Fig. 55.16 Progressive nodular histiocytosis in a 48-year-old man with nodular lesions in the posterior axillary fold. (Courtesy of Professor J.M. Naeyaert, University Hospital, Gent, Belgium.)

Histologically, this is a dermal disease with neither epidermal involvement nor epidermotropism. Early lesions show an accumulation of xanthomatized and scalloped histiocytes with some infiltrating lymphocytes. In older lesions the histiocytes are spindle shaped and arranged in a storiform pattern. Occasional giant cells may be present. Cells are positive for CD68 and factor XIIIa and negative for S100 and CD1a [4].

Progressive nodular histiocytosis is not generally associated with systemic involvement or other disorders. In one case report, a 57-year-old man had suffered from progressive nodular histiocytosis for 26 years and during that time had developed chronic myeloid leukaemia, hepatosplenomegaly, hypothyroidism, hyperuricaemia and hypocholesterolaemia, although the relationship between progressive nodular histiocytosis and the systemic disorders remains unclear [5].

Progressive nodular histiocytosis is a benign disease and no treatment has yet been shown to be effective in reducing the size of skin lesions or in inducing remission.

Xanthoma disseminatum

Synonyms
- Disseminated xanthosiderohistiocytosis
- Montgomery's disease

Fig. 55.17 Xanthoma disseminatum. (Courtesy of Dr R. Cerio, Royal London Hospital, London, UK.)

Fig. 55.18 Xanthoma disseminatum with verrucous lesions over the back of a 10-year-old boy.

This is a rare non-familial disease, characterized by proliferation of histiocytic cells in which lipid deposition is a secondary event. The disease predominantly affects male children and young adults, with involvement of the skin, mucous membranes of eyes and upper respiratory tract, the meninges and rarely other organs including liver, spleen and bone marrow [1–4].

The clinical lesions of xanthoma disseminatum are erythematous, yellow-brown papules and nodules, which are symmetrically distributed on the trunk, face and proximal extremities (Fig. 55.17). The lesions become confluent, especially in flexures, to form xanthomatous plaques, which may become verrucous (Fig. 55.18). In 30% of patients, the mucous membranes are affected, with particular involvement of the lips, pharynx, larynx, conjunctivae and bronchus. Involvement of the upper respiratory tract is not uncommon and may lead to stridor and respiratory distress requiring tracheostomy. Upper respiratory tract involvement has been fatal in one reported case of a 61-year-old woman with involvement of large and medium-sized bronchi who died of acute respiratory failure [5]. Lower respiratory tract involvement is very rare but in one 8-year-old boy, resulted in bronchiectasis [6].

Meningeal involvement is common, with infiltration at the base of the brain leading to diabetes insipidus in up to 40% of cases. Other manifestations of meningeal involvement are seizures and growth retardation. Intracranial involvement presenting as a discrete mass simulating glioma has been reported [7] and progressive intracranial disease may be fatal [8]. Progressive bone disease has been reported in xanthoma disseminatum [9,10], but this is a rare complication of the disease. Lytic bone lesions have been reported in a patient with xanthoma disseminatum, but are very rare [11,12]. Hepatic involvement is rare but a 12-year-old boy has been reported with liver dysfunction secondary to liver involvement by xanthoma disseminatum presenting as sclerosing cholangitis [13].

A clinical variant of this disease was described by Halprin and Lorincz [14] under the name xanthosiderohistiocytosis. In this variant, there is diffuse infiltration of the skin, subcutaneous tissue and muscle, giving rise to sclerodermatous changes in the skin and muscle wasting. The foamy histiocytes that are involved contain significant amounts of iron, which gives the skin a greenish-brown colour.

Histologically, xanthoma disseminatum is a dermal disease, characterized by early infiltration of the dermis with spindle-shaped mononuclear cells, foamy histiocytes, giant cells, lymphocytes, polymorphs and eosinophils. Lesional cells in xanthoma disseminatum have irregular scalloped borders with extensive cytoplasm and ovoid vesicular nuclei. Cells label strongly with factor XIIIa and KP1 [15]. Iron and lipid can be detected in the histiocytes. In older lesions, more foamy histiocytes are evident and Touton giant cells may be observed. At the ultrastructural level, histiocytic cells contain myeloid bodies and membrane-bound fat droplets.

Xanthoma disseminatum is a self-limiting disease but may persist for years. Lesions are only mildly radiosensitive. Skin lesions of xanthoma disseminatum are disfiguring and patients often request treatment. The carbon dioxide laser has been used with good results [16] and azathioprine and cyclophosphamide have been effective in some patients with cutaneous disease [17]. Conjunctival involvement can be treated with surgery. Systemic involvement with lung, liver or CNS involvement requires active

treatment. Surgery has been used in CNS disease but recurrences may occur [8]. Liver involvement in one patient responded to systemic steroids and azathioprine [13]. Response to various modalities including radiotherapy, alkylating agents and antimetabolites has been variable [18].

Diffuse plane xanthomatosis

Synonyms
- Atypical xanthoma disseminatum
- Diffuse normolipaemic plane xanthomatosis

This is a rare, non-lipaemic disease in which xanthomatous lesions develop in the skin in association with paraproteinaemia. The disease generally occurs in adults but rare paediatric cases have been reported [1]. Patients present with large, flat, plaque-like, xanthomatous skin lesions involving the eyelids, neck, upper trunk, buttocks and flexures [2,3]. Serum lipids are usually normal. About 50% of patients have a myeloproliferative disorder with multiple myeloma, granulocytic or lymphocytic leukaemia [4]. One patient with tumour stage cutaneous T-cell lymphoma developed diffuse plane xanthomatosis coincident with the appearance of new lymphoma lesions [5]. The majority of patients have a circulating paraprotein and have some abnormalities of serum complement [6,7].

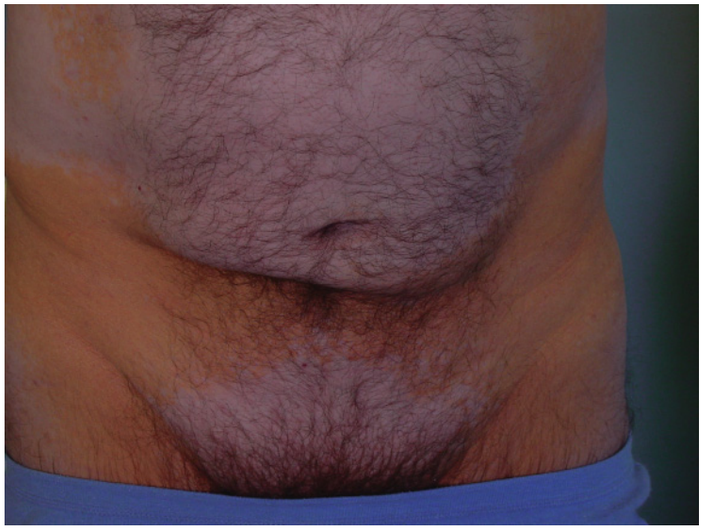

Fig. 55.19 Diffuse plane xanthomatosis in a 73-year-old man of 7 years' duration with associated IgGκ paraprotein.

The histological features include both xanthomatous and inflammatory elements. Accumulations of foamy macrophages infiltrate the dermis, with a distinct perivascular accentuation, and are associated to a variable degree with a mixed inflammatory cell reaction. There are no reported immunohistochemical studies in the world literature but a recent patient we have seen with characteristic skin changes (Fig. 55.19) and an IgGκ paraprotein, showed that the foamy macrophages were CD1a negative but strongly positive for CD68 and factor XIIIa.

The condition arises as a result of perivascular deposition of lipoprotein–immunoglobulin complexes. Antilipoprotein antibodies are formed in association with paraproteinaemia [7]. Although serum lipid levels are usually normal, they may be raised, possibly due to reduced clearance of lipoprotein–antibody complexes. Treatment of this condition is that of the underlying myeloproliferative disease or paraprotein. Theoretically, plasma exchange should be of value but its use has not yet been reported.

Class IIb histiocytosis: histiocytoses involving cells other than Langerhans' cells and dermal dendrocytes

Reticulohistiocytoma

Synonyms
- Solitary epithelioid histiocytoma
- Solitary histiocytoma

This is an uncommon tumour which is generally solitary and asymptomatic. Lesions less than 1 cm in diameter, presenting as papules or dome-shaped nodules, tend to occur in young adults but may appear from early childhood to old age. Lesions may occur anywhere on the body including the genitalia. Oral mucosal lesions have been reported [1].

Histology shows nodules of epithelioid histiocytes with abundant, glassy cytoplasm extending from the papillary dermis to the mid-dermis associated with lymphoid cells and occasionally neutrophils. Cells may have a lacuna space-like clearing at the periphery and scalloped cytoplasm. Cells are CD68 and CD163 positive and generally CD1a and S100 negative. In a study of five cases of solitary reticulohistiocytoma, factor XIIIa was found to be positive [2] but in a larger study of 44 cases, factor XIIIa was generally negative; however in five cases, histiocytic cells close to the dermoepidermal junction were found to be variably positive for factor XIIIa [1].

Treatment is surgical excision. Follow-up in 12 patients, with a median follow-up of 13 years, showed no recurrence following primary excision.

Multicentric reticulohistiocytosis

Synonyms
- Reticulohistiocytic granuloma
- Lipoid dermatoarthritis
- Giant-cell histiocytoma
- Reticulohistiocytoma cutis
- Multicentric giant-cell reticulohistiocytosis

Definition. This is a rare histiocytic proliferative disease in which joints, skin and mucous membranes are affected [1]. The arthropathy usually precedes nodular skin involvement and mucosal infiltration. Other organs may be involved and 20% of patients have an associated internal malignancy. This must be differentiated from solitary or multiple reticulohistiocytomas that are restricted to skin with neither associated arthropathy nor internal malignancy.

Aetiology. Pathogenesis is unknown. The cells involved are phagocytic histiocytes, and the disease is considered to be a reactive histiocytosis. No infective agent has been implicated but there is evidence of exposure to tuberculosis in some patients. In one study, 33% of patients had evidence of exposure to tuberculosis and 5% of patients had active tuberculosis on clinical examination [2]. There is no recorded genetic link. Those cases with internal malignancy have no clinical or pathological differences from those without associated malignancy.

Pathology. The characteristic pathological picture in the skin and mucous membranes is of infiltration by mononucleated and multinucleated giant cells with voluminous ground-glass cytoplasm. In early lesions, the predominant infiltrating cells are histiocytes, lymphocytes and eosinophils, with few giant cells, but the giant cell infiltrate quickly follows. The giant cells are large (100 μm) with 1–20 nuclei. The cells are periodic acid–Schiff (PAS) positive, contain diastase resistant material and variable amounts of lipid and free or esterified cholesterol. In older lesions, fibrosis usually signals regression of the lesions, with a reduction in the inflammatory cell infiltrate.

Ultrastructural studies have shown inclusions of type IV collagen inclusions in multicentric reticulohistiocytosis. These inclusions were both intracytoplasmic and extracytoplasmic. Such inclusions are usually found in lymphohistiocytic neoplasms, suggesting that multicentric reticulohistiocytosis is a proliferative rather than an inflammatory disorder [3].

Immunocytochemical studies show a histiocytic phenotype of the cells, which are positive for acid phosphatase, ATPase, lysozyme and α_1-antitrypsin [4]. The cells are also positive for vimentin, CD45 and CD68, but negative for CD1, S100 and CD34 and factor XIIIa [5]. Cells contain TNF-α, IL-1β and IL-12 [6]. Ultrastructural studies have shown that the cells contain dense bodies, coated vesicles, fat droplets in limiting membranes and myeloid bodies [7].

Clinical features. The disease typically affects women, with a female to male ratio of 3 : 1 [8]. It is a disease of middle age, and rarely affects children [9] or adolescents. Some 60% of patients present with polyarthritis, which typically affects the hands. The interphalangeal joints are affected symmetrically and are erythematous with an accompanying deforming polyarthritis, which ultimately results in shortening of the fingers and mutilation (Fig. 55.20). Other joints may be involved, including the knees, shoulders, wrists, hips, ankles, feet, elbows, spine and temporomandibular joints. Radiography of the affected joints shows destruction of the articular surfaces, with bone resorption and eventually secondary osteoarthritis [10]. Two case reports have highlighted the presence of osteolytic bone damage in this disease, in one patient affecting the bones of the upper limb [11] and in the second the skull, mimicking Langerhans' cell histiocytosis [12]. The authors suggest that the osteolytic lesions are due to the action of pro-inflammatory cytokines, TNF-α and IL-1, in inducing osteoclastic activity [12].

The classical skin lesions are firm brown or yellow papules and plaques, which predominantly affect extensor surfaces, particularly on the hands and forearms. The face (Fig. 55.21), scalp, hands and ears are often affected but involvement of the lower trunk and legs is rare. Coral bead-like lesions may occur around the nail

Fig. 55.20 Multicentric reticulohistiocytosis showing the characteristic skin changes, with multiple firm papular lesions on the sides of the fingers and obvious destructive arthropathy. (Courtesy of Professor N. Saxe, Groote Schuur Hospital, Cape Town, South Africa.)

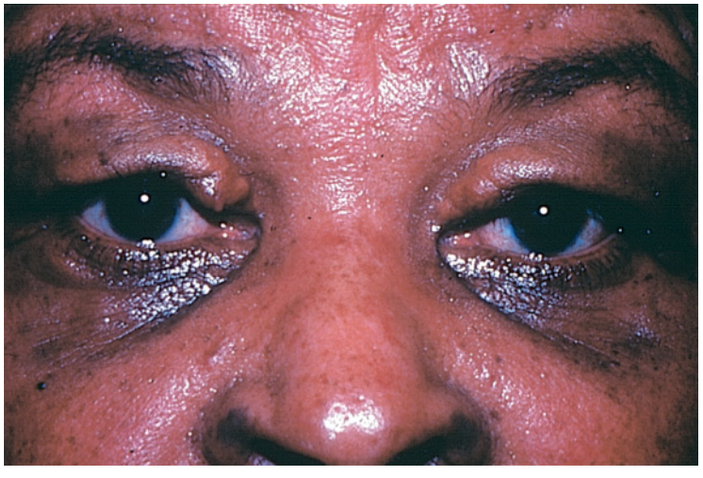

Fig. 55.21 Multicentric reticulohistiocytoma with characteristic lesions around the eyes. (Courtesy of Professor N. Saxe, Groote Schuur Hospital, Cape Town, South Africa.)

folds, which may result in nail dystrophy. Skin lesions are of variable size and rarely ulcerate. Large nodular lesions in proximity to affected joints and cystic swellings of tendon sheaths may occur. About 25% of patients complain of pruritus associated with skin lesions. Diffuse cutaneous reticulohistiocytosis without arthropathy [9] and isolated reticulohistiocytomas [13] have been described. The cutaneous lesions have the same histology as lesions in multicentric reticulohistiocytosis but are not associated with joint problems or neoplasms.

More than 50% of patients have mucosal involvement affecting the mouth, gingiva, pharynx, larynx and sclera. Characteristically, the lips and tongue are involved [14], and 30% of patients have abnormalities of serum lipids. Laboratory findings are normal with a negative rheumatoid factor. Even in the most active stages of the disease, the erythrocyte sedimentation rate is only marginally elevated.

Constitutional symptoms of pyrexia and weight loss may occur. Involvement of bone marrow, skeletal muscle, lymph nodes, heart, pericardium, lungs, pleura, bones, liver, duodenal mesentery and kidney have been reported. Deaths have occurred with cardiac involvement [15]. Multicentric reticulohistiocytosis has been reported in association with Sjögren's syndrome [16] and thyroid involvement [17].

Around 20% of patients have been found to have an associated internal malignancy. The commonest tumours are gastric, ovarian [18], breast and uterine carcinomas [19], myeloma [20], melanoma [21] and lymphomas. Rare case reports have described Ki-1 lymphoma occurring in association with multicentric reticulohistiocytosis [22]. Myelodysplastic syndrome has been reported in one patient with multicentric reticulohistiocytosis, although this patient had been treated with cytotoxic drugs for many years and the myelodysplasia may have been drug related [23]. The diagnosis of multicentric reticulohistiocytosis precedes that of the neoplasm in most cases, and the disease may relapse with recurrence of the neoplasm [24].

Prognosis. The prognosis is good if there is no systemic malignancy, the disease becoming quiescent in 7–8 years. Fatal cardiac involvement may occur with widespread systemic involvement [15]. It does, however, leave considerable morbidity, with a crippling arthropathy and scarred skin.

Diagnosis. Multicentric reticulohistiocytosis has been clinically mistaken for dermatomyositis in a patient with a macular eruption in a photodistribution [25], lupus erythematosus [26] and lepromatous leprosy [27]. Biopsy of skin nodules helps to differentiate multicentric reticulohistiocytosis from eruptive xanthomas and juvenile xanthogranulomas. The disease can usually be clinically differentiated from other disorders involving cutaneous nodules and arthritis (e.g. rheumatoid arthritis, sarcoidosis, gout and xanthomatosis).

Treatment. No treatment is of consistent value in this disease. Systemic steroids may be successful for brief periods but their long-term value is uncertain. Combination of systemic steroids with azathioprine has been used with success [28]. One case report of a patient with joint and skin involvement showed persistent improvement in all sites with the bisphosphonate, alendronate [29]. Non-steroidal anti-inflammatory agents have no effect on the arthropathy. Immunosuppressive drugs give variable results. Cyclophosphamide is reported to give high success rates [30], and ciclosporin has been reported to give good results [31]. Some case reports suggest that TNF-α antagonists may have a role in the treatment of this disease [32,33].

Familial haemophagocytic lymphohistiocytosis

Synonyms
- Familial haemophagocytic reticulosis
- Generalized lymphohistiocytic infiltration
- Familial erythrophagocytic lymphohistiocytosis
- Familial histiocytic reticulosis
- Familial lymphohistiocytosis
- Farquhar's disease

This is a rare reactive histiocytosis in which there is widespread infiltration of multiple organs by lymphocytes and mature histiocytes showing prominent cytophagocytosis. It is rapidly fatal in most patients. The incidence is 1.2 per million children [1], with a slight preponderance in boys. Three-quarters of cases are familial, and it is generally considered to be an autosomal recessive disease [2].

The genes responsible in some cases have been identified and studies have identified subsets of familial haemophagocytic lymphohistiocytosis (FHL) depending on the genetic defect. In one patient a constitutional inversion in chromosome 9 (p23;q31) was observed in cells from bone marrow, lymphocytes and fibroblasts [3]. This locus accounts for approximately 10% of cases (FHL-1) [4]. FHL-2 represents 20–30% of all cases and is characterized by mutation in genes coding for perforin, a lytic granule constituent (*PRF-1*; MIMI 70280). The mutation in the perforin gene occurs at position 374, resulting in a premature stop codon. A study of 34 families and linkage studies of a subset of consanguineous families indicates that perforin mutations account for 20–40% of cases of FHL [4]. FHL-3 represents 20–25% of all cases and is characterized by mutations in *MUNC13–14* genes [4]. Other mutations include nonsense and missense mutations and deletions of amino acids [5].

Fever is usually the first sign of the disease, with symptoms of an upper respiratory or gastrointestinal tract infection in 30%. Pallor, anorexia, vomiting and irritability are often noted. Hepatosplenomegaly is usually present at presentation and is progressive. Moderate lymphadenopathy is common. Around 50% of patients develop a transient, non-specific, maculopapular rash, which is often seen at times of high fever, but no persistent skin infiltration is seen. About 20% of patients have neurological symptoms, due to meningeal involvement, usually with convulsions but also with other signs of meningeal irritation.

Laboratory tests show anaemia, thrombocytopenia and raised liver enzymes and hyperbilirubin. Hyperlipidaemia (with elevation of triglycerides and very low-density lipoproteins) and hypofibrinogenaemia are common.

Immunological testing shows abnormalities of both the humoral and cellular limbs of the immune system. Natural antibody titres are low, antibody titres after previous immunization are low and there is an impaired response to primary immunization. All T-cell responses to mitogens, antigens and alloantigens are reduced. There is also a T-cell-suppressor factor, probably related to triglycerides, in the plasma of the patients [6]. Cytotoxic T-cell and

natural killer cell activity is markedly reduced or absent in affected patients.

A number of studies have now demonstrated hypercytokinaemia in this disease, with elevated amounts of circulating IFN-γ, TNF-γ and IL-6 during active disease [7]. Serum levels of IL-6 have been shown to be of no prognostic importance [8]. Soluble CD8 has also been shown to be elevated, suggesting a role for cytotoxic T cells in the pathogenesis of this disease.

Histologically, the involved tissue shows a diffuse infiltrate with lymphocytes and mature histiocytes. The histiocytes exhibit active phagocytosis, especially of erythrocytes but also of leukocytes and occasionally platelets. The histiocytes stain positively for acid phosphatase, non-specific esterase, lysozyme and α_1-antichymotrypsin. A striking histological finding is lymphocyte depletion of lymph nodes, spleen and thymus.

Prognosis is poor, with median survival of 2–3 months [9] from diagnosis and 96% dying within 12 months. Central nervous system disease and persistently low natural killer cell activity are associated with poorer prognosis [10]. Long-term survivors have been reported after chemotherapy, but maintenance therapy is always required.

Initial treatment regimens used splenectomy, exchange transfusion [11] and chemotherapy [12], including vinblastine and intrathecal methotrexate. Henter *et al.* [13] reported a more successful regimen using etoposide and teniposide with prednisolone and intrathecal methotrexate until remission is achieved, followed by maintenance therapy with teniposide or etoposide. A recent study advocated the use of antithymocyte globulin in early stages of the disease showing low toxicity and good responses [14].

Bone marrow transplantation and haemopoietic stem cell transplantation [15] are now regarded as being the most effective treatments for this disease. Results are much better when HLA-identical siblings are used as donors. Studies have now shown that even partial engraftment is compatible with long-term remission [10,16].

Familial sea-blue histiocytosis

This is a rare inherited abnormality of lipid metabolism [1] in which characteristic histiocytic cells are found in the bone marrow and other tissues. The histiocytes are identified by the May–Gruenwald stain, which colours the cytoplasmic granules a deep azure blue, hence the name 'sea-blue histiocytosis'.

Familial sea-blue histiocytosis in an autosomal recessive trait [2]. It usually presents in young adulthood with hepatosplenomegaly and thrombocytopenia, although the age at presentation ranges from 1 to 83 years. The skin, lungs, gastrointestinal tract, eye and nervous system may be involved. In the skin, patchy and irregular brownish-grey pigmentation of the face, upper chest and shoulders has been reported. In one case [3], skin involvement, with eyelid swelling and facial nodules, was confirmed histologically. In the eye, white stippled deposits may be observed at the margins of the fovea or macula, with discoloration of the macular region. Neurological symptoms occur early, with ataxia, epilepsy and dementia.

Sea-blue histiocytosis is not malignant, but it may disseminate and lead to death from liver or lung involvement. The biological abnormality is poorly understood, but the condition probably represents a storage disease in which glycolipid, phospholipid or both accumulate in histiocytic cells in various organs. Sea-blue histiocytes have also been described in chronic myelogenous leukaemia [4,5], adult Niemann–Pick disease [6], following the prolonged use of intravenous fat emulsions in children [7] and in partial sphingomyelinase deficiency [8].

Hereditary progressive mucinous histiocytosis

This is a rare autosomal dominant genodermatosis, which was first described in 1988. All case reports to date have been in women, thus suggesting a link to hormones [1]. Skin lesions appear in the first decade of life and gradually increase throughout life. Lesions consist of skin-coloured to red-brown papules that characteristically affect the nose, hands, forearms and thighs. Two sets of case reports have described mothers and daughters who have both presented with the disease [2,3]. Histologically, the epidermis is normal but within the dermis there are small collections of epithelioid histiocytes with telangiectatic vessels in the upper dermis in early lesions. As tumours develop, the infiltrate changes to nodular mid-dermal aggregates of tightly packed, spindle-shaped cells. In both early and established lesions, there is moderate to extensive mucin production by the epithelioid histiocytes and spindle-shaped cells. On electron microscopy, the spindle-shaped cells are shown to be dendritic histiocytes with abundant lysosomal storage organelles, myelin bodies and zebra bodies.

Immunohistochemically, these cells stain with CD68 and MS1 [3]. The condition is progressive, with gradual increase in numbers of tumours throughout life. These patients show no evidence of spontaneous resolution. No systemic involvement has been described and no treatment seems to have any impact on the disease [4,5].

Malakoplakia

Malakoplakia is an immunodeficiency disease in which macrophages fail to phagocytose and digest bacteria adequately. The term 'malakoplakia', which means soft plaque, was adopted as a descriptive term [1].

Malakoplakia can affect many organs but most commonly affects the urinary and gastrointestinal tracts [2,3]. Cutaneous lesions are rare, non-specific and variable. Draining abscesses, sinuses, ulcers, fluctuant masses, isolated tender nodules and grouped papules have been reported. Mucous membranes may be affected, including the tongue [4] and cervix [5]. The disease generally runs a benign self-limiting course, but fatal cases have been reported [6].

Histologically, sheets of large histiocytic cells with abundant cytoplasm are present in the skin, affecting any level from epidermis to subcutaneous fat. The cells have fine eosinophilic granules in their cytoplasm and are referred to as Hansemann cells. They also contain one or more round basophilic inclusion bodies (Michaelis–Gutmann bodies). Michaelis–Gutmann bodies are 5–15 μm and stain positively with PAS, von Kossa stain (for calcium) and Perls ferrocyanide reaction (for ferric iron). They are considered pathognomonic for this disease and are thought to represent abnormal degradation of bacteria, with calcium and iron deposited on the remaining glycolipid.

The commonest bacterium found in this disease is *Escherichia coli* [7,8], although *Staphylococcus aureus* has also been cultured [9]. Mycobacteria have been identified in two cases of cutaneous malakoplakia using polyclonal anti-*Mycobacteria bovis* antibodies [10]. In some patients, the disease is related to drug-induced immunosuppression [11]. In one patient [6], intracellular cyclic guanosine monophosphate (cGMP) levels were found to be low, and *in vivo* and *in vitro* treatment of the cells with bethanechol chloride, a cholinergic agonist, increased cGMP and restored their bactericidal activity.

Necrobiotic xanthogranuloma

The syndrome of necrobiosis with xanthomatous granulomas and an associated paraprotein has been recognized since 1966 [1–3], but it was not until 1980 that it was recognized as a distinct dermatosis [4].

The characteristic clinical lesions are periorbital nodular and ulcerative lesions, which have the reddish-yellow colour of xanthomas (Fig. 55.22). On the trunk and limbs, subcutaneous nodules and xanthomatous plaques are present with atrophy and

Fig. 55.22 Early lesions of necrobiotic xanthogranuloma with characteristic distribution in the periorbital area. (Courtesy of Dr A. Layton, Leeds General Infirmary, Leeds, UK.)

Fig. 55.23 Established lesions of necrobiotic xanthogranuloma on the abdomen showing xanthomatous plaques and atrophy. (Courtesy of Dr P. Holt, University Hospital, Cardiff, UK.)

ulceration (Fig. 55.23). The eyes are often affected with conjunctivitis, keratitis, uveitis, iritis and proptosis. Blindness has been reported in two affected patients [4]. Only one case report of a patient with typical cutaneous lesions and cerebral involvement presenting as tonic–clonic seizures has been published [5]. Systemic symptoms have been reported, including nausea, vomiting, fatigue, epistaxis, back pain and Raynaud's phenomenon. Atypical forms of necrobiotic xanthogranuloma have been reported, including solitary tumours of the skin [6].

The majority of cases have an associated paraprotein, usually an IgG κ or λ monoclonal protein. In a series of 22 patients, 16 had IgG monoclonal protein, three had multiple myeloma, three had cryoglobulinaemia and one had normal serum protein electrophoresis [7].

Decreased levels of C1 inhibitor have been reported in some patients with necrobiotic xanthogranuloma, occasionally associated with angio-oedema. Immune complex formation resulting from autoantibodies against the paraproteins have been implicated in the depletion of C1 inactivator [8].

Histologically, confluent granulomatous masses are present as either sheets or nodules, replacing much of the dermis and extending into the subcutaneous tissue [9]. Hyaline areas of necrobiosis separate individual nodules. Numerous giant cells are present, with Touton cells and bizarre angulated giant cells. Cholesterol clefts, lymphoid nodules (some of which develop germinal centres) and perivascular aggregates of plasma cells are frequent features. Less common, but characteristic when present, are palisading cholesterol cleft granulomas and xanthogranulomatous panniculitis. Granulomatous invasion of blood vessels with thrombosis has been described.

The pathogenesis of necrobiotic xanthogranuloma is unknown. Bullock *et al*. [10] suggested that the abnormal paraprotein becomes complexed with lipid and deposited in the skin, where it produces a foreign-body granulomatous reaction.

Treatment is generally directed to the associated paraproteinaemia. Alkylating agents such as melphalan, with or without prednisolone, have resulted in temporary clearing of the skin [11]. In one patient where cytotoxic drugs had failed, plasmapheresis reduced the level of the circulating monoclonal IgG and resulted in clearing of the skin [12]. Successful treatment with chlorambucil 2 mg/day for 7 months has been reported in a 51-year-old man with necrobiotic xanthogranuloma and associated paraproteinaemia [13]. Radiotherapy was successful in one case involving the eye [14]. Cutaneous disease has been successfully treated with carbon dioxide laser with no evidence of relapse after 12 months [15].

Sinus histiocytosis with massive lymphadenopathy

Synonym
- Rosai–Dorfman disease

Sinus histiocytosis with massive lymphadenopathy (SHML) is a rare histiocytic proliferative disorder that is defined by its histopathological features [1,2]. A registry of this disease contains information on 423 patients [3].

SHML is currently considered to be a reactive rather than a malignant histiocytosis [4]. An infectious cause has been suggested by the occurrence of fever and pharyngitis, which often precede the onset of SHML. However, the search for a possible infectious agent has been inconclusive. Some patients show evidence of Epstein–Barr virus infection while others have demonstrable infection with *Klebsiella rhinoscleroma* and *Brucella*, but these are not consistent findings. A study failed to show evidence of human herpesvirus 6 and 8 in skin lesions [5].

The onset of SHML is usually in young adults, with a range from birth to 74 years. The sex incidence is equal. Clinical presentation is usually with painless lymph node enlargement, which may reach massive proportions. About 90% of patients present with cervical adenopathy, the rest presenting with axillary, inguinal or mediastinal node enlargement. Fever, weight loss, malaise and night sweats have been reported, usually at presentation.

Extranodal involvement is common, with 43% of patients having at least one extranodal site of involvement. Skin is the most common extranodal site and may be involved without nodal disease. Pure cutaneous SHML may remain localized to the skin with no systemic involvement even with long-term follow-up [6]. Skin lesions are usually yellow, but may be violaceous or purple. Macular erythema, papules, nodules or infiltrated plaques have been reported (Fig. 55.24). Scaling is often present and telangiectasia may be observed. Skin lesions may occur at any site [7]. Of patients with skin SHML, 50% have evidence of one or more additional extranodal sites, particularly involving the nasal cavity, with polyps and paranasal sinuses.

Other organs involved in SHML include bone with lytic bone lesions [8], salivary gland, central nervous system, genitourinary system, lower respiratory tract, liver, gastrointestinal tract, heart and thyroid gland. Isolated central nervous system involvement in SHML is well recognized. In a report of 11 cases, seven were male and four female, with an age range of 22–64 years. Presentation was with headaches, seizures, numbness or paraplegia. Eight cases involved the cranial area and three the spinal cord. Most lesions were dura based and only one case involved the brain parenchyma [9]. Treatment of these patients was surgical, with one patient dying of surgical complications and nine showing no evidence of disease progression after a mean of 15 months follow-up.

Laboratory investigations usually show a mild normochromic normocytic anaemia or hypochromic microcytic anaemia with elevation of erythrocyte sedimentation rate. Serum proteins are often abnormal, with a low serum albumin and polyclonal gammopathy. Serum lipids are normal.

Fig. 55.24 A 41-year-old Asian woman with cutaneous SHML presenting as a pruritic papular and plaque lesion on the upper thigh.

Histology of involved nodes reveals the pathognomonic features of SHML. The sinuses are expanded by large pale histiocytes. The histiocytes have abundant pale-pink cytoplasm and indistinct margins or may have glassy eosinophilic cytoplasm and well-defined cytoplasmic membrane. Nuclei are round or oval, usually with a single small nucleolus. Occasionally, multinucleate cells or cells showing nuclear atypia are present but mitoses are rare. Lymphophagocytosis or emperipolesis (phagocytosis of leukocytes, particularly lymphocytes) is always present, and less frequently intracytoplasmic plasma cells, neutrophils and red blood cells may be seen. Between the expanded sinuses, lymphocytes and plasma cells are present and reactive germinal centres are occasionally seen. Rarely, neutrophils are observed scattered throughout the involved node. Electron microscopy shows numerous lipid vacuoles and moderate numbers of lysosomes in the cytoplasm of the histiocytes. The surface of the cells is often thrown into complex, convoluted, villous processes.

In extranodal SHML, the histological picture is strikingly similar to that seen with nodal disease, with what appears to be abnormal lymph node architecture, dilated sinuses and reactive germinal centres in the extranodal site. Extranodal SHML usually shows more fibrosis and lymphophagocytosis.

On immunophenotypic analysis, SHML cells show pan-macrophage markers (EBM11, HAM56 and Leu M3, FcIgG and C3 receptors), monocyte markers (OKM5 and Leu M1), activation antigens (Ki-1, transferrin receptor and CD25) and lysosomal enzymes (lysozyme and α_1-antichymotrypsin) [10]. Surprisingly, however, these cells also display factor XIIIa, a marker of dermal dendrocytes [11], and the S100 antigen that is usually present on dendritic cells; and of two frozen samples tested, both were positive for NA1/34, one for OKT6 but neither for Leu 6. These three monoclonal antibodies react with different epitopes on CD1a, which is characteristic for Langerhans' cells. The exact cell lineage is therefore still uncertain.

The prognosis in SHML is reasonably good. In 238 patients followed for more than a year [7], 49 were well and clear of the disease, 126 had persistent disease, three had progressive disease and 21 patients died, although four deaths were unrelated to SHML. Poor prognostic features in this disease are immunological abnormalities and multiple extranodal sites of disease.

Many treatments have been tried, including the vinca alkaloids, etoposide, ciclosporin and X-rays but no ideal treatment has been identified and the response is poor [12]. A review of the literature showed that 32 of 40 patients received no treatment and underwent spontaneous regression. Radiotherapy gave complete remission in three of nine patients. Surgical debulking was successful in eight of nine patients, resulting in complete remission. Chemotherapy was generally unsuccessful [13], but a case report showed complete resolution of disease with low-dose 2-chlorodeoxyadenosine in a child with nodal and extranodal disease [8].

Virus-associated haemophagocytic syndrome

Synonyms

- Virus-induced histiocytosis with erythrophagocytosis
- Virus-induced histiocytic medullary reticulosis

Virus-associated haemophagocytic syndrome is a rare reactive histiocytosis in patients with an active viral infection. Patients can be divided into two groups: group 1 have no evidence of underlying disease; group 2 are receiving immunosuppressive therapy for underlying disease [1–3]. The disease results from a cytokine storm derived from an inappropriate immune reaction caused by proliferating or activated T cells or natural killer cells associated with macrophage activation or inadequate apoptosis of immunoresponsive cells.

Any age group can be affected and, although children and neonates are often affected, many adult cases have been reported. The syndrome presents suddenly with fever, constitutional symptoms, hepatosplenomegaly, lymphadenopathy, pancytopenia, coagulopathies with thrombocytopenia and hypofibrinogenaemia, raised liver enzymes and bilirubin, pulmonary involvement and skin rashes. Non-specific, generalized, macular eruptions occur fairly frequently.

The viruses implicated include adenovirus, herpesvirus [4], human herpesvirus 6 [5], Epstein–Barr virus, measles virus [6], parainfluenza virus type 2, enterovirus, cytomegalovirus [7] and influenza A (H3N2) [8]. In the bone marrow, lymph nodes and other involved tissue, there is infiltration by histiocytes showing erythrophagocytosis. These cells are banal looking histiocytes with no cytological evidence of malignancy.

The differential diagnosis includes familial haemophagocytic lymphohistiocytosis, malignant histiocytosis and LCH. In the past, many patients with virus-associated haemophagocytic syndrome have been misdiagnosed as malignant histiocytosis and given inappropriate treatment with cytotoxic drugs. It is important to differentiate between these two entities, as the administration of cytotoxic drugs in a viral disease such as virus-associated haemophagocytic syndrome can precipitate a fulminant fatal infection.

The prognosis is variable. In a series of 19 patients [9], 30% died in the acute stages of the disease. The other patients recovered completely in 1–8 weeks with no recurrence in a follow-up period of 32 months. Prognosis is related to prompt introduction of immunosuppressive therapy to control the cytokine storm; ciclosporin or systemic steroids are used in low-risk groups and etoposide-containing regimens in high-risk groups [10].

Class III histiocytosis: malignant histiocytoses

Class III histiocytoses are malignancies of the monocyte/macrophage series of cells. These diseases are separated into monocytic leukaemia, malignant histiocytosis and true histiocytic lymphoma on clinical criteria, but there is an enormous overlap and it may not always be possible to differentiate them.

In monocytic leukaemia, the malignancy primarily affects the bone marrow and blood but extramedullary involvement is common. In malignant histiocytosis, the histiocytes retain their ability to migrate through the body, which results in widespread involvement of the reticuloendothelial system. In true histiocytic lymphoma, the cells are derived from fixed tissue histiocytes and the tumours are localized, although they may disseminate.

In a study by the International Lymphoma Study Group [1], tumours of histiocytes were phenotypically assessed using a panel of markers. Four groups were identified:

1 Histiocytic sarcoma: CD68 and lysozyme positive, CD1a and CD21/35 negative, with 33% showing S100 reactivity. This tumour was predominantly extranodal and associated with a high mortality.
2 Langerhans' cell sarcoma: CD68, lysozyme, CD1a and S100 positive but CD21/35 negative. This tumour was predominantly extranodal, with a 50% mortality rate.
3 Follicular dendritic cell sarcoma: CD21/35 positive. This tumour was localized to lymph nodes and associated with a low mortality.
4 Interdigitating dendritic cell sarcoma: S100 positive, 50% CD68 positive, CD1a and CD21/35 negative.

Most of these tumours were localized to lymph nodes and associated with a low mortality. This is a useful phenotypic aid for recognizing tumours of histiocytic origin. In the Histiocyte Society classification, malignant histiocytosis and true histiocytic lymphoma can be subdivided into tumours of these four phenotypes.

Monocytic leukaemia

Definition. Monocytic leukaemia may be acute or chronic. The acute myelogenous leukaemias have been classified in the Franco–American–British classification according to the characteristics of the cells involved. Acute myelomonocytic leukaemia is classified as M5. Acute myeloid leukaemia (AML) M(5) can be immunophenotypically subdivided into AML-M(5a) and AML-M(5b) with AML-M(5a) expressing higher levels of CD68 and CD11b. Prognosis does not seem to differ in these two subtypes [1]. The chronic myelomonocytic/monocytic leukaemias usually transform into acute forms of the leukaemia in a matter of months.

The monocytic leukaemias typically exhibit increased extramedullary disease and organomegaly, and are associated with reduced remission rates and a poorer prognosis.

Aetiology. The aetiology of monocytic leukaemias is unknown. A characteristic karyotype has been reported in M5 leukaemias, translocation t(9;11)(p22;q23).

Pathology. Leukaemic cells in monocytic leukaemia show varying degrees of monocyte differentiation. In acute forms of the disease, the cells stain positively for peroxidase, Sudan black B and non-specific esterase. The cells also contain granules that stain for α-naphthylbutyrate esterase [2]. The cells demonstrate CD13 and CD33, with 30% of cells exhibiting HLA-DR. Monocyte-associated membrane antigen (CD14) expression is variable [3].

Ultrastructurally, the cells have irregular nuclei with nuclear blebs, numerous pinocytic vesicles and perinuclear fibrillar bodies [4].

Skin infiltration favours the lower dermis and subcutaneous fat, with prominent involvement of adnexal structures, nerves and vessels of the superficial and deep plexus. Cellular atypia may be prominent and mitotic figures are common. Differentiation from other forms of leukaemia depends on examination of the blood and bone marrow and special stains in skin sections. The best marker for monocytic leukaemia is non-specific esterase.

Clinical features. Skin lesions in monocytic leukaemia may be specific, for example leukaemia cutis, or non-specific, related to anaemia, thrombocytopenia, infection or drugs. Leukaemia cutis occurs in about 20% of patients with acute monocytic leukaemia [3,5]. Specific skin lesions are light-red, brown or violaceous macules and nodules [6]. These are firm and generally asymptomatic. Skin lesions may undergo rapid cycles of development and spontaneous regression. Skin involvement is not related to the circulating white cell count. Gum involvement occurs in 25–50% of patients.

The prognosis in acute monocytic leukaemia is not related to skin involvement, and leukaemia cutis may spontaneously regress. The prognosis depends on the age of the patient, presence of renal failure and serum β_2-microglobulin levels. Aggressive chemotherapy is associated with complete remission in 60% of patients.

Diagnosis. Diagnosis is made on clinicopathological features of the disease. Differentiation from other forms of leukaemia cutis demands examination of the blood or bone marrow and the use of special stains. M4 and M5 leukaemias are associated with elevated serum lysozyme levels [2].

Treatment. Treatment of leukaemia cutis is that of the underlying leukaemia. Leukaemia cutis in monocytic leukaemia has a tendency to spontaneous regression, but large lesions or ulcerating lesions may be treated with local radiotherapy. Acute monocytic leukaemia is sensitive to the currently used chemotherapeutic

regimes used in acute myeloid leukaemia with similar response rates to the other acute myeloid leukaemias [7].

Malignant histiocytosis

Synonyms

- Malignant reticulohistiocytosis
- Malignant reticulosis
- Histiocytic medullary reticulosis
- Sinusoidal haematolymphoid malignancy
- Malignant astrocytosis
- Aleukaemic reticulosis
- Histiocytic reticulosis

Definition. Malignant histiocytosis is a widespread neoplastic proliferation of histiocytic cells that typically involves liver, spleen, lymph nodes and bone marrow. The cells usually arise from sinusoidal histiocytes, although very rare cases of malignant histiocytosis of Langerhans' cell phenotype have been reported.

Aetiology. Malignant histiocytosis is a neoplastic proliferation of cells of the mononuclear phagocyte system. There is no evidence of a viral aetiology in this disease and no reported familial incidence. There have been reports of a characteristic chromosomal translocation t(5;6)(q35;p21) in malignant histiocytosis [1,2]. The major problem with these reports is that the large cell anaplastic lymphoma (Ki-1-positive lymphoma) is often grouped with malignant histiocytosis, but these are T-cell lymphomas. However, the 5q35 break-point does appear to be specific for malignant histiocytosis [3].

Incidence. Malignant histiocytosis is a rare disease with a male to female ratio of 3.5 : 1. It has been reported in all age groups, with a median age of 35 years [4]. Childhood disease is uncommon with few reported series [5]. The disease tends to occur earlier in women (second to third decades) than in men (third to fourth decades) [6]. Reports have suggested an increased incidence of this disease in parts of tropical Africa, with reports from Malawi [7] and Uganda [8].

Pathology. The histological picture in skin and lymph nodes is similar and the diagnosis can be established in either site. Characteristically, there is an infiltrate of histiocytic cells showing varying degrees of atypia that are typically non-cohesive. Cells are large (up to 50 μm in diameter) with abundant cytoplasm and distinct cytoplasmic membranes.

The histiocytic cells are heterogeneous. Some show more marked histiocytic differentiation, with pale cytoplasm, prominent vacuolation or even foamy cytoplasm, and exhibit phagocytosis of erythrocytes, leukocytes and cellular debris. Other cells are more 'primitive', with deeply eosinophilic or amorphous cytoplasm. Nuclei are usually lobulated, with finely granular or reticulated chromatin and prominent or bizarre nucleoli. Nuclear membranes tend to be thickened. Mitoses are common.

Cytochemical and immunohistochemical studies have shown that the cells in malignant histiocytosis are negative for chloracetate esterase, Sudan black B, alkaline phosphatase and β-glucuronidase [9]. Presence of non-specific esterase, acid phosphatase and lysozyme is variable, with the better differentiated cells showing these enzymes [10]. The more differentiated phagocytosing cells usually stain for factor XIIIa and the antimonocyte monoclonal antibody MOI [11]. In some cases, EMA, HLA-DR, CD25, CD30, CD68 and CD71 have been detected. In rare cases, CD1a or CD21/35 may be found. In lymph nodes, the architecture is disarranged but not effaced by the malignant cells.

In the skin, there is extensive perivascular and periappendageal infiltration of the dermis, with extension into subcutaneous fat. In advanced lesions, fat necrosis may occur. The epidermis and papillary dermis are characteristically spared but in the more tumid lesions epidermal ulceration may be present.

Clinical features. Malignant histiocytosis is usually of acute onset, with fever, sweats, wasting, generalized painful lymphoadenopathy and hepatosplenomegaly. As the disease progresses, jaundice, purpura, anaemia and leukopenia occur. In 50% of patients, extranodal extension of the disease is seen, most commonly affecting the skin, bone and gastrointestinal tract.

In the skin, single or multiple lesions may be present [12,13], ranging from skin coloured to violaceous. Large lesions may ulcerate. A widespread, papulonodular eruption similar to that in acute monocytic leukaemia may also be seen.

In bone, the lesions are focal, destructive, lytic and may become widespread with associated hypercalcaemia. Gastrointestinal involvement is usually observed late in the disease. Small and large bowel may be involved, with infiltration of the lamina propria and local intraluminal masses. This presents with obstruction or haemorrhage or both. A rare presentation with multiple lesions is with malabsorption.

In the past, this disease has been associated with a poor prognosis. However, with aggressive management (radiotherapy or radiotherapy and chemotherapy) complete remission has been reported in up to 50% of cases, with a mean duration of complete remission of over 12 months [4]. Microscopic evidence of vascular invasion carries a poor prognosis.

Diagnosis. The major differential diagnosis is with large cell anaplastic lymphomas, in which the clinical and histological features

may be similar. Other diseases that may be confused with malignant histiocytosis are familial haemophagocytic lymphohistiocytosis, virus-associated haemophagocytic syndrome, Hodgkin's disease and SHML. Diagnosis can usually be established on clinicopathological features of the disease, although special stains may be needed to exclude large cell anaplastic lymphoma.

Treatment. Malignant histiocytosis is sensitive to both radiotherapy and chemotherapy but treatment must be started early, as many patients die before therapy can be started [5]. Chemotherapy is usually with a combination regimen, which includes doxorubicin and radiotherapy. In one series, complete remission was achieved in seven of nine patients treated [4]. In a study of 27 children with malignant histiocytosis, complete remission was achieved in 22 children using a regimen of vincristine, cyclophosphamide, doxorubicin and prednisolone, with a 5-year survival of 81% [14]. In patients who relapse after conventional chemotherapy, autologous bone marrow transplantation has successfully achieved long-term remission [15]. Large skin tumours or ulcerated tumours can be treated with local radiotherapy. A review of the treatment of malignant histiocytosis has been published [16]. Conventional chemotherapy and radiotherapy are still the mainstay of treatment.

True histiocytic lymphoma

Synonyms
- Reticulum cell sarcoma
- Histiosarcoma
- Monocytic sarcoma

Definition. A malignant histiocytic neoplasm that may disseminate.

Aetiology. The aetiology is unknown. The disease represents malignant proliferation of non-Langerhans' cell histiocytes or more rarely of Langerhans' cells. Differentiation from malignant histiocytosis may be difficult.

Pathology. True histiocytic lymphoma exhibits many of the features described in malignant histiocytosis, infiltrating cells being predominantly dermal and non-cohesive. Nemes and Thomazy [1] suggest that the cells in true histiocytic lymphoma are more differentiated than those in malignant histiocytosis and that the cell population is more homogeneous, showing phagocytosis and labelling for factor XIIIa. These cells stain with macrophage markers CD11c and CD68 and are negative for T- and B-cell markers [2]. A rare spindle cell variant has been described which expressed CD163, CD68, CD45, lysozyme and NSE [3].

Clinical features. This is a localized tumour of malignant histiocytes that may be nodal or extranodal. In 40% of patients, presentation is with the painless enlargement of one or more groups of superficial lymph nodes. Constitutional symptoms of malaise, anorexia, sweating and fever may be present.

Extranodal presentation may be with bone, gastrointestinal tract or skin lesions. Bone and gastrointestinal tract lesions are as described in malignant histiocytosis. Skin lesions are localized bluish-red tumours that can attain a large size. An isolated skin tumour of true histiocytic lymphoma in a 79-year-old patient has been described that reached 20 cm in diameter at presentation [4]. In one case report from Japan, an isolated dark-red skin tumour developed on the leg of a 49-year-old woman. Histology showed a monomorphous infiltrate of large cells, with erosion of the overlying epidermis. These cells were CD1a positive and on electron microscopy contained multiple Birbeck granules. This Langerhans' cell, true histiocytic lymphoma disseminated to regional lymph nodes, liver, lungs, kidneys, bone marrow and skin and the patient died 3 years after diagnosis [5]. Hepatosplenomegaly occurs in only a minority of patients with true histiocytic lymphoma, and peripheral blood involvement is rare. In one case report, a 44-year-old man with true histiocytic lymphoma was treated with autologous bone marrow transplantation and subsequently developed histiocytic leukaemia classified as M5c monocytic leukaemia [6].

Prognosis. True histiocytic lymphoma is treatable, and the prognosis is probably better than in malignant histiocytosis.

Treatment. True histiocytic lymphoma is both radiosensitive and chemosensitive. Complete remission has been achieved in localized skin disease using electron-beam therapy [4]. Reports of therapeutic responses are difficult to evaluate because of doubt over the diagnosis in older series.

Introduction

For many clinical dermatologists, soft-tissue tumours arising in the dermis, subcutis or deeper soft tissues are a confusing group of lesions. This is probably partly explained by the facts that there

is a very long list of soft-tissue tumours, and that a large majority of these can arise in the skin or affect it secondarily. Most of these tumours have no characteristic clinical appearance, and present as non-specific, dermal, or deep-seated nodules. However, it is necessary for all clinical dermatologists to have an understanding of the range of tumours that may arise in the dermis, and also of the likely biological behaviour of individual lesions. Although cutaneous malignant soft-tissue tumours are rare, many benign lesions may be histologically confused with a malignancy. Furthermore, there is a group of soft-tissue tumours that have low-grade malignant potential (intermediate malignancy) with frequent local recurrences but little or no potential for metastatic spread (e.g. dermatofibrosarcoma protuberans). These tumours may cause important morbidity, and their recognition is therefore essential for the planning of treatment and follow-up. Recognizing a wide range of soft-tissue tumours is also important as a number of these lesions—particularly when multiple—may be markers of genetic syndromes (for example, multiple neurofibromas and plexiform neurofibroma in neurofibromatosis type I).

A broad division can be made between tumours according to the morphological lines of differentiation. The latter include fibroblastic, myofibroblastic, neural, vascular, muscular and adipocytic types. In a number of tumours, the line of differentiation is not clear, as a normal cell of origin cannot be identified (e.g. epithelioid sarcoma). In a still larger group of tumours, their origin is descriptively ascribed to fibrohistiocytic cells, but with mounting evidence that many of these lesions have fibroblast and/or myofibroblastic differentiation and almost none display true histiocytic differentiation. The list of tumours discussed in this chapter is not all-inclusive. For a full account of the very wide range of these tumours, the reader is referred to the standard major work in this field [1]. True histiocytic tumours are discussed in Chapter 55, and keloids and hypertrophic scars in Chapter 45. Metastatic malignant tumours are covered in Chapter 62.

The most useful biological triage is into totally benign lesions; lesions that may recur locally but never or almost never metastasize; and those that are truly malignant and may metastasize. The great majority of dermal or superficial soft-tissue tumours come into the first two categories, whilst truly malignant soft-tissue tumours much more frequently arise below the deep fascia. In the case of these rare malignant tumours, there is a relationship between bulk and prognosis, smaller lesions carrying a better prognosis. More superficially situated lesions tend to carry a better prognosis than those deeply situated. Mitoses (particularly abnormal mitotic figures) and necrosis both tend to be associated with malignant rather than benign lesions.

The usual clinical presentation of many of the tumours described in this chapter is of a non-specific lump or nodule. An incisional biopsy should be arranged, and it must be adequately deep so that the nature of the lesion at its deepest margin can be determined. Once the pathologist has established the nature of the tumour, appropriate definitive surgery can be planned. Prior consultation with the pathologist is strongly recommended, as samples may be needed for cytogenetics, electron microscopy or immunohistochemistry. All of these may be helpful in arriving at an accurate diagnosis.

Fibrous and myofibroblastic tumours

Fibrous papule of the face [1]

Synonym
- Fibrous papule of the nose

Definition and incidence. A small facial papule with a distinctive fibrovascular component on histological examination. The condition is relatively common, and several large series have been reported [2–4].

Clinical features [2–4]. The lesions usually occur singly on the nose. Occasionally, they may occur on the forehead, cheeks, chin or neck, and there may be several lesions [5]. The lesion usually presents in middle life, and both sexes are equally affected.

The papule develops slowly as a dome-shaped, skin-coloured or slightly red or pigmented lesion, which is usually sessile. Most are asymptomatic, but about one-third bleed on minor trauma.

Pathology [2–4]. The epidermis appears normal, although there may be an increased number of clear cells overlying the lesion. In the dermis there is increased collagen with a hyalinized appearance and scattered, somewhat dilated vascular channels (Fig. 56.1). In the background there is increased cellularity with mono- and multinucleated cells with a histiocyte-like appearance. In some lesions epithelioid or clear cells may predominate [6,7]. There are prominent dilated capillaries, but relatively few elastic fibres.

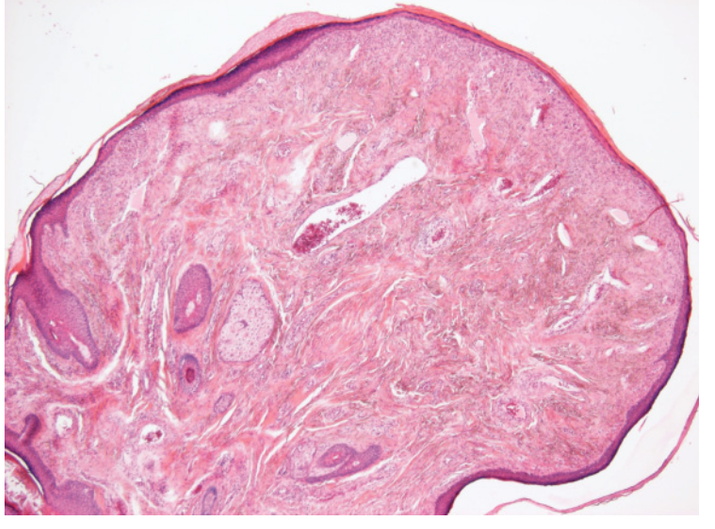

Fig. 56.1 Fibrous papule with hyalinized collagen bundles and increased dilated vascular channels.

It has been suggested that the condition may be a variant of a melanocytic naevus [2,4], but others disagree [3]. S100 protein, which is an immunohistochemical marker of neuroepithelial elements, is present neither in the stellate cells in the papillary dermis nor in the mesenchymal 'naevus' cells [8].

Treatment. The lesion is benign, but it may easily be excised or surgically pared for cosmetic reasons.

Storiform collagenoma [1,2]

Synonym
- Sclerotic fibroma

Definition. Storiform collagenoma is a fibrous hypocellular cutaneous lesion which, when multiple, may be associated with Cowden's disease or PTEN hamartoma syndrome (multiple hamartoma and neoplasia syndrome; see Chapter 62) [3].

Clinical features. It usually presents as a small, solitary, asymptomatic papule in adults of either sex, with wide anatomical distribution.

Pathology. It typically consists of a fairly well-circumscribed dermal nodule with prominent, hypocellular, hyalinized collagen bundles in a storiform pattern (Fig. 56.2). Bland spindle-shaped cells are rare. A similar histological pattern may be seen in the late stages of lesions as diverse as pleomorphic fibroma, fibrous histiocytoma (FH) and myofibroma and it has been proposed that it does not represent a distinctive entity but a reaction pattern [4,5].

A more cellular variant containing multinucleated bizarre cells has been described as giant cell collagenoma [6]. The latter is a potential link between pleomorphic fibroma (see below) and sclerotic fibroma as it has been proposed that both entities are part of the same spectrum [7].

Treatment. Simple excision is curative.

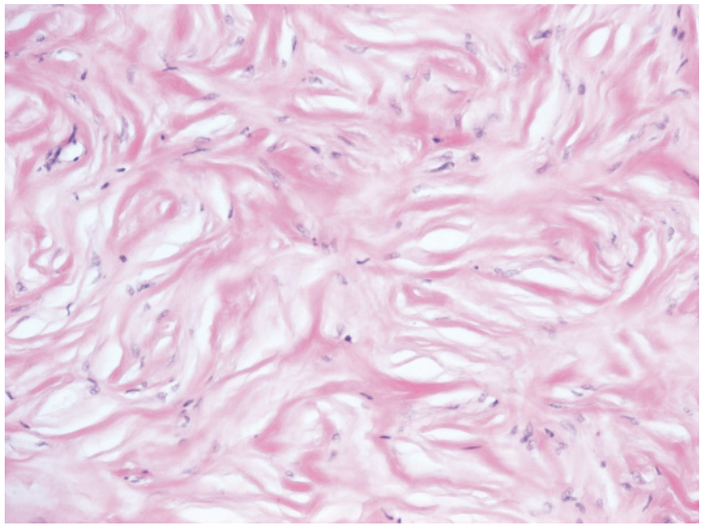

Fig. 56.2 Storiform collagenoma. Poorly cellular stroma composed of hyalinized collagen in a storiform pattern.

Pleomorphic fibroma

Definition [1]. Pleomorphic fibroma is a relatively rare lesion with features very similar to those of a fibroepithelial polyp (skin tag), but characterized histologically by bizarre mono- or multinucleated stromal cells.

Clinical features. Lesions present in adults as a polyp, with no sex predilection and a wide anatomical distribution, including a subungual location [2].

Pathology. Normal or mildly acanthotic epidermis surrounds a collagenous and vascular stroma containing scattered bizarre mono- or multinucleated cells with hyperchromatic and pleomorphic nuclei. Mitotic figures are rare.

Treatment. Simple excision is curative, and there is no tendency for local recurrence.

Acquired digital fibrokeratoma [1]

Definition. A benign lesion, possibly a reaction to trauma, which occurs on the fingers and toes [2] (Fig. 56.3), although the palms and the soles have occasionally been involved.

Clinical features. The lesion usually occurs in adults as a solitary, dome-shaped lesion, with a collarette of slightly raised skin at its base. Occasionally, it may be elongated or pedunculated. Giant lesions may occasionally occur [3]. The surface may appear to be slightly warty.

There is a wide clinical differential diagnosis, which includes dermatofibroma, viral wart, supernumerary digit and cutaneous horn. Histologically, the lesion is extremely similar to the Koenen tumour [4], the periungual fibrous papule that arises from the nail fold in tuberous sclerosis.

Pathology. The histology shows thick collagen bundles, thin elastic fibres and increased vascularity. Occasionally, there is an obvious increase in fibroblasts, and rarely the collagen bundles may be separated by oedema [5]. The epidermis is relatively normal, but acanthosis and hyperkeratosis may occur.

Treatment. Acquired digital fibrokeratoma is cured by simple excision.

Nodular fasciitis [1–4]

Synonym
- Subcutaneous pseudosarcomatous fibromatosis

Definition. A rapidly enlarging subcutaneous nodule, which is due to a benign proliferation of myofibroblasts and fibroblasts and has a superficial resemblance to a sarcoma.

Incidence and aetiology. A number of quite large series have been published in the last 10 years, suggesting that the condition is not uncommon. It is most frequent in young adults, but has been reported in patients from 5 months to 75 years. There is no predilection for either sex. It is not associated with other diseases. There is no evidence that trauma initiates the lesions.

Clinical features [1–4]. The majority of tumours appear as tender, rapidly growing masses beneath the skin. The average size is 1–3 cm in diameter. The commonest situation is the upper extremities, particularly the forearm, but the lesion can occur anywhere, including the orbit and the mouth [5]. Lesions on the head and neck often present in children. In nearly half the patients, the tumour has been noticed for only 2 weeks or less when they come for advice.

Pathology [1–4]. These lesions may look extremely worrying in view of the high mitotic rate and rapid growth (see below). The tumour is only focally circumscribed and it is composed of bundles of fairly uniform fibroblasts and myofibroblasts with pink cytoplasm, vesicular nuclei and a single, small nucleolus. Myxoid change and mucin deposition is often prominent, resulting in a typical tissue culture-like appearance (Fig. 56.4). In the background, there are numerous small, delicate blood vessels, extravasated red blood cells and scattered mononuclear inflammatory cells. Multinucleated giant cells may be seen, and they resemble osteoclasts. Mitoses are usually numerous, but there are no abnormal forms. Hyalinized collagen bundles are often present and may display a keloidal appearance. At the periphery, compact bundles of fibroblasts and capillaries probe the fascial planes and may infiltrate fat or skeletal muscle. It is not surprising that this histological picture is relatively often confused with that of a malignant tumour. Variants of nodular fasciitis include those with metaplastic bone (ossifying fasciitis); a variant that involves the periosteum (periosteal fasciitis); a variant that involves the scalp and tends to occur in children (cranial fasciitis); and a variant within the lumen of a blood vessel (intravascular fasciitis) [6]. A rare variant of intradermal nodular fasciitis has also been described [6,7]. Intra-articular location may also be seen [8]. Tumour cells are variably positive for smooth muscle actin and calponin [9] and usually negative for smooth-muscle markers including desmin and h-caldesmon [10]. The histological diagnosis may be very difficult, especially in small biopsies. Confusion with a sarcoma

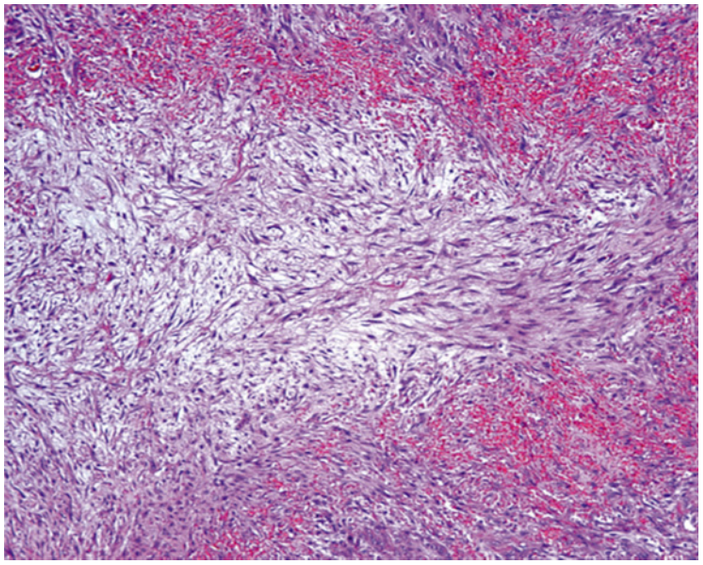

Fig. 56.4 Typical tissue culture-like appearance of nodular fasciitis with prominent myxoid background.

or with fibromatosis are major pitfalls, with obvious detrimental consequences.

Immunohistochemistry may be useful in the distinction between fibromatosis and nodular fasciitis. The former tend to display nuclear beta-catenin positivity, while the latter are usually negative or display cytoplasmic positivity only [11]. However, some fibromatoses, especially those superficially located, are negative for this marker and the diagnosis should be based on careful clinicopathological correlation.

Treatment. Resolution usually follows incomplete surgical removal. Simple excision is therefore an adequate treatment. Local recurrence is exceptional.

Fibro-osseous pseudotumour of the digits [1,2]

Definition. This is a reactive myofibroblastic proliferation with bone formation, which occurs exclusively on the digits.

Clinical features. It presents predominantly in young adults, with a predilection for females. The fingers are more commonly affected than the toes. The lesion grows rapidly and it is not attached to bone.

Pathology. The tumour is ill-defined and similar to nodular fasciitis, except for the fact that there is formation of osteoid and mature bone. Oedematous stroma, vascular proliferation and bundles of spindle-shaped myofibroblast-like cells are seen intermixed with osteoid and mature bone. Mitotic figures are found and their number depends on the age of the lesion.

Treatment. Local recurrence is rare, and excision is the treatment of choice.

Ischaemic fasciitis [1–4]

Synonym
- Atypical decubitus fibroplasia

Definition. Ischaemic fasciitis is a reactive fibroblastic/myofibroblastic proliferation that simulates malignancy and occurs as a result of alterations in local circulation and sustained pressure.

Clinical features. Most patients are elderly and immobilized, and there is a slight predilection for females. The lesion presents as an asymptomatic subcutaneous mass, predominantly over bony prominences that may extend to deeper soft tissues and to the overlying dermis.

Pathology. The lesion is poorly circumscribed and contains areas of fibrosis, vascular proliferation, necrosis and focal myxoid change. Thrombosed blood vessels with recanalization and areas of fibrinoid necrosis, focal haemorrhage and mononuclear inflammatory cells are additional features. In the background, there are variable numbers of spindle-shaped myofibroblasts/fibroblasts with vesicular or hyperchromatic nuclei and a prominent nucleolus. Mitotic figures may be seen, but are not prominent.

Treatment. Excision of the lesion is an adequate treatment.

Superficial acral fibromyxoma [1,2]

Definition. Superficial acral fibromyxoma is a distinctive, recently delineated, benign, dermal and/or subcutaneous, fibroblastic tumour with a strong predilection for hands and feet.

Incidence and aetiology. Lesions are relatively rare and are regarded as neoplastic.

Clinical features. Most cases present as a long-standing, solitary mass measuring between 1 and 2 cm, on the hands and feet (particularly the digits, often in a subungual location), of middle-aged adults and with some predilection for males.

Pathology. Tumours are circumscribed and consist of bland stellate and spindle-shaped cells in a variably prominent myxoid and collagenous stroma and with small blood vessels in the background. Some lesions are more cellular and have been described in the literature under the rubric of cellular fibroma of the digits [3]. In myxoid areas, mast cells are often seen. Scattered multinucleated cells may be seen in some cases. Mitotic figures are very rare. Tumour cells are diffusely positive for CD34 and may be focally positive for EMA and CD99.

In the past, it is likely that these tumours were classified as neurofibromas because of the cytomorphology of tumour cells and the myxoid background, with fairly frequent mast cells. However, neurofibroma is rare in acral sites and tumour cells are positive for S100 and only focally positive for CD34.

Prognosis and treatment. These lesions are entirely benign and local recurrence is very rare. Simple local excision is the treatment of choice.

Fibrous hamartoma of infancy [1–5]

Definition. This is a benign, fibroblastic/myofibroblastic, deep dermal and subcutaneous tumour presenting in children and characterized by three distinctive pathological components, as described below.

Incidence and aetiology. This is a rare tumour, often considered to be a hamartoma, but probably neoplastic in nature.

Clinical features. Most cases present in children aged under 2 years, as an asymptomatic, solitary, skin-coloured plaque/nodule only a few centimetres in diameter. Rarely, pigmentary changes and or hypertrichosis may be seen [6]. A quarter of the cases present at birth. Males are more affected than females. The tumour grows rapidly and has a predilection for the axillae, arm and shoulder girdle [1–3]. A familial association has not been reported.

Pathology. The tumour is composed of three components:
1 Bundles of interlacing, elongated, bland, wavy spindle-shaped cells in a variable collagenous background
2 Nests of more immature round cells with focal myxoid change
3 Mature adipose tissue.
A focal resemblance to a neurofibroma may be seen when the first component predominates, but tumour cells are actin-positive and S100-negative [7].

In the dermis overlying the tumour, eccrine glands may show secondary changes including hyperplasia, papillary projections and squamous syringometaplasia [8].

Treatment. Simple excision is the treatment of choice [5]; recurrences are exceptional.

Calcifying fibrous tumour/pseudotumour [1–3]

Definition. This is a rare, benign, hypocellular tumour characterized by dense collagen bundles, areas of calcification and a patchy mononuclear cell infiltrate. This lesion has no relation with inflammatory myofibroblastic tumour as was originally suggested [3].

Clinical features. Most lesions occur in children, and less commonly in young adults, as a fairly large, subcutaneous or deeper asymptomatic mass with a wide anatomical distribution. Cases may also occur in internal organs [3].

Pathology. The tumour typically consists of haphazardly arranged collagen bundles with scattered bland fibroblasts, focal small calcifications and focal aggregates of lymphocytes and plasma cells. Tumour cells are positive for CD34 and may be focally positive for smooth-muscle actin and more rarely for desmin [3].

Treatment. Local recurrence is rare, and the treatment of choice is simple excision.

Calcifying aponeurotic fibroma [1,2]

Definition. This is a rare, fibroblastic tumour characterized by a nodular proliferation of bland spindle-shaped cells surrounding nodules at different stages of calcification. Cartilage and, less commonly, bone formation may be seen.

Clinical features [1]. Most cases present in children, with a predilection for the hands and, less commonly, the feet. Occurrence at other sites is rare but tumours may present in places as diverse as the knee, the back and the thigh [2]. Tumours are small, slowly growing and usually asymptomatic. Multiple lesions are exceptional [3].

Pathology. The growth pattern is multinodular. Tumour cells are elongated, with scanty pink cytoplasm, vesicular nuclei and very rare mitotic figures. Tumour nodules frequently contain areas of calcification, which are surrounded by tumour cells in a pattern reminiscent of palisading.

Treatment. Local recurrence is observed in up to 50% of the cases, but malignant transformation is exceptional [4] and conservative treatment is therefore indicated.

Dermatomyofibroma

Synonym
- Dermal plaque-like fibromatosis

Definition [1–4]. A benign, dermal and superficial subcutaneous myofibroblastic proliferation microscopically mimicking a fibromatosis. The tumour, however, has no potential for local recurrence and lacks an infiltrative growth pattern.

Clinical features. It presents as a solitary, asymptomatic, skin-coloured or hypopigmented plaque measuring less than 4 cm in diameter. Multiple lesions are rarely seen and an exceptional case has presented with a linear pattern [5]. Most lesions occur on the trunk, and there is a predilection for young adults, particularly females. Children are only exceptionally affected [6].

Pathology. Low-power examination reveals a plaque-like proliferation of fascicles of myofibroblast-like cells with an almost parallel orientation to the epidermis. Tumour cells are bland, and mitotic figures are very rare. The tumour does not destroy adnexal structures, but may extend focally into the subcutaneous tissue. Rare cases with haemorrhage may mimic plaque-stage Kaposi's sarcoma [7]. The latter, however, is always positive for human herpes virus 8 (HHV8). Tumour cells are variably positive for smooth-muscle actin and calponin.

Treatment. Simple excision is curative.

Angiomyofibroblastoma [1–4]

Definition. Angiomyofibroblastoma is a distinctive, benign neoplasia that occurs almost always in the pelvis and perineum, particularly affecting the vulva. There is some overlap with another tumour that presents in the pelvis and perineum (cellular angiofibroma, see below) and also with aggressive angiomyxoma [5].

Clinical features. Tumours are rare and present mainly in the vulva of young to middle-aged females and rarely elderly women. Cases in males are exceptional and usually affect the scrotum. Lesions are subcutaneous, asymptomatic and measure less than 5 cm in diameter.

Pathology. Lesions are well-circumscribed and consist of a mixture of round and spindle-shaped bland cells in a myxoid or oedematous stroma with numerous small, dilated blood vessels. There is a tendency for tumour cells to surround the vascular

channels. Mitotic activity is not usually present. In a number of cases there are collections of mature adipocytes [4].

Cytological atypia secondary to degeneration is sometimes seen. Tumour cells are positive for desmin and for oestrogen and progesterone receptors. They are only focally positive for smooth-muscle actin and muscle-specific actin. Some tumours are variably positive for CD34.

Prognosis and treatment. Tumours are benign with no tendency for local recurrence. The treatment is simple excision. Only one malignant tumour has been reported [6].

Cellular angiofibroma [1–4]

Synonym
- Male angiomyofibroblastoma-like tumour

Definition. Cellular angiofibroma is a distinctive, benign neoplasm that occurs almost exclusively in the vulva and less commonly in the scrotum and inguinal soft tissues of men. Some cases overlap histologically with angiomyofibroblastoma and a relationship with spindle cell lipoma has been suggested [2].

Clinical features. Tumours are relatively rare, affecting mainly females and presenting as a small, well-circumscribed, asymptomatic, subcutaneous nodule. In males tumours tend to be larger and may be related to a hydrocele or a hernia [2].

Pathology. Tumours are sharply circumscribed but not encapsulated and are characterized by short, usually bland, spindle-shaped cells with scanty, ill-defined pale pink cytoplasm. These cells are arranged in bundles and the degree of cellularity varies. In the background there are thin collagen bundles and numerous small to medium-sized blood vessels. Mitotic figures are rare and cytological atypia may be occasionally seen in some cases. Scattered mononuclear inflammatory cells, mainly lymphocytes, and degenerative changes are often identified. The latter consist of haemorrhage, thrombosis, hyalinization and haemosiderin deposition. In myxoid areas, mast cells are present and many tumours contain variable numbers of mature adipocytes. The most consistent immunohistochemical finding is the presence of diffuse positivity for CD34 in many cases. Muscular markers including actin and desmin tend to be negative but positivity has been reported in male tumours. In a few cases, there is focal positivity for oestrogen and progesterone receptors.

Prognosis and behaviour. Lesions are benign and there is no tendency for local recurrence. Simple excision is the treatment of choice.

Elastofibroma [1–3]

Definition. Elastofibroma is a reactive, probably degenerative, process of the elastic fibres of deep soft tissues that occurs almost exclusively around the shoulder. Although the lesion is regarded as degenerative, the finding of chromosomal alterations (see below), and of clonality in some cases, has led to the suggestion that it represents a neoplastic process [4].

Clinical features. It presents as an asymptomatic, slowly growing mass on the posterior upper trunk of middle-aged individuals. Lesions in other locations, including internal organs, are exceptional. Multiple lesions are usually bilateral and may be symmetrical [5].

Pathology. The mass is poorly circumscribed, and the appearances are characteristic. Abundant hypocellular hyalinized collagen containing numerous large, thick eosinophilic elastic fibres is the most distinctive feature. Sometimes the fibres are beaded and fragmented. Staining for elastic tissue nicely highlights the changes. Comparative genomic hybridization in a series of elastofibromas has found chromosomal alterations in a percentage of cases. The most common alteration consists of gains at chromosome Xq12-q22 [6].

Treatment. Simple excision is all that is necessary, as the tumours do not have a tendency to recur.

Infantile myofibromatosis and adult myofibroma [1–6]

Synonyms
- Congenital generalized fibromatosis
- Infantile haemangiopericytoma

Definition. This tumour is composed of cells showing differentiation towards perivascular contractile cells, and has been described in the past as infantile haemangiopericytoma [7]. Infantile myofibromatosis and adult myofibroma/myofibromatosis are best regarded as part of the spectrum of lesions recently described as myopericytomas (see section on tumours of perivascular cells, p. 56.42) [8,9].

Clinical features [1–3]. Most cases of infantile myofibromatosis present before the age of 2 years, with slight male predominance. Congenital tumours occur in up to a third of the cases. Multiple lesions are present in 25% of patients. The preferred sites are the head and neck, followed by the trunk. Familial cases are rare. Involvement of other organs, including the gastrointestinal tract, lungs and bone, is seen in some cases. Multicentric involvement may be associated with mortality. Multiple lesions in the skin and soft tissues behave in a benign fashion and may regress spontaneously. Solitary myofibroma tends to occur in adults, with the same anatomical distribution as that of cutaneous and soft-tissue lesions presenting in infantile myofibromatosis [5,6]; multiple superficial tumours are rarely seen in adults. Intraoral lesions tend to be more common in young adults [10,11]. Exceptionally, associated thrombocytopenia has been reported [12].

Pathology [1,2,5–8]. Tumours have a distinctive biphasic growth pattern:

1 Areas composed of bundles of mature, spindle-shaped myofibroblasts with pink cytoplasm and vesicular nuclei
2 Areas composed of immature round cells, with scanty cytoplasm arranged around small blood vessels, often displaying a haemangiopericytoma-like pattern ('staghorn-like').

Protrusion of tumour cells into vascular lumina is frequent, often mimicking vascular invasion. Old lesions often undergo hyalinization of the more mature areas. Mitotic figures and necrosis are relatively common. Tumour cells, particularly in the mature areas, are focally positive for actin.

Treatment. Lesions tend to regress spontaneously, but it is important to remember that patients with visceral tumours may die from the disease. Solitary lesions are treated by simple excision and do not tend to recur locally.

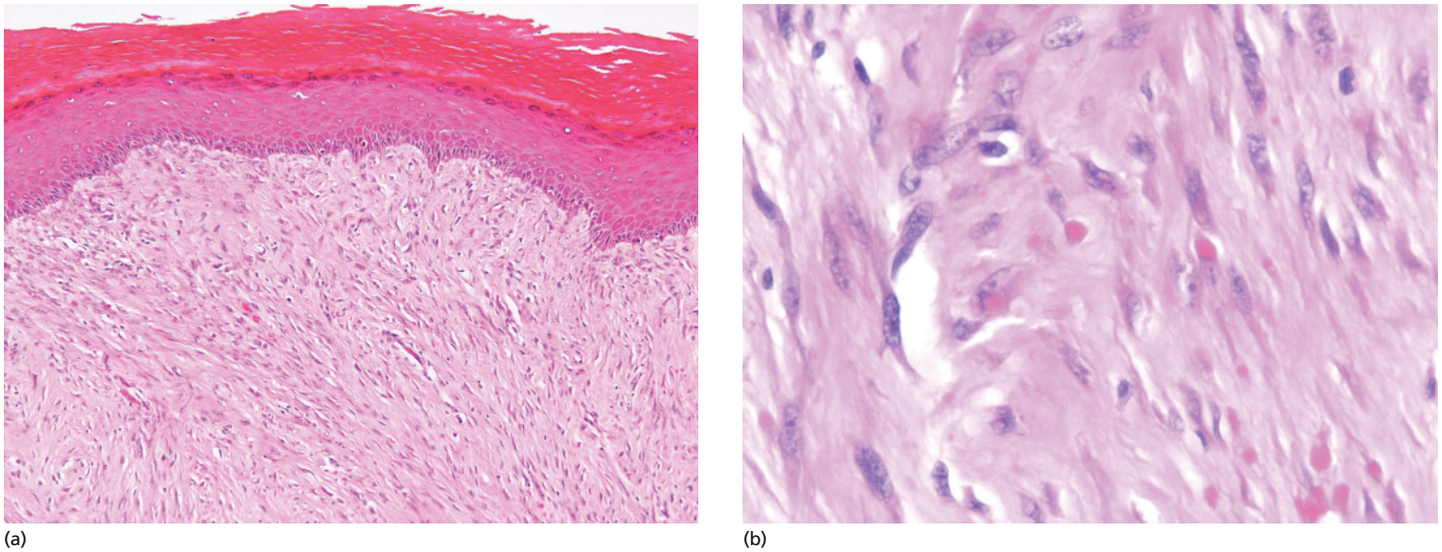
Inclusion body (digital) fibromatosis [1–3]



Synonym
- Infantile digital fibromatosis

Definition. Inclusion body fibromatosis is a fibro/myofibroblastic proliferation that almost only occurs on the fingers and toes. It is characterized by bright, round, intracytoplasmic, eosinophilic inclusions.

Clinical features. Most lesions present either at birth or during the first year of life as small, multiple nodules with predilection for the third, fourth and fifth digits. Involvement of the first digits (thumb and hallux) does not occur. New lesions often develop over a long period of time. Only rare cases have been described at other sites or in adults [4,5]. Spontaneous regression is sometimes seen [6]. Aggressive behaviour has not been described.

Pathology. Monomorphic bundles of bland, myofibroblast-like cells are seen in the dermis (Fig. 56.5a) and often the subcutis. Tumour cells have vesicular nuclei, an inconspicuous nucleolus and pink cytoplasm. Some mitotic figures may be seen. A distinctive feature is the presence of variable numbers of small, round, eosinophilic, intracytoplasmic inclusions in tumour cells (Fig. 56.5b). These are periodic acid–Schiff (PAS)-negative, but stain red with Masson's trichrome. They also stain for actin.

Treatment. Simple excision may be required for lesions that interfere with function, but simple observation of histologically confirmed lesions may be all that is necessary.

Fibroma of tendon sheath [1,2]

Definition. This is a distinctive, well-circumscribed fibroblastic tumour, presenting almost exclusively on the distal extremities.

Clinical features [1,2]. It is a small, slowly growing, asymptomatic tumour, presenting in young to middle-aged adults and with a marked predilection for the distal upper limb, particularly the hand and fingers. Rare lesions may present with carpal tunnel syndrome [3]. Lesions on the foot are much less common.

Pathology [1,2]. The neoplasm is multilobular and well-circumscribed and consists of cellular or poorly cellular areas on a background of variably hyalinized stroma. Stromal clefting is usually prominent. Tumour cells are spindle-shaped, with scanty cytoplasm and vesicular nuclei. Cytological atypia tends to be absent, and the mitotic count is low. A t(2;11)(q31-32;q12) has been demonstrated in a case of fibroma of tendon sheath [4].

Treatment. About 25% of cases recur locally, but the growth is not destructive. Simple excision is therefore the treatment of choice.

Collagenous fibroma [1,2]

Synonym
- Desmoplastic fibroblastoma

Definition. Collagenous fibroma represents a distinctive, subcutaneous, fibroblastic tumour consisting of a prominent collagenous stroma.

Clinical features. It is relatively common and presents in adults as an asymptomatic nodule less than 4 cm in diameter, at any body site.

Pathology. This is a well-circumscribed tumour composed of bland elongated or stellate cells, with a background collagenous stroma and focal myxoid change. Mitotic figures are very rare. A translocation t(2;11)(q31;q12) has been found in two cases of collagenous fibroma suggesting that this is a non-random association in this type of tumour [3].

Treatment. Simple excision is the treatment of choice, as there is no tendency for local recurrence.

Nuchal fibroma [1,2]

Definition. Nuchal fibroma is a dermal or subcutaneous tumour consisting of hypocellular dense collagen.

Clinical features. Tumours are rare and occur in adult males. Patients often have diabetes. The great majority of cases present on the nape of the neck. Coexistence with scleroedema is possible, probably reflecting the association with diabetes, and lesions identical to nuchal fibroma are now recognized to occur in Gardner's syndrome (Chapter 62) and are known as Gardner-associated fibromas [3,4]. The latter may be multiple, present in various locations and may recur. These lesions may be the first clue as to the existence of Gardner's syndrome.

Pathology. Dense aggregates of collagen with very few cells and entrapment of adipose tissue.

Treatment. Simple excision is the treatment of choice but local recurrence is possible.

Palmar and plantar fibromatosis (superficial fibromatoses) [1,2]

Synonym Plantar fibromatosis
- Ledderhose's disease

Synonyms Palmar fibromatosis
- Dupuytren's disease
- Dupuytren's contracture

Definition. Palmar and plantar fibromatoses are superficial neoplastic proliferations of fibroblasts and myofibroblasts that have a tendency for local recurrence, but do not metastasize.

Incidence and aetiology. Palmar fibromatosis is more common than plantar fibromatosis. Both lesions are more common in men, but the sex difference is more marked in palmar lesions. Both conditions affect middle-aged to elderly patients and are more uncommon in younger individuals. However, children may rarely be affected, particularly by plantar fibromatosis [3]. Affected patients are mainly of Northern European origin; non-whites are rarely affected. Coexistence between the two variants of fibromatoses and desmoid tumours, penile fibromatosis (Peyronie's disease) and knuckle pads may be seen. Genetic predisposition, as well as trauma, is thought to play an important role in the pathogenesis of these conditions. Associations with diabetes, alcoholic liver disease and epilepsy have also been described.

Clinical features. Palmar fibromatosis presents as indurated nodules or as an ill-defined area of thickening, bilateral in about 50% of cases, that may result in contracture. Plantar fibromatosis usually consists of a single nodule. Functional limitation is common.

Pathology. Early lesions are fairly cellular and consist of bundles of bland fibroblasts with some collagen deposition. The latter increases considerably in older lesions. Interestingly, although superficial fibromatoses are very similar histologically to deep fibromatosis (abdominal, extra-abdominal and mesenteric fibromatosis), the behaviour of superficial fibromatosis is not usually aggressive. This may be due to the fact that deep fibromatosis often display mutations of the *APC* gene or somatic mutations of the gene encoding beta-catenin, while these mutations are absent in superficial fibromatosis. Intriguingly however, although deep fibromatoses often display nuclear expression of beta-catenin, this is also seen in a smaller percentage of superficial fibromatoses without gene mutations [4].

Treatment. Complete excision is desirable, as there is otherwise a risk of local recurrence.

Penile fibromatosis [1–3]

Synonym
- Peyronie's disease

Definition. Although usually regarded as a variant of superficial fibromatosis, it is more likely that this disease represents a reactive fibrotic disorder of unknown aetiology.

Clinical features. It presents as a solitary nodule or multiple nodules close to the corpus cavernosum on the dorsal surface of the shaft. Most patients are middle-aged, and in most the lesion is small. Pain and curvature of the penis on erection are frequent complaints. The presence of diabetes mellitus increases the severity of the disease [4].

Pathology. In early lesions, there is a patchy chronic mononuclear inflammatory cell infiltrate and focal vasculitic changes. These changes lead to dense bands of hyalinized collagen in late stages.

Lipofibromatosis [1]

Definition. Lipofibromatosis is a locally aggressive childhood tumour composed of variable amounts of mature adipose and fibroblastic elements.

Clinical features. Tumours present in infants and children, with the majority of cases presenting in the first decade of life. Some tumours are congenital. There is a male predominance. The classical presentation is of a slowly growing, ill-defined mass. There is a predilection for the hands and feet, but other sites in the limbs, and less commonly on the trunk, may be affected. The rate of local recurrence is high.

Pathology. Tumours are infiltrative and consist of lobules of mature adipose tissue intermixed with bundles of fibroblast-like cells with no cytological atypia and low mitotic activity. By immunohistochemistry, tumour cells are focally positive for S100 protein, CD34, bcl-2, actin, EMA and CD99. The lesion closely resembles a fibrous hamartoma of infancy but has more prominent adipose tissue and lacks the third cellular component seen in the latter, which consists of round, primitive-looking cells in a myxoid background.

Prognosis and treatment. In view of the local aggressive nature of this tumour, complete excision is desirable.

Dermatofibrosarcoma protuberans [1–3]

Definition. Dermatofibrosarcoma protuberans (DFSP) is a locally invasive tumour arising in the dermis and showing fibroblastic differentiation.

Incidence and aetiology [1–3]. DFSP is uncommon, more common in black than in white patients, and slightly more common in females than males [4]. Most patients present in the third and fourth decades of life. The incidence in the USA has been estimated as 4.2 cases per million [4]. Some cases develop at the site of previous trauma, reports have included a burn scar [5] and the site of vaccination. Exceptional cases have been associated with previous radiotherapy to the area [6].

Fig. 56.6 Recurrent abdominal dermatofibrosarcoma protuberans.

Clinical features. The tumour is more often situated on the trunk (up to half of the cases), particularly in the flexural regions, than on the extremities or the head [1,2]. Involvement of the limbs is usually proximal. Presentation on hands and feet, particularly on the digits, is vanishingly rare. It may begin in early adult life with one or more small, firm, painless, flesh-coloured or red dermal nodules (Fig. 56.6). There are rare examples of DFSP occurring in infancy [7–9], and congenital cases have been described [9,10].

The tumour starts as a plaque, which may occasionally be atrophic [8,11]. Progression is usually very slow, and may occur over many years; a significant proportion of tumours only become protuberant after a long period of time [12]. Eventually, nodules develop, coalesce and extend, becoming redder or bluish as they enlarge to form irregular, protuberant swellings. At this stage, the base of the lesion is a hard, indurated plaque of irregular outline. In the later stages, a proportion of lesions become painful and there may be rapid growth, ulceration and discharge.

Local recurrence of ordinary DFSP is reported to vary from 15% to up to 60% [3,13,14], and that of the fibrosarcomatous variant is as high as 75% [15–18]. Metastases to lymph nodes and internal organs tend to be extremely rare in pure DFSP [15,19,20] but occur in up to 20% of cases with fibrosarcomatous transformation [16–18].

Pathology [1–3,13]. The tumour is usually a solitary, multinodular mass. The dermis and subcutaneous tissue are replaced by bundles of uniform, spindle-shaped cells with little cytoplasm and elongated hyperchromatic, but not pleomorphic, nuclei. Usually there is little mitotic activity. Deeper involvement may be seen in some cases. Laterally, the tumour cells infiltrate widely between collagen bundles of the deeper dermis and blend into the normal dermis, forming quite definite bands, which interweave or radiate like spokes of a wheel; this is described as a 'storiform' pattern (Fig. 56.7). The interstitial tissue contains collagen fibres, except in the most cellular parts of the tumour. The subcutaneous tissue is

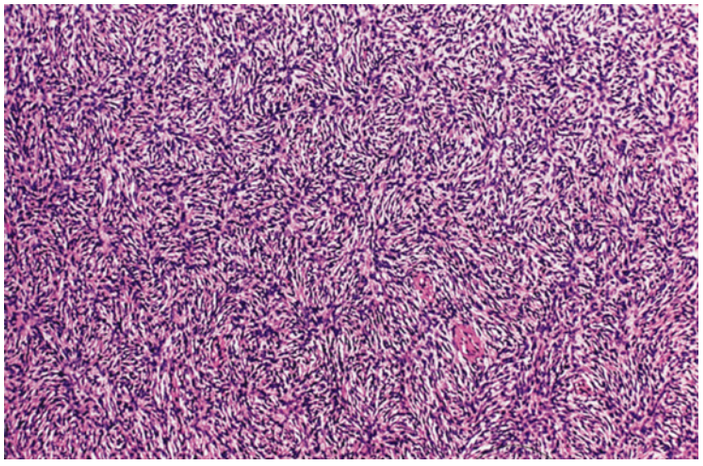

Fig. 56.7 Pathological appearance of dermatofibrosarcoma protuberans, showing the storiform or 'cartwheel' distribution of the fairly uniform, spindle-shaped tumour cells.

extensively infiltrated and replaced in a typical lace-like pattern. Myxoid change may be focal or, rarely, prominent; in the latter setting, the histological diagnosis is difficult [21,22]. Some tumours are colonized by scattered, deeply pigmented melanocytes, a variant known as pigmented DFSP (Bednar tumour) [23,24]. A further variant consists of myoid nodules and is thought to represent myofibroblastic differentiation [25]. Rare cases show focal granular cell change.

Fibrosarcomatous DFSP [16–18,26] is an important variant of this tumour, which is recognized by the focal presence of areas with long, sweeping fascicles of tumour cells intersecting at acute angles in a typical 'herring-bone' pattern, almost identical to that seen in fibrosarcoma. In these areas, mitoses are increased and there is more nuclear hyperchromatism. P53 expression is increased in fibrosarcomatous areas [26]. Identification of the presence of this pattern, and its quantity, is very important, as it is related to metastatic potential. Fibrosarcomatous areas are more common in recurrent tumours.

Very rare variants of DFSP may show areas of high-grade sarcoma either in the primary tumour or in a recurrence [27].

DFSP may show areas of giant cell fibroblastoma (see below) and either tumour may recur, displaying features of the other tumour [28].

The majority of the lesions are positive on staining with the antibody CD34, although this is not specific for DFSP [13]. Other markers are usually negative but in some cases focal positivity for epithelial membrane antigen may be seen. Fibrosarcomatous areas often show decreased staining with CD34 [18].

Cytogenetic studies are helpful, as ring chromosomes indicative of a 17;22 translocation are invariably found [28]. However, it is important to highlight that some cases demonstrate a variant ring chromosome with cryptic rearrangements of chromosomes 17 and 22 [29]. This chromosomal translocation involves the collagen type I alpha 1 (*COL1A1*) gene on chromosome 17 and the platelet-derived growth factor B (*PDGFB*) gene on chromosome 22. The abnormal fusion transcripts resulting from this translocation leads to autocrine stimulation of PDGFB and platelet-derived growth factor receptor beta (PDGFRB) and cell proliferation. The fusion transcript is found in almost all examples of the tumour by polymerase chain reaction (PCR) and fluorescence *in situ* hybridization (FISH) [30]. The same cytogenetic abnormality is found in giant cell fibroblastoma, confirming that both tumours are part of the same spectrum (see below).

Diagnosis. In the early stages, it may be impossible to distinguish this tumour from a histiocytoma or a keloid. Some lesions may also be confused with morphoea profunda. The slow progression, deep red or bluish-red colour, and the characteristic irregular contour and extended plaque-like base, are strongly suggestive of DFSP.

Treatment. The tumour should be excised completely, with a generous margin of healthy tissue [31]. The best chance of achieving a complete cure with no recurrence is early detection of small tumours. Local recurrence invariably follows inadequate removal; the clearance necessary to cure the tumour is often underestimated [32]. A margin of between 2 and 4 cm has been recommended [14,33]. Mohs micrographic surgery has been reported as effective in reducing the rate of local recurrence [34,35]. If this type of treatment is used it should be performed using formalin-fixed paraffin-embedded sections rather than frozen sections, and evaluation should be by an experienced pathologist. Although Mohs surgery clearly reduces the rate of local recurrences, the latter still occur and sometimes this happens more than 5 years after surgery [36]. Postsurgical radiotherapy has been advocated to reduce the rate of local recurrence [37] but this type of treatment has not been assessed in large series of patients. In recent years, it has been demonstrated that imatinib mesylate, a potent inhibitor of a number of protein kinases including the platelet-derived growth factor receptor, results in good clinical response in patients with large unresectable or metastatic tumours [38–42].

Giant cell fibroblastoma [1–4]

Definition. This is a locally recurrent, fibroblastic tumour, closely related to DFSP. It is characterized by spindle-shaped, oval or stellate, mono- or multinucleated cells in a fibromyxoid stroma with irregular pseudovascular spaces lined by tumour cells.

Clinical features [1–4]. The large majority of cases present as a subcutaneous, ill-defined mass in the first few years of life. It is rare in young adults and more exceptional in older adults. The trunk is much more commonly involved than the proximal limbs. Tumours measure a few centimetres in diameter, have a predilection for males and tend to be asymptomatic.

Pathology. Solid fibromyxoid areas with variable collagen deposition contain stellate and spindle-shaped mono- and multinucleated tumour cells with hyperchromatic nuclei. Dilated, irregularly branching pseudovascular spaces are commonly seen scattered throughout the lesion. These spaces are lined by tumour cells, which often appear multinucleated (Fig. 56.8). Mitotic figures are exceptional. Aggregates of perivascular lymphocytes in an onion-ring pattern and focal haemorrhage are often seen [4]. Focal areas identical to DFSP may be seen and can occupy a substantial part of the tumour. Excised lesions can recur as a pure giant cell fibroblastoma, as a tumour with focal DFSP, or as pure DFSP [4–7]. Tumour cells are focally positive for CD34 and only very focally positive for actin. Ring chromosomes with sequences of chromosomes 17 and 22, identical to those found in DFSP, have been described in this tumour, confirming their close histogenetic relationship [8,9].

Treatment. Recurrence may be seen in about half of the cases, but metastasis has not been reported.

Myxoinflammatory fibroblastic sarcoma [1–3]

Synonyms

- Inflammatory myxohyaline tumour of the distal extremities with virocyte or Reed–Sternberg-like cells
- Acral myxoinflammatory fibroblastic sarcoma

Definition. Myxoinflammatory fibroblastic sarcoma is a distinctive, neoplastic process with marked predilection for acral sites, and with histological features closely mimicking an inflammatory process due to the presence of prominent inflammation and virocyte-like inclusions in the nuclei of tumour cells. The latter features were initially thought to indicate an infectious aetiology. However, no firm evidence of this has yet emerged.

Clinical features. Most patients are middle-aged adults with an equal sex incidence. Characteristically, tumours are long-standing, asymptomatic and slowly growing, usually measuring no more than 4 cm. The great majority occur on acral sites, particularly the hands and wrists, followed by the feet. However, lesions may rarely present elsewhere on the limbs (arm, forearm and thigh) [4] and exceptionally elsewhere in the body, including the neck [5]. Most cases are clinically diagnosed as a ganglion cyst or as a giant cell tumour of tendon sheath.

Pathology. Lesions are lobulated and poorly circumscribed and involve the subcutaneous fat and often extend to the dermis and deeper tissues, sparing bone. Low-power examination is misleading and the initial impression is that of an inflammatory process. Lobules of hyalinized and myxoid tissue containing variable numbers of inflammatory cells are seen. The latter include lymphocytes, histiocytes, neutrophils and less commonly eosinophils and plasma cells. Closer examination reveals variable numbers of neoplastic cells that vary from round to spindle-shaped. Some of these cells may be multinucleated. Round cells mimic ganglion cells with nucleoli resembling viral inclusions. Less commonly, vacuolated tumour cells resembling lipoblasts are seen. Mitotic activity is very low. Immunohistochemistry shows that tumour cells are variably positive for CD34 and CD68 and are rarely positive for smooth-muscle actin and exceptionally for keratin. Very few cases have been subjected to cytogenetic studies [6,7]. In two cases published, one showed a complex karyotype with a reciprocal translocation t(1;10)(p22;q24) and loss of chromosomes 3 and 13 [6] and the other a translocation t(2;6)(q31;p21.3) [7]. These findings support the theory that these lesions are neoplastic.

Prognosis and treatment. The rate of local recurrence is high, varying from 11 to 67% in different series [1,2]. Distal metastases are exceptional and are mainly to regional lymph nodes. The treatment of choice is wide local excision and this often implies amputation.

Fibrohistiocytic tumours

Giant cell tumour of tendon sheath [1–3]

Definition. This is a benign tumour that in its localized variant occurs mainly on the hands, and consists of a nodular proliferation

of histiocyte-like cells with scattered multinucleated giant cells and variable numbers of mononuclear inflammatory cells. The diffuse variant of this tumour that involves joints is not discussed further in this chapter.

Clinical features. Tumours present mainly on the hands with predilection for the fingers. They are typically between 1 and 3 cm in diameter and asymptomatic, although they may interfere with function. There is a predilection for young females. Multiple tumours are very rare [4].

Pathology. It is a multinodular lesion composed of sheets of histiocyte-like cells with bland vesicular nuclei, intermixed with multinucleated giant cells, foamy cells, siderophages and scattered mononuclear inflammatory cells. Hyalinization, haemosiderin deposition and cholesterol clefts are often seen. No histological features predict lesions that recur locally [3].

Treatment. Excision is the treatment of choice; the rate of local recurrence is around 30%.

Fibrous histiocytoma (dermatofibroma) [1–4]

Synonyms
- Histiocytoma cutis
- Subepidermal nodular fibrosis
- Sclerosing angioma

Definition. Fibrous histiocytoma (FH) is a benign dermal and often superficial subcutaneous proliferation of oval cells resembling histiocytes, and spindle-shaped cells resembling fibroblasts and myofibroblasts. Their line of differentiation remains uncertain, but these lesions are descriptively classified as fibrohistiocytic tumours because of the microscopic appearance of the tumour cells. The aetiology of FH is unknown, but recent cytogenetic studies demonstrating clonality favour these lesions being neoplastic [5,6]. The neoplastic nature of FH is also suggested by their clinical persistence and by the frequency of local recurrence of some variants (cellular, aneurysmal and atypical; see below) as well as the exceptional anecdotal metastases of some tumours (cellular and atypical types). The previous theory that they are a dermal response to injury, such as an insect bite, has been challenged [7].

Clinical features. FH is commonest on the limbs and appears as a firm papule, which is frequently yellow-brown in colour and slightly scaly (Fig. 56.9). If the overlying epidermis is squeezed, the 'dimple sign' will be seen, indicating tethering of the overlying epidermis to the underlying lesion. Giant lesions (>5 cm in diameter) are occasionally seen [8] and large tumours are more often encountered in some of the variants (see below). Multiple lesions may develop and eruptive variants have been described. The latter may be familial [9], or may be associated with immunosuppression (HIV) [10], with systemic disease, including autoimmune diseases such as lupus erythematosus and neoplasia, particularly haematological malignancies [11–15], and even with highly active antiretroviral therapy (HAART) [16].

Fig. 56.9 Clinical appearance of a fibrous histiocytoma or dermatofibroma.

A number of clinicopathological variants of FH have been described, which should be recognized by clinicians and pathologists in order to avoid a misdiagnosis of malignancy. These variants include: cellular FH [17,18], aneurysmal FH [19,20], atypical FH (pseudosarcomatous FH, dermatofibroma with monster cells) [21,22] and epithelioid FH [23,24]. A further variant, described as 'atrophic' [25], may mimic a scar and does not usually pose a problem in differential diagnosis. Rare cases may be ulcerated, erosive or lichenoid [26].

Cellular FH represents less than 5% of all FHs [17]. Like ordinary FH, it has a predilection for the limbs of young adults, but it tends to occur more commonly in males. However, the distribution of age and site is wide; cellular FH is not infrequent in children, and on sites such as the head, neck, fingers and toes. The size of these lesions is also larger than that of ordinary FH. Most cellular FHs are less than 2 cm in diameter, but lesions measuring more than 5 cm may occur. Recognition of this variant is important, because it has a local recurrence rate of 25%, and metastases have been reported anecdotally in a small number of cases [18,27].

Aneurysmal FH has the same age and sex distribution as ordinary FH [19,20]. Tumours are usually rapidly growing and may attain a very large size. They clinically mimic a vascular tumour.

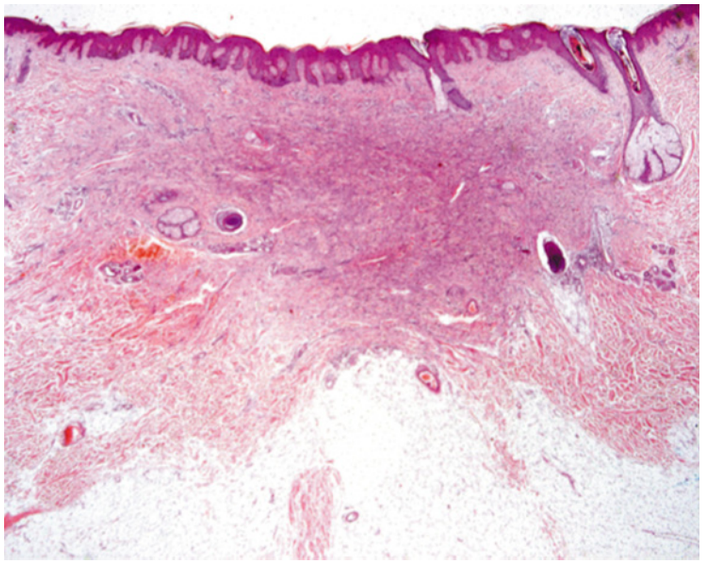

Fig. 56.10 Histological appearance of dermatofibroma, showing epidermal hyperplasia overlying the dermal sclerotic component.

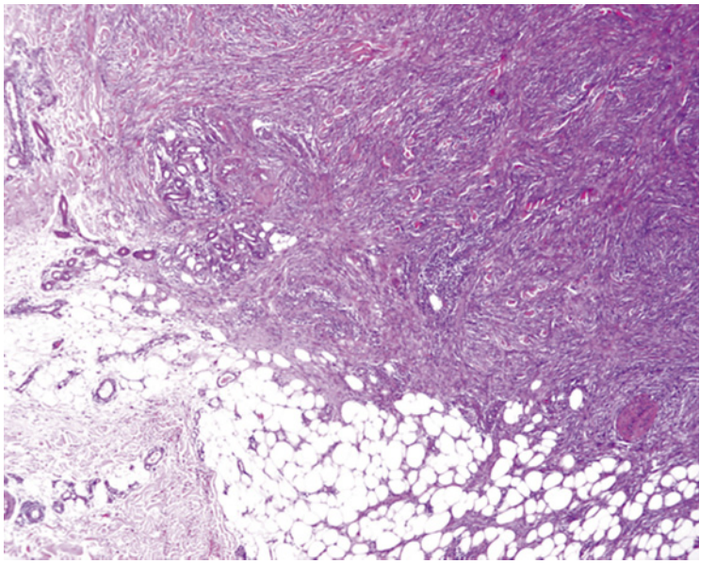

Fig. 56.11 Cellular fibrous histiocytoma. Note the increased cellularity, fascicular appearance and focal extension into the subcutis.

Exceptional tumours are multiple [28]. The rate of local recurrence is 19% [19].

Atypical FH presents mainly in young adults, with a predilection for the lower limbs [21,22]. It is commoner in males than in females. The clinical presentation is that of a papule, nodule or plaque, usually less than 1.5 cm in diameter. The rate of local recurrence is around 14%, and exceptional metastases have been reported [22].

Epithelioid FH [23,24] presents on the limbs of young patients, with a predilection for females. The typical clinical appearance is that of a polypoid, often vascular, lesion resembling a non-ulcerated pyogenic granuloma.

Pathology. The overlying epidermis frequently shows a degree of epidermal hyperplasia [29] (Fig. 56.10). The latter displays different patterns including changes mimicking a squamous papilloma, a seborrhoeic keratosis and lichen simplex chronicus. Occasionally, the epidermal proliferation is associated with immature follicular structures, which are often confused with a basal cell carcinoma. In the dermis, there is a localized proliferation of histiocyte-like cells and fibroblast-like cells, associated with variable numbers of mononuclear inflammatory cells. Foamy macrophages, siderophages and multinucleated giant cells are also variably present. A focal storiform pattern is often seen. The tumour blends with the surrounding dermis. Collagen bundles at the periphery of the lesion are surrounded by scattered tumour cells and appear somewhat hyalinized. As variable expression of factor XIIIa antigen is often seen, it has been suggested that this tumour shows differentiation towards dermal dendrocytes [30]. Focal myofibroblastic differentiation is often suggested, particularly in the cellular variant. Older lesions show focal proliferation of small blood vessels in association with haemosiderin deposition and fibrosis, hence the older name of 'sclerosing haemangioma'.

Cellular FH [17] also shows epidermal hyperplasia, but the lesions are more cellular, less polymorphic and consist of bundles of spindle-shaped cells with pink cytoplasm and a focal storiform pattern (Fig. 56.11). The mitotic rate varies, and necrosis may be found in up to 12% of cases. Extension into the subcutaneous tissue is more prominent than that seen in ordinary FH. However, the pattern of infiltration is mainly along the septae, and only focally into the subcutaneous lobule in a lace-like pattern. The cellularity and growth pattern often make distinction from DFSP difficult, particularly in small biopsies. DFSP is, however, more monomorphic, tends to infiltrate the subcutaneous tissue diffusely and is generally uniformly positive for CD34 [30]. Cellular FH may be focally positive for CD34, but this is predominantly seen at the periphery of the tumour. Staining for FXIIIa is positive in FH and negative in DFSP. Furthermore, cellular FH is often focally positive for smooth muscle actin, whereas this marker is negative in DFSP.

Aneurysmal FH [19,20] shows extensive haemorrhage, with prominent cavernous-like pseudovascular spaces (Fig. 56.12) which are not lined by endothelial cells. The mitotic rate varies, but may be prominent. The background is that of an ordinary FH.

Atypical FH [21,22] shows variable numbers of mono- or multinucleated, pleomorphic, spindle-shaped or histiocyte-like cells on a background of an ordinary FH. These cells may be very prominent, making the histological diagnosis difficult. Mitotic figures, including atypical forms, may be seen. These lesions used to be classified as 'atypical fibroxanthoma occurring in non-sun-exposed skin of young patients'.

Epithelioid FH [23,24] contains a predominant population of cells with abundant pink cytoplasm and vesicular nuclei, and there is often myxoid change and a prominent vascular component. Distinction from a Spitz naevus may be difficult, but in epithelioid

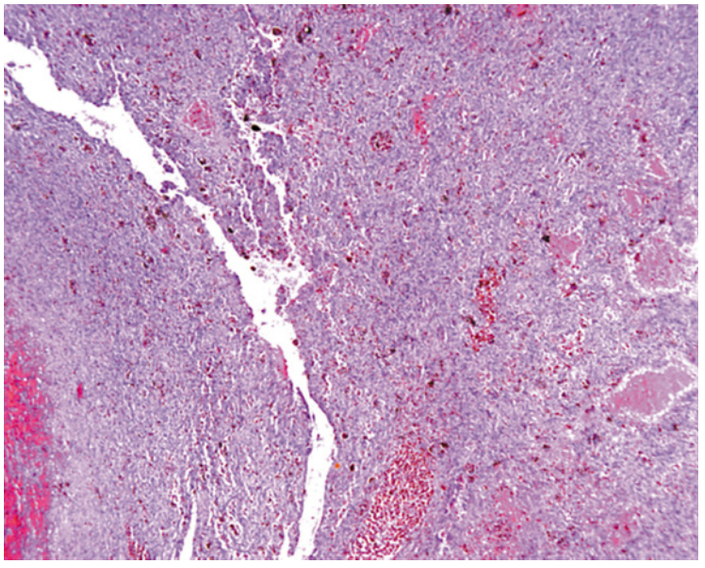

Fig. 56.12 Aneurysmal fibrous histiocytoma. Prominent haemorrhage and cavernous-like spaces obscure the typical background of a fibrous histiocytoma.

FH there is no junctional component, tumour cells are not nested and they are negative for S100.

Many histological variants of FH have been described; recognizing these variants is important to avoid misdiagnosis. They include lesions with palisading, granular cell change [31], abundant lipid (ankle-type) [32], clear cell change [33], balloon cell change [34] and keloidal change [35]. The presence of lipid within lesions of FH is not usually associated with systemic lipid abnormalities [36].

Treatment. Most FHs are no more than a cosmetic nuisance, and no treatment is necessary. However, cellular, atypical and aneurysmal variants should be completely removed, because of the risk of local recurrence and the occurrence of occasional distant metastases in the first two variants.

Medallion-like dermal dendrocytic hamartoma [1,2]

Definition. This is a very rare lesion that appears to derive from dermal dendrocytes and is usually congenital.

Clinical features. The handful of cases described have occurred in females with predilection for the trunk. Lesions are round or oval and have an atrophic appearance and a yellow–red colour.

Pathology. The epidermis appears atrophic and in the dermis there is a fairly monotonous proliferation of spindle-shaped bland cells. These cells are positive for CD34, factor XIIIa and fascin. The appearance may resemble DFSP, which may occasionally be congenital, and distinction between the two conditions is very important. However, medallion-like dermal dendrocytic hamartoma does not replace the subcutaneous tissue in a lace-like pattern and the proliferating cells are positive not only for CD34 but also for FXIIIa, a marker that is usually negative in dermatofibrosarcoma protuberans.

Treatment. Simple excision is the treatment of choice.

Hemosiderotic fibrohistiocytic lipomatous lesion [1,2]

Synonym

- Haemosiderotic fibrolipomatous tumour

Definition. This is a distinctive, benign, rare lesion that occurs almost exclusively on the foot, particularly the ankle, and that was initially thought to represent a reactive process [1]. A relationship with impaired circulation, particularly stasis, has been suggested [3]. However, other authors suggest that it is more likely to be neoplastic and related to a lesion described as pleomorphic angiectatic hyalinizing tumour [4]. The latter is regarded as a tumour of intermediate malignancy that occurs in most cases in deeper soft tissues and will not be described further in this chapter.

Clinical features. Lesions present as a slowly growing, fairly well-defined subcutaneous tumour, which tends to be asymptomatic and has some predilection for middle-aged to elderly females. Size is variable and may be several centimetres in diameter.

Pathology. The tumour is fairly circumscribed and it is composed of lobules of mature adipose tissue with scattered areas containing variable numbers of spindle-shaped cells which may be slightly hyperchromatic and often contain abundant intracytoplasmic haemosiderin. Histiocyte-like cells may also be seen. These cells are bland and only rarely slightly atypical. In the background there may be a few mononuclear inflammatory cells, mainly lymphocytes. Mitotic figures are exceptional. Spindle cells are positive for calponin and CD34 and may be positive for CD68 but negative for other markers, including desmin and h-caldesmon.

Prognosis and management. Tumours are benign and local recurrences occur rarely. The treatment of choice is simple excision.

Angiomatoid fibrous histiocytoma [1–5]

Synonym

- Previously known as angiomatoid malignant fibrous histiocytoma

Definition. Angiomatoid FH was initially described as a variant of malignant FH [1]. It has recently been reclassified as a neoplasm with low-grade malignant behaviour, unrelated to malignant FH. Although it is considered to be 'fibrohistiocytic' due to the cytological resemblance of tumour cells to histiocytes, focal positivity of these cells to desmin raises the possibility of muscular differentiation. However, the lesion is now regarded as of uncertain histiogenesis.

Clinical features. It presents in children and young adults, with no sex predilection, as an asymptomatic blue or skin-coloured, subcutaneous or deeper mass. Primary dermal tumours are exceptional. Most cases occur on the limbs and patients may present with systemic symptoms including fever, anaemia and weight loss. Generalized lymphadenopathy may also be seen.

Pathology [1–4]. Low-power examination reveals haemorrhagic, pseudovascular, cavernous-like, cystic spaces filled with red blood cells. Mononuclear inflammatory cells are prominent and germinal centres are present in some cases. Tumour cells are arranged in sheets and consist of short spindle-shaped and round cells with pink cytoplasm and vesicular nuclei. Cytological atypia is sometimes present, and the mitotic count tends to be low. Tumour cells are focally positive in some cases to desmin [3,4], muscle-specific actin, calponin, CD99 and CD68, but not for smooth muscle actin.

Initial cytogenetic studies demonstrated a translocation between chromosomes 16p11 involving the *FUS* (*TLS*) gene and chromosome 12q13 involving the *ATF1* gene. The resultant protein (FUS/ATF1) is similar to the protein present in clear cell sarcoma (EWS/ATF1) involving t(12;22)(q13;q12) [6]. However, other cases show a different fusion gene, *EWSR1-CREB1*, which seems to be, in fact, the most common fusion gene in these tumours [7].

Prognosis and management. Most cases are cured after adequate excision, but local recurrence is observed in about 15% of patients

and, exceptionally, metastasis to neighbouring soft tissues or regional lymph nodes may occur. Complete excision and follow-up are therefore indicated. Local recurrence is more likely with deep tumours, those with an infiltrative growth pattern and those that are incompletely removed [2].

Plexiform fibrous histiocytoma [1–4]

Synonym
- Plexiform fibrohistiocytic tumour

Definition. Plexiform FH is a distinctive, predominantly subcutaneous tumour with two distinctive components:
1 A fibro/myofibroblastic fascicular component
2 A nodular histiocytic-like component, which also includes giant cells.
Despite its new name, it does not represent a plexiform variant of an ordinary FH (dermatofibroma).

Clinical features [1–4]. It mainly occurs in children and young adults, most commonly in females, and has a predilection for the upper limbs. An exceptional case has been congenital [5]. The tumour is solitary, measures no more than a few centimetres in diameter and is asymptomatic.

Pathology [1–4]. Low-power examination reveals a predominantly subcutaneous tumour, with focal involvement of the dermis and a distinctive plexiform growth pattern. Purely dermal lesions are occasionally seen [6]. Two components are usually identified and consist of fascicles of bland spindle-shaped fibro/myofibroblast-like cells and nodules of histiocyte-like cells with scattered giant cells, focal haemorrhage and haemosiderin deposition. In some tumours, one of the components may predominate. The spindle-shaped cells stain focally for smooth muscle actin, and the cells in the nodules are focally positive for CD68.

Prognosis and treatment. Local recurrences are observed in up to 30% of cases. Metastases to regional lymph nodes or to the lungs have been reported [1,3,7]. Complete surgical excision and follow-up are therefore indicated. The histological features do not predict cases with more aggressive behaviour.

Atypical fibroxanthoma [1–4]

Definition. Atypical fibroxanthoma (AFX), by definition, arises in sun-damaged skin of elderly people. Ultraviolet radiation-induced *p53* mutations have been observed in these lesions, confirming the association with sun-damaged skin [5]. Tumours described in younger patients in non-sun-damaged skin represent examples of atypical FH.

Clinical features. The lesions occur most frequently on the ears, bald scalp and cheeks of elderly males (Fig. 56.13). Females are

Fig. 56.13 Typical clinical appearance of an atypical fibroxanthoma with a polypoid architecture.

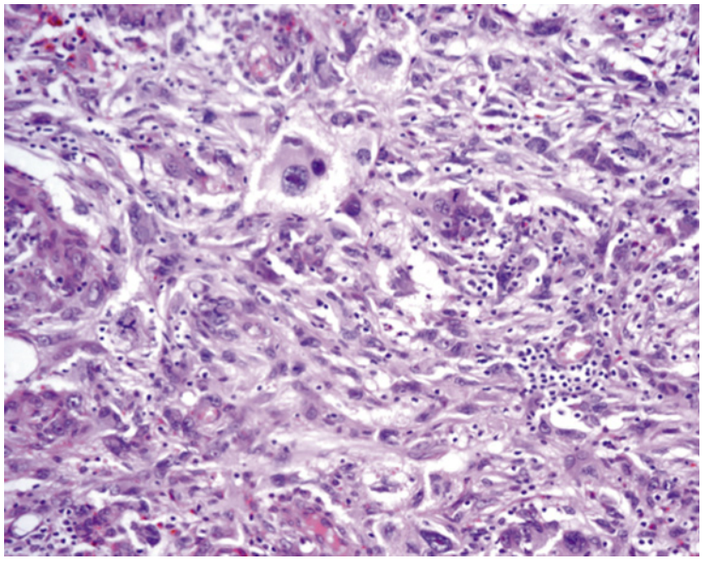

Fig. 56.14 Prominent cellular pleomorphism in a case of atypical fibroxanthoma.

much less frequently affected. The lesions are often ulcerated and have a red, fleshy appearance; they rarely exceed 30 mm in diameter, and are usually of less than 6 months' duration. Exceptional cases occur in association with xeroderma pigmentosum [6] or as a result of immunosuppression in cardiac transplant [7]. Multiple lesions have been reported [8]. Local recurrence may be seen in about 10% of cases and metastases to lymph nodes and internal organs are occasionally reported [9,10]. However, since the advent of immunohistochemistry, reports of metastatic tumours have been very rare. This suggests that many lesions reported in the past as metastatic AFX, which were diagnosed by examination of haematoxylin and eosin stained slides alone, probably represented other tumours, such as spindle cell melanomas or sarcomatoid squamous cell carcinoma.

Pathology. The tumours are exophytic, fairly well circumscribed and surrounded by an epidermal collarette. The remarkable and paradoxical feature of AFX is its histological resemblance to a highly malignant soft tissue sarcoma (Fig. 56.14) [11–13]. It arises in the dermis and may extend into the fat, but the edge is pushing rather than infiltrative. It is composed of large, spindle-shaped and histiocyte-like pleomorphic cells, many of which appear multinucleated. The cells are arranged in a haphazard fashion and mitotic figures, including atypical forms, are frequent. The histiocytic cells may contain lipid or haemosiderin [14,15]. A series of a less pleomorphic spindle cell variant, which may cause considerable problems in differential diagnosis, has been described [16]. Rare cases display prominent sclerosis [17] which may indicate regression. In some tumours there is focal or prominent clear or granular cell change [18–20]. The diagnosis of AFX is a diagnosis of exclusion. An immunohistochemical panel to rule out melanoma (S100), sarcomatoid squamous cell carcinoma (pan-keratin, mainly MNF 116 and AE1/AE3, as the low molecular weight keratin Cam 5.2 is usually negative in sarcomatoid squamous cell carcinoma of the skin) and even leiomyosarcoma (desmin, h-caldesmon) should be performed in all cases. The basic panel should be enough to accurately diagnose most cases of AFX. Other markers have been described that are often positive in AFX, and tend to be negative in other tumours that enter the differential diagnosis. These include CD99, CD10 and pro-collagen 1 [21–23].

Treatment. The benign behaviour of the tumour enables it to be treated by limited local removal. Although rare cases are treated by Mohs micrographic surgery [24], tumours are usually relatively well-circumscribed and the former treatment is rarely needed to achieve good clearance. Radiotherapy is not recommended.

Malignant fibrous histiocytoma [1–4]

Definition. 'Malignant FH' is an umbrella term encompassing a heterogeneous group of neoplasms that initially included five different clinicopathologic subtypes: pleomorphic, myxoid, giant cell, inflammatory and angiomatoid. There is little relation between the different subtypes; the angiomatoid variant has recently been reclassified in the group of fibrohistiocytic tumours and the name changed to 'angiomatoid FH'. The concept of pleomorphic malignant FH has been challenged as not representing a distinct group of neoplasms but a heterogeneous category, including pleomorphic poorly differentiated sarcomas. If cases classified as such are extensively studied with ancillary studies including immunohistochemistry, electron microscopy and more recently cytogenetics [5,6], a large percentage may be reclassified as pleomorphic variants of other soft-tissue tumours, including liposarcoma, rhabdomyosarcoma and leiomyosarcoma. The myxoid variant of malignant FH is now known as 'myxofibrosarcoma', and it is likely to show fibroblastic differentiation; this tumour often involves the skin because of its frequent origin in the subcutis, and it will therefore be discussed in more detail below. Angiomatoid FH has been described under fibrohistiocytic tumours. The inflammatory and giant cell variants of malignant FH hardly ever involve the skin and will not be discussed further.

Myxofibrosarcoma [1–4]

Synonym
- Myxoid malignant fibrous histiocytoma

Definition. Myxofibrosarcoma is a neoplasm of the subcutis and deeper soft tissues with variable cellularity, myxoid change and cells with pleomorphic nuclei. The cellular end of the spectrum is identical to a pleomorphic malignant FH, and the diagnosis is made based on the presence of myxoid areas with less cellularity and a lobular pattern. The myxoid change should be seen in 10% or more of the tumour before a lesion is classified as myxofibrosarcoma.

Clinical features. This tumour mainly presents in middle-aged to old adults, with a slight predilection for females and for involvement of the extremities, particularly the lower limbs and followed by the trunk [4]. Typically, an asymptomatic mass, measuring several centimetres in diameter, is found in the subcutis or deeper soft tissues. This is one of the sarcomas that more often involves the dermis as a result of extension from the subcutis or deeper soft tissues, rather than having a dermal origin.

Pathology [4]. These tumours have a lobular growth pattern. They are classified according to the degree of cellularity and pleomorphism into low, medium and high grade. Low-grade tumours are paucicellular and consist of round or elongated bland and pleomorphic cells in a prominent myxoid stroma. The atypical cells have irregular hyperchromatic nuclei, and mitotic figures are relatively frequent. In the background, a fairly prominent number of thin-walled vascular channels with a typical curvilinear pattern are seen. Vacuolated, Alcian blue-positive cells, focally mimicking lipoblasts, are relatively frequent. In some tumours, hypocellular areas blend with more cellular areas containing cells with increased pleomorphism; such tumours are classified as intermediate-grade. Tumours with high cellularity (high-grade) are indistinguishable from the so-called pleomorphic malignant FH and may have necrosis. Grading of lesions is important, because the rate of local recurrence and metastasis varies (see below). Some tumours, particularly high-grade lesions, may have epithelioid morphology [5]. Tumour cells are positive for vimentin and only rarely display very focal positivity for actin.

Prognosis and treatment [4]. Excision with clear margins is essential. High-grade lesions have a higher tendency for local recurrence and for metastatic spread to regional lymph nodes. The overall 5-year survival is around 60%. Tumours with epithelioid morphology appear to have a more aggressive behaviour [5].

Low-grade fibromyxoid sarcoma [1–3]

Synonym
- Hyalinizing spindle cell tumour with giant rosettes

Definition. This distinctive neoplasm is regarded as a low-grade variant of fibrosarcoma and it is characterized by deceptive, bland

spindle-shaped cells in a stroma with curvilinear blood vessels and either collagenous or myxoid background.

Clinical features. The tumour usually presents as a slowly growing lesion in young to middle-aged adults, with an equal sex incidence; it has a predilection for the proximal extremities, followed by the trunk. Tumours tend to be long-standing and asymptomatic and present as a mass, measuring several centimetres in diameter, and located in the subcutis or deeper soft tissues. Subcutaneous lesions are often clinically diagnosed as a lipoma.

Pathology [1–3]. The tumour consists of a proliferation of wavy, bland, spindle-shaped cells arranged in short fascicles and surrounded by a collagenous or myxoid stroma. Cellularity varies and tumour cells are usually bland with very rare mitotic figures. Frequent, elongated, thin-walled blood vessels are seen throughout the tumour. Only a small number of cases display some degree of cytological atypia. As a result of the deceiving histological appearances, the tumour is often diagnosed as benign. In a proportion of cases there are focal areas with hyalinized collagen surrounded by epithelioid tumour cells forming rosettes. This variant of the tumour was originally described as hyalinizing spindle cell tumour with giant rosettes [4]. The presence of rosettes does not influence the behaviour of the neoplasm. Immunohistochemistry is of limited value as tumour cells are negative for most markers. They may be, however, positive for epithelial membrane antigen (EMA) and this may lead to a misdiagnosis of perineurioma.

Tumours show a distinctive translocation, t(7;16)(q33;p11), leading to fusion of the *FUS* and *CREB3L2* genes [5]. This finding is very useful for confirmation of the diagnosis by fluorescent in situ hybridization (FISH).

Prognosis and treatment. Excision with clear margins is essential. In the largest series of cases reported so far it has been shown that local recurrence occurs in 9% of cases, metastases in 9% and mortality in 2% [6]. It seems that areas with higher grade morphology do not confer a more aggressive behaviour. However, this needs to be confirmed in further studies. Metastatic spread may occur many years after the original diagnosis and therefore long-term follow-up is indicated.

Reactive vascular lesions

Intravascular papillary endothelial hyperplasia [1–4]

Synonyms

- Masson's pseudoangiosarcoma
- Masson's vegetant intravascular haemangioendothelioma

Definition. Intravascular papillary endothelial hyperplasia is regarded as a form of organizing thrombus in which endothelial cells line hyalinized papillae.

Incidence and aetiology. This is a relatively common lesion, which usually presents as a primary phenomenon within a thrombosed blood vessel, usually a vein [2–4]. The secondary variant is commonly seen as an incidental finding within other vascular tumours, or in lesions such as haemorrhoids. Exceptionally, the same phenomenon is seen within a haematoma [4]. The primary form presents in young adults, with a slight predilection for females.

Clinical features. The primary form presents as a slowly growing solitary asymptomatic or slightly painful bluish nodule less than 20 mm in diameter. The site of predilection is the head and neck, followed by the hand (particularly the fingers). Multiple lesions are exceptional [5].

Pathology. The pathology is that of a widely dilated vascular channel in the dermis or subcutis, containing an organizing thrombus and prominent papillary projections with a hyalinized collagenous core. The papillae are lined by a single layer of usually bland endothelial cells with few mitotic figures. The presence of hyalinized collagen lined by endothelial cells produces an appearance similar to the 'dissection of collagen bundles' described in angiosarcoma. Distinction from angiosarcoma, however, is easy, as the latter is only exceptionally purely intravascular; it also displays cytological atypia, multilayering and mitotic figures. In secondary forms of Masson's tumour, the changes are seen within one or several vascular channels of a vascular tumour, usually a cavernous haemangioma or a vascular malformation.

Diagnosis. The clinical diagnosis suggested is usually that of a vascular tumour.

Treatment. Simple excision is usually curative and there is no tendency for local recurrence.

Reactive angioendotheliomatosis [1–3]

Definition. A reactive vascular proliferation, which is usually multifocal and which is associated with a number of systemic diseases. In the past, it was divided into a reactive and a malignant form. With the advent of immunohistochemistry, it became apparent that the malignant form is a variant of aggressive intravascular lymphoma (see Chapter 57).

Incidence and aetiology. This condition is rare and involves adults, with a wide age range and no sex predilection. Most cases present with cutaneous involvement only and are idiopathic. It has been described in association with systemic diseases, including bacterial endocarditis, peripheral vascular atherosclerotic disease, cryoglobulinaemia [2], liver and renal disease, antiphospholipid syndrome [4], amyloidosis [5] and sarcoidosis [6]. It is not clear how systemic diseases induce this vascular proliferation.

Clinical features. Most patients present with multiple erythematous and/or haemorrhagic macules, papules and plaques on the trunk and limbs. Patients with fewer, more localized, lesions may also be seen. In the latter cases, the association with systemic disease is not usually present. In patients with antiphospholipid syndrome or cryoglobulinaemia, ulcerated lesions may be present.

Pathology [7]. The dermis and, in some cases, the subcutis show a multifocal proliferation of clusters of capillaries lined by plump endothelial cells with little or no cytological atypia. A layer of pericytes surrounds each capillary. In some areas, dilated capillaries appear to contain smaller vascular channels within their lumina. Patients with cryoglobulinaemia show thrombosis of capillaries by hyaline eosinophilic globules.

Treatment. There is no treatment available, but the condition is usually self-limited and resolves spontaneously within a few weeks.

Glomeruloid haemangioma [1,2]

Definition. This is a distinctive multifocal vascular proliferation that occurs in association with POEMS syndrome (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M* protein and *s*kin changes; Chapter 62) or with multicentric Castleman's disease. This condition is best considered as a form of reactive angioendotheliomatosis in the setting of POEMS syndrome.

Incidence and aetiology. This is a rare disease that presents almost exclusively in the context of POEMS syndrome and multicentric Castleman's disease. It presents in adults, with no sex predilection. Exceptional cases with no clinical features of POEMS syndrome have been reported [3,4].

Clinical features. Patients present with multiple vascular papules on the trunk and limbs. Only a minority of these vascular lesions have the histological appearance of glomeruloid haemangioma; most have the histological appearance of cherry angiomas, or overlap with other vascular lesions, including cirsoid aneurysm (p. 56.26).

Pathology. The histological appearances in a typical case are striking, consisting of a multifocal dermal proliferation of clusters of closely packed dilated capillaries with a striking similarity to renal glomeruli. A layer of pericytes surrounds each capillary. Vacuolated cells are focally present and, in some cases, there are eosinophilic hyaline globules within the lumina of capillaries. These globules represent deposits of protein.

Treatment. The lesions do not tend to regress spontaneously. Individual lesions can be removed surgically, but because of their numbers this is not generally a practical option.

Benign vascular tumours

Lobular capillary haemangioma (pyogenic granuloma) [1,2]

Synonym
- Granuloma telangiectaticum

Definition. A vascular nodule that develops rapidly, often at the site of a recent injury, and which is composed of a lobular proliferation of capillaries in a loose stroma.

Incidence and aetiology. This is a common lesion affecting both sexes with a predilection for males [3] except for lesions that occur in the oral cavity which are more common in females [4]. It may occur at any age with a peak in the second decade of life [3], and is seen quite often in children and young adults but is unusual in the elderly [5]. In a minority of cases, a minor injury, usually of a penetrating kind, has occurred a few weeks before the nodule appears. Lesions may also occur at the sites of burns [6]. In other cases, no injury can be recollected, but this is likely on the basis of the patient's occupation or the body site affected. The balance of evidence indicates a reactive lesion.

Granuloma gravidarum is a variant of pyogenic granuloma that presents in the oral cavity during pregnancy.

Clinical features. The tumour is vascular, bright red to brownish-red or blue-black in colour. It is partially compressible, but cannot be completely blanched and does not show pulsation. The surface of early, bright-red lesions is usually thin, intact epidermis. Older and darker lesions are frequently eroded and crusted, and may bleed very easily. Occasionally, the surface is raspberry-like or even verrucous. The size is commonly between 5 and 10 mm, but may reach 50 mm. The outline is rounded. The base is often pedunculated and surrounded by a collar of acanthotic epidermis; the lesion may be sessile. The common sites are the hands, especially the fingers (Fig. 56.15), the feet, lips, head and upper trunk, and the mucosal surfaces of the mouth and perianal area. The initial evolution is rapid, but growth ceases after a few weeks. Spontaneous disappearance is rare. Lesions are not painful; patients mainly complain of the appearance or of recurrent bleeding. Rarely, pyogenic granulomas may occur within a port wine stain [7]. There are reported cases of multiple pyogenic granulomas developing after exfoliative dermatitis [8] and, in a periungual location, after HAART [9]. Lesions mimicking pyogenic granuloma may occur during therapy with gefitinib [10], systemic 5-fluorouracil [11] and capecitabine [12]. Eruptive forms of this tumour have rarely been reported [13]. In this setting, distinction from bacillary angiomatosis is crucial, as the latter often presents with multiple lesions that can be clinically and histologically difficult to distinguish from pyogenic granuloma. Multiple lesions closely resembling pyogenic granulomas have been reported after systemic [14] and topical [15] treatment with retinoids.

Fig. 56.15 Clinical appearance of a pyogenic granuloma on a typical site at the tip of the finger.

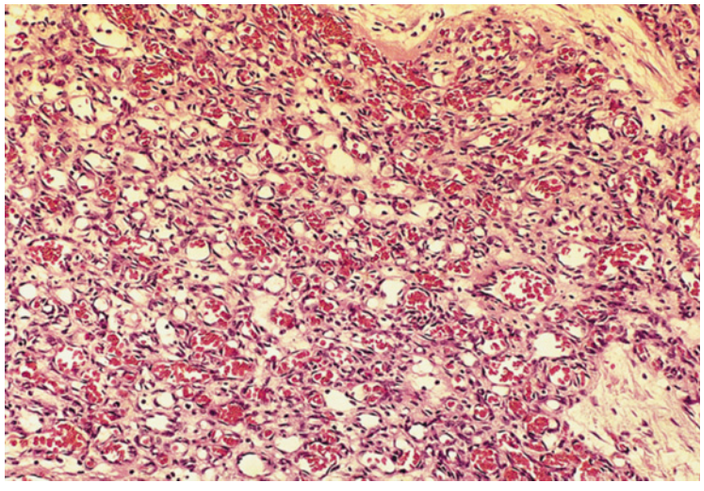

Fig. 56.16 Typical lobules of capillaries in a myxoid background, in a case of pyogenic granuloma.

Subcutaneous [16,17] and intravascular [18] variants are rarely seen and do not have distinctive clinical features. Interestingly, two cases of subcutaneous lesions have been described in patients with antiphospholipid antibodies [19].

Pathology. There is a lobular proliferation of small blood vessels, which erupt through a breach in the epidermis to produce a globular pedunculated tumour. The epidermis forms a collarette at the base of the lesion and covers part, or all, of the tumour in a thin layer. The proliferating vessels are set in a myxoid stroma, lacking in collagen in the earlier stages and relatively rich in mucin. The endothelial cells are plump, as in new granulation tissue, lining the vessels in a single layer. They are surrounded by a mixed cell population of fibroblasts, mast cells, lymphocytes, plasma cells and, where the surface is eroded, polymorphonuclear leukocytes (Fig. 56.16). Mitotic figures may be prominent. Older lesions tend

to organize and partly fibrose and may show focal bone formation. Late lesions can display focal degenerative atypia, raising the possibility of malignancy. In rare instances, particularly in children, and sometimes following treatment, satellite lesions which have a similar pathology to the primary lesion may develop around a pyogenic granuloma. These respond to simple destructive measures, thus ruling out malignancy [20]. In exceptional cases extramedullary haemopoiesis may be seen [21]. Bacillary angiomatosis shows an almost identical histology to that of pyogenic granuloma [22]. However, in bacillary angiomatosis, pale epithelioid endothelial cells are prominent, neutrophils and nuclear dust are seen throughout the lesion and violaceous amorphous aggregates of bacilli which are positive with either Giemsa or Warthin–Starry stains are easily identified. The causative organism may also be identified by PCR.

Diagnosis. In most cases, the history and clinical appearance leave little doubt about the diagnosis, and microscopic confirmation is straightforward. In 38% of one case series, the clinical diagnosis of pyogenic granuloma proved to be wrong [23]. The errors included keratoacanthoma and other epithelial neoplasms, inflamed seborrhoeic keratoses, melanocytic naevi, 'juvenile' and malignant melanoma, virus warts, molluscum contagiosum, angioma, glomus tumour, eccrine poroma, Kaposi's sarcoma and metastatic carcinoma.

Treatment. The pedunculated lesions are easy to treat by curettage with cauterization or diathermy coagulation of the base. A considerable proportion of pyogenic granulomas recur after such treatment, because the proliferating vessels in the base extend in a conical manner into the deeper dermis. In some areas—for instance in the nail fold or on the palmar aspect of a finger—it may be reasonable to carry out curettage and hope for the best. Wherever possible, it is desirable to excise a narrow, but deep, ellipse of skin beneath the lesion and close the wound with sutures. A small number of lesions have been treated with topical imiquimod 5% cream both in children and adults with complete resolution [24,25]. Other treatment modalities that have been used include Nd:YAG laser [26], cryosurgery [27], intralesional steroids, flash lamp pulsed dye laser and even injection of absolute ethanol [28].

Cirsoid aneurysm [1–4]

Synonyms
- Cutaneous arteriovenous haemangioma
- Acral arteriovenous tumour

Definition. Cirsoid aneurysm is a small vascular proliferation characterized by small to medium-sized channels with features of arteries and veins. As opposed to deeper tumours showing similar features, shunting is absent.

Clinical features. Most lesions present on the head and neck region of young adults, with no sex predilection, as a small, blue/red, asymptomatic papule.

Pathology. The dermis contains a mixture of scattered blood vessels with thick walls and features of veins and arteries (Fig. 56.17).

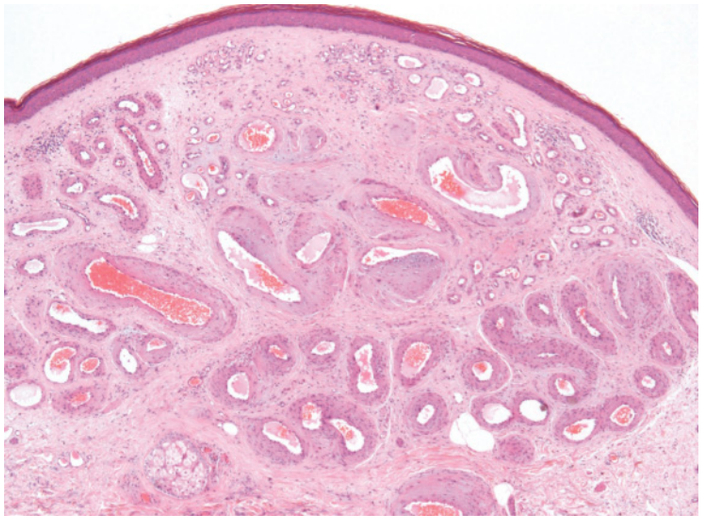

Fig. 56.17 A dermal collection of thick and thin walled blood vessels in a typical case of cirsoid aneurysm.

Treatment. As there is no associated shunting or deep component, simple excision is the treatment of choice.

Epithelioid haemangioma [1,2]

Synonyms

- Angiolymphoid hyperplasia with eosinophilia
- Pseudopyogenic granuloma
- Histiocytoid haemangioma

Definition. A benign, locally proliferating lesion composed of vascular channels lined by endothelial cells with abundant pink cytoplasm and vesicular nuclei. There has, on occasion, been a difficulty with nomenclature such that the term Kimura's disease has been applied but this condition is now viewed as distinct from angiolymphoid hyperplasia with eosinophils. In Kimura's disease, the lesions occur in younger patients, are deeper-seated, are associated with lymphadenopathy, have no initial overlying skin lesions and do not contain epithelioid endothelial cells [3,4]. Furthermore, peripheral blood eosinophilia is much more common in Kimura's disease. Exceptionally, angiolymphoid hyperplasia with eosinophilia may co-exist with Kimura's disease [5].

Incidence and aetiology. These lesions have now been reported from many parts of the world. The cause is unknown, but most studies suggest a reactive process [6].

Fig. 56.18 Epithelioid haemangioma, or angiolymphoid hyperplasia with eosinophilia. (Courtesy of Dr R.H. Champion, Addenbrooke's Hospital, Cambridge, UK.)

Clinical features [7–11] (Fig. 56.18)**.** Affected individuals are commonly young adults who present with a cluster of small, translucent nodules on the head and neck, particularly around the ear or the hairline. The lesions may also involve the oral mucosa [12]. Less frequently, lesions can involve the trunk and extremities. Involvement of deeper soft tissues and internal organs, including bone, can be seen. Both sexes are equally affected. Individual nodules rarely exceed 2–3 cm in diameter, but occasionally deeper extension and larger subcutaneous lesions occur. Spontaneous regression is seen in the majority of cases after a variable period of time. Peripheral blood eosinophilia may be present but only in less than 10% of patients.

Pathology [2,13]. A poorly circumscribed lobular lesion is seen. It is composed of clusters of proliferating capillaries and, often, thicker blood vessels lined by plump, epithelioid endothelial cells (Fig 56.19) with little cytological atypia and rare mitotic figures. Around the blood vessels there is a cellular inflammatory infiltrate composed mainly of lymphocytes and large numbers of eosinophils. However, only less than half of cases contain a prominent infiltrate. Older lesions show sclerosis of the stroma and the endothelial cells become more prominent. A frequent finding, particularly in larger lesions, is the involvement of larger blood vessels. Rare cases are entirely intravascular [14,15]. The endothelial cells stain for vascular markers including CD34, von Willebrand factor and CD31. In cutaneous cases, endothelial cells are negative for pan-keratin.

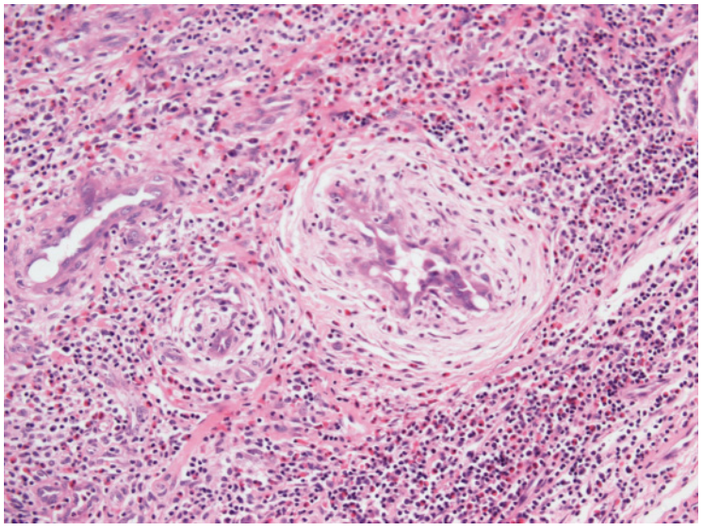

Fig. 56.19 Vascular channels lined by epithelioid endothelial cells with abundant pink cytoplasm in a case of epithelioid haemangioma.

Treatment. The natural history of the lesion is such that if a confident diagnosis is made on a small lesion, it is reasonable to observe the lesion for 3–6 months and await spontaneous regression. Both surgery and radiotherapy are effective, but local recurrences are common. Treatment with Nd-YAG laser has been effective [16] and there is an anecdotal report of response to imiquimod cream [17].

Cutaneous epithelioid angiomatous nodule

Definition. This is a recently described tumour within the spectrum of vascular lesions characterized by epithelioid endothelial cells [1–3]. It is regarded by some as part of the spectrum of epithelioid haemangioma.

Clinical features. It is rare, with only a handful of cases reported. Lesions consist of a papule or nodule presenting in an adult, with a predilection for the trunk and limbs and, less commonly, involving the face. Multiple lesions are rare and there is no tendency for local recurrence.

Pathology. The majority of lesions are superficial, well-circumscribed and surrounded by an epithelial collarette. Occasional, deeper tumours may be observed. It is composed of sheets of epithelioid endothelial cells with abundant pink cytoplasm, vesicular nuclei and a single, small nucleolus. Cytological atypia is mild or absent and mitotic figures are variable. There is little tendency for formation of vascular channels but individual endothelial cells often contain intracytoplasmic vacuoles. In the background, scattered mononuclear inflammatory cells and eosinophils may be seen.

Acquired elastotic haemangioma [1]

Definition. This is a distinctive vascular lesion that develops in sun-exposed skin in association with solar elastosis.

Incidence and aetiology. Acquired elastotic haemangioma is rare and seems to be aetiologically related to chronic sun-exposure.

Clinical features. Lesions present mainly on the forearms or neck of middle-aged to elderly patients, with a predilection for females. The clinical presentation consists of a small, red or blue, circumscribed and asymptomatic plaque.

Pathology. Lesions are well circumscribed and consist of a superficial, band-like proliferation of capillaries in the background of solar elastosis. Each capillary is surrounded by a layer of pericytes.

Treatment. Simple excision is the treatment of choice and there is no tendency to local recurrence.

Hobnail haemangioma [1–4]

Synonym

- Targetoid haemosiderotic haemangioma

Definition. This is a benign vascular dermal proliferation characterized by small channels lined by endothelial cells with little cytoplasm and a prominent dark nucleus (hobnail cells). Formation of small papillae is also often seen. The original name proposed for this condition was based on a distinctive targetoid clinical appearance produced by bleeding and haemosiderin deposition. However, only a minority of lesions present with this typical appearance and, therefore, the alternative name of hobnail haemangioma has been proposed.

Incidence and aetiology. It is relatively uncommon and occurs mainly in young to middle-aged adults with a slight predilection for males. Trauma may play a part in its pathogenesis [4]. Occasionally, lesions vary according to the timing within the menstrual cycle [5].

Clinical features. This entity presents as a rapidly developing, asymptomatic, solitary red or brown lesion, which in some cases has a central, raised, violaceous papule and is surrounded by a paler brown halo (targetoid appearance) [1]. Any body site may be affected, but it has predilection for the lower limbs and trunk. The oral mucosa may also be affected [3].

Pathology. Pathological examination shows dilated vascular channels in the papillary and high reticular dermis, with a single layer of endothelial cells lining intraluminal papillary projections. These cells have a hobnail ('matchstick') appearance. They may occasionally be more numerous and appear to fill the lumen of the vessel. The vascular channels tend to disappear in the mid and lower reticular dermis, and the endothelial cells become less prominent and lose the hobnail appearance. Haemosiderin deposition is prominent and can be highlighted with a Perl's stain. The endothelial cells stain for the lymphatic marker podoplanin (D2-40), suggesting that these lesions represent lymphangiomas rather than haemangiomas [6]. The pathological appearance may resemble Kaposi's sarcoma, but this differential diagnosis can usually be resolved by clinicopathological correlation, as hobnail haemangioma is a solitary entity whereas Kaposi's sarcoma is usually composed of multiple lesions. Histological distinction can be made if attention is paid to the symmetry of the lesion, the presence of hobnail endothelial cells with papillary projections and the absence of inflammation in hobnail haemangioma. Furthermore, hobnail haemangioma is not associated with HHV8 while all cases of Kaposi's sarcoma are associated with this virus.

Diagnosis. It is usually suspected clinically if lesions have a targetoid appearance. The diagnosis is otherwise made histologically.

Treatment. Simple surgical excision is the treatment of choice; there is no tendency for recurrence.

Microvenular haemangioma [1–3]

Definition. This is a benign dermal vascular lesion characterized by proliferation of small vascular channels with features suggestive of venules.

Incidence and aetiology. It is relatively rare and presents mainly in young adults, with no sex predilection. Presentation in children is very rare [4]. Although the histological appearances suggest venular differentiation, this has not been proven.

Clinical features. It presents as a solitary, red–brown or bluish papule, nodule or plaque with predilection for the limbs. Most lesions are less than 10 mm in diameter.

Pathology. There is a superficial and deep dermal proliferation of angulated, thin-walled, vascular channels, all of which are surrounded by a single layer of pericytes. These channels are lined by flat, bland, endothelial cells and are surrounded by somewhat hyalinized collagen. A frequent finding is the infiltration of arrector pili muscles by vascular channels. Inflammation is not usually a feature. These lesions are negative for HHV8.

Treatment. Simple surgical excision is the treatment of choice; there is no tendency for local recurrence.

Sinusoidal haemangioma [1]

Definition. This is a benign dermal and/or subcutaneous variant of cavernous haemangioma composed of thin-walled, dilated vascular spaces in a typical sieve-like distribution.

Incidence and aetiology. Lesions are rare and present in adults, with a slight predilection for females.

Clinical features. Sinusoidal haemangioma presents as a solitary, blue, asymptomatic nodule, particularly on the trunk or upper limbs. The dermis and subcutaneous tissue overlying the breast is not uncommonly involved and may suggest a diagnosis of angiosarcoma (differentiating features are discussed below; see also p. 56.37).

Pathology. The lesion is usually well circumscribed, but several lobules of subcutaneous tissue may be focally affected by the tumour. A striking feature is the presence of back-to-back, dilated and congested thin-walled vascular channels. These channels are interconnected, and transverse sectioning is, in part, responsible for the distinctive sinusoidal appearance. Pseudopapillary projections are focally present and thrombosis with dystrophic calcification may also be seen. Focal cytological atypia secondary to degenerative changes may be seen. Distinction from angiosarcoma, particularly in tumours presenting in the breast, is based on the fact that the latter occurs in the breast parenchyma and only invades the dermis and subcutis secondarily. Tumour cells in angiosarcoma also display cytological atypia, multilayering and mitotic figures.

Treatment. Simple surgical excision is the treatment of choice, and there is no tendency for local recurrence.

Spindle cell haemangioma [1–5]

Synonym
- Spindle cell haemangioendothelioma

Definition. This is a benign vascular tumour. Although initially described as a low-grade malignant lesion with a high tendency for local recurrence and minimal potential for metastasis, further studies demonstrated that it is a benign multifocal process, often associated with a vascular malformation [3–5]. Confirmation of its benign nature has led to change of the name 'haemangioendothelioma' for 'haemangioma', as the former implies low-grade (intermediate-grade) malignant potential [6].

Incidence and aetiology. Spindle cell haemangioma is relatively rare. Males and females are affected equally, and the age range is wide. Often, lesions present in childhood or early adulthood and tend to be long-standing. The process appears to be reactive or may be a form of malformation, and it is often associated with lymphoedema, Maffucci's syndrome (multiple enchondromas) [7], early-onset varicose veins or Klippel–Trenaunay syndrome.

Clinical features. The majority of cases present in the distal limbs, particularly the hands and feet, as multiple cutaneous or subcutaneous, red or bluish nodules. Deeper tumours are rare. Presentation at other sites including the neck and oral cavity is very rare [8,9]. Lesions continue to appear over many years, indicating multifocality rather than true recurrences. Most nodules are less than a few centimetres in diameter; they may occasionally be painful.

Pathology. Low-power magnification reveals single or multiple, fairly well-circumscribed, haemorrhagic nodules. Origin from a pre-existing blood vessel is often seen, and individual lesions may be entirely intravascular. Dilated, thin-walled, congested, cavernous-like vascular spaces are intermixed with more cellular areas composed of bland, short, spindle-shaped cells, with formation of slit-like spaces. Scattered, more epithelioid cells, with pink cytoplasm and prominent vacuolation, are also seen. The spindle-shaped cells are a mixture of endothelial cells, pericytes and fibroblasts. Focal degenerative cytological atypia may be present. Immunohistochemistry reveals staining for CD31 and CD34 and focal staining for smooth muscle actin.

Diagnosis. The clinical appearances usually suggest a vascular process, but the final diagnosis usually requires histological confirmation.

Treatment. Single lesions are easily treated with simple excision. Treatment is more difficult in the presence of multiple lesions, as new lesions are more likely to appear over time.

Symplastic haemangioma

Definition. This is not a distinctive variant of haemangioma but represents extensive degenerative changes in a pre-existing haemangioma, closely mimicking malignancy [1–3]. Only a handful of cases have been reported. From personal experience with a small number of cases, the pre-existing vascular lesion is often either not identifiable or it represents a cirsoid aneurysm.

