EIGHTH EDITION

Rook's Textbook of Dermatology

EDITED BY
Tony Burns
Stephen Breathnach
Neil Cox
Christopher Griffiths

WILEY-BLACKWELL

Rook's Textbook of Dermatology

The Editors
From l to r, Tony Burns, Stephen Breathnach, Christopher Griffiths and Neil Cox standing in front of a portrait of Arthur Rook, the father of the *Textbook of Dermatology*.

We dedicate this edition to Neil Cox, who died shortly before the book went to press. Neil was a hugely talented dermatologist whose contribution to the specialty has been outstanding. In addition to a multitude of other publications, he has contributed to and edited two editions of *Rook's Textbook*. Enormously hard-working, his input has been of inestimable value. He will be sorely missed.

Tony Burns
Stephen Breathnach
Christopher Griffiths

Rook's Textbook of Dermatology

EDITED BY

Tony Burns
MB, BS, FRCP, FRCP(Edin)
Emeritus Consultant Dermatologist, Leicester Royal Infirmary, Leicester

Stephen Breathnach
MA, MB, BChir, MD, PhD, FRCP
Consultant Dermatologist, St John's Institute of Dermatology, Guy's and St Thomas' NHS Foundation Trust, St Thomas' Hospital, London, and Consultant Dermatologist, Epsom & St Helier University Hospitals NHS Trust, Epsom, Surrey

Neil Cox
BSc, MB, ChB, FRCP(Lond & Edin)
Consultant Dermatologist, Department of Dermatology, Cumberland Infirmary, and Visiting Professor, University of Cumbria, Carlisle

Christopher Griffiths
BSc, MD, FRCP, FRCPath
Professor of Dermatology and Consultant Dermatologist, The Dermatology Centre, University of Manchester, Salford Royal Hospital, Salford, Manchester

Contents

Contributors, ix

Preface to Eighth Edition, xv

Preface to First Edition, xvi

VOLUME 1

1 Introduction and Historical Bibliography, 1.1
D.A. Burns & N.H. Cox

2 Comparative Dermatology, 2.1
D.A. Burns, N.H. Cox & P.B. Hill

3 Anatomy and Organization of Human Skin, 3.1
J.A. McGrath & J. Uitto

4 Functions of the Skin, 4.1
C.B. Archer

5 Diagnosis of Skin Disease, 5.1
N.H. Cox & I.H. Coulson

6 Epidemiology of Skin Disease, 6.1
H.C. Williams

7 Evidence-Based Dermatology, 7.1
M. Bigby & H.C. Williams

8 Skin and Skin Disease Throughout Life, 8.1
G.W.M. Millington & R.A.C. Graham-Brown

9 Racial Influences on Skin Disease, 9.1
L.C. Fuller & E.M. Higgins

10 Histopathology of the Skin: General Principles, 10.1
E. Calonje

11 Molecular Biology, 11.1
E.A. O'Toole

12 Inflammation, 12.1
M. Steinhoff, R.W. Groves, P.E. LeBoit & T.A. Luger

13 Clinical Immunology, Allergy and Photoimmunology, 13.1
G.P. Spickett & T. Schwarz

14 Wound Healing, 14.1
E.A. O'Toole & J.E. Mellerio

15 Genetics and Genodermatoses, 15.1
A.D. Irvine and J.E. Mellerio

16 Prenatal Diagnosis of Genetic Skin Disease, 16.1
J.A. McGrath

17 The Neonate, 17.1
D.G. Paige, A.R. Gennery & A.J. Cant

18 Naevi and other Developmental Defects, 18.1
C. Moss & H. Shahidullah

19 Disorders of Keratinization, 19.1
M.R. Judge, W.H.I. McLean & C.S. Munro

20 Psoriasis, 20.1
C.E.M. Griffiths & J.N.W.N. Barker

21 Pruritus, 21.1
M.W. Greaves

22 Urticaria and Mastocytosis, 22.1
C.E.H. Grattan & A. Kobza Black

23 Eczema, Lichenification, Prurigo and Erythroderma, 23.1
J. Berth-Jones

24 Atopic Dermatitis, 24.1
P.S. Friedmann, M.R. Ardern-Jones & C.A. Holden

VOLUME 2

25 Contact Dermatitis: Irritant, 25.1
S.M. Wilkinson & M.H. Beck

26 Contact Dermatitis: Allergic, 26.1
M.H. Beck & S.M. Wilkinson

27 Occupational Dermatoses, 27.1
J.S.C. English

28 Mechanical and Thermal Injury, 28.1
C.T.C. Kennedy, D.A.R. Burd & D. Creamer

29 Cutaneous Photobiology, 29.1
J.L.M. Hawk, A.R. Young & J. Ferguson

30 Bacterial Infections, 30.1
R.J. Hay & B.M. Adriaans

31 Mycobacterial Infections, 31.1
V.M. Yates

32 Leprosy, 32.1
D.N.J. Lockwood

33 Virus Infections, 33.1
J.C. Sterling

34 Syphilis and Bacterial Sexually Transmitted Infections, 34.1
G.R. Kinghorn

35 HIV and the Skin, 35.1
C.B. Bunker & F. Gotch

36 Mycology, 36.1
R.J. Hay & H.R. Ashbee

37 Parasitic Worms and Protozoa, 37.1
F. Vega-López & R.J. Hay

38 Diseases Caused by Arthropods and Other Noxious Animals, 38.1
D.A. Burns

39 Genetic Blistering Diseases, 39.1
J.-D. Fine & S.M. Burge

40 Immunobullous Diseases, 40.1
F. Wojnarowska & V.A. Venning

41 Lichen Planus and Lichenoid Disorders, 41.1
S.M. Breathnach

42 Disorders of the Sebaceous Glands, 42.1
A.M. Layton

43 Rosacea, Perioral Dermatitis and Similar Dermatoses, Flushing and Flushing Syndromes, 43.1
J. Berth-Jones

44 Disorders of Sweat Glands, 44.1
I.H. Coulson

VOLUME 3

45 Disorders of Connective Tissue, 45.1
N.P. Burrows & C.R. Lovell

46 Subcutaneous Fat, 46.1
D.H. McGibbon

47 Diseases of the Veins and Arteries: Leg Ulcers, 47.1
P.S. Mortimer, K.G. Burnand & H.A.M. Neumann

48 Disorders of Lymphatic Vessels, 48.1
P.S. Mortimer

49 Purpura and Microvascular Occlusion, 49.1
N.H. Cox & W.W. Piette

50 Vasculitis, Neutrophilic Dermatoses and Related Disorders, 50.1
N.H. Cox, J.L. Jorizzo, J.F. Bourke & C.O.S. Savage

51 The 'Connective Tissue Diseases', 51.1
M.J.D. Goodfield, S.K. Jones & D.J. Veale

52 Non-Melanoma Skin Cancer and Other Epidermal Skin Tumours, 52.1
A.G. Quinn & W. Perkins

53 Tumours of the Skin Appendages, 53.1
E. Calonje

54 Lentigos, Melanocytic Naevi and Melanoma, 54.1
J.A. Newton Bishop

55 Histiocytoses, 55.1
A.C. Chu

56 Soft-Tissue Tumours and Tumour-like Conditions, 56.1
E. Calonje

57 Cutaneous Lymphomas and Lymphocytic Infiltrates, 57.1
S.J. Whittaker

58 Disorders of Skin Colour, 58.1
A.V. Anstey

59 Metabolic and Nutritional Disorders, 59.1
R.P.E. Sarkany, S.M. Breathnach, A.A.M. Morris, K. Weismann & P.D. Flynn

60 Necrobiotic Disorders, 60.1
D.A. Burns

61 Sarcoidosis, 61.1
D.J. Gawkrodger

62 Systemic Disease and the Skin, 62.1
N.H. Cox & I.H. Coulson

VOLUME 4

63 The Skin and the Nervous System, 63.1
C.B. Archer & D.J. Eedy

64 Psychocutaneous Disorders, 64.1
L.G. Millard & J. Millard

65 Disorders of Nails, 65.1
D.A.R. de Berker & R. Baran

66 Disorders of Hair, 66.1
A.G. Messenger, D.A.R. de Berker & R.D. Sinclair

67 The Skin and the Eyes, 67.1
J.N. Leonard & J.K.G. Dart

68 The External Ear, 68.1
C.T.C. Kennedy

69 The Oral Cavity and Lips, 69.1
C. Scully & A. Hegarty

70 The Breast, 70.1
D.A. Burns

71 The Genital, Perianal and Umbilical Regions, 71.1
C.B. Bunker & S.M. Neill

72 General Aspects of Treatment, 72.1
A.Y. Finlay and C.H. Smith

73 Topical Therapy, 73.1
J. Berth-Jones

74 Systemic Therapy, 74.1
S.M. Breathnach, C.H. Smith, R.J.G. Chalmers & R.J. Hay

75 Drug Reactions, 75.1
S.M. Breathnach

76 Erythema Multiforme, Stevens–Johnson Syndrome and Toxic Epidermal Necrolysis, 76.1
S.M. Breathnach

77 Dermatological Surgery, 77.1
C.M. Lawrence & N.R. Telfer

78 Lasers and Flashlamps in the Treatment of Skin Disorders, 78.1
R.J. Barlow

79 Radiotherapy and Reactions to Ionizing Radiation, 79.1
C.G. Kelly & I. Peat

80 Minimally Invasive Treatments and Procedures for Ageing Skin, 80.1
N.J. Lowe

Index

The index to all four volumes can be found at the end of Volume 4

Contributors

Adriaans, Beverley M.

MD, FRCP
Consultant Dermatologist, Department of Dermatology, Gloucestershire Royal Hospital, Gloucester GL1 3NN
Co-author of
Chapter 30: Bacterial Infections

Anstey, Alexander V.

MD, FRCP
Consultant Dermatologist, Department of Dermatology, Royal Gwent Hospital, Newport NP20 2UB
Author of
Chapter 58: Disorders of Skin Colour

Archer, Clive B.

BSc, MD, PhD, MSc Med Ed(Lond), FRCP (Edin, Lond)
Consultant Dermatologist, Honary Clinical Senior Lecturer, Bristol Dermatology Centre, Bristol Royal Infirmary, Bristol BS2 8HW
Author of
Chapter 4: Functions of the Skin
Co-author of
Chapter 63: The Skin and the Nervous System

Ardern-Jones, Michael R.

BSc, MRCP, DPhil
Senior Lecturer and Honorary Consultant in Dermatology, Division of Infection, Inflammation and Immunity, School of Medicine, University of Southampton, Southampton General Hospital, Southampton SO16 6YD
Co-author of
Chapter 24: Atopic Dermatitis

Ashbee, H. Ruth

BSc, PhD
Principal Clinical Scientist, Mycology Reference Centre, Department of Microbiology, Leeds General Infirmary, Leeds LS1 3EX
Co-author of
Chapter 36: Mycology

Baran, Robert

MD
Head of Nail Disease Centre, Le Grand Palais, 42 Rue des Serbes, 06400 Cannes, and Consultant Dermatologist, Gustave Roussy Cancer Institute, 94805 Villejuif, France
Co-author of
Chapter 65: Disorders of Nails

Barker, Jonathan N.W.N.

BSc, MD, FRCP, FRCPath
Professor of Clinical Dermatology, St John's Institute of Dermatology, King's College London, Guy's Hospital, London SE1 9RT
Co-author of
Chapter 20: Psoriasis

Barlow, Richard J.

MD, FRCP
Consultant Dermatologist, St John's Institute of Dermatology, St Thomas' Hospital, Lambeth Palace Road, London SE1 7EH
Author of
Chapter 78: Lasers and Flashlamps in the Treatment of Skin Disorders

Beck, Michael H.

FRCP, MBchB
Honorary Clinical Lecturer Occupational and Environmental Health Group, University of Manchester and Retired Consultant Dermatologist and Director of Contact Dermatitis Investigation Unit, Department of Dermatology, Salford Royal Hospital, Stott Lane, Salford M6 8HD
Co-author of
Chapter 25: Contact Dermatitis: Irritant
Chapter 26: Contact Dermatitis: Allergic

Berth-Jones, John

FRCP
Consultant Dermatologist, Department of Dermatology, University Hospitals Coventry and Warwickshire, Walsgrave, Coventry CV2 2DX
Author of
Chapter 23: Eczema, Lichenification, Prurigo and Erythroderma
Chapter 43: Rosacea, Perioral Dermatitis and Similar Dermatoses, Flushing and Flushing Syndromes
Chapter 73: Topical Therapy

Bigby, Michael

MD
Associate Professor of Dermatology, Harvard Medical School and Beth Israel Deaconess Medical Center, 330 Brookline Avenue, Boston MA 02215, USA
Co-author of
Chapter 7: Evidence-Based Dermatology

Bourke, John F.

MD, FRCP(Ire)
Consultant Dermatologist, Department of Dermatology, South Infirmary-Victoria Hospital, Old Blackrock Road, Cork, Ireland
Co-author of
Chapter 50: Vasculitis, Neutrophilic Dermatoses and Related Disorders

Breathnach, Stephen M.

MA, MD, PhD, FRCP
Consultant Dermatologist, St John's Institute of Dermatology, Guy's and St Thomas' NHS Foundation Trust, St Thomas' Hospital, Lambeth Palace Road, London SE1 7EH
Editor
Author of
Chapter 41: Lichen Planus and Lichenoid Disorders
Chapter 75: Drug Reactions
Chapter 76: Erythema Multiforme, Stevens–Johnson Syndrome and Toxic Epidermal Necrolysis
Co-author of
Chapter 59: Metabolic and Nutritional Disorders
Chapter 74: Systemic Therapy

Bunker, Christopher B.

MA, MD, FRCP
Consultant Dermatologist, Chelsea and Westminster and Royal Marsden Hospitals, Professor of Dermatology, Division and Faculty of Medicine, Imperial College London, Department of Dermatology, 369 Fulham Road, London SW10 9NH
Co-author of
Chapter 35: HIV and the Skin
Chapter 71: The Genital, Perianal and Umbilical Regions

Burd, D. Andrew R.

MBChB, FRCS, MD
Professor, The Chinese University of Hong Kong, Department of Surgery, 4/F Clinical Science Building, Prince of Wales Hospital, Shatin, New Territories, Hong Kong
Co-author of
Chapter 28: Mechanical and Thermal Injury

Burge, Susan M.

DM, FRCP
Consultant Dermatologist, Churchill Hospital, Old Road, Headington, Oxford OX3 7LJ
Co-author of
Chapter 39: Genetic Blistering Diseases

Burnand, Kevin G.

MBBS, FRCS, MS
Professor of Surgery, Academic Department of Surgery, St Thomas' Hospital, Lambeth Palace Road, London SE1 7EH
Co-author of
Chapter 47: Diseases of the Veins and Arteries: Leg Ulcers

Burns, David Anthony

MB BS FRCP
Emeritus Consultant Dermatologist, Leicester Royal Infirmary, Infirmary Square, Leicester LE1 5WW
Editor
Author of
Chapter 38: Diseases Caused by Arthropods and Other Noxious Animals
Chapter 60: Necrobiotic Disorders
Chapter 70: The Breast
Co-author of
Chapter 1: Introduction and Historical Bibliography
Chapter 2: Comparative Dermatology

Burrows, Nigel P.

MD, FRCP
Consultant Dermatologist and Associate Lecturer, Department of Dermatology, Addenbrooke's Hospital, Hills Road, Cambridge CB2 2QQ
Co-author of
Chapter 45: Disorders of Connective Tissue

Calonje, Eduardo

MD DipRCPath
Consultant Dermatologist, Department of Histopathology, St John's Institute of Dermatology, St Thomas' Hospital, Lambeth Palace Road, London SE1 7EH
Author of
Chapter 10: Histopathology of the Skin: General Principles
Chapter 53: Tumours of the Skin Appendages
Chapter 56: Soft-Tissue Tumours and Tumour-like Conditions

Cant, Andrew J.

BSc, MD, FRCP, FRCPCH
Consultant in Paediatric Immunology & Infectious Diseases, Children's BMT Unit, Newcastle General Hospital, Westgate Road, Newcastle upon Tyne NE4 6BE
Co-author of
Chapter 17: The Neonate

Chalmers, Robert J.G.

MB, FRCP
Consultant Dermatologist, Dermatology Centre, University of Manchester, Salford Royal Hospital, Stott Lane, Manchester M6 8HD
Co-author of
Chapter 74: Systemic Therapy

Chu, Anthony C.

FRCP
Professor of Dermatologic Oncology, Buckingham University and Consultant Dermatologist, Hammersmith Hospital, Du Cane Road, London W12 0HS
Author of
Chapter 55: Histiocytoses

Coulson, Ian H.

BSc, MB, BS, FRCP
Consultant Dermatologist, Dermatology Unit, Burnley General Hospital, Casterton Avenue, Burnley BB10 2PQ
Author of
Chapter 44: Disorders of Sweat Glands
Co-author of
Chapter 5: Diagnosis of Skin Disease
Chapter 62: Systemic Disease and the Skin

Cox, Neil H.

BSc, MB, ChB, FRCP
Consultant Dermatologist, Department of Dermatology, Cumberland Infirmary, Carlisle CA2 7HY and Visiting Professor, University of Cumbria, Carlisle CA1 2HH
Editor
Co-author of
Chapter 1: Introduction and Historical Bibliography
Chapter 2: Comparative Dermatology
Chapter 5: Diagnosis of Skin Disease
Chapter 49: Purpura and Microvascular Occlusion
Chapter 50: Vasculitis, Neutrophilic Dermatoses and Related Disorders
Chapter 62: Systemic Disease and the Skin

Creamer, Daniel

BSc, MD, FRCP
Consultant Dermatologist, Department of Dermatology, King's College Hospital, Denmark Hill, London SE5 9RS
Co-author of
Chapter 28: Mechanical and Thermal Injury

Dart, John K.G.

MA DM FRCS FRCOphth
Consultant Ophthalmologist, Moorfields Eye Hospital NHS Foundation Trust, 162 City Road, London EC1 2PD and Honorary Reader in Ophthalmology, University College London
Co-author of
Chapter 67: The Skin and the Eyes

de Berker, David A.R.

BA, MBBS, MRCP
Consultant Dermatologist, Bristol Dermatology Centre, Bristol Royal Infirmary, Marlborough Street, Bristol BS2 8HW
Co-author of
Chapter 65: Disorders of Nails
Chapter 66: Disorders of Hair

Eedy, David J.

MD, FRCP
Consultant Dermatologist, Department of Dermatology, Craigavon Area Hospital, 68 Lurgan Road, Portadown, Co Armagh BT63 5QQ
Co-author of
Chapter 63: The Skin and the Nervous System

English, John S.C.

FRCP
Consultant Dermatologist, Department of Dermatology, Queen's Medical Centre, Clifton Boulevard, Nottingham NG7 2UH
Author of
Chapter 27: Occupational Dermatoses

Ferguson, James

MD, FRCP
Professor and Consultant Dermatologist, Photobiology Unit, Department of Dermatology, Ninewells Hospital and Medical School, Dundee, Tayside DD1 9SY
Co-author of
Chapter 29: Cutaneous Photobiology

Fine, Jo-David

MD, MPH
Professor of Medicine (Dermatology) and Pediatrics, Vanderbilt University, School of Medicine, 1900 Patterson Street, Nashville, TN 37203, USA
Co-author of
Chapter 39: Genetic Blistering Diseases

Finlay, Andrew Y.

