is around an axis that is not within the long axis of the hair.

Aetiology. In those cases in which classic pili torti of early onset appears to have occurred as an isolated defect, examples suggesting autosomal dominant and recessive inheritance can be found.

Pathology. The earlier reports emphasized that the affected hairs were flattened and twisted through 180° around their long axis at irregular intervals along the shaft. Hairs can manifest fragility with the shape making them more vulnerable to the effects of weathering.

Clinical features. The hair is usually normal at birth, but is gradually replaced by abnormal hair, which becomes clinically evident as early as the third month, or not until the second or third year. There is a wide variation from case to case in the fragility of the hair, and hence in the clinical picture. Affected hairs are brittle and may break off at a length of 5 cm or less, or grow longer in areas of the scalp less subject to trauma. There may therefore be only a short, coarse stubble over the whole scalp or there may be circumscribed baldness, irregularly patchy or occipital. Affected hairs have a spangled appearance in reflected light. The cosmetic appearance of isolated pili torti can improve greatly with transition from childhood to early adulthood [4].

Table 66.7 Diseases where pili torti and other twisted hair abnormalities are found.

Name	Genetics	Mechanism	Features
Pili torti—isolated [1]	Both dominant and recessive reported	Not known	Pili torti, fragile hair, sometimes with hypoplastic dental enamel; could be female carrier of Menkes' syndrome
Menkes' syndrome [2]	X-linked recessive carried on Xq12-q13	Mutation in gene encoding the Cu^{2+} transporting ATPase, alpha protein	Blond fine hair in boys, with poor neonatal development, evolving into status epilepticus and brain damage as cumulative copper metabolism damage progresses
Female carrier of Menkes' syndrome	Ditto	Ditto	Pili torti in 43% of obligate female carriers
Björnstad's syndrome [5,6]	Autosomal recessive disease due to mutation in BC1SL gene on 2q33	Altered function of mitochondrial respirasome protein, in turn affecting transmission of inner ear neurosensory hair responses	Neurosensory deafness with hypogonadism in some instances (Crandall's syndrome)
Twisted hairs—poor evidence for true pili torti			
Bazex syndrome [7,8]	X-linked dominant Xq24-q27	Possible loss of efficacy of a DNA repair protein produced by the UBE2A gene	Hypotrichosis, follicular atrophoderma, and multiple basal cell neoplasms; hypohidrosis also reported
Pseudomonilethrix [9]	Putative dominant inheritance	Probably an artefact in hair plucking or twisting	Intermittent nodes and internodes in hair shafts that mimic monilethrix, but may be in the form of a flattened spiral
Trichothiodystrophy [10]	Autosomal recessive 19q13.2-q13.3, 6p25.3, 2q21	Transcription syndrome with defects in transcription factors II H and possibly others	Multiple phenotypes and subtypes, with flattened fragile hair that can twist; common factor is sulphur deficiency in hair amino acid constituents
Anorexia nervosa [11]	Acquired	May be mediated through lack of vitamin C	Wiry hair
Retinoid hair [12,13]	Acquired	Secondary to systemic retinoid therapy	Wiry hair with hair loss and dry skin
Scarring alopecia [14]	Acquired	Secondary to scarring inflammation, most common with folliculitis decalvans	Wiry hair at the margins of active scarring follulitis
Tuberous sclerosis complex [15]	Autosomal dominant	16p13.3, 12q14, 9q34	Corkscrew hairs, multiple hamartomas, renal cysts and epilepsy

Netherton's syndrome (bamboo hair) [1–3]

Netherton [4] observed bamboo-like nodes in the fragile hairs of a girl with 'erythematous scaly dermatitis'. It has gradually become apparent that ichthyosis linearis circumflexa (ILC) and 'bamboo hairs' (trichorrhexis invaginata) (Fig. 66.59) are two features of a single syndrome [5]. Most cases of Netherton's syndrome have had ILC but some have ichthyosis vulgaris [6] or both conditions, or ichthyosiform erythroderma. Features of ILC may be seen in variants of psoriasis. It is controversial as to whether it occurs as an isolated disease in the absence of Netherton's syndrome, or whether it is the fluctuating prevalence of the hair shaft changes that leads to difficulty in detecting both characteristics at the same time in some patients.

ILC is thus an almost constant feature of the syndrome, with hair shaft defects of various types and degrees of severity. The inheritance of Netherton's syndrome appears to be determined by an autosomal recessive gene of variable expressivity. Girls are affected more than boys. The underlying defect has been localized to a gene on chromosome 5q32, known as *SPINK5*, an acronym for serum protease inhibitor [7]. The gene product is termed LEKTI (lymphoepithelial kazal-type-related inhibitor). The protein has antitrypsin and antichymotrypsin-like activities, which serve to inhibit the natural proteolytic activity of serine proteases. Where a mutation removes this inhibition, the proteases degrade cadherins of the corneodesmosome, desmoglein 1 and desmocollin 1 in

Fig. 66.59 Light microscopy revealing a trichorrhexis invaginata node likened to bamboo.

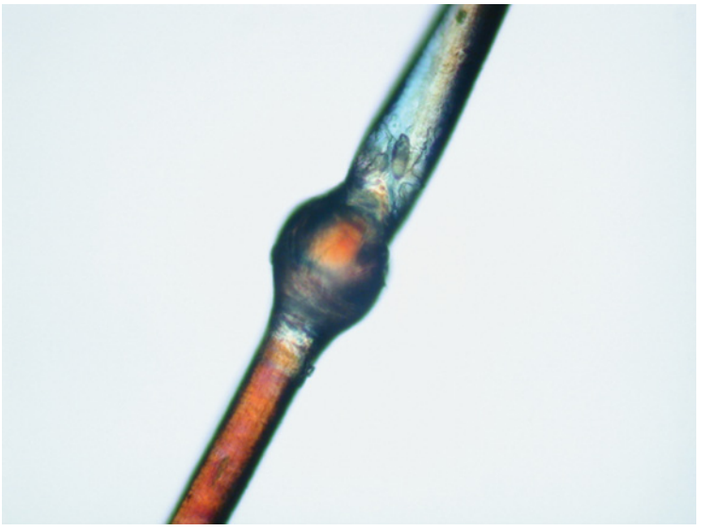

Fig. 66.60 Netherton's syndrome with an invaginate node showing partial twisting of the hair at the upper pole.

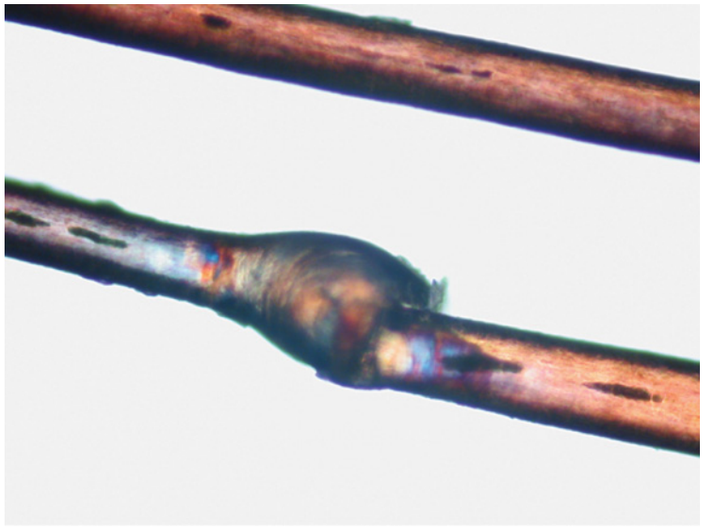

Fig. 66.61 Netherton's syndrome with the invaginate node acting as a point of weakness in the hair shaft.

the upper epidermis, with additional loss of filaggrin. This reduction of the epidermal barrier represents the pathology of the associated skin disease, typically with features of atopic dermatitis [8,9]. Immunohistochemical techniques are under development to allow tissue diagnosis of Netherton's syndrome on the basis of absence of LEKTI immunostaining. Identification of the gene has allowed prenatal diagnosis [10].

Pathology. As Netherton's syndrome results in fragile hair, samples should be cut at the scalp surface, thus reducing the chances that the hair will break at the point of diagnostic interest, making diagnosis more difficult. Light microscopy is the best tool for detecting features of Netherton's syndrome in hair. However, an individual may have multiple hairs with characteristic changes in one sample and then no features in another sample taken some months later. Because of this it is important that samples of at least 100 hairs are carefully examined on several occasions before a definite negative is asserted. Alternatively, finding a single trichorrhexis invaginata node in a single hair is a conclusive positive (Figs 66.60 & 66.61).

To assess such large numbers of hairs it is necessary to use the light microscope, as electron microscopy will only allow assessment of small lengths of a small number of hairs. Detail of the surface features is enhanced using partially crossed polarizing filters, and the cortical anatomy of the hair is revealed if the hair is prepared on a slide in histological mounting medium. Scanning electron microscopy of the hair shafts shows focal defects that produce the development of torsion nodules, invaginated nodules (trichorrhexis invaginata) and trichorrhexis nodosa [11,12].

Where diagnosis is difficult, sampling the eyebrows may provide confirmation [13]. The proximal remnant of an invaginate node may resemble a golf tee and can allow diagnosis where classic nodes are absent [3].

Clinical features [14]. The patient may present primarily either with cutaneous changes or complaining of sparse and fragile hairs. Generalized scaling and erythema are present from birth or early infancy, but the degree, extent and persistence of the erythema are very variable. In some cases, the erythema may be slight and transient. In many it has the characteristics of atopic eczema accompanied by an elevated IgE. On the trunk and limbs, the fine, dry scales are associated with a polycyclic and serpiginous eruption whose horny margin slowly changes its pattern.

The hair defects may be detected only if deliberately sought, but in most cases are readily apparent clinically [14]. The hair is short, dry, lustreless and brittle, and the eyebrows and lashes are sparse or absent. Jones *et al.* [15] described two cases in which neonatal hypernatraemia occurred. The severity of the phenotype does not show strict correlation with the mutation, and members of the same kindred may share a mutation but have different degrees of disease [16].

Treatment. Management of Netherton's syndrome is discussed in Chapter 19. There is no specific treatment for the hair dystrophy other than avoidance of physical and chemical trauma.

Trichorrhexis nodosa

Trichorrhexis is best regarded as a distinctive response of the hair shaft to injury [1]. If the degree or frequency of the injury is sufficient, it can be induced in normal hair, and this is probably the most common scenario. The cuticular cells become disrupted, allowing the cortical cells to splay out to form nodes [2]. If, however, the hair is abnormally fragile, trichorrhexis may follow relatively trivial injury. The trauma of hairdressing procedures has often been incriminated [3]. Scratching may produce identical changes in pubic hairs [3]. The cumulative effect of shampooing, brushing, sea bathing and sunlight has led to seasonal summer recurrences [4].

Congenital and hereditary defects of the hair shaft resulting in fragility can predispose to trichorrhexis nodosa.

Trichorrhexis nodosa is a feature of the rare metabolic defect argininosuccinic aciduria, in which it is associated with mental retardation [5]; there is a deficiency of the enzyme argininosuccinase. Some 20 patients have been reported [6,7]. The hair tends to be dry, brittle and lustreless and may show trichorrhexis nodosa, but it does not occur in all patients with this metabolic disorder.

Trichorrhexis nodosa may occur in certain families as an apparently isolated defect of the hair; node formation and fracture are induced by minimal trauma and develop during the early months of life. Wolff *et al.* [8] described as 'trichorrhexis congenita' the presence from birth of trichorrhexis nodosa confined to the scalp, with normal teeth and nails.

Localized autosomal recessive hypotrichosis. This recently described disorder presents with brittle hair which fractures readily leading to extensive loss of hair. The hair may appear unusually stiff. Hair microscopy shows trichorrhexis nodosa. Monilethrix-like beading may also be seen [9]. Localized autosomal recessive hypotrichosis is due to mutations in the gene for the desmosomal protein desmoglein 4 (*dsg4*) [10,11] (Fig. 66.62).

Fig. 66.62 Localized autosomal recessive hypotrichosis due to *dsg4* mutation.

Fig. 66.63 Trichorrhexis nodosa. Polarized light examination demonstrates the splayed cortical fibres radiating from the transverse fracture in a trichorrhexis node.

Pathology. In simple trichorrhexis nodosa, the shaft may appear normal with the light or electron microscope, except at the nodes; or the shaft, apart from the proximal 1 cm, may show signs of abnormal wear and tear [2]. At the nodes, the cuticle bulges and is split by longitudinal fissures (Fig. 66.63). If fracture occurs transversely through a node (trichoclasis), the end of the hair resembles a small paintbrush.

Clinical features. In trichorrhexis nodosa complicating a congenital defect of the hair shaft, the hair breaks so easily that large or small portions of the scalp show only broken stumps and alopecia may be gross. However, the common situation is where trauma plays a major part and predisposition has a relatively minor role. In this setting there are three principal clinical presentations [12].

1 Distal trichorrhexis nodosa occurs in all races. Often it is discovered incidentally, and only a few whitish nodules are seen near the ends of scattered hairs. If many hairs are affected, the patient may complain that the hair is dry, dull or brittle. The longer the hair, the more likely it is to occur.

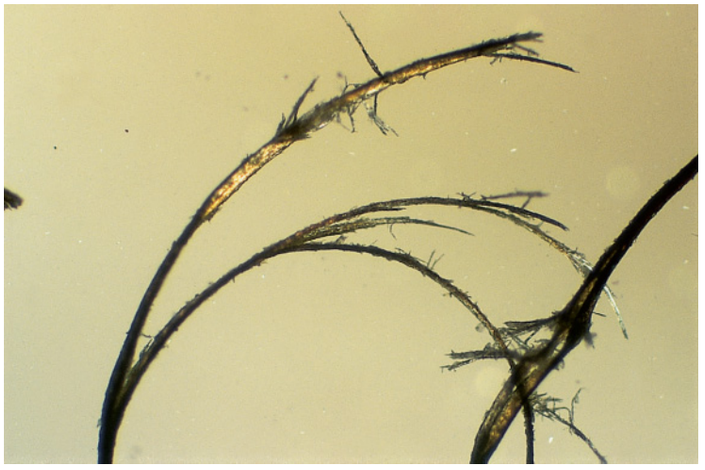

Fig. 66.64 Proximal trichorrhexis nodes and dramatic split ends (trichoptilosis) are visible in hair from an Afro-Caribbean woman.

2 There is a generalized variant seen in Afro-Caribbean women called proximal trichorrhexis nodosa. The scalp hair is universally short and brittle and demonstrates severe weathering on light microscopic examination (Fig. 66.64). There may be an association with the follicular degeneration syndrome where there is a central scarring alopecia in the absence of an overt inflammatory process [13].

3 The third clinical form was well described by Sabouraud [14] but it appears now to be rare. In a localized area of scalp, moustache or beard, some hairs are broken and others show from one to five or six nodules [15].

Diagnosis. The congenital forms must be differentiated from other shaft defects. The distal acquired form may simulate dandruff or even pediculosis. In all cases, diagnosis depends on careful microscopy. Excessive physical and chemical (cosmetic) trauma must be avoided, apart from shampooing.

Trichothiodystrophy

The term trichothiodystrophy (TTD) was coined [1] to describe brittle hair with abnormally low sulphur content. The term covers a range of phenotypes, with low sulphur fragile hair representing the central defining criterion [2–5]. TTD can be classified according to the constellation of features that accompany the hair changes [4].

Using current criteria, approximately 50% of those with TTD are photosensitive. In this group, there is phenotypic and genetic crossover with xeroderma pigmentosum (XP). Of the different complementation groups within XP, most of the photosensitive TTDs share features with XP complementation group D, some with XP complementation group B and a small group represent an isolated photosensitive category, termed TTD-A [6]. The common genetic defect in XPD and photosensitive TTD is within the *ERCC2* (excision repair cross-complementation 2) gene on chromosome 19q as defined by *in vitro* complementation studies. Mutations of the *ERCC3* gene on chromosome 2q have a corresponding role in XPB. These genes code for a transcription factor TFIIH, which has a dual function. First it acts as a helicase, which unravels the double helix of segments of photodamaged DNA as part of nucleotide excision and repair (NER). Secondly, it acts to enable transcription of segments of DNA to produce RNA and gene expression. A range of mutations in this gene can lead to changes in function of TFIIH. Where defects in NER occur, there is cumulative photodamage to the DNA, which is clinically expressed as photoageing and dysplasia. In XP, this ultimately predisposes to skin cancer, but not in TTD. Equally, the genetic basis for TTD can result in neuroectodermal changes that are not part of XP. A further mystery is that the genetic defect in Cockayne's syndrome arises within the same gene and affects the same transcription factor, but results in a different phenotype.

Pathology. The hair is brittle and weathers badly [5], with abnormalities inversely proportional to the sulphur content [2]. With trauma it may fracture with a clean transverse break (trichoschisis) or may form nodes somewhat resembling trichorrhexis nodosa. The hairs are flattened and can be twisted into various appearances—rather like a ribbon or shoe lace. Details of these changes are clarified by scanning electron microscopy [5]. The shaft is irregular, with ridging and fluting, and the cuticular scales are patchily absent. Transmission electron microscopy demonstrates a decrease in high-sulphur protein staining in the hair shaft and a reduction of this protein in the exocuticular part of the cuticle cells [7].

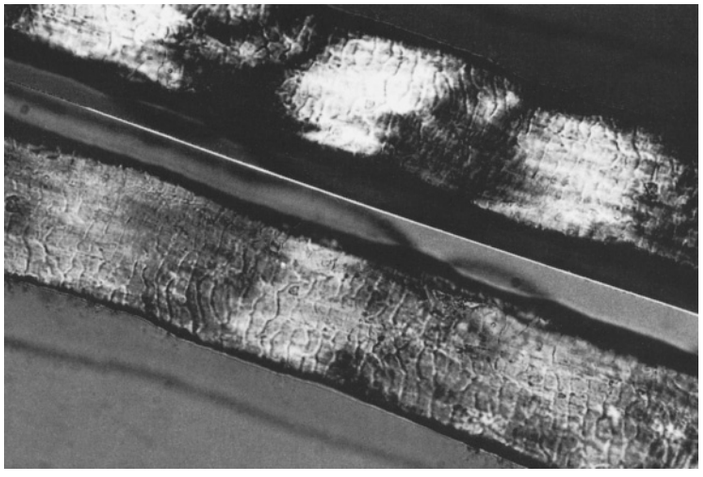

Fig. 66.65 Trichothiodystrophy. Alternating bright and dark zones in the polarizing microscope. (Courtesy of D. Van Neste, Brussels.)

Using crossed polarizing filters with a light microscope the hairs show alternating bright and dark zones (Fig. 66.65). This feature is sensitive for TTD [2,8], but not specific. It may occur in a range of genetic and acquired disorders where the longitudinal organization of cortical fibres within the hair is thrown into a sine wave pattern through loss of rigidity [9]. As a sign, it may arise at different stages in infancy. In one instance it has been used prognostically when identified in a fetal eyebrow biopsy obtained *in utero* [10]. Other cases illustrate that the sign may fail to develop until a few months of age [11].

Clinical features. There is a wide range of phenotypic characteristics, depending on the variant of TTD (Table 66.8). The hair is sparse, short and brittle, but the degree of alopecia varies considerably. There may be lamellar ichthyosis. The nails may be dystrophic. Mental and physical development may be normal but one or both may be slightly, moderately or severely retarded. The central feature of altered hair remains the basis of diagnosis, but the mechanism linking the associated features requires further elucidation.

Table 66.8 Classification of trichothiodystrophy.

Type	Findings	Eponym/acronym
A	Hair ± nails	
B	Hair ± nails + mental retardation	Sabinas
C	Hair ± nails + mental retardation, folliculitis, retarded bone age ± caries	Pollitt
D	Brittle hair ± nails, infertility, developmental delay, short stature	BIDS
E	Ichthyosis, BIDS, hair ± nails, mental retardation, short stature ± decreased gonadal function ± lenticular opacities/cataracts + failure to thrive/ 'progeria' + microcephaly ± ataxia ± calcifications of the basal ganglia + erythroderma and scale	Tay and IBIDS
F	Photosensitivity and IBIDS	PIBIDS
G	TTD with immune defects; hair ± mental retardation + chronic neutropenia or immunoglobulin deficiency	Itin
H	Trichothiodystrophy with severe intrauterine growth retardation and failure to thrive, developmental delay, recurrent infections, cataracts, hepatic angioendotheliomas

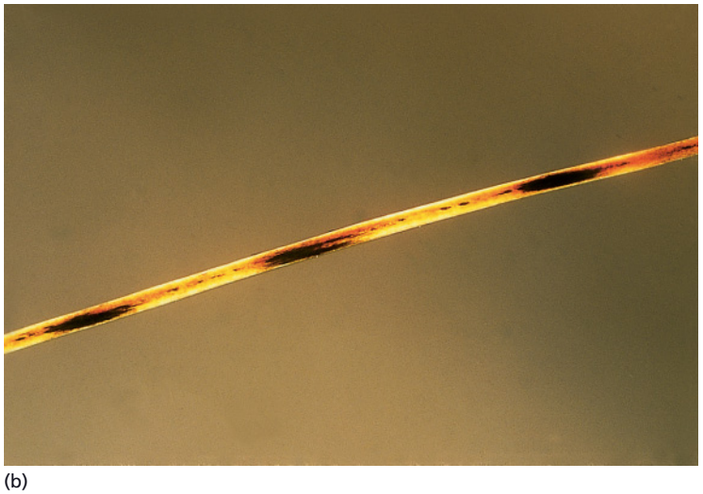
Structural defects without increased fragility

Pili annulati (ringed hair) [1,2]



Aetiology. This abnormality is characterized by hair showing alternate light and dark bands along its length. In extreme cases there may be some additional fragility as the lighter areas seen with light microscopy represent a split in the hair cortex. The condition is inherited as an autosomal dominant, and although the molecular basis of the abnormality remains unknown, the genetic defect maps to chromosome 12q [2,3].