Clinical features. These are not distinctive. However, the patient is usually an adult, and the description is usually of a long-standing lesion that has rapidly increased in size.

Pathology. These tumours are often polypoid and well-circumscribed and do not tend to be ulcerated. The typical histological picture consists of dilated and congested, thin to thick-walled vascular spaces surrounded by a variable cellular stroma with frequent myxoid change and haemorrhage. Stromal cells and smooth muscle cells within the vessel walls show variable cytological atypia, consisting of nuclear enlargement and hyperchromatism. The endothelial cells lining the vascular spaces may be plump but do not display cytological atypia, multilayering or mitotic activity, allowing distinction from an angiosarcoma. Often cells have a bizarre appearance and multinucleated cells are common. Mitotic figures may be found but tend to be rare. Very occasional, atypical mitotic figures may also be seen.

Vascular tumours of intermediate malignancy

Kaposiform haemangioendothelioma [1–5]

Synonym
- Kaposi-like infantile haemangioendothelioma

Definition. Kaposiform haemangioendothelioma is a locally aggressive, vascular neoplasm, which occurs mainly in the abdominal cavity [1] but can affect primarily the skin or deeper soft tissues.

Incidence and aetiology. This tumour is rare and presents mainly in young children under the age of 2 years, with no sex predilection. Some lesions are congenital [6]. Rare cases occur in older children and adults. In 20% of cases, there is an association with lymphangiomatosis [3]. It appears clear that this lesion is truly neoplastic. Although it is not malignant, it causes morbidity and mortality due to its location and the frequent occurrence of consumption coagulopathy (Kasabach–Merritt syndrome).

Clinical features. The most common presentation by far is that of a large, retroperitoneal, infiltrative mass. Involvement of neighbouring organs and the very common association with Kasabach–Merritt syndrome may lead to death. This complication is less common in more superficial tumours, particularly those located in the dermis and subcutaneous tissue [5,7,8]. Multifocal lesions are exceptional [9].

Pathology. The growth pattern is lobular and infiltrative. Multiple nodules with haemorrhage and surrounding fibrosis are seen. Tumour lobules are composed of bland, spindle-shaped cells with poorly defined, pink cytoplasm. Cleft-like spaces are often seen between spindle-shaped cells, and the resemblance to Kaposi's sarcoma can be striking. However, numerous capillaries, often associated with microthrombi, are also present in tumour lobules. Epithelioid endothelial cells with focal vacuolation are also present. These features, along with the striking lobular architecture of the tumour and negative staining for HHV8, allow distinction from Kaposi's sarcoma. Podoplanin (D2-40), a marker of lymphatic endothelium, is positive in the spindle cells and lymphatic channels around tumour lobules [10]. This finding not only suggests a lymphatic line of differentiation for this tumour, but it is also useful in making the histological diagnosis and in differential diagnosis from other tumours such as tufted angioma in which the tumour lobules are negative for D2-40 [11]. However, it has been suggested that Kaposiform hemangioendothelioma and tufted angioma are part of the same spectrum [12].

Treatment. Complete excision is desirable as local recurrence is frequent, but this may be difficult to achieve when involvement is extensive. Spontaneous regression does not occur. Treatment of Kasabach–Merritt syndrome is difficult and good response has been reported with vincristine [13]. Anecdotal cases responding to interferon-α have been described [14].

Giant cell angioblastoma [1,2]

Definition. This is a very rare entity of which only a handful of cases have been reported. It is not clear whether it represents a true vascular tumour and, until it is more clearly delineated and defined, it has not been included in the latest WHO classification of vascular tumours.

Clinical features. Tumours are congenital and have been described on the hand, the palate and the scalp. The tumour is diffusely infiltrative and slowly growing. Two of the reported cases showed no progression after incomplete excision.

Pathology. The tumour is composed of infiltrative vascular channels lined by a single layer of bland endothelial cells and intermixed with solid nodules composed of spindle-shaped cells, histiocyte-like cells and osteoclasts. A plexiform growth pattern is often seen.

Treatment. Two cases have been successfully treated with interferon-α-2b [3].

Retiform haemangioendothelioma [1–3]

Synonym
- Hobnail haemangioendothelioma

Definition. Retiform haemangioendothelioma is a rare variant of low-grade angiosarcoma with a tendency for local aggressive behaviour. It is characterized by arborizing vascular channels lined by endothelial cells with hobnail morphology.

Clinical features [1–4]. Retiform haemangioendothelioma presents mainly in young adults, with no sex predilection, as a slowly growing, asymptomatic, dermal and subcutaneous plaque or nodule. Rarely lesions present as a bruise [5]. Exceptional cases present with multiple lesions [6]. Rarely there is an association with lymphoedema or radiotherapy. Local recurrence occurs in up to 60% of cases. So far, there has only been one report of a tumour metastasizing to a regional lymph node, and a further lesion has spread locally to soft tissues [7]. No tumour-related deaths have been reported.

Pathology. Scanning magnification is distinctive and reveals arborizing, thin-walled, narrow, vascular channels with a striking resemblance to the rete testis. The growth pattern is infiltrative, and the vascular spaces are lined by bland hobnail endothelial cells with prominent nuclei and scanty cytoplasm. Intravascular papillae with collagenous cores, similar to those seen in papillary endolymphatic angioendothelioma, are sometimes seen. The surrounding stroma often appears hyalinized; a prominent mononuclear inflammatory cell infiltrate is common. The endothelial cells stain for vascular markers. There is no relationship to HHV8.

Treatment. Wide local excision is the treatment of choice.

Papillary intralymphatic angioendothelioma [1]

Synonyms
- Endovascular lymphatic angioendothelioma
- Dabska's tumour

Definition. Defining this entity is difficult because, since its original description in 1969, few further convincing cases have been described [1–4]. Furthermore, the original series included some examples of what is now known as retiform haemangioendothelioma. Recently, the tumour has been better characterized under the preferred name of 'papillary endolymphatic angioendothelioma' [5]. It belongs to the family of tumours with hobnail endothelial cells, and it is characterized by dilated, cavernous-like lymphatic spaces with frequent papillary projections.

Clinical features. It presents mainly in infants and children, with 25% of the cases occurring in adults. There is no sex predilection. Presentation is as a slowly growing, asymptomatic plaque or nodule with a predilection for the limbs. In the original series of six cases, a tendency for local recurrence and metastasis to regional lymph nodes was reported [1], but in a recent series of 12 cases, none of the eight cases with follow-up recurred locally or metastasized [5]. It therefore seems likely that the behaviour of this tumour is benign. Further studies are needed to confirm whether it deserves to be kept in the group of tumours of intermediate behaviour.

Pathology. This tumour is composed of dilated, thin-walled channels simulating a cavernous lymphangioma. These channels are lined by bland hobnail endothelial cells with very rare mitotic figures. A striking feature is the formation of intraluminal papillary tufts with hyaline cores. Aggregates of mononuclear inflammatory cells may be seen around the vascular channels.

Treatment. Until the issue regarding the biological behaviour of this tumour is resolved, complete excision is recommended.

Kaposi's sarcoma [1–3]

Synonyms
- Kaposi's disease
- Granuloma multiplex haemorrhagicum
- Idiopathic multiple pigmented sarcoma

Definition. A multifocal, endothelial proliferation predominantly involving the skin and other organs and associated with formation of vascular channels and proliferation of spindle-shaped cells. It is not clear whether Kaposi's sarcoma is a reactive vascular proliferation or a neoplastic process (see below).

Aetiology and pathogenesis. In the mid 1990's, Chang *et al.* described a new human gammaherpesvirus associated with Kaposi's sarcoma [4]. This virus is closely associated to Epstein–Barr virus, was named human herpesvirus type 8 (HHV8), and it is associated with all clinical variants of Kaposi's sarcoma (HIV/AIDS-related Kaposi's sarcoma, the African endemic type, Kaposi's sarcoma induced by iatrogenic immunosuppresion and Mediterranean endemic Kaposi's sarcoma) [5,6]. The virus can be found in the blood of patients before lesions of Kaposi's sarcoma develop [7]. This gives further support to the belief that this virus, along with genetic, immunological and environmental factors, is closely involved in the pathogenesis of Kaposi's sarcoma [8].

The multifocal development, symmetry of lesions, slow evolution of the classic form of the disease, regression when immunosuppression is reduced or stopped, and histology both of inflammation and of cells lacking cytological atypia, has led many to suggest that Kaposi's sarcoma is a reactive condition and not a neoplastic process. A few reports demonstrating the presence of clonality tend to support the hypothesis that this disorder is neoplastic [9]. Recent studies have suggested that the disease, in fact, starts as a reactive angioproliferative and inflammatory process, but progresses to become a monoclonal neoplastic process [10,11]. This is probably the result of close complex interactions between inflammatory cytokines, angiogenic factors, HHV8 and, in HIV-positive patients, the HIV virus itself [12]. In the latter setting it has been demonstrated that the HIV-1 trans-activating protein Tat-1 promotes the development of lesions by increasing the activity of different cytokines and angiogenic factors [13].

For many years, the line of differentiation of the proliferating cell in Kaposi's sarcoma remained difficult to elucidate. The suspicion has always been that the main proliferating cells are endothelial cells with lymphatic differentiation. This has recently been substantiated by the development of lymphatic endothelium-specific antibodies, including Lyve-1, podoplanin (D2-40) and Prox-1, which are positive in the proliferating cells in Kaposi's sarcoma [14,15].

At present, there are four recognized clinical subsets of Kaposi's sarcoma. These are:

1 Classic
2 Endemic
3 Iatrogenic
4 Human immunodeficiency virus (HIV)-related (Chapter 35).

Classic Kaposi's sarcoma [16–18] is as described originally by Kaposi. It is found mainly in elderly males, particularly from Southern Europe (mainly Italian and Greek) or Jews of Eastern European origin. The lesions begin slowly and insidiously around the ankle and slowly spread up the leg (Fig. 56.20). Lymphoedema

Fig. 56.20 Classic Kaposi's sarcoma arising on the feet of a male patient of Mediterranean origin.

can occur as a complication. Lesions in other locations, including the oral mucosa, are very rare. Involvement of internal organs is not usually seen. The disease is very rarely responsible for the death of the patient. An association with haemopoietic malignancies may be seen.

Endemic Kaposi's sarcoma [19,20] is found in equatorial Africa, mainly in the Democratic Republic of Congo, Uganda [21,22] and Rwanda. In adults, males predominate, but this form is also seen in children. Crops of cutaneous, vascular lesions develop, and may be associated with gross oedema. Visceral lesions may also occur; the prognosis is poor if there is extracutaneous involvement.

Iatrogenic Kaposi's sarcoma [16,23,24]. This is seen in transplant patients and after cytotoxic chemotherapy for lymphomas. Drug-induced immunosuppression to prevent rejection of transplanted organs markedly increases the risk of developing lymphomas and other tumours, including Kaposi's sarcoma. In transplant patients, Kaposi's sarcoma is 150 times more common than expected and affected patients may be younger than those with other types of Kaposi's sarcoma (excepting those with HIV infection). In a large, retrospective study over 23 years, Kaposi's sarcoma developed in 3.9% of cases of kidney transplant patients [23]. Both systemic and cutaneous involvement may occur, and the progress of the disease may be aggressive, causing the death of the patient. If it is possible to remove the immunosuppression, the lesions will regress.

Kaposi's sarcoma associated with HIV infection [25–28]. This variant was first recognized in 1979 [29,30] when an epidemic of Kaposi's sarcoma was identified in the homosexual community in New York. Since that time, it became firmly associated with the later stages of HIV infection. It is much commoner in homosexual and bisexual men than in others at risk, such as drug abusers or haemophiliacs. Kaposi's sarcoma usually develops in the later stages of the disease and it may be a presenting feature of HIV infection. With the advent of highly active antiretroviral therapy (HAART) the incidence of Kaposi's sarcoma in HIV/AIDS has decreased dramatically in the Western world [31]. As a result of HAART it is rare to see patients presenting with widespread lesions of Kaposi's sarcoma and the latter may regress as a result of this therapy, making the clinical and histological diagnosis even more difficult. This is not true, however, in third world countries, particularly in Africa [32,33] where the availability of HAART is still very limited. In patients on HAART and according to the degree of restoration of the immune system, lesions may regress; also, if they develop during treatment they are usually limited in number and extent. It is more common now to see patients with early lesions consisting of only one or two flat, macular lesions (Fig. 56.21) than with extensive nodular or plaque lesions. However, in patients with prominent immunosuppression, as still seen in many sub-Saharan African countries, the lesions may occur anywhere on the body, develop with explosive rapidity and become large nodules. The face and mucous membranes, such as the soft palate, are relatively frequently involved (Fig. 56.22). Involvement of lymph nodes, lungs and gastrointestinal tract is common.

Fig. 56.21 Patch-stage Kaposi's sarcoma in an HIV-positive patient.

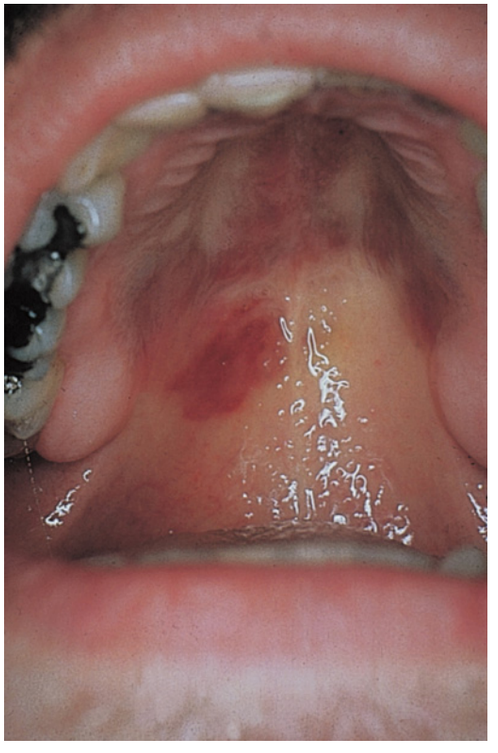

Fig. 56.22 Early lesion of Kaposi's sarcoma in an HIV-positive patient.

Clinical features [2,34–36]. Kaposi's sarcoma tends to occur in males. The lesions have a dark-blue or purplish colour. Initially, they may be almost macular and when they become tumid, pressure may produce partial blanching to reveal a brown tinge. The process usually begins on the extremities, most commonly on the feet and occasionally on the hands, ears or nose. Individual tumours enlarge to a diameter of 10–30 mm and stop growing. The process is multifocal, and adjacent areas may fuse to form a plaque or tumour. Oedema of the limb may follow, or at times precede, the appearance of the tumour. There are few subjective symptoms;

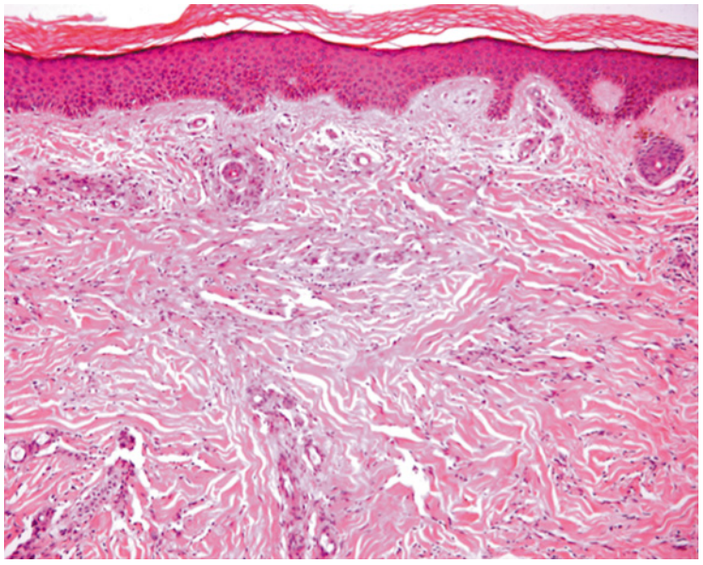

Fig. 56.23 Patch-stage Kaposi's sarcoma. Note the dermal proliferation of small, thin-walled, irregular lymphatic-like channels around pre-existing, normal blood vessels and adnexal structures.

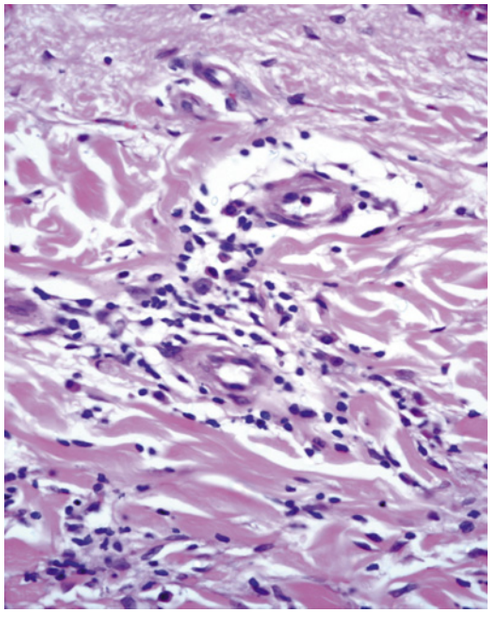

Fig. 56.24 Patch-stage Kaposi's sarcoma. Small, irregular vascular channels lined by bland endothelial cells. Note the promontory sign, in which a normal pre-existing capillary seems to be floating in a newly formed channel.

pain may be felt in nodules on pressure areas. The lesions may involute to leave pigmented scars, or may become eroded, ulcerated or fungating. New lesions may appear along the course of superficial veins, and in time most patients have more or less symmetrical lesions. The rate of spread is remarkably variable. It tends to be slow in Europeans and more rapid in Africans, where oedema is often the first sign. Lymph nodes, mucosal surfaces and internal organs, particularly the small intestine, may all be involved as the disease progresses. Kaposi's sarcoma may at times start in other organs and run its course without skin manifestation. Visceral involvement is the common pattern in African children, with lymph nodes as the main tissue involved.

Patients presenting with Kaposi's sarcoma associated with severe immunosuppression have subtle lesions, which may well be missed by the unwary [2]. They may have only one or two lesions scattered over the body, and these may resemble slight areas of trauma or a simple bruise. The lesions are therefore quite dissimilar from the classic, florid lesions developing on the lower limbs of the older patients from central Europe.

Pathology [37–39]. The cutaneous lesions of Kaposi's sarcoma can generally be divided into patch, plaque and nodular stages. These stages often overlap clinically and histologically. In the patch stage of the disease, there is a proliferation of jagged, irregular, lymphatic-like vascular channels lined by a single layer of bland endothelial cells; these channels particularly surround pre-existing blood vessels and adnexal structures (Fig. 56.23). Normal, pre-existing capillaries and even adnexal structures seem to be floating within the newly formed channels, the so-called 'promontory sign' (Fig. 56.24). From the early stages a patchy, variably prominent, mononuclear inflammatory cell infiltrate containing plasma cells is seen. This is associated with extravasation of red blood cells and haemosiderin deposition. In some cases, numerous, irregular, widely dilated, lymphatic-like channels impart a prominent lymphangiomatous appearance (lymphangiomatous Kaposi's sarcoma) [40].

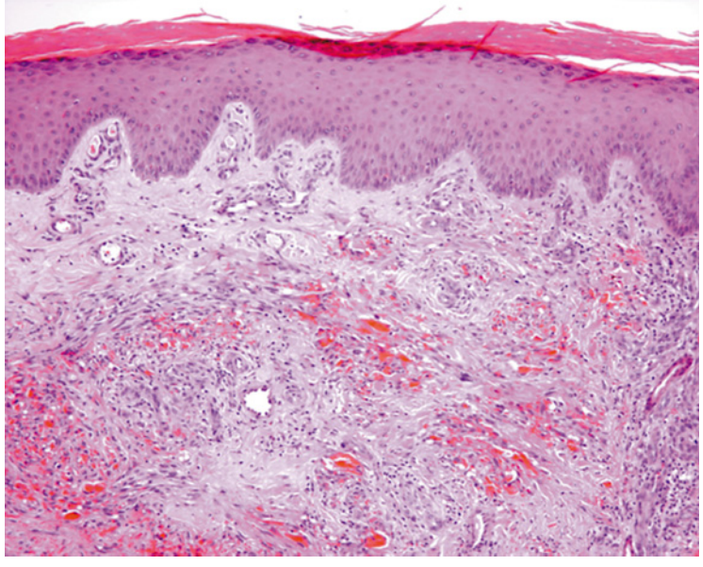

Fig. 56.25 Plaque-stage Kaposi's sarcoma. More diffuse proliferation of vascular channels with prominent haemorrhage.

The plaque stage is an exaggeration of the patch stage (Fig. 56.25). The vascular channels increase in number, and a network of bland spindle-shaped cells with pink cytoplasm develops. Dilated vascular channels in a back-to-back pattern may also be seen. Intra- or extracellular, hyaline, PAS-positive, eosinophilic globules are common, and probably represent degenerate red blood cells [41]. Involvement of the whole dermis and superficial subcutis is frequent.

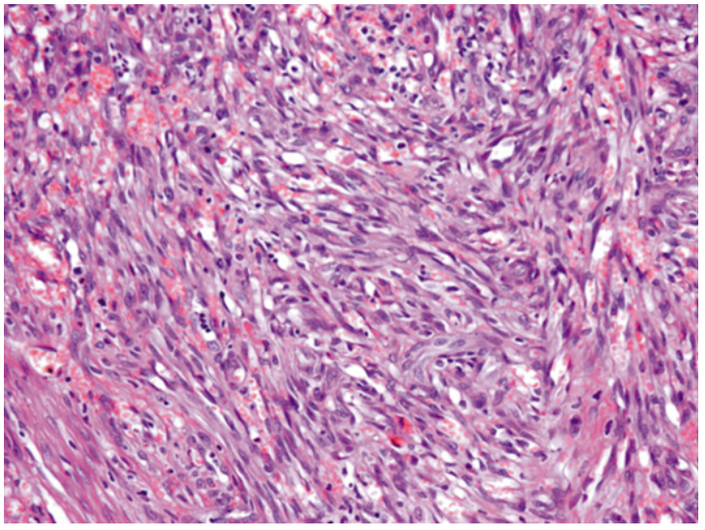

Fig. 56.26 Nodular Kaposi's sarcoma. Note the typical, sieve-like appearance, with blood cells between the cleft-like spaces.

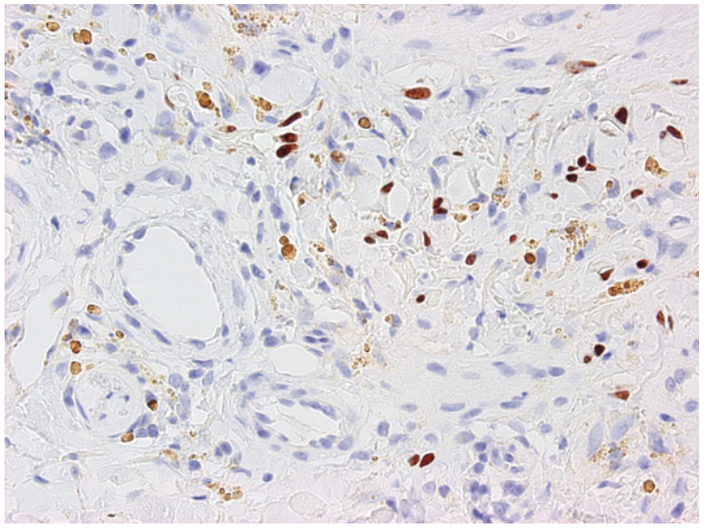

Fig. 56.27 Immunohistochemistry for the LNA of HHV8 in a case of Kaposi's sarcoma highlighting the presence of nuclear staining in the proliferating endothelial cells.

In the nodular stage, there are fairly well-circumscribed nodules of generally bland, spindle-shaped cells forming frequent cleft-like spaces that impart a typical sieve-like appearance (Fig. 56.26). Extravasated red blood cells are plentiful, as are hyaline globules. Mitotic figures are common. The periphery of the nodules may display a more angiomatous appearance.

Rarely, lesions of Kaposi's sarcoma may be partially or totally in an intravascular location, particularly within a vein [42].

Very rare examples of Kaposi's sarcoma display a high degree of cytological atypia and behave in an aggressive fashion.

The histology of lesions of Kaposi's sarcoma that have regressed after chemotherapy or with angiogenesis inhibitors, including Col-3 or HAART, may be very difficult to interpret [43]. Regression may be partial or complete. In completely regressed lesions there is absence of irregular lymphatic-like channels and spindle-shaped cells, increase in the number of capillaries in the superficial dermis and a superficial, perivascular lymphohistiocytic inflammatory cell infiltrate with variable numbers of siderophages. Partially regressed lesions show prominent decrease in the number of lymphatic-like vascular channels and spindle-shaped cells and focal inflammation with siderophages. The residual spindle-shaped cells tend to be arranged around superficial and mid-dermal capillaries. These changes are correlated with prominent decrease in the expression of LAN-1.

A useful aid in the histological diagnosis of Kaposi's sarcoma is a monoclonal antibody against the latent nuclear antigen 1 (LNA-1) of HHV8, which stains tumour cells in all cases of the disease [44]. Positive cases demonstrate granular nuclear staining (Fig. 56.27). *In situ* hybridization was the only technique initially used to demonstrate the virus, but this is a more expensive and time consuming technique and it is not widely available.

The pathological differential diagnosis includes many benign vascular tumours or reactive proliferations, including spindle cell haemangioma, tufted angioma, microvenular haemangioma, hobnail haemangioma, progressive lymphangioma and, on the lower legs, a 'venous' dermatitis (acroangiodermatitis). Angiosarcoma is also often considered in the differential diagnosis, but in the latter there is clear evidence of cytological atypia, mitotic activity and multilayering.

Differential diagnosis. The early lesion is most likely to be confused with a wide variety of benign vascular proliferations. It must also be distinguished from fibrous histiocytoma or from other types of soft-tissue tumours. Its evolution from a macular lesion and its characteristic colour, slow development and multifocal distribution make the diagnosis likely in most instances. Cases in which the tumour is preceded by oedema may cause difficulty, as angiosarcoma may arise in chronic lymphoedema. In prolonged venous hypertension of the lower legs, or in association with underlying vascular malformations, nodules with a close resemblance to Kaposi's sarcoma may develop (acroangiodermatitis, pseudo-Kaposi's sarcoma); they differ, however, in lack of progression, and a spindle-cell proliferation is not seen in the histological sections.

Treatment. Where a small area is involved, excision or radiotherapy can be used. Superficial radiotherapy is rapid and effective, and is the treatment of choice for the majority of patients with nodular disease of the extremities. For more extensive disease a number of treatment options have been used including antiviral, cytotoxic and immunomodulator drugs. In HIV/AIDS regression of lesions may be seen with HAART [45]. Liposomal doxorubicin may also be a useful treatment and interleukin-12, either alone or in combination with the latter, may also induce remission in AIDS patients with Kaposi's sarcoma who are on HAART [46]. Pegylated liposomal doxorubicin has been used with success on its own, as second line treatment of AIDS-related Kaposi's sarcoma and in advanced, classic Kaposi's sarcoma [47,48].

Malignant vascular tumours

Angiosarcoma [1–4]

Synonyms
- Malignant haemangioendothelioma
- Haemangiosarcoma
- Lymphangiosarcoma

Definition. A malignant vascular tumour, arising from both vascular and lymphatic endothelium. Except for the pure epithelioid variant of angiosarcoma (see below), cutaneous angiosarcoma almost exclusively occurs in three settings: idiopathic angiosarcoma of the face, scalp and neck [2–4], angiosarcoma associated with chronic lymphoedema (Stewart–Treves syndrome) [5–9] and post-irradiation angiosarcoma [10–12]. In this chapter, the terms 'angiosarcoma' and 'lymphangiosarcoma' are used interchangeably.

Incidence. This is a rare tumour in any form. Angiosarcoma of the scalp and face of the elderly is very rare, affects mainly males and it is almost invariably fatal.

Stewart–Treves syndrome occurs in 0.5% of patients who survive mastectomy for more than 5 years. The mean age at appearance of the angiosarcoma is 62 years, and the mean interval between mastectomy and the appearance of the tumour is 10.5 years [9]. Two cases have been reported in men following mastectomy [13]. Not all patients have received radiotherapy in association with the mastectomy, and not all have had axillary nodes removed.

Lymphoedema is not invariably present, or it may be late in appearing and antedate the tumour by only a short time. The incidence and cause of postmastectomy lymphoedema have been reviewed [14]. In the majority of cases, the clinical course and autopsy findings have shown that the treatment of the breast carcinoma was successful and that patients have had less frequent involvement of the axillary nodes than usual [9]. A small number of cases have arisen in lymphoedema of the lower limb, or in the upper limb without breast cancer and mastectomy [15]. Most of these patients were women.

Multiple primary malignancies have occurred in 8% of cases of Stewart–Treves syndrome [6] and a systemically acting carcinogen has been suggested [8,9]. There is no evidence to support this.

Post-irradiation angiosarcoma is rare and most cases arise in the skin after radiotherapy for breast or, less commonly, internal cancer [10–12].

Angiosarcoma occurring in other settings is very rare. Presentation in children is extremely rare [16]. Angiosarcoma may also exceptionally occur in benign vascular tumours including vascular malformations [17], in a large blood vessel [18], in association with a plexiform neurofibroma in neurofibromatosis [19], in a schwannoma [20], in a malignant peripheral nerve sheath tumour [21,22], in xeroderma pigmentosum [23], in a gouty tophus [24], in association with vinyl chloride exposure [25], in association with immunosuppression in organ transplantation [26] and as the mesenchymal component in a metaplastic carcinoma [27]. An exceptional case of an angiosarcoma producing granulocyte colony-stimulating factor and inducing a leukaemoid reaction has been described [28].

Fig. 56.28 Typical haemorrhagic appearance of an angiosarcoma.

Clinical features [3,4,29,30]. In all types of angiosarcoma, the first sign may be an area of bruising, often thought by the patient to be traumatic (Fig. 56.28). Dusky blue or red nodules develop and grow rapidly, and fresh, discrete nodules appear nearby. In some cases, haemorrhagic blisters are a prominent feature. As the tumours grow, the oedema may increase and older lesions may ulcerate. Multifocality is a very frequent finding; this makes surgical excision very difficult, particularly in those cases occurring on the face and scalp. Dissemination occurs early, with the first visceral deposits usually being in the lung and pleural cavity.

Most studies reporting outcome have confined their attention to idiopathic angiosarcoma of the face, neck and scalp, in which the reported 5-year survival is low, at between 12% and 33% [3,31]. Angiosarcomas arising in the setting of chronic lymphoedema and after radiotherapy appear to be equally aggressive. Combined series of idiopathic angiosarcoma of the face and scalp, other cutaneous angiosarcomas and angiosarcomas occurring in internal organs report 5-year survival rates varying between 24 and 34% [1,32–34]. Features found to affect prognosis vary between different studies. Tumour size and completeness of excision appear to be more reliable factors to predict outcome [28]. It has been suggested that a high mitotic count correlates with poor prognosis and that a heavy mononuclear inflammatory cell infiltrate correlates with good prognosis [3,5,28]. A recent study of cutaneous sporadic angiosarcomas, excluding those associated with radiotherapy or with chronic lymphoedema, has found by univariate analysis that factors associated with higher mortality include older age, lesions on trunk and limbs compared to those on the head and neck, necrosis and an epithelioid cell morphology [35]. Tumours with necrosis and epithelioid morphology were classified as high risk and confirmed by multivariate analysis to be associated with higher mortality. The depth of invasion correlated with higher risk of local recurrence. The caveat with this study is that it combines traditional head and neck angiosarcomas with those showing a more pure epithelioid cell morphology that usually occur elsewhere and are usually classified under a different category.

Pathology [4,36–38]. In the well-differentiated tumour, vascular channels infiltrate the normal structures in a disorganized fashion, as if trying to line every available tissue space with a layer of endothelial cells. The collagen is characteristically lined by tumour cells in a pattern that has been described as ‘dissection of collagen’ (Fig. 56.29). Tumour cells may be plumper than normal, double-layered in places and form solid, intravascular buds. The pattern of growth is more suggestive of lymphatic vessels than blood vessels, but both are probably involved. Haemorrhage is often prominent. Less well-differentiated tumours show more atypical, pleomorphic, endothelial cells, often with a spindle-cell morphology, which may be heaped into several layers or become syncytial.

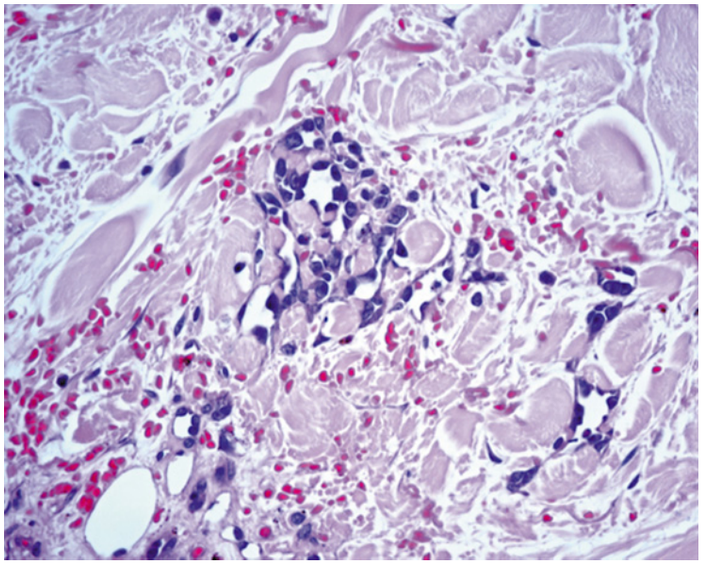

Fig. 56.29 Well-differentiated angiosarcoma, with thin-walled irregular vascular channels lined by atypical endothelial cells. Note the dissection of collagen pattern.

Advancing malignancy may be associated with loss of vascular pattern and proliferation of cell masses. Rare cases are composed of granular cells [39]. In exceptional cases, tumours may be extensively infiltrated by lymphocytes or macrophages. In these cases, distinction from a lymphoma may be difficult [40,41].

Immunohistochemical studies have indicated that antibodies to CD31 are the most reliable markers for routine use, compared with antibodies against von Willebrand factor and CD34 [7]. However, a panel of antibodies including the three markers is recommended in difficult cases as positivity to the various markers varies. Recently, an antibody against the carboxy terminal of the Fli-1 protein, a nuclear transcription factor member of the ETS family of DNA-binding transcription factors, has been shown to be a fairly specific marker of endothelial cells [42].

Cytogenetics studies of soft tissue and cutaneous angiosarcoma are limited to a few case reports. Most analyzed cases have shown complex cytogenetic aberrations [43,44].

Treatment [3]. All angiosarcomas, regardless of the setting in which they occur, have a bad prognosis. In the less malignant types, wide excision and grafting has controlled some cases. The response to radiotherapy is disappointing and is usually only palliative. In the early stages of angiosarcoma of a limb, radical amputation may offer a hope of cure. In idiopathic angiosarcoma of the head and neck, a very small percentage of patients with smaller lesions (usually less than between 5 and 10 cm in diameter at presentation) can be successfully treated with radical wide-field radiotherapy and surgery [1,32–34]. The best chance of survival in these patients resides in wide surgical excision followed by radiotherapy [45].

Epithelioid haemangioendothelioma [1–3]

Definition. Epithelioid haemangioendothelioma is a distinctive tumour characterized by epithelioid endothelial cells arranged in strands or as individual units, in a myxoid or hyalinized stroma. It was initially described as a low-grade malignant tumour, but it has recently been proposed that it should be classified as a fully malignant neoplasm, in view of the associated morbidity and mortality [3]. However, small, primary cutaneous lesions appear to have an indolent behaviour.

Clinical features [1–3]. This tumour may occur in many internal organs, and it is more commonly seen in deeper soft tissues. Involvement of the skin may occur primarily or as a result of direct extension from a deep-seated primary. Less than 10% of cases occur primarily in the skin. Tumours present in middle-aged adults, with an equal sex incidence. Cutaneous tumours are usually small, but deeper lesions are often several centimetres in diameter. Pain is a frequent complaint, probably due to angiocentricity. Involvement of other organs, including the lung, liver and bone, may be seen in some cases, and it is not clear whether this represents multicentricity or metastatic spread.

Pathology [1–3]. The neoplasm is infiltrative and is composed of strands, cords and nests of endothelial cells in a hyaline or myxoid stroma. Dermal lesions often consist of a fairly well-defined nodule. The tumour cells have epithelioid morphology and consist of pink cytoplasm, vesicular nuclei and inconspicuous nucleoli. Angiocentricity is commonly seen. Formation of vascular channels is not readily apparent but a common finding is the presence of intracytoplasmic vacuoles with or without red blood cells. A small number of cases display cytological atypia, which may be prominent, and a high mitotic count. There is no clear correlation between cytological grade and behaviour. Occasional tumours overlap with epithelioid angiosarcoma. Staining for endothelial cell markers, especially factor VIII-related antigen and CD31, is usually positive, and 20% of cases are focally positive for keratin [3,4].

Prognosis and treatment. Purely cutaneous tumours appear to have a benign behaviour, but there is some tendency for local recurrence. Deeper tumours have a recurrence rate of up to 15% and a mortality rate of 20%. Complete excision with clear margins is therefore necessary.

Epithelioid angiosarcoma [1–3]

Definition. A distinctive variant of angiosarcoma composed almost exclusively of endothelial cells with an epithelioid morphology, often mimicking a carcinoma. This tumour represents the malignant end of the spectrum of tumours with epithelioid cell morphology.

Incidence. This is a rare tumour that mainly occurs in deep soft tissue, but that may present primarily in the skin or other organs.

Clinical features [1–3]. Cutaneous tumours present in young to middle-aged adults, mainly in males, with a predilection for the extremities. The typical presentation is that of solitary, or more rarely multiple, asymptomatic papules or nodules which are often haemorrhagic. It is not clear whether multiple lesions represent multifocality or metastatic disease. Occasional cases have been reported in association with a foreign body [4], radiotherapy [1] or an arteriovenous fistula [5]. Epithelioid angiosarcoma arising in another organ may present with cutaneous metastases [6].

Pathology [1–3]. Sheets of atypical epithelioid cells with abundant pink cytoplasm, vesicular nuclei and a single eosinophilic nucleolus occupy the dermis and/or subcutis. Haemorrhage and haemosiderin deposition is often seen. Formation of vascular channels is not readily apparent, and the main feature is the presence of intracytoplasmic vacuoles with or without red blood cells in variable numbers of tumour cells. Mitotic figures are common. Tumour cells are variably positive for vascular markers including

CD31, CD34, Fli-1 and von Willebrand factor. In 50% of cases, there is positivity for cytokeratin. Focal positivity for epithelial membrane antigen is also seen in some cases. Ordinary angiosarcomas such as those occurring on the head of elderly patients, those associated with radiotherapy and those associated with chronic lymphoedema may display focal areas with epithelioid endothelial cells. This is no reason to classify these tumours as epithelioid angiosarcomas.

Prognosis and treatment. Although it was initially suggested that cutaneous epithelioid angiosarcoma has a relatively good prognosis, this was based on only very few cases with limited follow-up [2]. Overall, the behaviour of these tumours appears to be aggressive, and complete excision and close follow-up are therefore indicated.

Lymphatic tumours

Cavernous lymphangioma, cystic hygroma and lymphangioma circumscriptum are described in Chapter 48.

Progressive lymphangioma

Synonym
- Benign lymphangioendothelioma

Definition This is a benign dermal tumour composed of irregular, lymphatic channels dissecting between collagen bundles.

Clinical features [1–4]. Most cases present in middle-aged adults, but the age range is wide and children may be affected. The tumour presents as a slowly enlarging red macule, usually several centimetres in diameter with predilection for the limbs. Males are slightly more affected than females. Multiple lesions are exceptional [3].

Pathology [1–4]. Low-power examination reveals an ill-defined, often pan-dermal, proliferation of irregular, thin-walled lymphatic channels dissecting between collagen bundles. These channels tend to be orientated parallel to the epidermis and are lined by a single layer of bland endothelial cells. Involvement of the subcutaneous tissue is rare. Distinction from the lymphangiomatous variant of Kaposi's sarcoma is often very difficult, but in the former there are aggregates of inflammatory cells including plasma cells, and the cells lining the vascular channels are usually positive for HHV8. Distinction from a well-differentiated angiosarcoma is based on the absence of cytological atypia and mitotic figures.

Treatment. Excision is all that is required; there is no tendency for local recurrence.

Atypical vascular proliferation after radiotherapy [1–7]

Definition. Atypical vascular proliferation after radiotherapy (AVPR) defines a group of vascular lesions that occur months or years after radiotherapy—mainly, but not exclusively, after breast cancer. Lesions may also present after radiotherapy for ovarian and endometrial carcinoma.

Incidence and aetiology. These lesions are rare and there is a clear aetiological link with radiotherapy [1–7]. The demonstration of staining of the endothelial cells for lymphatic markers suggests a lymphatic line of differentiation. Although it has been suggested that AVPR represents part of a spectrum of lesions with post-radiation angiosarcomas [4], this view has recently been challenged in a study that stated that all lesions in this group are benign [7]. The problem with the latter study is that follow-up was limited.

Clinical features. AVPR presents a few years or months after radiotherapy for breast cancer (by comparison, post-irradiation angiosarcomas usually but not always tend to present many years after radiotherapy) [1–3]. The clinical lesions are not distinctive and vary from macules to papules. Occasional cases may mimic lymphangioma circumscriptum. As mentioned before, it is controversial whether these lesions are uniformly benign or whether they overlap with radiation-induced angiosarcoma.

Pathology. Irregular lymphatic-like vascular channels, lined by a single layer of endothelial cells, are seen in the dermis and may be multifocal. The endothelial cells are flat or have a hobnail appearance, and papillary projections can also be found. Careful examination of multiple sections is recommended to make sure that there are no mitotic figures or cytological atypia, as distinction from a well-differentiated angiosarcoma can be very difficult.

Treatment. Complete conservative excision of these lesions with close follow-up is recommended.

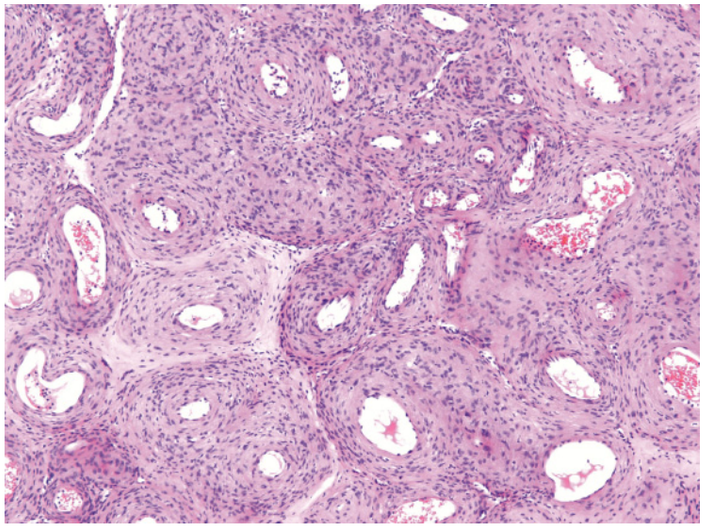

Fig. 56.30 Numerous vascular channels surrounded by layers of pericytes in an onion ring distribution in a case of myopericytoma.

Tumours of perivascular cells

Myopericytoma

Definition. For many years, tumours thought to differentiate towards pericytes (perivascular myoid cells) were divided into two main categories: infantile hemangiopericytoma and adult hemangiopericytoma. Both variants, however, appear to have very little in common except for the histological presence of a pericytomatous pattern characterized by elongated, branching thin-walled vascular spaces with a stag-horn pattern. With the combination of immunohistochemistry and electron microscopy, most tumours previously classified as adult hemangiopericytoma on light microscopy represent other tumours, including synovial sarcoma, mesenchymal chondrosarcoma and solitary fibrous tumour [1]. In very few cases the line of differentiation remains obscure, and these represent the 'true' adult hemangiopericytomas. They are more likely to arise from an undifferentiated mesenchymal cell than from a pericyte. 'True' adult hemangiopericytomas do not usually occur in the skin and will not be discussed further here.

The concept of myopericytoma was introduced to describe a group of lesions characterized by short, oval to spindle-shaped myofibroblasts and a characteristic concentric perivascular growth [2]. Tumours tend to be mainly deep dermal and subcutaneous and include lesions classified in the past as glomangiopericytoma, myopericytoma, myofibroma and myofibromatosis in adults. Infantile hemangiopericytoma and infantile myofibromatosis represent identical conditions and the former term has been abandoned.

Infantile myofibroma/myofibromatosis has already been described in the section on myofibroblastic tumours (p. 56.9).

Clinical features. Myopericytoma is relatively rare and presents mainly in middle-aged adults with a predilection for the limbs, especially the distal lower limb. Lesions are small (no more than 2 cm in diameter), long-standing, usually asymptomatic and may be solitary or, rarely, multiple [2–4]. Exceptionally they are painful. In the setting of multiple myopericytomas, these often develop simultaneously with a predilection for a single anatomic site. Very rarely, malignant examples of myopericytoma have been reported [5].

Pathology. The histological spectrum of myopericytoma is wide and varies from lesions that are very similar to myofibromatosis (p. 56.9), to tumours that closely resemble glomus tumours and even to angioleiomyoma. Lesions are well circumscribed and composed of a mixture of solid cellular areas intermixed with variable numbers of vascular channels. The later are often elongated and display prominent branching resulting in a stag-horn appearance (hemangiopericytoma-like). The cells in the solid areas are bland, round or short and spindle-shaped with eosinophilic or amphophilic cytoplasm and vesicular nuclei. Mitotic figures are exceptional. A common feature is the presence of concentric layers of tumour cells around vascular channels resulting in a typical onion ring appearance (Fig. 56.30). Myxoid change may be focally prominent. Occasional findings include hyalinization, cystic degeneration and bone formation. Nodules of tumour cells may protrude into the lumina of vascular channels. Rare examples are entirely intravascular [6]. In some cases, tumour cells closely resemble glomus cells and are characterized by round punched-out central nuclei and pale eosinophilic cytoplasm. These cases are referred to as glomangiopericytomas. Tumour cells are positive for smooth-muscle actin and in most cases negative for desmin.

Glomus tumour [1–3]

Synonyms
- Glomangioma
- Glomangiomyoma

Definition. A tumour of the myoarterial glomus, composed of vascular channels surrounded by proliferating glomus cells. The tumours have variable quantities of glomus cells, blood vessels and smooth muscle. According to this finding, they are classified as either solid glomus tumour, glomangioma or glomangiomyoma.

Incidence and aetiology. Glomus tumours are comparatively uncommon. Some are present at birth; they rarely appear during infancy, but from the age of 7 years onwards the incidence increases gradually. There may be a history of trauma preceding the tumour. Multiple tumours are 10 times more frequent in children than in adults [3,4]. The occurrence of familial cases with autosomal dominant inheritance [1,5,6], and the association of multiple tumours with malformation of the same limb, suggests involvement of genetic factors. This theory has been confirmed by the identification of the *glomulin* gene for multiple inherited glomangiomas (also known as glomuvenous malformations [7]) at chromosome 1p21-22 [8–10].

Clinical features. A solitary glomus tumour is a pink or purple nodule varying in size from 1 to 20 mm; it is conspicuously painful (Fig. 56.31). Pain may be provoked by direct pressure or a change in skin temperature, or may be spontaneous. There is an equal sex incidence; adults present mainly during the third or fourth decades of life. The commonest site is the hands, particularly the fingers, followed by other sites on the extremities including the head, neck and penis [11]. Tumours beneath the nail are particularly painful, and patients present for treatment while the lesions are still very small. The affected nail has a bluish-red flush. An association between subungual glomus tumour and neurofibromatosis type 1 has been reported [12]. Glomus tumours may also involve internal organs.

Multiple glomus tumours are larger and usually dark blue in colour, and are situated deep in the dermis. They are less restricted to the extremities, may be widely scattered and are not usually painful [13–16]. In some cases, grouped multiple tumours may be painful, and pain, intermittent discoloration and sweating of a limb may precede the development of a palpable tumour.

Pathology. The tumour is lobulated, well-circumscribed and situated in the dermis. The proportion of glomus cells to vascular spaces varies. The smaller, painful lesions tend to be mainly cellular. The larger, multiple and often painless lesions are angiomatous, with only a band of cells around the dilated vascular channels. The glomus cell is cuboidal, with a well-marked cell membrane and a round central nucleus. The cells align themselves in rows around the single layer of endothelial cells of the vascular spaces and in a somewhat less orderly fashion further out. Numerous, non-myelinated nerve fibres course through the cellular masses. More than 50% of tumours can be classified as glomangiomas, and a minority (less than 15%) are classified as glomangiomyomas (Fig. 56.32). Electron microscopy [17–19] suggests that glomus cells are transversely cut smooth muscle cells and that there are many mast cells around the tumour, but that nerve fibres are not associated with the glomus cells. Tumour cells are universally positive for smooth muscle actin and are usually negative for desmin. Positivity for CD34 may be seen [20]. An oncocytic variant has been described [21], and also variants developing within a cutaneous nerve [22] and within a vein [23]. Malignant glomus tumour (glomangiosarcoma) is exceedingly rare. Even tumours that are histologically malignant rarely metastasize, but they have a potential for local recurrence [24,25].

Fig. 56.31 Clinical appearance of a glomus tumour.

Diagnosis. The solitary tumour is to be distinguished from other painful tumours such as leiomyoma and eccrine spiradenoma. Distinction is usually only possible on histological examination. The multiple glomangioma may be indistinguishable clinically from a cavernous haemangioma, and is possibly identical to 'blue rubber bleb' naevus [5].

Treatment. Surgical excision is usually curative. Local recurrence is very rare and occurs mainly after incomplete excision. Most

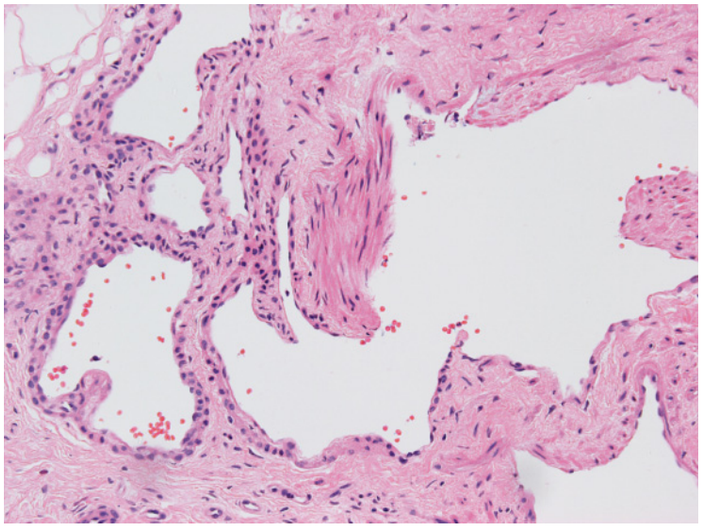

Fig. 56.32 A typical case of glomangiomyoma displaying vascular channels, smooth muscle and thin layers of glomus cells.

recurrences are seen in deeper lesions with an infiltrative growth pattern. These lesions have been described as infiltrating glomus tumours [24].

Neuromuscular hamartoma [1,2]

Synonym
- Triton tumour

Definition. These lesions appear to be combined hamartomas of both muscular and neural tissue.

Clinical features. The clinical appearance is of a subcutaneous mass.

Pathology. Multinodular masses of skeletal muscle are mixed with both myelinated and unmyelinated nerve fibres. Malignant triton tumours, composed of a mixture of schwannoma-like material and rhabdomyosarcoma, are very much commoner than the benign variety of triton tumour.

Management. Surgical excision is required.

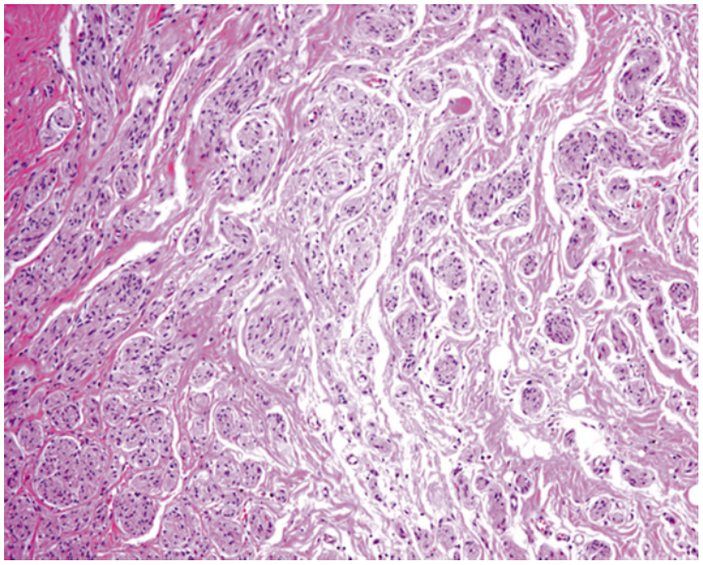

Fig. 56.33 Histological appearance of an amputation neuroma. Small nerves proliferate in the dermis in a background of fibrosis.

Multiple mucosal neuromas [1]

Synonym
- Sipple's syndrome

In Sipple's syndrome, multiple neuromas of the oral mucosa may be associated with phaeochromocytoma, parafollicular thyroid cysts secreting calcitonin, medullary thyroid carcinoma and opaque nerve fibres on the cornea (Chapters 15 and 62).

Amputation stump neuroma [1]

Synonym
- Traumatic neuroma

Definition. This is a benign response of nerve tissue to injury.

Clinical features. A small, tender nodule is found in a scar site.

Pathology. Foci of proliferating nerve tissue surrounded by scar tissue are typically seen (Fig. 56.33). Accessory digits may show a very similar pattern of tissue involvement.

Management. Surgical excision is usually required. The problem can be prevented by apposing ends of nerves at sites of injury.

Morton's neuroma [1,2]

Synonym
- Morton's metatarsalgia

Definition. This is the result of damage to the plantar digital nerve, followed by fibrosis. The condition has been associated with the use of high-heeled footwear.

Clinical features. It is most common in women, who complain of severe pain, usually between the third and fourth metatarsals, especially when walking.

Pathology. On pathological examination, there is very prominent perineurial, endoneurial and epineurial fibrosis. Perivascular fibrosis and intimal thickening are also seen.

Management. Excision is the recommended therapy and is curative.

Solitary circumscribed neuroma

Synonym
- Palisaded encapsulated neuroma

Definition. This is a distinctive variant of cutaneous neuroma composed of variable proportions of the normal components of nerve tissue.

Clinical features [1–3]. It is fairly common and presents mainly on the face of adults as a small, asymptomatic papule, which may resemble a naevus. There is an equal sex incidence.

Pathology [1–3]. Examination reveals a well-circumscribed, partially encapsulated dermal nodule (Fig. 56.34), often associated with a nerve in the deep dermis. It is composed of uniform cells with pink cytoplasm in a collagenous background and with artefactual clefting between bundles. The capsule displays epithelial membrane antigen-positive perineurial cells. Most of the cells within the nodule are S100-positive, and special stains may demonstrate axons.

Treatment. Simple excision is curative.

Schwannoma

Synonym
- Neurilemmoma

Definition. A tumour of nerve sheaths composed of Schwann cells.

Incidence. The tumour is relatively rare in the skin and relatively uncommon in other sites including soft tissues. It arises most frequently from the acoustic nerve. Bilateral acoustic schwannomas are characteristic of neurofibromatosis type 2. A further manifestation of the latter is the occurrence of multiple cutaneous plexiform schwannomas [1]. There is no association with neurofibromatosis type 1. In the peripheral nervous system, it is usually found in association with one of the main nerves of the limbs, usually on the flexor aspect near the elbow, wrist or knee, the hands or the head and neck [2]. It may be seen on the tongue. Other sites include the wall of the gastrointestinal tract and the posterior mediastinum. It may occur at any age, but is most common in the fourth and fifth decades. Females are affected more often than males [3].

Clinical features [4]. They are rounded or ovoid, circumscribed nodules varying in size up to 5 cm, usually firm (but sometimes soft and cystic) in consistency, and sometimes painful. The colour is pink-grey or yellowish. Small lesions may be intradermal, but larger ones are subcutaneous. They usually grow slowly. Malignant transformation of a schwannoma is exceedingly rare and may contain areas of epithelioid angiosarcoma [5–7].

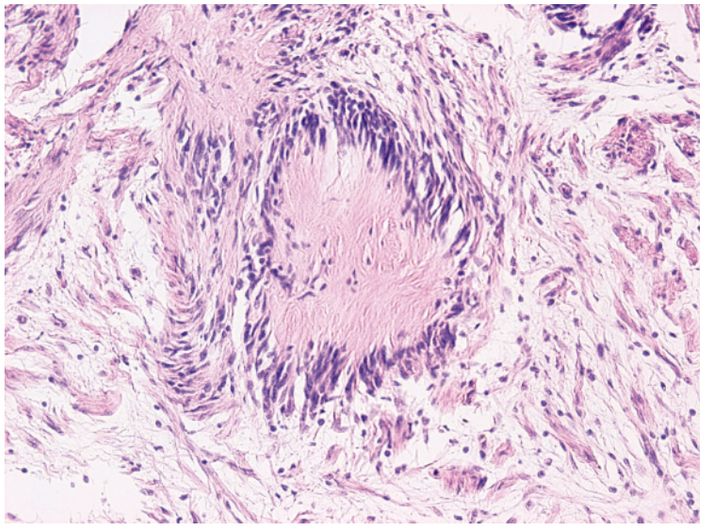

Fig. 56.35 Typical Verocay body in a case of schwannoma.

Pathology [2,8]. The tumour is rounded, circumscribed and encapsulated. It is situated in the course of a nerve, usually in the subcutaneous fat. The cells are spindle shaped with poorly defined cytoplasm and elongated, wavy, basophilic nuclei. Variable amounts of collagen are seen in the background. Cells are arranged in bands, which stream and interweave. The nuclei display palisading and are arranged in parallel rows with intervening eosinophilic cytoplasm in a typical appearance known as Verocay bodies (Fig. 56.35). Cellular areas known as Antoni A areas are intermixed with areas showing prominent myxoid change known as Antoni B areas [9]. The latter areas are likely to be the result of degeneration. In some tumours, there is mucous secretion, producing a vacuolated stroma. Scattered mononuclear inflammatory cells are often seen. In some cases, the nerve of origin may be found associated with the capsule. Electron microscopy shows that tumour cells have typical features of Schwann cells [10]. S100 protein staining is strong and uniform [11]. For many years it was thought that schwannomas lack axons and this was regarded as a useful way in distinguishing these tumours from neurofibromas which contain variable numbers of axons. The presence of the latter is demonstrated by immunostaining for neurofilaments. This view, however, has been challenged recently as both hereditary and sporadic schwannomas may contain axons, suggesting that both entities may in fact be more closely related than previously thought [12]. This explains the rare occurrence of hybrid lesions combining features of neurofibroma and schwannoma [13].

There are several variants of schwannoma, which may be confused histologically with other benign or malignant tumours.

Ancient schwannoma [14] often occurs in a deep location and is characterized by prominent degenerative changes, which often result in cytological atypia. Ectatic blood vessels, haemorrhage, haemosiderin deposition and focal inflammation consisting of lymphocytes are often seen. There is loss of Antoni A areas, which makes histological diagnosis difficult.

Cellular schwannoma [15] also tends to have a predilection for deep soft tissues. It is characterized by high cellularity, with almost complete absence of Antoni B areas. This, coupled with the presence of mitotic figures, often leads to a misdiagnosis of malignancy [16]. A multinodular plexiform variant may occur in children and some examples are congenital.

Plexiform schwannoma [17,18] tends to occur in younger patients, may be painful and has a predilection for the dermis. Multiple cellular nodules composed of bland Schwann cells are seen in the dermis. Distinction from plexiform neurofibroma is important, as these tumours are not usually associated with neurofibromatosis type 1. Multiple cutaneous plexiform schwannomas, however, are associated with neurofibromatosis type 2 [1,19].

Melanotic schwannoma [20] only exceptionally occurs in the skin; it has a predilection for spinal nerve roots. Tumour cells are epithelioid and melanin pigment is prominent. The importance of this variant is that they are capable of malignant behaviour and may be a marker of Carney complex (Chapter 62).

Pacinian schwannoma is a rare variant composed of structures closely resembling the Pacinian corpuscles.

Neuroblastoma-like schwannoma is very rare and characterized histologically by areas composed of round, blue, small Schwann cells which may form perivascular rosettes or rosettes with collagenous cores [21]. The tumour in other areas has the typical appearance of a schwannoma and the immunohistochemical profile is typical of the latter.

Epithelioid schwannoma is an infrequent type of schwannoma composed predominantly of cells with epithelioid morphology [22]. However, although these tumours are positive for S-100 protein, they lack palisading, are composed of uniform tumour cells and contain a population of CD34-positive cells. It has therefore been proposed that these lesions do not represent classical examples of schwannomas [23].

Glandular schwannoma [24,25] represents in most cases an ordinary schwannoma with entrapment of normal sweat glands.

Diagnosis. Of the various nodular dermal and hypodermal tumours, schwannoma is most likely to be mistaken for a glomus tumour when painful, and for a lipoma, epidermoid cyst, synovial ganglion, juxta-articular node or neurofibroma when asymptomatic. The diagnosis can be suspected when it is in the course of a nerve; otherwise, histological examination is necessary.

Treatment. Simple excision is curative.

Solitary neurofibroma [1–4]

Definition. An isolated lesion probably arising from the endoneurium and composed of a mixture of Schwann cells, fibroblasts and perineurial fibroblasts. It is not related to neurofibromatosis type 1. Although it appears to be hamartomatous in nature, the demonstration of clonality suggests a neoplastic origin [5].

Fig. 56.36 Multiple soft papules, typical of neurofibroma in a patient with neurofibromatosis type 1.

Fig. 56.37 Clinical appearance of a plexiform neurofibroma.

Clinical features. Both sexes and any body site may be affected. It usually appears during the third decade as a slow-growing, small, polypoid lesion. Multiple neurofibromas are rare outside the setting of neurofibromatosis type 1 (Fig. 56.36).

Simple excision is curative. Malignant change is said not to occur outside the setting of neurofibromatosis type 1.

Pathology. These lesions differ from neurilemmomas in that they do not have a capsule, they are only focally positive for S100 protein, and they do not usually have well-defined Antoni A and Antoni B areas. Instead, they are composed of bland, spindle-shaped cells with wavy nuclei in a myxoid or collagenous stroma. Mast cells are usually prominent. Degenerative changes are sometimes seen but mitotic activity is absent. Less than 50% of the cells in these lesions are S100-positive. There is also focal positivity for CD34 and epithelial membrane antigen (EMA).

Several histological variants of neurofibroma have been described, including epithelioid neurofibroma, granular cell neurofibroma, pigmented neurofibroma [6] and a variant with dendritic cells and pseudorosettes [3,7].

Cytogenetic analysis in a single case of solitary neurofibroma has found a reciprocal translocation t(4;9)(q31;p22) [8].

Plexiform neurofibroma

This tumour is considered to be pathognomonic of neurofibromatosis type I (see Chapter 15). However, it has been contested whether the presence of a single plexiform neurofibroma in the absence of other signs of neurofibroma can be regarded as pathognomonic of neurofibromatosis type I [1,2]. It presents in children and young adults of either sex, with predilection for the lower limbs and the head and neck. Tumours are large and located in the dermis, subcutis and even deeper soft tissues. The overlying skin is folded and hyperpigmented and the lesion is described as having an appearance like a 'bag of worms' (Fig. 56.37). This reflects the typical histological appearance of nerve trunks of different sizes randomly distributed throughout the involved tissues (Fig. 56.38). Careful histological examination of these lesions is

necessary because the presence of any mitotic activity usually indicates malignant transformation.

Surgical removal of these lesions is usually very difficult because of the extensive involvement. When planning the surgical removal of these tumours, surgeons should remember that there is a tendency for haemorrhage within the tumour that may lead to morbidity or mortality.

Diffuse neurofibroma

This lesion presents as a diffuse, poorly-defined induration or plaque-like lesion of the skin and subcutaneous tissue in children or young adults, with a predilection for the trunk and head and neck area. Only a minority of cases are associated with neurofibromatosis type 1. The histological features are identical to those of a solitary neurofibroma except for the fact that there is diffuse replacement of involved tissue by the tumour. Local recurrence is frequent unless the lesion is widely excised.

Perineurioma [1–4]

Synonym

- Storiform perineural fibroma

Definition. Perineurioma is a tumour originally described in soft tissues. It is relatively common in the skin and it is composed of cells showing differentiation towards perineural fibroblasts.

Clinical features. The lesion has predilection for the lower limbs of young females. Tumours are small and asymptomatic. A distinctive, sclerosing variant has been described, affecting most commonly, but not always, the hands [4,5].

Pathology. Tumours are well-circumscribed and composed of bipolar and slender bland, thin, spindle-shaped cells with scanty cytoplasm and wavy nuclei. They are often arranged in concentric whorls (Fig. 56.39) or in a storiform pattern. Cellularity varies and is low in the sclerosing variant where hyalinized collagen predominates. The architecture may be plexiform in some cases [6]. Tumour cells are distinctively positive for EMA. They are also positive for a tight junction associated protein, claudin-1 [7]. Focal positivity for factor XIIIa and CD34 may also be seen.

Treatment. Lesions are entirely benign, and simple excision is the treatment of choice.

Dermal nerve sheath myxoma [1–3]

Synonym

- Neurothekeoma

Definition. This is a myxoid tumour that is thought to display nerve sheath differentiation.

Clinical features [1,2,4]. It presents most commonly on the upper limbs (particularly the fingers and hands) and lower limbs (mainly the knees, shins or feet) of young adults, with a predilection for males. The trunk and head and neck are rarely affected. Lesions are long-standing, small, usually less than 1 cm, skin-coloured and asymptomatic.

Pathology [1–3]. The dermis shows a well-defined tumour composed of lobules that vary in size and shape and are separated by fibrocollagenous stroma. Each lobule is composed of slender stellate or spindle-shaped Schwann cells with bland nuclei and indistinct cytoplasm margins in the background of prominent myxoid change. Mitotic figures are very rare. Tumour cells are uniformly positive for S100. They are also positive for glial fibrillary acid protein and CD57 [4]. EMA-positive cells are seen in the periphery of tumour lobules. These tumours have no relationship with the so-called cellular neurothekeoma [5].

Treatment. Simple excision is curative. There is high tendency for local recurrence [4].

5 Rosati LA, Fratamico CM, Eusebi V. Cellular neurothekeoma. *Appl Pathol* 1986; **4**: 186–91.

Cellular neurothekeoma [1–4]

Definition. Despite its name, this tumour is not related to dermal nerve sheath myxoma, and its line of differentiation has not been established. It should not be confused with ordinary nerve sheath myxomas showing focal cellular areas [1–3].

Clinical features. The tumour presents as a small, asymptomatic papule in children and young adults, more common in females than males and with a predilection for the upper limbs and face and neck [4,5]. Multiple lesions are exceptional [6].

Pathology. In the dermis and frequently extending into the subcutis [5], there is an ill-defined tumour composed of nests and fascicles of epithelioid or spindle-shaped cells (Fig. 56.40) with vesicular nuclei and a single small eosinophilic nucleolus. Lesions presenting in the face may extend into the underlying skeletal muscle. Mitotic figures are relatively common and scattered multinucleated cells (osteoclast-like) may be seen. Tumour cells resemble melanocytes, and this often leads to the lesion being confused with a melanoma. However, there is no junctional activity, and cells are invariably negative for S100. Some tumours have larger size, more cytological atypia and increased mitotic count, and these tumours have been classified as atypical cellular neurothekeoma [4,5]. However, this does not seem to be related to a more aggressive behaviour. Tumour cells are often positive for smooth muscle actin (in about 57% of cases), NKI-C3, neuron-specific enolase and PGP 9.5 [5].

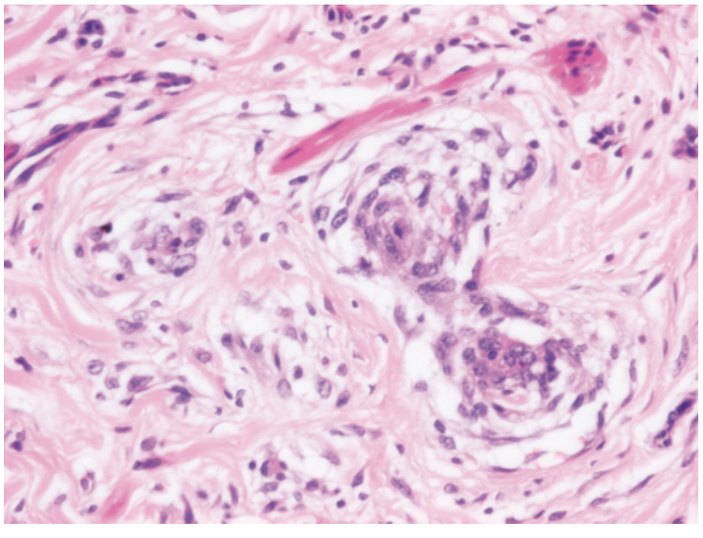

Fig. 56.40 Cellular neurothekeoma. Nests of epithelioid cells in the background of a hyalinized stroma. In cases with cytological atypia and mitotic activity, confusion with a melanoma is more likely.

Treatment. Simple excision is curative, and there is very little tendency for local recurrence [5].

Granular cell tumour [1–4]

Synonyms
- Abrikossoff's tumour
- Granular cell myoblastoma

Definition. A tumour composed of cells with characteristic granular cytoplasm. The histogenesis of the classic granular cell tumour seems to be neuroectodermal. However, it is worth remembering that many tumours of different histogenesis may show granular cell change, due to the cytoplasmic accumulation of secondary lysosomes.

Incidence. This is a rare tumour, occurring in the tongue as well as in the skin, and also in a variety of deeper locations including internal organs. Females are slightly more affected than males, and it is common in the third to fifth decade of life. It can occur in childhood [5,6].

Clinical features. The tumour is usually solitary, situated in the skin, the gingiva [7], or beneath the epithelium of the tongue. It is firm and rounded but with rather indefinite margins, sessile or pedunculated, and between 5 and 20 mm in diameter, although larger tumours may be seen. The colour may vary from flesh colour to pink or greyish-brown. It is most common in the tongue, where the epithelium over it may be thickened. On the skin surface, the epithelium covering the tumour is usually normal,

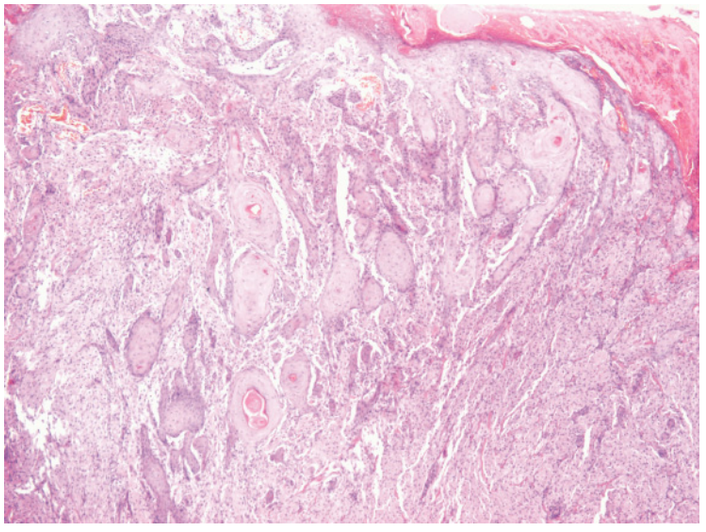

Fig. 56.41 Prominent pseudoepitheliomatous hyperplasia mimicking a squamous cell carcinoma in a case of granular cell tumour.

although it may thicken or at times ulcerate. There is no particular site of predilection. Multiple tumours may occur [8], and several have been reported in children, one of whom also had axillary freckling [5]. The tumour grows slowly.

A malignant type of granular cell tumour that metastasizes has been reported [9,10]. Among the internal sites reported are muscle, lip, jaws, parotid gland, pharynx, larynx, trachea, bronchus, lung, chest wall, breast, lacrimal sac, orbit, heart, oesophagus, common bile duct, urinary bladder, spermatic cord, male urethra, perineum, anal region, vulva and ovary [6,11].

Pathology [12,13]. Large polyhedral cells arranged in sheets, which infiltrate the dermal connective tissue and subcutaneous fat, form the tumour. The cytoplasm is pale and contains brightly acidophilic granules. The nuclei are relatively small and round, and tend to be vesicular. Clear cell change may occasionally be prominent [14]. The epithelium over the area may show pseudoepitheliomatous hyperplasia and in small biopsies this may be confused with a squamous cell carcinoma (Fig. 56.41). Perineural extension is often seen. Occasionally, tumour cells involve the epidermis and distinction from melanoma may be difficult [15]. However, although S-100 positivity is seen in both tumours, other melanocytic markers, including HMB45 and melan-A, are negative in granular cell tumour. The original suggestion that the cells are myoblasts probably arose from examination of tumours of the tongue in which infiltration between the striated muscle bundles gave the impression of origin from the muscle. The general belief now is that the cells are of neural or nerve sheath origin [16–21].

Diagnosis. Histological examination is usually necessary to separate this tumour from other tumours of the deeper dermis.

Treatment. Local recurrence, mainly due to incomplete excision, is uncommon, and simple excision is therefore the treatment of choice.

Meningothelial heterotopias [1–8]

Synonym
- Cutaneous meningioma

Lesions with meningothelial elements presenting in the skin and soft tissue were divided into three groups by Lopez *et al*. [4]. The first two groups of lesions represent meningothelial heterotopias or hamartomas. The main difference between both groups is that affected patients are children in the first group and adults in the second group. The third group consists of intracranial meningiomas that extend secondarily into the skin or soft tissues. This group will not be discussed in more detail here.

A small number of cases of meningothelial heterotopias have been associated with von Recklinghausen's disease [1]. The tumour occurs over the scalp or in the paraspinous region of the trunk of

children and young adults. Occasionally it appears to be familial [6]. The lesions resemble 'soft naevi'. On the scalp, the area may be bald. The skin is adherent to the mass, which is dermal or subcutaneous, and there may be a central depression with epidermal atrophy or ulceration. A connection with the cranial cavity is not usually demonstrated. The size ranges from 2 to 10 cm.

Pathology [6–8]. Low-power examination often reveals a lesion with a striking resemblance to a lymphangioma. Irregular dilated spaces are seen dissecting between collagen bundles. The spaces are partially lined by plump epithelioid cells, which are also seen in clusters in the surrounding stroma. Focal formation of psammoma bodies may be present. The dermal collagen and blood vessels also appear to be increased. Some lesions contain more solid areas. The presence of meningothelial cells can be demonstrated by positive staining for EMA.

Glial heterotopic nodules [1,2]

Synonym
- Nasal glioma

Definition. This represents the presence of heterotopic mature glial tissue in the dermis or subcutis, predominantly on the central face. It may be considered to be a developmental defect in the closure of the neural tube. However, rare cases occur away from the midline, suggesting a different unexplained mechanism for its occurrence [3].

Clinical features. Most lesions present in infants or children as a subcutaneous mass on the bridge of the nose. Presentation in adults is exceptional. Communication with the cranial cavity is present in up to 20% of cases.

Pathology. Nodules of astrocytes in a neurofibrillar background are characteristic. Less commonly, oligodendrocytes are seen; neuronal elements are exceptional.

Treatment. Excision is curative, but it is very important to make sure that an underlying communication with the cranial cavity is ruled out, as failure to do so may result in complications such as meningitis or cerebrospinal fluid leakage.

Epithelial sheath neuroma [1]

Definition. This is a novel, rare and intriguing dermal lesion that combines a neural and an epithelial component. Although some features suggest that this may be a hamartoma, the fact that it has only been described in adults makes this possibility unlikely.

Clinical features. In view of the fact that so few cases have been described, very little can be said about the clinical features. The clinical presentation is not distinctive and lesions appear to have a predilection for the back.

Pathology. Histologically there are scattered, prominent nerves in the superficial dermis, encased by mature, non-dysplastic squamous epithelium with focal keratinization and dyskeratotic cells. Immunohistochemistry displays the normal staining of nerves and epidermis respectively.

Prognosis and treatment. Lesions appear to be benign and no recurrences have been reported so far.

Pigmented neuroectodermal tumour of infancy [1,2]

Synonyms
- Melanotic progonoma
- Retinal anlage tumour

For many years, there has been a debate as to whether this tumour is of neural or melanocytic origin [3–5]. Recent evidence seems to indicate that this tumour recapitulates the early stages of development of the retinal epithelium [6].

Clinical features. This tumour occurs most frequently in the anterior part of the maxilla, usually in infants less than 6 months old, and often presents as a pigmented oral mass [7]. It has been reported also in the anterior fontanelle, the shoulder, epididymis, femur and mediastinum. There is a slight predilection for males. It may cause a high urinary excretion of vanillylmandelic acid [3]. This tumour has been mistaken in the past for malignant melanoma, and could also be confused with a cellular blue naevus.

The clinical appearance is that of a rapidly expanding nodule in the jaw, which may affect dentition. Although classified as benign, the lesions may cause considerable local destruction, and around 5% of cases may metastasize and prove fatal [8].

Pathology [9,10]. A mass of irregular alveolar spaces surrounded by fibrous stroma is seen. Two types of cells are easily recognized: small round blue cells with scanty cytoplasm in a fibrillary matrix, and large epithelioid cells with pink cytoplasm and vesicular nuclei. These cells often contain melanin. Both types of tumour cells stain for synaptophysin and neurone-specific enolase, and are negative for S100. The large cells are positive for cytokeratin and HMB45.

Treatment. Complete surgical excision is the treatment of choice.

Malignant peripheral nerve sheath tumour [1,2]

Synonyms
- Neurofibrosarcoma
- Malignant schwannoma

Definition. A malignant tumour arising from the nerve sheath.

Aetiology. Cutaneous tumours usually arise from a plexiform neurofibroma in patients with neurofibromatosis type 1 [3]. Rare cutaneous lesions may arise within ordinary neurofibromas or *de novo* [4]. Deep-seated lesions arise *de novo* or in association with neurofibromatosis type 1. Patients with this disease develop malignancy in 30–50% of cases.

Incidence. It is an uncommon tumour. It occurs in young adults, or even children, when it complicates multiple neurofibromatosis. Sporadic cases occur in older individuals.

Clinical features [5]. The diagnosis should be suspected when a previously static tumour in a patient with neurofibromatosis begins to enlarge or becomes painful. The pain may become radicular as the lesion progresses but the tumours are not always associated with nerve trunks. The commoner sites are the flexor aspects of the limbs. A minority of cases occur as a complication of radiotherapy.

Pathology. The basic pattern is that of fascicles of tumour cells, often with a herringbone pattern and resembling a fibrosarcoma. Tumour cells tend to concentrate around blood vessels and myxoid change is common. The degree of pleomorphism and the number of mitotic figures varies. Immunohistochemical markers are not usually of help in the diagnosis as S-100 is only focally positive and often entirely negative.

Treatment. Wide local excision or amputation is necessary because of the aggressive behaviour of the tumour, and even then the prognosis is not good. Systemic metastases, particularly to the lungs, are common. The prognosis is worse in cases occurring after previous radiotherapy.

Clear cell sarcoma [1–5]

Definition. Clear cell sarcoma is a distinctive, malignant soft-tissue tumour that displays melanocytic differentiation.

Clinical features. Most cases occur on the lower limbs, with a predilection for the foot. The upper limb is affected in about 25% of cases. There is a predilection for females. Tumours tend to grow around tendons, are usually less than 3 cm in diameter and are often painful. Primary dermal tumours are exceptional.

Pathology. The lesion has a lobular growth pattern. Tumour cells are fairly homogeneous and contain clear or pale pink cytoplasm and a prominent eosinophilic nucleolus. Mitotic figures are not prominent, but multinucleated giant cells with a wreath-like arrangement of the nuclei are often identified. Loose, thin bands of collagen surround tumour cells. Secondary involvement of the dermis is relatively common. Necrosis is sometimes seen. Melanin is sometimes identified, and S100, HMB45 and melan A are usually positive. Electron-microscopic examination of tumour cells reveals the presence of melanosomes.

Cytogenetic analysis often reveals a translocation t(12; 22)(q13;q12); this translocation is not found in melanoma, which often has mutations in the *BRAF* gene (a feature not seen in clear cell sarcoma) [6,7]. The clear cell sarcoma translocation results in an *EWSR1—ATF1* fusion gene [8].

Prognosis and treatment [1–4]. About 50% of patients develop metastatic disease, often many years after the initial diagnosis. Prognosis is associated with mitotic index, size of the tumour and presence of necrosis [9,10]. The 5- and 10-year survival rates are 52% and 25% respectively [9]. Wide excision is the treatment of choice. Chemotherapy does not seem to be effective in the treatment of disseminated disease.

Peripheral primitive neuroectodermal tumour [1,2]

Synonyms
- Peripheral neuroepithelioma
- Extraosseous Ewing's sarcoma

Primary cutaneous or subcutaneous peripheral primitive neuroectodermal tumour is extremely rare, and only a handful of cases have been reported in the literature. The tumour presents in children and has no distinctive clinical features, although it is often confused with a vascular tumour. It has been suggested that superficial tumours have a better prognosis than those presenting in deeper soft tissues, but the number of cases reported and their follow-up is too limited for this to be certain. The histological diagnosis includes tumours composed of small, blue, round cells, for which immunohistochemistry plays an important role in diagnosis. Tumour cells are diffusely positive for CD99. This tumour usually presents a reciprocal chromosome translocation t(11;22)(q24;q12) that is an important aid in diagnosis.

Tumours of muscle

Congenital smooth muscle hamartoma

This lesion is described in Chapter 18.

Leiomyoma [1–3]

Definition. A benign tumour of smooth muscle derived from the arrector pili muscle, from the media of blood vessels, or from smooth muscle of the scrotum, labia majora or nipples (genital leiomyoma) [4,5].

Incidence. The tumour occurs in three main types, all of which are relatively uncommon.

Pilar leiomyoma (leiomyoma cutis) originates in the pilomotor muscle and is the most frequent. It can occur at any age from birth onwards, but appears usually in early adult life. It has been reported in identical twins, in siblings and in several generations of a family [6–8]. The cases with a familial background have all had multiple tumours. The sexes are affected equally.

Genital leiomyoma (dartoic myoma) arises in the smooth muscle of the genitalia and areola of the nipple [9,10]. It can occur at any age. The cutaneous variety is about six times more frequent than the genital type [11].

Angioleiomyoma arises from the muscular coat of veins, and is seen mainly in middle age or later as a solitary nodule on a limb. It is rather more prevalent than glomus tumour in published series [6,12,13]. Females are more commonly affected than males.

Clinical features [6,14]. Pilar leiomyoma generally presents as a collection of pink, red or dusky brown, firm dermal nodules of varying size but usually less than 15 mm diameter (Fig. 56.42). The nodules are often subject to episodes of pain and may be tender. The pain can be provoked by touching or chilling the skin, or by emotional disturbance, and is often worse in winter. Some lesions contract and become paler when painful [12,15]. The condition usually begins with the appearance of one small nodule, which gradually increases in size, and further similar lesions appear nearby or at some other area. Adjacent tumours may coalesce to form a plaque. The areas most commonly affected are the extremities, with the proximal and extensor aspects somewhat favoured. The trunk is involved more often than the head and neck. Multiple lesions may be regional and unilateral, or more than one region

Fig. 56.42 Clinical appearance of multiple leiomyomas.

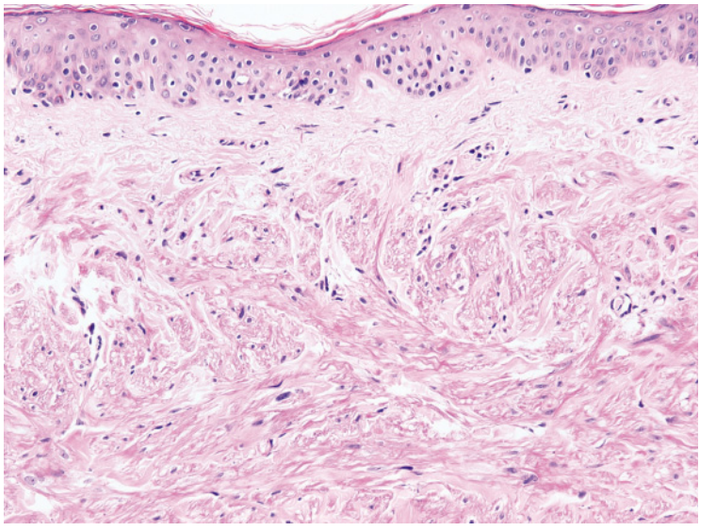

Fig. 56.43 Pathology of leiomyoma, showing spindle-shaped cells with eosinophilic cytoplasm arranged in bundles closely resembling the arrector pili muscle.

can be affected. Solitary lesions may occur, apart from the dartoic type. The gene that predisposes to multiple pilar leiomyomas has been mapped to chromosome 1q 42.3-q43 [16]. It also predisposes to uterine leiomyomas (multiple cutaneous and uterine leiomyomatosis, MCUL) and to renal cancer [17]. This is as a result of mutations in the gene encoding the enzyme fumarate hydratase [18]. In patients with associated renal cancer the syndrome is known as hereditary leiomyomatosis and renal cancer.

Genital leiomyoma is a solitary dermal nodule occurring most commonly in the scrotum, but also appearing on the penis, labia majora and nipple area. Scrotal tumours are often large. Pain is less frequent than with leiomyoma cutis. Contraction in response to stimulation by touch or cold can occur.

Angioleiomyoma is usually a solitary, flesh-coloured, rounded, subcutaneous or deep dermal tumour up to 40 mm in diameter. It is more frequent on the lower limb than the upper and may appear on the trunk or face. About half the reported cases have been painful [6,12]. Lesions are long-standing and present between the fourth and sixth decades of life. Pain may be triggered by changes in temperature, pregnancy or menses.

Pathology [12,14,19,20]. The smooth muscle cells proliferate to produce interweaving bundles of spindle-shaped cells, which are strongly eosinophilic (Fig. 56.43). The nuclei are long and thin, and the general appearance of the mass in ordinary sections may suggest a hypertrophic fibrous reaction. The smooth muscle cells can be distinguished from collagen by their different reaction with trichrome stains, and by the presence of myofibrils, which stain with phosphotungstic acid haematoxylin, and by their blunt-ended nuclei. Tumour cells are positive for actin and desmin.

The tumour of pilomotor origin (leiomyoma cutis, multiple cutaneous leiomyomas) is usually composed of numerous dermal nodules with vague margins where the cells penetrate the surrounding collagen bundles, and an upper border that approaches the papillary body. Associated epidermal hyperplasia is common. Focal nuclear atypia likely to be degenerative in origin and very low mitotic activity (up to one per 10 high-power fields) may be seen without this being indicative of malignant degeneration [21]. Genital leiomyomas are nodular tumours with a similar appearance. Scrotal tumours are less circumscribed and more cellular than those developing in the vulva. The angiomyomas are related to veins in the subcutaneous tissue, and are rounded and well circumscribed [22]. Vessels of variable thickness are intermixed with bundles of mature smooth muscle. Focal degenerative cytological atypia may be seen, but mitotic figures are absent. Calcification, hyalinization and thrombosis of vessels are often seen.

Diagnosis. The multiple type should cause little difficulty, and even without pain it is fairly distinctive. The solitary painful lesion may be mistaken for a glomus tumour or an eccrine spiradenoma, and a history of contraction is helpful. In practice the diagnosis can be elusive.

Treatment. Surgical excision cures the solitary tumour. The severity of the pain may make the patient demand treatment, and extensive lesions require plastic surgery. Excision of an area containing multiple tumours is often followed by their appearance in the neighbourhood of the treated area. Medical treatments that may relieve pain include calcium-channel blockers and gabapentin.

Leiomyosarcoma [1–4]

Definition. A malignant tumour displaying smooth muscle differentiation. Tumours are divided into those occurring in the subcutaneous tissue and those arising in the dermis. Pure dermal lesions have a very different behaviour from those arising in the subcutis and it is therefore important to separate them (see below).

Incidence. This is a rare tumour. Dermal leiomyosarcoma presents predominantly on the lower limbs of young adults, with a predilection for males. Subcutaneous leiomyosarcoma affects middle-aged to elderly patients with slight predilection for males.

Clinical features [5,6]. The tumour may be situated in the dermis, when it is reddish in colour and may bleed on trauma. It is usually larger than a leiomyoma and dermal lesions may be painful. The majority of tumours have, however, arisen in the subcutaneous or deeper tissues as nodular tumours, ulcerated plaques [7] or diffuse swellings [8]. It may invade underlying muscle fascia. It is most common on the thigh, followed by the head and neck, arm and trunk, and may arise from the penis [9] or vulva. It is unlikely to be diagnosed clinically. An exceptional tumour has been reported arising in a naevus sebaceous [10]. Dermal leiomyosarcomas have a 40% recurrence rate, but they almost never metastasize [11]. Subcutaneous tumours metastasize in up to 50% of cases and they are associated with a mortality of about 30%.

Pathology [3,11–15]. The lesion is distinguished from other dermal malignant tumours composed of spindle-shaped cells by the presence of fascicles of eosinophilic spindle-shaped cells with vesicular cigar-shaped nuclei. The degree of differentiation varies and necrosis tends to be present in deeper tumours, but not in those arising primarily in the dermis. Most tumours are actin- and desmin-positive, but staining for the latter may be lost in poorly differentiated variants. Dermal variants tend to be consistently positive for both markers. Rare cases have a desmoplastic stroma making histological diagnosis difficult [16,17]. About 30% of leiomyosarcomas are immunohistochemically positive for keratin, but this is less commonly seen in cutaneous examples.

Treatment. Wide surgical excision is necessary, as local recurrence follows inadequate excision.

Skeletal muscle tumours

Rhabdomyosarcomatous congenital hamartoma

This lesion is described in Chapter 18.

Rhabdomyoma

Rhabdomyomas are divided into adult, fetal and genital types. They mainly occur in soft tissues, vulva or vagina, upper respiratory tract and internal organs. Presentation in the skin is almost never seen, and they will not be discussed further in this chapter.

Cutaneous rhabdomyosarcoma

Malignant tumours with skeletal-muscle differentiation are classified into two large groups, namely embryonal and alveolar types. Although rhabdomyosarcomas represent up to 8% of tumours in children, primary involvement of the skin by this tumour is very rare [1]. Much more common is involvement of the skin by direct extension from deeper soft tissues. Only 16 cases of primary cutaneous rhabdomyosarcoma have been reported in the literature so far, and only five of these have occurred in adults [2,3]. The most common subtype occurring in the skin is the alveolar variant. The majority of cases have presented on the face. The prognosis is difficult to estimate because of the rarity of these cases and the limited follow-up available.

Tumours of fat cells

Lipoma, angiolipoma and hibernoma

These lesions are described in Chapter 46.

Lipoblastoma and lipoblastomatosis

Definition. Lipoblastoma is a tumour that occurs almost exclusively in infants and children. It is characterized by a proliferation of immature fat cells in a myxoid stroma (that may mimic myxoid liposarcoma) and intermixed with mature adipocytes [1]. Lipoblastoma is a well-circumscribed, subcutaneous tumour; lipoblastomatosis refers to a deeper lesion or those that have an infiltrative growth pattern.

Clinical features [1–3]. Most cases present during the first few years of life, with a predilection for males. The majority of tumours occur on the limbs as an asymptomatic mass no more than a few centimetres in diameter. Lipoblastoma is much more common than lipoblastomatosis.

Pathology [1–3]. Tumours have a characteristic lobular appearance. Each tumour lobule is separated by fibrous septae and consists of a mixture of small, univacuolated, signet-ring cells, spindle-shaped or stellate cells and scattered mature adipocytes. In the background, there are prominent myxoid changes and numerous small vessels in a typical 'crow's-feet' distribution, mimicking a myxoid liposarcoma. Distinction from the latter may be very difficult, especially in small biopsies. The clinical information is therefore crucial, as myxoid liposarcoma is vanishingly rare in children and almost never occurs before the age of 10 years [4]. Furthermore, lipoblastoma tends to be less cellular than myxoid liposarcoma and has a lobular architecture. Over time, maturation occurs, and in some cases most of the tumour is composed of mature fat cells.

Cytogenetic studies in lipoblastoma have shown rearrangements on chromosome 8q [5,6].

Treatment. The tumour is benign, and simple excision is the treatment of choice. Deeper lesions have some tendency for local recurrence.

Spindle cell and pleomorphic lipoma [1–5]

Definition. Spindle cell lipoma is composed of mature adipocytes and variable numbers of short, bland, spindle-shaped cells with indistinct cytoplasm. Pleomorphic lipoma is composed of mature adipocytes, cells with hyperchromatic nuclei and frequent multinucleation, and collagen bundles. Both types of tumour may overlap, and they are therefore considered to be part of the same spectrum.

Clinical features [1,2,4,5]. Spindle cell lipoma usually presents as a small subcutaneous nodule on the upper back or nape of the neck of middle-aged to old patients, with marked predilection for males. Occasional, purely dermal examples may be seen [6]. Multiple lesions, and familial cases, occur rarely [3]. Pleomorphic lipoma has a similar clinical presentation.

Pathology [1,2,4]. Spindle cell lipoma presents as a well-circumscribed tumour composed of mature adipocytes intermixed with short, spindle-shaped cells with wavy nuclei. Hyalinized collagen bundles and focal myxoid change are prominent. Pseudovascular spaces are prominent in some cases. The spindle-shaped cells stain for CD34 and the adipocytes are positive for S100. Pleomorphic lipoma is also well-circumscribed and composed of mature adipocytes intermixed with uninucleated or multinucleated cells with hyperchromatic nuclei. The nuclei in the multinucleated cells are often arranged in a circle (floret cell). The histological diagnosis may be quite difficult in cases with few or no mature fat cells [7]. Rare variants contain real prominent vascular spaces [8].

Cytogenetic studies of both tumours have shown variable abnormalities, most commonly in chromosome 16q and rarely in chromosomes 13q and 6p [9,10].

Treatment. There is little tendency for local recurrence, and simple excision is therefore the treatment of choice.

Atypical lipomatous tumour [1–4]

Synonym
- Well-differentiated liposarcoma

Definition. This is a lesion composed of lobules of mature adipose cells, with scattered larger cells with variation in nuclear size and hyperchromatism. The term 'atypical lipomatous tumour' is usually used for neoplasms occurring in the subcutis or within skeletal muscle. Similar tumours occurring in the abdominal cavity are regarded as well-differentiated liposarcomas, in view of the fact that they have a potential to cause death as a result of extensive growth. Only subcutaneous lesions will be discussed here.

Clinical features [1–3]. Subcutaneous atypical lipomatous tumours occur in middle-aged to old adults with predilection for the lower limbs. Tumours may be large, are asymptomatic and have the same clinical appearance as a lipoma.

Pathology. Typically, lobules of mature adipose tissue, with or without fibrous tissue and myxoid change, are seen. Focal variation in the size and shape of adipocytes is seen and this is associated with nuclear enlargement and hyperchromatism. Vacuolated cells may also be found. Atypical cells are often present in the fibrous tissue. Some tumours are classified as cellular based on the presence of non-lipogenic areas of increased cellularity with low-mitotic activity [5]. Dedifferentiated tumours are lesions that develop a high-grade sarcomatous component that is associated with poor prognosis [6]. This change does not usually develop in tumours that are superficially located.

Cytogenetic studies of these neoplasms have found chromosomal abnormalities in most cases. About a third of cases show supernumerary ring chromosomes affecting chromosome 12q.13–15 [4]. This results in amplification of *MDM2* and *CDK4* genes [7]. Expression of these genes can be detected by FISH, real-time PCR or immunohistochemistry, making it a useful diagnostic aid. Of these methods, FISH and real-time PCR, but particularly the former, are more sensitive than immunohistochemistry for detection of these amplifications [8].

Prognosis and treatment. There is a tendency for local recurrence, but metastases are not seen unless the tumour undergoes dedifferentiation which does not tend to happen in superficially located tumours, particularly those in the subcutaneous tissue [6]. Complete surgical excision is indicated.

Liposarcoma [1]

Myxoid and round cell liposarcoma and pleomorphic liposarcoma are vanishingly rare in the skin. Only a few cases of primary cutaneous liposarcoma have been described. Follow-up is limited, but the behaviour seems to be better than that of their deeper counterparts, probably reflecting early detection and treatment and the easy accessibility to the skin. Liposarcoma will not be discussed further in this chapter.

Tumours of uncertain histogenesis

Superficial angiomyxoma [1,2]

Definition. Superficial angiomyxoma is a dermal or subcutaneous tumour composed of a mixture of small blood vessels and sparse spindle-shaped cells in a prominent myxoid stroma.

Clinical features [1,2]. Most cases occur in adults as an asymptomatic solitary papule or nodule with equal sex incidence. Lesions are usually less than 3 cm and have a wide anatomical distribution with a predilection for the trunk, head and neck and genital skin. In patients with multiple lesions, the possibility of Carney complex should be considered (see Chapter 62) [3].

Pathology. Tumours are multilobulated, with copious myxoid stroma, numerous delicate small blood vessels and spindle-shaped or stellated bland cells, probably representing fibroblasts. Aggregates of inflammatory cells, mainly neutrophils, are frequent. In up to 30% of cases epithelial structures, probably representing hyperplastic trapped adnexal structures (particularly hair follicles), are identified.

Treatment. Local recurrence is seen in up to 30% of cases [3], but the behaviour is benign and therefore excision is the treatment of choice.

3 Carney JA, Headington JT, Wu SP. Cutaneous myxomas: a major component of the complex of myxomas, spotty pigmentation and endocrine overactivity. *Arch Dermatol* 1986; **122**: 790–8.

Digital myxoma [1]

Synonym
- Cutaneous myxoid cyst

Digital myxoma is relatively rare and presents mainly on the fingers as a small, solitary painful nodule. Females are much more commonly affected than males and there is a tendency for local recurrence. Lesions are poorly circumscribed and consist of abundant myxoid stroma with only scattered, bland, spindle-shaped cells.

Dermal non-neural granular cell tumour

Synonyms
- Primitive polypoid granular cell tumour
- Primitive non-neural granular cell tumour

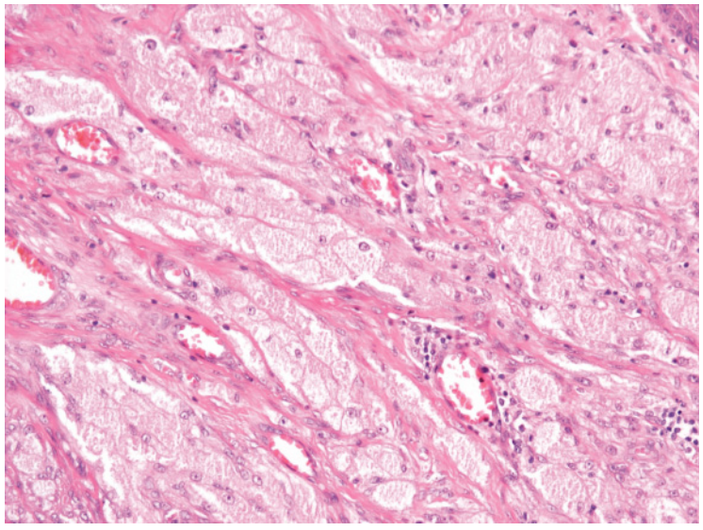

Fig. 56.44 Large cells with prominent granular cell change in a case of dermal non-neural granular cell tumour.

Definition. This is a distinctive dermal tumour with no specific line of differentiation, initially described as primitive polypoid granular cell tumour in 1991 [1]. Tumours are not related to neural granular cell tumours, which are uniformly S-100 positive. They occur both in the dermis and in subcutaneous tissue.

Clinical features. This tumour usually presents as an exophytic, small, cutaneous lesion with a wide anatomical distribution, wide age range and no sex predilection. Not all tumours are polypoid. Clinical behaviour is usually benign with only rare local recurrences [2–4]. However, a single case of metastasis to a regional lymph node has been reported [3].

Pathology. Histologically, lesions show rounded or spindle-shaped cells with prominent granular cell change (Fig. 56.44). Polypoid tumours have an epithelial collarette. Nuclear pleomorphism varies but does not tend to be prominent. Mitotic figures may be prominent. Multinucleated cells are sometimes seen. There is diffuse positivity for NKI-C3, which is a non-specific marker for lysosomes, and focal positivity for CD68 and NSE. Tumour cells do not stain for keratin, EMA, actin, desmin, H-caldesmon or S-100 [3,4].

Treatment. Complete conservative excision is the treatment of choice.

Perivascular epithelioid cell tumour ('PEComa')

Definition. Perivascular epithelioid cell tumour is part of a spectrum of neoplasms that includes clear cell 'sugar' tumour of the lung, angiomyolipoma, lymphangioleiomyomatosis and clear cell myomelanocytic tumour of the falciform ligament [1–3]. Occurrence in the skin and soft tissue is rare but it is likely that the lesion is under-recognized. Although tumour cells are usually positive for melanocytic markers such as HMB45 and melan-A, the cell of origin has not been identified.

Clinical features. Cutaneous lesions are rare [4] and mainly occur in the lower extremities with a strong predilection for females.

Pathology [3,4]. Histology is distinctive and consists of bland epithelioid cells, typically arranged radially around thin-walled vascular channels. A smaller population of spindle cells is often seen. Tumour cells have pale pink cytoplasm and vesicular nuclei. Malignant examples may be seen but have not been reported in the skin. The immunophenotype is distinctive, as the tumour cells stain for melanocytic markers including HMB45, MITF-1, Melan-A and tyrosinase and for muscular markers including SMA and calponin. They are usually negative for S-100 and keratin.

Treatment. Simple excision is the treatment of choice.

'Aggressive' angiomyxoma [1,2]

Definition. 'Aggressive' angiomyxoma is a distinctive tumour occurring in the genital region and pelvis, predominantly of females. It is characterized by bland, spindle-shaped cells in the background of a prominent myxoid stroma and frequent, thick-walled blood vessels.

Clinical features. This tumour occurs almost exclusively in females of reproductive age, but rare lesions have been described in males [3]. Cases in children are exceptional and may involve the spermatic cord [4]. Tumours are slowly growing and by the time of presentation they are large and ill-defined, often measuring 10 cm or more. The most commonly affected sites are the vulva and perineum. Extension into deeper soft tissues is often found.

Pathology. The lesion is infiltrative and is composed of spindle or stellate-shaped, bland cells with scanty cytoplasm, surrounded by prominent myxoid stroma. Small to medium-sized, thick-walled blood vessels are seen throughout the tumour. Mitotic figures are very rare. Rare cases contain multinucleated giant cells [5]. Interestingly, tumour cells are positive for actin and desmin. Tumour cells are often positive for oestrogen and/or progesterone receptors [6].

Cytogenetics in one case demonstrated a translocation t(8;12)(p12;p15) involving a rearrangement of *HMGIC* (a DNA architectural factor gene) [7], and analysis in a further case found a translocation t(5;8)(p15;q22) [8].

Prognosis and treatment. Local recurrence is observed in up to a third of cases, and complete surgical excision is usually difficult because of the infiltration of surrounding tissue. However, recurrences are not usually destructive, and radical surgical procedures are therefore not indicated.

Epithelioid sarcoma [1–3]

Definition. A distinctive, malignant soft-tissue tumour composed of cells with epithelial differentiation. It is not clear whether this tumour represents a primary soft-tissue carcinoma or a sarcoma with epithelial differentiation.

Incidence. It is an uncommon tumour, affecting males more often than females and tending to begin in early adult life.

Clinical features [4,5]. The presenting sign can be a dermal nodule that grows outwards and may ulcerate early, a nodule or lobular subcutaneous tumour that is painless and grows slowly, or a tumour attached to deeper structures that is rather poorly defined and causes pain, paraesthesiae or muscular wasting when growing along a large trunk nerve. As a result of prominent perineurial and perivascular extension of tumour cells, multiple nodules in a sporotrichoid distribution may be seen. The distal extremities are the usual situation for the tumour, particularly the flexor aspect of the finger and the palm. It may grow at a deceptively slow rate.

A distinctive variant of epithelioid sarcoma previously described as 'extrarenal rhabdoid tumour' has been reported in older patients who present with a large mass on the proximal limbs, genitalia, buttocks, trunk or head and neck [6,7]. This variant is known as 'proximal-type epithelioid sarcoma'.

Pathology [8,9]. The tumour is composed of firm nodules, 5–50 mm or larger in diameter surrounded by fibrous tissue and fat. It is often closely associated with fascia, periosteum, tendon or nerve sheaths. The cut surface is greyish-white and flecked or mottled with yellow or brown, reflecting the presence of areas of necrosis. Microscopically, there are masses of large, round, polygonal or spindle cells with acidophilic cytoplasm. Spindle cells are often present and may predominate. The larger nodules have necrotic centres and show so-called 'geographical necrosis', which may be mistaken on scanning power microscopy for a granuloma. Mitotic figures are common, and binucleate cells occur. Variable cytological atypia is always present and may be prominent. Intercellular hyalinized collagen increases the acidophilia, while calcification, with osteoid or bone formation, may take place in the necrotic areas. The tumour spreads along dense fibrous structures and may ulcerate in areas with little subcutaneous fat. Local recurrence after excision is common, and metastasis, principally to lymph nodes, lung and pleura, may occur. Tumour cells show clear histological, ultrastructural and immunohistochemical evidence of epithelial differentiation.

The proximal type of epithelioid sarcoma shows a similar multinodular growth pattern but tumour cells are larger and with a more rhabdoid appearance consisting of abundant cytoplasm and large nuclei with or without a prominent eosinophilic nucleolus. Immunohistochemically, tumour cells in both variants of epithelioid sarcoma have the same profile. They are positive for vimentin, keratin and EMA, and 50% of cases are positive for CD34 [10].

No distinctive and consistent cytogenetic abnormality has been identified in this tumour. However, lesions often display chromosomal gains and the most frequent of these is on chromosome 22q [11,12].

Diagnosis. Superficial lesions can easily be mistaken for an ulcerating squamous cell carcinoma, deeper ones are usually regarded as inflammatory in nature. Histological diagnoses have varied, with granulomatous inflammation and synovial sarcoma being the commonest benign and malignant diagnoses, respectively.

Prognosis and treatment. Complete removal by surgical excision is essential if local recurrence and eventual metastasis are to be avoided, and the earlier this is done the less likely is the process to spread along fascial planes. Surgical excision followed by radiotherapy is often recommended. Involvement of regional lymph nodes is associated with distant metastasis and death [13]. Local recurrence and metastasis may occur years after the original diagnosis. The survival rate has been estimated at between 65% and 70% [8,13]. Features associated with poorer prognosis include male sex, older age at diagnosis, proximal location, rhabdoid phenotype, tumour size, mitotic rate, necrosis, vascular invasion, local recurrence and lymph node metastasis [3,8,9,13].

Ossifying lesions in the dermis [1]

A wide range of subcutaneous lesions may occasionally show partial ossification. The most common are pilomatricomas and melanocytic naevi. Other soft-tissue lesions, such as soft-tissue chondromas and fibromyxoid tumours, may show metaplastic bone formation.

Reference

1 Fletcher CDM. Calcifying and ossifying soft tissue lesions presenting in the skin. *J Cutan Pathol* 1996; **23**: 297.

Osteoma cutis [1]

Definition. A true bony new growth arising within the skin from bone-forming tissue and showing no tendency to invade.

Incidence and aetiology. Osteoma cutis is a rare tumour. Most osseous nodules in the skin are not true neoplasms, but result from metaplastic ossification, which usually occurs in a focus of calcification; the initiating lesion is frequently an inflammatory granuloma or scar. The majority of these lesions are best classified as dystrophic ossification rather than as osteomas. Dystrophic ossification has been reported in scleroderma, in old acne cysts and at sites of puncture of the skin or of haematomas. They may be found in melanocytic naevus, pilomatricoma, histiocytoma and chondroid syringoma, and may be secondary to basal cell carcinoma [2,3]. Another cause is Albright's hereditary osteodystrophy, in which cutaneous ossification has recently been recognized with

increasing frequency [4–6]. Rarely, multiple miliary osteomas of the skin can occur after acne [7,8], sometimes with neurotic excoriations or after dermabrasion [9]. There remain a minority of reported cases that appear to be primary osteomas, the majority of which are multiple and on the face or scalp [9–11].

There is no point in trying to estimate the age and sex incidence for a group as heterogeneous as individuals with dystrophic calcification of the skin. It seems likely that primary osteomas will become even more rare if hereditary osteodystrophy and other causes are sought.

Clinical features. Metaplastic osteomas are frequently small and clinically undetectable in the primary lesion. They are usually situated deep in the dermis or subcutaneous tissue. They may be seen when radiographs of the area are taken, but are most commonly first noticed by the histology technician as a hard body that damages the knife edge. The distinguishing feature, if the tumour is found clinically, is the stone-hard texture on palpation, similar to pilomatricoma. A case of osteoma cutis associated with diaphyseal aclasis has been reported [12].

Pathology [3]. Whether metaplastic or primary, the microscopic picture is of a small circumscribed nodule of osseous tissue with trabeculae enclosing fat and, occasionally, marrow cells.

Treatment. If required, simple excision is curative.

Cutaneous calculus [1,2]

Synonym
- Subepidermal calcified nodule

This small tumour, which is relatively common, has a characteristic yellowish white colour and is situated in the subepidermal tissue. It is seen most commonly on the face in children; it varies in size up to 10 mm or so, but may occasionally be larger and plaque-like, and it has a hard consistency. The epidermis over it may be verrucose. Episodes of inflammation and shedding of a portion of the lesion may occur. Microscopic examination shows calcareous bodies in the superficial part of the dermis. A histiocytic or foreign-body reaction often surrounds some of the calcified bodies. The exact histogenesis is uncertain. Calcification of naevus cells has been suggested. The lesion can be removed easily by curettage.

Introduction

Over the past 20 years, advances in understanding the biology of lymphoid cells have greatly improved our knowledge of primary cutaneous lymphomas. Various node-based classifications of lymphomas, including the Kiel classification first introduced in 1980 and updated in 1988 [1], were of relatively little value for primary cutaneous lymphoma as they were based purely on detailed pathological assessment of nodes with no clinical correlation. In contrast, the current World Health Organization/European Organization of Research and Treatment of Cancer (WHO–EORTC) classification is based on clinical, pathological, immunopathological, molecular and cytogenetic findings [2], and implicitly recognizes that the site of origin of extranodal lymphomas rather than just tumour morphology determines clinical behaviour, which in turn has a critical influence on prognosis and therapeutic approach.

In 1975, it was demonstrated that the great majority of lymphoid infiltrates associated with the skin were of T-cell type and Edelson introduced the term cutaneous T-cell lymphoma (CTCL) [3]. In Europe, the work of the Dutch Cutaneous Lymphoma Working Party (DCLWP) and the Graz group delineated different subsets of primary cutaneous T- and B-cell lymphomas, which led directly to the EORTC proposal for classification of primary cutaneous lymphomas and the recent WHO–EORTC classification (Table 57.1) [2,4]. This consensus is now reflected in the 2008 WHO classification of haematologic malignancies as all the primary cutaneous lymphoma variants have been recognized as distinct entities [5].

Mycosis fungoides (MF) is the most common primary CTCL subset, but other subsets with clearly identifiable clinicopathological features and varying prognoses have also been described. A critical observation has been the realization that lymphomas with a similar pathology arising in different organs have different prognoses and a distinct molecular pathogenesis; nodal CD30$^+$ anaplastic large cell lymphomas are usually ALK$^+$ and can be associated with a poor prognosis, especially for ALK$^-$ variants, whereas primary cutaneous CD30$^+$ anaplastic large cell lymphomas are invariably ALK$^-$ and generally associated with a good prognosis [2]. Primary cutaneous B-cell lymphomas represent [2] about one-third of all primary cutaneous lymphomas, and primary cutaneous follicle centre lymphomas are now recognized as pathogentically distinct from nodal follicular lymphomas. The majority of these primary cutaneous B-cell lymphomas have an excellent prognosis [2].

The concept of a subset of circulating lymphocytes with a special avidity or affinity for the skin has been supported by the identification of T cells expressing the cutaneous lymphocyte antigen

Primary cutaneous intravascular large B-cell lymphoma	6	<1	65

NR – not reached.

(CLA; HECA 452), which binds to its ligand, E-selectin, on dermal endothelial cells [6]. These subsets of skin trafficking T cells comprise the skin-associated lymphoid tissue (SALT), and contribute to the skin immune system (SIS), in a similar manner to other mucosal sites such as the gut mucosa-associated lymphoid tissue (MALT). The expression of the chemokine receptors CCR4 and CCR10 by tumour cells may also contribute to epidermotropism in cutaneous T-cell lymphoma (CTCL) while the expression of the lymph node chemokine receptor CCR7 may contribute to tumour dissemination in Sézary syndrome (SS) [7].

The identification of T-cell clones in skin using T-cell receptor (TCR) gene analysis has established both the neoplastic nature and lineage of a wide variety of cutaneous lymphoproliferative entities, and both TCR and immunoglobulin gene analysis are now part of the standard diagnostic assessment of cutaneous lymphoid infiltrates [8]. The presence of a lymphoid clone is not synonymous with malignancy and its significance in benign cutaneous lymphoid infiltrates is at present unknown. It is unclear whether these techniques will also provide prognostic information but they complement existing staging approaches, particularly for analysis of lymph node and peripheral blood in MF and SS.

It has been apparent for some time that the original American Joint Committee on Cancer (AJCC) staging system for MF/SS was not ideal, with markedly variable outcomes for patients with stage IIB and slightly better outcomes for stage III than stage IIB. Also there has been a lack of consensus regarding the measurement of tumour burden in peripheral blood. This has led to new staging proposals for MF/SS and non-MF/SS primary cutaneous lymphomas, which now require prospective validation [9,10].

The underlying molecular pathogenesis of CTCL is unknown but various abnormalities have been identified, including inactivation of genes controlling the cell cycle and apoptosis [11]. These abnormalities appear to be associated with disease progression and may contribute to treatment resistance. In addition, molecular cytogenetic techniques have detected a consistent pattern of chromosomal abnormalities, indicating the location of putative genes that may have a fundamental role in the pathogenesis of CTCL [11].

Several novel therapies have been licensed for CTCL, including a retinoid, bexarotene, that binds to the retinoid X receptor (RXR), a diphtheria interleukin-2 (IL-2) fusion toxin, denileukin diftitox (Onzar; Ontak), and a histone deacetylase inhibitor, suberoylanilide hydroxamic acid (SAHA/vorinostat) [12–15]. A number of other novel therapies have been proven to have efficacy in CTCL and offer promising alternatives to existing therapies [16]. These studies have also facilitated the current development of more robust response criteria for MF and SS.

Primary cutaneous T-cell lymphomas

Mycosis fungoides

Definition. The most common variant of primary CTCL, generally associated with an indolent clinical course and characterized by well-defined clinicopathological features.

Aetiology. The aetiology of MF is not yet established. The HTLV-1 retrovirus was first isolated from a patient with CTCL and subsequently it was appreciated that this patient had adult T-cell leukaemia–lymphoma (ATLL). Because of clinical and pathological similarities to cutaneous involvement in ATLL, there has been an intensive search for HTLV-1 and related viruses in MF. However, although an association with HTLV-1 has been suggested, subsequent extensive investigations have failed to identify conclusively any of the currently recognized HTLV-associated viruses in MF [1–5]. For over 20 years, one of the theories associated with the development of MF has been that this is a disease of antigen persistence associated with chronic lymphocyte stimulation and eventual transformation of benign lymphocytes to a low-grade malignant T-cell lymphoma [6]. This is a plausible and attractive theory, but as yet the antigen or antigens responsible for this transformation have not been identified.

A number of case–control studies have investigated the possibility of environmental agents precipitating or aggravating early CTCL. One study from the east coast of North America [7] recorded a significantly higher incidence of allergies and of fungal and viral infections in patients who developed CTCL compared with healthy controls, and also reported that a higher proportion of CTCL patients had worked in the petrochemical, textile, machine and metal industries. Other case–control studies have suggested possible links with occupational exposure to glass, pottery and ceramics [8], as well as workers exposed to solar radiation [9]. Other studies have not confirmed these observations but did record a significantly higher incidence of atopic disease in MF patients [10] and there have been subsequent reports of CTCL developing in patients with severe atopic dermatitis [11]. An association with atopic disease has not been confirmed in another case–control study [12]. A more recent study from North America has also failed to confirm any clear occupational or environmental exposure [13] but other studies have observed a higher than expected prevalence of other malignancies, including non-lymphoma cutaneous malignancies in patients with MF [14]. Further reports have also suggested that there is a possible increased incidence of non-melanoma skin cancer, melanoma and also lung cancer in MF but whether or not this is related to prior therapy remains to be clarified [15–17].

The incidence of MF (0.64/100 000 for CTCL) is increasing but the explanation for this is unclear. The rise could represent a combination of improved diagnosis and previous coding problems as well as a genuine increasing disease incidence, as seen for non-Hodgkin's lymphoma [18].

Clinical features. Mycosis fungoides is characterized by typical cutaneous stages of disease, consisting of patches and plaques involving less than 10% of the body surface area (stage T1/IA), more than 10% of the body surface area (stage T2/IB), tumours (stage T3/IIB) and erythrodermic disease (stage T3/III). Patients may progress from having limited patches and plaques to extensive plaques or tumours and even erythroderma [19]. However, many patients do not show any evidence of progression. Stage IA MF is characterized by subtle, fine scaly and often slightly atrophic erythematous patches on the trunk, usually involving the limb girdle areas, breast and particularly the buttocks (Fig. 57.1). There may be mild pruritus but patients are often asymptomatic. At this stage, the clinical differential diagnosis includes pityriasis rosea, fungal infection, mild dermatitis or even a rather atypical form of psoriasis. Plaques are more obvious, persistent, polymorphic, erythematous lesions with a similar distribution but, with the development of stage T2/IB, there is usually involvement of the head, neck and limbs as well as the trunk (Figs 57.2 & 57.3). Individual plaques may become very large, and there may be some degree of regression, giving rise to unusual arcuate and horseshoe-shaped lesions that can show considerable variation in colour, degree of scaling and border definition. Striking psoriasiform scaling can sometimes be a feature. There is some evidence that the overall

Fig. 57.1 Early mycosis fungoides showing plaques in the buttock area.

Fig. 57.2 More advanced mycosis fungoides showing typical polycyclic plaques.

thickness of plaques in stage T2/IB may have prognostic significance [20]. Once again, patients may complain of pruritus or be asymptomatic. Rarely, individual plaques may become eroded or ulcerated and painful, which is often associated with secondary bacterial infection and such patients may have a very poor quality of life and high morbidity despite having an early stage of disease. Tumours can show considerable variation in size (Fig. 57.4), and if there are only a few small tumours it may be difficult to categorize as truly stage T3/IIB disease. Many patients with early stages (T1/IA–T2/IB) of disease do not progress but rarely patients may gradually develop an erythroderma (stage T3/III), which is usually associated with severe pruritus. A *tumeur d'emblée* form of MF, in which patients rapidly develop large nodules and tumours without the prior presence of patches and plaques, has been described in the past [21], but it is now appreciated that many of these patients have other CTCL variants, which should be excluded on the basis of a critical assessment of the histological and immunophenotypical features. Patients may also rarely present with erythrodermic stages of disease and the differential diagnosis for these patients includes inflammatory dermatoses and Sézary syndrome.

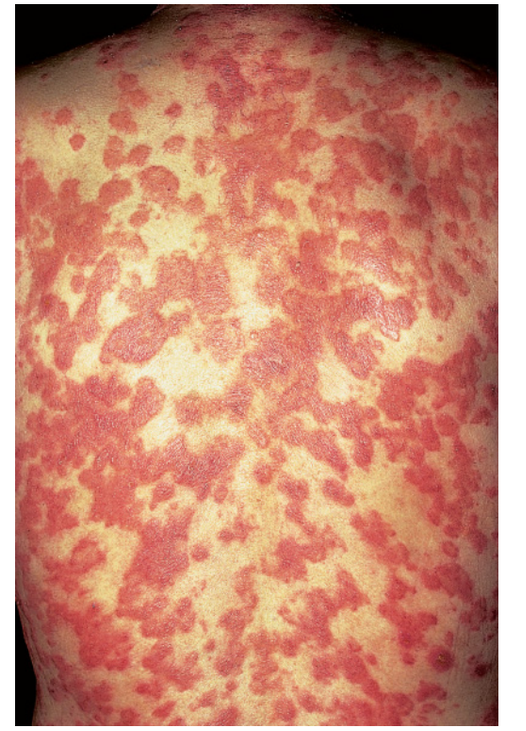

Fig. 57.3 Further stage of mycosis fungoides showing plaques involving more than 10% of the body surface.

Fig. 57.4 Nodular mycosis fungoides showing striking nodules on the back of the neck. Similar lesions were present on all four limbs.

The development of peripheral lymphadenopathy in MF alters the staging regardless of the cutaneous stage of disease [22]. Although the great majority of patients with early stage disease do not develop overt clinical involvement of lymph nodes or other organs (see prognosis), a small proportion do eventually show generalized, systemic spread and may exhibit typical 'B' symptoms with fever and weight loss. Histological involvement of central lymph nodes and other organs is a very poor prognostic sign. Any systemic organ can be involved but apart from liver, spleen and bone marrow, other sites commonly involved include the pulmonary, skeletal, nasopharyngeal and central nervous systems (CNS).

There are a large number of clinical variants of MF. Some plaques have a rather verrucous [23] or hyperkeratotic appearance, and bullae may rarely develop in the course of progression of individual plaques [24]. Rare ichthyosiform variants have been described [25]. An important subset of patients have MF that appears to be associated with pilosebaceous follicles, giving rise to a follicular clinical pattern often with alopecia (pilotropic or folliculotropic MF; see below) and there is evidence that these patients may be resistant to treatment and have a poorer prognosis independent of their stage of disease [26]. Rarely, younger patients present with a purpuric eruption not unlike the pigmented purpuric dermatosis associated with capillaritis but with histological features of MF [27]. Non-white younger adult patients may also present with a hypopigmented variant of MF [28,29], characterized by striking hypopigmented scaly patches often involving the trunk and especially the pelvic girdle area rather than the limbs. Histologically, these lesions tend to show marked epidermotropism, in contrast to the subtle clinical features. In poikilodermatous MF, patients develop clinical lesions characterized by either widespread or isolated poikiloderma, which may or may not be associated with typical patches and plaques of MF. The trunk is usually involved and the breasts and pelvic girdle area may also be affected (Fig. 57.5). The poikiloderma is typically characterized by atrophy, pigmentation and telangiectasia and must be distinguished from poikiloderma resulting from other disorders by appropriate histology. Rarely, patients may have extensive poikiloderma as a feature of erythrodermic disease. These clinical variants do not have any prognostic significance with the exception of folliculotropic/pilotropic MF [26].

Fig. 57.5 Poikilodermatous mycosis fungoides showing involvement of both breasts.

Clinical differential diagnosis. In the early stages of MF, the clinical differential diagnosis may include such diverse conditions as allergic contact dermatitis, atopic dermatitis, psoriasis and fungal infection. Any patient with persistent polymorphic plaques, particularly involving the pelvic girdle area, should have a skin biopsy and histological confirmation of the disease. Multiple biopsies may be required to confirm a clinical suspicion of MF in early stages of disease and criteria for the early diagnosis of MF have been published by the International Society for Cutaneous Lymphoma (ISCL) [30].

Staging. There are two staging systems in current use that have prognostic significance [1–3]. The Tumour, Nodes, Metastases classification and the staging system suggested by the North American MF Cooperative Group are given in Tables 57.2 and 57.3. All patients should have a defined stage so that appropriate advice can be given regarding prognosis and treatment.

All patients with MF should have a full clinical examination and adequate diagnostic biopsies for histology and immunophenotypic and preferably molecular studies as, even for stage IA disease, studies suggest that patients with a detectable T-cell clone have a shorter duration of response and a higher rate of treatment failure [4]. Occasionally, multiple skin biopsies and the opinion of experienced dermatopathologists are required to make a diagnosis. Peripheral blood samples should be taken for routine haematology, biochemistry, serum lactate dehydrogenase (LDH), Sézary cells, lymphocyte subsets, CD4 : CD8 ratio, HTLV-1 serology and, ideally, TCR gene analysis of peripheral blood mononuclear cells. These tests are necessary to distinguish patients with ATLL and those patients with peripheral blood T-cell clones identical to skin who may have a poor prognosis. Any palpable and bulky peripheral nodes should be biopsied but the practice of 'blind' lymph node biopsy of non-palpable nodes is not essential, although histological evidence of lymphoma can very rarely be detected in the absence of palpable lymphadenopathy. Chest X-ray should be performed in those with advanced stages of disease. Staging CT scans of the chest, abdomen and pelvis are indicated in all those patients with stage IIA, IIB, III and IV MF, but not in those with stage IA or IB MF [5]. Peripheral nodes with a diameter greater than 1.5 cm are considered to be abnormal in patients with cutaneous lymphomas whereas for central nodes a diameter greater than 1.0 cm is considered to be the limit. The value of PET-CT in MF has yet to be established but this may increase the detection rate of systemic disease with PET activity correlating with histologic lymph node grade [6]. Bone marrow aspirate and trephine biopsies may be indicated in patients with stage IIB, III and IV MF and those patients with peripheral blood involvement, as indicated by the presence of Sézary cell counts representing more than 5% of the total leukocyte count, although the overall positive yield will be low [7,8]. The ISCL and EORTC have published a revised staging system for MF/SS which is currently being validated in prospective studies [9]. This staging system attempts to distinguish patients with early stage IA/IB who only have patches and to stratify more accurately lymph node disease incorporating molecular analysis for T-cell clones as well as assessing the degree of peripheral blood involvement more specifically (Table 57.4). Prospective validation of this staging system will also clarify the prognostic relevance of features such as folliculotropism and large cell transformation.

Table 57.4 Proposed revised staging classification for mycosis fungoides/Sézary syndrome.

TNMB stages	
Skin	
T_1	Limited patches, papules and plaques covering <10% of the skin surface; may further stratify into T_{1a} (patch only) vs T_{1b} (plaque ± patch)
T_2	Patches, papules and plaques covering ≥10% of the skin surface; may further stratify into T_{2a} (patch only) vs T_{2b} (plaque ± patch)
T_3	One or more tumours (≥1 cm diameter)
T_4	Confluence of erythema covering ≥80% body surface area
Node	
N_0	No clinically abnormal peripheral lymph nodes; biopsy not required
N_1	Clinically abnormal peripheral lymph nodes; histopathology Dutch grade 1 or NCI $LN_{0–2}$
N_{1a}	Clone negative
N_{1b}	Clone positive
N_2	Clinically abnormal peripheral lymph nodes; histopathology Dutch grade 2 or NCI LN_3
N_{2a}	Clone negative
N_{2b}	Clone positive
N_3	Clinically abnormal peripheral lymph nodes; histopathology Dutch grades 3–4 or NCI LN_4; clone positive or negative
N_X	Clinically abnormal peripheral lymph nodes; no histologic conformation
Visceral	
M_0	No visceral organ involvement
M_1	Visceral involvement (must have pathology confirmation and organ involved should be specified)
Blood	
B_0	Albescence of significant blood involvement; ≤5% of peripheral blood lymphocytes are atypical (Sézary cells)
B_{0a}	Clone negative
B_{0b}	Clone positive
B_1	Low blood tumour burden; >5% of peripheral blood lymphocytes are atypical (Sézary cells) but does not meet the criteria of B_2
B_{1a}	Clone negative
B_{1b}	Clone positive
B_2	High blood tumour burden; ≥1000/μL Sézary cells with positive clones

Prognosis (Table 57.5). Multivariate analysis has established that age at onset (over 60 years), skin stage and the presence of nodal (IVA) or visceral (IVB) disease are independent prognostic factors in MF [1–6]. Studies have confirmed that a patient's life expectancy is not adversely affected in stage IA disease [6]. Patients with stage IB–IIA disease at diagnosis have a 72–86%/49% overall 5-year survival, while patients with stage IIB disease have a 40–65% 5-year survival [6–8]. The 5-year survival of patients with erythrodermic stage III disease is 41–57%, for those with stage IVA 27–40% and for stage IVB disease 0–27% [6–8]. The presence of a peripheral blood T-cell clone may indicate which patients with early stage disease are likely to develop disease progression but this requires confirmation in large studies [9]. The development of lymph node disease has a significant impact on prognosis [10]. Sézary syndrome patients by definition are staged as T4 N1–3 M0 B1 and have a poor prognosis, with an overall median survival of 32 months from diagnosis [11]. Recent studies of erythrodermic CTCL have shown that the presence of peripheral nodal disease is the most important prognostic factor in a multivariate analysis, although the peripheral blood tumour burden is also very close to significance [12]. In addition, prognostic data on a large series of patients have suggested that patients with thick plaques may have a worse prognosis than those with thin or patch stage disease and this has formed the basis for a suggested modification of the staging system, although the reproducibility of this histological assessment has not been confirmed [13].

A high incidence of second malignancies in MF patients, notably non-melanoma skin cancer and pulmonary small cell lung cancer (including small incidence of melanoma), and also of malignancies in relatives of patients, mainly lymphomas and leukaemias, have been reported [14–16]. Other types of lymphoma–leukaemia and Hodgkin's lymphoma have also been described in association with MF and Sézary syndrome [17–20].

DSS, disease-specific survival; NR, not reached; OS, overall survival.

Comments:

1. All actuarial survival curves calculated according to method of Kaplan–Meier and based on stage at diagnosis.
2. In the study by Doorn *et al*. [7] (and in a subsequent publication: van Doorn *et al*. *Arch Dermatol* 2002; **138**: 191–8), the presence of follicular mucinosis was an independent poor prognostic feature, possibly related to depth of infiltrate in patients with stage IB disease (DSS of 81% and 36% and OS of 75% and 21% at 5 and 10 years respectively). A lack of a complete response to initial therapy was also associated with a poor outcome ($P < 0.001$) in a multivariate analysis as well as increasing clinical stage and the presence of extracutaneous disease. A different staging system was used in this study (based on Hamminga *et al*. [2]) but for the purposes of this table the staging has been altered to be consistent. Only three patients had stage IVB disease and only 18 patients each had stage IIA and IVA disease. Therefore the results for these stages must be interpreted cautiously.
3. In the study by Zackheim *et al*. [8], black patients had a relatively more advanced stage of disease than white patients. The TNM classification was used in this study. Lymph node stage had an unfavourable impact on survival but this trend did not reach significance for each individual T stage because of a lack of sufficient power (an estimated 1700 subjects required) and IIA/IVA patients were not designated separately. Similar considerations apply to peripheral blood involvement. Similar outcomes for patients with stage IIB (T_3) and III (T_4) disease is consistent with other studies but this might reflect a lack of lymph node staging data included in this study.
4. The study by Kim *et al*. [6] included data on 525 patients and showed that the majority presented with early stage disease and that independent multivariate prognostic factors were age, skin stage and presence of extracutaneous disease at presentation. With the exception of stage IA, the relative risk for death is greater in MF than in a control population; 2.2 for stage IB/IIA; 3.9 for stage IIB/III; 12.8 for stage IV disease.

Pathology [1–3]. The features of MF vary according to the clinical stage. The earliest pathological features of MF are the presence of a moderate, predominantly lymphocytic infiltrate in the papillary dermis. Many of the small lymphoid cells may be hyperchromatic and show a tendency to 'line up' just below the dermal–epidermal junction. Even at this early stage, the affinity of these T lymphocytes for the epidermis and papillary dermis is apparent, as there is rarely significant involvement in the underlying reticular dermis.

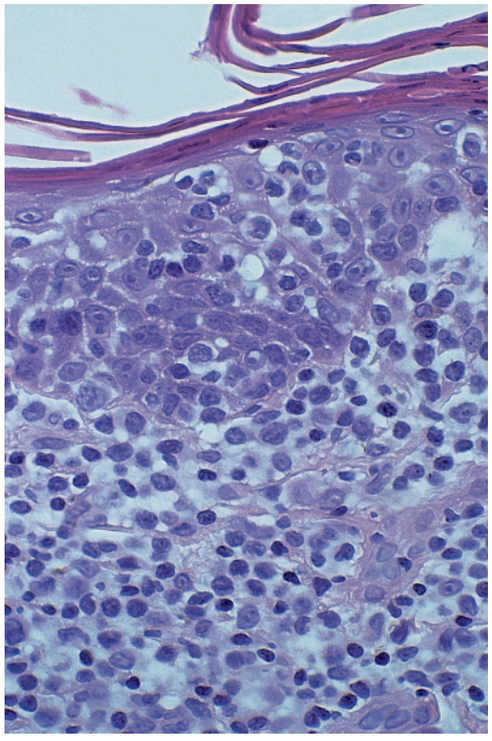

Fig. 57.6 Histology of mycosis fungoides showing striking epidermotropism with the presence in the epidermis of cytologically atypical small dark cells proven on marker studies to be $CD4^+$ helper T lymphocytes.

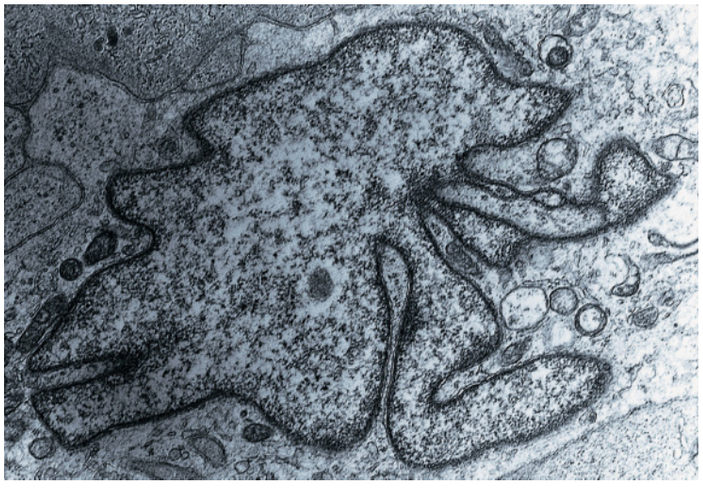

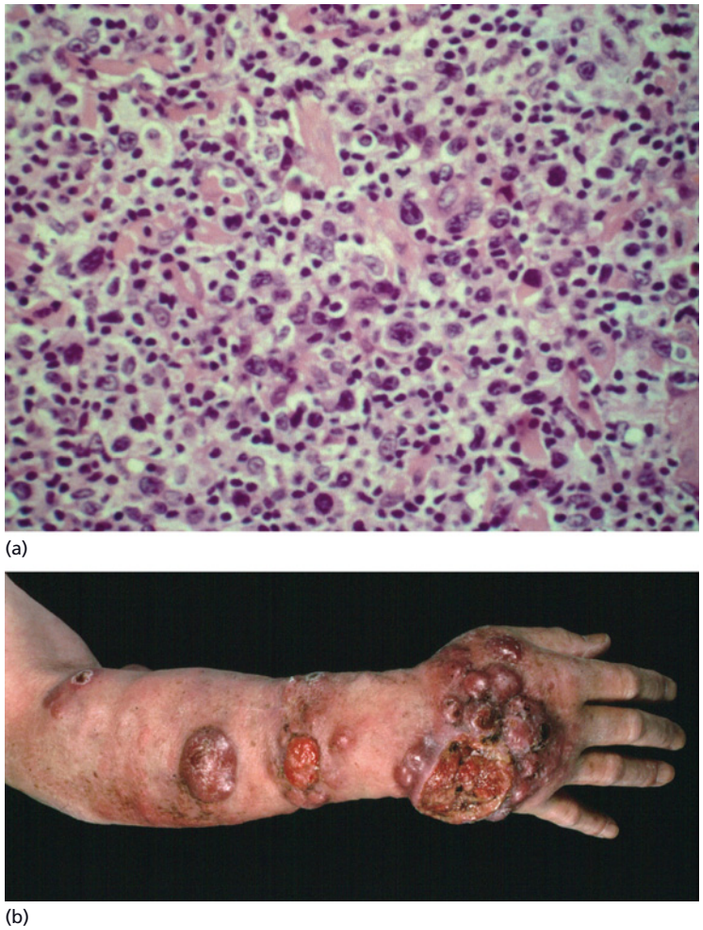

Fig. 57.7 Electron micrograph of T cell infiltrating the epidermis in mycosis fungoides, showing the striking cellular contours of the typical cell of Lutzner with a typical high nuclear contour index.

(a)

(b)

Fig. 57.8 High-power view (a) of large cell transformation in mycosis fungoides (b).

As the disease progresses with the development of thicker plaques, prominent epidermotropism (Fig. 57.6) is seen. This describes the selective colonization of the epidermis by these atypical T cells and is characterized by single-cell colonization, often along the basal layer, or by clusters of atypical lymphocytes in the epidermis—so-called Pautrier microabscesses. The lymphocytes in the epidermis are often strikingly cerebriform (Fig. 57.7), with a very irregular nuclear outline and heavy nuclear staining as well as a characteristic halo appearance to the cells. If these cells are examined either under high power or with thin sections, the cerebriform and irregular nature of the nuclei can be better appreciated in three dimensions. In early MF, the T-cell lymphocytic infiltrate may be associated with a number of other cell types including small numbers of plasma cells or eosinophils, but as the infiltrate becomes more intense and more epidermotropic, the infiltrate becomes monotonous and monomorphic. Granulomatous features may be rarely present and a prominent histiocytic infiltrate can be seen, so called interstitial MF [4].

In more advanced stages of disease (IIB–III), the striking epidermotropic quality of the lymphocytic infiltrate may be lost, with scattered larger tumour cells showing marked cellular atypia. Large cell transformation may also occur and is a poor prognostic feature on univariate analysis, although this does not appear to be independent of age and stage of disease on multivariate analysis [5]. An earlier study showed no difference in survival for stage IIB patients showing histological features of large cell transformation compared to those without, but there was a significant difference in survival from diagnosis [6]. Large cell transformation (Fig. 57.8) is defined as the presence of more than 25–50% of large cells

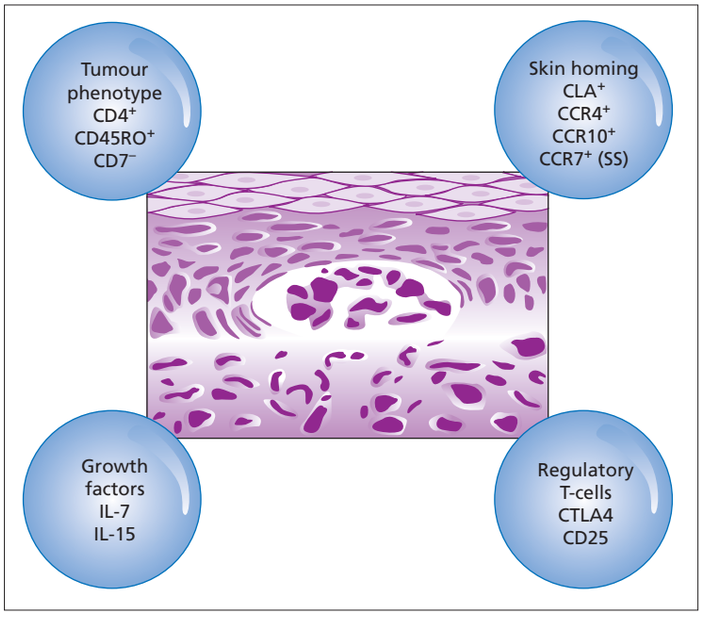

Fig. 57.9 Immunopathology of mycosis fungoides/Sézary syndrome.

(either CD30 positive or negative) within the dermal infiltrate or the development of microscopic dermal nodules consisting of larger cells with pleomorphic and occasionally anaplastic morphology [5]. It is important to distinguish large histiocytic cells from large tumour cells with an anaplastic morphology and occasionally the presence of reactive germinal centres in MF can also cause histological confusion.

The differentiation between large cell transformation in MF and the association with a primary cutaneous CD30$^+$ lymphoproliferative disorder such as lymphomatoid papulosis or anaplastic large cell lymphoma, which have a good prognosis, is crucial and based on a careful clinical assessment of the patient. The development of large tumours in patients with typical patches or plaques of MF would suggest large cell transformation of MF if the histological criteria were fulfilled. In contrast, the presence of very large numbers (more than 75%) of CD30$^+$ large cells in only one or a few isolated tumours developing in patients with no concurrent or previous clinical evidence of MF, as indicated by patches and plaques, suggests that the patient has a primary cutaneous CD30$^+$ lymphoproliferative disorder.

Immunopathology (Fig. 57.9). The tumour cells in MF are CD3$^+$, CD4$^+$, CD45RO$^+$ and usually CD7$^-$ T cells. This is the phenotype of a mature helper T cell of memory subtype [7]. The tumour cells are CLA$^+$, CCR4$^+$, CCR10$^+$ consistent with a skin homing T cell [8,9]. In rare cases, the tumour cells are CD8$^+$ rather than CD4$^+$ but this does not appear to have any prognostic significance [10]. Interestingly, CD8$^+$ cases of MF are more common in childhood and in hypopigmented variants [11]. CD8$^+$ MF must be distinguished from an epidermotropic cytotoxic variant of CTCL with a poor prognosis (see below). Occasionally, there is a very prominent infiltrate of reactive tumour infiltrating CD8$^+$ T cells expressing cytotoxic proteins, which may indicate a good prognosis [12–14]. The dermal infiltrate often consists of a prominent population of CD1a$^+$ dendritic cells and CD68$^+$ histiocytic cells. In advanced disease, tumour cells may express an aberrant phenotype with either loss of T-cell surface antigens 'null-cell phenotype' or expression of the CD30 antigen either by scattered larger tumour cells or by prominent dermal nodules consisting of large pleomorphic or anaplastic tumour cells [5,7]. The latter feature may be associated with large cell transformation but CD30 expression per se does not appear to have any prognostic significance [5]. The tumour cells usually express the αβ T-cell receptor and only rarely express cytotoxic proteins with disease progression [14].

A subset of CD4$^+$ CD25$^+$ T-cells has been defined with suppressive function. These regulatory T cells (T-regs) are cytotoxic T-lymphocyte antigen 4+ (CTLA4+) and express the transcription factor FoxP3. Studies in MF/SS have analysed the expression of FoxP3, as well as T-reg function, and have established that a proportion of the intraepidermal and dermal T cells in early stages of MF are FoxP3$^+$ T-cells but this decreases significantly with more advanced disease [15,16]. This suggests that in MF the presence of T-regs may be a good prognostic factor and that T-regs may actually suppress the expansion of tumour cells. Whether tumour cells also function as T-regs remains to be established; CTLA4 is expressed by a proportion of Sézary cells, and Sézary cells which have immunosuppressive T-reg function have only been described in a minority of SS patients [17–19].

Pathological differential diagnosis. In early MF, the main differential diagnosis includes a dermatitis reaction. The epidermotropic quality of the T-cell infiltrate in MF may be helpful, as may the cytology of the individual T cells, as in MF these intraepidermal lymphocytes tend to be larger than surrounding keratinocytes and have intensely stained nuclei with a very irregular outline. Spongiosis, if present in association with epidermotropic T cells or Pautrier microabscesses, is minimal, whereas this tends to be more striking in dermatitis reactions. A useful clue may be the characteristic basal layer colonization and the larger size of the intraepidermal T cells compared to the dermal mononuclear cells [20].

The pathological diagnosis of early MF can still, however, be extremely subjective and is best made in full collaboration with the clinician and only after careful correlation with the clinical features. It is often wise to take several biopsies from separate lesions, and if necessary to arrange for repeat biopsies to be carried out as the clinical picture evolves over a period of months or even years. An algorithm for establishing an early clinical and histological diagnosis of MF has been proposed by the ISCL (Table 57.6) [21].

Immunophenotypic studies are usually of minimal value in differentiating early MF from other cutaneous lymphocytic infiltrates, as the majority of these cells will also be CD3$^+$, CD4$^+$ although a predominance of larger CD4$^+$ cells within the epidermis compared to the mixed population of smaller cells within the dermis can sometimes be helpful [7,20].

The differential diagnosis of early MF from conditions such as arthropod bites and lymphomatous drug eruptions can also be difficult, and good clinicopathological correlation is essential. In

Table 57.6 ISCL diagnostic criteria for early mycosis fungoides (4 points).

Criteria	Major (2 points)	Minor (1 point)
Clinical Persistent and/or progressive patches and plaques plus 1. Non-sun exposed location 2. Size/shape variation 3. Poikiloderma	Any 2	Any 1
Histopathological Superficial lymphoid infiltrate plus 1. Epidermotropism 2. Atypia	Both	Either
Molecular/biological Clonal TCR rearrangement		Present
Immunopathological 1. CD2, 3, 5 <50% 2. CD7 <10% 3. Epidermal discordance		Any 1

general, reactions to arthropod bites tend to show a higher proportion of eosinophils, and the disposition of the infiltrate in lymphomatous drug reactions will be perivascular rather than epidermotropic. In a proportion of cases, however, the diagnosis is suspected on clinical grounds but cannot confidently be made with certainty on histological examination. In these cases, sequential biopsies at 3–6-month intervals may be needed.

Pathology of extracutaneous disease. The usual pattern of extracutaneous spread is from the skin to the draining peripheral lymph nodes and thereafter to other organs such as the liver and spleen, but pulmonary, skeletal and CNS involvement have been documented.

An NCI classification system was proposed in 1985 (Table 57.4) [22]. In this system, lymph node architecture is preserved in LN1–3 in which dermatopathic changes may predominate. LN1 is characterized by single infrequent atypical cells, LN2 shows small clusters of atypical lymphocytes and LN3 shows larger aggregates of atypical cells in paracortical areas. LN4 is characterized by partial or complete effacement by atypical cells [22].

A further histological assessment of peripheral nodes is utilized and based on the study by Scheffer *et al*. [23]. Those biopsies with no abnormalities are recorded as LN0 while those with dermatopathic changes are designated LN1 (dermatopathic lymphadenopathy), which is characterized by enlargement of the paracortical area of the lymph node because of the presence of large numbers of macrophages and pale dendritic (interdigitating reticulum) cells (grade 1 = LN1–2). The macrophages contain aggregates both of melanin and lipid material, giving rise to the older term 'lipomelanic reticulosis'. Histological evidence of possible involvement (grade 2 = LN3) is characterized by the additional presence of small clusters of larger atypical mononuclear cells within the expanded paracortical areas (Fig. 57.10). In contrast, partial (grade 3 = LN4) or complete effacement (grade 4 = LN4) of the lymph node architecture is consistent with definite lymphomatous involvement (Fig. 57.10).

A comparison of these systems has shown that both have a poor prognosis for partial or totally effaced nodes with non-effaced nodes showing no difference in survival [24]. In the WHO classification system, a modification of these classifications has been proposed whereby LN1 and LN2 have been grouped together as grade I (no histological involvement), with LN3 as grade II and LN4 as grade III, both representing definite histological involvement, although this system has not yet been validated [25]. However, there is a subtle difference in this system because in the WHO proposal grade I can be characterized by scattered but not clusters of atypical cerebriform cells, whereas nodes showing clusters of atypical cerebriform cells are graded as II (LN3).

The ISCL EORTC revised staging classification suggests grouping lymph node biopsies N1– with no definite histologic involvement (grade 1/LN1–2), N2– possible involvement (grade 2/LN3) and N3– definite involvement (grade 3–4/LN4) with each group reflecting the results of TCR gene analysis as clone present or absent, but this has not yet been validated prospectively [26].

T-cell receptor gene analysis. TCR gene analysis consists of analysis of DNA from tissue samples for the detection of clonal rearrangements of the TCR genes as a marker of a monoclonal T-cell population. A similar approach can be used to identify a B-cell clone using analysis of immunoglobulin genes. A clonal lymphoid population is usually synonymous with a neoplastic proliferation but this does not signify malignancy. In contrast, the malignant potential of a lymphoid clone is related to the underlying molecular abnormalities. Analysis of TCR genes in MF is now a standard approach that has diagnostic, prognostic and therapeutic implications. Originally, Southern blot analysis of the β TCR gene was employed but this approach is time-consuming, requires large amounts of high-quality DNA and is relatively insensitive [1,2]. Consequently, most studies are now based on more sensitive PCR techniques and several different methods are employed including denaturing gradient gel electrophoresis (DGGE), temperature gra-

dient gel electrophoresis (TGGE), single-strand conformational gel electrophoresis (SSCP) and gene scan methods for analysis of the γ TCR gene [3–8]. Although MF tumour cells usually express an αβ TCR, the γ TCR gene is rearranged in lymphocytes expressing both a γδ and an αβ TCR and this gene is much easier to analyse comprehensively than the β TCR gene. These different electrophoretic approaches have not been compared adequately but most results are broadly consistent and the standardization of this technique has been partly achieved by the use of Biomed 2 primers for the γ and βTCR genes [9].

T-cell clones can be detected in a proportion (approximately 70% overall) of patients with early stage disease and are almost invariable in patients with later stages of disease [5,6]. The lack of T-cell clones in all patients with early stages of disease almost certainly reflects a lack of sensitivity of the technique, although studies have shown that those early stage patients without a T-cell clone achieve a higher complete remission rate with skin-directed therapy than those with a T-cell clone [10]. This suggests that the proportion of non-tumour cells in the infiltrate, possibly reflecting the host immune response, may also be critical. Identical T-cell clones can be detected in peripheral blood of a proportion of patients with all stages of disease and this may have independent prognostic significance [7,11]. In contrast, non-identical peripheral blood T-cell clones can also be detected and may not be pathological, emphasizing that results from all samples must be carefully compared [12]. In patients with both MF and lymphomatoid papulosis or $CD30^+$ large cell anaplastic lymphoma, identical T-cell clones can be found, suggesting a common pathogenesis [1,2,13]. T-cell clones identical to those in the skin can also be detected in dermatopathic lymph nodes (LN1–LN2) and this might provide independent prognostic information, although larger studies are required to prove this conclusively [14–16]. Assessment of enlarged lymph nodes with fine needle aspirate in CTCL has shown that T-cell clones cannot be detected with the same frequency compared to TCR gene analysis of excised nodes, suggesting sampling error [17]. Because of the sensitivity of these PCR-based techniques, T-cell clones have rarely been detected in non-neoplastic inflammatory disorders and therefore it is critical that the presence or absence of a clonal TCR gene rearrangement must always be interpreted in conjunction with the clinical and pathological features. Recent PCR-based studies have also detected clonal T-cell proliferations in some cases of pityriasis lichenoides acuta, small and large plaque parapsoriasis and pityriasis lichenoides chronica [18–23]. The clinical significance of these findings is unclear at present. Although these results would appear to support clinical impressions that large plaque parapsoriasis probably represents early stage MF, small plaque parapsoriasis has been thought to be a separate inflammatory condition that is not related to MF. The findings in pityriasis lichenoides acuta support previous suggestions that this represents part of a spectrum with lymphomatoid papulosis and, intriguingly, lesions resembling pityriasis lichenoides chronica can be associated with MF [23].

Fig. 57.11 Clinical appearance of follicular mucinosis showing boggy mucin-secreting plaques on the trunk.

Follicular mucinosis [1–4]

Synonym
- Alopecia mucinosa

Definition. Boggy cutaneous plaques showing follicular prominence and histological evidence of mucinous degeneration of hair follicles that is often associated with an atypical pilotropic T-cell infiltrate and clinical features of MF (pilotropic or folliculotropic MF).