MBBS, FRCP (London & Glasgow)
Professor of Dermatology, Department of Dermatology, Cardiff University School of Medicine, Heath Park, Cardiff CF14 4XN
Co-author of
Chapter 72: General Aspects of Treatment

Flynn, Paul D.
PhD, FRCP, MRCPI
Consultant Physician, Acute and Metabolic Medicine, Addenbrooke's Hospital, Cambridge CB2 2QQ and Fellow and Director of Studies in Medical Science, Sidney Sussex College, Cambridge
Co-author of
Chapter 59: Metabolic and Nutritional Disorders

Friedmann, Peter S.
MD, FRCP, FMedSci
Professor of Dermatology, Dermatopharmacology Unit, Southampton General Hospital, Tremona Road, Southampton SO16 6YD
Co-author of
Chapter 24: Atopic Dermatitis

Fuller, L. Claire
MA, FRCP
Consultant Dermatologist, Department of Dermatology, Kent and Canterbury Hospital, Ethelbert Road, Canterbury, Kent CT1 3NG
Co-author of
Chapter 9: Racial Influences on Skin Disease

Gawkrodger, David J.
MD, FRCP, FRCPE
Consultant Dermatologist and Honorary Professor of Dermatology, Department of Dermatology, Royal Hallamshire Hospital, Glossop Road, Sheffield S10 2JF
Author of
Chapter 61: Sarcoidosis

Gennery, Andrew R.
MD, MRCP, MRCPCH, DCH, DipMedSci
Reader, Paediatric Immunology, Children's BMT Unit, Newcastle General Hospital, Westgate Road, Newcastle upon Tyne NE4 6BE
Co-author of
Chapter 17: The Neonate

Goodfield, Mark J.D.
MD, FRCP
Consultant Dermatologist, Department of Dermatology, Leeds General Infirmary, Great George Street, Leeds LS1 3EX
Co-author of
Chapter 51: The 'Connective Tissue Diseases'

Gotch, Frances
PhD, FRCPath
Professor of Immunology, Department of Immunology, Imperial College School of Medicine, Chelsea and Westminster Hospital, 369 Fulham Road, London SW10 9NH
Co-author of
Chapter 35: HIV and the Skin

Graham-Brown, Robin A.C.
BSc, MB, BS, FRCP, FRCPCH
Consultant Dermatologist and Honorary Senior Lecturer, University Hospitals of Leicester, Leicester LE1 5WW
Co-author of
Chapter 8: Skin and Skin Disease Throughout Life

Grattan, Clive E.H.
MA MD FRCP
Consultant Dermatologist, Department of Dermatology, Norfolk and Norwich University Hospital, Colney Lane, Norwich NR4 7UY
Co-author of
Chapter 22: Urticaria and Mastocytosis

Greaves, Malcolm W.
MD, PhD, FRCP, FAMS
Emeritus Professor of Dermatology, Cutaneous Allergy Clinic, St John's Institute of Dermatology, St Thomas' Hospital, Lambeth Palace Road, London SEI 7EH
Author of
Chapter 21: Pruritus

Griffiths, Christopher E.M.
BSc, MD, FRCP, FRCPath
Professor of Dermatology and Consultant Dermatologist, The Dermatology Centre, University of Manchester, Salford Royal Hospital, Salford, Manchester M6 8HD
Editor
Co-author of
Chapter 20: Psoriasis

Groves, Richard W.
MBBS, FRCP
Head, Clinical Immunodermatology, St John's Institute of Dermatology, Guy's Hospital, Great Maze Pond, London SE1 9RT
Co-author of
Chapter 12: Inflammation

Hawk, John L.M.
BSc, MD, FRACP, FRCP
Emeritus Professor of Dermatological Photobiology and Honorary Consultant Dermatologist, St John's Institute of Dermatology, St Thomas' Hospital, Lambeth Palace Road, London SE1 7EH
Co-author of
Chapter 29: Cutaneous Photobiology

Hay, Roderick J.
DM, FRCP, FRCPath, FMedSci
Professor of Cutaneous Infection, Dermatology Department, King's College Hospital, Denmark Hill, Camberwell, London SE5 9RS
Co-author of
Chapter 30: Bacterial Infections
Chapter 36: Mycology
Chapter 37: Parasitic Worms and Protozoa
Chapter 74: Systemic Therapy

Hegarty, Anne
BA BDentSC, MSc, MFDRCSI, MBBS
Consultant in Oral Medicine, The Charles Clifford Dental Hospital, Wellesley Road, Sheffield S10 2SZ
Co-author of
Chapter 69: The Oral Cavity and Lips

Higgins, Elisabeth M.
MA, FRCP
Consultant Dermatologist, Department of Dermatology, King's College Hospital, Denmark Hill, Camberwell, London SE5 9RS
Co-author of
Chapter 9: Racial Influences on Skin Disease

Hill, Peter B.
BVsc, PhD, DVD, DipACVD, DipECVD, MRCVS
Specialist in Veterinary Dermatology, Veterinary Specialist Centre, North Ryde, Sydney, NSW 2113, Australia
Co-author of
Chapter 2: Comparative Dermatology

Holden, Colin A.
BSc, MD, FRCP
Consultant Dermatologist, Department of Dermatology, Epsom and St Helier NHS Trust, Wrythe Lane, Carshalton, Surrey SM5 1AA
Co-author of
Chapter 24: Atopic Dermatitis

Irvine, Alan D.
MD, FRCPI, MRCP
Consultant Paediatric Dermatologist, Our Lady's Hospital for Sick Children, Crumlin, Dublin 12, Ireland
Co-author of
Chapter 15: Genetics and Genodermatoses

Jones, Stephen K.
BMedSci, BM, BS, FRCP (London & Edinburgh)
Consultant Dermatologist, Department of Dermatology, Clatterbridge Hospital, Bebington, Wirral CH63 4JY
Co-author of
Chapter 51: The 'Connective Tissue Diseases'

Jorizzo, Joseph L.
MD
Professor, Former and Founding Chair, Department of Dermatology, Wake Forest University School of Medicine, Winston-Salem, NC, USA
Co-author of
Chapter 50: Vasculitis, Neutrophilic Dermatoses and Related Disorders

Judge, Mary R.
MD, FRCP, DCH
Consultant Dermatologist, Department of Dermatology, Salford Royal Hospital, Greater Manchester M6 8HD
Co-author of
Chapter 19: Disorders of Keratinization

Kelly, Charles G.
MSc, FRCP, FRCR
Consultant Clinical Oncologist, Northern Centre for Cancer Treatment, Newcastle General Hospital, Westgate Road, Newcastle upon Tyne NE4 6BE
Co-author of
Chapter 79: Radiotherapy and Reactions to Ionizing Radiation

Kennedy, Cameron T.C.
MA, MB, BChir, FRCP
Consultant Dermatologist and Clinical Senior Lecturer, Bristol Dermatology Centre, Bristol Royal Infirmary, Marlborough Street, Bristol BS2 8HW
Author of
Chapter 68: The External Ear
Co-author of
Chapter 28: Mechanical and Thermal Injury

Kinghorn, George R.
MD, FRCP (London & Glasgow)
Consultant and Honorary Professor of Genitourinary Medicine, Department of Genitourinary Medicine, Royal Hallamshire Hospital, Glossop Road, Sheffield S10 2JF
Author of
Chapter 34: Syphilis and Bacterial Sexually Transmitted Infections

Kobza Black, Anne
MD, FRCP
Honorary Senior Lecturer, St John's Institute of Dermatology, St Thomas' Hospital, London SE1 7EH
Co-author of
Chapter 22: Urticaria and Mastocytosis

Lawrence, Clifford M.
MD, FRCP
Consultant Dermatologist, Department of Dermatology, Royal Victoria Infirmary, Queen Victoria Road, Newcastle upon Tyne, Tyne and Wear NE1 4LP
Co-author of
Chapter 77: Dermatological Surgery

Layton, Alison M.
MB, ChB, FRCP
Consultant Dermatologist, Harrogate and District Hospital, Lancaster Park Road, Harrogate, North Yorkshire HG2 2SX
Author of
Chapter 42: Disorders of the Sebaceous Glands

LeBoit, Philip E.
MD
Professor of Pathology and Dermatology, Division Chief, Dermatopathology, University of California San Francisco, 1701 Divisadero Street, San Francisco CA94115, USA
Co-author of
Chapter 12: Inflammation

Leonard, Jonathan N.
BSc, MD, FRCP
Consultant Dermatologist, Department of Dermatology, St Mary's Hospital, Praed Street, London W2 1NY
Co-author of
Chapter 67: The Skin and the Eyes

Lockwood, Diana N.J.
MD, FRCP
Consultant Physician and Leprologist, Hospital for Tropical Diseases, Mortimer Market, Capper Street, London WC1E 6AU
Author of
Chapter 32: Leprosy

Lovell, Christopher R.
MD, FRCP

Preface to the Eighth Edition

Just over forty years ago, the first edition of *Textbook of Dermatology* was published under the leadership of Arthur Rook, Darrell Wilkinson and John Ebling. Now designated *Rook's Textbook of Dermatology*, but known to many dermatologists as 'The Rook book', or simply 'Rook', it is in its eighth edition.

The editorial team that supervised compilation of the seventh edition has also been involved in preparation of the current edition. As always, we would like to express our gratitude to previous editors and contributors whose efforts have provided the framework upon which this book has expanded and continued to evolve over the years. We are also indebted to contributors to earlier editions who have generously allowed some of their material to be retained for the present edition, and to those colleagues who have donated colour photographs. The origin of these is given in the legend to each figure, and where no acknowledgement is given the figures have been provided by the authors of that chapter.

Our aim is to continue to provide an updated reference guide to dermatological diseases, and to encourage understanding of scientific aspects of dermatology, although the book is not intended to provide extensive details of research in the basic sciences. Nowadays there is electronic access to vast amounts of information, but we believe that a reference textbook, which can be readily accessed in the clinic or consulting room, or perused at leisure in an armchair, continues to be a valuable resource.

For this edition, every chapter has been updated, and several have been extensively modified and expanded, including the chapters on comparative dermatology and radiotherapy and reactions to ionizing radiation. There is also a separate chapter on the sexually transmitted diseases. Changes to chapters dealing with lasers and dermatological surgery reflect developments in recent years, and a new chapter describing skin rejuvenation procedures is indicative of the interest in this aspect of dermatology.

We thank our long-suffering wives and families for their tolerance and support over many years.

We should also like to thank the production team of Wiley-Blackwell for their efforts throughout the preparation of this edition, in particular Julie Elliott, Martin Sugden, Anne Bassett, the indexer Caroline Sheard, and the copy editor and proof reader.

Preface to the First Edition

No comprehensive reference book on dermatology has been published in the English language for ten years and none in England for over a quarter of a century. The recent literature of dermatology is rich in shorter texts and in specialist monographs but the English-speaking dermatologist has long felt the need for a substantial text for regular reference and as a guide to the immense monographic and periodical literature. The editors have therefore planned the present volume primarily for the dermatologist in practice or in training, but have also considered the requirements of the specialist in other fields of medicine and of the many research workers interested in the skin in relation to toxicology or cosmetic science.

An attempt has been made throughout the book to integrate our growing knowledge of the biology of skin and of fundamental pathological processes with practical clinical problems. Often the gap is still very wide but the trends of basic research at least indicate how it may eventually be bridged. In a clinical textbook the space devoted to the basic sciences must necessarily be restricted but a special effort has been made to ensure that the short accounts which open many chapters are easily understood by the physician whose interests and experience are exclusively clinical.

For the benefit of the student we have encouraged our contributors to make each chapter readable as an independent entity, and have accepted that this must involve the repetition of some material.

The classification employed is conventional and pragmatic. Until our knowledge of the mechanisms of disease is more profound no truly scientific classification is possible. In so many clinical syndromes multiple aetiological factors are implicated. To emphasize one at the expense of others is often misleading. Most diseases are to some extent influenced by genetic factors and a large proportion of common skin reactions are modified by the emotional state of the patient. Our knowledge is in no way advanced by classifying hundreds of diseases as genodermatoses and dozens as psychosomatic.

The true prevalence of a disease may throw light on its aetiology but reported incidence figures are often unreliable and incorrectly interpreted. The scientific approach to the evaluation of racial and environmental factors has therefore been considered in some detail.

The effectiveness of any physician in practice must ultimately depend on his ability to make an accurate clinical diagnosis. Clinical descriptions are detailed and differential diagnosis is fully discussed. Histopathology is here considered mainly as an aid to diagnosis but references to fuller accounts are provided.

The approach to treatment is critical but practical. Many empirical measures are of proven value and should not be abandoned merely because their efficacy cannot yet be scientifically explained. However, many familiar remedies old and new have been omitted either because properly controlled clinical trials have shown them to be of no value or because they have been supplanted by more effective and safer preparations.

There are over nine hundred photographs but no attempt has been made to provide an illustration of every disease. To have done so would have increased the bulk and price of the book without increasing proportionately its practical value. The conditions selected for illustrations are those in which a photograph significantly enhances the verbal description. There are a few conditions we wished to illustrate, but of which we could not obtain unpublished photographs of satisfactory quality.

The lists of references have been selected to provide a guide to the literature. Important articles now of largely historical interest have usually been omitted, except where a knowledge of the history of a disease simplifies the understanding of present concepts and terminology. Books and articles provided with a substantial bibliography are marked with an asterisk.

Many of the chapters have been read and criticized by several members of the team and by other colleagues. Professor Wilson Jones, Dr R.S. Wells and Dr W.E. Parish have given valuable assistance with histopathological, genetic and immunological problems respectively. Many advisers, whose services are acknowledged in the following pages, have helped us with individual chapters. Any errors which have not been eliminated are, however, the responsibility of the editors and authors.

The editors hope that this book will prove of value to all those who are interested in the skin either as physicians or as research workers. They will welcome readers' criticisms and suggestions which may help them to make the second edition the book they hope to produce.

CHAPTER 1
Introduction and Historical Bibliography

What is dermatology?, 1.1
The evolution of dermatology, 1.1
The dermatologist's work, 1.5
Selected historical bibliography, 1.8

What is dermatology?

Dermatology is defined in The New Oxford Dictionary of English as 'The branch of medicine concerned with the diagnosis and treatment of skin disorders' [1]. However, dermatologists do not confine themselves merely to a study of intrinsic disorders of the skin, but must also study internal medicine and the many environmental and occupational factors that so frequently cause skin problems.

A plethora of external factors, including numerous chemicals, can adversely affect the skin in some circumstances. The clinical dermatologist must be knowledgeable about these potential hazards, and this will often require a detailed study of the multiplicity of chemicals, plants, animals, parasites, microorganisms, radiation, climatic conditions, etc. to which the skin is exposed. In many cases, the dermatologist will need to obtain exact details of what is involved in the patient's occupation and hobbies, and many dermatologists build up a considerable knowledge of the different jobs involved in their local industries.

The dermatologist must also have a good knowledge of internal medicine, as most systemic diseases can occasionally affect the skin, either directly or as a result of a complication of the disease or its treatment. Drugs taken by the patient have to be considered by the dermatologist, because the unwanted effects of many drugs include provocation of rashes. This applies not only to prescribed medication, but also to over-the-counter and complementary/alternative remedies. The use of complementary medicine is increasing in the Western world, and many individuals with dermatological problems use such remedies [2–4], their availability having been made easier by the advent of the Internet [5].

A dermatologist must also pay attention to the psyche, as psychological factors play an important part in dermatology. The skin is of major importance in our 'body image', and the fact that skin diseases are often regarded with revulsion by the general population adds to the distress they cause, so that the psychological disturbance induced by skin problems may be out of all proportion to their 'medical' significance. Sometimes, these psychological problems are exacerbated by the reactions of the patient's relatives, friends or colleagues, and in other cases they are partly accounted for by feelings of guilt or despondency, induced by the belief that skin diseases are due to 'uncleanliness' of some kind (with or without sexual overtones). In recent years there has been increasing awareness of the impact of skin diseases on social and leisure activities, work and sexual relationships, and questionnaires such as the Dermatology Life Quality Index (DLQI) have been employed to measure the impairment of quality of life (see Chapter 72). Not only may skin diseases cause stress or depression, but also psychological stress from another cause can exacerbate, or even be involved in causation of, some skin diseases.

Whatever the complexity of these psychological nuances, the dermatologist must be aware of their existence and try to deal with them accordingly. As described later (Chapter 64), some patients have 'skin problems' that are imagined or self-inflicted, and the presentation to the dermatologist seems to be a 'cry for help' with marital or other social problems. In other cases, the dermatological consultation may be a manifestation of an underlying psychological disorder such as depression or schizophrenia.

The evolution of dermatology

Skin diseases predate written records, and many of the earliest medical writings deal with dermatological subjects. The history of dermatology is too large a subject to be covered in this book, although a selected historical bibliography is given at the end of this chapter. The development of modern dermatology is briefly outlined below.

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

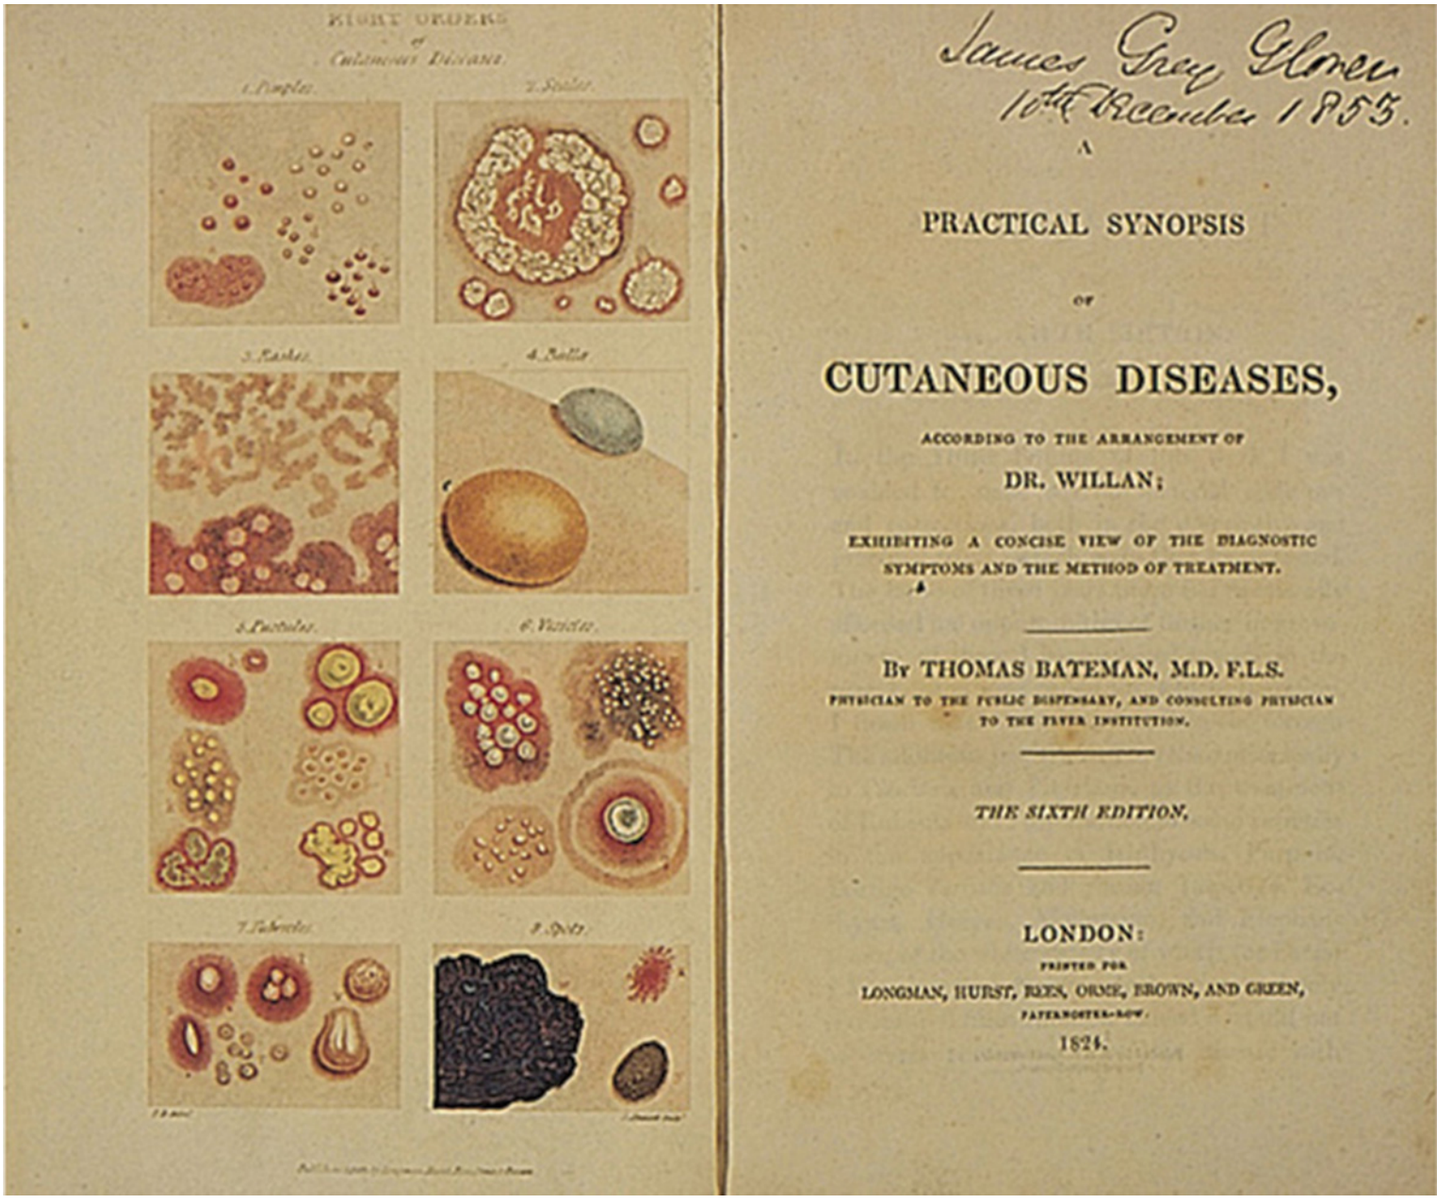

Fig. 1.1 The title page and facing plate from the 6th edition (1824) of Thomas Bateman's *A Practical Synopsis of Cutaneous Diseases, According to the Arrangement of Dr Willan*. The plate shows the eight orders of cutaneous eruption in Willan's classification.