Pathology and pathogenesis [2]. With the light microscope the abnormal dark bands alternating with normal light bands are reversed. The bright appearance of the abnormal bands in reflected light is caused by air spaces in the cortex (Fig. 66.66) [4]. Detection of the cortical defect is made easier if the hair is mounted in histological mounting medium because this enhances transmission of light through the hair. Although this illustrates that the pathology can result in structural weakness, it only rarely leads to a clinical complaint of fragility [5].

Electron microscopic studies [5,6] showed that the clusters of air-filled cavities, randomly distributed throughout the cortex in the abnormal bands, lie partly within cortical cells and between

(a)

(b)

Fig. 66.66 (a) Pili annulati. Hair shaft by transmitted light showing an abnormal dark band (central part) caused by multiple cortical air spaces. This corresponds to a bright region as seen by reflected light. (b) The abnormality is intermittent, causing the beaded or ringed appearance.

macrofibrils, or in the case of larger cavities appear to replace cortical cells.

Clinical features. Pili annulati is normally diagnosed as a coincidental finding or as part of pursuance of the unusual, but quite attractive, spangled appearance. The condition has been reported in association with alopecia areata on several occasions. It is uncertain whether this represents a genuine association or if medical scrutiny reveals the otherwise subtle diagnosis [7]. The axillary hair is occasionally affected [8].

The diagnosis is readily established on microscopy of affected hair. A defect in which partially twisted shafts have an elliptical cross-section has been named pseudo-pili annulati because such hair may give an impression of alternating light and dark bands [9].

Prognosis and treatment. The prognosis is good in the sense that the severity of the defect does not increase with age.

Woolly hair

Woolly hair is more or less tightly coiled hair occurring over the entire scalp or part of it. In those of African origin, woolly hair is the norm. Tight coiling, knots and fractures are common [1]. Woolly hair in non-African individuals may be generalized or localized. The generalized forms may be inherited. The investigation by Hutchinson *et al.* [2] was important in delineating the clinical types.

Hair microscopy in all the woolly hair disorders reveals nonspecific features that are consistent with a woolly, stiff hair phenotype. This usually arises in association with grooves, partial twists, irregularity of bore and sometimes features of trauma. When a hair shaft has an irregular shape and is stiffer, it is more prone to damage. The changes are often subtle, and are better appreciated on assessment of at least 20 and preferably 50 hairs or more. Isolated reports describing hair morphology often fall into the trap of describing individual hairs rather than the population of hairs as a whole. This mistake can be compounded by using scanning electron microscopy for the main assessment rather than as a supplementary tool. Although electron microscopy is excellent for revealing great detail in a small number of hairs, it is very poor at showing the characteristics of a population of hairs, which is the usual determinant of a phenotype.

Autosomal dominant woolly hair. This was reported in six generations of a German family [3]. A dominant form of woolly hair in an English family was associated with ichthyosis and deafness [4]. Additional features in a Dutch family with woolly hair included dental caries, acral keratoderma and facial abnormalities [5].

Naxos disease [6]. This autosomal recessive disorder is due to a mutation in the plakoglobin gene [7]. In addition to woolly or bristly hair, Naxos disease is characterized by palmar–plantar keratoderma and cardiomyopathy.

Carvajal disease [8]. The phenotype is similar to Naxos disease, with woolly hair, palmar–plantar keratoderma and cardiomyopathy. Carvajal disease is a recessive disorder due to a mutation in the gene for desmoplakin [9,10].

Acquired woolly hair. This is a heterogeneous group. It occurs most commonly in the context of patterned hair loss [11]. It may also be caused by drugs such as valproate and retinoids [12,13].

Woolly hair naevus [14–16]. This is a naevoid condition with a circumscribed patch of hair showing altered colour and texture. The hair may be fine in infancy, becoming coarser with age, especially at puberty. It is commonly associated with melanocytic or epidermal naevi elsewhere on the skin. Ocular defects and precocious puberty have also been reported [17,18].

Uncombable hair syndrome

Synonyms
- Spun-glass hair
- Cheveux incoiffables
- Pili trianguli et canaliculi

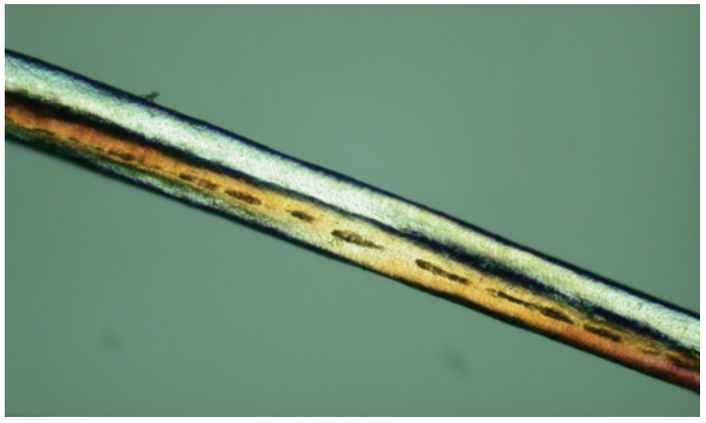

Fig. 66.67 Triangular cross-section of the hair contributes to stiffness.

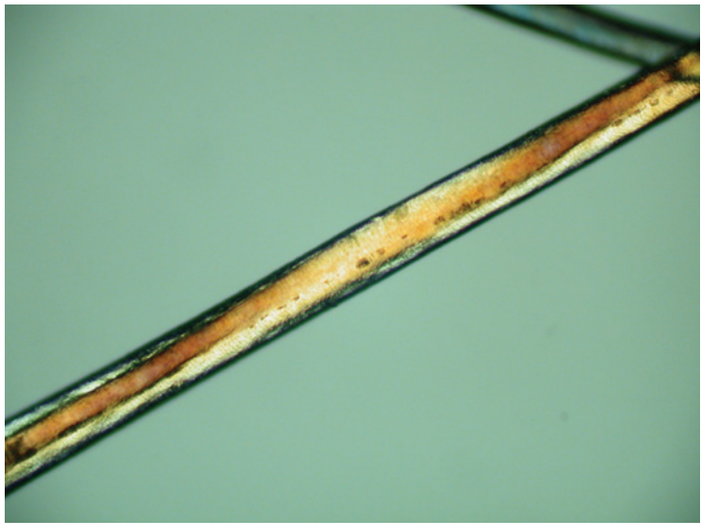

Fig. 66.68 Light microscopy reveals grooving when using partially crossed polarizing filters.

Aetiology [1]. This is a combination of a striking clinical presentation and distinctive hair shaft defect first described by Dupré *et al.* [2]. Since then, many more cases have been reported, some of them under the name of 'spun-glass hair'. Others have preferred the term pili trianguli et canaliculi, with emphasis on the triangular cross-section and longitudinal groove that is commonly found on microscopy. The mode of inheritance is probably autosomal dominant [3].

Pathology. Light microscopy reveals the features in a hair shaft that make it rigid: the triangular cross-section (Fig. 66.67) and longitudinal grooving (Fig. 66.68). Twisting can also be present and contributes to stiffness to a minor degree. Scanning electron microscopy can be helpful on selected hairs (Fig. 66.69) [4–6]. The term 'pili trianguli et canaliculi' has been proposed for these defects. The pili canaliculi are present in all cases, pili trianguli in the majority and pili torti in a few [6]. Van Neste *et al.* [7] have suggested that the misshapen dermal papilla alters the shape of

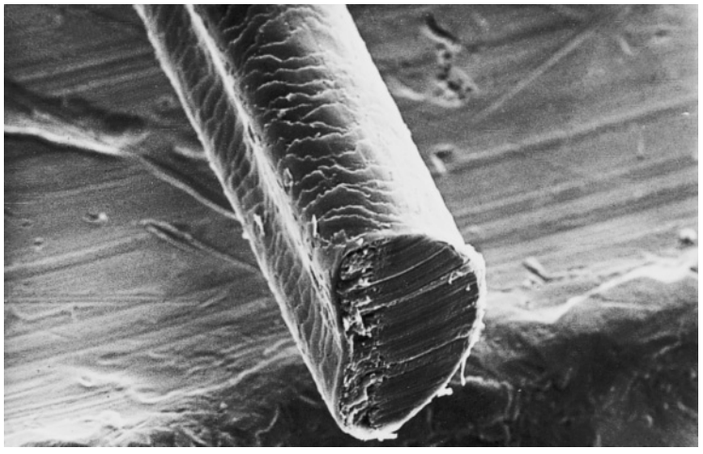

Fig. 66.69 Uncombable hair syndrome. Scanning electron micrograph showing triangular cross-section and canalicular depression or gutter along one side.

the internal root sheath, which hardens (before the hair within) in a triangular cross-sectional shape; the hair then hardens into a shape complementing the root sheath. The defect resembles the 'straight hair naevus' of which it may be a diffuse form.

Clinical features [4,5]. The abnormality may first become obvious from 3 months to 12 years of age. The hair is normal in quantity and sometimes also in length, but the wild, disorderly appearance totally resists all efforts to control it with brush or comb. In some cases, these efforts lead to the hair breaking, but increased fragility is not a constant feature [8]. The hair is often a silvery blonde colour. The eyebrows and eyelashes are normal. The appearance becomes less marked with time [9]. Some people with loose anagen syndrome may have a similar appearance [10].

With light microscopy the diagnosis is dependent upon the experience of the microscopist as the three-dimensional aspect of the shaft changes can be difficult to establish. No treatment is known, although oral biotin therapy has been suggested [11].

Loose anagen hair syndrome [1]

This condition features anagen hairs that are loosely anchored and easily pulled from the scalp [2–4]. The majority of cases are fair-haired children, aged 2–9 years, mostly girls. There is usually a pattern of autosomal dominant inheritance. They typically have slightly unruly hair, which is of uneven length and patchy in quality. Variants of this include those with stiff, uncombable hair and those in whom shedding is the primary complaint. All three phenotypes may coexist within the same family [5]. The children may present with patchy alopecia, leading to a misdiagnosis of alopecia areata, but which, in fact, represents modest hair pulling. The child is well, and there are no other ectodermal abnormalities.

Hair is usually easily and painlessly plucked with the hair-pull test, although this is not a constant or specific finding [6]. Microscopy of plucked hair may show ruffling of the cuticle adjacent to the anagen bulb, giving the appearance of a 'floppy sock' (Fig. 66.70). The hair shaft may have twists and grooves, and be angular in cross-section. The root sheath is absent or there may be a small everted remnant.

The hair becomes more normal with age, although the pull test may still yield abnormally large numbers of hairs into adulthood [7].

There have been isolated reports of loose anagen syndrome associated with hypohidrotic ectodermal dysplasia [8] and ocular coloboma [9].

Histological examination shows premature keratinization of the inner root sheath layers of Huxley and Henle. Trichograms show 98–100% anagen hairs. Keratin K6irs is an inner root sheath keratin proposed as a protein that might control manifestations of the disorder [10]. In one report, mutations in the gene coding for such a keratin supported this possibility [11].

Some authorities have had good results with 5% topical minoxidil [11], although it is not commonly employed and is not of clear value.

Trichostasis spinulosa

This is probably a normal, age-related phenomenon—easily overlooked—in which successive telogen hairs are retained in predominantly sebaceous follicles [1]. When it was specifically sought, 51 cases were seen in 1 month in Madras [2].

Aetiology. Trichostasis is found most commonly in the middle-aged or elderly and is said by most authors to occur particularly on the nose and face [3]. Other sites were perhaps not always examined, for others have found it to be not uncommon on the trunk, limbs [4] and interscapular area [5].

Pathology. The affected follicles contain up to 50 vellus hairs embedded in a keratinous plug. A mild perifolliculitis is often present. The condition must be differentiated from the 'multiple hairs' of Flemming–Giovannini in which up to seven hairs grow from a composite papilla with a common outer root sheath [6]. Follicles may contain *Malassezia* yeasts and *Propionibacterium acnes* [5].

Clinical features [7]. It is reported at all adult ages, although it appears more common in the elderly. The lesions, which closely resemble comedones, may occur predominantly on the nose, forehead and cheeks, or the face may be spared and the nape, back, shoulders, upper arms and chest may be affected. The lesions vary greatly in number. On inspection with a hand lens, the 'comedones' seem to be unusually prominent and in some cases a tuft of hairs may be seen projecting through the horny plug.

Treatment. Keratolytic preparations have often been recommended but we have found them of little value. The most effective treatment is topical retinoic acid [8], which should be used as in the treatment of acne. Depilatory wax [7], specialized cleaning pads [9] and pulsed diode laser [10] have been advocated.

Pili multigemini

Synonym
- Pili bifurcati

The term pili multigemini [1] describes an uncommon developmental defect of hair follicles as a result of which multiple matrices and papillae form hairs that emerge through a single pilosebaceous canal. The incidence of multigeminate hairs in the general population is unknown. Numerous follicles showing this defect have been seen in a patient with cleidocranial dysostosis [2].

Pathology. From two to eight matrices and papillae, each with its internal root sheath, form hairs that are often flattened, ovoid or triangular in configuration and may be grooved. In the follicular canal, contiguous hairs may adhere, bifurcate and then re-adhere.

Clinical features. Multigeminate follicles occur mainly on the face, especially along the lines of the jaw. Tufts of hair may be seen emerging from a few or many follicles. Their discovery is often a matter of chance, but the patient may complain of recurrent inflammatory nodules, leaving scars.

Treatment. If the hairs are plucked, they regrow [2]. A single report of ablation after three treatments with a ruby laser may indicate that this is a therapeutic option [3].

Weathering of the hair shaft [1,2]

All hair fibres undergo some degree of cuticular and secondary cortical breakdown from root to tip before being shed during the telogen or early anagen phase of the hair cycle. The term 'weathering' of hair has been limited by some authorities to structural changes in the hair shaft resulting from cosmetic procedures; indeed, both *in vivo* and *in vitro* studies carried out by cosmetic scientists have shown the type of damage that factors such as combing, brushing, bleaching and permanent waving can cause [3,4]. Scalp hair, having a long anagen phase and being subject to more frictional damage and cosmetic treatment, shows more deep cuticular and cortical degeneration than fibres from other sites.

Weathering of scalp hair has been studied in greater detail than hair from other sites. At the root end, surface cuticle cells are closely apposed to deeper layers. Within a few centimetres of the scalp, the free margin of these cells lifts up and breaks irregularly [5]. Increasing scale loss leads to surface areas denuded of cuticle. Many fibres show complete loss of overlapping scales well proximal to the tip (Fig. 66.71). This is particularly common on long hair shafts, which frequently have a frayed tip. Proximal to terminal fraying, longitudinal fissures may be present between exposed cortical cells. Hairs subjected to considerable friction damage may show transverse fissures and some nodes of the type seen in trichorrhexis nodosa [6,7]. Hair that has been bleached or permanently waved may show shaft distortion. The most severe changes are mostly seen near the distal part of the hair shaft in normal scalp hair.

Hair knotting (Fig. 66.72) and braids (Fig. 66.73) are a significant source of hair shaft trauma, with loss of cuticle and damage to cortical fibres.

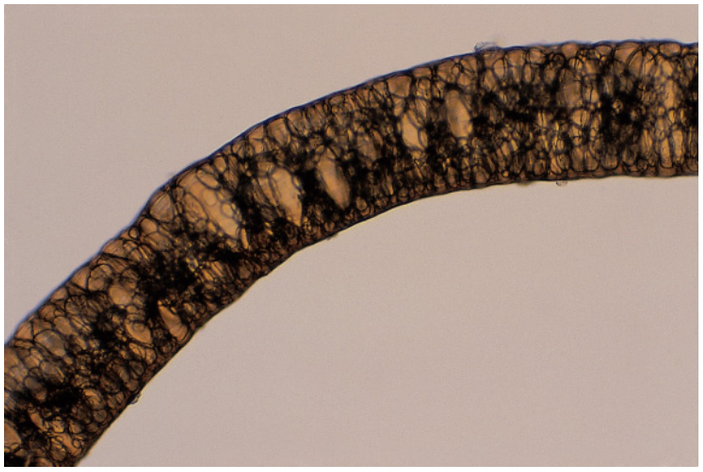

Fig. 66.74 Appearance of normal scalp hair after exposure to naked flame. Bubbles form within the cortex.

Fig. 66.75 Circumferential keratin cast resembling a cuff around the hair shaft.

Trichorrhexis nodosa is the most severe form of weathering. Many of the changes seen in normal hair towards the tip are visible more proximally in congenitally weakened hair [8,9] and in trichorrhexis nodosa caused by overuse of cosmetic treatments [10]. In some hair structural abnormalities, such as monilethrix and pili torti, specific weathering patterns may be seen.

Excessive growth of hair [1–3]

Growth of hair that in any given site is coarser, longer or more profuse than is normal for the age, sex and race of the individual is regarded as excessive. The terms hirsutism and hypertrichosis are often confused. The term hirsutism will be restricted to androgen-dependent hair patterns of typically terminal hair, and the term hypertrichosis will be applied to other patterns of excessive hair growth. In some areas it is difficult to make the distinction, such as in the excess facial hair in porphyria cutanea tarda. This is typically referred to as hypertrichosis, but the point can be argued.

Hypertrichosis

The terminology used in describing different patterns of hypertrichosis is inconsistent, as reports have given synonymous terms to clinically different forms of the problem. Baumeister *et al.* [1] sought to unravel the matter. Hypertrichosis usually conforms to the classification of localized or generalized of congenital or acquired pattern, where congenital is loosely interpreted as that seen in early infancy.

Congenital generalized hypertrichosis

Hypertrichosis lanuginosa

In congenital hypertrichosis, the fetal pelage is not replaced by vellus and terminal hair but persists, grows excessively and is constantly renewed throughout life. In the acquired form, the previously normal follicles of all types revert at any age to the production of hair with lanugo characteristics [1].

Aetiology. Traditionally, cases of congenital hypertrichosis have been classified into two groups—'dog faced' and 'simian'—but a survey [2] suggests that there may be only a single genotype, with considerable interfamily variation in the phenotype. With one exception [3], all published pedigrees suggest autosomal dominant inheritance.

Clinical features [2,4–7]. The child is usually noticed to be excessively hairy at birth (Fig. 66.76). The hair gradually lengthens until by early childhood the entire skin, apart from the palms and soles, is covered by silky hair, which may be 10 cm or more long. Long eyelashes and thick eyebrows are conspicuous features. Some affected individuals are normal at birth and sometimes for the first few years of life, before the universal replacement of other hair types by lanugo. Once established, the hypertrichosis is permanent, but some diminution of hairiness of trunk and limbs may be noted in later childhood. At puberty, axillary, pubic and beard

Fig. 66.76 Congenital hypertrichosis lanuginosa. (Courtesy of Dr Partridge, Leamington, UK.)

hairs retain their downy character. Hypodontia or anodontia and deformities of the external ear are apparently associated in some families, but the physical and mental development of most patients has been normal. In a Mexican family, hypertrichosis was associated with an osteochondral dysplasia [8].

The status of the apparently recessive form is still more uncertain. Three children of a normal mother were densely hairy at birth and died within a week. Neonatal shaving was of cosmetic benefit in one rare case [6].

Treatment of children with long-pulsed ruby laser can result in a useful reduction of hair, although the benefits tend to wane over 6–12 months. Morley reported a 63% reduction in hair counts at 6 months [9].

Universal hypertrichosis

Not all people with congenital universal hypertrichosis will represent the same entity. If it is possible to make the distinction between lanugo and vellus hair, those with vellus hair may be classified as a form of universal hypertrichosis known as the Ambras syndrome, in which there are dysmorphic features. There is a debate concerning the distinction between Ambras syndrome and other forms of generalized hypertrichosis. Baumeister [10] argues that the uniformity of facial growth and the hypertrichosis of the external ear help set Ambras syndrome apart from other extreme forms of universal hypertrichosis where facial hair is not uniformly distributed and the ear hair growth is less marked. Although those outside the diagnosis of Ambras syndrome may have other associated features, such as gingival hyperplasia [11], there are some areas of overlap with respect to rearrangements on chromosome 8 [12,13].

There are also individuals who might be classified as demonstrating universal hypertrichosis, but with less extreme manifestations and without associated or dysmorphic features. The hair pattern is normal, but in any site the hairs are larger and coarser than usual. The eyebrows may be double. Inheritance is determined by an autosomal dominant gene. The features begin to merge into what is considered the normal spectrum.