Clinical features. There appear to be two distinct forms of follicular mucinosis, one associated with MF and an entirely separate, benign, inflammatory form of follicular mucinosis, which is not associated with the development of MF. The clinical features of these two types of follicular mucinosis are identical; follicular papules and plaques often associated with severe pruritus and with a predilection for the face and scalp but the trunk and limbs can be affected and the classic patches and plaques of MF may also be present. A younger age group is affected by inflammatory forms but there are no satisfactory criteria for distinguishing this from MF-associated follicular mucinosis, suggesting that both may represent forms of MF. Prominent giant comedones are often a feature with acneiform lesions (Fig. 57.11), and significant alopecia may be present, rarely with mucinorrhoea [5].

Pathology. There is degeneration of involved hair follicles, associated in MF with a prominent pilotropic atypical T-cell infiltrate. In MF there may also be associated interfollicular epidermotropism. Although these histological features distinguish follicular mucinosis from pilotropic MF, both conditions may simply represent points on a spectrum [5]. Mucin stains such as alcian blue show the presence of large quantities of mucin (Fig. 57.12). In MF, a pilotropic or folliculotropic infiltrate may also occur without mucinosis. In contrast, the inflammatory form of follicular mucinosis does not show a prominent atypical pilotropic T-cell infiltrate, although repeated biopsies may be required to fully exclude MF. It may be impossible to distinguish these two forms with confidence and there is an emerging consensus that most, if not all, patients with follicular mucinosis have a form of CTCL (pilotropic mycosis fungoides) [6]. However, histologic features of follicular mucinosis, without atypia, can also occur as an incidental histological feature in the context of a variety of inflammatory dermatoses [7].

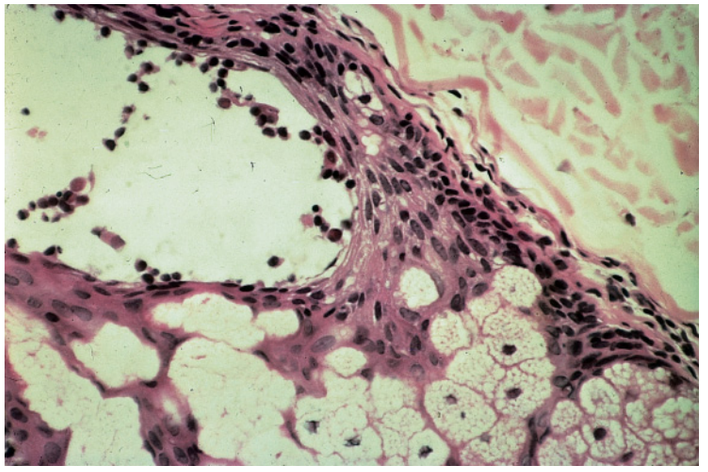

Fig. 57.12 Histology of lesion illustrated in Fig. 57.11 showing degeneration of the hair follicle.

Immunophenotype. The tumour cells in both follicular mucinosis and folliculotropic/pilotropic MF are usually $CD3^+$, $CD4^+$ and $CD8^-$. Prominent $CD30^{+/-}$ blast cells may be associated with a poor prognosis [5,6]. T-cell receptor clonal gene rearrangements can be detected in both MF-associated follicular mucinosis and so-called benign forms of inflammatory follicular mucinosis, consistent with suggestions that both may represent MF variants [6,8].

Pathogenesis. It is accepted that follicular mucinosis represents a follicular (pilotropic) variant of MF with mucinous degeneration of the hair follicle, although the reason for mucin deposition is not currently known. This is supported by the presence of this clinical and histological pattern in patients with typical features of MF. The poor prognosis of folliculotropic variants may relate to the poorer efficacy of skin-directed therapies because of the depth of the associated T-cell infiltrate or a currently unknown pathogenetic difference.

Treatment. There is emerging evidence that follicular variants of MF have a worse prognosis, with disease-specific survival rates of 81% at 5 years and 36% at 10 years [5,9]. Mycosis fungoides associated with follicular mucinosis is treated with skin-directed therapy

as for early stages of MF, but patients may also require systemic treatment with IFN-α or retinoids (bexarotene). Radiotherapy is ideal for isolated plaques of folliculotropic MF. Total skin electron beam therapy may be appropriate for resistant cases. Dapsone can be effective for inflammatory forms of follicular mucinosis. However, if the hair follicles have been destroyed, scarring alopecia will be present and the hair loss permanent.

Pagetoid reticulosis

Synonym
- Woringer–Kolopp disease

Definition. A localized, solitary variant of CTCL, which histologically shows intense epidermotropism.

Clinical features. This entity was first described in 1939 [1] and is rare but appears to affect younger adults [2]. It is characterized by an isolated, persistent, scaly plaque, commonly involving an acral site (Fig. 57.13). The lesion may be asymptomatic and slowly expands, but no further plaques develop on other body sites. A more generalized variant with multiple plaques at other sites has also been described (Ketron–Goodman), but it is likely that this represents an epidermotropic variant of MF or the more recently described $CD8^+$ epidermotropic CTCL variant [3] (see below).

Fig. 57.13 Pagetoid reticulosis. Striking solitary scaling lesion on the side of the foot of a young male.

Pathology. Biopsies show very striking colonization of an acanthotic epidermis [4,5] by atypical, large, pale, mononuclear cells, which usually either fail to express lymphoid markers or express an aberrant T-cell phenotype. Originally there was controversy over whether these cells were derived from histiocytes, Langerhans' cells or Merkel cells. However, the detection of an aberrant T-cell phenotype ($CD4^-$ and $CD8^-$) in some cases and clonal TCR gene rearrangements has clearly established that this entity represents a CTCL variant [6–8].

Pathogenesis. This entity may either represent a localized epidermotropic variant of either MF [9] or the more recently described $CD8^+$ epidermotropic CTCL [3]. However, the underlying pathogenesis will not be understood fully until the fundamental biology of MF has been clarified.

Treatment. The natural history of this lesion is of very slow local extension with an excellent prognosis. Successful remission and probable cure has been reported with both surgical excision and low-dose superficial radiotherapy.

Granulomatous slack-skin disease

Definition. A rare disease characterized clinically by the slow development of pendulous folds of lax erythematous skin and histologically by dermal granulomas and elastolysis.

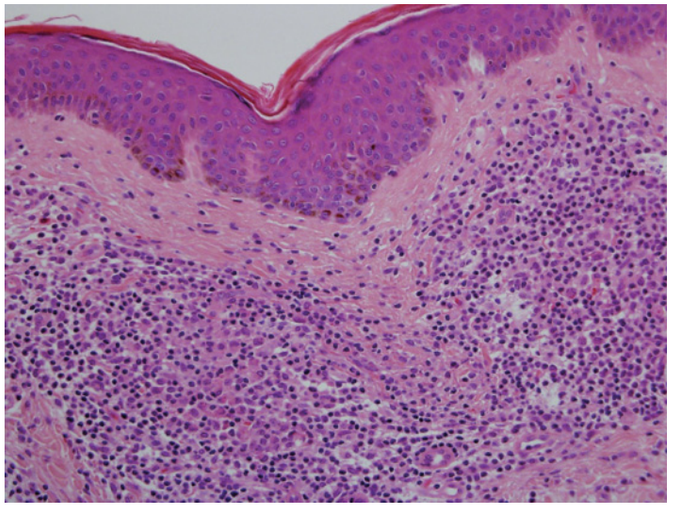

Fig. 57.14 Granulomatous slack skin showing prominent, lax folds of markedly indurated axillary skin with superficial scaling and wrinkling.

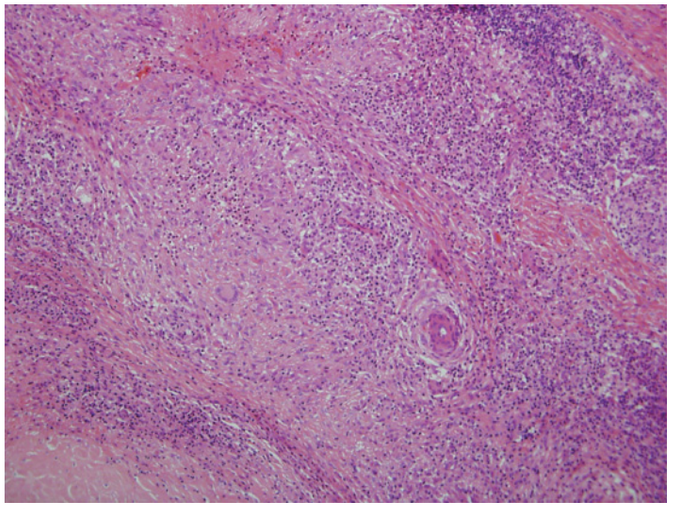
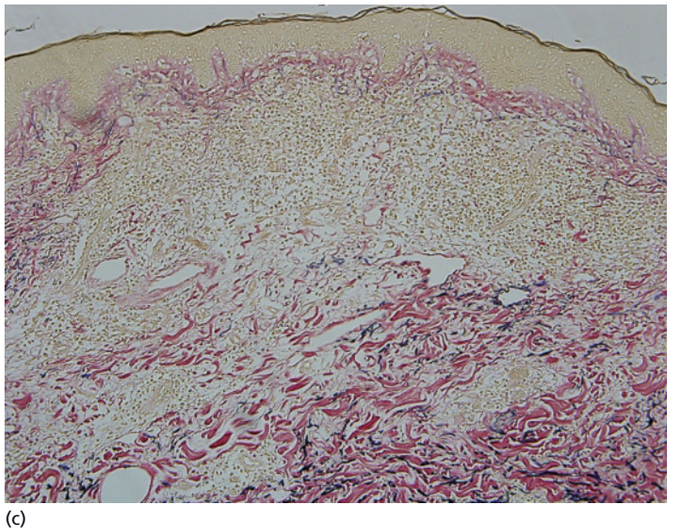


Clinical features. The lesions develop slowly, usually in middle-aged adults, and then progress over several years [1]. They are typically flexural in distribution and consist of thickened, pendulous folds (Fig. 57.14). This condition appears to be caused by cutaneous elastolysis associated with an underlying lymphoma. Several patients have died of Hodgkin's disease or non-Hodgkin's lymphoma [2–4] and the otherwise unaltered epidermis may show epidermotropism, similar to that seen in MF. The condition must be distinguished from other forms of cutis laxa.

Pathology. Histology reveals a dense granulomatous dermal infiltrate (Fig. 57.15) with destruction of dermal elastic tissue (elastolysis) [5–7]. The destruction appears to be mediated by histiocytic giant cells [8]. Similar granulomas may occasionally be found in the spleen and lymph nodes [4]. The lymphocytic infiltrate in the dermis shows some cytologic atypia and has an aberrant T-cell phenotype suggestive of lymphoma. TCR gene analysis has also confirmed that T-cell clones are present, suggesting a CTCL variant in most cases [9], but whether this condition represents a granulomatous variant of MF or a different type of CTCL is currently unclear [10], especially as a novel balanced translocation has recently been detected in granulomatous slack skin [11].



Treatment. No definitive therapy has yet been identified but radiotherapy, retinoids and surgery have been reported to be effective [12–14].

Sézary syndrome [1–4]

Definition. The presence of a clinical triad consisting of erythroderma, peripheral lymphadenopathy and atypical mononuclear cells (Sézary cells) comprising 5% or more of peripheral blood lymphocytes on a buffy coat smear (B1), or more than 20% of total lymphocyte count or a total Sézary count of more than 1000×10^9/L (B2). The presence of a peripheral blood T-cell clone as indicated either by a CD4:CD8 ratio greater than 10, aberrant expression of pan T-cell antigens, cytogenetics or TCR gene analysis is now also required to confirm that the patient has a malignant disease, Sézary T-cell lymphoma–leukaemia [5].

Clinical features. The majority of patients are elderly males and may develop the syndrome either *ab initio* or as progression from classical MF. Many patients describe a prolonged history of 'dermatitis'. Patients present with a generalized exfoliative erythroderma, and may have systemic problems because of shunting of blood through grossly dilated cutaneous vasculature, and resulting high-output cardiac failure. There may be associated ectropion, scalp alopecia, palmoplantar hyperkeratoses and fissuring and the nails often show gross subungual hyperkeratoses (Fig. 57.16). Peripheral lymphadenopathy is often present. The distinction from erythrodermic MF (T4 N0–3 M0/stage III–IVA) is based on the degree of peripheral blood involvement (more than 5% Sézary cells per 100 lymphocytes (T4 N0–3 M0B1/stage III–IVA) as suggested in the original National Cancer Institute (NCI) staging system) [6]. However, there has been a debate about the diagnostic and prognostic relevance of the proportion of peripheral blood Sézary cells as low numbers of Sézary cells can be detected in the peripheral blood of healthy individuals and patients with inflammatory dermatoses. In 1988, the NCI published a revised staging system, with over 20% Sézary cell count (per 100 lymphocytes) as the B1 rating [7], based on previous studies showing that this figure had prognostic significance in Sézary syndrome [8,9]. However, this has been shown to include some patients with benign disorders and may actually represent a larger tumour burden (B2). An absolute Sézary cell count of over $1000/mm^3$ has recently been proposed as a criterion for the diagnosis of Sézary syndrome, which most closely represents the B2 rating for peripheral blood involvement, but this figure may exclude those patients with a lower tumour burden (more than 5% per 100 lymphocytes; B1), who nevertheless have a neoplastic form of SS [5,10]. The recent ISCL EORTC proposal for a revision of the staging system provides a well-defined staging of peripheral blood in SS and should clarify these issues [11]. A recent study suggests that the presence of lymph node disease in Sézary syndrome is an independent prognostic factor while the degree of peripheral blood involvement also has some prognostic significance [12]. The prognosis for patients with SS is poor, with a median survival of 35 months from diagnosis. Most die of opportunistic infection. However, with improved earlier diagnosis the prognosis may now be better.

Fig. 57.16 Sézary syndrome showing erythroderma with palmoplantar hyperkeratoses and prominent nail dystrophy.

Immunopathology. Skin biopsies can show large numbers of atypical mononuclear cells in the dermis with epidermotropism, but it has been shown that non-diagnostic and lymphomatoid

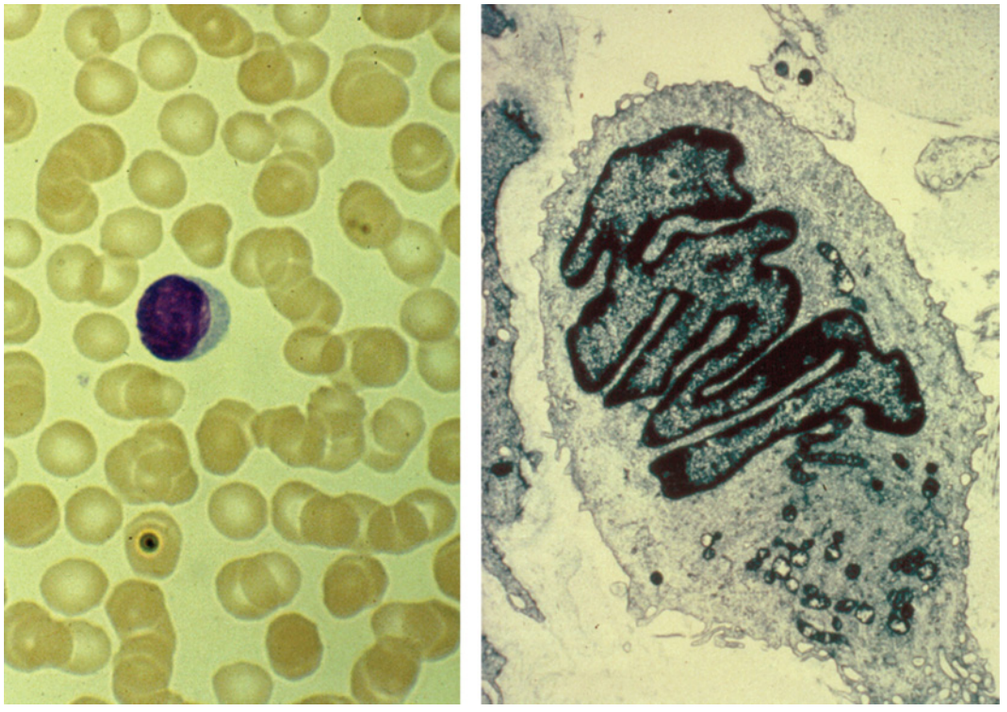

Fig. 57.17 High-power view of Sézary cells in peripheral blood showing large cell with very large nucleus and minimal cytoplasm and ultrastructural features of a typical cerebriform nucleus.

histology is frequently seen in proven cases of SS [13]. The presence of atypical (Sézary-like) peripheral blood cerebriform mononuclear cells has also been reported in a variety of inflammatory conditions including actinic reticuloid, erythroderma associated with dermatitis and psoriasis, and severe drug reactions, but in general the percentage of atypical cells in such conditions is lower than in SS (Fig. 57.17) [14,15]. In addition, T cells with the morphological and ultrastructural features of Sézary cells can be identified in the peripheral blood of normal healthy individuals [16,17]. However, it is important to realize that the total lymphocyte count does not have to be raised for the diagnosis to be made, and the presence of a normal total white cell count without careful morphological examination of the 'tail' of a blood smear or of a buffy coat preparation may mask this diagnosis. Consequently, it can be difficult to conclusively distinguish cases of T-cell leukaemia–lymphoma from inflammatory dermatoses. Large Sézary cell variants (over 16 μm diameter) are easier to recognize but small Sézary cell variants (12–14 μm) are more common and are more difficult to distinguish from activated lymphocytes [4]. Sézary cells are usually $CD3^+$, $CD4^+$, $CD7^-$, $CD26^-$ T cells but $CD26^+$, $CD7^+$ and $CD8^+$ variants have been reported and CD26 loss can occur in control populations albeit at low levels [18–23]. Absolute CD4 counts and CD4:CD8 ratios are elevated. A CD4:CD8 ratio greater than 10 distinguishes most cases of T-cell leukaemia–lymphoma from inflammatory dermatosis associated with Sézary cells but is not pathognomonic as it usually represents a large peripheral blood tumour burden. A consensus has now been agreed that diagnostic criteria should include the clinical triad of features plus the presence of a peripheral blood T-cell clone detected either by expression of aberrant pan T-cell antigens, cytogenetics or TCR gene analysis [5]. Those patients without evidence of a T-cell clone may have a benign inflammatory dermatosis with an excellent prognosis [24]. Sézary syndrome should also be distinguished from other T-cell malignancies such as T-prolymphocytic leukaemia, which can present with cutaneous involvement including rarely erythroderma, although this diagnosis is usually apparent on the basis of clinicopathological and immunophenotypic features [25].

Molecular features (MF/SS) (Fig. 57.18). The underlying molecular pathogenesis of MF and SS has not yet been fully characterized. No disease-specific translocations have yet been identified [1], but studies have shown consistent abnormalities of cell cycle (Fig. 57.19), DNA repair and apoptotic pathways which contributes to both genomic instability and a failure of activation-induced cell

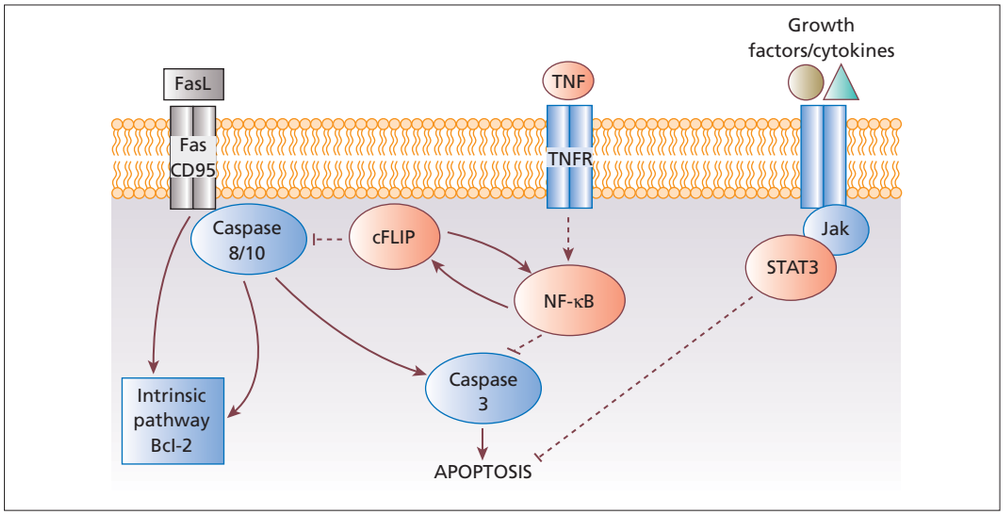

Fig. 57.20 Abnormalities of T-cell activation induced cell death in mycosis fungoides/Sézary syndrome causing defective T-cell homeostasis (grey, loss of function; red, gain of function).

death, which is primarily responsible for T-cell homeostasis (Fig. 57.20).

Extensive studies have shown complex but consistent and recurrent numerical and structural chromosomal abnormalities in all stages of disease [1–9]. In SS an abnormal karyotype is a poor prognostic factor [10]. These studies, using conventional cytogenetics, allelotyping, metaphase and array comparative genomic hybridization (CGH) techniques, have shown similar patterns of chromosomal losses (1p, 13, 19, 17p and 10q) and gains (4, 8q and 17q), and patterns of loss of heterozygosity (9p, 10q and 17p) in both MF and SS suggesting a shared pathogenesis. Minimal regions of deletion have been detected on 10q, suggesting a number of potential candidate genes [11,12]. High resolution array CGH studies have confirmed these 10q findings in SS and suggest a high frequency (40–75% of cases) of candidate gene abnormalities, including gains of *cMYC* and *STAT3/5* and loss of cMYC antagonists including *MXI1* and *MNT* and *p53* [13]. Gains of *Her 2/neu* gene copy number at 17q have also been detected using fluorescent *in situ* hybridization (FISH) in a small series of SS patients [14]. High resolution array CGH studies in early stages of MF have also shown recurrent losses (7p, 7q, 9q, 12q, 16q and 19) with gains (8q and 21q) and specific deletions of tumour suppressor genes *BCL7a*, *SMAC/DIABLO* and *RHOF* [15].

Although as yet no disease-specific balanced translocation has been defined, a balanced t(12;18)(q21;21.2) translocation was recently described in a patient with SS and led to the identification of a *NAV3* gene deletion on chromosome 12q21-22 using interphase FISH in a majority of MF and SS patients [16]. However, subsequent studies have not detected specific *NAV3* deletions in a separate series of MF and SS patients; 12q losses were detected in a few cases but in only two cases did the 12q deletions include *NAV3* [17].

Specific chromosomal abnormalities have been detected in early stages of disease, suggesting that chromosomal instability occurs early [18]. Microsatellite instability (MSI) has also been detected in some studies, and has been attributed to hypermethylation of the mismatch repair enzyme gene promoter, *MLH1* [19]. Undoubtedly MSI also contributes to genomic instability in MF/SS. Telomerase activity is increased in MF/SS [20], which is essential to prevent tumour cell senescence but also will potentially contribute to genomic instability.

Specific gene abnormalities in MF/SS include overexpression and mutation of *p53* in advanced stages of disease [21–24]. In one study, UVB-type *p53* mutations were found [23]. Additional 17p copy number losses also contribute to loss of p53 function in MF/SS [6]. *p53* abnormalities are not found in early stages of disease, suggesting that inactivation of *p53* is related to disease progression, similar to findings in other nodal and extranodal lymphomas. At present, it is unclear if *p53* abnormalities are associated with treatment resistance and a poor prognosis, as seen in other non-Hodgkin's lymphomas, but loss of p53 would contribute to both apoptotic defects and genomic instability. Inactivation of both *p14*, *p15* and *p16* genes has also been detected in MF [25–27]. This is a consequence of 9p deletions involving the *CDKN2A* locus and epigenetic abnormalities due to hypermethylation of gene promoter sequences rather than mutation (Fig. 57.19). It is still unclear whether this is restricted to late-stage disease and transformation. Other genes shown to be inactivated through epigenetic mechanisms involving promoter hypermethylation include tumour suppressor genes, *BCL7a*, *PTPRG* and *p73* [28]. Deletions of *BCL7a* have also been demonstrated in early stages of MF [15]. The tumour suppressor gene on 10q, *PTEN*, has been shown to be homozygously deleted in a proportion of patients, suggesting that the pro-apoptotic AKT signalling pathway is dysregulated [11]. Recent studies have identified infrequent mutations of the *Fas* gene on 10q in early stages of MF and loss of *Fas* expression in advanced disease, providing a further mechanism by which tumour cells may escape apoptosis [29,30]. Fas-mediated apoptosis may also be inhibited in tumour cells by over-expression of *cFLIP* which inhibits the extrinsic apoptotic pathway [31] (Fig. 57.20). Dysregulation of the intrinsic apoptotic pathway has also been detected in MF/SS [32]. Gains of oncogenes, including *RAF1* and *CTSB*, have been detected in a small series of MF/SS cases [33]. In addition, gains of *JUNB* on chromosome 19p have been detected in a large series of MF/SS patients and this appears to be due to chromosomal amplification in some cases with over-

expression in tumour cells identified in tumour samples as well [34]. JunB is a member of the AP1 transcription factor family involved in controlling cell proliferation and differentiation. JunB is also essential for expression of a Th2 cytokine profile and so over-expression in MF/SS may explain the characteristic Th2 cytokine expression by MF/SS [35].

Gene expression studies in MF have shown abnormalities of TNF signalling pathways and gene expression signatures which reportedly distinguish inflammatory dermatoses from MF [36]. A further array cDNA study of MF has identified three signature profiles using consensus clustering which distinguishes those patients with: (i) early stage disease (IA–IIA) who respond to therapy; (ii) an intermediate group (stage IB–III) who show a degree of resistance to therapy; and (iii) a poor prognostic group (predominantly stage IIB) [37]. Both these findings have yet to be validated and may explain more about the host immune response than the actual tumour gene expression profile.

In SS, cDNA array studies have identified a gene signature that is reported to be associated with poor prognosis and a diagnostic gene signature that can be used to distinguish it from inflammatory dermatoses has also been described [38,39]. A further study using a different array platform showed expression of a tyrosine kinase receptor, *EphA4* and a transcription factor, *Twist* [40]. The functional relevance and validation of these findings requires further study. Several studies have now confirmed over-expression of T-plastin in SS. This is an actin bundling protein and the T-plastin isoform is normally only expressed in epithelial tissues and could prove to be an important biomarker [38,41].

Fundamental questions remaining include the cause(s) of the genomic instability which defines MF/SS even at early stages as well as a need to define the specific genomic abnormalities that distinguish SS from MF. However, it is apparent that critical abnormalities of apoptosis are prevalent in both MF and SS and almost certainly this affects T-cell homeostasis. Such defects are probably essential acquired abnormalities allowing tumour cells in MF/SS to adopt a malignant phenotype. Defective activation-induced cell death in MF/SS is further exemplified by other key findings (Fig. 57.21); constitutive expression of STAT3 protein which is integral to cytokine mediated T-cell activation and inhibition of IL-2 mediated expression of STAT5 have been clearly defined in advanced stages of disease such as SS [42–44]. In addition, constitutive expression of NFkB has also been shown in both MF and SS [45,46]. The consequent dysregulation of multiple signalling pathways controlled by STAT and NFkB will contribute to prevention of tumour cell apoptosis in MF/SS and these pathways may also be potential therapeutic targets.

Treatment of mycosis fungoides and Sézary syndrome

Current therapy of MF and Sézary syndrome includes:

1 Topical steroids
2 Topical chemotherapy—mechlorethamine (nitrogen mustard) and carmustine (BCNU)
3 Phototherapy—both UVB and psoralen with UVA (PUVA) and UVA-1
4 Radiotherapy, including total skin electron beam therapy (TSEB)
5 Immunotherapy (IFN-α, IFN-γ and IL-12)
6 Retinoids
7 Combination therapies
8 Systemic single and multiagent chemotherapy
9 Photopheresis
10 Toxin therapies
11 Monoclonal antibodies
12 Histone deacetylase inhibitors
13 Other novel therapies.

The choice of initial treatment for the MF patient will depend on the stage of the disease as well as the general condition and age of the patient (performance status). At present, there are very few published studies that could form the basis for evidence-based therapy, mainly because of the rarity of the condition and also because of the variation between individual patients in disease pattern and progress. A large proportion of patients with MF are frail, elderly and likely to succumb either to other general medical problems or to the side effects of overenthusiastic therapy. In addition, the patient's quality of life should always be considered when selecting a treatment regimen. One of the few randomized trials of treatment of MF reported on 103 patients who received either TSEB (3000 cGy total skin electron beam) together with cyclophosphamide, daunorubicin, etoposide and vincristine (a rigorous 'treat to cure' regimen) or sequential topical therapy consisting of nitrogen mustard, superficial radiotherapy and TSEB, progressing to PUVA if required (a 'gentle palliative' regimen). After a median follow-up time of 75 months, there was no difference in disease-free or overall survival between the 52 patients who received TSEB plus chemotherapy and the 51 who received sequential palliative topical therapy [1]. This study established a consensus that therapy in MF should be based on stage of disease and aimed at disease palliation rather than an aggressive intent to cure. Therefore the current consensus is that patients with early

Stage Prognostic group	1st line	2nd line	3rd line
Stage IA-IIA Good prognosis	SDT	SDT + α-interferon/ bexarotene	TSEB Trials
Stage III Intermediate prognosis	PUVA ECP/bexarotene/ α-interferon	TSEB Single-agent chemotherapy Antibody therapies	Trials RISCT
Stage IIB/IV* Poor prognosis	Radiotherapy (TSEB) Chemotherapy (single/multiagent)	Trials Toxin therapy RISCT	Palliation

SDT, skin directed therapy; RISCT, reduced intensity stem cell transplant; TSEB, total skin electron beam therapy; ECP, extracorporeal photopheresis.

* Maintenance therapy with SDT ± α interferon/bexarotene for residual skin disease (patches/plaques).

stage disease should receive skin directed therapies. Systemic therapies are reserved for those with either early stage disease resistant to skin directed therapy or advanced disease (Table 57.7) [2]. The precise role of a wide variety of novel therapeutic approaches remains to be established but these studies have helped to develop an emerging consensus about the optimal methods for assessment of disease response assessment [3–4].

Skin directed therapy

Topical steroids

For patients with limited early stage MF, life expectancy may not be adversely affected and it is acceptable to simply use emollients with or without moderate-potency topical steroids. Potent topical corticosteroids can produce a clinical response, although this is usually short-lived [1].

Topical chemotherapy—nitrogen mustard (mechlorethamine) and carmustine (BCNU)

Topical mechlorethamine (nitrogen mustard) 0.01% or 0.02%, either as an aqueous solution (normal saline) or ointment base (emulsifying ointment), is effective for superficial disease with response rates of 51–80% for IA, 26–68% for IB and 61% for IIA disease [1–5]. The aqueous solution is relatively unstable, and the ointment base—more commonly than the aqueous solution—can cause irritancy or an allergic dermatitis in sensitized individuals (35–58%), but efficacy is similar. This product must not be used in pregnancy and there are rare reports of non-melanoma skin cancer in patients treated with topical mechlorethamine. There is no consensus as to whether mechlorethamine should be applied to individual lesions or to the whole skin, daily or twice weekly, or about the duration of topical therapy after a clinical remission has been produced; responses can be sustained for prolonged periods.

Topical BCNU is an alternative topical chemotherapeutic agent in MF, with similar efficacy to mechlorethamine as indicated by response rates of 86% in stage IA, 47% in stage IB and 55% in stage IIA patients [6]. Alternate day or daily treatment with 10 mg BCNU in 60 mL dilute alcohol (95%) or 20–40% BCNU ointment can be used. Hypersensitivity reactions occur less often (5–10%) than with mechlorethamine. All patients treated topically with carmustine should have regular monitoring of their full blood counts and treatment is normally given for only 2–4 weeks to avoid myelosuppression; maintenance therapy is contraindicated.

Topical retinoids

Recently, a novel retinoid, 1% Targretin (bexarotene) gel, has been approved by the Food and Drug Administration (FDA) for topical therapy in stage I MF in patients who are resistant to, or intolerant of, other topical therapies [1]. In open uncontrolled studies, response rates of 63% with 21% complete response rates have been reported in 67 patients with early stage (IA–IIA) disease. Median time to and duration of response were 20 and 99 weeks, respectively.

Other topical therapies

There has only been one randomized placebo-controlled trial of topical therapy in MF. Topical peldesine cream (BCX-34, an inhibitor of the purine nucleoside phosphorylase enzyme) showed no benefit, compared to vehicle, with complete responses of 28% and 24%, respectively, emphasizing the difficulties in interpretation of uncontrolled studies of topical therapy in early stages of MF [2].

Phototherapy and photochemotherapy

The clinical benefit of PUVA (photochemotherapy) was noted over 25 years ago and complete response rates of 79–88% in stage IA and 52–59% in stage IB disease have been reported [1–5]. Flexural sites ('sanctuary sites') often fail to respond completely and the duration of response varies. There is no significant response in tumour (IIB) stage disease. One study has shown that 56% of stage IA and 39% of stage IB complete PUVA responders had no recurrence of disease after 44 months follow-up without maintenance therapy [6]. A recent retrospective study on long-term outcome for MF patients treated with PUVA reported that 50% of patients with a higher cumulative UVA dose achieved a longer duration of response but these patients also received maintenance therapy while those who relapsed early did not [7]. Furthermore, there was no difference in clinical outcome in terms of disease progression or survival in the two groups. Maintenance therapy is rarely effective at preventing relapse and therefore should be avoided if possible so as to limit the total cumulative dose, as patients will often require repeated courses over many years.

PUVA is an ideal therapy for patients with stage IB–IIA disease who are intolerant of, or fail to respond to, topical therapies such as mechlorethamine, although both therapies can be complementary for some patients. Treatment regimens have varied in reported studies of PUVA in CTCL with two to four times weekly and different protocols for incremental dosage, but usually two to three times weekly treatment is acceptable until disease clearance or best partial response. Many patients will inevitably have a high total cumulative UVA dosage and the risks of non-melanoma and melanoma skin cancer are consequently increased for these patients. Efforts should be made to restrict the total PUVA dosage to less than 200 treatment sessions or a total cumulative dose of 1200 J/cm^2. In some circumstances patients may receive a greater total dosage if clinically justified and with the consent of the patient. PUVA remains one of the most effective therapies for patients with early stage disease but there are surprisingly no data to establish if PUVA can improve overall survival or reduce rates of disease progression in stage IB. PUVA therapy is rarely tolerated in erythrodermic (stage III) disease but occasional patients will respond repeatedly.

Broad- and narrow-band UVB and high-dose UVA-1 phototherapy have also been used in MF with success [8–10]. There have been no adequate comparative studies of different phototherapy regimens in CTCL but narrow-band UVB therapy may be an effective option in patients with patches as opposed to plaques.

Radiotherapy and electron beam therapy

MF and other CTCL variants are very radiosensitive malignancies and individual thick plaques, or tumours can be treated successfully with low-dose superficial radiotherapy (orthovoltage or electrons) often administered in several fractions (e.g. two or three fractions of 400 cGy at 80–120 kV). Large tumours may require a different energy source. Radiotherapy is often used with other therapeutic modalities such as PUVA, and closely adjacent and overlapping fields can often be retreated because of the low doses used [1].

Whole body TSEB therapy has been evaluated extensively in CTCL [2,3]. Different field arrangements have been used in an attempt to treat the whole skin uniformly to a depth of 1 cm with various total dosage administered and additional radiotherapy to shielded areas. A meta-analysis of open uncontrolled and mostly retrospective studies of TSEB as monotherapy in 952 patients with CTCL has established that responses are stage dependent, with complete responses of 96% in stage IA, IB and IIA disease but disease relapse rates are very high, indicating that this approach is not curative even in early stage disease [4]. In stage IIB disease, complete responses are less common (36%), but erythrodermic (stage III) disease shows complete responses of 60%. Greater skin surface dose (32–36 Gy) and higher energy (4–6 MeV electrons) are associated with a higher rate of complete response and 5-year relapse-free survivals of 10–23% were noted [4]. A retrospective study of erythrodermic disease has also shown 60% complete responses with 26% progression-free at 5 years [5]. In this study, the overall median survival was 3.4 years with a median dose of 32 Gy given as five weekly fractions over 6–9 weeks. Patients with stage III disease did best compared to those with significant nodal or haematological (IVA–B) disease. The duration of response was also longer for those who received more than 20 Gy using 4–9 MeV [5].

Comparative studies of TSEB versus topical mechlorethamine in early stage MF show similar response rates and duration of response, suggesting that TSEB therapy should be reserved for those who fail first- and second-line therapies [6,7]. Adverse effects of TSEB include temporary alopecia, telangiectasia and skin malignancies, and the treatment is only available in a limited number

of centres [8]. Although TSEB is usually only given once in a lifetime, several reports have documented patients who have received two or three courses, although the total dosage tolerated and duration of response have been lower with subsequent courses [9,10]. EORTC consensus guidelines have been produced for TSEB [11].

Systemic therapy

Immunotherapy

Different forms of immunotherapy have been evaluated in CTCL, with the intention of enhancing antitumour host immune responses by promoting the generation of cytotoxic T cells and Th1 cytokine responses. Studies of IFN-α have shown overall response rates of 45–74%, with complete responses of 10–27% [1–3]. Various regimens have been employed (from 3 MU three times weekly to 36 MU/day) and it appears that response rates are higher for larger-dosage regimens (overall responses of 78% compared to 37% for the lower-dosage regimen) [2]. Overall response rates are also higher in early (IB–IIA 88%) compared to late (III–IV 63%) stages of disease [2].

Other small pilot studies have shown that both IL-12 and IFN-γ can produce clinical responses in CTCL but their therapeutic value remains to be established [4,5]. Ciclosporin has been used in CTCL, particularly in erythrodermic variants, to relieve severe pruritus but there is some evidence that treatment may actually cause rapid disease progression and its use in CTCL is not recommended [6].

Retinoids

Oral retinoid therapy has been used both as a single agent and in combination with interferons and PUVA in the management of MF (see below). A non-randomized, small study comparing acitretin and isotretinoin in MF and SS has shown no obvious differences, with complete responses of 21% in both groups [1].

Phase II and III studies of a novel synthetic retinoid in CTCL prompted licensing of this retinoid for MF/SS [2,3]. Bexarotene (Targretin) is the only retinoid that selectively binds and activates the RXR receptor. Bexarotene has been shown to promote apoptosis and inhibit cell proliferation. It is relatively selective and therefore should have little effect on the RAR receptor involved in cell differentiation. In phase II and III studies of 152 patients with CTCL, response rates from 20% to 67% have been reported [2,3]. The most effective tolerated oral dosage is 300 mg/m^2/day, although responses improve with higher dosage. Side effects are transient and generally mild but most patients while on therapy require treatment for hyperlipidaemia and central (hypothalamic) hypothyroidism according to an algorithm [4,5]. At a dosage of 300 mg/m^2/day in early stage disease (IA, IB, IIA), overall response rates of 54% have been noted [2], while advanced MF patients (stage IIB–IVB) have shown overall response rates of 45% with a notable reduction in pruritus in stage III disease [3].

Combination therapy

Combined IFN-α and retinoids produces similar response rates to IFN alone and is not recommended [1]. Studies comparing PUVA and IFN-α with IFN-α and acitretin in early stage disease have shown complete response rates of 70% and 38%, respectively, but there are no data on duration of response [2]. Uncontrolled studies

of combined PUVA and IFN-α (maximum tolerated dosage 12 MU/m^2 three times weekly) in MF and SS have shown overall response rates of 100%, with 62% complete response rates [3]. This combination may also be useful in patients with resistant early stage disease, such as those with thick plaques and folliculotropic disease. Open studies comparing PUVA with combined PUVA and acitretin have shown a similar complete response rate (73 and 72%, respectively), although the cumulative dose to best response was lower in patients receiving the combination therapy [4]. Current randomized controlled studies are comparing: (i) PUVA versus PUVA and IFN-α in early stage MF; (ii) the role of maintenance IFN-α after induction of a complete response with PUVA and IFN; and (iii) PUVA alone compared to PUVA combined with bexarotene. At present there are few data on the impact on disease-free and overall survival.

Systemic chemotherapy

MF and SS are relatively chemoresistant and responses are usually short lived [1]. This may partly reflect the low proliferative rate of tumour cells and a high prevalence of inactivating *p53* mutations, which produce a relative resistance to tumour cell apoptosis. A systematic review of published data on different regimens has shown complete response rates of 33% in 526 patients treated with single-agent chemotherapy with a median duration of 3–22 months [2]. Combination chemotherapy regimes (including cyclophosphamide, doxorubicin, vincristine, prednisolone (CHOP)) in 331 patients produced complete response rates of 38%, with a median duration of 5–41 months [2]. CTCL patients are prone to infection and septicaemia is a common preterminal event.

Chemotherapy should not be used in patients with early stage IA, IB or IIA disease. However, treatment of stage IIB and IVA disease remains problematic. Individual tumours and effaced peripheral lymph nodes will respond to superficial radiotherapy and additional chemotherapy should be considered in patients with a good performance status (WHO 0–2). However, responses are likely to be short-lived and patients should be entered into ongoing clinical trials. Single-agent chemotherapy that has been shown to produce a clinical response in stage IIB–IVB disease, and especially erythrodermic patients, includes oral chlorambucil (four to six cycles of 0.15–0.2 mg/kg/day for 2 weeks every 28 days), methotrexate and etoposide, and the intravenous use of the purine analogues 2-deoxycoformycin, 2-chlorodeoxyadenosine and fludarabine [2]. Open studies of 2-deoxycoformycin in MF and SS have reported response rates of 35–71%, with complete response rates of 10–33% [3,4]. Methotrexate has been reported to produce a complete response rate of 41% in 29 patients with erythrodermic (stage III/T4) disease, with a median survival of 8.4 years with single weekly doses of 5–125 mg. However, this study was uncontrolled and it is unclear if the patients included represented an usually good prognostic group [5]. In contrast, liposomal doxorubicin [6,7] and gemcitabine [8,9] have shown excellent responses in stage IIB and IVA non-erythrodermic MF with overall responses of 88% (44% complete remission (CR)) and 70–85% (10–22% CR), respectively, but once again the duration of response is often short-lived with a median duration of response of 10 months for CR patients treated with gemcitabine [9]. In a further study, liposomal doxorubicin showed similar responses (56% overall response rate (ORR) with 20% CR) in both transformed MF and erythrodermic SS patients [10].

Recent pilot studies assessing the use of TSEB and/or total body irradiation (TBI) combined with high-dose conditioning chemotherapy prior to autologous stem cell transplantation in patients with stage IIB–IVA disease have shown good clinical responses [11,12] but high relapse rates and there are no data available at present to indicate if this approach affects disease-free or overall survival. Allogeneic stem cell or bone marrow transplantation has only been used in a few patients with encouraging results [13–15], but the associated mortality suggests that this approach is difficult to justify. However, reduced intensity allogeneic stem cell transplantation has shown promising results in small studies [16] with clear evidence of a graft-versus-lymphoma effect indicating that this may potentially have a durable effect for selected CTCL patients [17].

Photopheresis

Extracorporeal photopheresis (ECP) involves administration of oral psoralen, followed by *ex vivo* collection of an enriched buffy coat preparation using a cell separator. These leukocytes are then passed through thin polythene tubing with exposure to UVA and the cells thereafter returned to the patient. This regimen is repeated on 2 successive days and the 2-day cycle repeated monthly or fortnightly in an accelerated regimen. A specially designed photopheresis apparatus is required for this technique. The underlying theory is that a proportion of the UVA-exposed leukocytes, including some tumour lymphocytes, undergo apoptosis and that dendritic cells are activated during the *ex vivo* circulation with induction of a host antitumour immune response after the treated cells are returned to the patient. Different models of autoimmune disease support this suggestion [1,2] and recent evidence has also shown activation of dendritic cells during an expanded period of *ex vivo* incubation overnight (transimmunization) [3].

ECP is licensed by the FDA for the treatment of CTCL but there are no randomized studies to clarify whether ECP has an impact on overall survival. The original open study of ECP in 29 patients with erythrodermic CTCL reported a response rate of 73% but response rates in patients with earlier stages of MF were much lower (38%) [4]. Subsequently, a median survival of 62 months was reported in the original cohort of 29 erythrodermic patients, which compares favourably with historical controls (30 months) [5]. A study of 33 patients with SS treated with ECP reported a median survival of 39 months, which was similar to historical controls from the same institution [6]. Other studies have shown more prolonged median survival data [7]. An accelerated regimen consisting of nine collections rather than six for each cycle and an increase to treatment every 2 weeks has shown overall response rates of 50%, with 18% complete responses in erythrodermic disease [8]. A systematic review of response rates in erythrodermic disease (stage III–IVA) with ECP has shown overall responses of 35–71%, with complete responses of 14–26% [9]. Other studies are more difficult to interpret because they have either involved small numbers, patients with earlier stages of disease and in most studies many of the patients have been on other concurrent therapies [10,11]. Preliminary pilot studies suggest that the combination of IFN-α and ECP is more effective than ECP alone but this has yet to be confirmed in randomized studies [12,13]. There are isolated case reports of combined ECP and IFN-α and/or bexarotene that have induced complete clinical and molecular responses [14–16].

Randomized, controlled trials of ECP are required to establish an effect on disease-free and overall survival. There have been claims that the CD8 count is critical in predicting whether patients will respond to ECP [5], although others have provided evidence that the total baseline Sézary count is the only predictor of response [17].

Toxin therapies

Denileukin diftitox, a DAB_{389}–IL-2 fusion toxin (Ontak USA/Onzar Europe), received provisional FDA approval for the treatment of

resistant or recurrent CTCL after completion of open-label, phase I/II studies. Onzar is a recombinant fusion protein consisting of peptide sequences for the enzymatically active domain (389) of diphtheria toxin and the membrane translocation domain of IL-2 that is capable of inhibiting protein synthesis in tumour cells expressing high levels of the IL-2 receptor, resulting in cell death. Phase III studies of 71 heavily pre-treated patients with stage IB–IVA, and more than 20% $CD25^+$ T cells, showed an overall response rate of 30%, including 10% with complete responses [1]. Patients were assessed with a rigorous skin scoring system and documented responses were defined as lasting at least 6 weeks. The median duration of response was 6.9 months (range 2.7–46.1 months). The optimally tolerated intravenous regimen is 18 µg/kg/day for 5 days, repeated every 21 days for four to eight cycles. Adverse effects include fever, chills, myalgia, nausea and vomiting, and a mild increase in transaminase levels. Acute hypersensitivity reactions occurred in 60%, invariably within 24 h and during the initial infusion but this can be prevented with steroid pre-treatment [2]. A vascular leak syndrome characterized by hypotension, hypoalbuminaemia and oedema was defined retrospectively within the first 14 days of a given dose in 25% of patients. Myelosuppression is rare. Five per cent of adverse effects are severe or life-threatening. The clinical relevance of antibody responses to denileukin diftitox is unclear. The duration of clinical response has not yet been established and current studies are comparing different regimens of Onzar and are also assessing the use of this therapy in $CD25^-$ tumours. This therapy is not likely to be appropriate for early stage disease but may be useful in advanced disease.

Monoclonal antibody therapy

The first antibody approach was a humanized chimeric anti-CD4 monoclonal antibody used to treat eight patients with CTCL, of whom seven showed a clinical response but this was of short duration [1]. A radiolabelled anti-CD5 antibody has also been used in MF with some objective results [2] and CAMPATH (anti-CD52/alemtuzumab) has also been studied in patients (stage III) with overall responses in 55–85% and a median response duration/time to treatment failure of 12 months [3,4]. Studies of a fully humanized anti-CD4 antibody (Zanolimumab) in bexarotene-refractory MF/SS have shown overall responses of 56% and median response duration of 81 weeks [5].

Histone deacetylase inhibitors

A novel class of drugs has been assessed in both MF and SS in a series of open label studies. These histone deacetylase (HDAC) inhibitors affect gene expression by inhibiting deacetylation of histone proteins which causes the chromatin structure to adopt an open configuration therefore allowing binding of transcription factors to promoter regions and gene transcription. While the effect of these drugs on histone proteins within chromatin is best understood there are almost certainly widespread effects on non-histone proteins as well, which may be therapeutically important. There are four classes of HDAC inhibitors and several including SAHA and depsipeptide have been studied in both MF and SS [1–3]. Phase I/II studies of SAHA (vorinostat) have shown overall response rates of 30% with a median time to progression of 5 months [1,2]. This has prompted the US Food and Drug Administration to license vorinostat for second line-therapy of MF/SS. Side-effects include lethargy, thrombocytopenia. gastrointestinal symptoms and prolongation of the QT interval. Whether HDAC inhibitors are best used as maintenance therapy or in combination for advanced disease remains unclear but constitutive expression of STAT3 may indicate resistance to histone deacetylase inhibition in MF/SS [4].

Other novel therapies

Several novel therapies currently being assessed in open phase II studies show promise of significant efficacy in both MF and SS [1] including the proteasome inhibitor, bortezomib (Velcade) [2] but whether additional studies will confirm this promise is currently unclear.

Primary cutaneous CD30+ lymphoproliferative disorders

Primary cutaneous CD30+ lymphoproliferative disorders consist of a spectrum of conditions; lymphomatoid papulosis and CD30+ anaplastic large cell lymphomas which are defined on the basis of clinical and pathologic features. Where a distinction cannot be made, patients are designated as 'borderline cases'. This group represents approximately 30% of all primary cutaneous lymphomas.

In the skin, CD30+ lymphoproliferative disorders are invariably of T-cell origin although nodal CD30+ lymphomas can be derived from B, T or null cells. By definition, primary cutaneous CD30+ disorders do not have any systemic or nodal involvement [1–3]. CD30 positivity was originally identified on Reed–Sternberg cells in Hodgkin's disease, but is expressed on a proportion of activated T and B lymphocytes. In general, cutaneous lymphomas that are CD30+ *ab initio* are associated with a good prognosis, in contrast to CD30+ lymphomas in other anatomical sites such as the lymph nodes where CD30 positivity is more commonly associated with a poor prognosis and is invariably associated with a disease-specific t(2;5)(p23;q35) translocation not found in primary cutaneous CD30+ lymphoproliferative disorders [4]. In MF, the situation in which tumour cells acquire CD30 expression, during the course of disease, is also generally associated with a poor prognosis [5].

Molecular studies show the presence of the Epstein–Barr genome in a proportion of CD30+ infiltrates in Hodgkin's disease, but this has not been found in patients with lymphomatoid papulosis [6]. CD30 is a cell-surface receptor for tumour necrosis factor-α like cytokines [7], and it has been demonstrated that CD30 expression can be up-regulated by EBV. The pathogenesis of primary cutaneous CD30+ lymphoproliferative disorders remains unknown but studies have suggested that there may be restriction of the normal T-cell repertoire in peripheral blood [8] and abnormalities of Notch signalling [9].

Lymphomatoid papulosis

Definition. This term was first used in 1968 by Macaulay to describe a 'self-healing rhythmical paradoxical papular eruption, histologically malignant but clinically benign' [1–6]. It is a chronic recurrent self-healing papulonecrotic or papulonodular eruption with histological features of a CD30+ cutaneous lymphoma.

Clinical features. Affected patients have recurrent crops of papular or papulonecrotic or nodular lesions predominantly affecting the trunk, although any body site can be involved and regional localized patterns may occur (Fig. 57.22) [7]. These lesions grow rapidly over a few days and develop ulcerated necrotic centres. Healing occurs slowly over 3–12 weeks, with fine atrophic circular or varioliform scars, but the cycle recurs every few months, with no obvious initiating factor. The lesions generally occur first in adult life and may recur in crops for up to 40 years. Over time, every individual skin lesion will resolve and there may eventually be a persistent remission. A small number of cases have been reported in children [8,9].

The original description of lymphomatoid papulosis suggested a benign and non-progressive chronic pattern of the disease, but there are well-documented rare cases both of patients with lymphomatoid papulosis developing primary cutaneous or nodal CD30+ large cell anaplastic T-cell lymphoma or more commonly MF, and of patients with pre-existing MF developing lesions indistinguishable from those of lymphomatoid papulosis [10,11]. A follicular variant of the condition has also been described [12]. A proportion of patients have developed Hodgkin's disease, or develop lymphomatoid papulosis-like lesions with a preceding history of Hodgkin's disease [13–15].

Pathology. The histological features are a relative lack of epidermotropism and Pautrier abscesses, but the presence in the dermis

(a)

(b)

Fig. 57.23 Composite high-power view of atypical cerebriform cells in type B lymphomatoid papulosis (a) and large 'Reed–Sternberg-like' ($CD30^+$) cells in type A histology (b).

of a mixed infiltrate composed of atypical lymphocytes with large nuclei and frequent abnormal mitoses, eosinophils, neutrophils, extravasated red cells and large histiocytic cells [16]. Some of these cells may show gross cytological atypia (Fig. 57.23). The epidermis may be ulcerated and the infiltrate may extend deeply into the reticular dermis. True vasculitis is rarely seen.

Lymphomatoid papulosis can be divided on histological grounds into types A, B and C subgroups [17]. In the A subgroup there appears to be a predominance of scattered large, strikingly atypical $CD30^+$ cells similar to those seen in Hodgkin's disease [18]. In the B subgroup, smaller atypical T lymphocytes with convoluted nuclei similar to those seen in MF predominate and are $CD3^+$ and $CD4^+$ but $CD30^-$. Rare cases of lymphomatoid papulosis are $CD8^+$ [19]. Group C lesions have large clusters of $CD30^+$ cells and an overall pattern suggestive of an anaplastic $CD30^+$ large cell lymphoma. Many cases, however, have all types of lesions coexisting simultaneously or a mixed pattern of A and B. Some patients with clinical lesions resembling pityriasis lichenoides et variol's acuta (PLEVA) show a lymphomatoid histology and this probably represents a form of lymphomatoid papulosis (type B) [20,21]. Recent studies have shown that *MUM1*, a transcription factor expressed in myeloma and lymphomas with plasmacytoid differentiation as well as activated T-cells and Hodgkin's lymphoma, is expressed by the $CD30^+$ cells in a majority of cases of lymphomatoid papulosis but only rarely in primary cutaneous $CD30^+$ ALCL [22]. Furthermore *TRAF1*, expressed by activated T-cells and in Hodgkin's lymphoma, is also differentially expressed in PC$CD30^+$ lymphoproliferative disorders, with expression restricted mostly to lymphomatoid papulosis as opposed to PCALCL [23]. The functional significance of differential *MUM1* and *TRAF1* expression in lymphomatoid papulosis remains to be confirmed.

Clonal TCR gene rearrangements can be identified and are identical in different lesions from the same patient, but some biopsies may not show a clonal pattern either because of an inability to detect a small clonal T-cell population as a result of a lack of sensitivity, or because of a non-T-cell lineage in type A lesions [4,24]. Identical T-cell clones can be detected in skin biopsies from patients with both MF and lymphomatoid papulosis [24]. Studies using laser captured $CD30^+$ cells and sequencing of TCR genes have shown contradictory findings with one study suggesting that the large $CD30^+$ cells show clonal TCR gene rearrangements while other studies have shown that these large $CD30^+$ are polyclonal and that the monoclonal population resides in the smaller population of $CD30^-$ cells [25,26]. The t(2;5) characteristic of nodal $CD30^+$ lymphomas is not detected in lymphomatoid papulosis [27].

Treatment. There is no current treatment that alters the natural history of the disease but some therapies appear to accelerate healing and may reduce or prevent the frequency and severity of new crops of lesions for a short time. There is no evidence that intensive combination chemotherapy alters beneficially the course of lymphomatoid papulosis, and indeed there are individual case reports suggesting that high-dose intensive chemotherapy may cause transition to a more aggressive $CD30^+$ lymphoproliferative disorder. Topical or intralesional steroids and topical nitrogen mustard applied to developing lesions may accelerate clearance, but have little effect on well-developed lesions. Narrow-band UVB therapy and PUVA both appear to benefit individual patients for short periods of time. Low-dose oral methotrexate appears to be the most useful systemic therapy, and there are reports of a beneficial effect with oral dapsone [28,29].

Long-term follow-up is necessary in all cases because of the risk of progression to a more aggressive lymphoma such as a primary cutaneous $CD30^+$ anaplastic lymphoma, MF or Hodgkin's disease in less than 5% of cases. The prognosis in patients with both MF and lymphomatoid papulosis appears to be excellent [10]. There appear to be no currently available clinical or pathological prognostic markers to indicate whether such progression is likely.

An excellent recent review of 118 patients with lymphomatoid papulosis followed for many years suggests that approximately 4% will develop extracutaneous disease within 10 years [30].

Primary cutaneous (anaplastic) CD30+ large cell lymphoma

Definition. A primary cutaneous CD30+ anaplastic (or rarely pleomorphic or blastic) large cell lymphoma in which the CD30+ tumour cells comprise the majority of the infiltrate. Clinical features of mycosis fungoides are absent.

Clinical features. These lymphomas are usually seen in adults and present as large solitary or multiple and often ulcerated nodules, most often on the trunk (Fig. 57.24) [1]. There are no patches or plaques of MF elsewhere, and some individual lesions may regress spontaneously. Some individuals develop disease localized to a limb. Progression to extracutaneous sites is rare but has been recorded in approximately 10% [1,2] and recent evidence suggests that patients with extensive regional disease may be at risk of disease progression [3,4]. Careful staging consisting of bone marrow and CT scans are required to exclude systemic CD30+ anaplastic large T-cell proliferation in which there is secondary cutaneous involvement. Disease-related 5-year survival rates of 90% have been reported but as low as 50% for generalized tumours [1,3–5].

Flynn *et al.* described patients with large ulcerative nodules, often on the thighs and buttocks, which show variable rates of spontaneous resolution and were labelled as 'regressing atypical histiocytosis' [6]. These 'borderline cases' are now considered to be closely related to both lymphomatoid papulosis and primary cutaneous CD30+ large cell lymphoma with the detection of a T-cell phenotype and clonal rearrangements of the TCR gene confirming a T-cell origin [2,7,8].

A rare variant has been described in which there are palpable and pathologically involved regional lymph nodes at presenta-

Fig. 57.24 CD30+ cutaneous lymphoma showing typical ulcerated lesion on shoulder.

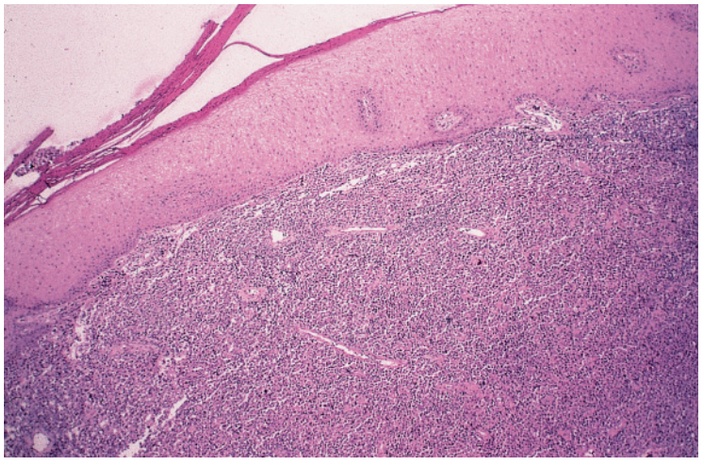

Fig. 57.25 Low-power view of CD30$^+$ infiltrate showing lack of epidermotropism but dense infiltrate in the underlying dermis.

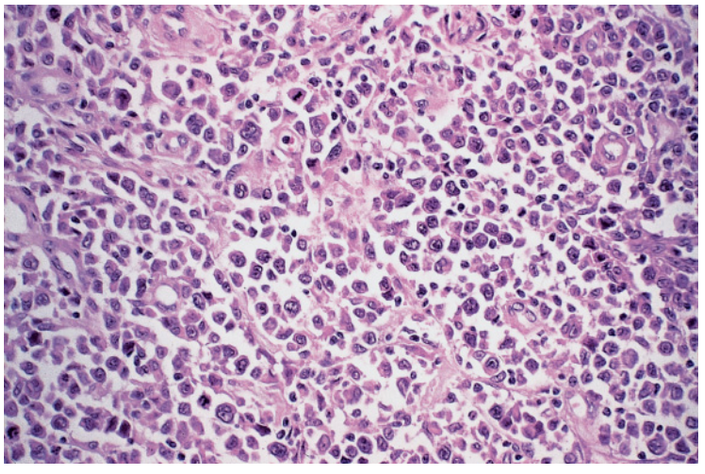

Fig. 57.26 CD30$^+$ lymphocytic infiltrate showing striking large atypical cells.

tion, but no evidence of lymphoma beyond the regional nodal basin [1]. The limited evidence to date on treatment and prognosis suggests that this lymphoma is similar, if not identical, to primary cutaneous CD30$^+$ anaplastic large cell lymphomas.

Pathology. Biopsy shows a dense lymphocytic infiltrate consisting of sheets of large atypical cells with an anaplastic morphology and mitoses, but usually there is no epidermotropism as seen in MF (Figs 57.25 & 57.26). The tumour cells variably express T-cell antigens and the vast majority will be CD30$^+$. Some tumour cells show a pleomorphic or blast-like morphology [1,2,9,10]. Pseudoepitheliomatous hyperplasia may occur. Clonal TCR gene rearrangements are detected in almost all cases consistent with a T-cell origin [11].

Immunophenotype. The tumour cells are generally CD4$^+$ and by definition CD30$^+$ with expression of cytotoxic proteins [9,10]. There is variable loss of other T-cell antigens such as CD2, CD5 and CD3. Some cases are CD8$^+$. Tumour cells are EMA and CD15. ALK is not expressed, in contrast to those systemic CD30$^+$ lymphomas with secondary cutaneous involvement, but CD56 may be rarely expressed. The t(2;5) is absent [12]. While the morphology and phenotype are similar in lymphomatoid papulosis [13], the key distinguishing feature is the presence of cohesive nodules and sheets of anaplastic cells in PCALCL. Recent studies also suggest that in PCALCL the tumour cells generally do not express *MUM1* and *TRAF1* in contrast to lymphomatoid papulosis [14,15].

Pathogenesis. Primary cutaneous CD30$^+$ ALCL express CCR3 and Th2 cytokines [16] as well as CCR4 as in MF/SS. There is no evidence for the t(2;5) chromosomal translocation seen in a high proportion of nodal CD30$^+$ anaplastic lymphomas (NPM-ALK) [12], but molecular studies in PCCD30$^+$ALCL have shown allelic loss at 9p21-22, although the frequency of p16 loss/inactivation has yet to be determined [17]. Array CGH studies have also shown chromosomal imbalances with gains of chromosomes 1p and 5 and amplification of several different oncogenes as well as *JUNB*, a member of the AP1 transcription family [18]. Recent studies have also shown over-expression of AP1 proteins in Pc CD30$^+$ ALCL which might explain the characteristic Th2 cytokine profile [19].

Treatment. Both excision and localized radiotherapy are acceptable methods of treating isolated lesions [20]. The recurrence rate on the treated site is very low, but over time new lesions may develop elsewhere on the skin. Spontaneous clearance of even quite large lesions is recorded, and therefore a short period of observation after the diagnosis is made is also acceptable. Systemic chemotherapy, including CHOP, may be effective but cutaneous recurrence is likely, and chemotherapy is therefore not the treatment of choice for disease confined to the skin. Low-dose methotrexate may also be effective. Rare variants with regional nodal disease have been successfully treated with radiotherapy and do not always require systemic chemotherapy.

Subcutaneous panniculitis-like T-cell lymphoma (SPTL)

Definition. This is a rare cytotoxic T-cell lymphoma, representing less than 1% of all non-Hodgkin's lymphomas, which usually affects younger adults with an equal sex incidence [1,2]. Two subsets have been defined consisting of those cases derived from an αβ T cell which have an indolent course and those derived from a γδ T cell [3]. The term SPTL is now restricted to those lymphomas derived from an αβ T cell [1].

Clinical features. Patients present with indolent, slowly expanding, subcutaneous nodules usually involving the limbs, which may initially be misdiagnosed as panniculitis (Fig. 57.27) [4–6]. Occasionally, patients present with more diffuse erythematous induration mimicking a cellulitis. Ulceration is rare. Lymphadenopathy is usually absent at presentation. There is often a prolonged indolent phase before the diagnosis is established [7]. Cases must be carefully distinguished from lupus panniculitis as both conditions share similar clinical and pathological features [8,9]. Systemic symptoms may occur, particularly in those patients who develop a haemophagocytic syndrome consisting of fever, pancytopenia and hepatosplenomegaly although this is more common in those with a γδ T-cell lymphoma [10,11]. The prognosis is reasonable with a 5-year survival of 80%, and dissemination to extracutaneous sites is rare in contrast to primary cutaneous γδ T-cell lymphomas which has a poor prognosis [1].

Fig. 57.27 Subcutaneous panniculitis-like T-cell lymphoma: indurated and eroded deep plaque on the thigh.

Pathology. There is a diffuse infiltrate restricted to and extending throughout the subcutis without epidermotropism [1,3,5,11]. In contrast, primary cutaneous γδ T-cell lymphomas may show prominent involvement of the subcutis which is indistinguishable but there is invariably associated dermal and/or epidermal involvement [1]. The degree of cellular atypia can be minimal but medium-sized and occasionally large pleomorphic cells are usually present (Fig. 57.28). Rimming of the tumour cells around fat cells is a characteristic feature, although not restricted to SPTL [12]. A prominent reactive inflammatory infiltrate is common and the tumour cells may show vascular invasion with angiocentricity. Necrosis and erythrolymphophagocytosis may be present. Indolent cases were previously diagnosed as benign cytophagic histiocytosis (Weber–Christian disease) [13,14].

Immunophenotype. Tumour cells have a mature T-cell phenotype and are usually $\beta F1^+$ $CD3^+$ $CD8^+$ $CD4^-$ [1,3,9]. CD30 and CD56 are generally negative. They express cytotoxic molecules including granzyme B, perforin and TIA-I [15]. Clonal rearrangements of the TCR genes are present [3,16].

Pathogenesis. There is no evidence for an association with EBV, and the underlying molecular pathogenesis remains to be established but recent studies have characterized a specific pattern of chromosomal abnormalities using CGH, LOH and FISH techniques, which have shown losses of 10q, 17p and 19 similar to MF/SS, with additional 5q and 13q gains, which appear to be distinct from findings in MF/SS [17].

Treatment. Patients with αβ subcutaneous panniculitis–like T-cell lymphoma can be treated successfully with systemic steroids and there are reports of responses to ciclosporin [1,18]. Superficial radiotherapy can be used for individual lesions. Denileukin

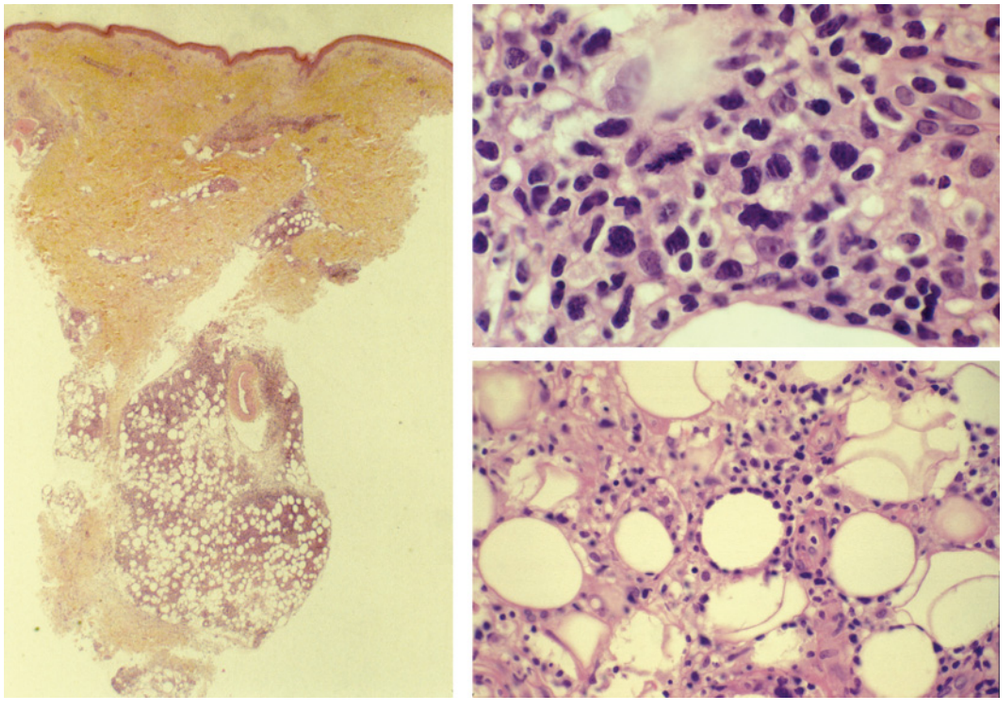

Fig. 57.28 Low-power view of subcutaneous infiltrate with high-power view showing rimming of fat cells by atypical mononuclear cells and medium/large pleomorphic tumour cells seen in subcutaneous panniculitis-like T-cell lymphoma.

diftitox has been used successfully in SPTL [19]. Combination chemotherapy can be associated with successful clinical responses and resolution of haemophagocytic syndrome, although this is usually restricted to those with extracutaneous disease [1]. High-dose therapy and autologous/allogeneic stem cell transplantation has been successful in patients with refractory disease [20,21].

Primary cutaneous peripheral T-cell lymphoma (unspecified)

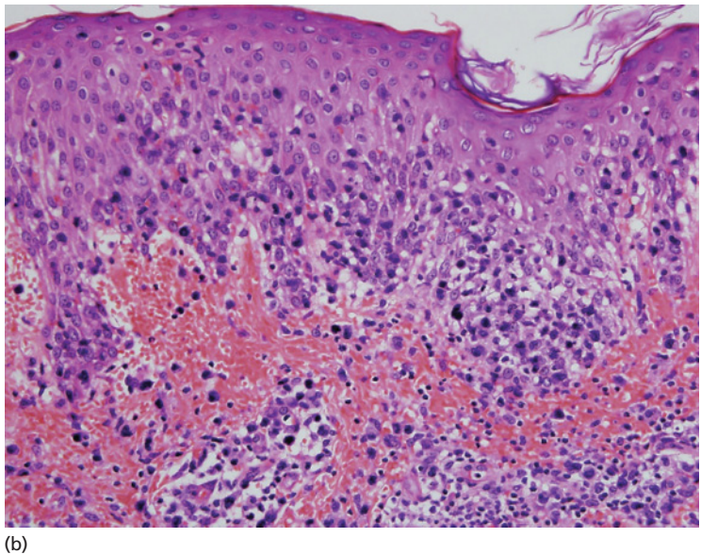
Definition. These lymphomas represent a heterogeneous group of T-cell malignancies which are not defined by any of the recognized clinicopathologic subsets. In all cases mycosis funogides

must be carefully excluded especially on the basis of the clinical features. Several subtypes (listed below) are currently considered as provisional entities based on characteristic clinical, pathologic and immunophenotypic features [1]. For patients who do not fulfil the characteristic features of these provisional entities, the designation of peripheral T-cell lymphoma (not otherwise specified (NOS)) should be used and the prognosis is generally poor with a high probability of systemic involvement. Full staging investigations are required for all patients to exclude a systemic nodal/extranodal peripheral T-cell lymphoma.

Primary cutaneous aggressive epidermotropic CD8$^+$ T-cell lymphoma (provisional)

Definition. A primary cutaneous CD8$^+$ T-cell lymphoma that expresses cytotoxic proteins and shows a prominent epidermotropic infiltrate [1,2]. Although there are currently few reports of this entity, the distinctive pathological and immunophenotypic features and poor prognosis suggest that it represents a distinct subtype of CTCL [1–3].

Clinical features. These patients rapidly develop generalized papules, plaques, nodules and/or tumours (Fig. 57.29a) which may show ulceration and necrosis [1,2]. Mucosal involvement may occur. The characteristic clinical features and distribution of MF, namely polymorphic patches and plaques and involvement of the limb girdle areas, are absent. Primary cutaneous CD30$^+$ lymphoproliferative disorders with a CD8$^+$ phenotype should also be distinguished. The prognosis is very poor, with a 5-year survival of 18% [1].



Pathology. These lymphomas show a prominent epidermotropic band-like infiltrate (pagetoid) with nodular infiltrates of large or small- to medium-sized pleomorphic or blastic T cells often accompanied by haemorrhage in the upper dermis (Fig. 57.29b). Angiocentricity and invasion can be a feature. These cutaneous lymphomas must be distinguished from MF and primary cutaneous γδ T-cell lymphomas [1,4]. An indolent CD8$^+$ cutaneous lymphoma characterized by solitary nodular lesions, often around the ear, has been suggested to be a distinct entity but appears to be very rare [5], and its relationship to epidermotropic CD8$^+$ T-cell lymphoma is unclear.

Immunophenotype. The tumour cells are CD8$^+$ and usually βF1$^+$ CD45RA$^+$ and CD3$^+$ [1–3]. The tumour cells also express cytotoxic proteins such as T-cell intracellular antigen-I (TIA-I), granzyme B and perforin. CD4, CD45RO, CD56 and CD30 are negative. Epstein–Barr virus (EBV) is not detected, in contrast to nasal-type natural killer (NK)/T-cell lymphomas [1,4].

Pathogenesis. This CTCL subset may previously have represented disseminated pagetoid reticuloses (Ketron–Goodman). Clonal TCR gene rearrangements are detected but the pathogenesis has not been established. Although the number of cases reported is small, these cases can be distinguished from peripheral T-cell lymphomas derived from γδ T-cells (βF1 negative) which show clonal rearrangements of the γ TCR gene with the β TCR gene in a germline configuration [1,6].

(b)

Fig. 57.29 (a) Primary cutaneous aggressive epidermotropic CD8$^+$ cutaneous T-cell lymphoma showing necrotic haemorraghic plaques and (b) an epidermotropic infiltrate of large pleomorphic lymphoid cells and marked papillary dermal haemorrhage.

Treatment. These patients have a very poor prognosis and dissemination to visceral sites such as CNS, testis and lung is more common than to nodal sites. Responses to radiotherapy and chemotherapy are limited and the treatment of choice may be a reduced intensity allograft procedure.

Primary cutaneous γδ T-cell lymphomas (provisional entity)

Definition. A T-cell lymphoma consisting of γδ T-cells with a cytotoxic phenotype which may present primarily with skin involvement. A subgroup of patients with subcutaneous panniculitis-like T-cell lymphoma derived from γδ T-cells are included in this category [1–3].

Clinical features. The characteristic presentation is the sudden appearance of multiple cutaneous plaques, nodules or tumours which may be ulcerated and with no preceding polymorphic plaques or patches of typical MF. The clinical presentation may be similar to primary cutaneous $CD8^+$ aggressive epidermotropic lymphomas but some patients present with only subcutaneous involvement. Mucosal involvement and extranodal involvement is common. Some cases of disseminated pagetoid reticulosis (Ketron–Goodman) may have represented cutaneous γδ T-cell lymphomas [4]. A haemophagocytic syndrome may complicate some cases. The prognosis is very poor [1–3].

Pathology. Prominent nodular or diffuse infiltrates are characteristic with medium to large pleomorphic or blast like T cells. Epidermotropism may occur but the infiltrate is often extensive with dermal and subcutaneous patterns. Angiocentricity and rimming of fat cells may occur [1].

Immunophenotype. The tumour cells are usually $CD2^+$ $CD3^+$ $CD5^-CD7^{+/-}$ and $CD56^+$ but are $CD4^-CD8^-$ and $\beta F1^-$. EBV is negative and clonal TCR gene rearrangements are usually present.

Pathogenesis. This variant must be distinguished from transformed MF, ATLL, primary cutaneous aggressive epidermotropic cytotoxic $CD8^+$ CTCL and blastic NK-cell or extranodal NK/T-cell lymphomas (nasal type).

Treatment. Superficial radiotherapy and multiagent chemotherapy are usually required but the overall prognosis is very poor and reduced intensity allografts may be appropriate.

Primary cutaneous $CD4^+$ small/medium sized pleomorphic T-cell lymphoma

Definition. This subtype of CTCL must be distinguished clinically from MF and is characterized by small to medium sized pleomorphic tumour cells which are $CD4^+$ [1].

Clinical features. Patients present with solitary or a few small plaques, nodules or tumours, often on the upper trunk or head and neck, without typical patches or plaques of MF. Patients are HTLV-1 negative. The estimated 5-year survival is 62–80%, but this is only based on small series [1–4]. Systemic involvement is very unusual.

Pathology. There are dense nodular or diffuse infiltrates of small to medium-sized pleomorphic T cells within the dermis, often extending into the subcutis [1–3]. Occasional larger pleomorphic cells may be present but are a minority. Epidermotropism may be present.

Immunophenotype. The tumour cells are usually $CD4^+$ and $CD3^+$ but loss of some T-cell antigens is common [1–3]. CD30 and CD8 are negative and cytotoxic proteins are not expressed. Clonal TCR gene rearrangements are present [5].

Pathogenesis. Currently, little is known about the underlying aetiology and pathogenesis of this rare group of primary cutaneous lymphomas. Cases must be distinguished from MF and pseudo T-cell lymphomas and also peripheral T-cell lymphoma (NOS) in order to avoid inappropriately aggressive therapy.

Treatment. In view of the excellent prognosis, superficial radiotherapy is appropriate for solitary lesions. Single-agent chemotherapy and IFN-α have been reported to be effective [3,4].

Adult T-cell leukaemia–lymphoma (HTLV-1-associated)

Definition. Adult T-cell leukaemia–lymphoma (ATLL) is a peripheral T-cell leukaemia–lymphoma caused by the human retrovirus HTLV-1. HTLV-1 infection is prevalent in certain parts of the world, including Japan, central Africa, the Caribbean and south-eastern states of the USA, and consequently ATLL is endemic in these regions. Sporadic cases are found throughout the world. The disease has a long latency and the incidence of ATLL among HTLV-1 carriers has been estimated to be 2.5% [1]. The virus can be transmitted in breast milk and in blood products. There is a slight male predominance and the median age of onset is 55 years [1].

Clinical features. Patients with ATLL often have extensive lymph node and peripheral blood involvement but the skin is the most common extranodal site of disease (50% of patients) and primary cutaneous disease can occur [2,3]. Other extranodal sites of disease include bone, lung, liver, gastrointestinal tract and CNS. Cutaneous involvement is characterized by widespread or solitary papules, nodules, tumours or erythroderma, often associated with intense pruritus (Fig. 57.30) [4,5]. Patients may present with patches and plaques that are clinically indistinguishable from MF [6]. Several clinical variants have been defined [7]: an acute variant is characterized by a leukaemic phase with generalized lymphadenopathy and hepatosplenomegaly often associated with cutaneous involvement and hypercalcaemia with lytic bone lesions. Opportunistic infections are common because of a relative T-cell immunodeficiency. A lymphomatous variant is similar but with the absence of peripheral blood involvement. A chronic variant is typically characterized by cutaneous disease and a peripheral blood lymphocytosis without hypercalcaemia. The smouldering variant is also characterized by prominent cutaneous disease without overt peripheral blood involvement. Pulmonary lesions may occur. Progression from the chronic and smouldering variants to acute disease occurs in at least 25% of cases but often only after a long duration [6]. HTLV-1 serology is invariably positive [7]. Patients with cutaneous ATLL have shown marked photosensitivity mimicking actinic reticuloid [8,9].

Pathology. In the skin, a prominent epidermotropic infiltrate consisting of medium to large cells with a pleomorphic nuclear morphology is usually found, particularly in the acute and lymphomatous variants (Fig. 57.31) [3–7]. Blast-like cells may be present. Pautrier-like microabscesses and a cerebriform nuclear morphology can be seen, simulating MF. However, the degree of cellular atypia may also be mild, causing diagnostic difficulties. Eosinophilia is often present. Granulomatous features have been rarely described [6]. In the peripheral blood, the tumour cells have polylobulated nuclei ('flower cells'). Lymph nodes usually show a leukaemic pattern of infiltration, with preservation and dilatation of lymph node sinuses containing tumour cells. Rarely, Hodgkin-like features are present within an expanded lymph

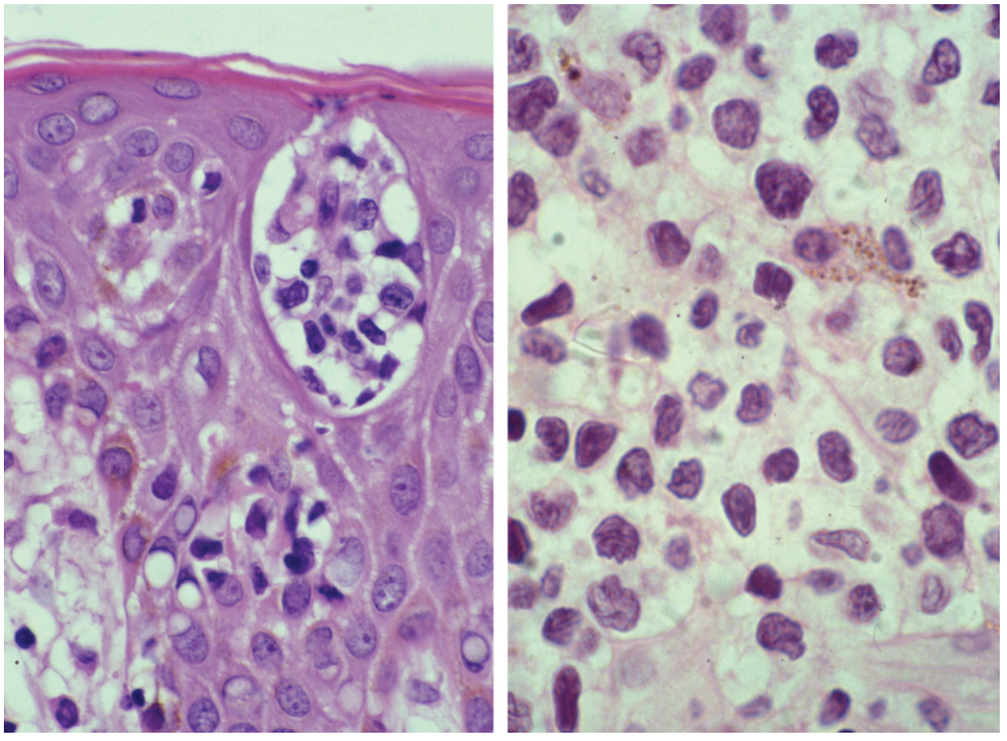

Fig. 57.31 Adult T-cell leukaemia–lymphoma: prominent atypical cells forming a Pautrier microabscess and large pleomorphic cells within the dermis.

node paracortex containing a diffuse infiltrate of small, mildly atypical lymphocytes and scattered $CD30^+$, $CD15^+$ Reed–Sternberg-like EBV-positive cells resulting from expansion of EBV-positive cells as a consequence of a relative T-cell immunodeficiency [10].

Immunophenotype. Tumour cells are $CD2^+$, $CD3^+$, $CD5^+$ and $CD7^-$. Most cells are $CD4^+$, although $CD8^+$ and $CD4^-$, $CD8^-$ variants also occur [11]. CD25 expression is almost universal. Large blast-like cells can be $CD30^+$ but are ALK^-. Cytotoxic proteins are not expressed. Analysis of TCR genes shows clonal TCR gene rearrangements.

Pathogenesis. HTLV-1 is the underlying cause of ATLL. The virus is randomly integrated into the host genome following expression of viral reverse transcriptase, and the viral tax protein is a potent transactivation factor that induces expression of numerous host genes with additional molecular abnormalities producing a malignant phenotype [12]. The HTLV-1 proviral DNA is clonally integrated, confirming a pathogenetic role for the virus in individual cases [11]. Tumour burden can be assessed by monitoring viral RNA expression levels [13].

Treatment. Cutaneous disease can respond to skin-directed therapy but patients with the acute and lymphomatous variants have a poor prognosis (less than 10% 5-year survival) and require combination chemotherapy. In contrast, patients with the chronic (30% 5-year survival) and smouldering (65% 5-year survival) variants can have a prolonged course, although disease transformation eventually occurs for most patients [7]. Combination azathioprine and IFN therapy is a standard of care for those with chronic and smouldering variants of ATLL [14,15], and trials of antibody therapies have suggested promise for daclizumab (anti-CD25) [16]. Younger patients may be candidates for stem cell transplantation and reduced intensity allograft procedures have been shown to induce a graft-versus-lymphoma effect [17].

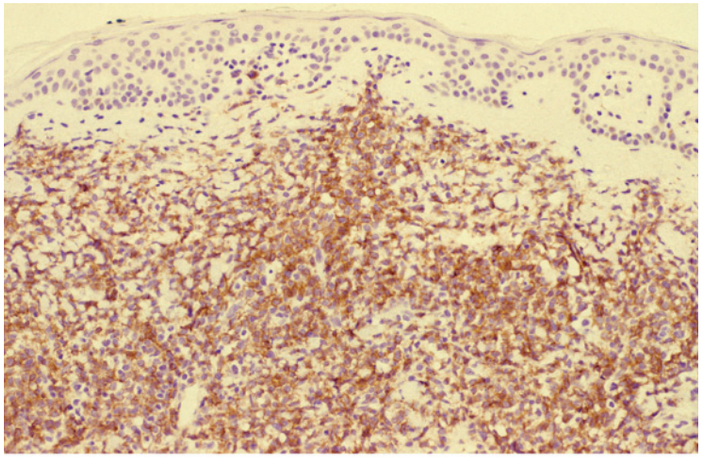
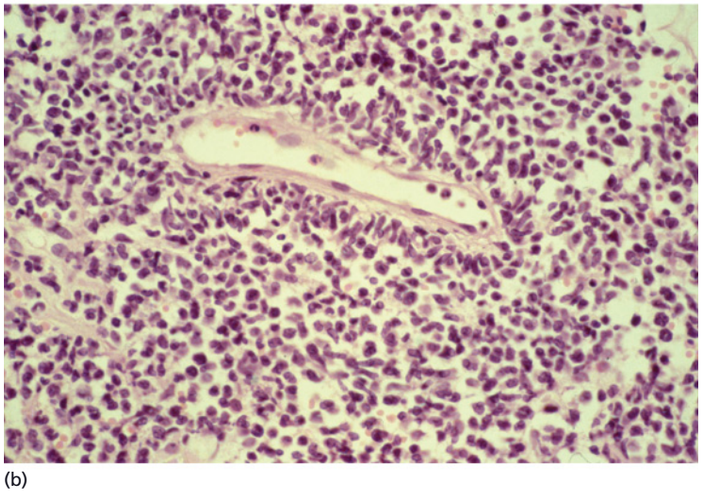
CD4$^+$/CD56$^+$ haematodermic neoplasm (blastic NK-cell lymphoma)

Definition. This is a rare haematologic neoplasm, which is now thought to be derived from plasmacytoid dendritic cells and shows a predilection for extranodal sites, particularly the skin, and a tendency to leukaemic dissemination [1]. Previously, this tumour was erroneously thought to be derived from NK-cells because of CD56 expression. There is no racial predisposition. Elderly male patients are mostly affected and the prognosis is poor.



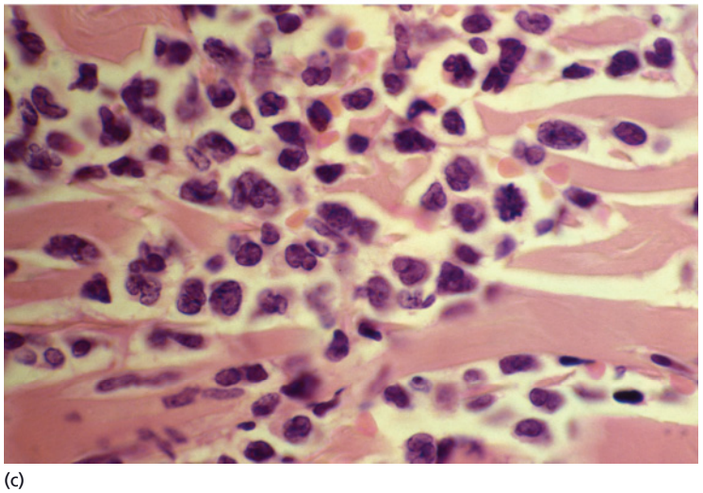
Clinical features. Patients usually present with multiple and rarely solitary, large, dusky mauve dermal tumours, which can become ulcerated (Fig. 57.32). There is no specific site predilection but the upper trunk is often affected. Primary cutaneous disease is common but lymphadenopathy and peripheral blood/bone marrow involvement is likely during the course of disease [2–5]. This neoplasm must be differentiated from myelomonocytic leukaemia and is closely related to 'aleukaemia' leukaemia cutis.

Pathology. A dense monomorphic infiltrate of medium-sized tumour cells with a fine chromatin resembling lymphoblasts is seen throughout the dermis with a well-defined grenz zone (Fig. 57.33) [4,5]. Occasionally, tumour cells show a rosette pattern. Necrosis and angiocentricity are usually absent.



Immunophenotype. Tumour cells are CD56$^+$ with variable expression of CD4, CD45RA and CD43 but do not express surface CD3. CD2, CD7 and cytoplasmic CD3ε are usually negative [3–5]. Cytotoxic proteins may be rarely expressed. Rare cases are CD34$^+$CD68$^+$ and TdT$^+$. Because of a morphological resemblance to myeloblastic and precursor T-lymphoblastic leukaemia which also express CD56, it is important to confirm that the tumour cells are negative for surface CD3, CD33 and myeloperoxidase/lysozyme. TCR gene analysis reveals a germline pattern for all TCR genes consistent with a non-lymphoid origin [4–6]. The tumours are CD123$^+$ TCL1a$^+$, confirming a derivation from rare peripheral blood plasmacytoid dendritic cells [7,8].

Pathogenesis. EBV has not been detected in tumour cells and no disease-specific cytogenetic abnormality has been detected [5,6]. Comparative genomic hybridization techniques and gene expression studies have shown a distinct pattern of chromosomal abnormalities and over-expression of the oncogene, *FLT3*, and loss of expression of the *Rb1* gene [9–12]. These studies have also shown that CD4$^+$ CD56$^+$ haematodermic neoplasms and cutaneous infiltrates of myeloid leukaemia have different chromosomal and gene expression profiles.



Treatment. Combination chemotherapy and radiotherapy can produce a partial remission, which is invariably short-lived, and the prognosis is very poor with a median survival of 14 months reported. Survival may be better in patients less than 40 years old and high TdT expression. Myeloid leukaemia protocols may be appropriate [12].

Extranodal NK/T-cell lymphoma (nasal type)

Definition. This rare type of extranodal EBV-positive angiocentric lymphoma preferentially involves the nasal cavity and nasopharynx but also shows a predilection for the skin and used to be referred to as polymorphic reticuloses or angiocentric immunoproliferative lesion [1–4]. The disease is more prevalent in Asia and Central and South America. Most cases are derived from NK cells but rare cases have a cytotoxic T-cell phenotype.

Clinical features. Involvement of the nasal cavity, nasopharynx, paranasal sinuses, orbit and oropharynx is associated with tissue destruction ('lethal midline granuloma'). Secondary involvement of other extranodal sites including the skin and gastrointestinal tract occurs but primary cutaneous disease is rare. Cutaneous plaques, nodules and tumours may ulcerate and become necrotic. Purpura, bullous lesions, cellulitis and diffuse maculopapular rashes have been described [5–9]. A haemophagocytic syndrome can develop rarely and systemic symptoms are common. Bone marrow and peripheral blood involvement is rare but such cases can be indistinguishable from aggressive NK-cell leukaemia.

Pathology. There is a diffuse infiltrate in the dermis and often the subcutis with prominent angiocentricity and angiodestruction [1–4,6]. Extensive necrosis is common. Tumour cells can show a variable morphology with small/medium and large pleomorphic/anaplastic cells. An associated heavy mixed inflammatory infiltrate is common and pseudoepitheliomatous hyperplasia may be found, which can lead to diagnostic confusion.

Immunophenotype. Tumour cells are CD56$^+$, CD2$^+$, surface CD3$^-$ and cytoplasmic CD3ε$^+$. Most cases express cytotoxic proteins, namely granzyme B, perforin and TIA-I [1–4,6]. Rare cases are CD30$^+$ and this may confer a more favourable prognosis [6]. TCR genes are in a germline configuration consistent with an NK-cell origin. However, rare cases of extranodal NK/T-cell lymphomas have a CD56$^-$, CD3ε$^+$ cytotoxic phenotype and show a clonal TCR gene rearrangement consistent with derivation from a cytotoxic T cell [4,7,10,11].

Pathogenesis. EBV is present in almost all cases of extranodal NK/T-cell lymphoma, whether CD56$^+$ or CD56$^-$ [3]. EBV is present in a clonal episomal form, suggesting that the virus has a critical pathogenetic role. No disease-specific cytogenetic abnormality has been identified but deletions of 6q and isochromosome 6q are common and genomic abnormalities are distinct to those found in NK-cell leukaemias [12,13].

Reports have implicated EBV-infected cytotoxic T cells in the pathogenesis of both the photosensitive disorder hydroa vacciniforme and hypersensitivity to mosquito bites in patients from Asia and South America [14]. Furthermore, there is now substantial evidence that such patients are at risk of developing extranodal NK/T-cell lymphomas with a fatal outcome [15–18]. This suggests that in genetically susceptible individuals an EBV-driven NK/T-cell lymphoproliferative inflammatory disorder has the potential to transform into an aggressive EBV-associated NK/T-cell lymphoproliferative disorder [14].

Treatment. The prognosis is poor despite aggressive chemotherapy, particularly for those patients with disease outside the nasal cavity [4]. The multidrug resistance phenotype is often expressed in cutaneous cases and the median survival for patients presenting with cutaneous disease is 12–15 months although the prognosis may be better for those patients with only cutaneous involvement (27 months) [6–9].

Primary cutaneous B-cell lymphomas

Primary cutaneous B-cell lymphomas constitute approximately one-quarter of all primary cutaneous lymphomas [1]. Increasing recognition of this group of primary cutaneous lymphomas led to controversy following the first publication of the EORTC classification of primary cutaneous lymphomas which included a subgroup of diffuse large B-cell lymphomas situated almost exclusively on the leg [2]. In addition, the description of a low-grade primary cutaneous lymphoma derived from follicle centre cells, which was distinct from both nodal follicular lymphoma and primary cutaneous diffuse large B-cell lymphoma, also caused controversy although this entity was recognized in the early WHO classification [3]. However, there is now a consensus classification of cutaneous B-cell lymphomas, illustrated by the recent WHO–EORTC classification which defines three specific subtypes of primary cutaneous B-cell lymphoma: marginal zone (MZL), follicle centre cell (FCL) and diffuse large B-cell (LBCL) lymphomas [4]. Full staging investigations are essential for patients with a cutaneous B-cell lymphoma to exclude secondary cutaneous involvement with a nodal lymphoma. Most primary cutaneous B-cell lymphomas are indolent with an excellent long-term prognosis, with the exception of PCLBCL [4,5]. An ISCL–EORTC TNM classification has been proposed for staging primary cutaneous lymphomas other than MF and SS (Table 57.8) [6]. This staging classification has shown prognostic relevance for PCLBCL as multifocal disease appears to be a poor prognostic feature but the value of staging the skin tumour burden in PCMZL and PCFCL has not yet been shown to have an impact on prognosis [7,8]. Recent ISCL–EORTC

Table 57.8 Proposed staging classification of non-mycosis fungoides/Sézary syndrome primary cutaneous lymphomas.

T	
T_1	Solitary skin involvement
T_{1a}	a solitary lesion <5 cm diameter
T_{1b}	a solitary lesion >5 cm diameter
T_2	Regional skin involvement; multiple lesions limited to 1 body region or 2 contiguous body regions
T_{2a}	all-disease-encompassing in a <15-cm diameter circular area
T_{2b}	all-disease-encompassing in a >15- and <30-cm diameter circular area
T_{2c}	all-disease-encompassing in a >30-cm diameter circular area
T_3	Generalized skin involvement
T_{3a}	multiple lesions involving 2 non-contiguous body regions
T_{3b}	multiple lesions involving ≥3 body regions
N	
N_0	No clinical or pathological lymph node involvement
N_1	Involvement of 1 peripheral lymph node region that drains an area of current or prior skin involvement
N_2	Involvement of 2 or more peripheral lymph node regions or involvement of any lymph node region that does not drain an area of current or prior skin involvement
N_3	Involvement of central lymph nodes
M	
M_0	No evidence of extracutaneous non-lymph node disease
M_1	Extracutaneous non-lymph node disease present

Table 57.9 Summary of cytogenetic findings in primary cutaneous B-cell lymphomas.

Cytogenetic abnormality	PCMZL	PCFCL	PCLBCL
t(14;18) IgH : MALT1	22% (21/95)	0% (0/6)	0% (0/14)
t(14;18) IgH : BCL2	11% (9/80)	17% (24/143)	7% (4/54)

PCMZL, primary cutaneous marginal zone lymphoma; PCFCL, primary cutaneous follicle centre cell lymphoma; PCLBCL, primary cutaneous diffuse large B-cell lymphoma; ND, not determined.

consensus recommendations for the management of primary cutaneous B-cell lymphomas have been published and conservative management is appropriate for PCMZL and PCFCL, although more aggressive therapy may be required for PCLBCL [9]. Distinction between cutaneous B-cell pseudolymphomas and marginal zone lymphomas can be particularly difficult. Systemic B-cell non-Hodgkin's lymphomas such as small cell lymphocytic lymphoma and mantle cell lymphomas are only found within skin as secondary cutaneous involvement associated with underlying nodal disease [10–11], although very rarely mantle cell lymphomas can be restricted to skin [12].

The pathogenetic relationship between these primary cutaneous B-cell lymphomas and their nodal counterparts remains unclear (Table 57.9). Specific translocations characteristic of marginal mucosa associated lymphoid tissue (MALT) lymphomas of nodal and extranodal origin have been detected in a minority of primary cutaneous marginal zone lymphomas. Genomic abnormalities detected in nodal diffuse large B-cell lymphomas have been identified in a primary cutaneous large B-cell lymphoma, suggesting a similar pathogenesis [4]. However, primary cutaneous follicle centre cell lymphomas appear to be distinct pathogenetically from nodal follicular lymphomas [4].

In 1982, Burgdorf *et al*. suggested that Lyme disease was caused by the tick *Ixodes ricinus*, and subsequently the spirochete *Borrelia burgdorferi* was recognized as being the vehicle responsible for carrying infection from the tick to human [13]. Prior to the publication by Burgdorf *et al.*, it had been recognized that patients with acrodermatitis chronica atrophicans, now known to be part of the cutaneous spectrum of Lyme disease, could develop low-grade cutaneous B-cell lymphomas [14–16]. These patients developed multiple plaques and nodules superimposed on lesions of acrodermatitis chronica atrophicans. In a small number of reported cases, the lesions of acrodermatitis chronica atrophicans cleared with antibiotic therapy, but the B-cell lymphoma nodules often persisted [17]. Nevertheless, this suggested the possibility that *Borrelia* might have a role in the pathogenesis of PCMZL [18]. For those patients without clinical evidence of acrodermatitis the causal relationship has been more controversial, with some studies detecting positive *Borrelia* serology and the presence of *Borrelia* in tumour DNA using PCR [19,20] and others consistently reporting negative results [21–23]. Nevertheless this suggests that chronic antigenic stimulation in skin, such as the presence of *Borrelia burgdorferi* infection, may rarely encourage emergence of a neoplastic B-cell clone from a previously benign reactive proliferation of B lymphocytes.

Marginal zone lymphoma

Definition. An indolent cutaneous B-cell lymphoma derived from post-germinal centre cells and characterized by a proliferation of small lymphocytes, marginal zone B-cells (small centrocyte-like), lymphoplasmacytoid cells and plasma cells with monotypic cytoplasmic immunoglobulin [1–3]. Primary cutaneous marginal zone lymphoma (PCMZL) is considered part of the spectrum of extranodal marginal zone B-cell lymphomas which often involve mucosal sites (MALT lymphomas).

This category also includes primary cutaneous immunocytoma [4] and rare primary cutaneous plasmacytoma without overt evidence of underlying myeloma or localized bony or other extramedullary involvement [5,6]. Extraosseous lesions in multiple myeloma are common, and the skin is infiltrated in approximately 10% of cases [7] but primary involvement of the skin without evidence of bone involvement is extremely rare.

Clinical features. These lymphomas present as asymptomatic solitary or multiple dermal papules, plaques or nodules on any body site, although the trunk is most often involved (Fig. 57.34) [1–4]. Spontaneous resolution can occur. Full staging investigations are indicated and a benign monoclonal paraproteinaemia may be present. In cases of plasmacytoma skeletal surveys are required to exclude underlying myeloma. There is a slight male predominance. Anetoderma associated with individual lesions has been described [8]. The estimated 5-year survival is 98–100% [3,4,9].

Fig. 57.34 Marginal zone primary cutaneous B-cell lymphoma: typical urticated dermal erythematous papules and plaques predominantly situated on the trunk.

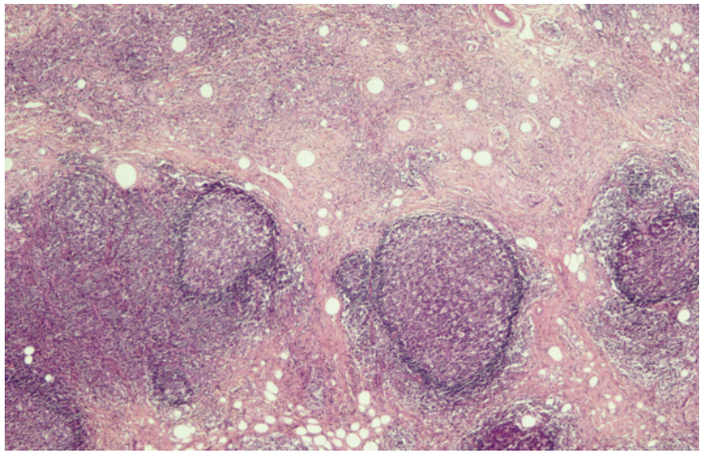

Fig. 57.35 Marginal zone primary cutaneous B-cell lymphoma: reactive germinal centres with a non-epidermotropic monomorphic infiltrate of lymphoplasmacytoid cells and mature plasma cells.

Pathology. Histology is characterized by nodular or diffuse dermal infiltrates of small- to medium-sized lymphocytes, marginal B-cells (centrocyte-like), lymphoplasmacytoid cells and plasma cells, often with a reactive T-cell infiltrate [1–4]. There is no epidermotropism. Reactive follicular structures are often present and tumour cells present within expanded marginal zones and interfollicular areas may colonize these follicular structures (Fig. 57.35). This pattern has to be distinguished immunophenotypically from rare follicular patterns of PCFCL [10,11]. Occasional scattered centrocytes, centroblasts and immunoblasts may be

present. Tumour cells, characterized by monotypic κ or λ positive larger paler lymphoplasmacytoid cells, are concentrated at the periphery of the cellular aggregates or residual follicular structures. PAS-positive intranuclear or intracytoplasmic inclusions may be present [1–3]. Cases with a monomorphic infiltrate of plasma cells (immunocytoma-like) are included [4]. Rare cases of cutaneous plasmacytoma have to be distinguished from benign reactive plasma cell infiltrates (plasmacytosis) by identifying monotypic light chain expression.

Immunophenotype. Tumour cells express CD20, CD79a and Bcl-2, but are Bcl-6, CD5 and CD10 negative [3,12]. PCMZL of the skin should be distinguished from cutaneous infiltrates chronic B-lymphocytic leukaemia, which are $CD5^+$. Plasma cells are $CD138^+$ and $CD79a^+$ (but $CD19^-$ and $CD20^-$) and the infiltrate usually shows either κ or λ light chain restriction (although this can often be difficult to detect in cutaneous sections because of non-specific staining of collagen). Reactive follicles are $Bcl\text{-}6^+$ and $CD10^+$ positive but $Bcl\text{-}2^-$.

Clonal immunoglobulin gene rearrangements are detected in most cases [13]. False-negative results may occur because of somatic hypermutation, which interferes with primer annealing in the analysis of immunoglobulin genes as for follicle centre cell lymphomas although this is less common with the current standardized Biomed primers [14]. The demonstration of light chain restriction and/or a clonal immunoglobulin gene rearrangement represents a critical technique for distinguishing these low-grade cutaneous lymphomas from reactive cutaneous B-cell infiltrates (pseudolymphomas).

Pathogenesis. PCMZL is considered to be part of the spectrum of extranodal marginal zone B-cell lymphomas which were first described in the stomach, the so-called MALT lymphoma, and have since been described in the thyroid, salivary gland, orbit and lung as well as the skin.

As would be expected, PCMZL shows a plasma cell signature in a subset of cases [15]. No disease-specific cytogenetic abnormalities have been identified in PCMZL, although CGH techniques have shown amplification of the *BCL2* locus on chromosome 18 [16]. Fas mutations have rarely been described [17]. Studies (Table 57.9) have also clearly demonstrated that approximately 50% of PCMZL have identical translocations to those found in other extranodal MALT lymphomas, including the t(14;18) involving the *IgH* gene locus and the *MALT-1* gene, which is mostly found in monocytoid variants [18–20]. Trisomy 3 and 18 have also been detected in up to 40% of cases [20,21]. The t(11;18) which produces a fusion protein involving the *AP12* gene and the *MALT-1* gene has also been detected in PCMZL [21,22], although other studies have failed to detect this translocation [17,20,23]. Other translocations found in extranodal marginal zone B-cell lymphomas, such as the t(1;14) involving the *Bcl-10* gene on 1q, have not yet been identified in PCMZL [17,20,21,23]. The t(14;18) involving *Bcl2* has also not been consistently detected in PCMZL [20,24] except in isolated reports [18,25].

Development of immunocytomas has been reported in patients with acrodermatitis chronica atrophicans and has led to speculation about the role of *Borrelia burgdorferi* producing chronic antigen stimulation, leading to neoplastic transformation. The detection of *Borrelia* DNA in some cutaneous lesions of PCMZL, using polymerase chain reaction (PCR), has provided support for this role, but the frequency of positivity varies considerably in different geographical regions, with positive results in central Europe and Scotland [26,27] but no evidence of an association in the USA [28,29]. To date, most cases of PCMZL associated with *Borrelia* have been κ-chain positive.

Treatment. Radiotherapy (low dose) is appropriate and some patients may be managed simply by observation in view of the excellent long-term prognosis [30–32]. Surgical excision may be used for isolated small lesions. The role of IFN-α has not been established but it may be effective either systemically or intralesionally [32]. In cases associated with *Borrelia burgdorferi* relevant antibiotic therapy is appropriate [33]. In patients with multifocal disease chlorambucil may be appropriate [31,32]. Cutaneous recurrences are common and can be treated in a similar manner.

Follicle centre cell lymphoma

Synonym
- Crosti's lymphoma

Definition. An indolent primary cutaneous B-cell lymphoma derived from follicle centre cells (PCFCL) and consisting of a mixture of centrocytes (small/large cleaved cells) and centroblasts (larger non-cleaved cells).

Clinical features. Patients present with clinically non-specific solitary or grouped papules, nodules or tumours, most commonly on the head and neck or trunk [1–3], although any body site may be involved (Figs 57.36–57.38). A gradual increase in size of pre-existing lesions and the appearance of new nodules over a period of years is likely without treatment [1–3]. Rarely, multifocal lesions may occur. Staging investigations including CT scans of the chest, abdomen and pelvis, and bone marrow aspirate and trephine

Fig. 57.36 Primary cutaneous follicle centre cell lymphoma. Extensive erythematous plaque and nodular lesions on the lower back.

Fig. 57.37 Typical clinical presentation of primary cutaneous follicle centre cell lymphoma on the scalp.

Fig. 57.38 Primary cutaneous follicle centre cell lymphoma. Cutaneous presentation of a systemic follicular t(14;18) lymphoma on the trunk with subtle dermal papules and plaques.

biopsies are negative at the time of diagnosis. The estimated 5-year survival of PCFCL is 94–97% [3,4].

Pathology. The histology of PCFCL is variable but the infiltrate shows no epidermotropism and there is a clear grenz zone in the papillary dermis. In the reticular dermis and subcutaneous fat, there is a 'bottom-heavy' nodular or diffuse infiltrate composed of a mixture of centrocytes (small/large cleaved cells), centroblasts (large non-cleaved cells with prominent nucleoli) and a prominent infiltrate of reactive T cells with the remnants of poorly formed germinal centres [1–3]. Some tumour cells show a 'strap-like' or 'fibroblast-like' morphology. The growth pattern may be follicular, follicular and diffuse, or diffuse. Individual patients may show different histological patterns in biopsies from the same group of lesions. PCFCL has to be distinguished from marginal zone lymphomas with follicular colonization of reactive germinal centres. Prominent larger tumours tend to show a more diffuse infiltrate of larger centrocytes, centroblasts and occasional immunoblasts with fewer reactive T cells and no evidence of follicular structures. Such lymphomas should be distinguished from PCLBCL although the presence of a monotonous infiltrate of centroblasts and immunoblasts should be classified as a PCLBCL [3]. A subset of PCFCL shows neoplastic follicular structures with an expansile growth pattern, a thin poorly formed mantle zone and an absence of tingible body (starry sky) macrophages similar to nodal follicular lymphoma although the phenotypic and molecular features are distinct [5].

Immunophenotype. The tumour cells express B-cell associated markers such as CD19, CD20, CD22 and CD79a but are $CD5^-$ [3,6]. CD10 and monotypic cytoplasmic and/or surface immunoglobulin are variably expressed by the neoplastic cells [7]. Follicular structures can be more clearly defined by identifying networks of $CD21^+$ and $CD23^+$ follicular dendritic cells. The tumour cells are mostly Bcl-2 negative, in contrast to systemic nodal follicular lymphoma and diffuse large B-cell lymphoma (DLBCL) in which a significant proportion of the tumour cells are $CD10^+$ and Bcl-2 positive [8]. In those cases with a follicular growth pattern CD10 may be expressed and Bcl-2 may be weakly positive. In contrast, Bcl-6 is usually expressed by PCFCL tumour cells indicative of somatic mutation, as also seen in nodal follicular lymphoma and DLBCL [4]. *MUM-1* and *FOXP1* are usually negative but may be rarely expressed [9,10]. Clonal immunoglobulin gene rearrangements are present in most cases. However false-negative cases are common, caused by somatic hypermutation affecting the primer binding for PCR immunoglobulin gene analysis [11]. Extensive somatic mutation of variable region genes has been identified, which is also consistent with an origin from germinal centre cells [12,13].

Pathogenesis. The relationship between PCFCL and nodal systemic follicular and diffuse large B-cell lymphomas remains unclear. While there are morphological similarities, PCFCL follows an indolent clinical course and the immunophenotypic features (CD10 expression is mostly confined to PCFCL with an exclusively follicular growth pattern and Bcl-2 is usually negative or rarely only weakly positive) are distinct. Microdissection of tumour cells has also confirmed the germinal centre cell origin of PCFCL $Bcl\text{-}2^-$ tumour cells, with no evidence of the t(14;18) translocation, also suggesting a different pathogenesis to nodal follicular lymphoma [13]. Gene expression studies have detected a germinal centre B-cell signature in PCFCL [14] distinct from the activated B-cell signature detected in primary cutaneous DLBCL [15]. While the t(14;18), characteristic of nodal systemic follicular lymphoma and a significant proportion of DLBCLs, has not been consistently detected in most studies of PCFCL [8,16–18], other studies especially from the USA have detected the t(14;18) in a proportion of $CD10^+$ and Bcl-2 positive PCFCL with a follicular growth pattern [19,20], suggesting that there might be some unexplained geographical or histological subset distinction although there are no obvious prognostic differences. A study using a FISH based technique has detected the t(14;18) translocation involving *Bcl-2* in 41% of 27 cases in which a PCR based technique had failed to identify any *Bcl-2* rearrangement [21]. However, this study restricted the cases of PCFCL to those with a follicular growth pattern only.

CGH studies have also identified patterns of chromosomal gains and losses associated with specific oncogene abnormalities in PCFCL including *c-REL* amplification but a consistent pattern has not yet emerged [22,23]. FISH studies (Table 57.9) have not identified chromosomal breakpoints involving the IgH, *myc* or *bcl-6* loci [24] although one study did show a t(3;14) in two of 27 cases involving *Bcl6* and IgH in PCFCL (21). Inactivation of both the cyclin-dependent kinase inhibitors, namely the *p15* and *p16* genes, by promoter hypermethylation has been detected in a proportion of cases but the clinical significance is unclear [25]. A recent study has identified aberrant somatic hypermutation affecting certain oncogenes in PCFCL including *BCL6*, *PAX5*, *MYC* and *RhoH/TTF* similar to findings in nodal and primary cutaneous LBCL [26].

At present, a detailed characterization of the molecular abnormalities in PCFCL is required to clarify the pathogenetic relationship between PCFCL and systemic nodal follicular and diffuse large B-cell lymphomas.

Treatment. Superficial radiotherapy is the treatment of choice for solitary, recurrent and multifocal cutaneous disease, except in rare cases with very extensive cutaneous disease or systemic involvement when single-agent treatment with chlorambucil or combination chemotherapy may be indicated [27–31]. Solitary lesions may be excised, although subsequent radiotherapy is probably advisable to reduce the risk of local recurrence [28]. Recurrences occur in approximately 30% of cases, are usually confined to the skin and do not signify a worse prognosis [30]. Therefore treatment options remain similar.

Diffuse large B-cell lymphoma

Definition. Primary cutaneous diffuse large B-cell lymphoma (PCLBCL) is a rare primary cutaneous lymphoma characterized by a diffuse proliferation of large B cells consisting of centroblasts and immunoblasts occurring most commonly on the leg [1]. PCLBCL is closely related to systemic nodal diffuse large B-cell lymphomas, which is the most common form of non-Hodgkin's lymphoma.

Clinical features. PCLBCL affects an elderly population with a female predominance. These lymphomas tend to develop on the lower limbs, predominantly as large dermal nodules or tumours, which are either solitary or multifocal and rapidly enlarging (Fig. 57.39) [1]. PCLBCL can also rarely occur at other cutaneous sites (PCLBCL/other) [2]. Full staging investigations are critical to exclude systemic involvement. The prognosis of PCLBCL is poor, with a 5-year survival of 41–58% [1–4].

Pathology. There is a diffuse non-epidermotropic infiltrate of large cells with morphological similarity to centroblasts and immunoblasts which may extend to involve the subcutis (Fig. 57.40). The infiltrate is monotonous with relatively few associated inflammatory cells or reactive T-cells present. Germinal centres

Fig. 57.39 Clinical presentation of primary cutaneous large B-cell lymphoma on the legs.

are not apparent and mitoses are prominent. Morphological variants recognized in cutaneous disease include cleaved and round cell types but the reproducibility of this distinction is poor [3]. Initially it was reported that the presence of round cell morphology was an adverse prognostic feature. However, this may be explained by subsequent recognition that the cleaved cell type, showing a predominance of large centrocytes and multilobated cells, with few exceptions represents diffuse PCFCL (Crosti's lymphoma) [2].

Immunophenotype. The tumour cells are $CD19^+$, $CD20^+$, $CD22^+$ and $CD79a^+$ with monotypic expression of surface and/or cytoplasmic immunoglobulin in some cases [2,5]. Tumour cells are usually strongly Bcl-2 positive [5,6] and Bcl-6 is also expressed by most cases with evidence of *Bcl-6* gene mutations [5,7]. CD10 expression is only rarely detected in PCLBCL [5]. *MUM-1* and *FOX-P1* are invariably expressed by tumour cells in PCLBCL in contrast to PCFCL [8].

Pathogenesis. Although PCLBCL by definition arises *de novo* in the skin, some tumours might result from high-grade transformation of a low-grade primary cutaneous B-cell lymphoma such as PCFCL [9]. At present, it is unclear whether PCLBCL has the same pathogenesis as primary nodal DLBCL. When PCLBCL presents at sites other than the leg, it is important to distinguish this from diffuse forms of PCFCL, because PCFCL has an excellent prognosis [9].

Clonal rearrangements of immunoglobulin genes are present in most cases with false-negative results resulting from somatic hypermutation [10]. No disease-specific cytogenetic abnormalities have been identified. The t(14;18) translocation has not been identified in Bcl-2 positive cutaneous cases [11–14], except in rare cases from one series [15], The t(14;18) is a common feature of nodal DLBCL reflecting a likely transformation from nodal follicular lymphoma and is found in nodal DLBCL with secondary cutaneous involvement [12]. Unlike PCFCL and PCMZL, 6q losses and 2p, 12 and 18q gains are characteristic findings in PCLBCL and chromosomal amplification of the *bcl2* gene may account for bcl-2 overexpression in PCLBCL [15–17]. In addition, inactivation of *p15* and *p16* genes by promotor hypermethylation and deletion of the 9p21.3 locus containing the *p14/16* genes has been detected [17,18] and CGH studies have identified specific oncogene abnormalities including *c-REL* and *MALT1* gene amplification [16,17]. Recent studies suggest that *p16* loss may have prognostic significance [19]. Studies (Table 57.9) have also shown rare translocations involving *myc* and IgH in PCLBCL in contrast to PCFCL [14,15]. *BCL6* rearrangements have not been detected in PCLBCL [15] but mutations of the *BCL6* gene have been detected [7] and this provides an alternative explanation for over-expression of Bcl-6.

Recent studies in nodal DLBCL using microarray technology have confirmed that these tumours are heterogeneous in origin with the detection of three distinct gene expression profiles which also have prognostic significance: one characteristic of germinal centre cells; one with an expression profile consistent with activated peripheral blood B cells; and one with an indeterminate profile [20,21]. Studies have shown that PCLBCL has an origin from activated B-cells compared to PCFCL which show a germinal centre B-cell gene expression profile [22].

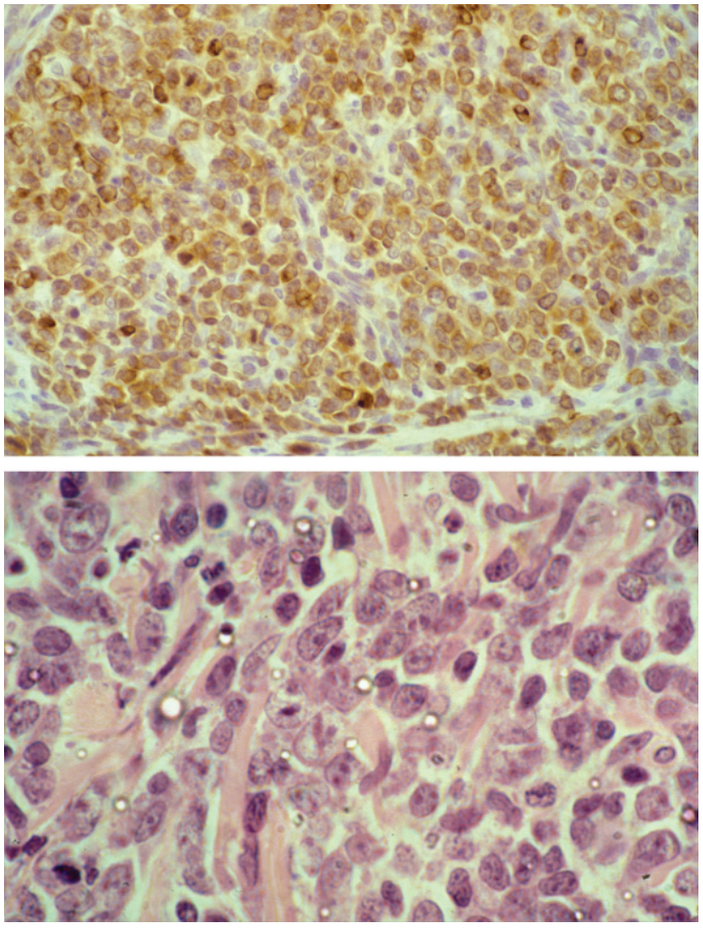

Fig. 57.40 Primary cutaneous large B-cell lymphoma showing a diffuse pattern of large mononuclear cells and strong Bcl-2 positivity.

Prognosis. The prognosis for PCLBCL is poor, with a 41–58% 5-year survival, but this is generally better than for nodal DLBCL [1–4]. Although studies initially suggested that *Bcl-2* expression was site-related (lower limbs and multifocal lesions are more frequently Bcl-2 positive) and associated with a worse prognosis [3], the prognostic significance of *Bcl-2* expression has since been disputed [23]. Recent studies have shown that multifocal disease and location on the leg, are associated with a worse prognosis in multivariate analysis [2,4,8].

Treatment. In elderly patients with solitary tumours, radiotherapy may be appropriate but multiagent chemotherapy is usually required, especially for multifocal disease [24,25,26]. The role of rituximab (a chimeric mouse/human anti-CD20 antibody which induces antibody-dependent cytotoxicity) as a single agent in cutaneous disease has yet to be determined [27,28], but CHOP chemotherapy (R-CHOP) is now the standard of care in nodal DLBCL and an appropriate consideration for patients with PCLBCL. Intralesional rituximab may prove to be effective for selected patients in whom radiotherapy or R-CHOP is not possible [29].

Secondary cutaneous B-cell lymphomas

Intravascular large B-cell lymphoma [1–11]

Synonyms
- Malignant angioendotheliomatosis
- Angiotrophic lymphoma

Definition. A rare extranodal B-cell lymphoma characterized by accumulation of large B cells within small blood vessels. This tumour usually involves multiple extranodal sites including the CNS, lung and skin, and symptoms and/or signs at these sites may be the presenting feature.

Clinical features. Patients present with diffuse, tender, hard, infiltrated plaques, commonly on the thigh (Fig. 57.41); the clinical appearance may suggest a sclerotic connective tissue disorder or panniculitis. A variety of clinical features may occur as a consequence of occlusion of small vessels including telangiectatic skin lesions. Colonization of benign haemangiomas by tumour cells has been reported. The prognosis is poor, although rare cases with disease confined to the skin may have a better outlook with a 3-year survival of 56% versus 22% if spread beyond the skin.

Pathology. The tumour cells are large and show striking atypia with an occasional anaplastic morphology. These cells are situated entirely within dilated vessel lumina in the dermis and subcutis (Fig. 57.42). Occlusion of vessels by tumour cells and fibrin thrombi may be present.

Immunophenotype. The tumour cells are positive for B-cell-associated antigens consistent with origin from a peripheral post-germinal centre B cell. Clonal immunoglobulin gene rearrangements are present. Rare cases are derived from T cells and show a clonal TCR gene rearrangement. Rarely, factor VIII, an endothelial cell-related antigen, may be positive but this is thought to be caused by absorption of antigen by tumour cells rather than indicating an endothelial cell origin.

Treatment. There are some reports of partial response to combination chemotherapy, but the disease has a poor prognosis and is usually fatal.

Lymphomatoid granulomatosis

Definition. An angiocentric and angiodestructive extranodal EBV-positive B-cell lymphoma, which invariably involves the lungs and may involve the skin and CNS [1–3].

Clinical features. Patients most frequently present with pulmonary symptoms associated with systemic malaise, arthralgias, weight loss and fever. The skin (50% of cases), CNS and kidneys are also often directly involved. The cutaneous lesions described are diverse but include subcutaneous nodules and plaques, more superficial plaques and a diffuse erythematous maculopapular eruption (Fig. 57.43) with epidermal atrophy and purpura [4–10]. Necrosis and ulceration may also occur [4]. Some patients have a fluctuating course with spontaneous remissions but eventually progressive disease develops.

Pathology. The striking feature is the angiocentricity of the infiltrate and gross vessel destruction sometimes accompanied by fibrinoid necrosis (angiodestruction) [7]. The infiltrate is polymorphous and contains both lymphocytes and histiocytes with pleomorphic or large (immunoblast-like) tumour cells and often a prominent reactive T-cell infiltrate. Multinucleated cells may be present although well-formed granulomas are rare. The presence of large transformed cells is associated with a worse prognosis.

Immunophenotype. The tumour cells are EBV$^+$, express CD20 and are variably CD79a$^+$. CD30 may be expressed but the cells are CD15$^-$. The reactive T cells are CD3$^+$ and CD4$^+$. Clonal immunoglobulin gene rearrangements can be detected in most cases and Southern blot analysis usually confirms the presence of clonal episomal EBV [8].

Pathogenesis. Lymphomatoid granulomatosis is an EBV-driven lymphoproliferative disorder that can be associated with immunodeficiency states including post-transplantation and long-term therapies such as methotrexate for rheumatoid arthritis [9,10]. This lymphoma should be distinguished from extranodal NK/T-cell lymphoma (nasal type), which is also EBV$^+$ and characterized by an angiodestructive histology [8].

Treatment. Although some patients have spontaneous remissions, the development of high-grade disease is associated with a median survival of less than 2 years. Short-lived remissions with high-dose chemotherapy have been described. There are reports of responses to cyclophosphamide and IFN-α, particularly for patients with low-grade disease [11].

Secondary cutaneous T-cell lymphomas

Angioimmunoblastic T-cell lymphoma

Synonym
- Angioimmunoblastic lymphadenopathy (AILD)

Definition. AILD is a nodal T-cell lymphoma derived from follicular helper T-cells and associated with a complex dysregulation of B-cells [1]. Extranodal involvement of sites, including skin, is well recognized [2].

Clinical features. Patients may present with systemic and/or peripheral lymphadenopathy often accompanied by 'B' symptoms [2]. Splenomegaly occurs in over 50% of cases and many patients will have advanced disease and bone marrow involvement at diagnosis [2]. Autoimmune phenomena are common, including neurological abnormalities, arthritis, hypergammaglobulinaemia, haemolytic anaemia and thrombocytopenic purpura [2]. Cutaneous extranodal involvement is common (45% of cases) and rarely can be a presenting feature [2]. Skin changes are highly variable and can be subtle, including maculopapular and papulonodular eruptions. Erythroderma, haemorrhagic and urticarial eruptions have been described as well as dermal plaques [3]. Occasionally, cutaneous involvement in AILD can mimic drug eruptions and infections [4,5].

Pathology. The nodal pathologic features in AILD are characterized by hyperplastic follicles and a prominent arborizing vascular proliferation with expanded follicular dendritic cells. There is an associated polymorphous infiltrate with clusters of large clear cells [1]. The infiltrate consists of $CD10^+$ T-cells and an expansion of EBV infected B-cells (EBER positive). Cutaneous involvement is characterized by variable features; a non-specific perivascular lymphocytic infiltrate with minimal atypia and capillary hyperplasia can be found in some biopsies or more prominent dermal perivascular infiltrates showing cytologically atypical pleomorphic cells and occasionally more obvious dense infiltrates of atypical lymphocytes are present [6]. Granulomatous infiltrates and vasculitis have been reported [6]. There is no epidermotropism. The atypical cells express T-cell antigens and are also $CD10^+$ [3].

Pathogenesis. Clonal rearrangements of TCR genes are detected in a majority of cases but additional monoclonal or oligoclonal IgH rearrangements are often found consistent with the characteristic EBV^+ B-cell proliferation seen in lymph nodes from AILD patients [1]. The recent finding of *CXCL13* expression by tumour cells in AILD has confirmed a derivation from follicular helper T cells [1]. Specific patterns of chromosomal abnormalities, including deletions of chromosome 7, have been reported but no disease-specific translocations [1].

Treatment. The disease can be indolent but transformation is associated with a poor prognosis. Immunomodulatory therapies have been used successfully including ciclosporin, steroids, thalidomide and angiogenesis inhibitors such as bevacizumab [1].

Post-transplant lymphoproliferative disorder (PTLD)

Definition. Lymphomas occurring in solid organ transplant recipients on immunosuppressive therapy. The incidence varies according to the organ transplanted (heart–lung : renal transplant rates of 10–1% respectively) and although extranodal lymphomas are overrepresented in PTLD, primary cutaneous involvement is very rare. Less than 20 cases have been reported of primary cutaneous B-cell PTLD and primary cutaneous T-cell PTLD is even less frequent [1–2].

Clinical features. The clinical features described are diverse; solitary or multiple plaques, nodules or tumours, with or without ulceration, have been described affecting any site. Systemic involvement and in particular involvement of the transplanted organ must be excluded in patients with primary cutaneous PTLD. Spontaneous resolution has been reported. For primary cutaneous T-cell PTLD, erythroderma is the most common clinical presentation but all types of CTCL have been described [3].

Pathology. Diffuse dermal infiltrates extending to the subcutis and consisting of large pleomorphic lymphocytes or centroblasts. Plasmacytoid differentiation and plasmablasts may be a feature. Necrosis may be present. For PC B-cell PTLD the tumour cells express B-cell antigens while PC T-cell PTLD may be $CD30^+$ but histological features mimicking all types of CTCL have been described [2,3].

Pathogenesis. B-cell PTLD is associated with EBV infection and progression from an early reactive phase can be identified. Three distinct types of PTLD are recognized: (i) plasmacytic hyperplasia is a polyclonal proliferation associated with multiple copies of EBV and occurring early after transplantation; (ii) polymorphic lymphoproliferative disorder usually occurring several years after transplantation is a monoclonal EBV proliferation with a single copy of EBV but without secondary genomic abnormalities; and (iii) malignant lymphoma is a monoclonal EBV infection with a single copy of EBV and associated secondary genomic abnormalities and widespread disease. Rare cases of PC B-cell PTLD have been associated with HHV-8 infection [4]. No viral association has been described for systemic or cutaneous T-cell PTLD although rare EBV^+ T-cell lymphomas have been reported. Primary cutaneous presentations can also occur in non-organ transplant recipients such as HIV^+ patients or those with other forms of profound immunodeficiency. Similarly EBV^+ lymphoproliferative disorders can develop in patients who have undergone high-dose chemotherapy for primary lymphomas although cutaneous involvement has not been reported as yet in this context.

Treatment. While surgery and radiotherapy can be used, reduction in immunosuppression is often effective [5]. Both chemotherapy and rituximab have been reported to be effective. While the prognosis for B-cell PTLD is generally good [6], both primary cutaneous and systemic T-cell PTLD have a very poor prognosis.

Pseudolymphomas

Definition. Benign but persistent lymphoid proliferations in the dermis, which may be difficult to distinguish from a low-grade malignant lymphoma and possibly may rarely transform to a lymphoma in some cases [1–3]. The term cutaneous lymphoid hyperplasia has been suggested and both terms are more commonly used to describe a pathological rather than a clinical appearance. Confusion between pseudolymphoma and lymphoma can easily arise if a biopsy is submitted to the pathologist without an adequate history of recent events such as drug ingestion or scabies infestation.

Aetiology. T-cell pseudolymphomas may arise as a form of adverse drug reaction. The range of drugs causing T-cell pseudolymphomas is wide but includes anticonvulsants, angiotensin-converting enzyme inhibitors, β-blockers, cytotoxics, antirheumatics, antibiotics, antidepressants and many others [4–8]. Persistent contact dermatitis may produce a T-cell pseudolymphoma [9]. Persistent nodular scabies and arthropod bites may also cause a T-cell pseudolymphomatous histology [10], possibly caused by retained foreign material stimulating a persistent antigenic reaction [11,12]. There are three reports in the literature of putative CTCL arising in association with silicone breast implants, which may be examples of this phenomenon [13]. Actinic reticuloid (see below) may resemble a cutaneous T-cell lymphoma histologically. Jessner's lymphocytic infiltrate (see below) can also be classified as a T-cell pseudolymphoma, although there is a view that it is a variant of cutaneous lupus erythematosus.

B-cell pseudolymphomas may arise in the course of Lyme disease with *Borrelia burgdorferi* infection [14], in tattoos as a reaction to certain pigments [15,16], after vaccination and trauma [17], acupuncture [18] and within scars after herpes zoster infection [19]. The classic entity of lymphocytoma cutis histologically resembles a B-cell pseudolymphoma, and is at present of unknown aetiology.

Fig. 57.44 Clinical appearance of a persistent photosensitive drug eruption induced by co-trimoxazole (Septrin).

It is generally wise to be guarded in the diagnosis and prognosis of pseudolymphoma, as in a number of cases clear progression from apparent pseudolymphoma to malignant lymphoma has been recorded. This appears to confirm the concept that chronic, initially benign, reactive inflammatory conditions may very rarely progress to frank lymphoma or that indeed these conditions may be low grade lymphomas initially which then transform and adopt a more obvious malignant cellular cytology/morphology.

Clinical features. Both T- and B-cell pseudolymphomas may present as multiple cutaneous nodules (Fig. 57.44) as in persistent nodular scabies or lymphocytoma cutis. T-cell pseudolymphomas may also present as persistent erythema sometimes developing into an exfoliative erythroderma [20]. This is characteristic of T-cell pseudolymphomas caused by drug reactions or contact dermatitis. B-cell pseudolymphomas may also be associated with palpable lymphadenopathy, adding to diagnostic confusion.

Pathology [21–26]. If the distinction between lymphoma and pseudolymphoma is to be made, it is vital to give the pathologist a good clinical history as the pathological, phenotypic and molecular differentiation is not absolute. The salient feature of a pseudolymphoma is the presence of T- or B-cell lymphoid proliferations. A few mitotic figures may be present, but the degree of cytologic atypia is minimal. T-cell pseudolymphomas may be band-like or nodular in distribution, whereas B-cell pseudolymphomas are

usually nodular. Germinal centre formation may or may not be present in B-cell pseudolymphomas but typically reactive germinal centres have tingible body macrophages. Rarely, the lymphoid cells may be very bizarre and resemble mitogen-stimulated lymphocytes seen *in vitro* during the lymphocyte-transformation test [27]. In general, T-cell pseudolymphomas do not show significant epidermotropism such as Pautrier's microabscesses.

Immunophenotypic studies show a normal T-cell phenotype and a mixed κ/λ expression. When germinal centres are present, Bcl-2 is not expressed in B-cell pseudolymphomas [28]. TCR and immunoglobulin gene analysis usually show evidence of a polyclonal proliferation, but rarely a monoclonal pattern has been detected, suggesting a neoplastic proliferation, but the significance of this finding is unclear at present [29–33].

Management. If the diagnosis of pseudolymphoma is considered likely, the presumed cause should be removed if possible. This is probably easiest in the case of an adverse drug reaction, but it may take weeks or even months for the cutaneous reaction to subside. In the cases of persistent nodular scabies or other pseudolymphomas that cause symptomatic itch, application of topical steroids will accelerate clearance.

Pityriasis lichenoides [1–8]

Synonym
- Mucha–Habermann disease

Definition. This disorder or group of disorders is difficult to classify. Clinically, pityriasis lichenoides is divided into two main conditions: pityriasis lichenoides chronica (PLC) and pityriasis lichenoides et varioliformis acuta (PLEVA; Mucha–Habermann disease). A third, much rarer and aggressive form, febrile ulceronecrotic Mucha–Habermann disease (FUMHD) also occurs [2,5–7]. Despite their names, the distinction between PLC and PLEVA is based on clinical morphology and histology (see below) rather than the course of the disease [6], as both conditions last for an average of about 18 months with an episodic course.

PLC is the most common type, occurring largely in children and young adults, with a male predominance [9], although a recent large study suggested that PLEVA is the most common pattern in younger children (57% compared with 37% PLC and 6% mixed pattern) [8]. In contrast, in adults there is an approximately equal sex incidence [6,9]. All types are rare in infancy and old age, but PLEVA has been reported at birth [10]. Some patients may have simultaneous lesions of both PLC and PLEVA types, or may have transitional lesions; FUMHD usually occurs in isolation but can evolve from PLC or PLEVA [7]. There is a strong male predominance in FUMHD (about 75%), and most cases occur in the second or third decade of life [6].

Clinical features [1–10]. The skin eruption is usually the first manifestation of the disease, and generally the only manifestation in PLC, but constitutional symptoms such as fever, headache, malaise and arthralgia may precede and/or accompany the onset of PLEVA.

PLEVA. The eruption develops in crops, and consequently appears polymorphic. The initial lesion is an oedematous pink papule that undergoes central vesiculation and haemorrhagic necrosis, which may be intense. In the vesicular forms [4], the vesicles may be small or so large that the eruption appears frankly bullous. The rate of progression of individual lesions varies greatly, as does the frequency and extent. New lesions may cause irritation or a burning sensation as they appear, but often they are asymptomatic. The trunk, thighs and upper arms, especially the flexor aspects, are chiefly affected, but the eruption may be generalized. Lesions of the palms and soles are less common, and the face and scalp are often spared; erythematous or necrotic lesions of mucous membranes may be present. Lesions heal with scarring, which may be varioliform. PLEVA in pregnancy carries a potential risk of premature labour if there are mucosal lesions in the region of the cervical os [7].

FUMHD. In the acute ulceronecrotic form there is high fever and large necrotic lesions; new crops may continue to develop over many months. About 50–75% of cases occur in adults, with a fulminating course that may even be fatal [2,8–10]. General malaise, weakness, myalgia, neuropsychiatric symptoms and lymphadenopathy occur, with non-specific serological markers of inflammation such as raised ESR and C-reactive protein; there may be serological evidence of associated viral infection.

PLC. The characteristic lesion is a small, firm lichenoid papule 3–10 mm in diameter, and reddish brown in colour. An adherent 'mica-like' scale can be detached by gentle scraping to reveal a shining brown surface—a distinctive diagnostic feature. Over the course of 3 or 4 weeks the papule flattens and the scale separates spontaneously to leave a pigmented macule which gradually fades. Post-inflammatory hypopigmentation may occur, and is occasionally persistent, but scarring is unusual in PLC. The body site distribution is the same as for PLEVA but an isolated acral form may occur [11,12]; segmental forms have been reported.

The course of pityriasis lichenoides varies. If the onset is acute, new crops may cease to develop after a few weeks, and many cases are clear within 6 months. However, acute recurrences may occur over a period of years, or chronicity may supervene. In some cases, all lesions are of the chronic scaling type from the onset, and new crops of similar lesions may develop from time to time over the years. Uncommonly, acute attacks occur after chronic lesions have been present for months or years. In general, the immediate prognosis is said to be better when the onset is acute and the lesions in successive crops are also of the acute type, but one large study of 124 children showed only a small difference in clearance times between PLEVA (mean 18 months) and PLC (mean 20 months) [13]. A smaller study comparing adults and children found that the disease tended to run a longer course in children, with greater extent of lesions, more pigmentation, and poor response to conventional treatments [14].

Differential diagnosis. The acute vesicular form must be distinguished from varicella; acute necrotic lesions may suggest other necrotic skin infections, vasculitis or pyoderma gangrenosum. Lymphomatoid papulosis is a particularly difficult differential diagnosis in patients with necrotic lesions in view of its histological similarity, discussed above, although lymphomatoid papulosis is usually characterized by less vesicular and more necrotic papulonodular lesions than those of PLEVA.

PLC must be differentiated from guttate psoriasis and lichen planus. The acral form of PLC in particular may mimic psoriasis, and secondary syphilis needs to be excluded especially if the palms and soles are involved or if there are mucosal lesions. The single, detachable 'mica-like' scale on the red-brown papule is a characteristic sign of PLC. Gianotti–Crosti syndrome is less likely to be confused with pityriasis lichenoides, but insect bites and drug eruptions should be included in the differential diagnosis.

Aetiology and pathogenesis. Pityriasis lichenoides has been reported mainly from Europe and America, but there is no specific geographical variation in incidence. The aetiology is unknown. Nosologically, pityriasis lichenoides has been considered to be a variant of parapsoriasis and to show overlap with lymphomatoid papulosis [1,2]. Evidence of T-cell clonality has also been detected in most cases of PLEVA and some cases of isolated PLC without MF [4–6], and in FUMHD [7]. PLEVA has also been reported with an associated lymphoma [8]. PLC-like lesions have also been described in patients with typical features of mycosis fungoides and identical T-cell clones have been identified in both types of cutaneous lesions from the same patients which may explain the overlap with 'parapsoriasis' [9]. Therefore these findings suggest that at least some cases represent a cytotoxic $CD8^+$ T-cell lymphoproliferative disease which may coexist with other primary cutaneous T-cell lymphomas.

Histological features of an underlying vasculitis in PLEVA suggest an immune complex-mediated pathogenesis. In support of this hypothesis there are many documented cases of infective or drug triggers (see below). Seasonal peaks of onset in autumn and winter [10], and rare familial outbreaks [11], suggest the possibility of an infectious trigger. Numerous potential infectious triggers have been summarized in reviews [1,2], and include toxoplasmosis [12,13], cytomegalovirus [14], parvovirus B19 [15], adenovirus, EBV [16], varicella-zoster virus, HIV [17], measles vaccine, streptococci [18], staphylococci and *Mycoplasma* infections. In many such reports, there is evidence of seroconversion at the time of onset or of resolution of pityriasis lichenoides when the infective trigger was treated thus supporting a casual relationship. Parvovirus B19 genomic DNA was identified in lesional skin in 30% of patients with PLEVA [19]. A therapeutic response of PLC to tonsillectomy in the setting of chronic tonsillitis has been reported [20], as well as responses to antibiotics such as erythromycin [21,22] or tetracycline [23]. Resolution has also followed pegylated interferon and ribavirin in a patient with hepatitis C infection. Other reported triggers include medications, such as chemotherapeutic agents, oral contraceptives, astemizole, and possibly herbs. Therefore the combination of several well-documented infective triggers (mainly viral) and the nature of the cellular infiltrate suggest that pityriasis lichenoides may be caused by an antiviral immune response leading to aberrant skin recruitment of CLA^+ $CCR4^+$ $CD8^+$ T-cells [24].

These findings collectively suggest that pityriasis lichenoides is a diverse group of entities which share a similar morphologic pattern due to a variety of underlying aetiologies including a reactive immune complex mediated hypersensitivity vasculitis to different triggers, an immune response to a T-cell dyscrasia or a primary cutaneous T-cell lymphoma.

Pathology [1,2]. The histology varies with the stage, intensity and extent of the reaction; changes are more severe in PLEVA than in PLC. In early lesions, an infiltrate of predominantly small lymphocytes surrounds and involves the walls of dilated dermal capillaries, which show endothelial proliferation. In PLEVA, the infiltrate may be deep, dense and wedge-shaped rather than predominantly perivascular. The epidermis is oedematous, with an interface dermatitis comprised mainly of $CD8^+$ lymphocytes; some necrotic keratinocytes are generally present, especially in PLEVA. Intraepidermal and perivascular extravasation of erythrocytes is typical. Later, over the centre of the lesion, a parakeratotic scale forms, containing lymphocytic pseudo-Munro abscesses and prominent exocytosis of lymphocytes and a little cytologic atypia can be present. If the reaction is still more intense, as occurs in FUMHD, frank necrosis occurs and the lesion may be difficult to distinguish from other forms of acute necrosis of the skin on histology. In FUMHD there may be marked fibrinoid necrosis of deep vessels with luminal thrombi, partial necrosis of follicles and complete necrosis of eccrine glands.

Immunofluorescent studies variably demonstrate IgM, C3 and fibrin in vessel walls of fresh lesions [2]. Macrophages are increased in number and Langerhans' cells decreased. HLA-DR is expressed by the lymphocytic infiltrate and the overlying epidermis.

There is a histological resemblance to many other conditions, including common inflammatory conditions such as psoriasis and resolving eczema. The most important is the distinction from parapsoriasis and particularly (as they may also be clinically similar) differentiation between PLEVA and lymphomatoid papulosis. The most useful distinction from lymphomatoid papulosis is that the latter shows a more pronounced collection of papulonodular lesions with a predominant population of large atypical $CD30^+$ cells (usually $CD4^+$ but occasionally $CD8^+$) whereas atypical $CD30^+$ cells in pityriasis lichenoides are usually few and invariably $CD8^+$ [9]. *CLA* and *TIA-1* are expressed in both conditions and indicate a proliferation of cytotoxic T-cells [25].

Treatment [1–5]. Treatment options include antibiotics such as tetracyclines or erythromycin (preferred in young children because of dental pigmentation side effects of tetracycline) [1], and phototherapy of different types, including natural sunlight, UVB [2], narrow-band UVB, UVA1 and PUVA [3]. Results of phototherapy for pityriasis lichenoides are summarized in [4]. Topical corticosteroids may improve symptoms and healing of lesions but are not felt to alter the course of the disease [1]. A report of topical tacrolimus suggested success in a refractory case of PLC [5]. In more aggressive disease of PLEVA or FUMHD pattern, and less commonly in PLC, various immunosuppressive agents and intravenous immunoglobulin have been used.

Parapsoriasis

This term has caused confusion since its introduction in 1902 because of a lack of a universally agreed definition of the clinical entities to be included. For this reason, many dermatologists prefer not to use the term at all, and to substitute one of the many synonyms for clinical conditions that might be included in one of the parapsoriasis groups. There is unresolved controversy as to whether two of the parapsoriasis variants are either precursors to cutaneous lymphoma in the form of MF (so-called premycotic eruptions) or established, but early, MF from the outset. There is a broad division of parapsoriasis into small and large plaque variants, each with a number of synonyms. The evidence that the majority of cases of small-plaque parapsoriasis are a chronic, benign condition is reasonable. In contrast, large series of patients with large-plaque parapsoriasis have recorded the development of definite MF in 11% of cases but whether these cases were MF from the outset remains unclear at present [1]. Unfortunately, TCR gene rearrangement studies have been in conclusive, although the proportion of cases with evidence of monoclonality is lower in small-plaque parapsoriasis. Long-term follow-up of these cases is now required.

Small-plaque parapsoriasis [1,2]

Synonyms
- Chronic superficial scaly dermatitis
- Persistent superficial dermatitis
- Digitate dermatosis
- Xanthoerythroderma perstans

Definition. A chronic asymptomatic condition, characterized by the presence of persistent, small, scaly plaques, mainly on the trunk.

Clinical features. The lesions usually appear insidiously and asymptomatically on the trunk and, to a lesser extent, on the limbs of young adults. Individual lesions are monomorphic round or oval erythematous patches, 2.5–5 cm in diameter, with slight scaling (Fig. 57.45). Some have a slightly yellow, waxy tinge. The lesions persist for years or even decades, and may be more obvious in the winter months. There is sparing of the pelvic girdle area and the striking polymorphic appearance of individual patches in MF is lacking.

Pathology. This is non-specific. There are small focal areas of hyperkeratosis and parakeratosis, and in the underlying dermis there are small aggregates of morphologically normal CD4$^+$ T cells, mainly around the vasculature. There is no epidermotropism, and no Pautrier's microabscesses.

Immunophenotypic studies reveal a normal mature T-cell phenotype. One report has identified a 'dominant T-cell clone' in two out of five cases of small-plaque parapsoriasis, using PCR analysis [3]. The significance of this observation in terms of relationship to MF and disease progression is not yet clear. There is also a report of a higher frequency of clonal T cells in the peripheral blood of patients with small-plaque parapsoriasis [4] with no evidence of clonality in the skin, although the significance of this finding is

Fig. 57.45 Typical chronic superficial scaly dermatitis showing linear plaques on the trunk that change little over time.

now questionable because non-pathological T-cell clones can occasionally be found in the peripheral blood of normal, healthy volunteers.

Treatment. Often little treatment is needed. Emollients may help control the scaling, and a course of UVB phototherapy may result in temporary clearance of the lesions, but recurrence is invariable [5].

Large-plaque parapsoriasis

Synonyms

- Parakeratosis variegata
- Retiform parapsoriasis
- Atrophic parapsoriasis
- Poikilodermatous parapsoriasis

Definition. A chronic condition characterized by the presence of fixed, large, atrophic, erythematous plaques, usually on the trunk and occasionally on the limbs.

Clinical features. Patients present with persistent, large, yellow–orange atrophic patches and thin plaques on the trunk and limbs. Involvement of covered skin on the breast and buttock areas should suggest MF and in these cases patches and plaques may show striking polymorphism and poikiloderma with slow progression [1].

Pathology [2,3]. There is frequently epidermal atrophy, and a lichenoid or interface reaction may also be seen at the dermal–epidermal junction. There is a band-like lymphocytic infiltrate in the papillary dermis, and there may also be free red cells present. The histology is not diagnostic for MF and most biopsies only show a mild dermatitis.

Immunophenotypic studies reveal a normal T-cell phenotype. TCR gene rearrangement studies have shown a clonal T-cell population in the skin in six of 12 patients, but progression to overt CTCL was only noted in one of the 12 patients [4].

Treatment. Topical emollients, UVB and PUVA are all helpful in offering symptomatic relief. Topical steroids should be used with caution because of the atrophic nature of the condition.

Actinic reticuloid [1,2]

Definition. This condition was first described by Ive *et al*. in 1969 [3]. The original description was of a group of elderly, exclusively male patients who developed a severe and very disabling photosensitivity involving reaction to light throughout the UVB, UVA and visible part of the spectrum. A number of these patients had a past history of contact dermatitis and a milder form of photosensitivity ('persistent light reactors'), but the true relationship between contact dermatitis, particularly to plants of the Compositae family [4], persistent light reactors (chronic actinic dermatitis) and actinic reticuloid is not yet established. The photosensitivity is very severe.

Clinical features. The clinical features are the symptoms of severe and persistent photosensitivity with erythema, oedema and striking 'leonine' thickening of the light-exposed skin of the face, neck and hands which can mimic closely the features of erythrodermic MF/SS (Fig. 57.46) [5].

Patients with atopic dermatitis may be more likely to develop actinic reticuloid, and this should be considered in those with chronic atopic dermatitis who develop photosensitivity [6].

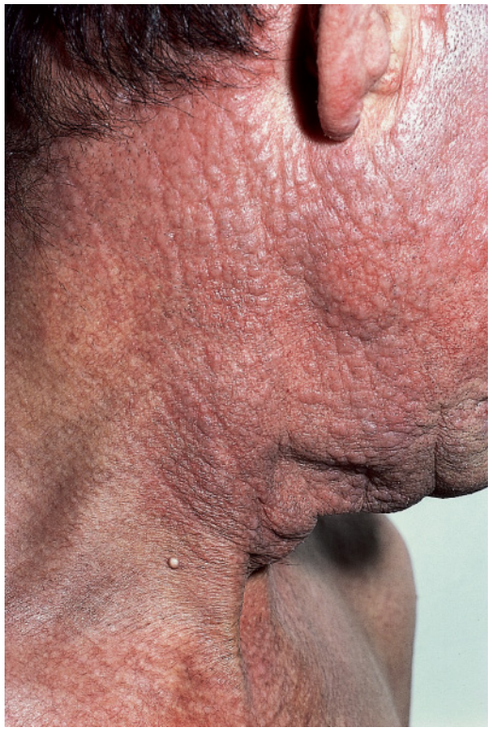

Fig. 57.46 Actinic reticuloid showing marked infiltration of light-exposed skin of the face, with a striking change in skin texture at the collar area and normal skin on the area usually covered by clothing.

Pathology. The histological picture is that of an intense, superficial and deep lymphocytic infiltrate extending from the papillary dermis deep into the reticular dermis. Signs of actinic damage to collagen are present and some of the lymphocytic cells are large and atypical mimicking a cutaneous lymphoma, hence the term 'reticuloid'. The majority of the lymphoid infiltrate consists of $CD8^+$ T cells.

TCR gene analysis does not show a clonal T-cell population [7], but the development of a T-cell clone has been reported in a single patient with mild photosensitivity who developed MF [8]. A recent case series of patients with MF/SS and a report of a patient with cutaneous ATLL suggests that patients with cutaneous lymphomas can show marked photosensitivity with clinical features mimicking chronic actinic dermatitis/actinic reticuloid, emphasizing the importance of considering carefully a diagnosis of a cutaneous T-cell lymphoma in patients with actinic reticuloid [9,10].

Treatment. Treatment is based on light avoidance and the use of both the titanium dioxide-containing physical barrier creams and the newer, more effective chemical UVA and UVB blockers. Low-dose systemic steroid therapy, ciclosporin, hydroxyurea [11] and azathioprine [12] may be effective in some patients.

The prognosis for recovery is poor and the majority of patients tend to have severe photosensitivity for the remainder of their lives.

Lymphocytoma cutis

Synonyms
- Spiegler–Fendt sarcoid
- Lymphadenosis benigna cutis of Bafverstedt

Definition. Lymphocytoma cutis is a benign, cutaneous B-cell lymphoproliferative condition. It presents as papules, nodules or plaques usually on the head and neck and pursues a chronic course [1–3].