Dermatology evolved as a branch of internal medicine during the 19th century. Previously, many diseases of the skin had fallen within the province of the quack or the surgeon, and indeed many of the older surgical textbooks devote much attention to the treatment of skin disease. The physicians of that time were little concerned with the skin, apart from the eruptions of the acute infectious fevers. In the early 18th century, individuals such as Daniel Turner advocated use of preparations applied to the skin as treatment for internal diseases. During the last decades of the 18th century, however, many of the great physicians began to record their observations on the diseases of the skin, and this continued throughout the 19th century. Towards the end of that century, skin diseases, particularly the chronic infections such as syphilis and tuberculosis, formed a significant part of the general physician's practice, and by the early 20th century some physicians were beginning to specialize in dermatology. This trend towards increasing specialization has continued ever since.

In the first half of the 20th century, dermatology was slow to develop along scientific lines. The emphasis was very much on the clinical description, naming and classification of the numerous skin disorders, and this led to a profusion of synonyms which are daunting to those attempting to get to grips with dermatological nomenclature. Only empirical treatment was available, and it was often ineffective, messy and malodorous. Dermatology certainly lagged behind some of the other medical specialties in its understanding of basic disease processes. In retrospect, this seems to

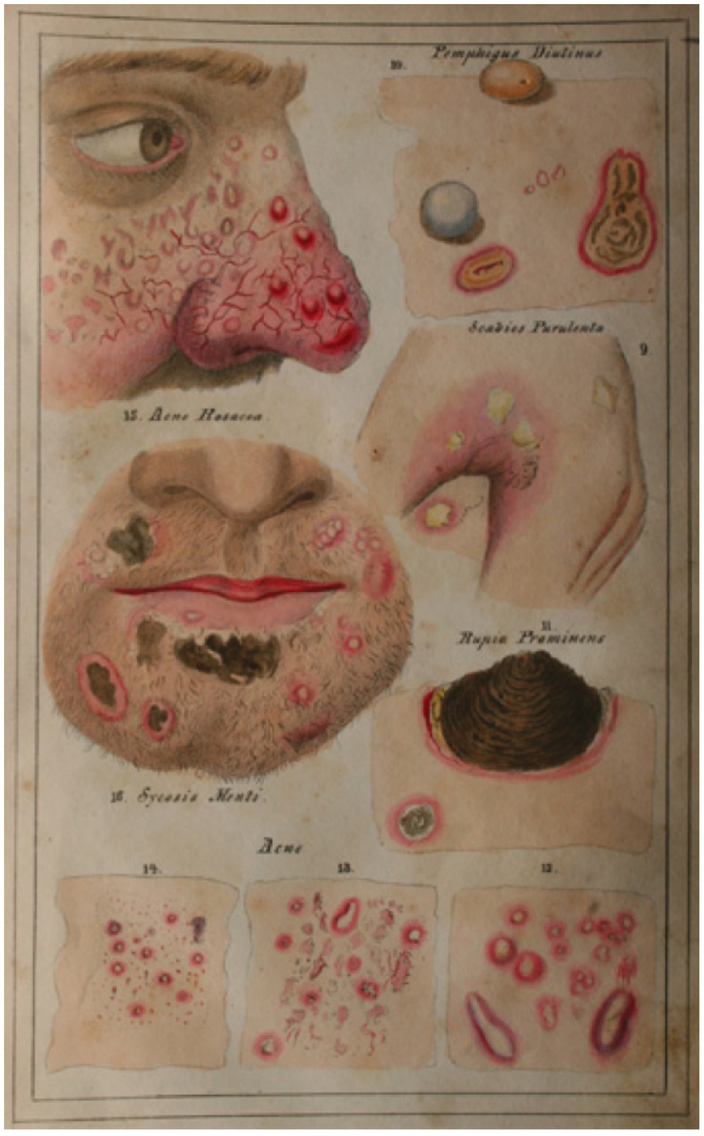

Fig. 1.2 A variety of mainly pustular disorders, from N Worcester, *A Synopsis of the Symptoms, Diagnosis and Treatment of the More Common and Important Diseases of the Skin* (1845).

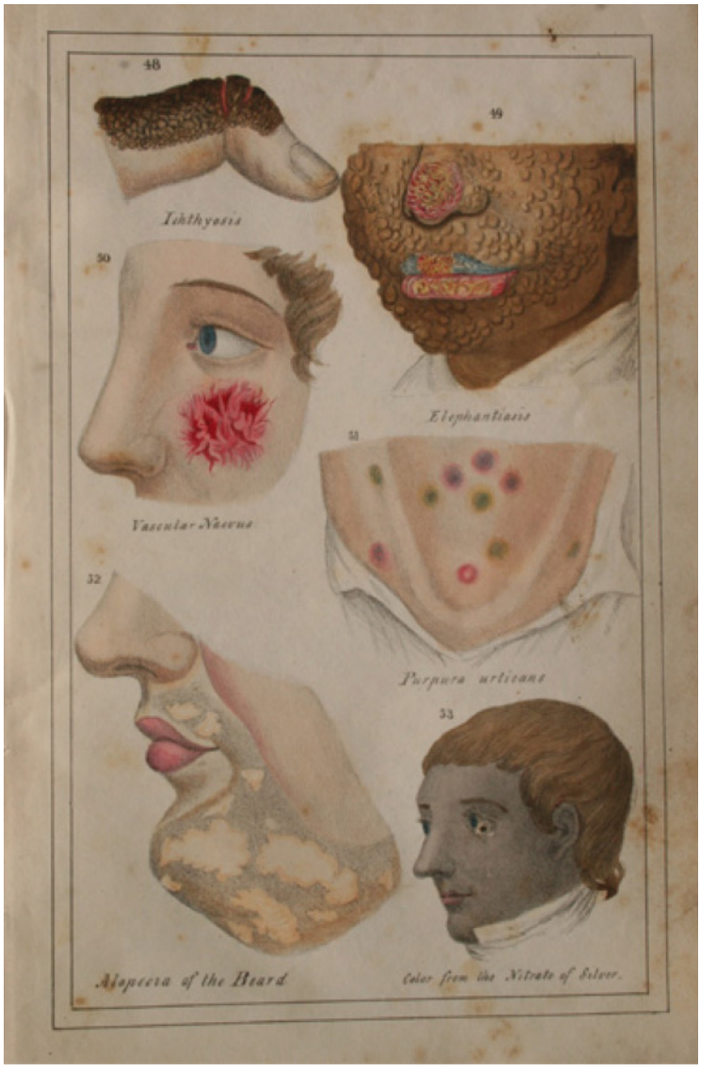

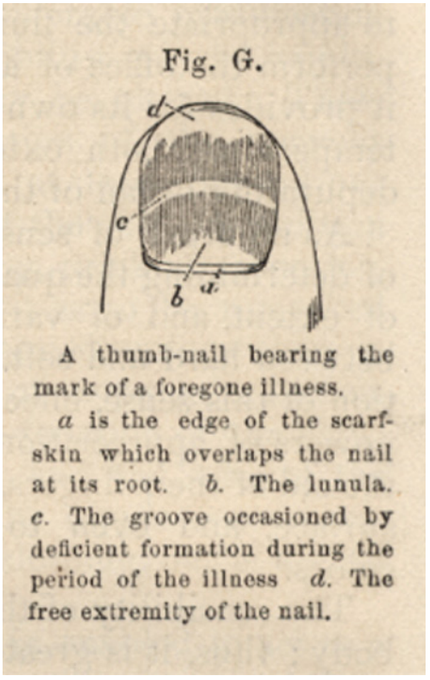

Fig. 1.3 Illustrations from N Worcester, *A Synopsis of the Symptoms, Diagnosis and Treatment of the More Common and Important Diseases of the Skin* (1845), including a dramatic illustration of argyria (made more startling by the shift in position of the blue colouring of the pupil of the eye).

have been due to two main factors. The first was that most skin diseases could be identified by external examination alone, and therefore seemed to need no further investigation. The second, and perhaps more important factor, was that most skin diseases could not be investigated by the relatively crude tests that were available at that time. It was only when skin biopsy became a standard technique, with the plethora of pathological knowledge that followed, that an understanding of the pathogenesis of many skin diseases began to emerge.

In the second half of the 20th century, there was an explosion of dermatological knowledge, mainly as a result of the introduction of sophisticated research techniques which not only led to a better knowledge of the pathogenesis and treatment of skin disorders, but also facilitated the development of more targeted treatments. The need for measurement and a more scientific approach in dermatology was made over 40 years ago [1], and research, at least during training, became the norm for generations of dermatologists. Advances in pathology techniques, especially immunopathology, helped the understanding of skin disease. More recently, the techniques of molecular biology have also been applied (Chapter 11), leading to, amongst other things, important developments in genetics and the understanding of mechanisms underlying cancer. As a result, increasing numbers of non-medical scientists are studying the skin, and its accessibility, which paradoxically inhibited investigation in the first half of the 20th century, is now of course very helpful to the research worker.

Dermatological treatment patterns have changed over the last 50 years, and will no doubt continue to do so. Recent advances in treatment include topical immunosuppressants, immune response modifiers, enzyme replacement treatments (e.g. for

Fig. 1.4 An early picture of a Beau's line, from the section on nail growth in Erasmus Wilson's *Diseases of the Skin; a System of Cutaneous Medicine*. This is from the 1868 revised 6th edition. Erasmus Wilson also published major works on anatomy.

Fig. 1.6 Infantile eczema. From: JV Shoemaker, *A Practical Treatise on Diseases of the Skin* (1890).

Fig. 1.5 Cutaneous horns. From: JV Shoemaker, *A Practical Treatise on Diseases of the Skin* (1890).

Fabry's disease) and biological therapies for psoriasis and other dermatoses. Further sophistication in treatment should parallel increasing knowledge of the roles of inflammatory mediators in disease, and gene therapy is on the horizon. Some older treatment modalities, such as radiotherapy, are used much less, but are still of considerable value in selected cases (Chapter 79) and have even increased in use for some conditions such as lentigo maligna.

Dermatology is thus changing at an ever-accelerating pace, both in the amount of scientific knowledge and treatments available, and with regard to disease patterns and patients' expectations. Increasing specialization within dermatology is becoming more common, with the expansion of expertise in dermatological surgery, laser therapy, photobiology, contact allergy, histopathology, and other areas; some dermatologists now only work in subspecialty areas such as paediatric dermatology, skin surgery, etc. Certainly, dermatologists can no longer be regarded only as general physicians with an interest in the skin, although some training in internal medicine is still regarded as desirable in most countries. In the UK, trainee dermatologists are expected to have completed a minimum of 2 years of general professional training and to have passed a postgraduate examination in general medicine (Membership of the Royal College of Physicians, MRCP) before they can start their specialist training in dermatology. The specialist training entails 4 years in an approved training post, with an annual assessment of progress, on satisfactory completion of which the trainee is awarded a Certificate of Completion of Training (CCT).

It seems possible that the days of the generalist dermatologist are numbered. Future dermatologists will perhaps regard themselves as dermatological physicians, surgeons or researchers and train accordingly. The future cannot be predicted, but it seems certain that with the increasing sophistication of populations throughout the world, the demand for dermatological expertise is likely to increase.

Fig. 1.7 Discoid lupus erythematosus, from Henry Radcliffe Crocker's *Atlas of Diseases of the Skin* (1896). Radcliffe Crocker made many contributions to dermatology; this atlas was available in an unbound form, apparently so that the colour plates could be used for teaching.

The dermatologist's work

There are probably at least 2000 different skin conditions that might present to the dermatologist, and the conditions seen vary enormously in severity. They range from cosmetic problems, such as dry skin or wrinkles, through a huge variety of acute or chronic diseases, which may be disfiguring, itchy or painful, but are rarely fatal, to life-threatening conditions, which, if untreated, may prove fatal within days (e.g. toxic epidermal necrolysis), weeks (e.g. pemphigus), months (e.g. malignant melanoma) or years (e.g. mycosis fungoides). In the UK, about 70% of consultations for dermatological problems are related to skin cancer, acne, psoriasis, viral warts and other infections, benign tumours, leg ulcers, and various forms of dermatitis [1]. In an audit of dermatology services in Edinburgh, UK, in November 2005, management of patients with eczema and psoriasis accounted for one-third of outpatient clinic visits. It was notable that, compared with data from 1980, attendances for both benign and malignant skin tumours had increased six-fold [2].

Obviously, the pattern of disease varies from one country to another, and even in the same city the work of dermatologists will differ, depending on their particular interests and expertise and on the social mix of their patients. Involvement with cosmetic procedures, in particular, varies according to the constraints of the health-care system in which the dermatologist works.

Fig. 1.8 Sarcoma cutis, from Radcliffe Crocker, *Atlas of Diseases of the Skin* (1896). The reasons behind wide excision of melanoma are readily apparent.

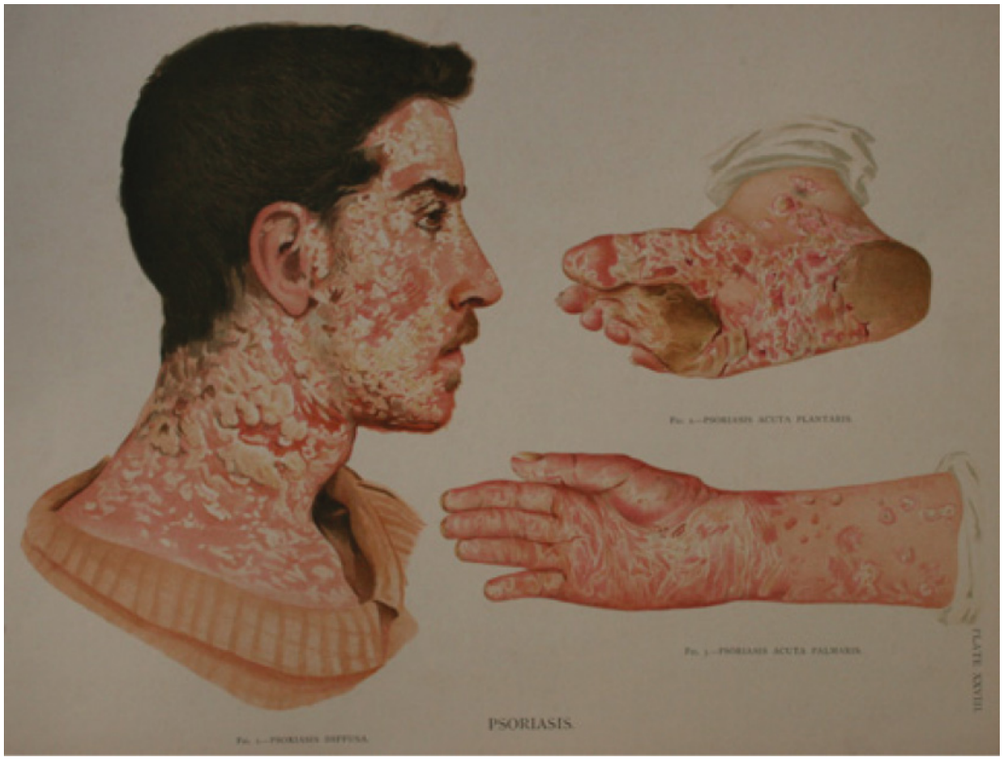

Fig. 1.9 Psoriasis, from Radcliffe Crocker, *Atlas of Diseases of the Skin* (1896); the illustration is as valid now as it was then.

Space precludes any detailed consideration of the work of dermatologists throughout the world, but in the British system patients are normally first seen by a primary-care physician (general practitioner [GP]) who refers the patient to the hospital consultant if he or she thinks it necessary or advisable (secondary care). It has been estimated that around one in seven primary care consultations relates to a dermatological problem [3,4]. Hospital dermatology services are provided by consultant dermatologists and their supporting staff. The British Association of Dermatologists provides guidelines for provision of services in secondary care [5], and the current working target with regard to consultant dermatologists is 1/100 000 population (assuming that there is provision of some supporting medical staff and nursing expertise), although in parts of the UK this is not achieved. There is government pressure in the UK for some dermatology services to be provided in smaller community settings [6], rather than in secondary-care hospitals. A more seamless 'Integrated service' has been proposed, with dermatologists having a greater role in teaching, care of complex patients, and administration of this new model of care [7]. This system would involve more non-medical practitioners such as expert nurses and pharmacists, but the mainstay of the intermediate level of care is likely to be provided by GPs, who have undertaken additional training in dermatology and work as a team, performing some independent clinics and some clinics with consultant staff. Subsequent research has shown potential advantages of this intermediate grade (termed GP with a Special Interest, GPwSI) in provision of local services for patients, but there is also some unease about the relatively small amount of training that some such individuals undertake and some aspects of care have been documented as less safe or more expensive [8,9].

In the USA, the dermatologist-to-population ratio increased from 1.9 per 100 000 in 1970 to 3.5 per 100 000 in 2002 [10], although there is considerable interstate and intrastate variation in this ratio [11]. There are, of course, some countries from which dermatologists are conspicuously absent.

There is continuing concern about provision of an adequate number of trained dermatologists to satisfy increasing demand, and that an increase in the number of dermatologists specializing in surgical and cosmetic procedures might lead to a shortage of those dealing with 'medical' dermatology patients [10–16]. It is also important that planning should take account of factors such as age [17], the high proportion of women in dermatology and the changing roles of nursing staff [18].