Congenital generalized hypertrichosis associated with other syndromes

Hurler's syndrome and other mucopolysaccharidoses (see Chapter 15). Hypertrichosis is usually present from early infancy or early childhood on the face, trunk and limbs and may be a conspicuous feature. The eyebrows are often bushy and confluent. In abortive forms, the hair growth may first appear after puberty and be more limited in extent.

Congenital macrogingivae (see Chapter 69) [1]. Exuberant overgrowth of the gingivae as an isolated congenital defect is not uncommon. The association with profuse hypertrichosis of trunk, limbs and lower face has been reported on several occasions. Some patients have markedly acromegaloid features [2] or thyroid disease [3].

Cornelia de Lange syndrome (see Chapter 15). These mildly microcephalic, mentally defective children have a low hairline and profuse overgrowth of the eyebrows. The forehead is covered with long fine hair. Hypertrichosis is usually also conspicuous on the lower back, and may be generalized.

Winchester syndrome. This rare hereditary disorder is characterized by dwarfism, joint destruction and corneal opacities. The skin in many parts of the body becomes thickened, hyperpigmented and hypertrichotic [4,5].

Berardinelli's syndrome [6]. From early life, growth and maturation are accelerated and there is lipodystrophy with muscular hypertrophy. Enlargement of the liver and hyperlipidaemia are other constant features. The skin is coarse and often hypertrichotic.

Trisomy 18 (see Chapter 15). Generalized hypertrichosis of variable degree is present in these patients.

Hypertrichosis has been reported in the rare hereditary globoid leukodystrophy, Krabbe's disease. Most patients die in infancy [4].

Teratogenic syndromes

Fetal alcohol syndrome [7]. Mental and physical retardation affects the infants of many mothers with chronic alcoholism. The cutaneous changes include hypertrichosis and capillary haemangiomatosis.

Congenital localized hypertrichosis

Naevoid hypertrichosis

The growth of hair abnormal for the site and the age of the patient in its length, shaft diameter and colour and may occur as a circumscribed developmental defect, either isolated or associated with other naevoid abnormalities [1], such as duplication of the thumb [2].

Melanocytic naevi (see Chapter 54) may be accompanied by a vigorous growth of coarse hair. The hair may be present from infancy or may develop at puberty. Less often, circumscribed hypertrichosis may occur as the only clinical abnormality. Histologically, the epidermis is acanthotic and the follicles are large, but there is no excess of melanocytes.

Hypertrichosis is a characteristic feature of Becker's naevus (see Chapter 18). The coarse hairs develop in the same body regions as the pigmentation, usually the thoracic or pelvic girdle, but pigmentation and hypertrichosis are not coextensive. It has been suggested that this naevus is a functional one, being androgen dependent; acne may also occur in the same site [3]. It has also rarely been reported in association with limb asymmetry and other ipsilateral anatomical abnormalities [4].

True linear hypertrichotic naevi are rare and hair growth may not be sustained [5].

A tuft of hair in the lumbosacral region, the so-called faun-tail naevus, is often associated with diastematomyelia (Fig. 66.77).

Fig. 66.77 Lumbosacral hypertrichosis ('faun tail'), here associated with diastematomyelia.

Acquired generalized hypertrichosis

Acquired hypertrichosis lanuginosa associated with malignancy

Aetiology. In its most dramatic severe form, this syndrome is rare. It usually accompanies a serious, and often terminal, illness. Fine downy hair grows over a large area of the body, replacing normal hair and primary and secondary vellus. Approximately 60 cases have been reported and all except two (in which there was no follow-up) were suffering from malignant disease of the gastrointestinal tract, bronchus, breast, gall bladder, uterus, bladder or other organs [1–5]. One patient with lymphatic leukaemia had acquired ichthyosis as well as hypertrichosis, and one had a lymphoma. The hypertrichosis may precede the diagnosis of a neoplasm by several years [6].

Pathology. In one case [7] the lanugo follicles lay almost parallel to the surface, and were apparently derived from mantle follicles.

Clinical features [8–10]. In the milder forms ('malignant down' [7]), hair is confined to the face, where it attracts attention by its appearance on the nose and eyelids and other sites that normally are clinically hairless. As the growth of hair continues, it may ultimately involve the entire body, apart from the palms and soles. Existing terminal hair of scalp, beard and pubes may not be replaced, and may contrast in colour and texture with the very fine, white or blonde lanugo. Such hair may grow abundantly, even on the previously bald scalp. The hair may grow exceedingly rapidly, up to 2.5 cm/week, and may be more than 10 cm long.

Non-malignant acquired generalized hypertrichosis

There is a range of non-malignant systemic diseases in which hypertrichosis may develop. Generally, the hair is coarser and less profuse than the lanugo hair associated with systemic malignancy. However, at any single point early in the process, the distinction may not always be obvious.

Endocrine disturbances

Hypothyroidism [1]. A profuse growth of hair on the back and the extensor aspects of the limbs develops in some children with hypothyroidism.

Hyperthyroidism. Coarse hair often grows over the plaques of pretibial myxoedema as it may over other forms of inflammation on the anterior shin.

Possible diencephalic or pituitary mechanisms. Severe, generalized hypertrichosis has been reported in young children after encephalitis [2] and after mumps followed by the sudden onset of obesity [3]. A diencephalic disturbance is postulated. Generalized hypertrichosis occurred in a girl after traumatic shock [4] and remitted in 6 months. There are many reports of hypertrichosis after head injuries, especially in children. The hair growth is first noticed 4–12 weeks after the injury (which seems to be of no consistent type) and appears as fine silky hair on the forehead, cheeks, back, arms and legs, and may be asymmetrical. It is sometimes shed after a few months, but may persist.

Other conditions

Malnutrition [5]. Gross malnutrition, which may be primary or occur in coeliac disease or other malabsorption states or in severe infections, may cause profuse generalized hypertrichosis in children.

Anorexia nervosa. An increased growth of fine downy hair on the face, trunk and arms, sometimes of severe degree, has been reported in 20–77% of adult cases [6,7], and is also seen in children [8]. The prevalence of hypertrichosis in bulimia is reported to be half of that in anorexia, and both are associated with approximately 60% prevalence of scalp alopecia [6].

Dermatomyositis [9]. Excessive hair growth has been noted mainly in children and principally on the forearms, legs and temples, but it may be more extensive.

Epidermolysis bullosa. Gross hypertrichosis of the face and limbs has occurred in association with epidermolysis bullosa of the dystrophic type, although this is rare (see Chapter 39).

Hypertrichosis is seen affecting the extensor surface of the arm (Fig. 66.78) in a sporadic or familial form in children, resolving in adolescence. Although associations with other disorders have been sought, it appears as a largely isolated finding [10].

Table 66.9 Iatrogenic hypertrichosis.

Drug	Comment
Steroid—systemic, injected and topical [1]	Analogous to Cushing's syndrome, with additional local effects with injection or topical use
Diphenylhydantoin [2]	Takes 2–3 months to be apparent
Psoralen [3]	Possibly linked to degree of photosensitization and only shortly outlasts treatment
Diazoxide [2]	
Minoxidil [2,4]	Systemic and topical effect; after only a few weeks—may affect forehead when applied to scalp
Ciclosporin [5,6]	Associated with sebaceous hyperplasia
Latanoprost and bimatoprost [7,8]	Increases growth of eyelashes and adjacent vellus hairs when used as eye drops—analogue of prostaglandin F2α

Table 66.10 Causes of local hypertrichosis.

Example	Comment
Carrying sacks [1]	Hypertrichosis on one shoulder
Carrying religious artefacts [2]	Hypertrichosis on one shoulder
Self-harm [3]	Mentally retarded patient with arm-chewing
Vaccination	Upper arm
Post-surgery [4]	After excision of warts
Chronic inflammation [5–8]	At site of chronic venous insufficiency or thrombophlebitis; following burns and insect bites; chronic eczema
Epidermolysis bullosa [9]	In chronically involved skin
Post-fracture [10]	At site of plaster cast on arms and legs

Iatrogenic hypertrichosis

Iatrogenic hypertrichosis is almost universally due to medication, and can be from systemic, injected or local topical use [1] (Table 66.9).

Acquired localized hypertrichosis

Cutting or shaving the hair influences neither its rate of growth nor the calibre of the hair shaft. However, any chronic local inflammatory or traumatic process may influence hair growth (Table 66.10, Fig. 66.79).

Fig. 66.79 Circumscribed hypertrichosis in an area of steroid-treated lichen simplex.

Porphyria (see Chapter 59). Hypertrichosis of exposed skin is a common feature of the very rare congenital erythropoietic porphyria; appearing first on the forehead, it later extends to the cheeks and chin and, to a lesser degree, to other exposed areas. It is also present in many cases of the much more common erythropoietic protoporphyria [11].

In porphyria cutanea tarda, hypertrichosis is a common finding [12], and may accompany the pigmentation, plethora, blistering and scleroderma-like changes on exposed skin. Darkening of scalp hair in a subject with white hair at the onset of porphyria cutanea tarda has been reported [13], and hypertrichosis has been reported as the presenting complaint in one subject in whom porphyria cutanea tarda was the underlying cause [14]. In black people, hypertrichosis and pigmentation may be present without blistering [15].

The most extreme degree of hypertrichosis is seen in children with hepatic porphyria induced by hexachlorobenzene or other chemicals. Hypertrichosis is frequent in porphyria variegata. The temples, forehead and cheeks are covered with downy hair. There is also increased pigmentation.

Some forms of localized hypertrichosis are caused by the local application or effect of drugs and are discussed in the section on iatrogenic causes of hypertrichosis (see above).

Hirsutism

Perception of hirsutism is by definition subjective, and women present with a wide variation in severity [1]. Both the severity of the hirsutism and the degree of its acceptance are dependent on racial, cultural and social factors. Even the criteria for the definition of hirsutism used by physicians vary widely [2–6]. In order to resolve this issue, different groups have evolved different grading schemes for body hair growth. The scheme employed in the study by Ferriman and Gallwey [3], which has become the standard grading system, defined hirsutism purely on quantitative grounds. Hirsutism is graded as numerical scores beyond an upper limit of twice the standard deviation from the mean. Scoring can be on a global basis assessing 8–11 body sites, or it can be based on a single site. Others have examined women complaining of hirsutism and compared them with controls; they have demonstrated that there is a considerable overlap in the grades of hirsutism between the two groups [4,6]. Hair on the face, chest or upper back is a good discriminating factor between hirsute women and controls with similar hair growth scores. In clinical practice, it has often been suggested that 'real' hirsutism is simply that which the woman in question thinks is excessive.

Facial and body hair is less commonly seen on oriental people [7], black people and native Americans than on white people [8]. Even among white people there are differences; hair growth is heavier on those of Mediterranean than those of Nordic ancestry [9]. The pattern of hair growth in hirsutism within different racial groups is identical [3–6]. However, different criteria have made the determination of the comparative incidence and severity within these groups difficult to assess. Only one study of a random population stated how many women considered themselves to be hirsute. McKnight [5] examined 400 unselected students, 60% of whom were Welsh: 9% were considered by both the women and investigator to be hirsute and 4% were considered to be disfigured by their facial hair growth. This investigation also included studies of hair growth in women who were not complaining of hirsutism. It is important to the definition of hirsutism that a sizeable proportion of normal women have some terminal hairs on their face, breasts and lower abdomen.

Lorenzo [10] studied 90 hirsute women and found an increased incidence of hirsutism in their female relatives compared with control populations. McKnight [5] reported that 14% of hirsute Welsh women gave a positive family history. This tendency to familial clustering in hirsutism might be anticipated, as some of the underlying disorders that result in hyperandrogenism have a familial basis. For example, congenital adrenal hyperplasia is autosomal recessive and linked to MHC [11], and a very strong family relationship has been reported in the polycystic ovary syndrome (PCOS) [12].

Studies of the psychological burden of hirsutism among women seeking medical treatment suggest that it has a significant impact [13,14] and adversely affects quality of life [15].

Endocrine factors and hirsutism [1]

Hirsutism attracts a wide range of endocrine investigations, which differ according to the presentation and the specialty background of the clinician. However, the assumption that hirsutism is wholly related to androgens can be challenged on an individual and general level. The increasing awareness of insulin metabolism and

hirsutism has highlighted this and, on an individual level, it is very clear that many women with unwanted hair have no endocrinological disturbance.

There have been several attempts to correlate hair growth in women with plasma androgen levels but these reports have yielded conflicting results. Reingold and Rosenfield [2] noted a considerable variability between hair growth scores and free testosterone, but no significant relationship. Ruutiainen *et al.* [3] have calculated a complex formula for multiple plasma androgen levels:

$$\text{Testosterone/SHBG} + \text{androstenedione}/100 + \text{dehydroepiandrosterone sulphate}/100$$

This correlates with hair growth only in women with idiopathic hirsutism. In a further study, the same group [4] found a relationship between hair growth and salivary testosterone levels, but in this study no selection of patients was required. The equation demonstrates the significance of sex hormone binding globulin (SHBG) as a factor modifying the effects of circulating androgen.

The first sign of androgen production in women occurs 2–3 years before the menarche and is caused by adrenal secretion [5]. The major androgens secreted by the adrenal are androstenedione, dehydroepiandrosterone (DHA) and DHA sulphate (DHAS). Their control during postpubertal life is unknown, but it is thought that androstenedione and DHA may be controlled by adrenocorticotrophic hormone (ACTH), as their serum levels mirror those of cortisol [6].

Ovarian androgen production begins under the influence of the pubertal secretion of luteinizing hormone (LH) and takes place in the theca cells. The predominant androgen secreted by the ovaries is androstenedione during the reproductive years, and testosterone after the menopause [7].

In normal women, the majority of testosterone production (50–70%) is derived from peripheral conversion of androstenedione in skin and other extrasplanchnic sites [8,9]. The remaining proportion is secreted directly by the adrenals and ovaries. The relative proportion estimated from each gland varies between reported studies: 5–20% from the ovary and 0–30% from the adrenal [10]. DHA is the source of less than 10% of circulating androstenedione and 1% of circulating testosterone [11,12].

Androgen transport proteins

In non-pregnant women, the majority of circulating androgens are bound to a high-affinity β-globulin, sex hormone-binding globulin (SHBG). A further 20–25% is transported loosely bound to albumin, and approximately 1% circulates freely. The free steroid is believed to be active, and the binding protein is therefore of paramount importance. The affinity of androgens for SHBG is proportional to their biological activity.

The function of SHBG is unknown. It is probable that its main role is to buffer acute changes in unbound androgen levels and to protect androgens from degradation. Burke and Anderson [13] suggested that it also acts as a biological amplifier. High oestrogen levels increase SHBG and therefore reduce available androgen; high androgen levels reduce SHBG and increase available free androgen.

Androgen pathophysiology in hirsutism [1,2]

The growth of normal secondary sexual hair is a response of the hair follicles to androgens. Abnormal degrees of hair growth are therefore often seen in endocrine disorders characterized by hyperandrogenism. However, not all women with greater amounts of secondary sexual hair will have abnormal androgens. Many will lie within the range of normal for their age and ethnic origin—albeit possibly at an extreme of the spectrum. For those objectively classified as hirsute, many will have underlying polycystic ovary syndrome (PCOS). Most of the others will have no detectable hormonal abnormality and are usually classified as having 'idiopathic' hirsutism. This subgroup is gradually becoming smaller as diagnostic techniques for PCOS become more refined.

Polycystic ovary syndrome [1,2]. There are currently two prevalent diagnostic consensus criteria for PCOS:

1 1990 National Institutes of Health criteria [2]—the two criteria below need to be fulfilled for the diagnosis of PCOS
   — Clinical (acne or hirsutism) and/or biochemical hyperandrogenaemia (measured elevated androgen levels)
   — Menstrual irregularity
2 2003 Rotterdam criteria [3]—two of the three criteria below need to be fulfilled for the diagnosis of PCOS
   — Clinical (acne or hirsutism) and/or biochemical hyperandrogenaemia (measured elevated androgen levels)
   — Menstrual irregularity
   — Polycystic ovarian morphology on ultrasonography

In both instances it is necessary to exclude other specific disorders, such as non-classical adrenal 21-hydroxylase deficiency, Cushing's syndrome, hyperprolactinaemia and androgen-producing tumours. The 1990 criteria lack the presence of polycystic ovaries as a requirement for diagnosis. The reasoning behind this is that a woman may have the metabolic syndrome of PCOS in the absence of the ultrasonically detected abnormal ovaries. Failure to detect such cystic ovaries should not undermine management of the metabolic syndrome. It is equally true that there are polycystic ovaries in normal women [4] or mildly polycystic ovaries in hirsute women with normal menses [5]. The latter finding has led to the inclusion of women who were previously labelled as having idiopathic hirsutism under the diagnosis of PCOS by some clinical groups. An estimated one-third of women in the UK have polycystic ovaries—defined as 10 or more follicles/ovary detected on ultrasound [6]. One-third of these women will suffer from PCOS. The pattern of these features will depend upon the presenting complaint, be it dermatological, endocrinological or gynaecological. In a gynaecology service, Conway *et al.* [7] found the following clinical features in a series of 556 patients: hirsutism (61%), acne (24%), alopecia (8%), acanthosis nigricans (2%), obesity (35%), menorrhagia (1%), oligomenorrhoea (45%), amenorrhoea (26%) and infertility (over 29%). However, those patients who present to a dermatologist almost invariably have acne and/or hirsutism.

Laboratory investigations in PCOS usually reveal an elevated level of luteinizing hormone (LH), often with an increased LH : follicle-stimulating hormone (FSH) ratio. Testosterone, androstenedione and oestradiol levels are also often raised [7], although these tests are neither wholly sensitive nor specific.

Ideas concerning the pathogenesis of PCOS have been as controversial as the diagnosis, and different authorities embrace beliefs that it is primarily caused by an ovarian abnormality with excess androgen secretion, inappropriate gonodotrophin secretion with abnormal LH pulses, a disorder of the adrenal glands and cortisol production or a defect in insulin action and secretion with hyperinsulinaemia and insulin resistance. In addition to the presence of elevated testosterone, commonly in the range of 2.6–4.8 nmol/L [8], 50% or more of patients will have hyperinsulinaemia of varying degrees [9]. This appears to be the case for both the classically obese and the non-obese PCOS patient [10]. Insulin acts to inhibit production of SHBG and stimulates ovarian testosterone production. Both effects amplify androgenic features in PCOS. Excess insulin production is related to the feedback loop of peripheral insulin resistance which increases in PCOS. This is characteristic of type 2 diabetes mellitus, which is a disease that is more common in PCOS. Consistent with this association, PCOS patients are also at higher risk of dyslipidaemias and coronary artery disease [11]. Altered glucose tolerance, hyperinsulinaemia and hirsutism are all exacerbated by obesity, and the relationship between diabetes and hyperandrogenism in women, or 'diabetes of bearded women', has been recognized for many years [12].

Such features are not invariably part of PCOS. Hyperinsulinaemia may be an autonomous process causing acanthosis nigricans (AN), which acts as a cutaneous marker for the insulin resistance (IR). The combination of AN and IR occurs in 5% of women with hyperandrogenism (HA) [13] and in 7% of women presenting with hirsutism [14]. Women with HAIR-AN have marked features of virilism: muscular physique, acne, alopecia and hidradenitis suppurativa [15]. The cause of hyperinsulinaemia is not always apparent, but its effects can be partly reversed by troglitazone [16], and its significance is illustrated by the evolution of HAIR-AN syndrome with an insulin-secreting tumour, cured by partial pancreatectomy [17].

Leptin is a protein secreted by adipocytes that increases energy expenditure and decreases appetite [18]. In genetically obese *ob/ob* mice, leptin is functionally deficient and the mice develop obesity, insulin resistance, diabetes and infertility. In recent years, there has been much interest in determining the role of this protein in PCOS. High serum levels appear primarily related to obesity rather than the diagnosis of PCOS alone [18] and there is evidence that its fluctuations are synchronized with those of luteinizing hormone [19]. However, although there is some correlation between polymorphisms of the leptin gene and insulin regulation, no mutation specific to PCOS has yet been identified [20].

Family studies of PCOS suggest there is a strong heritable component. However, to date 70 candidate genes have been evaluated with no conclusive result [21], possibly consistent with the multifactorial mechanism and variability of the disease.

SAHA syndrome. The term SAHA syndrome is used by some to describe the constellation of features that arise with cutaneous virilization [22]. The acronym stands for *s*eborrhoea, *a*cne, *h*irsutism and *a*ndrogenetic alopecia. The term does not suggest any specific aetiology; all the causes of hirsutism need to be considered and investigated where clinically indicated. As with all women with hirsutism, androgen-receptor sensitivity can be implicated where there are no apparent endocrine abnormalities. The four features exist together in only 20% of women embraced by this diagnosis, but the concept is favoured by some as a clinical label encompassing the range of problems associated with the diagnosis of hirsutism.

Ovarian tumours. Hirsutism is an almost universal feature in virilizing ovarian tumours; however, functioning tumours that cause virilization represent approximately 1% of ovarian tumours [23]. Amenorrhoea or oligomenorrhoea develop in all premenopausal patients, and alopecia, clitoromegaly, deepening of the voice and a male habitus develop in approximately half of the patients [24,25]. The majority of patients with virilizing ovarian tumours have raised plasma testosterone levels [23,25]. As a rule, these levels exceed double the upper limit of normal and combine with the more extreme and evolving clinical picture to distinguish these women from those with PCOS.