Aetiology. This is at present unknown.

Clinical features. More cases are reported in females than males. Most patients show solitary or grouped, asymptomatic, erythematous or violaceous papules, nodules or plaques, on the head, especially the ear lobes, and rarely the trunk or limbs (Fig. 57.47). Occasionally, they may have a translucent appearance. They are asymptomatic and not tender, painful or itchy. Lesions are often multiple and may be in all stages of development. They enlarge slowly and may reach a diameter of 3–5 cm. Associated sunlight sensitivity has been reported in some patients. Bafverstedt [4] has described an unusual form of lymphocytoma that presented as a solitary tumour of scrotal skin. Disseminated or miliary lymphocytoma cutis is also rare [5], and occurs in older patients on any body site.

Pathology [6,7]. The epidermis is usually unaffected and is often separated by a relatively acellular grenz zone from the dermis, which is replaced by a nodular dense infiltrate extending through the full thickness of the dermis but without cellular atypia. In

Fig. 57.47 Clinical presentation of a patient with lymphocytoma cutis.

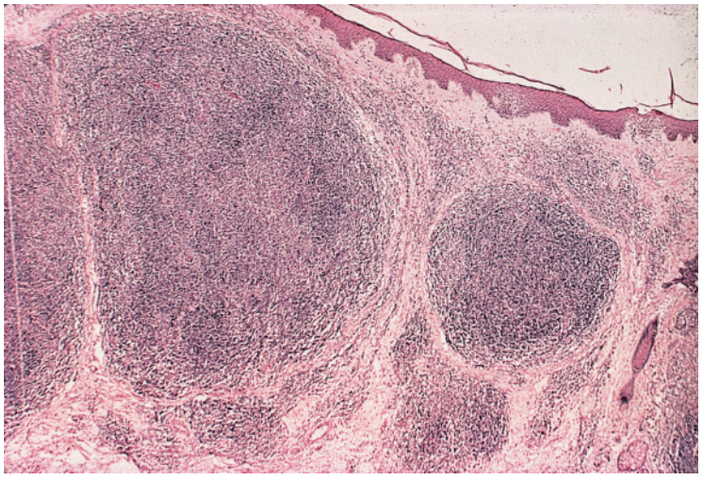

Fig. 57.48 Histology of Spiegler–Fendt sarcoid showing striking lymphoid follicles.

classic cases, lymphocytes and histiocytes form a follicular arrangement resembling the appearance of a lymph node (Fig. 57.48). Mitotic figures may be visible in the cells of the follicles and occasional eosinophils may also be present. Appendages and blood vessels are spared. In some instances, there is no tendency for lymphoid follicle formation, although the histological appearance with normal lymphocytes and histiocytes is otherwise similar. The histological differential diagnosis includes primary cutaneous lymphoma, particularly of marginal zone origin.

Immunopathology. The majority of lymphocytes in the dermis are B cells. Germinal centres are frequently seen in lymphocytoma cutis, and appropriate markers will confirm the morphological similarity of these structures to the germinal centres of lymph nodes. A cuff of reactive T cells may be seen around the periphery of the main B-cell aggregate.

Differential diagnosis. Histological examination should distinguish lymphocytoma cutis from granulomatous disorders including sarcoidosis, granuloma faciale and rosacea. Distinction from primary cutaneous B-cell marginal zone lymphoma (MZL) is difficult, although the presence of atypical lymphoid cells would suggest a primary cutaneous MZL. Insect bite reactions may also be impossible to distinguish with any confidence from lymphocytoma cutis.

Jessner's benign lymphocytic infiltration, tumid discoid lupus erythematosus (LE) and polymorphic light eruption can also cause difficulties. However, in Jessner's lymphocytic infiltrate, which characteristically waxes and wanes in severity, the dermal lymphocytic infiltrate is dominated by T cells. The presence of basal cell liquefaction degeneration and positive direct immunofluorescence helps distinguish LE.

Treatment. There is no treatment of proven value for lymphocytoma cutis. Penicillin and radiotherapy have been advocated in the past without adequate clinical trials. Intralesional steroids have also been advocated. Miliary lesions may partially respond to topical steroids. Hydroxychloroquine has also been effective.

Prognosis. Lymphocytoma cutis is a benign disorder in both localized and disseminated forms, although often running a very protracted course. Long-term follow-up of these patients suggests that a small proportion progress to or begin as a primary cutaneous B-cell lymphoma (MZL) and therefore the prognosis must be guarded [8–11].

Jessner's lymphocytic infiltrate [1]

Definition. A chronic benign T-cell lymphoproliferative disorder, usually of exposed skin.

Fig. 57.49 Clinical appearance of a young woman with Jessner's lymphocytic infiltrate.

Clinical features. Females are more often affected than males [2]. Both children [3,4] and familial cases [5,6] have been recorded. Benign lymphocytic infiltration of Jessner is characterized by the presence of red tumid nodules, usually on facial skin (Fig. 57.49). The lesions may involute spontaneously, but more commonly are persistent, and new lesions develop over time. There is variation in seasonal activity of the lesions, with winter exacerbations. The individual lesions are smooth raised non-scaling erythematous nodules or plaques and are commonly asymptomatic, although some patients complain of burning or pruritus.

Pathology [7–11]. Biopsies reveal a lymphocytic infiltrate predominantly in the lower dermis and concentrated tightly around blood vessels (Fig. 57.50). The epidermis and papillary dermis are relatively normal, and within the lymphocytic infiltrate there is no evidence of cellular atypia, germinal centre or follicle formation. The great majority of these cells are $CD4^+$ T cells.

Differential diagnosis. The clinical differential diagnosis includes a fixed drug eruption and cutaneous discoid LE. The lesions are usually more numerous than would be associated with a fixed drug eruption, although the histology is very similar. The individual lesions of Jessner's lymphocytic infiltrate are smooth and non-scarring, in contrast to the scaling atrophic scarring associated with chronic discoid LE. In addition, Jessner's lymphocytic infiltrate does not demonstrate a lupus band as seen at the dermal–epidermal junction in chronic discoid LE. However, there is a view that Jessner's lymphocytic infiltrate is a variant of LE.

Treatment. This is unsatisfactory, and lesions tend both to persist and to increase in numbers. There are individual case reports of successful therapy with topical steroids, systemic steroids, PUVA, radiotherapy, dapsone, hydroxychloroquine and gold [12].

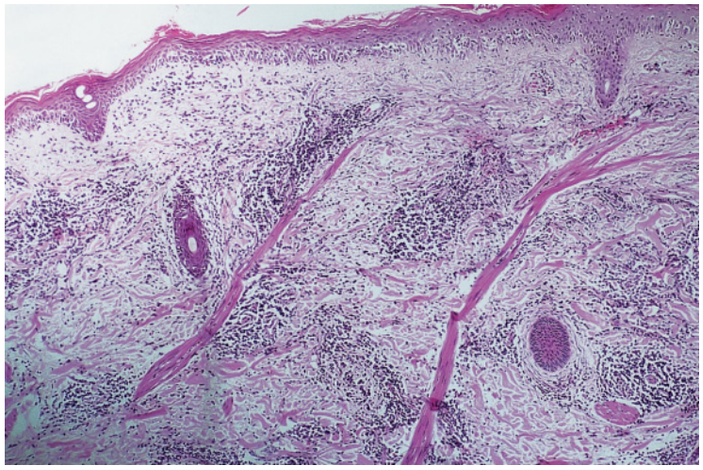

Fig. 57.50 Pathological pattern of Jessner's lymphocytic infiltrate. Note perivascular distribution and absence of epidermotropism.

Leukaemia cutis [1–3]

Diagnosis. The diagnosis of the specific type of leukaemia depends on detailed examination of the blood and bone marrow. The cutaneous infiltrate rarely indicates the type of leukaemia involved.

Specific cutaneous lesions occur most often in myelomonocytic leukaemia and T-cell malignancies such as T-cell prolymphocytic leukaemia and T-ALL [4]. Cutaneous involvement in

Fig. 57.51 Specific deposits in a child with leukaemia. Note two large nodular lesions on the back.

the other forms of leukaemia is unusual as a presenting feature, and usually appear after the diagnosis has been established. There are a few cases where the diagnosis of leukaemia has been established first by analysis of the skin lesions [5]. These lesions usually consist of small, reddish papules or nodules which may be fleeting or persistent. Clinically, they may resemble lesions of Sweet's syndrome, sarcoidosis, panniculitis, other granulomas or cutaneous lymphoma (Fig. 57.51). Ulceration, especially around the ankles, simulating gravitational ulceration, has been described in chronic lymphatic leukaemia and may represent the development of a leukaemic deposit in an area of low vascular resistance.

Although 'non-specific' lesions are said to be common, they are rarely reported by dermatologists. Generalized pruritus may be a presenting symptom and prurigo-like papules develop in some cases. Erythroderma has been recorded in association with an underlying T-cell leukaemia such as T-cell prolymphocytic leukaemia which must be distinguished from Sézary syndrome. There is usually marked exfoliation and the skin may be markedly thickened, especially over the face. The histological features in the skin may or may not be diagnostic.

Disseminated or unusually severe herpes zoster is common in association with all types of malignant disease. Specific leukaemic infiltrations into herpetic scars may occur and bullous lesions have been recorded [6]. In multiple myeloma, both generalized and local amyloidosis is common. Anhidrosis has been recorded. Patients with myelomatosis may subsequently develop variants of acute myelogenous leukaemia [7,8] and it has been suggested

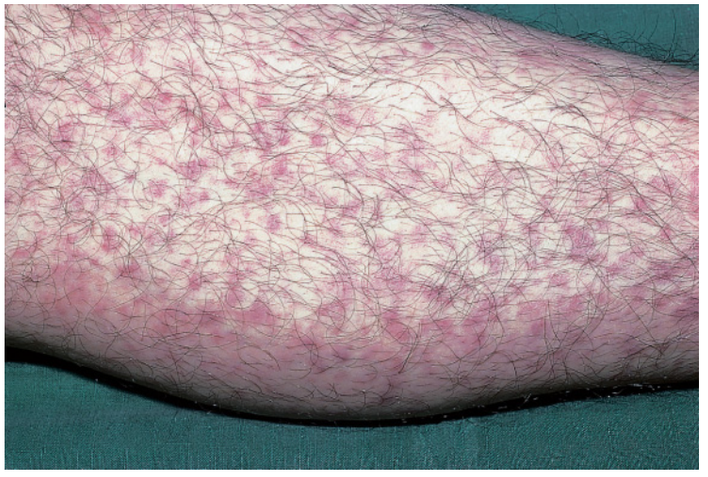

Fig. 57.52 Purpuric lesions in an adult patient with myelocytic leukaemia.

that this complication is the result of treating the underlying disease with irradiation or alkylating agents [9].

Three cases of a perniotic syndrome associated with monocytosis and neutropenia have been described as a possible association with a preleukaemic state [10]. Sweet's disease and bullous pyoderma have also been associated with leukaemia (see Chapter 52).

Thrombocytopenic purpura is a characteristic symptom of the acute leukaemias and may occur on skin or mucous membranes, often as the presenting symptom (Fig. 57.52).

Beek [9] recorded 289 cases of lymphatic leukaemia with skin lesions and, in these, tumours were present in 50%, the head being the most common site. Erythroderma was present in 25%, herpes zoster in 26%, prurigo-like papules in 21%, bullae in 10%, varicelliform eruptions and urticaria in 3%. Haemorrhagic gangrene of the skin has also been recorded. The usual age at presentation of patients with lymphatic leukaemia is 45–54 years, but those with cutaneous lesions tend to be older. Skin lesions in myelogenous leukaemia are much less frequent, with only 72 recorded cases. When the skin is involved the prognosis is poor.

A relatively specific picture is observed in a number of patients with chronic T-cell lymphatic leukaemia [6]. These patients are frequently elderly males and may present with diffuse generalized erythroderma, splenomegaly and lymphadenopathy. This may be caused by lymphokine release by the malignant T cells during their passage through the dermal vasculature, as skin biopsy of these lesions does not reveal a specific cutaneous infiltrate, or epidermotropism characteristic of MF.

Diagnosis. Diagnosis of all these conditions is based on pathological examination of material from blood, bone marrow, lymph nodes and skin [8,11–13].

Treatment. The treatment for leukaemia cutis is management of the underlying disease, with symptomatic measures for the skin lesions when required. Superficial radiotherapy may be useful, giving rapid symptomatic relief, and regression of specific cutaneous deposits.

Cutaneous Hodgkin's disease

The existence of a variant of Hodgkin's disease that begins in the skin is still debated, and it can be difficult if not impossible to differentiate from Hodgkin's disease beginning in the nodes, which spreads in a contiguous manner at an early stage to the skin [1–5]. Invariably, cutaneous Hodgkin's disease only occurs as direct extension from an underlying involved regional lymph node. Thus, careful clinical examination, followed if appropriate by node biopsy and CT scans, should be performed before a diagnosis of primary cutaneous Hodgkin's disease is made. In view of the cytological similarity between the cells of lymphomatoid papulosis and those of Hodgkin's disease, this differential diagnosis must be carefully considered and positively excluded.

Clinical features. One review of 1810 cases of Hodgkin's disease reports only nine (0.5%) with specific cutaneous lesions [6] but a more recent study records involvement in 16 of 465 cases (3.4%) [7]. They usually consist of small nodules, but ulcerative lesions have been recorded and rarely are the presenting symptom.

Pathology [1,2,8]. To consider the diagnosis of Hodgkin's disease either involving the skin as a secondary process, or originating in the skin, the cutaneous infiltrate should consist of nodules of atypical lymphoid and histiocytic cells, including the presence of Reed–Sternberg cells that are $CD30^+$ and lymphoid cells that are $CD15^+$ [9–11]. CD15 positivity is not seen in lymphomatoid papulosis.

Non-specific cutaneous signs associated with Hodgkin's disease [5,12] are very common and occur in 3–50% of cases. These include pigmentation, pruritus, prurigo, atrophy, alopecia, exfoliative dermatitis and herpes zoster.

Pigmentation. This is melanin pigmentation and is very common. It resembles the pigmentation of Addison's disease, being most marked in areas that normally show some darkening such as the axillae, groins and around the nipples. Less often it is more widespread, and occasionally a bizarre pigmentation occurs. The mucous membranes are usually spared.

Pruritus. This often occurs together with pigmentation. Pruritus is not infrequently the presenting feature of the disease, and may precede the presence of palpable nodes by months or years. It tends to start on the legs. It is especially severe in patients who show other general symptoms such as fever and weight loss. Both pigmentation and pruritus occur in association with enlarged mediastinal or retroperitoneal glands, the presence of which should always be suspected when itching is severe.

Prurigo. This is a development from pruritus. In addition to the widespread irritation, there are excessively itchy papules, which are scratched until the skin surface is removed and is replaced by a blood crust. The papules and crusts are usually found on the trunk. When present in association with enlarged superficial glands, this forms a very characteristic picture, often called Hodgkin's prurigo.

Ichthyosiform atrophy. An acquired ichthyosis occurring in the course of a chronic wasting disease is fairly common. Hodgkin's disease is probably the most common condition to be associated with this change. It usually starts on the legs and may remain restricted, but in severe cases progresses until it becomes universal. It resembles ichthyosis vulgaris, with thin, dry and rather firmly attached scales. It is not static and may regress for a time, only to return later. Red streaks are often visible between the scales. The patient is usually wasted and severely ill. Malabsorption from the gut may occur in some cases and contribute to this problem.

Alopecia. Hair loss is common in Hodgkin's disease. It can be caused by rubbing or scratching to relieve itching. It may also be part of the ichthyosiform atrophy or be caused by endocrine dysfunction, when specific infiltration occurs in organs such as the pituitary or adrenal. Rarely, it may be brought about by specific infiltration in the scalp.

Exfoliative dermatitis. Erythroderma and exfoliative dermatitis have been recorded as occurring in Hodgkin's disease on many occasions [4]. Most recorded cases would probably be more correctly included under ichthyosiform atrophy.

Herpes zoster. Herpes zoster is common in the course of Hodgkin's disease, but disseminated zoster is much less likely to occur in Hodgkin's disease than in chronic lymphatic leukaemia.

Miscellaneous conditions. Many other non-specific skin lesions have been described in association with Hodgkin's disease, but

they are probably incidental. Erythema nodosum is seen occasionally and is apparently caused by the disease itself; in these cases, differentiation from sarcoidosis may be difficult, but the Kveim test or node biopsy should establish the diagnosis.

Lennert's lymphoma

Definition. A rare variant of systemic lymphoma with a characteristic histology, first described in 1968 as a variant of Hodgkin's disease [1].

Clinical features. Most patients have lymphadenopathy, fever, fatigue and weight loss. The skin is involved very rarely as a secondary event and this usually consists of clinically non-specific papules or nodules [2]. One patient presented with chronic cutaneous infection and pyoderma [3], and another simulating atypical granuloma annulare [4].

Pathology. The characteristic pattern is an infiltrate with a high content of epithelioid histiocytes, admixed with $CD4^+$ cells. If the skin is involved, there may be a subcutaneous infiltrate consisting of epithelioid histiocytes and T cells. Reed–Sternberg cells are rare [2,3].

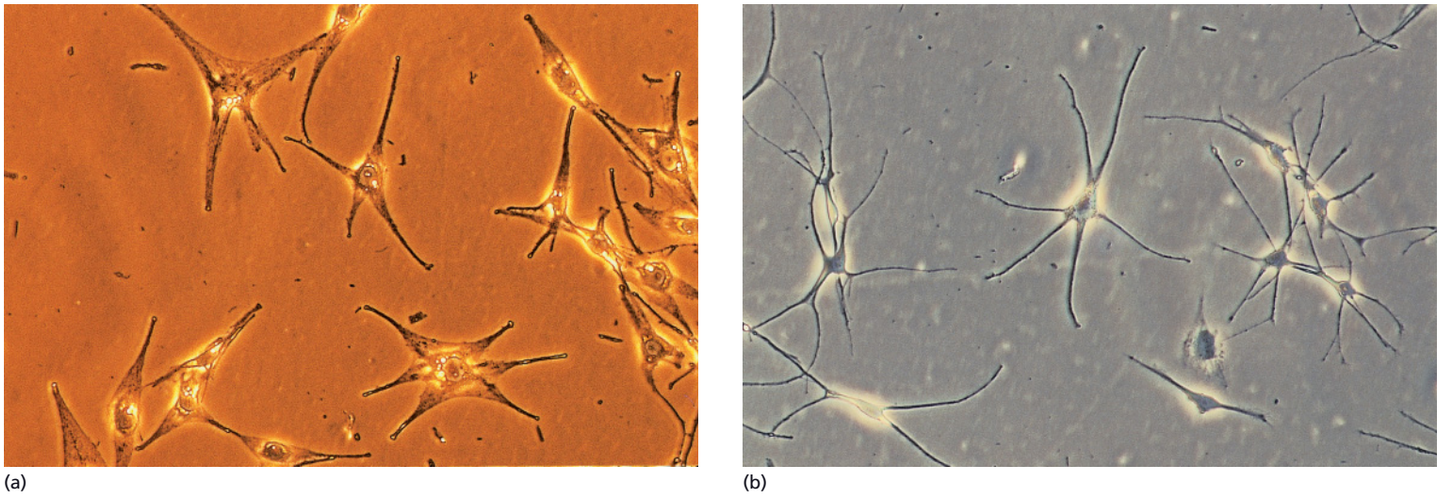
The colour of the skin [1–7]



Normal skin colour is determined by a number of chromophores, the most important of which is melanin. Besides melanin, other chromophores that contribute significantly to skin colour include haemoglobin (in both the oxygenated and reduced state) and carotenoids. Racial and ethnic differences in skin colour are related to the number, size, shape, distribution and degradation of melanin-laden organelles called melanosomes. These are produced by melanocytes (Fig. 58.1) and are transferred to the surrounding epidermal keratinocytes. Two types of melanin pigmentation occur in humans [1]. The first is *constitutive* skin colour, which is the amount of melanin pigmentation that is genetically determined in the absence of sun exposure and other influences. The other is *facultative* (inducible) skin colour or 'tan', which results from sun exposure. Increased pigmentation can also be due to endocrine, paracrine and autocrine factors [1,2].

The least pigmented human subjects are almost white and have a skin colour similar to that of an albino. In contrast, the darkest pigmented human subjects are deep brown or black-brown in colour. Most peoples of the world fall between these two extremes and are moderate brown or yellow-brown in colour. The Caucasian peoples of Europe exhibit a light brown colour that can be enhanced by exposure to sunlight. The ability to tan is marked in the Mediterranean and Middle Eastern peoples. In contrast, some of those from the western parts of Northern Europe have fair skin, red hair, and a tendency to develop red-brown freckles after exposure to sunlight. The definitive method for objective measurement of skin colour uses the recording spectrophotometer adapted for reflectance readings [3]. Application of reflectance chromameters in clinical practice includes the measurement of skin colour, the measurement of ultraviolet (UV)-induced pigmentation, and the quantification of the bleaching effect of depigmenting agents [3].

In some ethnic groups, a sharply demarcated linear border is seen between more and less pigmented skin [4]. This has been studied most extensively in the Japanese and in black Americans, and is most frequently observed in darkly pigmented individuals. Six major forms (designated A–F) of natural pigmentary demarcation boundaries in the skin have been described [4]. These are summarized in Table 58.1.

A blue colour is seen in the congenital pigmentation termed 'Mongolian spot', a form of dermal pigmentation that can occur on any part of the body, although it is most commonly found in the sacral region [5,6]. These spots fade after birth, but can persist in certain sites as in the naevus of Ota (see p. 58.36). Blue naevus is an example of acquired blue pigmentation of skin. The blue coloration of the skin in both of these lesions is due to an optical effect that alters the perceived colour of brown pigment in the dermis. The melanin dispersed in the dermis absorbs incident visible light such that the diffuse reflectance in the longer (red) wavelengths is reduced, giving the pigmented sites a blue appearance.

F: Lines on face

Carotenoids are lipid-soluble yellow to orange-red pigments that are exogenously produced and can be obtained only from plants in the diet. Carotenoids serve a photoprotective role in green plants, but their photoprotective effect in humans is small, even when taken in excess [7]. Carotenoids are found in the epidermis as well as the subcutaneous fat. When present in excess, carotenoids impart a yellowish hue to the skin which may sometimes be prominent [7].

The evolution of pigmentary systems and their variety throughout the animal kingdom are reviewed in Chapter 2.

The melanocyte [1–3]

Epidermal melanin unit

The estimated mass of all pigment cells within the body is about 1.5 g. Most of these are melanocytes within the epidermis [1]. The process of melanin production within these melanocytes is a three-stage process, which involves not only the production of melanosomes within the melanocyte, termed melanogenesis, but also the trafficking and transfer of these pigment granules via long arborizing dendrites to surrounding epidermal keratinocytes. Each epidermal melanocyte together with the epidermal cells that it serves, comprises an 'epidermal melanin unit' as first described by Fitzpatrick and Breathnach in 1963 [2,3]. Although the number of active epidermal melanin units varies considerably in the different regions of the body (Fig. 58.2), the number of keratinocytes served by each melanocyte remains constant. It is estimated that a single melanocyte supplies melanosomes to a group of about 36 viable keratinocytes. This intricate interface between melanocytes and their keratinocytes is essential for skin pigmentation. Adequate pigmentation of the skin is as dependent upon successful transport and transfer of melanosomes to keratinocytes as it is on the formation of the organelle itself.

Distribution of melanocytes [1–3]

Melanocytes are situated in the basal epidermis (Fig. 58.3). The number of melanocytes within the skin shows little variation between different races or between the sexes. However, the capacity of melanocytes to synthesize melanin, both in the basal state (constitutive colour) and after stimulation (facultative colour) by sunlight, shows great variation. Melanocytes in those with dark

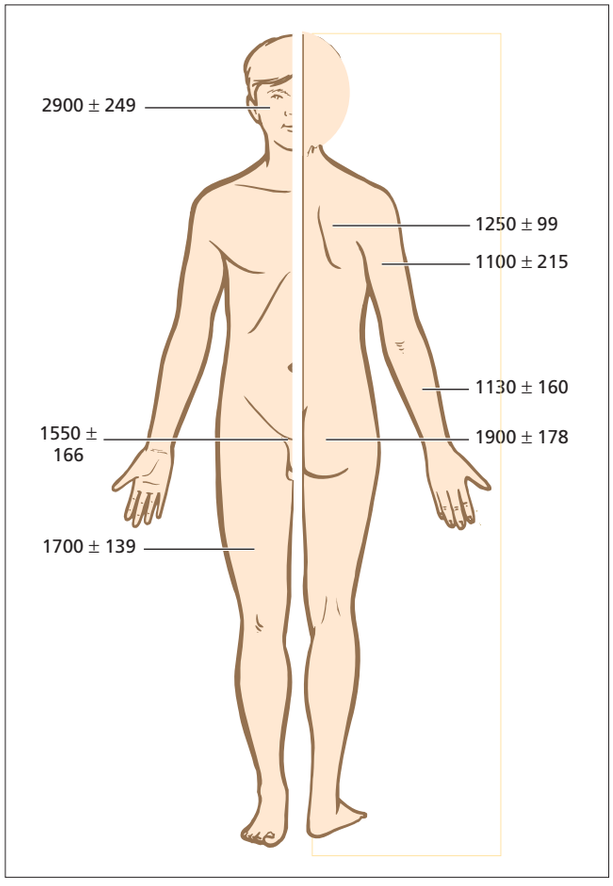

Fig. 58.2 Regional variation in the distribution of epidermal melanocytes. The figures are mean values per mm^2 ± standard error of the mean. (From Rosdahl & Rorsman [1].)

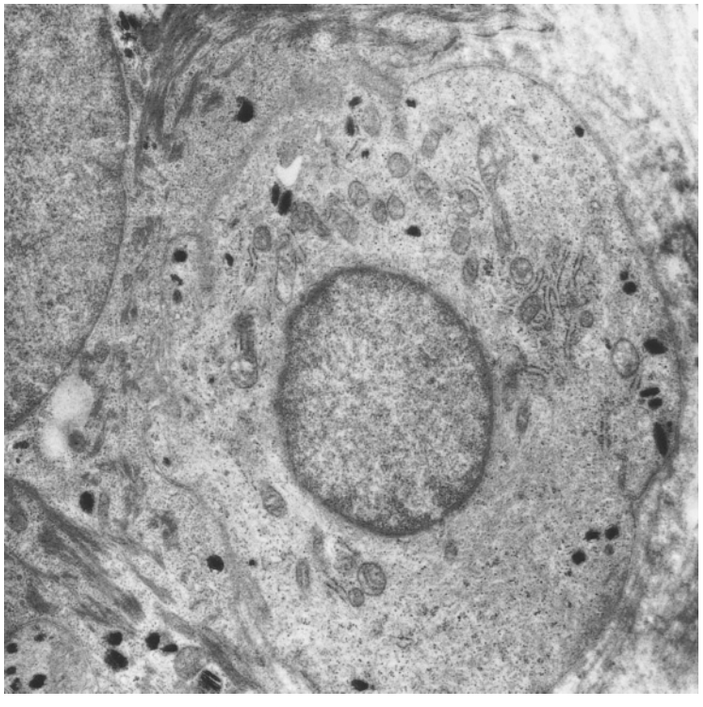

Fig. 58.3 Melanocyte in the basal layer of the epidermis, × 12 000.

skin or with the facility to tan darkly have a great capacity to synthesize melanin and to transfer it to surrounding keratinocytes. In contrast, those with fair skin and lack of tanning facility have very limited capacity. Melanocytes are found in nearly every tissue but are most numerous in the epidermis, hair follicles and the eye [1,2]. A reduction in the number of melanocytes occurs with ageing, with a decrease in melanocyte density of about 6–8% per decade [3]. The density of melanocytes is about two-fold higher in exposed than in non-exposed skin [2].

Melanoblast migration and differentiation

Pigment cells arise from the neural crest [1], a region of the embryonic ectoderm that originates from the margins of the neural plate at the time when it sinks in to form the tubular central nervous system. The developmental potential of neural crest cells has been studied by a variety of means including clonal analysis, cell grafting experiments and lineage-specific marker studies. Collectively, these studies indicate that most early neural crest cells are multipotent, and become fate-restricted over time [2–4]. Melanoblasts originate in the neural crest and migrate laterally, first to the dermis and then to the basal lamina of the epidermis. Immunocytochemical marker studies with the melanocyte-specific HMB-45 antibody have revealed that melanoblasts appear in the epidermis by 7 weeks' gestation, with a cell density of about 50% of that observed at birth [4]. Ultrastructural studies on early human embryos have demonstrated the presence of melanocytes containing melanosomes showing early melanization [5]. HMB-45 staining has revealed an approximately two-fold increase in melanocyte numbers between gestation weeks 10 and 14, possibly due to mitosis of cells already *in situ* rather than due to addition cell migration. Melanocytes associated with hair follicles arrive at their final location by following the downgrowth of epidermal cells in developing hair follicles [6].

Studies in mice have demonstrated that melanocyte lineage segregation starts early in neural crest development, with melanoblasts specified prior to or coincident with their emigration from the neural tube [7]. Initial segregation of melanocyte lineage involves the Wnt/β-catenin pathway [8]. The transcription factor *mi* is relatively specific for melanocytes differentiation, as was first identified in the *microthalmia (mi)* mutant. *Mi* encodes the transcription factor Mitf, which regulates several melanocyte-specific genes [9,10]. In humans, mutations in *mi* are associated with Waardenburg's syndrome type 2A, an autosomal dominant condition characterized by deafness and patchy abnormal pigmentation [11]. *Sox10* and *Pax3* are two other genes associated with Waardenburg's syndrome, probably through regulation of expression of Mitf protein [12]. *Pax3* appears to prime cells for differentiation, whereas *Wnt* signalling allows cells to proceed along this route [13].

Much of our knowledge about melanocytes development in humans has been derived from studies on mouse pigment mutants [11]. To summarize this body of work in broad terms, mouse coat colour mutants arise from three main groups: those that affect the subcellular structure of melanocytes, those that disrupt the normal synthesis of melanin and those that alter development and differentiation of normal melanocytes. Where possible in the following chapter, molecular and biochemical mechanisms for pigmentary abnormalities in humans with genetic disorders will be highlighted.

Melanosome transport [1–10]

Melanosome transport depends upon effective dendrite formation by melanocytes. Ultraviolet radiation and melanocyte-stimulating hormone are both known to stimulate this process [1]. Melanocyte dendrite formation requires actin polymerization, which in turn is controlled by the activity of the small guanosine triphosphate (GTP)-binding proteins Rac and Rho [2–4]. These are themselves controlled by regulatory associated proteins. Direct visualization of melanosome trafficking by video microscopy has revealed evidence to suggest that transfer of melanosomes along dendrites occurs on microtubules [5,6], a process driven by dynein (a minus end microtubule motor) and kinesin (a plus end microtubule motor) [7,8]. Dynein binds microtubules and adenosine triphosphate and produces forces which move the dynein and melanosome complex along the microtubule. Both dynein and kinesin remain bound to the melanosomes and their regulation modifies the direction of melanosome movement along the microtubules [9]. Three individual proteins work together in the final stages of melanosome trafficking. One of these, myosin Va, functions to facilitate the 'capture' of melanosomes at the actin-rich tip of the dendrite [7]. Another, Rab protein, Rab27A, associates with the membrane of melanocytes and then forms a complex with myosin Va and a third protein, melanophylin. The ability of melanophylin to bind actin, in addition to its ability to link with Rab27A and myosin Va, has led to the postulate that transfer of melanosomes from microtubules to actin filaments at the tip of melanocyte dendrites is the final part of the transport process prior to melanosome transfer [10].

Melanosome transfer to keratinocytes [1–7]

The successful synthesis of a melanosome, and its transport to the tip of a dendrite, is followed by transfer of the melanosome to the keratinocyte. Both ultraviolet radiation and the hormone MSH stimulate this transfer, while niacinamide has been shown to suppress it [1]. However, the exact mechanism by which the melanosome is transferred to the keratinocyte remains unclear. One possibility is exocytosis of melanosomes from the tips of dendrites with subsequent keratinocyte uptake by endocytosis. In support of this, exocytosis-associated proteins soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor (SNARE) and Rab3a have both been identified on melanosomes [2–4]. Furthermore, *in vivo* high-resolution time-lapse digital images of this process have identified long, dynamic filopedia arising from the melanocyte dendrite tips packed with melanosomes [4]. The filopedia have been observed to attach and detach from the keratinocyte membrane; melanocytes have been observed travelling in both directions within the filopedia [4]. Work from several groups has revealed that lectins and their glycosolated ligands may function as receptor-ligand pairs in these melanocyte-keratinocyte interactions [5–7].

Melanocyte culture [1–8]

Melanocytes fail to grow, and usually die, in culture media used for skin fibroblasts or keratinocytes. In contrast to many other cell types, melanocytes do not produce any of the growth factors that are known to stimulate them [1]. Following an intensive search, the first highly effective natural melanocyte mitogen was identified as basic fibroblast growth factor (now termed FGF2) [2]. As more mitogens for melanocytes emerged, it was apparent that a combination of synergistic growth factors was required to stimulate quiescent or moribund melanocytes in culture [1,3]. Additional stimulatory peptides include mast cell growth factor/stem cell factor (M/SCF, also known as Kit ligand and Steel factor), hepatocyte growth factor/scatter factor (HGF/SF), endothelins and, to a lesser degree, melanocyte-stimulating hormone (MSH). In the presence of FGF2, phorbol ester and cyclic adenosine monophosphate these peptides act synergistically on melanocytes in culture [1,4]. A more recent addition to the list of melanocyte mitogens is leukaemia inhibitory factor (LIF) [5]. With the exception of FGF2, most of these factors also promote melanocyte differentiation [6,7]. Endothelin 1 (ET1) can also sustain the viability of human melanocytes in the absence of other growth factors and can also stimulate the formation and elongation of dendrites [4,8].

Table 58.2 Main types of epidermal melanin pigments. (Courtesy of Prota [2].)

Eumelanins	Brown or black nitrogenous pigments, insoluble in all solvents, which arise by oxidative polymerization of 5,6-dihydroxyindoles derived biogenetically from tyrosine
Phaeomelanins	Alkali-soluble pigments, ranging from yellow to reddish-brown; most of them contain sulphur in addition to nitrogen and arise by oxidative polymerization of cysteinyl-dopa via 1,4-benzothiazine intermediates
Trichochromes	A variety of sulphur-containing phaeomelanic pigments with a well-defined structure, characterized by a $\Delta^{2,2'}$-bi(1,4-benzothiazine) chromophore

Biochemistry of melanogenesis [1–5]

Melanins are usually classified into two main groups: the brown to black insoluble eumelanins, and the yellow to reddish-brown alkali-soluble phaeomelanins (Table 58.2). Both pigments are derived from dopaquinone, which is formed by the oxidation of the common amino acid L-tyrosine by tyrosinase.

Eumelanin formation

Dopaquinone is a highly reactive intermediate and in the absence of sulfhydryl compounds it forms cyclodopa. The redox exchange between cyclodopa and dopaquinone then gives rise to the red intermediate dopachrome and dopa. Dopachrome then rearranges to 5,6-dihydroxyindole (DHI) and to a lesser extent to 5,6-dihydroxyindole carboxylic acid (DHICA). Finally, these two compounds are oxidized and polymerized to produce eumelanins. In addition to tyrosinase, dopachrome tautomerase and Tryp1 (DHICA oxidase) are now both recognized as having a role in the regulation and promotion of eumelanogenesis [1].

Pheomelanin formation

In contrast to eumelanins, pheomelanins contain sulphur in addition to nitrogen and are formed from cysteinyldopa (Fig. 58.4). Further oxidation of the thiol adducts leads to the formation of pheomelanin via benzothiazine intermediates. Most melanin pigments in skin are mixtures or copolymers of eumelanins and pheomelanins. However, the situation is complicated by the fact that some pheomelanin-like pigments may be structural variants of eumelanins [2]. Thus, in the presence of metal ions, black insoluble eumelanin may be oxidized chemically or photochemically to a soluble form (melanin-free acid), which is light in colour [3,4].

Trichochromes

A further complication is that red human hair contains, in addition to pheomelanins, small amounts of intensely coloured pigments known as trichochromes [2,5], originally isolated from the red feathers of New Hampshire hens. Trichochromes are sulphur-containing pigments of a well-defined structure, of which six variants have so far been identified (Fig. 58.5).

Regulation of human pigmentation by ultraviolet light and by endocrine, paracrine and autocrine factors

Regulation of human melanocytes is complex; in addition to a direct stimulatory effect of ultraviolet radiation, there are also effects mediated by endocrine, paracrine and autocrine factors. Constitutive melanin content is determined by the rate of synthesis by melanocytes and by the rate and mode of melanosome delivery to keratinocytes. The response of cultured melanocytes to ultraviolet radiation involves growth arrest in conjunction with increased melanogenesis. A differential response is observed between melanocytes derived from individuals of skin types I or II and those from skin types V or IV, with the former showing more prolonged growth arrest, more cyclobutane pyrimidine dimers and less melanogenesis. Exposure of human skin to ultraviolet radiation induces a number of epidermal cytokines and growth factors which in turn induce proliferation of melanocytes and/or melanogenesis. Many devoted sun-worshippers know that by deliberately overdosing on sun exposure, the inflammatory sunburn that ensues is more effective at inducing tanning than a more patient, non-burning approach.

Melanocyte response to UV radiation

Sun exposure is associated with an increased number of active melanocytes in sun-protected skin in the same individual. Friedmann and Gilchrest [1] were the first to demonstrate this direct responsiveness in cultured melanocytes, by showing that irradiation with solar-simulated ultraviolet light resulted in a dose-dependent decrease in proliferation and an increase in pigmentation. More recently, research using sub-lethal doses of UVB showed inhibition of melanocyte proliferation as a result of arrest in G_2 phase of the cell cycle, and an increased tyrosinase activity and melanin content [2]. Melanocytes derived from different skin types all showed a similar pattern of response [2]. Subsequent research has confirmed that this UV-induced growth arrest of melanocytes is related to increased levels of the tumour suppressor gene product p53, with lightly pigmented melanocytes experiencing a more prolonged growth arrest, and a more sustained increase in the p53 protein, than occurs in darkly pigmented melanocytes [3]. Furthermore, lightly pigmented melanocytes show more cyclobutane pyrimidine dimers (a reliable marker for UV-induced DNA damage) after UV irradiation than occurs in heavily pigmented melanocytes [3]. In addition to increased activity of melanocyte tyrosinase, sun exposure leads to elongation and branching of melanocyte dendrites, and an increase in the number and size of melanosomes.

Melanocyte regulation by endocrine factors

The effects of oestrogens on cutaneous pigmentation have been recognized for more than 60 years [4,5]. High levels of oestrogens during pregnancy are implicated in the increased pigmentation that occurs on the face, areola, lower central abdomen and genitalia. Oestrogens have been shown to stimulate melanogenesis in cultured melanocytes by increased tyrosinase activity [6]; these include α-oestradiol, β-oestradiol and oestriol [7]. However, no specific receptors for oestrogens have yet been identified in melanocytes.

In Addison disease the diffuse brown hyperpigmentation results from the melanogenic action of melanocortins derived from the pituitary. The melanocortins are all derived from a precursor molecule, pro-opiomelanocortin. Other melanocortins released from the pituitary in increased quantities in Addison disease include β-lipotrophin, γ-melanotrophin (γ-MSH), β-melanotropin (β-MSH) and α-melanotropin (α-MSH). These peptides all have a stimulatory effect on melanocytes [8], and, in the absence of negative feedback to inhibit their secretion, the hyperpigmentation produced is insidious and progressive (Fig. 58.6). Human melanocytes express the melanocortin 1 receptor (MC1R) that binds α-MSH and ACTH with the same affinity [9]. α-MSH causes a small rise in cAMP but has no effect on basal or ultraviolet-stimulated melanogenesis in human melanocytes [10].

Melanocyte regulation by paracrine and autocrine factors

Post-inflammatory hyperpigmentation is believed to be mediated by immune inflammatory mediators including IL-1α, IL-1β, IL-6 and TNF-α [11]. Human melanocytes have also been demonstrated to respond to, and synthesise, IL-1α and IL-1β, which suggests an autocrine as well as a paracrine regulatory role [12]. Other inflammatory mediators that act on human melanocytes include ecosanoids, metabolites of arachidonic acid. Melanocytes respond to PGE_2 with increased melanogenesis and dendrite formation [13]. Scott *et al.* demonstrated an increase in dendricity of human melanocytes in response to PGE_2 and $PGF_{2\alpha}$ [14]. Basic fibroblast growth factor was the first paracrine factor for human melanocytes to be identified. It exerts its effect by binding to a tyrosine kinase receptor that is expressed on human melanocytes [15]. In contrast to IL-1α, IL-1β, IL-6 and TNF-α and the ecosanoids, basic fibroblast growth factor is not secreted by keratinocytes; direct contact between melanocytes and keratinocytes is required for its

Fig. 58.6 Diffuse hyperpigmentation with darkening of hair and mucous membranes in a woman with Nelson's syndrome following bilateral adrenalectomy.

biological effects [16]. Additionally, leukotrienes C_4 and D_4 have been shown to act as potent mitogens on cultured human neonatal melanocytes [17].

Endothelins are a further important group of peptides that act upon melanocytes in a paracrine manner [18]. Endothelin-1 (ET-1) is both mitogenic and melanogenic for human melanocytes that express ET-1 receptors [19]. ET-1 acts synergistically with α-MSH and basic fibroblast growth factor to stimulate human melanocytes proliferation [20]. Endothelin-3 (ET-3) has similar effects to ET-1; both peptides bind the endothelin receptor on melanocytes with equal affinity [21]. Furthermore, endothelins appear to have a role in protecting melanocytes: Kadekaro *et al.* demonstrated that treatment of human melanocytes with ET-1 reduced UVR-induced apoptosis and prolonged melanocyte survival [22].

Biological significance of melanin

The major biological function of melanin is generally assumed to be protection of the lower layers of the skin against UV light. If human pigment has such adaptive significance, we might expect to find that, among the races of the world, pigment is geographically distributed in relation to solar intensity. It appears to be generally true that pigmentation is greatest in the tropics and reduced in temperate zones, reappearing to some extent in northern races subjected to prolonged snow glare [1]. However, there are exceptions, for example native Americans are not notably different in skin colour throughout the whole continent, and Tasmanians are dark even though they live in a temperate climate.

The damaging role of UV light is well illustrated by the high incidence of epidermal carcinoma in Europeans exposed to excess sun. The evolutionary usefulness of pigmentation may be twofold. On the one hand, it protects against damage by sunburn. On the other, since it efficiently absorbs UV radiation and is readily activated to a free radical by incident light, it may serve to eliminate genetically damaged cells by a phototoxic mechanism.

Not all the effects of pigmentation are advantageous. There is no doubt that pigmentation increases the heat load in hot climates, so that black people absorb 30% more heat from sunlight than do white people, although this factor may be offset by more profuse sweating [2,3]. In addition, in cold climates pale skin has the advantage that heat loss by radiation is reduced.

A further disadvantage of pigmentation is that it hinders synthesis of vitamin D, so that in areas of poor nutrition black children are more liable to rickets than white children. Thus, loss of pigmentation may facilitate vitamin D synthesis in temperate climates. It might be presumed that the retention of pigment in Arctic latitudes, while providing a protection against snow glare, is only permitted by natural selection because of the high-fat diet in these areas.

Since pigmentation appears to be not entirely advantageous to life in the tropics, other hypotheses about its biological significance have been advanced. For example, Wassermann [4,5] suggested that the major adaptation of black people to tropical Africa is in the ability to survive malaria, multiple parasites and tropical diseases under the hazards of intense solar radiation and, more often than not, poor nutrition. He suggests that diseases, not climatic conditions, are the primary selective factors, and lists evidence that black Africans, in comparison with white people, show increased reticuloendothelial activity and increased serum γ-globulin fractions. These features are inversely related to the size and activity of the adrenal cortex. Because of their primary decrease in adrenocortical function, black people show increased MSH and adrenocorticotrophic hormone (ACTH) activity, which enhances melanogenesis. Pigmentation might thus be a secondary phenomenon.

Classification of disorders of melanin pigmentation

Disorders of melanin pigmentation can be divided on morphological grounds into two types. The first is hypermelanosis, where there is an increased amount of melanin in the skin. This excess may be confined to the epidermis, when the skin appears browner than normal, or it may be present in the dermis, producing a slaty-grey or blue appearance. The second type is hypomelanosis, where there is a lack of pigment in the skin, which therefore appears white or lighter than the normal colour. Amelanosis is the term applied when there is a total lack of melanin in the skin. Hypermelanosis and hypomelanosis can be generalized and diffuse, or may be localized and circumscribed. Sometimes, localized areas may have a segmental or dermatomal pattern. The term 'depigmentation' is used to describe a loss of pre-existing pigment from the skin. Leukoderma is a white skin that may be congenital or acquired and can be due to a variety of aetiological factors. Examination of the skin with a source of long-wave UV light, for example Wood's lamp, is often helpful in localizing abnormal variations in melanin pigmentation in the skin and as an aid to the diagnosis of various disorders [1].

Fig. 58.7 Occupational vitiligo due to tertiary-butylphenol.

Changes in pigmentation can arise in a number of ways and can be due to a variety of genetic and environmental factors. It is also pertinent to consider non-melanin pigmentation as a cause of cutaneous colour changes, as discussed at the end of this chapter.

Hypermelanosis similarly can be due to many factors, both genetic and acquired (Fig. 58.7). It can be due to an increased number of melanocytes in the skin such as occurs in the dermal melanocytoses: the naevus of Ota, the naevus of Ito and the Mongolian spot. Many of the hypermelanotic disorders are due to an increase in melanogenesis due to genetic factors. Some may be induced by UV light, hormones and chemical compounds. Finally, the degradation of melanosomes may vary in different disorders of pigmentation.

Constitutive pigmentation, human pigmentation and the response to sun exposure

Genetic factors play the primary role in determining the degree of pigmentation that is normal for the individual. Variation in skin pigmentation is not due to differences in the number of melanocytes but is explained by differences in melanocyte structure and function; melanogenic activity, the size and number of melanosomes, the type of melanin deposited onto melanosomes, and the donation of mature melanosomes to adjacent keratinocytes all contribute to the resulting colour of the skin and are genetically

determined. Thus, constitutive skin colour, as well as how the colour changes in response to exposure to sunlight, are both genetically determined, and show relatively little variation within different racial groups. There is, however, marked variation in human skin colour between the main racial groupings ranging from white (Caucasoid), through lightly pigmented (Asian and Oriental), to black (Negroid and Australoid and some Asian races). Racial differences in melanocyte morphology and function are apparent, but there is little inter-racial variation in the density of melanocytes at a particular skin site. Ultrastructural studies have shown that melanosomes in white skin are small and tend to be in membrane-bound complexes containing three or more within the keratinocytes [1]. The ellipsoidal melanosomes of aboriginals and black people are larger, about 1 μm in length, and tend to be distributed as singlets rather than being aggregated. These larger melanosomes can be found intact in the stratum corneum. The melanosomes in the complexes in white people show degradative changes even in the basal layer of the epidermis and are presumably broken up by lysosomal enzymes [2]. Whether melanosomes are individually dispersed or aggregated in melanosomal complexes appears to depend on the size of the melanosome [1].

Melanin in the skin exerts its photoprotective effect by reducing the penetration of ultraviolet light through the epidermis and by quenching reactive oxygen radicals that contribute to the sun-induced DNA damage [3]. The superior photoprotection of the black epidermis is due not only to its increased melanin content but also to melanogenic activity, the size and number of melanosomes, the type of melanin deposited onto melanosomes, and the donation of mature melanosomes to adjacent keratinocytes. A classification of sun-reactive skin types based on sunburn and tanning history has been in widespread use since its introduction (Table 58.3) [4]. Two types of pigmentation of the skin in humans occur in response to sun exposure. The first is immediate pigment darkening, sometimes referred to as the Meirowsky phenomenon or 'IPD'. This is best observed in those with hyperpigmented skins and is most effectively induced by long-wave UV light (UVA). It is transient and, although rapidly induced, soon fades. The second is the increased pigmentation that follows the erythemal response. This is the delayed tanning reaction and can be seen 48–72 h after skin exposure to UV light.

Table 58.3 Classification of sun-reactive skin types.

Skin type	Sun sensitivity	Pigmentary response
I	Very sensitive, always burn easily	Little or no tan
II	Very sensitive, always burn	Minimal tan
III	Sensitive, burn moderately	Tan gradually (light brown)
IV	Moderately sensitive, burn minimally	Tan easily (brown)
V	Minimally sensitive, rarely burn	Tan darkly (dark brown)
VI	Insensitive, never burn	Deeply pigmented (black)

Hypermelanosis

Ephelides

Synonym
- Freckles

Freckling is probably determined by an autosomal dominant gene [1]. It is most frequent in individuals with red or blonde hair and blue eyes, particularly in those of Celtic (Scottish, Irish, Welsh) extraction. Red-haired individuals with fair skin (and freckles) have a significantly higher incidence of the gene encoding melanocortin receptors [2,3].

Pathology [4]. There is no increase in the number of melanocytes in the pigmented macules but their melanosomes are long and rod-shaped, like those found generally in dark-skinned people. They form melanin more rapidly after exposure to sunlight than do those in the surrounding pale skin, which are spherical and often granular, and are of the type usually found in fair- and red-haired individuals. With the light microscope, the only abnormality detectable is an increase in the quantity of melanin in the epidermis.

Clinical features (Fig. 58.8). Freckles are small macules of hyperpigmentation, usually measuring 2–4 mm in size. They first appear at about the age of 5 years as light-brown pigmented macules on

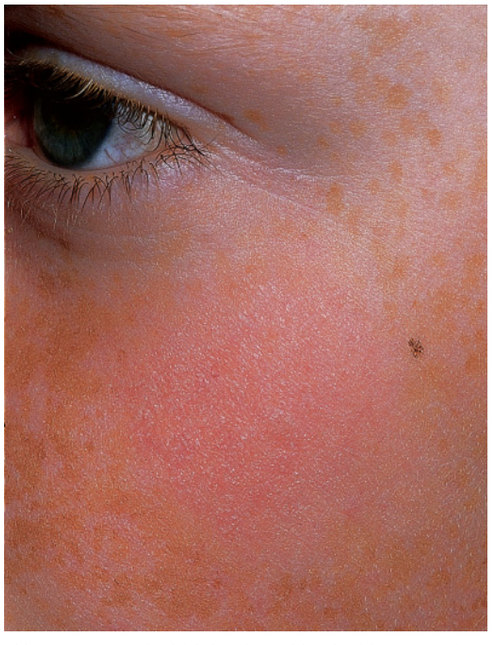

Fig. 58.8 Freckles, one area of which has been bleached by a superimposed patch of pityriasis alba.

light-exposed skin. They are most numerous on the face, upper back, and dorsal forearms and hands. They increase in number, size and depth of pigmentation during the summer months and are smaller, lighter and fewer in number in the winter. They may be cosmetically disfiguring or may enhance appearance, but are not otherwise of significance.

The incidence of melanocytic naevi is increased in freckled individuals.

Treatment. Freckles seldom require treatment and may sometimes be regarded as a desirable cutaneous feature. Application of 2–4% hydroquinone with a UVA-blocking sunscreen in the morning and retinoic acid in the evening produces significant lightening in most freckles. Alternatively, they are amenable to removal by laser [5,6]. Solar lentigines may be improved in appearance by topical treatment which includes retinoic acid [7].

Freckles in various syndromes. Freckles are a feature of a number of inherited and acquired disorders described in this chapter. These include xeroderma pigmentosum [8], neurofibromatosis, Moynahan's syndrome and progeria. The lesions in the various forms of lentiginosis (see below) must also be differentiated. Their distribution and the lack of relationship to light exposure should be noted.

Lentiginosis

The histological and clinical features of lentigo, together with other lesions in which the number of melanocytes is increased, are fully described in Chapter 54. A lentigo is a benign, pigmented macule in which there is an increased number of melanocytes. The term 'lentiginosis' is applied either when lentigines are present in exceptionally large numbers, or when they occur in a distinctive distribution. The following clinical syndromes are recognized.

Generalized lentiginosis

Lentigines are commonly multiple but appear singly or in small crops at irregular intervals from infancy onwards. Their pathogenesis is unknown and in the great majority of cases no genetic factor is demonstrable.

Unilateral lentiginosis (zosteriform lentiginosis)

Lentigines may occur on one side of the body [1]. Cases have been reported with and without associated neurological abnormalities [2–4]. The lentigines can be zosteriform and occur in a dermatomal-like distribution [5–7]. These cases are usually without central nervous system abnormalities and are naevoid. Lentigines have also been reported within naevoid hypopigmentation [8]. A case of unilateral lentiginosis with contralateral naevus depigmentosus has been reported [9].

Inherited patterned lentiginosis in black people [1]

O'Neill reported generalized lentiginosis in 10 adult black patients, with onset in childhood; seven showed familial clustering, suggesting autosomal dominant inheritance [1]. Distribution of the lentigines included the face, lips, extremities, buttocks, palms and soles, but not mucosal surfaces.

Reference

1 O'Neill JF, James WD. Inherited patterned lentiginosis in blacks. *Arch Dermatol* 1989; **125**: 1231–5.

Eruptive lentiginosis [1,2]

Widespread occurrence of very large numbers of lentigines that develop rapidly over the course of a few months to years is typical of eruptive lentiginosis. The condition usually occurs in adolescents and young adults who show no evidence of systemic abnormalities. In 1956, Degos and Carteaud described telangiectatic papules that darkened and evolved into depressed, scaly lentigines [1]. In spite of the misleading title of their report, Eady *et al.* reported two patients in whom very large numbers of lentigines developed over 2 years; histology and electron microscopy confirmed the diagnosis of eruptive lentiginosis [2].

Multiple lentigines syndrome (LEOPARD syndrome, MIM #151100) [1–4]

In 1969, Gorlin *et al*. postulated that multiple lentigines represented one aspect of a syndrome and proposed the acronym LEOPARD (Lentigines, Electrocardiographic abnormalities, Ocular hypertelorism, Pulmonary stenosis, Abnormalities of genitalia, Retardation of growth and Deafness of sensorineural type) [1]. It is determined by an autosomal dominant gene with high penetrance and variable expression [2]. Lentigines are present at birth or first appear early in life and increase in number until puberty. They are most numerous on the neck and upper trunk, but occur all over the body, including the scalp, genitalia, palms and soles. Cardiac abnormalities are frequent—sometimes pulmonary or subaortic stenosis but more commonly conduction defects [3]. Several patients with this syndrome have died at an early age from obstructive cardiomyopathy [4]. Growth tends to be retarded. Ocular hypertelorism and mild mandibular prognathism are the most usual of a variety of skeletal abnormalities. Inconstant features are deafness and genital abnormalities. The deafness, which may be profound, is of sensorineural type. The genital abnormalities include gonadal hypoplasia, hypospadias and delayed puberty.

Centrofacial lentiginosis (MIM 151000) [1]

This poorly defined syndrome remains an enigma more than 30 years after the last English language report of the disorder. It is characterized by a triad of clinical features: lentigines limited to the medial face, neuropsychiatric problems and dysraphic anomalies. It is apparently determined by an autosomal dominant gene. Small brown or black macules appear during the first year and increase in number up to the age of 8 or 10 years. Their distribution is restricted to a horizontal band across the centre of the face. The mucous membranes are not involved. Associated defects include coalescence of the eyebrows, a high-arched palate, absent upper median incisors, sacral hypertrichosis, spina bifida and scoliosis. Mental retardation is frequent and many affected individuals are epileptic.

Peutz–Jeghers syndrome (MIM 175200)

Synonym
- Periorificial lentiginosis

Definition. Peutz–Jeghers syndrome is an autosomal dominant disorder with a high degree of penetrance. It is characterized by hamartomatous polyps in the gastrointestinal tract in association with mucocutaneous melanin pigmentation and an increased rate of soft tissue malignancy. All races are affected.

History. The first reported cases of what is now known as 'Peutz–Jeghers syndrome' were twin sisters reported by a British physician, Dr Connor, in 1895 [1]. Interestingly, one of the sisters died from intestinal obstruction at the age of 20, while the other died of breast cancer aged 59 years [2,3]. They were illustrated by the British surgeon Jonathan Hutchinson in 1896 [4]. The first description of intestinal polyposis in this condition was by the Dutch physician, Dr Johannes Peutz in 1921 [5]. In 1949, Jeghers confirmed the association of intestinal polyposis with hyperpigmentation of the skin and mucous membranes and described its familial characteristics [3]. It was the American, Dr A Bruwer, who was the first to coin the term 'Peutz–Jeghers syndrome' in the title of his paper on the disorder [6].

Genetics. Variable penetrance and clinical heterogeneity make it difficult to determine the exact frequency of Peutz–Jeghers syndrome. In about 40% of cases there is no family history and these represent new mutations. The disorder is due to inactivating germline mutations in the serine–threonine kinase gene *LKB1* (*STK11/LKB1* gene), mapping to 19q13.3 [7]. This gene is now the focus of additional research interest due to its central role as a signalling pathway for tumour suppression [8].

Clinical features. A recent review of Peutz–Jeghers syndrome confirmed the variability of the manifestations [9]. The syndrome is characterized by mucocutaneous pigmentation, multiple gastrointestinal hamartomatous polyps and by an increased risk of developing malignant tumours involving several different organs [9]. Both sexes and all races may be affected. The pigmented macules usually appear in infancy and early childhood, but may be present at birth or may develop later in life. The oral mucous membrane is consistently involved; round, oval or irregular patches of brown or almost black pigmentation 1–5 mm in diameter are irregularly distributed over the buccal mucosa, gums, hard palate and lips, especially the lower lip. The pigmented macules on the face are smaller, often under 1 mm, and darker, and are concentrated around the nose and mouth. Larger macules may be present on both aspects of the hands and feet and may be conspicuous on palms and soles. The oral pigmentation is usually permanent, but the macules on the lips and skin may become less prominent after puberty. Rarely, the nails may be pigmented, diffusely or in longitudinal bands. Mucosal and facial pigmentation without evidence of intestinal polyposis may be found in relatives. Indistinguishable pigmentary changes beginning in adult life also occur sporadically in individuals without intestinal involvement.

Symptoms attributable to the polyps usually occur between the ages of 10 and 30 years, but may occur in early childhood or be delayed until later adult life. The most common symptoms are repeated attacks of abdominal pain caused by intestinal obstruc-

tion. Rectal bleeding is common and haematemesis may occur with gastric or duodenal polyps. Many patients are anaemic.

Pathology. The pigmented macules show an increase in the amount of melanin in the basal layer of the epidermis. Polyps are found throughout the gastrointestinal tract. They are most numerous in the jejunum and ileum and less frequent in the colon, rectum, stomach and duodenum. In general, the polyps are benign hamartomas. The malignant potential of the polyps is not as great as in some other genetically determined syndromes with colonic polyps, but is not negligible. There is also increased incidence of malignancy in other organs, including the pancreas, breast, uterus and ovary.

Diagnosis. The mucosal pigmentation is the most constant feature of the syndrome. Freckling occurs in those of fair complexion, but the macules in freckling are light-influenced, are not focused on the skin around the nose and mouth and do not involve the mucous membranes. Examination of relatives may assist the diagnosis. At a stage when the polyps are already giving rise to symptoms they may not always be radiologically detectable.

Management. Cancer genetic counselling is now a key component to the successful management of patients with Peutz–Jeghers syndrome [10]. This also provides an opportunity for predictive testing of at-risk family members [10]. Age-related cancer risks for *STKL/LKB1* mutation carriers may be used to inform the cancer surveillance strategy [11]. Additionally, patients with mutations on exon 6 of *LKB1* appear to be at higher risk of developing cancer, which may justify a more vigilant protocol [11]. Guidelines for Peutz–Jeghers syndrome management recommend colonoscopic polypectomies every 1–3 years [12]. In many cases, it may be appropriate to undertake regular endoscopic examinations of the upper gastrointestinal tract and of the whole colon, together with barium follow-through studies of the small intestine every 2 years or so. In females, increased risk of breast cancer and gynaecological malignancy confirm that breast and pelvic examination should be included in the cancer surveillance programme [13]. In view of the generally benign nature of the polyps, routine radical surgery is not required. Individual polyps may require endoscopic or surgical removal. Prophylactic colectomy is recommended for cases with numerous colonic polyps, dysplastic polyps and uncontrolled bleeding [12]. Screening for at-risk individuals (first degree relatives of Peutz–Jeghers syndrome patients) should be annually from birth for history and physical examination for melanotic spots, precocious puberty and testicular tumours [9]. At-risk individuals who are asymptomatic and free from stigmata at age 8 years should be offered genetic testing for mutation analysis in the *STK11/LKB1* gene [14].

Polyposis, skin pigmentation, alopecia, and fingernail changes (MIM: 175500)

Synonym
- Cronkhite–Canada syndrome

Definition. Cronkhite and Canada first described the syndrome that now bears their names in 1955 [1]. The syndrome is rare, non-inherited and is characterized by generalized gastrointestinal polyposis, cutaneous hyperpigmentation, hair loss and nail atrophy.

Aetiology. Nutritional, infectious and immunological associations have been considered, but the cause of Cronkhite–Canada syndrome remains elusive. All cases have been sporadic. The skin changes are assumed to be the result of malabsorption associated with the protein-losing enteropathy.

Clinical features. Sixty per cent of reported cases occur in men. It has a worldwide distribution, with mean age of symptom onset at 59 years (range 31–86 years). No familial cases have been reported. Hyperpigmentation is present in most patients [2–4]. It consists of light to dark brown, lentigo-like macules ranging in size up to 10 cm in diameter. These hyperpigmented macules are scattered but are most numerous on upper and lower extremities, and the face. The hands tend to show diffuse pigmentation of the palms and fingers, with macular pigmentation of the dorsae. The mucosal surfaces are usually spared, although the buccal mucosa is occasionally affected. In some patients hyperpigmentation is generalized.

Diarrhoea, abdominal pain and weight loss, beginning in adult life, are the presenting manifestations. Alopecia, patchy at first but becoming total, begins a few months later, and dystrophic changes in the nails develop at the same stage. The nail dystrophy is distinctive but not pathognomonic and could be explained by the formation of ventral nail in the absence of normal nail production by the matrix [5]. Exceptionally, the nail changes may precede gastrointestinal symptoms by months or years [6].

Management. Treatment of the malabsorption leads to reversal of hyperpigmentation in most cases. However, the overall prognosis is generally poor.

Cutaneous lentiginosis with atrial myxomas (Type I: OMIM 160980; Type II: OMIM *160980) [1–4]

Synonyms
- Carney complex
- CNC
- Carney syndrome
- NAME syndrome
- LAMB syndrome

Definition. In 1986, Carney described the complex that is now associated with this name [1]. Carney syndrome is a complex with three associated features: (i) primary pigmented nodular adrenocortical disease, a pituitary-independent, primary adrenal form of Cushing's syndrome; (ii) lentigines and blue naevi of the skin and mucosae; and (iii) a variety of non-endocrine and endocrine tumours, including atrial myxomas.

Aetiology. This inherited disorder shows an autosomal dominant pattern of inheritance. In more than 50% of patients with Carney syndrome disease-associated mutations are present in the gene encoding the R1-α regulatory subunit of cyclic monophosphate-dependent protein kinase on chromosome 2p16 [2]. Cytogenetic studies of tumours from patients with Carney syndrome suggest that the responsible gene may not have a tumour suppression function [3].

Clinical features. NAME syndrome and LAMB syndrome are simply variations of Carney syndrome and are terms that could usefully be dropped. NAME syndrome comprises *n*aevi, *a*trial myxomas, *m*yxomas of the skin and *e*phelides [4]. LAMB syndrome comprises *l*entigines, *a*trial myxomas, *m*ucocutaneous myxomas and *b*lue naevi [5]. Cardiac myxomas are the most important internal myxomas, due to the causation of cardiac symptoms and potentially life-threatening effects [6]. Carney syndrome often affects the adrenal cortex, thyroid and pituitary glands and gonads [7]. Life-long echocardigraphic screening and surveillance in all family members of affected cases is important [8].

Arterial dissections and lentiginosis (MIM: 600459)

Arterial dissections and lentiginosis is a familial syndrome that was first described in 1995 in two sets of siblings from a series of 240 patients with arterial dissections seen at the Mayo Clinic (Rochester, MN, USA) [1]. Six additional sporadic cases were also reported.

Genetics. The gene for this disorder has yet to be identified. However, disease expression in offspring from a consanguineous marriage suggests that it is autosomal recessive.

Clinical features. The lentigines are located on the trunk and the extremities, particularly the lower legs. The arteries prone to dissection include the aorta, renal artery and extra-cranial internal carotid artery. These vessels are the same that are prone to dissection in Marfan syndrome and other connective tissue diseases.

Laugier–Hunziker syndrome [1–5]

This rare syndrome of unknown aetiology was first recognized and described by Laugier and Hunziker in 1970 [1]. It has no known genetic basis. It is characterized by macular pigmentation of the lips and buccal mucosa together with linear black streaks of the nails [2]. Onset is usually in adult life. There have been no systemic changes reported, and the condition is therefore regarded as having a benign prognosis. Histological examination of affected skin shows accumulation of melanin in the basal layer keratinocytes and an increased number of melanophages in the papillary dermis [3]. Ultrastructural examination revealed numerous mature melanosomes in the cytoplasm of basal layer keratinocytes and melanophages in the papillary dermis [3]. Conjunctival and genital hyperpigmentation have also been reported [4]. The differential diagnosis of striate melanonychia is considered in Chapter 65. The term 'essential mucocutaneous hyperpigmentation' has been proposed to replace the eponym for this condition [5].

Penile melanosis/vulvovaginal melanosis [1–4]

Acquired, irregular, brownish or slaty-brown discoloration of the glans or shaft of the penis or of the vulva and vagina may give rise to fears of malignant potential. Histologically, there is only an increase of pigment without any increase or atypia of the melanocytes.

Incontinentia pigmenti (MIM #308300)

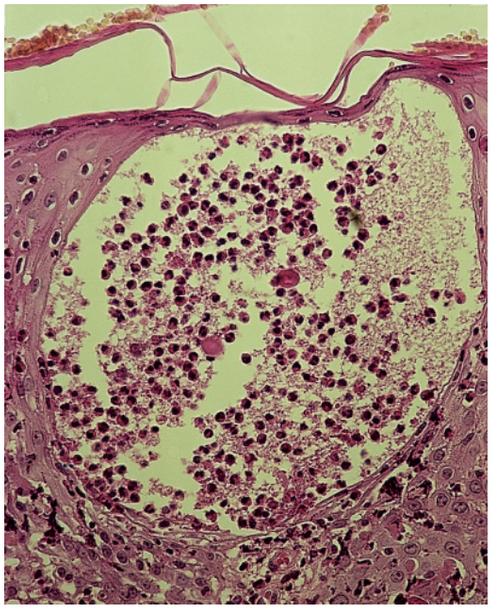
Synonyms
- Bloch–Sulzberger syndrome
- Bloch–Siemens syndrome

Historical background. A number of cases of probable incontinentia pigmenti (IP) were presented in Europe in the early 20th century. However, it was Bloch who first used the term 'incontinentia pigmenti' for this condition [1], and Sulzberger who provided a more detailed account of Bloch's patient [2].

Definition. Incontinentia pigmenti is a rare and complex hereditary syndrome in which vesicular, verrucous and pigmented cutaneous lesions are associated with developmental defects of the eye, teeth and central nervous system [3,4].

Aetiology. Most pedigrees are small, but accumulated genetic data point to an X-linked dominant trait that is lethal for hemizygous affected males [5]. The IP gene has been mapped to Xq28 [6,7]. The 23-kb gene encodes nuclear factor B essential modulator (NEMO), and consists of 10 exons. More than 80% of cases of IP are caused by a deletion of exons 4–10 [8]. Mutations involving other alleles of the NEMO gene result in phenotypes different from IP, including anhidrotic ectodermal dysplasia with immunodeficiency [9,10].

Pathology. The bullae are situated beneath the horny layer or within a spongiotic epidermis. The dermis shows non-specific inflammatory changes with a cellular infiltrate, including numerous eosinophils. The infiltrate extends into the epidermis, and the contents of the bullae may consist predominantly of eosinophils [11] (Fig. 58.9). The lichenoid papules show hyperkeratosis, acanthosis and oedema of the basal layer, many cells of which are degenerate. Macrophages laden with melanin are present in the upper dermis. In the warty lesions, the hyperkeratosis is further increased, and within the irregularly acanthotic epidermis are hyaline bodies representing individual cell keratinization. The epidermal changes at this stage may suggest pseudoepitheliomatous hyperplasia. The pigmented patches show diminution or absence of pigment in the basal cells and large quantities of melanin in melanophages in the upper dermis. The epidermis may be normal or slightly acanthotic.



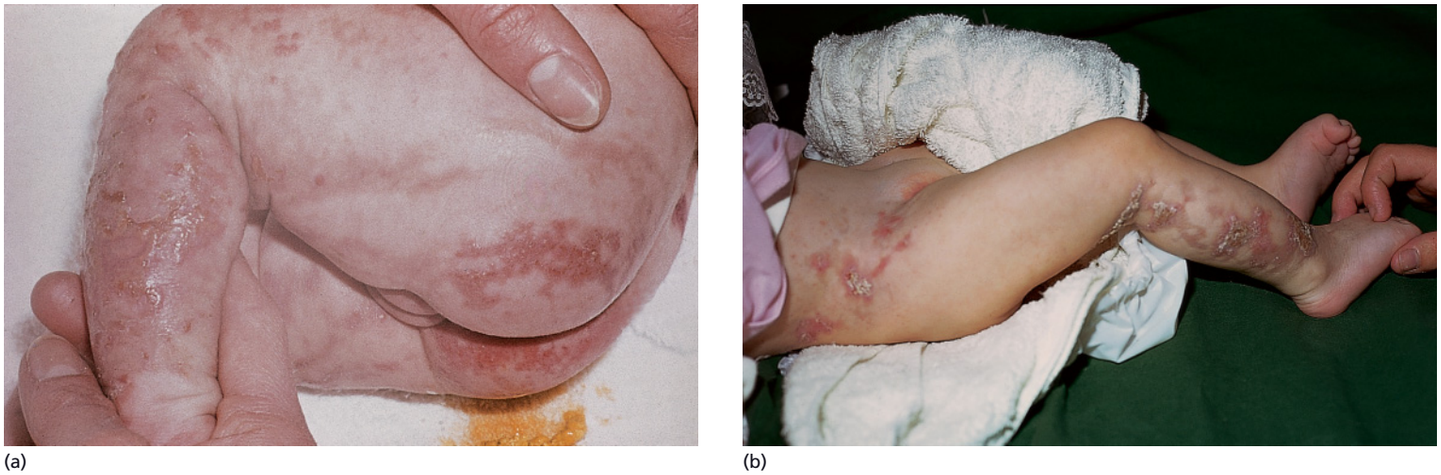


Fig. 58.9 Incontinentia pigmenti. Intraepidermal vesicle containing eosinophils. The spongiotic epidermis has been invaded by an inflammatory infiltrate that includes many eosinophils. Dyskeratotic cells are present.

Ultrastructural studies [12] show that, particularly in the early stages, there are many dyskeratotic cells in the epidermis. In addition to eosinophils, there are activated lymphocytes, basophils and mast cells, especially in the upper dermis. In all three stages, melanophages are present.

Clinical features. Two large studies have defined the clinical features of IP; Carney reviewed 653 cases from the world's literature [4], and more recently Landy and Donnai reported their experience of over 100 cases [5]. The skin changes are often present at birth, have usually developed before the end of the first week and rarely appear after the first 2 months. Four distinct clinical stages are recognized:

Stage 1: inflammatory macules, papules, vesicles and pustules
Stage 2: hyperkeratotic and verrucous lesions
Stage 3: grey-brown pigmentation
Stage 4: atrophic, hypopigmented and depigmented bands or streaks that are hairless and anhidrotic and fail to tan on sun exposure [13].

(a) (b)

Fig. 58.10 Incontinentia pigmenti: (a) linear groups of blisters in a child aged 3 weeks; (b) linear warty lesions on the lower leg of the same child aged 3 months.

The sequence of these stages is irregular, their duration variable and they may overlap. It is possible that the earlier inflammatory stages can occur *in utero* and do not progress after birth. The most striking feature of IP is the clear, tense bullae in linear array that tend to develop along lines of Blaschko on the trunk and limbs (Fig. 58.10). These lesions are usually in recurrent crops; less often they are generalized. The crops persist for a few days or for a month or two. They are accompanied or followed by smooth red nodules or plaques, often irregularly linear, on the limbs and trunk. The plaques may be extensive and may precede the bullae. They may be bluish-purple in colour and may ulcerate. Linear warty lesions may be present on the dorsa of hands and feet at birth, but more typically develop in early infancy, tending to wane by 6 months of age. The pigmentation, which may be the only abnormality, may be present from the outset or may appear as the inflammatory lesions are subsiding. Inflammatory lesions can develop in areas that are already pigmented. Activity may rarely persist into adult life [14]. The pigmentation, ranging in colour from blue-grey or slate to brown (Fig. 58.11), is characteristic of the syndrome, and the bizarre 'Chinese letter pattern' is diagnostic. The hair is usually normal, but in about 25% of cases patches of cicatricial alopecia, resembling pseudopelade, are present from birth or develop in infancy at or near the vertex. The nails are usually normal but may be small and dystrophic.

A number of extra-cutaneous features are also reported (Table 58.4).

Diagnosis. The combination of bullae with linear nodular or warty lesions in a female infant is pathognomonic. During a purely bullous phase the following differential diagnosis should be considered and excluded: infantile pemphigoid, herpes simplex infection, mastocytosis, Langerhans' cell histiocytosis, epidermolysis bullosa. Biopsy of the skin in the blistering phase is often of help in establishing the diagnosis (see Fig. 58.10) with the presence of many eosinophils in the epidermis and dermis.

Treatment. Usually no treatment is necessary other than the control of secondary infection. Systemic therapy with corticosteroids or sulfapyridine (sulphapyridine) is usually unsuccessful. Skilled dental supervision will minimize the cosmetic disability. As with other serious genetically determined disorders, family counselling should be offered. Ophthalmic examination in infancy is mandatory. Dental examination should also be carried out in the early infantile period after the age of one. If neurological features are present, the child should be seen by a neurologist.

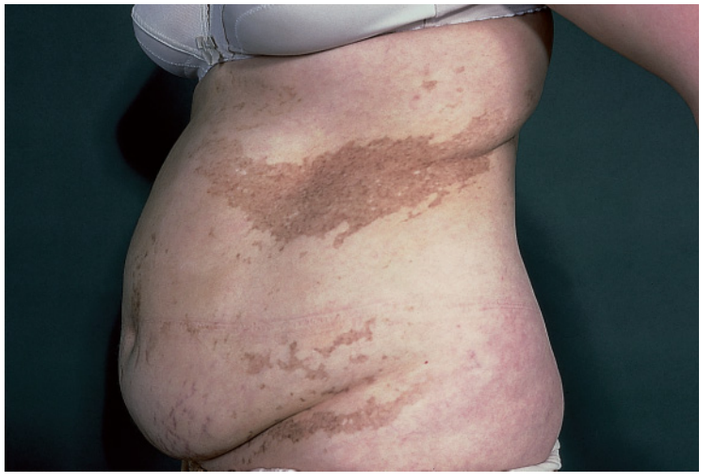

Fig. 58.11 Slate-grey pigmentation on the abdomen of a woman who had blistering lesions in childhood and who gave birth to a child with typical incontinentia pigmenti.

Prognosis. The prognosis is determined by the spectrum of clinical features [5]. Thus, those with neurological features tend to do less well than those with more minor manifestations of the syndrome. The pigmentary changes typically fade during childhood years.

Fanconi's anaemia (OMIM 227650) [1–8]

Definition. Fanconi's syndrome is a rare, autosomal recessive condition characterized by widespread, mottled skin pigmentation, bone marrow failure and a tendency to develop malignancy. The syndrome was first described in three brothers with aplastic anaemia, skeletal malformations, genital hypoplasia, retarded growth and pigmented macules on the trunk [1]. The full syndrome occurs more frequently in boys than in girls.

Pathogenesis. Most of the Fanconi genes have been cloned yet the exact function of their gene products remains uncertain [2]. Possibilities include a role in DNA repair, cell cycle control, regulation of oxidative stress or even the maintenance of apoptosis and telomeres [3].

Clinical features. The age of onset is usually between 4 and 10 years, and either cutaneous or haematological abnormalities may be the presenting manifestation [4]. In most cases there is generalized, dusky or olive-brown pigmentation, often most intense on the lower trunk, flexures and neck. Typically, scattered over the dusky areas are depigmented macules of 'raindrop' type and macules of darker pigmentation. Rarely, only café-au-lait macules are present. The oral mucosa is not involved [5].

A constant feature is progressive hypoplastic anaemia with neutropenia and thrombocytopenia, usually presenting as an increased bleeding tendency. The haematological manifestations appear earlier in males. The pancytopenia usually causes death in 2–5 years. Treatment of anaemia with anabolic steroids improves survival. Haematological defects may also be present in otherwise normal siblings. There is an increased incidence of acute leukaemia and other neoplasms.

Diagnosis. The diagnosis of Fanconi's anaemia is usually suspected in a child with hypogonadism, pigmentary changes and aplastic anaemia. The association of pigmentation of very similar type with pancytopenia is seen only in dyskeratosis congenita. Prenatal diagnosis is now possible by demonstrating increased spontaneous and induced chromosomal breakage in cultured fetal amniocytes or chorionic villous cells [6]. Complementation groups can be determined using retroviruses expressing FANCA, FANCC or FANCG cDNA [3].

Prognosis. The prognosis is poor due to aplastic anaemia. Bone marrow or cord blood transplant can be curative [7]. Average life expectancy for Fanconi's anaemia is 20 years [8].

McCune–Albright syndrome (OMIM 174800, 139320) [1–8]

Albright *et al*. [1] described a syndrome, in 1937, characterized by polyostotic fibrous dysplasia, skin pigmentation and (in females) precocious puberty. In McCune–Albright syndrome, fibrous dysplasia of bone occurs in association with hyperpigmented skin lesions (café-au-lait macules), gonadotropin-independent sexual precocity, and/or endocrine and non-endocrine manifestations [2].

Aetiology. McCune–Albright syndrome results from somatic mutations during early development, resulting in a widespread mosaic of normal and mutant-bearing cells. Thus, the clinical presentation of each patient is determined by the extent and distribution of abnormal cells. These mutations encode constitutively active forms of G(s)α, the ubiquitously expressed G protein α-subunit that links hormone receptors to intracellular cAMP generation. These mutations result in the loss of amino acid residues required to deactivate the G protein, leading to prolonged activation of G(s)α and its downstream effectors. This explains why McCune–Albright syndrome patients suffer from the effects of excess stimulation of multiple peripheral endocrine glands, without having appropriately raised stimulatory hormones. The skin hyperpigmentation is one such example of this phenomenon; increase in skin pigmentation is mediated through G(s)α/cAMP. Parental origin of the mutated allele influences the clinical presentation, as G(s)α is imprinted and expressed only from the maternal allele in some tissues [3].

Simple monostotic and polyostotic fibrous dysplasia affects the sexes equally and is relatively common. Fibrous dysplasia with associated pigmentation is unusual and is more frequent in females than in males. The full McCune–Albright syndrome with precocious puberty is seen mainly in girls [2–4], although males may develop isolated testicular enlargement [5].

Pathology. In the majority of patients, the number of melanocytes is not increased either in the lesions or in normal skin, and in split-skin preparations the giant pigment granules characteristically seen in Malpighian cells and melanocytes in neurofibromatosis are rarely to be found [6].

Clinical features [7]. Cutaneous pigmentation usually develops between the ages of 4 months and 2 years, but may be present at birth. Extensive light-brown patches, often with an irregular or serrated margin, occur mainly on the trunk, buttocks and thighs, but may rarely involve the face and neck. They tend to be asymmetrical and to be most extensive on the side showing the most severe bone involvement (Fig. 58.12).

Fig. 58.12 Large pigmented macules in a child with Albright's syndrome. (Courtesy of Professor N.R. Rowell, Leeds General Infirmary, Leeds, UK.)

The bone lesions usually reveal themselves during the first decade by aching pain, pathological fractures and secondary deformities [3]. Bony overgrowth at the base of the skull may produce defective vision or proptosis. Serum calcium and phosphorus are normal but alkaline phosphatase may be elevated if the bone lesions are numerous. In females, precocious puberty, manifested by breast enlargement or by vaginal bleeding and growth of pubic hair, occurs below the age of 5 years in about 50% of cases and between 5 and 10 years in 30%. Growth in childhood is accelerated but the epiphyses unite prematurely. Other developmental abnormalities may be associated. The prognosis for life is good and the pathological fractures unite normally.

Diagnosis. There is no single clinical feature of the pigmented lesions that reliably differentiates McCune–Albright syndrome from neurofibromatosis, in which bone lesions and endocrine disturbances may also occur. The presence of many café-au-lait macules, freckles in the axillae and Lisch nodules on the iris are diagnostic for neurofibromatosis. Giant pigment granules may also rarely be found in McCune–Albright syndrome. Peptidic nucleic acid clamping is a rapid, reliable and economical method to diagnose McCune–Albright syndrome [8]. Negative results by peptidic nucleic acid clamping should be confirmed by nested polymerase chain reaction [8].

Other hereditary disorders with hypermelanosis

Increased pigmentation is an incidental or inconstant feature of many other genetically determined syndromes characterized predominantly by ectodermal dysplasia or diffuse connective-tissue defects. Such conditions are described in other chapters but are briefly mentioned below in differential diagnosis. There are also a number of unusual syndromes of which pigmentation is the most conspicuous or the only manifestation. The inter-relationships, classification and nomenclature of some of these syndromes, of which few examples have been reported, are not reliably established [1,2].

Familial progressive hyperpigmentation (MIM *145250) [1–4]

Familial progressive hyperpigmentation was first reported using this diagnostic term by Chernosky *et al*. in 1971 [1]. They described a black family with diffuse macular areas of hyperpigmentation that were present at birth and increased in size and number with age. Pigmented macules also involved mucosal surfaces. Four individuals in two generations were affected. More recent reports in both large and small kindreds suggest autosomal dominant inheritance [2–4]. The diagnosis is made on the basis of the extent and depth of the hyperpigmentation in the absence of an alternative explanation. Histological features include markedly increased amounts of melanin throughout the epidermis, with great density in the basal layer and no pigmentation in the dermis. There is no known effective treatment, but the prognosis is good with no adverse associations.

Periorbital hyperpigmentation

Some darkening of the skin around the eyes is not uncommon. Familial periorbital hyperpigmentation is characterized by dark circular areas around the eyes. Peters [1] reported a kindred of 20 individuals in five generations and first speculated that this might be an autosomal dominant disorder. Additional large pedigrees have confirmed the heritable nature of this condition [2–4]. The sexes are equally affected. Increased pigmentation is first noted below the lower eyelids at the approach of puberty. There is wide variation in its ultimate extent and intensity, but it is seen more frequently in individuals with dark complexions [5]. There is no known treatment for this disorder.

Naegeli–Franceschetti–Jadassohn syndrome (MIM *161000) [1–11]

Synonym
- Naegeli's syndrome

This rare syndrome, inherited as an autosomal dominant condition, is known in one large Swiss family [3]. A very similar condition with associated onychodystrophy is described in an English family [4].

Reticulate pigmentation develops during the second or third year in a previously normal child. It may become very extensive and is not preceded by any inflammation. Often the neck and axillae are particularly affected. The fine network of hyperpigmentation differs from the irregular splashes and whirls seen in incontinentia pigmenti. Keratoderma of the palms and soles is usual. Hypohidrosis with intolerance to heat is common. The hair and nails are normal, except in the English family where the fingernails and toenails are of almond shape. The teeth may be normal or defective, with yellow discoloration of the enamel. Mental and physical development is normal. In addition to pigmentary incontinence, varying amounts of colloid–amyloid bodies have been found in the superficial dermis [5].

A number of cases have been described that show a combination of some of the features of Naegeli–Franceschetti–Jadassohn syndrome and of incontinentia pigmenti [6–8].

Reticulate hyperpigmentation may be associated with alopecia, nail changes and growth retardation [7] and there may be a history of blisters [9]. There may or may not be sweating defects [10].

Reticular pigmentation with milia has also been described as a variant of Naegeli–Franceschetti–Jadassohn syndrome [11].

Dermatopathia pigmentosa reticularis (OMIM *125595)

Definition. Dermatopathia pigmentosa reticularis was first described by Hauss and Oberste-Lehn in 1958 [1]. It is characterized by widespread reticulate pigmentation in combination with alopecia, nail changes, palmoplantar hyperkeratosis and loss of dermatoglyphics.

Aetiology. It is a rare form of autosomal dominant ectodermal dysplasia, closely related to Naegeli–Franceschetti–Jadassohn syndrome. Loss of protection against proapoptotic signals by a defect in the N-terminal part of keratin molecules may partly explain the unusual features of this syndrome.

Genetics. Both Naegeli–Franceschetti–Jadassohn syndrome and dermatopathia pigmentosa reticularis have been mapped to a common 6-cM interval on 17q11.2-q21 [2,3] which supports the idea that they are allelic disorders [4].

Clinical features. Onset is usually in early childhood or from birth. There is reticulate hyperpigmentation which is most prominent on the trunk. An isolated case from the Netherlands also presented ainhum-like constrictions of the digits [5].

Mendes da Costa–van der Valk syndrome

Synonyms
- Dystrophia bullosa hereditaria
- Typus maculatus

Patients with this rare syndrome, determined by a sex-linked recessive gene, present at birth or in early infancy with universal alopecia associated with red-brown pigmentation on the face and extremities [1]. Affected individuals, all boys, develop non-traumatic intraepidermal bullae, irregularly scattered on trunk and limbs. Conspicuous, coarsely reticulate pigmentation develops on the face and limbs in association with macular atrophy. Some patients are physically and mentally retarded and life expectancy is short [1].

Cantú's syndrome (MIM 114620)

This is an autosomal dominant disorder characterized by hyperkeratosis and hyperpigmentation [1]. Multiple small (1 mm diameter) macules develop on the face, forearms, hands and feet during childhood and adolescence. Some of these coalesce to produce larger lesions. The palms and soles show punctate hyperkeratoderma [1].

Dyskeratosis congenita (MIM #305000, 224230, 127550)

Synonym
- Zinsser–Engman–Cole syndrome

History. The first description of dyskeratosis congenita is credited to Zinsser [1]. The condition was further defined by Engman [2] and Cole [3].

Genetics and pathogenesis. Three different patterns of inheritance have been reported for dyskeratosis congenita: X-linked recessive (MIM 305000), autosomal recessive (MIM 224230) and autosomal dominant (MIM 127550). Of these, the X-linked recessive variant is the commonest, the autosomal dominant variant

the mildest with the best prognosis [4]. The gene for the X-linked variant, *DKC1,* was mapped to Xq28 [5,6] and then identified by Heiss *et al.* in 1998 [7]. The protein encoded by this gene, dyskerin, has been shown to be associated with human telomerase RNA [8]. This in turn led to the identification of *TERC,* which codes for telomerase component 3, as a candidate gene for autosomal dominant dyskeratosis congenita. Subsequent gene studies confirmed the presence of short telomeres and mutations in *TERC* in autosomal dominant dyskeratosis congenita [9,10].

Clinical features. Dyskeratosis congenita is a progressive, degenerative disorder characterized by reticulate hyperpigmentation with poikiloderma of the neck, chest and thighs. Cutaneous and mucosal changes occur in childhood, followed in the second and third decade by marrow failure and malignancy. Other features include nail dystrophy and leukoplakia of the oral, ocular and anal mucous membranes [11–13].

Management. Leukoplakia should be closely monitored for early signs of malignant transformation. Oral retinoids may help to cause regression of skin or mucous membrane dysplasia. Marrow aplasia requires treatment from a haematologist. About half of patients with dyskeratosis congenita die from bone marrow failure.

Becker's syndrome [1–4]

This is different from Becker's naevus. Becker reported three sisters in 1939 with discrete or confluent brown macules on the neck and forearms, present from early infancy [1]. There was no atrophy or telangiectasia. In another case, somewhat similar mottled pigmentation of neck and elbows appeared at the age of 10 years [2].

Two other syndromes defy classification: diffuse pigmentation of the trunk and neck, beginning in the first year, with later development of small white macules in the pigmented areas [3]; and diffuse pigmentation with conspicuous macular depigmentation on the trunk, associated with macular and reticulate pigmentation of the neck [4].

Acromelanosis [1–21]

Diffuse hyperpigmentation of the dorsal aspects of fingers and toes is not uncommon in individuals of dark complexion [1]. It has been reported in individuals of mixed race, white-skinned, black-skinned and oriental people. There may be more than one genotype. The pigmentation begins in infancy or childhood and increases in depth and extent [2,3]. There may be increased pigmentation in the flexures of the finger joints and in the larger joint flexures. A single case report of acromelanosis with hyperpigmentation of genital mucosa in a baby girl has been reported from Spain [4]. The condition must be differentiated from hyperpigmentation induced by repeated trauma. The term 'acromelanosis' has also been used to describe acquired hyperpigmentation of the hands or feet as a manifestation of a drug reaction [5].

Reticulate acropigmentation [6–21]

Reticulate acropigmentation generally has an autosomal dominant pattern of inheritance. Two main variants have been reported: reticulate acropigmentation of Kitamura and reticulate hyperpigmentation of Dohi.

Reticulate acropigmentation of Kitamura

Reticulate acropigmentation of Kitamura is characterized by a network of freckle-like areas of pigmentation which develop on the dorsa of the hands in the first two decades [6–9]. The reticulate pigmentation may subsequently involve most parts of the body (Fig. 58.13). Palmar pits and breakages of epidermal ridge pattern are found. Several individual cases and families have been reported with features of both Kitamura's disease and reticulate pigmented anomaly of the flexures (Dowling–Degos disease) [10–12]. Histologically, the pigment macules show epidermal atrophy and an increased number of melanocytes. It is unclear if bony abnormalities reported in a Saudi female with Kitamura's syndrome were coincidental or linked [13]. Differing patterns of inheritance suggest that this is not always an autosomal dominant disorder [14].

*Symmetrical dyschromatosis of the extremities (MIM *127400)* [15–21]

Synonyms

- Dyschromatosis symmetrica hereditaria
- Reticulate acropigmentation of Dohi

Fig. 58.13 Reticulate acropigmentation of Kitamura. (Courtesy of Dr W.A.D. Griffiths, St John's Institute of Dermatology, London, UK.)

Symmetrical dyschromatosis of the extremities is an autosomal dominant disorder caused by mutations in the double-stranded RNA-specific adenosine deaminase gene (*ADAR1* or *DSRAD*) [15,16]. The syndrome has been reported from Japan, where it is not uncommon, and also in European [17], Afro-Caribbean and Indian patients [18]. During infancy or early childhood, mottled pigmentation with areas of depigmentation develop on the dorsa of the hands and feet and sometimes on the arms and legs [19]. The face is spared, apart from a few scattered, small, discrete, pigmented macules. A single case of neurofibromatosis occurring in association with reticulate acropigmentation of Dohi has been reported from Singapore [20]. A comprehensive review of the literature on acropigmentation of Dohi that included cases reported in Japanese, identified 185 cases worldwide [21].

Reticulate pigmented anomaly of the flexures (OMIM 179850) [1]

Synonym
- Dowling–Degos disease

Reticulate pigmentation of the flexures arises during childhood. The characteristic histological finding is filiform downgrowths in the epidermis with hyperpigmentation of the deepest areas [1–3].

Zosteriform reticulate hyperpigmentation [1–3]

The description of this disorder is encapsulated by its name. There may be an associated change in the texture of the skin within the lesions. This condition arises in children. All four cases reported from Japan showed eosinophilia [1,2].

Schimke immuno-osseous dysplasia (OMIM #242900) [1]

Schimke immuno-osseous dysplasia is a rare autosomal recessive spondyloepiphyseal dysplasia characterized by short stature, unusual facies, hyperpigmented macules, proteinuria with progressive renal failure, lymphopenia with recurrent infections and cerebral ischaemia. There is no effective treatment for patients suffering from this syndrome other than supportive measures.

Neurofibromatosis (OMIM *162200) (see Chapter 15)

Café-au-lait marks are present in 90% of patients with neurofibromatosis, particularly in those with NF-1, and may appear early. They are round or oval patches of light-brown pigmentation. They are also found in 10% of normal subjects. The presence of one or two is not diagnostic in the absence of other signs of the disease but if six or more are present, with a diameter of 5 mm or more, the probability of neurofibromatosis is high.

Extensive melanotic macules can also occur and resemble those seen in Albright's syndrome; however, these tend to be confined to a particular site and are on either side of the midline. Axillary freckling is common in neurofibromatosis and is an aid to the diagnosis. Lisch nodules and iris hamartomas are present in most patients over the age of 6 years (Fig. 58.14). Giant pigment granules (macromelanosomes) are found in the café-au-lait macules (Fig. 58.15).

NF-1 accounts for 85% of all neurofibromatosis. The NF-1 gene has been identified on the proximal long arm of chromosome 17 [1,2]. It is inherited as an autosomal dominant trait with variable penetrance and expression, and a spontaneous mutation rate of around 50%. NF-2 has the same mode of inheritance, high spontaneous mutation rate, high penetrance and variable expression as NF-1. The NF-2 gene is located near the centre of the long arm of chromosome 22 [3].

Werner's syndrome (MIM #277700) [1–5]

Werner's syndrome is a rare, autosomal recessive disorder characterized by primary growth retardation, premature ageing, an increased prevalence of malignancy, high levels of atherosclerosis and type 2 diabetes [1]. Localized or diffuse hyperpigmentation is commonly seen [2]. Less commonly, depigmented spots with greying of the hair are present [2–3]. Most cases are caused by mutations in the gene encoding the RecQ helicase WRN [4].

Marked genomic instability explains the increased cancer risk in Werner's syndrome [5].

Gaucher's disease and Niemann–Pick disease

(see Chapter 59)

Pigmentation of two types occurs in adults with Gaucher's disease: brown patches of chloasma type on the face, neck and hands; and symmetrical pigmentation of the lower legs with a sharp lower margin and an irregular upper margin. There may also be a brown, wedge-shaped thickening of the bulbar conjunctiva.

In the acute infantile form of Gaucher's disease, the skin is not pigmented, but in Niemann–Pick disease there is diffuse brown pigmentation, most marked on the face.

Xeroderma pigmentosum (see Chapter 15) [1]

Freckle-like pigmentation of the face and other exposed skin begins in infancy or early childhood. The light- or dark-brown macules are associated with telangiectases, small white atrophic spots and later with keratoses and tumours. The freckled sun-exposed skin with associated severe photosensitivity in a young child is a striking clinical phenotype not easily overlooked.

Hypermelanosis in endocrine disorders

Some of the mechanisms by which endocrine glands influence melanogenesis are discussed on pp. 58.5–58.7. Here are considered clinical syndromes showing endocrine-induced pigmentary changes (see also Chapter 62).

Addison's disease [1–4]

Increased pigmentation is such a well-known feature of Addison's disease that its absence may significantly delay diagnosis and endanger life [1,2]. When present, the hyperpigmentation of Addison's disease is typically diffuse, and is most intense on areas exposed to light [3]. It is also accentuated in the flexures, at sites of pressure and friction, and in the creases of palms and soles [3]. Normally pigmented areas, such as the nipples and genital skin, darken. Pigmentation of the buccal mucous membrane is often present, and the conjunctival and vaginal mucous membranes may also be involved [3]. However, less distinctive patterns of pigmentation are not exceptional, and in any unexplained cases of hypermelanosis adrenal function should be carefully evaluated. Similarly, patients without hyperpigmentation, but with other features suggesting Addison's disease should have adrenal function assessed. Vitiligo-like lesions may also occur in Addison's disease [3].

The hypermelanosis is the result of increased secretion of melanotrophic hormones by the pituitary. Affected patients have elevated plasma levels of β-MSH-like immunoreactivity [4]. Absence of hypermelanosis in Addison's disease was explained in a single case by a high degree of melanosome degradation in secondary lysosomes [1].

Acromegaly

Pigmentation of Addisonian pattern is present in some cases of acromegaly, and may be a striking feature.

Cushing's syndrome [1–4]

Pigmentation of Addisonian pattern has been noted in about 10% of reported patients with Cushing's syndrome. It is an indication of secretion of ACTH and β-MSH by the pituitary and suggests the presence of a pituitary tumour. After adrenalectomy, progressive hypermelanosis develops in a proportion of patients, about 10%, in spite of adequate hormone replacement therapy. Only in half of these patients is the sella turcica enlarged [1,2]. These patients with Nelson's syndrome [3] show marked hypermelanosis, with the mucous membranes also being involved (see Fig. 58.6). The hair is often darker and there are sometimes multiple lentigines and longitudinal pigmented bands in the nails. High levels of both β-MSH and ACTH are found in the plasma, with degree of clinical hyperpigmentation correlating well with the quantity of β-MSH in the plasma [4].

4 Abe K, Nicholson WE, Liddle GW *et al*. Normal and abnormal regulation of β-MSH in man. *J Clin Invest* 1969; **48**: 1580–5.

Hyperthyroidism

Pigmentation occurs in about 10% of patients with primary thyrotoxicosis [1]. It is usually diffuse and is broadly of Addisonian pattern, although involvement of the mucous membranes is uncommon and pigmentation of nipples and genital skin is less striking. The eyelids are occasionally conspicuously pigmented (Jellinek's sign). Some patients show chloasmal rather than diffuse

pigmentation. The incidence of vitiligo is increased. Diffuse pigmentation was present at birth in the infant of a thyrotoxic mother [2].

2 Arakawa T. Hyperpigmentation of the skin with DOPA-uria of a newborn. *Tohoku J Exp Med* 1963; **80**: 329–37.

Pregnancy and menstruation

Increased pigmentation is almost invariable in pregnancy and is most marked in brunettes. A blotchy hypermelanosis of the face involving the cheeks, forehead and chin is frequently seen. This was called chloasma, but the term 'melasma' is now preferred (see p. 58.34). The pigmentation may involve the neck and is associated with darkening of the nipples, the linea alba to form the linea nigra, and the anogenital skin. The pigmentation usually fades after parturition, but may persist for months and years. The same pigmentation can be idiopathic and familial and is particularly seen in those who tan readily when exposed to bright sunlight [1,2]. It is noted by some women to be more apparent just prior to menstruation [3].

Oral contraceptives

Melasma (chloasma) (see p. 58.34) is frequently seen in women on oral contraceptives. No one oral contraceptive appears to be more liable than any other to cause pigmentation in predisposed subjects. The hypermelanosis is made more apparent with sun exposure. These patients also develop the same pigmentation when pregnant [4]. The pigmentation takes a long time to fade after discontinuing oral contraception and, as after pregnancy, it may never fade completely.

The mechanism is not fully elucidated and although MSH may be involved it plays a minor part. Oestrogens and progesterone are involved in the increased pigmentation but other factors are also implicated [2]. In a study of idiopathic melasma it was suggested that some of the patients had mild ovarian dysfunction [5]. Plasma concentrations of MSH are normal in patients with idiopathic melasma [5] and in those on oral contraceptives [6].

Phaeochromocytoma

Pigmentation of Addisonian pattern occurs in some cases of malignant phaeochromocytoma. Hypertension, headaches, profuse sweating, palpitation and apprehension will suggest the diagnosis, which is established by the abnormal plasma catecholamines.

Carcinoid syndrome

Hyperpigmentation of the skin has been noted in a number of patients with this syndrome.

ACTH administration [1,2]

A small proportion of patients treated with ACTH in high dosage (120 units/day) develop pigmentation of Addisonian pattern. The pigmentation, which is accompanied by a combination of Addisonian and cushingoid manifestations, fades when the dose is reduced. The incidence of melanosis appears to be rather higher in patients treated with tetracosactrin [2].

Hypermelanosis in other systemic disorders

Increased pigmentation is an inconstant feature of a wide variety of systemic disorders and may be associated with malignant disease. In most instances, the mechanism is obscure although, in some, elevated levels of β-MSH-like immunoreactivity are found. A genetic predisposition may be present in those affected. The hypermelanosis may be diffuse or localized. It may be confined to the epidermis, when the skin appears brown in colour, or it may be in the dermis, when often the skin is a slate-grey or blue colour. Pigments other than melanins may also be present.

Neoplastic disease [1–5]

In cachectic states there may be diffuse hyperpigmentation of the skin as in Addison's disease. The mechanism is uncertain. In the ectopic ACTH syndrome, which may occur in patients with oat cell carcinoma of the bronchus, pigmentation is usual. The tumour has been shown to produce a distinct MSH-like compound [1].

In adults, acquired acanthosis nigricans may rarely be associated with internal malignancy, almost invariably an adenocarcinoma. The hypermelanosis affects the axillae, nipples and umbilicus, which also show a warty papillomatosis. These skin changes may later become generalized. The mucous membranes are frequently involved.

A diffuse dermal melanosis, having a slaty-blue colour, can occur secondary to melanoma and melanogenuria [2,3]. Ultrastructural studies on this rare condition have shown in one patient [4] single-cell metastases disseminated widely through the skin; in another [5] the dermal histiocytes contained many lysosomal bodies containing electron-dense granular material, presumably melanin.

Lymphomas [1–3]

Pigmentation is an uncommon manifestation of lymphomas, occurring in 10% of cases of Hodgkin's disease and in 1 or 2% of cases of lymphosarcoma and lymphatic leukaemia. The pigmentation is of Addisonian type, but allegedly without involvement of the mucous membranes. Malnutrition may be a factor and post-inflammatory pigmentation after scratching may modify the clinical pattern. Diffuse progressive hyperpigmentation can also be a manifestation of mycosis fungoides [1,2]. A number of different clinical patterns of early mycosis fungoides have been described, including pigmented purpura-like lesions [3]. Several of the cytostatic drugs used for the treatment of these disorders can also produce increased pigmentation of the skin.

Diseases of the nervous system [1–3]

Pigmentation, usually conforming to the Addisonian pattern, occurs in some diseases of the nervous system, particularly those involving the diencephalon and the substantia nigra. Intense pigmentation is a feature of Schilder's disease [1] but some increase in pigmentation is not uncommon in hepatolenticular degeneration [2] and in ependymomas. It is occasionally noted in chronic schizophrenia. In post-encephalitic Parkinsonism, it may be diffuse but may be melasmal. Pigmentation may sometimes develop after intense and prolonged emotional stress [3].

Rheumatoid arthritis and Still's disease [1,2]

Pigmentation, usually generalized, is occasionally observed in rheumatoid arthritis and is a more frequent feature of Still's disease. It may sometimes be caused by medication taken to treat the rheumatoid arthritis, such as minocycline [1] or methotrexate [2].

Systemic sclerosis, scleroderma and morphoea [1–9]

Generalized pigmentation in systemic sclerosis and scleroderma may be intense and diffuse or of Addisonian type, but without mucous membrane involvement [1]. It may involve predominantly the face and limbs but is often far more extensive than the scleroderma (Fig. 58.16). Hyperpigmentation in systemic sclerosis is seen most commonly in patients with pigmented skin, and is less common in whites [2]. Keratinocyte endothelin-1 production has been implicated as playing a central role in the pathogenesis of cutaneous hyperpigmentation in systemic sclerosis [3], as has local expression and systemic release of a stem cell factor [4]. Levels of soluble cell surface L-selectin are elevated in systemic sclerosis with diffuse hyperpigmentation [5].

Pigmentation may also be a conspicuous feature of morphoea [6] and is occasionally the presenting symptom (Fig. 58.17). Hyperpigmentation is sometimes a feature of atrophoderma of Pasini and Pierini [7], and has also been reported in the linear atrophoderma of Moulin [8]. Prominent post-inflammatory hyperpigmentation has been reported in a case of porphyria cutanea tarda with idiopathic myelofibrosis and CREST syndrome [9]. A colorimetry device has helped to define the pigmentation changes of extensive scleroderma [10].

Dermatomyositis and lupus erythematosus [1,3]

Diffuse pigmentation may accompany or follow the cutaneous lesions of dermatomyositis [1]. Acanthosis nigricans has also been reported in association with dermatomyositis [2]. In systemic lupus erythematosus, diffuse pigmentation of light-exposed skin occurs in about 10% of cases. It may gradually darken, although the disease is controlled by treatment. Longitudinal melanonychia may occasionally be a feature of systemic lupus erythematosus [3].

Multiple organ failure [1]

Patients with multiple organ failure who survive for long periods are susceptible to hyperpigmentation. Renal failure, hepatic failure and polypharmacy may all contribute to this. An unusual case of intense green colour in a patient with multiple organ failure was attributed to dyes in the liquid tube feeds [1].

Reference

1 Czop M, Herr DL. Green skin discoloration associated with multiple organ failure. *Crit Care Med* 2002; **30**: 598–61.

Renal failure [1–4]

Chronic renal disease with nitrogen retention is frequently accompanied by increased pigmentation of the skin. This hypermelanosis is diffuse and brown in colour. It is most intense on the hands and face. Hyperpigmented macules are common on the palms and soles [3]. Elevated levels of β-MSH are found in the plasma of these patients [1,2] and cause the excess production of melanin in the skin. The increased levels of β-MSH-like immunoreactivity are due to slow clearance by the kidney rather than increased production by the pituitary. Lipochromes and carotenoids deposited in the skin may also play a part. Paradoxically, hypopigmentation with acquired lightening of hair is sometimes a feature of chronic renal failure [4].

Anaemia [1–8]

Hyperpigmentation of the skin occurs in vitamin B_{12} deficiency and is more common in dark-skinned races [1]. A diffuse brown pigmentation is also seen occasionally in patients with folic acid deficiency [2,4]. Pigmentation of the fingertips and nails of a patient with B_{12} deficiency has been reported [5]. The pigmentation seen in association with B_{12} deficiency often has a rather dappled and mottled appearance, and particularly affects the face, hands and feet [3,5,7]. Sometimes, only the fingers are affected. Treatment with vitamin B_{12} reverses the pigmentation of the skin to normal [7,8]. Pigmentation also occurs in megaloblastic anaemia associated with pregnancy [2]. In the haemolytic anaemias, hypermelanosis and haemosiderosis may develop on the lower legs.

Primary biliary cirrhosis

A diffuse hypermelanosis is seen in patients with cirrhosis due to many aetiological factors, and is particularly striking in patients with primary biliary cirrhosis. The hyperpigmentation is particularly striking on sun-exposed sites. The excess melanin is dispersed widely in the epidermis [1]. No significant difference from normal controls is observed in the levels of MSH-like peptides [1].

Haemochromatosis

The disease haemochromatosis was first described by Troisier, Hanot and Chauffard in 1865 [1]. The term 'haemochromatosis' was subsequently coined by von Recklinghausen in 1899 in recognition that the skin pigmentation originated from the blood [1]. Pigmentation, bronzed or greyish in colour, initially involves exposed sites but later becomes generalized [2,3]. It is present in most cases [3], but may be subtle. The diagnosis should be suspected when pigmentation of this pattern occurs in middle-aged men in association with an enlarged liver and diabetes [4]. The diagnosis is confirmed by the high level of serum iron. Hyperpigmentation is reversible with phlebotomy [5]. Haemochromatosis is a common disease whose diagnosis is often overlooked [6]. However, only 50% of homozygous patients show clinical features of the disease [7].

Amyloidosis

Localized pigmentation, often symmetrical, is seen in both lichen and macular amyloidosis [1,2]. The macular type of amyloidosis may be mistaken for post-inflammatory hyperpigmentation, but the lesions usually have a distinctive 'ripple' pattern, and microscopic studies reveal the presence of amyloid. Melanophages are found in the papillary dermis. The melanin contained in these dermal cells is derived from degenerating basal keratinocytes and melanocytes [1,3]. Macular amyloidosis is seen most commonly on the upper back (interscapular areas), chest, buttocks, forearms and shins.

Vitamin A deficiency

Severely malnourished patients with the ocular lesions of vitamin A deficiency tend also to show cutaneous changes. In children, dry skin is the main manifestation of vitamin A deficiency and may be associated with hyperpigmentation of the face and limbs. In adults there is dryness and scaling of the skin with desquamation and generalized hyperpigmentation. Conjunctival pigmentation has been noted particularly in oriental races and may be striking, especially in the lower fornix and bulbar conjunctiva.

Pellagra

Pellagra, the classic clinical manifestation of niacin deficiency, is characterized by erythema and hyperpigmentation of sun-exposed sites. It was first described by Gaspar Casal in the Asturias region of Spain in 1735 [1]. The nutritional basis for the disorder was established by Joseph Goldberger of the United States Public Health Service in the 1910s [2]. However, it was Conrad Elvehjem of the University of Wisconsin who finally proved that pellagra was caused by a deficiency in niacin [3]. Affected skin becomes hard, dry and cracked and in extreme cases is black in colour [4]. The sites of involvement are the sun-exposed skin of the face, neck, dorsa of hands and feet, and sometimes the forearms. Mucosal sites are also affected. Treatment of pellagra consists of 300 mg of oral niacin per day.

Malabsorption syndromes

In sprue and other malabsorption syndromes, pigmentation is of common occurrence and may sometimes be prominent [1,2]. It may be of Addisonian type but without involvement of the mucous membranes, or may occur in well-defined patches on the face and neck and occasionally on the trunk. The scaly inflammatory plaques (see Chapter 59) that may develop in these syndromes are usually followed by intense pigmentation.

Vagabond's disease

This classically occurs in those in whom lack of food is combined with lack of cleanliness, and heavy infestation with pediculi. The

pigmentation is basically of Addisonian pattern and the mucous membranes may be involved. The pathogenesis is uncertain, but the hypermelanosis is probably post-inflammatory and related to the scratching from the pediculosis infestation. Areas of hypomelanosis occur and there is a decrease in the number of melanocytes that show degenerative changes [1]. Adrenal function is in most cases normal [2].

Peripheral neuropathy with dysproteinaemia, skin changes and endocrinopathy

Synonyms

- Crow–Fukase syndrome
- Shimpo's syndrome
- PEP syndrome
- POEMS syndrome

This multisystem disorder, characterized by polyneuropathy, dysglobulinaemia, anasarca, pigmentation, scleroderma, hypertrichosis, endocrinopathy, hepatosplenomegaly and lymphadenopathy, is discussed in Chapter 62.

Hypermelanosis of drug origin [1–4]

Skin pigmentation may be induced by a wide variety of drugs [1]. Several mechanisms are involved in drug-induced changes of pigmentation of the skin. These include increased melanin synthesis, increased lipofuscin synthesis, deposition of drug-related material and post-inflammatory hyperpigmentation. For example, the phenothiazines, particularly chlorpromazine, react with melanin to form drug–pigment complexes. In contrast to melanin, the chlorpromazine–melanin complexes are not metabolized by the body. On discontinuing chloropromazine and related phenthiazines, the pigmentation sometimes fades slowly, but more often is permanent. Many drugs induce hypermelanosis as a non-specific post-inflammatory change in predisposed subjects. The pigmentation following fixed drug eruptions is of this type. Other drugs induce pigmentation more directly; in the case of arsenic it is believed that it combines avidly with sulphydryl groups in the epidermal cells and promotes the action of tyrosinase. A post-inflammatory hyperpigmentation of the skin is seen following the resolution of drug-induced lichenoid reactions. Oestrogens stimulate melanin production, and drug-induced hyperpigmentation may be seen with the combined oral contraceptive. Hyperpigmentation in AIDS patients may occur as a complication of drug therapy, most notably with zidovudine which causes pigmentation of nail, skin and oral mucosa.

Chlorpromazine and related phenothiazines [1–10]

Blue-grey pigmentation of the sun-exposed areas of the skin is seen in a small percentage of patients receiving high doses of chlorpromazine for long periods [1,2]. The pigmentation is cumulative and some develop a purplish tint. Related phenothiazines may cause a similar effect, but chlorpromazine is usually implicated [3]. Some of those affected also develop cataracts, corneal opacities and pigmentation of the conjunctivae [4]. The nail beds are also affected in severe cases [2]. The mechanism is uncertain, as discussed above, but probably involves drug–melanin complexes. There is extensive deposition of melanin-like material throughout the reticuloendothelial system and involving the parenchymal cells of internal organs. The pigment found in the cells of the dermis stains as for melanin [1,2]. Electron microscopy studies [5] show increased melanin in the epidermis and perivascular macrophages in the dermis that contain electron-dense particles. Radioactively labelled chlorpromazine is found to localize in tissues containing melanin [6]. It is believed that this drug or some metabolite is bound to melanin in the tissues [8]. The level of immunoreactive β-MSH in the plasma of these patients is within the normal range [7]. A blue-grey pigmentation of the sun-exposed areas of skin has also been reported with trifluoperazine and imipramine [9,10].

Hydantoin [1,2]

Phenytoin (diphenylhydantoin) is the prototype of the hydantoin derivatives. Some 10% of patients receiving hydantoin preparations develop pigmentation of the face and neck, resembling chloasma, which fades in a few months when the drug is stopped. It has been suggested that hydantoin exerts a direct action on the melanocytes inducing dispersion of melanin granules in the cutis, in addition to increased pigmentation of the basal epidermis.

A patient on this drug developed pigmentation of Addisonian type and other evidence of hypoadrenalism [2].

Arsenic (see Chapter 75)

Prolonged ingestion of inorganic arsenic may result in diffuse pigmentation, most intense on the trunk, where macular areas of depigmentation within areas of hyperpigmentation produce the distinctive 'raindrop' appearance [1]. Many cases also show arsenical keratoses, but the severity of the two manifestations of arsenic poisoning is not necessarily proportionate and either may be present alone.

Antimalarial drugs [1–5]

About 25% of patients receiving chloroquine or hydroxychloroquine for several years develop bluish-grey pigmentation on the face and neck and sometimes the lower legs and forearms. With continued therapy, the areas darken, particularly oval patches on the shins, which increase in size. A blue-black colour may develop. Also, these patches are more pigmented in the light-exposed areas. The nail beds may be affected diffusely or in transverse bands and the hard palate may be bluish-grey. Bleaching of the colour of the hair occurs and when associated with pigmentation of the skin should suggest the diagnosis [4]. Corneal and retinal changes may develop following pigmentation of the skin due to antimalarials [3]. Chloroquine has been shown to have an affinity for dermal melanin [4]. A yellowish pigmentation of the skin is common with mepacrine [5]. Pigmentation appears to result from complexes of melanin, haemosiderin and mepacrine, in combination with sulphur [5]. Quinine and quinidine may also produce a generalized pigmentation [3,6].

Antitumour agents [1–7]

Long-term administration of busulfan (busulphan) produces a diffuse brown pigmentation, particularly in non-white people with a dark complexion. Less commonly, Addison's disease is simulated [2,3]. Light and electron microscopy studies suggest that busulfan has both a stimulatory and a toxic effect on melanocytes [4]. Both busulfan and doxorubicin cause mucous membrane pigmentation. Other cytostatic drugs that may produce hyperpigmentation include cyclophosphamide, bleomycin, fluorouracil, hydroxyurea, daunorubicin, methotrexate, mithramycin, mitomycin, thiotepa and adriamycin [6,7]. Topical cytostatic drugs that produce localized hyperpigmentation include carmustine, mechlorethamine and fluorouracil. Patients on cyclophosphamide [5], bleomycin, daunorubicin, doxorubicin and fluorouracil can develop banded or diffuse pigmentation of the nails. Hair pigmentation may be induced by methotrexate, and pigmentation of the teeth may be seen with cyclophosphamide.

Fixed eruptions [1–6]

Circumscribed areas of slate-brown pigmentation commonly follow the erythematous and bullous stages of fixed eruptions (see Chapter 75) but almost universal brown pigmentation has followed the long-continued ingestion of phenolphthalein [3]. Fixed eruptions are particularly frequent in black people. More or less symmetrical, discrete patches are usually seen but the melanosis may be diffuse or melasmal, and the mucous membranes may be involved [4,5]. The slate-brown colour in fixed drug eruption is due to pigmentary incontinence with melanophages in the upper dermis [6].

Post-inflammatory hypermelanosis

Hypermelanosis commonly follows acute or chronic inflammatory processes in the skin. The intensity and persistence of the hypermelanosis are greater in dark-skinned subjects. The degree

of inflammation appears to be of less significance in determining the pigmentary response than the nature of the dermatosis, for it may be frequent and severe after some conditions and slight after others. Disorders where there is disruption of the basal layer of the epidermis, such as lichen planus or lupus erythematosus, frequently develop areas of slate-brown hypermelanosis. Similarly, in fixed drug eruptions, hyperpigmentation occurs owing to damage of cells in the basal layer. There is pigmentary incontinence with melanophages in the upper dermis [1]. In the late phase of chronic graft-versus-host reaction, there is a poikilodermatous appearance with hyperpigmentation [2].

Hypermelanosis of the epidermis may also occur in inflammatory disorders, but more frequently there is hypomelanosis of the skin. This results from an increased mitotic rate of keratinocytes and diminished transfer of melanosomes from the melanocyte to these cells, which also exhibit a reduced transit time from the basal layer to being shed on the skin surface. Very frequently in inflammatory disease in the skin, hypermelanosis and hypomelanosis occur together, often with a slaty-blue colour due to the presence of melanophages in the upper dermis. There may be an associated loss of functional melanocytes in the skin [3].

The cause of the pigmentation is usually obvious, although the preceding lesions have sometimes not been noticed by the patient or have been transitory or clinically imperceptible. The pattern and distribution of the pigmentation will sometimes allow a retrospective diagnosis, as in lichen planus, herpes zoster, dermatitis herpetiformis and papular urticaria. Pigmentation is often conspicuous after lichenoid drug eruptions, and is a feature of lipomelanic reticulosis.

An unexplained, but not excessively rare, clinical syndrome has been reported in some dark-skinned white people [4]. A small, irregular patch of hypermelanosis of the interscapular skin is often intensely pruritic. It seems likely that this condition is in fact notalgia paraesthetica [5,6] (see Chapter 63).

Reticulate pigmentation following the vascular network is characteristic of erythema ab igne (see Chapter 28), which may occur at any site regularly exposed to the heat of a fire or a hot-water bottle. A reticulate pigmentation is also seen in prurigo pigmentosa, a dermatosis mostly occurring in Japan [7].

Post-inflammatory hyperpigmentation may occur following trauma to the skin. It can occur following dermabrasion and particularly in those who are racially pigmented. Unusual patterns may declare their origin, for example the tooth-mark pattern on an ill-treated child [8] or the symmetrical pigmentation of the sides of the chin in a patient who, as a nervous tic, chews the buccal mucosa [9].

In late secondary syphilis, especially in women, so-called syphilitic leukoderma is occasionally seen. Diffuse hypermelanosis of the sides and back of the neck and the shoulders is mottled with depigmented macules 1–2 cm in diameter. The Wassermann reaction is always positive. A deep-blue or slate-grey hyperpigmentation is seen in late pinta (see Chapter 30).

Tanning with UV light

Tanning is the term used to describe the pigmentary response of the skin following exposure to ultraviolet radiation. Tanning occurs in three distinct phases: immediate pigment darkening, persistent pigment darkening and delayed tanning. Immediate pigment darkening (IPD) occurs in response to low doses of UVA. It appears within minutes of UV exposure and typically fades within 10–20 min. Clinically, immediate pigment darkening manifests as grey-brown pigmentation. IPD is believed to result from oxidation and redistribution of pre-existing melanin. Higher doses of UVA induce persistent pigment darkening (PPD) which persists for 2–24 h. This pigmentation is brown and is also caused by oxidation and redistribution of pre-existing melanin. Delayed tanning involves the formation of new melanin due to increased numbers of melanocytes and increased melanocyte activity. Both UVA and UVB are able to induce delayed tanning, but UVB is more effective. Delayed tanning becomes visible about 72 h after UV exposure and persists for 1–2 weeks before gradually fading as keratinocytes are shed from the skin surface.

Tanning and DNA damage are closely associated. Repeated suberythemal doses of UV light induce tanning but have also been shown to induce DNA damage [1]. Tanning salon exposure has also been demonstrated to induce cyclobutane pyrimidine dimers and p53 protein expression in epidermal keratinocytes, changes linked with the early stages of cutaneous carcinogenesis [2]. It is widely believed by lay people that a tan provides good protection against sunburn [3]. However, tanned skin has been shown to be less effective against formation of DNA photoproducts than constitutive pigmentation [3] and has a sun protection factor of 3–5 at best. Population-based surveys reveal that tanning remains popular, particularly with the young, and that episodes of sunburn remain common [4,5]. However, newer sunbeds with a greater proportion of UVB are significantly more carcinogenic than the older lamps that emitted primarily UVA, with little UVB [6,7].

Photodynamic and phototoxic reactions [1–5]

Drugs and other chemicals with photodynamic and phototoxic activity have the potential to induce skin hyperpigmentation. Tanning follows the sunburn-like reactions to drugs such as demethylchlortetracycline and imipramine, but does not usually occur after photoallergic reactions [3].

If the photodynamic agent is applied directly to the skin, the intensity of the pigmentary response is greatly enhanced. Transient hyperpigmentation has been reported due to photodynamic therapy in acne [4] and localized scleroderma [5]. Hypermelanosis may sometimes be heavy and persistent following photodynamic and phototoxic reactions. The more or less diffuse patterns of pigmentation so induced are considered below, together with other facial melanoses. Two distinctive clinical syndromes are Berloque dermatitis and phytophotodermatitis.

Phytophotodermatitis

Synonyms
- Meadow dermatitis
- Strimmer dermatitis
- Weed-wacker dermatitis

This is an inflammatory and pigmentary reaction of the skin to light, potentiated by furocoumarins in plants (Fig. 58.18). All the plants reliably recorded as inducing this reaction in humans have been shown to contain furocoumarins, including cow parsley (*Anthrisus sylvestris*) and giant hogweed (*Heracleum sphondylium*) [1,2]. The reaction occurs in those exposed to sunlight after these plants have been crushed on the skin. There is some individual variation in susceptibility but with adequate exposure most will react. If the inflammatory phase is severe, bullae are formed. Milder cases show pigmentary changes without inflammation. Serial dilutions of psoralens may, in exceptional cases, be needed to distinguish photoallergy from phototoxicity [3].

Common clinical patterns for phytophotodermatitis include a bizarre network of pigmented streaks on the legs or arms (meadow dermatitis), and much finer spots and small streaks on forearms and legs from contact with plant material during strimming (strimmer dermatitis). Squeezing limes outside when preparing cold drinks can cause blistering of the hands if carried out on sunny days. Handling celery either at harvest or when it is sold can cause phytophotodermatitis of the fingertips if it takes place in direct sunlight [4].

Fig. 58.18 Phytophotodermatitis. Linear, streaky pigmentation following an acute blistering reaction caused by giant hogweed and sunlight.

Berloque dermatitis (Fig. 58.19) [1–4]

Berloque dermatitis results from the potentiation of UV-stimulated melanogenesis by 5-methoxypsoralen (bergapten) in perfumes containing bergamot oil. There is wide variation in susceptibility, with the reaction occurring in only a small proportion of those exposed [1]. This variation depends on the readiness with which the bergapten is absorbed, the quantity applied, and the intensity and duration of exposure to UV light. Susceptibility is increased by stripping the horny layer. Hot humid conditions favour absorption. The pigmentation occurs in susceptible subjects who have been exposed to light after the application of perfume [2,3]. The distribution of the lesions is therefore variable but their configuration is usually distinctive. Deep-brown pigmentation follows the pattern formed by the trickle of the droplets of perfume over the skin from their points of application. The pigmentation fades after weeks or months. The condition is now much less frequent, although it is a continuing cosmetic problem [4].

PUVA lentigines [1–5]

These pigmented macules are a common complication of PUVA therapy occurring on treatment-exposed areas [1–3]. There is a dose effect with a tendency to greater numbers of lentigines in those who have had more therapy [3]. They vary in appearance and may be numerous in number and small in size. Occasionally, larger irregular lentigines are seen, some with a stellate configuration [3] (Fig. 58.20). PUVA lentigines are usually permanent and show little tendency to remit. A less common clinical pattern is localization of lentigines to sites previously affected by psoriasis, creating an appearance not unlike a naevus spilus [2]. The histology is that of a lentigo. The melanocytes are hypertrophic and some may be cytologically atypical [3]. Similar melanocytic macules have been reported following use of a sunbed [4]. PUVA has also been reported to cause hyperpigmentation of the nails [5].

Erythema dyschromicum perstans

Synonym
- Ashy dermatosis of Ramirez

This clinical syndrome of unknown origin was first reported by Ramirez of El Salvador in 1957 [1]. He initially used the term 'los cenicientos' (the ashen ones) for the ashy discoloration of the skin, but subsequently called this condition 'erythema dyschromicum perstans' [2]. It occurs in both sexes from childhood to old age, and is not uncommon in individuals of intermediate skin colour. Most published cases have been from Central America [3]. Histologically, the active border shows vacuolar degeneration of the basal cells. The epidermis contains much pigment and there is pigmentary incontinence; the dermal vessels are sleeved with an infiltrate of lymphocytes and histiocytes, and there are many melanophages [4]. Ultrastructural studies show vacuoles within the cytoplasm of basal and suprabasal keratinocytes that contain many melanosomal complexes. One study found IgM cytoid bodies on direct immunofluorescence [5].

Clinically, the condition is characterized by numerous macules of varying shades of grey with a red, slightly raised and palpably infiltrated margin. They vary in size and tend to coalesce over extensive areas of the trunk, limbs and face. Against the general greyish background are macules of hypomelanosis or hypermelanosis. The condition is persistent and slowly extends, but causes no symptoms. The pigmented macules resemble very closely the lesions of late pinta, but the negative dark-field examinations, negative serological tests for syphilis and lack of response to penicillin are important features that allow the dermatologist to exclude this treponematosis. There is no established therapy for this condition [6].

Facial melanoses

Hypermelanosis involving predominantly the face and the neck is relatively common and often presents a complex diagnostic problem. Several more or less well-defined clinical syndromes can be recognized, but many transitional forms defy classification. The causes of the pigmentation are often obscure.

Genetic and racial factors are important, the increased pigmentation occurring more frequently in those with dark skins, especially Oriental people. Endocrine factors play a major role in melasma and are implicated to some degree in other melanoses. External agents (light and photodynamic chemicals) are essential factors in the occupational melanoses but are also concerned in Riehl's melanosis, erythrosis and poikiloderma of Civatte. Other unknown factors are certainly implicated, and wide individual variation in susceptibility must be postulated.

Cosmetics may occasionally cause facial melanosis. Facial melanosis is, of course, also a conspicuous feature of Addisonian pigmentation.

Melasma (Figs 58.21 & 58.22)

Synonyms
- Mask of pregnancy
- Chloasma

Fig. 58.22 Melasma.

This common acquired hypermelanosis is seen mainly in women, and occurs mainly on sun-exposed skin on the face, only occasionally affecting the forearms. Many cases are attributed to pregnancy or the combined oral contraceptive pill. In the context of pregnancy melasma is regarded as a normal physiological change, along with darkening of the nipples and linea nigra. It is not uncommon at any time during the years of reproductive activity and has been attributed, without acceptable proof, to a variety of ovarian disorders. The rarity of melasma in post-menopausal women on oestrogen-containing hormone replacement therapy and the fact that men are occasionally affected suggests that oestrogen alone is not the causative agent. Despite light microscopic, ultrastructural and immunofluorescence studies, the condition remains an enigma [1]. An endocrine mechanism is postulated but the cause of melasma is unknown.

Clinical features. Hypermelanosis affects the upper lip, cheeks, forehead and chin and is more apparent following sun exposure. Affected skin is brown in colour. The pigmentary changes are usually bilateral and are frequently symmetrical. After pregnancy or after stopping oral contraceptives the condition may fade but is often persistent. Melasma-like hyperpigmentation has been reported from use of phenytoin or mephenytoin (hydantoins). Up to 10% of cases of melasma are seen in men, particularly Latin Americans and those from the Middle East or Asia.

Treatment. A variety of topical treatments are effective at lightening melasma [2–5], but these treatments should be combined with assiduous sun-protection measures if the reduced pigmentation is to be maintained.

Riehl's melanosis

Synonyms
- Melanodermatitis toxica
- Pigmented cosmetic dermatitis

Background. A distinctive pattern of grey-brown facial pigmentation was first described by Riehl in Vienna between 1916 and 1920 [1]. Riehl attributed this pigmentation to contact with noxious substances or to wartime living conditions. It was subsequently seen in Europe and Asia during and after the Second World War and has also occurred in Argentina [2] and in the South African Bantu [3]. The condition is more frequent in women, and tar derivatives and fragrances are suspected to be the cause [4]. An outbreak of Riehl's melanosis in Japan was attributed to contact dermatitis to cosmetic ingredients and prompted the phrase 'pigmented cosmetic dermatitis' for this condition [5].

Histopathology. In the early stages there is liquefaction degeneration of the basal layer of the epidermis and a perivascular or band-like dermal infiltrate with pigmentary incontinence. Later, the epidermis appears normal but many melanophages are present in the upper dermis [6]. Ultrastructural studies show intercellular and intracellular oedema of keratinocytes and a multilayered basal lamina, as well as many melanophages in the dermis [6].

Course, prognosis and treatment. Brownish-grey pigmentation develops quite rapidly over the greater part of the face but is more intense on the forehead and temples. Smaller pigmented macules, often perifollicular, lie beyond the indefinite margin. The pigmentation may extend to the chest, neck and scalp, and occasionally involves hands and forearms. Horny plugs fill the follicles and there may be some scaling. Where a contact cause can be identified and avoided, there follows a slow improvement over many months.

Poikiloderma of Civatte (Fig. 58.23) [1]

Background. This characteristic pattern of reticulate hyperpigmentation of the face and neck was first reported in 1923 by Civatte [1].

Fig. 58.23 Poikiloderma of Civatte on side of neck.

Clinical features. It tends to occur in women aged 30–50. Poikilodermatous changes develop on the sides of the neck with hyperpigmentation, telangiectasia and dermal atrophy. The submandibular and submental areas are spared thus implicating sunlight in the pathogenesis of this condition. Milder forms are common and few patients seek medical advice.

Treatment. Laser therapy with the tuneable dye laser may be effective but care is needed as it may also cause scarring and may even worsen the appearance [2]. Photoprotection with a high SPF sunscreen may help prevent disease progression.

Pigmented peribuccal pigmentation of Brocq

Background. It was Brocq in 1923 who first reported a case of perioral hyperpigmentation in a clinical pattern that now bears his name [1].

Clinical features. This syndrome occurs predominantly in middle-aged women and has rarely been reported in men. A photodynamic substance in cosmetics is probably responsible. Diffuse brownish-red pigmentation develops symmetrically around the mouth but spares a narrow perioral ring. It may extend up the centre of the face to the forehead and in some cases there are well-defined patches of pigmentation over the angles of the jaw and the temples. The erythematous component, and hence the intensity of the pigmentation, may fluctuate over short periods. The pigmentation is usually persistent but tends gradually to fade if the cause is eliminated. A similar post-inflammatory hyperpigmentation is seen in some patients with perioral dermatitis and may be the result of topical steroid therapy [2].

Erythromelanosis follicularis of the face and neck

This syndrome, of unknown origin, was originally described in Japan by Kitamura [1]. Affected individuals are usually young or middle-aged males [2,3] although it has also been reported in adult females [4]. Histologically, there is slight hyperkeratosis. The hair follicles are enlarged and contain lamellar horny masses. The sebaceous glands are also enlarged. The epidermis overlying the affected follicle is flattened and contains excess melanin. In the dermis, an inconspicuous lymphocytic infiltrate surrounds dilated vessels.

The clinical picture is distinctive. A background of reddish-brown pigmentation with telangiectasia is studded with pale follicular papules. The hairs are lost from the majority of affected follicles in the vellus region, but less conspicuously from the terminal hair of scalp or beard. The pigmentation involves the skin in front of, beneath and behind the ear, extending to the side of the neck. It spreads slowly, is persistent and is not influenced by treatment. The distribution and lack of clinical follicular keratosis or scarring readily distinguish erythromelanosis from the various forms of keratosis pilaris and from other facial melanoses.

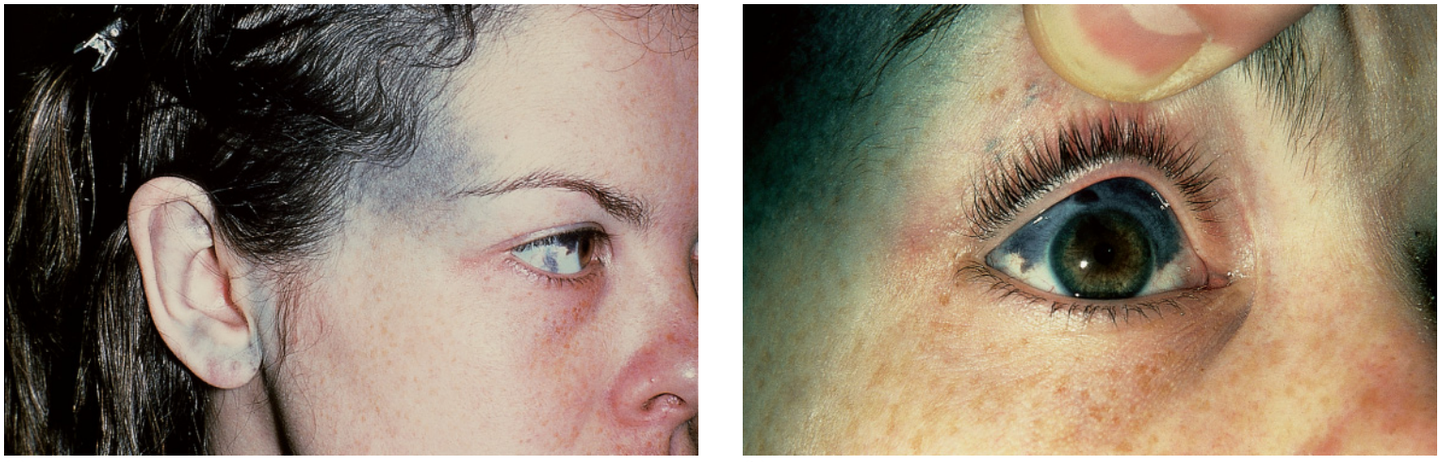
Dermal melanocytosis

Synonym
- Ceruloderma



Hyperpigmentation of the skin may be due to the presence of functional fusiform and dendritic melanocytes that lie in the dermis [1]. Although dermal melanocytes are common in other mammals, they are not often seen in humans. These cells have failed to reach their proper location in the basal layer of the epidermis in their migration from the neural crest of the developing embryo. Several conditions are grouped under the term 'dermal melanocytosis'. In all of them, the affected areas have a slate-brown or blue colour (ceruloderma) due to an optical effect from the pigment lying in the dermis.

Mongolian spot (Fig. 58.24) [1–4]

Mongolian blue spots are seen in 90% of Oriental babies and less frequently in black babies. The usual site of involvement is the lumbosacral region. The spots are poorly circumscribed areas of slate-brown or blue-black pigmentation that are sometimes extensive and may be mistaken for bruises. A case of generalized dermal melanocytosis of the newborn has been described [2]. Mongolian blue spots usually fade in early childhood, although the aberrant extrasacral spots can persist [3]. Very extensive Mongolian blue spots may regress more slowly, and some areas may persist indefinitely. The dermal melanocytes in persistent Mongolian spots have an extracellular sheath [4], as also seen in the naevus of Ito. The aetiology of this birthmark is unknown.

Naevus of Ota

Synonyms
- Nevus fuscocaeruleus ophthalmomaxillaris
- Oculodermal melanocytosis

(a) (b)

Fig. 58.25 (a) Naevus of Ota in a white subject. (b) Marked blue coloration of the sclera in the same patient.

Naevus of Ota was first described by the Japanese dermatologist Ota in 1939 [5]. The hyperpigmentation affects one side of the face in the area supplied by the ophthalmic and maxillary divisions of the trigeminal nerve [6,7]. Occasionally, it is bilateral. It is usually congenital but may appear later in life. It is more prevalent in the Japanese but is observed in other races. The colour is variable, but is usually either slate-brown or blue. The sclera is involved and there may be hyperpigmentation of the cornea, iris, retina, ocular muscles and orbit [8] (Fig. 58.25). Sometimes, there is pigmentation of the hard palate. An ipsilateral sensorineural deafness occurring in a patient with naevus of Ota has been reported [9].

Naevus of Ota does not improve with time. Malignant change in the cutaneous lesions of naevus of Ota is extremely rare. However, melanomas are more common in the choroid, iris, orbit and brain of these patients [10]. A bilateral, acquired dermal melanosis of the face resembling naevus of Ota has been described [11]. Promising results with the Q-switch ruby laser have been reported in the treatment of naevus of Ota, with multiple treatments increasing the response rate [12].

Naevus of Ito (Fig. 58.26) [4,12,13]

In this condition, the increased pigmentation affects the area supplied by the posterior supraclavicular and lateral brachial cutaneous nerves. It is relatively common in the Japanese.

Fig. 58.26 Naevus of Ito.

Blue naevus

These commonly occur on or near the dorsa of hands and feet, usually early in life. Malignant transformation does not occur in the common blue naevus. However, the cellular blue naevus may rarely undergo malignant change.

Disseminated dermal melanocytosis [1]

Progressive dermal melanocytosis has been described in a patient who developed profuse, bluish, bruise-like spots in childhood. The woman died in the fifth decade from melanoma.

Hypermelanosis associated with other cutaneous lesions

Hypermelanosis is a characteristic feature of urticaria pigmentosa but the mechanism of its production is unknown. Tyrosinase-positive cells have been found in the upper dermis in some cases. In the childhood type, the light-brown macules often exceed 2 cm in diameter and the lesions are frequently nodular. In the adult types, the smaller and more numerous macules are purplish-brown in colour and not palpably infiltrated, and often fail to urticate on friction. They are usually widely distributed over the trunk and limbs.

The differential diagnosis of hypermelanosis

The very large number of conditions associated with widespread or localized hypermelanosis cannot readily be classified. The present classification is based on the colour of the skin and on various causative factors. The hypermelanosis may be due to genetic and naevoid factors (Table 58.5) or it is acquired and due to a variety of factors (Table 58.6).

The areas of hypermelanosis may be circumscribed or may be diffuse with intensification of the normal pattern of pigmentation. Hypermelanosis confined to the face and neck is considered on pp. 58.34–58.35. In acquired, circumscribed patches of hypermelanosis, a post-inflammatory origin should be considered (see p. 58.30).

Treatment of hypermelanosis

Hypermelanosis, particularly affecting areas on the face, can be the cause of marked cosmetic disability and give rise to much mental distress. Treatment depends essentially on establishing the cause and if possible reversing the conditions that have given rise to the hypermelanosis. In the majority of cases, topical therapy has no place, although some who are perturbed about their cosmetic disability will demand treatment with a skin-bleaching preparation. Because in many cases exposure to sunlight intensifies the pigmentation, a photoprotective preparation should be prescribed and applied during sunny weather. Cosmetic camouflage may also be indicated.

A number of compounds have been used in skin-bleaching preparations and of these hydroquinone is the most safe. Preparations containing 2% hydroquinone, although not very effective,

are of help in producing cutaneous depigmentation [1]. Although higher concentrations of hydroquinone are more potent, these preparations frequently irritate the skin and may produce, if used for long periods of time, an exogenous ochronosis and pigmented colloid milium [2,3]. A formulation of hydroquinone and retinoic acid has some effect in depigmenting human skin and is of use in the treatment of hypermelanotic conditions such as melasma [4–6]. It is not very effective for post-inflammatory hyperpigmentation. Topical tretinoin has been found to be effective in the treatment of actinic lentigines ('liver spots') in photodamaged skin [7] and also improves melasma [8]. The monobenzylether of hydroquinone is responsible for many therapeutic and cosmetic disasters and the compound should be used only to bleach away the remaining pigmented areas in patients with extensive vitiligo [9]. Several other substituted phenols, such as 4-isopropylcatechol, can produce cutaneous depigmentation; however, this compound and others are irritant and may produce sensitization [10].

Hypomelanosis

Genetic and naevoid disorders

A number of genetically determined or naevoid conditions are characterized by localized and/or generalized hypomelanosis of the skin. These are listed in Table 58.7.

Albinism [1–9]

There are many distinct types of oculocutaneous albinism (OCA), each of which is characterized by partial or complete failure to produce melanin in the skin and the eyes. The classification is rapidly changing with the advent of advances in molecular genetics (e.g. rufous OCA is now *TRP-1* gene-related OCA or type III OCA). Melanocytes are present in normal distribution but fail to synthesize melanin adequately. These conditions are inherited as autosomal recessive disorders; one rare type with apparent autosomal dominant inheritance is now felt to be due to quasi-dominant pedigree patterns or to partial expression of OCA II in OCA I heterozygotes (Table 58.7). The gene encoding tyrosinase has been localized to chromosome 11 [2] and many different mutations are now recognized for OCA [3]. The gene for type II OCA has been mapped to chromosome 15q11.13 [4]. Tyrosinase-negative albinism is characterized by hair bulbs that, after plucking and incubation with tyrosine, fail to produce darkening. In tyrosinase-positive albinism, the hair bulbs do darken in this test and the precise metabolic defects have yet to be ascertained. The tyrosinase-positive types are the most common. Ultrastructural studies of skin and hair show that in tyrosinase-negative albinos most of the melanosomes are stage 1 and stage 2 without any melanization. Other types may show melanosomes up to stage 3 of their development.

In ocular albinism, only the eyes are clinically involved, although careful investigation of the melanocytes in the skin does show some changes. There are four different types, two X-linked, one dominant and one recessive. Carrier females of the X-linked types may show irregular retinal pigmentation. In two types there is an associated deafness, the melanocytes apparently failing to play a protective role in the ear. In most albinos this defect leads to little or no change in ear function.

Table 58.7 Hypomelanosis due to genetic and naevoid factors (MIM numbers in parentheses).

Oculocutaneous albinism (OCA)	
Tyrosinase negative (type IA, #203100)	Recessive
Yellow mutant (type IB, #606952)	Recessive
Temperature sensitive (type 1TS; included in IB #606952)	Recessive
Tyrosinase positive (type II, *203200)	Recessive
Brown	Recessive*
Minimal pigment (203280)	Recessive
Platinum	Recessive†
TRP-1 gene-related (type III) (was rufous OCA, #278400)	Recessive
Hermansky–Pudlak syndrome (203300)	Recessive
Chédiak–Higashi syndrome (#214500)	Recessive
Autosomal dominant	Dominant‡
Ocular albinism	X-linked
With deafness	X-linked, recessive, dominant
Albinoidism (*126070)	Dominant§
Cross syndrome (*257800)	Recessive
Piebaldism (#172800)	Dominant
Waardenburg syndrome (#193150, #193510)	Dominant
Phenylketonuria (*261200)	Recessive
Vitiligo	Polygenic
Tuberous sclerosis (#191100)	Dominant
Achromic naevus	
Incontinentia pigmenti achromians	

* Brown OCA is currently included as a type of OCA II.
† Platinum OCA may be an allelic variant of minimal pigment OCA.
‡ Dominant OCA probably does not exist: instances appear to be due to quasidominant pedigree patterns or to partial expression of albinism II in OCA I heterozygotes.
§ The term 'albinoidism' is applied to both pigmentary dilution (MIM *126070) and OCA II.

(a)

(b)

Fig. 58.27 (a) Tyrosinase-positive oculocutaneous albinism in a black woman aged 40 years. (b) Dark-brown freckles on light-exposed areas.

Incidence. Albinism is found in all races and the prevalence varies considerably. In the UK, the incidence is estimated at 1 in 20 000. In the USA, the incidence of albinism is estimated at 1 in 39 000 in Caucasians and 1 in 28 000 in Afro-Caribbeans. In some countries it is more common, particularly where there is a tendency towards inbreeding and especially in isolated communities. The Cuna tribe on the San Blas islands off the coast of Panama have the highest incidence of albinism in the world (63 per 10 000). In Nigeria, the incidence of albinism is much higher in the south [5]. There are no adequate studies of the incidence of the different genotypes of OCA in the different races.

Clinical features. In all races there is marked dilution of the pigmentation of the skin, hair and eyes. In tyrosinase-negative OCA the skin is pink in colour, the hair is white and the patients show a prominent red reflex. This is the most severe variant of OCA.

In tyrosinase-positive OCA, some pigment is formed and with increasing age is to be found in the iris, skin and hair, the latter often developing a flaxen-yellow colour. These patients may also tan and in black people the skin has a yellowish-brown colour that with age develops dark-brown freckles, particularly in sun-exposed areas (Fig. 58.27). Also in this type, the iris is less translucent and in black people may be brown in colour.

In both types, patients have photophobia; often they have a characteristic facial expression due to apparent squinting. Errors of refraction are common, especially in the tyrosinase-negative type (OCA IA), and almost all patients have horizontal or rotatory nystagmus, sometimes with head nodding. In the tyrosinase-positive type, visual acuity may improve as patients get older and they may have less severe nystagmus [6]. There are abnormalities of the optic pathway. Foveal hypoplasia occurs in the tyrosinase-negative type [6].

In the yellow mutant type of albinism, the newborn resembles the tyrosinase-negative type, but by the age of 1 year the hair is yellow-red in colour. Hair bulbs incubated in tyrosine plus cysteine produce an intensification of the yellow-red pheomelanin. This type of albinism is prevalent in the Amish communities in the USA [7].

The other types of albinism listed in Table 58.7 have pigment changes described by their names. Each has a rather distinctive racial predisposition.

In temperate climates, the prognosis for the albino is good, the visual defects constituting the greatest disability. In the tropics the fate of albinos is grim. At an early age [8] most of them develop in solar-exposed skin many actinic keratoses, squamous cell carcinomas and, occasionally, melanomas. Some die young from these tumours [5].

Treatment. No treatment is possible other than prescribing photoprotective preparations and limiting sun exposure, vigorous enforcement of which from early childhood can be very helpful. The regular examination of all albinos for the early detection and treatment of premalignant and malignant conditions of the skin is

advisable, especially in the tropics. Prenatal diagnosis of albinism has been reported [9].

Albinoidism (MIM *126070)

Albinoidism is the name applied to families where there is some partial defect in melanin production in the skin but only minimal changes in the eyes. The biochemical basis of this is uncertain. Several families are described with this type of albinism [1,2]. Although there is hypopigmentation of the skin and hair, it is not as marked as in OCA. Slight tanning is reported and the hair-bulb test is positive. A diffuse punctate pattern of iris transillumination is seen. The eyes are usually normal, but there may be photophobia. In one large Swiss pedigree there was high-grade myopia [2]. The condition appears to have autosomal dominant inheritance, but in some families it is recessive.

Hermansky–Pudlak syndrome (MIM #203300)

Hermansky–Pudlak syndrome is a rare type of OCA associated with a haemorrhagic diathesis [1]. About 250 cases have been reported, most of whom are from Puerto Rico or the south of the Netherlands [1]. Two different mutations in the gene for Hermansky–Pudlak syndrome have been identified. Tyrosinase-positive OCA occurs in association with a bleeding tendency and deposits of a ceroid-like pigment in the cells of the reticuloendothelial system [2]. The bleeding tendency is attributed to a storage-pool platelet defect. The platelets have decreased numbers of dense granules and reduced levels of serotonin and ADP [3]. Pulmonary fibrosis, granulomatous colitis and lupus nephritis have been associated [4]. There is no defect in circulating lymphocytes or neutrophils [5]. Two cases of Hermansky–Pudlak syndrome have been complicated by systemic lupus erythematosus [6].

Chédiak–Higashi syndrome (MIM #214500)

Chédiak–Higashi syndrome is a rare, autosomal recessive disorder characterized by hypopigmentation of the skin and eye [1]. The skin is fair, the retinae are pale and the irides translucent. The hair is light blonde or silvery grey. These children are very susceptible to bacterial and viral infections, and intractable respiratory and cutaneous infections usually prove fatal before the age of 10 years. Longer survival is possible but later the lymph nodes, spleen and liver are enlarged and a malignant lymphoma develops. A similar condition is seen in Aleutian mink [2], Hereford cattle [3] and the beige mouse [4].

The hereditary defect concerns membrane-bound organelles of various cell types and is due to mutations in a gene encoding a protein known as lysosomal trafficking regulator. The melanocytes contain giant pigment granules (Fig. 58.28), which arise by autophagocytosis and fusion of large melanosomes that show degradative changes within the cells [5]. Similar defects of granules and other organelles occur in white cells and platelets. Cytoplasmic inclusions are present in a variety of cells of neuroectodermal origin. The white cells are defective in combating infection and if children with this condition survive infancy, they usually die later from a malignant lymphoma.

Griscelli syndromes type I (MIM #214450) and type II (MIM #607624)

Griscelli syndrome type I comprises partial albinism with neurological deficiency due to mutations in the myosin type V gene.

Griscelli syndrome type II, due to mutations in the *RAB27A* gene, combines partial albinism and immunodeficiency [1], but is distinct from Chédiak–Higashi syndrome. It is inherited as an autosomal recessive condition. In addition to pigmentary dilution, there is immune deficiency and the affected children are prone to recurrent pyogenic infection. There is hypogammaglobulinaemia and defective cell-mediated immunity with lymphohistiocytosis and haematophagocytosis.

1 Griscelli C, Durandy A, Guy-Grand D *et al*. A syndrome associating partial albinism and immunodeficiency. *Am J Med* 1978; **65**: 691–702.

Prader–Willi syndrome (MIM #176270) and Angelman syndrome (MIM #105830) [1]

Both syndromes are associated with mental retardation, abnormal behaviour and hypopigmentation. In both there are deletions of the same region of chromosome 15, with deletion on the paternal chromosome in Prader–Willi syndrome and the maternal in Angelman syndrome.

Reference

Cross' syndrome (MIM *257800)

Synonym
- Oculocerebral syndrome with hypopigmentation

Cross' syndrome is one of the 'silvery hair' syndromes and is characterized by generalized hypopigmentation associated with ocular anomalies, mental and physical retardation, ataxia and spasticity [1]. It is probably determined by an autosomal recessive gene [2,3]. The pigmentary and ocular defects are manifest from birth. The hypopigmentation resembles albinism; blood tyrosine levels are normal and the light-coloured hair pigments poorly in tyrosine solution. The ocular defects include microphthalmos, a small opaque cornea and coarse nystagmus. Spasticity soon becomes evident, and physical and mental development is retarded [3].

Piebaldism (MIM #172800) [1–11]

Piebaldism is a rare autosomal dominant condition characterized by stable areas of vitiligo-like amelanotic skin associated with a white forelock [2,3]. The incidence of piebaldism is estimated at less than 1 in 20 000. Both sexes are affected equally, and no race is spared. A similar condition of 'white spotting' is seen in mice and results from deletion or mutation of the c-*kit* proto-oncogene that codes for an embryonic growth factor called Steel factor [4]. Missense and frameshift mutations of the *kit* proto-oncogene, which encodes the cellular receptor tyrosine kinase for the mast cell/stem cell growth factor, are responsible for a range of phenotypes with piebaldism [5,6].

The plurality of defects revealed by electron microscopy suggests that a number of different gene loci are concerned. Ultrastructural studies have shown either an absence of melanocytes and melanosomes in the hypomelanotic areas or sometimes reduced numbers of abnormal large melanocytes. In the hypermelanotic islands in the areas of hypomelanosis, melanocytes are present that produce normal melanosomes but also abnormal spherical and granular melanosomes [9]. When transferred to the keratinocytes, these show abnormal degradation and fusion.