Many skin diseases, for example warts, acne vulgaris or psoriasis, can be quickly diagnosed by their clinical features, and need little or no further investigation. At the other extreme, there are some patients, for example those with lymphoma, who need detailed and time-consuming investigations both to confirm the diagnosis and as a basis for treatment.

The most common investigations performed in a dermatology clinic, other than simple blood tests or swabs for microbiology, are skin biopsies. Other investigations include the extraction and identification of scabies mites, the microscopic examination of hairs, microscopy for fungal mycelia or spores, patch testing and photopatch testing. In occasional cases, special procedures may be needed, such as the examination of pets for animal parasites, or a visit to the patient's workplace or home to search for possible allergens.

Fig. 1.10 Structure of the skin, from WS Gottheil, *Skin Diseases* (1897).

Fig. 1.11 Scabies, from RW Taylor, *A Clinical Atlas of Venereal and Skin Diseases* (1889).

Fig. 1.12 Impetigo contagiosa, from the *Portfolio of Dermochromes* by Professor Jacobi (1903). The English adaptation of the text was performed by JJ Pringle of the Middlesex Hospital. The majority of the illustrations were of models in the Breslau Clinic.

The management of this infinite variety of skin disorders ranges from simple reassurance and explanation through the gamut of topical and systemic remedies, to the performance or supervision of numerous physical procedures such as UV irradiation, photochemotherapy, curettage and cautery, surgical excision and laser treatment. Some dermatologists will also undertake complicated and specialized techniques such as prenatal investigation and Mohs micrographic surgery, which may require close collaboration with other specialists, and newer techniques such as photodynamic therapy are finding a niche in the dermatologist's armamentarium.

Greater patient expectations and a generally more litigious attitude in society have combined in recent years to fuel physicians' concern about being sued, and the increasing complexity of dermatological practice and involvement in cosmetic procedures may heighten the risk. Thankfully, however, litigation is still relatively infrequent in dermatology compared with other specialties [19–21]. Evidence-based guidelines have been produced for many dermatological conditions, both in the UK [22] and in many other countries [23,24], and are probably helpful in encouraging good practice (although evidence that they fundamentally alter practice is lacking); manufacturers of some drugs used in dermatology produce quite rigid guidance (for example, for administration of isotretinoin in females), and dermatologists in the UK are also subject to various government directives, such as those from the National Patient Safety Agency and the National Institute of Health and Clinical Excellence. These may apply to uses of certain medications (e.g. prescribing of methotrexate, or of specific biological agents,

for psoriasis) or may cover a broader remit, such as guidelines for management of skin cancer [25].

An appreciation of the evolutionary history of skin structure and biochemistry, and knowledge of skin diseases in animals [1], gives perspective to the human condition but also may provide clues to understanding human skin disease, models for its investigation and targets for development of gene therapy for genodermatoses [2]. Useful historical overviews of comparative dermatology are provided by Beerman [3] and Rosser & Ongley [4].

The evolutionary sources of the skin components [1–5]

Although the anatomy of skin differs greatly between animal classes and shows considerable variety in relation to the exigencies of lifestyle even within groups, it is nevertheless possible to recognize various long-standing elements. Structural materials, such as cross-linked proteins similar to collagen, are found in the most primitive animals. For example, supporting structures of aromatically cross-linked proteins associated with polysaccharides are found in coelenterate polyps, and the cuticles of parasitic worms such as *Ascaris*, are composed of collagen proteins linked by disulphide bonds. Among the vertebrates, keratin first seems to have occurred in the lips and in the breeding tubercles of some fish, but similar materials are found in invertebrates.

Glands and pigment cells have an equally long history. The simplest glands are the unicellular goblet cells, which secrete mucus in coelenterates and fish alike. Multicellular glands of various degrees of complexity are ubiquitous.

Melanins, which are pigments produced by the oxidation of tyrosine, are equally widespread and are found, for example, in worms, molluscs, arthropods and echinoderms, as well as throughout the vertebrates.

The epidermis and the dermis and their derivatives

Invertebrates

Life began in the sea, just as the human fetus develops bathed in the amniotic fluid. Among the simplest and most archaic animals are the coelenterates, namely the corals, jellyfish and their allies.

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

Such forms have only two layers of cells: an ectoderm in contact with the aquatic environment, and an endoderm lining the gut cavity. The ectoderm may, nevertheless, contain gland cells, stinging cells, pigment cells and sensory cells, and its outer surface may bear microvilli, suggesting an absorptive function [1]. Microvilli are similarly found on the outside of the integument of flukes and tapeworms, which are internal parasites [2,3], and on the amniotic border of periderm of the human embryo.

Marine worms and their relatives in fresh water and on land have a thick cuticle outside their epidermis [4,5]. Arthropods, animals with jointed limbs, of which crustacea and insects are examples, have a tough exoskeleton, which has helped some of their forms to colonize land. In crabs and lobsters this cuticle is hardened by the inclusion of calcareous material. Insect cuticle is composed of chitin, a polysaccharide containing amino groups, assembled into microfibrils and embedded in a protein matrix [6,7]. A critical function of the cuticle is restriction of water loss. An obvious disadvantage of the exoskeleton is that growth can only occur if it is periodically shed, a procedure that leaves its owner vulnerable to predation or other damage [8].

One interesting feature of annelid worms is that they bear stiff bristles or chaetae, made of a keratin-like material with properties similar to that of human hair. Although of epidermal origin, chaetae are not composed of aggregated cells produced by an active matrix. Lateral cells may add substance or provide tanning agents, but the bulk of each chaeta is secreted by only a single basal cell [9].

Vertebrates

In all vertebrates, animals with a backbone, the skin is characterized by an outer stratified epidermis and an underlying dermis, also known as the corium or cutis. The epidermis consists of closely packed cells, which are renewed from the basal layer and which constitute a barrier. The dermis is a connective tissue of mesodermal origin and is made up mainly of extracellular ground substance and collagen fibres manufactured by scattered cells.

The evolution of the vertebrates and their successful colonization of land is associated with a variety of structures, such as glands, scales, feathers and hair, as well as horns, claws and nails. Some of these, notably the scales of fish, are derived from the dermis or have substantial dermal components. Most, however, are epidermal, although their formation is orchestrated by interactions with the dermis.

Fish [10–12]

With few exceptions, such as eels and some catfish, fish have scales of one type or another. Sharks have placoid scales (dermal denticles), which project from the skin. It is their presence that gives shark leather, or shagreen, its characteristic rough feel. In essence, the placoid scale has the same structure as a mammalian tooth, of which it is regarded as a forerunner (Fig. 2.1). Its bulk is formed by a cone of dentine, of dermal origin, which during its formation becomes capped with enamel deposited by an epidermal enamel organ [13].

Bony fish have elasmoid scales, consisting of plates of collagen with superficial mineralization, covered by a thin layer of dermis and epidermis. The skin of catfish has been investigated as a model of membranes, having permeation characteristics similar to mucous membranes [14] and a collagen matrix structure resembling sclera. Fish scales can be hydrolysed and made into 'fish scale collagen (FSC)' sheets that have been investigated as a wound dressing material [15], which has significantly advantageous cost issues in under-developed countries where fish scale is otherwise a waste product.

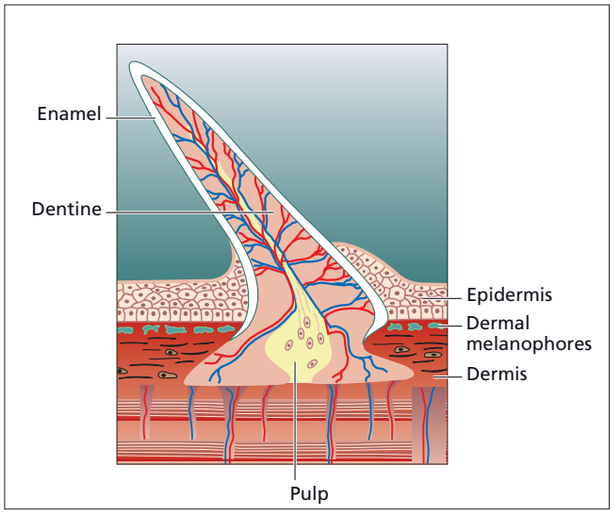

Fig. 2.1 Placoid scale of a shark.

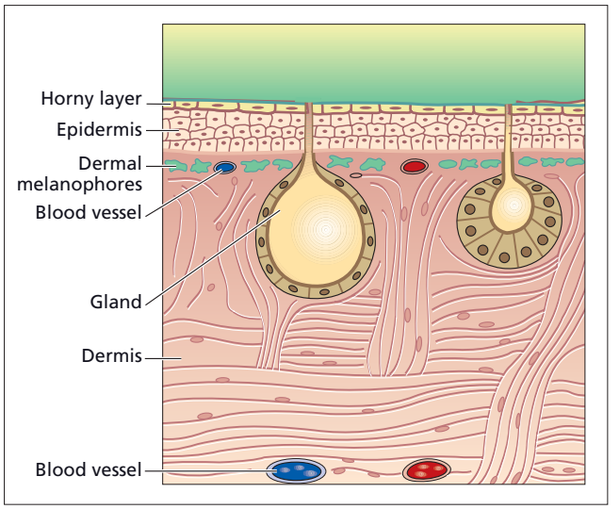

Fig. 2.2 Section of frog skin. Note the flattened superficial horny layer, only one cell deep, which is periodically sloughed as the 'scarf skin', the dermal chromatophores and the multicellular glands.

Amphibia [16,17]

Amphibians were the first vertebrates to emerge from the water, although they still depend on it for reproduction. Their epidermis has several layers of cells, which are formed by a basal stratum germinativum and ultimately become keratinized to form a very thin horny layer, only one cell deep in most species, which is intermittently sloughed (Fig. 2.2). Although the amphibia have lungs, they also respire through their moist skin.

Reptiles [18]

Reptiles are truly terrestrial, in that they do not need an aqueous environment for the development of their larvae. Their chief problem, prevention of desiccation, is solved by possession of scales, which in essence are overlapping folds of skin. An additional property of scales is that they allow the passage of infrared radiation from the sun. The cold-blooded reptiles are dependent on this external source of heat to achieve and maintain a constant body temperature similar to that of mammals.

Reptile scales contain a thick stratum corneum in which waxes are sandwiched between keratinized cells. Snakes and lizards do not, like mammals, renew their epidermis by continuous proliferation and exfoliation of cells. The vertically stratified epidermis is periodically shed as a whole, subsequent to the formation of a complete new generation of epidermal cells below it. In crocodiles and turtles, total shedding does not occur, but regional sheets of stratum corneum are periodically desquamated.

Birds [19]

The most obvious integumental feature of birds is the possession of feathers, which are considered to have evolved from reptile scales and, like scales, they are periodically moulted and replaced.

The legs and feet of birds bear scales, and some other areas, such as the comb and wattles of the domestic cockerel, are naked. The epidermis of birds, as distinct from its derivatives, is thin, and so is the dermis in most species, although ostrich skin is thick enough to be processable into leather.

Mammals [20–22]

Mammals, in general, are characterized by hair, but not all possess it. The epidermis also produces a range of other derivatives such as quills, claws, nails, hooves and horns. Antlers are made of bone, but they are covered with epidermis, the velvet, when newly grown; other horns, such as those of sheep, have a heavily keratinized epidermal sheath over underlying bone. The horn of the rhino is an exception, consisting of tubules and cortex growing from a papillary epidermis over the frontal bones [23]. The bony plates of the armadillo are similarly of dermal origin.

Hair, wool and quill are all produced by follicles that are ingrowths of epidermis enclosing a papilla of mesodermal cells in their bases. The hair is not considered to be the homologue of the scale and the feather. It is more likely that the first hairs to arise in evolution were part of sensory structures between the scales of some ancestral reptile [24]. Spines of animals such as the hedgehog and porcupine are protective, but have also led to interesting evolutionary issues; the hedgehog flea (*Archaeopsylla erinacei*) appears to be quite species-specific, although it will transiently infest other animals such as dogs. The converse is also true—one author collected 2000 fleas from hedgehogs and only one (a mole flea) was not the highly adapted *A. erinacei* species [25]. A feature of human hair that is occasionally important is its facility to retain heavy metals and other chemicals. This facility can be used for example to prove arsenic poisoning; spines of the hedgehog have been similarly used to assess pollution by silver, copper, lead, arsenic and other elements [26].

Seasonal change in hair growth is characteristic of mammals, the hair becoming more dense in colder parts of the year followed by hair fall (moulting) in warmer months. In many species there is a softer warm underfur, and a harsher guard hair coat for protection against the elements. In humans, moulting as such is not readily apparent but hair fall and regrowth is not completely random; in March, 90% of scalp hair is in anagen in temperate climates, but hair fall doubles by about August or September [27]. Nail growth shows no seasonal variation.

Mammalian epidermis is of several types. Most furry species, from rodents to sheep, have a thin epidermis, which is only two or three cells deep. Human epidermis lacks a protective pelt and, perhaps in compensation, is somewhat thicker. The epidermis of the palms and soles has a much thicker stratum corneum than skin that bears hair follicles.

The elephant, rhinoceros and hippopotamus all have skins with very thick hyperkeratotic horny layers. Whales, which lack hair, also have a very thick epidermis, although the cells remain parakeratotic, that is they retain their nuclei. Whale skin has a highly indented dermoepidermal junction, which suggests a very high rate of epidermal cell production. The whole epidermis bears a remarkable and striking similarity to that of psoriatic human epidermis.

Glands

Glands are organs that manufacture and discharge their products either by extrusion (*merocrine*) or by complete disintegration (*holocrine*) of their cells.

Glands of vertebrates

Amphibia [1]

Amphibian glands are of a number of types and have various functions, including the production of mucus, poison and even courtship stimulants.

Reptiles [2]

Multicellular glands, both holocrine and merocrine, are found in reptiles. So-called 'generation glands' in lizards and snakes are connected with the shedding and sloughing cycle. Odour-producing glands, used in both courtship and aggression, are present in most reptiles, including turtles and crocodiles as well as lizards and snakes.

Birds

In birds, the only conspicuous glands are the large uropygial or preen glands, although there are also some small tubular glands in the vent region [3]. The uropygial gland is holocrine and secretes an oily material by way of ducts which open on a papilla. Histologically, it closely resembles both the mammalian sebaceous glands and the holocrine glands of reptiles. The product of the uropygial gland is transferred by the beak of the bird to the feathers, and is important for their maintenance.

Mammals

Nearly all mammals have both holocrine and merocrine glands. Whales alone lack sebaceous glands. Only whales, elephants, sea cows and scaly anteaters have no tubular glands in their skin.

Merocrine glands occur in many different sites and serve several functions. The tubular glands associated with hair follicles were designated by Schiefferdecker [4] as 'apocrine', on the grounds that secretion involved decapitation of at least some of the cells, as distinguished from 'eccrine' glands in which the cells remain intact. Although electron microscopy has cast doubt on these criteria, the terms remain useful. Alternative designations of 'epitrichial' and 'atrichial' have been proposed, but apocrine glands do not invariably open into hair ducts. In primates, most tubular glands can, in fact, be clearly assigned to one type or the other on histochemical grounds.

A major function of sebaceous and apocrine glands is the production of scent for intraspecific communication. Although sebaceous units occur throughout hairy skin and so, in some species, do apocrine units, they also occur in batteries to form discrete scent organs [5,6]. Such structures are found in most mammalian orders and can occur in almost any area of the body.

Eccrine glands are found in two sites. On footpads, including human soles and palms, they occur in many different mammals, and their main function appears to be to increase surface friction by moistening the keratin. On hairy skin, however, where they function to cool the body by sweating, they occur only in primates and are most abundant in humans.

An interesting phenomenon in the hippopotamus is the function of 'sweat' produced by subdermal glands. At first colourless, then red, and finally brown as the pigment polymerizes, this fluid contains red and orange pigments that have anti-UV and antibacterial properties. The protective action of this 'sunscreen' may explain why albino hippos seem to have healthy skin [7].

Pigment cells

Animal colours [1–5]

Colours abound throughout the animal kingdom. Some, such as the metallic sheen of beetles and the gleam of the feathers in the peacock's tail, are produced by *interference*, that is by the reflection of light from both the outer and inner surfaces of a film. So-called structural colours can also be produced by *diffraction*, or by *scattering* of the shorter waves of white light by very small particles, a phenomenon that produces the pale blue of the clear sky or the bright blue on the mandrill's face. The blue colour of the human Mongolian spot is a similar optical effect.

Most colours are, however, due to pigments. The most widespread and the most important in man is *melanin*, which also gives colour to the feathers of blackbirds, black beetles and slugs, and fills the ink sacs of the octopus and the squid. Melanin exists in two forms: black or dark-brown *eumelanin* and reddish or yellow *phaeomelanin*. Both are oxidation products of tyrosine.

Not all brown or black pigments are melanin. Insects and crustacea have *ommochromes*, synthesized from the amino acid tryptophan. Another group are the white, yellow and orange *pterins*, which give colour to the wings of butterflies and to spotted salamanders. There are the widespread *carotenoids*, imparting colour to red sponges, goldfish and pink flamingos, for example, as well as to human skin. None can be synthesized by animals; all are acquired by eating plants. Of particular importance in human skin coloration is the oxygen-carrying pigment of the blood, *haemoglobin*, which is responsible for the pink tint of white people and the bright red of human lips and baboons' buttocks.

Chromatophores and melanocytes

In many animals, pigment is formed in specialized cells. Pigment cells start their evolutionary history in coelenterates and appear to reach the peak of their variety in each of two unrelated groups: the molluscs and the vertebrates.

Molluscs

Molluscs contain not only melanins and ommochromes but also porphyrins and bilichromes. The squid, cuttlefish and octopus have assemblages of differently coloured pigment cells, or chromatophores, containing yellow, orange, red, red–brown, blue, violet–black or black ommochromes. Underlying these are so-called iridiophores and leukophores, which absorb, reflect and scatter light [4,6,7]. The chromatophores can be expanded rapidly or contracted by smooth-muscle fibres that are attached to the periphery of each cell [8]. Contraction of the muscle pulls out the cell and its pigment into a flat plate, and relaxation causes the cell and pigment to concentrate into a small dot. The animals are thus able to change colour and pattern to match their backgrounds extremely rapidly. The information about background is obtained through the eye and mediated through colour centres in the brain [9].

Fig. 2.3 Brindle coat colour in a dog.

Vertebrates in general

The pigment cells of vertebrates differ from those of molluscs in that their size is not controlled by muscle fibres. There are two mechanisms of colour change, each involving a distinctive cell. Short-term *physiological* colour change is brought about by active redistribution of pigment-containing organelles within the boundaries of relatively large cells, which are collectively known as *chromatophores*. Long-term *morphological* colour change results from alterations in the numbers of smaller pigment cells known as *melanocytes*, or in the amount of pigment each produces. The dendritic pigment cell of the human epidermis is an example. Genetic control of switching between synthesis of red–yellow phaeomelanin versus black–brown eumelanin is under the control of two genes, *Agouti* and *Melanocortin-1*, in all vertebrates except domestic dogs in which a more complicated system has been demonstrated. A genome-wide linkage scan of Labrador–greyhound cross dogs segregated for black, yellow and brindle coat colours (Fig. 2.3) showed that a different gene, the K locus on chromosome 16, is additionally involved in colour switching in the dog [10].

Fish

Fish contain chromatophores in both the dermis and the epidermis, but in most species the dermal chromatophores are the more important [11]. Several types can be distinguished, namely black or brown melanophores, red erythrophores and yellow xanthophores. In each, the pigments, namely melanins, carotenoids and pteridines, are contained within organelles. In addition, there are leukophores and iridiophores containing colourless pigments, mainly guanine. Iridiophores cannot translocate the pigment-containing organelles; the guanine is deposited in crystalline platelets. Their function is to produce physical colours by reflection, scattering or diffraction.