Hirsutism in pregnancy. Hirsutism has only rarely been reported to develop during pregnancy; it may be caused by the development of PCOS or a virilizing tumour. PCOS has been reported to present with virilization during the first or third trimester and may regress postpartum [26]. Androgens freely cross the placenta and virilization of a female fetus may occur [27]. The range of tumours occurring during pregnancy has been reviewed by Novak *et al.* [28].

Congenital adrenal hyperplasia. Cholesterol is metabolized in the adrenal cortex, via a complex pathway, into aldosterone, cortisol, androgens and oestrogens. A defect in cortisol synthesis results in redistribution of the precursors to other pathways, which results in overproduction of the other hormones. In approximately 95% of cases, 21-hydroxylation is impaired [29] so that 17-hydroxyprogesterone (17-OHP) is not converted to 11-deoxycortisol. Because of defective cortisol synthesis, ACTH levels increase, resulting in overproduction and accumulation of cortisol precursors, particularly 17-OHP. This causes excessive production of androgens, resulting in virilization.

Congenital adrenal hyperplasia (CAH) is divided into four categories:

1 Salt-losing, which presents in infancy with dehydration
2 Simple virilizing, in which children present with precocious puberty and short stature
3 Non-classical, attenuated or acquired; and it is this variant that is likely to present to the dermatologist with degrees of hirsutism in otherwise well women
4 Cryptic.

The diagnosis of non-classical late-onset CAH (LO-CAH) cannot be made clinically, and dynamic endocrine investigations are required to differentiate between it, PCOS and idiopathic hirsutism. These women may have only mild degrees of hirsutism, normal physique, normal menses and no metabolic sequelae to the changes in cortisol pathways; however, approximately 80% will have polycystic ovaries [30].

21-Hydroxylase deficiency is the most common defect found with (more than 90%) LO-CAH. As many as 3–6% of women presenting with hirsutism may be affected with this form. It is an allelic variant of the classical childhood salt-wasting type. It is associated with a mutation of the gene controlling cytochrome P-450, *CYP 21*, on chromosome 6 [31]. Among a group of 56 women with LO-CAH, a range of mutations was found. Some put the woman at risk of progeny with classical salt-losing CAH if the father is heterozygous for the same mutation. This raises the significance of detailed analysis of this pathway in such women and the genotypic basis in the woman and male partner [32]. 3β- and 11β-hydroxylase deficiencies are less common forms of CAH and are consequently less frequently found in hirsute women [33].

Acquired adrenocortical disease. Adrenal carcinomas usually present with abdominal swelling or pain; however, 10% of both adenomas and carcinomas may present with isolated virilization [34]. The combination of virilization and Cushing's syndrome strongly suggests the presence of a carcinoma. The testosterone level is usually markedly raised in the latter.

Patients with Cushing's syndrome are said to have both hypertrichosis, a generalized diffuse growth of fine hair resulting from hypercortisolaemia, and androgen-induced coarse hair in the usual male pattern [35].

Hyperprolactinaemia. The exact relationship between prolactin and hirsutism is not clear. The incidence of hirsutism in the amenorrhoea–galactorrhoea syndrome has been reported as 22–60% [36]. This may be caused by a direct effect of prolactin on adrenal androgen production or by PCOS, with which it is frequently associated; prolactin has also been reported to attenuate cutaneous 5α-reductase activity both *in vivo* and *in vitro* [37].

Fig. 66.80 Facial hirsutism: in this case not associated with any systemic disease or detectable biochemical endocrine abnormality.

Idiopathic hirsutism (Fig. 66.80). Idiopathic hirsutism is the diagnostic label given to those hirsute women in whom no overt underlying endocrine disorder can be detected. There are a number of subtle dynamic alterations in the androgen metabolism of some hirsute women compared with non-hirsute women: daily testosterone production can be increased 3.5- to 5-fold; the majority of androgen is secreted as testosterone (hirsute 75%, versus normal <40%) rather than as androstenedione [38]; increased androgens in hirsute women are associated with lower levels of SHBG, which binds less testosterone and increases its free level [39]. More free testosterone is therefore available for peripheral metabolism and clearance; these two factors disguise the increased rates of testosterone production.

Normal values for total testosterone are found in 25–60% of hirsute women and in 80% of those with regular menstrual cycles [40]. This may be a result of the effect of SHBG or the wide fluctuations in plasma testosterone seen in hirsute women, or it may reflect the role of androgen receptor sensitivity. The finding of a small elevation of testosterone is not a holy grail, and the tendency to repeat the test many times in the setting of hirsutism is only warranted in progressive or extreme cases where a neoplasm is suspected. Although many women classified as having idiopathic hirsutism may have subtle PCOS, others may be completely normal.

Diagnostic approach to the hirsute woman (Table 66.11)

Most women consulting with concern over hirsutism will provide two key clues. The first will be the appearance and the second the history. The main area of patient concern is usually the face, but this is not always easy to assess. The patient may spend hours every day plucking or otherwise managing the excess hair and so appear to be someone with no clinical problem. The account of such self care leads the examination to other body sites, where the most sensitive is the chest and back for pathological hirsutism. Although there are scoring systems, these are mainly of scientific interest or as a means of monitoring response to treatment. The presence or absence of terminal hair at specific sites is important to document. This can be supplemented by an approximation of how dense the growth is—ranging from a few scattered hairs to confluence. Other features of androgenization to be noted are acne, androgenetic alopecia, acanthosis nigricans and obesity. Malignant androgen-secreting tumours may also lead to clitoromegaly, increased muscle bulk and a deeper voice.

If the clinician is able to corroborate the complaint of hirsutism, the history becomes important as a means of determining whether it is likely to have broader biological significance. Of primary importance is the duration of the problem and its rate of evolution. A short history of a dramatic change raises concern that there might be an androgen-secreting tumour. A slow evolution during puberty would make such a diagnosis unlikely. Menstrual regularity is a further important detail, where lifelong menstrual disturbance suggests PCOS, recent marked alteration suggests a new evolving diagnosis, and the absence of any menstrual problem is likely to mean that there is no hormonal basis to the hirsutism. A drug history may point to an ingested source of androgens (e.g. glucocorticoid or anabolic steroids) and those used to enhance athletic performance. The progestogenic components of many contraceptive preparations are relatively androgenic and this is often cited as a cause of hirsutism, but it has not been a major factor in our experience.

The extent to which it is necessary for hirsute women without suspicious signs or history to be investigated is debatable. If the primary concern is to exclude an androgen-secreting tumour, a measure of serum testosterone is a good screening tool. This might

Table 66.11 Investigations where hirsutism suggests an endocrinological origin (after Setji & Brown [1]).

Test	Looking for	Comment
Total testosterone	Androgen-secreting tumour	This is a useful screening test. If it is more than twice the upper limit of normal then it should trigger more extensive investigation for an androgen-secreting tumour. Up to that level above normal, it probably represents PCOS, but this should be clarified.
Dehydroepiandrosterone sulphate	Androgen-secreting tumour of the adrenal glands	DHEAS is a supplementary test if there is a raised testosterone or other reason to pursue the possibility of an androgen-secreting tumour. Although modest elevations in dehydroepiandrosterone sulphate can be seen in polycystic ovary syndrome, greater elevations should prompt a complete evaluation for an adrenal androgen-secreting tumour.
Morning 17-hydroxyprogesterone	Late-onset congenital adrenal hyperplasia	This screens for non-classical congenital adrenal hyperplasia which in turn might be suggested by a family history or the more complete variant of CAH.
24-h urine for cortisol and creatinine	Cushing's syndrome	Look for the classic features of Cushing's syndrome with hypertension, abdominal striae, central abdominal weight gain and moon face.
Prolactin	Hyperprolactinaemia	There may be associated galactorrhoea. Some advocate this test in all women with irregular menstrual cycles.
Thyroid function studies	Hyper- or hypothyroidism	May help explain altered menstruation, but will rarely be a cause of hirsutism.
Imaging	Localizing abnormality within ovaries or adrenals	Choice of imaging needs to be directed by specific line of enquiry by someone expert in endocrinological or gynaecological tumours.

need to be repeated, and if there is heightened concern it can be supplemented by measurement of the dehydroepiandrosterone sulphate (DHEAS). Clarifying the diagnosis of PCOS may be appropriate (Table 66.12) or further investigation arranged in collaboration with a primary care physician or gynaecologist. Pursuing the diagnosis of LO-CAH is controversial. In some hands the diagnosis will not alter management. Others advocate the use of dexamethasone indefinitely, with all the attendant risks of osteoporosis and other metabolic sequelae [2].

However, there may be reduced fertility [3] and if the woman is heterozygous for a mutation that predisposes to the salt-losing variant, her progeny may be at risk if their father is heterozygous for the same mutation [4]. This last point raises the question of whether the diagnosis should be sought more rigorously. Although it may not alter clinical management of the hirsutism, it may be of significance to the reproductive plans of the woman. At present, defining whether the woman is heterozygous for a mutation of the CYP21 gene that can lead to the salt-losing variant of CAH in offspring is limited to gene analysis. The phenotype and endocrine investigations are not sufficiently sensitive to distinguish between heterozygosity for a range of CAH mutations of differing significance. The standard screening test for such mutations is estimation of the basal (early morning) plasma 17-hydroxyprogesterone level.

It remains an overriding priority to exclude a virilizing tumour if this is suggested by the history and examination [1,5]. The clinician can then determine which investigations are indicated.

Treatment [1–4]

Treatment can be as simple as giving clear advice on how to use products available at the chemist, to a complex mix of topical, laser and systemic therapies alongside management of related endocrinological pathology. In all settings there is usually an element of psychological support needed, which may amount to a requirement for counselling or other specialist services. The schema for management of PCOS addresses the core elements of management of all women with hirsutism (Table 66.13).

Cosmetic measures

Where a woman has failed to make full use of physical methods of hair removal it is helpful if the dermatologist is familiar with what is available [4] or can direct her to a reliable beautician or other expert in cosmetic care for advice (Table 66.14). The easiest measure is to bleach the hair with hydrogen peroxide. This produces a yellow hue because of the native colour of keratin. Hair plucking is widely performed, but the act of plucking not only removes the hair shaft but also stimulates the root into anagen and there is only a brief delay while the shaft grows through the epidermis. Shaving avoids this problem by removing all the hairs but is followed by growth only of the hairs that were previously in anagen. Negative aspects of shaving the face are that it is seen as a masculine activity and also that the regrowing hair has a sharp bevel, accentuating the rough feel.

Depilatory creams contain thioglycolates that dissolve sulphur bonds within keratin molecules, making the hair gelatinous. They are irritant and require care in terms of strength of preparation and duration of exposure. It is often the case that the patient has used a depilatory cream once and given up because she became

Table 66.12 Options for investigation and assessment directed to the diagnosis of PCOS.

Test	Normal range (may vary with local laboratory assays)	Comment
Pelvic ultrasound	To assess ovarian morphology and endometrial thickness	Ultrasound criteria are 10 or more cysts, 2–8 mm in diameter, arranged either peripherally around a dense core of stroma or scattered throughout an increased amount of stroma
Testosterone	0.50–3.5 nmol/L	It is unnecessary to measure other androgens unless total testosterone is >5 nmol/L, in which case comprehensive assessment is indicated
Luteinizing hormone	2–10 IU/L	FSH and LH best measured during days 1–3 of a menstrual bleed; if oligo-/amenorrhoeic then random samples are taken
Follicle stimulating hormone	2–8 IU/L	
Fasting glucose	<5.5 mmol/L	Fasting level below 5.5 mmol/L makes impaired glucose tolerance very unlikely
Fasting lipid profile		

Table 66.13 Management of polycystic ovary syndrome.

Aspects of PCOS	Points for the dermatologist to cover	Points for multidisciplinary involvement
Psychosocial	Address body image and eating behaviours Screen for depression Discuss stress management Provide non-judgmental support	Specialist counselling or behavioural therapy
Cosmetic	Discuss depilatory products available over the counter: bleaching, thioglycolate, waxing Discuss use of eflornithine hydrochloride 13.9% cream, laser therapy, and electrolysis Discuss use of oestrogen-containing oral contraceptives to suppress androgens if no contraindications Consider spironolactone 50–100 mg twice daily for refractory hirsutism or acne Discuss other aspects of androgenization—acne, androgenetic alopecia, acanthosis Discuss obesity, if relevant, and direct to local services	
Metabolic	*Consider referral to primary care physician or general physician*	Assess diabetes and cardiovascular disease risk Assess risk for non-alcoholic fatty liver disease Discuss lifestyle therapies such as nutrition and physical activity
Cycle control	*Consider referral to gynaecologist or work with primary care physician*	Assess bleeding pattern and risk for endometrial hyperplasia Provide therapies to prevent endometrial hyperplasia: oestrogen-progestin therapy
Ovulation	*Consider referral to gynaecologist or work with primary care physician*	Discuss fertility goals Discuss therapies to increase ovulation frequency: weight loss, metformin Consider referral to reproductive endocrinology for assisted reproductive technologies
Sleep apnoea	*Consider referral to respiratory physician or work with primary care physician*	Screen for sleep apnoea Refer for sleep study if indicated

Table 66.14 Physical and topical measures in the management of hirsutism.

Method	Practitioner	Cost	Efficacy	Longevity	Side effects
Pluck	Self	Zero	+	2–4 weeks	Soreness; folliculitis
Shave	Self	Low	++	1–2 weeks	Folliculitis; stubble
Bleaching	Self	Low	+	1–3 weeks	Good for concealing modest amounts of hair
Waxing, sugaring	Self or beautician	Medium	++	2–4 weeks	Can treat larger areas, but then more soreness
Depilatory creams	Self or beautician	Medium	++	1–2 weeks	Irritant dermatitis; needs care on sensitive areas
Eflornithine cream	Self on prescription	Medium	+/–	4 weeks	Folliculitis; can be used in conjunction with laser or IPL therapy
Electrolysis	Beautician	High	++(+)	weeks–months	Long-term therapy; folliculitis and scarring
Intense pulsed light	Technician	High	++(+)	?6–9 months after course of treatment	Course of multiple treatments with top-ups in following years Can be painful, burn and scar, especially on dark skin, and no use for light hair
Laser	Technician	High	+++	?6–12 months after course of treatment	As above

Table 66.15 The principal systemic treatments in hirsutism.

Drug	Dose	Duration	Side effects
Dianette™ [12–14]	As in oral contraceptive pill (OCP)	>6 months	OCP side effects plus additional thromboembolic risk?
Cyproterone acetate [12,13,15]	50–100 mg in postmenopausal or as supplement to Dianette	>12 months	As above
Spironolactone [16–21]	50–200 mg daily	>6 months	Menstrual irregularities, breast tenderness, diuretic effects
	As in OCP with withdrawal bleed or continuous		
Other drugs			
Finasteride [22–25]			
Metformin [26–28]			
Flutamide [29,30]			
GnRH [30–32]			

sore or it did not work. Results can be improved by employing the cream in the same way that one might use dithranol when treating psoriasis, using small test areas to gain experience.

Waxing is performed by the application of a sheet of soft wax to the skin and, as soon as it has hardened with the hair shafts embedded, abruptly peeling it off, removing all the shafts. This is a painful method and is often complicated by folliculitis. Certain natural sugars, long used in parts of the Middle East, are becoming popular in place of waxes, as they appear to depilate as effectively but with less trauma. Both methods require the hair to be long enough for the wax, resin or sugar to gain sufficient purchase on the hair shaft.

Electrolysis is a more permanent method of hair removal [4]. A fine electrical wire is introduced down the hair shaft to the papilla, which is destroyed by an electrical current. Laser thermolytic hair removal is now widely used. Although its long-term efficacy is not yet known, laser-assisted hair removal has been in use for sufficient time to allow a reasonable estimate of its efficacy and safety. A Cochrane review observed that the data to support laser and intense pulse light treatment were poor, but favoured alexandrite and diode lasers over others. Lack of follow-up data was a particular shortcoming [5]. Most practitioners will select patients for dark hair and light skin. This maximizes the absorption of laser energy by the hair and minimizes absorption by the skin. Nevertheless, it is still possible for soreness and crusting to occur following treatment. In darker skin this can be associated with post-inflammatory pigmentary changes. Treatments are usually administered as part of a course of at least three visits separated by intervals of several weeks. This reflects the biology of the follicle, which is most responsive to abalation when in anagen. The gap between treatments allows those hairs initially in telogen to move into anagen. Sommer *et al.* [6] compared the hair counts 36 weeks after four treatments to the face with a normal pulse ruby laser with the effects of a single pulse. Hair counts were reduced by 61% and 41%, respectively. A randomized trial in hirsute PCOS women examined the effects of alexandrite laser therapy given monthly for 6 months, demonstrating a reduction in hair growth, patient anxiety scores, time spent on other depilatory activities and an improvement in quality of life score [7]. There was no follow-up period and the treatment was provided free. There is some evidence that supplementing laser therapy with eflornithine cream results in a greater benefit sooner than with either treatment alone [8]. Broad-band intense pulsed light (IPL) represents a cheaper technology with less restriction on the licensing of those who use it. It is likely to achieve some of the benefits of laser therapy [9].

Drug therapy [10]

The main systemic therapies for hirsutism are antiandrogens (Table 66.15). These can be effective in the absence of abnormal androgen levels. Any benefits are lost within months of stopping treatment [11]. Hence, the patient and the person with responsibility for prescribing need to be aware of the following parameters when medication is commenced:

1. All medications have potential side effects and they may need monitoring by blood tests and other measures.
2. Pregnancy is contraindicated with these drugs, and a pregnancy prevention plan is required for the duration of therapy—which may be long term.
3. Not everyone will respond to treatment and therefore some semi-objective measure of efficacy and timescale for assessment need to be discussed, e.g. frequency of use of depilatory aids at outset and 6 months, or photographs.
4. At what point is it envisaged that the treatment will be stopped?
5. Who will take responsibility for long-term prescribing and monitoring, where medication is being used outside the licensed indication?

When the hirsute woman has PCOS, prescribing may cross boundaries with treatment of other aspects of the disease and care may be shared with other clinicians. When the woman is otherwise completely healthy, the issues of using unlicensed medication in the absence of disease have to be weighed against the loss of function arising from the hirsutism. Our preferences are spironolactone or an oral contraceptive with a non-androgenic progestagen—Dianette™, Marvelon™ and Yasmin™ are examples. Cyproterone acetate, present in Dianette™, can be prescribed alone in post-menopausal women, but its use raises some concerns, cited below.

Cyproterone acetate [12]. Cyproterone acetate (CPA) is a synthetic progestogen that acts as both an antiandrogen and an inhibitor of gonadotrophin secretion. It reduces androgen production, increases the metabolic clearance of testosterone and binds to the

androgen receptor; in addition, long-term therapy is associated with a reduction in the activity of cutaneous 5α-reductase. Although CPA is a potent progestogen it does not reliably inhibit ovulation. It is usually administered with cyclical oestrogens in order to maintain regular menstruation and to prevent conception in view of the risk of feminizing a male fetus.

A Cochrane review found that cyproterone acetate has only poor quality data to support its use, although subjective improvements are recorded [12]. Several regimens have been advocated. Low-dose therapy (Dianette; Schering AG) is an oral contraceptive containing 35 µg ethinylestradiol and 2 mg CPA, taken daily for 21 in every 28 days. However, many of the dose-ranging and efficacy studies have been performed using the preparation that contained 50 µg ethinylestradiol; this may be relevant, as only the higher dose of oestrogen increases SHBG. Current dosage recommendations for CPA usually advise that 50 mg or 100 mg CPA should be administered for 10 days/cycle (e.g. day 1–10 or 5–15). However, there have now been many dose-ranging studies that suggest that there is no dose effect. Objective studies comparing Dianette with and without extra CPA found no difference in the reduction of overall hirsutism grades, although the rate of onset of benefit was faster with the additional cyproterone [13].

Side effects of CPA include weight gain, fatigue, loss of libido, breast tenderness, nausea, headaches and depression. All these side effects are more frequent with higher dosage. As with all medication for a cosmetic problem, safety can be a concern for those needing long-term treatment. Contraindications to its use are the same as for the contraceptive pill and include cigarette smoking, age, obesity and hypertension. Venous thromboembolism is the adverse effect of greatest medical significance. A case–controlled study indicated that risk of this was four times greater in women taking an oral contraceptive containing CPA as the progestogen in comparison with those containing levonorgestrel [14].

One retrospective study of 188 women taking CPA 50–100 mg/day described side effects in 23%. Nine per cent of the total group stopped therapy because of these effects, but it is difficult to discern whether the problems were a result of the CPA or ethinylestradiol that many also took. Most of the problems were related to mood, weight or menstrual disturbance. Within the group, 24 had been treated for 5 years or more, nine for 10 years or more and two for 15 years [15].

Spironolactone [16,17]. Spironolactone is a popular and relatively safe treatment for hirsutism. Formal proof of its efficacy is not to the highest standards, although a Cochrane review concluded that it was of some value [18]. The discovery of its benefit in hirsutism was serendipitous—a 19-year-old hirsute woman with PCOS was treated with spironolactone (200 mg/day) for concurrent hypertension and she noted after 3 months the need to shave less frequently.