Clinical features. Patches of skin totally devoid of pigment are present at birth and usually remain unchanged throughout life. Most common is a frontal median or paramedian patch, associated with a mesh of white hair (white forelock); rarely, this may be the only lesion. Often, white patches occur on the upper chest, abdomen and limbs, bilaterally but not necessarily symmetrically (Fig. 58.29). Occasionally, they are found on the face, particularly the chin. The hands and feet, as well as the back, remain normally pigmented. Islands of normal or hypermelanotic skin occur in the white areas, or less often on normal skin.

Piebaldism can easily be distinguished from vitiligo where the lesions are acquired later in life and their configuration and distribution are quite different. In piebaldism, there is almost invariably a white forelock and the pattern of arrangement of the lesions is quite characteristic. Also the presence of islands of normal pigmented skin in the hypomelanotic areas is typical. If the interpupillary distance is increased or the patient is deaf, the diagnosis of Waardenburg's syndrome (see below) must be considered. The patterns of hypomelanosis as seen in the localized and systematized types of naevus depigmentosus differ from piebaldism. Microscopy of the skin in naevus depigmentosus reveals normal numbers of melanocytes with sometimes rather stubby dendrites [9]. A progressive variant of piebaldism has been described in association with a novel mutation in the *kit* gene [11].

Treatment. Photoprotective preparations should be prescribed to protect the amelanotic areas from burning with sun exposure.

Fig. 58.29 Piebaldism. The lesions had been present from birth.

Cosmetic camouflage or skin dyes may be helpful for some patients. Skin grafts, minigrafts and grafts of autologous cultured melanocytes have some promise [12,13]. PUVA therapy is generally disappointing, as are topical corticosteroids.

Tietz's syndrome (MIM #103500)

Tietz reported a six-generation pedigree with the constant association of total absence of pigment in the skin and hair, normal eyes, complete deaf-mutism and hypoplasia of the eyebrows [1]. An autosomal dominant gene appeared to be implicated. There is some doubt that this syndrome is a distinct entity.

The analogy with a syndrome in cats, in which severe deafness is associated with total absence of skin pigment but normal eye colour, suggests that Tietz's syndrome probably represents a 'generalized white spot' rather than albinism.

Waardenburg syndrome (MIM #193150) [1–8]

Historical background. Waardenburg syndrome (WS) was first described by a Dutch ophthalmologist in 1951 [1].

Aetiology. All of the abnormalities of Waardenburg syndrome involve the neural crest. Waardenburg syndrome is therefore considered to represent a global disorder of neural crest development.

Clinical features. Waardenburg syndrome is characterized by lateral displacement of the inner canthi and the lacrimal puncta, prominent nasal root and medial eyebrows, congenital deafness and heterochromic irides [2,3]. Other pigmentary changes are a 'dappled' appearance of the skin, a white forelock, and premature greying of hair, eyebrows and cilia. A few patients show piebaldism; pigment-free patches may be large and multiple or small and inconspicuous. WS has been reported in both black and white people.

Classification. Four classical clinical variants of WS have been described. Type I is the classic form [4], while type II lacks dystopia canthorum but has a high incidence of congenital sensorineural deafness and heterochromia. Type III resembles type I but is associated with limb abnormalities in addition to dystopia canthorum. Type IV, like type III, is autosomal recessive and is characterized by associated Hirschsprung's disease and, in some cases, by more extensive hypopigmentation [5]. Recent molecular genetic findings have demonstrated at least nine distinct genetic subtypes of Waardenburg syndrome, several of which correspond to distinct clinical subtypes not included in these four classical subtypes. Thus, a new and more comprehensive classification can be anticipated soon.

Incidence and genetics. It is a relatively rare autosomal dominant condition with an estimated incidence of 1 in 20–40 000 [6]. Autosomal recessive forms of Waardenburg syndrome are rare. Variable expression and penetrance explain milder or incomplete

phenotypes. A number of different mutations of the *PAX*-3 gene on chromosome 2q35 have now been reported in different forms of type I and type III. None of the cases of type II have been linked to 2q markers but type IIA is now known to be due to mutations in the *MITF* gene. Mutations in the endothelin-3 gene [7] and in endothelin-B genes have been reported in type IV, and mutations in the *SOX10* gene [8] have also been implicated as causing WS. Types IIB and IIC are further subdivisions linked to genes mapping to chromosomes 1p and 8p, respectively.

Albinism–deafness syndrome (MIM #300700) [1–4]

Synonyms
- Ziprkowski–Margolis syndrome
- Woolf syndrome

Albinism–deafness syndrome (ADFN) is a rare X-linked recessive syndrome that was first described (separately) by Ziprkowski [1] and Margolis [2] in 1962. Ziprkowski reported 14 members of an Egyptian–Jewish family with males showing deaf-mutism, heterochromic irides and piebald-like hypomelanosis of skin and hair [1]. The skin appears completely amelanotic at birth, but pigmented macules develop on the extremities, trunk and scalp. The hair usually remains white. Genetic linkage studies and somatic cell hybrid mapping studies localize the *ADFN* gene to Xq26.3-q27.1 [3]. However, the gene has not yet been identified. Piebaldism in association with congenital nerve deafness [4] has been reported in two brothers with no other manifestation of ADFN. It is unclear whether this is the same or a genetically distinct condition.

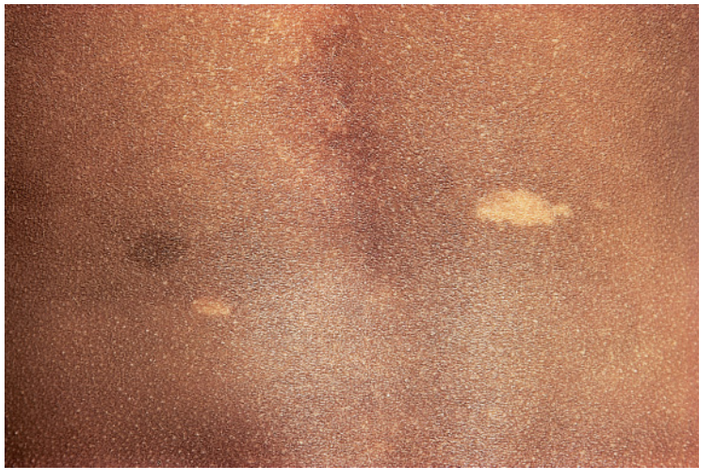

Fig. 58.30 Ash-leaf-shaped hypopigmented macules in tuberous sclerosis.

Hypomelanotic macules of tuberous sclerosis

In this neurocutaneous disorder (see Chapter 15), transmitted as an autosomal dominant trait, hypomelanotic macules are found in about 50–100% of affected babies [1–3]. It is a significant feature as it is often the earliest feature of tuberous sclerosis [1]. These macules are usually multiple, irregularly scattered and frequently have a lance–ovate shape, likened by Thomas Fitzpatrick in 1968 to the leaflet of the mountain ash [1] (Fig. 58.30). The macules are of diagnostic significance in a baby with fits, especially infantile spasms [1]. They are best identified in the fair-skinned with the aid of a Wood's lamp. Electron microscopy of the macules shows the presence of normal or reduced numbers of melanocytes that have poorly developed dendrites containing fewer and smaller melanosomes than normal [2]. The gene responsible for tuberous sclerosis has been localized to 9q34 (*TSC1*) and 16p13.3 (*TSC2*) [4,5].

Naevus depigmentosus

Synonym
- Achromic naevus

Definition. This is a rare, localized area of depigmented skin, first described by Lesser in 1884 [1]. It remains stable in size and colour over time and typically has no associated findings.

Clinical features. This circumscribed area of depigmentation is congenital, but may not be apparent at birth. There are three clinical variants; the commonest is the single, circumscribed, rounded lesion. Segmental and systematized forms are very rare, and may resemble hypomelanosis of Ito. Lesions occur most commonly on the trunk. Hairs within the depigmented macules are usually depigmented. Histology may show either normal or reduced numbers of melanocytes [2]. A functional defect in melanocytes, with morphological abnormalities of melanosomes, has been identified [3].

Hypomelanosis of Ito (MIM *300337) [1–8]

Synonym

- Incontinentia pigmenti achromians of Ito

In 1952 the Japanese dermatologist Minor Ito described a 21-year-old woman with widespread, symmetrical, depigmented whorls and streaks that had started at the age of 5 years [1]. This neurocutaneous disorder is variable in extent and may be unilateral or bilateral. The areas of hypomelanosis occur along Blaschko's lines, a requirement for the diagnosis of this condition (Fig. 58.31). There may be associated disorders in the musculoskeletal system, teeth, eyes and central nervous system [2]. Convulsions and mental deficiency occur commonly in the reported cases [3]. The appearances resemble the late stages of incontinentia pigmenti, but this is clearly a quite separate disease without the preceding inflammatory stages and without the sex-linked inheritance of incontinentia pigmenti. There is no basal layer damage and no pigmentary incontinence. Nearly all cases are sporadic suggesting a postzygotic mutation. The mutation can only survive in a mosaic and is usually lethal when transmitted to offspring due to the lack of admixture with normal cell lines. However, one case of inheritance of hypomelanosis of Ito has been reported, consistent with X-linked dominant inheritance with lethality to male embryos [4]. The white streaks are usually present at birth and tend to progress thereafter. Eventually, they may repigment. The skin lesions have to be distinguished from the more bizarre-shaped depigmented naevi and from focal dermal hypoplasia where the skin also shows atrophic changes.

Vogt–Koyanagi–Harada syndrome

Historical background. In 1906 Vogt reported a patient with atraumatic, idiopathic uveitis, poliosis and alopecia, a syndrome that in time would be associated with his name [1]. In 1926, Harada reported five cases of bilateral posterior uveitis and retinal detachment [2]. In 1929, Koyanagi reported 16 patients with headache, fever, dysacousia, vitiligo, poliosis, alopecia, bilateral anterior uveitis with occasional exudative retinal detachment [3]. Various combinations of synonym have been used for this disorder, which is now generally referred to with the above three names, and abbreviated to VKHS.

Aetiology. The aetiology of VKHS has yet to be established. An abnormal response to a virus, and immunological mechanisms, have been postulated.

Pathology. Electron microscopy of depigmented skin shows an absence of melanocytes as in vitiligo [4]. Colloid–amyloid bodies are also found at the dermal–epidermal junction [5]. Inflammatory

skin lesions are characterized by a chronic, mixed inflammatory cell infiltrate [6].

Clinical features [7,8]. VKHS mainly affects dark-skinned people or white people with dark pigmentation. It is rare but widely distributed. Most cases occur in the third and fourth decades but children may be affected. It affects the skin, eyes, inner ears and meninges. Criteria for diagnosis are as follows:

- No history of ocular trauma or surgery preceding the initial onset of uveitis
- No clinical or laboratory evidence suggestive of ocular disease entities
- Bilateral ocular involvement: an early sign is diffuse choroiditis; a late sign is ocular depigmentation
- Neurological and auditory findings: meningismus, tinnitus, cerebrospinal fluid pleocytosis
- Skin and hair changes: alopecia, vitiligo, poliosis.

Typically, this condition is first diagnosed by ophthalmologists as the uveitis starts the march of symptoms and signs.

Diagnosis. The association of vitiligo with loss of pigment in brows and lashes and with the residual ocular defects should clearly differentiate this syndrome from any other.

Alezzandrini's syndrome [1–4]

Historical background. Alezzandrini was involved in three papers describing the syndrome that now bears his name in the late 1950s and early 1960s [1–3].

Aetiology. The aetiology of this syndrome is unknown.

Clinical features. Alezzandrini's syndrome has only been reported in a small number of cases [1–4]. It is characterized by unilateral, facial vitiligo associated with unilateral retinal degeneration, white hair, poliosis and deafness. There are similarities with the Vogt–Koyanagi–Harada syndrome in which skin, eye and auditory changes are also observed.

Vitiligo [1–3]

Aetiology. Vitiligo affects all races and has a long history [4]. It is stated that it occurs in 1% of the world's population [2]. An epidemiological survey on the island of Bornholm in Denmark [5] found the prevalence to be 0.38%. It is likely that this figure applies also to other countries in north-west Europe. The incidence of vitiligo in those with racially pigmented skins is higher (and the social impact greater), although reliable figures are not available. There is a preponderance of females in most series based on outpatient attendances, but the frequency in the population is probably the same in both sexes [5]. Between 30 and 40% of patients have a positive family history [2], and a genetic factor is undoubtedly involved. Inheritance may be polygenic or may be determined by an autosomal dominant gene of variable penetrance. Vitiligo has been reported in monozygotic twins [6].

Various theories have been suggested for the aetiology of vitiligo; the same mechanism may not apply to all cases.

- *Autoimmune hypothesis*: this is based on the clinical association of vitiligo with a number of disorders also considered to be autoimmune (Table 58.8). Organ-specific autoantibodies to thyroid, gastric parietal cells and adrenal tissue are found in the serum more frequently in patients with vitiligo than in the general population [11,12]. A complement-fixing antibody to melanocytes has been found in the serum of several patients who in addition to vitiligo had alopecia areata, mucocutaneous candidiasis and multiple endocrine insufficiencies [11]. Antibodies to normal human melanocytes have been detected using a specific immunoprecipitation assay [13,14], and have a cytolytic effect [15]. T-cell profiles are abnormal in vitiligo, with a decrease in T-helper cells [16–18].

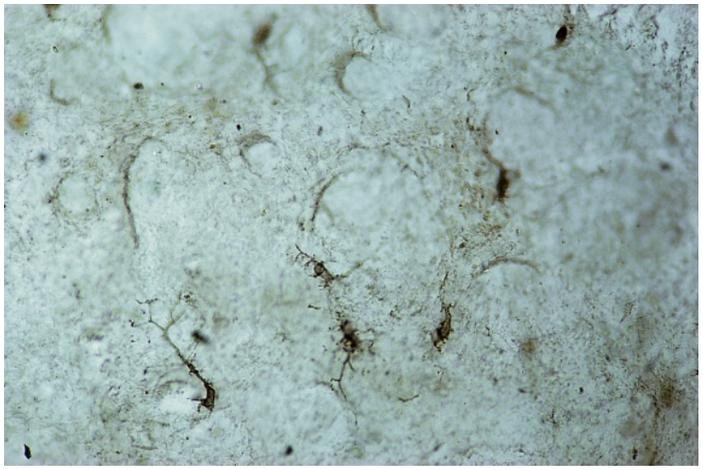

Fig. 58.32 Vitiligo. Epidermal sheet of marginal depigmented area showing marked reduction in number of melanocytes.

Fig. 58.33 Vitiligo.

- *Neurogenic hypothesis* [19]: this suggests that a compound is released at peripheral nerve endings in the skin that may inhibit melanogenesis and could have a toxic effect on melanocytes. Although vitiligo may sometimes occur in a dermatomal distribution and electron microscopy shows abnormalities of terminal portions of peripheral nerves, there is little support for this hypothesis. However, recent studies on neuropeptide and neuronal markers in vitiligo suggest that neuropeptide Y may have a role [20].
- *Self-destruct theory of Lerner* [2]: this suggests that melanocytes destroy themselves due to a defect in a natural protective mechanism that removes toxic melanin precursors. This hypothesis is based on the clinical features of vitiligo and on experimental studies of cutaneous depigmentation by chemical compounds that have a selective lethal effect on functional melanocytes [21]. These compounds can produce a leukoderma indistinguishable from idiopathic vitiligo.

It has been suggested that defective keratinocyte metabolism plays a major role, with low catalase levels in the epidermis of vitiligo [22]. A new hypothesis involving defective tetrahydrobiopterin and catecholamine biosynthesis has been put forward to explain the pathogenesis of this disorder [23].

Fig. 58.34 Isomorphic or Koebner phenomenon at site of a scratch in a patient with vitiligo.

Pathology. There is a marked absence of melanocytes and melanin in the epidermis. Histochemical studies [24] show a lack of dopa-positive melanocytes in the basal layer of the epidermis (Fig. 58.32). Recent immunohistochemical studies with a large panel of antibodies show only an occasional melanocyte in lesional skin [25]. Electron microscopy studies [9,26,27] confirm the loss of melanocytes, which appear to be replaced by Langerhans' cells. In the epidermis of areas around the margins of vitiligo are abnormalities of keratinocytes [9] as well as degenerating melanocytes. There is increased cellularity of the dermis and occasional colloid amyloid bodies are found. In inflammatory vitiligo, where there is a raised erythematous border, there is an infiltrate of lymphocytes and histiocytes. This infiltrate is also found in the marginal areas of some biopsies [27].

Clinical features [2,3]. Vitiligo can begin at any age, but in 50% of cases it develops before the age of 20 years. The condition is gradually progressive, sometimes extending rapidly over a period of several months and then remaining quiescent for many years.

Hypomelanotic macules are usually first noted on the sun-exposed areas of skin, on the face or on the dorsa of hands (Fig. 58.33). These areas are prone to sunburn. Rarely, itching in the absence of sunburn may occur. Damage to the 'normal' skin frequently results in an area of depigmentation—an isomorphic or Koebner phenomenon (Fig. 58.34).

The amelanotic macules in vitiligo are found particularly in areas that are normally hyperpigmented, for example the face, axillae, groins, areolae and genitalia. Areas subjected to repeated friction and trauma are also likely to be affected, for example the

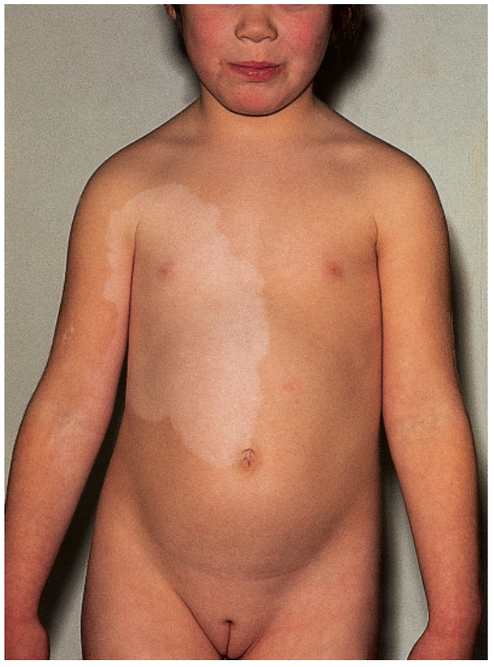

Fig. 58.35 Segmental vitiligo.

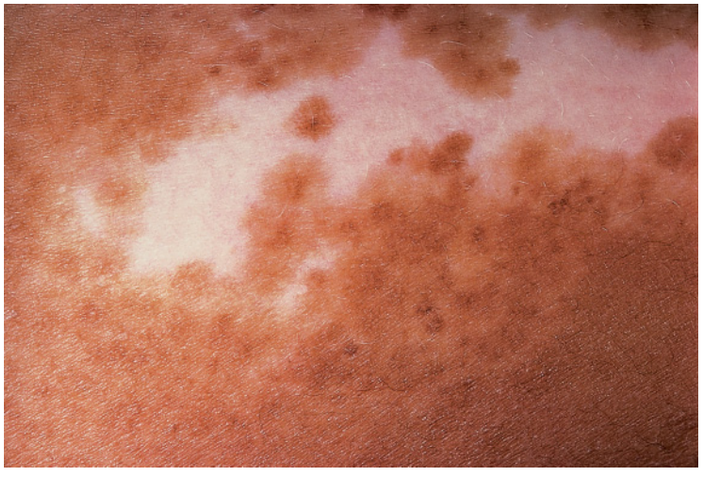

Fig. 58.36 'Trichrome' vitiligo.

dorsa of hands, feet, elbows, knees and ankles. The distribution of the lesions is usually symmetrical, although sometimes it is unilateral and may have a dermatomal arrangement (Fig. 58.35). Rarely, there is complete vitiligo, although a few pigmented areas always remain.

The pigment loss may be partial or complete, or both may occur in the same areas (trichrome vitiligo) (Fig. 58.36).

The macules have a convex outline, increase irregularly in size and fuse with neighbouring lesions to form complex patterns. The hairs in the patches frequently remain normally pigmented, but in older lesions the hairs too are often amelanotic. The margins of the lesions may become hyperpigmented. The main symptom is the cosmetic disability, although some patients present because of sunburn in the amelanotic areas. Vitiligo commonly starts in children, who are more likely to show segmental vitiligo, autoimmune diseases or to have a family history of canities [28].

Spontaneous repigmentation is noted in about 10–20% of patients, most frequently in sun-exposed areas. It is usually seen in younger patients, the repigmentation being quite trivial and mainly perifollicular.

In addition to premature greyness of the hair, uveitis also rarely occurs [29]. Careful examination of the ocular fundus may show abnormalities [30]. There have also been suggestions of an increased incidence of deafness [31].

Associated disorders. A number of conditions occur in association with vitiligo and are listed in Table 58.8. Halo naevi [2,3] occur not infrequently and often antedate the onset of vitiligo. Areas of depigmentation sometimes develop in patients with malignant melanoma [10]. Vitiligo with uveitis, central nervous system involvement and premature greying of the hair occurs in the Vogt–Koyanagi syndrome (see p. 58.45).

Diagnosis. The distribution, age of onset and hyperpigmented border will suggest the diagnosis. In piebaldism, the lesions are present at birth, are usually confined to the head and trunk, and rarely show a hyperpigmented border. Careful examination of the texture of the unpigmented skin should exclude lichen sclerosus and scleroderma. Post-inflammatory leukoderma, which is frequent in the darker races, shows an irregular mottling of hyperpigmented and hypopigmented blotches. Hypomelanosis of the affected skin is commonly seen in pityriasis alba, producing slightly scaly areas with rather ill-defined edges on children's faces. Hypopigmented slightly scaly macules are seen in pityriasis versicolor. These areas often fluoresce a golden yellow when examined under a Wood's lamp. The hypomelanotic macules in leprosy are anaesthetic.

Treatment. The treatment of vitiligo is unsatisfactory and in most cases the patient is best advised to seek effective cosmetic camouflage for the lesions on exposed skin. In sunny climates, the prescription of sunscreens is often necessary.

Treatment with systemic psoralens, 4,5′,8-trimethylpsoralen, 8-methoxypsoralen or 5-methoxypsoralen, combined with exposure to sunlight or to light sources providing high-intensity long-wave UV light, is effective in a proportion of cases [3,32,33]. The patient is instructed to take the psoralens in a dose of 0.6 mg/kg 2 h before carefully controlled, graduated exposure to sunlight, preferably around midday. Therapy is continued for at least 6 months and in some for several years. In the majority of patients, the areas retain the pigment long after psoralen therapy has been discontinued. The use of topical applications of psoralens is hazardous and may result in untoward blistering of the skin. Khellin has also been used with UVA [34].

Narrow-band UVB phototherapy has been found to be effective and safe for vitiligo [35].

In some patients, the more potent topical corticosteroid preparations, 0.1% betamethasone valerate and 0.05% clobetasol propio-

nate, are effective in producing repigmentation of areas of vitiligo, but often at the price of some atrophy [36].

In those patients with extensive vitiligo and only a few residual areas of hyperpigmentation, skin-bleaching creams, such as 20% monobenzylether of hydroquinone, are of use [37].

The use of grafting techniques, minigrafts and autologous cultured melanocytes is interesting but may be limited by the Koebner phenomenon [38–40]. Minigrafting has been carried out with success in some patients with more widespread vitiligo [41]. A systematic review of autologous transplantation methods in vitiligo has recently been performed [42].

Halo naevus [1,2]

Synonyms
- Sutton's naevus
- Leukoderma acquisitum centrifugum

Definition and aetiology. Leukoderma acquisitum centrifugum designates the development of a halo of hypomelanosis around a central cutaneous tumour. This tumour is usually a benign melanocytic naevus but may be a neuroid naevus, a blue naevus, a neurofibroma, or a primary or secondary malignant melanoma [1]. The phenomenon, which is not uncommon, is usually seen in children or young adults of either sex.

Halo naevi occur with increased frequency in patients with certain organ-specific autoimmune disorders, as does vitiligo (see above), with which it is often associated. An immunological association of halo naevus with cutaneous malignant melanoma exists. Antibodies against the cytoplasm of malignant melanoma cells are found in the serum of patients with halo naevi [3]. Multiple halo naevi may occur in patients with melanoma.

Pathology [1,4]. Most halo naevi are compound naevi. There is frequently a lymphocytic infiltration of the naevus and the constituent cells may show damage. Ultrastructural studies show the apposition of mononuclear cells with naevus cells that show cytotoxic changes [5]. In the depigmented halo, there is an absence of melanocytes, but Langerhans' cells are present [6]. Melanophages are often present in the dermis.

Clinical features [1,7]. Circular areas of hypomelanosis occur around pigmented naevi, particularly on the trunk, less commonly on the head and rarely on the limbs. Multiple lesions are common, the halos being about 0.5–1.0 cm wide and developing simultaneously or at intervals around several, but not all, naevi (Fig. 58.37). The condition is usually seen in young people. The naevus tends to flatten and may disappear completely. The depigmented areas often persist, but may pigment after many years. Eczema around naevi (Meyerson's naevi) is discussed in Chapter 54.

Treatment. Normally none is required. The usual diagnostic criteria must be applied if there is any possibility that the central tumour is a melanoma. It should be remembered that a halo around a benign naevus is relatively common, whereas malignant melanoma is rare, and a melanoma surrounded by a halo is extremely rare. Mutilating surgery must never be undertaken without preliminary histological examination by an experienced pathologist.

Acquired hypomelanosis

The disorders in which there is frequently an acquired loss of melanin pigment not due to genetic factors are shown in Table 58.9.

Chemical depigmentation

A number of chemicals can produce cutaneous depigmentation when applied to the skin [1,2]. Several substituted phenols produce an occupational leukoderma in workers coming in contact with them (see also Chapter 27). Of these, *p*-tertiary-butylphenol is the most important [2–4]. Occupational leukoderma occurs in workers in contact with the monobenzylether of hydroquinone [5]; this compound is used in the treatment of hypermelanosis and can produce confetti-like areas of depigmentation in the treated areas [6] (Fig. 58.38). The monomethylether of hydroquinone can induce a similar leukoderma [7]. Several phenolic germicidal preparations can produce depigmentation of the skin [4]. 4-Tertiary-butylcatechol is also a cause of occupational leukoderma [8], and this may follow contact sensitization [9]. The areas most likely to be affected in occupational leukoderma are the dorsa of the hands (see Fig. 58.7), but other areas are involved, not necessarily in contact with the chemicals. The depigmented areas frequently enlarge, and new ones appear even after the patient is no longer

‡ Partial loss of pigment in circumscribed areas.
§ Loss of pigment in hair.

in contact. The areas may or may not repigment. Treatment with psoralens is usually ineffective. In the hypomelanotic and amelanotic areas, there is often an almost complete absence of melanocytes [3,4]. Experimental studies [1,10] indicate that these substituted phenols have a selective lethal effect on functional melanocytes.

Fig. 58.39 Hypopigmentation in a girl with resolving psoriasis.

Post-inflammatory and infections

Hypomelanotic areas occur following the resolution of areas of eczema and psoriasis (Fig. 58.39). These are also seen in pityriasis lichenoides and cutaneous T-cell lymphoma [1].

Fig. 58.40 Pityriasis alba. (Courtesy of St John's Institute of Dermatology, London, UK.)

The superficial eczema known as pityriasis alba (see Chapter 23) commonly presents with white, somewhat scaly, and not so well-defined areas of skin, which are most noticeable on the cheeks of racially pigmented children (Fig. 58.40).

Hypopigmented macules occur in the superficial fungal infection pityriasis versicolor, a condition frequently mistaken for vitiligo. Hyperpigmented areas are also present. It is suggested that the fungus forms oxidation products of unsaturated fatty acids of skin surface lipids that inhibit the tyrosinase activity of melanocytes [2]. Other mechanisms are suggested, including the fungus acting as a sun barrier in a thickened stratum corneum. Light and electron microscopy studies of hypopigmented macules [3,4] and of hyperpigmented areas [5] have been unhelpful in determining the mechanisms involved and are confusing. The lack of sunburn in the pale areas may be explained by the fact that the causative yeast produces pityriacitrin, an indole compound that has a broad spectrum of ultraviolet absorption [6].

In a number of inflammatory disorders of the skin, there are areas of hypomelanosis and in these there may be a loss of functional melanocytes. This loss is seen in lupus erythematosus and lichen planus. Hypopigmentation is seen in sarcoidosis [7,8] and leprosy [9]. A leukomelanoderma occurs in syphilis.

Idiopathic guttate hypomelanosis [1–3]

This clinical entity, also known as disseminate lenticular leukoderma [4], can be mistaken for vitiligo. It is common. The lesions in white people most frequently occur in sun-exposed areas of the limbs. Solar damage is a factor in these cases. Non-actinic lesions occur in black people and may be on the trunk in unexposed areas [1].

Clinically, the lesions are porcelain-white macules, usually 2–6 mm in size but sometimes much larger. The borders are sharply defined, often angular and irregular. The skin markings are normal. Histologically, there is a decrease in pigment granules. Histochemical and ultrastructural studies [5,6] show a reduction in the number of melanocytes, many of which lack mature melanosomes. It has been suggested that this disorder results from an age-related somatic mutation of melanocytes.

Symmetrical progressive leukopathy [1]

This has been reported from Japan and Brazil, where it is relatively common. Punctate leukoderma develops in young adults, symmetrically on the front of the shins and on the extensor aspects of the arms, and less often on the abdomen and interscapular region. It is persistent.

Cutanous lymphoma [1,2]

Cutaneous T-cell lymphoma may sometimes show prominent hypopigmentation. In poikilodermatous mycosis fungoides, clinical lesions are characterized by widespread poikiloderma rather than plaques or nodules. On clinical examination there is alternating increase and decrease in pigmentation associated with epidermal atrophy. In hypopigmented mycosis fungoides, the areas of hypopigmentation are more prominent than in poikilodermatous mycosis fungoides [1,2].

Endogenous non-melanin pigmentation [1]

A variety of substances that are normal constituents of the body may, if present in excess or in an abnormal form or site, give rise to alterations in skin colour. Other substances formed only by patients with certain metabolic defects may also produce pigmentary changes. Special stains of histological specimens, or techniques such as spectroscopy, may help to identify the nature of exogenous and other non-melanin pigments.

Haemosiderosis

The deposition in the tissue of the iron-containing pigment haemosiderin is commonly the result of the local destruction of red blood cells, but also occurs in haemochromatosis. The presence of haemosiderin stimulates melanogenesis, and hypermelanosis may dominate the clinical and histological picture. Such is the case in haemochromatosis (see Chapters 59 & 62). Much more frequently, haemosiderin in the skin is derived locally from red blood cells (Chapter 49); in such conditions, the pigmentation is orange–red at first, later fading through ochre and tawny shades.

Hypostatic haemosiderosis

Haemosiderosis of the lower legs is extremely common in the presence of venous insufficiency. Recently involved areas show grouped points of reddish pigment, but recurrent extravasation of red cells combined with increasing hypermelanosis soon produce a more or less uniform deep brown or coppery colour. The pigmentation usually persists even if the venous insufficiency is relieved.

Sickle-cell anaemia and congenital haemolytic anaemia

Haemosiderosis and melanosis may give rise to conspicuous pigmentation of the lower leg in the third decade or earlier.

Schamberg's disease and related disorders [2]

(see Chapter 49)

Haemosiderosis without clinically evident hypermelanosis is seen in Schamberg's disease and other types of capillaritis. Reddish-brown plaques with cayenne-pepper points beyond their margins are present on the legs and thighs and sometimes on the arms.

Small patches of haemosiderosis, most numerous on the lower legs but progressively involving thighs and buttocks, are characteristic of drug reactions to ureides. Haemosiderosis of the trunk is a feature of some reactions to clothing.

Jaundice

Jaundice results from the staining of the skin with bilirubin, which has a great affinity for elastic tissue, hence the early involvement of the sclerae. The range of yellow shades produced by bilirubin may be modified by the presence of biliverdin, which adds a greenish hue. Bronzing is the effect of added melanin pigmentation and is often seen in jaundice of long duration. The sclerae are not involved in carotenaemia and only rarely in mepacrine pigmentation (p. 58.55).

2 Satoh T, Yokozeki H, Nishioka K. Chronic pigmented purpura associated with odontogenic infection. *J Am Acad Dermatol* 2002; **46**: 942–4.

Bronze baby syndrome [1–3]

This striking grey-brown discoloration of the skin of neonates follows phototherapy for hyperbilirubinaemia and is often associated with evidence of liver dysfunction. The serum is also brownish. The nature and origin of the pigment are uncertain. The changes are reversible unless there is some underlying liver disease.

Riboflavinaemia [1]

Yellow skin and hair have been described in a patient with myeloma, due to riboflavin being avidly bound by a monoclonal antiflavin antibody.

Reference

1 Farhangi M, Osserman EF. Myeloma with xanthoderma due to an IgG monoclonal anti-flavin antibody. *N Engl J Med* 1976; **294**: 177–83.

Carotenaemia [1]

Carotene, a lipochrome, contributes a yellow component to the colour of normal skin. In the presence of excessive blood carotene levels, this yellow component is increased, and is most conspicuously accentuated where the horny layer is thick on the palms and soles. The sclerae are not discoloured. The most striking coloration is seen in food faddists who overindulge in oranges or carrots. Some increased yellowness is seen in conditions with hyperlipaemia, diabetes, nephritis and hypothyroidism, and where conversion of carotene to vitamin A is impaired by an inborn metabolic error [2] or by hepatic disease. However, it is now more commonly seen in young women drastically reducing their weight and eating foodstuffs with high carotene content [3,4].

Carotenaemia is seen in patients on oral supplements of β-carotene as a photoprotective agent in erythropoietic protoporphyria [5,6] and in those taking carotenoids that contain canthaxanthin.

Ochronosis (see Chapter 59)

In alkaptonuria, a deficiency in homogentisic acid oxidase causes accumulation of homogentisic acid throughout the body. Ochronosis is the term used to describe the pigmentary changes that occur in connective tissue in patients with alkaptonuria [1]. The term was coined by Virchow in 1866 for the ochre-like (pale yellow) colour of the connective tissue when viewed down a microscope. Ochronosis is present in about 75% of patients with alkaptonuria, and the majority show some pigmentation. Most frequent is darkening of the ear cartilages and of the sclerae and conjunctiva. Less often the axillary skin is pigmented and there is brown mottled pigmentation of the face, sometimes in a butterfly distribution, and of the neck and trunk. Rarely, pigmentation of the palmar and plantar skin is seen [2]. Examination of the urine establishes the diagnosis.

Exogenous pigments

A wide variety of chemicals, either from industrial or medicinal exposure, can produce discoloration of the skin. Some of these may not only produce an alteration of pigmentation by being deposited in the dermis but may also result in an increase in the amount of melanin in the skin. Of importance are the metals silver, gold, mercury and bismuth, which are cumulatively deposited in the dermis and can produce permanent disfiguring pigmentation. A number of drugs can cause discoloration of the skin. These include the antimalarials, the phenothiazines, clofazimine and minocycline. Of less importance is the transient staining of the skin produced by picric acid, dinitrophenol and chemical dyes.

Metals

Argyria [1–8]

Silver may be deposited in the skin either from industrial exposure or as a result of medication with silver salts [2–4]. Blue macules have appeared at sites of acupuncture needles [6]. Cases have followed the use of silver salts for the irrigation of nasal, oral and urethral mucous membranes and the excessive use of an oral smoking remedy containing silver acetate [2,7]. 'Food supplements' may also contain colloidal silver [8]. The pigmentation is usually a slate-grey colour and may be clinically apparent after a few months, but usually takes many years to develop and depends on the degree of exposure. The hyperpigmentation is most apparent in sun-exposed areas of skin, especially the forehead, nose and hands (Fig. 58.41). In some patients, the entire skin has a slate blue-grey colour. The sclerae, nails and mucous membranes may become hyperpigmented. Light and electron microscopy studies

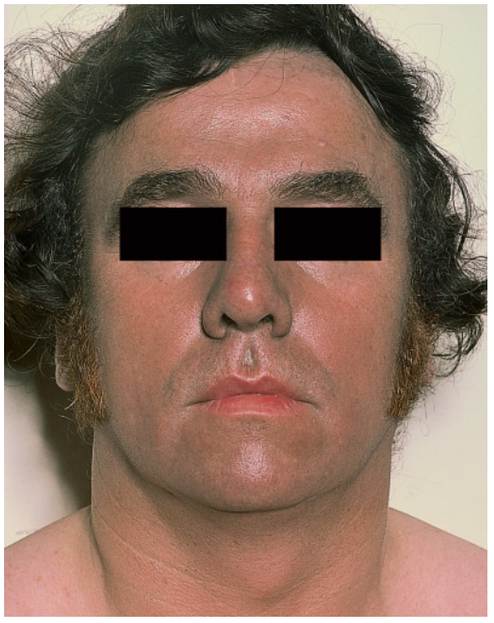

Fig. 58.41 Occupational argyria.

[1,5,6,8,9] show silver granules in the dermis that are most numerous in relation to the basal lamina of the eccrine sweat glands, and in the dermal elastic fibres. Furthermore, silver particles may be seen lying free within the cell cytoplasm of epithelial cells of the secretory segment of eccrine sweat glands and in mast cells [8,9]. Silver granules are readily visible with dark-field illumination. X-ray-dispersive microanalysis confirms that the granules contain silver [1,6]. Silver is widely deposited in the tissues as well as in the skin. The diagnosis of argyria is established by skin biopsy. The pigmentation is permanent; treatment with depigmentary preparations is not effective.

Chrysiasis [1–5]

Chrysiasis and chrysoderma are terms used to describe permanent pigmentation of the skin due to parenteral administration of gold salts. Excessive administration of gold leads to its deposition

in connective tissue. Chrysiasis has not been observed in any patient who has received less than 50 mg/kg of gold thiosulphate, and it has not failed to develop in any patient receiving more than 150 mg/kg. It may first develop after a few months or after a long latent period. The pigmentation is blue-grey or may show a purplish hue, and is limited to light-exposed skin and to the sclerae [3]. The oral mucous membrane is not affected. The diagnosis is confirmed histologically on microscopy with dark-field illumination and on electron microscopy with electron probe microanalysis [4]. The granules of gold are larger and more irregular than those of silver. The pigmentation is permanent [5].

Mercury [1–4]

Repeated applications of mercury-containing compounds can produce localized hyperpigmentation of the treated areas [1–3]. Systemic administration of mercury results in gingival hyperpigmentation. The pigment is observed in the upper dermis around capillaries and associated with collagen and elastic fibres. Electron microscopy shows an increase in melanin pigmentation and the metal is present as granules in dermal macrophages [1,3]. A case report of homicidal subcutaneous injection of metallic mercury resulted in widespread skin lesions, remote from the radiologically visible mercury; these appeared at 40 days and began to clear at 6 months [4].

Bismuthia

The administration of bismuth at regular intervals over a period of years has often been practised, yet generalized pigmentation is extremely rare. The diffuse grey pigmentation resembles that of argyria and involves also the sclera and the oral and sometimes the vaginal mucous membrane [1].

A distinctive blue-black line occurs at the gingival margin. This is due to deposition of bismuth that reacts with hydrogen sulphide formed by bacteria in the mouth [2].

Drugs

Mepacrine [1,2]

Pigmentation of the skin is first noticed a few days after the administration of mepacrine commences and may persist for several weeks after it ceases. The dye is deposited in the skin. A bright-yellow or greenish-yellow colour develops first and remains most prominent on the face, hands and feet, but occurs diffusely with accentuation in the skin flexures. The sclerae are sometimes affected, which may mimic jaundice [2]. The melanin-containing pigment induced by antimalarials is discussed in Chapter 75.

Clofazimine (Lamprene) [1–4]

This synthetic riminohenazine dye used in the treatment of leprosy produces an initial redness of the skin due to an accumulation of the drug. Later, with prolonged treatment, a violaceous brown colour develops that is most noticeable in lesional areas [1]. Histochemical studies indicate a ceroid-lipofuscin pigment as well as clofazimine inside macrophage phagolysosomes [2,3]. Reddish-blue pigmentation has been reported within scarred areas of lupus erythematosus in one patient [4].

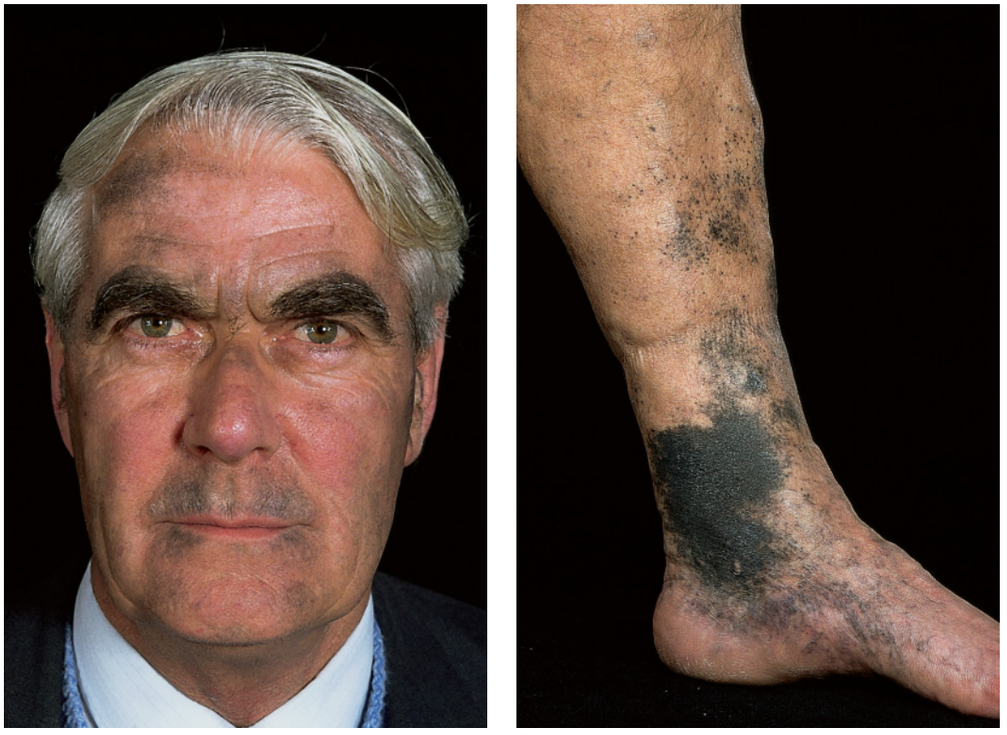
Hydroxyurea [1]



Nail pigmentation has been reported in association with use of hydroxyurea and most commonly consists of longitudinal melanonychia. Occasionally all 20 nails are affected and there is associated hyperpigmentation of the skin.

Reference

1 Aste N, Fumo G, Contu F *et al*. Nail pigmentation caused by hydroxyurea: report of nine cases. *J Am Acad Dermatol* 2002; **47**: 146–7.

Minocycline [1–8]

Long-term therapy with minocycline may result in pigmentation, but this is generally agreed to be rare. Three types of cutaneous pigmentation are seen in patients treated with minocycline [6] (Fig. 58.42):

(a) (b)

Fig. 58.42 (a) Hyperpigmentation of the skin in sun-exposed areas of the face due to long-term therapy with minocycline. (b) Blue-black pigmentation on the lower legs in the same patient.

1 A focal type with well-demarcated blue-black pigmentation at sites of previous inflammation as first described in acne scars [1]
2 A more diffuse and generalized pigmentation that is most apparent in sun-exposed areas of skin and nails [2], but may also involve the sclera [5]
3 A more persistent brown-grey change most prominent on sun-exposed sites.

The pigmentation usually occurs following prolonged courses and high doses of this drug. Histological studies show the presence of brown-black granules in the upper dermis that stain for iron [1,3]. Electron microscopy reveals electron-dense material in dermal macrophages and X-ray microanalysis confirms the presence of iron [4]. Partial resolution of the pigmentation occurs after the drug is stopped [6]. Similar blue-black pigmentation of the legs has resulted from treatment with the 4-quinolone antibiotic pefloxacin [7] and the tetracycline antibiotic methacycline [8].

Amiodarone [1–5]

Amiodarone is a drug used for prolonged periods in the treatment of ventricular tachycardia. It induces photosensitivity in more than 50% of patients; however, fewer than 5% develop cutaneous hyperpigmentation [1–5]. A grey-blue pigmentation of the face and other sun-exposed areas is a rare late effect of this drug, and may also involve non-exposed sites (Fig. 58.43) [1]. Yellow-brown granules are present in dermal histiocytes. Ultrastructural studies show membrane-bound dense lysosomal bodies in macrophages that probably contain degradation products of the drug bound to lipofuscin [1,2]. Dose reduction or withdrawal of amiodarone can lead to complete disappearance of the pigmentation [5].

Picric acid, dinitrophenol and other chemicals

Picric acid, self-administered by malingerers to simulate jaundice, stains the skin yellow. Dinitrophenol, formerly used in industry

Fig. 58.43 Bluish pigmentation on the nose caused by amiodarone therapy.

and as a metabolic stimulant, also produces yellow staining of the skin and of the sclerae. Trinitrotoluene, santonin and acriflavine also stain the skin yellow.

Tattoos

Accidental tattoos

Pigmented particles may be accidentally introduced as contaminants of wounds or may, at high velocity, penetrate previously intact skin.

Superficial abrasions contaminated with chemically inert particles may be followed by disfiguring tattoos. Such irregularly spattered pigmentation is quite commonly seen after road accidents and blast injuries. Some particles may eventually be extruded, but the disfigurement is often permanent. Small lesions may be excised and larger areas treated by dermabrasion, the results of which depend on the depth to which the particles have penetrated.

Collier's stripes [1]

These are a very distinctive occupational mark in coalminers. The bluish grey, linear or angular stripes develop at the sites of abrasions. The commonest sites are the forehead, bridge of the nose, wrists and elbows. Histologically, particles of coal dust up to 100 µm in diameter are seen at all levels in the dermis. They tend to be grouped around blood vessels.

Therapeutic agents

Iron salts. The use of solutions of ferric sulphate and ferric chloride in the treatment of dermatitis has been followed by a reddish-brown tattoo [2,3]. The pigmentation may disappear after a few months or may persist indefinitely [4].

Occupational contact with iron salts [5] produced red-brown punctate perifollicular pigmentation of the forearms in a man employed in pickling metal in hydrochloric acid.

Gentian violet (pararosaniline chloride). This has, exceptionally, given rise to a tattoo when applied to a wound of the face [6].

Decorative tattoos (see also Chapter 28) [1–5]

History and prevalence. From ancient origins the practice of tattooing has developed along more or less parallel lines in most countries. Tattoos have been used to accentuate beauty, as a permanent adornment or to make a statement. Occasionally, tattoos serve to accentuate aggression or ugliness in order to make the wearer more intimidating. Tattoos with words or a name as a symbol of dedication or devotion have always been popular. Tattoos have also been used for more sinister motives. Tattoos were used as a means of identification by the Nazis in the Second World War for members of concentration and labour camps as well as for members of the SS. Formerly associated with religious ceremonies, fertility and marriage rites, tattooing in contemporary westernized civilizations thus fulfils a number of diverse functions and in so doing it survives and flourishes.

Contemporary life finds tattooing more popular than ever [1], even among the elite [2]. Tattoos are no longer the exclusive preserve of street gangs, prisoners and members of the armed forces [1,2]. Not all who submit to tattooing are emotionally unstable, immature individuals. Indeed, tattooing is viewed by many as an acceptable fashion accessory like any other, and is increasingly popular in Western societies with the young and with women, as well as the more traditional male stereotypes [1,2]. Tattooing and body piercing are now so common that health-care workers are advised to maintain a non-judgemental attitude to tattoos [1], even in the face of the unexpected [4]. The decision to have a tattoo may be taken when an individual is in no position to make such a lifelong commitment, for example when intoxicated, under peer pressure or when mentally unwell [5]. Tattoos may also be a manifestation of deliberate self-harm [6].

Another contemporary trend is the use of temporary black henna 'tattoos' [3,7]. These are not true tattoos but represent application of a black dye to produce a tattoo-like appearance that lasts for a few days. Unfortunately, a high concentration of the well-known contact sensitizer paraphenylenediamine is usually present in these 'tattoos', which results in a risk of contact allergy [3,7].

Techniques and materials. The professional tattooist uses an electric needle to introduce particles of pigment into the dermis; the amateur, often a child, pricks particles of soot or Indian ink into skin with any pointed object. The individual's choice of design may be motivated by subconscious psychological factors. The pigments commonly employed include:

- Blue-black (carbon)
- Red (cinnabar and vegetable dyes)
- Light blue (cobaltous aluminate)
- Green (chromic oxide or chromium sesquioxide)
- Yellow (cadmium sulphide)
- Brown (ochre, iron oxides).

Complications of tattoos

Unhappiness with the tattoo

Many regret having a tattoo, which may cause a significant psychological, social and financial burden [8].

Introduction of infection

Significant infection of tattoos is now unusual, and pyogenic infection, although the most frequent, is seldom serious. Erysipelas and gangrene, necessitating amputation, are mentioned in the older literature. Syphilis and tuberculosis have been inoculated by the tattoo needle, and small outbreaks have been traced to an infected operator. The tattooing of many people in rapid succession has been suspected of transmitting infective hepatitis. Also there is the risk of transmitting retrovirus infection. The transmission of leprosy is suspected [9]. Both vaccinia and warts have developed in recently inflicted tattoos.

Allergic reactions to pigment

Once the initial inflammatory changes have subsided, by far the most frequent reaction observed in tattoos is the development of allergic sensitivity to one of the pigments.

In most cases, the tattoo pigment itself, or a derived compound formed locally in the tissues, provokes the development of hypersensitivity, which is manifest clinically by the sudden onset of irritation, swelling and redness in a part of the tattoo a few weeks or many years after its infliction. In recent years, lichenoid tattoo reactions have been reported; these appear to be confined entirely to the red areas (Fig. 58.44) [10]. These resemble the reactions to cinnabar (mercuric sulphide); although this pigment has now been replaced by vegetable dyes, cases do still occur [11].

The allergic reaction can remain localized but may become generalized as a patchy eczematous eruption or an exfoliative dermatitis. In some cases, the primary sensitization is induced by some other contact with the metal, and the reaction in the tattoo accompanies or follows an attack of contact dermatitis.

Mercury [12]. The red areas of the tattoo are affected. The reaction may eventually subside spontaneously, but the risk of a generalized eruption is high. The tattoo reaction may be accompanied by erosions of the oral mucosa in contact with amalgam dental fillings [13]. Patch tests are positive to mercuric chloride and ammoniated mercury but not necessarily to cinnabar.

Fig. 58.44 Lichenoid reaction in red areas of a tattoo.

Chrome [14]. The green areas are affected. The patient is often primarily sensitized by exposure to cement. Patch tests with 0.5% potassium dichromate are positive.

Cobalt [15]. The light-blue areas are affected. In three patients, the tattoo reaction was accompanied by the simultaneous development of uveitis [16]. Patch tests are positive with 2% cobalt chloride.

Manganese [17]. A reaction in the purple areas of a tattoo was due to manganese.

Carbon [18]. A case is reported of a reaction in the black areas of a tattoo, presumably to carbon particles.

Light-induced reactions [19]. A high proportion of yellow tattoos develop redness and swelling only on exposure to sunlight, and the same phenomenon is occasionally observed in red tattoos. The mechanism is uncertain, although the yellow pigment, cadmium sulphide, has photoconducting properties.

Localization of skin disease in tattoos

Some skin disorders show a predilection for tattooed skin, in which they may appear first or be accentuated. Syphilis in the secondary or tertiary stage has often been observed in tattoos but tends to spare the red areas, apparently deterred by the mercury. Lichen planus and psoriasis may be localized in tattoos but show no colour predilection. Lupus erythematosus is more rarely seen. A sarcoidal granuloma in a tattoo may be the presenting manifestation of generalized sarcoidosis [20]. Melanoma has been reported in a tattoo [21], although the association may be fortuitous. Foreign-body granulomas of sarcoid type are extremely unusual after decorative tattoos, but have been reported in ochre tattoos [22]; ochre has a high silica content.

Treatment of tattoos [1–9]. The removal of a tattoo may become essential on account of the development of one of the complications considered above, most commonly an allergic reaction within the tattoo. Some cases will settle with intralesional or even topical steroids, but more often excision of the offending area of tattoo, followed if necessary by grafting, is the only satisfactory treatment to secure elimination of all particles of pigment.

Far more frequently, removal of a tattoo is sought on aesthetic or cosmetic grounds, often only a few weeks after its infliction. If the area involved is small and simple or serial excision without grafting is practicable, this is undoubtedly the treatment of choice. If grafting is essential, the inevitable cosmetic imperfections of grafts are such that alternative procedures may be considered. Salabrasion using table salt is of use [6]. Some good results have been achieved with lasers, but scarring, at times quite troublesome, is likely to remain. The best results are with Q-switched red or near-infrared laser systems [7]. Infrared coagulation has also been used [8]. The keratotome [9] gives moderately good results and at least partially obliterates the design. For very extensive tattoos, dermabrasion or chemosurgery [4] have been advocated. The choice of technique should be influenced by personal predilections, and the experience of the plastic surgeon consulted. The patient should be warned that there is usually some residual pigment following superficial abrasion and there may be scarring.

The cutaneous porphyrias

R.P.E. Sarkany, pp. 59.1–59.21

Introduction

The porphyrias are a group of disorders caused by defects in the biosynthesis of haem. Their relevance to the skin arises from the phototoxic properties of the porphyrins, which accumulate in most porphyrias and cause photosensitivity.

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

The majority of the porphyrias are inherited. Many of them affect other organs as well as the skin. The recognition and management of both the genetic and internal consequences of porphyrias presenting in the skin are a key challenge for the dermatologist.

Clinical management in these disorders is made easier when the clinician understands their theoretical basis. Thus, this section is divided into two halves. The first provides a theoretical basis for understanding the porphyrias, the general principles of clinical management and a clinician's guide to laboratory testing. The second half covers individual porphyries in detail.

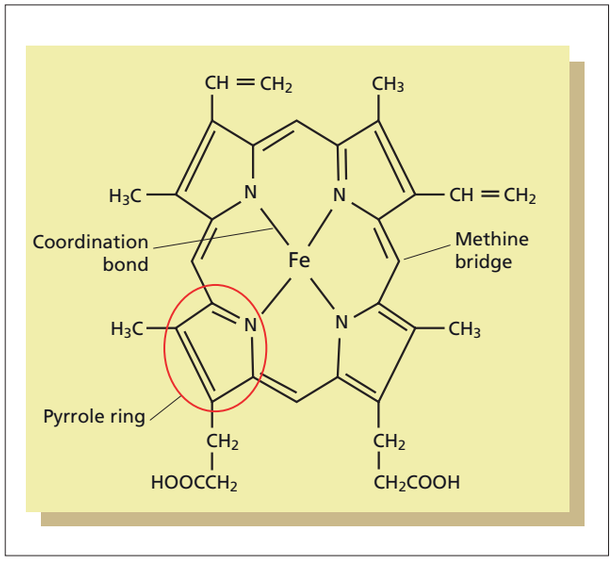

Fig. 59.1 The haem molecule and its key structural features. The alternation of single and double bonds around the tetrapyrrole ring indicates the aromaticity of the molecule, central to its chemical characteristics. The four coordination bonds between iron and nitrogen atoms are shown. The two remaining bonds between the iron and either molecular oxygen or amino acid residues lie perpendicular to the page.

General considerations: theoretical basis, clinical features and laboratory testing in porphyria

A theoretical basis for understanding the porphyrias

The phototoxicity of porphyrins

The phototoxic properties of porphyrins are responsible for the cutaneous features of the porphyrias. Porphyrins are intermediates in the biosynthesis of haem, and consideration of the chemical features of the haem and porphyrin molecules is necessary to understand the cause of porphyrin phototoxicity.

The chemistry of porphyrins and haem [1]. A pyrrole is a ring composed of four carbon atoms and one nitrogen atom. Four pyrroles linked into a ring create a tetrapyrrole, a remarkable and biologically critical molecular structure found in chlorophyll, haem and vitamin B_{12}. A porphyrin is a special type of tetrapyrrole in which four pyrrole rings are linked by methine bridges into a large ring structure.

Haem is the molecule created by the insertion of ferrous iron into the centre of the porphyrin molecule, protoporphyrin IX (Fig. 59.1). Essentially, incorporation of iron into the porphyrin molecule enables it to become biologically useful. Iron's capacity to bind to molecular oxygen, and to transfer electrons (by moving between the 2+ and 3+ oxidation states) makes it potentially useful in biological systems, but free iron precipitates in the presence of water. For iron to be useful, it has to be kept soluble by protecting its binding sites against water. In addition, subtle modification of the electronic structure of the iron atom can optimize its ability to transfer electrons and reversibly bind molecular oxygen. Binding of iron to the porphyrin molecule solubilizes iron and also optimizes its electronic structure. The porphyrin's central cavity is the right size to fit an iron atom, and its four central nitrogen atoms occupy four of the iron's coordination binding sites, leaving only two free. A key feature of the porphyrin structure is that each double bond is adjacent to a single bond, so it is 'aromatic' with 18 of its electrons being delocalized and free to move around the molecule (Fig. 59.1). This electron current results in the central nitrogen atoms tending to donate electrons to the iron atom, as well as other subtler electronic interactions involving transient changes in the porphyrin's electronic state [2]. Haem can bind to a variety of proteins, and the nature of this interaction reflects the protein's function. In proteins with electron transport functions, such as respiratory cytochromes, amino acids bind to both remaining coordination binding sites on the iron so that haem can transfer electrons through alterations in the iron's oxidation state. In proteins with oxygen-binding functions, such as haemoglobin, an amino acid binds to one of the iron's remaining coordination binding sites, leaving the sixth site free to bind to oxygen. In summary, the aromatic porphyrin structure is well suited to complexing with iron to form haem, rendering the iron useful for electron transfer (respiratory cytochromes), reversible oxygen binding (haemoglobin and myoglobin), and oxidation and reduction reactions (cytochrome P450, catalase), with fine tuning of the iron's functionality being determined by the apoprotein which binds to the haem.

Photochemistry of the porphyrins [3,4]. The complex electronic structure of the large aromatic porphyrin molecule results in its 18 delocalized electrons having unusual excitation characteristics. These electrons are excited by relatively long wavelength light. The main absorption peak is at 408 nm ('Soret band') [3], and this long wavelength of exciting light predisposes to phototoxic behaviour by the porphyrin; these photons have insufficient energy to chemically alter the porphyrin structure, so that alternative fates for the energy, particularly fluorescence and phosphorescence, become more likely [4]. Thus, following excitation by light around the 408 nm peak, electrons either return to the non-excited ground state by releasing the energy as the characteristic red fluorescence, or the porphyrin's excited singlet state transforms (by intersystem crossing) to the longer-lived excited triplet state. Transfer of energy from this excited triplet state to neighbouring molecules leads to the phototoxicity responsible for the clinical features of the cutaneous porphyrias. Thus cutaneous disease in the porphyrias can be thought of as a by-product of the unusual porphyrin structure which enables haem-proteins to fulfil their biological functions.

Enzyme deficiencies and the porphyrias

The porphyrias all result from a partial deficiency of one of the enzymes required for the biosynthesis of haem, thus causing accumulation of the enzyme's substrate. The toxicity profile of the accumulated molecule determines the clinical features of the resulting porphyria. A basic understanding of the biosynthetic pathway enables the clinician to interpret laboratory results and to predict the clinical features of each porphyria on the basis of each porphyrin's properties.

The biosynthesis of haem [1,2] (Fig. 59.2). Haem is synthesized from simple biochemicals (glycine and succinyl CoA) via an eight-step pathway, each step being catalysed by an enzyme. Synthesis of the pyrrole ring (porphobilinogen (PBG)) is followed by assembly of the tetrapyrrole structure (hydroxymethylbilane). One of the pyrrole rings (the 'D' ring) is 'flipped' around to create the III isomer (the alternative I isomer forms in the absence of the cosynthase enzyme). Next, the carboxylic acid side-chains of uroporphyrinogen III are progressively decarboxylated via coproporphyrinogen III to protoporphyrinogen, which is then oxidized to protoporphyrin IX. It is likely that the progressive decarboxylation to remove six of the eight electron-withdrawing carboxylate groups increases the flux of electrons onto the molecule's central nitrogens to facilitate coordination with iron. Finally, ferrous iron is chelated into the protoporphyrin's central cavity to form haem. Around 80% of haem is synthesized in erythroid cell precursors in the bone marrow (for haemoglobin production). The decarboxylation of uroporphyrinogen to coproporphyrinogen, and thence to protoporphyrinogen, decreases water solubility, so that uroporphyrinogen is only excreted via the kidneys whereas hydrophobic protoporphyrinogen and protoporphyrin are exclusively excreted into the bile. Coproporphyrinogen is excreted by both routes. Physiological concentrations of porphyrins stay low because of the high efficiency of haem synthesis.

Clinical features of the porphyrias: general considerations

Porphyrias present with either skin disease or acute attacks or both.

The classification of the porphyrias [1,2]

In any porphyria, a partial enzyme deficiency causes the accumulation of porphyrins. The enzyme deficiency associated with each disorder is shown in Fig. 59.3. The porphyrias have previously been classified, according to the predominant site of porphyrin accumulation, into the erythropoietic group (congenital erythropoietic porphyria and erythropoietic protoporphyria) and the hepatic group (all the others). This division is not of value clinically. For the clinician, the key division is between porphyrias that cause acute attacks and those that cause skin disease. In this chapter the following classification is used for the six common porphyrias:

1 Cutaneous disease only:
Porphyria cutanea tarda (PCT)
Congenital erythropoietic porphyria (CEP)
Erythropoietic protoporphyria (EPP).
2 Cutaneous disease and acute attacks:
Hereditary coproporphyria (HC)
Variegate porphyria (VP).
3 Acute attacks only:
Acute intermittent porphyria (AIP)

Porphyria and the skin

The cutaneous porphyrias share many features. Consideration of these underlying similarities is necessary for a logical approach to clinical management of patients.

All the cutaneous porphyrias, except EPP, present with fragility and blistering of light-exposed skin; the term 'bullous porphyrias' is often used for this group of diseases. Not only can they appear very similar clinically, but the mechanism underlying the skin disease in all cutaneous porphyrias is a local porphyrin phototoxicity reaction. This shared pathogenetic mechanism means that the histopathological appearances in each of these conditions are also similar. As a result, these disorders can only be reliably differentiated by biochemical analysis. The other important similarity between them is that they are all caused by Soret wavelength light (408 nm), so the same strategy for photoprotection applies to them all, as detailed below.

The pathogenesis of skin disease in porphyria (Fig. 59.4) [1–3]. Photons of violet light, with a wavelength peak at 408 nm, transform the porphyrin molecule into an excited singlet state. This may revert to the unexcited ground state by emission of the characteristic red porphyrin fluorescence, but intersystem crossing can convert it to the excited triplet state, long-lived enough to interact with other molecules, particularly molecular oxygen, converting it to excited singlet oxygen in the process. The singlet oxygen stimulates production of hydroxyl radicals which damage tissue directly, and also indirectly by stimulating complement activation [4], mast cell degranulation [5] and matrix metalloproteinase activity [6]. The site of this phototoxic reaction in the skin determines the clinical characteristics of the porphyria. In EPP, lipophilic protoporphyrin tends to localize to membranes including endothelial cell membranes, and to remain within erythrocytes, and the phototoxic reaction involves upper dermal blood vessels causing pain. In PCT, the water-soluble uroporphyrin diffuses easily into surrounding tissues and the phototoxic reaction occurs in the upper dermis, causing lysis of cells in the superficial dermis with the formation of membrane-limited vacuoles which merge to produce a blister under the basal lamina, producing the characteristic clinical presentation [7]. In VP, copro- and protoporphyrin accumulate (Fig. 59.3), but patients suffer from PCT-like upper dermal blisters rather than EPP-like acute pain. This is likely to be

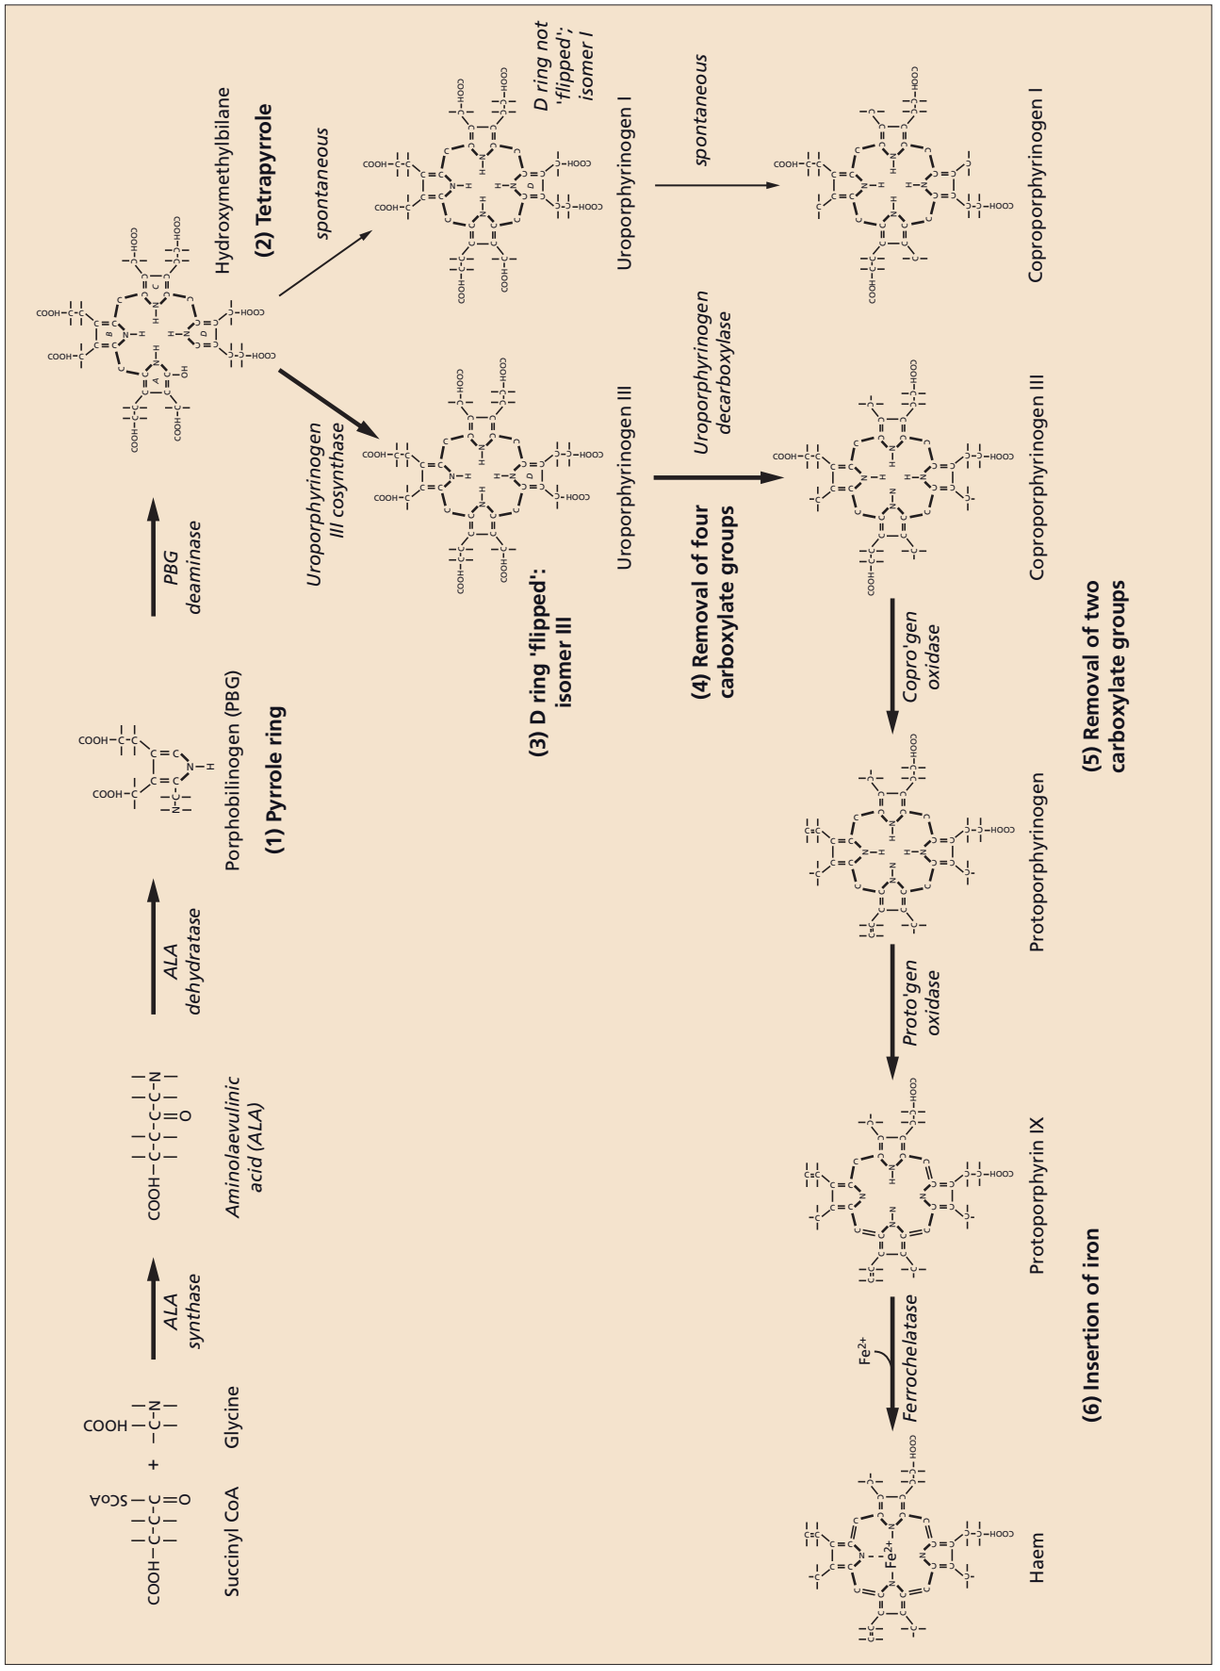

Fig. 59.2 The pathway of haem biosynthesis showing the six key structural changes.

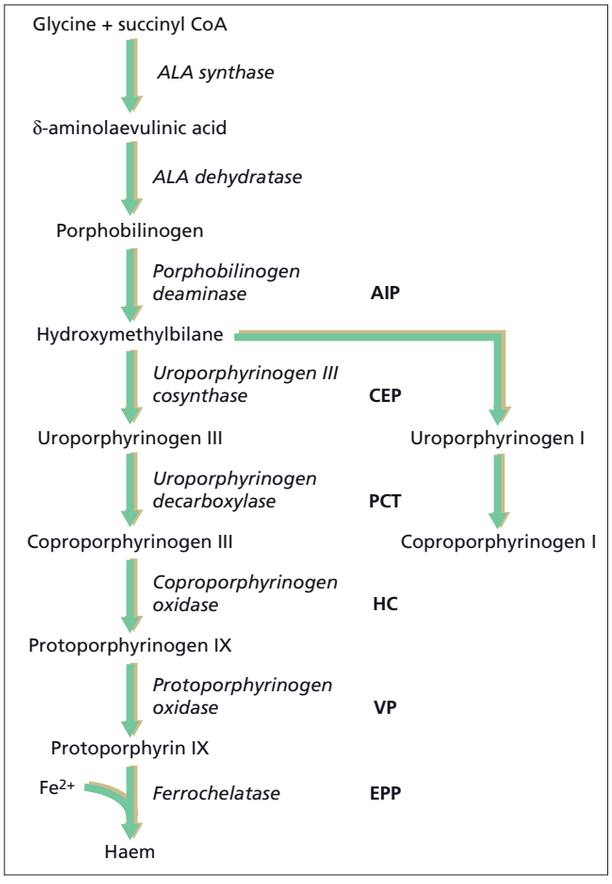

Fig. 59.3 The pathway of haem biosynthesis showing the enzyme deficiency associated with each porphyria. (The abbreviations of disease names are defined in the text relating to classification of the porphyrias.)

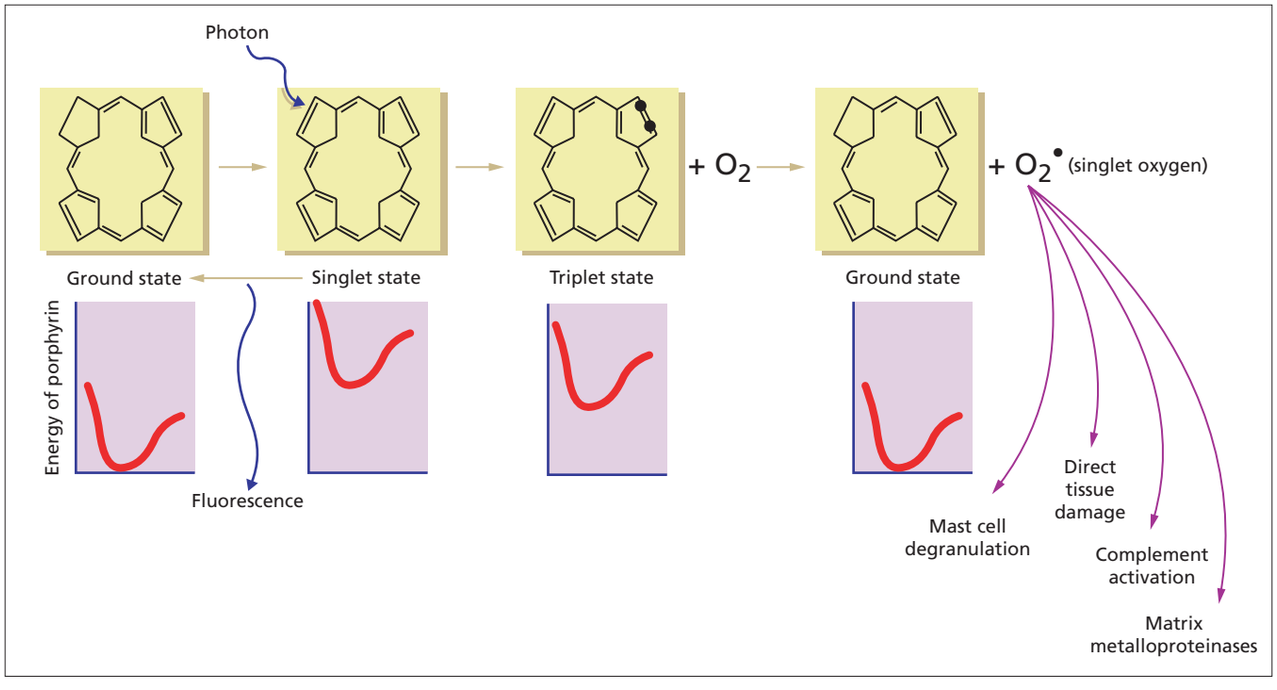
because, although hydrophobic porphyrins predominate in plasma in VP, hydrophilic porphyrins, particularly uroporphyrin, predominate in the skin, probably due to secondary local photoinactivation of uroporphyrinogen decarboxylase (UROD) in the skin by coproporphyrin [2]. In addition, the protoporphyrin in VP is conjugated to a peptide which may reduce its phototoxicity.

There is no simple correlation between the plasma porphyrin concentration and the severity of cutaneous disease in porphyria because of the large number of local variables which can alter the extent of the phototoxic reaction in the skin, and an increased plasma porphyrin concentration is not always associated with cutaneous disease [8].

Histopathology of the skin in porphyria [9,10]. In all the cutaneous porphyrias, homogeneous material is seen within vessel walls of the upper dermal and papillary vascular plexus. It is periodic acid–Schiff (PAS)-positive and diastase resistant, and contains a protein polysaccharide complex, lipids and tryptophan. Immunofluorescence reveals immunoglobulins (mainly IgG) in a similar vascular distribution, and IgG at the dermal–epidermal basement membrane zone, in involved skin. Electron microscopy shows reduplication of the vascular basal lamina and the presence of masses of fine fibrillar material, mainly around these blood vessels and often also at the dermal–epidermal junction. In EPP the vessel wall changes are more pronounced, whereas the basement membrane zone changes predominate in affected skin in PCT and VP. In the bullous porphyrias, bullae are subepidermal with the split occurring in the lamina lucida [11] (Fig. 59.5) leaving the dermal papilla protruding into the blister cavity, an appearance called 'festooning' [10]. The findings in bullous porphyrias are indistinguishable from those of pseudoporphyria. In EPP in the acute



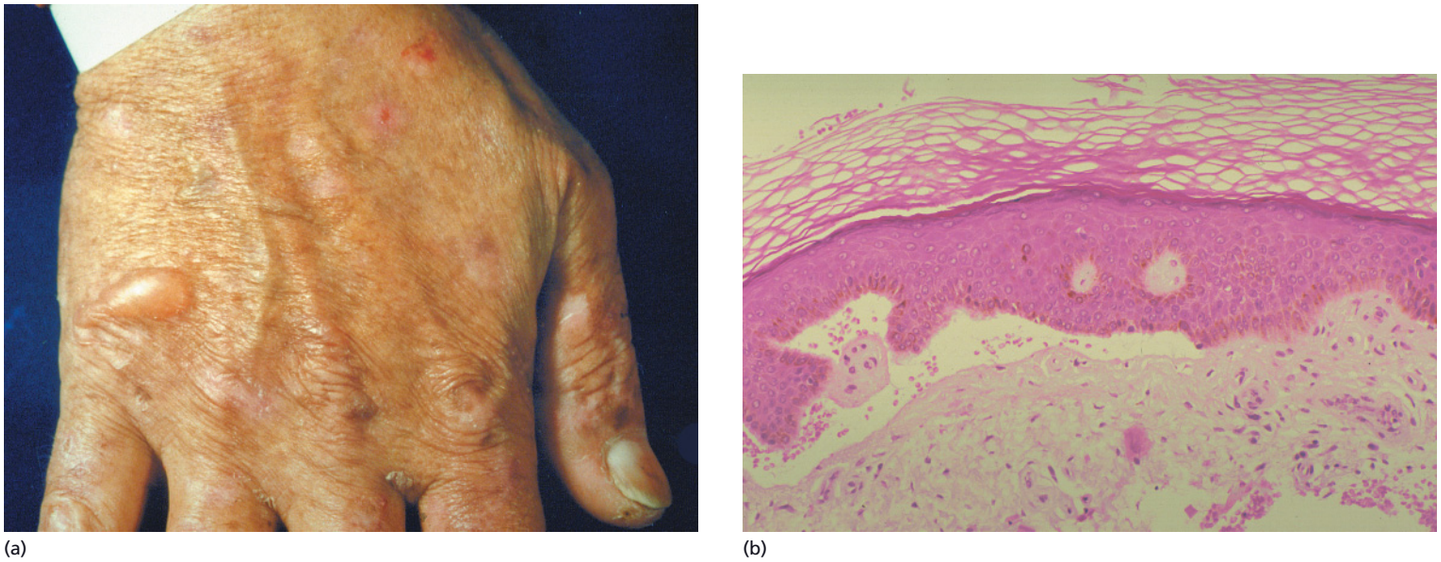


Fig. 59.4 The pathogenesis of skin disease in porphyria.

(a) (b)

Fig. 59.5 Typical subepidermal bulla in a bullous porphyria: (a) clinical appearance, (b) histological appearance.

phase there is visible endothelial damage in superficial dermal vessels [12]. Electron microscopy shows the 'amorphous' material seen in vessel walls on light microscopy in light-exposed skin to be a replicated, layered and fragmented basement membrane, with fine fibrillar material permeating the capillary connective tissue sheath and extending beyond the vessel walls, caused by the repeated episodes of damage [13,14].

General considerations in the management of skin disease in porphyria. Apart from PCT, and to some extent CEP, where effective specific treatments exist, the management of the skin in the other cutaneous porphyrias is based on preventing violet (Soret wavelength) light penetrating the epidermis. The connection between sun exposure and symptoms is obvious in EPP, but is not obvious to patients with the bullous porphyrias where fragility and blistering are not related to individual episodes of sun exposure. It can therefore be difficult to convince these patients of the importance of photoprotection. Basic measures include sun avoidance behaviour, sun-protective clothing and hats. Most sunscreens, including UV-absorbent chemical 'total sunblocks', do not protect against the visible violet Soret wavelength [15]; any sunscreen providing significant visible light protection will be opaque rather than transparent. Sunscreens containing reflectant particles, particularly large particle size titanium dioxide (pigmentary grade), zinc oxide and iron oxide, can effectively protect against violet light [16], and cosmetically acceptable sunscreens with reasonable protection up to 430 nm are available commercially, for example Dundee sunscreen (Tayside Pharmaceuticals, Dundee, UK) [15,16]. Dihydroxyacetone paint induces formation of a light-absorbing brown pigment in the stratum corneum, and has been used in some patients with EPP [17]. Some reasonably clear window films can absorb some violet light, and are useful on car or home windows, particularly in EPP and CEP [18]. This author generally uses two films which are clear and provide reasonable, though not complete, protection against Soret wavelength light (Dermagard film, Bonwyke, Hants, UK; and CLS200XSR film, Madico, USA). The Madico TA81XSR film is yellower but does provide better protection. Clearly, films applied to car windows must comply with local legislation, which varies considerably in different parts of the world.

Acute attacks of porphyria [1,2]

AIP, HC and VP can all cause acute attacks, and HC and VP may also cause cutaneous disease. (A rare autosomal recessive acute porphyria, aminolaevulinic acid (ALA) dehydratase porphyria, has also been reported but does not cause skin disease, and will not be discussed further.)

Definition. An acute and potentially fatal illness, frequently triggered by drugs and hormones which are metabolized by cytochrome P450. It is characterized by an acute neurotoxic reaction in many tissues.

Prevalence. The commonest acute porphyria is AIP, followed by VP. HC is rare. The prevalence of clinically overt acute porphyria in Europe is 1–2/100 000 inhabitants, but over 90% of individuals possessing AIP or VP gene defects are asymptomatic, so the enzyme deficiencies are common; PBG deaminase deficiency, which causes AIP, is present in 0.2% of all blood donors [3].

Aetiology [4]. Impaired activity of PBG deaminase is associated with acute attacks. The deficiency can be primary (as in AIP) or secondary, the latter being due to inhibition of the enzyme by accumulated coproporphyrinogen and protoporphyrinogen (as in HC and VP) [5]. In the liver, haem is mostly incorporated into cytochrome P450 proteins, whose production is induced by many of the drugs and hormones metabolized by the P450 system. When a drug or hormone induces cytochrome P450, and hence acutely increases the hepatic requirement for haem, the inability of the pathway to respond adequately because of the PBG deaminase deficiency is exposed. This acute hepatic haem deficiency in turn causes secondary accumulation of ALA and increased ALA synthase activity due to loss of end-product negative feedback. The symptoms of the acute attack result from neuronal dysfunction, the pathogenesis of which is not fully understood though postulated mechanisms include disturbed metabolism of neurotransmitters (due to reduced activity of haem-containing hepatic tryptophan dioxygenase), direct neurotoxicity of accumulated ALA (which structurally resembles the neurotransmitter γ-aminobutyric acid (GABA)) and acute haem deficiency within neurones.

Factors that may precipitate an acute attack [1]. The most common precipitants are drugs and the menstrual cycle, with recurrent attacks often occurring in the late luteal phase. Alcohol, cannabis, fasting, stress and infection may also trigger attacks. It is not possible to predict whether a specific drug will provoke an attack in an individual. Drugs should be prescribed only after reference to an up-to-date drug list. The author recommends using the lists available on the Internet from the Welsh Medicines Information Centre [6] or the European Porphyria Initiative [7]. These lists are regularly reviewed and updated by experts, and are lists of drugs, by type, that are known to be safe in acute porphyria, that is the lists are designed to answer questions such as 'which antihypertensive can be safely used in a patient with acute porphyria?'. The recommendations on such lists are not absolute and do not substitute for clinical judgement. The risk of a drug provoking an attack is obviously highest where that drug has previously caused an attack in that patient, and in any patients who have previously had symptoms suggestive of an acute attack.

Clinical presentation [1,2]. Acute attacks are five times more common in females, and most frequently occur between the ages of 10 and 40 years. They are rare before puberty. The severity of acute attacks varies from mild abdominal pain, sometimes accompanied by vomiting and constipation, through to very severe attacks with bulbar palsy and respiratory paralysis. Severe, constant abdominal pain occurs in almost all acute attacks. It can be in any quadrant or even in the back, buttocks and thighs, and may require large amounts of opiate analgesia. There may be guarding but no true peritonism. Vomiting and constipation (due to partial ileus) occur in at least half of attacks. The pulse rate and blood pressure are often moderately raised, dehydration is common and hyponatraemia (probably caused by inappropriate secretion of vasopressin) may be severe enough to cause convulsions. The pain, tachycardia, hypertension and partial ileus are all caused by an acute autonomic neuropathy. Sensory or sympathetic involvement, manifest as severe dysaesthesia or causalgia, is rarer. A motor neuropathy occurs in 5–10% of cases, usually heralded by aching pains in the limbs and sometimes by disappearance of the abdominal pain. It may cause a severe acute Guillain–Barré-type syndrome. The motor neuropathy usually occurs when porphyrinogenic drugs have been administered inadvertently during the developing acute attack. Respiratory paralysis is the commonest cause of death. Confusion, abnormal behaviour, agitation and hallucinations occur in up to 50% of attacks. Porphyria is not related to any chronic psychiatric disease, except generalized anxiety.

Biochemical diagnosis of an acute attack [8,9]. The diagnostic finding is of increased urinary PBG excretion. Although qualitative screening tests may be useful in an emergency, their low sensitivity makes it essential to also carry out a quantitative assay. Commercially available kits can provide a rapid and reasonably sensitive semi-quantitative assay, after which a specific quantitative assay should be carried out (reliable quantitative assay kits are commercially available). A normal urinary PBG concentration excludes an acute porphyric attack (except in ALA dehydratase porphyria). An increased PBG concentration does not necessarily mean that an acute attack is occurring since urinary PBG falls between attacks but does not always return to normal, particularly in AIP. The higher the PBG concentration, the more likely an acute attack, but, in the presence of an increased urinary PBG, an acute attack can only be diagnosed on clinical grounds. Urinary ALA is

also increased during an acute attack but to a lesser extent than PBG and is not as useful diagnostically (the only exception being ALA dehydratase porphyria in which only ALA is increased and urinary PBG is normal).

Long-term management of patients with acute porphyria [1,2]. The dermatologist may diagnose VP (or less commonly HC) on the basis of cutaneous disease before any acute attack has occurred. Once an acute porphyria has been diagnosed, the patient should be given a list of drugs with information about their safety in acute porphyria. Many lists exist both of 'safe' drugs and 'unsafe' drugs [6,7]. It is obviously vital for clinicians and patients to be clear about whether they are dealing with a list of 'safe' or of 'unsafe' drugs, and there are advantages to using a 'safe' list, as discussed above. It is important to recognize that a list of safe drugs is a guide, and that no drug can be guaranteed to be safe in an individual patient. Conversely, drugs which do not appear on a 'safe' list should not be withheld in patients who need them to treat a serious or life-threatening illness; in that situation expert advice should be sought from a specialist centre.

The patient should also be advised to abstain from alcohol, cannabis and from prolonged calorie-restricted diets, and to wear an emergency identification bracelet (e.g. MedicAlert) so that medical staff are aware of the diagnosis if the patient is ever found in an unconscious or confused state. Screening of relatives is essential to identify those with clinically latent disease, who are also at risk of acute attacks. The choice of test and interpretation of results can be complex and details are covered in the 'laboratory testing' section and under each individual disorder in this chapter. Such testing is ideally carried out in a specialist centre. Relatives diagnosed with an acute porphyria need the same advice as the index case. Conversely, patients with PCT, EPP and CEP can be reassured that acute attacks are not part of their disease.

Treatment of the acute attack [1,2]. The key to managing an acute attack is early diagnosis. Once the diagnosis has been made, avoidance of acute attack-inducing drugs is essential to prevent exacerbation. Supportive treatment includes analgesia, sedatives and antiemetics (in each case using drugs known to be safe in acute porphyria) and careful management of fluid balance with rehydration and correction of hyponatraemia. The specific treatments are intravenous haematin or haem arginate (Normosang, Orphan Pharmaceuticals), which have now replaced carbohydrate as the treatment of choice. These drugs suppress hepatic ALA synthase activity and so reduce ALA and PBG accumulation. Haem arginate is more effective when given earlier during an attack, increasing the importance of early diagnosis. Advice from a specialist centre should be sought when treating an acute attack.

A clinician's guide to laboratory testing in porphyria [1–3]

Although clinical features may raise the possibility of a porphyria, the cutaneous presentations of several porphyrias are very similar. Precise diagnosis is essential in porphyria because of the great differences in clinical management between porphyrias which can be clinically indistinguishable. An accurate diagnosis can only be made on the basis of porphyrin analyses carried out in an experienced laboratory. The clinician's role is to suspect the diagnosis of cutaneous porphyria, and then to use laboratory testing to confirm whether this is the diagnosis, and if so to precisely identify the porphyria. For any porphyria characterized by acute attacks, testing for latent porphyria in relatives will then be necessary.

What samples to send. In an adult with suspected bullous porphyria, it is generally sufficient to analyse urine and either plasma (where fluorimetry is available) or faeces (where it is not). However, urine, plasma and faeces need to be analysed in children, because of the increased complexity of the differential diagnosis. Faecal analysis is also necessary in instances when urine and plasma results do not differentiate HC from CEP, and in renal failure, where urine may be unavailable and plasma analysis unhelpful because renal failure increases plasma porphyrins. In suspected EPP, red cells and either plasma or faeces should be analysed.

Handling of samples. Laboratory testing of body fluids measures porphyrins, since porphyrinogens are spontaneously oxidized to their respective porphyrins outside the body. PBG has a tendency to polymerize to other molecules but porphyrins are reasonably stable when protected from light and oxidants. Thus, all specimens should be kept at room temperature or at 4°C in the dark and ideally should be analysed within 48 h of collection.

For urine and faecal analysis, fresh random specimens (10–20 mL urine or 5–10 g dry weight faeces) are preferable to 24 h collections. Random specimens yield equally useful results, and 24 h collections delay samples reaching the laboratory. Very dilute urine (creatinine <4 mmol/L) is unsuitable.

Laboratory analysis of porphyrins. Old-fashioned qualitative screening methods for detecting porphyrins in specimens (often involving a Wood's light) are insensitive, and negative results from such tests are not of value. Whether testing urine, faeces, red cells or whole blood, quantitative screening using spectrophotometric or fluorimetric techniques is necessary and yields results as a total porphyrin concentration. Whole blood or red cell por-

phyrin testing measures both the total and free protoporphyrin concentrations. Plasma is analysed by fluorimetric scanning, a diagnostically powerful and simple qualitative technique. In urine and faeces, the finding of an increased porphyrin concentration will lead on to high-performance liquid chromatography (HPLC) which can be used to rapidly identify the accumulated porphyrins (Fig. 59.6). For PBG measurement in urine, qualitative tests are insensitive, and quantitative measurement, usually using a kit, is required, with semi-quantitative test kits being useful in emergencies where a result is needed quickly.

Interpretation of results [4] (Table 59.1). In cutaneous porphyrias, the accumulated porphyrin can usually be detected in plasma as an emission peak on spectrofluorimetry. Uro- and coproporphyrin are excreted into the urine and copro- and protoporphyrin into the faeces. Protoporphyrin accumulates in red cells in EPP.

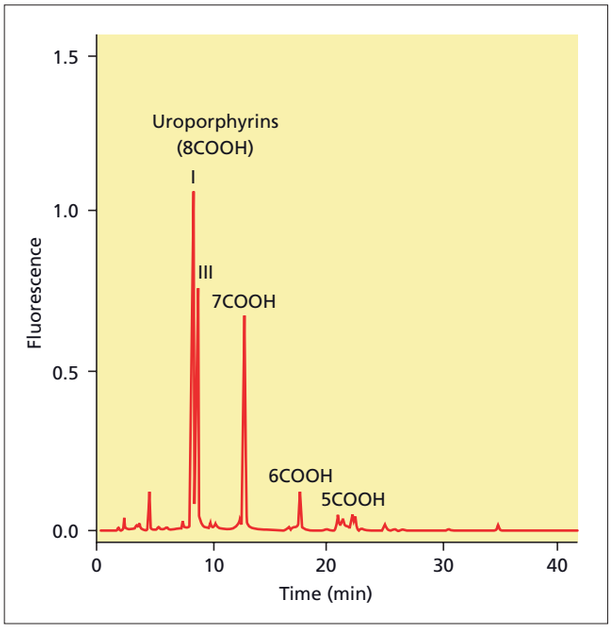

Fig. 59.6 High-performance liquid chromatography (HPLC) analysis: the more carboxylate groups it possesses, the faster a porphyrin molecule passes through the column. After passing through the column, porphyrins are detected by fluorimetry. This HPLC trace of urine shows the porphyrin profile typical of porphyria cutanea tarda (PCT). (Courtesy of Dr A. Deacon, King's College Hospital, London, UK.)

1 **Plasma spectrofluorimetry.** In plasma spectrofluorimetry, the sample is excited by 410 nm light, and fluorescent emissions detected. An emission peak at 615–620 nm indicates the presence of uro- or coproporphyrin and suggests a diagnosis of PCT, HC, CEP or HEP (urine analysis will differentiate PCT and HEP from the other two conditions). A peak at 624–626 nm indicates the presence of a porphyrin–peptide conjugate diagnostic of VP. This 624–626 nm peak is a sensitive indicator of VP and may even persist during periods of clinical remission when faecal excretion becomes normal. It is also positive in most cases of latent VP (in relatives) [5,6]. A peak around 633 nm (it can lie between 626 and 634 nm) is caused by protoporphyrin and suggests EPP, and EPP is an unlikely diagnosis in the absence of this peak. Plasma porphyrin concentrations, particularly uroporphyrin, increase in renal failure and can be as high as those found in patients with PCT.
2 **Whole blood/red cell.** An increased free protoporphyrin concentration is the diagnostic finding in EPP. The total protoporphyrin concentration includes both free and zinc-protoporphyrin. Zinc-protoporphyrin is also increased in iron deficiency, lead poisoning and certain anaemias. In a child with plasma, urine and faecal results typical of PCT, red cell UROD activity needs to be measured to exclude hepatoerythropoietic porphyria (HEP).
3 **Urinary and faecal analysis.** An increased total porphyrin concentration suggests a diagnosis of cutaneous porphyria. The total urinary porphyrin concentration is used to monitor disease activity in PCT. HPLC analysis is used to identify the porphyrins once an increased concentration has been found.
   (a) **In urine.** An increase in uroporphyrin (and other highly carboxylated porphyrins especially heptacarboxy-porphyrin) is typical of PCT though this does not exclude VP. Plasma spectrofluorimetry differentiates these two conditions and faecal analysis is required where this is unavailable. When PCT goes into remission and the total urinary porphyrin concentration returns to normal, it may still be possible to diagnose PCT from the characteristic urinary HPLC pattern. Coproporphyrinuria, in the presence of normal faecal porphyrin levels, does not indicate porphyria

Table 59.1 The major biochemical findings in the cutaneous porphyrias. (Adapted from Deacon and Elder [4].)

	Urine	Faeces	Red cell	Plasma fluorimetry
Congenital erythropoietic porphyria	Uroporphyrin I; coproporphyrin I	Coproporphyrin I	Zinc- and free protoporphyrin; uroporphyrin I; coproporphyrin I	Peak at 615–620 nm
Porphyria cutanea tarda	Uroporphyrin III; heptacarboxy-porphyrin	Isocoproporphyrin; heptacarboxy-porphyrin	Normal	Peak at 615–620 nm
Hereditary coproporphyria	Coproporphyrin III	Coproporphyrin III	Normal	Peak at 615–620 nm
Variegate porphyria	Coproporphyrin III	Protoporphyrin; coproporphyrin III; X-porphyrin	Normal	Peak at 624–627 nm
Erythropoietic protoporphyria	Normal	Protoporphyrin (not diagnostically helpful)	Free protoporphyrin	Peak at 626–634 nm

and can be caused by certain drugs, lead toxicity and hepatobiliary disease.

(b) **In urine and faeces.** Increased coproporphyrin suggests VP, but does not exclude HC. Isomer III to isomer I ratios are increased in every porphyria except CEP (where they are decreased). In CEP, excess type I isomers of uro- and coproporphyrin are present in urine and type I coproporphyrin in faeces.

(c) **In faeces.** In the presence of a plasma spectrofluorimetry peak at 615–620 nm, if urine HPLC does not show the PCT pattern, faecal analysis is required to differentiate HC (increased coproporphyrin III concentration) from CEP (increased coproporphyrin I concentration). Increased faecal isocoproporphyrin is characteristic of PCT. In renal failure, faecal analysis is vital, since urine may be unavailable and plasma porphyrins are increased in renal failure (PCT is the porphyria most commonly associated with renal failure). Increased faecal protoporphyrin is suggestive but not diagnostic of EPP, since it can also derive from bacterial degradation of haem in the gut and may indicate gastrointestinal haemorrhage when porphyrin concentrations are normal elsewhere.

Biochemical diagnosis of an acute attack of porphyria [3,4]. This is discussed above (Acute attacks of porphyria, p. 59.7). A definitive diagnosis of VP or HC can usually be made on the basis of detailed porphyrin analysis. A definitive diagnosis of AIP requires enzyme or genetic tests.

Screening of relatives. In VP and HC, porphyrin levels are normal before puberty. Over the age of 15 years, a plasma fluorimetry scan is a reasonably sensitive biochemical test for latent VP in asymptomatic relatives of patients, picking up most cases. A positive scan is diagnostic of latent VP but a negative result is uninformative [5,6]. Faecal analysis, to measure the ratio of coproporphyrin isomers, will pick up some cases of latent HC after puberty [7]. In VP and HC, a negative porphyrin screening test in a relative needs to be followed by DNA analysis before latent disease can be excluded. The lack of any common mutations in porphyria (apart from South African VP) means that the causative mutation usually has to be identified for each family.

The individual porphyrias

Porphyrias that cause cutaneous disease but do not cause acute attacks

Congenital erythropoietic porphyria (Günther's disease)

Definition. A severe and rare childhood porphyria causing lifelong mutilating photosensitivity and haematological disease.

Aetiology. Congenital erythropoietic porphyria (CEP) is caused by an autosomal recessive inherited deficiency of the uroporphyrinogen III cosynthase enzyme. Since this enzyme is required to form the biologically useful type III porphyrin isomers, its absence results in non-enzymatic reactions producing large amounts of type I isomer porphyrins which cannot participate in haem formation, and which massively accumulate in erythroid cells and then gradually leak into the plasma. The incidence in the UK is 2 per 3 million live births and less than 100 cases have ever been reported worldwide. Rare adult onset cases of acquired CEP have been reported secondary to myelodysplasia [1].

Clinical features [2–4]. CEP has a wide spectrum of presentation, from hydrops fetalis through to severe disease starting in infancy and also mild forms presenting later in life. The first sign of CEP is often the child's mother noting brown discoloration of amniotic fluid at the onset of labour, or observing pink or brown porphyrin staining of nappies (which fluoresce red-orange under Wood's light).

The skin in CEP [2,4]. Severe photosensitivity begins in infancy, often in the neonatal period, with blisters developing in light-exposed skin on minimal light exposure. Phototherapy for neonatal jaundice may trigger lesions. Most children are so sensitive to the light that they have problems throughout the year. Exposed (and sometimes non-exposed) skin is fragile. The repeated bouts of inflammation with vesicles and bullae, often complicated by secondary infection, cause mutilating scarring, particularly of the face and hands (Fig. 59.7). This photomutilation is associated with erosion of the terminal phalanges, onycholysis and destructive changes affecting the pinnae and nose. A diffuse pseudoscleroderma-tous thickening of exposed skin often gradually develops, with microstomia and sclerodactyly-like changes [4]. Hypertrichosis is found in most patients, particularly on the upper arms, temples and malar region. Patchy hypo- and hyperpigmentation occur even in minimally exposed areas.

A milder late onset form, presenting at any age from the third decade onward, has been described; this presents in a manner similar to PCT, and occurs either as a result of mild inherited gene mutations [5] or as an acquired disease secondary to bone marrow myelodysplasia [1].

Involvement of eyes and internal organs [4]:

- Eyes. Keratoconjunctivitis, blepharitis, cataracts, corneal ulcers, scars, cicatricial ectropion and scarring alopecia of eyelashes and eyebrows may all occur. Scleromalacia, pterygium formation, optic atrophy and retinal haemorrhage are less common.

Fig. 59.7 Congenital erythropoietic porphyria (CEP): scarring of skin with resorption of terminal phalanges. (Courtesy of Dr A. du Vivier, King's College Hospital, London, UK.)

- Bones and teeth. When teeth emerge, they are almost always stained brown (and fluoresce under Wood's light). Decreased bone density, osteopenia and osteolytic lesions secondary to erosion by hyperplastic bone marrow are seen on X-ray and are associated with vertebral compression and collapse, and with pathological fractures. In the hands there is resorption of terminal phalanges with acroosteolysis and cortical bone rarefaction. Occasionally, strict avoidance of the sun may impair vitamin D metabolism.
- Haematology [2,4]. The high concentrations of porphyrins in red cells cause haemolytic anaemia, severe enough to induce marrow hyperplasia often with visible expansion of the maxillary bones in the face. Hypersplenism is common. The haemolysis can be fully compensated or may cause a severe anaemia, and is occasionally so severe that some patients become transfusion dependent. The severity of the anaemia often fluctuates strikingly over time. Very severe haemolytic anaemia may even cause hydrops fetalis. Bone marrow examination reveals normoblastic hyperplasia, and under violet illumination most normoblasts have persistent red fluorescence localized to their nuclei, with haem-containing inclusion bodies being seen in the nuclei of these fluorescent cells.

Differential diagnosis. The photosensitivity differentiates CEP from other scarring blistering disorders of childhood, including epidermolysis bullosa dystrophica. The cutaneous changes may resemble HEP (the homozygous form of familial PCT) or homozygous VP. The cutaneous disease in late-onset CEP is clinically indistinguishable from PCT or VP.

Biochemical findings [2]. The uroporphyrinogen III cosynthase enzyme deficiency results in the massive accumulation in all tissues of type I isomers of porphyrins, mainly uroporphyrin, along with coproporphyrin and smaller amounts of 7-, 6- and 5-carboxylic acid porphyrins. Red cells and urine contain large amounts of uro- and coproporphyrin (mainly type I) and faeces contains increased concentrations of coproporphyrin (mainly type I). A plasma spectrofluorimetry peak is seen at 615–620 nm. The absence of isocoproporphyrins and the normal level of 5-carboxylic porphyrin excretion in faeces distinguish CEP from HEP.

Prognosis. In the past, most patients died by the age of 40 years but improvements in supportive care (particularly use of antibiotics) have improved the prognosis, though the haematological complications may be fatal. Long-term hypertransfusion causes significant problems with iron overload as patients reach adulthood, even when iron chelation has been used. Bone marrow transplantation now holds out the promise of cure for these patients (see below).

Treatment [6]. The photosensitivity is so severe that photoprotection is crucial. Sun avoidance and use of sun protective clothing and hats are essential. Opaque sunscreens containing pigmentary grade titanium dioxide or zinc oxide, possibly with added iron oxide, may be of limited value [7,8], and amber window films on home or car windows can reduce exposure to Soret wavelength light (TA81XSR, Madico, USA) [9], though more opaque films may be necessary (which are obviously not allowed on car windows). Prompt treatment of secondary infection is important.

β-Carotene may help cutaneous disease in some patients [2].

Many therapies reduce the porphyrin concentrations by suppressing erythropoiesis. Hypertransfusion with regular blood transfusions to maintain a polycythaemia inhibits endogenous haemoglobin production and decreases porphyrin formation, and may reduce haemolysis and cutaneous symptoms in moderately affected patients. However, splenomegaly may increase transfusion requirements and the value of hypertransfusion often decreases at puberty [6]. Hypertransfusion is frequently complicated by iron overload, even when desferrioxamine has been used, and blood-borne infections can be a complication. Hydroxyurea has been used with hypertransfusion and may be useful in transfusion-dependent CEP [10]. Intravenous haematin has been tried in late-onset disease [11]. Haemolysis worsens the porphyria by causing anaemia and usually necessitates blood transfusion. Splenectomy may reduce haemolysis though the improvement may be temporary [6]. Lights during surgical procedures may cause phototoxic reactions and filters should be used over the operation lights during any unavoidable surgery, preferably a yellow filter (e.g. Madico TA81XSR).

Since 1991, allogeneic bone marrow transplantation (bone marrow or umbilical cord blood stem cells) from a human leukocyte antigen (HLA)-compatible donor has emerged as the treatment of choice in severe CEP. It provides a long-term cure [12,13] though the difficulties of finding a tissue-matched donor, and the dangers of marrow transplantation, mean that it should be reserved for the most severely affected patients [14]. Gene therapy has been successfully used *in vitro*, but no *in vivo* studies have been carried out yet [15].

Genetic counselling. Since CEP is autosomal recessive, parents will be unaware of the risk until an affected child has been born, and the risk of disease is in further offspring rather than subsequent generations. For parents of an affected child, the chance of each future offspring suffering from the disease is 25%. The diagnosis may be made before birth by measuring the uroporphyrin I concentration in amniotic fluid, which is increased as early as 16 weeks *in utero*. If the mutations in the index case have been identified, or the fetus is homozygous for the common C73R mutation, prenatal diagnosis from chorionic villous biopsy is possible [16].

Porphyria cutanea tarda [1,2]

Definition. Porphyria cutanea tarda (PCT) is the commonest of all the porphyrias. It is characterized by fragility and blistering of exposed skin. It is usually acquired and is often associated with liver disease. It does not cause acute attacks.

Aetiology and classification. PCT results from deficiency of UROD [3]. This causes accumulation of uroporphyrin and other highly carboxylated porphyrins. Seventy-five per cent of patients have the *type I* (*sporadic*) form in which the enzyme deficiency is acquired and restricted to hepatocytes, due to inhibition of a normal UROD enzyme [3]. Twenty-five per cent have *type II* (*familial*) disease where the enzyme deficiency is hereditary, present in all tissues and associated with a UROD gene mutation. The penetrance of this autosomal dominant inherited form is so low that a family history is present in under 7% of cases, and since at least a 75% reduction in enzyme activity is required for clinical expression, some enzyme inhibition in the liver also occurs in familial PCT. Thus, UROD mutations are increasingly thought of as a risk factor for the development of PCT, rather than as representing a completely separate familial form of the disease. *Type III* disease is rare and characterized by an hereditary enzyme deficiency localized to the liver. *Toxic porphyria*, in which halogenated aromatic hydrocarbons inhibit the enzyme, is rare and mainly affects workers making herbicides [4]. A major epidemic of toxic porphyria in the 1950s in Turkey was caused by hexachlorobenzene added as a fungicide to seed wheat [5].

In PCT, the UROD enzyme is inactivated by an inhibitor which binds to its catalytic site. The inhibitor is generated in the liver by reactive oxygen species in the presence of iron (Fig. 59.8) [6]. The

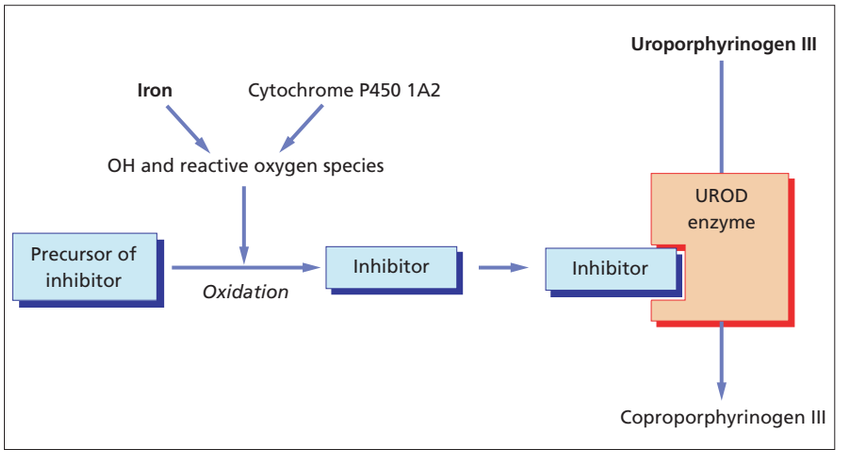

Fig. 59.8 Porphyria cutanea tarda (PCT) is caused by production of an inhibitor of uroporphyrinogen decarboxylase (UROD) in the liver, in the presence of iron. (Adapted from Elder [2].)

Fig. 59.9 Porphyria cutanea tarda (PCT): erosions, blisters, pigmentary changes and scarring.

accumulated uroporphyrin diffuses from the plasma into surrounding tissues, causing a phototoxic reaction in the upper dermis in sun-exposed skin. This leads to lysis of cells in the superficial dermis with the formation of membrane-limited vacuoles which merge to produce a blister cavity under the basal lamina [7].

Histopathology [8]. The bullae in PCT are subepidermal with a sparse inflammatory infiltrate and 'festooning' of dermal papillae into the bullae. There is deposition of PAS-positive diastase-resistant fibrillar glycoprotein material in and around upper dermal blood vessel walls, and reduplication of the basement membrane. Immunofluorescence reveals IgG, a little IgM, fibrinogen and complement at the epidermal–dermal junction. Morphoea-like lesions in PCT are histologically indistinguishable from other forms of morphoea.

Clinical features (Fig. 59.9) [9]. Sporadic PCT usually presents in middle age whilst the familial form can occur at a younger age. Almost all patients notice increased fragility on light-exposed skin, particularly the backs of the hands and forearms, with minor trauma shearing the skin away to leave sharply marginated erosions. Most patients suffer from bullae, which can be over 1 cm in diameter and may be painful. They crust and resolve over a few weeks, leaving atrophic scars, milia and often mottled hyper- or hypopigmentation. Patients rarely associate development of new lesions with sun exposure, but symptoms are generally worse in the summer. Other common features are: patches of scarring alopecia following resolution of bullae on the scalp; hypertrichosis, usually on the upper face and forehead, sometimes on the ears or arms [10] and occasionally affecting the whole body; hyperpigmentation in a melasma-like pattern on the cheeks and around the eyes, or in a diffuse pattern on light-exposed skin, or occasionally in a reticulate distribution [9,10]. Photo-induced onycholysis [11] and accelerated solar elastosis [10] may also occur. Morphoea-like plaques may develop, particularly on the head and upper trunk. They are histologically indistinguishable from true scleroderma and mainly occur in longstanding untreated disease. It has been postulated that they arise as a result of the induction of collagen synthesis by uroporphyrin I [12]. These plaques may calcify, and may require excision and grafting if they ulcerate [13].

On the scalp, the morphoea-like change may cause a slowly expanding scarring alopecia starting in the frontoparietal and occipital areas [9,10,14], and even sclerodactyly or the facial changes of systemic sclerosis have been reported. Rare presentations of PCT include cicatricial conjunctivitis [15] and hair darkening [16].

Hepatoerythropoietic porphyria [10,17]. The homozygous form of familial PCT, hepatoerythropoietic porphyria (HEP), is associated with over 90% reduction in UROD activity. It usually causes a severe disease clinically similar to CEP, with photosensitivity during infancy causing immediate pain on sun exposure, blisters on sun-exposed skin, and mutilating scarring of face and fingers. Prominent hypertrichosis, fluorescent teeth, eye involvement and shortened distal phalanges also occur. Haemolysis is milder than in CEP, and life expectancy is normal. HEP can occasionally present with a milder disease similar to PCT. Since the mutated alleles in HEP have to be associated with some residual enzyme activity to be compatible with life, the UROD gene mutations in HEP patients are different to those found in type II PCT [18].

Differential diagnosis. PCT can be clinically indistinguishable from VP, drug-induced pseudoporphyria, renal pseudoporphyria, HC, late-onset Günther's disease or mild HEP. Biochemical analysis is necessary to diagnose PCT and it is particularly important to exclude VP and HC among the differential diagnoses, since they can cause acute attacks.

Biochemical findings [2]. In PCT, the urinary porphyrin concentration is increased, consisting mainly of uroporphyrin, some heptacarboxylic acid porphyrin, and sometimes also hexa- and pentacarboxylic acid porphyrins. A plasma spectrofluorimetry peak is seen at 615–620 nm. Isocoproporphyrin accumulates in the faeces. Urine analysis alone is insufficient to diagnose PCT, since a few patients with VP have the PCT urine pattern ('dual porphyria') [19]. In patients with renal failure, faecal analysis is essential, since plasma porphyrins are increased by haemodialysis and urine collection may not be possible. The biochemical marker of disease activity and response to treatment is quantitative urinary porphyrin excretion measured in a random urine sample.

In HEP, the findings are as in PCT, but with the additional finding of a raised red cell zinc-protoporphyrin, and lower red cell UROD activity than occurs in type II PCT.

The investigation of the patient with PCT. PCT is essentially a liver disorder with secondary effects in the skin. It is crucial to investigate patients thoroughly both regarding other systemic diseases predisposing to the development of PCT, and in order to assess the severity of any liver disease.

1 Risk factors for the development of PCT [20]. The major risk factors for developing PCT are subclinical genetic haemochromatosis, hepatitis C infection, alcohol and oestrogens. They all predispose to the inhibition of the UROD enzyme in the liver. Since some inhibition of the hepatic enzyme is also required for

clinical expression of familial PCT, the same risk factors apply to sporadic and familial PCT. Since most of the risk factors have significant implications both for treatment and for the patient's general health, it is essential to investigate for risk factors in all patients diagnosed with PCT.

(i) Haemochromatosis. As expected in a disorder where hepatic iron plays a key role, almost all patients have increased stainable iron in the liver, and total body iron stores are increased in at least 60% of patients [2,20,21]. In the USA and Northern Europe, around 20% of PCT patients have true hereditary haemochromatosis [20,22] with homozygosity for the Cys282Tyr haemochromatosis mutation. Homozygosity for this mutation increases the risk of developing PCT 60-fold [20]. The clinical relevance of heterozygosity for the mutation is unclear. In Southern Europe, haemochromatosis is a less important risk factor. The iron overload found in PCT patients who do not have haemochromatosis is milder, and its cause obscure.

(ii) Hepatitis C infection. In Southern Europe, 70–90% of all PCT patients are infected with the hepatitis C virus [23,24], compared with around 60% of patients in the USA [20] and 7–36% in Northern Europe [25,26].

(iii) Alcohol. Between 30% and 90% of PCT patients consume over 40 g of alcohol daily, and 2% of all alcoholics with cirrhosis develop PCT [6].

(iv) Oestrogens. Ingested oestrogens, in the oral contraceptive pill or in hormone replacement therapy, are the sole risk factor in over a quarter of female patients [20]. Stopping the hormone may be sufficient to induce remission if the duration of therapy has been short [27]. If it is not possible to stop the hormone therapy, transdermal drug delivery is a safer alternative than the oral route [28].

There are other less common risk factors for developing PCT: haemodialysis predisposes to PCT [10], though PCT is less common in renal failure than pseudoporphyria—faecal porphyrin analysis differentiates these disorders. Human immune deficiency virus (HIV) infection predisposes to PCT [29], an association which may be due to coinfection with the hepatitis C virus [30]. Non-insulin dependent diabetes mellitus, systemic lupus erythematosus, dermatomyositis, hepatitis A and B infection, haematological malignancy, sideroblastic anaemia, thalassaemia and the drug tamoxifen have all been reported to be associated with PCT [2,9,31,32].

Most patients possess more than one risk factor for developing PCT, with hepatitis C infection and alcohol being strongly linked in men.

2 Liver disease in PCT [21]. Since PCT is primarily a liver disorder with secondary effects in the skin, liver disease is a major concern. In almost all cases, liver biopsy reveals increased stainable iron, fatty change and intracellular porphyrin crystals. Fifty per cent of patients have more severe changes (lobular necrosis or inflamed fibrotic portal tracts), and cirrhosis occurs in 15% [21]. As one would expect, the most severe liver disease tends to occur in patients who have alcoholism, hepatitis C infection and iron overload [20]. The accumulated porphyrins are carcinogenic to the liver, and so PCT confers an additional risk for developing hepatocellular carcinoma on top of the risk conferred by the hepatitis C infection present in many patients [33]. In Southern Europe around 3% of PCT patients develop hepatocellular carcinoma during the decade after presentation [34], and the incidence of hepatic malignancy is probably lower than this in countries with lower hepatitis C infection rates. Risk factors for developing hepatocellular carcinoma are thought to be a symptomatic period longer than 10 years prior to treatment, severe changes on hepatic histology at presentation, hepatitis C infection, male sex and age over 50 years at presentation [35,36]. The converse situation, where a primary hepatic tumour secretes porphyrins to cause a PCT-like skin disease, is rare [37]. Hepatic function must be assessed at presentation in all PCT patients, and patients at high risk of hepatic malignancy require regular ultrasounds and serum α-fetoprotein measurement to detect carcinoma at a treatable stage [35]. PCT should be managed as a liver disorder, and the threshold for referral to a hepatologist should be low.

Treatment

Photoprotection. Visible light sunscreens containing pigmentary grade titanium dioxide or zinc oxide, sometimes with added iron oxide [38,39], filter films for car and home windows, gloves, hats and clothes play an important role in controlling symptoms during the period of several months before specific therapies take effect.

Elimination of risk factors. Stopping oestrogen therapy [27], if it has not been used for more than 2 years, can induce remission. However, elimination of the underlying cause by abstaining from alcohol, or by treating hepatitis C with interferon-α [40], does not always induce remission. All patients should be advised to abstain from alcohol or oestrogen therapy to prevent exacerbation of the disease.

Specific treatments. Definitive treatment with venesection or low-dose antimalarials is required in almost all cases. Venesection depletes iron stores and eliminates hepatic iron overload, thus restoring normal enzyme activity. Around 500 mL of blood is removed every week or every 2 weeks, aiming to decrease transferrin saturation to 15%, haemoglobin to 11–12 g/dL and plasma ferritin to below 25 μg/L [41,42]. Blistering usually resolves within 2–3 months, skin fragility within 6–9 months [43], and porphyrin concentrations generally normalize within 13 months or so [9], at which point treatment should be stopped. Hypertrichosis [9] and sclerodermoid lesions [14] respond more slowly during the years after treatment has stopped. Excision and grafting may be needed for ulcerated sclerodermoid lesions [9]. Desferrioxamine leads to earlier remission than venesection because it rapidly chelates hepatic iron, and it may be of value in PCT with renal failure but it is expensive and requires use of a subcutaneous pump at night [44,45]. Erythropoietin mobilizes hepatic iron into haemoglobin and is the treatment of choice for PCT in renal failure where patients are too anaemic for venesection and cannot excrete chloroquine [46]. Low-dose antimalarials are a very effective treatment for PCT. They work by complexing with uroporphyrin and promoting its excretion into the bile [47]. Daily doses of chloroquine cause a potentially dangerous acute hepatitis but chloroquine at the low dose of 125 mg [48,49] or 250 mg [50,51] taken twice a

week is safe and effective. It leads to clinical remission within 6 months or so and biochemical remission after 6–15 months, at which point treatment is stopped [48–51]. Retinopathy does not seem to occur with such low doses of chloroquine [50]. Hydroxychloroquine (200 mg twice weekly) can be used but duration of remission is shorter than with chloroquine [52,53].

Low-dose chloroquine is the treatment of choice except in the following situations, in which venesection is preferable: (i) patients who do not respond to chloroquine; (ii) patients with a pathologically high serum ferritin concentration or homozygous for the Cys282Tyr mutation (if genetic analysis is available), who require iron depletion to protect internal organs; and (iii) patients with significant hepatitis C liver disease, who require iron depletion since hepatic siderosis increases their virally induced liver damage [54] and reduces the effectiveness of interferon [55]. Anyway, chloroquine is usually less effective in the patients with haemochromatosis [56]. However, chloroquine is not contraindicated in these situations, and may be needed when venesection is not possible, particularly in patients with hepatitis C liver disease where venous access is impaired by previous intravenous drug abuse.

Remission with low-dose chloroquine generally lasts 17–24 months [49,50]. With venesection, relapse generally occurs around 2.5 years after the end of treatment [9,48]. Long-term follow-up is necessary for all patients to monitor for relapse (by measuring urinary porphyrin excretion), and for the management of coexisting liver disease.

Genetic counselling [57]. Familial and sporadic PCT can be differentiated by measuring red cell UROD activity. Since additional inhibition of the hepatic enzyme is required for clinical expression of disease in familial PCT, UROD mutations can be considered as a risk factor for developing the disease rather than as a different form of PCT. In view of the identical management of sporadic and familial PCT, the lack of evidence that identifying latent PCT in relatives alters outcomes, and the very low penetrance of familial PCT, it is difficult to justify family screening in familial PCT. It is therefore of little value to measure red cell UROD activity unless one is trying to differentiate HEP from PCT.

Erythropoietic protoporphyria

Definition. EPP is an hereditary porphyria characterized by painful, lifelong photosensitivity and occasionally liver disease.

Incidence and aetiology. The prevalence of EPP is around 1/100 000 [1]. EPP results from deficient activity of ferrochelatase, the final enzyme of haem biosynthesis. This causes the accumulation of protoporphyrin predominantly in cells of the erythroid series, which causes a phototoxic reaction as the porphyrin-laden cells pass through small upper dermal blood vessels and are exposed to the Soret wavelength in sunlight. The photoactivated porphyrin from red cells and plasma causes an acute injury to the endothelium mediated by singlet oxygen and the hydroxyl radical [2,3]. Many ferrochelatase gene mutations have been identified in EPP patients and none are particularly common [4]. A few adult-onset cases have been reported which are associated with haematological malignancy and may be associated with chromosomal deletions involving the ferrochelatase gene [5].

Histopathology [6,7]. In the acute phase there is visible endothelial damage in superficial dermal vessels [8]. In the chronic phase, in exposed areas of skin, the repeated episodes of damage to small vessels in the upper dermis cause deposition of PAS-positive diastase-resistant hyaline material in the walls of blood vessels of the upper dermal and papillary vascular plexuses. Immunofluorescence shows immunoglobulins (mainly IgG) in a similar distribution. On electron microscopy the hyaline material can be seen to be a greatly replicated, layered and fragmented basement membrane, with fine fibrillar material permeating the capillary connective tissue sheath and extending beyond the vessel walls [6,9].

Clinical features [1,10]. Unlike the other cutaneous porphyrias, EPP causes immediate pain on exposure to bright sunlight. It presents most commonly in the first year, quite often in babies who usually present with crying in their prams in sunny weather, or crying for no obvious reason at night in the summer. Onset later in childhood does occur but onset in adulthood is rare. In spring and summer, after anything from a few minutes to an hour or two of sun exposure, patients describe discomfort, tingling or itching in exposed skin, particularly the dorsae of the hands and the face. If exposure continues, severe burning pain follows which can last anything between an hour and several days. Children often find partial relief with cold water and wet cloths, and this feature may be diagnostically useful. Usually the only physical sign during an attack is oedema, which may be subtle (Fig. 59.10). Erythema is less common. The lack of physical signs often leads to delay in diagnosis, with some patients initially being labelled as malingerers. Many patients experience a 'priming phenomenon' in which sunlight tolerance is reduced on the day after significant sun exposure [11]. In severe attacks, purpuric lesions and crusted erosions or vesicles may occur; these take a week or two to resolve after the attack settles down, and the pain may be severe enough to require hospital admission. Rare cases of EPP with prominent purpura and histological changes resembling a leukocytoclastic vasculitis [12], acute photo-onycholysis [13] or erythematous plaques [14] have been described. Physical signs may develop during childhood, with slight thickening of skin over the metacarpophalangeal and interphalangeal joints, superficial vermicular waxy scarring on the nose, shallow linear, punctate or small circular scars on cheeks and forehead and radial scars around the lips (Fig. 59.11). The skin over the nose, cheeks and forehead can become roughened and 'pebbly' in texture. Fifteen per cent of patients have no physical signs at all [1]. Children with EPP suffer from social isolation due to difficulty joining friends to play outside, and sensitivity to psychosocial issues is important for clinicians. Although EPP is lifelong, childhood and adolescence

Fig. 59.10 Oedema during an acute painful attack in a child with erythropoietic protoporphyria (EPP).

Fig. 59.11 Typical scars on the cheeks in erythropoietic protoporphyria (EPP).

are frequently the most difficult times because it is easier for adults to organize their lives to reduce sun exposure, but it is not surprising that the disease has such a profound impact on quality of life [1]. Symptoms often improve and porphyrin levels fall during pregnancy [1,15]. Patients may develop a mild hypochromic microcytic or normocytic anaemia, which can be associated with decreased serum iron levels and increased serum iron binding capacity [10]. With the exception of patients with EPP liver failure, operating theatre lights do not cause any problems during or after surgery in EPP patients [16]. Anaesthetists can also be reassured that acute attacks do not occur in EPP. In contrast, operating theatre lights can cause a devastating and potentially fatal phototoxic reaction in patients undergoing liver transplantation for protoporphyric liver failure.

Biochemical investigation [17]. The diagnostic finding is of an increased red cell free protoporphyrin concentration. Protoporphyrin is seen as a peak at 633 nm on plasma fluorimetric scanning. Sixty per cent of EPP patients have an increased faecal protoporphyrin concentration though this is not very useful diagnostically because of its lack of specificity. Urinary porphyrins are normal except in biliary impairment, when coproporphyrinuria develops.

Treatment [1]. No therapy has ever been proven to be effective in EPP mainly because of the lack of an objective test for disease activity in EPP, and high placebo rates make useful clinical trials difficult. This author's experience is that results with the specific therapies are generally fairly disappointing, and that attention to sunlight protection is the key to management.

Photoprotection. Basic measures include sun avoidance behaviour, sun-protective clothing and hats. It is important to use correct sunscreens [18,19]. Dihydroxyacetone paint has been used in some patients with EPP [20], and window films, which absorb violet light, can be useful for car or home windows, particularly in severely affected patients; all of these are discussed in detail on p. 59.6.

The acute reaction. For the acute reaction, complete sun avoidance (even through windows) leads to earlier resolution, and fans and cold water provide some pain relief. Antihistamines and most analgesics are of little value. For severe attacks, hospital admission may be necessary, for light avoidance and analgesia (usually opiate).

Specific therapies. Oral β-carotene is the most widely used treatment, usually at a dose around 180 mg daily in adults (90 mg daily in children) taken throughout the spring and summer. It is postulated to scavenge free radicals involved in the acute phototoxic reaction. Although some patients report that it reduces symptoms, others do not, and proof of efficacy from controlled trials is lacking. Patients may need to take it for several months before any effect is observed. The most common adverse effect of β-carotene is reversible skin discoloration. A controlled trial of *N*-acetyl cysteine has shown no benefit [21]. Short courses of a few weeks of psoralen and long-wave UV radiation (PUVA) [22] and narrow-band UVB [23] used in the early spring may be valuable, particularly in milder cases, and probably increase photoprotection by inducing epidermal thickening and pigmentation. Unlike PUVA, narrow-band UVB does not overlap with the EPP action spectrum and so cannot trigger attacks of pain. Many other systemic treatments with antioxidant or free radical scavenging properties have been used in EPP in an uncontrolled way on small numbers of patients, with conflicting and generally unconvincing results.

Genetic counselling. Although rare cases of autosomal recessive inheritance have been reported [24,25], EPP is generally an autosomal dominant disorder with incomplete penetrance, the disease resulting from co-inheritance of a gene mutation on one ferrochelatase allele with a low expression variant on the other allele. This

low expression variant is present in around 10% of the Caucasian population and is associated with reduced ferrochelatase mRNA levels resulting from the presence of the polymorphic variant IVS3-48C [26]. This low expression variant is common in Japan and South-East Asia and rare in Africa, which may explain the observed variations between continents [27]. Overall, the probability of each offspring of an EPP patient suffering from the disease is under 10%, but testing for the IVS3-48C polymorphism in a patient's partner is now available and can indicate more precisely whether there is a significant probability of future offspring being affected. This is useful for patients who would not consider having children if there were a significant likelihood of them having the disease. For a disorder which is rarely life-threatening, termination of pregnancy and thus antenatal diagnosis are not relevant.

Liver disease in EPP [24]. Protoporphyrin is excreted exclusively into the bile. It precipitates to form gallstones in around 12% of patients. It is also hepatotoxic, particularly to bile canaliculi, and severe liver damage occurs in around 1% of patients. EPP liver failure is most common in the teens and twenties. Usually a patient develops jaundice, worsening photosensitivity and often upper abdominal pain over a period of weeks or months. Investigation shows severe or total cholestasis, and a dramatically high red cell protoporphyrin concentration (due to its impaired excretion), which causes the worsening photosensitivity. Liver histology reveals deposition of protoporphyrin in vacuoles within bile canaliculi and hepatocytes, which may be accompanied by cirrhosis (Fig. 59.12). Although such acute episodes may resolve spontaneously, the porphyrin-induced cholestasis may become increasingly severe and itself further increase the protoporphyrin concentration in a vicious cycle, in which case the patient will die unless a liver transplant can be performed. Under operating theatre lights during the transplant surgery, the very high protoporphyrin concentration may cause a severe phototoxic reaction with postoperative burns, massive haemolysis and a severe neuropathy. Yellow filters blocking out light below 460 nm (e.g. Madico TA81XSR) must be used over the operating theatre lights, and do not impair the surgeon's view [16]. Even if these immediate postoperative complications are avoided, protoporphyric liver disease recurs in the graft in most patients over several years, severe enough to require retransplantation in a minority [28]. Recently, two patients with severe liver disease have been treated by bone marrow transplantation (in one of them with a liver transplant). Although the marrow transplantation does cure the EPP, the dangers of the procedure mean that it is reserved for these rare, life-threatening situations [29,30].

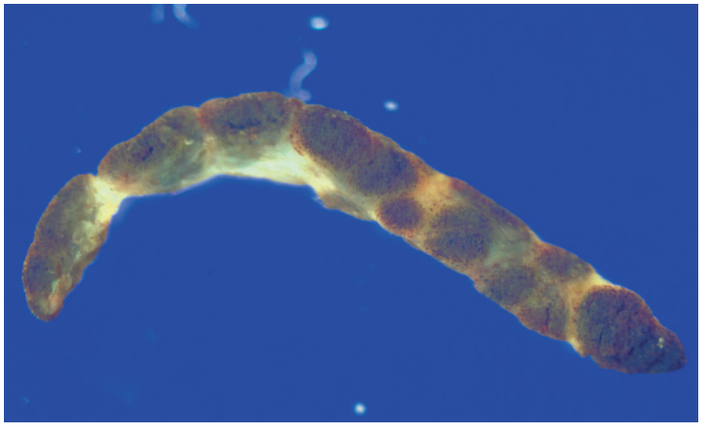

Fig. 59.12 Liver biopsy in protoporphyric liver disease, showing nodules of cirrhosis and black staining by deposits of protoporphyrin.

It is vital to recognize impending protoporphyric liver failure early enough that arrangements can be made for a liver transplant if it should become necessary. Thus, all EPP patients should have liver function tests and red cell protoporphyrin concentration checked at least once a year. The appearance of coproporphyrin in the urine has been proposed as an indicator of significant liver disease in EPP [31]. Worsening photosensitivity may be the only clinical indication of the development of severe liver disease. Although protoporphyric liver failure is rare, mild abnormalities of liver function tests are common in EPP [31]. Since the significance of these abnormalities is unclear, it is advisable to monitor closely in these patients, and to refer the patient to a hepatologist if the abnormality is persistent or deteriorating. In such patients, an ion exchange resin such as cholestyramine may protect the liver against further porphyrin toxicity. The major difficulty for the dermatologist is the lack of any means of identifying those EPP patients at risk of liver failure. Since several cases have been described in siblings, patients with a relative who has suffered protoporphyric liver failure should be treated as being at increased risk of developing it themselves. Recessive inheritance of EPP may increase the risk of severe hepatic disease, though it is not clear how significant an association this is [24].

Iron deficiency anaemia may trigger or exacerbate hepatic disease by increasing porphyrin accumulation [24], and subsequent iron replacement may make the situation temporarily worse by acutely stimulating haem biosynthesis.

Porphyrias that cause cutaneous disease and acute attacks

Hereditary coproporphyria

Like VP, this porphyria presents from puberty onwards. The skin is not affected in most patients suffering from this rare acute porphyria but around 10–20% [1] of patients have cutaneous involvement with fragility and blistering in sun-exposed areas, indistinguishable from that seen in PCT or VP. The skin disease may be triggered or exacerbated by intercurrent liver disease [2]. HC is caused by an autosomal dominant inherited deficiency of coproporphyrinogen oxidase. The biochemical findings are of a 615–620 nm peak on plasma spectrofluorimetry, increased uro- and coproporphyrin concentrations in urine, and increased coproporphyrin in faeces. Predominance of the type III isomer in faeces is a sensitive indicator of HC [1]. Rare variants include a homozygous form characterized by short stature, acute attacks and skin changes with prominent hypertrichosis and pigmentation [3], and harderoporphyria which causes haemolysis in the neonate or bullae.

Variegate porphyria

Definition. A rare inherited disease usually characterized by photo-induced skin fragility and blistering, which may cause acute attacks.

Aetiology and incidence. VP is caused by an autosomal dominant inherited deficiency of protoporphyrinogen oxidase. In addition to causing photosensitization, accumulated coproporphyrinogen and protoporphyrinogen also inhibit PBG deaminase, the probable mechanism for acute attacks in VP [1]. In South Africa, VP is common (due to a founder effect) with a prevalence in whites and Afrikaner-descended non-whites of 1/200. Elsewhere the prevalence is around 0.5–1/100 000 [2]. At least 80% of South African carriers of a pathogenic VP mutation are completely asymptomatic [3].

Pathogenesis of skin lesions in VP. It is perhaps unexpected that the accumulated copro- and protoporphyrin should cause PCT-like upper dermal blistering rather than EPP-like acute pain. This is likely to be because, although hydrophobic porphyrins predominate in plasma, hydrophilic porphyrins, especially uroporphyrin, predominate in the skin. This local accumulation is thought to result from secondary local photo-inactivation of UROD in the skin by coproporphyrin [3]. In addition, the protoporphyrin in VP is conjugated to a peptide which may reduce its phototoxicity.

Clinical features [2–4]

Skin. Of those patients with symptomatic VP, around 70% of patients have cutaneous involvement, and only around 17% of these patients will ever suffer an acute attack [5]. VP only very rarely presents before puberty, and usually the skin disease begins in adolescence or young adulthood. Patients describe skin fragility, usually fairly mild, affecting sun-exposed skin particularly on the backs of the hands [2,3]. The skin disease is generally indistinguishable from PCT, with painful tense bullae occurring in sun-exposed skin, as well as scarring, pigmentary abnormalities, sometimes pseudosclerodermatous changes of the hands and fingers, and occasionally photo-onycholysis. However, a significant number of patients do not describe worsening in the summer,

and the patients who do describe seasonal variation often have their worst problems in late summer and autumn. In addition, around half of patients with VP describe mild, transient, light-related eruptions in the early summer. The examination findings of scarring, patches of hypo- and hyperpigmentation at sites of blisters, milia and mild hypertrichosis particularly around the eyes, are indistinguishable from PCT. Intercurrent biliary obstruction exacerbates the cutaneous disease since the accumulated porphyrins are excreted into the bile. Acute photosensitivity can occur in patients with disturbed liver function. Hormonally induced hepatic dysfunction may explain the exacerbations of skin disease seen in females taking oral contraceptives and during pregnancy. VP sometimes goes into clinical and biochemical remission in old age.

Acute attacks [2,3,5,6]. As in other acute porphyrias, women are three times as frequently affected as men, and 70% of acute attacks occur between the ages of 20 and 40 years. Around 17% of patients with cutaneous VP ever suffer an acute attack; the number has declined recently due to improved use of prophylactic measures. The severity of acute attacks varies from mild abdominal pain, sometimes accompanied by vomiting and constipation, through to very severe attacks with bulbar palsy and respiratory paralysis. The presentation, diagnosis and management of acute attacks is covered in the section on acute attacks of porphyria, p. 59.7.

Homozygous VP [7]. In this disease, a mutation on both protoporphyrinogen oxidase alleles results in an enzyme activity less than 20% of normal, compared to the 50% in other VP patients. In homozygous VP, fragility, bullae and often hypertrichosis develop in exposed (and sometimes non-exposed) skin in neonates or infants and the skin disease may be severe. Delayed development, epilepsy, sensory neuropathy, nystagmus, various hand deformities and growth retardation also commonly occur. Acute attacks do not occur in these patients. The biochemical findings are the same as in VP, except for the lower enzyme activity.

Differential diagnosis. VP cutaneous disease is easily distinguished from non-photosensitive blistering disorders. It can be clinically very similar to PCT, late-onset CEP, HC and pseudoporphyria. Biochemical analysis is required to diagnose VP.

Biochemical findings. A plasma spectrofluorimetry peak around 626 nm (caused by a porphyrin–protein complex) is diagnostic of VP in the absence of a raised free red cell protoporphyrin level, and is present in virtually all symptomatic cases of VP. It may persist during periods of clinical remission when faecal excretion becomes normal and is a more sensitive test than measurement of faecal porphyrins [8]. A persistently normal faecal protoporphyrin concentration in adulthood in patients with the VP genetic defect has been proposed as a prognostic marker indicating a greater likelihood of the VP never causing any clinical problems and staying clinically latent [6]. The urine contains increased levels of coproporphyrin, and increased concentrations of copro- and protoporphyrin are found in faeces. In a few patients, the urine shows the typical PCT pattern of uroporphyrin accompanied by hepta- and sometimes hexa- and pentacarboxylic acid porphyrins, a situation known as 'dual porphyria' [9]. Thus, urinary analysis alone can result in the misdiagnosis of VP as PCT, with potentially disastrous consequences. During acute attacks, urinary PBG (and ALA) are raised. The urinary PBG usually falls to normal within weeks of the attack resolving, but may stay a little increased outside the context of an acute attack [10].

Treatment. The key to successful management of the skin disease is photoprotection with sun avoidance using clothes, hats and gloves. Opaque sunscreens, containing pigmentary grade titanium dioxide or zinc oxide sometimes with the addition of iron oxide, are protective against Soret wavelength light [11,12]. The skin disease is rarely severe enough to require filter films for car and home windows. Since the relationship between sun exposure and skin lesions is not obvious, the role of light in producing the skin lesions should be explained to the patient. β-Carotene and canthaxanthin have also been claimed to provide limited protection in some patients, and UVB phototherapy may also be of value [3]. If liver function tests indicate biliary obstruction, relief of this will reduce cutaneous symptoms. The risk of acute attacks is the key issue for safe management of patients and their families. Patients should be directed to a list of drugs to avoid [13,14], including those which can induce attacks, and also those known to induce cholestasis, and cannabis; they should also be advised to wear an emergency identification bracelet, to avoid low calorie diets, and to become teetotal. Liver transplantation has been successfully used to cure variegate porphyria (and acute intermittent porphyria) in cases where acute attacks are frequent, severe and uncontrollable by medical means [15].

Genetic counselling. It is important to identify relatives who have latent VP because of the risk of acute attacks. The plasma 624–626 nm peak is found in the majority of cases of latent VP but only from teenage onwards. A positive plasma fluorimetry result is diagnostic of latent VP but a negative result is uninformative [16,17]. The only completely reliable way to identify those carrying the VP gene defect if the plasma scan is negative is to identify the protoporphyrinogen oxidase gene mutation in the index case and then assess its presence or absence in relatives. This is labour intensive because, outside South Africa, most families have their own private mutation. Relatives found to have the gene defect are at a low risk (roughly 5–10%) of acute attacks and should take all the precautions taken by any patient diagnosed with an acute porphyria. The risk of a patient passing the mutated gene on to each offspring is 50%, and around 20% of those carrying the mutation will eventually develop symptoms of some sort.

Mucinoses [1–5]

S.M. Breathnach, pp. 59.21–59.30

Mucins are jelly-like acid glycosaminoglycans (formerly known as mucopolysaccharides) of the ground substances and probably play a part in the extravascular exchange of metabolites. Mucin is normally produced in small quantities by fibroblasts. Acid glycosaminoglycans, such as hyaluronic acid and heparin, stain with toluidine blue, colloidal iron, or with Alcian blue at pH 2.5, the coloration depending on the number and nature of the acid groups [6]. Periodic acid Schiff (PAS) stains heparin, but not hyaluronic acid. In general, acid glycosaminoglycans stain much brighter in frozen fixed tissue, or in specimens preserved in 1% cetylpyridinium chloride solution [7], rather than in formalin-fixed biopsies [8].

Neutral glycosaminoglycans are glycoproteins in which the hexosamine sugar polymer is incorporated in a protein chain. Hale and Alcian blue stains are negative but PAS stain is positive. The mucins in the skin and their histochemistry have been well reviewed [9]. Histopathological examination of many cutaneous mucinoses reveals that collagen fibres are fragmented [10].

Classification of the cutaneous mucinoses [1–5]

Mucinous infiltration of the skin is found in many widely differing disorders, some affecting the skin only, others related to systemic disease [1–5,11]. The association of HIV infection with lichen myxoedematosus seems to be more than coincidental [12]. They can be classified as shown in Table 59.2.

Table 59.2 Classification of the cutaneous mucinoses.

Primary
Diffuse (degenerative-inflammatory mucinoses):
Generalized myxoedema (Chapter 62)
Pretibial myxoedema (Chapter 62)
Lichen myxoedematosus (papular mucinosis, scleromyxoedema)
Acral persistent papular mucinosis
Cutaneous papular mucinosis of infancy
Self-healing papular cutaneous mucinosis; juvenile and adult
Hereditary progressive mucinous histiocytosis
Reticular erythematous mucinosis (plaque-like mucinosis)
Scleredema (Chapter 51)
Follicular forms:
Follicular mucinosis (alopecia mucinosa)
Urticaria-like follicular mucinosis
Focal (neoplastic-hamartomatous mucinoses):
Cutaneous focal mucinosis
Mucous (myxoid) cyst
Mucinous naevus
Secondary
Papular and nodular mucinosis associated with lupus erythematosus
Collagen vascular diseases (especially dermatomyositis, lupus erythematosus)
Malignant atrophic papulosis (Degos' syndrome) [13]
Papular mucinosis in L-tryptophan-induced eosinophilia–myalgia syndrome
Papular mucinosis of the toxic oil syndrome
Mucinosis accompanying mesenchymal and neural tumours

Lichen myxoedematosus

Synonyms

- Papular mucinosis
- Lichen fibromucinodosis
- Scleromyxoedema

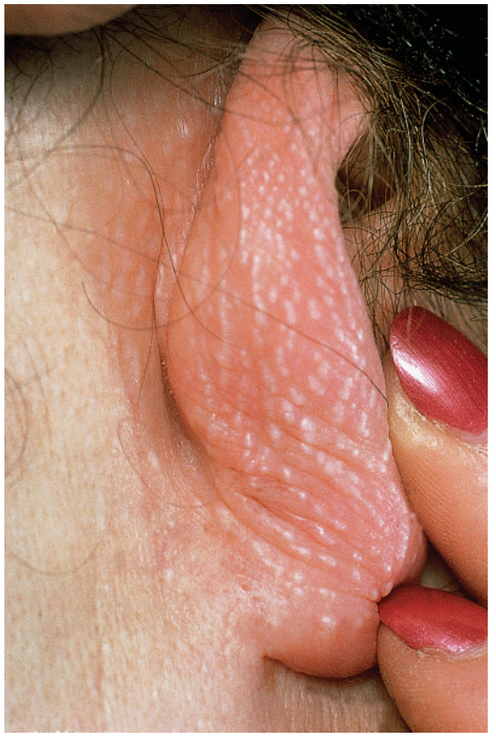

Fig. 59.13 Lichen myxoedematosus. Close-up of micropapules behind earlobe. (Courtesy of St Thomas' Hospital, London, UK.)

Fig. 59.14 Scleromyxoedema. View of forehead showing sclerodermoid appearance and linear papulation. (Courtesy of St Thomas' Hospital, London, UK.)

Lichen myxoedematosus is a cutaneous myxoedematous condition characterized by formation of numerous lichenoid papules which coalesce to form generalized plaques, causing extensive thickening and hardening of the skin [1–3] (Fig. 59.13). It is a rare disorder characterized by proliferation of fibroblasts with fibrosis and excessive deposition of acid glycosaminoglycans in the skin, and is distinct from scleroderma [4].

It has been proposed [2,3] that there are really only two main divisions of lichen myxoedematosus: (i) a generalized papular and sclerodermoid form (scleromyxoedema) with systemic, even lethal, manifestations; and (ii) a localized form, without a demonstrable paraprotein, which runs a more benign course. The localized form in turn is subdivided into five subtypes: (i) a discrete papular form involving any site [5]; (ii) acral persistent papular mucinosis involving only the extensor surface of the hands and wrists [6]; (iii) papular mucinosis of infancy, a paediatric variant of the discrete form or the acral form of persistent papular mucinosis; (iv) self-healing papular mucinosis, of juvenile and adult types; and (v) a nodular form.

A third group of atypical or intermediate forms, not meeting the criteria for either scleromyxoedema or the localized form, includes cases of (i) scleromyxoedema without monoclonal gammopathy; (ii) localized forms with monoclonal gammopathy and/or systemic symptoms; (iii) localized forms with mixed features of the subtypes; and (iv) poorly-specified cases and a localized papular form.

Scleromyxoedema is usually associated with a monoclonal gammopathy. Serum from patients with lichen myxoedematosus, even after elution of the IgG paraprotein, can stimulate synthesis of DNA and cell proliferation in cultured fibroblasts [7].

Histopathology [2,8,9]. Mucinous deposits occur in the middle and deeper layers of the dermis, where they displace collagen fibres, but do not involve the dermal papillae or accumulate around blood vessels. Histochemically, the mucinous deposits are heterogeneous mixtures of acid glycosaminoglycans, which stain positively with Alcian blue and toluidine blue. Large, stellate, elongated fibroblasts are present within the mucinous stroma [10]. Mucin deposition in the media and adventitia of vessels and in many organs including the myocardium is reported, and the skeletal muscles may be infiltrated with lymphocytes [11].

Clinical features [1,12–14]. In scleromyxoedema (the Arndt–Gottron syndrome) the pattern of lichen myxoedematosus is confluent, papular and sclerotic. Diffuse thickening of the skin underlies the papules. The facial features may be distorted by exaggeration of the facial ridges (Fig. 59.14), and flexion of the fingers may be limited. Multiple periorbital myxomas may progress to scleromyxoedema [15]. The involvement of the hands may simulate the sclerodactyly of scleroderma (Fig. 59.15), but the clinical appearance of numerous small papules of more or less uniform size, often in linear patterns on an erythematous and palpably thickened background, is very distinctive.

No endocrine abnormalities have been demonstrated, but cardiovascular abnormalities may occur in 10% of cases [8], whereas others may complain of extreme muscular weakness and lassitude due to myopathic or neurological involvement [16]. Occasionally, systemic involvement may occur in other internal organs [17].

An IgG class paraproteinaemia is almost always found on serum electrophoresis, although total serum protein values are usually normal [1,18]. Bone marrow studies may show a mild plasmacytic infiltration. Radiological survey of the skeletal system is normal. In one case, acid glycosaminoglycan levels in the serum were elevated [19].

Fig. 59.15 Scleromyxoedema. Sclerodermoid appearance of finger. Same patient as shown in Fig. 59.14. (Courtesy of St Thomas' Hospital, London, UK.)

Localized lichen myxoedematosus is characterized by small, firm, waxy papules of limited distribution [1], although a rare nodular form has larger lesions.

Diagnosis. Infiltrates appearing in and around old scars may simulate 'scar sarcoidosis'. Papules on the dorsa of the hands and ears may cause confusion with granuloma annulare. Systemic scleroderma may show many features simulating scleromyxoedema. However, in scleroderma the skin is thickened and bound-down, whereas in scleromyxoedema it is also thickened but moveable over the subcutis. Papules are absent in scleroedema and scleroderma, but common in scleromyxoedema. Nephrogenic systemic fibrosis, previously known as nephrogenic fibrosing dermopathy, a fibromucinous scleromyxoedema-like disorder associated with renal dysfunction, has been linked to administration of gadolinium-based contrast medium (see Chapter 75).

Prognosis. The prognosis of scleromyxoedema is poor despite a multiplicity of potential treatments. Death may result from nonspecific complications such as bronchopneumonia, coronary occlusion or from haematological malignancies.

Treatment. The potential for spontaneous long-term regression renders treatment of scleromyxoedema difficult to assess [20]. Localized lichen myxoedematosus of the discrete type has been treated with tacrolimus ointment [21]. Topical betamethasone and dimethylsulphoxide (DMSO) has produced regression in one case [22]. Systemic steroids alone may be ineffective [23,24]. Oral aromatic retinoids produce inconsistent but occasionally successful results [25,26]. Thalidomide has been advocated [27–29], as has interferon-α [30]. Plasmapheresis can be beneficial if combined with pulsed corticosteroid and/or immunosuppressive therapy [31,32]. Other therapies reported to be successful in isolated cases include extracorporeal photochemotherapy [33,34], intravenous immunoglobulin [35–37] and electron-beam therapy [38]. High-dose melphalan chemotherapy with autologous stem cell transplantation offers durable remission in most patients [39–41]. Aggressive surgical intervention for palliation of severe aesthetic and functional disability may be indicated [42].

Acral persistent papular mucinosis

Acral persistent papular mucinosis has been proposed as a distinct form of cutaneous mucinosis [1–4]. The characteristic findings include discrete papules or annular lesions on the extensor surfaces of the hands, wrists and forearms, mucinous deposits within the dermis, persisting for several years, and usually an absence of systemic abnormalities. However, a monoclonal IgA of kappa light chain isotype was detected in one case [5]. Familial occurrence has been reported in two sisters [6]. The accumulation of lysosomal structures in acral persistent papular mucinosis may be a distinctive feature of the disorder [7]. However, it is still debatable whether acral persistent papular mucinosis is a distinct entity [8] or whether it is a variant of the discrete papular form of lichen myxoedematosus [1]. A case resembling acral persistent papular mucinosis has been described in which transient carpal tunnel syndrome appeared, suggesting that extracutaneous involvement might occur [9]. 'Aypical' soft minuscule mucinous papules occurred localized to the axillae of a mother and her (identical) twin daughters; again, it is difficult to classify this entity [10].

Papular mucinosis of infancy [1–4]

In this rare condition, opalescent papules may be noted at birth [2] or develop a few months later [1,3]. The papules are scattered on the dorsa of the hands or around the elbows, and may have a linear distribution [2]. Focal mucinous material is deposited in the papillary dermis without overt fibroblast proliferation. It is not clear what the long-term outlook of cutaneous mucinosis of infancy is, but some cases appear to progress [3]. Thus, certain cases of cutaneous mucinosis of infancy are in fact the infantile presentation of lichen myxoedematosus [5].

Self-healing papular mucinosis; juvenile and adult

Self-healing juvenile cutaneous mucinosis [1–5] is a rare disorder characterized by an early age of onset accompanied by inflammatory phenomena and spontaneous resolution over a few months. The condition has also been reported in a child undergoing chemotherapy for nephroblastoma [6], and in two brothers [7]. Clinically, there are papules, nodules or plaques with a predilection for the head and trunk rather than the extremities. Histologically, there is dermal mucinosis and a mild increase in fibroblasts and mast cells. It is postulated that a temporary alteration of fibroblast synthetic function occurs, possibly as a result of a viral infection. Rare cases of self-healing cutaneous mucinosis have been reported in adults [8–10].

Hereditary progressive mucinous histiocytosis [1]

Hereditary progressive mucinous histiocytosis (MIM 142630) is a rare, probably autosomal dominant, disease in which small skin-coloured papules or nodules begin to appear anywhere in the first decade of life. In contrast to other benign histiocytic skin diseases there is no spontaneous resolution, so that a steadily increasing number of papules is noted. To date the disease has been confined to females. Histologically, the disease is associated with a progressive proliferation of histiocytes (non-X type) and dermal mucinosis but there is no evidence of any known lysosomal storage disease.