There are two modes of regulation: hormonal and nervous. Hormones, in particular the melanocyte-stimulating hormone (MSH) of the pituitary, appear to provide the more primitive mechanism. It is the only one present in lampreys, the prevailing

means of control in sharks, and it is retained in the evolution of amphibia, reptiles and mammals. Only in some bony fish does nervous control take over, making it possible, for example, for the flounder, a flat fish, to mimic a chequerboard on which it is placed.

Amphibia and reptiles

Amphibia also have both dermal chromatophores, of similar types to those found in fish, and dendritic epidermal melanocytes [12].

The pattern is continued in reptiles [13]. Lizards have a layer of melanophores in the dermis, with two to four layers of iridiophores above them and, more superficially, xanthophores and erythrophores [14,15]. In addition, melanocytes occur in the basal layer of the epidermis and transfer melanosomes into the keratinocytes.

Birds

In birds [16], melanocytes are responsible for transferring eumelanin and phaeomelanin into the feather germ to produce black, grey, brown and related tints, and also to form the dark background for structural blue and interference colours. Carotenoids, also, may be responsible for yellow and red, and sometimes even for green, violet and blue. It is of interest that the pelican can produce cosmetic coloration of the plumage by a rose-coloured secretion from the preen gland.

The striking white colour of many aquatic birds, for example, the albatross, seagull and swan, is entirely structural. Pigment-free feathers contain irregularly distributed air-filled cavities, which equally reflect all wavelengths of light. Some blue, green and violet coloration, for example that of kingfishers and parrots, is produced by scattering or interference.

Mammals [5]

In comparison with their vertebrate relatives—fish, amphibia, reptiles and birds—and, indeed, many invertebrates, mammals are drab animals. Even the power to perceive colours has been lost in most mammalian orders. Animals as diverse as crabs, octopuses, insects, fish and birds all have colour vision, but dogs are colour blind, and the bull remains indifferent to the redness of the rag even if enraged by the antics of the matador. One evolutionary explanation is that for many millions of years our ancestors were small, insect-eating, nocturnal mammals for which colour vision had no adaptive advantage. An alternative explanation is that hairs were initially mechanoreceptors that allowed more precise information about objects in contact with the skin; however, increasingly dense hair coats meant that the colour changes related to dermal chromatophores in reptiles became less important in hair-bearing mammals.

All was not lost forever. Something was retained and something was regained. All mammals retain epidermal melanocytes, and monkeys, apes and humans share with some species of squirrel the power to appreciate colours. The return of colour as an item of social commerce is symbolized, for example, by the rump of the sexually receptive female macaque or the bright-blue scrotum of the vervet monkey.

However, drab coat colours in young mammals (typically paler than in the adult) may elicit protective behaviour by adults at times of danger, and often have important camouflage function. Adult coat colours may help to camouflage predators, such as tigers, or their prey; in some instances, extrinsic pigments also provide camouflage (for example, algae that grow on the fur of the sloth).

Colours, patterns, genetics and pigment biology

Experiments in thousands of species, investigation of spontaneous mutations such as albino animals, and some of the techniques used in animal models (discussed earlier) have contributed to understanding of the genetics and molecular mechanisms in pigmentation, as well as providing models for some human diseases. Some aspects are discussed in Chapter 58; recent reviews and an extensive text are also available [17,18]. Some examples are briefly outlined here.

Amongst fish, the common aquarium zebra fish (zebra danio, *Danio rerio*) has been extensively investigated. The wild type has horizontal dark blue and silver stripes, but many mutant types are found. Some, such as the *leopard* pattern, which has spots instead of stripes caused by a *connexin-40* mutation, and more recently described with *connexin-41.8* mutations [19], are sold for tropical aquaria as a specific colour pattern (leopard danio) distinct from the zebra danio. The *sparse* mutant (due to a *kit* mutation that influences melanocyte migration and survival) has much paler and less well defined stripes but with normal fins and tail; the *panther* mutant is due to mutation in a *kit*-related gene *colony stimulating factor-1 receptor* (*csf1r*) that affects xanthophore migration. Other mutants include *touchstone*, in which defects in *trpm7* cause apoptosis of melanoblasts and melanophores after migration; *choker* (defects in *stromal-derived factor 1a*, *sdf1a*, that codes for a chemokine that attracts melanophores), *obelix* (*jaguar*) in which a defect in *kir7.1* affects potassium channels and leads to fewer wider stripes compared with the wild type, *colourless* (*sox10* defects), *nacre* (a variant lacking melanophores, due to mutations in *microphthalmia-a*, *mitfa*), *lockjaw* and *mont blanc* (defects in *transcription factor activating protein-2a*, *tfap2a*), *picasso* (a blotchy-patterned zebrafish due to mutations in *erbb3*, coding for a tyrosine kinase receptor) and *rose* (mutation in the *endothelin receptor b1*, *ednrb1*).

In mammals, colours and patterning of the hair coat of mice have been extensively investigated, in part due to the large amount of background knowledge of mouse biology and the massive range of mutations, and also because of the short breeding time and ease of husbandry of these animals. Coat lengths, colours and patterns in different breeds of domestic animals are additionally of commercial importance for breeding and showing. An important aspect of hair colouring and patterns that has been described in many mammals is that of 'pigment type switching'. This determines the production of eumelanin versus phaeomelanin and is described in detail in [20]. Key genes are *Melanocortin 1 receptor* (*Mc1r*) and *Agouti* (*A*); the Agouti protein, in conjunction with the proteins Attractin (Atrn) and Mahoganoid (Mgrn1), inhibits Mc1r function and causes phaeomelanin production. Additional genes play a part in some specific colour variations. These include the *K* gene (*Dominant black*) described above in dogs, which has a dominance pattern favouring black over brindle colouring, and brindle over yellow [10]. The *Tortoiseshell*

(or *Orange*) gene on the X chromosome is well known, causing a characteristic coat pattern in domestic cats and Syrian hamsters with this gene. Brindle colouring in dogs (Fig. 2.3) has not been demonstrated to have a specific causative mutation, but black mask (melanistic mask), in which a black muzzle occurs and may extend up to the ears, appears to be related to a specific (M264V) mutation in *Mc1r* [21].

The merle pattern (or 'blue merle') in dogs is characterized by areas of diluted pigment, associated with auditory and ophthalmological abnormalities. It is inherited as an autosomal dominant trait with incomplete penetrance. It is caused by retrotranspondon insertion in *SILV* [22], leading to the suggestion that this may be a candidate gene for the phenotypically similar Waardenburg's syndrome (WS) in humans. However, several mouse models of this syndrome have been described [23], including *Splotch* (*Sp*) mice, in which a mutation in *PAX3* has elucidated the molecular basis of WS types I and III; *microphthalmia* mice, which have a mutation in *mi* (equivalent to the human *MITF*, mutations which may explain some cases of WS type II), and a chemically induced mutation in *endothelin 3* (*Edn3*) in mice [24], a mutation which had also been documented in some cases of human WS IV. This is not unexpected, as several types of Waardenburg's syndrome have been documented; indeed, the WS type IV phenotype is also caused by mutations in the *endothelin-B receptor* gene (*EDNRB*) and in a transcription factor *SOX-10*. However, it suggests that numerous inherited or induced mutations in animals may provide useful information about human disease, as investigation of large pedigrees is much simpler than in many human diseases.

Animal models and human disease

Animal models and animal equivalents of human disease are discussed in several chapters throughout this book, and only a brief discussion is provided here. Clearly, animal research extends to all areas of medicine, not just dermatology, and includes testing of drugs; a view has been expressed that medical progress depends on animal models, although the extent to which this is true has been debated [1]. Caution has been advocated in extrapolating from animal research to humans [2]. There is also a significant public objection to animal research and pressure to use different methods; some drugs, for example, can be tested on cell cultures or on cultured human skin equivalents.

There are several different ways in which animals may have a role in human dermatology research, other than pharmaceutical studies. Some diseases that appear to be identical or very similar in humans and animals may give clues about epidemiology, pathogenesis or genetic aspects. Those diseases due to identifiable mutations may be especially useful, but some multifactorial diseases also have considerable similarity between humans and animals. For example, the similarity between human and canine atopic dermatitis and allergic reactions has led to detailed studies comparing human and canine mast cells [3] (note, however, canine mast cell tumours are a very different entity from human mast cell proliferations, see p. 2.22).

Experiments involving immunodeficient mice such as the 'nude' mouse have been widely used in dermatology, typically transplanting human skin affected by a dermatosis; much work on psoriasis was performed using such models [4–6]. An alternative use of such models is by transplanting normal human skin in order to study skin constituents or for attempts to provoke dermatoses; for example, injecting normal human skin grafted to

severe combined immunodeficient mice with adenovirus-linked complementary DNA to provoke interleukin-8 (IL-8) synthesis caused development of pyoderma gangrenosum-like skin lesions. This observation supported the view that IL-8, a potent neutrophil chemoattractant, might be involved in the aetiology of pyoderma gangrenosum [7].

Rapid advances in genetic knowledge and DNA technology allowed generation of chimeric animals (by injection of stem cells into blastocysts), transgenic animals (for example, by injection of a specific gene and its regulatory sequences into a fertilized oocyte, to create an animal that expresses the desired protein) and of 'knockout' mice in which a specific gene has been deleted (achieved by injecting cultured stem cells with a 'knockout vector', a DNA construct containing an altered or inactive gene flanked by long sequences homologous to those around the gene of interest, such that the active gene is replaced during DNA replication in a process termed homologous replication). Such methodologies [8,9] allow the effects of abnormally present, absent or altered genes to be studied. Multiple knockouts may be combined, sometimes with effects that may not be fully predicted; for example, it is not surprising that mice with triple knockout of involucrin, envoplakin and periplakin have a defective epidermal barrier, but they also have defective filaggrin processing due to upregulation of a protease inhibitor (serpina1b), delayed degradation of some desmosomal proteins, and a $CD4^+$ T-cell infiltrate with reduction in γδ T cells, similar to the situation in atopic dermatitis [10].

A potential difficulty of this technology is that there may be several different models for human diseases. This is additionally complicated when genetic techniques of inbreeding, backcrossing, positional cloning and congenic substitution mapping are also considered. For example, in addition to the multiple knockout of cornified envelope proteins described above, other mouse models of atopic dermatitis include the Naruto Research Institute Otsuka Atrichia (NOA) mouse, the NC/Nga mouse (NC) and the APOC1 mouse (in which there is transgenic overexpression of human apolipoprotein C1 [11]). Mouse models of atopic dermatitis are discussed in more detail in [12].

Similarly, although there is no accepted animal equivalent of psoriasis, there are several animal models of this condition [13–18]. Hundreds of other models exist for a wide range of human diseases (such as systemic sclerosis [19]), physiological functions, and aspects of carcinogenesis (such as tumour angiogenesis with fluorescent imaging, using the AngioMouse model [20], and tumour inflammation [21]).

Comparative clinical dermatology

Introduction

Diseases of the skin represent one of the most common manifestations of illness seen in animals. A survey of small animal practitioners in 1985 revealed that skin disorders were the most common reason for visits to veterinary practitioners—a situation similar to that with humans. Throughout evolutionary history, the skin, in its capacity as a protective barrier, has been subjected to continuous attack by biting insects, pathogenic microorganisms and environmental insults. The skin immune system has evolved responses to try to deal with such assaults, but in doing so has generated mechanisms that can harm the skin, resulting in allergic inflammation and autoimmune reactions. Genetic mutation over time has also resulted in non-fatal variations in skin structure and function, leading to genodermatoses that have not been eliminated by natural selection.

This wide variety of disease pathomechanisms occurs throughout the animal kingdom and, in domesticated species, the

resulting dermatoses have been studied extensively. Our knowledge of veterinary dermatology has risen exponentially in recent decades and, in companion animal species such as dogs and cats, has reached a high level of sophistication. In dogs, over 300 different skin diseases have been characterized both clinically and histopathologically and, in most, the precise aetiology or underlying pathogenesis is known. Skin conditions in less common species are also well documented, including such diverse aetiologies as squamous cell carcinoma of the ventral scent gland in gerbils, epitheliotropic lymphoma in hamsters and dysecdysis (failure of skin shedding) in snakes.

A knowledge of comparative dermatology provides a fascinating insight into the similarities and differences between human skin diseases and those seen in other animals. Some conditions, such as atopic dermatitis and pemphigus, are seen in multiple species. Others, such as psoriasis, are only seen in humans. Many show species or breed dispositions, such as the tendency for dogs to suffer from massive proliferation of their *Demodex* mite populations. These similarities or differences are not only interesting in their own right, they can also provide animal models to study human diseases, as briefly described above.

There are also some important differences between animal and human dermatology. Some disorders that are similarly named have very different characteristics and behaviour, such as mast cell tumours in dogs and equine sarcoids; *Trichophyton verrucosum* causes little reaction, and is a self-limiting infection in cattle, but is highly inflammatory in humans. A selection of such conditions will be briefly discussed later in the chapter. Some of the apparently similar disorders are listed in Table 2.1.

At a practical level, there are also significant differences in therapeutics (other than economic viability). The presence of fur in mammals precludes use of many topical preparations, especially as animals groom and potentially may ingest topical therapy. Dermatoses or wounds often tend to be licked frequently, producing secondary eroded areas (pyotraumatic dermatitis, hot spot or acute moist dermatitis). Similar localized lesions are termed lick granuloma or acral lick dermatitis. Local treatments, and attempts to retain dressings or bandages on licked areas, have limited success. Thus, especially for more widespread dermatoses, there is greater use of treatments that can be used as a bath, there are many interesting treatments for ectoparasites (including spot treatments applied to an area the animal cannot lick, such as the nape of the neck), and there is significant use of systemic therapies. The last-mentioned issue itself carries problems that may not apply in humans, such as different metabolism and reactions between species; cats, for example, notoriously have adverse reactions to medicines that are generally widely used in other animals. Any form of tumour removal, and diagnostic biopsies from some sites, are likely to require general rather than local anaesthesia, and novel methods to assist safe handling of some animals may have to be employed (such as putting aggressive snakes in a refrigerator for a few hours). Diagnosis and treatment in fish and reptiles can pose problems that differ from those in mammals, due to the presence of scales and (in the case of fish) the aquatic environment.

A brief bibliography of relevant texts is provided below, mainly relating to small animal veterinary dermatology [1–9].

Table 2.1 Some animal disorders that are similar to human diseases.

Type of disorder	Examples
Genetic	Epidermolysis bullosa (many animals)
	Hyperelastosis cutis (probably equivalent to Ehlers–Danlos syndrome; occurs in dogs, cats, horses)
	Some congenital hair shaft abnormalities
	Canine Darier's disease
Dermatitis and inflammatory	Atopic dermatitis (more similar in dogs than in cats)
	Contact dermatitis
	Sweet's syndrome (dogs)
Infections	Impetigo and pyodermas (but usually due to *Staphylococcus pseudintermedius* in small animals)
	Lyme disease (dogs)
	Rickettsial infection (dogs)
	Leishmaniasis
Parasitic diseases	Scabies (canine)
Drug eruptions	Erythema multiforme, exfoliative dermatitis, vasculitis, fixed drug eruption (some species), urticaria, toxic epidermal necrolysis (some species)
Hair disorders	Alopecia areata
	Androgenetic alopecia (some primates)
Metabolic and endocrine disorders	Thyrotoxicosis (common in cats), hypothyroidism
	Zinc deficiency
	Amyloidosis
	Phaeochromocytoma
Autoimmune diseases	Bullous pemphigoid, pemphigus foliaceus, linear IgA disease, cicatricial pemphigoid, epidermolysis bullosa acquisita
	Lupus erythematosus
Neoplasia	Squamous cell carcinoma
	Many other benign and malignant tumours

Parasitic disease (see also Chapter 38) [1–6]

Infestation of the skin with ectoparasites is far more common in animals than in humans. In mammals and birds the skin is covered in hair or feathers, providing a larger area in which parasites can dwell. Animals also have lower hygiene standards than humans, and may live or be kept in large groups allowing effective contagion. Some parasites, such as fleas, *Sarcoptes* and *Cheyletiella*, can be zoonotic.

Infestation with fleas commonly results in skin disease in dogs and cats, causing a pruritic dermatosis over the dorsum (back). In

areas with cold winters, there is a seasonal effect, with more cases in summer and autumn. The skin reacts to salivary antigens that elicit immediate (type I), delayed (type IV) and late-phase IgE-mediated hypersensitivity reactions, termed flea bite dermatitis or canine flea allergy dermatitis (FAD). Chronic cases may develop self-induced alopecia with lichenification and hyperpigmentation, and occasionally nodular lesions. Lesions affect predominantly the caudal part of the body, especially the lumbosacral region and base of the tail, perineum and thighs. This is an extremely common disorder and difficult to manage fully as fleas are ubiquitous; a study of 2653 dogs and 1508 cats demonstrated flea infestation in 21% of cats and almost 7% of dogs, with features of FAD in 8% of cats and 3.3% of dogs [7]. Secondary damage to the skin as well as secondary pyoderma are common complications. It should be noted that systemic flea control agents, that rely on the flea ingesting blood from the dog, may give some long-term control by reducing the flea population but are slow to work as the affected animal is still getting antigenic stimulation from bites; external flea control chemicals, or combination treatments, have been felt to be more effective. However, this conclusion has been questioned lately, as studies have shown that fleas may feed for a shorter period of time in dogs treated with systemic ectoparasiticides than with topically acting agents.

The human flea, *Pulex irritans,* which no longer infests humans in developed countries, can be found on pigs (whose skin is similar to that of humans) but, again, not in developed countries.

Lice are occasionally found on dogs and cats, but are common on horses, cattle, pigs and poultry. Unlike fleas, lice are totally host-specific, and do not spread from one species to another or cause zoonoses. Infested animals usually have low-grade pruritus and mild scaling over the trunk, neck and head. In primates, the gorilla carries *Pthirus gorillae*, the ancestor of the human crab louse (*Pthirus pubis*), chimpanzees carry *Pediculus* species (*P. schaeffi*) but not *Pthirus*, and orang-utans do not have any lice.

Sarcoptic mange is seen commonly in dogs, foxes and pigs, but rarely in horses and cattle. In dogs (canine sarcoptic acariasis) it is one of the most pruritic skin diseases, causing papular dermatitis and erythema, especially on the margins of the ears, over the elbows and on the hocks. Alopecia and areas of crusting, secondary to scratching, may be profound. In some situations it may behave in an enzootic fashion; for example, dogs kennelled together, such as hounds for fox-hunting, may all be affected (Fig. 2.4). The pathogenetic mechanisms of pruritus appear to be similar to the situation in humans, and a canine equivalent of crusted (Norwegian) scabies may also occur. The causative mite, *Sarcoptes scabiei* var. *canis* is relatively species-specific, but can be transmitted to cats and to humans; although it cannot reproduce on human skin, it can cause a transient papular eruption.

In cats, feline scabies is due to the mite *Notoedres cati*, causing feline notoedric acariasis or 'head mange' [6]. It is particularly common where there are large populations of feral cats. Like canine scabies, the ears are commonly affected but the rash may spread to affect the whole facial area and front legs, gradually involving the whole body. Greasy scaling and crusting, alopecia, lichenification and obvious pruritus are apparent; generalized dermatopathic lymphadenopathy occurs. Although also fairly species-specific, transient transfer to dogs and humans may occur.

Fig. 2.4 Sarcoptic mange in a dog, transmitted in an enzootic fashion.

The main differential diagnoses of the pruritic infestations in cats and dogs include atopic dermatitis, food allergies, *Malassezia* overgrowth and pyodermas. Allergic contact dermatitis may also need to be considered. Otodectic acariasis and pemphigus foliaceus are also in the differential diagnosis of head mange in cats. The specific body distribution, demonstration of mites, microbiology samples from pyodermas and response to treatment all help in making these diagnoses; histology is not usually required but, if performed, eosinophils are usually more prominent in infestation than in atopic dermatitis.