Spironolactone has several antiandrogenic pharmacological properties. It reduces the bioavailability of testosterone by interfering with its production and increases its metabolic clearance. It binds to the androgen receptor and, like CPA, long-term therapy is associated with a reduction in cutaneous 5α-reductase activity [19]. Different regimens of spironolactone have been studied, varying between 50 and 200 mg taken either daily or cyclically (daily for 3 weeks in every 4). Within this dosage range, the one chosen will depend on the severity of the hirsutism. A 3 out of 4 week cycle will result in a withdrawal bleed in the fourth week, which is similar to that seen with the oral contraceptive. However, spironolactone cannot be relied on as a contraceptive and care must be taken to avoid conception while taking the drug.

Spritzer *et al.* [20] compared the relative benefits of a combination of CPA 50 mg/day and ethinylestradiol 35 µg/day with spironolactone 200 mg/day over 12 months. Both groups were stratified for those with PCOS and idiopathic hirsutism. In both groups, those with idiopathic hirsutism did equally well. However, those with PCOS did significantly better with the CPA/ethinylestradiol combination. Where spironolactone is used in combination with ethinylestradiol 35 µg and CPA 2 mg, there may be some modest advantage [21].

When compared with finasteride 5 mg, spironolactone 100 mg produced a significantly greater improvement during a 9-month trial [22]. Spironolactone may feminize a male fetus. Long-term high-dose spironolactone has been shown to produce tumours in rodents. Some clinicians feel that this finding makes long-term use inappropriate in healthy young patients with hirsutism.

5α-Reductase inhibitors. 5α-Reductase inhibitors are a potential systemic therapy for hirsutism. Finasteride inhibits the type 2 isoenzyme of 5α-reductase and has been assessed in small placebo-controlled trials, with some benefit after 6 months' therapy. Small, randomized, head-to-head trials suggest that finasteride works over a 6–12-month period, but is probably not quite as good as Dianette or spironolactone [22,23]. Supplementing spironolactone with finasteride might result in a greater improvement than treatment with finasteride alone [24]. Trials of topical finasteride have had mixed results [25]. Other systemic and topical 5α-reductase inhibitors are likely to be available in the near future. This group of drugs feminizes a male fetus, which is a drawback in the therapy of women of child-bearing potential and has precluded a drug licence for the treatment of hirsutism.

Corticosteroids. Corticosteroids have a logical place in the treatment of LO-CAH. However, any benefits that they may have in this setting need to be balanced against their well-described side effects. Although their use is justified on the basis of physiological replacement, it is likely that pharmacological regimens will far exceed this, with consequent problems. Spritzer *et al.* [33] demonstrated the superiority of ethinylestradiol 35 µg with CPA 2 mg over hydrocortisone in the treatment of hirsutism associated with LO-CAH.

Metformin. Metformin is a biguanide originally used in the treatment of type 2 diabetes mellitus. It has found a place in the treatment of hirsutism associated with hyperinsulinaemia and insulin resistance. In this setting, it can reduce levels of insulin, increase insulin sensitivity and, particularly when associated with a low-calorie diet, result in weight loss [26]. In many, this constellation of problems will be part of PCOS, and metformin has also been shown to assist in normalization of menstruation and improvement in lipid profiles [27]. These broader metabolic effects can

make it a useful therapy where hirsutism is not the only problem, and it is not a drug likely to be prescribed by a dermatologist [28].

Eflornithine. Eflornithine was originally used orally in the treatment of hyperactivity in childhood. It is an inhibitor of ornithine decarboxylase and is able to delay the initiation of anagen, leaving the follicle in telogen. Limited studies show some reduction in hirsutism when used as a cream on women's faces [34]. It may also supplement the efficacy of laser when used as combined therapy [8].

Flutamide [29]. This acts as a pure antiandrogen and works by binding to androgen receptors. However, it has no antigonadotrophic effect, and the result of binding to central androgen receptors is that it prevents the negative feedback effect of testosterone, and consequently androgen levels rise. There has been a single study in hirsutism in which flutamide (250 mg twice daily) was administered with an oral contraceptive for 7 months; 12 out of 13 patients demonstrated a subjective reduction in hair growth and improvement in acne [30]. Flutamide is potentially hepatotoxic and requires close monitoring to avoid liver complications. It is not used in the UK.

Gonadotrophin-releasing hormone agonists. Gonadotrophin-releasing hormone (GnRH) agonists inhibit LH production and this results in profound suppression of ovarian androgen production. These agents are presently under investigation, but preliminary studies suggest that they effectively reduce hair growth and acne in women with PCOS [31], and may be superior to finasteride [32]. Drawbacks are cost and the need for monthly injections.

Hair pigmentation [1–3]

In humans, hair pigmentation depends entirely on the presence of melanin from melanocytes. The perceived colour will depend also on physical phenomena. The range of colours produced by melanins is limited to shades of grey, yellow, brown, red and black,

Fig. 66.81 Human anagen follicle, showing pigment donation to the hair cortex. There is pigment incontinence in the dermal papilla (Masson–Fontana stain).

depending on the amount and ratio of eumelanin (black) and phaeomelanin (red).

It is important to remember that much of the research on melanogenesis and its cellular control is in relation to epidermis outside the follicle. Many aspects of hair bulb melanogenesis are likely to be the same. Hair melanin is formed by melanocytes situated in the hair bulb epithelium around the upper half of the dermal papilla amongst cells destined to form the hair cortex. Ultrastructurally, hair bulb melanocytes appear more melanogenic than epidermal melanocytes, and their population density is much greater than in the epidermis (approximately one melanocyte to four basal keratinocytes in the upper hair bulb compared with a ratio of 1 : 25 in the basal layer of the epidermis [4]). Melanocytes are also present in the basal layer of the infundibulum and, in small numbers, in the outer root sheath of the lower part of the follicle. These latter cells are DOPA-negative and non-melanized and are thought to form a melanocyte reservoir in the skin. Under certain circumstances (e.g. during repigmentation of vitiligo), outer root sheath melanocytes proliferate and migrate to the epidermis [5]. In humans, hair bulb melanocytes donate pigment almost exclusively to cells undergoing early differentiation to form the hair cortex (Fig. 66.81). Therefore there is a close spatial and functional relationship between hair bulb melanocytes and the cells that act as pigment receptors (cortical keratinocytes).

Melanogenic activity in the hair follicle is closely linked to the hair cycle. In the telogen follicle, non-melanogenic melanocytes are found in the basal layer of the outer root sheath and in the secondary germ region [6]. These cells are assumed to be the precursors of active melanocytes during the next anagen phase, and either migrate or are carried into the hair bulb in early anagen development. They congregate in the upper part of the anagen hair bulb amongst cells destined to form the hair cortex. Melanogenesis begins well after epithelial proliferation has started and coincides with the onset of morphological evidence of cortical differentiation. Tyrosinase activity becomes apparent in Anagen 3, and pigment transfer to cortical epithelium begins in the Anagen 4 stage of development [7–9]. In pigmented hair follicles, intense melanogenesis continues throughout the remainder of anagen (Anagen 5 and 6), and then ceases with the onset of catagen. The close anatomical and functional association of hair bulb melanocytes with cells to which pigment is donated, cells destined to form the hair cortex, suggests that interaction between these two cell types has a key role in regulating pigmentary activity. The fate of hair bulb melanocytes during catagen is uncertain. Non-melanizing melanocytes have been observed in the regressing epithelial column in human catagen follicles [10], but apoptotic deletion of follicular melanocytes has also been described during this stage of the hair cycle [11].

Melanogenesis [1–3]

Functional melanocytes respond to the peptide hormones α-melanocyte stimulating hormone (α-MSH) or ACTH through the MC1R receptor to stimulate melanin production. This receptor is a transmembrane G-protein. When bound to melanocortin peptides, intracellular cyclic adenosine monophosphate (AMP) rises, resulting in tyrosinase gene expression, melanocyte proliferation and increased dendricity. There may also be switching of melanin type. Loss-of-function mutations in the *MC1R* gene are associated with a switch from eumelanin (dark) to phaeomelanin (red) production [4,5]. The phaeomelanosome, containing the key enzyme of the tyrosinase pathway, produces light red-yellowish melanin,

whereas the eumelanosome produces darker melanins via induction of additional TYRP1, TYRP2, SILV enzymes, and the P-protein. Intramelanosomal pH, governed by the P-protein, may act as a critical determinant of tyrosinase enzyme activity. There is significant genetic variation in the genes from which these proteins arise. Over 30 variant alleles have been identified in the *MC1R* gene alone. Functional correlation of *MC1R* alleles with skin and hair colour provides evidence that this receptor molecule is a principal component underlying normal human pigment variation.

In black hair follicles, deposition of melanin within melanosomes continues until the whole unit is uniformly dense. Lighter coloured hair shows less melanin deposition, and blonde hair follicles show melanosomes with a moth-eaten appearance. Red and blonde hair follicles have spherical melanosomes; those in brown and black hair are ellipsoidal.

Pigment is incorporated into hair cortex. No pigment is donated to presumptive cuticular and internal root sheath cells, although pigment granules have been detected in the cuticle of human nostril hair and in the coats of many animals [6]. Melanocytes are functional only during the anagen phase of the hair cycle. Some melanocytes undergo apoptotic deletion during catagen, but amelanotic melanocytes can be found in telogen hair bulb epithelium, possibly derived from the melanocyte reservoir in the outer root sheath [7,8]. In murine follicles, melanocytes are also present in the dermal papilla during telogen [8].

Hair colour resulting from physical phenomena

The whiteness of hair seen when melanin is absent is an optical effect resulting from reflection and refraction of incident light from various interfaces at which zones of different refractive index meet. Thus, in general, non-pigmented hair with a broad medulla appears paler than non-medullated hair. Normal 'weathering' of hair along its length may lead to the terminal part appearing lighter than the rest as a result of a similar mechanism—the cortex and cuticle become disrupted and form numerous interfaces from internal reflection and refraction of light. This also applies in trichorrhexis nodosa (excessive 'weathering'), in which patients often note a lightening in colour of the brittle hair, and in the white bands of pili annulati. Because these optical lightening effects are caused by reflection and refraction of incident light, when such hairs are viewed by transmitted light microscopy they appear dark. Newly formed, unpigmented hair with no medulla appears yellowish rather than white. This is probably the intrinsic colour of dense keratin as orientated in hair fibres. Findlay [9] showed that the perceived colour is affected by the physical characteristics of the hair shaft and may bear little relationship to the true chromaticity of the shaft.

Hair fibre tryptophan content increases with age and within age groups, and is higher in dark hair than fair hair. The exception is with white hair and the significance of these findings is uncertain [10].

Lanugo hair present *in utero* is unpigmented. Vellus hair is also typically unpigmented but, in men in particular, some vellus fibres may pigment slightly after puberty. Hair colour varies according to body site in most people. Eyelashes are usually the darkest. Scalp hair is generally lighter than genital hair, which often has a reddish tint even in subjects having essentially brown hair. Apart from individuals with red scalp hair, a red tint to axillary hair is most common in brown-haired individuals.

Hairs on exposed parts may be bleached by sunlight. Very dark hair first lightens to a brownish-red colour but rarely becomes blonde even after strong sunlight exposure; brown hair, however, may be bleached white.

Variation in hair colour

Genetic and racial aspects [1–3]

Ethnic differences in hair colour are very conspicuous, as are the differences in hair morphology, although colour and hair form are inherited separately [4]. Dark hair predominates in the world. Among white people there is wide variation in colour within geographical regions. Blonde hair is most frequent in northern Europe and black hair in southern and eastern Europe; foci of blondeness are to be found even in North Africa, the Middle East and in some Australoids. Congoid, Capoid, Mongoloid and Australoid hair is mainly black.

Red hair

This has attracted more attention than other colours because it is less common, so distinctive and, to date, is the only hair colour for which the genetic basis is known. The incidence of red hair varies from 0.3% in northern Germany to as high as 11% in parts of Scotland. In mice the synthesis of eumelanin or phaeomelanin is determined by activation or blockade, respectively, of the melanocortin receptor-1 (MC1R). The receptor is activated by α-MSH and blocked by agouti signalling protein derived from the dermal papilla. It is not yet clear whether there is a human equivalent for agouti. However, three variant regions within the highly polymorphic human *MC1R* gene confer reduced function of the receptor and are associated with red hair. Most red-haired individuals are homozygous or compound heterozygous for these *MC1R* polymorphisms.

Heterochromia

This implies the growth of hair of two distinct colours in the same individual. A colour difference between scalp and moustache is

not uncommon. In fair-haired individuals, pubic and axillary hair, eyebrows and eyelashes are much darker than scalp hair. In humans, eyelashes are generally the most darkly pigmented hairs. Variation in colour of individual hair shafts is also seen in normal human scalp. More rarely, discrete patches of lighter or darker hair may occur, which may occur in a Blaschko's distribution [5,6].

There are several case reports of segmental heterochromia, in which demarcated variations in colour occur along a single hair shaft [7–9]. This usually takes the form of intermittent loss of pigmentation. Some cases have been associated with iron deficiency anaemia and have recovered following treatment with an iron supplement [7,8].

Greying of hair (canities)

Greying of hair is usually a manifestation of the ageing process. In white races, white hair first appears at the age of 34.2 ± 9.6 years, and by the age of 50 years 50% of the population have at least 50% grey hairs [10]. The onset in black people is 43.9 ± 10.3 years, and in Japanese between 30 and 34 years in men and between 35 and 39 years in women. The beard and moustache areas commonly become grey before scalp or body hair. On the scalp, the temples usually show greying first, followed by a wave of greyness spreading to the crown and later to the occipital area.

The visual impression of greying is due to an admixture of pigmented and white hairs. Melanization of pigmented hairs on a grey scalp may be reduced compared with normally pigmented hairs but it is not known if a decline in pigmentation occurs along the length of a hair shaft, that is during a single anagen cycle, or whether the level of reduced or absent pigmentation is established at the onset of an anagen cycle. Loss of hair pigmentation is associated with a decrease and eventual cessation of tyrosinase activity in the lower bulb [11]. Melanocytes are absent from the bulbs of white hairs [12,13] although non-melanized melanocytes are still present in the outer root sheath [14].

Rapid onset, allegedly 'overnight', greying of the hair has excited the literary, medical and anthropological worlds for centuries [15]. Historical examples include Sir Thomas More and Marie Antoinette, whose hair became grey over the night preceding their executions. The probable mechanism for rapid greying is the selective shedding of pigmented hairs in diffuse alopecia areata, the non-pigmented hairs being retained (Figs 66.82 & 66.83).

In general, greying of hair is progressive and permanent, but there are occasional reports of repigmentation of previously non-pigmented hair [16–18].

Premature greying (Fig. 66.84)

The association between premature greying and certain organ-specific autoimmune diseases is well recognized although there are limited published data. In a controlled study of 125 patients with pernicious anaemia, 11% had premature greying, defined as onset before the age of 20, compared with 2% in the control group [19].

Premature greying is a feature in a number of genetic diseases. It occurs in the early ageing disorders, Werner's and Rothmund–Thomson syndromes, which are due to defects in DNA helicases [20]. In progeria, premature greying is associated with marked

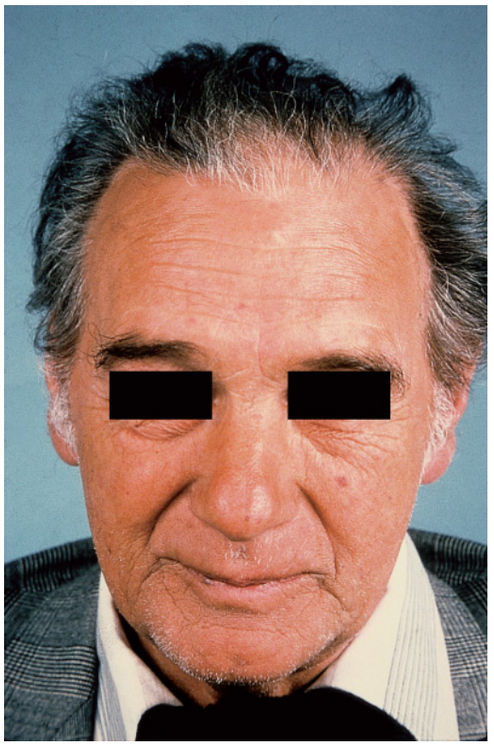

Fig. 66.82 Slight greying of hair. (Courtesy of Dr D. Fenton, St Thomas' Hospital, London, UK.)

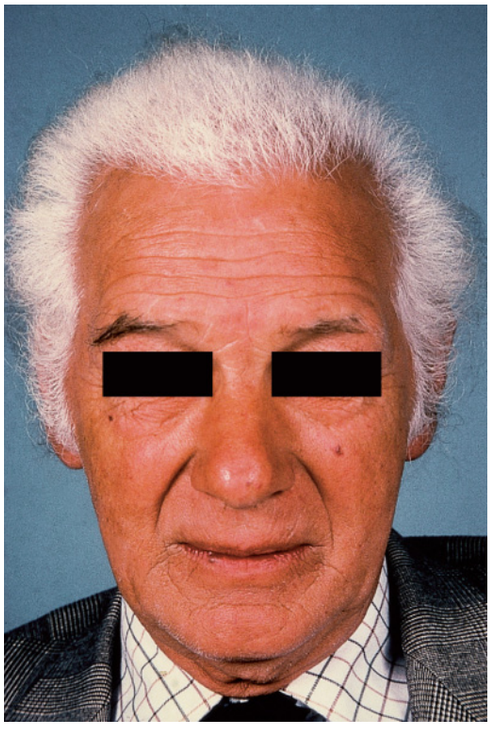

Fig. 66.83 Rapid greying of the hair. Same patient as Fig. 66.82 taken 1 week later. Caused by alopecia areata. (Courtesy of Dr D. Fenton, St Thomas' Hospital, London, UK.)

Fig. 66.84 Premature greying of hair, which commenced at 19 years of age in this individual.

loss of scalp hair as early as 2 years of age. In Book's syndrome, an autosomal dominant trait, premature greying is associated with premolar hypodontia and palmoplantar hyperhidrosis [21]. One-third of patients with chromosome 5p syndrome (cri du chat syndrome) have prematurely grey hair [22].

Poliosis

Poliosis is defined as the presence of a localized patch of white hair resulting from the absence or deficiency of melanin in a group of neighbouring follicles. Pigment absence can be congenital or acquired. In many cases of the former it is brought about by physically or functionally abnormal melanocytes from birth, or abnormal migration during embryogenesis. Such migratory defects may be restricted to the skin, but there can be associated abnormalities in other organs such as the ear or eye, where melanocytes or related neural crest cells have an important role.

Acquired forms of poliosis are due to vitiligo or to regrowth of non-pigmented hair following alopecia areata.

Hereditary defects [21]

Piebaldism (white spotting or partial albinism) is an autosomal dominant abnormality with patches of skin totally devoid of pigment, which remain unchanged throughout life. The borders of unpigmented areas are hyperpigmented. Heterochromia iridis occurs in some. Most commonly, a frontal white patch occurs—the white forelock—which may be the only sign. Melanocytes are decreased in number, but are morphologically abnormal and contain normal non-melanized premelanosomes, and also premelanosomes and melanosomes of abnormal appearance [23]. In most cases, piebaldism is caused by mutation in the *KIT* proto-oncogene [24] mapping to chromosome 4q12. In one kindred with a severe and progressive phenotype, the *KIT* mutation affected function of tyrosine kinase [25]. Piebaldism may also be due to deletions of the gene for the neural crest transcription factor *SNA12* [26].

Waardenburg's syndrome (WS) [27] is a heterogeneous condition, usually divided into four types, with absence of melanocytes from cochlear, skin, eye, hair and other structures. Features are present at birth. Type 1 WS is characterized by dystopia canthorum, with lateral displacement of the medial canthi, hypertrophy of the nasal root and hyperplasia of the inner third of the eyebrows with confluent brows [28]. Total or partial iridial heterochromia may occur, as may perceptive deafness. The white forelock is present in 20% of cases. Premature greying may develop with or without the white forelock [29]; a minority have piebaldism and congenital nerve deafness but no other overt signs of WS, suggesting that this association may be genetically distinct. Type 1 WS is caused by loss-of-function mutations in the *PAX3* gene which plays a part in control of neural crest cells during embryogenesis. Type 3 WS (Klein–Waardenburg syndrome, with abnormalities of the arms) is an extreme presentation of type 1, and affected individuals are usually homozygotes. Type 4 WS (Shah–Waardenburg syndrome with Hirschsprung's disease) can be caused by mutations in the genes for endothelin-3 or one of its receptors, EDNRB. Type 2 WS is a heterogeneous group, approximately 15% of whom are heterozygous for mutations in the *MITF* (microphthalmia-associated transcription factor) gene. All these forms show marked variability, even within families, and at present it is not possible to predict the severity, even when a mutation is detected. A mutation in *MITF* is also responsible for Tietz syndrome, in which complete deaf mutism and eyebrow hypoplasia are associated with generalized hypopigmentation rather than the localized pigment loss of WS [30].

Poliosis of scalp hair and eyelashes [31] occurs in tuberous sclerosis complex. Depigmented hair may be the earliest sign of the disease [32].

The pathognomonic signs of Von Recklinghausen's neurofibromatosis relate to hyperpigmented areas—café-au-lait macules and axillary and perineal freckling. Scalp hypopigmented patches must not be mistaken for vitiliginous changes.