Cutaneous focal mucinosis [1–3]

Cutaneous focal mucinosis has been accepted as a distinct entity, although recently it has been classified as a superficial angiomyxoma [4,5]. Clinically, it is characterized by a solitary, asymptomatic, flesh-coloured papule or nodule that can occur on the face, trunk or extremities. Histologically, there is localized accumulation of mucin in the dermis with an increased number of fibroblasts. The fibroblasts appear to function as mucoblasts with many large condensing vacuoles or secretory granules in their cytoplasm [2]. It is suggested that cutaneous focal mucinosis arises as a result of a dysfunction of the fibroblasts in a localized area only. If treatment is required, local excision is satisfactory, since recurrence is unusual. The condition may show some overlap with other mucinoses, for example REM syndrome and scleromyxoedema [6].

Focal cutaneous mucinosis forms part of the Birt–Hogg–Dubé syndrome, where it is associated with multiple fibrofolliculomas and a predisposition to renal cancer [7].

Oral focal mucinosis of the tongue, causing a clinically elevated mass, is an uncommon clinicopathological entity which is considered to be the oral counterpart of cutaneous focal mucinosis [8].

Mucinous naevus

The association of dermal mucinosis in association with a congenital plaque-like lesion in the interscapular area was first reported in a 16-year-old female [1]. In the absence of an overt connective tissue naevus and associated systemic disease, it was felt the lesion represented a congenital cutaneous mucinosis (mucinous naevus). Analysis of further cases suggests that these lesions may be a connective tissue naevus of proteoglycan type, and the only type to contain hyaluronic acid [2].

Reticular erythematous mucinosis [1]

Synonyms
- REM syndrome
- Plaque-like cutaneous mucinosis [2]

This syndrome comprises areas of reticular erythema on the trunk with a mucinous and round cell infiltrate in the dermis, and is frequently called the REM syndrome. Plaque-like cutaneous mucinosis is essentially the same disease process [3].

Aetiology. The aetiology is unknown, but there is some clinical and also experimental evidence that light is a factor in the pathogenesis of this disorder [4,5]. REM syndrome can be associated with the production of a monoclonal paraprotein, suggesting that the disease may involve disturbance of immune mechanisms [6]. Immunophenotypic studies have suggested a potential overlap between REM syndrome and Jessner's lymphocytic infiltration [7]. An hormonal influence may be operative [8]. Interleukin (IL)-1β may be involved in the abnormal hyaluronic acid metabolism in REM syndrome, as patient fibroblasts exhibit an abnormal response to stimulation by exogenous IL-1β [9]. Rare familial cases have been reported [10].

Pathology. The epidermis appears normal. In the papillary and upper reticular dermis there is a perivascular, and occasionally perifollicular, infiltrate largely composed of small mononuclear cells and populations of FXIIIa+/hyaluronan synthase 2+ dermal dendrocytes, which have been postulated to be responsible for accumulation of hyaluronan, rather than this being derived from fibroblasts [11]. There is separation of collagen bundles and fragmentation of elastic fibres. Histochemical stains show an increase in dermal mucin with a profile consistent with hyaluronic acid [4].

Fig. 59.16 Reticular erythematous mucinosis syndrome. View of anterior chest to show erythematous rash in photodistributed location.

Direct immunofluorescence is usually negative for immunoglobulins, fibrin and complement [4], although granular basement-membrane deposits of IgM, IgA and C3 have been described in isolated cases [5,12].

Clinical features. Most affected patients are female [1,3,4,13] and usually middle aged, but the condition has been reported in children [14]. Areas of pink, reticulate or sheet-like erythema are present on the central part of the chest and back, particularly over the sternum and on the upper back (Fig. 59.16). There is usually no pruritus, although sometimes the areas become itchy following sun exposure, and the erythema may be then more apparent. The areas become infiltrated and then slowly increase in size. Coexisting disorders reported in association with occasional cases of REM syndrome include hyperthyroidism, hypothyroidism, discoid lupus erythematosus, carcinoma and thrombocytopenic purpura [15]. Evolution of REM syndrome to systemic lupus erythematosus has been reported [16]. Mycosis fungoides presenting as reticular erythematous mucinosis has been documented [17].

Treatment. Topical steroids are ineffective, but fortunately antimalarials are almost invariably effective in controlling the eruption [1,4,13]. Ciclosporin appears to be of no value in treating REM syndrome [18]. UVB radiation combined with steroid impregnated tape [19], and use of the pulsed dye laser [20], have been beneficial.

Follicular mucinosis

Synonym
- Alopecia mucinosa

Definition and nomenclature. Follicular mucinosis is an inflammatory disorder characterized clinically by infiltrated plaques with scaling and loss of hair, and histologically by the accumulation of acid glycosaminoglycans in the sebaceous gland and the outer root sheath of the hair follicles. The condition was first described by Pinkus in 1957 [1] under the name alopecia mucinosa, but alopecia is not always evident, especially when only vellus follicles are involved.

Aetiology [2–6]. The cause of follicular mucinosis is unknown, but cell-mediated immune mechanisms may play a role in its pathogenesis [7]. Follicular mucinosis may be subclassified into three groups. The first and largest group consists of patients with solitary or only a few lesions, clearing spontaneously in 2 months to 2 years. In a second group are patients in whom the lesions persist, or new lesions continue to develop over many years. In the third group (about 15% of cases [2]) the mucinosis is associated with a lymphoma [4–6]; in such cases, histological evidence of the

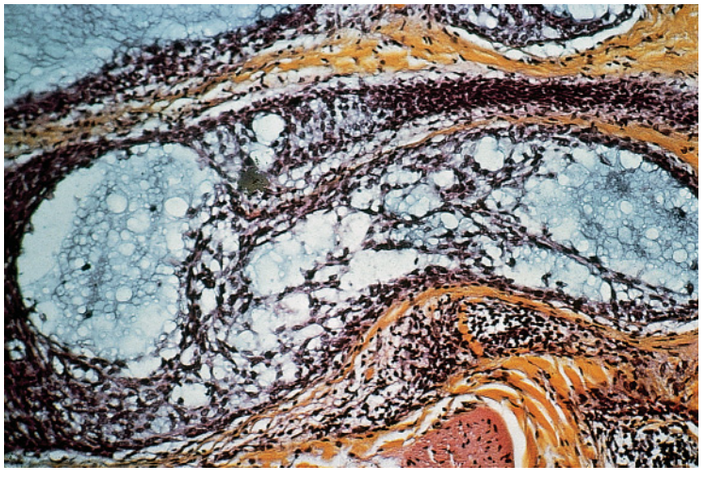

Fig. 59.17 Follicular mucinosis. Marked spongiosis and mucinous degeneration of outer root sheath of a follicle. Alcian blue, H&E, × 50. (Courtesy of St John's Institute of Dermatology, London, UK.)

Fig. 59.18 Follicular mucinosis. 'Boggy' erythematous plaque on forehead. (Courtesy of St John's Institute of Dermatology, London, UK.)

lymphoma is present from the onset, but it may be overlooked until the sections are later re-examined with hindsight.

Patients with lymphoma-associated follicular mucinosis tend to be older (age 20–70 years; average 45 years) than those with benign disease (age 2–75 years; peak between 20 and 40 years), but there is no absolute distinction in age incidence [2,8,9].

Some authorities regard follicular mucinosis as a non-specific follicular reaction [3], as similar changes have been observed in association with lupus erythematosus, angiolymphoid hyperplasia [10], Hodgkin's disease [11], cutaneous B-cell lymphoma [12], secondary extramedullary cutaneous plasmacytoma [13] and alopecia areata [14].

Pathology [2,3]. The earliest change appears to be oedema of the outer root sheath and sebaceous gland, with formation of cystic spaces in which mucin accumulates. The entire depth of the follicle may be involved, but the degree of damage to the hair matrix is variable. Later, the sebaceous glands may appear to be absent, or the whole follicle may be converted into a cystic cavity containing mucin and degenerate root-sheath cells (Fig. 59.17). Dermal inflammatory changes are variable, and may become granulomatous. Electron-microscopic studies [15] have shown changes in the keratinocytes of the follicular epithelium. Autoradiographic studies [16] have failed to show increased synthesis of glycosaminoglycans in affected follicles.

Histopathological findings may not allow clear-cut differentiation between idiopathic and lymphoma-associated follicular mucinosis [4]. In general, the presence of large numbers of eosinophils in the inflammatory infiltrate and marked mucinous changes in the follicular epithelium favour a benign form, whereas lymphocytic epidermotropism and a dense perifollicular infiltrate with atypical cells suggests an associated lymphoma. Similarly, monoclonal rearrangement of the T-cell receptor (TCR) gamma gene on polymerase chain reaction analysis does not reliably differentiate the benign and lymphoma-associated forms. In one study, TCR gene rearrangements were found in about 50% of tested cases from both idiopathic primary and lymphoma-associated groups of patients [5], whilst a study of patients with primary follicular mucinosis found no evidence of progression to cutaneous T-cell lymphoma despite the presence of a clonal TCR gene rearrangement [17]. When a lymphoma is demonstrated, this is usually of T-cell type [18–21], although B-cell lymphoma has been reported [12]. A follicular variant of mycosis fungoides is being increasingly recognized, although overt mucinous spongiosis is not necessarily present [21]. Syringolymphoid hyperplasia with alopecia and anhidrosis is a syringotropic variant of follicular mucinosis and should be viewed as a facultative precursor lesion of mycosis fungoides [22].

Clinical features [2,23]. In the acute benign form, the earliest changes are grouped, skin-coloured papules or erythematous plaques, with some scale, and with prominent follicles. Each plaque, commonly 2–5 cm in diameter but sometimes larger, changes little in appearance. Multiple lesions may be present from the onset or may develop within a period of a few weeks. The face, scalp, neck and shoulders are commonly affected. The hairs are shed from the affected follicles, so that alopecia may therefore be the presenting symptom when the scalp or eyebrow region is involved. Spontaneous recovery usually takes place within a few months, but may be delayed for a year or more.

In the chronic form, the lesions are often more numerous and more widely distributed and their morphology tends to be more variable. There may be elevated, flat or domed plaques or nodules, some of which may ulcerate. The plaques and nodules are often of soft, gelatinous consistency; sometimes mucin can be squeezed out of affected follicles (Fig. 59.18). Non-infiltrated, red, scaly plaques, patchy scaling, alopecia (Fig. 59.19) and indurated plaques may all be present. In some cases, leprosy may be simulated [24]. Presentation with an unusual acneiform eruption has been recorded [25].

Rarely, follicular papules may be generalized without obvious grouping. Irritation may be troublesome and persistent. Destruction of follicles may give rise to patches of permanent alopecia, which may be studded with horny plugs. This chronic form may

Fig. 59.19 Follicular mucinosis. Circumscribed patch of hair loss associated with erythematous plaque on forearm. (Courtesy of St John's Institute of Dermatology, UK.)

persist for many years without any evidence of associated disease. An unusual case associated with erythroderma and boggy plaques on the scalp and face, associated with alopecia and purulent paronychia and nail loss, has been described [26].

Unfortunately, no single clinical feature distinguishes lymphoma-associated cases from the chronic benign form. Extensive cystic changes have been recorded in the lymphoma-associated type [27]. Contrary to earlier opinion [2,7] lymphoma-associated follicular mucinosis has been reported where the lesions occurred on the head and neck [19,28]. The temporal relationship between lymphoma and follicular mucinosis is very variable. Gross manifestations of the lymphoma may have been present for some time before the mucinosis develops; in other cases, the first indication of the lymphoma is uncovered by histology.

Diagnosis. The loss of hair in plaques with prominent follicles but minimal inflammatory changes should suggest the diagnosis. Sometimes, mucin can be expressed from the follicle. Eczema, seborrhoeic dermatitis, lichen simplex, pityriasis rosea, traumatic alopecia and tinea capitis can all be closely simulated. Biopsy and serial sectioning of the tissue should confirm the diagnosis.

Treatment. There are no clear guidelines for treating follicular mucinosis. Some improve spontaneously, while treatment with topical and intralesional steroids has been claimed to be of benefit. Superficial radiotherapy may be beneficial in some of the lymphoma-associated cases [28], but some cases fail to respond [29]. Response to dapsone [30], isotretinoin [31] or photodynamic therapy [32] has been reported. Low-dose systemic steroids may benefit widespread pruritic follicular mucinosis, and interferon therapy, with or without acitretin, has also proved successful [33,34].

Urticaria-like follicular mucinosis

Urticaria-like follicular mucinosis appears to be a variant of follicular mucinosis, largely confined to middle-aged men, in which urticarial pruritic papules or plaques appear on the head and neck on an erythematous 'seborrhoeic' background [35]. The lesions tend to fade but recur for months to years leaving neither follicular plugging nor alopecia. Sun exposure may temporarily clear the eruption. The histopathological features are identical to follicular mucinosis but the prognosis is good, with a long, benign course.

Secondary mucinoses [1]

Dermal mucinosis may be associated to a greater or lesser extent with histopathological features otherwise typical of the disease in question [1]. In some, the mucinous deposition may be so striking as to suggest the diagnosis, for example Degos' disease [2]. Cutaneous mucinosis and polymyositis have been reported as presenting features of hypothyroidism [3].

Papulonodular mucinosis associated with systemic lupus erythematosus [1–6]

Papulonodular mucinosis is a distinct but rare cutaneous manifestation occurring in patients with discoid, subacute cutaneous or systemic lupus erythematosus. It presents as indolent, flesh-coloured papulonodules or plaques [7] on the neck, trunk and upper limbs due to diffuse mucinosis in the dermis. It differs from the diffuse mucinosis that may be found in lesional skin of lupus erythematosus in that it occurs in areas free of specific lupus erythematosus lesions. Clinical recognition is important because in one-third of cases it precedes both clinical and serological evidence of systemic lupus erythematosus, sometimes by several years. Cutaneous mucin deposition in papulonodular lupus erythematosus is associated with increased glycosaminoglycan production by dermal fibroblasts, which appears to be due to an unidentified serum factor [8].

Collagen vascular diseases

Dermal mucinosis occurs in lupus erythematosus [1] and dermatomyositis, and has been linked in some patients to parvovirus B19 infection [2]. Marked periorbital oedema from massive mucinosis has been reported in a patient with discoid lupus erythematosus [3]. Infiltrated erythematous plaques on the back progressing to erythematous and elastic, soft, tumorous masses over 20 cm in diameter were recorded in a patient with systemic lupus erythematosus [4]. Dermatomyositis may present as plaque-like mucinosis [5,6]. Papular and nodular mucinosis has been recorded as a presenting sign of progressive systemic sclerosis [7], and development of multiple, large, soft skin lesions over the interphalangeal joints of both hands, resembling cutaneous focal mucinosis, has also been reported [8]. Lesions typical of papular mucinosis without evidence of paraproteinaemia occurred in a patient with generalized morphoea [9]. Dermal mucinosis has been associated with severe chronic cutaneous graft-versus-host disease of the sclerodermoid variety [10].

Papular mucinosis in L-tryptophan-induced eosinophilia–myalgia syndrome [11]

The L-tryptophan-induced eosinophilia–myalgia syndrome, due to ingestion of contaminants of L-tryptophan, was first recognized in 1989. The skin lesions include a diffuse morbilliform eruption, urticaria and angio-oedema, dermographism, alopecia and cutaneous induration. Papular mucinosis may coexist for a while, although the lesions slowly regress after cessation of L-tryptophan ingestion. There is associated weakness, fatigue, arthralgia and pneumonitis.

Cutaneous mucinosis in the toxic oil syndrome [12]

Toxic oil syndrome occurred in Spain in 1981 related to the ingestion of adulterated oil. During the late recovery stages, an asymptomatic papular eruption developed on the arms, thighs and legs due to dermal mucin deposition. The papular eruption gradually resolved but sometimes led to sclerodermoid changes.

Lysosomal storage disorders

A.A.M. Morris, pp. 59.30–59.36

Lysosomes are a major site for the degradation of macromolecules and contain more than 50 acid hydrolases. Lysosomal storage disorders are inherited conditions in which deficiency of one or more hydrolases leads to the accumulation of various molecules in lysosomes. Typically, these are progressive multisystem diseases but the clinical features vary depending on the precise disorder and the severity of the enzyme deficiency. The presence of some residual enzyme activity reduces the severity of problems, delays their onset and may completely prevent the involvement of some organs (such as the brain in some disorders). Dermatological abnormalities are seen in lysosomal disorders affecting the degradation of glycosaminoglycans, glycoproteins and sphingolipids. Two characteristic dermatological findings are angiokeratomas (discussed later) and a combination of thickened skin and hypertrichosis. This combination, together with abnormalities of the facial skeleton, gives rise to a 'coarse' facial appearance. These facial features are seen in most mucopolysaccharidoses and glycoprotein breakdown disorders and in a few sphingolipidoses. Though it is widely used among professionals, the term 'coarse' should be avoided when talking to families, as many find it offensive. Lysosomal disorders are often associated with characteristic histological abnormalities, especially on electron microscopy. If a mucopolysaccharidosis or glycoprotein breakdown disorder is suspected, the next step is analysis of urinary glycosaminoglycans and oligosaccharides. Definitive diagnosis requires demonstration of the enzyme deficiency, usually in leukocytes.

Mucopolysaccharidoses [1,2]

The mucopolysaccharidoses (MPS) result from deficiencies of the enzymes required for the normal degradation of glycosaminoglycans (GAGs, formerly known as mucopolysaccharides). GAGs are long sugar chains composed of alternating sulphated hexuronic acid and hexosamine residues; in connective tissue, they are bound to core proteins to form proteoglycans. Dermatan sulphate, heparan sulphate and keratan sulphate are the main GAGs that accumulate in the MPS disorders; one or more GAGs are found in each disorder. Characteristic clinical features include coarse facial features, hepatosplenomegaly, bone dysplasia (known as dysostosis multiplex) and developmental regression. Some of these features, however, are absent in some disorders. Moreover, there is a considerable range of severity for each disorder; for MPS I, the spectrum is divided into Hurler syndrome (severe), Hurler–Scheie (intermediate) and Scheie syndrome (relatively mild). MPS III (Sanfilippo syndrome) can result from deficiencies of four different enzymes. The biochemical and clinical features of the different disorders are summarized in Table 59.3. The clinical features of MPS IX are not yet clear as only one case has been reported in detail [3].

Genetics. All the mucopolysaccharidoses are inherited as autosomal recessive traits except for MPS II (Hunter syndrome), which is X-linked.

Dysmorphism. MPS patients seldom show abnormalities at birth, except that some have umbilical or inguinal hernias. Patients presenting with an MPS-like phenotype at birth are likely to have mucolipidosis type II or GM_1 gangliosidosis (see below) [4]. The dysmorphism of MPS becomes more apparent with time (Fig. 59.20). Hypoplasia of the mid-facial bones leads to a flat nasal bridge. The skin is thickened, as are the lips, and the tongue is enlarged. The mouth is often slightly open due to adenoidal hypertrophy and the need for mouth breathing. Many patients have generalized hypertrichosis and some have synophrys. Corneal clouding is seen in MPS I, VI and VII. The hands appear podgy with short, broad digits. The facial dysmorphism is relatively subtle in MPS III (Sanfilippo syndrome), which presents with developmental delay. Facial abnormalities are not seen in MPS IV (Morquio disease), which presents with skeletal problems.

Dermatological features. In addition to the hypertrichosis and thickened skin mentioned above, ivory-white papules or nodules are often seen on the back of patients with severe MPS II (Hunter syndrome) [5–7]; similar pebbly skin may also occur in MPS I (Hurler and Hurler–Scheie syndromes) [8]. Individual nodules range from 1 to 10 mm in size and they may coalesce to form ridges or a reticular pattern. Typically, they are found laterally, between the angles of the scapulae and posterior axillary lines (Fig. 59.21). Papules may also be found on the upper arms and outer thighs. Typically, the papules appear at 1–4 years of age and progress for a few years; they may clear spontaneously in older patients. Mongolian blue spots are common in Hurler and Hunter syndromes and, in addition to the sacrococcygeal region, they may be found on the upper back, the anterior trunk or the limbs [9–11]. The spots fade more slowly than in the general population; in Japanese patients they persist until teenage years [11].

Other clinical features. Developmental regression is the dominant feature in MPS III. After presenting with developmental delay, patients have a period of hyperactivity, behaviour problems and sleep disturbance at 3–10 years of age; following this, they gradually deteriorate into a vegetative state. Learning difficulties are also present in Hurler syndrome and severe cases of MPS II and VII. Other neurological problems may include sei-

Table 59.3 Classification of the mucopolysaccharidoses.

Number	MIM no.	Eponym	Clinical features	Enzyme deficiency	GAGs stored and excreted
MPS IH	252800	Hurler	Dysmorphism, corneal clouding, DM, HSM, PR, heart disease, death in childhood	α-L-iduronidase	DS, HS
MPS IS	252800	Scheie	Dysmorphism, corneal clouding, DM, normal IQ and life span	α-L-iduronidase	DS, HS
MPS IH/S	252800	Hurler–Scheie	Phenotype intermediate between I H and I S	α-L-iduronidase	DS, HS
MPS II	309900	Hunter (severe)	Dysmorphism, DM, HSM, heart disease, PR, death before 15 years	Iduronate sulphatase	DS, HS
		Hunter (mild)	Normal IQ, short stature, survive to adulthood	Iduronate sulphatase	DS, HS
MPS IIIA	252900	Sanfilippo A	PR, regression, hyperactivity, mild somatic features	Heparan-N-sulphatase	HS
MPS IIIB	252920	Sanfilippo B	Similar to III A	α-*N*-acetyl-glucosaminidase	HS
MPS IIIC	252930	Sanfilippo C	Similar to III A	Acetyl-CoA glucosamine *N*-acetyl-transferase	HS
MPS IIID	252940	Sanfilippo D	Similar to III A	*N*-acetyl-glucosamine 6-sulphatase	HS
MPS IVA	253000	Morquio A	DM, odontoid hypoplasia, corneal clouding	Galactose-6-sulphatase	KS
MPS IVB	253010	Morquio B	Milder DM, slow neurodegeneration	β-galactosidase	KS
MPS VI	253200	Maroteaux–Lamy	Dysmorphism, DM, corneal clouding, normal IQ	*N*-acetyl-galactosamine 4-sulphatase	DS
MPS VII	253220	Sly	Hydrops fetalis, dysmorphism, DM, HSM, PR	β-glucoronidase	DS, HS
MPS IX	601492	Natowicz	Soft tissue masses in the one reported patient	Hyaluronidase	Hyaluronan

The terms MPS V and MPS VIII are no longer used.
IQ, intelligence quotient; DM, dysostosis multiplex; HSM, hepatosplenomegaly; PR, psychomotor retardation; DS, dermatan sulphate; HS, heparan sulphate; KS, keratan sulphate.

Fig. 59.20 Facial features of an 8-year-old boy with Hunter syndrome (MPS II).

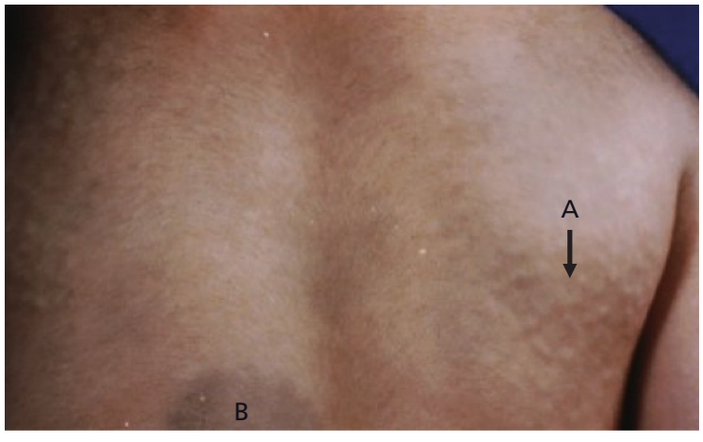

Fig. 59.21 'Pebbling' of the skin (A) and extensive Mongolian blue spot (B) on the back of a boy with Hunter syndrome (MPS II). (Reproduced from J.E. Wraith [2] with permission of author and publisher.)

zures, hydrocephalus, spinal cord compression and carpal tunnel syndrome.

Dysostosis multiplex is a particular problem in patients with MPS IV, who have very short stature and a high risk of atlanto-axial dislocation. Dysplasia of the hip and knee leads to arthritis and sometimes to dislocation. Joint problems, short stature and kyphosis are also seen in the other mucopolysaccharidoses. Ear, nose and throat infections, upper airway obstruction and deafness are common. Valvular heart disease is another frequent problem and is often the cause of death. MPS VII is rare but may present with hydrops fetalis.

Histology. The skin may show distinctive changes even in the absence of clinical skin abnormalities. A few Malpighian cells in the epidermis are distended with pale cytoplasm. Fibroblasts, Schwann cells and some smooth muscle and sweat gland cells show cytoplasmic metachromasia when stained with toluidine blue (due to the presence of GAGs) [12,13]. Fragmentation of collagen and increased tissue mucin may be seen. In Hunter syndrome, examination of the nodules shows pooling of

metachromatic material between the collagen bundles of the lower reticular dermis [14].

Ultrastructurally, in all forms of MPS, dermal fibroblasts and Schwann cells contain membrane-bound cytoplasmic vacuoles; these may appear empty or contain fibrillogranular material [12–14].

Diagnosis. If MPS is suspected, it may be worth undertaking a skeletal survey to look for dysostosis multiplex. 'Spot tests' for urine GAGs are unreliable, especially for MPS III and IV. Quantitation usually shows increased amounts of GAGs in the urine but even this can miss patients at the mild end of the spectrum. Two-dimensional electrophoresis allows the clearest discrimination between different GAGs. The diagnosis can be confirmed by enzyme assay in leukocytes, plasma or fibroblasts. The main differential diagnoses are other lysosomal disorders, such as the glycoprotein breakdown disorders, mucolipidoses and the severe forms of galactosialidosis and GM_1 gangliosidosis (see below).

Treatment. Symptomatic treatment is important and requires a multidisciplinary approach. Ear, nose and throat, orthopaedic and neurosurgery may all be needed. Medication can be useful for sleep and behaviour problems, especially in MPS III. Haematopoietic stem cell transplantation (HSCT) is an established treatment for Hurler and Maroteaux–Lamy syndromes, using bone marrow or umbilical cord blood [15]. Transplantation in infancy leads to improvement in most systems and can preserve normal developmental progress in Hurler syndrome but the skeletal problems progress [16] and ophthalmological problems persist. Moreover, HSCT is associated with a high morbidity and mortality. Enzyme replacement therapy is now available for MPS I, II and VI [17–19]. Its major limitation is the inability of the enzyme to cross the blood–brain barrier. Bone and heart valve disease are also resistant to enzyme replacement therapy, though outcomes can be improved by starting treatment early.

Mucolipidoses [1]

The term 'mucolipidosis' (ML) was originally used to describe lysosomal disorders with clinical features of MPS and the sphingolipidoses. ML I is now called sialidosis; it is considered with the other disorders of glycoprotein degradation. ML IV presents in infancy with psychomotor retardation and corneal clouding; though there are no dermatological problems, electron microscopy reveals a variety of inclusions in skin, as in other tissues [2].

ML II and III refer to different severities of an autosomal recessive disorder (MIM 252600), in which multiple lysosomal enzymes fail to enter their organelle. The underlying problem is a deficiency of UDP-*N*-acetylglucosamine-1-phosphotransferase, which is needed for lysosomal enzymes to acquire a mannose-6-phosphate residue. The transport of lysosomal enzymes into the lysosome depends on the binding of this residue to a mannose-6-phosphate receptor. ML II (I cell disease) refers to the severe end of the spectrum; patients often present at birth with coarse facial features. They also have gum hypertrophy, severe neurological involvement, dysostosis multiplex and cardiomyopathy, which is frequently the cause of death. In patients with ML III, the main problem is arthritis caused by the skeletal dysplasia. Other features may include mild learning difficulties and dysmorphism. MPS excretion is normal in ML II and III but there are abnormal urinary oligosaccharides. The diagnosis is established by demonstrating raised levels of the mistargetted lysosomal enzymes in plasma. Cultured fibroblasts from patients with ML II and III contain dense cytoplasmic inclusions, which gave rise to the name, I cell disease [3]. Histology reveals vacuoles in fibroblasts and other mesenchymal cells in skin and elsewhere; ultrastructurally, the vacuoles are membrane-bound and contain electron-lucent or fibrillogranular material [4].

Table 59.4 Glycoprotein storage disorders, sphingolipidoses and mucolipidoses with cutaneous features

Name	Enzyme deficiency	Cutaneous features*	Other clinical features*	Abnormal urine oligosaccharides	Sample for enzymology
Fucosidosis	α-L-fucosidase	MLF (mild), AK	PR	(+)	leukocytes
α-Mannosidosis	α-Mannosidase	MLF	PR, deafness, DM, HSM, frequent infections	+	leukocytes
β-Mannosidosis	β-Mannosidase	AK	PR, deafness, frequent infections	(+)	leukocytes
Sialidosis type I	neuraminidase		(Late onset) myoclonus, CRS	(+)	cultured cells
Sialidosis type II	neuraminidase	MLF	(Early onset) PR, DM, HSM	(+)	cultured cells
Aspartylglucosaminuria	aspartylglucosaminidase	MLF, AK	PR, regression, seizures	(+)	leukocytes
GM1 gangliosidosis	β-galactosidase	MLF, AK, T	Early onset form: hydrops, HSM, DM, PR, regression, spasticity, CRS	+	leukocytes
			Late onset: Dysarthria, dystonia, DM, PR	+	leukocytes
Galactosialidosis	PPCA	MLF, T	Early onset form: hydrops, HSM, Heart disease, DM, PR, CRS	+	leukocytes
		AK, MLF (mild)	Later onset: myoclonus, ataxia, PR, CRS	+	leukocytes
Fabry	α-galactosidase A	AK, hypohydrosis	Acroparaesthesia, renal failure, heart disease, strokes		leukocytes
Schindler	α-*N*-acetylgalactosaminidase		(Early onset) PR, regression, spasticity		
Kanzaki	α-*N*-acetylgalactosaminidase	AK, MLF (mild)	(Late onset) PR		
Niemann–Pick A	sphingomyelinase	Papules, pigmentation	HSM, lymphadenopathy, PR, regression, spasticity, CRS		leukocytes
Niemann–Pick B	sphingomyelinase	Papules, pigmentation	HSM, lung disease		leukocytes
Gaucher type I	β-glucosidase	Pigmentation, T	Bone pain, DM, HSM		leukocytes
Gaucher type II	β-glucosidase	Collodion baby	HSM, squint, stridor, dysphagia, spasticity		leukocytes
Gaucher type III	β-glucosidase		HSM, abnormal eye movements, regression		leukocytes
Farber	ceramidase	Nodules	Hoarse voice, arthritis, PR, regression, CRS		leukocytes
Mucolipidosis type II	multiple	MLF	Gum hypertrophy, DM, PR, cardiomyopathy	+	plasma
Mucolipidosis type III	multiple	MLF (mild)	Arthritis, DM, PR	+	plasma
Multiple sulphatase def.	multiple	MLF ± ichthiosis	PR, regression, HSM, DM (references A & B)	+	leukocytes
ISSD	sialic acid transporter	MLF, hypopigmentation	PR, HSM, DM, hydrops/ascites (references C & D see Table footnote)	+	cultured cells

* Features that are characteristic or have been reported in a number of patients.

MLF = Mucopolysaccharidosis-like facies; AK = angiokeratomas; T = telangiectasia; PR = psychomotor retardation; DM = dysostosis multiplex; HSM = hepatosplenomegaly; CRS cherry red spot; PPCA = protective protein/cathepsin A; ISSD = infantile free sialic acid storage disease

Mucolipidosis type I is now called sialidosis.

Disorders of glycoprotein degradation

Most secreted and cell surface proteins are glycosylated, with oligosaccharides attached to asparagine (*N*-linked glycoproteins) or to serine or threonine (*O*-linked glycoproteins). The oligosaccharide components of glycoproteins are degraded by lysosomal hydrolases which sequentially remove the terminal monosaccharides. Deficiency of an enzyme prevents subsequent degradation steps and leads to the storage of various oligosaccharides and/or glycopeptides, depending on the precise defect [1,2]. The disorders of glycoprotein degradation are all very rare and are sometimes called glycoproteinoses or oligosaccharidoses. They resemble the mucopolysaccharidoses in several respects, including the facial appearance in many cases. Angiokeratomas are found in some disorders. Mucopolysaccharides are not present in the urine but abnormal oligosacharides may be detected by thin-layer chromatography and staining with orcinol (α-mannosidosis), resorcinol (sialidosis) or ninhydrin (aspartylglucosaminuria). In other disorders, abnormal oligosaccharides are not consistently detected (β-mannosidosis, fucosidosis). Enzyme assays are, therefore, important for diagnosis. Most of the assays can be performed on leukocytes but neuraminidase can only be measured reliably in cultured cells. Because it can be difficult to distinguish these disorders from the sphingolipidoses on clinical grounds, many laboratories offer a set of lysosomal enzyme assays on leukocytes for screening patients with relevant clinical features. The clinical and biochemical features of these disorders are summarized in Table 59.4 (along with relevant mucolipidoses and sphingolipidoses).

Fig. 59.22 Angiokeratoma corporis diffusum on the limbs of a 7-year-old girl with fucosidosis.

Genetics. All the disorders of glycoprotein degradation are inherited as autosomal recessive traits.

Fucosidosis (MIM 230000) [1]

Patients with α-L-fucosidase deficiency usually present by the age of 3 years with developmental delay, followed by neurological deterioration. Approximately 50% patients lose the ability to sit and talk by 10 years of age [3]. Most patients have a mild MPS-like facial appearance and short stature, with dysostosis multiplex that principally affects the spine. Angiokeratomas usually appear in mid- to late childhood and they are present in 85% of patients aged over 20 years [3]. The angiokeratomas usually have the same appearance and distribution as in Fabry's disease but they may be confined to the limbs (Fig. 59.22). Similar lesions may occur on the lips, gums or tongue [4]. Other clinical features include hypohydrosis [5], recurrent infections, hepatosplenomegaly and epilepsy. Bone marrow transplantation may improve the neurological outcome [6].

Ultrastructure of endothelial cells and fibroblasts reveals numerous cytoplasmic vacuoles that appear empty or contain fine granular material [5]; by contrast, concentric lamellar inclusions are seen in Fabry's disease. Lamellar inclusions are, however, seen in Schwann cells and in the myoepithelial cells of sweat glands in fucosidosis [5]. Fucose-containing oligosaccharides can be detected in the urine of some patients but not others. The diagnosis is confirmed by measuring enzyme activity in leukocytes or cultured fibroblasts.

The mannosidoses [1]

α-Mannosidase deficiency (MIM 248500) is associated with MPS-like facial features, learning difficulties, deafness, corneal clouding and cataracts, dysostosis multiplex, hepatosplenomegaly and frequent infections.

β-Mannosidase deficiency (MIM 248510) is associated with learning difficulties, deafness and frequent infections; the face is not coarse but angiokeratomas appear in some patients during late childhood or adulthood. Ultrastructural examination shows lysosomal vacuoles containing granular material in basal keratinocytes, endothelial cells, fibroblasts and eccrine sweat glands [7,8].

Abnormal urinary oligosaccharides can readily be detected in α-mannosidosis but the mannose-containing disaccharides excreted in β-mannosidosis can easily be missed, especially during infancy. Both diagnoses can be confirmed by enzyme measurement in leukocytes.

Sialidosis (MIM 256550) [1]

This disorder results from a deficiency of α-neuraminidase (also called sialidase). Mildly affected patients are said to have sialidosis type I: they present as adolescents or adults with myoclonus and visual impairment associated with a macular 'cherry red spot' on fundoscopy. Sialidosis type II refers to more severely affected patients, who present in infancy or childhood with an MPS-like phenotype, developmental delay, dysostosis multiplex and hepatosplenomegaly [9]. Histology shows vacuolation of many cell types, particularly reticuloendothelial cells and fibroblasts. Abnormal urinary oligosaccharides can be seen when stained with resorcinol. Cultured fibroblasts are needed to demonstrate the enzyme deficiency because normal activity is low in leukocytes.

Aspartylglucosaminuria (MIM 208400) [10]

This disease is caused by deficiency of aspartylglucosaminidase, which catalyses the final step in the lysosomal breakdown of glycoproteins. Patients usually present with developmental delay at 2–4 years of age. They make some developmental progress until puberty following which they regress and may develop epilepsy. Subtle facial dysmorphism is present in children; from adolescence onwards, there is coarsening of the facial features, with sagging skin, thick lips, a broad low nasal bridge and coarse hair [11]. Facial angiofibromas are common in adults, as are gingival overgrowths and oedema of the buccal mucosa [12]. Angiokeratomas are less common and may be confined to the limbs [13,14]. Ultrastructurally, dermal fibrocytes have enlarged lysosomes containing scanty fibrillogranular material. The diagnosis can be established by demonstrating aspartylglucosamine in the urine or by measuring the enzyme activity in leukocytes or cultured fibroblasts. The disorder is extremely rare in most countries but a common mutation in the Finnish population has led to a higher incidence there [13].

α-N-acetyl-galactosaminidase deficiency (MIM 104170) [15–17]

This extremely rare disorder leads to the accumulation of oligosaccharides, glycopeptides and glycosphingolipids with terminal α-*N*-acetyl-galactosamine residues. The few reported patients have presented either as infants with neurodegeneration and histologi-

Table 59.5 Lysosomal diseases associated with angiokeratomas.

Name/eponym	Enzyme deficiency	Usual age of onset	Ultrastructure of lysosomal storage in mesenchymal cells
Fabry	α-galactosidase A	>10 years (males), adulthood (females)	Dense concentric lamellar inclusions
Fucosidosis	α-L-fucosidase	Mid- to late childhood	Vacuoles with granular material
Kanzaki	α-*N*-acetylgalactosaminidase	Adulthood	Vacuoles with fibrillary material
Galactosialidosis	β-galactosidase and neuraminidase	Adulthood	Vacuoles with granular material
GM_1 gangliosidosis	β-galactosidase	Infancy	Vacuoles with fibrillogranular material
Aspartylglycosaminuria	aspartylglucosaminidase	Late childhood or adulthood	Vacuoles with fibrillogranular material
β-Mannosidosis	β-mannosidase	Late childhood or adulthood	Vacuoles with granular material

cal features of neuroaxonal dystrophy (Schindler disease) or as adults with angiokeratomas and mild learning difficulties (Kanzaki disease) [15–17]. The angiokeratomas appeared first between the knees and the umbilicus but later spread to the breasts, limbs, face, mouth and gastric mucosa. Ultrastructural examination showed clear vacuoles with scanty fibrillary contents, especially in endothelial and eccrine sweat gland cells [16]. Adult patients have slightly coarse facial features, lymphoedema in the legs and peripheral neuroaxonal degeneration [16,17].

Angiokeratoma corporis diffusum

Angiokeratoma corporis diffusum is the dermatological hallmark of several rare inherited lysosomal disorders, summarized in Table 59.5. Fabry's disease is much the commonest of these disorders. Angiokeratomas are mainly found in the milder (late-onset) forms of galactosialidosis and α-*N*-acetylgalactosaminidase deficiency and they are only an occasional finding in GM_1 gangliosidosis, aspartylglycosaminuria and β-mannosidosis. The angiokeratomas are accompanied by various problems affecting other parts of the body, depending on the underlying diagnosis. Fucosidosis, β-mannosidosis, aspartylglycosaminuria and Kanzaki disease have been described above; the other disorders primarily affect sphingolipid degradation and are described below. There have been a few reports of patients with angiokeratoma corporis diffusum in whom no specific enzyme deficiency has been identified [1–4]. In some cases, the presence of cytoplasmic vacuolation and associated clinical features suggests an unrecognized lysosomal disorder [2]; in cases without these features, a different aetiology seems more likely [3,4].

In each of the disorders, the skin lesions develop slowly as clusters of individual telangiectases or small angiomas. The colour ranges from dark red to blue-black. They are flat or slightly raised and do not blanch with pressure. The larger and older lesions may become hyperkeratotic. Bleeding can occur from the larger angiokeratomas. In patients with sparse angiokeratomas, the differential diagnoses include purpura, angioma serpiginosum and other types of angiokeratoma: solitary, circumscriptum, Fordyce type (scrotal) and Mibelli type [5]. Angiokeratomas can be removed by argon laser treatment if bleeding is a recurrent problem or for cosmetic reasons.

Sphingolipidoses

Sphingolipids are amphiphilic molecules found in cell membranes. In all sphingolipids, the lipophilic component is ceramide. The hydrophilic portion is phosphorylcholine in sphingomyelin and usually an oligosaccharide in the glycosphingolipids. Glycosphingolipids containing neuraminic acid are called gangliosides. Sphingolipids are degraded in a stepwise fashion by lysosomal hydrolases and deficiencies of these enzymes (or their protector/activator proteins) cause the sphingolipidoses [1]. In some sphingolipidoses (e.g. Tay–Sachs disease), problems are confined to the nervous system; these are not considered further here. Other sphingolipidoses may be associated with an MPS-like facial appearance, angiokeratomas or other dermatological abnormalities. In many of these disorders, histology reveals vacuolated cells, whose ultrastructural appearance provides clues to the diagnosis. Thin layer chromatography reveals abnormal urinary oligosaccharides in a few disorders but the diagnosis is generally established by enzyme assays on leukocytes (or cultured cells). The clinical and biochemical features of the sphingolipidoses with dermatological features are included in Table 59.4.

Genetics. All the disorders are rare and show an autosomal recessive pattern of inheritance, except Fabry's disease, which is X-linked.

GM_1 gangliosidosis (MIM 230500) [1,2]

Deficiency of acid β-galactosidase leads to the accumulation of GM_1 ganglioside, other glycosphingolipids, galactose-containing oligosaccharides and keratan sulphate. GM_1 gangliosidosis is very rare and has a wide range of severity. Some patients present with hydrops fetalis or as neonates with hypotonia, hepatosplenomegaly and dysmorphism. The face is often puffy, with macroglossia, gum hypertrophy and a depressed nasal bridge; radiological investigation reveals dysostosis multiplex. These patients develop spasticity, seizures, dysphagia, loss of vision and macular cherry red spots; most die by 2 years of age. Other patients present with regression in early childhood and develop a spastic quadriplegia. The most mildly affected patients present later in childhood or as adults with dysarthria, dystonia and an abnormal gait; they may have mild learning difficulties and skeletal dysplasia, affecting the spine and hip. Widespread angiokeratomas have been reported in a few infants with GM_1 gangliosidosis [3]; the age of onset contrasts with other disorders, in which angiokeratomas seldom appear before mid-childhood. Telangiectasia and extensive Mongolian blue spots have also been reported in some infants [3,4]. Electron microscopy shows vacuolated histiocytes, fibroblasts and endothelial cells with fibrillogranular material in the vacuoles. The diagnosis is made by demonstrating β-galactosidase deficiency in leukocytes, with normal neuraminidase activity (which excludes galactosialidosis). There is no treatment for early-onset forms but substrate reduction therapy with miglustat may help late-onset patients.

Galactosialidosis (MIM 256540) [1,5]

In this extremely rare disorder, there is a combined deficiency of neuraminidase and β-galactosidase. The primary defect is in a protein (PPCA) that normally protects the two enzymes from rapid proteolysis. The protective protein is also called cathepsin A (hence PPCA) and has peptidase activity towards certain neuropeptides. The most severely affected patients present with hydrops fetalis or with MPS-like facial dysmorphism and organomegaly in the neonatal period and die within the first year from renal or cardiac failure. Many of these patients have telangiectases [6] and a few have angiokeratomas. Other patients present in early childhood with coarse facies, organomegaly, dysostosis multiplex and neurodevelopmental problems. Mildly affected patients are mostly Japanese. They present in late childhood or adulthood with myoclonus, ataxia, mental retardation and loss of vision with cherry red spots. They have no organomegaly but do have mild MPS-like facial features and spinal abnormalities. Half of these patients have angiokeratomas, similar to those seen in Fabry's disease [7]. Electron microscopy shows vacuoles, some containing granular material, in endothelial cells and fibroblasts. The diagnosis is made by finding deficiencies of β-galactosidase, neuraminidase and cathepsin A in leukocytes or cultured fibroblasts.

Fabry's disease (MIM 301500) [1]

A.A.M. Morris & S.M. Breathnach, pp. 59.36–59.39

Synonym

- Anderson–Fabry disease

This is a rare X-linked sphingolipidosis, with an estimated incidence of 1 in 40 000–60 000 male births [1,2]. Affected males usually present in childhood with episodes of pain in the extremities, followed by the appearance of angiokeratomas. Most adult males develop renal failure, cardiac and cerebrovascular disease. Many heterozygous females also develop symptoms, though the onset is usually later.

Aetiology. Deficiency of the lysosomal enzyme, α-galactosidase A, leads to the accumulation of glycosphingolipids with terminal galactose residues, predominantly globotriaosylceramide (galactose–galactose–glucose–ceramide) but also galabiosylceramide (galactose–galactose–ceramide) and blood group B substances [1]. These are found in the lysosomes of endothelial, perithelial and

vascular smooth muscle cells; the swollen endothelial cells encroach on the lumen of blood vessels, leading to focal increases in pressure and aneurysmal dilatation of the weakened vascular wall. Glycosphingolipids also accumulate in renal glomeruli and tubules, cardiac muscle, autonomic ganglion cells and the corneal epithelium. More than 300 mutations have been identified in the GLA gene; none are highly prevalent. Some mutations seem to be associated with mild variants (e.g. N215S with the 'cardiac' variant) [3] but others are found in both mild variants and in classical disease [3,4].

Clinical features. The first symptoms are usually episodes of severe burning pain in the palms and soles (acroparesthesiae). These occur in 70–85% of male patients, usually starting between 5 and 15 years, though it may take many years for the diagnosis to be established [4]. Acroparesthesiae occur in 50–70% of females, with a mean age of onset of 15 years [5,6]. Painful crises are often triggered by fever or exertion and may last hours or days. Pain may diminish spontaneously in older men.

Angiokeratomas are found in 65–70% of male and 35–40% of female patients [4,5,7]. In males, they often start to appear shortly before puberty (age of onset 19 ± 14 years, mean ± SD) whereas in females they usually appear later (28 ± 17 years). The initial lesion is a dark-red or black telangiectatic macule or papule up to 4 mm across, that does not blanch with pressure; there is usually mild hyperkeratosis over larger lesions. Angiokeratomas are clustered and numerous in some patients but they are sparse in most women and in many men [7]. In men, the commonest sites are around the umbilicus (Fig. 59.23) and in the bathing-trunk area, affecting the inner thighs, lower back, buttocks, penis and scrotum. Lesions may also be found on the upper arms, around the border of the lips, around the nail folds and on the palms and soles; these are usually macular angiomas with minimal hyperkeratosis [7]. In women, lesions are most frequent on the trunk and proximal limbs; genital lesions are rare. Telangiectases are present in 23% of males and 9% of females, usually on the lips, buccal mucosa, ears or conjunctivae [7,8]. The other common dermatological problem is anhidrosis or hypohidrosis (in 53% of males and 28% of females) [7,9]. This probably results from an autonomic neuropathy. It is associated with heat and exercise intolerance, and sometimes with unexplained bouts of fever. Onset is most often in the third decade. Hyperhidrosis occurs in about 10% of patients, predominantly females, often starting in adolescence [10]. Later, vasomotor disturbances may cause the hands to be blue or blanched, or there may be flushing of the extremities. Lymphoedema is much commoner than in the general population [7] and may be due to lymphatic microangiopathy [11].

Fig. 59.23 Angiokeratoma corporis diffusum around the umbilicus in a man with Fabry's disease.

Cardiac involvement occurs in almost all adult males [1,2,4]. It includes left ventricular dilatation and hypertrophy, mitral valve regurgitation, arrhythmias and ischaemic heart disease. Most adult males have proteinuria, hypertension and gradually deteriorating renal function. Without enzyme replacement therapy, end-stage renal failure is usually reached between 40 and 50 years of age, though it can occur much earlier [1,4]. Cerebrovascular disease is also common and may lead to early strokes or transient ischaemic attacks. Other patients develop severe neurological problems without any obvious thrombotic episodes, presumably due to the involvement of multiple small vessels [1]. Vertigo, dizziness and high frequency hearing loss are common.

Most male patients have the full syndrome but atypical, milder variants have been reported. Men with the 'cardiac variant' usually present after the age of 40 years with cardiomyopathy and proteinuria [2]. Cardiac and cerebrovascular disease are commoner in heterozygous women than previously thought [5]. In a survey of 248 female patients, 26% had left ventricular hypertrophy (mean age of onset 50 years) and 7% had suffered strokes (mean age 50 years) [6].

Slit-lamp examination reveals an asymptomatic corneal dystrophy in most adult male and female patients [12]. Glycosphingolipid deposits under the epithelium initially cause superficial haziness, which progresses to characteristic whorled streaks radiating to the periphery (cornea verticillata). Identical appearances have been reported after long-term chloroquine or amiodarone [13]. Other ophthalmological findings include lens opacities and tortuosity of the conjunctival and retinal vessels.

Episodes of abdominal pain and diarrhoea are common and there may be achalasia of the oesophagus. Some patients suffer arthritis in the distal interphalangeal joint of the hand.

Prognosis. Men and women with Fabry's disease have a reduced life expectancy due to renal, cerebrovascular and cardiac disease. In a cohort of male patients, the median survival was 50 years, approximately 20 years less than the normal population [4]. School attendance, sport and social activities were all affected and only 57% of patients were in employment [4]. In a cohort of heterozygous women, the median survival was 70 years, approximately 15 years less than the normal population [5].

Histopathology. Light microscopy of the angiokeratomas shows dilated vessels in the upper dermis beneath a thinned epidermis, with or without hyperkeratosis (Fig. 59.24). Vacuolated cells are present in the media and intima of small blood vessels. The accumulated glycosphingolipids are birefringent and, in frozen sections, they appear as 'Maltese crosses' in polarized light [1]. Electron microscopy shows cytoplasmic inclusion bodies in the

Fig. 59.24 Angiokeratoma corporis diffusum: H&E, × 4. Dilated blood-filled vessels in papillary dermis.

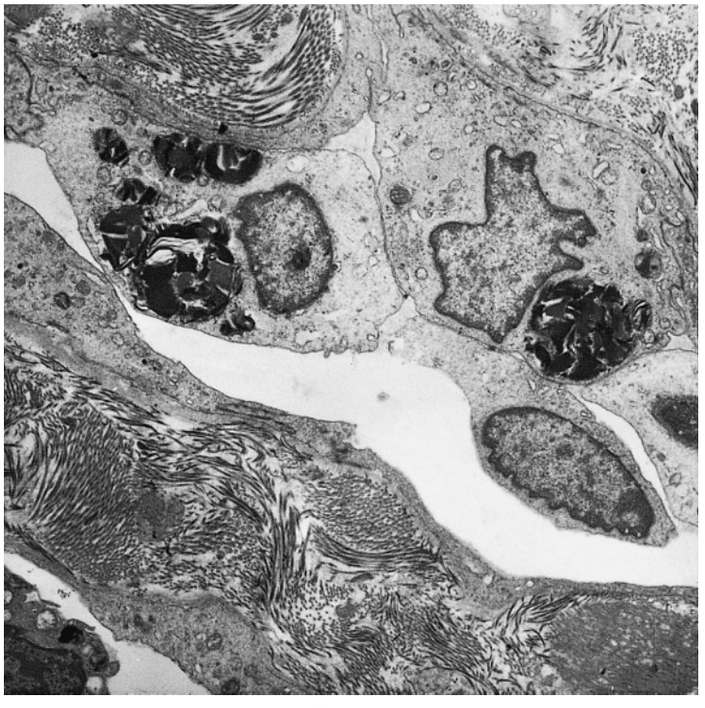

Fig. 59.25 Angiokeratoma corporis diffusum. Electron-dense cytoplasmic inclusion bodies are present within endothelial cells. (Courtesy of Dr P.H. McKee, King's College, London, UK.)

endothelial (Fig. 59.25) and perithelial cells of blood vessels, smooth muscle, perineural cells and dermal macrophages. The inclusions are electron-dense and lamellar, with a periodicity of 4–6 nm [1,14]. In contrast, other lysosomal disorders associated with angiokeratomas have electron-lucent vacuoles containing scanty fibrillary or granular material. The inclusions in Fabry's disease represent lipid deposits within lysosomes [14]. They are present in clinically unaffected skin, even in infancy [15], and in other tissues (e.g. myocardial and glomerular epithelial cells).

Diagnosis. If the angiokeratomas are sparse, it may be difficult to distinguish them from angiokeratomas without systemic disease. The diagnosis of Fabry's disease can be established by skin histology or slit-lamp examination of the cornea. In males, it should be confirmed by demonstrating α-galactosidase A deficiency in plasma or leukocytes (or cultured skin fibroblasts). This technique is unsuitable for heterozygous females, who often have normal enzyme activity. Urinary globotriacylceramide concentrations are raised in most heterozygous females [16] but the assay is not widely available. Molecular analysis is, therefore, the preferred technique for confirming the diagnosis in women, though occasionally it is difficult to distinguish pathogenic mutations from benign polymorphisms.

Treatment. The acroparesthesiae may respond to carbamazepine, gabapentin or phenytoin [17,18] or they may require opiates. Angiokeratomas can be removed by laser therapy for cosmetic or other reasons but this is seldom requested [19]. Cardiac complications should be managed conventionally. Aspirin may reduce the risk of stroke. Smoking should be avoided; statins should be prescribed if there is hyperlipidaemia and hypertension should be controlled. ACE inhibitors should be started if there is proteinuria. Patients developing renal failure warrant dialysis or transplantation; glycolipids do not reaccumulate in the graft [20].

Enzyme replacement therapy (ERT) with recombinant human α-galactosidase A has been shown to clear microvascular deposits of globotriaosylceramide from the kidneys, heart and skin [21]. It reduces neurogenic pain [22], reduces left ventricular hypertrophy [23] and prevents the development of renal impairment in patients with normal baseline renal function [24]. In the UK, ERT is now started following diagnosis in symptomatic male patients; in female patients, it is started if there is cardiac, neurological or renal disease, troublesome gastrointestinal symptoms or pain that cannot be controlled by other means.

Gaucher's disease (MIM 606463) [1]

A.A.M. Morris, pp. 59.39–59.42

This autosomal recessive disorder results from deficiency of acid β-glucosidase (glucocerebrosidase). Glycosphingolipids (principally glucosylceramide, also known as glucocerebroside) accumulate in macrophages in the liver, spleen and bones. Though Gaucher's disease is rare, it is the most prevalent lysosomal disorder (1:57 000 in Australia [2]).

Clinical features. Gaucher's disease is classified clinically into type 1 (non-neuronopathic), type 2 (acute neuronopathic) and type 3 (subacute neuronopathic). Type 1 is much the commonest, particularly in Ashkenazi Jews, in whom the incidence is over 1:1000, mainly due to a high prevalence of the N370S mutation. It presents in childhood or adulthood, with hepatosplenomegaly, features of hypersplenism (usually thrombocytopenia) or bone problems. Some children and adolescents suffer painful 'bone crises' due to ischaemia, typically in the femoral head or shaft. Later, loss of bone mass can lead to pathological fractures [3]. Lung infiltration is a rare but serious complication. The prognosis for type 1 Gaucher's disease depends on the severity of the mutations [4]; some patients can die by the age of 20 years without treatment, whereas some N370S homozygotes never develop symptoms.

Cutaneous features are common but not troublesome in type 1 Gaucher's disease [5]. In a series of 50 South African patients, 50% had diffuse yellow-brown pigmentation, 40% reported easy tanning, 30% had brown macules and 20% had telangiectasia [6]. Thrombocytopenia may lead to petechiae or ecchymoses.

Fig. 59.26 The hand of a 'collodion baby' with Gaucher's disease type 2.

Type 2 Gaucher's disease presents during the first 6 months of life with brainstem problems, such as squint, dysphagia and hyperextension of the neck, followed by episodes of apnoea. Other features include stridor, spasticity, epilepsy, lung disease and hepatosplenomegaly. Most type 2 patients die by the age of 2 years [7]. There is also a perinatal-lethal form that usually presents with hydrops fetalis. Some of these patients have severe ichthyosis, leading to the collodion baby phenotype (Fig. 59.26) [8]. The baby is encased in thick, tight, shiny skin that cracks and desquamates to leave erythroderma. The thickened skin causes ectropia of the eyes. The skin may return to normal if the baby survives for more than a month.

Type 3 disease is particularly common in the Norrbottnian population of northern Sweden, where it is associated with homozygosity for the L444P mutation. These patients usually present with hepatosplenomegaly in infancy, followed a few years later by an eye movement disorder, impaired hearing and other neurological problems [9]. Some type 3 patients have progressive myoclonic epilepsy and dementia with less severe organomegaly.

Pathology. Numerous characteristic histiocytes (Gaucher cells) are found in the spleen, liver, bone marrow and lymph nodes, with smaller numbers in other organs. Gaucher cells are large cells with pale-staining cytoplasm that has a delicate, striated, 'wrinkled tissue paper' appearance, best seen in thicker sections (10 μm). They differ markedly from the foam cells seen in other lipidoses. Ultrastructurally, Gaucher cells have membrane bound twisted tubular inclusions that represent aggregated glucocerebroside molecules within lysosomes [1,10].

Diagnosis. The diagnosis should be confirmed by enzyme assay in lymphocytes, leukocytes or cultured fibroblasts or by mutation analysis.

Treatment. Enzyme replacement therapy (ERT) is safe and effective for the treatment of type 1 Gaucher's disease but it is expensive and requires slow intravenous infusion at least every 2 weeks [11–13]. In the UK, all paediatric patients receive ERT, as do adults

with significant symptoms but not those who only have mild splenomegaly or mild skeletal abnormalities. Miglustat is an oral drug that decreases the accumulation of glucocerebroside by reducing the synthesis of glycosphingolipids (substrate reduction therapy) [14]. In the UK, it is used in mildly affected patients who are unable or unwilling to receive ERT. Diarrhoea and weight loss are common side effects. Splenectomy reduces abdominal distension and can relieve thrombocytopenia but it is seldom indicated in countries that can afford ERT. Other supportive measures include transfusion of blood products, bisphosphonates and analgesia.

There is no effective treatment for type 2 Gaucher's disease. ERT relieves the systemic complications in type 3 Gaucher's disease but it does not cross the blood–brain barrier; addition of miglustat or haematopoietic stem cell transplantation should be considered if there is neurological deterioration [15].

Niemann–Pick disease types A and B (MIM 257200) [1]

Aetiology. Niemann–Pick disease (NPD) types A and B are autosomal recessive sphingolipidoses, caused by sphingomyelinase deficiency. Sphingomyelin accumulates in histiocytes and leads to hepatosplenomegaly. In NPD type A, sphingomyelin also accumulates in the brain, leading to progressive neurodegeneration during early childhood. NPD type B is non-neuronopathic. Both types are very rare but type A is more common in Ashkenazi Jews. (NPD type C is an unrelated disorder characterized by defective intracellular lipid trafficking.)

Clinical features. Classical NPD type A patients present with diarrhoea, vomiting and failure to thrive in the first 2 months. By 6 months of age, there is hepatosplenomegaly, lymphadenopathy, trunkal hypotonia and spasticity in the limbs. Deafness and blindness are common and half the patients have retinal cherry red spots. Most patients die by 3 years of age. Other NPD type A patients have milder systemic features and juvenile or adult-onset neurological disease [2]. Type B patients usually present with splenomegaly or hepatosplenomegaly, sometimes not until adulthood. Interstitial lung disease, poor growth, hyperlipidaemia and thrombocytopenia are common. Nevertheless, some patients have a normal lifespan [3].

The skin may show patches of waxy induration and brownish-yellow pigmentation [4]. Papular, papulonodular or suppurative lesions may be found on the face or trunk [5,6], occasionally becoming confluent [6]. These may be commoner in patients with NPD of intermediate severity. Xanthomas and xanthogranulomas [7], café-au-lait macules and Mongolian blue spots have also been reported. Thrombocytopenia may lead to purpura or bruising.

Pathology. Niemann–Pick cells are the hallmark of NPD; some are present in virtually all tissues, including the skin [4,5]. They are large, usually mononucleate histiocytes, whose cytoplasm is filled with lipid droplets, giving rise to a foamy appearance. In cryostat sections, they stain readily with Sudan stains and contain doubly refractile material. Ultrastructurally, the cytoplasm contains concentric lamellar inclusions [5]. Similar cells are found in Wolman disease, cholesterol ester storage disease and lipoprotein lipase deficiency; Niemann–Pick cells stain poorly with PAS, in contrast to Gaucher cells. The diagnosis can be confirmed by measuring sphingomyelinase activity in leukocytes or cultured fibroblasts.

Treatment. There is no effective treatment for NPD type A. Trials of enzyme replacement therapy are planned for NPD type B.

Farber's disease (MIM 228000) [1]

Synonym
- Disseminated lipogranulomatosis

Farber's disease is an extremely rare autosomal recessive lipid-storage disease of infants, in which deficiency of lysosomal acid ceramidase leads to the accumulation of ceramide [1,2].

Clinical features. Patients usually present in early infancy with a hoarse cry, painful swollen joints and subcutaneous nodules. The most commonly affected joints are those of the hand and wrist, elbows, knees and ankles. The subcutaneous nodules may be associated with erythematous papules and are generally close to affected joints or over pressure points, such as the occiput and lower spine. Laryngeal involvement can lead to stridor as well as hoarseness. Most patients have psychomotor retardation, poor weight gain and die in early childhood from respiratory infections. A few patients present with hydrops fetalis or neonatal hepatosplenomegaly [2]. In other patients, neurodegeneration is the main feature [3]; these patients usually have cherry-red spots at the macula.

Histopathology. In the skin and subcutaneous tissue, dense areas of mixed granulomatous infiltration are found among a fibrovascular stroma. Groups of large, foamy histiocytes are found towards the centre of the granulomas. Ultrastructurally, the histiocytes have cytoplasmic vacuoles containing curvilinear inclusions (Farber bodies) [2,4]. Histochemical studies indicate that the storage material consists of ceramide and glycolipids [1,2]. The diagnosis can be confirmed by enzyme assay in leukocytes or fibroblasts.

Treatment. Symptomatic treatment includes analgesia and corticosteroids. Haematopoietic stem cell transplantation does not prevent neurological deterioration but may be appropriate for atypical patients without neurological involvement [5].

Lipoid proteinosis (MIM 247100) [1,2]

Synonyms
- Urbach–Wiethe disease
- Hyalinosis cutis et mucosae
- Lipoglycoproteinosis

Aetiology. Lipoid proteinosis is a very rare, autosomal recessive disorder, characterized by infiltration of hyaline material into the skin, oral cavity, larynx and internal organs. The exact nature of the hyaline material is still uncertain. The disorder is caused by mutations in the extracellular matrix protein 1 (ECM1) gene [3]. ECM1 binds to various proteins (perlecan, fibulins and matrix metalloproteinase-9) but its function is unknown [1]. Interestingly, antibodies to ECM1 are present in 75% of patients with lichen sclerosis [4]. Lipoid proteinosis is common in the Namaqualand region of South Africa, where cases can be traced back to a German immigrant [2].

Clinical features. Lipoid proteinosis usually presents in infancy with hoarseness, which can progress to complete aphonia. The vocal cords are thickened, with nodules here and on the epiglottis. Occasionally, stridor necessitates a tracheostomy [5]. The lips, pharynx, soft palate, uvula and tonsils develop yellow-white submucous infiltrates. The tongue is enlarged and firm with infiltrates on its under-surface. The frenulum becomes short and thick, restricting tongue movement, such that it cannot be protruded. There may be recurrent inflammation of the salivary glands [2].

The first skin lesions are often blisters in early childhood, which become eroded and crusted after minor trauma [2]. Acneiform, pock-like scars appear on the face and elsewhere, either following trauma or spontaneously. Infiltration of the skin can cause waxy papules, hyperkeratosis or warty plaques, which may become darker with time. These lesions may affect the palms or backs of the hands, the forehead or the elbows, where they can be prominent and resemble xanthomas. Characteristic 'beaded' papules are present along the margins of the eyelids but they may be subtle (moniliform blepharosis) (Fig. 59.27). There may be loss of eyelashes or patchy alopecia due to scalp involvement [6]. Some patients complain of itching or increased sensitivity to sunlight [2].

Fig. 59.27 Lipoid proteinosis. Typical 'beaded' papules present along the margins of the upper eyelids. (Courtesy of Dr R.C.D. Staughton, Chelsea and Westminster Hospital, London, UK.)

Epilepsy and psychiatric problems occur in a number of patients and may be associated with intracranial calcification (e.g. in the temporal lobes or amygdala) [7]. Visceral involvement has also been reported [8]. Problems progress until early adult life but subsequently stabilize.

Histopathology. The epidermis shows hyperkeratosis and irregular acanthosis. The dermis is thickened and the upper dermis contains large deposits of extracellular hyaline material that stains strongly with PAS. There is also thickening of the (PAS-positive) basement membranes at the dermal–epidermal junction and around blood vessels and sweat glands. Immunofluorescence labelling for type IV collagen confirms the basement membrane thickening. Staining for type I and type III collagen is decreased in the upper dermis; the deposits of hyaline material do not stain with anticollagen antibodies [6]. Ultrastructurally, there are multiple concentric rings of basement membrane around blood vessels and irregular reduplication of the lamina densa at the dermal–epidermal junction. The hyaline deposits are featureless. Lysosomes containing curved tubular inclusions have been reported in histiocytes and eccrine sweat glands [9] but this is not thought to be a primary lysosomal disorder. Histochemical diagnosis is now possible using an antibody to ECM1 [10].

Diagnosis. The combination of hoarseness from early childhood, thickening of the tongue and frenulum and cutaneous nodules suggests the diagnosis. Erythropoietic protoporphyria also causes waxy papules and depressed scars but the scars are confined to sun-exposed skin; on histology, the hyaline material is less extensive and there are fine lipid droplets. Xanthomatosis and amyloidosis are also excluded by the histological appearances. In adults, other differential diagnoses include lichen myxoedematosus and myxoedema with hoarseness.

Treatment. Microlaryngoscopy and dissection of the vocal cords can be successful. Dermabrasion [11], chemical skin peeling, blepharoplasty and carbon dioxide laser therapy [12] may be helpful. Oral dimethylsulphoxide was reported to help one patient [13] but not others [14]. Beneficial effects of etretinate [15] and of penicillamine [16] have also been reported.

Amyloid and the amyloidoses of the skin

S.M. Breathnach, pp. 59.42–59.58

Amyloidosis is a generic term, originally coined by Rudolf Virchow in 1854, which denotes extracellular deposition of a proteinaceous substance composed of one of a family of biochemically unrelated proteins, depending on the underlying condition, and which is usually associated with considerable tissue dysfunction [1–7]. A classification based on the biochemical nature of amyloid fibril proteins is shown in Tables 59.6 and 59.7. Amyloidosis now tends to be classified on the basis of characterization of the fibril proteins (of which over 20 have now been identified) rather than according to clinicopathological features. Fibrils in primary and myeloma-associated systemic amyloidosis, as well as in nodular primary localized cutaneous amyloidosis, are composed of immunoglobulin protein AL, whereas in secondary systemic amyloidosis they are composed of a non-immunoglobulin protein termed protein AA. Fibrils in other forms of primary localized cutaneous amyloidosis, and in secondary localized cutaneous amyloidosis, contain material related to cytokeratin [8].

Amyloid proteins, regardless of biochemical constitution, share certain characteristic physicochemical properties, tinctorial properties (Congophilia and green birefringence under polarized light) and a fibrillar ultrastructure. Paired, 7.5–10.0 nm, rigid, linear, non-branching, aggregated, hollow fibrils of indefinite length constitute the bulk of amyloid deposits, regardless of clinicopathological type or the tissue involved, and are arranged in a loose meshwork. Amyloid fibrils have been shown by X-ray diffraction crystallography and infrared spectroscopy to have, at least in part, a beta-pleated sheet configuration; this probably accounts for their ability to bind Congo red and for the low solubility and resistance to proteolytic digestion of amyloid.

Non-fibrillar amyloid proteins

All types of amyloid contain small amounts of a protein termed amyloid P component (AP) derived from, and identical to, serum amyloid P component (SAP), present in the blood of all normal

Table 59.6 Biochemical nature of fibril proteins in systemic amyloidosis.

Clinical type of amyloidosis	Amyloid fibril protein	Precursor substance
Primary (immunocyte dyscrasia)	AL	Monoclonal immunoglobulin light chains
Myeloma-associated	AL	Monoclonal immunoglobulin light chains
Secondary (chronic active disease)	AA	Serum amyloid A protein (SAA)
Haemodialysis-associated (periarticular, bony and renal)	β2-microglobulin	
Heredofamilial		
Predominantly nephropathic		
Familial Mediterranean fever	AA	SAA
Muckle–Wells syndrome	AA	SAA
Predominantly neuropathic		
Familial amyloid polyneuropathy	Transthyretin variant or apoliprotein A1 or gelsolin	
Non-neuropathic forms (Ostertag)	Apoliprotein A1 or lysozyme variant or fibrinogen α chain	
Predominantly cardiomyopathic	Transthyretin variant	
Cardiomyopathy with persistent atrial standstill	Unknown	
Senile systemic	Transthyretin from plasma	

Table 59.7 Biochemical nature of fibril proteins in organ-limited (localized) amyloidosis.

Nodular (skin, lung, genitourinary)	AL
Primary localized cutaneous	
Nodular	AL
Macular amyloid and lichen amyloidosus	?Altered cytokeratin
Secondary localized cutaneous amyloidosis	?Altered cytokeratin
Hereditary syndromes	
Hereditary cerebral haemorrhage with amyloidosis	
Icelandic type	Cystatin C
Dutch type	β-protein
Cerebral amyloid angiopathy and cortical plaques (Alzheimer's disease, senile dementia, Down's syndrome)	Amyloid β-protein (Abeta)
Sporadic Creutzfeldt–Jakob disease, kuru	Prion protein
Focal senile amyloidosis	
Heart atria	Atrial natriuretic peptide
Joints	Unknown
Seminal vesicles	Seminal vesicle exocrine protein
Prostate	β2-microglobulin
Ocular deposits (corneal, conjunctival)	Unknown
Endocrine amyloidosis (APUD organs, APUDomas)	
Elderly non-insulin-dependent diabetics, benign insulinomas of the pancreas, normal aged pancreas	Islet amyloid polypeptide (homology with calcitonin gene-related peptide)
Medullary carcinoma of the thyroid	Precalcitonin-related

individuals [1–3]. SAP prevents proteolysis of the amyloid fibrils of Alzheimer's disease, of AA amyloidosis and of AL amyloidosis, and may contribute to persistence of amyloid *in vivo* [9]. AP is constantly associated with the microfibrillar sheath of elastic fibres throughout the body in normal adults [10]. AP binds to isolated amyloid fibrils *in vitro* in a calcium-dependent manner, which may account for the frequent observation of amyloid deposition in the vicinity of elastic fibres [11]. Amyloid deposits also contain extracellular matrix components, including glycosaminoglycans and proteoglycans, which may be involved in the pathogenesis [12].

Staining reactions [1–3]

Special stains for amyloid include the triphenyl-methane dyes methyl and cresyl violet for the demonstration of metachromasia, the PAS method, the substantive cotton dyes Congo red and Sirius red with or without fluorescence [4] or polarized light microscopy (Fig. 59.28), and fluorescence with thiazole dyes such as thioflavine T (Fig. 59.29). Immunohistochemical staining with anti-SAP has also been advocated [5].

The staining properties depend to some extent upon the duration of fixation in formalin and tend to be far brighter on frozen fixed material. Congophilia is the most specific [6]. Unfortunately, methyl violet and Congo red staining may be equivocal and inadequate for detecting small deposits of amyloid; false-positive results occur in colloid milium (which may mimic nodular amyloidosis histopathologically [7]) and in lipoid proteinosis. False-positive staining with thioflavine T is seen with stromal hyaline deposits, collagen fibres and colloid bodies in lichen planus; anti-

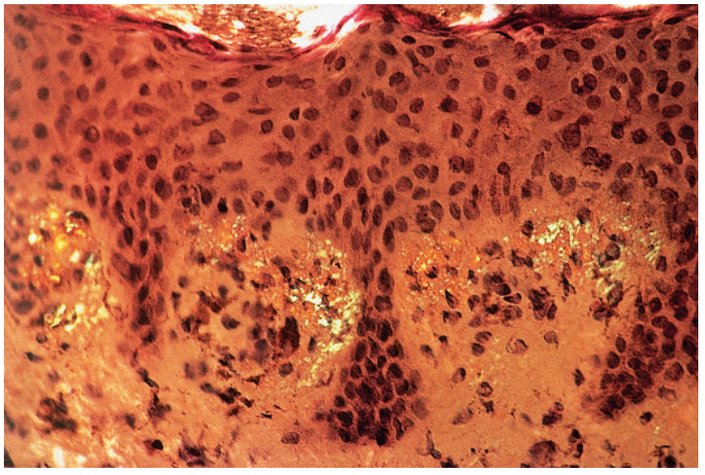

Fig. 59.28 Lichen amyloidosus. Alkaline Congo red, × 100. View under polarized light to show specific green fluorescence in amyloid deposits in papillary dermis.

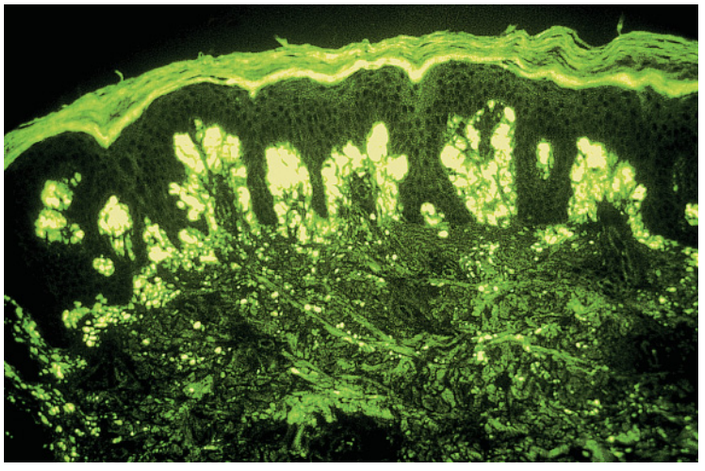

Fig. 59.29 Cutaneous amyloidosis. Thioflavine T, × 50. Viewed under fluorescence microscopy to show bright-yellow staining of amyloid deposits.

SAP also stains colloid bodies and elastotic elastic fibres. Use of a battery of stains is therefore recommended. In some cases it may be necessary to resort to electron microscopy to look for the characteristic ultrastructure of the fibrils. *In vivo* scintigraphy techniques using ^{123}I-labelled human SAP component can be used to delineate amyloid deposits in systemic amyloidosis and to monitor the effects of therapy [8].

AL type amyloid, unlike AA type amyloid, retains its affinity for Congo red and its typical polarization characteristics after exposure to potassium permanganate [9]. Immunohistochemical staining with specific antisera [10,11], or either amino acid sequencing or mass spectroscopy of material extracted from fibrillar deposits (using sections of formalin-fixed, paraffin-embedded biopsy specimens) [12], are used to differentiate between the various types of fibril protein in amyloid deposits. Immunohistochemical staining with antikeratin antibody EAB-903 using formalin-fixed tissue appears to be a useful method in the differential diagnosis of primary localized cutaneous amyloidosis [13].

Primary localized cutaneous amyloidosis

In primary localized cutaneous amyloidosis (PLCA) there is deposition of amyloid in previously apparently normal skin, with no evidence of deposits occurring in internal organs. Various subtypes of PLCA are recognized, including the more common macular and papular (lichen amyloidosus) types and the rare nodular (tumefactive) form. Both macular and papular lesions can occur in the same patient.

Aetiology. Nodular PLCA may be regarded as a form of extramedullary plasmacytoma, since the fibrils are of immunoglobulin AL type, and are thought to arise as a result of local aberrant light chain material production by clonally expanded plasma cells [1,2]. Modified β_2-microglobulin has also been reported to be a component of amyloid fibrils of primary localized cutaneous nodular amyloidosis [3].

The aetiology of other forms of PLCA remains unknown. Lichen amyloidosus is commoner among the Chinese [4]. Macular amyloidosis is rare in Europe and North America, but is much more common in Central and South America, the Middle East and Asia, suggesting the importance of genetic factors [4–9]. The occurrence of rare familial cases reinforces this view [9–16]. Familial primary localized cutaneous amyloidosis is an autosomal-dominant disorder mapped to 5p13.1-q11.2. Mutations in the OSMR gene, encoding oncostatin M-specific receptor beta (OSMRβ), have been reported [17]. OSMRβ is a component of the oncostatin M (OSM)

type II receptor and the IL-31 receptor; OSM and IL-31 signalling have been implicated in keratinocyte proliferation, differentiation, apoptosis and inflammation. Primary cutaneous amyloidosis has been described in identical twins, who also had numerous congenital abnormalities [18]. A review of the current literature has revealed no instance of systemic deposition of amyloid.

Fibrils in lichen amyloidosus and macular amyloidosis do not bind antibodies to protein AA or prealbumin [19], and although immunoglobulins, κ and λ light chains, and complement are frequently observed in deposits of macular and papular PLCA [20], they are not thought to be integral constituents of the fibrils, since they are readily eluted. The close proximity of the amyloid deposits to the lower epidermis in macular amyloidosis and in lichen amyloidosus suggests that the epidermis plays a role in its pathogenesis [21,22]. It has been proposed that focal epidermal damage and filamentous degeneration of keratinocytes is followed by apoptosis and conversion of filamentous masses (colloid bodies) into amyloid material in the papillary dermis [23,24]. There may be a contribution from the dermal–epidermal junction [25]. In support of this theory is the fact that dermal amyloid deposits in these forms of PLCA react immunohistochemically with antihuman cytokeratin antibody [26–28]. It is not clear why colloid (keratin) bodies produced in other dermatoses such as lichen planus are not transformed into amyloid. It has been proposed that in lichen amyloidosus specific immunological tolerance to the presence of colloid bodies in the papillary dermis favours their transformation into amyloid by macrophages or fibroblasts, whereas in lichen planus a brisk inflammatory response ensures their removal [29].

PLCA is associated with chronic friction, perhaps causing epidermal damage, as in the so-called friction amyloidosis seen especially in the Japanese as a result of rubbing the skin vigorously with a nylon towel or brush, bath sponge, towel, plant sticks or leaves [30–33], and in nodular prurigo and lichen simplex chronicus [34]. The association of macular amyloidosis with notalgia paraesthetica supports the role of chronic pruritus in development of macular amyloidosis [35,36]. In the dyschromic forms of primary cutaneous amyloidosis, hypersensitivity to UVB with a possible DNA-repair defect may be significant [37]. An association of maculopapular amyloidosis with chronic active Epstein–Barr viral infection was reported [38].

Pathology. In papular and macular forms of PLCA, the amyloid deposits are confined to the papillary dermis, and do not involve blood vessels or adnexal structures [1,2]. In macular amyloidosis, the deposits of amyloid are composed of small, multifaceted, amorphous globules, similar in size to the hyaline bodies found in lichen planus. They may be so sparse that more than one biopsy is necessary to confirm the diagnosis, and are easily missed without the use of special stains. The epidermis is usually of normal thickness but pigmentary incontinence with melanophages is a notable feature. In papular lichen amyloidosus, focal deposits of amyloid are often large enough to expand the dermal papillae and displace the elongated rete ridges laterally (Fig. 59.30). The overlying epidermis shows considerable irregular acanthosis and hyperkeratosis. The amyloid deposits are in close apposition to the basal layer of the epidermis and contain a few melanophages. Near the amyloid deposits, there is usually a sparse lymphohistiocytic perivascular infiltrate.

By contrast, in the nodular or tumefactive forms of PLCA the dermis, subcutis and blood vessel walls are diffusely infiltrated with amyloid as seen in primary systemic amyloidosis (Fig. 59.31). However, there is usually a perivascular infiltrate of plasma cells [3–5].

Table 59.8 Clinical classification of primary localized amyloidosis.

Papular or lichen amyloidosus
Macular amyloidosus
Maculopapular amyloidosis
Nodular or tumefactive
Familial (dyschromic)

Clinical features [1–7]. Several distinctive clinical forms of PLCA have been described (Table 59.8). Because macular amyloid and lichen amyloidosus may coexist in an affected individual (biphasic amyloidosis), they are regarded as variants of a single pathological process [6].

The papular form (lichen amyloidosus) is perhaps the best known. It usually presents as a pruritic eruption of multiple, discrete, hyperkeratotic papules, scaly and often hyperpigmented, distributed principally on the shins (Figs 59.32 & 59.33). The calves, ankles, dorsa of the feet and thighs, and the extensor aspects of the arms and abdominal or chest wall, may also be involved. A rare bullous variant of lichen amyloidosus has been documented [8]. A 'thermosensitive' form sparing skin overlying the superficial limb veins has been described [9]. Papules may coalesce to form thickened plaques, closely simulating hypertrophic lichen planus or lichen simplex chronicus. The condition usually persists for many years with localized pruritus as the prominent symptom.

The predominant sign in macular amyloidosis is clusters of small, pigmented macules, about 2 or 3 mm in diameter, which may coalesce to produce macular hyperpigmented areas. A reticulate or 'rippled' pattern of pigmentation is a characteristic diagnostic feature in many cases (Figs 59.34 & 59.35). The lesions tend to be associated with mild to moderate pruritus, but pruritus may be absent in 18% of cases. The lesions may be confined to the interscapular area (Fig. 59.34), but more commonly are extensively distributed over the back or chest [10,11]. Macular amyloidosis on the back has been reported to follow prolonged chronic friction

(see above). Lesions may also occur on the extensor aspect of extremities, and occasionally on the chest and buttocks. Hypopigmented areas may produce a 'poikilodermatous' appearance. The condition usually presents in early adult life and persists for many years; both sexes are equally affected. Macular amyloidosis can be misdiagnosed as post-inflammatory pigmentation, resolving lichen planus or neurodermatitis, or as the reticulate hyperpigmentation of the neck ('dirty neck') that has been described in association with atopic eczema [12,13]. Amyloid-like material has been demonstrated by electron microscopy, but not at light microscope level, in the atopic dirty neck [14].

Unusual variants of PLCA include: macular forms with widespread diffuse hyperpigmentation without papules but with poikiloderma-like facial involvement [15]; causing periocular hyperpigmentation [16]; simulating naevoid hyperpigmentation [17]; following Blaschko's lines [18]; resembling incontinentia pigmenti [19,20]; and a poikiloderma-like form [21–23]. Amyloidosis

cutis dyschromica is assumed to be a congenital disorder with hypersensitivity to UVB radiation, with possible DNA repair defects; hyperpigmented and hypopigmented xerotic lesions with deposits of amyloid in the papillary dermis occur in sun-exposed skin [24,25]. Primary cutaneous amyloidosis of the auricular concha, in which small papules are grouped on the concha of the ear, is also believed to be a variant of PLCA, and may coexist with lichen amyloidosus [26,27].

Associations of PLCA in a few kindreds with pachyonychia congenita [28], dyskeratosis congenita [29], familial palmar–plantar keratoderma [30] and multiple endocrine neoplasia type 2a (caused by germline mutations in the RET proto-oncogene) with multiple cutaneous neuromas and medullary thyroid carcinoma, have been described; in the latter, macular lichen amyloidosus is confined to the interscapular region [31–33]. Cases of PLCA have also been described in association with a variety of connective tissue disorders: systemic lupus erythematosus [34], systemic sclerosis [35], dermatomyositis [36], primary biliary cirrhosis and scleroderma [3,37], and Raynaud's phenomenon with livedo reticularis [38]. An association with angiolymphoid hyperplasia and Kimura's disease has been reported [39,40].

Anosacral cutaneous amyloidosis is a rare syndrome described in Japanese and Chinese males, in which pigmented macules and glossy hyperkeratotic lesions radiate out from the anus [41]. Fifty per cent of patients present below the age of 60 years, and the disease may be misdiagnosed as lichen simplex chronicus, post-inflammatory hyperpigmentation or tinea cruris.

The nodular or tumefactive form is a rare variant of PLCA (Fig. 59.36). Most reported patients have been females. Single or more commonly multiple nodules or plaques, indistinguishable from those associated with plasma cell dyscrasia-related systemic amyloidosis, may occur on the face, trunk, limbs, genitalia or palate [1,3,5,42–55]. They vary in size from a few millimetres to several centimetres. The overlying skin is often atrophic, and there may be petechial haemorrhages within the nodules. Some cases are associated with diabetes mellitus and Sjögren's syndrome [45,46].

Fig. 59.36 Nodular or tumefactive cutaneous amyloidosis. Close-up of tumour on side of nose. (Courtesy of St John's Institute of Dermatology, London, UK.)

The condition, as with localized nodular amyloidosis in other organs [56], may follow a prolonged benign course over many years [47,48]; however, some patients later develop paraproteinaemia and overt systemic amyloidosis [1,3]. In a series of 16 patients, only one progressed to systemic amyloidosis over a follow-up period ranging from 8 months to 24 years (mean 10 years), and this patient had a serum monoclonal lambda protein initially [57]. Rare familial cases of nodular cutaneous amyloidosis have been reported [58].

Treatment. In general, the treatment of PLCA is disappointing. Milder cases can be helped by hydrocolloid dressings [1] or by using potent topical corticosteroids with or without occlusive dressings, but usually in the short term only. Calcipotriol or phototherapy are similarly of limited use [2,3]. There have been reports of response to topical DMSO therapy in some [4–7] but not all [8] cases. Acitretin therapy has been beneficial in some but not all patients, either alone [9–11] or in combination with bath-PUVA photochemotherapy [12]; the condition relapses after therapy is stopped. A trial of long-term cyclophosphamide 50 mg daily in lichen amyloidosus found that itching was markedly decreased within 4 months [13]. Dexamethasone cyclophosphamide pulse therapy stopped itching after five sessions and lesions cleared after nine sessions with no relapse during 30 months of follow-up [14]. Ciclosporin given to treat atopic eczema coincidentally improved lichen amyloidosus [15]. Dermabrasion may have a long-term beneficial effect on papular lichen amyloidosus of the shins [16]. Pulsed dye laser therapy has been used [17].

Nodular PLCA shows a good response to excision and grafting [18], shave removal [19], curettage and cautery [20], cryotherapy, dermabrasion [21] or the carbon dioxide or pulsed dye laser [22–24], but subsequent recurrence is likely.

Secondary localized cutaneous amyloidosis [1–3]

Microscopic deposits of amyloid material have been described in association with a variety of cutaneous tumours, including intradermal melanocytic naevus [4], sweat gland tumours, pilomatrixoma, dermatofibroma, seborrhoeic wart, photosensitive annular elastolytic giant cell granuloma [5], solar keratosis, porokeratosis of Mibelli [6,7], disseminated superficial actinic porokeratosis [8], Bowen's disease [9,10], basal cell carcinoma [11,12] and trichoepithelioma [13,14]. The amount of amyloid material in tumours is usually clinically insignificant but massive deposits may occur and cause diagnostic difficulty [15]. A similar phenomenon has been noted following PUVA therapy [16,17].

Systemic amyloidosis

Systemic types of amyloidosis include those associated with plasma cell dyscrasia, either overt as in multiple myeloma, or occult as in 'primary' systemic amyloidosis, amyloidosis secondary to a variety of chronic diseases, and in the heredofamilial amyloidoses. Clinically evident involvement of the skin is frequent in 'primary' systemic and myeloma-associated systemic amyloidosis, but occurs only rarely in secondary systemic amyloidosis. Although there is a degree of overlap, primary and myeloma-associated systemic amyloidosis typically involve the tongue, heart, gastrointestinal tract, skeletal and smooth muscle, carpal ligaments, nerves and skin, whereas secondary systemic amyloidosis affects the liver, spleen, kidneys and adrenals [1]. Skin manifestations are associated with a number of systemic heredofamilial syndromes of amyloid deposition including familial Mediterranean fever [2], the Muckle–Wells syndrome [3] and heredofamilial amyloid polyneuropathy [4].

Primary and myeloma-associated cutaneous amyloidosis

Aetiology. In primary and myeloma-associated amyloidosis, the fibrils are composed of 'protein AL' (amyloid L-chain protein) and appear to be a consequence of plasma cell dyscrasia, although bone marrow aspiration may not reveal any abnormality. Amino acid sequence analysis has demonstrated that protein AL consists of fragments of immunoglobulin polypeptide light chain, particularly the variable (amino-terminal) region, or of an intact immunoglobulin light chain, or of both [1–4], and is usually associated with a similar abnormal immunoglobulin light chain in the serum, commonly of λ class. Abnormal light chain material is almost always present in the serum or urine, even in so-called primary systemic amyloidosis, and can be demonstrated on tissue culture of bone marrow cells from affected patients. Only a proportion of

Bence Jones proteins produce amyloid fibrils on digestion [5], which may account for the fact that amyloidosis develops in only about 15% of patients with myelomatosis. Amyloidogenic immunoglobulin AL monoclonal proteins appear to be preferentially of λ type, of lower molecular weight, and of lower isoelectric point [6]. Domains may be destabilized by specific amino acid residue changes due to point mutation, rendering them susceptible to the formation of ordered, fibril-like aggregates *in vitro* [7]. The organ tropism (i.e. whether there is predominant renal, cardiac or hepatic involvement) in AL amyloidosis may reflect germ-line gene use and plasma cell burden [8]. Rare cases of AH amyloidosis associated with monoclonal gammopathy and renal amyloid deposition, in which the amyloid fibrils are composed of immunoglobulin heavy chain variable region (VH) fragments, are recorded [9].

Histopathology [1–5]. In primary and myeloma-associated amyloidosis, deposits of amyloid are usually superficially placed in the papillary dermis as amorphous, faintly eosinophilic, often fissured masses, with associated thinning or obliteration of the rete ridges, accounting for the papules seen clinically. Amyloid deposits in the deep reticular dermis and subcutis give rise to the clinical appearance of nodules and tumefactions, and infiltration of blood vessel walls correlates with the clinical finding of purpura. Marked thickening of blood vessel walls due to amyloid infiltration has been described [6]. Usually, there is little in the way of any inflammatory infiltrate, unlike nodular PLCA in which infiltration of plasma cells is a significant feature [3,4]. In areas of alopecia, amyloid deposits may surround and compress pilosebaceous units with resultant atrophy and loss of hair from the shafts. Amyloid may also be deposited in arrector pili muscles, in the lamina propria of sweat glands and ducts, and around individual fat cells in the subcutis as characteristic 'amyloid rings'. Amyloid deposition in the nail fold and bed of dystrophic nails has been reported [7]. An affinity for amyloid to coat elastic fibres has been noted [8].

Clinical features [1–10]. The mean age of onset of primary amyloidosis is about 65 years, and there is a slight male preponderance. Presenting symptoms may be rather non-specific, and include fatigue, weight loss, paresthesiae, hoarseness, oedema, dyspnoea, and syncope secondary to orthostatic hypotension. These features may predate the histological diagnosis by up to 2 years. The classical presentation with symptoms of carpal tunnel syndrome, macroglossia, specific mucocutaneous lesions which occur in up to 40% of cases, hepatomegaly and oedema should always alert the clinician to the presence of an underlying plasma cell dyscrasia.

Amyloidosis is the commonest cause of macroglossia in adults [11], and occurs in about 10% of cases. The tongue is usually diffusely enlarged and firm (Fig. 59.37), but it may also be fissured,

Table 59.9 Cutaneous lesions in primary and myeloma-associated systemic amyloidosis.

Common	Less common
Petechiae, purpura, ecchymoses	Pigmentary changes
Waxy, translucent or purpuric papules	Scleroderma-like infiltration
Nodules	Bullous lesions
Plaques	Alopecia
Tumefactive lesions	Cord-like blood vessel thickening
	Nail dystrophy
	Cutis laxa; localized redundant skin folds and depressions

Fig. 59.38 Primary systemic amyloidosis. Prominent eyelid purpura following coughing. (Courtesy of St John's Institute of Dermatology, London, UK.)

with haemorrhagic papules, nodules, plaques or even bullae on its surface. There may be permanent tooth indentations along its lateral borders. Macroglossia may be so extensive as to cause dysphagia.

The commonest skin lesions are those related to intracutaneous haemorrhage due to infiltration of blood vessel walls by amyloid deposits (Table 59.9). Petechiae, purpura and ecchymoses may occur spontaneously or after minor trauma on normal or clinically involved skin, especially in the body folds, for example eyelids, sides of neck, axillae, umbilicus, oral and anogenital regions. Purpuric haloes may occur around long-standing Campbell de Morgan spots [12]. Eyelid purpura after pinching, and periorbital purpura after proctoscopy ('post-proctoscopic palpebral purpura'), coughing (Fig. 59.38), vomiting or the Valsalva manoeuvre, are characteristic. Pigmentary changes include jaundice due to hepatic disease, cardiac failure or severe haemorrhage, pallor due to anaemia and hyperpigmentation due to haemorrhage.

Fig. 59.39 Primary systemic amyloidosis. Purpuric plaques situated on upper eyelids. (Courtesy of St John's Institute of Dermatology, London, UK.)

Smooth, shiny, waxy papules or plaques, often with a haemorrhagic component, may also be found (Fig. 59.39). Translucent areas may resemble vesicles. Flexural areas are sites of predilection, including the eyelids, retroauricular region, neck, axillae, umbilicus, inguinal and anogenital regions. Lesions may also be found on the central face, lips, tongue and buccal mucosa. Widespread nodules may occur, coalescing to form large tumefactions. They may resemble condylomata lata on perianal and vulval skin [13,14], and when widespread may appear like xanthomas [15]. Diffuse infiltration of large areas, especially on the face, hands and feet, may simulate scleroderma [16,17], or on the face produce a myxoedema-like appearance. Alopecia may be patchy or widespread [18], and the scalp skin may be thrown into longitudinal folds resembling cutis verticis gyrata. Nail involvement due to infiltration of the nail matrix by amyloid may produce longitudinal striation (Fig. 59.40), crumbling, brittleness and partial anonychia, and may be a presenting sign [19–21]. Chronic paronychia with palmodigital erythema has also been described [22]. Signs which occur rarely include bullae of the skin or mucous membranes as a result of shearing within dermal amyloid deposits [23–27], which may result in changes resembling porphyria cutanea tarda or epidermolysis bullosa acquisita (Fig. 59.41). Extensive amyloid infiltration may lead to cord-like thickening of superficial blood vessels [28]. Extensive cutaneous ulceration has been recorded [29]. Amyloid elastosis is an unusual syndrome in which papulonodular cutaneous lesions are associated with widespread amyloid infiltration of visceral and cutaneous blood vessels, particularly in relation to elastic fibres [30,31]. Acquired cutis laxa has also been reported [32,33]. Localized elastolytic cutaneous lesions may present as soft, loose folds or indentations on the fingertips [34]. Other cases of cutis laxa may reveal fibrillar extracellular deposits, which are different from amyloid fibrils [35].

Hepatomegaly occurs in about 50%, and splenomegaly in about 10% of patients. The nephrotic syndrome or congestive cardiac failure (each of which occur in about 30% of cases), and rarely

Fig. 59.40 Primary systemic amyloidosis. Close-up of thumbnail showing longitudinal ridging and splitting. A nail biopsy in this case confirmed amyloid deposition. (Courtesy of St John's Institute of Dermatology, London, UK.)

protein-losing enteropathy from amyloid involvement of the small bowel, may cause pitting oedema. Ascites may develop. Cardiac infiltration results in angina, infarction, congestive cardiac failure, orthostatic hypotension or arrhythmias [36]; it accounts for death in about 40% of cases of AL type systemic amyloidosis. Pulmonary involvement is common but usually asymptomatic. Amyloid infiltration of blood vessels may lead to claudication of the legs or jaw. Gastrointestinal tract involvement [37,38] may simulate inflammatory bowel disease with haemorrhage; malabsorption is found in 5% of cases. The carpal tunnel syndrome [39] has been reported in up to 25% of patients with 'primary' systemic amyloidosis. Neurological complications [40] include peripheral neuropathy [41], initially of the lower extremities, which tends to pursue a chronic course; there may be superimposed autonomic neuropathy leading to orthostatic hypotension, diarrhoea, loss of bladder control or impotence. Muscle weakness may be caused by neuropathy, or by amyloid infiltration of muscle or its vascular supply; infiltration between muscle fibres leading to pseudohypertrophy is reported [42]. Lymphadenopathy occurs in about 10% of patients [43]. Sjögren's syndrome or sicca syndrome due to amyloid infiltration of lacrimal and parotid glands [44] are occasional presenting features. Amyloid deposition in joints may mimic rheumatoid arthritis [45], and deposition around the shoulders may cause extensive soft-tissue enlargement (the shoulder-pad sign) [46]. Giant cell arteritis and polymalgia rheumatica are recorded [47], as are isolated factor X deficiency [48], disseminated intravascular coagulation and fibrinolysis with severe bleeding.

Diagnosis. The diagnosis should always be considered when a patient presents with the triad of carpal tunnel syndrome, macroglossia and mucocutaneous skin lesions [1,2]. Biopsy of classical mucocutaneous lesions should be the procedure of first choice. Biopsy of even clinically normal forearm skin has been reported positive in up to 50% of cases of primary and myeloma-associated disease. Fine-needle biopsies of the subcutaneous fat from clinically normal abdominal skin have a high positive yield in AL- and AA-type amyloidosis as well as in heredofamilial amyloidoses [3–5]. Rectal biopsy is positive in up to 80% of cases of AL or AA amyloidosis, jejunal biopsy in about two-thirds, but gingival biopsy in only 19%. Gastric biopsy may produce a higher yield than rectal biopsy. Ninety-six per cent of hepatic, and 90% of renal and of splenic percutaneous needle biopsies, as well as carpal tunnel tissue biopsies at the time of decompression, are positive. Bone marrow aspiration may be positive in up to 45% of cases. Electrocardiography, echocardiography, angiocardiography, technetium scanning and endomyocardial biopsy are useful in the diagnosis of amyloid heart disease [6–8]. Computed tomography, ultrasound examination, and Doppler analysis of blood flow may be useful in renal amyloidosis. Sural nerve biopsy in patients with peripheral neuropathy [9], and synovial fluid analysis in patients with arthropathy, may be helpful. Scanning with ^{123}I-labelled SAP component enables specific localization and imaging of amyloid deposits *in vivo* [10,11].

Immunoelectrophoresis of both serum and concentrated urine is essential if the clinical presentation suggests the presence of a plasma cell dyscrasia, as conventional urine heat tests and simple electrophoresis of serum and urine may not detect small amounts of paraprotein or Bence Jones protein. Protein electrophoresis of serum shows a spike pattern in just under half of patients with primary AL, and in about two-thirds of those with myeloma. Immunoelectrophoresis of serum reveals a monoclonal protein in two-thirds of patients with AL amyloidosis; only 45% have a monoclonal heavy chain, while 20% have free monoclonal light chains (Bence Jones proteinaemia). Immunoelectrophoresis of concentrated urine reveals a monoclonal light chain in about two-thirds of cases (λ to κ ratio 2 : 1). When screening of both serum and urine is performed, the frequency of patients with an identifiable monoclonal protein rises to about 86%. A combination of immunofixation on agarose gel electrophoresis and bone marrow plasma cell light chain λ to κ ratio analysis improves diagnostic sensitivity [12]. Nevertheless, in some cases with the clinical features of AL amyloidosis it is not possible to demonstrate a paraprotein, even after prolonged follow-up for as long as 24 years [13].

Skeletal survey may be useful, as 50% of patients with myeloma-associated amyloidosis have radiological abnormalities, compared with only 6% of those with primary amyloidosis. Most myeloma cases, but no primary systemic amyloidosis cases, have more than 15% plasma cells in the marrow. In general, myeloma is not present

if a patient has no lytic bone lesions, hypercalcaemia or anaemia, has only a small serum or urine monoclonal component, and has less than 25% bone marrow plasma cells.

Prognosis. Prognosis in primary systemic and myeloma-associated amyloidosis is poor, the major causes of death being cardiac and renal failure, and is linked to degree of plasma cell clonality and marrow infiltration [1]. The prognosis of AL amyloidosis has improved, with a currently reported median survival of about 40 months compared to 13 months in the early 1990s. Autologous stem cell transplantation (ASCT) achieves the highest rates of complete clonal response but is associated with substantial treatment-related mortality unless restricted to highly selected patients. Newer chemotherapy regimens which can be used more widely may achieve better safety and respectable efficacy [2]. Median survival on high-dose melphalan and autologous stem-cell transplantation was 4.6 years [3] and 4.75 years respectively [4] in other series; 21% of patients died within the first year of treatment-related complications or progressive disease, but median survival exceeded 10 years for patients achieving a complete haematological response [4]. Median survival was only 26 months in patients undergoing dialysis [5]; a good renal response after high-dose melphalan and stem cell transplantation is a favourable marker [6]. Occasional patients surviving longer than 10 years have been recorded [3,7–10]. Patients presenting with amyloid neuropathy without associated cardiac, renal or hepatic involvement may have a better prognosis (median survival 40–50 months; 5 years survival 31.6%) [11]. Survival for more than 10 years has been recorded in a patient with primary systemic amyloidosis with sensorimotor polyneuropathy only [12].

Treatment. Most patients receive a trial of chemotherapy, usually melphalan and prednisone, with or without autologous bone marrow stem-cell transplantation [2,3,13–17]. There is a risk of development of leukaemia or a dysmyelopoietic syndrome [14]. Other chemotherapeutic regimens have been used [18–20]. Cardiac [21,22] or renal transplantation can prolong survival; renal amyloidosis is not an absolute contraindication to transplantation, although amyloid may re-accumulate in the transplanted kidney.

Secondary systemic amyloidosis

In secondary systemic amyloidosis, the fibrils are composed of a non-immunoglobulin protein designated protein AA [1]. A precursor of protein AA, known as serum amyloid A protein (protein SAA), is present in the serum of normal individuals as an apolipoprotein of high-density lipoprotein, and behaves as an acute phase reactant.

Secondary amyloidosis occurs as a complication of many chronic inflammatory diseases in which the immune system is stimulated [2,3]. These include acute recurrent and chronic infections, rheumatoid arthritis [4], juvenile chronic arthritis [5], ankylosing spondylitis [6], Reiter's syndrome, Behçet's syndrome [7], Sjögren's syndrome, dermatomyositis, scleroderma, systemic lupus erythematosus [8], inflammatory bowel disease [9], Hodgkin's disease, non-Hodgkin's lymphoma [10], histiocytosis X [11], Schnitzler's syndrome [12] and some solid non-lymphoid tumours, as well as Castleman's disease [13] and Rosai–Dorfman disease [14]. Secondary systemic amyloidosis may also arise as a complication of a number of dermatoses [15], such as venous ulceration [16], generalized psoriasis and psoriatic arthritis [17,18], pustular psoriasis [19], lepromatous leprosy [20], hidradenitis suppurativa, chronically infected burns, chronic skin infection in drug addicts [21], nodular non-suppurative panniculitis [22], giant, ulcerated or metastatic basal cell carcinoma [23], acne conglobata [24], epidermolysis bullosa of dystrophic [25,26] and aquisita types, and X-linked anhidrotic ectodermal dysplasia.

Secondary systemic amyloidosis rarely produces specific skin lesions. An elbow skin nodule due to deposition of AA amyloid was reported in a patient with primary Sjögren syndrome, myopathy, severe osteoporosis, and vertebral fractures attributed to coeliac disease [27]. By contrast, secondary systemic amyloidosis commonly involves the kidneys (causing the nephrotic syndrome), spleen, alimentary tract and adrenals; the diagnosis should be confirmed by rectal or renal biopsy. Needle aspirates of abdominal wall subcutis may yield positive histological identification of amyloid [28]. Small or minute amyloid deposits are most often found around the adnexae, sometimes in small blood vessels and in the subcutis around fat cells: 'amyloid rings'.

There is no specific treatment, and many die from progressive renal failure. Treatment of the primary disease may arrest progression of the amyloidosis. Estimated survival at 10 years was 90% in patients whose median protein SAA level was under 10 mg/L, and only 40% among those whose median SAA level exceeded this in one study [29]. Median survival after diagnosis was 133 months, with renal dysfunction being the predominant disease manifestation in another recent study, which reiterated the prognostic value of the SAA level [30]. Renal disease has responded to colchicine therapy, cyclophosphamide, or high dose melphalan and autologous stem cell transplantation [4,31,32]. Etanercept therapy is reportedly of benefit in inflammatory arthritis-related AA amyloidosis [33–35]. Renal transplantation is certainly worthy of consideration.

Dialysis-related amyloidosis

In systemic amyloidosis related to haemodialysis, the major constituent protein of amyloid fibrils is β_2-microglobulin. Most of the clinical findings are related to amyloid deposition in osseo-articular tissues [1,2]. Extensive tissue deposition of β_2-microglobulin may rarely present as masses in the buttocks [3,4], or as lichenoid lesions [5,6].

Inherited systemic amyloidosis

Several distinct genetic types of amyloidosis are recognized, which may be associated with mutations in a number of plasma proteins including transthyretin (MIM *176300), apolipoprotein AI (MIM *107680), fibrinogen A α chain (MIM *134820), lysozyme (MIM *153450), gelsolin (MIM *137350) and the 55-kDa tumour necrosis factor (TNF) receptor [1–4]. The kidney, peripheral nerves and spinal ganglia, or the heart are predominantly affected. Skin manifestations are associated with a number of systemic heredofamilial syndromes of amyloid deposition, including familial Mediterranean fever [5], the Muckle–Wells syndrome [6] and heredofamilial amyloid polyneuropathy [7–10]. The most prevalent forms of the autosomal dominantly inherited hereditary sensory neuropathies are HSN I, associated with mutations in the *SPTLC1* gene, and CMT 2b, associated with mutations in the *RAB7* gene.

Familial Mediterranean fever is inherited as an autosomal recessive disorder, and is caused by mutations in the *MEFV* gene, leading to defects in the pyrin protein which normally blunts neutrophil-mediated inflammation, probably via IL-1 down-regulation [11–13]. It may involve erysipelas-like lesions on the lower legs, urticaria, Henoch–Schönlein purpura and vasculitic nodules [5]. Associated features are intermittent fevers with abdominal pain and joint effusions, and a tendency to peritonitis, pleurisy, synovitis and renal amyloidosis. Colchicine at a dose of 1 to 2 mg daily reduces the frequency of attacks and prevents development of secondary amyloidosis. There have been case reports of benefits with catecholamine blockade (prazosin), tumour necrosis factor antagonists (etanercept, thalidomide), and IL-1 receptor blockade (anakinra) [12,13].

The Muckle–Wells syndrome, which has autosomal dominant inheritance, is characterized by periodic attacks of fever, urticaria, conjunctivitis and arthropathy with limb pains, associated with progressive perceptive nerve deafness and renal amyloidosis [6,14–16]; cold urticaria [14,15] and hyperpigmented scleroderma-moid skin lesions [17] have been described. Levels of C-reactive protein, serum amyloid A, and IL-1β are elevated. Patients with Muckle–Wells syndrome have a mutation in *NALP3/CIAS1/PYPAF1*, the gene encoding cryopyrin, a component of the inflammasome that regulates the processing of IL-1β. Treatment with the recombinant human IL-1 receptor antagonist anakinra has resulted in resolution of clinical symptoms including deafness, and normalizes laboratory abnormalities [14,16].

Trophic skin changes with skin ulceration and sweating abnormalities may develop in heredofamilial amyloid polyneuropathy [7–10]. The Finnish type of heredofamilial neuropathic amyloidosis, a gelsolin-related systemic amyloidosis characterized by cranial neuropathy and corneal lattice dystrophy, may be associated with cutis laxa, blepharochalasis and lichen amyloidosus [18]. Cutis laxa is a principal clinical manifestation of hereditary gelsolin amyloidosis (AGel amyloidosis), an age-associated systemic disease with global distribution, caused by a G654A or G654T gelsolin gene mutation [19]. Heart and liver transplantation may be successful in familial amyloidotic neuropathy [20,21].

Nutrition and the skin

K. Weismann, pp. 59.58–59.81

Lack of essential nutrients is most commonly due to a reduced or insufficient intake of food, malabsorption (see below), vomiting or decreased passage time of food due to diarrhoea or fistulae. Some medications may interfere with utilization of nutrients. An increased metabolic requirement of nutrients occurs during periods of sudden weight gain, such as growth and convalescence. This may lead to relative deficiencies, as seen in patients receiving long-term parenteral nutrition who may become severely deficient in zinc (p. 59.73).

Often, the cutaneous changes of inadequate nutrition are varied, reflecting combined deficiencies. When there is an apparently isolated deficiency, an underlying genetic or enzymatic defect should be suspected.

Malabsorption

Malabsorption is a condition characterized by a decreased intestinal uptake of nutrients associated with an increased faecal excretion of fat (steatorrhoea). This leads to various degrees of lack of proteins, minerals, trace elements, fat-soluble vitamins, carbohydrates and water. Some causes of malabsorption are listed in Table 59.10.

Table 59.10 Various causes of malabsorption.

Chelating substances in the gut
Phytates
Insufficient digestive enzyme activity
Pancreatic diseases (pancreatitis, mucoviscidosis)
Defective micelle formation
Obstructive jaundice, liver cirrhosis
Contaminated small bowel syndrome (i.e. presence of an abnormal bacterial flora in the small bowel)
Gastric resection (lack of hydrochloric acid production)
Stagnant loop syndrome (strictures, surgical blind loops, scleroderma, diabetic enteropathy)
Colonic reflux (intestinal fistula, extensive small bowel resection)
Agammaglobulinaemia
Defective enzyme activity or carrier function in the intestinal mucosa
Disaccharidase deficiency
Coeliac disease
Acrodermatitis enteropathica (zinc deficiency)
Hartnup disease (pellagra)
Loss of absorption capacity
Intestinal resection and bypass operation
Crohn's disease
Pernicious anaemia
Interference with intestinal lymphatics
Lymphangiectasis
Tuberculous mesenteric adenitis
Hodgkin's disease
Inadequate transport mechanisms in the blood
Abetalipoproteinaemia
Miscellaneous
Polyarteritis nodosa
Lupus erythematosus
Amyloidosis
Mastocytosis
Diabetes mellitus
Zollinger–Ellison syndrome
Protein-losing enteropathy
Hyperthyroidism
Hypothyroidism
Cronkhite–Canada syndrome
Dermatogenic enteropathy

Clinical features

Non-specific cutaneous symptoms [1,2]. Non-specific symptoms may be observed in patients who have lost weight due to malabsorption or malignant disease. The skin changes reflect general illness rather than specific disease.

Itching and acquired ichthyosis. Itch is mostly caused by dry skin. Elderly patients are especially prone to developing dry skin, which becomes eczematized. Patients with cancer, chronic liver or kidney diseases, or with lymphoma, may develop an itchy atrophic ichthyosis [3]. Hypoferraemia may cause itch, which disappears after initiation of iron therapy. Serum ferritin is a sensitive indicator of the state [4]. Polycythaemia rubra vera may cause generalized itch (see Chapters 21 and 62).

Melanosis. Malnutrition due to malabsorption may cause symmetrical melanin hyperpigmentation of the skin, although melanocyte-stimulating hormone (MSH) levels are seldom increased. Other skin colour changes associated with malnutrition are those due to wasting and atrophy, and pallor due to anaemia.

Arsenic pollution of drinking water in a primitive rural area caused blackening of hands and feet [5].

Skin appendages. Brittle nails and hair loss are frequent findings in poorly nourished patients. In some cases, lack of zinc, iron and vitamins is the main cause. In the majority of patients the aetiology is probably multifactorial.

Specific cutaneous effects [1]**.** Vitamin deficiencies occur due to malabsorption. Lack of fat-soluble vitamins, in particular, may cause skin changes including follicular hyperkeratosis (lack of vitamin A), ecchymoses and haematuria (lack of vitamin K), and cheilitis, glossitis, neuritis and dermatitis (lack of vitamin B complex). Zinc deficiency-related skin changes may be seen.

Investigations. Patients presenting with skin changes suggestive of malabsorption should have a thorough medical examination and laboratory tests to determine both the causes and the consequences of malabsorption. Relevant tests include serum calcium, zinc, folate and albumin levels, faecal fat excretion and X-ray examination of the small intestine.

Treatment. The cause of malabsorption should be treated where possible, and dietary measures instituted to ensure adequate supply of all essential nutrients from a wide variety of foods [2].

Specific syndromes with malabsorption

Cronkhite–Canada syndrome [1]
See Chapter 62.

Whipple's disease
This is a rare disease of uncertain aetiology involving the gastrointestinal tract, skin, joints, heart and lymph nodes (Chapter 62). There is diffuse hyperpigmentation of the skin, and leg nodules or erythema nodosum may occur. The involvement of the heart includes inflammatory changes of the pericardium, myocardium and endocardium and may lead to valvular insufficiency [2].

Dermatitis herpetiformis (see Chapter 40)
Enteropathy is present in at least two-thirds of all patients and may respond to a gluten-free diet. Patients may be managed on a gluten-free diet alone, and it at least enables most patients to reduce their requirement for dapsone [3].

Mucoviscidosis

Synonyms
- Fibrocystic disease
- Cystic fibrosis of the pancreas (MIM #219700)

Mucoviscidosis is an inherited disorder characterized by three major components: chronic lung disease, exocrine pancreatic insufficiency and an abnormally high sodium concentration of the sweat.

Aetiology. The mode of genetic transmission is autosomal recessive. The basic metabolic defect is unknown. The mucous secretion has an increased viscosity resulting in obstruction of the small bronchial branches, the excretory ducts of the pancreas and the bile ducts of the liver. This eventually leads to respiratory disease, pancreatic insufficiency and hepatic failure. The high sodium concentration in sweat is due to a lowered reabsorption of sodium in the sweat glands [1] (Chapter 44).

Histopathology. The exocrine sweat glands and pancreas show electron-dense bodies, and there are fewer than normal secretory vacuoles in the 'dark cells' of the sweat coils [2].

Clinical features. The main presenting features are chronic pulmonary disease, exocrine pancreatic insufficiency with malabsorption, retarded growth and hepatic disease. Skin changes in the form of acrodermatitis enteropathica-like lesions due to essential fatty acid and zinc deficiency have been seen [3,4]. Several studies have indicated that atopy is more common in patients with cystic fibrosis than in the general population [5], although the prevalence of urticaria is not increased [6]. A purpuric rash may occur in patients with cystic fibrosis.

Diagnosis. The diagnosis is established by the finding of high sodium concentration in the sweat, absence of pancreatic enzymes in the duodenum, chronic respiratory disease, retarded growth and a family history of the disease.

Aquagenic wrinkling of the palms and fingers is characterized by formation of oedematous whitish plaques on the palms on exposure to water. Cystic fibrosis should be considered in patients with this type of reaction [7].

Treatment. Respiratory infection is controlled by prolonged antibiotic therapy according to bacterial cultures. Pancreatic insufficiency is treated by pancreatic enzyme preparations orally and a diet low in fat. The liver disease and the sweat abnormality are not amenable to treatment at present.

Vitamins [1]

Vitamins are biologically active organic compounds, which are indispensable for the normal functions of the body. They have no direct function as an energy source or as structural tissue components, but in most cases act as coenzymes in various enzyme systems.

Reference

1 Miller S. Nutritional deficiency and the skin. *J Am Acad Dermatol* 1989; **21**: 1–30.

Vitamin A

Vitamin A (retinol) is a cyclic polyene alcohol present in yellow and green vegetables, egg yolk, butter, liver and fish oils [1]. β-Carotene occurs in fruits, carrots and green vegetables, and is absorbed and converted to vitamin A in the body. The recommended daily allowance is 5000 i.u. (equivalent to 6000–12 000 i.u. β-carotene). The plasma level in normal adults is about 600 ng/mL [2]. Vitamin A is mobilized from liver stores and transported in plasma, in which it is bound to retinol-binding protein [3].

Vitamin A is essential for the reproductive system, bone formation, vision and epithelial tissues [4]. *In vitro* studies on human keratinocytes have shown that vitamin A affects their growth and differentiation [5]. In human volunteers, 150 000 i.u. daily of vitamin A produced demonstrable retardation of keratinocyte maturation [6]. Skin disorders with abnormal keratinization, such as ichthyosis, pityriasis rubra pilaris and Darier's disease, have been treated with high doses of oral vitamin A. There is a risk of intoxication by such treatment and stereoisomers of retinoic acid are now used instead [1,7].

Vitamin A deficiency

Vitamin A deficiency is seldom seen in the Western world today. It is observed mainly in diseases causing malabsorption and is often associated with deficiency of other fat-soluble vitamins.

Clinical features. Classical manifestations of vitamin A deficiency include xerophthalmia, follicular hyperkeratosis and generalized xerosis [8]. Follicular papules are seen especially on the dorsal and lateral areas of the extremities, so-called phrynoderma. Histologically, there is lamellated hyperkeratosis around the hair follicles with keratinous plugs and atrophy of the sebaceous glands [9]. Diagnosis is confirmed by the finding of a low vitamin A level in blood and a positive response to vitamin A supplementation.

Zinc deficiency may lead to vitamin A deficiency as zinc acts on the retinol-binding protein, which is the transport protein for vitamin A and which is indispensable for mobilization of the vitamin from the liver. Furthermore, zinc acts on the oxidation–reduction interconversion of vitamin A (alcohol dehydrogenase is a zinc metalloenzyme). Lack of zinc may provoke symptoms of vitamin A deficiency [10], and night blindness in alcoholics may be due to a combined lack of vitamin A and zinc [11].

Vitamin A intoxication

Aetiology. Chronic hypervitaminosis A is observed in young children if they are persistently overdosed with strong vitamin preparations. Most reported adult cases have ingested more than 100 000 i.u. daily for several months. There is probably a risk of toxic effects if more than 50 000 i.u. daily is ingested for longer periods [1].

Clinical features. There is lethargy, anorexia, weight loss and diffuse alopecia. The skin becomes pruritic, rough and dry with desquamation. The lips are dry and cracked. Follicular keratosis, patchy erythema and purpura may occur in hypervitaminosis A or due to administration of synthetic retinoids [2]. In young children, painful swellings of the limbs due to bone changes are conspicuous.

Diagnosis. Vitamin A intoxication is diagnosed by consistent clinical findings associated with an increased vitamin A level in the blood. Radiology may demonstrate bone changes in young children and in some adults.

Treatment. No treatment is needed except immediate discontinuation of the vitamin A.

Carotenoderma

β-Carotene is the natural provitamin of vitamin A (retinol). A high intake of food containing carotene, especially carrots, causes carotenaemia (increased carotene in plasma) and may induce carotenoderma due to excess carotenes in the sweat. The condition is characterized by orange discoloration of the stratum corneum, especially on palms, soles and in areas where sebaceous glands predominate. The condition is quite harmless and subsides gradually when the dietary habits are regulated. It may occur in pregnancy as a 'pica'.

Carotenaemia is also seen in patients with hyperlipidaemia (diabetes mellitus, myxoedema) and occurs in subjects unable to convert ingested β-carotene into vitamin A [12].

β-Carotene traps free radicals and has been studied together with vitamin E and selenium as a possible dietary factor that may inhibit cancers [13], although this hypothesis remains unproven [14].

Carotenoderma provides no photoprotection [15].

Vitamin D [1,2]

Vitamin D is a group of antirachitic steroid derivatives with similar biochemical activity. It is synthesized in the body as vitamin D_3 (cholecalciferol), and is present in the diet from some animal sources (as vitamin D_3) or from plant sources as vitamin D_2 (ergocalciferol). There is little vitamin D_3 in the diet although it is present in cod-liver oil, butter, eggs and liver. Vitamin D is synthesized in the skin from 7-dehydrocholesterol, which is present in abundance, by the action of 290–320-nm UV irradiation (to previtamin D) followed by a temperature-dependent conversion stage. Vitamin D_2 is synthesized from its inactive provitamin, ergosterol, in plants, also by the action of UV irradiation. With adequate exposure to sunlight, dietary vitamin D is unnecessary [1]. Cholecalciferol is hydroxylated in the liver to form 25-hydroxyvitamin D, and further hydroxylation takes place in the kidney to form the biologically active 1,25-dihydroxyvitamin D [1,2]. Vitamin D_2 follows the same hydroxylation pathway, and is equipotent to vitamin D_3. 1α-Hydroxyvitamin D_3 is a synthetic, highly potent vitamin D analogue used in the management of hypoparathyroidism, vitamin-D-resistant rickets and osteomalacia.

Circulating vitamin D is usually measured as 25-hydroxyvitamin D, low status being defined as a level below 30–60 ng/L. Low levels do not reflect the degree of exposure to solar ultraviolet light [3]. Sunbeds (tanning parlour) have been proposed as a means to increase vitamin D status. This claim is controversial since UVA does not participate in the production of vitamin D of the skin, and UVA exposure increases the risk of skin cancer and malignant melanoma [4].

Vitamin D regulates calcium and phosphorus absorption and deposition, and influences the level of serum alkaline phosphatase. The skin is of unique importance in the synthesis, storage and release of vitamin D into the circulation [2]. Lack of vitamin D in children results in tetany and rickets (rachitis), and causes osteomalacia in adults. Elderly people produce less vitamin D_3. In children, limited exposure to sunshine may play an aetiological role; the same applies to some Asian women in the UK in whom there may be a combination of dietary deficiency and little sunlight exposure. Regular use of sunscreens may also lead to reduced synthesis of vitamin D_3 [3]. It is remarkable how exposure to sunlight a few times a week can reduce the risk of osteoporosis, osteomalacia, muscle weakness and fractures [1]. The daily need for calciferol is 400–800 i.u.

Vitamin D intoxication (long-continued administration of more than 100 000 i.u. daily) causes anorexia, vomiting, headache, diarrhoea, hypercalcaemia and hypercalciuria with osteoporosis, resembling the action of parathyroid hormone. Treatment consists of withdrawal of vitamin D, a low-calcium diet and systemic corticosteroids.

Combined calcium and vitamin D supplementation has been shown to reduce the risk of osteoporosis in people aged 50 years or older. A minimum dose of 1200 mg calcium and 800 i.u. vitamin D daily is recommended [5].

Vitamin E [1,2]

Synonym
- α-Tocopherol

Tocopherols are present in oils of vegetables, seeds, corn, whole wheat flour, nuts and some meats; D-α-tocopherol is the most biologically active form. The main physiological activity of tocopherol is antioxidation. Whether the vitamin is essential to humans is still a matter of debate. In rats, guinea pigs and rabbits, a true vitamin effect has been demonstrated. Various dermatological diseases and conditions have been claimed to respond to vitamin E [1–3]. So far, no true benefit has been definitely documented. Fat-soluble vitamin E is located in the stratum corneum and seems to play a role in protecting this layer from damage [2]. An inhibitory effect on hyaluronidase and a protective effect on cellular membranes and on vitamin A oxidation have been suggested, but the clinical relevance is doubtful. Neurological function in children with chronic cholestasis was improved following large doses of vitamin E [4]. Large doses of vitamin E in a controlled trial have been shown to reduce the risk of myocardial infarction [5]. Vitamin E has also been used in dermatology to reduce dapsone-induced haemolysis [6] and headache [7].

Vitamin B complex

The vitamins of the B complex are of great clinical significance. Isolated deficiencies of certain B vitamins are uncommon. Mostly combined deficiencies of the vitamins belonging to the group are involved, often occurring as a result of insufficient supply of protein and other essential nutrients (zinc, essential fatty acids).

The vitamin B group includes:

1 Aneurin (thiamine) (vitamin B_1)
2 Riboflavine (vitamin B_2)
3 Niacin (nicotinic acid) (B_3)
4 Pyridoxine (vitamin B_6)
5 Cyanocobalamin (vitamin B_{12})
6 Folic acid
7 Pantothenic acid
8 Biotin (vitamin H).

Aneurin

Synonyms
- Vitamin B_1
- Thiamine

Aneurin is present in yeast, cereals, liver, meat, eggs and vegetables. It functions as cocarboxylase in carbohydrate metabolism and in numerous other enzyme systems. It is involved in growth processes and in the function of the nervous system. Deficiency results in accumulation of pyruvic and lactic acids. Dietary deficiency may be a consequence of consuming polished rice as the staple food or, more commonly, of insufficient nutrition associated with chronic alcoholism. Beer drinkers have a reduced risk of developing B vitamin deficiency due to the presence of the vitamins in beer. Hypovitaminosis B_1 may be associated with pregnancy, lactation, diabetes mellitus, ulcerative colitis, coeliac disease, achlorhydria or myxoedema [1].

Clinical features [1]. The classical form of vitamin B_1 deficiency is beriberi, characterized by anorexia, weakness, constipation, symmetrical progressive polyneuritis, cardiac insufficiency with oedema and wasting of musculature. The diagnosis is based on the history and a low urinary aneurin excretion following an injection of 1.0 mg of aneurin. Excretion of less than 50 µg indicates a deficiency state.

Treatment. Aneurin 2–3 mg is given three times daily in mild cases. With severe cardiac and gastrointestinal involvement, polyneuritis and muscular paresis, 20 mg aneurin twice a day given parenterally is indicated.

Riboflavine

Synonyms
- Vitamin B_2
- Lactoflavine

Riboflavine is a D-ribitol isoalloxazine derivative that is widely distributed in plant and animal tissues. It plays a part in intracellular redox reactions. Nutritional sources are milk and the same sources as those of vitamin B_1 [1]. The human requirement is 1–2 mg daily.

Clinical features. Deficiency becomes clinically manifest after several months of deprivation due to chronic illness and malnutrition, especially in elderly women who suffer from achlorhydria, or in malnourished children with malabsorption.

Ariboflavinosis may occur in alcoholic liver cirrhosis, and an association with other deficiencies, such as pellagra, is frequent. Clinically, there is photophobia due to conjunctivitis, sometimes with corneal vascularization, angular stomatitis (perlèche) and sore lips, tongue and mouth [1]. The tongue is purplish red and smooth. A scaly seborrhoeic dermatitis-like eruption may be seen around the nose, eyes, ears and genital area (oro-oculo-genital syndrome). There is an association with zinc deficiency as the content of the two nutrients in foodstuffs is correlated [2].

Treatment. Treatment consists of 5–15 mg riboflavine two to three times daily for 2 weeks and correction of dietary errors.

Pyridoxine

Synonyms
- Vitamin B_6
- Pyridoxal

Pyridoxine is a pyridine derivative, participating as a coenzyme in transaminase and decarboxylase reactions and in the metabolism of cystein, tryptophan and essential fatty acids. It is present in many foods including yeast, eggs and various grains. The recommended daily allowance is about 2 mg.

Although much is known about experimental deficiency in many species, the manifestations in humans are not well defined. Convulsions, anaemia and acrodynia may develop in infants [3]. Dermatitis has occurred and is attributed to disturbed metabolism of unsaturated fatty acids. Pyridoxine deficiency may follow therapy with isoniazid, hydralazine and penicillamine [4].

Vitamin B_{12}

Synonyms
- Cyanocobalamin
- Cycobemine

Vitamin B_{12} is involved in nucleic acid synthesis and erythrocyte production. Deficiency may occur in vegetarians, as plants do not contain the vitamin. Most frequently it is due to lack of the 'intrinsic factor' in pernicious anaemia. Hyperpigmentation, especially in dark-skinned races, may occur. It is most pronounced in skin flexures, such as finger and palm creases, and on the knuckles. Pigmented streaks of the nails may be seen. An enlarged, red tongue is a characteristic finding [5].

Folic acid

Folic acid is a compound consisting of pteridine, *p*-aminobenzoic acid and glutamic acid. It is present in liver, meat, green leaves and milk. In the organism, folic acid is converted to folinic acid, which is the biologically active form. The conversion requires the presence of vitamin C. Folinic acid is needed for the transport of one-carbon units and plays a role in growth and erythrocyte production. The daily requirement is estimated to be about 0.4 mg.

Although no consistent or specific cutaneous changes are related to folate deficiency, greyish brown pigmentation on light-exposed parts has been described in megaloblastic anaemia [5,6]. Cheilitis, glossitis and mucosal erosions are common. Pigmentation similar to that of vitamin B_{12} deficiency has been associated with folate deficiency in pregnancy and during lactation. Spotty pigmentation of palms and soles and pigmented palmar creases have been described. Folate deficiency is estimated by serum and erythrocyte folate levels. Subclinical deficiency may be present in patients with extensive skin disease.

Deficiency causing macrocytic anaemia may result in retinal haemorrhages [7].

Synthetic folic acid may cause anaphylactic reactions [8]. The requirement for folate supplementation during methotrexate therapy is discussed in Chapters 20 and 74.

Niacin

Synonyms
- Nicotinic acid
- Vitamin B_3

Niacin is an essential component of two coenzymes, coenzyme I (nicotinamide adenine dinucleotide, NAD) and coenzyme II (NAD phosphate, NADP), which either donate or accept hydrogen in a wide range of biochemical reactions. Tryptophan, an essential amino acid, can be transformed to niacin, which is converted to the amide in the body. Niacin is involved in the biosynthesis of ceramides as well as of other stratum corneum lipids which improve the epidermal permeability layer [9].

Pellagra [10]

Cellular deficiency of niacin, resulting from an inadequate dietary supply of niacin and tryptophan, is termed pellagra. In Western Europe and North America pellagra is only rarely encountered now, mostly in subjects living on an unbalanced diet, such as chronic alcoholics, and in patients with gastrointestinal diseases or severe psychiatric disturbances. Rare causes are functioning carcinoid tumours (Chapter 43) and Hartnup disease (p. 59.100). Therapy with isoniazid (which competes biochemically with niacin owing to a close structural resemblance), 6-mercaptopurine or 5-fluorouracil may provoke pellagra.

Fig. 59.42 Pellagra with erythematous, brownish scaling on the neck (Casal's necklace).

The classical triad of clinical features is *dermatitis*, *diarrhoea* and *dementia*, not invariably appearing in this order. Redness and superficial scaling appear on areas exposed to sunlight, heat, friction or pressure. The changes resemble sunburn and subside leaving a dusky, brown-red coloration, but this occurs more slowly than typical in sunburn and exacerbation follows re-exposure to sunlight. On the face, a symmetrical 'butterfly' eruption is frequently observed and there is often a characteristic well-marginated eruption on the front of the neck ('Casal's necklace'). Asymmetrical lesions may appear at sites of sun exposure, eczema, injury or stasis [11–12] (Figs 59.42–59.45).

Gastrointestinal symptoms include pain, diarrhoea and achlorhydria in 50% of cases. In mild instances, the mental disturbance may pass unnoticed, patients perhaps being slightly depressed or apathetic. Sometimes, there may be frank disorientation, restlessness or other severe central nervous system symptoms [13]. Peripheral neuritis and myelitis are occasionally encountered.

Histology. Histological examination shows hyper- and parakeratosis, acanthosis and multiple melanin granules throughout the epidermis. Such changes are suggestive, but not diagnostic, of pellagra.

Drug eruptions, various forms of porphyria, photodermatitis, lupus erythematosus and actinic reticuloid may cause diagnostic difficulty. The so-called pellagrous vulvitis, vaginitis and scrotal dermatitis may be attributed to accompanying ariboflavinosis and other deficiencies of the vitamin B group and of zinc.

Therapy. In severe cases, intravenous niacin is required in doses of 50–100 mg once or twice a day. Otherwise, oral niacin amide in a total dose of 0.5 g/day should be given. The amide is to be preferred, as it does not precipitate flushing, itching and burning as is seen following ingestion of niacin in large doses. Improvement can be expected within a day or two.

Kava dermopathy. Kava, a psychoactive intoxicating beverage used ceremonially and socially by Pacific Islanders, may produce a pellagra-like ichthyosiform dermopathy with widespread acquired ichthyosis [14,15]. Kava is produced by infusing dried roots of *Piper methysticum* with water or coconut milk. The cause of the skin disease has not been established; interference with tryptophan or niacin as previously suggested is not likely [15]. Interference with cholesterol metabolism akin to changes associated with lipid-lowering agents is a possibility. Kava dermopathy is curable with abstinence.

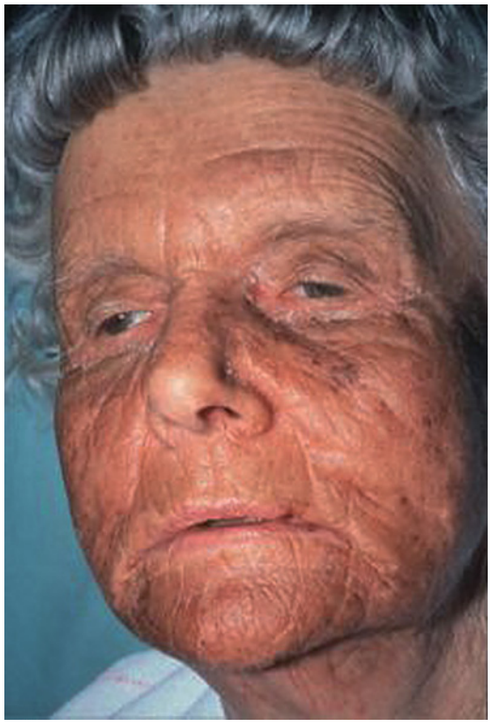

Fig. 59.43 Pellagra on the face provoked by sun exposure.

Biotin

Synonym
- Vitamin H

Biotin is a water-soluble, sulphur-containing, heterocyclic carboxylic acid involved in bacterial metabolism and possibly functioning as a coenzyme in decarboxylation and other enzymatic processes. Deficiency can be induced by feeding raw egg-white containing avidin which binds biotin and makes it poorly absorbable [16]. Short bowel syndrome in association with parenteral nutrition may cause biotin deficiency [17,18]. Symptoms include alopecia, conjunctivitis, eczema around the nose and mouth, nail dystrophy, hyperaesthesia, paraesthesia, depression and muscle pain. A multivitamin preparation supplying 60 µg of biotin daily cured an adult patient within 3 weeks [16]. Biotin seems to possess some antiseborrhoeic actions and has been used in high doses for therapy of Leiner's disease in infants (Chapter 17) [19].

Inborn errors of biotin metabolism [20]**.** The genetically determined disorders of biotin metabolism consist of two separate diseases: holocarboxylase synthetase deficiency and biotinidase deficiency. Both are transmitted as an autosomal recessive trait.

Holocarboxylase deficiency (MIM #253270) presents in the neonatal period, affected subjects having severe symptoms of organic acidaemia. The patients may have shown recurrent episodes of

(a) (b)

Fig. 59.44 Pellagra (a) in a patient with anorexia nervosa. (b) Note marked reaction in sun exposed areas on the feet.

Fig. 59.45 Pellagra on sun exposed dorsal hands.

vomiting from birth and rapid respiration as a sign of severe metabolic acidosis. There are seizures, hypo- as well as hypertonia, electroencephalogram abnormalities, and the disease progresses to death unless diagnosis and effective therapy supervene. An erythematous, scaly rash is prominent over most of the body in the patients who survive the first days of life. The skin lesions may resemble ichthyosis and seborrhoeic dermatitis. The pattern of excretion of organic acids is characteristic, especially 3-hydroxyisovaleric acid and 3-methylcrotonylglycine in urine being increased. Lactic acidaemia is striking. The molecular defect is in the enzyme holocarboxylase synthetase.

Biotinidase deficiency (multiple decarboxylase deficiency, MIM #253260) usually presents after 3 months of age. The cutaneous lesions may resemble those of acrodermatitis enteropathica, that is severe zinc deficiency, with periorificial eczematous rash on the face, nail dystrophy (onychoschizia) and skin infection. The hair is sparse, and there may be total alopecia. Neurological symptoms are prominent with myoclonic seizures, ataxia, lethargy and developmental delay [21]. There are low levels of biotin in blood and urine. The fundamental defect is in biotinidase, which normally acts on biocytin, a biotin–lysine complex, thereby separating biotin from lysine [19].

Biotin treatment. Both of the biotin-related disorders discussed above are treated with an oral dose of biotin, usually 10 mg/day but some patients need less and some have required as much as 40 mg/day.

Uncombable hair syndrome (Chapter 66) may respond to a low oral dose of biotin [22].

Vitamin C [1–3]

Synonym
- Ascorbic acid

Vitamin C is a relatively strong organic acid, chemically related to the carbohydrates. Only the laevo form is biologically active. Ascorbic acid is a strong reducing agent, easily oxidized to dehydroascorbic acid, with which it constitutes a reversible redox system. Vitamin C plays a central role in collagen and ground-substance formation, metabolism of aromatic amino acids (phenylalanine, tyrosine), reduction of folic acid to folinic acid and a broad range of biochemical redox reactions, including the preservation of sulphur-containing enzymes in a reduced form. It occurs naturally in cabbage, potatoes, green vegetables and fruits. The recommended daily dose is 30–80 mg; a daily intake of 10 mg prevents scurvy.

Vitamin C deficiency

Synonyms
- Scurvy
- Scorbutus
- Hypovitaminosis C

Unlike most other animals, humans and guinea pigs are unable to synthesize ascorbic acid due to lack of the enzymatic pathways

Fig. 59.46 Scurvy. Purpuric rash on the trunk. The lower extremities were also affected.

Fig. 59.47 Scurvy, showing purpura on the hard palate.

for synthesis of L-ascorbic acid from D-glucuronic acid. In the deficiency state, collagen and ground-substance synthesis are depressed, which leads to a multiplicity of symptoms involving bones, mucous membranes and skin.

Aetiology. Lack of vitamin C is still a serious problem in many parts of the world where access to fruit and vegetables is limited and where general malnutrition prevails. By contrast, most cases in developed countries are a consequence of food faddism, ignorance or alcoholism [4,5]. Danish beer no longer contains vitamin C as an antioxidant, and can therefore no longer prevent scurvy in alcoholics [6]. Malnourished children with scurvy (Barlow's disease) [7] may still be a paediatric problem [8] and vitamin C deficiency has been observed in teenagers living on processed food devoid of fresh fruit and vegetables [9]. In patients with chronic gastrointestinal disturbances, subclinical scurvy may be present. Elderly men living alone, who rarely get fresh fruit or vegetables and who may abuse alcohol, are particularly at risk.

Scurvy may be a presenting sign of undiagnosed psychiatric illness [10], and may appear with ecchymosis, perifollicular petechiae and haemorrhagic pustules on a previously injured extremity [11].

The cause of scurvy observed in liver transplant patients is not clear [12].

Clinical features [4]. (Figs 59.46 and 59.47). The initial skin change is follicular keratosis with coiled hairs on the upper arms, back, buttocks and lower extremities. Later, perifollicular haemorrhage with blood pigment discoloration especially on the legs, swollen bleeding gums, stomatitis and epistaxis occur. Large skin haemorrhages may be seen. Anaemia is usually present, and the patient appears resentful and mentally depressed. In the infant, dental development is impaired and oral changes may be severe. Tender subperiostal haematomas may develop and dominate the picture. Chronic hypovitaminosis C with 'woody' oedema and discoloration of the legs as the presenting feature has been described. Subnormal serum levels of vitamin C are present (normal range about 17–94 μmol/L). The significance of low values without clinical symptoms is doubtful.

Treatment. The scorbutic patient should be treated with oral vitamin C 100 mg three times daily in addition to protein-rich food [4]. The response is dramatic. It is advisable to continue the therapy for several weeks to ensure repletion of the emptied body stores.

Kwashiorkor and marasmus [1,2]

Kwashiorkor is a nutritional syndrome with characteristic cutaneous changes due to severe protein malnutrition with relative carbohydrate excess. In children, there is retardation of skeletal and mental development, muscular wasting, fatty infiltration of the liver and oedema. Marasmus is the result of prolonged starvation, a wasting syndrome, resulting in 40–50% reduction in body weight but with no peripheral oedema.

Kwashiorkor

Aetiology [2]. Protein–energy deficiency is one of the commonest and most widespread nutritional disorders in developing countries. The majority of kwashiorkor cases are found in countries where the diet consists of corn, rice or beans. Kwashiorkor is more common in children than in adults and is a major paediatric problem in certain parts of the world. The onset in infancy is during the weaning and postweaning period. In Europe and North America, occasional cases are seen in patients suffering from malabsorption or eating a diet that includes an inadequate amount of protein. Milder forms are probably not uncommon, particularly in the elderly.

Kwashiorkor refers to the 'deposed child' who is no longer suckled. It is a multiple deficiency syndrome. The cause is related to lack of essential amino acids, vitamins and trace elements, particularly zinc. The skin manifestations, hair changes and failure to thrive may mimic those seen in acrodermatitis enteropathica. Serum zinc is low, but this may be attributable partly to hypoalbuminaemia. Hospitalized children may show persistent hypozincaemia after clinical cure has occurred, indicating a need for zinc supplementation together with vitamins and protein-rich nutrition [3,4].

Clinical features [1,2,5]. The symptoms of kwashiorkor usually first develop between the age of 6 months and 5 years. The most important feature in the child is a failure to thrive, with inhibition of growth and mental development; oedema and muscle wasting are also found.

The skin lesions are initially erythematous and later purple or reddish brown in colour with marked exfoliation. In milder cases a lacquered 'flaky paint' ('enamel paint') or 'cracked skin' appearance is present. The hair is dry and lustreless and may become light red-brown in colour. In more severe cases it may be prematurely grey or show a 'pepper and salt' appearance, and become sparse, fine and brittle.

The skin often shows dyschromia with hypopigmentation, perhaps the result of phenylalanine deficiency, and patchy postinflammatory hyperpigmentation. In severe cases pigmentary changes are particularly striking. There is convincing evidence that the skin changes of kwashiorkor are primarily due to zinc deficiency [6]. Mucosal lesions, such as cheilosis, xerophthalmia and vulvovaginitis may be found, which are related to other deficiencies.

Mental disturbances are variable and may appear either as apathy or irritability. The child does not smile; when it does, it is a sign of recovery.

Table 59.11 Clinical features distinguishing kwashiorkor from pellagra.

Kwashiorkor	Pellagra
Children more than adults	Adults more than children
Dermatitis with systemic signs of apathy and oedema	Dermatitis precedes gastrointestinal and neuropsychiatric symptoms in most cases
Eruption generalized; pale, ill-defined; 'crackled skin'	Exposed areas; red, thickened, well-defined lesions; later, dry, branny scales
Hair light, 'pepper and salt' appearance, thin	Normal
Nails sometimes soft and thin	Normal
High mortality	Low mortality

Oedema is the result of hypoalbuminaemia (less than 2.5 g/100 mL). The α- and β-globulins are low, while an increase in gammaglobulin is usual.

Hypoglycaemia with hypothermia, coma and severe bacterial or parasitic disease are rare, often fatal, complications [7].

Mild cases of kwashiorkor appearing in the elderly show as a 'cracked skin' appearance on the front of the legs and lower abdomen. They have been reported under the title of geriatric nutritional eczema.

Prognosis. The short-term prognosis of mild cases which are given full dietary treatment is good, but mortality is high in severe and relapsing cases.

Diagnosis. Diagnostic difficulties occur in mild cases. The dietary history, 'cracked skin' and oedema, particularly when associated with pigmentary changes, should lead to the suspicion of protein deficiency. Acrodermatitis enteropathica may be mistaken for kwashiorkor. The features distinguishing kwashiorkor from pellagra are shown in Table 59.11.

Prevention and treatment. Prevention of kwashiorkor depends on increasing the supply of animal proteins, and on education and social welfare in poor areas.

In an established case, a complete and balanced diet should be given as soon as possible. Skimmed milk is the most useful treatment, presumably through its amino-acid content. Appropriate measures should be taken to correct any electrolyte disturbance.

Marasmus [1]

Aetiology. Marasmus is derived from the Greek *marasmos*, which means wasting. It is a result of severe protein and calorie deprivation for a prolonged period. Worldwide, marasmus is more frequent than kwashiorkor and is especially seen in developing countries where food is absent or scarce. Severely ill, hospitalized patients may show signs of marasmus. Low zinc levels are a predominant feature.

Clinical features. Patients have a wrinkled, loose, dry skin. There is a substantial loss of subcutaneous fat tissue, and the facial expression is described as 'monkey facies' due to loss of the buccal adipose tissue. Follicular hyperkeratosis may be prominent in

adults. The hair is thin and sparse and readily lost and the nails are fissured. Skin ulceration occurs.

Diagnosis. The combined finding of a severely reduced body weight, loss of subcutaneous fat, poor hair and nail growth and a loose, wrinkled, dry skin that appears too large is diagnostic. There is no peripheral oedema.

Prevention and treatment. This is as for kwashiorkor. Skin ulceration may respond to topical zinc paste or oral zinc supplementation in addition to a protein-rich nutritional supply.

Calcification and ossification of the skin [1–5]

Calcification or calcinosis cutis is the result of deposition of calcium and phosphate in organic matrices of the tissues. The process occurs in a wide range of different conditions. The mineral phase may be arranged in the manner seen in normal bone formation, *ossification*. If the deposition is not organized, the condition is termed *calcification*. The organic matrix consists largely of collagen or elastic tissue. All organic matrices of calcified or ossified tissues contain protein-bound phosphorus. In pathological ectopic calcification, the matrix is altered and contains acid proteins. In pseudoxanthoma elasticum, γ-carboxyglutamic acid, an amino acid present in calcium-binding proteins, has been found in high concentrations in the dermis. The solid phase of calcified tissue is made up of hydroxyapatite and amorphous calcium phosphate. Once formed, the focus increases in size by growth and may result in disorganized masses of pasta-like material.

Aberrant calcium deposition in the skin may be divided into three main groups:

1 Associated with localized or widespread tissue changes or damage (dystrophic calcification)
2 Unassociated with tissue damage or demonstrable metabolic disorder (idiopathic calcification)
3 Associated with an abnormal calcium and phosphorus metabolism (metastatic calcification) (Table 59.12).

Table 59.12 Various forms of calcinosis cutis.

Dystrophic calcification
Calcification usually associated with localized injury
Congenital
Fibrodysplasia ossificans
Traumatic
Subcutaneous injection with calcium-containing heparin
Radiotherapy
Foreign-body, haematoma, fat cell necrosis
Inflammatory
Acne, varicose veins, tuberculous granuloma, postoperative inflammation in scars
Degenerative infarcts (arterial, venous), venous stasis, parasitic cysts (e.g. echinococcal cysts)
Neoplastic
Benign: sebaceous cysts, lipomas, angiomas, calcifying epithelioma of Malherbe
Malignant: some liposarcomas
Calcification associated with widespread tissue injury
Dermatomyositis
Generalized scleroderma (Thibierge–Weissenbach or CREST syndrome)
Systemic lupus erythematosus
Acrodermatitis atrophicans
Pseudoxanthoma elasticum
Ehlers–Danlos syndrome
Idiopathic calcification
Calcinosis universalis; calcinosis circumscripta
Solitary nodular calcification of the skin ('cutaneous calculus')
Pinnal calcification
Tumoral calcinosis
Metastatic calcification
Hypercalcaemic
Hyperparathyroidism
Sarcoidosis
Vitamin D excess
Milk–alkali syndrome
Destructive bone disease
Metastatic carcinoma, lymphoma, multiple myeloma, leukaemia
Paget's disease
Normocalcaemic
Chronic renal failure
Pseudohypoparathyroidism

Dystrophic calcification [6]

The calcinosis is confined to the dermis or subcutaneous tissue and related to local connective tissue or fatty tissue damage, in the absence of any detectable abnormality of calcium metabolism. The calcification appears a variable time after the injury; for example, in dermatomyositis it occurs after a few years and in generalized scleroderma usually after 10 or more years. Dystrophic calcification may also occur in systemic lupus erythematosus [1,7,8].

Electrical injuries may be particularly likely to result in dystrophic calcification. An accumulation of calcium salts on dermal collagen fibres of pig skin was observed in scars following electrical injury [9]. Deposition of calcium salts in high concentration on a damaged skin surface may induce dermal calcification, as observed following electroencephalography in children [10]. In these cases, the skin was abraded prior to application of an electrode paste containing calcium chloride; lesions developed shortly after electroencephalography and disappeared in 2–6 months without therapy. An intact stratum corneum is protective.

Idiopathic calcification

Calcinosis universalis

The deposition of calcium in the dermis, subcutis and muscles is unrelated to any recognizable tissue injury or metabolic disorder.

Many cases reported in the literature under the diagnosis were probably suffering from undetected dermatomyositis, systemic lupus erythematosus or scleroderma, but there remain a number of instances in which no underlying disease is demonstrable [2].

Histopathology. Initially, calcium particles gather around fat cells. Electron microscopy of early lesions has shown apatite crystals lying in parallel to the collagen fibres [11].

Clinical features. Nodules or plaques 0.5–5.0 cm in size are symmetrically distributed over the extremities and, less commonly, the trunk. The lesions may become tender and ulcerate, discharging chalk-like creamy material consisting mainly of calcium phosphate with a small amount of calcium carbonate. After ulceration, a slowly healing sinus remains. Fingertip lesions are often painful, while in other sites there may be limitation of movement due to stiffening of the skin. The disease is eventually fatal.

X-ray examination is valuable for localizing the deeper deposits. Biochemical investigations are normal.

Treatment. Surgical removal of painful deposits may give temporary relief. In some instances, corticosteroids may be considered, although the response is variable. Cellulose phosphate combined with a low-calcium diet should be considered [12].

Calcinosis circumscripta

There may be only a few calcium deposits in the skin. Most cases of calcinosis circumscripta are found in generalized scleroderma or dermatomyositis but rarely it may occur as an idiopathic disorder [3]. Keloid formation with calcification has been described [13].

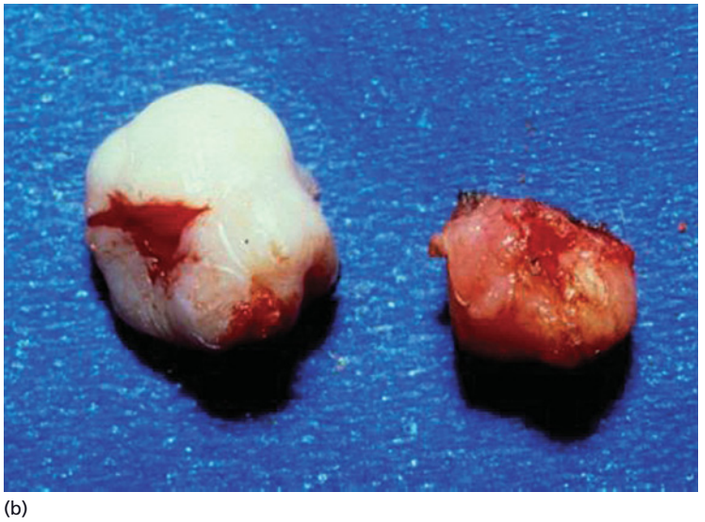
Idiopathic calcinosis of the scrotum [13,14]

Calcinosis scrotalis (Fig. 59.48) is a rare, benign disorder consisting of multiple asymtomatic firm nodules 0.2–1.0 cm in diameter. It is often misdiagnosed as scrotal cysts. Dystrophic calcification in the penis has been reported following trauma, Peyronie's disease and cytostatic therapy.

Calcifying epithelioma of Malberbe

See Chapter 53.

Tumoral calcinosis [2,15,16]



Tumoral calcinosis occurs most commonly in the native population of Africa, particularly among younger age groups. Clinically, the lesions present as swellings around the large joints (hip, elbow, ankle and scapula), but there is no actual involvement of the joint. Extrusion of calcified material, which has been likened to a suspension of procaine-penicillin, may take place. Histologically, there is initially collagen necrobiosis, which results in cyst formation and a foreign-body response. The calcification is first granular; later, dense deposits are seen [15]. The aetiology is unknown, but it is probably a form of dystrophic calcification caused by mechanical injury.