Infestation with *Cheyletiella* mites is relatively common in dogs, cats and pet rabbits, causing a diffuse scaling dermatosis over the dorsal trunk, and cheyletiellosis may be enzootic in catteries. The condition may be only mildly pruritic in pets but can lead to a pruritic papular dermatitis in their owners.

Demodicosis is a skin condition seen commonly in dogs but very rarely in other species. It is a follicular disorder caused by massive proliferation of commensal *Demodex* mites (including *D. canis, D. injai* and possibly a third species), which can lead to localized or generalized skin disease (demodectic mange). The localized form is usually seen in juvenile dogs and appears as focal patches of non-inflammatory alopecia, usually on the head or limbs, which can resolve spontaneously. The generalized form is more severe and can result in widespread areas of alopecia, scaling and comedones (Figs 2.5 & 2.6). This form of the disease does not self-cure and requires prolonged treatment with acaricidal agents. The tendency to develop demodicosis appears to be hereditary (data suggest an autosomal recessive mode of inheritance), and certain breeds seem to be predisposed to the generalized form. The pathogenesis has not been established, although some studies have demonstrated immunosuppression, and a hereditary *D. canis*-specific, T-lymphocyte defect may be involved.

In cats, other *Demodex* species are implicated, including *D. cati* and *D. gatoi*, leading to feline superficial demodicosis. Localized and generalized follicular forms occur, and a superficial contagious form due to *D. gatoi* which inhabits the epidermis and behaves rather more like sarcoptic than demodectic mange.

Mange in sheep (*Psoroptes ovis*) or cattle (*Chorioptes bovis*) is a common skin condition causing severe pruritus and damage to

the fleece or hide. In sheep, it is known colloquially as 'scab', and control of the parasite is a major economic burden on the sheep industry. The similar-appearing mites *Otodectes cynotis* (dogs and cats) and *Psoroptes cuniculi* (rabbits) are a common cause of otitis externa, especially in young animals, and there are reports of the former causing problems in humans [8,9].

In horses and farm animals, significant pruritic skin disease can be caused by biting flies such as *Culicoides* midges (the cause of a disease affecting the mane and tail known as 'sweet itch', and responsible for much distress in human visitors to the West coast of Scotland during the summer months), *Simulium* blackflies, *Tabanid* horse flies, stable flies and mosquitoes.

Ivermectin, which is used to treat filarial disease, scabies and lice in humans, but whose use is restricted, is employed to treat a variety of parasitic diseases in veterinary medicine. Adverse effects are uncommon in humans, but it must not be given to certain breeds of dog—collies, old English sheepdog, Australian shepherd, Shetland sheepdog, or crosses thereof—as it affects the central nervous system and may cause death.

Bacterial disease [1–3]

Bacterial skin infections are common in dogs, cats, horses, cattle, sheep and pigs. Interestingly, staphylococcal skin infections can be caused by three different organisms, depending on the species affected. In dogs, the most common type of superficial pyoderma is caused by *Staphylococcus pseudintermedius*. In horses, cattle and sheep, *S. aureus* would be the most likely isolate, whereas in pigs, *S. hyicus* is typically involved. Staphylococcal pyoderma in the dog is one of the commonest skin diseases seen in this species; the most frequent presentation is a papular or pustular eruption often affecting the ventral abdomen. A virtually pathognomonic lesion is the so-called 'staphylococcal ring', a circular patch of alopecia with a peripheral ring of erythema, surrounded by an epidermal collarette (Fig. 2.7). Although most canine impetigo is due to

Fig. 2.7 Typical lesions of staphylococcal folliculitis in a dog, comprising annular areas of erythema surrounded by epidermal collarettes.

S. pseudintermedius, *Pseudomonas* spp., *Enterobacter* spp. and *Escherichia coli* have been implicated. Impetigo is commonest in young animals; in older dogs it may be a clue to underlying Cushing's syndrome, hypothroidism or immunosuppression. Staphylococcal toxins [2] and superantigens [3] explain some of the pathogenicity. Deeper staphylococcal infections are also seen in the dog, characterized by furunculosis, nodules and draining tracts, and deeper *Pseudomonas* infection also occurs [4]. In most cases staphylococcal disease in the dog is secondary to an underlying cause, often atopic dermatitis, but is highly pruritic whether primary or secondary to atopic disease. There are species-specific differences in binding of staphylococci to corneocytes, and differences between atopic and non-atopic dogs [5]. Pemphigus foliaceus can resemble these superficial pyodermas, due to the bullous or pustular component.

Cats rarely suffer from staphylococcal skin infections, possibly because this group of pathogens is relatively poorly adherent to cat corneocytes [6]. However, the tendency of cats to fight makes them very susceptible to cutaneous abscesses caused by the oral cavity organism *Pasteurella multocida*—which can be problematic in animal bites of humans. The rump and face are common sites for cat bite abscesses. Abscesses are also common in farm animal species, and in horses are often caused by corynebacteria, clostridia and β-haemolytic streptococci.

Bacterial skin diseases are common in captive reptiles, amphibians and fish, usually as a result of poor husbandry. Typically, Gram-negative organisms are involved such as *Pseudomonas* or *Aeromonas* (an organism also present in the leech gut and complicating the use of medicinal leeches), resulting in ulcerative skin disease. Snakes and lizards lack lysosomal enzymes so tend to get pyogranulomas instead of frank abscesses. Tortoises and turtles can suffer from ulcerative diseases of the shell caused by the organisms *Citrobacter freundii* and *Beneckea chitinivora*.

Infections in horses that leave scarring may be very important in terms of the value of the horse. Staphylococcal infection may be due to *S. aureus, S. intermedius* or, less often, *S. hyicus* and has various names in common usage including summer itch, summer scab, saddle scab, acne and sweating eczema. An important infective differential diagnosis is dermatophilosis ('rain scald'), a disorder characterized by moist, raw, alopecic patches, caused by *Dermatophilus congolensis*. The spores may be found on fomites (such as gates) and thus transfer to other animals; wetting of the coat precipitates the disease. Other differential diagnoses include dermatophytosis (see below), other bacterial infections, demodicosis and pemphigus foliaceus.

As in humans, staphylococcal resistance to antibiotics is an increasing problem [7].

Fungal disease

Trichophyton verrucosum, the organism responsible for cattle ringworm (Fig. 2.8), is the usual cause of kerion in children, the severity of the inflammatory response being a manifestation of the reaction usually provoked when a zoophilic fungus infects a human. In cattle, the infection produces areas of scaling alopecia that are usually more evident when the animals are under cover during the winter months, but tend to clear in spring when they are put out to pasture.

Trichophyton mentagrophytes, from small rodents, and *T. erinacei*, from hedgehogs, tend to produce inflammatory lesions on exposed areas of human skin, and the latter has caused kerion [1]. The patient shown in Fig. 2.9 acquired infection with *T. erinacei* as a result of working at a hedgehog rescue centre.

Trichophyton equinum causes equine dermatophytosis and is readily transmitted from horse to horse, both by direct contact and on articles of tack [2,3]. Its transmission to humans, however, appears to be unusual, which is perhaps surprising in view of the popularity of equestrian pursuits, and there are only a few reports in the dermatological literature. In a survey of superficial fungal diseases carried out in the USA in 1994, there was no *T. equinum* strain among 1222 specimens [4], and in a Spanish survey, over a 36-year period, there was only one *T. equinum* strain in 3351 dermatophytoses [5]. Human onychomycosis caused by *T. equinum* is rare. Huovinen *et al*. [6] reported a case successfully treated with terbinafine.

Most cases of canine and feline dermatophytosis are caused by *Microsporum canis*, *Trichophyton mentagrophytes* (from rodent contact) and *M. gypseum* (from contaminated soil) [7,8]. In cats, up to 98% of infections are caused by *M. canis*. In cats and dogs, as in humans, *M. canis* infection usually produces patches of scaling

Fig. 2.8 Dermatophytosis in a cow.

Fig. 2.10 Generalized dermatophytosis in a terrier cross.

alopecia, and affected areas may fluoresce apple green under Wood's light. In animals, infection may be generalized (Fig. 2.10). Infections in dogs and cats with geophilic and unusual species of dermatophytes frequently cause highly inflamed lesions, and kerion in dogs and cats is often caused by *Microsporum gypseum*.

Atopic and other dermatitis

Atopic dermatitis (AD) has been most extensively studied in the dog [1–3], but is also recognized in cats, sheep and horses. In veterinary medicine it is considered that canine AD is a cutaneous manifestation of an allergic disease, and there are many pathogenetic and immunological similarities between AD in humans and dogs. Any breed of dog may be affected, but a hereditary basis is supported by a predisposition to develop AD in some, particularly terriers (Fig. 2.11), boxers, German shepherd dogs, Lhasa Apsos, Dalmatians, Irish setters, golden retrievers and Labrador retrievers.

As in humans, the usual presenting problem is pruritus (which is manifest as rubbing, scratching and licking in dogs), and secondary pyoderma is common. Lichenification occurs commonly, as in humans, and flea allergy may complicate the clinical picture. Clinical signs of AD appear between 1 and 3 years of age, and (unlike humans) rarely before 6 months of age. The disease tends to affect the face, ears, feet and ventrum. In addition to corticosteroids, and treatment of secondary pyoderma, ciclosporin is also a licensed treatment, but the mainstay of treatment in dogs is allergen-specific immunotherapy.

Feline AD is less well defined and less similar to human AD; cats can get both asthma and AD, but the two conditions do not usually occur together. Feline AD usually presents as pruritus with alopecia and excoriations around the head and neck, or as a 'miliary dermatitis', but some eosinophilic disorders (feline

Fig. 2.12 *Malassezia pachydermatis* overgrowth in a Basset hound resulting in widespread erythroderma. This condition responds well to antifungal therapy.

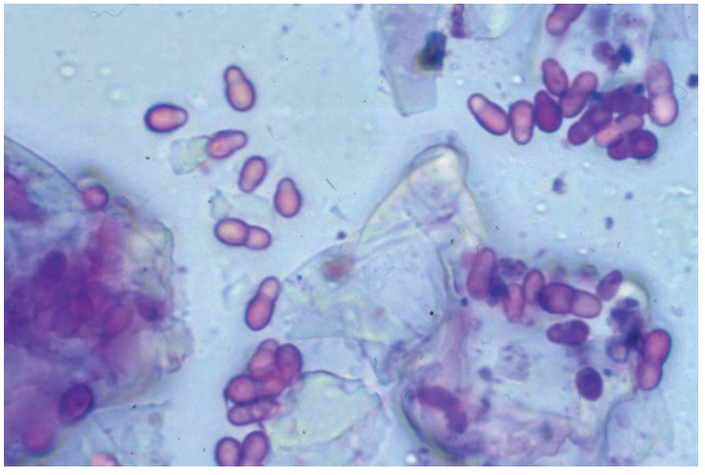

Fig. 2.13 Microscopic appearance of a skin sample from a dog with cutaneous *Malassezia* overgrowth.

eosinophilic plaque, feline eosinophilic granuloma and feline indolent ulcer) have also been suggested as manifestations.

There is also a spontaneous mouse model of AD in NC/Nga mice, and there are experimental mouse models of AD.

Various patterns of *Malassezia* dermatitis occur, the implicated organism being *Malassezia pachydermatis* in dogs (Figs 2.12 & 2.13), and either *M. pachydermatitis* or other *Malassezia* spp. in cats. In some instances, the infection may be secondary to other dermatitis (e.g. atopic), and it has also been described in cats with thymoma-associated exfoliative dermatitis and other forms of pre-existing skin damage. In dogs there is a breed predisposition, mainly Basset hounds, Westies and Cocker spaniels. In some respects this entity resembles human seborrhoeic dermatitis, with erythema and greasy scaling that may affect flexures, facial folds and ears. Other cases in which the abdomen, feet and forelegs are involved are less reminiscent of the human form; additionally, pruritus, which is sometimes significant (and may be due to an underlying dermatosis), is not typical in humans. In cats, *Malassezia* dermatitis may be related to immune deficiency (feline immunodeficiency virus, FIV, or feline leukaemia virus, FeLV).

Psoriasis

There is no natural animal model for psoriasis; a disorder found especially in Springer spaniels, and termed psoriasiform-lichenoid dermatosis, does not behave similarly or appear similar—it has psoriasiform epidermal hyperplasia but a lichenoid pattern of mixed inflammatory cell infiltrate [1]. This condition is usually antibiotic-responsive and is thought to be an aberrant response of the epidermis to staphylococcal antigens. A disorder termed 'psoriasiform dermatitis of the pawpads' has also been described, but histologically has subtle spongiosis and a mixed inflammatory infiltrate often including significant numbers of eosinophils [1]; it is probably an allergic or atopic phenomenon, but clinically may resemble the early stages of canine zinc-responsive dermatitis.

The SCID (severe combined immunodeficiency) mouse/human skin xenotransplantation model is a useful experimental model, and there are several transgenic animal models (see previously). For example, induced loss of Jun proteins in mice causes not only morphological and histological features resembling cutaneous psoriasis, but also arthritis; further support that these proteins may be involved in the pathogenesis of psoriasis includes the fact that the gene *JunB* is underexpressed in psoriasis lesions, and also that it is located in the *PSOR6* psoriasis susceptibility gene region [2].

Immune-mediated disease [1,2]

Many of the immune-mediated disorders identified in humans have been described in animals, including several immunobullous diseases, lupus erythematosus (LE), erythema multiforme (EM) and toxic epidermal necrolysis (TEN). Canine dermatomyositis is also described but has several differences from the human disease. Vitiligo also occurs, again with some differences from human patterns.

Bullous disorders

Bullous pemphigoid [3–5]. Canine, feline, equine and porcine (Yucatan minipigs) homologues of bullous pemphigoid (BP) in humans have been identified, but it is rare in animals. Whereas human BP is a disease of the elderly, there is much variation in the age of onset in animals—pigs around the time of puberty, dogs

Fig. 2.14 Pemphigus foliaceus in a cross breed dog. The nasal distribution is common.

during middle age and horses during senescence. The clinical phenotype of canine, feline and porcine BP is similar to that seen in humans, whereas that seen in horses differs considerably, with severe oral involvement, systemic signs and a poor prognosis.

In canine and porcine BP there is subepidermal inflammation consisting of neutrophils and eosinophils, and bullae are often haemorrhagic. In cats and horses there are few or no inflammatory cells in either the bullae or the superficial dermis. In all these species, IgG autoantibodies bind to a 180-kDa protein in the basement membrane zone.

Cicatricial pemphigoid (mucous membrane pemphigoid) [2,3]. This occurs in cats and dogs, but is very rare in the former. It is the most common autoimmune subepidermal blistering disease of dogs, whereas it is rare in humans. It is very similar to its human counterpart.

Pemphigus [2,3,5–9]. It was not until 1975 that the first description of a canine disease analogous to human pemphigus vulgaris (PV) was described in the veterinary literature. Since then, pemphigus foliaceus (PF) and pemphigus erythematosus have also been reported in the dog, and forms of pemphigus have been recognized in cats, horses, goats and llamas.

In contrast with humans, in whom PV is the most common form of pemphigus, in domestic animals it is PF (Fig. 2.14). The clinical features comprise a primary pustular eruption that can affect the face, nose, pinnae, trunk and footpads. The fragile nature of the pustules often leads to widespread crusting. There may be breed predilection for PF in dogs, as several breeds appear to be predisposed, but there is no breed predilection in cats. It is a relatively common immune-mediated skin disease in the horse, and the Appaloosa breed may be predisposed.

Canine PV is the least common of the pemphigus variants in the dog. There is no defined breed predilection. The disease occurs primarily in mature dogs. Lesions usually arise first in the oral cavity, on other mucosal sites or at mucocutaneous junctions. Other clinical features, histopathology and immunopathology are similar to human disease. Canine PV can be considered a natural model for the human disease.

In humans, Ashkenazi Jews in particular have an increased susceptibility to pemphigus vulgaris, and in South Africa, PV is more common in Indians than in black or white races.

Paraneoplastic pemphigus has been recorded in dogs [2,5].

There are mouse and hamster models of BP, and experimental mouse models of mucous membrane pemphigoid, PV and PF.

Epidermolysis bullosa acquisita [2–4,10]. Although a rare disease, epidermolysis bullosa acquisita (EBA) is recognized as one of the most common autoimmune subepidermal blistering dermatoses identified in dogs, and accounts for 25% of dogs with blistering diseases associated with antibasement membrane autoantibodies—ten times higher than in humans. Affected animals belong to several breeds, but a high proportion are Great Danes, suggesting genetic predisposition.

It is clinically, histopathologically and immunologically similar to its human counterpart.

Dermatomyositis [1,2,11]

In dogs, this occurs in several forms, all designated as variants of ischaemic dermatopathy/canine dermatomyositis. The causes and associations (listed below) are different from those in humans, and the crusting, alopecia and ulceration that may occur are not particularly reminiscent of human dermatomyositis. Additionally, the muscle disease is usually subtle.

Canine variants include:

1. A hereditary condition affecting particularly rough collies, Shetland sheepdogs and Beauceron shepherd dogs. Skin lesions first appear in dogs under 6 months old, and consist of erythema, scaling alopecia and crusting on the face, ears, carpal and tarsal areas, digits and tail tip. Pawpads may be affected, and pressure areas. Poor collateral blood flow of extremities and pressure areas has been implicated. Myositis, if present, occurs after the skin lesions, but can be severe and may affect mastication. Sunlight, oestrus and trauma can aggravate the disease.
2. Juvenile onset ischaemic dermatopathy, sometimes linked with (non-rabies) vaccination.
3. Two forms specifically occurring after rabies vaccination, one causing localized panniculitis and the other a generalized disease (generalized vaccine-induced ischaemic dermatopathy, GVIID).
4. Generalized idiopathic ischaemic dermatopathy (GIID), which has no major breed predilection but may be slightly more common in adult long-haired toy or miniature breeds.

Only the first of these would usually be classed as dermatomyositis, with the others being classified as ischaemic dermatoses.

Fig. 2.15 Cutaneous lupus erythematosus affecting the nasal planum of a dog, a typical predilection site.

There is no association with malignancy in the canine forms of this disease, although this underlies about 30% of human dermatomyositis.

Lupus erythematosus (LE) [2,5]

LE occurs in a number of animals, including dogs, cats and horses. Cutaneous LE is one of the most common autoimmune skin conditions in the dog and particularly affects long-nosed breeds including rough collies and the German shepherd dog. Lesions have some morphological similarity to those of humans, consisting of erythema, scaling, depigmentation and ulceration. The condition typically affects the nasal planum first (Fig. 2.15), and then the junction with hair-bearing skin, and then haired skin of the dorsal aspect of the muzzle; many cases are restricted to the planum. Lesions may also occur in the mouth and on the ears and genitalia.

Systemic lupus erythematosus (SLE) is rare in the dog and cat, but the features are similar to the disease in humans, and the suggested criteria for diagnosis are adapted from those of the American Rheumatism Association.

Less common variants include exfoliative cutaneous LE of the German short-haired pointer, which usually affects the head and back but may be generalized, and vesicular cutaneous LE of the Shetland sheepdog and collie, in which there is extensive ulcerative disease.

Cutaneous LE and systemic LE are rare in cats, and very rare in horses. The equine version tends to differ from that seen in small animals, in that the skin lesions in horses with systemic features are most commonly of discoid LE type, presenting as sharply defined areas of depigmentation around mucocutaneous junctions (skin around the eyes, nostrils, mouth and perianal region). The systemic features in horses include polyarthritis, fever, weight loss and various ocular features including uveitis and hypopyon.