Acquired defects [33]

In vitiligo, the white patches of skin may have white hairs within them. In alopecia areata, regrowing hair is frequently white. It may remain so, although in most cases hair pigmentation recovers.

The Vogt–Koyanagi–Harada syndrome [34,35] is a post-febrile condition comprising bilateral uveitis, labrynthine deafness, tinnitus and vitiligo, poliosis and alopecia areata [34,35]. It is likely to be an autoimmune disease, with the melanocyte, tyrosinase or tyrosinase-related protein as targets.

Alezzandrini's syndrome, which shows some similarity to Vogt–Koyanagi–Harada syndrome, combines unilateral facial vitiligo, retinitis, hypoacusis and poliosis of eyebrows and eyelashes [36].

Permanent loss of hair pigment may be induced by inflammatory processes that damage melanocytes (e.g. herpes zoster). X-irradiation often causes permanent hair loss, but less intense treatment leads to hypopigmented and, rarely, hyperpigmented hair.

Albinism [37,38]

The term albinism is applied to a group of genetic disorders characterized by generalized absence or reduced pigmentation in skin, hair and eyes. They are caused by mutations in genes involved in

Table 66.16 Clinical and genetic features of albinism.

	Cutaneous features	Associated abnormalities	Gene	Gene function
Oculocutaneous albinism Type 1 (OCA1)	Absence or near absence of skin and hair pigmentation	Photophobia, nystagmus, reduced visual acuity	Tyrosinase 11q14.3	Melanin synthesis
Oculocutaneous albinism Type 2 (OCA2)	Reduced pigmentation of skin and hair. Freckles and naevi may occur with age	Nystagmus, reduced visual acuity	*OCA2* (P gene) 16q24.3 15q11.2-12	Melanosome membrane protein
Oculocutaneous albinism Type 3 (OCA-3)	Minimal reduction in skin and hair pigmentation ('Rufous' albinism)	Mild ocular abnormalities	Tyrosinase-related protein-1 9p23	Melanin synthesis
Oculocutaneous albinism Type 4 (OCA-4)	Similar to OCA-2		Membrane-associated transporter protein 5p13.3	Unknown
Ocular albinism (OA)	None	Ocular depigmentation, nystagmus, reduced visual acuity	Xp22.3-22.2	Unknown
Hermansky–Pudlak syndrome	Variable absence of pigment in skin, hair and eyes	Variable ocular features Bleeding diathesis due to platelet dysfunction	*HPS* 8 genetically distinct variants	Trafficking from Golgi
Chediak–Higashi syndrome	Silver hair Large pigment granules in hair shafts	Ocular abnormalities Immunodeficiency Lymphoma	Lysosomal trafficking regulator gene 1q42.1-2	Translocation from Golgi
Griscelli syndrome	Silver hair Large pigment granules in hair shafts	Type 1 (MYO5A) Neurological abnormalities Type 2 (RAB27A) Immunodeficiency, haemophagocytosis	*MYO5A* 15q21 *RAB27A* 15q21	Translocation of melanosomes

the production and transport of melanin and may be accompanied by a variety of associated disorders. Apart from ocular albinism, which is X-linked, all are inherited in an autosomal recessive fashion. The clinical and genetic features are summarized in Table 66.16.

Colour changes induced by drugs and other chemicals

Some topical agents temporarily change hair colour. Dithranol and chrysarobin stain light-coloured or grey hair mahogany brown. Resorcin, formerly used a great deal in a variety of skin diseases, colours black or white hair yellow or yellowish-brown. The prostaglandin (PGF2α) analogues, such as latanoprost, used in the treatment of glaucoma, cause darkening of the iris and the eyelashes [39].

Some systemic drugs alter hair colour by interfering with the eumelanin or phaeomelanin pathway; in others, the mechanism is not known. Chloroquine interferes with phaeomelanin synthesis [40] and affects only blonde and red-haired individuals; the changes are completely reversible. Mephenesin, a glycerol ether muscle relaxant, causes pigmentary loss in dark-haired people [41]. The tyrosine kinase inhibitor imatinib, which inhibits the KIT and PDGF receptors, has diverse effects on pigmentation, causing both skin hypopigmentation [42] and reversal of hair greying [43].

Colour changes induced by nutritional deficiencies

Because specific dietary deficiencies are rare in humans, most clinical knowledge of their effects is derived from laboratory and animal studies. Copper deficiency in cattle causes achromotrichia because it is the prosthetic group of tyrosinase; loss of hair colour from this mechanism occurs in humans as Menkes' kinky hair syndrome. In protein malnutrition, exemplified by kwashiorkor, hair colour changes are a prominent feature; normal black hair becomes brown or reddish, and brown hair becomes blonde [44]. Intermittent protein malnutrition leads to the 'flag' sign of kwashiorkor (signe de la bandera). Alternating white (abnormal) and dark bands occur along individual hairs. Changes similar to those in kwashiorkor have been described in severe ulcerative colitis and after extensive bowel resection.

The lightening of hair colour from black to brown described in severe iron-deficiency anaemia may be an effect on keratinization rather than on melanocytic function [7].

Noppakun and Swasdikul [45] described a case of reversible white hair in vitamin B_{12} deficiency and commented on a variety of reversible and other hair colour changes in adult coeliac disease.

Hair colour in metabolic disorders

Phenylketonuria is an autosomal recessive disorder in which the tissues are unable to metabolize phenylalanine to tyrosine because of phenylalanine hydroxylase deficiency. Mental retardation, fits and decreased pigmentation of the skin, eyes and hair occur with eczema and dermographism. Black hair may become brown, and older institutionalized patients with phenylketonuria may have pale blonde or grey hair. Tyrosine treatment causes darkening towards normal colour within 1–2 months.

The pale hair colour seen in homocystinuria is probably caused by keratinization changes resulting from the error in methionine metabolism.

Light, almost white hair and recurrent oedema are manifestations of the hair condition 'oast house' disease. Methionine concentration in the blood is raised.

Darkening of grey hair has been reported in porphyria cutanea tarda [18].

Accidental hair discoloration

Hair avidly binds many inorganic elements and thus hair colour changes are occasionally seen after exposure to certain substances.

Exposure to high levels of copper in industry or inadvertently high concentrations in tap water [46] or in swimming pools may cause green hair, which is particularly visible in blonde-haired subjects [47,48]. A yellowish hair colour is not uncommon in white- or grey-haired heavy smokers, resulting from the tar in cigarette smoke; yellow staining may also occur from picric acid and dithranol. Trinitrotoluene (TNT) workers sometimes develop yellow skin and reddish-brown hair.

Hair cosmetics [1–3]

People have always been concerned about their hair, and have sought to modify it by grooming, colouring, cutting and wigs.

There are references in Egyptian papyruses to the importance of arranging the hair prior to seduction [4,5]. Now, hair care and hair cosmetics are big business and many of the advances have come from cosmetic science laboratories [6,7]. Some aspects of cosmetic management can lead to scalp and hair shaft problems.

Shampoos [1–6]

A shampoo may be defined as a suitable detergent for washing hair that leaves the hair in good condition. It must remove grease, as it is the latter that attracts dirt and other particulate matter. The polar group of a detergent achieves this by displacing oil from the hair surface. The evaluation of shampoo detergency is difficult and complicated. The consumer tends to equate detergency with foaming; in Western society, few shampoos sell unless they possess good foaming power. In the evaluation of detergents as shampoos no single criterion can be used, although instrumental methods have been devised. Efficacy can be based only on the subjective impression of the consumer.

Shampoo formulations

These vary enormously, but the basic ingredients can be resolved into a few groups: water, detergent and fatty material. Soap shampoos are made from vegetable or animal fats and remove dirt and grease as efficiently as detergents; however, a scum forms with hard water and most shampoos contain detergents as the principal washing ingredient. Detergents are synthetic petroleum products.

Shampoos contain:

1 Principal surfactants for detergency and foaming power
2 Secondary surfactants to improve and 'condition' hair
3 Functional additives to control pH and viscosity, or ingredients such as tar or antifungal agents
4 Preservatives
5 Aesthetic additives such as colorants and fragrance.

Shampoo safety

Shampoos must be non-toxic, and at concentrations used by the consumer not irritate either skin or eyes. New shampoo formulations are tested exhaustively prior to marketing, particularly to assess their propensity to cause eye irritation, scarring and corneal opacities. Skin irritation is not usually encountered from shampoos that have low eye irritancy potential. In general, the eye irritancy of detergents is greatest with cationics, followed by anionics, and least with non-anionics. There are exceptions to this, suggesting that shampoo irritancy may be caused by properties other than detergency, including surface activity, pH, wetting power, foaming power (Ross–Miles test), and wetting and foaming power together. Most shampoos are, in fact, irritant but not dangerously so. Allergic contact dermatitis resulting from biocides does occur (see Chapters 26 and 27).

Conditioners

Dry hair lacks gloss and lustre and is difficult to style. This results from natural weathering and is worsened by chemical and physical processes applied to the hair. Conditioners have a range of characteristics that may contribute to shine, reduction of static electricity, protection from ultraviolet radiation and possibly increased hair strength [7]. Conditioners comprise fatty acids and alcohols: natural triglycerides (e.g. almond, avocado, corn and olive oil); waxes (e.g. beeswax, jojoba oil, mink oil, lanolin); phospholipids (e.g. egg yolk and soya bean); vitamins A, B and E, protein hydrolysates of silk, collagen, keratin (horn and hoof), gelatine and other proteins; and cationic polymers. Conditioners are available in a variety of forms and are widely used. They provide lubrication and gloss, and render the hair easier to comb and style. The most commonly used are those combined with a shampoo as a 2-in-1 preparation. These cationic chemicals bind with the hair at the negatively charged surface and areas of weathering. In so doing they reduce static by electrically neutralizing the hair, and provide a physical coating to the areas of damaged hair shaft with materials such as dimethicone. Other forms of conditioner may be applied as a separate procedure, and can take the form of creams and emulsions applied for a few minutes after washing and then rinsed off. Deep conditioners are left on for up to 30 min, often with damp heat. Fluids, gels and aerosol foams aid styling. Hair oils are traditional conditioners. Men may use brilliantines, greases or oils to leave the hair glossy and sleek [3].

Where the hair is significantly dry or damaged, or the scalp is inflamed or eczematous, conditioner may be used as a shampoo substitute in the same manner that one might advocate an emollient as soap substitute on the skin of someone with eczema. The conditioner will mix with water to remove surface dirt and odour, but will not subject the hair and scalp to the powerful solvent effects of the shampoo.

Cosmetic hair colouring [1–4]

Since the days of the pharaohs, women in particular have used hair dyes to hide grey hair. Use has increased enormously during the past 50 years and now men are using hair dyes. Or perhaps they always did!

The penetration of dyes into hair depends on molecular size and the aqueous swelling of the hair at the time of application of the dye; basicity of the dye is also important. The most successful dyes are relatively small molecules.

Excluding bleaches, hair-colouring materials can be divided into three groups: vegetable, metallic and synthetic organic dyes. Synthetic organic materials are thought to give more 'natural' colours than those obtained with vegetable and metallic hair colorants.

Vegetable dyes

Henna may be used to give reddish auburn shades. It is obtained from shrubs found in North Africa and the Middle East: *Lawsonia alba*, *L. spinosa* and *L. inermis*. The dye is produced from dried leaves, which are removed before the plant flowers. The active principle is an acidic naphthoquinone (lawsone). Traditionally, it is applied as a thick paste 'pack', which is left *in situ* for 5–60 min. The effects last for up to 10 weeks. This process is non-toxic but messy, and fingernails may become stained. Henna rinses are mixtures of henna and powdered indigo leaves that produce blue-black shades. A wide range of products containing compound henna exist [5]. Ground flower heads of a Roman or German chamomile yield a yellow dye, 1,3,4,-trihydroxyflavone (apigenin). It stains only the cuticle and can be used to lighten or brighten hair. Other vegetable dyes include extracts from logwood and walnut shell, and these can be used by patients who are paraphenylenediamine sensitive. These products are obtainable at herbalists and beauty shops.

Metallic dyes

Traditionally, hair dyes for men have been of this type, as the colour changes occur less rapidly and are not as immediately obvious as with the oxidative dyes. Inorganic salts are used, which are altered by the hair and coat the surface as either oxides from reduction of the metal salts by keratin, or sulphides from the action of the sulphur in keratin on the metal. They all give a rather dull (metallic) appearance and may cause brittle or damaged hair if used too often.

Lead acetate, with precipitated sulphur or sodium thiosulphate, gives brown to black shades; grey hair may be changed through yellow to brown or black. Silver nitrate used alone produces a greenish-black colour; pyrogallol is used as developer. Colours from ash-blonde to black are possible by mixing silver nitrate variously with copper, cobalt or nickel; brownish-black skin staining is the great disadvantage. Bismuth salts give shades of brown. Newer metallic dyes, containing a metal plus an organic ligand, are used on textile fibres and in some hair-dye patents. Metallic dyes cannot be removed without hair damage, and should be left to grow out.

Synthetic organic dyes

This group has now been in use for more than 60 years. They are the most important type because of the comprehensive range of 'natural' colours that can be obtained. Most penetrate the hair cuticle so are potentially permanent, but in recent years less permanent types have been introduced.

Synthetic organic colorants are of three types:

1. *Temporary*. These wash out with one shampoo and last no longer than 1 week. Many temporary rinses belong to this group, including fashionable unnatural colours used by avant-garde sects and groups. They are available in aerosol sprays by incorporation into transparent polymeric plastics such as PVP; the disadvantage of such vehicles is their tendency to flake off on to clothing.
2. *Semipermanent*. In the UK, these have the widest appeal. They are used frequently at home and also in salons to brighten or subdue a natural colour, modify a permanent or bleached colour, or modify white or grey. They are of sufficiently small molecular size to penetrate the cortex. They are intrinsically coloured; no developing is required (see the oxidative permanent group). They are relatively easy to wash out with shampoos containing ammonia; other shampoos must be used 6–10 times to remove them. Some semipermanent dyes have an affinity for thioglycollate-waved hair. Many are now used in colour shampoos.
3. *Permanent* (developed or oxidation dyes). These do not rely on the natural colour of a single chemical dye-stuff (see semipermanents), but require an oxidative developer—hydrogen peroxide—to produce the final colour:

Paraphenylenediamine (PPD) and/or paratoluenediamine (PTD)
+
Hydrogen peroxide
↓
Applied to hair
↓
Quinone diamine (small molecule)
↓
Penetrate hair—to cortex
↓
Large molecules produced
(by diamine 'self' condensation and modifiers, e.g. pyrogallol)

Other substances may be included in specific formulations to give greater intensity to the dye (e.g. resorcinol and polyhidric phenols).

Oxidative dyes are potentially hazardous. The need for hydrogen peroxide enables lighter shades to be obtained and is chiefly responsible for the structural damage to hair that may occur if care is not exercised. Additives such as pyrogallol and resorcinol are potential irritants. The greatest problem is the potential of PPD (less so with PTD) to cause allergic dermatitis. Up to 10% of users may develop type IV allergy [6,7]. All dyes in this group are therefore sold with instructions to carry out preliminary patch testing 24–48 h before the proposed dye is used. Thus, the dye system is applied to skin either behind one ear or on the forearm—any redness, swelling or blistering implies allergy and the dyeing should not therefore proceed. A negative patch test does not mean that subsequent allergy cannot develop; it simply shows the subject is not allergic at the time the test is carried out. If allergy is shown, it is not sufficient merely to stop all future use of oxidative dyes; unfortunately, cross-sensitization also occurs with other aromatic benzenes (e.g. sulphonamides and some local anaesthetics), which must also be avoided for life. Modern formulations seem to cause less problems with allergy [8]. Hair dyes of this

group have been incriminated as possible carcinogens [9]. Chromosome breaks have occurred under experimental conditions [10] and an increased incidence of tumours [11] and aplastic anaemia [12] has been suggested and contested [13,14]. None of these reports is sufficiently conclusive to warrant the withdrawal of such dyes.

Permanent dyes last for several months; they must not be applied more frequently than every 2–3 weeks because hair damage will occur. Permanently dyed hair must therefore be allowed to grow out. However, if a light shade has been produced and the subject wishes a darker shade, then temporary rinses may safely be used as these only coat the hair surface and have no propensity to cause structural damage.

For less commonly used permanent dye formulations, such as 'highlights', the reader is referred to specialized texts [4].

Bleaches [15–17]

Bleaching is used both to lighten hair and to prepare it to take up hair dyes. Bleaching is an oxidative alkaline treatment that oxidizes and bleaches melanin. The hair lightens to reddish or yellow tones, depending on the underlying hair colour, and ultimately to platinum. Bleaching is very damaging to the hair, rendering it dry, porous and more prone to tangle. Overuse may cause disruption and fracture of the hair. Thus, it is advisable to perform permanent waving before bleaching. Home bleaching is usually performed with 6% hydrogen peroxide (20 volumes) with ammonia to speed the reaction, which otherwise takes 12 h. Salons use more powerful bleaching creams, powders and pastes, which are much faster. They are often applied to individual strands of hair, others being left untreated to give highlights, which lessens the problem of the darkened roots. Bleaching is terminated by shampooing or an acid rinse. The human eye perceives a more aesthetically acceptable blonde ('platinum' blonde) when the bleached hair is treated with a blue or lilac colorant.

Permanent waving [1–3]

Permanent waving is often referred to as 'a perm'. It has been defined as the process of changing the shape of the hair so that the new shape persists through several shampoos. During the last 70 years, increasing knowledge of keratin chemistry has enabled semipermanent chemical methods to be developed. Whatever the process used, three stages are involved in hair waving:

1 Physical or chemical softening of the hair
2 Reshaping
3 Hardening of fibres to retain the reshaped position.

Softening

Water can extend the hydrogen bonds between adjacent polypeptides in the keratin molecule, allowing temporary reshaping to be carried out—exposure to high humidity or rewetting immediately reverses the process. To obtain a more durable effect from water, steam may be used which, in a limited way, disrupts disulphide bonds. Heat and steam alone are rarely acceptable to modern women because their effects are temporary and the treatment is uncomfortable. Heat can be more effectively employed in conjunction with ammonium hydroxide and potassium bisulphite or triethanolamine as agents to reduce disulphide bonds; great skill is involved in this process as failure to judge the time of application of chemicals and heat may cause severe damage.

Since 1945, cold wave processes using substituted thiosulphates (thioglycolates) have largely superseded hot waving. Thioglycolates are potent reducers of disulphide bonds in the keratin molecule:

$$—S{=}S \rightarrow 2—SH$$

A typical cold waving lotion contains thioglycolic acid plus ammonia or monoethanolamine.

Acid permanent waves have recently become popular for salon use. They contain glyceryl monothioglycolate and produce a softer curl, and can be used on damaged and bleached hair. Their disadvantage is the high frequency of sensitization in the hairdressers using the product and, occasionally, sensitization of the client [4].

Reshaping

The type of rollers or curlers used to reshape the softened hair depends on the training of the hairdresser and the fashion desired. The degree of curl or tightness of the permanent wave depends both on the diameter of the roller and the size of the strand wound round the roller. Increasing the time of the exposure to the perming solution up to 20 min increases the curl, but longer times do not give a further increase. The strength of the solution used depends on the hair type, texture and previous bleaching. Home permanent waves are weaker and cannot achieve the same degree of curl. 'Tepid' waving involves using a weaker thioglycolate solu-

tion plus warm air. Neutralization is carried out initially with the curlers in place and again after they have been carefully removed. The reshaping stage is thus a great test of hairdressing skill and experience.

Hardening (neutralizing or setting)

In general, this process involves a reversal of the softening (reduction) stages:
oxidation

$$2\text{—SH} \rightarrow \text{—S=S—}$$

It is important to note that complete reversal to presoftened 'strength' cannot occur because many free SH groups may not be in a position for oxidation to be effective, for example:

$$2\text{—SH} \rightarrow \text{—S—C—S—} \quad (\text{C} = \text{carbon})$$

$$2\text{—SH} \rightarrow \text{—S—Ba—S—} \quad (\text{Ba} = \text{barium})$$

Atmospheric oxidation may efficiently neutralize the waving process. This method is slow and rollers must be left in position for several hours overnight. Chemical oxidation is now the rule. Hairdressers generally use hydrogen peroxide, whereas most solutions for home use contain sodium perborate or percarbonate (UK), or sodium or potassium bromate (USA). This is why hair is lighter after permanent waving. Some neutralizers contain shellac, which may react with alcohol groups to cause hair discoloration.

Practical procedures

Hot waving

This is almost never used. The procedure is:

1 Shampooing
2 Hair divided and rollers or curlers applied under slight tension
3 Waving solution applied
4 Heating.

Heating varies according to the solution used or the type of wave required. Electric rollers or exothermic reactive chemicals may be used. The latter allow free head movement during the waving. The skill of this procedure lies in good hair sectioning, judging the right amount of solution, correct winding tension and appropriate steaming time.

Cold waving

This also involves initial shampooing, hair division into locks, moistening with waving lotion and application of croquignole curlers. Further solution may then be applied. The softening time is 10–20 min. Occasionally, mild heat is included, using exothermic chemicals or the natural heat from the head by enclosing the scalp in a plastic bag. These may add to the comfort of the process. Rinsing then takes place, followed by neutralization with the oxidizing solution for up to 10 min. After removing the curlers, further 'hardening' solution is usually applied. 'Loose' curl waves last for no more than a few weeks but 'tight' curl styles may persist for 4–12 months.