Pinnal calcification [2]

Calcified ear cartilage has been observed in several conditions such as Addison's disease, ochronosis, acromegaly, diabetes mellitus, hyperthyroidism, systemic chondromalacia (von Meyenburg's disease), familial cold hypersensitivity and frostbite.

(a)

(b)

Fig. 59.48 (a) Calcinosis scrotalis; (b) solitary nodules after removal.

Metastatic calcification [3,17]

In metastatic calcification, calcinosis occurs as a precipitation of calcium salts in normal skin, subcutaneous tissue, muscles and internal organs.

Aetiology. In all cases, there is an increase in the serum levels of calcium or phosphate. Hypercalcaemia may be due to hyperparathyroidism, vitamin D intoxication, milk–alkali syndrome or destructive bone disease with excessive osteoclastic activity. Metastatic carcinoma, multiple myeloma, leukaemia and Paget's disease

of bone may all be associated with metastatic calcification. Calciphylaxis, now termed calcific uraemic arteriolopathy (Chapters 49 and 62), is a potentially fatal syndrome, in which there is usually a raised serum calcium phosphate product. Most cases occur in the context of chronic renal insufficiency in patients undergoing long-term renal dialysis, in whom there has been development of secondary or tertiary hyperparathyroidism [18].

Clinical features. The cutaneous manifestations are similar to those of calcinosis universalis. Additional clinical features reflect the primary disease.

Treatment. Only in hypervitaminosis D and the milk–alkali syndrome can improvement be expected by regulation of dietary habits and withdrawal of vitamin D and milk intake. In cases of renal insufficiency, restriction of dietary phosphate and oral administration of an aluminium hydroxide gel may be useful.

Ossification of the skin

Synonyms
- Osteomatosis
- Osteoma cutis

Osteomatosis represents cutaneous calcification with *de novo* bone formation in the skin [19]. It has been noted in suprapubic prostatectomy scars and in otherwise normal postoperative scars [20]. It may also occur in collagen vascular disease (lupus erythematosus, scleroderma and dermatomyositis) [21]. Cutaneous ossification without any known causative factor (also known as osteomatosis cutis, primary osteoma cutis or osteosis cutis) has been reported [17].

Post-acne osteoma cutis

This is a rare complication of long-standing acne vulgaris. It has been reported to occur as pigmented osteomas during tetracycline or minocycline therapy. The osteomas that represent metaplastic bone formation are located in the mid- or reticular dermis, and consist of concentric lamellae with lacunae, Haversian canals and marrow cavities. With the use of tetracycline, more patients develop bluish, 1–2-mm, moveable papules on the face. Treatment consists of surgery or local 0.5% tretinoin cream with resultant transepidermal elimination of the lesions [22].

Iron metabolism [1]

The total iron content of an adult man is 4–5 g, 60–70% of which is blood haemoglobin iron. Small amounts of ferritin iron are present in erythrocytes, plasma and leukocytes [1]. Iron is stored in the liver, spleen and bone marrow as ferritin and haemosiderin. It is released readily from these sites according to the body's needs. Serum ferritin levels vary with the iron status of the individual and with certain diseases. The body has a limited ability to excrete iron, and homeostasis is therefore regulated mainly by adjusting iron absorption. Iron compounds need to be reduced to the ferrous form (Fe^2) to be absorbed. Ascorbic acid, which can reduce and chelate iron, enhances iron absorption.

The mechanism of iron absorption is not completely understood. Recent evidence points to an iron-transport system involving the binding of iron to the plasma membrane of mucosal cells and the interaction of transferrin in plasma with these sites.

Total iron in faeces varies between 6 and 16 mg/day depending on the amount ingested. Most of it is unabsorbed food iron.

Iron deficiency

Iron deficiency is a major risk factor for disability and disease worldwide, affecting about two billion people. Targeted iron supplementation, fortification of foods and selective plant breeding are means to improve iron nutritional status in the developing world [2].

General symptoms include fatigue, palpitations on exertion, sore tongue with atrophic filiform papillae, angular cheilitis (per-

lèche), dysphagia and koilonychia (Chapter 65). Generalized itch may occur [3], and hair loss with or without morphological changes of the hair shaft may be seen [4,5]. In infants and children, anorexia, retarded growth and decreased resistance to infections are the outstanding features. The recommended daily allowance is 10 mg in infants, 10–15 mg in children, 18 mg in young males and females, and 10 mg in both sexes above 20 years of age [6]. Pregnant women should receive supplemental iron, as the increased need for iron can barely be met by ordinary diets [7].

The diagnosis of iron deficiency is based on low serum iron levels, clinical symptoms and improvement following iron therapy. Serum ferritin is significantly correlated to bone marrow haemosiderin iron and provides a convenient method for assessing iron stores in normal subjects [8].

Iron intoxication

Daily ingestion of 50–75 mg iron is reported as safe [1,2], and even higher intakes in some individuals turn out to be harmless. Chronic iron intoxication has been reported among Bantus consuming beer that is brewed in iron utensils. The iron is in a soluble form and may supply a substantial net supply of iron. Iron-contaminated cereals do not induce siderosis because iron is present in a less available form.

Haemochromatosis (MIM +253200 and others) [1,9]

Haemochromatosis is a syndrome characterized by the triad of hyperpigmentation, diabetes mellitus and cirrhosis of the liver, associated with increased iron deposition in the internal organs. Hypogonadism is frequently present. The female/male ratio is 1:10. Onset of symptoms is gradual, usually between 40 and 60 years.

Aetiology. Haemochromatosis can be found in the following conditions: idiopathic or primary haemochromatosis; chronic iron intoxication (e.g. Bantu haemochromatosis); chronic liver disease and iron overload (alcoholic haemochromatosis); hepatic haemosiderosis in anaemic patients with an ineffective erythropoiesis; and congenital transferrin deficiency. The cause of primary haemochromatosis is basically unknown, but a defective control of iron absorption is involved. The abnormality is inherited as an autosomal recessive trait (see Chapter 62). Erythrocyte ferritin is increased 60-fold in idiopathic haemochromatosis, which allows a distinction between this disorder and alcoholic liver disease with iron overload [10]. In alcoholic haemochromatosis, alcohol consumption, particularly red wine and iron-containing beverages, play an aetiological role. Whether the acquired form is seen in patients heterozygous for the trait is not known.

Histopathology. Liver biopsy in primary haemochromatosis shows marked iron deposits in the parenchymal cells and to a lesser degree in the Kupffer cells. The hyperpigmentation of the skin is due to increased epidermal melanin and upper dermal melanophages, but iron deposits can be identified in the deeper dermis.

Clinical features. The skin shows a distinctive grey-brown pigmentation, especially on the face, flexural creases and exposed parts. This may precede other signs by many years but can appear late in the course. Sometimes, the buccal mucosa is involved as in Addison's disease but adrenal insufficiency is not present. The various skin changes were studied in 100 patients [11]. There was almost 100% frequency of hyperpigmentation, 75% had hair loss (including axillary and pubic hair), about 50% had koilonychia and 45% had ichthyosis-like, atrophic dry skin. Less frequent signs included palmar erythema, striate onychia, leukonychia and spider angiomas (findings that may be seen in cirrhosis of any cause). Hepatomegaly, diabetes, testicular atrophy, heart disease and weight loss are additional findings. Arthropathy, present in 25–50% of the patients, resembles rheumatoid arthritis, but serology is negative.

Diagnosis. The diagnosis should be suspected in a patient with diabetes mellitus, liver cirrhosis and hyperpigmentation. Liver biopsy is usually diagnostic.

Routine laboratory tests may reveal evidence of chronic hepatic disease or of diabetes mellitus. Total serum iron is increased to the range 180–300 mg/100 mL [1], serum transferrin saturation is above 80%, and the transferrin level and the total iron binding capacity (TIBC) may be reduced [9,11]. Serum and erythrocyte ferritin is high, reflecting the increased iron stores [10]. HLA-typing has revealed an increased frequency of HLA-A3 and -B14 [12] but has largely been superseded by genotyping for the commoner haemochromatosis genes (Chapter 62).

Treatment. A liver concentration above 100 µmol/g iron weight is an indication for therapy [1,7]. Organ damage may be reversed by reducing the excessive iron stores by repeated venesection for 1–2 years. Serum iron and serum transferrin and transferrin saturation remain unchanged until excess iron has been removed. Serum or erythrocyte ferritin should be monitored as a guide to the efficacy of treatment. Family members should have their serum iron estimated and, if found to have iron overload, should be treated with prophylactic venesection.

Sulphur metabolism [1]

Sulphur is a vital element for the normal function of the human body. It is an essential component of the amino acids methionine and cysteine and of chondroitin sulphate, which are involved in keratinization and formation of dermal collagen, respectively. Dietary thionine and cysteine are the main precursors for the synthesis of sulphur-containing components in the body. In homocystinuria there is a metabolic block in the pathway; clinical features include tissue-paper scars on the hands and sparse, fair hair due to impaired keratin formation. When the supply of sulphur-containing amino acids is inadequate, less sulphur is available to maintain nail and hair growth, but the keratin produced seems to be normal [2]. The liver plays a central role in degradation of sulphur-containing amino acids. In chronic liver disease, low urinary levels of inorganic sulphate are present [1].

In exfoliative psoriasis with increased epidermopoiesis, relative sulphur depletion is found and the urinary excretion of inorganic sulphate is decreased. Hair loss in chronic exfoliative dermatoses may be related to diversion of sulphur-containing amino acids to synthesis of skin protein instead of hair keratin formation [2]. Mucopolysaccharide synthesis in the dermis is influenced by certain hormonal factors. Thyrotrophin (thyroid-stimulating hormone, TSH) has a stimulant action on connective tissue and the pituitary somatrophic hormone (growth hormone, GH) stimulates chondroitin sulphate formation.

Trichothiodystrophy

Trichothiodystrophy is a sulphur-deficient brittle hair syndrome associated with ectodermal dysplasias [3,4]. The hair is short and brittle with a characteristic microscopy in polarized light showing alternating light and dark bands (Chapter 66). There is a 50% decrease or more in the cysteine and sulphur content of the hair. The disease is inherited as an autosomal recessive trait; there are photosensitive (MIM #601675) and non-photosensitive (MIM #234050) variants. Collodion baby syndrome may herald trichothiodystrophy [5].

Zinc metabolism [1–3]

Zinc belongs to the group of essential trace elements that comprises zinc, iron, copper, manganese, nickel, cobalt, molybdenum, selenium, chromium, iodine, fluorine, tin, silicon, vanadium and arsenic. High concentrations of zinc are present in shellfish, legumes, nuts, whole grain and green leafy vegetables, whereas fruits usually contain insignificant levels. Wine, beer and spirits contain very low concentrations of zinc. The zinc supply depends largely on the protein content of the food, and protein undernourishment will lead to an insufficient zinc supply.

Recommended dietary allowance of zinc [4]**.** The daily oral intake of zinc should average 3 mg in infants less than 6 months, 5 mg in infants 0.5–1.0 years old, 10 mg in children 1–7 years old and 16 mg from 11 years old onwards. Pregnant and lactating women should receive 20–25 mg zinc daily.

Biological functions. More than 300 catalytically active zinc metalloproteins and more than 2000 zinc-dependent transcription factors involved in gene expression of various proteins have been recognized [5]. Zinc is indispensable to the normal function of all cells, cellular systems, tissues and organs in the human body. The essentiality is related mainly to its function as the metal moiety of important enzymes, such as alkaline phosphatase, alcohol dehydrogenase and several different dehydrogenases, and digestive enzymes. Zinc regulates DNA and RNA polymerases, thymidine kinase and ribonuclease, and plays an important role in immunological functions.

Zinc deficiency

Dietary zinc deficiency, like iron deficiency, is a worldwide risk factor, most prevalent in the developing world. It is involved in severe deficiency syndromes such as kwashiorkor, marasmus and growth retardation. It affects about 2 billion people mainly living on phytate- and fibre- rich cereals, and soy products [6].

Zinc deficiency may be caused by a specific absorptive defect, acrodermatitis enteropathica, or may be due to diseases of the gastrointestinal tract causing diarrhoea and malabsorption (conditioned, or acquired, zinc deficiency).

Acrodermatitis enteropathica (MIM #201100 and others)

Acrodermatitis enteropathica was first recognized in 1936 by the Swedish dermatologist Thore Brandt [7] and further described by Danbolt and Closs [8] (Fig. 59.49). It is a rare disease believed to be transmitted as an autosomal recessive trait. In Denmark, the prevalence is about 1/500 000 inhabitants. Adema disease in blackpied cattle of Dutch descent, an autosomal recessive disease due to reduced zinc absorption, represents an animal parallel to acrodermatitis enteropathica in man [9] (Fig. 59.50).

Aetiology. Zinc absorption in acrodermatitis enteropathica is abnormally low, in young patients about 2–3% compared to 27–65% in normal adults [10]. The cause of the specific zinc malabsorption is not known. It can be overcome by an oral zinc load. Without zinc therapy, serum zinc levels are consistently low.

Clinical features. The disease typically starts after weaning or earlier if the infant is not given breast milk. The child turns peevish, withdrawn and photophobic, and develops a vesicobullous dermatitis on hands, feet and periorificial areas. The scalp hair is lost. Diarrhoea is often present. Growth is retarded and there is a decreased resistance to infections. Wound healing is poor and skin lesions tend not to heal [3,11].

Fig. 59.49 Acrodermatitis enteropathica with typical eczematous skin lesions. The vermilion area is free, the hair growth poor and sparse.

Fig. 59.50 Adema disease. The black-pied calf shows stunted growth, a poor scaly fur and characteristic keratotic muzzle eczema.

Prognosis. Without proper management, the prognosis is poor and in the past a lethal outcome within 4–5 years was the rule.

Treatment. Halogenated 8-hydroxyquinolines (e.g. diodoquin) were formerly used successfully for therapy on an empirical basis. Experimental animal studies using rats have shown that 8-hydroxyquinolines, which were used as antibacterial agents, increase ^{65}Zn absorption significantly [3]. Zinc sulphate for acrodermatitis enteropathica was introduced in the 1970s [3,11]. An oral zinc dose of 2–3 mg/kg/day cures all clinical manifestations, apart from hair and nail growth, within a few days. Prolonged high-dose therapy up to adult age is necessary, then a continuous zinc supplementation is indicated, often with oral doses of 1–2 mg zinc/kg/day.

Endemic nutritional zinc deficiency [6]

Endemic zinc deficiency presenting with dwarfism and hypogonadism as the main symptoms has been reported from rural districts in Iran, Egypt and Turkey. The chronic zinc deficiency is attributed to the diet, which consists mainly of unleavened whole grain bread with a high fibre and phytate content. Zinc deficiency has been described in severely malnourished children in Jamaica, Egypt and various parts of Africa [12]. In the Western world anorexia nervosa has been reported with symptoms of acquired zinc deficiency, often described as 'acrodermatitis enteropathica' [13] although it is acquired deficiency.

Acquired zinc deficiency

Zinc depletion syndrome. Where there is disturbed bowel function, zinc loss is increased; if combined with decreased absorption and low dietary zinc intake, severe zinc depletion will develop within 1–3 months. Zinc depletion syndrome was originally identified in patients who received prolonged total parenteral nutrition without zinc [14,15]. Most patients had undergone extensive intestinal resections. The serum zinc level was decreased, often below 20 µg/100 mL (3 µmol/L) (normal range 70–125 µg/100 ml or 10–19 µmol/L).

Zinc deficiency in breastfed infants. Premature infants receiving mother's milk are at risk of developing zinc deficiency due to rapid growth and insufficient zinc supply via the breast milk. Premature infants have an extra need for zinc, and zinc absorption is lower than in mature infants (Fig. 59.51a). Zinc deficiency may also be seen in normal infants due to low zinc levels in their mother's milk (Fig. 59.51b) [16].

Diseases of liver and pancreas. Chronic zinc deficiency has been reported in patients suffering from malabsorption–malnutrition associated with alcoholic liver cirrhosis and alcoholic pancreatitis [17]. A defective exocrine pancreatic function causing malabsorption and increased urinary zinc excretion in liver cirrhosis add to a negative zinc balance.

Cancer chemotherapy. Cancer chemotherapy for leukaemia in children may provoke zinc deficiency [18].

Zinc deficiency and the skin [19]

Acute zinc deficiency. General symptoms include septicaemia, photophobia and mental depression. Skin changes consist of eczematous eruptions on face, hands, feet, in the anogenital regions and around the body orifices. Finger and palm skin creases show characteristic flat bullous lesions surrounded by brownish erythema (Fig. 59.52). Oozing lesions may be seen on the sacral area and heels in bedridden patients. Some lesions are necrotic and burn-like. There is angular stomatitis with perioral lesions sparing the vermilion border.

(a) (b)

Fig. 59.51 (a) Zinc deficiency in a premature breastfed infant and (b) in a normal breastfed infant.

Fig. 59.52 Acute zinc depletion syndrome with denuded finger tips and bullae on finger flexural creases.

Fig. 59.53 Chronic zinc deficiency with scaly eczema on the perianal area. Note peripheral collarette scaling.

Chronic zinc deficiency. The patient is listless and mentally depressed. Skin lesions are typically seen on areas subject to repeated pressure and trauma, such as elbows, knees, knuckles, malleolar regions of the ankles and the sacral area. The lesions are brownish and scaly, sometimes psoriasis-like (Fig. 59.53). Seborrhoeic dermatitis-like changes may be seen on the face, and acne may flare.

A non-itchy, scaly dermatitis on the trunk has been described in zinc-deficient alcoholics.

Hair and nail changes. In zinc deficiency, hair and nail growth ceases or stops. Diffuse thinning of the scalp hair progresses, eventually leading to total alopecia. Structural changes of the hair may be observed, such as broken spearhead-like endings, transverse striation of the shaft, pseudomonilethrix, longitudinal splits and

Fig. 59.54 Beau's line on thumbnail in a case of zinc depletion syndrome, appearing one month after start of zinc therapy. Note faster growth of left thumb nail, typically seen in right-handed patients.

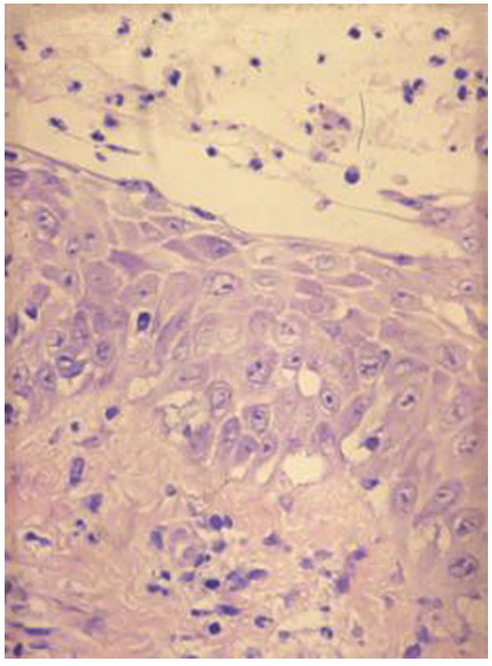

Fig. 59.55 Acute zinc deficiency with spongiotic dermatitis and degenerate basal cells.

bayonet hairs. Severe zinc deficiency causes total arrest of nail growth. Transverse depressions (Beau's lines) on the fingernails become visible about 4 weeks after zinc therapy is started and normal nail growth is re-established (Fig. 59.54) [20].

Pathology. In the acute stage, light microscopy reveals spongiosis, sometimes with suprabasal cysts and clefts (Fig. 59.55). The horny layer is often separated or lost, and necrosis of the epidermal cells may be seen. In chronic zinc deficiency, there are chronic eczema or psoriasis-like changes of the epidermis (Fig. 59.56). Electron microscopy of acute lesions shows degenerate basal cells

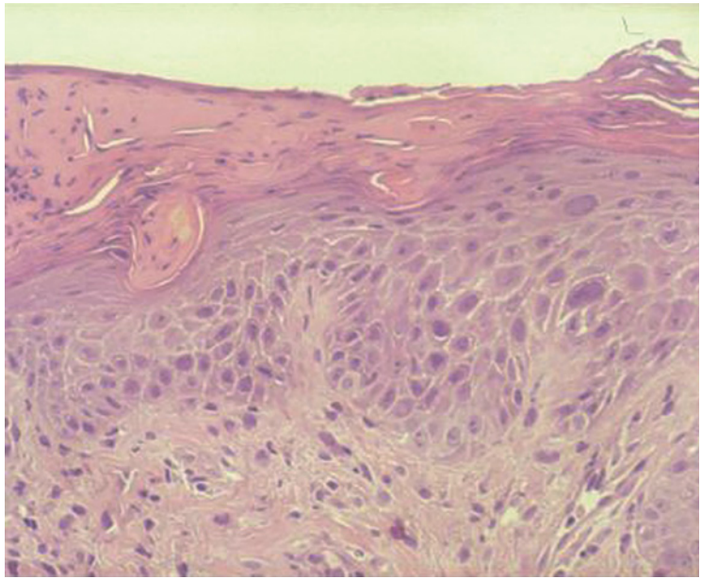

Fig. 59.56 Chronic zinc deficiency with parakeratosis, acanthosis and slight spongiosis.

with slender cytoplasmic protrusions and an intact basal lamina with multiple invaginations.

Diagnosis. Severe zinc deficiency is usually suspected from the clinical findings. The serum zinc and alkaline phosphatase levels are low and will rise during zinc therapy [19]. It is important to consider the level of plasma albumin as albumin binds 60–70% of circulating zinc. As a result, hypoalbuminaemia is associated with lowered serum zinc values, which may not necessarily reflect a state of zinc deficiency.

In suspect cases, a therapeutic trial with oral or parenteral zinc should be undertaken. If no clinical improvement occurs within a few days and the serum alkaline phosphatase remains stable as the serum zinc level goes up, the patient is not deficient in zinc.

Treatment with zinc. In adult patients, oral zinc sulphate ($Zn_2SO_4{\cdot}7H_2O$) tablets of 0.2 g (45 mg elemental zinc) are given two to three times a day (about 2 mg zinc/kg/day). Similar doses on a body weight basis are given to children. Parenterally, 0.2–0.3 mg zinc/kg/day (about 10–20 mg/day in adult patients) is sufficient and safe. For prophylactic purposes, total parenteral nutrition should supply no less than 70–80 µg zinc/kg/day. Infants and premature babies on parenteral nutrition should receive a prophylactic dose of 0.1–0.3 mg/kg/day [21].

There is no evidence of benefit from the use of zinc sulphate for patients with chronic leg ulcers [22], common cold [23] or acne vulgaris [24].

A variety of cutaneous disorders not related to zinc deficiency have been reported to respond to zinc supplementation. Zinc has no known pharmacological effect, so the significance of such observations seems dubious.

Copper metabolism

The normal adult body contains about 80 mg of elemental copper. Copper in plasma occurs in two forms: about 90% is firmly bound as the blue copper protein coeruloplasmin, the remainder is loosely bound to plasma proteins, primarily albumin. Copper competes with the albumin-binding sites for zinc, so fluctuations in concentration of one of these metals are reflected by a change in concentration of the other. Coeruloplasmin is an oxidase involved in iron utilization. It does not play a role in copper transport to the tissue; this is done by albumin, which is the true transport protein. Copper is part of superoxide dismutase, catalysing superoxide anion radicals into hydrogen peroxide and oxygen.

Copper-induced green hair

Green hair is usually caused by deposition of copper from exogenous sources. Usually, the patient has blond or reddish hair that has been exposed to physical or chemical damage (sun damage or bleaching) whereby high-sulphur matrix proteins (mainly cysteine) are exposed, and are therefore available to bind copper ions. A high copper concentration may occur in swimming-pool water due to copper-containing algicides, and in household tapwater due to copper piping [1,2]. Hair shampoo with an added copper-chelating agent such as dimethylcystein (penicillamine) can remove the green discoloration.

Copper deficiency

Copper deficiency has been reported to occur in infants receiving milk low in copper, and in malnourished children given high-calorie nutrition with an insufficient copper supply. The symptoms include anaemia, neutropenia and failure to thrive.

Menkes' kinky hair syndrome (MIM #309400). This is an X-linked defect in copper absorption, resulting in low copper levels in blood, liver and hair. There is progressive mental deterioration, metaphyseal lesions, degenerative aortic elastin and defective keratinization of hair (Chapter 66). There is no effective treatment [3].

Wilson's disease (hepatolenticular degeneration syndrome) (MIM #277900). This is a rare, inborn error of copper metabolism, inherited as an autosomal recessive trait [4]. It is characterized by cirrhosis of the liver and degenerative changes in the brain, particularly the basal ganglia. Deposition of copper takes place primarily in the liver, brain, kidneys and cornea (Kayser–Fleischer ring). The patients have low coeruloplasmin and plasma copper levels.

Treatment consists of cupriuretic chelating agents such as penicillamine or by competing intestinal copper absorption with oral zinc [4].

Selenium metabolism [1]

Selenium is an essential element of the enzyme glutathione peroxidase. It plays a role against oxidative damage by endogenous peroxides. Selenium deficiency has long been known in several animal species. Selenium-deficient rats grow slowly, develop cataracts, lose their hair and show aspermogenesis. In humans, selenium deficiency has been reported in children, causing hypopigmented skin lesions and various other symptoms. Treatment consists of supplementation of selenium in low doses of

2 mg/kg/day [2]. Patients with psoriasis, atopic dermatitis, dermatitis herpetiformis and acne vulgaris have a lower glutathione peroxidase activity than normal controls [3], although the significance of this is unclear. In a study on malignant melanoma, significantly lower serum selenium levels were demonstrated as compared with controls [4]. Serum selenium levels have been shown to be of a prognostic value in the follow-up of malignant melanoma and cutaneous T-cell lymphoma [5]. There is no apparent protective effect of selenium supplementation against the development of non-melanoma skin cancer [6–8].

Selenium is incorporated as the sulphide into shampoos for the treatment of seborrhoeic dermatitis. Selenium sulphide is water-insoluble and possesses a very low toxicity. A possible protective role of selenium on cancer, cardiovascular diseases and rheumatic diseases has attracted much attention but there is no proven reason to recommend selenium supplementation.

Skin disorders in diabetes mellitus

Diabetes mellitus [1,2]. Diabetes mellitus is a metabolic disorder characterized by elevated fasting and postprandial blood glucose levels and a variety of multisystem complications, mainly in the blood vessels, eye, kidney, nervous system and integument. Three main types can be distinguished. Type 1, also known as insulin-dependent diabetes mellitus or juvenile-onset diabetes, is characterized by abrupt onset of symptoms, insulinopenia, dependence on insulin injections, proneness to ketoacidosis and lack of ability to produce C peptide. Type 2, non-insulin-dependent diabetes mellitus or adult-onset diabetes, is characterized by lack of ketoacidosis except under stressful circumstances, ability to produce C peptide, a tendency to obesity and improvement following loss of weight. Type 3, secondary diabetes, is an additional type of diabetes, which occurs as a complication of pancreatic, hormonal or genetic disease or following ingestion of certain drugs or chemical compounds.

There are several reviews of skin disorders associated with diabetes mellitus [2–8].

Skin symptoms due to diabetic vascular abnormalities [3–5]

Diabetic microangiopathy. Both small and large blood vessels are affected in diabetes mellitus. In diabetic microangiopathy, there is proliferation of endothelial cells and deposits of PAS-positive material in the basement membrane of arterioles, capillaries and venules with resulting decreased luminal area [9]. Basement-membrane thickening is a characteristic finding in diabetic and prediabetic patients, but it is neither absolute nor pathognomonic for the disease [10]. The diabetic microangiopathy precedes manifest abnormalities of the disease, and it is possible that vascular changes are the primary expression of the disease. Microangiopathy is responsible for the retinopathy, nephropathy and possibly also neuropathy and dermopathy associated with diabetes.

Erysipelas-like erythema [10]. This condition is seen mostly in elderly diabetic patients with an average duration of diabetes mellitus of 5 years. Well-demarcated, red areas occur on the legs or feet, and there may be underlying destructive bone disease caused by a small vessel insufficiency. Cardiac decompensation may be involved.

Wet gangrene of the foot. This is a late manifestation of diabetic microangiopathy. Non-diabetic atherosclerotic subjects tend to develop a dry form as a result of large vessel insufficiency.

Diabetic rubeosis [11]. A peculiar rosy reddening of the face, and sometimes of the hands and feet, may be seen in long-standing diabetes. The changes have been attributed to decreased vascular tone or diabetic microangiopathy. Rubeosis may have some practical diagnostic significance, especially in fair-skinned patients.

Diabetic dermopathy (diabetic shin spots). This is the most common dermatosis associated with diabetes mellitus. Microangiopathy and neuropathy are involved [12]. Lesions are predominantly situated on the shins, forearms, thighs and over bony prominences. About half of patients show such lesions, more frequently men than women. The initial lesion is an oval, dull-red papule 0.5–1 cm in diameter. It evolves slowly, producing a superficial scale, leaving an atrophic brownish scar. The colour is due to haemosiderin in histiocytes near the vessels [13] (Fig. 59.57). Microscopically, a combination of vascular disease with PAS-positive thickening of the vessel wall and minor collagen changes is found. Although not confirmed in all studies, recent research suggests that there is a significant correlation between the presence of these lesions and other complications of diabetes, such as retinopathy, nephropathy and neuropathy [14].

Large vessel disease [4]. Atherosclerosis is the second form of vascular disease frequently associated with diabetes mellitus. The patient shows intermittent claudication with pallid and cool skin distally on the extremities. The postural test discloses delayed filling of the veins. Common clinical sequelae are myocardial infarction, cerebral thrombosis, nephrosclerosis and ischaemic gangrenous lesions of the legs and feet. Microangiopathy is usually present together with large vessel involvement.

Fig. 59.57 Diabetic dermopathy on both shins.

Fig. 59.58 Diabetic foot with neurotrophic ulceration and necrosis ('mal perforans').

Diabetic neuropathy

Elderly patients with an insidious onset of the disease are especially at risk. Commonly, there is a distal symmetrical polyneuropathy with mixed motor and sensory nerve involvement. The motor neuropathy of the foot is characterized by dorsally subluxed digits, distally displaced plantar fat pads, depressed metatarsal heads, hammer toes and pes cavus [3]. Proper foot care is essential to prevent formation of indolent perforating ulcers ('mal perforans'). A painless and slowly penetrating ulcer of the sole and of other pressure sites is suggestive of diabetic neuropathy. The ulcer is circular and punched out in shape, occurring in the middle of a callosity (Fig. 59.58). An initial subepidermal haemorrhagic bulla may give rise to discoloration of the surrounding skin [4]. Loss of temperature and pain sensation and absence of the ankle reflex (an early sign of diabetic neuropathy) indicate a neuropathic origin. Sensory abnormalities of the lower extremities include numbness, tingling, aching and burning. Burning feet and restless legs are common complaints, which intensify at night while lying down. Autonomic neuropathy may cause decreased or absent sweating of the lower extremities with compensatory sweating in other skin areas. Damage to autonomic nerves of the skin in chronic advanced cases is manifested by oedema, erythema and atrophy [3].

The complex nature of the diabetic foot requires special attention. There is a multifactorial aetiology [6,8]. Predisposing factors include abnormal plantar pressure points, foot deformities and minor trauma. Peripheral neuropathy causes ulcers, loss of ankle jerks and vibration sensation. The foot has accentuated plantar arches and hammer toes, there is interdigital maceration leading to bacterial and fungal infection. Diabetic angiopathy leads to ulceration, necrosis, gangrene and osteomyelitis [15].

Local treatment of the ulcer consists of repeated debridement, treatment of infection, dressings and pressure-relieving footwear [8,16]. Simple surgery such as split skin grafting or minor toe amputations may be necessary [16], and some patients require more complex orthopaedic procedures to correct abnormal foot shape.

Cutaneous infections in diabetes mellitus

Skin infections due to *Staphylococcus aureus* and group A *Streptococcus haemolyticus* are common in diabetic patients [17]. Before insulin and antibiotics were available, infections causing severe furuncles, carbuncles and styes were frequent among diabetic individuals. Invasive *Pseudomonas* infection of the ear can progress through cellulitis and osteitis to cranial nerve damage and meningitis with a high mortality rate, so-called malignant otitis externa (Chapter 68) [18].

Non-clostridial gas gangrene. This complication develops in the soft tissues near a gangrenous focus. It was diagnosed in 17% of diabetics who were admitted to hospital because of gangrene or ulceration [19]. The commonest pathogens are *Escherichia coli*, *Klebsiella*, *Pseudomonas* and *Bacteroides* spp. in various combinations. The outcome is generally good.

Candida albicans. *Candida albicans* infections of mouth, nail folds, genitals and intertriginous skin areas are frequent in diabetics. Candidiasis may be the presenting feature of diabetes, and is frequently seen in diabetic patients whose disease is not well controlled [3]. A high glucose level of the saliva seems to account for the oral infection [20]. Phimosis is a common complaint of diabetic men, and recurring candidal infection is usually the cause. Dermatophyte infections are not more frequent in diabetic than in non-diabetic individuals [21].

Insulin resistance and acanthosis nigricans [22–24]

Tissue resistance to insulin is a major feature underlying the development of acanthosis nigricans in many diseases (e.g. Cushing's syndrome, acromegaly, Laurence–Moon–Bardet–Biedel syndrome, Prader–Willi syndrome and congenital lipodystrophy). There are two syndromes of insulin resistance. The type A syndrome has been reported in hyperandrogenetic women with clinical signs of virilization or accelerated growth (the acronym HAIR-AN has been proposed: HA, hyperandrogenism; IR, insulin resistance; AN, acanthosis nigricans). A genetic defect at the insulin receptor or in a post-receptor pathway has been postu-

Fig. 59.59 Necrobiosis lipoidica with ulcerations on the shins.

Fig. 59.60 Scleredema diabeticorum with a 'buffalo hump' in a young woman with diabetes mellitus.

lated. The type B syndrome has been reported in older women with signs of immunological dysfunction. High plasma levels of insulin are thought to contribute to the development of acanthosis nigricans.

Various skin disorders associated with diabetes mellitus

Necrobiosis lipoidica [2–8]. Necrobiosis lipoidica is associated with diabetes mellitus (Fig. 59.59). Frequencies of diabetes between 42% and 62% have been reported in patients with necrobiosis lipoidica, whereas necrobiosis lipoidica is uncommon (0.3%) among diabetic patients [3]. See also Chapter 60.

Disseminated granuloma annulare (Chapter 60). This is rarely seen in diabetic patients; the evidence that granuloma annulare is associated with diabetes mellitus is inconclusive [8,25].

Pruritus. Pruritus was once considered a typical symptom of diabetes mellitus. The frequency of generalized pruritus in diabetic patients is unknown. Anogenital pruritus may be due to secondary infection with candidiasis or haemolytic streptococci.

Stiff joints and waxy skin. Waxy tight skin on the backs of the hands and limited joint mobility may be seen in patients with insulin-dependent diabetes [8,26].

Scleredema diabeticorum. Whether post-infectious scleredema and diabetic scleredema are identical diseases, with a more severe course in the diabetes-associated form due to altered host response, is still a matter of debate [27]. The most common sites of involvement are the neck and upper back (Fig. 59.60). The condition is mainly seen in overweight adults with non-insulin-dependent diabetes, is essentially permanent, painless and causes no morbidity. There is no specific treatment although penicillin, methotrexate, ciclosporin and PUVA have been used with various degrees of benefit.

Vitiligo (Chapter 58). Vitiligo occurs more frequently in diabetic individuals. In late-onset diabetes, a 4.5% frequency has been reported [28].

Lichen planus (Chapter 41). An increased incidence of abnormal glucose tolerance tests in patients with lichen planus, especially oral lichen planus, has been reported [29]. The overall support for a true association seems limited [6].

Haemochromatosis (Chapter 62). The main symptoms are liver disease, hyperpigmentation, joint disease, hypogonadism and, eventually, diabetes.

Eruptive xanthomas of the skin. Eruptive xanthomas may develop in diabetic patients with hyperlipidaemia. The lesions slowly resolve when the diabetes is properly managed (Fig. 59.61).

Finger pebbles. Among 60 patients with diabetes mellitus, 45 (75%) had a pebbly appearance of the knuckle and distal finger skin. Similar changes were observed in 21% of control subjects [30]. The changes may be of external origin (trauma) or internal (acanthosis nigricans).

Skin tags. Skin tags are small, soft, pedunculated lesions occurring on eyelids, neck and axillae, often associated with obesity. Among 216 patients with skin tags, 57 (26%) had diabetes of the non-insulin-dependent type, of whom only about one-quarter were classified as obese [31].

Fig. 59.61 Eruptive xanthomas in a diabetic patient with hyperlipidaemia.

(a)

(b)

Fig. 59.62 (a) Perforating collagenosis on the back of a 64-year-old woman with diabetic retinopathy. (b) Close-up view.

Local insulin reactions [6,32]. Insulin may cause immediate local reactions, starting as erythema, which turn urticarial within 30 min and subside within an hour; these are probably IgE mediated. Serious generalized immediate reactions are rare.

The most common reactions are delayed, starting about 2 weeks after onset of insulin therapy. An itchy nodule develops at the site of injection. It lasts for days and heals with hyperpigmentation and perhaps a scar. Delayed hypersensitivity is involved.

Insulin lipodystrophy. Insulin lipodystrophy is rare. Patients present with atrophic plaques at the sites of insulin injection. There is atrophy of the subcutaneous fat. The lesions seldom show complete spontaneous resolution. The mechanism is not known.

Reactive perforating collagenosis (folliculitis) (Fig. 59.62). There have been reports of perforating collagenosis in patients with diabetes with and without renal insufficiency. The cause is attributed to diabetic microangiopathy and lesions are due to minor injury such as pressure or scratching [8,33].

Diabetic bullae. Diabetic bullae are uncommon, but believed to be a distinct marker for diabetes [34,35]. The location is the lower legs and feet, occasionally hands and fingers. They range in size from less than one centimetre to several centimetres (Fig. 59.63). A typical blister arises on a non-inflamed base, and heals without scarring in 2–5 weeks. Histological examination shows intra- or subepidermal separation without acantholysis.

Xanthomas and abnormalities of lipid metabolism and storage

P.D. Flynn, pp. 59.81–59.103

Introduction [1,2]

Disorders of lipid metabolism are heterogeneous. They include the very rare and the very common. They range from monogenic diseases with high penetrance through polygenic disorders to those that are paradigms of gene–environment interaction. Some are entirely or partially secondary to other diseases such as diabetes mellitus, hypothyroidism, renal failure or hepatic disorders. Dyslipidaemias are of relevance to all medical and surgical disciplines, and to all involved in delivering health care in the 21st century, as most are associated with an increased risk of atherosclerosis and its complications. They are of particular relevance to dermatologists because they may present with subcutaneous lipid deposits, collectively known as xanthomata. These may require treatment in their own right for the relief of the symptoms they cause; they may also allow the identification and treatment of a dyslipidaemia before the onset of premature cardiovascular disease.

This account will include a brief description of the principal lipid metabolic pathways and an overview of the classification of the dyslipidaemias, followed by a more detailed discussion of some of the individual primary lipid disorders, focusing on those most likely to be seen by dermatologists. The section will conclude with summaries of the secondary dyslipidaemias and of the overall management of dyslipidaemia.

Lipid metabolism [1]

Most metabolic pathways initially appear daunting; those describing lipid metabolism are no exception. Circulating lipids (cholesterol, cholesterol esters, triglycerides and phospholipids) are insoluble and therefore have to be solubilized by combination

Table 59.13 Classification of lipoproteins (adapted from [1]).

Class	Density (g/ml)	Electrophoretic mobility	Lipids*	Apolipoproteins
Chylomicrons	0.93	Remains at origin	Triglycerides 86% Cholesterol 5%	Apo B-48, Apo C, Apo E
VLDL	0.93–1.006	Pre-β-lipoproteins	Triglycerides 55% Cholesterol 19%	Apo B-100, Apo C, Apo E
IDL	1.006–1.019	Slow pre-β-lipoproteins	Cholesterol 38% Triglycerides 23%	Apo B-100, Apo E
LDL	1.019–1.063	β-lipoproteins	Cholesterol 50% Triglycerides 6%	Apo B-100
HDL	1.063–1.210	α-lipoproteins	Cholesterol 19% Triglycerides 4%	Apo A-I, A-II, A-IV
Lipoprotein (a)	1.040–1.090	Slow pre-β-lipoproteins		Apo (a), Apo B-100

* Expressed as % of dry mass.

with proteins; the resulting particles are called lipoproteins and the proteins they contain are generally called apolipoproteins. Understanding of the production, clearance and interrelationships of lipoproteins is growing rapidly and the following account aims merely to provide an overview of current understanding and a framework into which future advances can (hopefully) be incorporated. It is worth remembering that the current classification of lipoproteins is a pragmatic one based on their densities, a physical property we can measure, rather than their biological functions, which we would like to measure; there is fortunately some correlation between the two but it is not always absolute. The classification is shown in Table 59.13.

To discuss the metabolic pathways linking these differing lipoprotein classes it is helpful to consider those involved in the absorption of dietary fats and their transport to places of storage (the exogenous lipid pathway), those involved in the transport of lipids from the liver to peripheral tissues where they are required (the endogenous pathway), and those involved in the return of excess cholesterol to the liver from peripheral tissues (reverse cholesterol transport). In reality all three are closely interrelated.

The exogenous lipid pathway [1,2]

The majority of fat absorbed from the diet derives from triglycerides. These are hydrolysed by pancreatic lipase and the resulting free fatty acids and monoglycerides pass across the brush border of the small intestine into the enterocytes. Here they are reassembled into triglycerides which are packaged with apo B-48 and apo A-I, A-II and A-IV, and the relatively small amount of dietary cholesterol that is absorbed, to form nascent chylomicrons that are released and enter the lacteals. Chylomicron formation is completed by the transfer of apo C and apo E from high density lipoproteins (HDL) before release from the thoracic duct into the systemic circulation. Here chylomicron apo C-II is recognized by endothelial-bound lipoprotein lipase which acts to hydrolyse triglycerides, releasing fatty acids that can be taken up by adipose tissue for storage, or by other cells (e.g. muscle) for oxidation to provide a source of energy, or that are released into the circulation where they are largely bound by albumin. This loss of triglyceride is accompanied by a loss of apolipoproteins (A-I, A-II, A-IV and C) producing a chylomicron remnant that is itself bound by receptors expressed on hepatocytes (principally the low-density lipoprotein (LDL) receptor and the LDL receptor related protein (LRP)) and then endocytosed. The triglycerides and cholesterol thus delivered to the hepatocyte can be stored in intracellular lipid droplets, excreted in the bile or be re-packaged into nascent lipoproteins to participate in the endogenous lipid pathway.

The endogenous lipid pathway

This lipid pathway starts in the hepatocyte where triglycerides, and to a lesser extent cholesterol and cholesterol esters, are assembled with apo B-100 to produce nascent very-low-density lipoproteins (VLDL) in a manner similar to the production of chylomicrons in enterocytes. (Indeed apo B-48 and apo B-100 are produced from the same gene, the former representing simply the amino terminal 48% of the latter.) Following secretion, VLDL accept further apo C and apo E from HDL and can thus be bound, like chylomicrons, by endothelial lipoprotein lipase with subsequent hydrolysis of their triglycerides and uptake of the released fatty acids by peripheral cells. The resulting VLDL remnants comprise a population of lipoproteins heterogeneous both in density and in affinity for the hepatic LDL receptors that mediate their removal from the circulation; the smaller remnants include intermediate density lipoproteins (IDL) which remain relatively longer in the circulation and so can be further processed, probably by hepatic lipase, to produce LDL. LDL are cleared from the circulation by LDL receptors, 90% of which are hepatic.

Reverse cholesterol transport [3–5]

The process of reverse cholesterol transport begins in peripheral tissues with the transfer of cholesterol, cholesterol esters and phospholipids to two pools of HDL precursor particles—discoidal apo A-I and A-IV, produced by the liver, and nascent pre-β HDL, produced from chylomicrons. Lipid transfer to these particles depends

on the lipid transporter ATP binding cassette A-1 (ABCA1); stabilization of the newly formed HDL depends additionally on the esterification and internalization of these transferred lipids by lecithin cholesterol acyl transferase (LCAT) and phospholipid transfer protein (PLTP). The cholesterol taken up by HDL returns to the liver by two principal routes. One involves the transfer of cholesterol esters from HDL to apo B containing lipoproteins (principally VLDL) mediated by cholesterol ester transfer protein (CETP) and subsequent uptake by hepatic LDL receptors; the other is mediated by direct uptake of HDL by hepatic scavenger receptors, mainly SR-B1. Cholesterol returned to the liver by reverse cholesterol transport can be stored in hepatocytes or converted into bile acids and then excreted.

Lipids, lipoproteins and atherosclerosis [1–4]

There is now near universal acceptance that there is a causal relationship between circulating lipid concentrations and the development of atherosclerosis and its clinical sequelae (angina, myocardial infarctions, strokes and peripheral vascular disease). That it has taken so long to reach this point reflects both the influence of other risk factors for cardiovascular disease (and their often complicated interaction with lipid metabolism) and the complexity of the metabolism and variable atherogenicity of the different lipoproteins. It is very clear that high LDL cholesterol levels confer an increased risk of cardiovascular disease (CVD) and that this risk is decreased if LDL cholesterol levels are reduced, evidence for the latter coming most clearly from trials of the 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMG CoA reductase) inhibitors, or 'statin' group of drugs. There is also evidence that some LDL are more atherogenic than others; a preponderance of small, dense LDL or increased levels of oxidized LDL are both associated with increased CVD risk. Elevated concentrations of lipoprotein(a), which differs from LDL only by the additional presence of apolipoprotein(a), are also correlated with increased risk of atherosclerosis.

Epidemiological studies have also shown a strong and consistent inverse relationship between HDL and risk of atherosclerosis, that is high HDL levels are associated with a lower risk of CVD. There are some exceptions, for example apo AI Milano, where low levels of HDL are, apparently paradoxically, linked to low levels of CVD. In fact apo AI Milano is extremely efficient both at accepting lipid species from peripheral cells and at transporting them back to the liver; at any one time there is high flux through the reverse cholesterol transport pathway but concentrations of HDL cholesterol are low. There is also growing evidence that HDL have additional antiatherogenic properties; under appropriate conditions they can be anti-inflammatory and antioxidant. Taken together, these factors may explain the conflicting results of trials that have attempted to reduce CVD risk by increasing HDL concentration; some have yielded positive results (e.g. the Helsinki Heart Study, VA-HIT and HATS) but others have not (e.g. the WHO Clofibrate trial, FIELD and ILLUMINATE). Interpretation of such trials is further compounded by the fact that the agents used also altered other lipid risk factors including LDL cholesterol and triglycerides. A number of epidemiological studies have shown an association between high fasting triglyceride concentrations and CVD risk, albeit a rather weaker one than for LDL or HDL cholesterol and one which often loses significance in multivariate analysis, especially when correcting for HDL cholesterol concentrations with which fasting triglyceride levels are often negatively correlated. High fasting triglycerides are certainly linked to acute pancreatitis, often as a consequence but sometimes as a cause, with the risk rising significantly once levels exceed 10 mmol/L.

Dyslipidaemias: classification

There are a number of classifications of disordered lipid and lipoprotein metabolism, none of them entirely satisfactory. Perhaps the most straightforward is the WHO classification, usually referred to as the Fredrickson classification, based on the class of lipoprotein present in excess (Table 59.14) [1]. However, this requires plasma ultracentrifugation, does not include disorders characterized by low levels of HDL cholesterol or secondary dyslipidaemias and is not a diagnostic classification.

Pragmatically, given that for most patients all that is likely to be available is a lipid profile comprising total cholesterol, triglycerides and HDL cholesterol with a calculated LDL cholesterol, it may be most convenient to group patients rather broadly as having hypercholesterolaemia, hypertriglyceridaemia, combined (or mixed) dyslipidaemia, or other dyslipidaemia; wherever possible, further characterization and diagnosis may be based on

Table 59.14 WHO classification of hyperlipoproteinaemias [1].

Type	Lipoprotein abnormality
I	Hyperchylomicronaemia
IIa	Elevated LDL
IIb	Elevated LDL and VLDL
III	Broad β-VLDL
IV	Elevated VLDL
V	Elevated chylomicrons and VLDL

Table 59.15 Working classification of dyslipidaemias.

	Lipid abnormalities	WHO type	Primary dyslipidaemias	Secondary causes
Hypercholesterolaemia	↑ TC	IIa	Familial hypercholesterolaemia	Hypothyroidism
	↑ LDL-C		Familial defective Apo B-100	Anorexia
	Normal Tgs		Polygenic hypercholesterolaemia	Cholestatic liver disease
				Nephrotic syndrome
				Acute intermittent porphyria
				Drugs: thiazide diuretics, corticosteroids
Combined dyslipidaemia	↑ TC	III	Familial dysbetalipoproteinaemia	Diabetes mellitus
	↑ LDL-C	IIb	Familial combined hyperlipidaemia	Metabolic syndrome
	↑ Tgs	IV		Lipodystrophies
	± ↓ HDL-C			Hypothyroidism
				Hepatocellular liver disease
				Nephrotic syndrome
				Chronic renal failure
				Paraproteinaemias
				Pregnancy
				Drugs: β blockers, antiretrovirals, retinoic acid derivatives
Hypertriglyceridaemia	↑↑ Tgs	I	Lipoprotein lipase deficiency	Diabetes mellitus
	↑ TC	IV, V	Apo CII deficiency	Alcohol excess
	↓ HDL-C			Chronic renal failure
				Paraproteinaemias
				Pregnancy (esp. 3rd trimester)
				Drugs: retinoic acid derivatives, oral contraceptives
Other dyslipidaemias	↓ HDL-C only		Tangier disease	
			Apo AI Milano	
	↑ HDL-C		Hyperalphalipoproteinaemia	Alcohol, anabolic steroids
	↓↓ LDL-C		Abetalipoproteinaemia	
	↓ LDL-C		Hypobetalipoproteinaemia	

additional tests. (The LDL cholesterol in a standard lipid profile is calculated from the Friedewald formula:

$$\text{LDL-C} = \text{total cholesterol} - \text{HDL cholesterol} - 0.42 \times \text{triglycerides}$$

To provide a valid estimate of the LDL cholesterol the sample should be taken from a fasting subject and the triglyceride level should be below 4.5 mmol/L.) Such a working classification is shown in Table 59.15; it might at first sight seem confusing that total cholesterol is raised in conditions characterized by predominant hypertriglyceridaemia but this reflects the much increased contribution of triglyceride-rich lipoprotein cholesterol to the total cholesterol in these disorders.

Xanthomata

The term xanthoma derives from the Greek 'xanthos' meaning yellow and is used to describe a variety of subcutaneous lipid deposits, even those that do not appear particularly yellow. All xanthomata contain macrophages loaded with cholesterol and cholesterol esters ('foam cells') [1]; any distinctive features of the different types of xanthoma are discussed below.

Tendon xanthomata

These occur most commonly attached to the extensor tendons over the knuckles and in the Achilles tendon, though other tendons can sometimes be affected. In these sites they can usually be moved from side to side. Occasionally, they can involve the periosteum at the site of insertion of the patellar tendon where they cannot be moved. As the accumulation of cholesterol is deep within the tendons the overlying skin does not appear yellow. The xanthomata contain collagen in addition to foamy macrophages and so feel quite hard. They are most frequently seen in familial hypercholesterolaemia [2,3], but are also a feature of the secondary hypercholesterolaemia seen in prolonged cholestasis and the rare lipid disorders cerebrotendinous xanthomatosis [4] and sitosterolaemia [5]. In all cases other than sitosterolaemia they are indicative of raised levels of LDL cholesterol, though they do not completely resolve with LDL-lowering treatment. However, in the occasional patients where the tendon xanthomata are painful this symptom does improve with LDL cholesterol reduction.

Xanthelasmata (Fig. 59.64)

Xanthelasmata are the xanthomata that develop around the eyes, and were among the earliest recognized historically. They most

Fig. 59.64 Extensive xanthelasmas palpebrarum. (Courtesy of Addenbrooke's Hospital, Cambridge, UK.)

Fig. 59.65 Tuberous xanthomas. (Courtesy of Addenbrooke's Hospital, Cambridge, UK.)

commonly affect the upper eyelids and the area around the medical canthus. They are relatively soft to the touch and range from pale yellow to yellow-orange in colour. They are seen in familial hypercholesterolaemia, type III hyperlipoproteinaemia and in chronic cholestasis (especially primary biliary cirrhosis) [6], but are also often seen in people with circulating lipid levels considered normal in Western populations. Given their rather prominent site they are often noticed by patients, to whom they may be a source of considerable cosmetic distress. They can be removed surgically, or by cauterization or by application of silver nitrate but often recur, particularly if LDL cholesterol levels are high. In these circumstances subsequent treatment to lower LDL cholesterol, for example with a 'statin', seems sensible even if not yet confirmed by clinical trial. Such treatment is often associated with regression of xanthelasmata in hypercholesterolaemic patients without the need for other intervention.

Tuberous xanthomata (Fig. 59.65)
Although starting as small xanthomata, usually over the extensor aspects of the elbows and knees, these can develop into quite

Fig. 59.66 Xanthomatosis and yellow palmar creases. (Courtesy of Addenbrooke's Hospital, Cambridge, UK.)

exuberant exophytic lesions several centimetres in diameter and height. They can develop over other pressure areas such as the heels and plantar surfaces of the feet, and very occasionally can occur in the bone marrow. They can be itchy and are susceptible to trauma given their position. They usually indicate the presence of type III hyperlipoproteinaemia [7]. They respond well to effective treatment of the combined dyslipidaemia characteristic of this disorder.

Palmar xanthomata (Fig. 59.66)
Linear palmar xanthomata consisting of an orange-yellow lipid deposition running along the palmar creases, and occasionally the flexor creases of the wrists, are pathognomonic of type III hyperlipoproteinaemia [7]. Like tuberous xanthomata they respond well to treatment of the dyslipidaemia. They were formerly known as xanthoma striata palmaris.

Eruptive xanthomata (Fig. 59.67)
These small xanthomata consist of small yellow papules 2–5 mm in diameter, arising out of a slightly wider red base and usually appear in large numbers over extensor surfaces, particularly of the buttocks, back, legs and arms. In extreme cases they can be itchy and have an even more widespread distribution, potentially leading to diagnostic confusion. Their foamy macrophages contain triglycerides as well as cholesterol [8]. They only occur with severe hypertriglyceridaemia of any cause (serum triglycerides at least greater than 20 mmol/L), and are therefore almost always accompanied by lipaemia retinalis, a creamy yellow discoloration of the retinal blood vessels, and a lipaemic appearance of blood or serum samples. Eruptive xanthomata resolve well within a couple of weeks of treatment of the hypertriglyceridaemia.

Planar xanthomata (Fig. 59.68)
These xanthomata are wide based and rather flat and can cover the areas usually affected by xanthelasmata, but are usually

Fig. 59.67 Eruptive xanthomas. (Courtesy of Addenbrooke's Hospital, Cambridge, UK.)

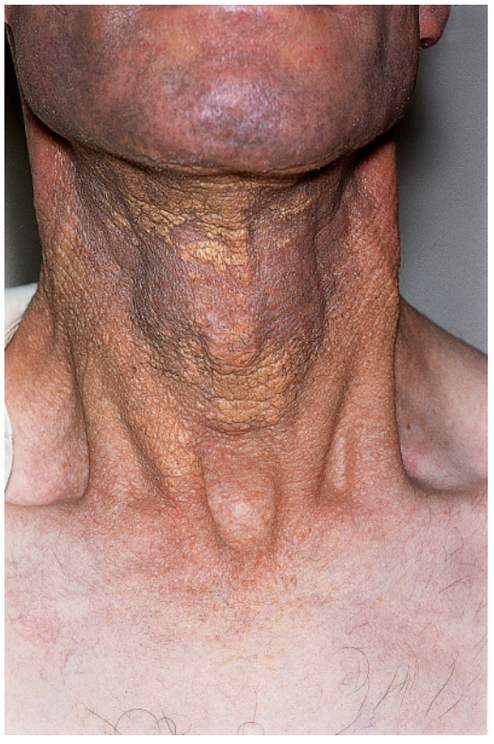

Fig. 59.68 Plane xanthomatosis. (Courtesy of Addenbrooke's Hospital, Cambridge, UK.)

broader and more widespread. They most frequently occur with paraproteinaemias (multiple myeloma or monoclonal gammopathy of uncertain significance (MGUS)) [9,10], when they often develop in areas subject to pressure from clothing or jewellery. Serum lipid levels are infrequently raised, indeed they may be below average, and the precise aetiology is unclear though complexes between immunoglobulins and lipoproteins are often found. When hyperlipidaemia is present a type III hyperlipoproteinaemic pattern is quite common. Occasionally planar xanthomata can be seen in lymphoma and systemic lupus erythematosus; they are also a feature of homozygous familial hypercholesterolaemia. Rarely, patients with paraproteinaemia develop necrobiotic xanthogranuloma with widespread, severe xanthelasmata that can cause complete closure of the eyelids accompanied by subcutaneous xanthogranulomata of the face and body [11].

Corneal arcus

Corneal arcus is not strictly a xanthoma, but does represent the deposition of cholesterol esters in the peripheral cornea. It is commoner in young people with familial hypercholesterolaemia (it is present in 50% of heterozygotes by the age of 30), but can occur with other causes of longstanding hypercholesterolaemia and in subjects with normal circulating lipid levels. In its early stages it is not a complete ring, but comprises superior and inferior crescents that may only be evident with eyelid retraction. With increasing age its specificity for familial hypercholesterolaemia falls even further. Corneal arcus does not regress with lipid-modulating drug treatment, but neither does it ever impair vision.

Primary dyslipidaemias

Hypercholesterolaemia

Familial hypercholesterolaemia

Clinical features. Familial hypercholesterolaemia (FH) is an autosomal co-dominant condition characterized by:

- High total and LDL cholesterol, slightly low HDL cholesterol and normal triglyceride concentrations

Table 59.16 Lipid concentrations in familial hypercholesterolaemia [6].

	Total Cholesterol (mM)	LDL-Cholesterol (mM)	HDL-Cholesterol (mM)	Triglycerides (mM)
Normal	4.52 ± 0.72	2.84 ± 0.64	1.37 ± 0.33	0.68 ± 0.28
Heterozygotes	7.73 ± 1.63	6.23 ± 1.55	1.11 ± 0.31	0.93 ± 0.58
Homozygotes	17.5 ± 4.39	16.1 ± 4.13	0.88 ± 0.26	1.14 ± 0.58

- Frequent tendon xanthomata (especially of the Achilles tendons)
- Premature onset of cardiovascular disease.

The familial clustering of these three features has been recognized since at least the late 19th century and was the subject of detailed studies in the 1930s [1,2]. In the 1950s, the development of ultracentrifugation for quantifying lipoproteins revealed that the biochemical hallmark of FH is an accumulation of LDL [3], and in 1973 Goldstein and Brown discovered the LDL receptor and showed that its defective functioning was the underlying cause of the condition [4]. Homozygotes number about 1 per million in Caucasian populations and can have total cholesterol levels of 15 mmol/L or higher, may be born with tendon xanthomas and can suffer from the clinical effects of coronary heart disease as early as their teens. They can also develop a supravalvular aortic stenosis. Heterozygotes occur at a frequency of about 1 in 500 in most Caucasian populations, though with notably higher frequency in certain groups, for example Afrikaners and the Lebanese, where there are marked founder gene effects. They have less marked elevations in their cholesterol than homozygotes (Table 59.16), but of untreated males 50% will have suffered a myocardial infarction (MI) and 24% will have died by age 50 years. Heterozygous females have a slightly delayed onset of CVD compared with males but 58% will have had an MI and 15% have died by the age of 60 if not treated [5]. FH thus accounts for a significant proportion of premature cardiovascular disease and of premature sudden cardiac death. There is a striking preponderance in FH of coronary arterial disease, as opposed to cerebrovascular or peripheral vascular disease.

The presence of tendon xanthomata is the principal cutaneous manifestation of FH [1], and may often be helpful in establishing the diagnosis. They are usually present in childhood in homozygotes and become more prevalent with age in untreated heterozygotes. They occur most frequently in extensor tendons, especially the Achilles tendons and those over the knuckles. They feel rather hard as they contain fibrous tissue as well as cholesterol, and they can become inflamed. They are not invariably present, especially if treatments to reduce the LDL cholesterol are begun at a sufficiently early age. They can also occur in two other disorders of sterol metabolism, cerebrotendinous xanthomatosis [6] and sitosterolaemia [7], both of which are extremely rare. Subcutaneous planar and tuberous xanthomata may occasionally be seen in FH homozygotes, but not heterozygotes. Corneal arcus is seen in many but not all cases and lacks both sensitivity and specificity for establishing the diagnosis though it does feature in some sets of criteria. Specifically, its presence and severity does not correlate with the risk of CVD in FH. Xanthelasmata are not commonly seen in FH; where they do occur they can respond to treatment that reduces LDL cholesterol concentrations. They can also be removed surgically but can recur more markedly thereafter; the efficacy of LDL reduction in this setting awaits confirmation but is quite common clinical practice.

Genetics and diagnosis. The majority of patients with FH have mutations in their LDL receptor associated with a variable degree of loss of function. As a result there is both defective clearance of VLDL from the circulation with consequent increased conversion to LDL and impaired clearance of LDL resulting in the significant elevation of LDL cholesterol concentration which accounts for the raised plasma total cholesterol. Over 1000 disease-associated mutations have so far been described in the LDL receptor gene (which is one of the largest human genes) [8]. They have been classified on the basis of the effect they have on the synthesis, expression and processing of the LDL receptor [9]:

Type 1 prevent receptor synthesis
Type 2 impair transport of the receptor from the endoplasmic reticulum to the Golgi
Type 3 affect receptor binding of circulating LDL
Type 4 prevent clathrin-mediated receptor clustering and internalization
Type 5 interfere with receptor recycling from the endosome.

Type 1 mutations tend to result in a complete absence of LDL receptor activity ('receptor negative') while the other classes of mutations usually cause markedly reduced but not completely absent activity ('receptor defective').

In a small proportion of patients with FH (around 2%) the mutation affects not the LDL receptor but the receptor binding domain in the LDL apo B-100 (familial defective apo B-100) [10]. This is almost always due to a mutation in codon 3500 (R3500Q) resulting in a substitution of arginine for glutamine; rarely it is due to a different mutation in codon 3500 (R3500W, in which tryptophan replaces arginine) or in codon 3531. Such patients are phenotypically indistinguishable from those with LDL receptor mutations though there is some evidence that their cardiovascular risk is not as dramatically raised. Recently, a new genetic locus has been found to account for some of the previously mutation-negative cases of FH; the gene codes for proprotein convertase subtilisin kexin 9 (PCSK9) [11], a serine protease whose activity appears to decrease LDL receptor expression and LDL clearance and thus increases LDL cholesterol concentration. It has emerged that statins upregulate PCSK9, so it represents an interesting target for agents to augment the LDL-lowering effect of these drugs. Finally, a small group of patients, all from Sardinia, have a phenotype similar to homozygous FH but inherited in a recessive pattern—autosomal recessive hypercholesterolaemia (ARH) [12].

Given the genetic heterogeneity underlying FH, diagnosis has largely rested on clinical and biochemical criteria. In the United Kingdom, the criteria used by the Simon Broome Register of patients with FH have been widely adopted (Table 59.17). Other sets of diagnostic criteria have also been developed, for example the Dutch Lipid Clinic Network Criteria [13] and the Make Early Diagnosis to Prevent Early Disease on Medical Pedigree (MEDPED) system [14]. Increasingly, advances in molecular biological

Table 59.17 Simon Broome Register criteria for diagnosing familial hypercholesterolaemia. (From Scientific Steering Committee of the Simon Broome Register Group. Risk of fatal coronary heart disease in familial hypercholesterolaemia. *BMJ* 1991; **303**: 893–6.)

Definite FH
- total cholesterol above 6.7 mM or LDL cholesterol above 4.0 mM in children under 16 or total cholesterol above 7.5 mM or LDL cholesterol above 4.9 mM in adults

plus
- tendon xanthomata in patient or 1st or 2nd degree relative

or
- FH mutation detected

Possible FH
- total cholesterol above 6.7 mM or LDL cholesterol above 4.0 mM in children under 16 or total cholesterol above 7.5 mM or LDL cholesterol above 4.9 mM in adults

plus
- family history of MI <50 in 2nd degree relative or <60 in 1st degree relative

or
- family history of total cholesterol >7.5 mM in 1st or 2nd degree relative.

techniques are proving helpful in diagnosing FH; this is particularly true where a disease-causing mutation has been identified in one family member.

Treatment. The hypercholesterolaemia of FH will only respond marginally to lifestyle measures such as reducing saturated fat intake. However, encouraging patients with measures that reduce cardiovascular risk, such as avoiding smoking and exercising regularly, clearly make sense, and may help account for the reduced risk of cancer, particularly lung and colon cancer, seen in the Simon Broome Register [15]. In recent years, statins have become the mainstay of treatment and they are likely to have played a large part in the reduction of cardiovascular mortality seen in recent years in FH. In comparison with the general population, statins usually have to be started at a much earlier age in patients with FH, and to achieve the desired reduction in LDL cholesterol (recently the National Institute for Health and Clinical Excellence (NICE) in the UK has advised a greater than 50% reduction) [16], higher doses of the more potent statins may well have to be used. Referral to a specialist lipid clinic is advised to allow counselling of young patients starting lifelong therapy, especially young women where the specific issue of the potential teratogenicity of the statins and family planning needs to be fully explored. Such clinics will have experience of other therapies that can prove helpful, including the bile acid sequestrants and LDL apheresis. Ezetimibe is a relatively new agent that works to reduce intestinal cholesterol absorption mediated by the recently described transporter Niemann Pick C-1 Like Protein 1 (NPC1L1); it is well tolerated and can augment the LDL reduction achieved by statins by a further 20% [17], but evidence that it is clinically effective in reducing CVD risk is still awaited. Tendon xanthomata and xanthelasmata may respond to the reduction in LDL cholesterol; corneal arcus does not. FH homozygotes must be referred for specialist assessment and treatment; their cholesterol does not respond well to statins or other drug therapies that work by up-regulating LDL receptor expression. These patients often require LDL apheresis and occasionally liver transplantation as well as coronary revascularization and aortic valve surgery [18].

Combined dyslipidaemia

Type III hyperlipoproteinaemia

Clinical features. Type III hyperlipoproteinaemia merits discussion for several reasons. It may have been the first recognized disorder of lipoprotein metabolism; Addison and Gull reported a patient with its typical cutaneous hallmarks in 1851. It has a plethora of aliases (including broad-beta disease, dysbetalipoproteinaemia and remnant removal disease) reflecting the gradual

emergence of our understanding of the biochemical basis of the condition. It is an excellent example of a disease resulting from a gene–environment interaction.

There are several skin manifestations of type III hyperlipoproteinaemia. The most characteristic are linear yellow-orange lipid deposits within the palmar creases and sometimes the flexor creases of the fingers and wrists. They are called striate palmar xanthomata (Fig. 59.66). Tuberous xanthomata are also common over the tuberosities of the elbows and knees (Fig. 59.65). They start as yellowish papules that gradually coalesce to form larger, sometimes exuberant, exophytic lesions. Where a central tuberous xanthoma is surrounded by several smaller lesions they are sometimes called tuberoeruptive xanthomata. They can also occur over the heel; being subcutaneous and yellow in colour they are not difficult to distinguish from Achilles tendon xanthomata. Patients with type III hyperlipoproteinaemia with particularly high triglyceride concentrations may also develop lipaemia retinalis and eruptive xanthomata over their buttocks (Fig. 59.67). Striate palmar and tuberous xanthomata can occasionally be seen in the paraproteinaemias and systemic lupus erythmatosus.

Estimates of the frequency of type III hyperlipoproteinaemia vary, reflecting the lack of clear diagnostic criteria, but range between about 1 and 10 in 10 000. There is evidence of an increased risk of both coronary artery and peripheral arterial disease, especially in those with all the clinical and biochemical features of the disorder in whom up to 50% have premature CVD [1]. Gout also appears common in this group of patients [2]. Type III hyperlipoproteinaemia has been associated with lipoprotein glomerulopathy, manifesting as proteinuria or the nephrotic syndrome [3]. Renal biopsy shows glomerular foam cells; the condition usually resolves with successful treatment of the abnormal lipid profile.

Biochemistry and genetics. Patients with type III hyperlipoproteinaemia have a characteristic lipoprotein electrophoretic pattern; indeed this remains the gold standard diagnostic test. There is an increase in small VLDL and IDL and a decrease in LDL. VLDL isolated from type III patients is uncharacteristically enriched with cholesterol esters and gives rise to a broad-β migrating band, rather than the usual pre-β band [4,5]. This results from an accumulation of VLDL remnants and chylomicron remnants and produces a marked increase in plasma total cholesterol and triglycerides. The underlying defect is an abnormal apoE [6], the apolipoprotein in remnant lipoproteins that mediates their binding to the LDL receptor and the LRP. There are three common isoforms of apo E: apo E2, E3 and E4, each differing by one amino acid (Table 59.18).

Apo E2 homozygosity represents by far the commonest abnormality associated with type III hyperlipoproteinaemia; its cysteine at residue 112 is within the receptor binding domain of the protein and its cysteine at residue 158 affects salt bridges within the protein and thereby the conformation of the receptor binding domain. Very occasionally, other apo E mutations are associated with type III hyperlipoproteinaemia, many of which severely reduce apo E mediated receptor binding and can cause the disorder in heterozygotes [7].

However, less than 10% of subjects homozygous for apo E2 develop type III hyperlipoproteinaemia, and most of the rest have lower than average lipid levels. It is clear that a second factor is required for the development of type III hyperlipoproteinaemia, either environmental or genetic. Increased production of chylomicrons or VLDL can be one such factor and may result from excessive caloric intake, increased alcohol consumption, obesity, type 2 diabetes mellitus, the metabolic syndrome or from an interplay of multiple genetic influences on lipoprotein metabolism (as presumed to underlie familial combined hyperlipidaemia (FCH)). Equally, increasing age, hypothyroidism or post-menopausal oestrogen deficiency can further impair apo E mediated receptor catabolism of lipoproteins and result in the development of the disorder.

Table 59.18 The amino acid differences between the isoforms of apo E.

	E2	E3	E4
Residue 112	Cysteine	Cysteine	Arginine
Residue 158	Cysteine	Arginine	Arginine

Treatment. Identification and treatment of any contributing lifestyle factors or diseases is clearly central to the management of patients with type III hyperlipoproteinaemia. Patients should be screened for obesity, diabetes and hypothyroidism and treated accordingly. Dietary advice should be given and exercise, which increases the activity of lipoprotein lipase and thereby reduces chylomicron and VLDL remnant production, encouraged. Such measures are often successful in improving the lipid profile on their own; in their absence drug therapy is usually less effective. Normally both statins [8] and fibrates [9] work well, both in improving the lipid profile and also in causing regression of the palmar and tuberous xanthomata. Occasionally combined statin and fibrate therapy may be required.

Hypertriglyceridaemias

Type I hyperlipoproteinaemia

Clinical, biochemical and genetic features. In type I hyperlipoproteinaemia there is an accumulation of chylomicrons alone. It results from a deficiency of lipoprotein lipase (LPL), and as such shows an autosomal recessive pattern of inheritance (though there is accumulating evidence that some heterozygotes for LPL deficiency may show a milder degree of hypertriglyceridaemia). The condition is extremely rare with a frequency of perhaps 1 per million in most populations, but with higher frequency in some populations such as French Canadians due to founder gene effects. An increasing number of mutations in the LPL gene have been described. Some cases result from apo CII deficiency, an essential factor for LPL activation; this discovery followed from the observation that the hyperchylomicronaemia was alleviated in some patients following plasma infusions [1].

Familial LPL deficiency causes extremely elevated levels of serum triglycerides, often greater than 20 mM. Total cholesterol levels are often substantially elevated as well, reflecting the extreme concentrations of chylomicrons which do contain some cholesterol and cholesterol esters as well as their predominant triglycerides. Blood, serum or plasma from such patients will appear milky and a creamy layer will separate on top of the sample if centrifuged or allowed to stand for some hours. Hyperchylomicronaemia will be present from childhood onwards in homozygous LPL deficiency. It remains unclear why LPL deficiency can cause an isolated accumulation of chylomicrons, given the role of the enzyme in VLDL catabolism. However, with increasing age there is a progressive shift towards a type V hyperlipoproteinaemic pattern (see below).

The principal concern in type I hyperlipoproteinaemia is the increased risk of acute pancreatitis with its attendant morbidity and mortality [2]. Whilst hypertriglyceridaemia may be a consequence of acute pancreatitis there is clear evidence it may also be a cause, perhaps accounting for up to 10% of cases. The risk increases with increasing fasting triglyceride levels, with a threshold around 10 mmol/L, rising markedly beyond 20 mmol/L, although other factors must play a part as some patients seem remarkably immune from attacks despite grossly elevated triglyceride concentrations. The mortality is further increased because the serum amylase, so often used as a sole diagnostic test for acute pancreatitis, may well not be elevated [3]. (It is possible that the very elevated triglyceride levels interfere with the amylase assay; dilution of the serum sample can sometimes reveal the raised amylase concentration.) As a result, many such patients have undergone laparotomy to establish the cause of their severe abdominal pain and the examination findings of generalized tenderness and guarding, with the consequent physical stress further exacerbating their hypertriglyceridaemia.

The characteristic skin finding in patients with type I hyperlipoproteinaemia is eruptive xanthomata (Fig. 59.67), yellowish papules several millimetres in diameter occurring over extensor surfaces, particularly the buttocks and the backs of the legs [4]. The rash may be itchy. It usually indicates triglyceride levels in excess of 20 mmol/L, and is seen with all causes of such severe hypertriglyceridaemia. It responds to lowering of the triglycerides, though it tends to last a few days longer than the lipid abnormality. Clearance of chylomicrons from the circulation by cells of the reticuloendothelial system can result in hepatomegaly and splenomegaly, with splenic infarcts in some cases. Lipaemia retinalis, with creamy yellow discoloration of the retinal arterioles and veins, can be seen on fundoscopy and in very severe hypertriglyceridaemia can appear almost fluorescent [5].

Treatment. The principal treatment of severe hypertriglyceridaemia involves strict restriction of all dietary fats (not just saturated fats) to reduce chylomicron production as much as possible [6]. Attention must be paid to any other factors that may increase the production of, or decrease the clearance of, the triglyceride rich lipoproteins (TRLs); good control of diabetes, weight reduction where appropriate, alcohol restriction and a review of all other medications are particularly important. Intake of refined carbohydrates should also be limited. Fibrates usually have little effect in genetic LPL deficiency. Nicotinic acid derivatives can be helpful. Bile acid sequestrants are contraindicated as they may increase the triglyceride level. Infusions of fresh frozen plasma are beneficial in those with apo CII deficiency who present with acute pancreatitis. Antioxidant therapy has proved very effective in reducing the frequency of attacks of acute pancreatitis in a number of patients with severe hypertriglyceridaemia [7]. All patients with severe hypertriglyceridaemia should have access to specialist lipid clinics.

Type V hyperlipoproteinaemia

Clinical and biochemical features. Type V differs from type I hyperlipoproteinaemia in that there is an accumulation of VLDL as well as chylomicrons. It is also far commoner, perhaps affecting 1 in every 5–10 000, and although it can result from LPL deficiency this only accounts for a very small proportion of cases. Patient samples will demonstrate some milkiness with the separation of a creamy layer after standing or centrifugation (made up of chylomicrons) but the serum or plasma will be opaque, representing the presence of VLDL. Patients with type V hyperlipoproteinae-

mia may have relatives with hypertriglyceridaemia as well, though many of these will have a type IV lipoprotein pattern (see below). This has led to the hypothesis that most type V patients have a reasonably marked defect in the catabolism of TRLs combined with some additional factor that either further decreases catabolism or additionally increases the production of TRLs. Such factors include obesity, poor diabetic control, alcohol consumption, pregnancy, drugs (oral contraceptives, highly-active antiretroviral therapy, β-blockers and thiazide diuretics being the main offenders), hypothyroidism, lipodystrophy and renal failure.

Lipid levels in type V hyperlipoproteinaemia may be as markedly elevated as in type I. Acute pancreatitis, eruptive xanthomata, hepatosplenomegaly, lipaemia retinalis and all the other clinical features of type I hyperlipoproteinaemia may be present. Additionally, hyperuricaemia, glucose intolerance and hepatic steatosis are often seen.

Treatment. The treatment of type V hyperlipoproteinaemia is exactly as for type I, though fibrates are generally far more effective.

Type IV hyperlipoproteinaemia

Clinical and biochemical features. In type IV hyperlipoproteinaemia VLDL accumulate but without any increase in chylomicrons. The degree of hypertriglyceridaemia is usually much less marked than in type I or type V hyperlipoproteinaemia, with many patients having fasting triglycerides less than 6 mmol/L and most less than 10 mmol/L. Patients with type IV hyperlipoproteinaemia are heterogeneous, the common abnormality being an increased production of VLDL by the liver [1], often accompanied by a partial defect in their catabolism [2]. As with other forms of hypertriglyceridaemia, LDL tend to be smaller and denser, a pattern of abnormalities associated with increased cardiovascular risk. Apart from those rare type IV patients with marked hypertriglyceridaemia, the clinical features of type I and type V hyperlipoproteinaemia are not present.

Treatment. Lifestyle modification along the lines of that advocated for severe hypertriglyceridaemia (see above) is appropriate for type IV hyperlipoproteinaemia. However, dietary fat restriction does not have to be so marked, and can be mainly restricted to saturated fats. Indeed intake of omega-3 unsaturated fatty acids may be beneficial. The need for drug therapy will largely be guided by estimations of the 10-year CVD risk; many type IV patients will require such treatment and the first line will often be the statins because of their proven efficacy in reducing that risk, even though they do not usually much affect hypertriglyceridaemia.

Other primary dyslipidaemias [1,2]

Cerebrotendinous xanthomatosis

This autosomal recessive condition is a rare cause of tendon xanthomata and xanthelasmata. It results from a defect in sterol 27-hydroxylase with consequent increased production of cholestanol and 7-hydroxycholesterol which accumulate in plasma and throughout the body. Accumulation in the central nervous system causes myelin destruction leading to mental retardation, seizures, spasticity and ataxia; peripheral neuropathy results from similar pathology in the peripheral nervous system. Presentation occurs during childhood or early adult life. Early-onset cataracts, diarrhoea and premature osteoporosis are additional features. Patients are at risk of cardiovascular disease, although plasma cholesterol levels are normal. Treatment with chenodeoxycholate reduces plasma cholestanol concentrations and improves the neurological manifestations of the disease.

Sitosterolaemia

This is another rare, autosomal recessive cause of tendon and tuberous xanthomata. It results from mutations in the genes *ABCG5* or *ABCG8* which encode the proteins sterolin-1 and sterolin-2 in enterocytes and hepatocytes. Sterolin-1 and sterolin-2 act together to form a lipid transporter that is thought to facilitate immediate excretion of any plant sterols absorbed across the small intestinal brush border. Defective function thereby allows much increased absorption of plant sterols into the body, principally β-sitosterol but also sitostanol, campesterol and stigmasterol. Patients suffer from impaired growth, anaemia, thrombocytopenia and arthritis and are at risk of premature CVD. Diagnosis is made by measuring serum plant sterol concentrations. It has recently been shown that ezetimibe reduces plant sterol levels effectively in this condition, suggesting a role for the Niemann–Pick C1-like protein in plant sterol transport in the intestine.

Tangier disease

In Tangier disease cholesterol esters accumulate in foam cells throughout the reticuloendothelial system. Clinically, this manifests most consistently as enlarged, yellow-orange tonsils, but similar deposits can also be seen in the rectal mucosa and generalized lymphadenopathy and hepatosplenomegaly can be found. Thrombocytopenia is a frequent finding, resulting usually from a combination of hypersplenism and foam cell infiltration of the bone marrow. Peripheral neuropathy and corneal opacities have also been described; the latter only evident on slit-lamp examination. The biochemical hallmark of Tangier disease is a low level of HDL-cholesterol with near complete absence of apo AI. Total cholesterol levels are also lower than average, partly because of the low HDL cholesterol but LDL cholesterol is also usually reduced. The disease results from mutations in the gene coding for ABCA1; this discovery led to the elucidation of the role of this lipid transporter in cellular cholesterol efflux, the first step in reverse cholesterol transport. It has been shown that the majority of HDL cholesterol arises from expression of ABCA1 in the liver, and that if liver ABCA1 is defective the newly secreted discoidal apo AI/AIV particles cannot be stabilized by incorporating cholesterol, are rapidly cleared by the kidney and cannot participate in peripheral cellular cholesterol efflux. (It is striking how much of our under-

standing of human lipoprotein metabolism has come from studies of rare dyslipidaemias.) Although there are reports of premature CVD in Tangier disease, this does not seem as common as might be expected from the low levels of HDL cholesterol.

Secondary dyslipidaemias [1]

Dyslipidaemias are frequently secondary to, or exacerbated by, a range of other diseases or medications. The following account is far from exhaustive but will concentrate on those that may produce xanthomata or follow from the use of drugs used by dermatologists.

Perhaps the commonest cause of secondary dyslipidaemia at present is diabetes mellitus. Type 1 diabetics frequently have quite high HDL cholesterol levels, but they also have a number of abnormalities of their LDL and VLDL and they are at high CVD risk. Type 2 diabetics have insulin resistance; their typical lipid profile includes relatively normal total and LDL cholesterol levels, but often somewhat increased triglyceride and reduced HDL cholesterol concentrations. These quantitative abnormalities are usually accompanied by qualitative changes in the LDL with a preponderance of highly atherogenic small dense LDL. As a result, type 2 diabetics are also at high risk of developing premature CVD. It is now recommended that statins should be considered for all diabetics over the age of 40 years, and in younger diabetic patients with other CVD risk factors including microalbuminuria. In some patients the development of type 2 diabetes, or worsening of its glycaemic control, can cause marked hypertriglyceridaemia (with a type IV or V hyperlipoproteinaemia) with all its clinical features including eruptive xanthomata, lipaemia retinalis and acute pancreatitis. This is most likely to occur on the background of some mild defect of triglyceride-rich lipoprotein clearance, and may be further exacerbated by the concomitant presence of obesity and excess alcohol intake. Diabetes can also precipitate the development of type III hyperlipoproteinaemia in those with the appropriate genetic background (usually homozygosity for apo E2); such patients may present to a dermatologist with the typical xanthomata of this condition. It follows that in any patient presenting with eruptive, tuberous or planar xanthomata a fasting glucose and/or HbA1c should be requested along with the lipid profile and other appropriate tests.

Patients with insulin resistance, but without type 2 diabetes mellitus, have a similar combined dyslipidaemia. In some a marked hypertriglyceridaemia can develop, sufficient to cause eruptive xanthomata. This is seen quite commonly in the lipodystrophies, a group of disorders with either partial or generalized loss of subcutaneous fat. They can be inherited (e.g. Dunnigan–Köbberling syndrome) or acquired. The latter is now most commonly seen in patients with human immunodeficiency virus/acquired immunedeficiency syndrome (HIV/AIDS) who are having treatment with protease inhibitors, especially saquinavir and ritonavir. Management of lipodystrophy-associated dyslipidaemia is likely to require specialist input; the principles are lifestyle change, especially strict dietary fat restriction in hypertriglyceridaemia, optimization of the drug regimen in HIV, and judicious, monitored use of lipid-modulating drug therapy, given the potential for significant interactions between statins, fibrates and the antiretroviral agents.

It has already been noted that xanthelasmata can be a feature of chronic cholestasis. This can occur, for example, in primary biliary cirrhosis and the presence of xanthelasmata should prompt a request for blood tests including a bilirubin and an alkaline phosphatase at least. Long-standing cholestasis is associated with hypercholesterolaemia due to the accumulation of an abnormal lipoprotein, lipoprotein X. It remains unclear whether this dyslipidaemia increases CVD risk, but it can cause a wide range of xanthomata as well as xanthelasmata. Both the dyslipidaemia and the xanthomata improve with relief of biliary obstruction; where this is not possible bile acid sequestrants can be helpful (and may also relieve the pruritus associated with cholestasis). Where necessary statins can be used, but cautiously to avoid accumulation and toxicity. Hepatocellular liver disease leads to specific lipoprotein abnormalities, principally abnormal HDL secondary to progressive deficiency of lecithin-cholesterol acyl transferase with mild hypertriglyceridaemia, but these are not usually severe enough to cause xanthomata.

Nephrotic syndrome is complicated by hypercholesterolaemia or a combined dyslipidaemia that can prove difficult to treat. Hypertriglyceridaemia is not usually marked though occasionally a type IV hyperlipoproteinaemia may occur. Xanthomata are not a frequent feature and the dyslipidaemia resolves if the nephrotic syndrome responds to therapy. Chronic renal failure leads to hypertriglyceridaemia, often exacerbated by haemodialysis or peritoneal dialysis, and this can sometimes lead to eruptive xanthomata especially if other risk factors are present. Lipoprotein(a) levels are elevated and may contribute to the increased CVD risk in this population but do not produce any dermatological signs.

The characteristic xanthomata associated with the paraproteinaemias (planar xanthomata and necrobiotic xanthogranuloma) have been discussed earlier. Their presence does not necessarily reflect a measurable dyslipidaemia, though a hyperlipoproteinaemia similar to type III may be present. The pathophysiology underlying paraproteinaemia-associated xanthomata and dyslipidaemia remains unclear although lipoprotein–immunoglobulin complexes are a common finding, usually involving VLDL. These abnormalities have occasionally also been reported in lymphoma and systemic lupus erythematosus. Very rarely, immunoglobulins directed against the LDL receptor can produce a hypercholesterolaemia with total and LDL cholesterol levels similar to those seen in FH homozygotes but without any tendon xanthomata. This has been referred to as 'pseudo familial hypercholesterolaemia'.

Many drugs can produce dyslipidaemia, alcohol perhaps being the commonest example and a frequent contributor to marked hypertriglyceridaemia. Of the prescription drugs used by dermatologists it is worth considering corticosteroids, ciclosporin and retinoic acid derivatives. Systemic corticosteroids increase total, LDL and HDL cholesterol levels. Unless they precipitate diabetes

mellitus in a susceptible individual, they do not cause hypertriglyceridaemia. Ciclosporin increases LDL cholesterol levels, sometimes quite significantly. It also inhibits cytochrome P450 3A4, the isoform responsible for the metabolism of fluvastatin, simvastatin and atorvastatin, so patients taking these statins should be advised of the possible interaction and the risk of myalgia. In some patients (e.g. those with hepatic or renal impairment, or taking other drugs that affect CYP450 3A4), it may be appropriate to reduce the statin dose or to change to an alternative (pravastatin or rosuvastatin are less dependent on CYP450 3A4). Retinoic acid derivatives often induce hypertriglyceridaemia; this is usually mild and does not necessarily require anything other than dietary modification. Occasionally, however, marked hypertriglyceridaemia with a type IV or V hyperlipoproteinaemic pattern can be provoked—usually in a susceptible individual who may well have evidence of dyslipidaemia prior to treatment. It is therefore sensible to include a full lipid profile on any pre-treatment blood tests and to repeat this several weeks after starting any retinoids.

Treatment [1]. Treatment of dyslipidaemia requires the identification and treatment of any secondary cause, dietary modification and drug therapy in appropriate cases. The mainstay of dietary therapy is a reduction in the total intake of fat, especially saturated fat. Associated dietary interventions that are worthwhile include increasing the intake of monounsaturated and omega-3 unsaturated fatty acids and of antioxidant vitamins (found in fresh fruit and vegetables); these may not alter the standard lipid profile but some do cause qualitative differences in various lipoproteins and they are of benefit in reducing cardiovascular risk. The only exception to this is in cases of severe hypertriglyceridaemia where all fat intake must be severely restricted (to 20–25 g per day) to reduce intestinal chylomicron production. Given that one of the principal aims of treating dyslipidaemia is to reduce CVD risk, dietary therapy should be accompanied by discussion of exercise, smoking cessation and weight optimization.

Statins are the most effective and best tolerated of the drugs available that reduce cholesterol levels. They act by inhibiting 3-hydroxy, 3-methyl-glutaryl CoA reductase, the rate-limiting step in intracellular cholesterol biosynthesis, with a consequent up-regulation of hepatic LDL receptor expression and increased clearance of LDL from the circulation. Throughout the various statin trials there has been a highly consistent relationship between the absolute reduction achieved in the LDL cholesterol level and the relative reduction in cardiovascular risk; other means of lowering LDL cholesterol levels (e.g. bile acid sequestrants and ileal resection) produce a strikingly similar relationship though based on a much smaller body of evidence. The role of statins in treating FH has already been discussed; they should also be offered to all patients with clinical cardiovascular disease, to all diabetics aged over 40 years (and to diabetics under age 40 years with other CVD risk factors including microalbuminuria), to patients with other diseases that predispose to CVD (e.g. renal failure, metabolic syndrome, rheumatoid arthritis, etc.), or to anyone whose 10-year CVD risk exceeds 20% after lifestyle modification. Some patients do develop muscle problems with statin therapy; it is wise to inform patients of this possibility when starting or changing statins, with the advice that if they develop widespread muscle ache or pain they should stop the drug and seek medical review. Risk factors for developing myalgia include high statin dose, hepatic or renal impairment and co-administration of drugs that inhibit cytochrome enzymes. Females of child-bearing age should be counselled about the potential teratogenicity of the statins; current advice is that they should stop the statins 1 month before starting to try to conceive and that if they do become pregnant while taking a statin they should be seen urgently in a specialist lipid clinic. Liver enzymes should be monitored periodically after introducing statins.

Bile acid sequestrants lower total and LDL cholesterol but rather less effectively than statins. Nonetheless they have been shown to reduce CVD risk. They have the advantage that they are not absorbed from the intestine, where they work by binding the bile acids resulting from hepatic cholesterol catabolism and preventing their reabsorption in the terminal ileum. They therefore do not cause myalgia or abnormal liver function tests and are safe during pregnancy and breastfeeding. However, they have the disadvantage of being unpleasant to take and do cause gastrointestinal side effects. Ezetimibe is the latest agent that reduces total and LDL cholesterol. It works by blocking the newly described intestinal lipid transporter Niemann–Pick C1 like protein. It is well tolerated. Evidence that it reduces CVD risk is still awaited, so it remains a second- or third-line agent for those unable to tolerate statins or bile acid sequestrants or who fail to achieve satisfactory lipid profiles with them. It is the drug of choice for sitosterolaemia.

Fibrates are also well tolerated. They are now known to exert their multiple effects as agonists of peroxisome proliferators-activated receptor α (PPAR-α). Their main lipid effect is to reduce triglyceride levels by decreasing VLDL, and they also reduce β-VLDL in type III hyperlipoproteinaemia. They can increase HDL cholesterol. Trial evidence of their overall clinical effect is mixed; some trials have certainly shown reduced CVD risk with fibrates but others have not and there are as yet no clear data that they reduce overall mortality. Their main clinical role is in the treatment of severe hypertriglyceridaemia and of type III hyperlipoproteinaemia. They can also improve the lipid profile of those type 2 diabetic patients whose CVD risk remains high and largely driven by high triglycerides and low HDL cholesterol despite optimal statin therapy. Such combination therapy seems to run a lower risk of myalgia, myositis and rhabdomyolysis than once thought, but should be instituted in a clinic with experience of its monitoring. Clinical trials of statin–fibrate co-administration are under way. Fibrates can increase the serum creatinine and potentiate oral anticoagulants so renal function and INR need to be checked after initiation.

For some time, high-dose nicotinic acid has been known to have very favourable effects on the lipid profile. It lowers total and LDL cholesterol and triglycerides, increases HDL cholesterol more than any of the other drugs so far discussed and is the only drug that significantly reduces lipoprotein(a) levels. The mechanisms by which it achieves these changes are largely unknown. However, its clinical use has been much limited by its side effects: severe

flushing especially at higher doses, hyperglycaemia (a particular issue for the diabetics whose lipid profile might best be helped by it), and worsening of peptic ulcer disease. A couple of trials have found a reduction in CVD or atherosclerosis progression, either in combination with diet or statins. A new preparation of nicotinic acid (Niaspan®) does seem to have a reduced tendency to cause flushing or hyperglycaemia; this is also shortly to be combined with a prostaglandin D2 receptor-1 antagonist, which promises further improvements in tolerability. At present, use of nicotinic acid derivatives remains largely confined to specialist lipid clinics.

Conclusion

Dyslipidaemias may present to dermatologists because they may cause subcutaneous and other lipid deposits collectively known as xanthomata. Not all such xanthomata are associated with abnormal circulating lipids, but where they are the underlying dyslipidaemia is likely to be severe and to require therapy that can reduce the risks of acute pancreatitis (in severe hypertriglyceridaemia) and of premature cardiovascular disease. Appropriate recognition of xanthomata and identification and management of any underlying dyslipidaemia can therefore be as effective a life saver as DC cardioversion during an acute MI in the Emergency Department—and more timely!

Disorders of amino-acid metabolism

There is a very wide array of disorders of the metabolism of the amino acids. This section will concentrate on those with significant cutaneous components in their presentation.

Hyperphenylalaninaemia syndromes

These syndromes result from defective hydroxylation of phenylalanine to tyrosine, with the consequent accumulation of phenylalanine in plasma, since this is the principal pathway for the breakdown of phenylalanine. This reaction is catalysed by phenylalanine hydroxylase (PAH) and requires the presence of the cofactor tetrahydrobiopterin (BH_4), which is itself converted to 4α-hydroxytetrahydropterin (also called 4α-carbinolamine) in the process. BH_4 is restored by the sequential action of 4α-carbinolamine dehydratase and dihydropterin reductase (DHPR). Synthesis of BH_4 from guanosine triphosphate (GTP) is catalysed by GTP-cyclohydrolase and 6-pyruvoyl tetrahydopterin synthase (6-PTS). The commonest clinical hyperphenylalaninaemia syndrome is phenylketonuria.

Phenylketonuria (MIM *261600)

Synonyms

- Hyperphenylalaninaemia type I
- Folling's disease
- Phenylpyruvic oligophrenia

Phenylketonuria (PKU) is a rare inherited disease defined by plasma phenylalanine levels exceeding 1000 µmol/L (normal range less than 120 µmol/L). (Patients with phenylalanine levels above the normal range but less than the defining concentration are described as having non-PKU hyperphenylalaninaemia.) PKU can be caused by primary deficiency of PAH, reduced BH_4 recycling secondary to DHPR deficiency (PKU2, MIM *261630), or impaired BH_4 synthesis secondary to GTP-cyclohydrolase or 6-PTS deficiency (MIM *261640). PAH deficiency is the commonest of these and causes 'classical' PKU; impaired BH_4 metabolism can cause plasma phenylalanine levels in excess of 1000 µmol/L, thus satisfying the biochemical diagnostic criterion for PKU, but the clinical course and treatment show some significant deviations from 'classical' PKU.

Aetiology [1,2]. Inheritance of PKU is autosomal recessive with an overall incidence of one in 8–12 000 live births. One in 50 individuals carry one of the mutant alleles. The genotype is markedly heterogeneous, PAH deficiency itself being caused by over 400 mutations at the PAH locus on chromosome 12q22–q24.1 [1]. The *DHPR* gene has been localized to chromosome 4 band 15.1p16.1 [1,3]. BH_4 deficiency is linked to three other loci: one on chromosome 4 and the others unmapped to date [3,4]. In PAH deficiency, hyperphenylalaninaemia requires exposure to phenylalanine, but in deficiencies of BH_4 recycling or synthesis PKU arises in the presence of the mutation alone. The usual gene dose effects are seen in heterozygotes.

In PKU, the accumulation of phenylalanine is accompanied by high levels of other derivatives of phenylalanine (such as phenylethylamine and phenylpyruvate, formed by decarboxylation and transamination, respectively) but there is ample evidence that it is the hyperphenylalaninaemia that is directly pathogenic. Tyrosine deficiency will reduce the availability of its metabolites, including acetoacetate and fumarate which contribute to the pool of two-carbon metabolites and glucose, so could contribute to impaired brain development. The oxidation rate in the brain is probably diminished but, although degenerative changes have been described in the cortex and basal ganglia and in the liver, they are inconstant [5–7]. In fact, there is little evidence of tyrosine deficiency in PKU, and tyrosine supplementation makes no impact on cognitive function. However, the reduction of melanin formation in the hair may be due to the inhibition of tyrosine–tyrosinase reaction by phenylalanine, and the hair will darken if large amounts of tyrosine are ingested. Disorders of BH_4 synthesis and recycling have additional pathological effects secondary to impaired tryptophan and tyrosine hydroxylation, as well as those secondary to hyperphenylalaninaemia.

Clinical features [1,5–7]. The clinical phenotype of PKU should now be a thing of the past because the damaging features of the disease can be reduced or prevented with early diagnosis and treatment. Affected infants are of average height and weight at birth, but thereafter show variable developmental delay. Unless diagnosis is made early, they present with psychomotor delay in early childhood leading on to mental retardation and often the need for long-term institutional care. Brain phenylalanine levels may better predict intellectual impairment than plasma concentra-

tions. About 50% have epilepsy, and extrapyramidal manifestations, such as athetosis and exaggerated tendon reflexes, may be found. The electroencephalogram is abnormal in 80% of patients and correlates with the metabolic phenotype. Magnetic resonance imaging has demonstrated changes consistent with disturbance in the water content of the white matter. It is not clear whether these are of clinical significance [8].

Recent studies have suggested that other clinical features previously associated with PKU may not be linked. However, patients almost invariably have fair skin and hair (due to impaired melanin synthesis). The fair and sensitive skin readily develops eczema. This may be of the atopic variety. Although clinical light sensitivity has been reported, the ability to tan and the erythemal response to UV radiation are normal [9]. The incidence of pyogenic infections is increased. Scleroderma-like lesions with involvement of the muscles have been described [10]. Eye abnormalities associated with hypopigmentation may occur [1,11]. Impaired physical growth affects the head circumference and height (abnormal long bone metaphyseal endplates) in the untreated condition [7,11].

There is clear evidence that in mothers with PKU, phenylalanine crosses the placental barrier (along a concentration gradient) causing impaired growth, congenital malformations, microcephaly, epilepsy or mental deficiency in the fetus [6]. Treatment is therefore recommended before conception and during pregnancy.

Diagnosis. Newborn screening is the established way to determine hyperphenylalaninaemia (HPA); plasma phenylalanine determination is far more sensitive than urine testing for phenylpyruvate and it is recommended that screening is performed on blood samples during the first week of life [12]. The most widely used method is based on the Guthrie test [13]. The test is performed on a dried capillary blood sample collected on filter paper and analysed by microbiological inhibition assay (Guthrie) or by chromatography, fluorimetry or tandem mass spectrometry. The latter test has few false negatives. Where hyperphenylalaninaemia is detected it is appropriate also to establish whether this is secondary to PAH deficiency or to abnormal BH_4 metabolism as the latter will require specific therapy to limit disease expression.

Prenatal diagnosis. Indications for this are uncertain, as treatment is experimental. Families at risk can have prenatal diagnosis by a combination of DNA analysis, enzyme activity, or amniocyte or chorion villus sample metabolite levels [1,3,12]. There are advantages to gene testing by DNA analysis, if alleles have been identified in an affected family member.

Treatment [5–19]. The aim of treatment is to normalize phenylalanine levels as soon and for as long as possible, and particularly during pregnancy. It is vital that the diagnosis is made early so that a low phenylalanine diet can be instituted immediately to avoid cerebral damage produced by high blood phenylalanine levels. Blood phenylalanine levels are routinely measured to monitor treatment. The diet is selectively restricted in phenylalanine to about 250–550 mg/day to keep the plasma phenylalanine level below the toxic range [20], and may need supplementation with tyrosine/tryptophan. The aim is to keep the plasma phenylalanine as low as possible and certainly less than 480 µmol/L. Phenylalanine is monitored twice weekly in the neonate, weekly in infants, 2–3 weekly in toddlers and ideally monthly thereafter even during adult life. This can now be achieved using dried blood spot samples. Particularly careful dietary treatment is necessary before conception and during pregnancy to reduce the risk of congenital heart disease [21–23] and abnormal brain development. Twice-weekly sampling blood tests are ideal to maintain levels of 100–250 µmol/L. There is evidence that reduction in maternal phenylalanine levels during pregnancy results in neonates with a higher birth weight [24].

The diet is based on a synthetic substitute for most of the dietary protein and should be continued throughout adult life as it has now been established that neurological sequelae can develop in the untreated affected adult [1,21,22,24,25]. Unfortunately, the response to dietary treatment is variable despite early and careful control. The amount of phenylalanine supplied in the diet should be low enough to prevent its accumulation in the blood, but high enough to allow protein synthesis and growth. Foods are given on an exchange basis using tables to indicate food with 1 g protein (equivalent 50 mg phenylalanine). Close collaboration with a metabolic dietician is an integral part of a successful treatment regimen and food diaries can also be helpful.

Non-PKU hyperphenylalaninaemia (types II and III)

Where phenylalanine levels are raised but do not exceed 1000 µmol/L the patient is described as having non-PKU hyperphenylalaninaemia [1]. The clinical spectrum of this condition ranges from the apparently normal infant to those indistinguishable from classical PKU. There is a general correlation between PAH activity and blood levels of phenylalanine [2]. Accurate classification usually requires testing with phenylalanine loading and measurement of metabolites [3,4]. Treatment needs to be modified according to the severity of the enzyme deficiency, but essentially is as for PKU.

Hyperphenylalaninaemia (types IV and V)

Hyperphenylalaninaemia types IV and V are due to deficiencies of tetrahydrobiopterin (BH_4) recycling or synthesis [1]. Together they account for 1–2% of all hyperphenylalaninaemias; failure of BH_4 recycling results from deficiency of dihydopteridine reductase (DHPR) and failure of synthesis from deficiency of either GTP cyclohydrase or 6-pyruvoyl tetrahydropterin synthase (6-PTS), the latter being about 20 times as common as the former.

Patients lacking DHPR have hyperphenylalaninaemia and other metabolic abnormalities reflecting the wide range of effects of DHPR [2]. They have defects of folate metabolism and are deficient in those neurotransmitters whose synthesis is dependent on tyrosine and tryptophan hydroxylation. They therefore have low urinary and cerebrospinal fluid levels of vanillyl mandelic acid (derived from norepinephrine), homovanillic acid (from dopamine) and 5-hydroxyindoleacetic acid (from 5-hydroxytryptamine). Treatment should aim to reduce plasma phenylalanine and to correct deficiencies of monoamines and folate metabolism. Thus the standard PKU diet should be instituted, together with supplementation of L-dopa (10–12 mg/kg/day) and 5-hydroxytryptophan (8–10 mg/kg/day) administered with a peripheral dopa decarboxylase inhibitor (e.g. carbidopa) to prevent nausea. Folinic acid (12.5 mg/day) is the recommended method of restoring normal folate balance. Early diagnosis is essential as in the absence of specific treatment there will be rapid neurological deterioration despite a low phenylalanine diet, and the earlier specific treatment starts the better the outcome. As the clinical picture is initially indistinguishable from PKU, biochemical diagnosis is required; urine screening for monoamine derivatives may help increase the suspicion of DHPR deficiency but direct assay of DHPR activity is now available and is the only reliable way to confirm or refute the diagnosis [3].

Patients with GTP cyclohydrolase deficiency have defective BH_4 synthesis [1]. They present with a progressive neurological disease with extrapyramidal features, mental retardation, seizures and occasional hyperthermia. Biochemically they have low levels of neopterin and biopterin as expected from a defect early in the biopterin synthetic pathway. Diagnosis can be confirmed by assaying GTP cyclohydrolase activity. Treatment with BH_4 as soon as possible is recommended, though the disorder is sufficiently rare that secure outcome data are not yet available. A commoner cause of reduced BH_4 synthesis is 6-PTS deficiency [4], which accounts for the commonest form of hyperphenylalaninaemia not resulting from PAH deficiency. These patients have high neopterin but low biopterin levels (and thus a high neopterin : biopterin ratio), and reduced synthesis of monoamine neurotransmitters (as in DHPR deficiency). They also present with the clinical features of PKU, with an additional progressive extrapyramidal syndrome. They typically have a low birth weight. Diagnosis rests on detection of hyperphenylalaninaemia, measurement of pterins, and correction of phenylalanine levels with test doses of BH_4. Treatment requires administration of BH_4, which is effective at reducing phenylalanine levels, but also administration of L-dopa and 5-hydroxytryptophan supplements (with a dopa decarboxylase inhibitor exactly as for DHPR deficiency) as BH_4 does not readily cross the blood–brain barrier.

Prenatal diagnosis. DHPR deficiency can now be detected prenatally by direct measurement of enzyme activity in amniocytes and by genetic screening in families with known mutations. GTP cyclohydrolase deficiency is more difficult to diagnose before birth as the enzyme is not expressed in amniocytes; but 6-PTS deficiency can be looked for by measurement of pterins in amniotic fluid and DNA analysis in families with previously defined mutations.

Tyrosinaemia

There are a number of inherited conditions that cause hypertyrosinaemia. These include inborn errors of metabolism (e.g. oculocutaneous and hepatorenal tyrosinaemia) and secondary causes (e.g. severe hepatocellular dysfunction and transient tyrosinaemia of the newborn). Tyrosine comes either from dietary intake or from hydroxylation of phenylalanine, and is the starting point of the synthetic pathways for catecholamines, thyroid hormone and melanin. Catabolism occurs mainly in hepatocytes and results in the formation of the gluconeogenic fumaric acid and the ketogenic acetoacetic acid. The inborn errors that lead to hypertyrosinaemia result from deficiency of one of the enzymes involved in this catabolic pathway.

Tyrosinaemia I (hepatorenal) (MIM *276700) [1–3]

This is a rare but well-documented, autosomal recessive disorder due to a deficiency in fumarylacetoacetic hydroxylase (FAH) which catalyses the last step in tyrosine catabolism. This enzyme has been located to chromosome 15. It can present as an acute or chronic form, and principally affects the liver, kidney and peripheral nerves.

The acute form presents in the first few weeks of life with failure to thrive, vomiting, jaundice, ascites and often gastrointestinal bleeding, and is often precipitated by infection or metabolic stress. An unusual odour said to resemble boiled cabbage may be detectable. Hepatomegaly may be present. Some acute crises proceed to liver failure and encephalopathy, while others resolve though may then recur. During acute attacks plasma tyrosine and methionine levels are high, as are transaminases (sometimes to a marked degree in severe attacks) and often α-fetoprotein.

The chronic form is characterized by chronic liver and renal disease (Fanconi-like syndrome) with death within the first decade. Some patients may develop porphyria-like neurological crises with painful paraesthesiae, autonomic dysfunction (with tachycardia and hypertension) and occasionally a progressive paralysis. These crises are due to the accumulation of succinylacetone, the most powerful known inhibitor of delta aminolaevulinic acid (δ-ALA) dehydratase [3]. Plasma tyrosine and methionine are elevated diagnostically and there is a global increase in urine amino acids, with particular increase in δ-ALA [3].

Secondary deficiency of hepatic 4-hydroxyphenylpyruvic acid dioxygenase (pHPPD) occurs in FAH deficiency, accounts for the increased tyrosine levels and was indeed originally thought to be the primary cause of hepatorenal tyrosinaemia. Some patients develop hypermethioninaemia, due to a secondary inhibition of methionine adenosyltransferase.

Cirrhosis is probably invariable in patients with hepatorenal tyrosinaemia and there is a very high incidence of hepatocellular carcinoma, though it is now thought that some of the initial estimates of this particular complication may have been overestimated [2]. Nonetheless, regular screening is recommended, despite some of the recognized pitfalls of liver ultrasound or CT in distinguishing benign and malignant nodules.

Diagnosis. Prenatal diagnosis is either by direct determination of the FAH enzyme activity or detection of succinylacetone directly or from its inhibitory activity in amniocytes or chorionic villus samples [2,4]. Neonatal screening is aimed at detecting increased levels of tyrosine, methionine or succinylacetone from blood spots on filter paper; more recently these have also been used for screening δ-ALA dehydratase. Several different mutations have been reported, and where the mutation is known, molecular analysis should be carried out.

Treatment. This is with a low tyrosine and phenylalanine diet which can reduce plasma tyrosine levels and does improve renal function, though with less certain benefit for liver disease. Treatment with NTBC (2-(nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione), which inhibits pHPPD, has been tried in a number of patients with hepatorenal tyrosinaemia with some benefit [5–7]. However liver transplantation, which cures the underlying metabolic defect, has revolutionized the prognosis for this condition and remains the treatment of choice [5–7].

Tyrosinaemia II (MIM *276710)

Synonym
- Richner–Hanhart oculocutaneous syndrome

This is a very rare disorder, inherited as an autosomal recessive trait, due to a deficiency of cytoplasmic tyrosine aminotransferase (TAT), which catalyses the first and rate-limiting step in tyrosine catabolism [1,2]. Males and females are equally affected. The skin, eyes and nervous system are the only organs affected.

The skin manifestations of oculocutaneous tyrosinaemia do not usually appear until after the first year of life. They consist of painful hyperkeratotic plaques on the soles and palms with a particular predilection for the fingertips and thenar and hypothenar eminences [3]. They do not itch but can be sufficiently painful that they prevent walking. Hyperhidrosis of the affected area may

also occur, as may leukokeratosis of the tongue [4]. Skin biopsy reveals hyperkeratosis, acanthosis and parakeratosis with homogeneous refractile eosinophilic inclusions in the stratum corneum and upper Malpighian layer; none of these are pathognomonic [1]. On electron microscopy lipid-like granules, myelin-like fragments, keratinocytes with increased tonofibrils and tightly packed microtubular and tonofibrillar masses have all been described. There is minimal, if any, evidence of inflammation and tyrosine crystals are not seen, unlike the conjunctival biopsies of these patients [5].

By contrast with the skin manifestations, eye symptoms are usually present in the first year, though they can develop later. They consist of episodes of pain, photophobia, redness and lacrimation. On examination, central corneal dendritic erosions are seen with prominent neovascularization also occurring quite frequently. There can be progression to corneal opacities with consequent reduced visual acuity [6,7]. A variable degree of mental retardation is present in less than 50% of patients with oculocutaneous tyrosinaemia [3].

Biochemically, this disease produces a highly characteristic pattern with plasma tyrosine as the only elevated plasma amino acid and the only amino acid excreted in the urine. Metabolites of tyrosine are also detectable in urine [1].

Diagnosis. This is made by detection of increased blood tyrosine levels, normal phenylalanine and increased urinary metabolites of 4-hydroxyphenylacetic acid, *N*-acetyltyrosine and 4-tyramine.

Treatment. Most patients respond to dietary restriction of tyrosine and phenylalanine [1,8] with the aim of reducing blood levels to less than 600 µmol/L. Skin and eye symptoms and signs usually respond fairly rapidly, though can recur if the diet is discontinued. Oral retinoids have proved beneficial but steroids make skin symptoms worse.

Alkaptonuria (MIM #203500) [1,2]

This is a rare metabolic disorder first described by Garrod in 1902 [1], which results from a single gene defect. It is characterized by a discrete biochemical lesion, with deposition of oxidized homogentisic acid pigment throughout the body, particularly in fibrous and cartilaginous tissues. Dark urine (homogentisic aciduria), distinctive cutaneous pigmentation (ochronosis) and arthritis are characteristic. Generally, it is considered a benign degenerative disorder with normal life expectancy [2].

Aetiology [1–3]. Alkaptonuria is characterized by a constitutional deficiency of homogentisic oxidase (homogentisic 1,2-dioxygenase activity), an enzyme usually found in liver and kidney. This leads to an accumulation of homogentisic acid, an intermediate metabolite of phenylalanine and tyrosine catabolism.

Ochronosis [4,5] describes the deposition of a melanin-like brownish-black pigment, derived from the oxidized product of homogentisic acid (benzoquinone acetic acid), in connective tissues and cartilage. The enzyme homogentisic acid oxidase contains an essential sulphhydryl group, which is inhibited by certain chemicals. These include various drugs such as phenol, resorcin, mepacrine and perhaps other antimalarials that may cause acquired ochronosis. An exogenous ochronosis can also occur from hydroquinone-containing skin-bleaching creams [4].

Genetics. Alkaptonuria is an autosomal recessive condition. The gene locus (*AKU*) has been assigned to chromosome 3q by consanguinity and by comparative mapping. The gene has been cloned to 3q21–q23 with demonstration that the human 1890 gene harbours missense mutations and co-segregates with the disease [3]. The incidence is one in 200 000 but in areas of consanguinity it is higher [6].

Histopathology. There is deposition of black pigment in the cartilage, fibrous tissue, tendons and atheromatous areas. The intervertebral discs, larynx, tracheal rings and articular cartilages are jet-black as if 'dipped in Indian ink'. Differentiation of the ochronotic pigment from melanin is difficult, and stains do not consistently differentiate between the two pigments.

Clinical features [2,7]. Cardinal features are due to homogentisic acid in urine, and pigmentation of cartilage, connective tissue and joints. The patient with the hereditary type is symptom-free until adult life. The only manifestations in childhood are discoloration of the urine and 'spotting or staining' of the napkins or clothing due to alkaline pH. The clinical sequence of events is alkaptonuria, then ochronosis and lastly ochronotic arthropathy (fifth decade). The cutaneous manifestations appear in the fourth decade. One of the earliest signs is thickening of the ear cartilage, associated with blue-black or grey-blue discoloration. The pinna feels noticeably thickened and inflexible, and in later stages there may be gross calcification. Cerumen is often brown or jet black. Scleral pigmentation is noted as early as the third decade; it appears as brown or grey deposits midway between the corneal margin and the medial canthus. The skin of the eyelids and forehead is also pigmented and the tarsal plates often appear blue on transillumination. All the tendons are similarly discoloured; the dark discoloration over the extensor tendons on the knuckles is best seen when the patient makes a fist. Widespread, dusky cutaneous pigmentation may be noted, but this feature is particularly marked over the cheeks, forehead, axillae and genital regions. The buccal mucosa and

larynx are also affected and the nails are sometimes distinctly coloured brown. Ochronotic changes affecting the ear drum and ossicles may produce deafness; prostatic concretions and black renal calculi, as well as calcific aortic disease, have been recorded. The urine is of normal colour but darkens on exposure to air or within seconds of adding an alkaline solution. Patients sometimes observe that both their sweat and urine discolour clothing.

Ochronotic arthropathy follows a fairly consistent clinical pattern. There is low back pain with stiffness early in the fourth decade; during the next 10 years the knees become involved and, later, the shoulders and hips. The friable articular cartilages lead to prolapsed intervertebral discs or a ruptured nucleus pulposus with accompanying acute pain. Spondylosis spreads to the thoracic spine; patients then assume a stooping posture and can lose up to 15 cm in height. Limitation of expansion of the chest provokes dyspnoea. The spinal X-ray appearances are diagnostic, consisting of narrowing of the lumbar disc spaces with intense calcification of the narrowed discs.

Marked atherosclerosis is common in the older age groups as well as valvulitis and calcification of aortic and mitral valves. In spite of their marked disability, many patients reach old age.

Diagnosis. The diagnosis is by demonstration on gas–liquid chromatography of homogentisic acid in the urine (by its reducing ability), or with specific enzyme tests [8].

Differential diagnosis. An incorrect diagnosis of glycosuria or diabetes can be made if the urine is tested with Fehling's solution (but this is rarely used now). The pigmentation of acquired ochronosis from exogenous foreign chemicals or drugs is identical to the genetic disorder, but is unaccompanied by homogentisic acid in the urine or by arthropathy.

The overall clinical picture and the localization of pigment thus distinguish the genetic disease from other pigmentation disorders such as Addison's disease, haemochromatosis, argyria, chronic photosensitivity pigmentation, cutaneous porphyria and pellagra. The ferric chloride urine test gives variable results; other phenolic compounds give similar colour reactions and thus, when the test is positive, the urine should be examined by chromatography.

Treatment [2]. Since the major damage induced by the metabolic defect is pigmentation and joint changes, treatment is directed towards reducing connective tissue damage by ascorbic acid (acting as an antioxidant), and by analgesics and physiotherapy for the arthropathy. A low protein diet limiting the amount of phenylalanine and tyrosine is not practicable as a long-term measure, although it could be used intermittently. Use of vitamins (B_{12}, C) may be helpful (for example ascorbic acid in reducing homogentisic acid oxidation).

Homocysteinurias [1–5]

Synonym

- Homocystinurias

Homocysteinurias are a group of rare, inborn errors of amino-acid metabolism first reported in 1962 [4]. They also encompass hypermethioninaemia and cystathioninuria. The defects arise when there is abnormality in transfer of the sulphur from methionine to homocysteine in the biochemical pathway responsible for the disposal of methionine and the formation of cysteine, resulting in the accumulation of homocysteine, methionine and other sulphurated metabolites in a wide range of tissues and in the urine.

Aetiology. Initially homocysteinuria was thought to be due solely to deficiency of cystathionine-β synthase (CBS; MIM *236200), but it is now apparent that homocysteine accumulation may also result from inherited defects in the 5-methyltetrahydrofolate–homocysteine methyltransferase reaction (MIM # 236250) [1,3,6]. These can be distinguished because there is an increase in urine methionine in the CBS deficiency whereas it is low in hyperhomocystinaemia secondary to defects of the folate pathway. Secondary forms of homocysteinuria can occur in vegetarians with vitamin B_{12} deficiency, or with treatment with isonicotinic acid. The accumulated homocysteine is believed to interfere with collagen cross-linking accounting for the wide range of clinical features.

Clinical features. CBS deficiency is inherited as an autosomal recessive trait, with a world prevalence of 1 : 344 000 though with wide variation between different countries [1]. Four major systems are affected: the eye, skeletal system, central nervous system and the vascular system. The newborn infant appears clinically normal, but lens dislocation, mental deficiency, growth disorder and cutaneous signs may develop slowly over the next few years. The skin features of homocysteinuria include fine, brittle hair and thin skin. Livedo reticularis of the legs and tissue-paper scars on the hands may be present. In some cases, hair examination shows no fluorescence with acridine orange, indicating abnormality of disulphide bonds. The cysteine content is normal. Abnormal glucose tolerance and increased growth hormone levels are often present.

Osteoporosis of the spine is common and predisposes to scoliosis. Lengthening and thinning of the long bones may lead to a variety of skeletal abnormalities and their presence together with the arachnodactyly that also occurs may lead to a Marfanoid

appearance. Other features include hepatomegaly (secondary to fatty change) and myopathy. Many patients with CBS deficiency exhibit some degree of mental impairment; developmental delay may be the presenting feature of the disease and about 20% also suffer seizures. Psychiatric abnormalities occur in about 50% of patients, including episodic depression (10%), chronic behavioural disorders (17%) [7], chronic obsessive–compulsive disorders (5%) and personality disorders (19%). Some children develop spontaneous venous and arterial thrombosis, probably secondary to increased platelet adhesiveness, and venous thromboembolic disease is a frequent cause of mortality [6,8]. There has been much interest in recent years in establishing whether milder forms of hyperhomocystinaemia, seen quite frequently in folate deficiency, may be associated with increased risk of cardiovascular disease [9,10]. Although the initial epidemiology seemed convincing, trials of folic acid supplementation have not generally reduced the clinical endpoints of atherosclerosis such as myocardial infarcts and strokes.

Differential diagnosis. Marfan's syndrome, an hereditary mesodermal dysplasia, exhibits visceral manifestations without mental deficiency. The hair is normal and homocysteine is absent from the urine.

Diagnosis. This is by detection of urinary homocysteine by a positive urinary cyanide–nitroprusside reaction. Recently, plasma homocysteine measurement (with increases of 50–200 µmol/L), confirmed by changes after methionine loading, is regarded as a more accurate assessment. Heterozygotes can be detected by assaying for the enzyme in the liver, phytohaemagglutinin-stimulated lymphocytes and in cultured fibroblasts. In addition, the presence of abnormal sulphur-containing metabolites can be detected in the urine after an oral load of L-methionine. CBS deficiency can be diagnosed by hypermethioninaemia or by detection of increased homocysteine in urine or blood. Methods for detecting heterozygotes rest on enzyme assays, metabolite measurements or a combination using liver tissue, cultured fibroblasts or phytohaemagglutinin-stimulated lymphocytes. Newer techniques include tandem mass spectrometry [11].

Treatment [1,12]. There are two aims of treatment: (i) control/elimination of the biochemical abnormality; and (ii) treatment of complications. Patients are usually divided into pyridoxine-responsive or non-responsive individuals, detected after the newborn period. For the newborn, diets restricting methionine and supplemented with cysteine have been used with encouraging results when started early in life. Large doses of vitamin B_6 (pyridoxine) in the form of pyridoxine hydrochloride 150–300 mg/day produce complete reversal of the biochemical abnormality in some cases. Some may become folate deficient; administration of vitamin B_{12} and folic acid improves clinical symptoms. For the non-pyridoxine responsive patients, a low protein diet with methionine-free amino acid supplements and exchanges, and minerals and vitamins may be helpful. In non-responsive patients diagnosed after birth (non-responsive after a trial of 500–1000 mg/day for several weeks), the use of betaine as a methyl donor agent to lower homocysteine levels can prove effective in lowering plasma homocysteine levels in combination with a low-methionine diet. Aspirin can help reduce the thrombotic risk and other cardiovascular risk factors, such as hypertension, diabetes and dyslipidaemia should be sought and treated appropriately.

Prognosis. Prognosis is more favourable than might be thought, with recent surveys showing that fewer than 5% of affected individuals die by the age of 20 years [1–3].

Hartnup disease (MIM *2345000) [1–3]

This is a very rare hereditary recessive disorder of neutral amino acid transport, which is characterized by a pellagrous eruption, a temporary and intermittent cerebellar ataxia, and a characteristic renal aminoaciduria with excessive indicanuria [1].

Aetiology [1,4]. Hartnup disease is believed to be caused by a genetic defect in the specific system for transport of neutral amino acids in the kidney and across the brush border epithelium of the intestine, leading to hyperaminoaciduria and urinary excretion of indolic compounds formed by bacterial action on the unabsorbed tryptophan [5–7]. It is likely that Hartnup disorder is a monogenic defect which interacts with polygenic and environmental factors giving a wide clinical spectrum [8]. The failure of absorption of tryptophan results in a deficiency in the synthesis of nicotinamide causing a pellagra-like syndrome.

Clinical features. The onset is usually in childhood between 3 and 9 years, but the first signs are occasionally encountered as early as 10 days after birth. The cutaneous signs precede the neurological manifestations. The rash is dry, scaly and well marginated, affecting the light-exposed areas, notably the forehead, cheeks, periorbital regions, the uncovered areas of the arms and the dorsal

surface of the hands. After exposure to sunlight, the skin reddens and blistering may occur. With recovery there is often desquamation and depigmentation.

Cerebellar ataxia is the most commonly encountered neurological feature. It usually develops later than the skin lesions. Other signs of cerebellar origin include nystagmus and diplopia, and occasionally tremor of the hands and tongue. Early reports suggested mental retardation, but this has not been the case with most patients. Minor cognitive defects have been reported. Less commonly, there are associated psychiatric disturbances such as depression, delusions and hallucinations. Exacerbations are most frequently seen in the spring or early summer [2], cutaneous manifestations being accompanied by transient ataxia. Rarely, the attacks are provoked by febrile illness. Other somatic abnormalities include oedema and hypoproteinaemia with fatty change in the liver [2], fever, diarrhoea and atrophic glossitis.

Intravenous tryptophan is metabolized normally and the serum amino acid profile is normal. The urine contains increased amounts of amino acids of the monoamine monocarboxylic groups [5], and it is the pattern of the amino acid excretion that confirms the diagnosis.

Differential diagnosis. The eruption in mild cases closely simulates infantile atopic eczema, seborrhoeic eczema or pityriasis alba; in Hartnup disease the covered areas are usually spared. Florid cases closely mimic nutritional pellagra. The congenital poikilodermas, particularly the light-sensitive hereditary disorders such as Cockayne's syndrome, may present diagnostic difficulties.

Treatment [2,3]. The rationale for the treatment is to replace the defect by giving nicotinamide (50–300 mg/day) orally. Treatment usually results in amelioration of the rash and may improve ataxia and psychotic behaviour. A high-protein diet may be a useful adjunct. Intravenous nutrition may be necessary in severely affected patients.

Prognosis. Symptoms become milder with increasing age.

Gout

This heterogeneous group of abnormalities of purine metabolism is characterized by hyperuricaemia, and recurrent attacks of acute arthritis in some cases, with the deposition of monosodium urates in the articular cartilage and urate deposits in the skin (tophi) (Fig. 59.69). Arthritis may be progressive and nephropathy is common. Nephrolithiasis due to uric acid may precede arthritis.

Fig. 59.69 Gouty tophi. (Courtesy of Dr R.H. Champion, West Suffolk Hospital, Bury St Edmunds, UK.)

Aetiology [1–4]. Uric acid is the degradative product of purine metabolism in humans. Increased circulating levels of uric acid arise because of overproduction or underexcretion of uric acid. Primary gout has long been recognized as a heterogeneous disorder; in up to 40% of patients the family history suggests a genetic component [4]. Population studies suggest that the disorder is multifactorial and attributable to a combination of genetic and non-genetic factors [1]. There are two very rare specific enzyme deficiencies associated with gout, which have X-linked inheritance. These are partial deficiency of hypoxanthine–guanine phosphoribosyl transferase (HGPRT; HPRT-related gout, MIM #300323) and increased activity of phosphoribosyl-pyrophosphate (PRPP) synthetase [5]. Most patients with primary gout appear to have reduced excretion of uric acid [6,7] but the molecular mechanisms underlying this remain poorly understood. Fewer than 10% of patients with primary gout have an increase in the rate of purine biosynthesis [8].

Secondary gout may result from decreased excretion of uric acid. The most important cause of this is diuretic therapy but it may also occur in a number of disease states, especially renal tubular disease. Increased uric acid production is commonly secondary to increased turnover of nucleic acids in conditions such as polycythaemia rubra vera, lymphoma, myeloma and leukaemia especially when patients are receiving active chemotherapy. A number of other disorders may be associated with hyperuricaemia and gout. 82% of patients with pure or combined hypertriglyceridaemia have increased uric acid levels, and conversely 74% of patients with gout have raised lipoproteins (TG, VLDL [5,9] and Lp(a) [10]); the link between the two is likely to be insulin resistance. There has been a suggestion that hyperuricaemia may be a risk factor for cardiovascular disease [9,11]. Hypertension, obesity, diabetes mellitus and ethanol consumption in susceptible persons may also be associated with gout [12].

Histopathology. Sodium urate crystals may be found in joint fluid. The crystals can be identified by microscopic examination and by their ability to polarize light strongly. In the dermis and medulla of the kidney, the urate crystals provoke a giant cell reaction [12,13].

Clinical features [1,3,4,7]. Hyperuricaemia develops at around puberty in males but usually later in females, often after the menopause. Patients normally remain asymptomatic until the fourth to sixth decades when the first attack of acute gouty arthritis occurs. Recurrent, self-limiting attacks usually follow after a period of about 6 months to 2 years. Initially single joints, classically the great toe, are involved, but later the condition may become polyarticular and then usually involves the joints of the lower extremities. Later in the disease, a chronic tophus state develops with deposits in cartilage, synovial membranes, tendons and soft tissues. The classical locations for tophi are the helix and antihelix of the ear, and the index fingers (Fig. 59.69). Criteria for clinical diagnosis of acute gout have been reported [3,14].

Acute uric acid nephropathy results from precipitation of uric acid crystals in the collecting ducts of the kidney and is most commonly seen in patients with leukaemia undergoing aggressive chemotherapy. Renal stones develop in up to one-quarter of patients [12] and renal colic may be a presenting manifestation of gout. Chronic urate nephropathy is common [6,15] and contributes significantly to the morbidity and mortality of gout [15].

Differential diagnosis. Pseudogout [2,16] (calcium pyrophosphate deposition disease) shows close similarities to gout (particularly the acute attacks), and is characterized by familial incidence and later chronic arthropathy, pseudotophi and precipitation by surgical operations and diuretic therapy. The serum uric acid level is normal, calcium pyrophosphate is found in synovial fluid and X-rays show articular calcification [2]. Multicentric reticulohistiocytosis is frequently accompanied by papules and nodules on the ears and fingers with an associated arthropathy. Rheumatoid arthritis with necrobiotic nodules is usually sufficiently characteristic to avoid confusion with gout. Psoriatic arthropathy may cause diagnostic difficulties.

Treatment [1,3,15,17,18]. All patients with gout or a raised uric acid level should be investigated for its cause. Acute attacks are treated by rest of the affected joint and with regular anti-inflammatory treatment, such as indomethacin. Where non-steroidal anti-inflammatory drugs are contraindicated, corticosteroids can sometimes be helpful. Colchicine (0.5 mg 6-hourly until symptoms subside, or a maximum oral dose of 6 mg has been reached) may also be useful in acute episodes. Side effects of diarrhoea, renal and hepatic damage need to be carefully monitored during treatment with colchicine. It is a matter of clinical judgement whether to treat asymptomatic hyperuricaemia.

Antiuricaemic therapy using allopurinol, a xanthine oxidase inhibitor, is effective after the acute event and in prophylaxis. Allopurinol should be avoided in an acute attack, and its introduction sometimes precipitates an acute attack. If this happens, reintroduction of allopurinol after a suitable interval should be covered by concomitant administration of colchicine or non-steroidal anti-inflammatory drugs for the first couple of weeks. Drugs such as probenecid and sulfinpyrazone may be used to increase uric acid excretion, but are usually less effective prophylaxis. Treatment must be tailored to the needs of individual patients [8,19].

Lesch–Nyhan syndrome (MIM #300322) [1–6]

Lesch–Nyhan syndrome results from a complete lack of the purine salvage enzyme hypoxanthine-guanine phosphoribosyltransferase (HGPRT). HGPRT is coded for by a single gene on the X chromosome (Xq26-q27), and is expressed in all tissues, and at high level in the basal ganglia. This enzyme catalyses the salvage of hypoxanthine and guanine to inosine monophosphate (IMP) and guanosine monophosphate (GMP). The principal clinical features are choreoathetosis, spasticity, mental retardation and self-mutilation, particularly biting of the lower lip in childhood. There may also be a macrocytic/megaloblastic anaemia. Patients are normal at birth, but by 6 months developmental abnormalities are apparent with choreiform movements usually being the first to appear. The origin of the neurological abnormality in humans is still unknown; HGPRT-deficient mice do not show any of the neurological features of Lesch–Nyhan syndrome. It is, however,

thought that it is the accumulation of purine metabolites rather than deficiency of purine nucleotides that is pathogenic with secondary effects on neurotransmitter function. Changes in terminal arborization of dopaminergic neurones have been found, probably occurring secondary to reduced concentrations of dopamine homovanillic acid, dopa and tyrosine decarboxylase in dopaminergic neurones in the putamen. Blood uric acid levels are high and, although there are no reports of gouty arthritis, renal function is impaired by deposit of urates. However, patients with partial deficiency of HGPRT may develop gouty arthritis and/or uric acid calculi though without any of the neurological and behavioural features of the full-blown syndrome.

Prenatal diagnosis. HGPRT analysis can be carried out on amniocyte or chorionic villus samples in the ninth week of pregnancy. Affected male heterozygotes can be identified by HGPRT assay on red cell lysates. Carrier females can be identified by HGPRT and $HGPRT^{-}$ mosaicism in hair roots; mosaicism can also be identified in cultured fibroblasts [7].

Treatment. Allopurinol, in appropriate dosage, can reduce plasma urate and urinary uric acid to reduce occurrence of gouty arthritis, urate nephropathy and renal calculi. There is no effective treatment of the neurological features. However, padded wheelchairs and physical restraints may reduce spinal injury and self-mutilation. Dental extraction may also assist in preventing the latter [5,7].

Granuloma annulare, 60.1 | Necrobiosis lipoidica, 60.12 | Granuloma multiforme, 60.17

Granuloma annulare

Introduction. Granuloma annulare was first described by Colcott Fox in 1895 [1], and established as a specific entity by Radcliffe Crocker in 1902 [2]. It is a disease in which, in typical cases, the skin and/or subcutis is involved in a process characterized by foci of alteration of collagen (necrobiosis) surrounded by histiocytes and lymphocytes. Clinical variants include localized, generalized, perforating and subcutaneous patterns [3,4].

Aetiology [1–3]. Although the aetiology and pathogenesis of granuloma annulare are unclear, it appears likely that it represents a reaction pattern to a variety of triggering factors. Reported triggering factors have included insect bites [4], scabies [5], a cat bite [6], waxing-induced pseudofolliculitis [7], tuberculin tests [8], BCG vaccination [9,10], hepatitis B vaccination [11,12] and chronic hepatitis B virus infection, with resolution soon after treatment with interferon-α [13], a possible relationship to antitetanus and diphtheria toxoid vaccination [14,15], and various forms of trauma such as occupational pressure on the fingers in a milkman [16] and saphenectomy [17]. In the past, its occurrence with tuberculosis was noted in a number of reports, and cases may still be encountered in which there appears to be an association between these two disorders [18,19]. Other infectious agents that have been implicated in the causation of lesions of granuloma annulare include human papilloma virus [20], varicella/zoster virus [21–29] (although persistence of viral DNA does not appear to be related to granuloma formation [26,30]), Epstein–Barr virus (EBV) [31,32] (although EBV could not be demonstrated in lesions occurring in HIV-positive patients [33]), parvovirus B19 [34], hepatitis C virus [35] and during pegylated interferon-α treatment for hepatitis C virus infection [36], and human immunodeficiency virus [33,37–46]. Although there has been evidence implicating *Borrelia burgdorferi* in some cases [47,48], it was absent in others [49]. Examination of several biopsy specimens using polymerase chain reaction amplification did not reveal any evidence of *Bartonella* infection [50]. Granuloma annulare at the site of an infection such as herpes zoster has been termed an 'isotopic' response.

Seasonally recurrent granuloma annulare has been described [51,52], and sun exposure may have acted as a precipitating factor in one of these cases [52]. Sun exposure is thought to have provoked or contributed to localization of lesions in a number of cases [53–56]. Disseminated granuloma annulare has occurred in a patient undergoing PUVA therapy [57]. Whether actinic granuloma is a distinct entity, or represents granuloma annulare on sun-exposed skin, has been the subject of debate [58–66].

A report of granuloma annulare occurring in the red areas of tattoos [67] prompted description of a similar case and the suggestion that both were examples of a perforating collagenosis [68].

There is a report of disseminated granuloma annulare occurring in the same sites as lesions of erythema multiforme minor [69].

Some cases of granuloma annulare-like lesions attributed to drugs may have been examples of drug-induced interstitial granulomatous reactions [70].

It has been suggested that an immunoglobulin-mediated vasculitis is the cause of the necrobiotic granulomas [2,71], but evidence from immunofluorescence studies is conflicting—some authors have demonstrated immunoreactants in vessel walls [71], whereas others have not [72,73]. An alternative view is that the pathogenetic mechanism is a delayed-type hypersensitivity response [2,73–77].

An increased prevalence of HLA-Bw35, compared with controls and those with localized lesions, has been demonstrated in individuals with generalized granuloma annulare [78].

The relationship between diabetes mellitus and granuloma annulare is discussed below, as are apparent associations with several other disorders.

Histopathology [1–5] (Figs 60.1 & 60.2). The most characteristic histological lesion in granuloma annulare is the necrobiotic granuloma, but there are three histological patterns that may occur: necrobiotic palisading granulomas, an interstitial form, and granulomas of sarcoidal or tuberculoid type [1]. Umbert and Winkelmann [3] found that the commonest histological pattern was the interstitial type, as did Friedmann-Birnbaum *et al*. [4]. The latter authors compared the histopathological features of localized and generalized granuloma annulare, and noted that the interstitial pattern was more frequent in localized than in generalized disease; the prevalence of the palisading granuloma pattern was almost equal in both clinical types. Dabski and Winkelmann [5] also found that the interstitial pattern was common in both these types of granuloma annulare, and in many cases it occurred alone, without palisading granulomas. However, they noted a prominent palisading pattern more frequently in localized disease than in the generalized variety. Observer variation and the existence of more than one pattern in the same section may have contributed to differences in the findings in these series.

Necrobiotic granulomas are characterized by foci of necrobiosis surrounded by histiocytes and lymphocytes, with the histiocytes

commonly forming a palisaded pattern. There are varying numbers of multinucleate giant cells in this peripheral zone. T cells in the lymphocytic infiltrate are of the helper/inducer phenotype (CD4+) [6–8], but in two cases associated with HIV infection a predominantly T-suppressor (CD8+) infiltrate was demonstrated [9,10]. Analysis of the T-cell repertoire and cytokine pattern has shown a T-cell response characterized by a combination of a few skin-specific clones together with many non-specific T cells, and abundant production of interleukin-2 [8]. The high local production of interleukin-2 could be responsible for the non-specific attraction of T cells to the granulomas.

Mucin is present within the foci of necrobiosis, and it can be seen more readily by staining with Alcian blue or colloidal iron. Small deposits of lipid material may also be present in these areas. Some form of collagen alteration, most commonly fragmentation of collagen bundles, was observed in 79% of cases of localized and 53% of cases of generalized granuloma annulare by Dabski and Winkelmann [5]. There is a marked reduction in, or absence of, elastic fibres [11,12]. Metalloproteinases are probably involved in the damage to collagen and elastic fibres [13,14]. The granulomas are situated in the superficial and mid-dermis and, in contrast with necrobiosis lipoidica, areas between them are relatively normal.

In the interstitial pattern there are no formed areas of necrobiosis, histiocytes and lymphocytes are present around blood vessels and between collagen bundles, and collagen fibres are separated by mucin.

The sarcoidal or tuberculoid pattern is uncommon, and may cause problems in diagnosis. The presence of mucin and eosinophils can help to distinguish granuloma annulare from sarcoidosis. Blau syndrome is rare but causes histological differential diagnostic difficulties as it comprises an interstitial infiltrate as well as a sarcoidal pattern.

There is a perivascular infiltrate of lymphocytes and histiocytes. Eosinophils are variably present [15]. In one study [16], the presence of eosinophils was strongly associated with a palisaded architectural pattern and the presence of necrobiosis. Plasma cells are rare. A vasculitis has been described in or near foci of necrobiosis [17].

Histiocytes express the marker PG-M1 [18]. They may show an increased mitotic rate, and recognition of this is important, in particular in differentiating granuloma annulare from epithelioid sarcoma [19–22].

Epidermal changes are inconspicuous except in perforating granuloma annulare. In this variant there is a superficial area of necrobiosis surrounded by palisading histiocytes, situated beneath a perforation in the epidermis [1,2,23]. The necrobiotic material is extruded via the perforation. At the margins of the perforation there are varying degrees of epidermal hyperplasia.

The lesions of subcutaneous granuloma annulare often contain large areas of necrobiosis, and they are similar to rheumatoid nodules both clinically and histologically. Patterson [24] found that Alcian blue staining of mucin in lesions of granuloma annulare was the most helpful distinguishing feature.

Other disorders with similar histological features include mycosis fungoides variants [25–28], interstitial granulomatous dermatitis (interstitial granulomatous dermatitis with arthritis; interstitial granulomatous dermatitis with plaques; palisaded neutrophilic granulomatous dermatitis) [29–35], and the interstitial granulomatous drug reaction [36,37].

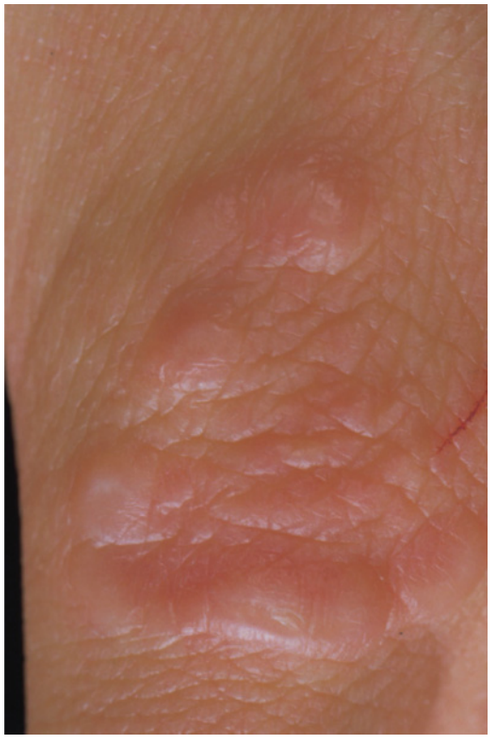

Fig. 60.3 Typical papules of granuloma annulare.

Clinical features [1,2]. Granuloma annulare can occur at almost any age—in one series the youngest patient was 1 year old and the oldest 76 [3]—but the majority of affected individuals are under 30 years of age [3]. It is twice as common in women as in men. There are a few reports of familial cases [3–9]. Clinical variants include localized, generalized, perforating and subcutaneous.

Localized granuloma annulare is the commonest form, and typically presents as a ring of small, smooth, flesh-coloured or erythematous papules (Fig. 60.3). Stretching the skin enables the papules to be seen more readily. The surface of the skin over the papules is intact and there is usually no scaling. Annular lesions tend to enlarge centrifugally. They may be solitary or multiple, and may occur anywhere on the skin, although the dorsa of the hands (Figs 60.4 & 60.5) and feet (Fig. 60.6), and the fingers (Fig. 60.7) are the commonest sites. Lesions are usually symptomless, although some may be tender to touch, and acute-onset, painful acral lesions have been described [10]. Some, often acral, lesions enlarge as nodules rather than having an annular morphology.

The other patterns of granuloma annulare may occur alone or in association with the annular lesions. In the generalized or disseminated pattern, there are numerous skin-coloured or erythematous papules, which may have an annular configuration or consist of myriad, symmetrically distributed, often coalescing lesions, on the trunk and limbs [11–14] (Fig. 60.8). The area enclosed by annular papules is often violaceous in colour. Pruritus may be a prominent complaint in generalized lesions [13]. Although generalized granuloma annulare may occur in children, the mean age

Fig. 60.4 Granuloma annulare on the dorsum of the hand—a typical site.

Fig. 60.5 Granuloma annulare on the dorsum of the hand. Altered pigmentation and atrophy in the centre of the lesions.

Fig. 60.7 Granuloma annulare on the side of a finger.

Fig. 60.6 Granuloma annulare on the dorsum of a child's foot. Often mistaken for tinea—but there is no scale and tinea in this site would be unlikely in a child.

Fig. 60.8 These annular lesions were part of an extensive eruption on the limbs in a patient with generalized granuloma annulare.

at onset is later than in the localized variety, and in the series of Dabski and Winkelmann [13] it was 51.7 years. The exact incidence of the generalized pattern is unknown, but 8.9% of all patients with granuloma annulare seen at the Mayo Clinic had a generalized or disseminated pattern [13]. As in the localized form, twice as many females are affected as males. Although in immunocompetent individuals localized disease is more common than generalized granuloma annulare, in HIV-infected patients the generalized pattern predominates [14–18]. The sparing of vaccination sites in a case of generalized granuloma annulare is an interesting phenomenon [19].

Perforating granuloma annulare was named by Owens and Freeman in 1971 [20]. In this uncommon variety, some of the papules develop yellowish centres and discharge a little clear, viscous fluid. This dries to form a crust, which eventually separates, and may leave a hypo- or hyperpigmented scar. Lesions may be localized or generalized [21–24]. A high incidence of perforating granuloma annulare has been reported in the Hawaiian Islands [22,23]. Perforating lesions have been present in some of the reported HIV-positive individuals with granuloma annulare. Generalized perforating granuloma annulare has been described in an infant [25].

Subcutaneous granuloma annulare is also uncommon. It occurs predominantly in children, and has been given a variety of names, including benign rheumatoid nodules [26], pseudorheumatoid nodules [27,28], deep granuloma annulare [29,30], subcutaneous palisading granuloma [31], isolated subcutaneous granuloma and subcutaneous necrobiotic granuloma [32]. Lesions are nodular and occur predominantly on the scalp and legs, particularly in the pretibial region [4,32–34], but unusual locations include periorbital subperiosteal [35], palm [36,37] and penis [38]. A congenital case has been recorded [39]. Magnetic resonance imaging features are diagnostically helpful [40–42].

Other reported variants of granuloma annulare include a papular umbilicated form on the dorsa of the hands in children [43], a case of 'follicular pustulous' granuloma annulare, in which palisading necrobiotic granulomas occurred in a perifollicular distribution [44], pustular generalized perforating granuloma annulare, in which a dense infiltrate of neutrophils was present in areas of necrobiosis [45], linear granuloma annulare [46,47], and 'patch' granuloma annulare, in which erythematous patches occur on the trunk and limbs [48]. It has been suggested that cases with 'linear' lesions may be examples of interstitial granulomatous dermatitis, and those with 'patch' lesions may represent examples of the interstitial granulomatous form of drug reaction [49].

Uncommon sites for lesions of granuloma annulare are the ears (Fig. 60.9), where the perforating variety is particularly unusual [50], penis [51–56], palms [57] and periocular regions [58–63]. Mucous membranes are spared, although there is a report of involvement of the oral mucosa in a patient with HIV infection [64].

A destructive form has been described [65,66].

The postal questionnaire survey carried out by Wells and Smith [3] revealed that in about 50% of patients the lesions resolved within 2 years. However, about 40% of those whose lesions cleared had a recurrence, in the majority of cases at the same sites as the original lesions. In this study, there did not appear to be any difference in prognosis between individuals with single lesions and those with multiple lesions, and although there is an impression that spontaneous resolution is less likely to occur with generalized granuloma annulare there does not appear to be any documented confirmation of this.

Fig. 60.9 Granuloma annulare on the ear.

There are reports of anetoderma secondary to generalized lesions [67], and mid-dermal elastolysis occurring with granuloma annulare [68] and subsequent to lesions resembling granuloma annulare [69]. In another case, loss of elastic fibres was presumed to be responsible for development of open comedones on the rim of granuloma annulare lesions occurring on light-exposed areas [70].

Levin *et al*. [71] have discussed the matter of resolution of lesions following biopsy, and have noted the paucity of information relating to this phenomenon in the literature. There appears to be anecdotal evidence of its occurrence, but little documentation. However, it is of interest, in this context, that scarification is one form of physical treatment that has been advocated in the past [72–74].

Differential diagnosis. When the typical annular arrangement of papules is present, the diagnosis is usually straightforward. However, granuloma annulare may be mistaken for tinea, although the latter is more inflammatory, and the annular margin is scaly. Other annular lesions and granulomatous conditions may cause diagnostic confusion, including annular lichen planus, erythema annulare centrifugum, erythema multiforme, erythema migrans of Lyme disease, tuberculides [1] and tertiary syphilis [2]. The morphology and distribution of lesions may simulate mycosis fungoides [3].

With regard to subcutaneous granuloma annulare, the differential diagnosis of subcutaneous nodules of the scalp and legs in children is extensive, and includes trauma, infection and tumours, and a diagnostic biopsy will usually be necessary. In adults, nodular lesions have to be distinguished from sarcoidosis and rheumatoid nodules.

The differential diagnosis of perforating granuloma annulare includes molluscum contagiosum [4], transepithelial elimination disorders such as perforating collagenosis and acquired perforating dermatosis, sarcoidosis and papulonecrotic tuberculide [5,6]. As mentioned above, epithelioid sarcoma may masquerade as perforating granuloma annulare.

Mycobacterium marinum infection has histologically simulated interstitial granuloma annulare [7], and other histological differential diagnoses include granulomatous mycosis fungoides [8], interstitial granulomatous dermatitis and interstitial granulomatous drug reaction, as mentioned above.

Associations. There has been much discussion of whether there is an association between granuloma annulare and diabetes mellitus [1–13]. A number of studies have not demonstrated any relationship, whereas others suggest an association [1–12]. In the latter, some have favoured an association with generalized granuloma annulare [4–6] and others an association with localized disease [3,7], and possibly localized nodular granuloma annulare [8]. It is of interest to note that in three reports [3,7,8] the majority of diabetics were insulin-dependent (type 1). One study, employing a case–control design, did not show any association between granuloma annulare and type 2 diabetes [9]. The patient population studied did not include anyone with type 1 diabetes. In order to clarify the situation, further, large-scale studies are required, in which the pattern of granuloma annulare and type of diabetes are recorded.

Thomas *et al*. [14] reported a man with granuloma annulare of the skin, and intra-abdominal lesions, insulin-dependent diabetes and polyendocrine disease, in whom there appeared to be a relationship between diabetic control and the granuloma annulare. Granuloma annulare has been described in a child with Mauriac's syndrome (juvenile diabetes, stunted growth and hepatomegaly) [15].

There are a number of reports of the coexistence of both localized and generalized granuloma annulare and autoimmune thyroiditis in women [16–22], and results of a case–control study indicated an association between localized granuloma annulare and autoimmune thyroiditis [22]. In one case with generalized granuloma annulare the skin lesions improved in concert with disappearance of antithyroid antibodies and restoration of the euthyroid state [17]. Generalized granuloma annulare has also been reported in a patient with a toxic adenoma of the thyroid (Plummer's disease) [23].

Recent reports suggest the possibility of an association between uveitis and granuloma annulare [24,25].

Li *et al*. [26] have summarized and analyzed reports addressing a possible relationship between granuloma annulare and malignant neoplasms. In the cases reviewed, skin lesions that had histological features of granuloma annulare, but were often atypical clinically (for example, painful lesions on the palms and soles), occurred in patients with a neoplasm (in 56% of cases this was a lymphoma). They concluded that there was no definite relationship between granuloma annulare and malignant neoplasms.

There are isolated reports of the occurrence of temporal arteritis in a patient with generalized granuloma annulare [27], and of the coexistence of granuloma annulare and morphoea [28].

There are a number of reports of the occurrence of granuloma annulare and necrobiosis lipoidica in the same patient [29–32], and of the association of granuloma annulare and sarcoidosis [33–36].

Treatment. The tendency of granuloma annulare to remit spontaneously complicates accurate assessment of the efficacy of any treatment, but in some patients explanation that this is the natural course of the disease is all that is required, and certainly in children it is preferable to await spontaneous resolution rather than subjecting them to the discomfort of some of the treatment methods. Potent topical steroids, with or without occlusion, are used by many dermatologists, but often with little benefit. Intralesional steroids, given by either needle injection or jet injector [1], appear to be more effective in the management of localized lesions. Cryosurgery also appears to be an effective treatment for localized disease. In a study of 31 patients, in which nitrous oxide and liquid nitrogen were employed, resolution was achieved in all, following a single freeze–thaw cycle in the majority [2]. The cosmetic result obtained by cryosurgery with nitrous oxide was independent of the size of the lesion, whereas in individuals treated with liquid nitrogen a better cosmetic result was obtained with smaller lesions. Because of this, the authors of the report proposed that use of nitrous oxide as refrigerant was preferable to liquid nitrogen.

Localized granuloma annulare has also been treated with local injections of low-dose recombinant interferon gamma [3]. Complete resolution of lesions occurred in the three treated patients, with no recurrence during 12 months of follow-up. More recently, photodynamic therapy was used successfully for localized disease [4], as was the pulsed dye laser [5].

Although some reports have indicated a beneficial effect of oral potassium iodide in the treatment of disseminated granuloma annulare [6,7], a double-blind, placebo-controlled, crossover study showed that it had no advantage over placebo [8]. PUVA therapy appears to be an effective treatment for generalized granuloma annulare, and good results have been reported using both oral and topical psoralens [9–17]. In many cases, however, maintenance therapy is required to sustain the benefit. Narrowband UVB [18] and UVA-1 phototherapy [19,20] have also been reported as effective in the treatment of generalized granuloma annulare. Etretinate [21–23] and isotretinoin [24–29] have both been of benefit in disseminated disease. Isotretinoin has also improved localized [30] and perforating granuloma annulare [31]. There are a few reports of the use of ciclosporin in generalized granuloma annulare [32–35], with good results in most cases. Other treatments which have been used with apparent benefit in isolated cases or small numbers of patients with disseminated granuloma annulare include low-dose chlorambucil [36–40], dapsone [41], antimalarials [42–44], niacinamide [45], pentoxifylline [46], tranilast [47], fumaric acid esters [48–50], clofazimine [51], topical vitamin E [52], a combination of vitamin E and a 5-lipoxygenase inhibitor [53], and defibrotide [54].