Vasculitis and panniculitis

These both occur in other species. Vasculitis is probably most commonly drug-induced or part of hypersensitivity reactions; it can occur in some situations that would be unusual in humans, for example post-vaccination (especially for rabies) and in canine dermatomyositis. It can occur as a paraneoplastic phenomenon. Vasculitis tends to affect the paw pads, edges of the pinnae or the tip and margins of the pinna.

Panniculitis, as in humans, has many causes; it is, for example, documented in pancreatitis or associated with pancreatic tumours (see Chapter 62 for discussion of this association in humans).

Erythema multiforme (EM) and toxic epidermal necrolysis (TEN) [2,5,12–14]

Equine erythema multiforme is said to be secondary to a number of factors, including drugs, infections and malignancy, and the basic lesions are either macular or vesicular.

EM is an uncommon disease in dogs. Many cases appear to be idiopathic, but some are associated with drug administration. Lesions are vesiculobullous and/or ulcerative in most cases, and involve the axillae, groins, mucocutaneous junctions, oral cavity and footpads. EM is very rare in the cat, and is usually associated with drug administration. The diagnosis is confirmed by skin biopsy.

TEN is rare in animals, and is usually triggered by drugs. There is a generalized vesiculobullous eruption and stomatitis, usually followed by a fatal outcome. As with human disease, there is debate about the value of systemic steroids in treatment.

Mechanobullous disorders

Mechanobullous disorders in animals are rare. Epidermolysis bullosa (EB) has been described in a variety of animals, including sheep, cattle, horses, cats and dogs. In dogs, reports of EB include lethal junctional epidermolysis bullosa (JEB) in a toy poodle [1], a non-lethal subtype of JEB in a mongrel [2], and a disorder corresponding to mild JEB in humans that occurs in a breed of German short-haired pointers [3]. Dystrophic EB has been reported in an Akita Inu [4]. Reported cases of EB in sheep include recessive dystrophic EB [5]. These animals provide useful models in the investigation of mechanobullous disorders in humans, and targets for development of gene therapy [6].

Drug eruptions

In addition to erythema multiforme and toxic epidermal necrolysis (TEN), discussed above, Stevens–Johnson syndrome (SJS), urticaria, exfoliative dermatitis, vasculitis, lupus erythematosus (LE)-like reactions, drug-induced pemphigus foliaceus and fixed drug eruptions (FDE) occur in several species. In many of these, as in humans, other triggers such as infections are possible alternative causes. The distinction between autoimmune pemphigus foliaceus, drug-induced pemphigus foliaceus and pemphigus foliaceus-like drug reactions may be difficult but drug-induced cases usually resolve after the causative drug is discontinued. In contrast, LE-like reactions may persist.

In horses, FDE and TEN may not occur, or have not been reported as such.

Cutaneous manifestations of systemic disease

As in humans, animals exhibit cutaneous manifestations of systemic diseases, such as infections, endocrinopathies and metabolic disorders, and the reader is referred to veterinary texts for further information. Only a few with human counterparts will be mentioned here.

Acrodermatitis enteropathica [1]

'Zinc-responsive dermatosis' occurs as two syndromes. Syndrome I is an uncommon condition, which is inherited as an autosomal recessive trait, and affects zinc absorption and metabolism (i.e. similar to acrodermatitis enteropathica). It is most consistent in white northern-bred dogs such as Siberian huskies, Alaskan malamutes and sometimes in Samoyeds. Affected dogs have erythema, crusting and alopecia around orifices, eyes, genitalia and pressure points. Syndrome II may represent acquired zinc deficiency. The clinical features are similar but usually more severe, and may affect any breed.

A disorder that has some similarities, but in which affected dogs do not thrive and eventually die, occurs in white bull terriers; it has been suggested that it may be a heterozygous form of the disease but due to the different clinical course is currently best viewed as a separate entity, known as lethal acrodermatitis.

Acanthosis nigricans [2]

Canine acanthosis nigricans (AN), in which there is hyperpigmentation and hyperkeratosis in the axillary and inguinal regions, occurs as a result of obesity, endocrinopathy (e.g. hypothyroidism, sex hormone imbalances) or pruritus associated with canine atopy or food allergy.

Superficial necrolytic dermatitis (SND; canine metabolic necrolytic dermatitis; hepatocutaneous syndrome) [2–5]

This is the canine equivalent of necrolytic migratory erythema (NME) in humans. NME usually occurs as a paraneoplastic process in the glucagonoma syndrome, but there are other associations, including liver disease. In canine SND the majority of affected animals have a concurrent hepatopathy (hepatocutaneous syndrome (HS)) and relatively few have glucagonoma syndrome (GS).

Clinical features of SND include erythematous crusting and hyperkeratosis on the paw pads, around the eyes and mouth and on the external genitalia. In some affected animals there has been a toxic insult to the liver, but the majority have hepatic changes that may represent a form of cirrhosis. Hypoalbuminaemia and diabetes mellitus are common accompanying features.

The precise pathomechanism of HS is unknown but it may be due to a hepatic metabolic abnormality causing amino acid catabolism; profound hypoaminoacidaemia is documented, and the liver may have a characteristic vacuolar hepatopathy with parenchymal collapse, visible as a honeycomb pattern on ultrasound. As in humans, GS is associated with a malignant tumour of the alpha islet cells of the pancreas.

SND occurs in cats, but is rare; it may be associated with pancreatic glucagonomas, hepatopathy, thymic amyloidosis or intestinal lymphoma.

Nodular dermatofibrosis [2,6–9]

Another paraneoplastic syndrome seen in dogs is nodular dermatofibrosis, in which cutaneous lesions which are composed of a dense proliferation of dermal collagen and develop mainly on the head, back and distal parts of the legs, are associated with renal cystadenocarcinomas and uterine leiomyomas. It is a syndrome that occurs in German shepherd dogs, and it resembles hereditary leiomyomatosis and renal cell cancer (HLRCC) (OMIM 605839) in humans.

In dogs with nodular dermatofibrosis, skin lesions precede clinical evidence of renal disease by months to years, and the renal tumours are bilateral. Multiple uterine leiomyomas are found in the majority of female dogs with this syndrome.

The HLRCC syndrome in humans is caused by mutations in the *fumarate hydratase* (*FH*) gene, which encodes one of the

tricarboxylic acid cycle's enzymes. It is thought that *FH* functions as a tumour suppressor. HLRCC-associated renal cancers are usually solitary, unilateral and aggressive.

Alopecia [1–6]

Alopecia is a common sign of disease in animals. It may be congenital or acquired. Congenital alopecia universalis occurs in some breeds of cat including Sphinx cats and Canadian hairless cats, some breeds may have hereditary hypotrichosis (Burmese, Birman, Devon Rex, Siamese), and hair shaft disorders include trichorrhexis nodosa, pili torti and hair shaft dysplasia of Abyssinian cats; congenital hair abnormalities in dogs are represented by the Mexican hairless dog, the Abyssinian dog, Chinese crested dog and the Xoloitzcuintli. Hypohidrotic ectodermal dysplasia in dogs causes sparse hair and, exactly as in humans, abnormal dentition including absent, pointed and malaligned incisors (Fig. 2.16).

Causes of focal acquired alopecia in animals include dermatophytosis, demodicosis, sarcoptic mange, dermatomyositis, flea allergy and alopecia areata (AA). Any pruritic skin disease can lead to focal patches of alopecia in animals. Spontaneous alopecia may be caused by folliculitis (demodicosis, dermatophytosis, staphylococcal infection, alopecia areata, pseudopelade, drug eruption), telogenization (endocrine disease, hair cycling abnormalities, excessive steroid use), follicular infiltration (cutaneous lymphoma), follicular destruction (scarring) or follicular dysplasias. More extensive and symmetrical alopecia occurs particularly in association with endocrine disorders such as hypothyroidism (Fig. 2.17), Cushing's syndrome and sex hormone-related problems. Cushing's syndrome in dogs causes alopecia, mainly of the trunk. It is rare in cats, but also causes alopecia or a dry coat, mainly apparent on the abdomen. In contrast, Cushing's syndrome is moderately common in older horses and the coat tends to become longer and denser (Fig. 2.18). In dogs, alopecia may occur after rabies vaccination.

(b)

Fig. 2.16 Congenital, X-linked ectodermal dysplasia, the canine analogue of anhidrotic ectodermal dysplasia. (a) Alopecia in a Springer spaniel puppy. (b) Pointed and malaligned incisor teeth in a collie cross.

Progress in research into alopecia areata in humans has been aided by the development of two animal models for human AA—the inbred rodent models of the C3H/HeJ mouse and the Dundee Experimental Bald Rat (DEBR) [7,8], and both of these have provided important data on the genetics and immunological abnormalities of AA. AA-like hair loss has been reported in dogs [9], cats, horses [5,10], cattle and non-human primates. However, an unexplained 'linear alopecia' in horses, although apparently idiopathic and not explained by dermatomal or vascular structures, is quite distinct, having a granulomatous folliculitis pathologically [11].

Fig. 2.17 Symmetrical, non-pruritic alopecia in a Dachshund suffering from hypothyroidism.

Fig. 2.18 Hypertrichosis in a pony suffering from Cushing's syndrome.

In primates, uacaris and stump-tailed macaques undergo progressive balding of the scalp analogous to androgenetic alopecia in humans (Fig. 2.19). The follicles become progressively smaller, with a change from terminal to vellus hair.

Paraneoplastic alopecia has been described in cats, either non-inflammatory or associated with paraneoplastic exfoliative dermatitis.

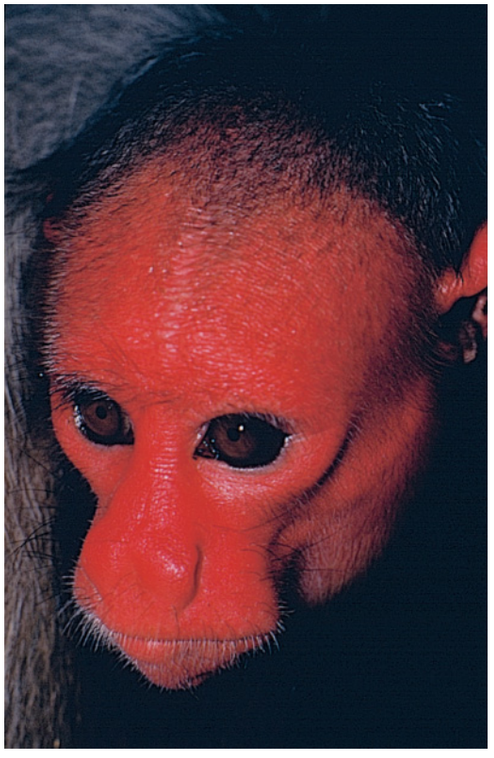

Fig. 2.19 *Cacajao calvus*, the white uacari. Uacaris are notable because both sexes undergo progressive balding of the scalp in which the follicles produce only vellus hairs. (Courtesy of E. Parker, Oxford Scientific Films Ltd.)

Neoplastic skin disease

Skin neoplasms are the most frequently diagnosed tumours of domesticated animals and tend to occur in older animals—feline squamous cell carcinoma (SCC) occurs at an average age of 11 years and canine SCC at an average age of 9 years. Actinic damage and solar-induced neoplasia occur in dogs and cats, and affect lightly-pigmented or unpigmented, sparsely-haired areas [1,2] (Fig. 2.20).

As with humans, the animals that lack pigment protection are particularly vulnerable in hot climates. The most commonly affected dog breeds are white English bull terriers, fox terriers, whippets, beagles, white boxers, American Staffordshire bull terriers and American bulldogs. White cats are most susceptible to solar damage, which particularly affects the ears.

Fig. 2.20 Squamous cell carcinoma on the white nose of a cat; this was excised and repaired with a flap from the nasal dorsum and glabella. (Courtesy of Mrs F.H. Cox, Carlisle, UK.)

As in humans, actinic damage leads to solar keratoses and subsequently SCC—in dogs and cats, SCCs occur more frequently than basal cell carcinomas, whereas the reverse is the case in humans. Papillomavirus structural antigens have been demonstrated in some SCCs, suggesting a viral aetiological role in at least some cases. White cats have SCC about 13 times as frequently as other cats [3]. There is an association of feline immunodeficiency virus infection with certain types of neoplasia, including SCC [4].

Selected other neoplasms with behaviour that differs from human 'equivalents' are discussed below.

Selected disorders that appear to differ from human disease

Although there are many similarities between human and animal diseases, some diseases differ. In some instances this represents similar nomenclature being used for fundamentally different disorders. There are inevitably some disorders that are distinct because of species differences, especially in animals that have diverged longer ago in evolutionary terms—there are also some breed-specific diseases, some of which have been discussed already. Clearly animals that have a scaly reptilian skin, or that have hooves, will have some diseases that differ from anything that occurs in humans. A few examples of disorders without human equivalents are listed in Table 2.2.

Of perhaps greater interest from a comparative point of view are diseases that have human equivalents (or similar names) but that behave differently or appear to have a different cause from that in humans. Some of these have been discussed above, such as superficial necrolytic dermatitis and canine dermatomyositis. Hypohidrotic ectodermal dysplasia, discussed above as a cause of sparse hair and abnormal dentition, does not have overt hypohidrosis (and the risk of hyperthermia, as seen in humans), because dogs only sweat from paw pads and their temperature control is by panting. Some other examples are listed in Table 2.3; a few disorders with specifically different behaviour compared with human counterparts, or similarly named diseases that are distinct between species, are discussed below.

Equine and other animal melanomas [1–6]

Equine melanomas occur most commonly in grey horses, and usually develop in older animals. It is estimated that up to 80% of grey horses older than 15 years develop melanoma, and the anus, vulva and tail are commonly involved. In a study of 296 grey horses of Lipizzaner breed (the greys used by the Spanish Riding School in Vienna) cutaneous melanomas were present in 148 horses (50%), and in 75% of cases lesions occurred underneath the tail [3]. Grey horses are born with dark hair-coats, but with age the hair becomes progressively white. Pigment is retained in the perianal area. However, in contrast with malignant melanoma in humans and in solid-coloured horses, pigment cell tumours frequently display almost benign clinical features in ageing grey horses.

An immunohistopathological study comparing human and equine melanotic tumours [4] revealed that grey horse melanomas have features in common with human blue naevi and desmoplastic malignant melanomas, whereas their resemblance to other types of human cutaneous malignant melanoma is less pronounced. In contrast with human malignant melanoma, melanomas in grey horses are encapsulated, and metastasis is retarded or inhibited by as yet unknown factors. It has been proposed that grey horse-specific genetic factors that inhibit metastatic processes may be responsible for this phenomenon. The authors of this study suggested that further investigation aimed at identifying the factors responsible for retarding metastasis might be of value in developing therapeutic strategies for the treatment of human melanoma.

Animal-type melanoma in humans is a deep, nodular, densely pigmented tumour with relatively good prognosis. It has recently been demonstrated to exhibit low nuclear expression of the π isoform of glutathione S-transferase (GST-π), one of a family of molecules involved in tumour progression, possibly explaining the better than expected prognosis [5].

Canine and feline melanomas [6] are also different from those in humans, as there does not appear to be a role of ultraviolet triggering, malignant transformation from preceding benign naevi appears to be rare, and *in situ* melanomas are also rare (although this may in part be because they are not noticed). Melanomas are rare anyhow, accounting for only 1–2% of skin tumours in cats

Table 2.2 Some animal diseases that do not have an obvious human counterpart.

Type of disease	Examples	Comment
Papulosquamous	Psoriasiform-lichenoid dermatosis	Epidermal morphology is the only resemblance to psoriasis
Infections and parasitic	Cheyletiellosis, parasitic mange	Crusted scabies is the nearest equivalent to mange, but in animals many other ectoparasites are important
	Scabies (cats)	Tends to affect the face ('head mange')
	Habronemiasis (summer sores) in horses	Seasonal nodular lesions due to hypersensitivity to larvae of *Habronema* spp. (stomach worm) that are excreted in faeces and then inoculated into the wound sites by flies
	Dermatophilosis (rain scald) in horses	Exudative lesions due to an actinomycete *Dermatophilus congolensis*
	Distemper (dogs)	Causes hyperkeratosis of the nasal planum and foot pad ('hard pad disease') ± impetigo
	Calcivirus infection (cats)	Ulceration of foot pads and perianal skin
	Feline rhinotracheitis	Can cause multiple oral and skin ulcers, sometimes with necrotizing facial rash on the nose and periocular area
Hypersensitivity reactions	Flea allergy dermatitis (FAD)	Common in dogs and cats
	Eosinophilic disorders in horses (hypersensitivity reactions are suspected but not proven)	Collagenolytic granuloma, axillary nodular necrosis, unilateral papular dermatosis
Hair disorders	Linear alopecia (and linear keratosis) of horses	Vertically orientated lesions, one or more stripes
	Black hair follicle dystrophy (occurs in horses and dogs)	Selective poor growth of black hairs associated with distorted follicles and melanophages
Neoplasia	Equine melanoma	See text
	Melanocytoma–acanthoma	See text
	Canine Sertoli cell tumour-associated skin disease	Causes feminization with gynaecomastia, typically also ventral and caudal alopecia and focal depigmentation
Species-specific diseases	Idiopathic ulceration of collies (rough collies and Shetland sheepdogs)	Represents a vesicular form of cutaneous lupus erythematosus; affects abdomen and groin, usually difficult to treat
	Hyperplastic dermatosis of the West Highland terrier ('armadillo Westie syndrome')	Resembles very severe seborrhoeic dermatitis, and may represent hypersensitivity to *Malassezia pachydermatis* but with a heritable component
	Facial dermatitis of Persian and Himalayan cats	Reminiscent of human seborrhoeic dermatitis but presumed to be hereditary, and differs from other seborrhoeic disease in cats as it is site-specific
	Schnauzer comedo syndrome (miniature Schnauzers)	Relatively common, dorsally situated comedones, may be crusted
Miscellaneous	Canine ear margin seborrhoea	Especially Dachshund breed. Very rare; although greasy scales of the edge of the pinnae resemble those of human seborrhoeic dermatitis it is felt to be a disorder of cornification; sometimes associated with hypothyroidism
	Feline acquired skin fragility syndrome	Fragile skin, that tears easily; has been associated with Cushing's syndrome, diabetes and liver disease
	Lupoid onychitis (symmetrical lupoid onychodystrophy)	Progressive nail destruction; may be multifactorial, some have lichenoid histology

and dogs; most studies suggest that they are less common in cats than in dogs. Cutaneous melanomas include spindle cell, desmoplastic, balloon cell (clear cell) and feline giant epithelioid melanoma. A disorder termed melanocytoma–acanthoma also occurs in dogs, but not in cats—this is rare, has follicular elements histologically, and is cured by excision. There appears to be no human equivalent of this neoplasm.

Sarcoid

Equine 'sarcoids' are the most common skin tumour in horses (also in donkeys and mules), and bear no relationship to human sarcoidosis. They vary from alopecic macules or warty plaques to subcutaneous nodules (fibroblastic tumours, Fig. 2.21) which may ulcerate, and even 'malevolent' sarcoids, which spread along fascia and around vessels [1]. In over 90% of cases, bovine papillomavirus types 1 (BPV-1) or 2 (BPV-2) are found. The presence of a BPV-transforming gene, *E5*, has also been implicated. BPV can be latent in the skin (as in humans) and may be reactivated at areas of trauma, a phenomenon noted in some cases of equine sarcoid. Contact with affected animals increases the risk of these lesions, and it has been suggested that some may spread after bites from flying insects. There is a high recurrence rate after surgical excision, but cryotherapy, hyperthermic therapies, intralesional

Table 2.3 Some animal disorders that share some features with, or have similar nomenclature to, human diseases, but that behave differently.