Hair straightening (relaxing) [1,2]

In principle, the methods used to straighten hair are similar to those used in permanent waving. The practice is almost exclusively used to straighten negroid hair and is also called relaxing. One survey found that relaxing formulations were used in 45% of black American women [3]. These practices are associated with a range of problems and ultimately may contribute to scarring alopecia [4].

Pomades

These are mostly used by men with relatively short hair. They are greasy and act by 'plastering' hair into position.

Hot-comb methods

Shampooing is carried out and the hair is towelled dry; oil is then applied (e.g. petroleum jelly or liquid paraffin), which acts as a heat-transferring agent. Heat pressing with hot combing is then used (148–260°F), causing breakage and reforming of disulphide bonds, allowing the hair to be moulded straight. Structural damage (and breakage) of hair is common with this process and scarring alopecia may occur as a result of hot waxes entering the follicles. Sweating and rain reverse this procedure.

Cold methods

The chemical methods employed use alkaline reducing agents (caustics), thioglycolates, ammonium carbonate or sodium bisulphite. Caustic soda preparations are usually creams and require the application of protective scalp oil or wax. They are combed through the hair and left for 15–20 min; the hair is combed and straightened again, then rinsed and neutralized. These preparations are limited to salon use because of their potential to cause irritant dermatitis and damage to the hair. Thioglycolate creams are the most common agents used; the cream is applied liberally to the hair, which is then combed until it is straight. The cream is then washed off and a neutralizer (oxidizing agent) applied. Other straighteners ('relaxers') do not contain thioglycolates (e.g. sodium bisulphite and ammonium carbonate, acidic ethylene glycol or 1,3-propylene glycol). Bisulphite straighteners are suitable for home use in combination with alkaline stabilizers.

Hair setting [1]

Setting lotions have changed considerably in recent years. The traditional semiliquid gels based on water-soluble gums (e.g. tragacanth, karaya and acasia) have been replaced by various synthetic polymers in a bewildering array of forms—aerosol foams and sprays, liquids and gels. Most are based on PVP in a gelled aqueous solution and give an attractive glossy, non-greasy appearance [2]. Some preparations incorporate other ingredients to condition or to add antistatic action, lustre or sheen.

Setting lotion and spray formulations are considered safe, after early reports of foreign body granulomatous inflammation [3,4] had been questioned and not supported by further cases. Hair sprays were incriminated as a possible cause of peripilar casts [5], but this was not confirmed by later work [6].

Methylolated compounds

Many cosmetic preparations, by their action on the keratin molecule, irreversibly weaken the hair. The cosmetic scientist has produced chemicals that attempt to combat this problem. The formulations contain methylolated compounds of varying strength depending on the type of hair under treatment and the solubility of the compound. Most preparations containing alkylated methylol compounds have greater stability and release very little formaldehyde [1].

Complications

Hair loss is often attributed to cosmetics, with relatively little evidence in support [1]. Matting of scalp hair is most commonly a sudden, usually irreversible, tangling of scalp hair resulting from shampooing of weathered hair [2]. Excessive bleaching, permanent waving and straightening procedures may induce excessive weathering and fragility of hair as well as irritant and allergic reactions of the scalp. Hairdressers suffer a high rate of occupational reactions to the agents used in hair care [3].

Complications from the use of synthetic hair fibre implantation for male pattern balding can be severe [4].

Introduction

This chapter is not intended to be a comprehensive account of all diseases that affect the skin and eyes, for which there are several reviews [1–7]. The main focus is on those conditions that commonly occur in clinical practice and that present a problem with management. It is also intended to alert the dermatologist to conditions that might threaten visual acuity and require urgent referral to an ophthalmologist. Also, many systemic diseases affect both the skin and eyes, and ophthalmic assessment will be of help in making the correct diagnosis and in long-term management of such patients.

Anatomy and physiology of the eye [1,2]

The eye and skin share a common embryological origin. The structure of the lid, conjunctiva, the lacrimal gland and associated drainage apparatus are of surface ectodermal origin while the remainder of the eye arises from epithelium of the ectodermal neural plate. The only mesodermal contribution to the eye is the myoblasts of the extraocular muscles. The anatomy of the eye is shown in Fig. 67.1. The eye appendages are as follows.

The eyebrows

This hair-bearing area rests on a very mobile fat and muscle pad overlying the superior orbital ridge. Its mobility is important as a means of facial expression. The eyebrows help protect the eye from bright light and sweat.

The eyelids

The eyelids have distinct anatomical layers, comprising the skin with subcutaneous tissue, the tarsal plate and conjunctiva, and striated muscles that effect lid movement (Fig. 67.2).

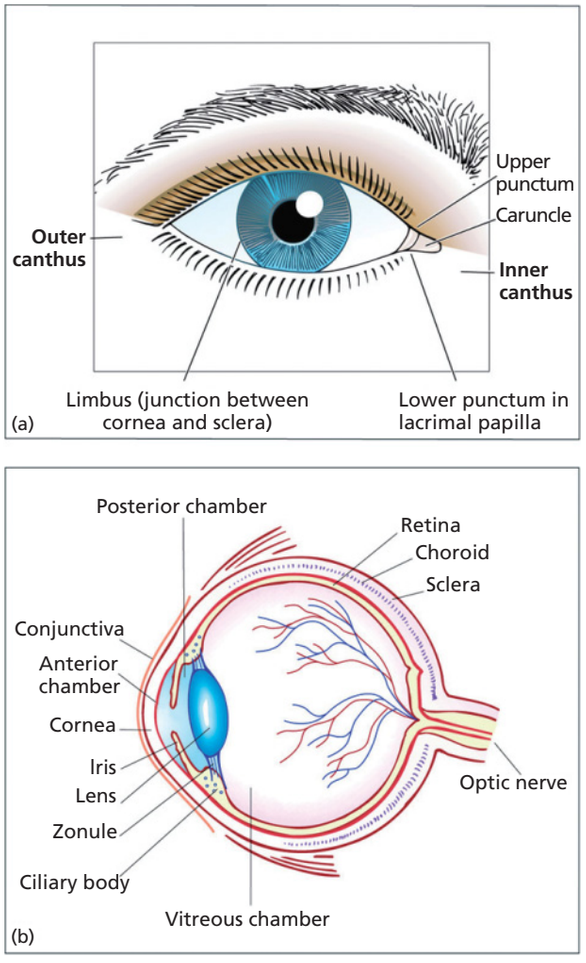

Fig. 67.1 Anatomy of normal eye. (a) The external appearance of the right eye. (b) Cross-section of the human eye.

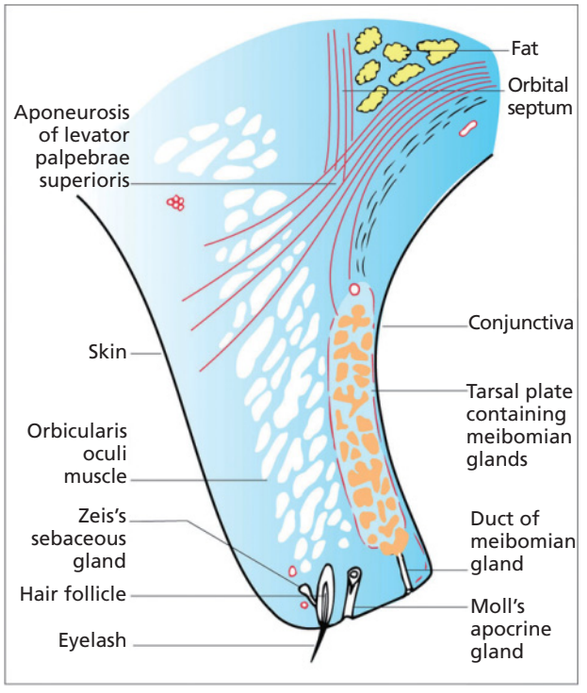

Fig. 67.2 Cross-section of upper eyelid.

The skin is thin and modified in several ways to protect the eyeball. It contains sebaceous glands associated with the fine hairs of the eyelashes (cilia) and both apocrine and eccrine sweat glands. There are about 300 eyelashes, arising in two rows along the eyelid margin, two-thirds of which are in the upper lid. They have no associated erector muscles, but rudimentary sebaceous glands (of Zeis) are present. Some lashes, particularly those of the lower lid, are associated with ancillary apocrine sweat glands (of Moll). The ducts of these glands open both into the lash follicles and directly onto the anterior lid margin between the lashes. The eyelashes help to protect foreign bodies from impinging on the eyeball. Each lash follicle has a rich nerve plexus, which is easily excited—light touch initiates reflex closure.

The tarsal plate of each eyelid gives the palpebral aperture shape and stability. They comprise dense, fibrous tissue surrounding modified sebaceous glands (meibomian glands). These secrete the outer lipid layer of the precorneal tear film through openings along the mucocutaneous junction of the eyelid margin. This lipid helps to stabilize the tear film and reduce evaporation. There are about 30 glands in the upper tarsal plate and 20 in the lower. Meibomian glands have up to 20 acini surrounding a central vertical duct and are visible through the conjunctiva.

The eyelids are lined by a mucous membrane called the palpebral conjunctiva. It is reflected over the anterior portion of the eyeball up to the edge of the cornea as the bulbar conjunctiva. The folds formed by the reflection of the conjunctiva from the lids onto the eyeball are called the superior and inferior palpebral fornices. The conjunctiva contains numerous goblet cells secreting mucin into the tear film. It also contains about 50 accessory lacrimal glands and its substantia propria contains neural tissue, mast cells, lymphocytes and lymphoid follicles, which are important in mediating local immunological reactions.

The striated muscle of the levator palpebrae superioris opens the eye, and the striated orbicularis oculi muscle closes it. Both are innervated by the facial nerve. Two divisions of the trigeminal nerve supply sensation to the eyelids; the upper lid and medial canthus are supplied by the ophthalmic division, and the remainder of the lower lid by the maxillary division.

The eyelid has a rich blood supply, mainly through the medial and lateral palpebral arteries, which are branches of the ophthalmic artery. There is also a rich anastomosis between adjacent arteries arising from the internal and external carotid. The blood drains through a network of veins to the facial and orbital veins and the cavernous sinus. Lymphatics drain the conjunctiva and tarsal plate to the post-tarsal plexus and the skin and orbicularis to the pre-tarsal plexus. The medial canthus and lower lid subsequently drain to the submandibular nodes whilst the lateral canthus and upper lid drain to the parotid and preauricular nodes.

The lacrimal glands

The main lacrimal gland is a modified sweat gland located in the lacrimal fossa, a bony depression just under the upper and outer

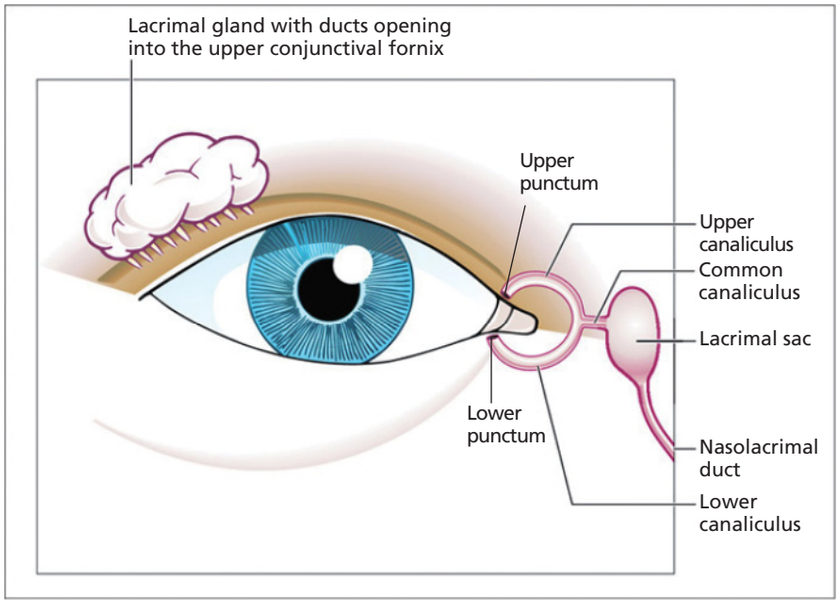

Fig. 67.3 The lacrimal apparatus of the right eye.

margin of the orbit. It produces an aqueous secretion, which discharges through a network of ductules onto the conjunctiva of the palpebral conjunctiva. In addition, there are a variable number of accessory lacrimal glands in the upper and lower conjunctival fornices. The lacrimal gland is innervated whereas the accessory glands are not.

The precorneal tear film

The eyelids make a vital contribution to the composition and stability of the precorneal tear film, which is about 40 µm thick. It is a three-layered structure consisting of a lower hydrophilic mucin layer secreted by goblet cells of the conjunctiva, a central aqueous layer secreted by the lacrimal gland, and a surface hydrophobic lipid layer secreted by the meibomian glands (as discussed above). Blinking consists of a lateral to medial movement of the eyelids, which enables resurfacing of the tear film of the cornea and propels the tears to the punctum of the tear duct; from here, they are actively removed by the lacrimal pump mechanism through the lacrimal canaliculi into the common canaliculus and lacrimal sac, and then via the nasolacrimal duct into the nose (Fig. 67.3).

The tear film has a number of functions:

1 To supply oxygen and other nutrients to the cornea
2 To remove particulate matter from the surface of the eye
3 To prevent drying of the eye
4 To act as a lubricant and prevent adhesion of the palpebral to the bulbar conjunctiva
5 To protect the eye surface through its antibacterial role; it contains white blood cells, various proteins, lysozyme and immunoglobulins.

Glossary of ophthalmological terms

A glossary is provided in Table 67.1.

Disorders affecting the eyebrows and eyelashes

There is a wide variation in the colour, distribution and density of the eyebrow hairs. The inheritance of the appearance of the eyebrows is polygenic. Some hereditary variations are of no known significance, but others are associated with other development defects or are part of a recognized syndrome.

Disorders of the eyebrows [1]

Synophrys

This term is applied when the eyebrows are profuse with a tendency to meet in the centre of the face. Synophrys is a feature of some genodermatoses (Chapter 15). The eyebrows also tend to become more bushy in the ageing male for reasons that are unknown. Bushy eyebrows may also occur in other acquired forms of hypertrichosis, for example due to drugs such as diazoxide, and fusion of the eyebrows has been reported in kwashiorkor.

Hypoplasia of eyebrows

Some inherited diseases are characterized by hypoplasia of the eyebrows (Chapter 15). Acquired conditions can cause sparsity or sometimes complete loss of the eyebrows. They may be the only site affected in alopecia areata. Thinning of the eyebrows occurs in hypothyroidism, erythroderma, follicular mucinosis and secondary syphilis. Lepromatous leprosy causes thinning of the outer third of the eyebrows in the early stages, often with depigmentation, progressing to total loss of the brows and lashes. Tuberculoid

Table 67.1 Glossary of ophthalmological terms.

Anophthalmia	Absence of eye
Astichiasis	Absence of lashes
Blepharitis	Inflammation of the eyelid margin
Blepharochalasis	Elastic tissue atrophy causing loose eyelid skin
Bruch's membrane	The retinal layer sandwiched between the retinal pigment epithelium and the vascular choroid
Coloboma	Congenital cleft created by failure of development of a portion of the eye or adnexal structures
Dermatochalasis	Laxness of the skin of the eyelids
Distichiasis	Accessory row of eyelashes
Ectropion	Eversion of the eyelid
Entropion	Inversion of the eyelid
Epicanthal fold	Accessory fold of skin at the inner canthal region of the eye
Epicanthus inversus	Lower lid fold larger than upper lid fold
Epiphora	Excess tearing
Episcleritis	Inflammation of the superficial scleral tissues
Hypertelorism	Increased distance between the two eyes measured radiologically
Hypopyon	The presence of pus in the anterior chamber
Keratitis	Inflammation of the cornea—various types are recognized, including: *filamentary keratitis*—the development of epithelialized mucous filaments on the corneal surface; *interstitial keratitis*—inflammation of the corneal stromal layer
Keratoconjunctivitis sicca	Corneal and conjunctival inflammation associated with impaired tear secretion and ocular dryness
Keratoconus	Conical distortion of the central cornea as a result of a degenerative process in the stroma
Keratopathy	Corneal abnormalities including: *exposure keratopathy*—from corneal exposure and drying of the cornea
Lagophthalmos	Persistent exposure of the eyeball despite closure of the eyelid
Limbus	Boundary between the cornea and sclera
Madarosis	Loss of the eyelashes
Pannus	Vascularized corneal scar
Phlyctenule	Wedge-shaped, peripheral corneal or conjunctival, nodule
Preseptal cellulitis	Cellulitis of the eyelids that has not penetrated through the orbital septum to involve the orbit
Symblepharon	Adhesions between the bulbar and palpebral conjunctiva resulting in complete or partial obliteration of the eyelid fornices
Telecanthus	Increased distance between the inner canthi
Trichiasis	Lashes that turn inward toward the cornea usually as a result of entropion
Uveitis	Inflammation of the uveal tract. It is subdivided into anterior uveitis, which is the most common, intermediate uveitis, posterior uveitis and pan uveitis. *Anterior uveitis* is subdivided into iritis, in which the inflammation predominantly affects the iris, and iridocyclitis, in which both the iris and the anterior part of the ciliary body (pars plicata) are equally involved. *Intermediate uveitis* involves the posterior part of the ciliary body (pars plana) and the extreme periphery of the choroid and retina. *Posterior uveitis* is inflammation located behind the vitreous base. *Pan uveitis* is involvement of the entire uveal tract.

leprosy, by contrast, does not cause loss of the eyebrows. Plucking the eyebrows for cosmetic reasons is common, but true trichotillomania of the eyebrows is unusual.

Inflammatory disorders affecting the eyebrows

The eyebrows are often involved in seborrhoeic dermatitis and psoriasis. Post-inflammatory cicatricial alopecia from discoid lupus erythematosus, folliculitis decalvans, lupus vulgaris or tertiary syphilis may cause loss of eyebrow hairs. Scarring with loss of eyebrows may also follow chemical and thermal burns or radiation. Loss of eyebrows can be camouflaged by the use of eyebrow pencils, permanent tattooing or by a hair prosthesis glued in place daily.

Disorders of the eyelashes

Trichomegaly [2–5]

This may be due to a genetic trait. Increased growth of the eyelashes has also been described in human immunodeficiency virus (HIV) infection and related to various drugs including ciclosporin, zidovudine, interferon and topical xalatan. Long lashes also occur in some patients with phenylketonuria.

Madarosis [1]

Madarosis is a decrease in the number or complete loss of lashes. A number of causes have been recognized and include alopecia areata, chronic anterior lid margin blepharitis, infiltrating tumours of the lid, burns, cryotherapy and radiotherapy, trichotillomania and discoid lupus erythematosus. Systemic diseases such as hypothyroidism and syphilis may also be responsible.

Abnormality of the eyelids

These include dermatochalasis, blepharochalasis and lid laxity. Numerous developmental defects can affect the palpabral fissure or size and shape of the eyelids. A number of hereditary dermatoses affect the eyelids (Chapter 15).

Ptosis

Drooping of the eyelids on one or both sides is a common genetic defect. Mild ptosis commonly develops in the elderly due to the laxity of the connective tissue. There are many important acquired causes, such as third nerve palsy, Horner's syndrome and myasthenia gravis, which require neurological referral. Ptosis may be associated with other ocular abnormalities.

Skin diseases affecting the eyelids

A large number of dermatological conditions can affect the eyelids as part of a generalized process. Usually there is little diagnostic difficulty as the diagnosis is made by examination of the rest of the skin. Psoriasis and lichen planus can both involve the lids and cause considerable irritation. These are chronic diseases and management can become a problem with use of potent topical corticosteroids on the eyelids over a prolonged period of time. Use of the new topical immunosuppressants, such as tacrolimus and pimecrolimus, may offer some promise for the future in reducing topical corticosteroid exposure. Unilateral involvement of an eyelid raises the possibility of infective conditions, including tinea and mycobacterial infections.

Psoriasis [1]

Eyelid involvement can occur in about 10% of patients with psoriasis. Men are more susceptible to ocular disease. Involvement of the eyelid gives rise to blepharitis, madarosis and development of psoriatic plaques. Chronic non-specific conjunctivitis may occur over time and lead eventually to keratoconjunctivitis sicca with symblepharon formation and trichiasis. Conjunctivitis usually complicates eyelid margin involvement; white or yellow psoriatic plaques can spread from the lid on to the conjunctiva itself. Corneal changes are rare and are most commonly related to exposure and trichiasis. Anterior uveitis is rare but has been reported in patients with psoriatic arthritis and is similar to that seen in Reiter's syndrome. Ocular psoriasis is treated with use of lubricants and topical corticosteroids. Patients with chronic eyelid involvement should be referred for ophthalmological assessment.

Contact dermatitis [2–8]

Contact dermatitis is the responsible cause in approximately half of patients with an eyelid dermatitis. The remainder have manifestations of atopic or seborrhoeic dermatitis. The eyelid skin is very sensitive to primary irritants. These can cause a dermatitis in their own right or can aggravate an underlying constitutional tendency in patients with either atopic or seborrhoeic dermatitis.