Recent reports suggest that topical imiquimod [55,56], tacrolimus [57,58] and pimecrolimus [59] may be helpful, and rapid reso-

lution of recalcitrant disseminated lesions on treatment with infliximab [60] and efalizumab [61] has been reported. Shupack and Siu [62] noted clearing of disseminated lesions in a patient treated with etanercept, but in a series of four patients reported by Kreuter *et al*. [63] there was either no change or deterioration during therapy with this agent.

Most of the treatments mentioned above have been employed in patients with perforating lesions, with varying degrees of success [64].

Lesions of subcutaneous granuloma annulare should be left to resolve spontaneously once the diagnosis has been confirmed [65].

Necrobiosis lipoidica

Introduction. Necrobiosis lipoidica was first described by Oppenheim, in 1930 [1], and subsequently named *necrobiosis lipoidica diabeticorum* by Urbach, in 1932 [2]. Because it is not peculiar to diabetes, it is now usually called necrobiosis lipoidica. It is similar in histological appearance to granuloma annulare, but has a distinctive clinical appearance characterized by sharply demarcated plaques of atrophic yellowish skin, which may ulcerate.

Aetiology [3]. This condition was originally regarded as a complication of diabetes mellitus, but it was soon realized that some patients with necrobiosis lipoidica did not have overt diabetes. The precise relationship of the diabetic state to necrobiosis lipoidica is still not clear, although they are undoubtedly associated as discussed below.

Some authors have considered vascular changes to be important in the pathogenesis of necrobiosis lipoidica, but in Muller and Winkelmann's histopathological study vascular involvement was very mild in about a third of the cases [4]. An altered plasma protein profile [5], elevated factor VIII-related antigen [6] and fibronectin [7] may contribute to the vascular changes.

The possible role of an antibody-mediated vasculitis as an initiating event in necrobiosis lipoidica has provoked debate, as results of immunofluorescence studies differ. Laukkanen *et al*. [8] did not demonstrate immunoreactants in lesional skin, but others have shown immunoreactants, principally IgM, C3 and fibrin, in vessel walls in the involved skin, and IgM, C3 and fibrinogen at the dermoepidermal junction [9,10]. Dahl [11] has discussed immunofluorescence findings in necrobiosis lipoidica.

Whatever the mechanism, there is evidence of impaired microcirculation in non-diabetic individuals with necrobiosis lipoidica compared with controls, as measured by laser-Doppler flowmetry [12].

Although vascular factors may play a role, the precise pathogenesis of necrobiosis lipoidica remains unknown.

Histopathology [1–3] (Fig. 60.10). The histological appearances are similar to those of granuloma annulare, but some features differ. The epidermis is normal or atrophic, and absent if there is ulceration. The dermal changes involve its full thickness, and often extend into the subcutaneous fat. Early lesions show a perivascular and interstitial mixed inflammatory cell infiltrate. Areas of necrobiosis are usually more extensive and less well-defined than in granuloma annulare. There is degeneration of collagen and elastin within lesions [4]. Histiocytes border the areas of necrobiosis. There are variable numbers of Langhans' or foreign-body giant cells. A perivascular inflammatory infiltrate includes occasional eosinophils and, in contrast with granuloma annulare, plasma cells. Lymphoid nodules, containing germinal centres, may be present in the deep dermis or subcutaneous fat [5]. Lipid can be demonstrated in the necrobiotic areas, and cholesterol clefts may be present [6]. Mucin may be present in the dermis, but it is not as prominent as in granuloma annulare.

Small, superficial blood vessels are increased in number and telangiectatic. Deeper dermal blood vessels often show thickening of their walls and proliferation of endothelial cells. The walls are often infiltrated with periodic acid–Schiff-positive, diastase-negative material. Histologically, comedo-like plugs at the periphery of lesions represent elimination of necrotic material through hair follicles [7,8]. Anaesthesia in the lesions appears to be related to a decreased number of nerves within them [9]. In old, atrophic lesions there is considerable fibrosis in the dermis and subcutis.

Clinical features [1–3]. Necrobiosis lipoidica may occur at any age, but usually develops in young adults and in early middle-age. In insulin-dependent diabetics the age of onset is earlier than in non-insulin-dependent and non-diabetic individuals [4]. It is rare in childhood [5,6]. The female:male ratio is 3:1. Familial occurrence is rare [7,8].

Typical lesions occur on the pretibial skin, and begin as a firm, dull-red papule or plaque which enlarges radially to become a yellowish, atrophic plaque with an erythematous edge (Figs 60.11 & 60.12). The surface is often glazed in appearance, and telangiectatic vessels may be prominent (Fig. 60.13). Lesions are usually symptomless. Hypoaesthesia or anaesthesia, and hypohidrosis, are features of the affected skin [2,9,10]. Comedo-like plugs may occur at the periphery of lesions [11]. In most cases, lesions are bilateral, and they are similar in appearance whether occurring in diabetic or non-diabetic individuals [1]. They tend to be persistent, and some may ulcerate [12] (Fig. 60.14). In one study [4], ulceration correlated with sensory impairment. Squamous cell carcinoma may develop in long-standing lesions [13–20].

Lesions can also occur on other parts of the body, including the trunk [21] and penis [22,23], and rarely may be diffuse [24]. They may also occur at sites of trauma [25–28]. The number of lesions, and their rate of progress, are very variable. Slow extension over many years is usual, but long periods of quiescence, or resolution with variable atrophy and scarring (Fig. 60.15), may occur.

Wilson Jones [29] described an 'atypical annular form' of necrobiosis lipoidica affecting the upper face and scalp margins. The majority of affected individuals were female, and some developed lesions of necrobiosis lipoidica elsewhere. Since then, other authors have described similar annular lesions occurring predominantly on the exposed skin of the head, neck and arms, and these have been named Miescher's granuloma [30] and actinic granuloma [31]. Hanke *et al.* [32] proposed the term 'annular elastolytic giant

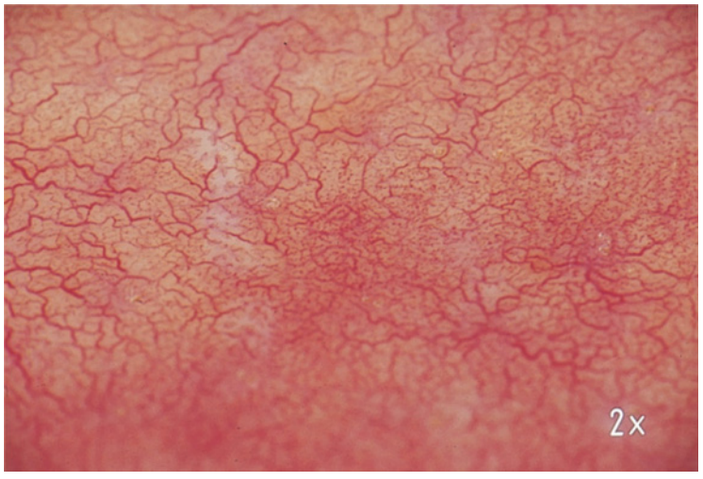

Fig. 60.13 Prominent telangiectasia in an area of necrobiosis.

Fig. 60.14 Ulcerated necrobiosis lipoidica.

cell granuloma' for these lesions. A similarity to granuloma multiforme (p. 60.17) is also apparent. The relationship of these disorders to each other, and to the necrobiotic granulomas, has provoked debate [3,33].

Differential diagnosis. Lesions with marked fatty infiltration, particularly when not on the legs, may be mistaken for xanthomas. Necrobiotic xanthogranuloma is a rare destructive xanthogranuloma, in which red-orange or yellowish indurated plaques most frequently involve the periorbital regions and trunk [34,35]. It is associated with systemic lesions and a monoclonal gammopathy (Chapter 62).

Fig. 60.15 'Burnt out' necrobiosis lipoidica—marked atrophy is evident.

Associations. Although it is accepted that there is a relationship between necrobiosis lipoidica and diabetes mellitus, there is some disagreement about the closeness of this association. In Muller and Winkelmann's large series of cases, 111 of 171 patients with necrobiosis lipoidica (65%) had diabetes, and several of the non-diabetic patients subsequently had abnormal glucose tolerance tests, whereas in a study from Ireland [2], of 65 individuals with necrobiosis lipoidica only seven (11%) were known to have diabetes at the time of presentation. Necrobiosis lipoidica is relatively uncommon in diabetic patients, with reported prevalences of 0.3% [1] and 1.2% [3], and appears to be rare (0.06%) in childhood diabetes [4].

It is most commonly seen in patients with type 1 diabetes [3,5], but also occurs in type 2 diabetes, and in recent years has been reported in children and adolescents with type 2 diabetes [6–9], including diabetes associated with Prader–Willi syndrome [10]. A survey of the records of 178 patients fitting the clinical criteria for maturity-onset diabetes of the young (MODY), which is a subtype of non-insulin-dependent diabetes, showed a prevalence of necrobiosis lipoidica of 2.8% [8].

There is some evidence that diabetic patients who have necrobiosis lipoidica are at higher risk of retinopathy and nephropathy than diabetics who do not [5,11,12]. In the past, it was noted that good control of diabetes did not appear to have a significant effect on the course of necrobiosis lipoidica [1], but it would be of interest to reassess this aspect of the disease in the context of advances in diabetes care in recent years.

Necrobiosis lipoidica has also been reported as occurring in association with ulcerative colitis [13] and Crohn's disease [14], ataxia–telangiectasia [15], and after jejunal bypass surgery [16]. Reports of its occurrence with granuloma annulare have been mentioned previously (p. 60.9). It has also been reported in association with sarcoidosis [17,18].

Magro *et al*. [19] have demonstrated histopathological evidence of an 'active vasculopathy' in the majority of a series of cases of necrobiosis lipoidica associated with systemic disease.

Treatment. Potent topical corticosteroids, particularly if applied beneath an occlusive dressing, and changed weekly, may help [1]. Locally injected triamcinolone, delivered by needle or jet injector [2], can improve the appearance, but atrophy usually remains. As there is evidence of extension of the inflammatory infiltrate into apparently normal skin surrounding active lesions, injection of steroids into perilesional areas might help to limit progression [3]. The use of oral steroids may be of benefit [4,5]. Petzelbauer *et al*. [5] employed short-course steroid therapy that resulted in cessation of disease activity in six patients, and no recurrence in a mean follow-up period of 7 months.

There are reports of benefit from PUVA therapy [6–12], UVA1 phototherapy—some patients improved but there was a poor response in others [13], topical tacrolimus [14], fumaric acid esters [15], thalidomide [16], chloroquine [17], photodynamic therapy [18], a combination of split-thickness autografting and immunomodulatory therapy [19], and etanercept [20].

Other treatments that have been employed in the past, with varying degrees of success, include fibrinolytic agents [21], high-dose nicotinamide [22], clofazimine [23], pentoxifylline [24–27], tretinoin (0.05%) [28], prostaglandin E1 [29,30], and aspirin or an aspirin/dipyridamole combination [31–33]. Aspirin alone was subsequently shown to be ineffective [34,35], and in a randomized, double-blind comparison with placebo, patients treated with an aspirin/dipyridamole combination did not show any significant improvement [36].

Pulsed dye laser has been employed, and may improve the telangiectatic and erythematous components [37], but skin breakdown can occur [38]. Ulcerated necrobiosis has been treated by excision and grafting [39–41], although recurrence tends to occur unless the excision is deep [41]. Other treatments employed include oral steroid [42], ciclosporin [43–45], mycophenolate mofetil [46], topical granulocyte-macrophage colony stimulating factor [47,48], infliximab [49], intravenous immunoglobulin [50], hyperbaric oxygen [51,52], topically applied bovine collagen [53], and grafting with bioengineered dermal tissue [54,55].

Granuloma multiforme

Definition. A chronic granulomatous skin condition, characterized clinically by firm papules aggregated into plaques or forming the edges of annular lesions, and histologically by focal necrobiosis and histiocytic granulomas. It has been reported from Africa, Indonesia and India [1–8]. Leiker *et al*. [1–3] first described granuloma multiforme and distinguished it from tuberculoid leprosy. Leiker called it Mkar disease, after the town where it was first studied. The condition is endemic in certain villages in eastern Nigeria, where the local inhabitants refer to it in the Ibo tongue as 'Ununo Enyi' (elephant ringworm) [4,7].

The disease appears to occur predominantly in females over the age of 40 years [4,7,9].

Aetiology. The morphology and histological features of lesions, and their distribution predominantly on exposed parts of the body, indicate that this disorder may be granuloma annulare on light-exposed areas. It has been suggested that the primary event may be sun-induced damage to dermal connective tissue [9].

Pathology [4,10]. There are focal areas of necrobiosis, with loss of elastic tissue, surrounded by histiocytes. Multinucleated giant cells are usually a prominent feature. There is a perivascular lymphocytic infiltrate with variable numbers of plasma cells and eosinophils.

Clinical features. The upper, uncovered parts of the body are predominantly affected. The initial lesions are small, flesh-coloured papules which become aggregated into plaques or form the elevated rims of annular lesions. In larger annular lesions the central area is often hypopigmented. Pruritus may be prominent. The condition lasts for many months or years, and may persist indefinitely.

Differential diagnosis. Leprosy is endemic in the same regions where granuloma multiforme is found, and can look very similar. However, there is no loss of sensation or sweating, or other evidence of neural involvement in granuloma multiforme. In addition, the histological changes are different.

Treatment. None is known to be effective.

Definition

There is no universally accepted definition of sarcoidosis. Many attempts have been made, but as long as its cause is unknown, definitions must be empirical and may also be inaccurate. Current definitions still have to avoid aetiological implications and the illogicalities that may result from them.

Scadding and Mitchell [1], after a full discussion of the difficulties, suggested the following: 'Sarcoidosis is a disease characterized by the formation in all or several affected organs or tissues of epithelioid cell tubercles, without caseation, although fibrinoid necrosis may be present at the centre of a few, proceeding either to resolution or to conversion of the epithelioid cell tubercles into hyaline fibrous tissue.'

The characteristic histology should be present in all affected tissue and similar in all parts of it. This excludes the sarcoid-like histology found in tuberculosis, brucellosis or leprosy. It is characterized by non-caseating epithelioid granulomas.

Main features

The most important features of sarcoidosis are as follows.

1 The disease process is usually generalized. The term is seldom applicable to a localized granulomatous reaction even though it may have similar histological findings.
2 The clinical manifestations are protean; the disease process is usually widespread; the course is protracted and usually benign, though sometimes with dangerous and disabling sequelae and complications.
3 The disease may affect any organ of the body (the adrenal gland possibly excluded). The lymph nodes, lungs, liver, spleen, skin, eyes, small bones of hands and feet, and salivary glands are most frequently affected.
4 All affected organs conform to a similar histological pattern.
5 Other changes present to a varying and inconstant degree include suppression or weakening of tuberculin and other intradermal responses, an increase in the serum gamma-globulins and a raised serum calcium level.
6 The Kveim reaction is positive in most active cases. This test is no longer available.

History [2–4]

The earliest description of a case which would now be categorized as sarcoidosis was probably Besnier's report in 1889 [5] of an association between reddish-blue lesions of the face and nose with swellings of the fingers [4]; the name 'lupus pernio' reflected his view that this might be a variant of lupus vulgaris. Tenneson in 1892 added the histological description [6]. In 1898 Hutchinson described two more cases of a skin eruption, probably sarcoidosis, to which he gave the name of 'Mortimer's malady' after one of his patients [7]. Boeck in 1899 [8] recorded his 'multiple benign sarkoid of the skin', and the current term 'sarcoidosis' stems from his misinterpretation of the histological changes. However, it was Boeck who first developed the concept of a disease involving both the skin and internal organs—a concept taken further by Schaumann [9], who again emphasized the generalized nature of the disease and showed that skin changes were not a necessary feature of it. The disease was further expanded by the inclusion of 'osteitis tuberculosa multiplex cystica' [10], uveoparotid fever [11], and pulmonary and other manifestations [12,13]. The introduction of mass radiography led to the recognition of hilar lymphadenopathy, with or without erythema nodosum, as an early benign form [14,15] and this has altered the whole concept

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

of the disease, which is now seen more often by chest and general physicians than by dermatologists.

Epidemiology [1]

The apparent increase in sarcoidosis over the last 40 years has been due partly to better detection, especially by mass radiography. However, even in countries with compulsory notification of the disease, there are bound to be many cases in an early, asymptomatic stage that remain undetected. For this reason, prevalence and incidence figures have to be interpreted with caution, though it is now clear that the disease has a worldwide distribution.

Sarcoidosis seems to be most prevalent (more than 10 per 100 000 population) in developed countries, but 'each succeeding world congress brings to the fore yet another country which has achieved manhood by joining in the world recognition of sarcoidosis' [2].

The danger of drawing inferences from unrepresentative collections of patients is well known [3], but certain groups do seem to be especially prone to sarcoidosis. It is, for example, more common in Afro-Caribbeans than in white inhabitants of the same area [4,5]. Other especially vulnerable groups include Puerto Ricans in New York and Irish immigrants to England. A useful study of 401 consecutive patients presenting to a district general hospital in the UK [6] gives a view of ethnic representation: Irish and Afro-Caribbean patients were disproportionately common in the material, but no attempt was made to assess incidence or prevalence in the population covered. Erythema nodosum was particularly common in the British and Irish; other skin manifestations occurred in 30 patients, 80% of whom were under 45 years of age.

Overall, sarcoidosis may be slightly more common in women than in men, and usually presents between the ages of 20 and 40 years. It is rare in young children [7]. The fact remains, however, that despite the voluminous data available, the factors influencing the prevalence and incidence of sarcoidosis remain obscure. Occupational, socioeconomic and climatic factors may be more important than have been recognized so far.

Aetiology

Despite intensive investigation, the cause of sarcoidosis remains unknown; it is not even clear whether the condition has only one or many causes. Most of the earlier theories have been discarded; others remain unproven. Evidence from genetic and environmental sources has been inconclusive, and immunological studies have, perhaps, raised more questions than they have solved. Speculations now lie in two main areas: infectious causes and genetic factors. Both may be interlinked.

Infectious agents

Many infectious agents have been put forward as the cause of sarcoidosis, but cultures are always negative and responses to treatment have not supported these beliefs. However, it remains possible that the disease represents an unusual host reaction to one or more infective agents—as yet unknown. Diagnostic confusion with tuberculosis led to speculation that *Mycobacterium tuberculosis*, perhaps in some transmuted form, might be responsible for the symptom complex of sarcoidosis. Recent evidence has lent some support for this. Serological studies have shown that patients with sarcoidosis have raised levels of antibodies to *M. paratuberculosis*, similar to those seen with Crohn's disease [1]. A polymerase chain reaction study revealed the presence of various subtypes of mycobacterial DNA (including *M. avium–intracellulare*) in 16 of 20 cases of cutaneous sarcoidosis [2]. In addition, it was reported that acid-fast cell-wall-deficient forms of *M. tuberculosis* have been grown from the blood of patients with active sarcoidosis [3]. However, a recent study failed to detect *M. tuberculosis* ribosomal RNA in fresh tissue specimens [4]. The significance of these findings is unclear at present, and the contribution of any mycobacteria to the pathogenesis of sarcoidosis is unknown. The onset of cutaneous sarcoidosis has been described following *M. marinum* infection [5]. It has been questioned as to whether *Propionibacterium acnes* may be involved in the aetiology of sarcoidosis, as *P. acnes* has been isolated from bronchial lavage in subjects with pulmonary sarcoidosis. However, it is known that *P. acnes* is a commensal in peripheral lung tissues and the findings do not appear to be specific for sarcoidosis [6].

Histoplasmosis and other fungi, which can produce granulomas exactly mimicking sarcoidosis, also have been suspected as possible causes, but their geographical limitations rule them out. Finally, it is always tempting to consider a viral cause for an obscure disease, but there is still no evidence to take this beyond mere speculation.

Genetic and familial factors

Familial sarcoidosis is well recognized and occurs more commonly than chance would predict. In ethnic groups known to have a high prevalence of sarcoidosis, the probability that an index case will have a sibling with sarcoidosis is about 10% [7]. In one study of 645 cases of sarcoidosis, 26 came from 12 families [8]. A literature search [9] found 182 affected sibling pairs; the excess of like-sex pairs was thought to reflect the effects of environmental exposure, which they are more likely to share than unlike-sex pairs. Far fewer examples of husband/wife sarcoidosis have been recorded [10] and this suggests that family aggregates occur either on a mainly genetic basis, or require a common environmental exposure during childhood. No consistent mode of inheritance has been found, although a recessive pattern may be more common [11].

Studies of human leukocyte antigens (HLAs) have not clarified the matter [12]. Differences between black and white subjects exist. Among black patients in the USA, sarcoidosis occurred significantly more frequently in individuals with BW15—but so did tuberculosis [13]. In London, white people with HLA-B8 were especially likely to have arthritis or erythema nodosum [14]. A recent Japanese study of 63 patients with sarcoidosis suggested that susceptibility for the disease may reside in the HLA-DRB1 locus, with resistance being conferred by the HLA-DRB1*1302 locus [15].

It seems likely that the HLA type can influence the pattern of the disease, rather than determine its occurrence. Recent studies suggest that the genes influencing clinical presentation of sarcoidosis in African Americans are different from those that underlie disease susceptibility [16].

Interferon-alpha (IFN-α) therapy

In more than 65 case reports [17], sarcoidosis has developed 15 days to 30 months after commencing IFN-α treatment. Some patients [18,19] had chronic myelogenous leukaemia and cutaneous lymphoma, conditions known to be associated with sarcoidosis on occasions. Others have had chronic hepatitis C [20]. Fifty per cent of cases have skin signs [19]. It is suggested that IFN-α might stimulate Th1 immune responses that are thought to be involved in sarcoidosis.

Histopathology [1]

The histological changes are similar in all organs affected and are remarkably constant. The essential feature is a monotonous repetition of aggregates of epithelioid cells with pale-staining nuclei, which form the characteristic, discrete sarcoidal granulomas (Fig. 61.1). Multinucleate giant cells are usually, but not invariably, present. An inconstant and variable rim of lymphoid cells surrounds the granuloma but this is never well developed—hence the term 'naked tubercle'. Caseation is absent, although an inconspicuous focus of fibrinoid necrosis or coagulation may occur within the granuloma. A fine reticulin network encircles the granuloma and may penetrate it (Fig. 61.2). The infiltrate tends to occur lower in the dermis than that of lupus vulgaris; in erythrodermic sarcoidosis, the granulomas are looser and less well defined. Epidermal changes can include hyperkeratosis, parakeratosis, acanthosis, atrophy and spongiosis: occasionally a lichenoid reaction is seen [2].

During the development of the granuloma, the loosely packed epithelioid cells of the early stage become more numerous and compact (their development is stimulated by IFN-γ produced by Th1 lymphocytes), and giant cells appear by their fusion. Reticulum appears and hyalinization becomes progressively more apparent as fibrosis gradually obliterates the characteristic features of the granulomas. This is the cause of the irreversible tissue scarring of the late stage of the disease. Polarizable foreign bodies were

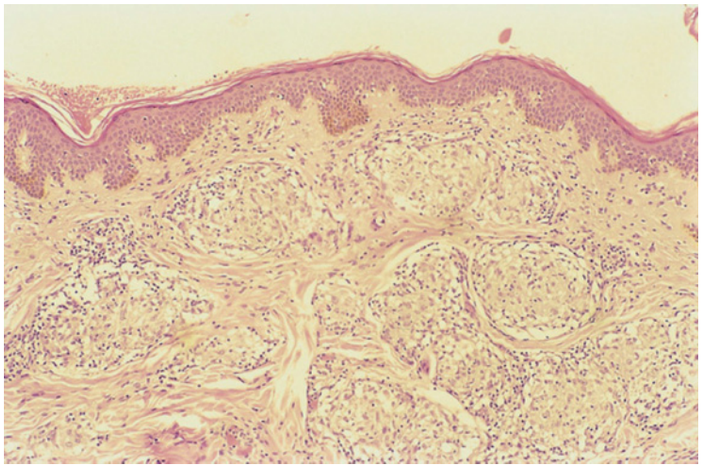

Fig. 61.1 Sarcoidosis. The epidermis is normal, while the superficial and mid-dermis contain numerous small granulomas without caseous necrosis. (Courtesy of Dr T.J. Stephenson, Royal Hallamshire Hospital, Sheffield, UK.)

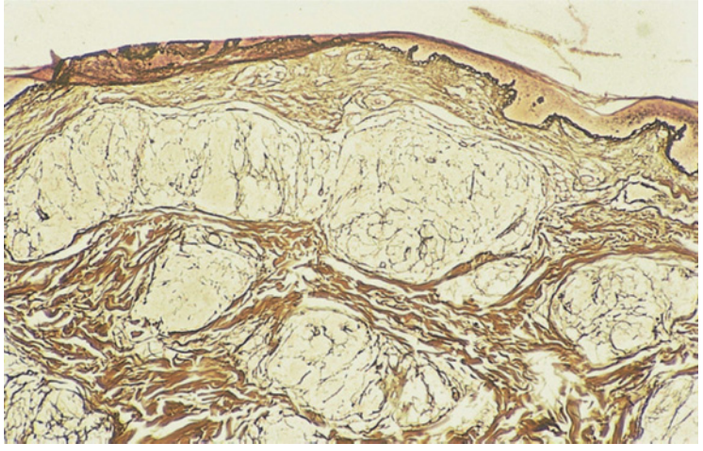

Fig. 61.2 Sarcoidosis. Reticulin stain of the section in Fig. 61.1, showing that the granulomas contain strands of staining reticulin, indicating that they lack caseous necrosis. (Courtesy of Dr T.J. Stephenson, Royal Hallamshire Hospital, Sheffield, UK.)

found in 12 of 50 cases of cutaneous sarcoidosis (all of whom also had systemic granulomatous disease), suggesting that, in some patients, a foreign body may be an inciting stimulus for granuloma formation [1,3].

Inclusion bodies

These are often found in the giant cells in sarcoidosis and other sarcoidal granulomas, but are not specific. Their numbers increase as lesions age. The following types are recognized.

1 *Schaumann (conchoid) bodies* (Fig. 61.3a) are basophilic concentric lamellar structures, 100 μm in diameter, composed of lipomucoglycoproteins impregnated with calcium and iron, and they show central, birefringent crystals.
2 *Asteroid (stellate) bodies* (Fig. 61.3b) are between 10 and 15 μm in size; their central core is surrounded by radiating spicules (the 'open umbrella frame'). They consist of collagen [4].

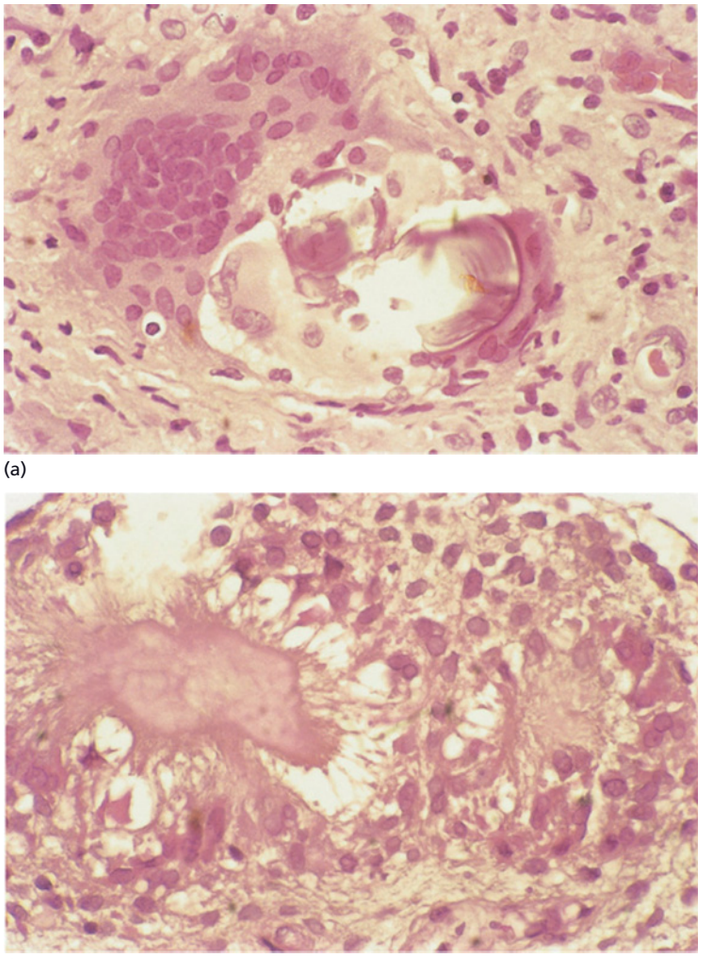

Fig. 61.3 (a) A Schaumann or conchoid body. These laminated calcospherites tend to fracture and to cause score marks. They stain basophilically. They are thought to arise from dystrophic calcification and it is suggested that they indicate chronicity. (b) High-power view of a granuloma in sarcoidosis showing an asteroid body within a giant cell. (Courtesy of Dr T.J. Stephenson, Royal Hallamshire Hospital, Sheffield, UK.)

Development of the granuloma [5]

Several strands of research have combined to increase our understanding of the complex cascade of cellular and mediator interactions involved in granuloma formation.

1 The technique of bronchoalveolar lavage, allowing easy harvesting of cells involved in the inflammatory process within the lungs.
2 Studies of evolving Kveim antigen-induced granulomas.
3 The use of monoclonal antibodies to characterize the cells found within the sarcoidal lesions.
4 The study of local immunological changes in cutaneous sarcoidosis, including the use of the techniques of molecular biology.

The architecture of a cutaneous sarcoid granuloma follows a pattern in which the centre consists of activated macrophages and epithelioid cells, surrounded by dendritic cells. Many activated CD4 helper/inducer T lymphocytes are present at the centre of the granuloma with a smaller population of CD8 suppressor/cytotoxic T lymphocytes at the periphery [6]. The antigen in

Table 61.1 Main histological features of sarcoidosis and tuberculosis.

Feature	Sarcoidosis	Tuberculosis
General structure	Monomorphic tubercles	Caseating tubercles
Form	Discrete, sharply defined 'naked tubercles'	Confluent, diffuse
Epithelioid cells	Large, grouped, predominant	Massed, irregular or at margin of caseation, less than 50%
Giant cells	Large, usually sparse Langhans' and foreign body cells	More numerous, Langhans' cells predominate
Lymphocytes	Sparse cuffing	More numerous and scattered
Inclusion bodies	Frequent	Occasional
Blood vessels	Usually normal or dilated	May show fibrinoid changes
Reticulin	Fine and abundant around tubercles	Destroyed
Caseation	No	Yes (but not lupus vulgaris)
Fibrinoid	Sometimes at centre of tubercle	Vascular and perivascular (late)
Healing process	Progressive hyalinization from periphery; gradual dissolution	Dense collagen mesh Retraction, fibrosis, calcification

sarcoidosis remains unknown, but the arrangements within the granuloma suggest an active immunological process. In addition, most workers have been able to demonstrate immune deposits within cutaneous granulomas, presumably as a consequence of the presence of circulating immune complexes known to occur in some patients with sarcoidosis. The most usual finding has been of immunoglobulin M (IgM) in the walls of dermal blood vessels or at the dermo-epidermal junction.

In the lung, an alveolitis precedes granuloma formation. Circulating blood monocytes appear in the lung, presumably in response to local chemotactic factors, and these aggregate into epithelioid cell granulomas. Pulmonary macrophages are induced by an unknown trigger mechanism to secrete interleukin-1 (IL-1), which is responsible for the migration of T lymphocytes to the site of disease activity. IL-1 also activates T cells and stimulates T-cell release of IL-2, which further amplifies local inflammatory activity. Activated T cells secrete chemotactic factors for monocytes and migration inhibitory factors. Fibrosis is enhanced by fibronectin and growth factors derived from alveolar macrophages.

Differential diagnosis

Typical tuberculosis is usually distinguishable by the histological features listed in Table 61.1. Sarcoidosis may be particularly hard to separate from lupus vulgaris if lymphocytes are more abundant than usual. In tuberculoid leprosy, epithelioid cells surround and are associated with the nerves, and there is more central necrosis. However, the histology of true sarcoidosis cannot always be distinguished from that of sarcoidal granulomas due to other causes—the key to the diagnosis of sarcoidosis lies in the uniformity of the histological changes in all affected organs.

Lupoid leishmaniasis, granulomatosis disciformis, rosacea and Crohn's disease may pose difficulties. Plasma cells and coagulation necrosis are features of syphilis. The granulomas of cat scratch fever are said to be larger than those of sarcoidosis. When sarcoid-like reactions occur in a scar, the possibility of a foreign-body reaction must be considered. Talc may be recognized by its refractile nature.

Immunological aspects [1,2]

Important advances have been made in our understanding of the immunology of sarcoidosis in recent years; yet the paradox of the disease remains. How is it that granulomas can evolve, presumably as a consequence of a local T-cell-mediated immune response to antigenic insult (e.g. a superantigen or a particulate antigen ingested by macrophages), in a condition apparently characterized by reduced cell-mediated immunity? Even if the cutaneous anergy of sarcoidosis is partly explained by a movement of activated helper T cells to sites of disease activity, leaving in the circulation an excess of anergic suppressor cells, then it still has to be accepted that Kveim-induced granulomas, at least, can develop during a state of depressed immune responsiveness.

Cell-mediated immunity

Depression of cell-mediated immunity is the hallmark of sarcoidosis; indeed, the first immunological defect to be demonstrated was lack of reactivity to tuberculin. Sensitivity to tuberculin is depressed to a variable degree and becomes negative in about two-thirds of patients [3]. However, there is no absolute correlation between reactivity and the state of the disease, and some failure of immunological response may persist despite apparent clinical resolution. Later, this anergy was shown to extend to other intradermal allergens such as candidine, strepkokinase–streptodornase and trichophytin antigens [4]. The combination of a depressed reaction to mumps antigen with normal circulating antibody responses is characteristic of, but not specific for, sarcoidosis.

The levels of circulating T lymphocytes expressing the γ/δ T-cell marker are increased in sarcoidosis, and correlate with the defect in cellular immunity [5]. T-cell receptor gene studies from blood and sarcoid lesions are consistent with an oligoclonal expansion of T cells from an antigen-driven response [6]. The formation of sarcoid granulomas, like tuberculoid, is characterized by the expression of a Th1 cytokine profile, i.e. the T-lymphocytes secrete IL-2, IFN-γ, and tumour necrosis factor-α (TNF-α) [7]; there is inactivation of Th2 lymphocytes. Th2-type granulomas have a prevalence of eosinophils and are seen, for example, in schistosomiasis.

The onset of sarcoidosis in HIV-positive patients after commencement of highly active antiretroviral therapy has been reported in 11 cases, leading to the suggestion that immune reconstitution was involved [8]. However, it is significant that sarcoidosis has developed in some patients with low $CD4^+$ counts (126–1080, mean 373 cells/mm^3) [8].

Humoral immunity

All classes of serum immunoglobulins are increased. Activated T lymphocytes release B-cell growth factor and a B-cell differentiation factor, which together increase immunoglobulin production at the sites of disease. Significantly raised levels of circulating antibodies may be found to rubella, measles, herpes simplex, the Epstein–Barr virus and cytomegalovirus [9]. With regard to atopy as defined by personal history, skin prick tests and total IgE levels, a recent Turkish study of 41 patients with sarcoidosis found that only four (10%) were atopic compared with the expected 25% [10]. Interpretation of a small series such as this is difficult.

General manifestations of sarcoidosis [1–3]

There is no disease with more varied manifestations. Its course is unpredictable. Several years may separate one manifestation from another, and any organ of the body may be involved. Symptoms result from invasion and replacement, pressure, anaemia, hypercalcaemia and fibrosis.

A full history must include details of race, area of residence, previous tuberculin testing and bacille Calmette–Guérin (BCG) vaccination, industrial exposure to beryllium and any previous disease, such as erythema nodosum, that may be related, even distantly.

Staging of the disease

Pulmonary sarcoidosis is classically divided into four stages on the basis of the chest radiograph:

Fig. 61.4 Chest radiograph showing bilateral hilar lymphadenopathy typical of sarcoidosis.

1 Stage 0: 5–10% of patients with sarcoidosis have a normal chest radiograph.
2 Stage I: bilateral hilar lymphadenopathy alone—seen on the presenting radiograph of 35–45% of patients (Fig. 61.4).
3 Stage II: bilateral hilar lymphadenopathy with parenchymal lung involvement of fine 'fluffy' or coarse type.
4 Stage III: late stage of pulmonary infiltration with fibrosis and pulmonary insufficiency.

Extrapulmonary manifestations of sarcoidosis cannot be staged in this way, although some generalizations are possible. Erythema nodosum is, *par excellence*, an early feature, occurring with stage I pulmonary disease, and carrying a good prognosis. Iridocyclitis and anterior uveitis are usually associated with the later stages and more persistent forms of the disease. An attempt can be made to classify sarcoidosis on the basis of the degree of internal involvement, and on the type of skin lesions, as 'early' (e.g. erythema nodosum and bilateral hilar lymphadenopathy), 'intermediate' (e.g. papular and nodular forms) and 'late' (e.g. plaque, subcutaneous or lupus pernio). However, this may be unreliable, as the prognosis mostly depends upon the extent of internal disease, and this may not become apparent until treatment is too late to be effective. Of this disease, it has been aptly said: 'One of its most singular details . . . is the frequency of its clinical silence'.

Systemic features

General symptoms

The onset is often marked by lethargy, loss of weight and general malaise, but may be symptomless. A dry cough, dyspnoea and chest pain are present in half the patients.

Bone and joint changes

An acute polyarthralgia may accompany erythema nodosum. A more chronic polyarthritis may appear later in the disease, chiefly

in Afro-Caribbeans. Bone changes, often asymptomatic, were found in 8% of 260 patients routinely examined radiologically [4]. Classically, they involve the small bones of the hands and feet in middle-aged women with lupus pernio. The most common change is lysis with bone cysts. The nasal bones, and occasionally the calvarium, may be involved in a way that mimics metastatic deposits [5].

Cardiac involvement [6]

Granulomatous infiltration of the conducting system may lead to heart block, papillary muscle dysfunction, congestive cardiac failure, pericarditis, chest pain, arrhythmias or even sudden death. The patients are often young, and the condition may be revealed only at post-mortem. Cardiac involvement is more common than was once believed, being found in 20–50% of autopsies on patients with sarcoid [6]. An abnormal electrocardiogram (ECG) was found in 14% of 401 patients examined routinely [4]. A careful cardiac examination should be a routine procedure in all cases of established sarcoidosis.

Muscle involvement

Polymyositis and myopathy occur rarely, and even muscle weakness and tenderness are uncommon despite the fact that random muscle biopsies in patients with sarcoidosis are positive in 50–80%. Tumour-type muscle sarcoidosis is very rare [7].

Nervous system involvement [8,9]

About 5% of patients with sarcoidosis have nervous system involvement and a wide variety of syndromes may result, including optic nerve lesions, cranial nerve palsies, meningoencephalitis, multiple sclerosis-like changes, peripheral neuropathy, mononeuritis multiplex and psychiatric changes. The facial nerve is frequently affected, with or without Heerfordt's syndrome (see below). Involvement of the hypothalamus or brain stem is rare but important. Sarcoidosis may also present as diabetes insipidus, hypopituitarism or endocrine abnormalities. The cerebrospinal fluid can show elevated protein and/or cells. Magnetic resonance imaging (MRI) may reveal abnormalities. Peripheral neuropathies often settle, but central nervous system manifestations seldom do so.

Ocular involvement [10]

The eyes are involved at some time in 25–50% of patients with sarcoidosis; eye disease is the first feature of sarcoidosis in about 10% of patients. The main types of ocular involvement are as follows:

1. *Uveitis*. Anterior and posterior uveitis are the most important and serious manifestations. Acute and chronic forms occur. The onset is usually insidious and 'mutton-fat' precipitates are found on the corneal epithelium. Iridocyclitis may be severe and recurrent. Complications include glaucoma, cataract and iris synechiae.
2. *Iris nodules*. These represent granulomatous infiltration of the stroma of the iris.
3. *Retinochoroiditis*. This usually occurs with chronic uveitis.
4. *Conjunctivitis*. Conjunctival nodules are common and are opaque, grey, slightly elevated lesions. 'Millet-seed' nodules may involve the eyelid margins. Biopsy will help to confirm the diagnosis of sarcoidosis; even 'blind' biopsies may reveal the disease.
5. *Lacrimal gland involvement*. Decreased lacrimal gland secretion is not uncommon (keratoconjunctivitis sicca is a presenting feature in about 10% of cases). Sarcoidosis is one cause of Mikulicz's syndrome (bilateral swelling of the lacrimal and salivary glands). Sjögren's syndrome can coexist with sarcoidosis and poses particular diagnostic problems.
6. *Optic nerves*. These may be involved as part of a widespread involvement of the central nervous system or as unilateral retrobulbar disease. Papilloedema, retrobulbar neuritis and optic atrophy may result.
7. *Orbital involvement*. This may cause unilateral proptosis.
8. *Other ocular syndromes*.
   (a) Lofgren's syndrome (erythema nodosum, bilateral hilar lymphadenopathy and acute iridocyclitis) is usually self-limiting.
   (b) Heerfordt's syndrome includes uveitis, parotid gland enlargement, fever and cranial nerve palsies, usually of the facial nerve.
   (c) Keratoconjunctivitis sicca with parotid and lacrimal gland enlargement.
   (d) Lupus pernio, chronic iridocyclitis, bone cysts and pulmonary fibrosis.

Pulmonary and upper respiratory changes [11]

Pulmonary changes dominate the later stages of the disease, and progressive diminution of respiratory function is the most common cause of incapacity. All patients with clinical or radiographic evidence of pulmonary involvement should be referred to a chest physician, who will decide on the need for and timing of treatment.

Upper respiratory involvement is often associated with chronic pulmonary disease and may be asymptomatic. Nasal stuffiness or blockage, with crusting and a nasal discharge, are common [12]. Cartilage or bone may be destroyed.

Renal involvement [13]

Symptoms are rare, but scattered granulomas can be found at autopsy in up to 40% of patients. Renal failure may be secondary to granulomatous invasion or to hypercalcaemia.

Reticuloendothelial system involvement

Lymph nodes are enlarged in about 50% of patients and may provide a convenient site for biopsy. An enlarged spleen can be felt in about 15% of cases [14]; hypersplenism may cause thrombocytopenia [15].

Involvement of the liver and other organs

It is evident that no organ is exempt from the occasional deposit of sarcoidal granuloma, and the dermatologist, as much as the general physician, should attempt to delineate the full extent of the disease in all patients. In no disease is it more important to look repeatedly 'under the skin' for other signs. Liver granulomas

are found in 63–87% of patients with sarcoidosis and mild elevation of the serum alkaline phosphatase or bilirubin is seen in up to 80% of cases [16], although the liver is only palpable in about 20% of patients.

Hypercalcaemia and hypercalciuria [17]

The frequency of hypercalcaemia varies greatly (from 2% to 40% in different series), but it is less common than hypercalciuria. In one series, 11% of 1760 sarcoid patients had hypercalcaemia, while 40% had hypercalciuria [18]. Persistent hypercalcaemia is manifest clinically as polyuria, nocturia or polydipsia in the absence of hypertension. It can cause nephrocalcinosis and renal failure. The details of the abnormal calcium metabolism in sarcoidosis are still debated: sarcoid granulomas can themselves produce 1,25-dihydroxyvitamin D [19], which may increase calcium absorption via the gut. Persistent hypercalcaemia is one indication for systemic steroid therapy.

Sarcoidosis and pregnancy

The condition may improve during pregnancy, only to relapse thereafter. Miscarriages and congenital abnormalities are not especially common [20].

Sarcoidosis of the skin

Between 20% and 35% of patients with systemic sarcoidosis have skin lesions [1], but cutaneous sarcoidosis can also occur without systemic disease. Significant pulmonary disease may be silent [2]. In six of 13 patients with cutaneous sarcoidosis, but without a past history of sarcoidosis, no other systemic signs of the disease were detected during prolonged follow-up [3]; in another series of 188 patients with cutaneous sarcoid, 50 had no systemic involvement [4]. Finally, the extent of any cutaneous lesions does not correlate with the extent of systemic disease.

Classification. This has been made more difficult by the use of eponyms that are no longer appropriate and which should now be discarded. A simple morphological classification is shown in Table 61.2, but more than one type of lesion may exist at the same time. The differences between the main patterns lie in the manner and extent of the involvement of the skin or subcutaneous tissues.

The specific lesions of sarcoidosis take the form of granulomatous infiltrates: erythema nodosum stands out from these as a non-specific accompaniment of early sarcoidosis without the characteristic sarcoidal granulomas.

Clinical features. The features of the specific cutaneous lesions arise from a dense accumulation of epithelioid cell granulomas in the dermis. In the deep nodular and infiltrative types, the

Table 61.2 Classification of sarcoidosis of the skin.

Type of cutaneous lesions	Stage of disease
Erythema nodosum	Acute ('benign')
Erythematous and erythematopapular	Acute and subacute
'Scar sarcoidosis'	Acute and subacute
Papular ('small nodular')	Acute and subacute
(Boeck) lichenoid variety	
Erythrodermic (Schaumann)	Subacute and chronic
Nodular	Subacute and chronic
Annular (or circinate)	
Angiolupoid (Brocq–Pautrier)	
Subcutaneous	
Plaque	Chronic
Lupus pernio	
Miscellaneous	Usually chronic
Ulcerative, psoriasiform, palmoplantar, ungual, mucosal	
Sarcoidosis of black Africans	

subcutaneous tissue is involved by extension. The lesions of sarcoidosis are generally recognizable as nodules or plaques with a greater degree of infiltration than would be expected from their surface appearance. Their colour ranges from yellow ochre to the livid violaceous hue which is most marked in lupus pernio. On diascopy, a pale yellowish-grey colour remains; sometimes, individual nodules are apparent. There is a tendency to form annular lesions. The epidermis is rarely affected, except for a light scaling, but some degree of vascular dilatation is frequent, especially in angiolupoid sarcoid. Scarring is unusual except in the papular and annular forms.

There is no characteristic distribution, though the small nodular type tends to involve the extensor aspects of the limbs, and rarely the trunk, while the large nodular type affects predominantly the face, hands and trunk. The manifestations of the disease vary from country to country: mucosal involvement, for instance, is rare in France but common in Scandinavia.

Classical forms

Angiolupoid form

A rare but characteristic variety. It affects women predominantly, almost always occurring at the side of the bridge of the nose towards the corner of the eye, below the inner edge of the eyebrow, or on the adjacent area of cheek. There are seldom more than two tumours. They are soft and hemispherical, with a well-marked orange-red or reddish-brown colour and of a more livid hue than other forms. This is due to the marked telangiectatic component, which alters the normal grey-yellow appearance on diascopy. There is little tendency to spontaneous resolution.

Annular forms (Fig. 61.5)

Annular lesions were seen in 32 of 188 white subjects with cutaneous sarcoid lesions [1] and occurred mainly in the chronic stage. They are formed by peripheral evolution and central clearing. They occur particularly on the forehead, face and neck. The central area may become depigmented and scarred. Ulceration is rare. The lesions may resemble annular necrobiosis of the scalp [2], but can be differentiated histologically. Diffuse papular forms may also show an annular configuration.

Erythema nodosum

Sarcoidosis is but one of the many causes of erythema nodosum—a subject dealt with in detail in Chapter 50. It occurs most often in the spring, in young women, and signals an early and usually 'benign' variety of sarcoidosis, with bilateral hilar lymphadenopathy and a tendency to involute spontaneously. Most cases resolve completely within 2 years.

The frequency with which erythema nodosum is reported in sarcoidosis varies from series to series, no doubt depending upon the selection of material. This was well shown in a worldwide survey of sarcoidosis [3] in which erythema nodosum pinpointed the onset of the disease in 600 (17%) of 3676 patients. The distribution was uneven between the countries studied, the condition affecting one-third of British patients and being less evident elsewhere. In a Danish series [1], 25 out of 188 patients with cutaneous sarcoidosis had erythema nodosum which tended to affect younger patients (mean age 30 years) than did infiltrative sarcoidal lesions (mean age 48 years).

Fig. 61.5 Annular sarcoidosis of the face.

Lupus pernio [4]

This is a relatively common skin manifestation of sarcoidosis. In a Danish series of 188 patients with cutaneous sarcoidosis, 22 had lupus pernio [1]. In contrast, in a Turkish series of 516 patients with various skin lesions only 14 had lupus pernio [4]. Lupus pernio tends to affect older patients, is twice as common in women as in men, and is more common in Afro-Caribbeans than in their white counterparts.

Large bluish-red and dusky violaceous infiltrated nodules and plaques occur more or less symmetrically on the nose (Fig. 61.6), cheeks, ears, fingers, hands and toes (Fig. 61.7). The lesions may feel soft, doughy or indurated. Discrete nodules with a typical appearance on diascopy may be found at the edge sometimes. The surface is often glistening, and the epidermis stretched, with large pilosebaceous follicles. Ulceration rarely occurs in the skin, gross mutilation, as in lupus vulgaris, never. Involved ear lobes may become massive ('turkey ears'). Other chronic skin lesions, including plaques and subcutaneous nodules, may accompany lupus pernio. Scarring alopecia may occur on the scalp.

Nasal involvement is associated with swelling, ulceration or crusting of the nasal vestibule, and patients may present with difficulty in breathing. Submucous resection carries the risk of nasal septal perforation and collapse of the nose.

Lupus pernio tends to be associated particularly with other forms of chronic fibrotic sarcoidosis, including upper respiratory

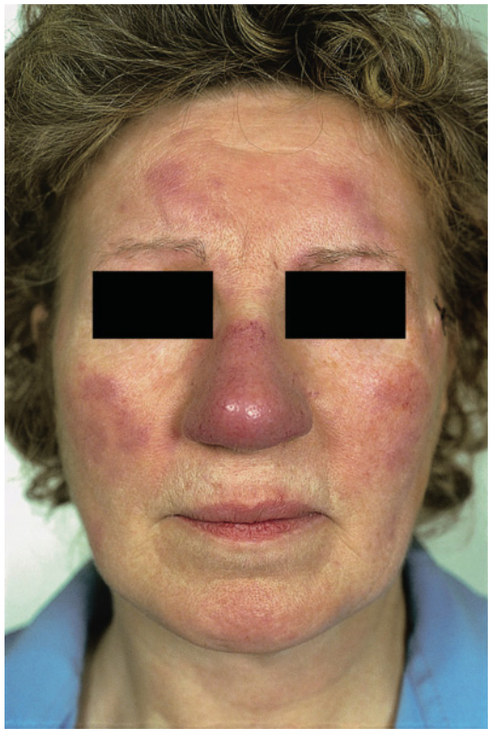

Fig. 61.6 Lupus pernio. (Courtesy of Dr F.A. Ive, Dryburn Hospital, Durham, UK.)

tract sarcoidosis, bone cysts, lacrimal gland and renal sarcoidosis, and with hyperglobulinaemia and hypercalcaemia [4].

Lupus pernio tends to persist: lesions of more than 2 years standing seldom resolve [4]. The facial disfigurement it causes may lead to emotional scarring, which may justify aggressive lines of therapy including plastic surgery [5]. Topical camouflage is an important adjunct to this therapy.

Maculopapular and erythematous forms (Fig. 61.8)

This is separate from the papular form (see below). Transient 'prodromal' maculopapular eruptions were noted in the early stages of sarcoidosis in no less than 8 of 33 patients who showed cutaneous signs of the disease [6] and are apparently seen most commonly by chest and general physicians. Diffuse forms of papular sarcoidosis do occur but are uncommon. Even less common are ill-defined patches of a lavender colour, sometimes slightly scaly or lightly infiltrated. On the face, these simulate rosacea. Sand-like lupoid grains are sometimes seen on diascopy, but more frequently there is a yellow discoloration. Transient parotid swellings and hepatosplenomegaly may be seen [7]. Such cases pursue a long course, fluctuating in severity. Pruritic maculopapular lesions have been described [8].

Nodular forms (Fig. 61.9)

Here the lesions are larger than 5 mm, usually single or relatively few, and remain circumscribed. Red or yellowish-red at first, becoming violaceous or purplish-brown later, they are soft or firm, round and most often affect the proximal parts of the limbs, the trunk and the face. Dilated vessels may be seen on the surface of the lesions which are extremely indolent. As they involute, the centre may become depressed, and the lesions are eventually replaced by brownish telangiectatic marks, or yellowish-white atrophic and fibrotic patches.

Papular (small nodular type) (Figs 61.10 & 61.11)

The papules are hemispherical and vary in size from 1 to 5 mm. Orange or yellowish-brown at first, they later become brownish-red or violaceous, painless and torpid. Only a few lesions or several hundred may appear, arising in crops but eventually becoming stationary. They particularly affect the face (especially in Afro-Caribbeans) and extensor aspects of the limbs, but rarely the trunk or mucous membranes.

On diascopy, the lupoid grains are of a more opaque appearance and colour than those of lupus vulgaris, resembling grains of sand. If probed with a needle they feel firm. When lesions disappear they often leave a pale, yellowish-white or telangiectatic scar. Occasionally they become confluent, merging into an erythematous plaque (Fig. 61.12). A ringed nummular configuration was present in the second of Schaumann's four cases [9].

Widely disseminated, hard, shotty, subcutaneous papules can appear with the granulomas lying in the deep subcutaneous tissues and fascial planes. A lichenoid variety is discussed separately on p. 61.14.

In general, the papular type carries a more favourable prognosis than do other types of infiltration. Confirmatory biopsy of other organs should be carried out, although this form may occur without other manifestations of the disease.

Histopathology. The infiltrate is in the high and mid-dermis. It may be hard to distinguish from acne agminata in which, however, caseation can be seen.

Differential diagnosis. Lupus erythematosus can be mimicked. Papular forms of secondary syphilis are distinguished by the course and associated features of this disease. Occasionally, acne agminata (Chapter 43) presents difficulties.

Plaque form (Fig. 61.13)

It is convenient to keep this form distinct. It involves chiefly the limbs, shoulders, buttocks and thighs. The lesions are characteristically diffuse, and extend further than is apparent on the surface. They may form placards of an irregular shape with more superficial nodules superimposed, sometimes having a crescentic or serpiginous outline resembling tertiary syphilis. On the legs, they may closely resemble necrobiosis lipoidica (Fig. 61.14). They are very persistent.

Scar sarcoidosis (Fig. 61.15)

Sarcoidosis appearing in a scar may be the only cutaneous sign of the disease, and is therefore of diagnostic importance. Scar involvement was seen in 26 of 188 white patients with sarcoidosis [1], and may represent a form of Koebner phenomenon. Long-standing scars, often on the knees, become inflamed and infiltrated, giving rise to typical purplish-red lesions which turn brown as they fade. There is some resemblance to a keloid, but the lesions do not itch. This form of sarcoidosis is as common in men as in women [10].

Fig. 61.12 Plaque-type sarcoidosis affecting the face in a black African. (Courtesy of Dr J.E. Bothwell, Barnsley District General Hospital, Barnsley, UK.)

Scar sarcoidosis occurs in three situations:

1 In the acute eruptive phase, following erythema nodosum, or in the scars of biopsies taken at that time.
2 At any later stage of the disease, sometimes moving in parallel with pulmonary changes and slightly in advance of iritis [6]. Exacerbation of the systemic disease may be preceded by this warning sign.

Fig. 61.14 Sarcoidosis of the plaque type on the shins, resembling necrobiosis lipoidica.

3 At inoculation sites—for example, after venepuncture [11], BCG or tuberculin tests. The involvement of tribal scarification marks is the commonest presentation of sarcoidosis in Nigeria [12,13].

The histology is typical. Confirmatory evidence of sarcoidosis should be sought (by chest radiograph, and biopsy from other organs), as local sarcoidal reactions may occur in scars contaminated with silica. A silica granuloma in a scar may, rarely, progress into scar sarcoidosis [14]. Tattoos may also show sarcoidal reactions.

Fig. 61.15 Scar sarcoidosis on the presternal area. (Courtesy of Dr D.A. Burns, Leicester, UK.)

Subcutaneous sarcoidosis [15]

It seems likely that the first case report of subcutaneous sarcoidosis was indeed that of Darier and Roussy in 1904 [16], although they considered that their patient had tuberculosis. However, the term 'sarcoid of Darier–Roussy' has been used so often for granulomatous conditions other than sarcoidosis that it has become devalued and should be discarded.

Nevertheless, subcutaneous sarcoidosis does exist, although it is rare, especially in white people. It takes the form of tender or painless persistent nodules, most often on the extremities of middle-aged patients, usually women [17]. Systemic involvement is usually present, sometimes as hilar lymphadenopathy [18], although usually not severe and not associated with chronic fibrotic disease [15]. Spontaneous resolution can occur [15].

Histopathology. The infiltrate is naturally greater in nodular lesions but remains circumscribed. In the subcutaneous form, the sarcoid process may at first be located in the septa and at the periphery of the fat lobules, eventually replacing the lobules with granulomatous nodules. In the angio-lupoid form, vascular dilatation is prominent.

Differential diagnosis. Lymphocytoma cutis can be separated by its histology. Four other diseases cause particular difficulty, and serial sectioning and cultures of biopsy material may be necessary. They are as follows:

1 *Tuberculoid leprosy*. Distinguished by loss of thermal appreciation and of the histamine flare, a positive Mitsuda test and invasion of nerves.
2 *Lupus vulgaris*. In its exuberant form, this can scarcely be distinguished, although vitropression is said to reveal more translucent nodules of an 'apple jelly' rather than a greyish-yellow colour. Ulceration and scarring ultimately occur. Histology helps, but does not decide: a therapeutic test with antituberculous drugs does.
3 *Lupoid leishmaniasis*. The same difficulties exist clinically and histologically. Leishman–Donovan bodies are rarely found. The Kveim test is negative.

4 *Local sarcoid reaction*. By definition, this is confined to local areas or sites of trauma. There are no other signs of sarcoidosis, and the Kveim test is negative.

Unusual and atypical forms

In addition to the 'classical' forms of the disease described above, a wide variety of unusual forms have been recorded, particularly in Afro-Caribbeans.

Alopecia

Alopecia of the scalp due to sarcoidosis is well recognized [1,2]. Alopecia of the shin has been a presenting sign of the disease [3]. Sarcoidal granulomas were found on histology, and the Kveim test was positive.

Atrophic forms

The rare atrophic types of cutaneous sarcoidosis may be localized to the legs [4,5] or generalized [6,7]. It is usually accompanied by ulceration.

Erythrodermic sarcoidosis

This is extremely rare. Red scaling patches extend and merge into infiltrated brownish-red sheets. Lymphadenopathy is usually pronounced. During resolution, typical papules and nodules may separate from the plaque, which gradually loses its infiltration and disappears. A reticulate yellowish stippling may be seen as it resolves. One unique case was associated with periarteritis and ulceration [8]; in another patient, a 6-year-old boy, the eruption resembled pityriasis rubra pilaris [9].

Hypopigmentation

Macular hypopigmentation or hypopigmented areas around a central indurated lesion were first recorded in eight of 145 patients (mostly Afro-Caribbeans) with sarcoidosis [10]. There have been several subsequent reports [11–13]. Lesions vary from 0.2 cm to 1 cm in diameter and occur mainly on the limbs [13]. They may be tender, but are not anaesthetic, and may be the first sign of the disease [14].

Histologically, epithelioid cell granulomas are usually present in the dermis; occasionally the changes are non-specific [11,14]. The melanocytes show degenerative changes but electron-microscopy studies have not been helpful [11]. The differential diagnosis includes leprosy, post-inflammatory hypopigmentation, idiopathic guttate hypomelanosis and pityriasis lichenoides chronica [15]. The condition does not respond to corticosteroids [11], but may repigment after prolonged psoralen and UVA (PUVA) therapy [14].

Ichthyosiform sarcoidosis [16–18]

More than 19 cases of ichthyosiform sarcoidosis have been reported [18]. It usually occurs on the lower legs as large, thick, polygonal adherent scales that may or may not overlie dark red papules and nodules. Biopsy reveals epidermal changes consistent with ichthyosis vulgaris, as well as non-caseating epithelioid granulomas in the dermis, even in the absence of clinically detectable dermal abnormality. Almost all patients with ichthyosiform sarcoidosis have systemic involvement. In patients with acquired ichthyosis, biopsy may be worthwhile to exclude occult sarcoidosis.

Lichenoid forms (Fig. 61.16)

The lichenoid variety of sarcoidosis consists of pinhead-sized papules, skin-coloured, erythematous or yellowish in hue, that can be follicular or closely grouped in round or oval clusters and show slight scaling [18]. It constitutes 1–2% of skin sarcoidosis and may pose difficulties in diagnosis [19]. Although the lichenoid form resembles lichen planus or lichen scrofulosorum, the tuberculin test is negative, the course is indolent and the histology characteristic. Arguments have, however, been adduced in favour in a mycobacterial cause, because of atypical features that are sometimes present [20].

Miscellaneous forms

Many have been described, including the following: pseudotumoral [21], psoriasiform [22,23] and pruriginous varieties [24]; lupus erythematosus-like and lupoid forms; a bizarre polymorphous light eruption type; perifollicular pustules and papules widely scattered over the body; keratotic lesions of the palms simulating psoriasis or syphilis [25], thrombophlebitis [26]; vulval disease [27]; and breast mass [28,29]. Hyperpigmentation may occur, particularly in Afro-Caribbeans [10]. Oedema of the lower leg, usually unilateral, is an uncommon manifestation of sarcoidosis [30]. It may occur due to vascular or lymphatic compression

Fig. 61.16 Lichenoid sarcoidosis. (Courtesy of Pro. Dr P. Frosch, Dortmund, Germany)

from enlarged inguinal or parailiac lymph nodes, or from direct granulomatous infiltration of the skin. Calcinosis with subcutaneous plaques was present in one unusual patient [31]. Pain after alcohol or showering has also been described.

Mucosal involvement

Buccal lesions or tongue involvement are occasionally found when sought [1]. The nasal mucosa is often affected in lupus pernio [2,3] and is a convenient site for biopsy. Difficulty in breathing, or a purulent catarrh, may be the presenting symptom. Yellowish-brown nodules or a diffuse infiltration with crusting occurs [4]. The nasal bones may be involved; or the nasal cartilage may collapse [5]. Nodules with a hyperpigmented halo, diffuse pale-yellow plaques or ulceration may be found on the buccal mucosa, palate, larynx or tongue.

Nail involvement [6]

This is rare, affecting only one in 400 patients with sarcoidosis in one series [7]. Changes recorded have included the following: thickening, opacity, fragility, layering, convexity, longitudinal ridging, pitting, atrophy, nail loss, pterygium and red or brown discoloration of the nail beds. Surrounding skin changes may be minimal, but in almost every case the nail abnormalities will be accompanied by cysts in the bone of the underlying terminal phalanx and a chronic disease course, often with lupus pernio.

Sarcoidosis in black Africans and African Americans (Fig. 61.17)

The lesions are often exuberant and bizarre, and the skin is especially affected, although erythema nodosum is uncommon [8,9]. Psoriasiform or lupus erythematosus-like lesions [10], verrucous

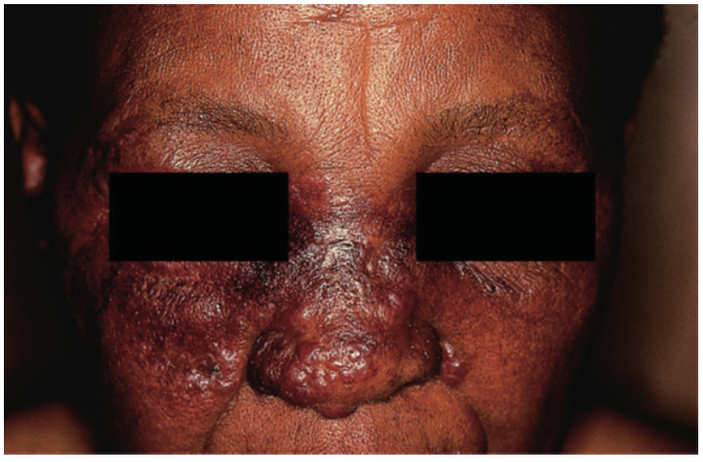

Fig. 61.17 Sarcoidosis in a black African, showing typical verrucous changes. (Courtesy of Dr J.E. Bothwell, Barnsley District General Hospital, Barnsley, UK.)

Fig. 61.18 Extensive ulceration of the foot and ankle due to sarcoidosis. (Courtesy of the late Dr R.H. Champion, Addenbrooke's Hospital, Cambridge, UK.)

and keloid-like forms [11,12], 'atypical' plaques or nodules [13], ulcerative lesions resembling papulonecrotic tuberculides [11], giant nodular forms and other atypical lesions occur, with more typical manifestations elsewhere. Shiny, waxy papules are a particular presentation [8]. The histological features may be equivocal and tuberculosis is a common cause of death. When the lesions are annular, histoplasmosis must be excluded [14].

Small ulcerating nodules, sometimes associated with deep, softer non-ulcerative lesions, have been described [10]. The histology is that of sarcoidosis but the infiltrate is diffuse, fibroblasts are numerous and the vessel walls in the subcutis are thickened.

Skin lesions in children [15,16]

Sarcoidosis in children is uncommon; a presentation with erythema nodosum is especially so. In one series of 48 children [15], 15 had erythema nodosum, 6 had other skin lesions, 12 developed uveitis or iridocyclitis and 2 had arthritis. Though papular forms of skin sarcoidosis are seen in older children, younger ones may present with uveitis or keratitis, progressive joint disease and skin lesions consisting of maculopapules, reddish-brown confluent plaques or eczema-like lesions [17,18]. Other reported cases have shown unusual features: follicular [19], miliary [20] or erythrodermic lesions with keratotic pitting [21]. The chest radiograph is often normal. The severity of eye or joint involvement may justify corticosteroid therapy, often for several years, despite the risks at this early stage.

The Blau syndrome, in which asymptomatic, red–brown papules (showing granulomas in histology) on the face, trunk and limbs are associated with arthritis and ocular disease in a child, has recently been identified, with mutations in the *NOD2* gene [23].

Ulcerated sarcoidosis [22,23] (Fig. 61.18)

This is a rare presentation: more than 35 cases have now been described, most of which were reported individually [24,25]. It usually occurs in women and black people. Ulcers develop most often on the legs [26] and may be punched-out and apparently appearing *de novo*, or arising on existing nodules and plaques, or, rarely, on extensive atrophic areas [27]. The possibility of necrobiosis lipoidica should be kept in mind, particularly in patients with diabetes [25]. The distribution of the ulcers may be unusual: a flexural distribution in one patient resembled that of metastatic Crohn's disease [28]. The granuloma may be of necrotizing type, with caseation or minimal fibrinoid necrosis [29]. True primary vasculitic changes are usually absent.

Verrucose forms [30]

Papular lesions may progress to crusted verrucose and sometimes ulcerative lesions [31], which may mimic halogen eruptions, fungal infections or tuberculosis.

Associated diseases

Some associated diseases are understandable against the background of depressed immunological responses; some are due to a simple blocking of the activity of an organ by granulomatous infiltration, and others are uncommon and poorly understood associations. In a disease as common as sarcoidosis, coincidental associations can be expected from time to time.

Infections

A critical review of previous reports of invasive fungal infections such as cryptococcosis [1] has suggested that in many of these the entire cause of the granulomatous illness was infection, rather than sarcoidosis complicated by infection. In the series which accompanied the review, 122 patients with sarcoidosis were, in fact, found to be remarkably free of infections: three had *Aspergillus* mycetomas in cystic areas in the lung and another also had pulmonary tuberculosis, but the only extrathoracic manifestation was one case of disseminated herpes zoster. Patients with sarcoidosis, however, are prone to extensive and stubborn wart virus infections, despite an unusually high prevalence of circulating antibodies to wart antigen [2].

Immunologically mediated conditions

In a series of 190 female patients with sarcoidosis, four had hyperthyroidism and four had Hashimoto's thyroiditis with antibodies [3]. Another patient in the same series had myxoedema and Addison's disease. Chronic urticaria may occur more frequently than would be expected by chance [4]. At least 14 cases of associated sarcoidosis and connective tissue disorders have been described [5].

Effects of infiltration

Granulomas, especially in the pituitary or thyroid gland, may cause endocrine disease. Invasion of the thyroid may be without effect or, if massive, can cause hypothyroidism [6]. Cushing's syndrome and diabetes insipidus, secondary to involvement of the pituitary, have been reported. The list of such cases may be extended to cover most endocrine diseases.

Vasculitis with sarcoidosis

There are occasional but well-authenticated reports of cutaneous vasculitis occurring in the course of sarcoidosis, usually early in the disease. In a series of six patients, five of them children, the vasculitis was associated with systemic illness including fever, lymphadenopathy, musculoskeletal and eye disease, and systemic steroids were given [7]. Three of these patients, all African Americans, had large-vessel disease on angiography. Erythema nodosum itself may be regarded as a form of vasculitis. Skin biopsy may show foci of epithelioid cell granulomas centred on damaged vessels [8]. An apparently unique case of leukocytoclastic vasculitis with epithelioid cell granulomas has been described [9] and annular forms documented [10]. The occurrence of vasculitis fits with the presence of circulating immune complexes in the early stages of sarcoidosis.

Malignancy

An analysis of 131 cases of coincident sarcoidosis and malignancy suggests an increased risk of developing lymphoproliferative disease [11]. The relationship between sarcoidosis and solid tumours was less clear-cut, but most marked with carcinoma of the cervix, lung, testis and uterus [12]. Sarcoidosis may precede the development of a lymphoma (the 'sarcoidosis–lymphoma syndrome') by 18 months to 28 years [13]. All types of lymphoma may develop [12], and there is an increased incidence of thyroid cancer and leukaemia. Five patients with sarcoidosis developed multiple myeloma (four several years later and one at the time of diagnosis of the sarcoidosis) [14].

Necrobiosis lipoidica and granuloma annulare

There have been several reports of patients with sarcoidosis and necrobiosis lipoidica [15,16], and with sarcoidosis and granuloma annulare [17]. To complete the circle of association, patients with both necrobiosis lipoidica and granuloma annulare have also been described. In one African American woman with pulmonary sarcoid, fresh lesions of histologically typical granuloma annulare were adjacent to histologically classic sarcoid papules, suggesting that the former progressed to the latter [18].

These associations may be fortuitous, but histological overlap between sarcoidosis and necrobiosis may occasionally be seen [19]. Granuloma annulare is important in the differential diagnosis of sarcoidosis, as is necrobiosis, particularly of the scalp and face. Granuloma annulare shares some aspects of collagen metabolism with sarcoidosis [20], but in granuloma annulare the Kveim test is negative [21,22].

Other associations

Associations with psoriasis and gout [23], pyoderma gangrenosum [24,25] and secondary syphilis [26] have been reported, but seem likely to have been coincidental. Two Kveim-positive patients were found to have primary biliary cirrhosis [27], and a sarcoidal plaque on the face has been described in a woman with primary biliary cirrhosis [28]. Two cases of porphyria cutanea tarda have also been reported [29,30].

Course and prognosis [1]

The prognosis of sarcoidosis is difficult to assess because of its frequent 'clinical silence' and the uncertainty of its onset. Several attempts have been made to list favourable and unfavourable factors [2–4], most of which have been mentioned elsewhere in this chapter. Table 61.3 is an attempt to summarize the course of sarcoidosis. The prognosis is generally better in females, in those with less severe pulmonary disease at the onset, and in patients with a positive tuberculin test and normal globulin levels [4]. HLA-B8 may be associated with a tendency to spontaneous resolution [5]. In the African American, the course may be fulminant.

Table 61.3 The course of sarcoidosis.

Prognosis	Stage	Cardinal features*	Unfavourable events
? Abortive cases, or may be absent 60% subside in 6–18 months	Prodromal	Malaise, fatigue, fever, depression, polyarthralgia	—
	Acute	*Erythema nodosum*, *scar sarcoidosis*, *erythematopapular rashes*, polyarthralgia, iridocyclitis, lymphadenopathy	? Sudden cardiac death
	Subacute	*Papular*, *nodular* or *scar*, pulmonary changes, lymphadenopathy, recurrent iritis, parotitis, spleen, liver	May be cardiac death
Prolonged intermission or resolution	Intermittent Chronic		
Gradual, often slow	Progressive	*Lupus pernio*, *erythrodermic*, bone cysts, cataracts, hypersplenism	Blindness
Irreversible but often extremely slow and patient survives, though disabled	Fibrotic regression	Progressive pulmonary fibrosis, nephritis, nephrosis, cataracts, glaucoma	Blindness, death
	Functional failure	Emphysema, cor pulmonale, nephrolithiasis, renal failure, tuberculosis	Death

* Skin signs are in *italics*.

About 60% of patients with stage I pulmonary disease will have recovered within 2 years [6,7]. The presence of erythema nodosum does not alter the prognosis. In the classic forms of the disease, the prognosis is quite different: only a small proportion of those in pulmonary stage II and beyond resolve spontaneously [7]. Morbidity from blindness, pulmonary disease, renal failure and the cosmetic and social effects of a disfiguring skin lesion are the not inconsiderable burdens of a disease that follows a relentless course of smouldering activity [8]. Despite corticosteroid therapy, half the patients continue to have abnormal respiratory function.

Most types of cutaneous sarcoidosis occur in the subacute and chronic stages, and their course is usually prolonged. Many papules and nodules tend to resolve within months or years, but plaques are even more resistant. Lupus pernio is especially persistent and is often accompanied by the involvement of other organs, further modifying the prognosis.

Mortality in sarcoidosis [9] has been estimated at 3–6% [4,7]. However, this may ignore undiagnosed deaths from cardiac involvement. Renal involvement is also a potential cause of death as, rarely, is progressive pulmonary disease.

Investigations

The most important single criterion for the diagnosis of sarcoidosis is the finding of typical granulomas histologically [1], but the need for histological support varies with the pattern of clinical features. For example, in the UK, patients with erythema nodosum and bilateral hilar gland enlargement may not require biopsy, although this is necessary in other forms of the disease. Other investigations may add weight to the diagnosis, and may be useful in monitoring the activity of the disease.

Biopsy

The involvement of several organs will allow the clinician to select the biopsy site best suited to the individual patient. The dermatologist has the advantage of dealing with a site easily accessible for biopsy, but it may still be necessary to confirm the presence of sarcoidosis as opposed to a sarcoidal reaction, and biopsies from other organs are then needed. In one series [2] involving 292 biopsies from 10 sites, 87% were positive, but biopsies from the skin proved less reliable than those from lymph nodes, parotid gland or nasal mucosa. Scars that become infiltrated provide acceptable histological evidence of sarcoidosis. A mucosal biopsy is an alternative to skin biopsy in lupus pernio. A conjunctival biopsy should be considered, and may be positive even if no obvious lesions can be seen [3], as may a biopsy of the lower lip [4].

A range of techniques is now available to obtain biopsy material from other areas. These include the removal of epitrochlear or scalene lymph nodes, mediastinoscopy with mediastinal node biopsy, liver biopsy, gastrocnemius muscle biopsy (even when there are no muscle symptoms) [5], and transbronchial lung biopsy or mediastinal node biopsy through a flexible fibrescope [6]. The last may be the most helpful and least disturbing for patients with suspected systemic sarcoidosis and intrathoracic manifestations, but carries some risk of pneumothorax. Bronchoalveolar lavage in patients with active pulmonary involvement shows an increase in the number of helper T lymphocytes present, but this is not specific for sarcoidosis.

Kveim test [7,8]

Fifty years after Kveim described it, the test that bears his name is still something of an immunological puzzle. Until relatively recently, it was a simple and useful way of supporting a diagnosis of sarcoidosis. The Kveim test is no longer available due to the infective risk of injecting human tissue, but nevertheless details of the test are of interest and will be outlined.

The test depends upon the ability of sarcoidal tissue, usually from the spleen of an affected individual, to evoke epithelioid cell granulomas like those of sarcoidosis when injected intradermally into a patient with sarcoidosis. Positive results were found in a high proportion of patients with active early disease, but became less common in chronic disease.

The technique used is important. An easily relocated site, usually on the forearms, was injected intradermally with 0.1–0.2 mL of shaken antigen using a 1-mL tuberculin syringe and a narrow-gauge needle. In a positive reaction, a papule usually appeared within 2–3 weeks and slowly increased in size. It was best excised at 6 weeks for histology.

A positive result was the unequivocal presence of an epithelioid granuloma, exactly mimicking the natural disease, though usually less profuse. Histological interpretation was difficult in 10–20% of responses; epithelioid cells may be diffusely scattered in the dermis or granulomatous aggregates of histiocytes may not be arranged in the usual circumscribed foci of an epithelioid granuloma. The occasional presence of birefringent particles can make interpretation more complicated. False-positive foreign body-type reactions had to be disregarded.

An adequate Kveim antigen had to be sensitive enough to detect at least 60% of cases of active sarcoidosis and specific enough to exclude all but 2–3% of non-sarcoid cases [9]. To achieve this, the antigen had to be validated by extensive tests on normal subjects and on patients with other conditions, such as Crohn's disease, in which false-positive reactions are known to occur [10]. The safety of the Kveim test with regard to it being free from infective agents, for example human immunodeficiency virus, cannot be guaranteed and hence it is no longer available. The active principle in Kveim material was heat stable, and also stable on storage, though

some loss of sensitivity was observed over a period of years [11]. The active material is particulate and probably lies within the membrane-containing elements of the sarcoidal tissue [12], although its exact constitution has not been established. It is not known whether the active ingredient is an antigen derived from the aetiological agent of sarcoidosis or whether a positive Kveim response is a manifestation of host predisposition to form granulomas on antigenic stimulation. These two hypotheses are not mutually exclusive.

Other investigations

A chest radiograph should be taken in all cases, no matter what the clinical presentation. Hand radiographs show cystic changes only in chronic disease, and usually only when there are clinical abnormalities in the fingers. Sputum should be examined and cultured for acid-fast bacilli, and a weak or negative tuberculin response may add weight to the diagnosis of sarcoidosis. An ECG is needed to exclude cardiac involvement. Pulmonary function tests may also be indicated. High-resolution computed tomography of the chest is helpful to define lung field involvement.

The erythrocyte sedimentation rate (ESR) is usually raised in active phases, and a rise in the ESR 6–8 weeks after the onset of erythema nodosum may indicate lung involvement [13]. Slight anaemia, neutropenia or lymphopenia are often noted, but these changes, and the hypergammaglobulinaemia that occurs in over half the chronic cases, are not of proven diagnostic or prognostic significance. Serum calcium should be checked, as an increase may lead to chronic renal failure.

Angiotensin-converting enzyme (ACE) [14] is produced by sarcoidal granulomas. Raised serum levels are found in some 60% of patients with sarcoidosis, but are also present in other conditions such as diabetes and alcoholic liver disease. This limits the value of the test as a diagnostic aid, although it remains a useful monitor of disease activity.

Other markers of disease activity [15] vary in their usefulness in sarcoidosis. They include lysozyme, β_2-microglobulin, neopterin, collagenase and fibronectin levels. The serum level of soluble intercellular adhesion molecule 1 (ICAM-1), which is shed from cell surfaces and is a measure of the inflammatory response, mirrors disease activity in active sarcoidosis [16]. Hydroxyprolinuria may indicate disease activity. Radioactive gallium-67 uptake occurs in some pulmonary infections and neoplasms as well as sarcoidosis, but if these can be excluded it provides a way of separating active from fibrotic pulmonary disease.

Treatment [1,2]

The chance of spontaneous remission favours a conservative approach to systemic therapy, which will usually carry the hazards of long-term immunosuppression, such as opportunistic mycobacterial infection [3] or a gross proliferation of viral warts [4]. At any time the pattern of the disease may change, but an expectant policy is often best if the course is not progressive and if vital structures are not involved.

Johns *et al*. [1] list the most frequent indications for systemic treatment:

1. symptomatic pulmonary disease
2. progressive or persistent parenchymal lung disease after 2 years
3. posterior ocular disease or anterior disease not responding to local steroids
4. persistent fever or weight loss
5. liver disease with significant dysfunction or hepatosplenomegaly
6. disfiguring skin disease or lymphadenopathy
7. nervous system disease
8. hypercalcaemia
9. myocardial disease
10. myopathy or myositis
11. thrombocytopenia
12. other significant organ involvement—for example, kidneys.

A major determinant is the degree to which a patient's normal life is disrupted by the disease, but objective measurements, such as pulmonary function tests, may be a more valuable way of monitoring therapy than symptoms alone.

A few patients with severe cardiac or pulmonary disease have come to transplantation; the sarcoidosis does not necessarily recur in the graft, perhaps due to the use of potent immunosuppressive agents [5].

In the skin clinic any decisions about the use of systemic therapy must take into account the seriousness of the accompanying internal involvement and the natural history of the particular type of skin lesion. Papular lesions, for example, are likely to fade without treatment, whereas lupus pernio is not.

Topical therapy

High-potency topical corticosteroids may sometimes prove helpful, as may intralesional triamcinolone injections. Tacrolimus, which inhibits hapten-induced production of Th1 cytokines and TNF-α by T cells, has been reported to be beneficial when used topically in cutaneous sarcoidosis [6]. Cryotherapy and radiotherapy have occasionally been used [2]. PUVA therapy has been successful in hypopigmented sarcoidosis [7] and in erythrodermic sarcoidosis [2]. In certain types of cutaneous sarcoidosis, for example lupus pernio, cosmetic camouflage advice is helpful.

Systemic therapy [8]

Corticosteroids are usually the most effective treatment, given at first in a relatively high dose, possibly 30 or 40 mg prednisolone daily, and then tapered over a period of several weeks to a lower maintenance dose of possibly 15 mg on alternate days. The length of the course of treatment will vary from case to case but is usually at least 6 months. Intravenous 'pulse' methylprednisolone, for example 1 g/week for 8 weeks, may be effective in those with the most severe neurological disease [5].

Immunosuppressive drugs may be tried if corticosteroids are contraindicated or have been ineffective. Methotrexate has been used with some success [9] and has been recommended for use with corticosteroids for lupus pernio [10]. Azathioprine, and mycophenolate mofetil (45 mg/kg/day), have been used for their steroid-sparing effects [11,12].

Biologic agents have recently been employed. The anti-TNF drugs infliximab and etanercept have been used successfully in cutaneous sarcoidosis—resistance to anti-TNF agents may require a switch to an alternative drug [13,14]. The anti-T-cell agent alefacept is described as beneficial in lupus pernio [15].

Other drugs which have been tried with some success include allopurinol, doxycycline and chloroquine [11,16]. Minocycline, 200 mg daily for 12 months, produced complete resolution in eight and partial improvement in two out of 12 patients with cutaneous sarcoidosis [17]. Levamisole is not recommended [18]. The response to ciclosporin has been variable [5]. Isotretinoin induced complete resolution in one case of cutaneous sarcoidosis [19]. Treatment with thalidomide (100–200 mg/day) in 12 patients with cutaneous sarcoidosis induced complete remission in four cases, partial improvement in six and no change in two [20]. Fumaric acid esters (FAEs) may give variable benefit [21]. In a small series of three patients with recalcitrant cutaneous sarcoidosis, all cleared after 4–12 months treatment with FAEs [22].

Laser, ultraviolet radiation and photodynamic therapies

Lupus pernio has been improved using the carbon dioxide laser [23]. UVA1 (340–440 nm) has been effective for forehead plaque sarcoid [24]. The use of photodynamic therapy can also be considered [25].

Other sarcoidal reactions

A number of infections and chemicals may cause sarcoid-like granulomas, although their features are seldom as clear-cut histologically [1,2]. Such reactions differ from sarcoidosis in several important respects:

1 They involve only those organs normally affected by the disease in question, or on the route of absorption or deposition of the chemical.
2 The Kveim test when performed has been negative.
3 The tuberculin reaction is usually not depressed.

The following text describes reactions which should be borne in mind in the differential diagnosis of sarcoidosis.

Infections

The problem of differentiating tuberculosis and leprosy from sarcoidosis has been dealt with on p. 16.13. Syphilis, brucellosis, fungus infections and some bacterial or viral diseases may produce a sarcoidal type of tissue response but any clinical resemblance is usually superficial.

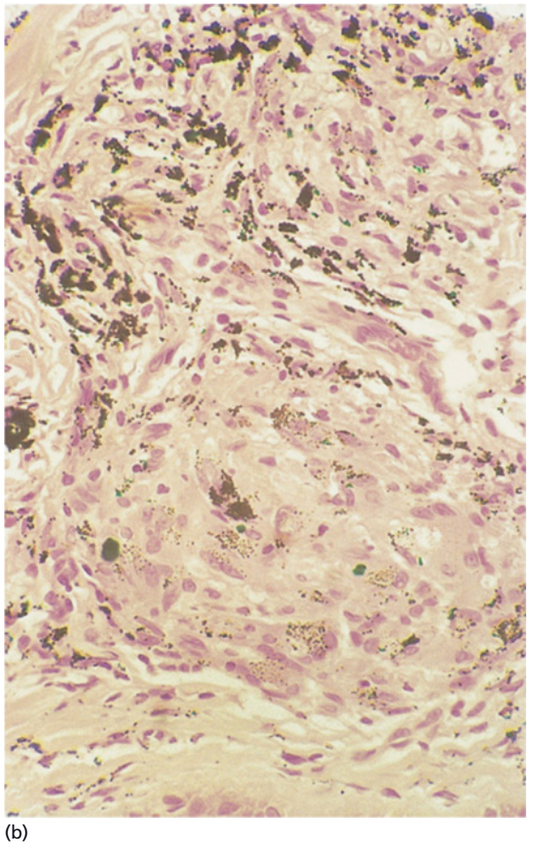
Foreign materials

Silicates occur in many common materials—for example, in talc, kaolin, quartz and as a constituent of slate, brick, gravel and coal. Silicosis from the inhalation of silica dust is an important industrial hazard, but wounds containing crystals of silica normally remain unchanged indefinitely. Talc has been the cause of granulomas in surgical wounds when used as a glove powder. The long delay between the implantation of silica and the appearance of the granuloma suggests that the silica may not be the immediate cause of the reaction. In one case, a silica granuloma has progressed to scar sarcoidosis [3]. It is wise to examine all sarcoidal reactions under polarized light: silica particles are doubly refractile and differ from Schaumann bodies in that the crystalline material is spiculated but not laminated.

Beryllium reactions [2] are rarely seen now that beryllium is no longer used in the manufacture of fluorescent lights. The cutaneous lesions of systemic berylliosis are indistinguishable histologically from those of sarcoidosis, whereas the granulomas due to local beryllium implantation show marked central necrosis.

Zirconium granulomas may form in the axillae as a delayed hypersensitivity reaction to the zirconium content of deodorants [1,4].

Sea-urchin spines may induce foreign-body or sarcoidal granulomas [5]. The exact cause of the reaction is unknown. Intralesional triamcinolone may help speed resolution if excision is not practicable [6].



Foreign-body reactions to lipids (fat granulomas, epidermal cysts) and reactions to other lipid and non-lipid extraneous matter are variable and often show many giant cells.

Thesaurosis [7] is a pulmonary infiltration occurring in those heavily exposed to polyvinyl–pyrrolidine hair sprays in hairdressing procedures.

Sarcoidal reactions in tattoos (Fig. 61.19). A granulomatous dermal infiltrate may accompany sensitization reactions to any pigment of the tattoo, or may occur alone [8]. Less commonly, a pure sarcoidal reaction is present as an indolent lump within a tattooed area. Regional lymph nodes may also show a sarcoidal reaction [9]. Such lesions may be accompanied by other signs of sarcoidosis or a positive Kveim test [10] and are occasionally the only skin manifestation of the disease [11]. The pulmonary disease may be silent [8]. The association of a sarcoidal reaction in a cobalt tattoo with uveitis in three cases and with erythema nodosum in one [12] emphasizes the need for a thorough investigation of all cases showing a sarcoidal type of infiltrate.

(b) Histology of a sarcoidal reaction to two varieties of tattoo pigment, one opaque and one green. (Courtesy of Dr T.J. Stephenson, Royal Hallamshire Hospital, Sheffield, UK.)

Cosmetic fillers. Sarcoidal granulomas developed in the skin of a woman with pulmonary sarcoidosis who had had facial skin treated with a cosmetic filler [13].

Other reactions. A sarcoid-like reaction has been reported from exposure to acrylic or nylon fibres, either as dust or from walking

on acrylic carpets [14]. The significance of a sarcoidal reaction to ear piercing [15] was not clear in the presence of a positive Kveim test.

Crohn's disease

The similarity between the histological and immunological features of Crohn's disease and sarcoidosis led to speculation about a common aetiology. However, the rarity of sarcoidosis of the intestine makes this unlikely, and earlier reports of positive Kveim tests in patients with Crohn's disease have not been fully substantiated [16].

Whipple's disease [17]

Sarcoid-like changes have been recorded in the skin and lymphatic glands [17]. Diarrhoea is an important distinguishing clinical feature and jejunal biopsy will confirm the correct diagnosis (Chapter 62).

Farmer's lung [18]

This is caused by the inhalation of mouldy hay containing fungal spores: sarcoid-type granulomas sometimes develop slowly around the air passages and the condition then runs a course not unlike pulmonary sarcoidosis.

Other conditions

Sarcoid-like granulomas can occur in the skin and lymph nodes of patients with lymphoma: most commonly in Hodgkin's disease [19], but also in non-Hodgkin's lymphoma [20,21]. Sarcoid reaction is described with other malignancies, for example papillary thyroid carcinoma [22].

Epithelioid cell granulomas may also be a feature of rosacea [23]. In one unusual case [24], rosacea-like facial lesions, with a sarcoidal histology, were seen in a patient with a poorly differentiated lymphoma.

An epithelioid cell granuloma histology is found in granulomatous cheilitis and the Melkersson–Rosenthal syndrome, sometimes in necrobiosis lipoidica [25] and in granulomatosis disciformis, and has been reported in giant cell and other forms of arteritis [26].

Introduction

The systemic associations of skin diseases have been stressed throughout this book. In this chapter many of these associations are listed again, along with some other important conditions. They are grouped so as to be helpful to the general physician or internist. It is hoped that such a presentation will also be useful to the dermatologist who is asked to help in the diagnosis of obscure internal disease. Many further references may be found by turning to the chapter in which the relevant dermatosis is considered in detail.

The texts listed below [1–5] provide much more information than it is possible to give here, and are also a source of additional references.

Endocrine disorders

The physiological effects of hormones on pigmentation, hair growth, sebaceous glands and connective tissue have been described in other chapters. This section is limited to discussion of specific endocrine pathology with cutaneous features. Additional detail is provided in several general references [1–6].

Pituitary syndromes

Hyperpituitarism [1–3]

Excessive secretion of growth hormone (GH, somatotrophin) causes an increase in plasma insulin-like growth factor-1 (IGF-1). These hormones stimulate synthesis of collagen and glycosaminoglycan in the skin and skeleton, leading to insidious hypertrophy of skin, subcutaneous tissues and viscera, and to periosteal bone growth. This causes acromegaly in the adult (most cases), and gigantism in children whose bony epiphyses have not yet closed.

*Acromegaly (MIM *102200)* [4] *and gigantism*

Aetiology. The usual cause (over 95%) is a benign adenoma or hyperplasia of the eosinophilic cells of the adenohypophysis, producing GH and often prolactin [4]. Other tumours, such as bronchial carcinoma, may occasionally cause acromegaly, usually by ectopic secretion of GH-releasing hormone (GH-RH). Individual, viable epidermal cells are larger than normal, and epidermal cell turnover is increased.

Clinical features. Periosteal new bone formation of the facial bones and skin causes the characteristic facies. Features are prognathism, frontal bossing, widely spaced teeth and acral hypertrophy, which causes elongated, blunt and thickened fingers. Dermatological features include a protruding, thickened lower lip, oedematous thick eyelids, a large and furrowed tongue (Fig. 62.1), triangular large ears, numerous skin tags ('fibroma molluscum'), widened skin pores, wet and oily skin due to hyperhidrosis and increased sebum production, acne and cutis gyrata of the scalp in more extreme cases. Eruptive seborrhoeic keratoses mimicking the sign of Leser–Trélat have been reported in acromegaly [5]. Hyperpigmentation develops in about half of the affected individuals due to increased levels of melanocyte-stimulating hormone (MSH), and acanthosis nigricans may occur. The scalp hair is initially coarse and there may be hirsutism, but later in the disease there is a decrease in gonadotrophin production, which causes the hair to become finer, with loss of secondary sexual hair. The nails are flat and wide and grow fast. Pachydermoperiostosis (Chapter 15) is an important differential diagnosis. In this disease, there is no macroglossia or prognathism, and the fingers are characteristically clubbed.

Fig. 62.1 Acromegalic macroglossia.

Non-cutaneous features include macroglossia, visual field defect and headache due to the neoplasm, arthropathy, carpal tunnel syndrome and proximal myopathy. Cardiovascular morbidity and mortality is markedly increased due to associated hypertension, left ventricular hypertrophy, cardiomyopathy, sleep hypoxia and apnoea, and hyperlipidaemia. Acromegalic subjects have an increased incidence of colonic adenomas and carcinomas [6].

Diagnosis. The clinical picture is, in most cases, suggestive of the diagnosis. Serum GH and prolactin levels are generally elevated, but vary considerably both in normal subjects and in those with acromegaly [4]; plasma IGF-1 is a more reliable test of chronically elevated GH levels [7]. Failure of GH levels to suppress during glucose challenge, and GH-RH stimulation tests, help to confirm the diagnosis. Magnetic resonance imaging (MRI) of the pituitary gland with contrast confirms the site and size of the tumour in most cases; three-quarters of subjects have a macroadenoma (>10 mm) at presentation but microadenomas as small as 2 mm can be identified using current imaging techniques.

Treatment. Neurosurgical removal of the tumour is the preferred treatment. Patients in whom this fails to achieve a cure may be treated with somatostatin analogues such as octreotide and lanreotide, dopamine agonists such as bromocriptine and cabergoline, GH receptor antagonists such as pegvisomant, or radiotherapy [1–3,7,8,10]. Colonoscopy surveillance is recommended as there is an increased risk of colonic polyps, carcinomas and tubulovillous adenomas.

Pituitary insufficiency [1–3,9,11]

Insufficiency of the adenohypophysis (anterior pituitary) may involve individual or multiple hormones. In classical hypopituita-

Table 62.1 The causes of anterior pituitary deficiency.

Neoplasia—adenomas (most), craniopharyngioma, metastases
Infection—tuberculosis, abscess
Trauma, surgical, iatrogenic
Congenital—familial, 'empty sella syndrome'
Vascular—Sheehan's syndrome (postpartum) and other infarction, bleeding, diabetes mellitus, vasculitis, antiphospholipid syndrome
Idiopathic
Hypothalamic—due to hypothalamic tumours, trauma, infiltration (Langerhans' cell histiocytosis, sarcoidosis), congenital causes of hypothalamic failure

rism, all endocrine cell functions of the pituitary gland are involved to a varying degree. However, the clinical picture is influenced by the cause of hypopituitarism; for example, adenomas may produce GH or prolactin, but may also cause compression atrophy of cells producing gonadotrophins. Concurrent loss of function of the posterior pituitary may occur if there is a hypothalamic lesion, such as Langerhans' cell histiocytosis.

Aetiology. Over 95% of cases of hypopituitarism are due to pituitary cell destruction [8]. Familial hypopituitarism has a genetic basis due to mutations in Pit-1 or its precursor Prop-1, resulting in deficient production of GH, prolactin and thyrotrophin. Causes of insufficiency of the anterior pituitary are listed in Table 62.1.

Clinical features. The various endocrine dysfunctions are typically insidious and less impressive than those seen in the primary glandular disorders. Pallor of the skin due to decreased MSH secretion results in generalized hypopigmentation, most apparent in the skin of the nipple areola and genitalia; in contrast with anaemia, the mucous membranes retain their normal colour. There is an increased sunburn tendency and lack of tanning, and there may be a degree of carotenaemia due to hypothyroidism. Loss of terminal hair due to decreased gonadotrophin secretion is observed in all patients, first in the axillae and later, but not invariably, in the pubic area. Fine wrinkling and dryness of the skin simulates advanced age. The face appears expressionless due to diminution of the facial skinfolds. The activity of sebaceous and sweat glands is reduced. Onycholysis, longitudinal ridging and brownish discoloration of the nail plate may be seen.

Pituitary dwarfism is characterized by proportionate retardation of somatic growth in conjunction with normal mental development. The cutaneous changes of old age may develop prematurely from the third decade onwards.

Erythromelalgia with non-healing skin ulcers has been reported as a presenting feature of GH deficiency in a child.

Diagnosis and treatment. Measurement of hormone levels—prolactin, IGF-1, thyroid-stimulating hormone (TSH) and thyroxine (T_4), cortisol, gonadotrophins—is required to detect subnormal levels; prolactin or IGF-1 may be elevated if the cause of hypopituitarism is a pituitary tumour. Posterior pituitary function should also be assessed, and visual field testing and MRI should be performed. Treatment is of the primary cause, together with hormone replacement [8,9].

Adrenal syndromes

Cushing's disease and syndrome [1–8]

Chronic glucocorticoid excess may occur due to increased secretion of adrenocorticotrophic hormone (ACTH, corticotrophin), usually from the pituitary (MIM *219090), due to glucocorticoid hypersecretion of adrenal origin (ACTH-independent, MIM *219080) or due to exogenous administration of glucocorticoids.

Aetiology. The commonest ACTH-dependent cause is that due to a pituitary adenoma (Cushing's disease or pituitary-dependent Cushing's syndrome), which accounts for about 70% of spontaneous cases; pituitary overproduction of ACTH leads to adrenal hyperplasia and thus to glucocorticoid excess. Other ACTH-dependent causes include the ectopic ACTH syndrome (for example, from small cell lung cancer or bronchial carcinoids) and, rarely, ectopic corticotrophin-releasing hormone (CRH) syndrome. ACTH-independent causes include cortisol-producing adrenocortical adenomas and carcinomas, various types of bilateral adrenal hyperplasia (including the Carney complex), and, most commonly, iatrogenic causes such as results from long-term administration of glucocorticoids, either systemically or from excessive use of topical, inhaled or intralesional steroids [4]. The glucocorticoid hormones, among other effects, impair synthesis of collagen and mucopolysaccharides and thus lead to atrophy and vascular fragility of the skin.

Clinical features. The cutaneous manifestations are quite similar whether caused by endogenous or iatrogenic hypercorticism, although there are additional effects mediated by androgens in patients with adrenal disease. The features are enumerated in Table 62.2; the thin skin and easy bruising are helpful in distinguishing Cushing's syndrome from simple obesity.

About 6–10% of patients with pituitary Cushing's disease have addisonian-like pigmentation [1], as oversecretion of the common

Table 62.2 Cutaneous manifestations of Cushing's disease.

Truncal obesity (classically deposits of fat over the clavicles and back of the neck, the 'buffalo hump')
Facial fullness and plethora ('moon facies') are most frequent
Slender limbs
Skin atrophy
Fragility, bruising and poor healing
Telangiectasia
Striae (typically wide and red)
Hirsuties
Hypertrichosis (downy facial hair in iatrogenic hypercorticism)
Acneiform lesions (often monomorphic and devoid of comedones and cysts)
Male-pattern baldness in women
Dermatophyte and yeast infections

precursor pro-opiomelanocortin causes overproduction of both ACTH and MSH.

Diagnosis. A 24-hour urinary cortisol and/or a 1-mg overnight dexamethasone suppression test are generally considered to be satisfactory screening tests. However, the 24-hour urinary cortisol is now felt to be least sensitive, and may miss mild or cyclical disease; it may be falsely low if there is renal impairment or an incomplete collection. Mildly elevated levels overlap with other causes of hypercortisolaemia, but values above fourfold greater than normal are indicative of Cushing's syndrome [8]. A midnight plasma cortisol level (100% specific if over 50 nmol/L) or a 2-day low-dose (0.5 mg 6-hourly) dexamethasone suppression test may resolve equivocal results. Additional tests may be required [2], as atypical presentations, other illnesses and various laboratory factors may influence interpretation of tests [6–8]. Venous sampling to measure ACTH levels is also performed in order to differentiate between ACTH-dependent and ACTH-independent Cushing's syndrome, the best available (but technically difficult) test being bilateral inferior petrosal sinus sampling (BIPSS) [7,8]. Additional investigations may include an MRI scan of pituitary to detect a microadenoma, and CT or MRI scan of chest and abdomen to detect a source of ectopic ACTH secretion.

Treatment. Trans-sphenoidal selective adenomectomy is the treatment of choice for pituitary-dependent Cushing's disease in adults, with radiotherapy as second choice; radiotherapy is more effective in children. Surgery only leads to long-term remission in about 60% of cases. Bilateral adrenalectomy is the third-choice definitive cure for pituitary Cushing's syndrome, and is the treatment of choice when the disease is caused by bilateral adrenal hypersecretion; lifelong replacement therapy with glucocorticoids and mineralocorticoids is then required. A substantial number of such patients eventually develop a pituitary macroadenoma and cutaneous hyperpigmentation (Nelson's syndrome, Fig. 62.2); this is best treated by pituitary surgery [5]. Unilateral adrenal disease (adenoma or carcinoma) is treated by unilateral adrenalectomy. Medical treatments may act at hypothalamic–pituitary level (serotonin antagonists, dopamine or GABA agonists, somatostatin analogues), at corticosteroid receptors (mifepristone) or on adrenal glands (metyrapone, aminoglutethimide, ketoconazole and others). Most of these agents have significant potential side effects.

Fig. 62.2 Diffuse pigmentation in Nelson's syndrome.

Pseudo-Cushing's disease [9,10]

A clinical and biochemical mimic of Cushing's disease has been described in alcoholics. The biochemical parameters are not as severe as seen in true disease, and the condition can resolve on alcohol abstinence [9]. Pseudo-Cushing's syndrome may represent a state of stress-induced hypercortisolaemia secondary to multiple episodes of subacute withdrawal from ethanol [10].

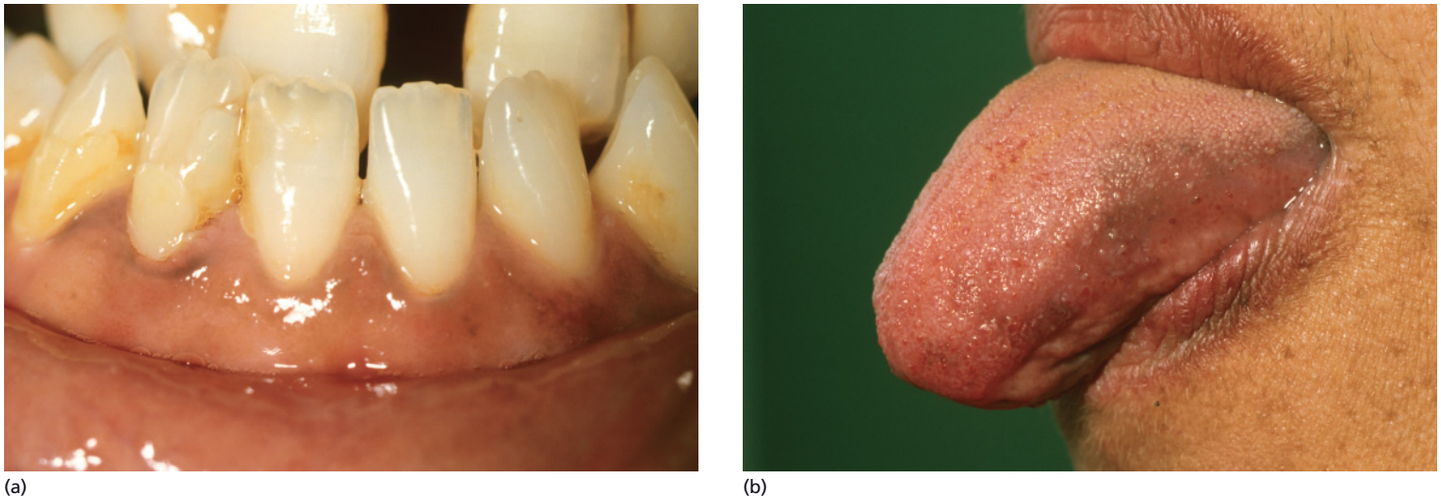
Adrenal insufficiency [1–8]

Synonyms
- Addison's disease
- Hypocorticism
- Hypoadrenalism

This condition is due to insufficient secretion or supply of adrenocortical hormones or hormonal compounds—mainly cortisol and mineralocorticoids.

Aetiology. Most cases of adrenal insufficiency occur due to prolonged supraphysiological glucocorticoid therapy for a variety of inflammatory and other diseases; this suppresses ACTH production, so abrupt discontinuation of treatment may cause acute adrenal insufficiency.

Primary adrenal insufficiency (Addison's disease) in developed countries is most commonly due to autoimmune adrenalitis. Most such patients show circulating antibody to the cortex cells; about 40% of adults and virtually all children with Addison's disease have other autoimmune-related disorders as part of a polyglandular syndrome [2,4–8]. There are also several genetic disorders that cause primary adrenal failure [8]. Other causes of primary adrenal damage include infections (tuberculosis is the commonest cause, others include HIV, CMV, cryptococcus, histoplasmosis and viral infections), metastatic malignant disease or (rarely) haemorrhage. The latter is of some dermatological importance, as it may rarely occur due to sepsis (Waterhouse–Friderichsen syndrome); this is classically described as a consequence of meningococcaemia, but in a study of paediatric deaths due to sepsis with bilateral adrenal haemorrhage the commonest cause was *Pseudomonas* infection.



Secondary adrenal insufficiency may occur due to hypothalamic or pituitary disease, leading to insufficient secretion of ACTH; patients with pituitary hyposecretion of ACTH lack the pigmentary changes that are characteristic of primary adrenal insufficiency, and mineralocorticoid production is generally maintained.

Clinical features [1–8]. General symptoms include wasting, fatigue, orthostatic hypotension, dizziness, anorexia, abdominal pain and amenorrhoea. Self-mutilation, presenting as gouges in the skin, has been reported as a result of psychiatric symptoms [9]. However, hyperpigmentation of the skin, due to increased secretion of pituitary MSH and ACTH as a response to low adrenal corticosteroid levels, is the cardinal dermatological feature. This develops insidiously and is often not recognized as abnormal by the patient. Patterns of increased pigmentation are enumerated in Table 62.3.

Mucous membrane lesions are usually spots or patches rather than diffuse pigmentation (Fig. 62.3), and the oral pigmentation may persist after glucocorticoid replacement therapy. Scar pigmentation only occurs in scars acquired during adrenal insufficiency and is permanent—scars that precede the disorder or occur during therapy are unaffected [6]. In women, in whom the adrenal gland is the main source of androgens, there may be loss of axillary and pubic hair and improvement in acne. Features of associated autoimmune disease may be present, notably vitiligo in 15% of patients with autoimmune causation. Calcification of the pinna has been described [10], but may occur in other endocrine conditions and is more commonly the result of frostbite or injury.

Table 62.3 Patterns of addisonian pigmentation.

Light-exposed areas—face, dorsa of hands
Areas subject to friction—elbows, knees, waistline, under bra straps
Accentuation of normally high pigmentation areas—genital, perineum, axillae, areolae, umbilicus
Palmar creases
Tongue and mucous membranes (Fig. 62.3)
Scars
Hair and nails—longitudinal melanonychia.
Darkening existing pigmented lesions (such as café-au-lait patches)
Eruptive lentigines

(a) (b)

Fig. 62.3 Pigmentation of (a) the gingivae and (b) the tongue in a woman who presented with darkening skin due to Addison's disease.

Similar pigmentation may be seen in Nelson's syndrome and in tumours causing ectopic ACTH secretion; in the latter case, cortisol production is increased, so the clinical picture and electrolyte changes may be those of Cushing's syndrome.

Rarely pigmentation is absent in Addison's disease, making diagnosis difficult, and patients with 'white' Addison's disease may present in addisonian crisis. They have metabolic Addison's disease, with low cortisol, flat short Synacthen responses, and elevated circulating ACTH and MSH levels. Absence of hyperpigmentation is explained by a high degree of melanosome degradation in secondary lysosomes called 'compound melanosomes', which overwhelm the increased stimulation of the skin pigmentation [11].

Diagnosis. Anaemia, lymphocytosis, hyponatraemia, hyperkalaemia and hypoglycaemia are expected. A short Synacthen test demonstrates impaired cortisol secretion in response to corticotrophin, and ACTH and cortisol production are subnormal in response to an insulin stress test. Adrenal calcification may be present in autoimmune or tuberculous disease. Primary adrenal failure can be identified by demonstrating elevated ACTH levels, presence of adrenal autoantibodies, and by stimulation tests such as the metyrapone test or CRH test. In acute presentation, where there may be severe hypotension, weakness and clinical shock, baseline blood tests should include serum cortisol and plasma ACTH, which can be assayed later to confirm the diagnosis, but intravenous fluids and cortisol replacement should be commenced without waiting for results. Associated coeliac disease has been reported in five (12.2%) of 41 subjects, in a study that suggested that coeliac serology should be performed as part of an autoimmune screen in any patient with Addison's disease [12].

Treatment. Primary adrenal failure requires glucocorticoid and mineralocorticoid replacement [5–8]. In secondary cases related to pituitary insufficiency, usually only cortisol is required [3]. During stress, such as when undergoing major surgery and in severe systemic infections, the need for cortisol is increased. The hyperpigmentation may start to regress within days, but generally takes weeks to months to fully resolve—the process is slower in hair and nails, and pigmented scars remain pigmented [6].

Congenital adrenal hyperplasia [1,2]

Congenital adrenal hyperplasia (CAH) is a family of autosomal recessive disorders caused by mutations that encode for enzymes involved in one of the various steps of adrenal steroid synthesis. These defects result in the absence or the decreased synthesis of cortisol from its cholesterol precursor. The anterior pituitary secretes excess adrenocorticotrophic hormone (ACTH) via feedback regulation by cortisol, which results in overstimulation of the adrenals and causes hyperplasia. Six variants are recognized, but only two will be discussed here as they are more likely to be seen by dermatologists. Symptoms due to CAH can vary from mild to severe depending on the degree of enzymatic defect.

21-hydroxylase deficiency

In the classical form of CAH, there is a severe enzymatic defect owing to mutations in the *CYP21* gene. This results in deficient 21-hydroxylase levels, and deficient cortisol synthesis, as they cannot convert 17-hydroxy progesterone to 11-deoxycortisol. Negative feedback results in increased CRF and ACTH secretion and adrenal gland hyperplasia. Rather than produce cortisol, the adrenal produces excess sex hormone precursors, and these are further converted to active androgens. Approximately 75% of patients cannot synthesize enough aldosterone as they cannot convert progesterone to deoxycorticosterone, and they may present with 'salt wasting' episodic hyponatraemic dehydration.

Classically, affected female fetuses undergo virilization of the genitalia prenatally and present with genital ambiguity at birth; however, prenatal treatment of CAH with dexamethasone to prevent ambiguity has been successfully utilized for over a decade. There are reports of neonatal acanthosis nigricans arising in classical disease [3].

Of greater relevance to dermatologists (as it is common) is the less severe, late-onset form of CAH; prenatal virilization does not occur. The milder enzyme deficiency was termed non-classical 21-hydroxylase deficiency (NC21OHD) in 1979 and was later found to be the most common autosomal recessive disorder in humans. Disease frequency of NC21OHD varies between ethnic groups with the highest ethnic-specific disease frequency in Ashkenazi Jews at 1 in 27. Similar to classical CAH, non-classical 21-hydroxylase deficiency may cause premature development of pubic hair, advanced bone age, accelerated linear growth velocity and diminished final height in both males and females. Severe cystic acne has also been attributed to non-classical CAH. Women may present with symptoms of androgen excess, including hirsutism, temporal baldness, and infertility. Menarche in females may be normal or delayed and secondary amenorrhoea is a frequent occurrence. Polycystic ovary syndrome may also be seen in these patients. In males, early beard growth, acne [4], and growth spurt may prompt the diagnosis of NC21OHD. Although many males appear to be asymptomatic, they may present with oligozoosper-

mia or diminished fertility. Non-classical CAH may be seen in both early-onset prepubertal acne [5], persisting acne in women [6] and in acne fulminans [7]. Some authors have questioned the importance of this finding, arguing that it is one of many factors in the eventual expression of clinical acne [8].

Diagnosis. In the classic disease, there is marked elevation of 17-hydroxyprogesterone. In the non-classical disease, resting 17-hydroxyprogeserone levels may be normal, but stimulation of the adrenal with low-dose intravenous ACTH will result in elevated levels of 17-hydroxyprogesterone. Gene markers can now be identified. Low-dose glucocorticoid treatment may then be a useful adjunct to treatment.

11-hydroxylase deficiency

This comprises 5–8% of CAH cases, affecting about 1 in 100 000 births. The 11-hydroxylase enzyme is coded for by the *CYP11B1* gene. There is an inability to convert 11-deoxycortisol to cortisol. A parallel defect exists in the synthesis of 17-deoxysteroids, so that deoxycorticosterone is not converted to corticosterone, and it accumulates. As some of its metabolites have mineralocorticoid activity, sodium retention, potassium loss and hypertension develop. A non-classical variant is not associated with hypertension. It may rarely account for the development of infantile acne in boys [9], and precocious puberty. It causes virilization and ambiguous genitalia in girls.

Diagnosis. Elevated deoxycorticosterone and 11-deoxycortisol confirms the diagnosis.

Hyperthyroidism [1–4]

Synonym
- Thyrotoxicosis

This is a hypermetabolic state that results from excessive production or administration of thyroid hormones—thyroxine (T_4) and triiodothyronine (T_3). It is most common in women.

Aetiology. Hyperthyroidism is usually due to Graves' disease (diffuse toxic goitre, Basedow's disease), but 10–15% of cases are due to other causes, including toxic multinodular goitre, adenoma, thyroiditis, and iatrogenic or factitious ingestion of T_4, iodine and iodine-containing drugs, such as amiodarone. Secondary hyperthyroidism may occur due to production of TSH or thyrotrophin-releasing hormone (TRH) from the pituitary or from tumours at other sites. Graves' disease is an autoimmune disorder in which there is a high incidence of antithyroid antibodies and of other autoimmune diseases. Thyroid-stimulating immunoglobulins (TSIs) such as long-acting thyroid stimulator (LATS, a 7S immunoglobulin) are typically present in Graves' disease. These bind to TSH receptors, acting as thyroid gland agonists.

Clinical features. Most of the features of hyperthyroidism (Table 62.4) are not specific to the cause. Increased sympathetic nervous

Table 62.4 Cutaneous features of hyperthyroidism.

Skin
Soft, smooth, velvety
Increased skin temperature
Palmar erythema, facial flushing
Increased sweating
Pruritus
Hyperpigmentation
Pretibial myxoedema*
Vitiligo*
Cutaneous signs of goitre: Pemberton sign and Maroni sign
Others—urticaria*, palmoplantar pustulosis*
Nails
Fast nail growth
Soft nails, koilonychia
Distal onycholysis (Plummer's nails)
Thyroid acropachy*
Hair
Fine thin hair, diffuse alopecia
Alopecia areata*

* Associated with autoimmune thyroid disease; not a feature of hyperthyroidism *per se*.

system activity causes vasodilatation, leading to warm skin, flushing, palmar erythema and increased sweating (especially of palms and soles). Hair is fine, with diffuse alopecia in about a third of patients. Nails may be thin, with koilonychia and onycholysis (Plummer's nails); the onycholysis typically commences on the fourth digit of the hands [5]. Hyperpigmentation, similar to that of Addison's disease, may occur due to increased corticotrophin (ACTH) levels, and may be diffuse or localized to scars, but usually spares the buccal mucosa. Hyperpigmented eyelids have been described (Jellinek's sign).

Facial suffusion may be provoked in patients with a large substernal goitre (Pemberton sign), and erythema (sometimes with pruritus) may occur in the skin overlying a toxic goitre (Maroni sign).

Pretibial myxoedema, thyroid acropachy (both discussed separately below) and exophthalmos are features of Graves' disease (collectively known as Diamond's triad), although pretibial myxoedema can also occur in Hashimoto's thyroiditis. The combination of *e*xophthalmos, pretibial *m*yxoedema and hypertrophic *o*steoarthropathy has also been termed the EMO syndrome. In addition to these linked conditions, cutaneous features of associated autoimmune disease may be present, especially vitiligo.

The associations between thyroid diseases and other dermatoses are considered separately below.

Diagnosis [6]. In most instances, negative feedback mechanisms cause suppressed serum TSH levels before T_4 or T_3 levels are elevated. The exception is when hyperthyroidism is of secondary type, due to increased TRH or TSH levels. Thyroid antibodies are less helpful, as they are common in euthyroid individuals, and TSI levels are not usually measured. Isotope scanning can confirm the cause (diffuse goitre, adenoma, etc.).

Treatment. Beta-blockers may be used in the initial phase of therapy to suppress the increased sympathetic activity. The hyperthyroid state can be reversed by surgery, radioactive iodine or therapy with antithyroid drugs (propylthiouracil and carbimazole). However, changes that are unrelated to the hormone production tend to persist. Ophthalmopathy is not influenced by a return to euthyroidism, and the prognosis in severe cases is doubtful.

Pretibial myxoedema

Synonym
- Localized myxoedema

Localized oedematous and thickened pretibial plaque formation occurs in 1–10% of patients with hyperthyroidism. It is usually a late feature, occurring after ophthalmopathy and diagnosis of hyperthyroidism (sometimes only becoming evident after antithyroid treatment has been initiated), but it can occasionally precede other features [1,2]. Almost all patients with pretibial myxoedema have ophthalmopathy [1]. The same process often occurs on the dorsum of the hallux, and may affect other sites, including the lower abdomen, arms, shoulders, neck and pinnae [3]. Pretibial myxoedema in euthyroid individuals is very rare [4], and must be distinguished from a recently described entity called chronic obesity lymphoedematous mucinosis [5], which arises on the calves and shins of the obese.

Aetiology. It is unclear whether circulating or local factors are the main determinant of pretibial myxoedema. It was demonstrated over two decades ago that serum of pretibial myxoedema patients caused a two- to threefold increase in hyaluronic acid production by cultured fibroblasts from the pretibial area of patients and normal subjects, but had no effect on those from the shoulder or prepuce [6]. Most patients with pretibial myxoedema, whether thyrotoxic or not, have elevated levels of LATS in their serum, so this specific antibody does not seem to be causally involved [7]. A role for TSI was proposed, as fibroblasts from the pretibial and orbital regions have TSH receptors; TSIs have agonist effects on TSH receptors. Ribonucleic acid sequences encoding parts of the TSH receptor, and TSH receptor-like immunoreactivity, have been demonstrated in fibroblasts from these sites in affected patients [8]. There is, however, no obvious association between the clinical manifestations and the presence of TSH receptor autoantibodies. Recent research demonstrated that patients with pretibial myxoedema, but not control subjects, have circulating immunoglobulin A2 (IgA2) fibroblast antibodies capable of binding to a 54-kDa antigen of dermal fibroblast cell lines [9]. IGF-1 has also been suggested to have a role in the pathogenesis [10]. However, the occurrence of pretibial myxoedema in both the donor and recipient site in a patient who had excision of pretibial myxoedema, with normal skin grafted into the area, suggests that there are local factors operative which are not explained by site-specific properties of the dermal fibroblasts [11].

Pretibial myxoedema also occurs in other situations, especially in chronic stasis dermatitis [12].

Histopathology. The dermis is thickened, especially in the middermis and deeper part, by extensive deposits of acid mucopolysaccharides, which may cause separation of the collagen fibres. Stellate, mucin-producing fibroblasts may be prominent.

Clinical features. In many instances, the lesions first appear on the anterolateral aspect of the lower limbs and only later extend to the back of the legs, and feet (Fig. 62.4). The nodules are pink or skin-coloured, sometimes yellow-brown and waxy, with promi-

Fig. 62.4 Elephantiasic pretibial myxoedema.

nent hair follicles giving a 'peau d'orange' appearance. They may occur in old or recent scars [11,13,14]; localized pruritus or hypertrichosis over the lesions may be a feature, and localized hyperhidrosis has also been reported [15,16]. Three clinical types are recognized:

1 Sharply circumscribed, in which both nodular and tuberous lesions appear on the shins and toes
2 Diffuse, producing solid non-pitting oedema of the shins and feet
3 Elephantiasic, in which there is both oedema and nodule formation

Treatment. Topical glucocorticoids, with or without occlusive dressings, or intralesional glucocorticoid injections, may be useful [1,17]. The long-term benefits of surgery vary, although debulking procedures may be of benefit (for example, for lesions on the toes) [18]. Octreotide [19,20], plasmapheresis (perhaps acting by removal of TSIs, although not all patients respond) [21], photochemotherapy and intravenous immunoglobulin [22] have been advocated. Graduated compression bandaging can be used as an addition to all therapies provided there is no vascular contraindication; pneumatic compression [23] has also been used.

Thyroid acropachy [1,2]

Clubbing of the fingers and toes in Graves' disease, associated with soft-tissue swelling of hands and feet and with periosteal new bone formation, is termed thyroid acropachy. It occurs in less than 1% of thyrotoxic patients, and is usually associated with exophthalmos and pretibial myxoedema (Diamond's triad), occurring in about 5% of patients with these other features. Acropachy usually appears some time after the other components of the syndrome, usually after treatment of Graves' disease. Pathologically, there is periosteal new bone formation involving the phalanges and other distal long bones, which is manifest radiologically as a

feathery pattern of lamellar new bone parallel to the diaphyses, sometimes with perpendicularly orientated new bone spicules, and which can be demonstrated as osteoblastic activity using a bone scan [2]. The proximal phalanges and first or second metacarpals are most commonly affected. Most patients have minimal or no symptoms, but in those with symptoms, stiffness is the most frequent; by comparison with hypertrophic pulmonary osteoarthropathy, pain and heat are absent. Pachydermoperiostosis (Chapter 15) shows some resemblance to acropachy, but other features of the syndrome are absent.

Hypothyroidism [1–3]

Synonyms
- Myxoedema
- Hypothyreosis

In hypothyroidism, there is a slowed metabolic rate involving all organs. It is caused by a decreased concentration of free thyroid hormone in the blood, or target cell resistance to thyroid hormone.

Aetiology. The most common cause is idiopathic (primary) hypothyroidism, which is an autoimmune disease, usually affecting women from the fourth decade; the prevalence rate is almost 2% in females but a tenth of this in males. A high percentage of patients with Hashimoto's thyroiditis (who may initially be thyrotoxic) eventually develop hypothyroidism, and iatrogenic hypothyroidism may occur as a late effect of radio-iodine treatment of thyrotoxicosis. Secondary hypothyroidism due to pituitary disease is uncommon, TSH production being relatively spared compared to sex hormone and ACTH production, but pituitary infarction, haemorrhage or neoplasm may lead to hypothyroidism in some cases. Severe iodine deficiency, or drugs such as lithium and bexarotene, may cause hypothyroidism. Congenital hypothyroidism (cretinism), usually due to absence of the thyroid, is rare. Tertiary hypothyroidism is due to hypothalamic failure of TRH production.

Clinical features. Cutaneous changes of hypothyroidism (Table 62.5) [1–7] were well known in the latter part of the 19th century [4]. The most prominent manifestation of hypothyroidism is related to dermal accumulation of mucopolysaccharides, in particular chondroitin sulphate and hyaluronic acid, which bind water in the tissue and lead to puffiness of the skin. Whilst characteristic, the features may be insidious in development, and some are of low specificity. For example, loss of the outer third of the eyebrow (madarosis, Hertog's sign) is common in many euthyroid elderly individuals. The yellowish skin colour is due to a combination of alterations in connective tissue of the dermis, carotenaemia and vasoconstriction (due to the slowed metabolic rate). The connective tissue changes also cause loss of support of dermal vessels and, along with decreased levels of clotting factors, predispose to purpuric lesions or bruising. Asteatotic eczema [5] and keratoderma of palms and soles [6] may occur, sometimes as the presenting feature. Features of previous autoimmune thyrotoxicosis, or of associated autoimmune diseases, may also be present. The hypometabolic state and low core temperature may cause cold extremities due to reflex vasoconstriction. Loss of hair is common, occurring in about 50% of affected individuals (Fig. 62.5).

Table 62.5 Cutaneous and oral features of hypothyroidism.

Skin
Pale, cold, scaly and wrinkled skin
Xerosis, asteatotic eczema, itch
Palmoplantar keratoderma
Absence of sweating
Ivory-yellow skin colour
Puffy oedema of hands, face and eyelids
Purpura and ecchymoses
Punctate telangiectases on arms and fingertips
Delayed wound healing
Xanthomatosis (secondary to hyperlipidaemia)
Nails
Brittle and striated nails
Slow nail growth
Hair
Coarse sparse scalp hair
Loss of pubic, axillary and facial hair
Loss of lateral eyebrows (madarosis)
Oral
Large tongue
Gingival swelling (in congenital hypothyroidism)
Oral candidosis

Fig. 62.5 Diffuse alopecia and coarse hair due to hypothyroidism.

In congenital hypothyroidism ('cretinism'), coarseness of features, lethargy, periorbital puffiness, swelling of hands and feet, macroglossia, cold and dry skin with livedo, umbilical hernia and poor muscle tone are pathognomic, but may not be apparent until a few months of age. Cutis marmorata occurs due to vasoconstriction. Without treatment, physical and mental development is retarded. The scalp hair is coarse, and the eyebrows may be confluent.

In juvenile hypothyroidism, abnormal physical and mental development is the principal manifestation of the disease. Some children develop hypertrichosis of the upper back and shoulders. The waxy, yellowish skin changes may be prominent, but the puffiness may be less apparent than in older individuals. Rarely, juvenile hypothyroidism is associated with sexual precocity; the penis and scrotum enlarge in males, or menstruation and galactorrhoea occur in females, but axillary and pubic hair do not develop.

Diagnosis. Protein-bound iodine, T_4 and T_3 levels are low. In primary hypothyroidism, the TSH level is elevated; in pituitary failure, it is low or undetectable. The histological changes in the dermis may be helpful in difficult cases [8]. Recognition of hypothyroidism in the elderly may be difficult. Symptoms and signs develop insidiously and may easily be taken as evidence of arteriosclerotic disease. Serum TSH is recommended as the primary investigation for screening of elderly patients.

Thyroid disease and other dermatoses

Thyroglossal cysts are in the differential diagnosis of other congenital cysts in the neck, such as branchial cysts or ectopic bronchial mucosa.

Thyroid cancer may give rise to cutaneous metastases, or to thyroxine-producing metastases which therefore cause features of thyrotoxicosis. Thyroid cancer is also a feature of syndromes such as Cowden's disease and multiple endocrine neoplasia (MEN) type 2, discussed elsewhere in this chapter.

Table 62.6 Some skin disorders and other diseases with prominent cutaneous manifestations that have been associated with thyroid dysfunction or with the presence of antithyroid antibodies.

Bullous diseases	*Others*
Dermatitis herpetiformis	Chronic urticaria
Bullous pemphigoid	Palmoplantar pustulosis
Pemphigus	Psoriasis
Pemphigoid gestationis	Atopic dermatitis
Endocrine diseases	Sweet's syndrome
Pernicious anaemia	Sarcoidosis
Diabetes mellitus	POEMS syndrome
Addison's disease	Granuloma annulare
Acanthosis nigricans with insulin resistance	Pseudoxanthoma elasticum
Autoimmune polyglandular syndromes I–III	Polyostotic fibrous dysplasia
Other autoimmune conditions	Melasma
Alopecia areata	Melanoma
Vitiligo	Lichen sclerosus
Premature greying (canities)	Xanthelasma
Connective tissue diseases	
Lupus erythematosus	
Scleroderma	
Dermatomyositis	
Sjögren's syndrome	

POEMS, *p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M* protein and *s*kin changes (syndrome).

There are associations between either the presence of antithyroid antibodies, or of overt thyroid dysfunction or thyroiditis, with a number of other skin diseases and disorders with cutaneous manifestations (Table 62.6) [1–13]. Some of these associations are based on small studies, but associations with disorders such as dermatitis herpetiformis and chronic urticaria are strongly supported by the available literature. About 20% of children with alopecia areata have thyroid antibodies, although clinical thyroid dysfunction is rare [13]. It is debatable to what extent management is altered by routinely testing for thyroid antibodies or thyroid dysfunction in the absence of other clinical symptoms, although there are reported instances where chronic urticaria, for example, has resolved after treatment of associated thyrotoxicosis; it has also been recommended that T_4 treatment should be considered in euthyroid patients with chronic urticaria if they have evidence of thyroid autoimmunity [7]. An increased incidence of hypothyroidism is reported in melanoma [14,15].

Parathyroid disease

Skin changes are not a particular feature of hyperparathyroidism, although subcutaneous calcification may occur (especially in hyperparathyroidism secondary to renal failure; see below) [1–4].

Itch is thought to be related to hyperparathyroidism [5], although this is poorly documented [6] and some of the documentation is inferred (from resolution in some instances of renal itch after parathyroidectomy, or paraneoplastic itch after resection of parathormone (PTH)-producing bronchial tumours). Hyperparathyroidism has also been linked to cutaneous T-cell lymphoma [7].

Hypoparathyroidism may cause skin changes somewhat similar to those of hypothyroidism—the skin may be dry, keratotic and puffy, with sparse, coarse hair. Nails are brittle and ridged, with cracking at the free margin, or crumbling of the distal nail plate. Chloasma or pellagra-like pigmentary disturbance is less common [3,8].

There are numerous reports of pustular psoriasis of the von Zumbusch type being provoked by hypocalcaemia, with resolution of the pustulation and erythroderma with resolution of the skin eruption on restoring normocalcaemia [9,10] and one of the authors has personal experience of a patient presenting with a severe pustular exacerbation of chronic plaque psoriasis associated with hypocalcaemic tetany due to primary hypoparathyroidism.

Calciphylaxis of the skin, resulting in localized necrosis due to vascular calcific occlusion, is usually seen in renal failure, but there are occasional reports of it occurring in the setting of normal renal function and hyperparathyroidism [11].

Chronic mucocutaneous candidiasis, especially of the nails and oral mucosa, may occur in conjunction with hypoparathyroidism when this occurs as part of the polyglandular autoimmune syndrome (see below) or in association with immunological defects such as Di George's syndrome (in which there is parathyroid gland agenesis) [1], but it is not a feature of post-thyroidectomy iatrogenic hypoparathyroidism.

Subcutaneous ossification is a feature of Albright's hereditary osteodystrophy, which encompasses both pseudohypoparathyroidism type Ia and pseudopseudohypoparathyroidism [1,12–14]. The somatic features include obesity, short stature and short metacarpals—Albright's sign is dimpling over the knuckle of the typically affected fourth metacarpal. The dominant condition occurs due to a heterozygous functional defect of the α-subunit of the stimulatory G protein (G_s α protein) of adenylate cyclase, with which PTH interacts at the cell surface. This is encoded by the *GNAS1* gene on chromosome 20q13.3, but there are tissue-specific differences in expression of G_s α and other *GNAS1* transcripts that are different for the maternal and paternal alleles [13]. It is now known that pseudopseudohypoparathyroidism is the same disorder as pseudohypoparathyroidism type Ia, but with the genetic defect inherited from the father; patients have the somatic features of pseudohypoparathyroidism, but with normal hormone responses [14].

Multiple endocrinopathy syndromes

It is common that autoimmune conditions may occur simultaneously—due to, for example, human leukocyte antigen (HLA) linkage. Some of these produce an overlap between endocrine disease and:

- Other autoimmune conditions, e.g. polyglandular autoimmune syndrome (see below), various combinations of Sjögren's syndrome and sarcoidosis with endocrine autoimmune conditions [1,2]
- Infections, such as in autoimmune polyglandular syndrome type I (see below)
- Ectodermal changes, e.g. alopecia areata (commonly), ANOTHER syndrome (*a*lopecia, *n*ail dystrophy, *o*phthalmic complications, *t*hyroid dysfunction, *h*ypohidrosis, *e*phelides and enteropathy, *r*espiratory tract infections) [3]
- Gastrointestinal disease, e.g. the triple A syndrome (Allgrove's syndrome) of achalasia, addisonianism and alacrima (MIM #231550); IPEX syndrome (*i*mmune dysregulation, *p*olyendocrinopathy, *e*nteropathy, *X*-linked syndrome) in which diarrhoea is a significant feature with an icthyosiform dermatitis, and also diabetes, throiditis and haemolytic anaemia [4]
- Pigmentary change, e.g. vitiligo (commonly), Carney complex (see cardiac disease, below), POEMS syndrome (see cardiac disease, below)
- Alopecia areata—associated with thyroid disease and other autoimmune conditions
- Bone disease, e.g. McCune–Albright syndrome (MIM #174800); G protein mutations cause dysregulation of cyclic adenosine monophosphate (cAMP), leading to growth and hyperfunction of many organs—features include hypophosphataemic osteodystrophy, hyperparathyroidism, hyperthyroidism, large irregularly shaped café-au-lait macules, Cushing's syndrome, acromegaly and hyperprolactinaemia
- Cerebral disease, e.g. triple H syndrome—*h*ippocampus (anterograde memory loss), *h*air follicle (alopecia areata), *h*ypothalamic–pituitary–adrenal axis (isolated ACTH deficiency) [5].

Autoimmune polyendocrine syndromes [6–13]

Three types of autoimmune polyendocrine (polyglandular) syndrome (APS) are described—types 1 to 3—although there may also be other, incomplete forms [13]. The pathogenesis of these disorders is discussed in detail in [8,13]. The most important example dermatologically is APS type 1 (MIM 240300), which is usually due to the R257X mutation of the *AIRE* gene on chromosome 21q22.3 [11] and is associated with about 13% of cases of Addison's syndrome [13]. It is also termed mucocutaneous candidiasis–endocrinopathy syndrome, multiple endocrinopathy syndrome, *a*utoimmune *p*olyendocrinopathy–*c*andidiasis–*e*ctodermal *d*ystrophy (APECED) syndrome, or Whitaker's syndrome. Table 62.7 outlines the diagnostic criteria; the dermatological features include mucocutaneous candidiasis, nail dystrophy, alopecia areata, vitiligo and cutaneous features of Addison's disease [9,11,13].

An interesting feature of vitiligo in this condition, which does not occur in isolated vitiligo or in other autoimmune combinations, is the presence of complement-fixing melanocyte autoantibodies [11]. Most patients also have adrenal cortex autoantibodies, and those with gonadal failure have steroid-producing cell antibodies. Nail dystrophy and tooth enamel defects comprise the ectodermal dystrophy component. Epidermolysis bullosa acquisita has also been reported in type 1 syndrome [12].

Patients with APS types 2 and type 3 more commonly have diabetes, but less commonly have alopecia or vitiligo, and do not have chronic mucocutaneous candidiasis. Addison's disease is present in all patients with APS type 2, which has been further divided by some authors according to the specific endocrinopathies present; thus, Addison's disease with autoimmune thyroid disease is termed Schmidt's syndrome, Addison's disease with immune-mediated diabetes (with or without thyroid disease) is Carpenter's syndrome. APS type 3 is defined as co-occurrence of autoimmune thyroid disease with two other autoimmune disorders in the absence of Addison's disease [14]. APS type 2 is due to defects in the *HLA* region on 6p21 or in *CTLA4* on 2q33. It should be noted that not all of the autoimmune components are actually endocrine in type; vitiligo is not uncommon, and Schmidt's multiple endocrine insufficiency syndrome has been reported with alopecia areata and the stiff man syndrome (due to autoantibodies to glutamic acid decarboxylase).

The MEN syndromes are discussed later in this chapter.

Table 62.7 Type 1 autoimmune polyglandular syndrome diagnostic criteria (defined by the presence of two or more of the three major features).

Major features
Chronic mucocutaneous candidiasis (usually by age 5 years, present in about 80%)
Chronic hypoparathyroidism (usually by age 10 years, present in about 90%)
Autoimmune adrenal insufficiency (usually by age 15 years, present in about 70%, frequently autoantibody positive)
Other features
Hypergonadotrophic hypogonadism (45%)
Diabetes mellitus
Thyroid antibodies or overt thyroid dysfunction
Alopecia areata (25%)
Vitiligo (10%)

Cutaneous markers of internal malignancy [1–11]

Introduction and classification

The different types of skin change associated with internal malignancy, and the links between systemic neoplasia and consequent or associated skin conditions, are so numerous that to report all documented associations here is impracticable. We suggest some broad categories for consideration; this includes disorders in those with a known internal malignancy but the emphasis is on skin manifestations that provide clues to internal malignancy or that indicate a need for malignancy screening. The main categories are:

1 Multisystem and haemopoietic tumours that involve the skin
2 Direct tumour spread from adjacent or deeper tissues
3 Cutaneous metastasis from internal tumours (indirect tumour spread to the skin)
4 Genetically determined syndromes with cutaneous manifestations, where there is a recognized predisposition to internal malignancy (also termed 'genodermatoses with malignant potential')
5 Paraneoplastic disorders—cutaneous reaction patterns that have an association with neoplasia involving various internal organ systems
6 Indirect cutaneous markers of internal malignancy (markers of exposure to carcinogens, cancers of the skin related to immunosuppression, infections, etc., in which those affected have a higher risk of internal malignancy).

Investigation for internal malignancy

Potential cutaneous markers of internal malignancy vary in their reliability for predicting underlying neoplasia. Additionally, other factors such as malaise, weight loss, non-specific or non-cutaneous focal symptoms may all play a part in deciding which patients to investigate and how extensively. There may be non-specific cutaneous markers of disease (such as purpura, stigmata of liver disease, etc.) that influence a decision; these are discussed elsewhere in this chapter. A clinical decision on the extent of investigation and screening, if any, must therefore be based on the strength of the association and on the clinical history and examination in the individual patient. It is helpful to consider various skin eruptions in terms of the likelihood of the cutaneous features suggesting the presence of internal malignancy—this may be obvious in some situations (e.g. internal tumours metastatic to the skin), but the strength of associations between some paraneoplastic dermatoses and internal malignancy varies hugely (as discussed later).

In some situations, simple investigations, such as chest radiography, full blood count, liver enzymes, non-specific markers of disease (such as erythrocyte sedimentation rate) or of possible tumour burden (such as lactate dehydrogenase), urine analysis and stool examination for occult blood, may be sufficient. Rapid changes in investigative techniques, such as the speed and accuracy of magnetic resonance imaging (MRI), emerging techniques such as positron emission tomography (PET scan), use of serological tumour markers (such as CA-125 for ovarian tumours, prostate-specific antigen, etc.) and, in inherited cancer susceptibility, the ability to identify individuals who have genes linked with malignant disease, are all altering the ease and extent of investigation that may be appropriate. Thus advice that was once very appropriate (such as the conclusion by many authors that investigation in dermatomyositis should be guided by careful clinical history and examination, and by pursuit of any abnormality of simple tests) must be viewed in the context not only of the tests that were readily available at the time, but also in the light of new tests that may help to identify subgroups with a higher than average risk of a malignancy being found.

Cutaneous adverse reactions to drugs used to treat malignancy are a related topic that will not be considered here, but is covered in Chapter 75 and in [11].

Multisystem and haemopoietic tumours that involve the skin [1–3]

This category includes a number of tumours, discussed in other chapters, in which the skin is involved as part of a multisystem neoplasm. The importance for dermatologists is that the diagnosis may present due to skin lesions, or that the skin may be the most accessible site for histological diagnosis.

The type of skin involvement that may occur in such disorders ranges from very non-specific (such as purpura, which may reflect

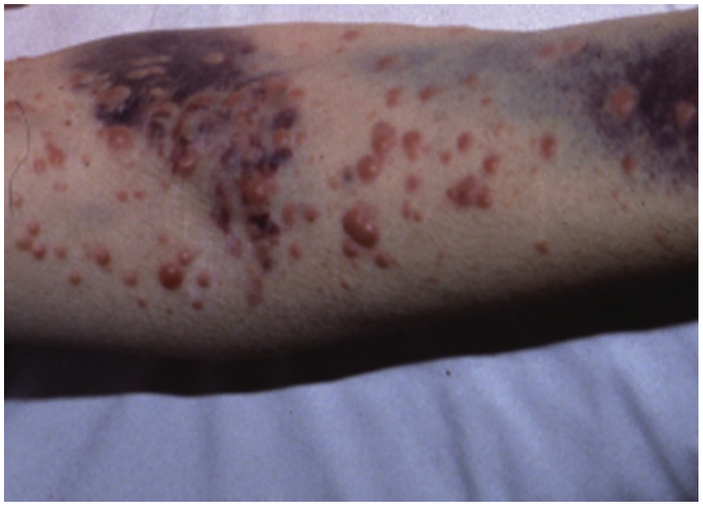

Fig. 62.6 Leukaemia cutis (acute myelogenous leukaemia) and purpura.

Fig. 62.7 Carcinoma erysipeloides. (Courtesy of Dr R. Emmerson, Royal Berkshire Hospital, Reading, UK.)

abnormal platelet numbers or function or both, or susceptibility to unusual infections in disorders where immunosurveillance is compromised), through to highly specific features such as cutaneous deposits of the malignancy (for example, lesions of leukaemia cutis). In some instances, there may be features that suggest a particular diagnosis (such as oral leukaemic deposits, which are most typically seen in myelomonocytic leukaemia), or other cutaneous disease associations (such as the rare association of neurofibromatosis type 1 with juvenile xanthogranuloma and juvenile myelomonocytic leukaemia).

This type of involvement of the skin as part of a multisystem tumour is somewhat different from metastases from solid tumours in both mechanism and in the fact that lesions are often widespread. Most relevant conditions are discussed in other chapters, but, as examples, skin involvement is an important component of many haemopoietic tumours, particularly lymphomas (Chapter 57); similarly, Langerhans' cell histiocytosis (Chapter 55) and Kaposi's sarcoma (Chapter 56) characteristically cause skin lesions.

Specific cutaneous infiltrations of the skin may occur with myeloproliferative disorders; this is commonly recognized with lymphoma, but can occur with leukaemia (Fig. 62.6) [4]. Some skin infiltrates that are characteristic of specific disorders are discussed elsewhere in this section.

Direct tumour spread from adjacent and deeper tissues [1,2]

Other than primary skin neoplasms, the skin may be involved by tumour as a result of cutaneous metastases from an internal tumour (see below), or by direct involvement in continuity with an adjacent organ. This may be the presenting feature of the underlying malignancy, as occurs in Paget's disease [2] (Chapter 52 and below), but more commonly occurs when an underlying tumour has been neglected (e.g. some breast carcinomas) or is refractory to treatment. It is a particular feature of malignant lymph node metastases (e.g. breast carcinoma, melanoma), and occasionally arises after diagnostic or therapeutic interventions such as needle aspiration of a tumour, pleural biopsy, drainage of malignant ascites or placement of other drains in the vicinity of a tumour. 'Tumour spillage', direct contamination of wounds with tumour cells during a laparoscopy or surgical procedure, was once a problem in nearly 20% of cases but is now uncommon; laparoscopic port site metastasis rates and laparotomy wound metastasis rates due to direct tumour inoculation are both in the order of 0.8% [3]. However, skin involvement may still occur from an abdominal viscus neoplasm or peripheral lung tumour that directly invades the skin.

Local and in-transit metastases from primary epidermal tumours are discussed in relevant chapters; melanoma is the most important tumour to behave in this fashion.

Direct invasion of the skin from a deeper tumour usually causes tumid ulceration or inflammation, but may present in less obvious ways; dermal infiltration causing sclerosis (carcinoma en cuirasse), vascular changes (carcinoma telangiectoides), a peau d'orange appearance, and more rarely a carcinoma erysipeloides (inflammatory metastatic carcinoma) pattern (Fig. 62.7) may all occur, especially with carcinoma of the breast. Although these patterns may occur as distant metastases, they most commonly occur in the skin in the vicinity of the primary tumour, all being most commonly associated with breast cancer, and are therefore usefully considered as a rather different pattern to those tumours that metastasize to distant sites.

All of these patterns may be difficult to diagnose unless there is clinical suspicion. *Carcinoma en cuirasse* may have an early inflammatory stage, and may include some nodularity, but at a later stage is very sclerodermoid in appearance. A particular diagnostic problem arises when a breast cancer has been treated with

radiotherapy, as this may cause post-irradiation morphoea; the latter is relatively well documented but the early inflammatory phase of post-irradiation morphoea that occurs in some patients is much less well recognized and may be very alarming clinically. Carcinoma en cuirasse may also occur with lung, gastrointestinal, renal and other malignancies [2]. *Carcinoma erysipeloides* resembles erysipelas but without the pyrexia or toxaemia; tumour cells lie within dilated lymphatic vessels in the skin. This pattern is again most commonly seen in breast carcinoma, but occurs due to melanoma and pelvic cancers (when it affects the lower abdomen or thigh); it can also occur due to carcinomas of the oral cavity or associated glands, as well as with upper abdominal cancers (stomach, pancreas) or lung cancer. *Telangiectatic metastatic carcinoma* is typically associated with breast cancer and may be difficult to diagnose as tumour cells may be quite scanty and telangiectasia quite subtle, although it may be more florid and resemble angiosarcoma. Less common patterns of direct tumour invasion include breast carcinoma presenting as an inframammary intertrigo-like pattern, and lymphatic obstruction by pelvic tumours or lymphadenopathy which may be accompanied by extensive tumour cells within the lymphatics, presenting as skin nodules. Oral tumours, usually squamous cell carcinoma, may extend to directly involve the skin of the face.

Paget's disease

Paget's disease occurs in mammary and extramammary forms. Paget's disease of the breast occurs due to an underlying ductal tumour; extramammary Paget's disease may occur without an underlying tumour, or distant to a tumour, and so does not have the close link with direct tumour spread of the mammary pattern but is conveniently discussed here.

Paget's disease of the breast [2,4–6]

This condition presents with scaling and erythema, sometimes with oozing and crusting, on or around the nipple (Fig. 62.8). It is generally viewed as a direct epidermal extension of an underlying ductal adenocarcinoma, and is important as the underlying tumour is usually small and superficial so early recognition may allow curative intervention. However, of the 30–50% with a palpable underlying lesion, half will have axillary lymph node involvement. The reason for the epidermotropic spread of tumour cells is uncertain but may involve a keratinocyte-derived chemoattractant for Paget cells, termed heregulin-α [5]. The main pathogenetic hypothesis for those cases that do not have an underlying carcinoma is derivation from Toker cells within the epidermis of the nipple and areola [2,5].

Fig. 62.8 Paget's disease of the breast causing destruction of the right nipple.

Clinically, eczemas, psoriasis, hyperkeratosis of the nipple and erosive adenomatosis are in the differential diagnosis of mammary Paget's disease. Histologically, there may be differential diagnosis problems from other disorders with Pagetoid spread, such as some melanomas or Bowen's disease, and also from a benign proliferation of Toker cells termed clear cell papulosis. Useful histopathological markers for mammary Paget's disease include epithelial membrane antigen (EMA), carcinoembryonic antigen (CEA), cytokeratins CK7 and CK8/18, as well as mucins such as MUC1 [5,6]. CD23, a lymphoid and apocrine/eccrine marker, is uniformly positive in mammary or extramammary Paget's disease [7].

Extramammary Paget's disease [2,5–10]

This rarer form of Paget's disease occurs in apocrine gland-bearing areas such as anogenital and axillary sites. About 60% of cases are vulval, 20% perianal and 15% penile or scrotal; there is thus a female predominance (although some populations, such as the Japanese [10], have a male predominance). Its histogenesis is less certain, and only about 25% of patients appear to have an underlying cancer. When the vulva is affected, cancers comprise about 10% in whom the cancer is locally arising (from apocrine sweat glands or Bartholin's glands) and about 15% in whom the carcinoma arises in the vagina, cervix, bladder, ovary, colon or rectum, or occasionally from more distant sites such as breast or gallbladder. Perianal Paget's disease is associated with an adnexal tumour in about 10% and a distant tumour in about 25% (rectum, stomach, ureter, breast); male genital Paget's disease is associated with a carcinoma of prostate, bladder, ureter, kidney or testes in about 10% of cases. In other cases, extramammary Paget's disease arises locally in the epidermis.

Most patients are over 60 years of age; clinical features include itch, burning sensation, oedema, bleeding and reddish-brown (or sometimes hypopigmented) plaques which may have a slightly more prominent margin. The margin may be obscured by secondary infection, and may be difficult to define in vaginal mucosa. Genital Paget's disease is often mistaken for an eczematous process, psoriasis or tinea. Histological and immunohistochemical features are similar to those of mammary Paget's disease; the antigen RCAS1 is particularly sensitive [5]. The prognosis is determined by the underlying tumour, if present, and the ability to adequately excise it; for those with a local epidermal origin, the depth of invasion and lymphatic spread dictate the prognosis, serum CEA being a useful indicator of survival [10].

Cutaneous metastasis from tumours affecting other organs [1–12]

Frequency of skin metastases

The skin is a relatively uncommon site for distant metastatic deposits, compared with organs such as liver, lung and bone. However, autopsy studies suggest a higher frequency of skin metastasis than may be apparent from clinical studies; in some studies up to 9% of patients with internal cancer have had skin metastases, a large analysis suggesting that 5% is usual [4], and in about 0.5–1% a metastasis is the presenting feature of internal cancer [1,2]. Of patients with metastatic cancer, 10% have cutaneous metastases [8]. Studies vary in cited frequency of skin metastases in part because some include metastasis from cutaneous melanoma whilst others exclude this and only refer to internally originating tumours; additionally, it can sometimes be difficult to know whether skin involvement is in contiguity or close proximity with a primary tumour of a different organ (direct invasion) or not (metastasis [12]). The most common sources of cutaneous metastases are (in generally accepted order of frequency): breast, (melanoma), lung, colon, stomach, upper aerodigestive tract, uterus and kidney; the most common skin metastases from a previously unknown primary tumour originate from the kidney, lung, thyroid or ovary [2,9,11].

Appearance of skin metastases

Cutaneous metastases generally present as solitary or multiple painless, firm to hard nodules, which may be skin-coloured, blue-brown or reddish-purple (Fig. 62.9); presentation with a solitary nodule is more common than with multiple nodules [9]. Ulceration of nodules may occur but is not usually a feature at initial presentation. They may also present as palpable subcutaneous nodules, often multiple (from a few to several hundred) in such instances. Other patterns include a morphoea-like sclerotic pattern, plaque morphology, scar infiltration, erysipelas-like pattern, infiltrated areas of alopecia (alopecia neoplastica), zosteriform metastases, embolic metastasis to digits (Fig. 62.10), and others.

The commonest, nodular, pattern presents with a solitary nodule about twice as frequently as with multiple nodules, although huge numbers of small dermal or subcutaneous nodules may be palpable in some such cases, even if not initially apparent or symptomatic.

Fig. 62.9 Subcutaneous metastasis from lung carcinoma; such metastases are typically multiple and many more firm nodules can usually be palpated if the patient is carefully examined.

Fig. 62.10 Embolic metastasis to the little finger of each hand from carcinoma of oesophagus.

Mechanisms and distribution [1]

Metastasis to the skin occurs as a result of lymphatic or haematogenous dissemination of tumour; direct infiltration of the skin by an underlying tumour is especially notable with breast carcinomas, and is discussed above. The reason for metastasis to specific organs is complex, involving both properties of the tumour cells, tumour cytokines (such as lymphangiogenic factors) and their interaction with host defences and tissues, and the distribution pattern within the skin is not random [2,12]. Indeed, 75% of metastases are found in the 25% of body surface area that comprises the head, neck and upper trunk [2].

Fig. 62.11 Metastasis to the groin in a patient with extensive pelvic prostatic carcinoma.