Allergic contact dermatitis can present after many years of exposure to the culpable allergen. Clinically it is characterized by severe itching, erythema and swelling of the eyelid, progressing to formation of vesicles. A large variety of allergens have been reported as causing an allergic contact dermatitis of the lid and include preservatives (used in cosmetics, topical medications and contact lens cleaning solutions), fragrances and the resin used in nail polish. Patients with suspected contact dermatitis of the eyelids should be patch tested. Careful history taking is of paramount importance to make sure the relevant allergens are included in the test battery. The possibility of transferring antigen from the hands to the eyelids needs to be considered. Maibach described the upper eyelid dermatosis syndrome in which patients have discomfort of the eyelids with or without dermatitis; it is thought to be unrelated to use of cosmetics.

Periorbital oedema [9,10]

The subcutaneous tissue of the eyelids is lax and prone to oedema. There are many systemic and dermatological causes of eyelid oedema that need to be considered. Systemic causes include angio-oedema, glomerulonephritis, hypoalbuminaemia (especially nephrotic syndrome), cardiac failure, superior venocaval obstruction and thyroid disease. Some systemic infections, such as infectious mononucleosis and scarlatina, cause periorbital oedema. It may be the presenting feature of dermatomyositis and has been reported in systemic lupus erythematosus.

The most common dermatological causes of periorbital oedema are angio-oedema, lymphoedema, allergic contact dermatitis and blepharochalasis; they are usually distinguished by the history. Angio-oedema is transient and often part of a more generalized urticarial eruption. Lymphoedema is permanent and tends to be worse first thing in the morning and improves during the day; it may be associated with underlying sinus disease or a chronic inflammatory condition such as granulomatous rosacea. Allergic contact dermatitis presents acutely with swelling, redness and itching. Blepharochalasis is an uncommon condition which may be inherited (autosomal dominant) or sporadic; it presents in the second decade with recurrent episodes of painless lid oedema, resulting in the development of excess skin and thickened subcutaneous tissue which may require treatment by blepharoplasty. Senile orbital fat prolapse through a deficient orbital septum may mimic periorbital oedema but is differentiated by the fact that there is minimal fluctuation in the associated swelling. Periorbital oedema may be the presenting feature of rosacea.

Changes in pigmentation [11–15]

There are considerable racial and familial variations of the degree of pigmentation of the eyelids (Chapter 58). Marked periorbital melanosis is seen as a genetic trait. Pigmentation of the periorbital skin can also be post-traumatic, post-inflammatory or can accompany melanocyte-stimulating hormone-induced melanosis of any cause. Chemical pigmentation can occur from prolonged use of a mercurial or silver preparation, producing a slate-blue or grey-brown discoloration. Mauve discoloration of the eyelids and periorbital area is an early part of chrysiasis from parenteral gold therapy. A grey discoloration can complicate long-term treatment with minocycline. Local increase in pigmentation may also be due to cosmetics containing phototoxic agents, usually psoralens. Increased pigmentation can also follow inflammatory dermatoses such as eczema and lichen planus. The eyelids may be involved in vitiligo. Hypopigmentation can complicate the use of topical medications including thiotepa eye drops and mercurial ointments.

Chronic blepharitis, rosacea and seborrhoeic dermatitis [1–4]

Description

Chronic blepharitis is a term that is used to describe a group of disorders in which the lid margin is always involved. These disorders often occur simultaneously. Not all of them result in inflammation of the lid margin. They are frequently associated with a conjunctivitis or keratoconjunctivitis. Chronic blepharitis may occur in the absence of any significant dermatological association, and its classification is further complicated both by the variable association of chronic blepharitis with rosacea and seborrhoeic dermatitis, and also by the term ocular rosacea, a condition which may occur in the absence of dermatological rosacea.

It is hardly surprising that this classification causes confusion amongst practitioners. This situation has arisen partly because there is no consensus about the terminology (although most modern authors use similar classifications based on McCulley's modification of Thygeson's classification) and, more probably, because the pathogenesis is very poorly understood, with few unifying concepts.

Table 67.2 summarizes a current classification, associations and features. It includes ocular rosacea amongst the meibomian gland disorders, with which it is always associated. Table 67.2 classifies the five types of blepharitis (including ocular rosacea) into those that principally affect the anterior lid margin structures (cutaneous margin with lash-bearing skin and associated glands) and those affecting the posterior lid margin (mucocutaneous junction, meibomian orifices). This classification corresponds with, and simplifies understanding of, the treatment of the different conditions, which differs between the anterior- and posterior-lid margin disorders but not between the individual conditions within each of these two groups. The commoner clinical signs of staphylococcal blepharitis are shown in Fig. 67.4. Ocular rosacea (Table 67.3, Fig. 67.5) is an important condition because of its severity and wide spectrum of clinical features.

In addition to these very common types of blepharitis, there are other chronic causes in which the pathogenesis is clear. These are all uncommon and are often misdiagnosed as one of the types of chronic blepharitis described in Table 67.2. They include fungal infection (e.g. *Candida*), parasitic infection (e.g. phthiriasis), protozoal infection (e.g. leishmaniasis), some neoplasms, and autoimmune conditions such as lupus erythematosus; some of these are illustrated in Fig. 67.6. They should be considered when therapy for conventional blepharitis fails.

Acute blepharitis is a clearly defined group of conditions, for which the causes are summarized in Table 67.4.

Epidemiology

The epidemiology has been dogged by difficulties of disease definition and the different perspectives of dermatologists and ophthalmologists. Chronic blepharitis is one of the commonest disorders in both ophthalmic and general medical practice. In general medical practice it makes up about 70% of ophthalmic referrals, which themselves account for between 2 and 7% of all outpatient consultations. Meibomian gland dysfunction is probably the commonest type of blepharitis and affects 20–40% of all patients consulting ophthalmologists for routine eye examinations. Between 3 and 58% of patients with rosacea have ocular involvement; this wide variation in cited frequency largely reflecting differences in disease definition. Approximately half of patients with rosacea have signs of ocular rosacea, whilst one-quarter of patients with ocular rosacea have no dermatological disease.

Immunopathogenesis [5]

There is some evidence to support hypotheses of pathogenesis in staphylococcal blepharitis and in meibomian dysfunction, but the pathogenesis is even more poorly understood in the other types of chronic blepharitis.

Staphylococcal blepharitis

In staphylococcal blepharitis [6–13] there is an association with *Staphylococcus aureus* and *S. epidermidis* colonization of the lid margins, although colonization by *S. aureus* is often transient and the numbers of either organism are often no greater than in normal controls. Although folliculitis, styes and lid margin ulcers may be due to infection by *S. aureus*, the persistence of lid inflammation after treatment and the sterile marginal ulcers are not explained by infection alone. The importance of cell-mediated immunity in the pathogenesis of the disease was shown by experimental studies in rabbits; when these were immunized with either whole *S. aureus* or with cell wall ribitol–teichoic acid, both ulcerative keratitis, phlyctenules and marginal corneal ulcers developed after second-

Table 67.2 Classification of types of chronic blepharitis (lid margin disorders).

Anterior lid margin*		**Posterior lid margin***

ary challenge, providing evidence for the hypothesis that these changes were due to the development of hypersensitivity to both viable and killed organisms. These findings could not be reproduced for *S. epidermidis*. However, evidence for a similar pathogenesis in humans is lacking; the relationship between the clinical signs of staphylococcal blepharitis and hypersensitivity to subcutaneous injections of either whole *S. aureus* or of *S. aureus* cell wall protein A is poor. *Staphylococcus epidermidis* is more often isolated than *S. aureus* from the lids of patients with staphylococcal blepharitis, but the role of a hypersensitivity response is assumed and not supported by any firm data. The pathogenesis of the, often severe, follicular and papillary conjunctivitis that accompanies this condition is assumed to be due to a combination of transient infection and hypersensitivity.

Meibomian gland disease (MGD) [14–16]

The meibomian lipids (meibum) are a complex mixture of cholesterol esters and esterified unsaturated fatty acids. These lipids are responsible for maintaining a stable tear film, reducing tear film evaporation (and, therefore, preventing drying of the ocular surface), preventing tear spill over the lid margins by lowering surface tension and reducing ocular surface contamination by sebum from the cutaneous surface of the lids, which otherwise forms dry spots.

Three factors have been invoked as contributing to MGD: (i) keratinization of the meibomian ductules; (ii) the effect of bacterial lipases on the meibum at the lid margin; and (iii) primary abnormalities in the production of meibum by individuals with MGD.

Normal meibomian gland ducts open just anterior to the mucocutaneous junction. As the duct lining is partially keratinized, abnormalities of keratinization, analogous to those present in the sebaceous glands of patients with rosacea, may be important in the pathogenesis of MGD by altering gland function. Bacterial lipases are produced by all the bacteria that colonize the lid margin and have the potential to break down meibum into free fatty acids, which will destabilize the tear film. These bacteria colonize the gland orifices and expression of lipid from deeper within the glands can stabilize the tear film. Meibomian lipids differ between individuals and, as analytical methods increase in sensitivity, the relative roles of primary abnormalities of meibum and those secondary to the effects of bacterial lipases in the pathogenesis of MGD are likely to become clearer.

Neither the pathogenesis of the conjunctival inflammation that is common in meibomitis (and which is a feature of ocular rosacea), nor that of the keratitis in ocular rosacea, has been explained.

Treatment [17–25]

The treatment of blepharitis is that of the underlying cause, if a specific cause can be identified. Treatment for the principal causes of chronic blepharitis is outlined in Table 67.5. The blepharitis should initially be classified into either anterior or posterior lid disease or both (Table 67.2). It is important to decide whether blepharitis is the cause of the symptoms; seborrhoea rarely causes symptoms and should not be used as a scapegoat to explain away symptoms possibly due to other, or undiagnosable, conditions. Other conditions that give rise to similar symptoms and signs (Table 67.2) should be excluded or treated. Symptoms of dry eye, and associated skin disorders, should also be treated.

Diffuse folliculitis is generally caused by *S. aureus* and requires a course of an appropriate systemic antibiotic. Laboratory investigations are of limited value—bacteriology samples can be taken from lid margins using swabs dipped in trypsin digest broth, but are usually only performed for recurrent disease that has not responded to initial therapy.

Chalazion will resolve in time; approximately 60% of lesions will resolve in 6 months and the remainder will resolve spontaneously, given longer. Resolution of chalazia can be hastened by incision and curettage; the lid is incised, usually from the conjunctival surface, under local anaesthesia, and the necrotic granulomatous tissue in the centre of the lesion removed with a curette. This leaves a linear conjunctival and tarsal scar. It is only recommended for cosmetic reasons or to improve vision in large lesions affecting the upper lid, which can cause temporary astigmatism.

Practice points for dermatologists are that the association between blepharitis and skin disease is variable, that treatment with tetracyclines may be beneficial for both the ocular and dermatological manifestations of these disorders, and that ocular rosacea and staphylococcal blepharitis may produce sight-threatening complications.

Table 67.5 Treatment of chronic blepharitis.

Aims of treatment	Therapeutic guidelines
For anterior lid margin disease (ALMD)	
Treat infection	Staphylococcal and mixed staphylococcal/seborrhoeic groups Topical antibiotics—chloramphenicol or fucidic acid—4 times daily to lid margins Oral oxytetracycline or erythromycin 500 mg twice daily for 10 days
Clean lid margins	'Lid scrubs': 1–2 times daily with cotton wool bud dampened in boiled water or with proprietary lid cleaning pads, to remove debris
Lid hyperaemia and exudate	Topical chloramphenicol and hydrocortisone 0.5–1.0% to lid margins 2–4 times daily for 1 month
For posterior lid margin disease (PLMD)	
Mechanically unblock meibomian glands	Apply hot compresses for 3–5 min to liquefy meibomian secretions, followed by massage* of tarsal plate with cotton wool bud (or finger), to express lipid from glands, 1–2 times daily
Alter meibomian secretions	Oral tetracycline (e.g. doxycycline 100 mg once daily) or erythromycin 250–500 mg twice daily for 12 weeks minimum
For the tear film	
Restore tear film	Artificial tears—drops 2–4 hourly, or Viscotears 3–4 times daily
For associated conjunctivitis (papillary or mixed follicular and papillary)	
Reduce inflammation	Fluoromethalone 0.1% four times daily for 1 week, progressively reducing to one time daily over a further 4 weeks
Treat associated skin disease	Seborrhoea—medicated soap and shampoo (ideally containing glycolic acid 10–15%) Rosacea—oral oxytetracycline (or doxycycline 100 mg) or erythromycin 250–500 mg twice daily for 12 weeks
For keratitis	
Coarse punctate keratitis and/or marginal keratoconjunctivitis	Fluoromethalone 0.1% four times daily for 1 week, progressively reducing to once daily over a further four weeks†
Corneal thinning and perforation	Exclude and treat any concomitant microbial keratitis and establish disease control by methods summarized above, apply tissue glue to perforations. Carry out tectonic keratoplasty, if necessary, once the inflammation is controlled.

* Lid scrubs, lid massage and low-dose systemic antibiotics take about 4–6 weeks to start to work. DO NOT assume treatment has failed until at least 8 weeks on treatment has elapsed, and continue the regime for a minimum of 2–3 months if benefit is shown. Then advise a maintenance regime of lid scrubs (for ALMD), hot compresses and tarsal massage (for PLMD), ± artificial tears. In the case of relapse, repeat a 3-month course of oral antibiotic treatment.

† More prolonged courses of corticosteroid or more potent corticosteroids may be needed under specialist ophthalmological supervision. Topical ciclosporin has recently been shown to be effective for controlling inflammation in posterior blepharitis in one randomized trial and another case series [24,25]. The author's experience with topical ciclosporin in ocular rosacea has been promising.

Atopy and atopic eye disease

Description and epidemiology [1–5]

This group of disorders, usually known as the allergic eye diseases, is better termed the atopic eye diseases to distinguish them from disorders that result from other hypersensitivity mechanisms. The atopic eye diseases comprise a group of disorders that have in common a papillary conjunctivitis and evidence of a type 1 allergic mechanism; the immunopathogenesis has recently been shown to be more complex than this. All of these diseases are uncommon, and only a small proportion of patients with atopic dermatitis have ocular disease. Table 67.6 summarizes these disorders and Fig. 67.7 shows the commoner clinical signs.

Of these disorders only atopic keratoconjunctivitis (AKC) (Fig. 67.7b,g), atopic blepharoconjunctivitis (ABC) and vernal keratoconjunctivitis (VKC) (Fig. 67.7c,d) are of interest to the dermatolo-

Table 67.6 Clinical characteristics and distinguishing features and diagnosis of the atopic eye diseases.

Disease	Disease course	Conjunctival signs	Corneal signs	Disease associations	Diagnostic tests
Seasonal allergic conjunctivitis (SAC)	Onset 5–20 years Spontaneous remissions common Rare in old age Strikingly seasonal	Hyperaemia. Stringy white discharge. Oedema Micropapillae if severe	None	Personal or family history of atopy including atopic dermatitis	*Cytology*: usually normal. Serum and tear IgE often elevated but not diagnostic
Perennial allergic conjunctivitis (PAC)	As for SAC but symptoms all year round with seasonal exacerbations	Hyperaemia, stringy white discharge, micropapillae common	None	Personal or family history of atopy including atopic dermatitis	
Atopic keratoconjunctivitis (AKC)	Onset between 20 and 50 years. Chronic course over many years (Fig. 67.7g). Spontaneous resolution in old age Non-seasonal	Micropapillae with intense infiltrate (Fig. 67.7b). Reticular and sheet scarring. Shortened fornices in some cases Trantas' dots*	Punctate epithelial keratopathy, pannus, macroerosion† and plaque‡ Pseudogerontoxon§. Herpes keratitis and bacterial keratitis (Fig. 67.7f) common	*Systemic*: atopy and atopic dermatitis in all cases *Ocular*: staphylococcal lid disease, cataract, keratoconus, herpes simplex keratitis (often bilateral)	*Cytology*: shows eosinophils and mast cells. Serum IgE elevated. Skin prick tests positive to many allergens but not diagnostic *Upper tarsal conjunctival punch biopsy*: the gold standard for disease confirmation after a 2-week abstention from use of topical corticosteroids *Tear IgE*: useful unless the serum IgE is very high
Atopic blepharoconjunctivitis (ABC)	As for AKC	Micropapillae with intense infiltrate, reticular scarring	None	Personal or family history of atopy	
Vernal keratoconjunctivitis (VKC)—*palpebral, limbal and mixed forms*	Onset between 5 and 15 years. Spontaneous resolution in 95% after 10 years Seasonal exacerbations usual	*Palpebral form*: giant upper tarsal papillae (Fig. 67.7c) often bilaterally asymmetrical *Limbal form*: micropapillae on upper tarsus but gelatinous macropapillae at limbus (Fig. 67.7d). Trantas' dots in both *Mixed form*: combines features of both diseases	*Palpebral form*: punctate epithelial keratopathy affecting upper half of cornea. Adherent mucus appearing as superficial syncytial opacity progressing to macroerosion and vernal plaque (Fig. 67.7e) *Limbal form*: keratopathy extending in from limbus with associated epithelial dysplasia	*Ocular*: keratoconus and cataract *Systemic*: atopy in variable proportions from 0–100% depending on geographical location (atopy common in Northern Europe but rare in Middle East)	

* Trantas' dots: white, pinhead sized dots consisting of eosinophils and necrotic epithelial cells usually at the limbus.
† Macroerosion: large epithelial erosions usually in upper half of cornea.
‡ Plaque (vernal plaque): laminated structure of protein and polysaccharide adherent to the anterior stroma with destruction of Bowman's layer.
§ Pseudogerontoxon: arcus-like appearance in relation to limbal pannus; may disappear in remissions.

Fig. 67.7 Atopic eye disease. (a) Normal upper tarsal conjunctiva; the tarsal vessels are clearly visible through the healthy conjunctival epithelium and substantia propria. (b) Atopic keratoconjunctivitis with an infiltrated, papillary, upper tarsal conjunctiva. Compare with the normal tarsal conjunctiva in (a). (c) Showing 'giant' or compound upper tarsal papillae and the mucous exudate that develops during an exacerbation. (d) Vernal keratoconjunctivitis (VKC) (limbal form) showing the typical pale limbal papillae. (e) Fully developed vernal plaque. (f) Bacterial keratitis complicating atopic keratoconjunctivitis (AKC) showing a corneal infiltrate. The eyes of this patient are shown in (g), with atopic eczema localized to the eyelids; the eczema is often generalized. The right eye shows the infection in (f).

gist because of their association with atopic dermatitis and will be described here. Of these, AKC and VKC are sight-threatening disorders that are often difficult to treat, although VKC occurs in children and 90% of cases resolve in adult life. The severity of symptoms is closely related to disease activity, and patients with minimal symptoms will respond to simple treatment with antihistamines and/or mast cell stabilizers, which have an excellent safety profile. However, acute exacerbations of AKC and VKC must be recognized and treated promptly as these may develop within hours and can lead to blinding corneal complications within 1–2 days.

Symptoms are similar for all of these atopic eye diseases. Typically there is itching, watering and the production of a sticky white and stringy mucous discharge. During exacerbations the symptoms increase in severity very rapidly—the itching may be superseded by extreme discomfort with soreness and a foreign body sensation, and the vision deteriorates. The lids may be difficult to open in the morning because of a combination of discomfort and discharge.

Signs that can be seen without a slit-lamp examination are thickened lids; in AKC and ABC the lid margins are usually inflamed, crusted and excoriated with madarosis (Fig. 67.7g). Lid margin signs are uncommon in VKC. The bulbar conjunctiva is inflamed during exacerbations but otherwise grossly normal except for the limbal region, which may be thickened and nodular (Fig. 67.7d) with the presence of pinpoint Trantas' dots at the apices of the nodules; these may be present in AKC and in the limbal type of VKC. The distinction between limbal and palpebral VKC is principally of interest to the ophthalmologist; in the UK the limbal form of the disease is generally easier to manage, although this may not be the case in Africa. The lower tarsal conjunctiva is usually less abnormal than that of the upper lid, which can be seen to be thickened and velvety when the lid is everted. In VKC, and in some cases of AKC, 'giant' compound papillae are easily seen (Fig. 67.7c). In adults with long-standing disease, there is sheet-like scarring of the upper tarsal conjunctiva and shortening of the lower conjunctival fornix. During exacerbations the tarsal conjunctiva becomes very inflamed and covered in adherent mucous. The corneal signs, with the exception of plaque (Fig. 67.7e) or ulceration due to superadded infection (Fig. 67.7f), are difficult to see without a slit lamp but fluorescein staining is diffuse during flare-ups of disease.

Diagnosis

The clinical features, together with a personal or family history of atopy, are usually sufficient for diagnosis. Laboratory investigations are only needed in patients who do not respond to therapy or who require topical (or systemic) immunosuppressive therapy for relief of symptoms, or when the diagnosis is uncertain. Serum IgE and skin prick tests have no value in the diagnosis of atopic conjunctivitis as the results do not indicate the antigens precipitating the eye disease. Ophthalmic investigations are the province of the ophthalmologist and are summarized in Table 67.6.

Immunopathogenesis [6–9]