Type of disease	Examples	Comment
Bacterial	'Pyoderma'	Covers various infections, usually due to staphylococcal spp. but mainly *S. pseudintermedius*, often secondary to excoriation and underlying pruritus
	Abscesses	Usually caused by bites or foreign bodies (thorns etc); organisms therefore differ from those likely in humans
Viral	Equine sarcoid, feline sarcoid	Equine variant may behave in a neoplastic fashion; unrelated to human sarcoidosis
Infestations	Demodicosis	Canine form and feline follicular form, see text
Inflammatory	Dermatomyositis (ischaemic dermatopathy)	May be hereditary; not associated with malignancy; see text for more detail
	Metabolic necrolytic dermatitis	Equivalent to necrolytic migratory erythema, but mainly caused by a hepatopathy causing severe hypoaminoacidaemia, the human form being mainly caused by glucagonomas
	Photosensitivity	May be similar, but occurs especially in cattle and horses due to ingestion of plant alkaloids (see text)
	Interdigital furunculosis (interdigital pyoderma)	Inflammation and crusting between paw pads The features are somewhat similar to a mixture of pilonidal sinus and lichenification, probably caused by a mixture of penetration by hairs, trauma and secondary bacterial and *Malassezia* infection Stocky breeds with short coarse hair are predisposed, e.g. mastiffs, boxers and bulldogs
	Paronychia	Similar to humans in having the potential to be acute or chronic, but different organisms Acute paronychia may be staphylococcal but *E. coli* also occurs; chronic changes often involve *Malassezia* spp. Immune-mediated diseases, especially pemphigus, may present with claw disease, and immune deficiency (feline leukaemia virus, feline immunodeficiency virus) infection should be considered
	Feline acne	Clinical resemblance to human acne (comedones, pustules) but usually confined to the chin, and sometimes around the lips; possibly related to poor grooming, and has been described behaving in a contagious fashion within households
Colour disorders	Vitiligo	May behave as in humans but strongly heritable in some breeds, no strong association with other autoimmune diseases, and may be limited distribution (nasal planum, 'snow nose')
Neoplasia	Melanoma	Rare; equine melanoma in particular has a different course

Fig. 2.21 Equine sarcoid, nodular form (the hair has been shaved prior to topical cytotoxic treatment). (Courtesy of Mrs F.H. Cox, Carlisle, UK.)

cytotoxics and radiotherapy have all been used. The lesions shown in Fig 2.21 were treated with a topical mixture of heavy metals and cytotoxic chemotherapy that has been advocated in the UK.

Feline sarcoids (fibropapillomas) have also been described, especially in cats living outdoors in rural areas ('barn cats'). These also contain papillomavirus that has high sequence homology with bovine, ovine, deer and European elk papillomavirus. Lesions are single or multiple, firm, sometimes ulcerated, and tend to occur around the muzzle area, on extremities or the tip of the tail, and occasionally intraorally.

Mast cell tumour [1–3]

In humans, mast cell proliferations (Chapter 22) usually occur as solitary (or few) localized mastocytomas, typically occurring in children and involuting over time, or as urticaria pigmentosa, which may be of childhood (usually self-resolving) or adult (more persistent) onset. Malignant mast cell proliferations are systemic and rare.

In contrast, in dogs, urticaria pigmentosa is rare but mast cell tumours are common (about 10–15% of all skin tumours, and multiple in 10–15% of cases) and typically aggressive. Most are in dogs aged 6–8 years, but onset may be earlier (especially in Chinese shar peis). There are some breeds that have a predilection for mast cell tumours, and some body site differences between breeds. The lesions are erythematous nodules that may be several centimetres in diameter, often with alopecia, and ulceration in larger lesions. Eosinophils are commonly present histologically along with cords and sheets of neoplastic mast cells. Similar to humans, mutations in *c-kit* can be demonstrated; increased expression of KIT and high proliferation assessed by Ki-67 are both linked with poorer prognosis. The more aggressive stage III tumours have a 2-year survival of less than 10%.

Feline mastocytomas generally occur in older animals, around 10 years of age, and have a much more benign behaviour, although those in young animals may be more aggressive.

Vitiligo [1]

Vitiligo with features very similar to the human disorder occurs in animals, the main difference being that leucotrichia is the norm; some confusion arises because other causes of loss of pigmentation have been given the same term. A degree of heritable tendency occurs, as in humans, although the strength of this varies between breeds—the Belgian Tervuren has a relatively high frequency, and Rottweilers, German shepherd dog, old English sheepdog and dachshund all have some predisposition. Vitiligo in dogs is much less common than in humans, and does not appear to be specifically linked with other organ-specific autoimmune diseases, although it has been reported with diabetes in a dachshund. It is even rarer in cats, although it may occur in Siamese cats (always female). In dogs, vitiligo is usually facial, especially the muzzle, and acral (acrofacial variant) or periorificial (this being similar to vitiligo in some humans). Depigmentation of claws and buccal mucosa occurs in some animals.

Another feature of vitiligo that is unusual is a site-limited variant that affects only the nasal planum (the non-hair-bearing area of the nose), which is called 'Dudley nose' or 'snow nose'; it is most common in some retrievers and in the Siberian husky and the Alaskan malamute.

Photosensitivity

In humans, the commonest causes of photosensitivity are idiopathic eruptions such as polymorphic light eruption, drug-induced photosensitivity and photosensitivity related to exogenous topical agents. Some photosensitivity disorders such as porphyrias combine genetic factors and toxins (such as alcohol in porphyria cutanea tarda).

Fig. 2.22 Photosensitivity in a cow; this is usually caused by ingestion of hepatotoxic plants.

In cattle and horses, ingested plant alkaloids, topical plant-derived photosensitizers and agents causing hepatic damage are much more important (Fig. 2.22). External chemicals implicated in equine contact photoallergy include sunscreens (sometimes applied to the muzzle of grey horses), antiseptics (such as triclosan or chlorhexidine used as treatments, for example for rain scald), antihistamines (for bites) and plants that contain psoralens, hypericins or phytoallexins (e.g. St John's wort, spring parsley, Bishop's weed and others) [1]. Ingestion of plants containing pyrrolizidine alkaloid, such as ragwort and common groundsel may cause severe photosensitivity; in the UK, it is an offence to allow ragwort to grow in fields where horses graze, or in adjacent fields. Elevated blood levels of phylloerythrins occur due to such alkaloid exposure, but also because of hepatic damage following infections (especially leptospirosis), biliary calculi, cholestasis and cholangiohepatitis, mycotoxins, chemical toxins (copper, phosphorus, others) and (limited to Corriedale lambs) as a genetic defect.

Components of normal human skin

Skin is the largest organ in the body. In a 70-kg individual, the skin weighs over 5 kg and covers a surface area approaching 2 m^2. Human skin consists of a stratified, cellular epidermis and an underlying dermis of connective tissue (Fig. 3.1). Beneath the dermis is a layer of subcutaneous fat, which is separated from the rest of the body by a vestigial layer of striated muscle.

The epidermis is mainly composed of keratinocytes and is typically 0.05–0.1 mm in thickness. It is formed by division of cells in the basal layer which give rise to the spinous layer. This layer contains cells that move outwards and progressively differentiate, forming the granular layer and the stratum corneum. The cellular progression from the basal layer to the skin surface takes about 30 days but is accelerated in diseases such as psoriasis. The 'brick-like' shape of keratinocytes is provided by a cytoskeleton made of keratin intermediate filaments. As the epidermis differentiates, the keratinocytes become flattened. This process involves the filament aggregating protein, filaggrin, a protein component of keratohyalin granules. Indeed, keratin and filaggrin comprise 80–90% of the mass of the epidermis. The outermost layer of the epidermis is the stratum corneum, where cells (now called corneocytes) have lost nuclei and cytoplasmic organelles. The corneocyte has a highly insoluble, cornified envelope within the plasma membrane, formed by cross-linking of soluble protein precursors, including involucrin and loricrin, the latter contributing 70–85% to the mass of the cornified cell envelope; it also contains several lipids (fatty acids, sterols and ceramides) released from lamellar bodies within the upper, living epidermis. Other cells in the epidermis are the melanocytes, Langerhans' cells and Merkel cells. Melanocytes are dendritic cells that distribute packages of melanin pigment in melanosomes to surrounding keratinocytes to give skin its colour. The number of melanocytes does not differ much between white and black skin. Rather it is the nature of the melanin and the size of the melanosomes that account for the different appearances. The Langerhans' cells are also dendritic in nature, although these are of mesenchymal origin and originate from bone marrow. Langerhans' cells are antigen-presenting cells and process antigens encountered by the skin to local lymph nodes and thus have a key role in adaptive immune responses in the skin. Merkel cells are probably derived from keratinocytes. They have a role as mechanosensory receptors in response to touch.

Human skin contains pilosebaceous follicles and sweat glands. The hair follicles comprise pockets of epithelium that are continuous with the superficial epidermis but which also envelop a small papilla of dermis at their base. A bundle of smooth muscle, the arrector pili, extends at an angle between the surface of the dermis and a point in the follicle wall. Above the insertion, there are holocrine sebaceous glands which open into the pilary canal. In some sites, such as the axillae, the follicles may be associated with apocrine glands. Also derived from the epidermis and opening directly to the skin surface are the eccrine sweat glands.

The epidermis is attached to the dermis via a complex network of proteins and glycoproteins that extend from inside basal

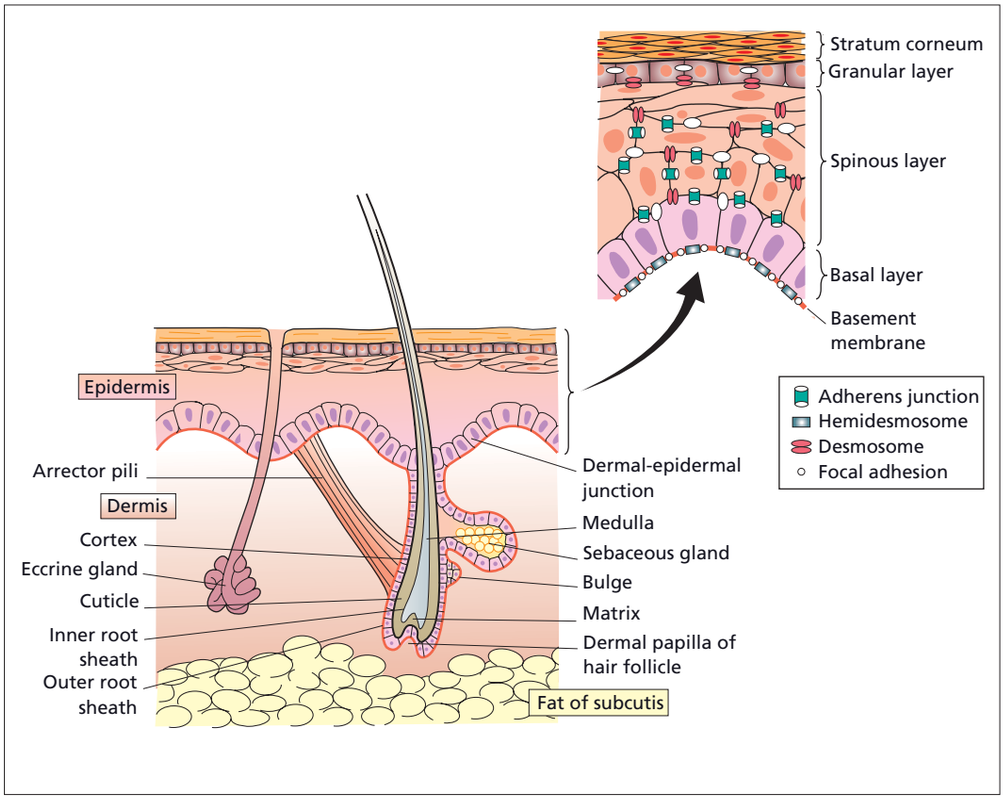

Fig. 3.1 The skin and its appendages.

keratinocytes into the superficial dermis. Besides adhesion, the dermal–epidermal junction components also contribute to cell migration (for example during wound healing) as well as epithelial–mesenchymal signalling events. Over 30 different macromolecules (collagens, laminins, integrins) interact within a basement membrane zone that is less than 200 µm across.

The dermis is a supporting matrix or ground substance in which polysaccharides and proteins are linked to produce macromolecules that have a remarkable capacity for retaining water. The thickness of the dermis varies from less than 0.5 mm to more than 5 mm. There are two principal types of protein fibre: collagen and elastic tissue. Collagen is the major extracellular matrix protein comprising 80–85% of the dry weight of the dermis. Twenty-nine different collagens have been identified in vertebrate tissue (depicted by Roman numerals in the order of their discovery, from I to XXIX), of which at least 12 are expressed in skin. The main interstitial dermal collagens are types I and III whereas the principal basement membrane collagen (at the dermal–epidermal junction and around dermal blood vessels, nerves and appendages) is type IV collagen. Triple-helical collagen monomers polymerize into fibrils and fibres, which then become stabilized by the complex formation of both intra- and intermolecular crosslinks. Collagen fibres are extremely tough and provide skin with its tensile strength. Elastic fibres account for no more than 2–4% of the extracellular matrix in the dermis and consist of two components, elastin and elastin-associated microfibrils, which together give skin its elasticity and resilience. Elastic microfibrils are composed of several proteins, including fibrillin, which surround the elastin and which can extend throughout the dermis in a web-like configuration to the junction between the dermis and the epidermis. The dermis also contains a number of non-collagenous glycoproteins including fibronectins, fibulins and integrins. These extracellular matrix components facilitate cell adhesion and cell motility. Between the dermal collagen and elastic tissue is the ground substance made up of glycosaminoglycan/proteoglycan macromolecules. These contribute only 0.1–0.3% of the total dry weight of the dermis but provide a vital role by maintaining hydration, mostly due to the high water-binding capacity of hyaluronic acid. About 60% of the total weight of the dermis is water.

The dermis has a very rich blood supply, although no vessels pass through the dermal–epidermal junction. There is a superficial and a deep vascular plexus. The motor innervation of the skin is autonomic, and includes a cholinergic component to the eccrine sweat glands and adrenergic components to both the eccrine and apocrine glands, to the smooth muscle and the arterioles and to the arrector pili muscle. The sensory nerve endings are of several kinds; some are free, some terminate in hair follicles and others have expanded tips.

Functions of skin

A key role of skin is to provide a mechanical barrier against the external environment. The cornified cell envelope and the stratum corneum restrict water loss from the skin while keratinocyte-derived endogenous antibiotics (defensins and cathelicidins)

provide an innate immune defence against bacteria, viruses and fungi. The epidermis also contains a network of about 2×10^9 Langerhans' cells, which serve as sentinel cells whose prime function is to survey the epidermal environment and to initiate an immune response against microbial threats, although they may also contribute to immune tolerance in the skin. Melanin, which is mostly found in basal keratinocytes, also provides some protection against DNA damage from ultraviolet radiation.

An important function of skin is thermoregulation. Vasodilatation or vasoconstriction of the blood vessels in the deep or superficial plexuses helps regulate heat loss. Eccrine sweat glands are found at all skin sites and are present in densities of 100–600/cm^2; they play a role in heat control and produce approximately 1 litre of sweat per hour during moderate exercise. Secretions from apocrine sweat glands contribute to body odour (pheromones). Skin lubrication and waterproofing is provided by sebum secreted from sebaceous glands.

Subcutaneous fat has important roles in cushioning trauma as well as providing insulation and a calorie reserve. In non-obese subjects, about 80% of the body's total fat is found in subcutaneous tissue. Fat also has an endocrine function, releasing the hormone leptin, which acts on the hypothalamus to regulate hunger and energy metabolism. Other functions of fat cells include tissue remodelling and phagocytosis.

Nails provide protection to the ends of the fingers and toes as well as being important in pinching and prising objects. Hair may have important social and psychological value, reflecting the notion that the appearances of human skin and its associated structures have a major impact on interpersonal relationships and personal well-being. Skin also has a key function in synthesizing various metabolic products, such as vitamin D.

Regional skin variation

There are two main kinds of human skin: glabrous skin (non-hairy skin) and hair-bearing skin. Glabrous skin is found on the palms and soles and has a grooved surface with alternating ridges and sulci giving rise to the dermatoglyphics (fingerprints). Glabrous skin has a compact stratum corneum which may be up to 10 times thicker compared to other body sites such as the flexures, where the epidermis is at its thinnest. Glabrous skin also contains encapsulated sense organs within the dermis, as well as a lack of hair follicles and sebaceous glands. In contrast, hair-bearing skin has both hair follicles and sebaceous glands but lacks encapsulated sense organs. Hair follicle size, structure and density can vary between different body sites; the scalp has large hair follicles that may extend into subcutaneous fat whereas the forehead has only small, vellus hair-producing follicles although sebaceous glands are large. The number of hair follicles remains unchanged until middle life but there is a changing balance between vellus and terminal hairs throughout life. In hair-bearing sites, such as the axilla, there are apocrine glands in addition to the eccrine sweat glands. Sebaceous glands are actively functioning in the newborn, and from puberty onwards, and the relative activity modifies the composition of the skin surface lipids. The structure of the dermal–epidermal junction also shows regional variations in the number of hemidesmosomal-anchoring filament complexes (more in the leg than the arm). In the dermis, the arrangement and size of elastic fibres varies from very large fibres in perianal skin to almost no fibres in the scrotum. Marked variation in the cutaneous blood supply is found between areas of distensible skin such as the eyelid and more rigid areas such as the fingertips. There may also be regional differences in biomechanical properties which can affect percutaneous absorption of creams and ointments.

Skin development

The skin arises by the juxtaposition of two major embryological elements: the prospective epidermis that originates from a surface area of the early gastrula, and the prospective mesoderm that comes into contact with the inner surface of the epidermis during gastrulation. The mesoderm not only provides the dermis, but is essential for inducing differentiation of the epidermal structures, such as the hair follicle. The melanocytes are derived from the neural crest.

After gastrulation, there is a single layer of neuroectoderm on the embryo surface; this layer will go on to form the nervous system or the skin epithelium depending on the molecular signals it receives (Fig. 3.2). Activation of Wnt signalling will block the ability of the ectoderm to respond to fibroblast growth factors (FGFs). Without FGFs the cells express bone morphogenic proteins (BMPs) and progress to an epidermal lineage. Conversely, lack of Wnt signalling promotes a neural fate [1].

The embryonic epidermis consists of a single layer of multipotent epithelial cells, which is covered by a special layer known as periderm that is unique to mammals (Figs 3.3 & 3.4). Periderm provides some protection to the newly forming skin as well as exchange of material with the amniotic fluid. The embryonic dermis is at first very cellular and at 6–14 weeks three types of cell are present: stellate cells, phagocytic macrophages and granule-secretory cells, either melanoblasts or mast cells. From weeks 14 to 21, fibroblasts are numerous and active, and perineural cells, pericytes, melanoblasts, Merkel cells and mast cells can be individually identified. The various structural components of the skin that can be recognized postnatally start to appear at different embryonic time-points, for example, hair follicles and nails (9 weeks), sweat glands (9 weeks for the palms and soles, 15 weeks for other sites) and sebaceous glands (15 weeks). Touch pads become recognizable on the fingers and toes by week 6 and reach their greatest development at week 15. After this, they flatten and become indistinct. It is these areas that determine the pattern of dermatoglyphics that take their place.

The mesoderm not only provides the dermis but is essential for inducing differentiation of the epidermal structures, such as the hair follicle in mammals [2]. The earliest development of the hair rudiments occurs at about 9 weeks in the regions of the eyebrow, upper lip and chin (Fig. 3.5).

Mesenchymal cells, derived from the dermomyotome, populate the skin and interact with the overlying epidermis to induce formation of hair placodes [3]. Key components of the mesenchymal signals to produce hair follicles include FGFs and BMP-inhibitory factors such as Noggin; excessive BMP stimulation can reduce hair

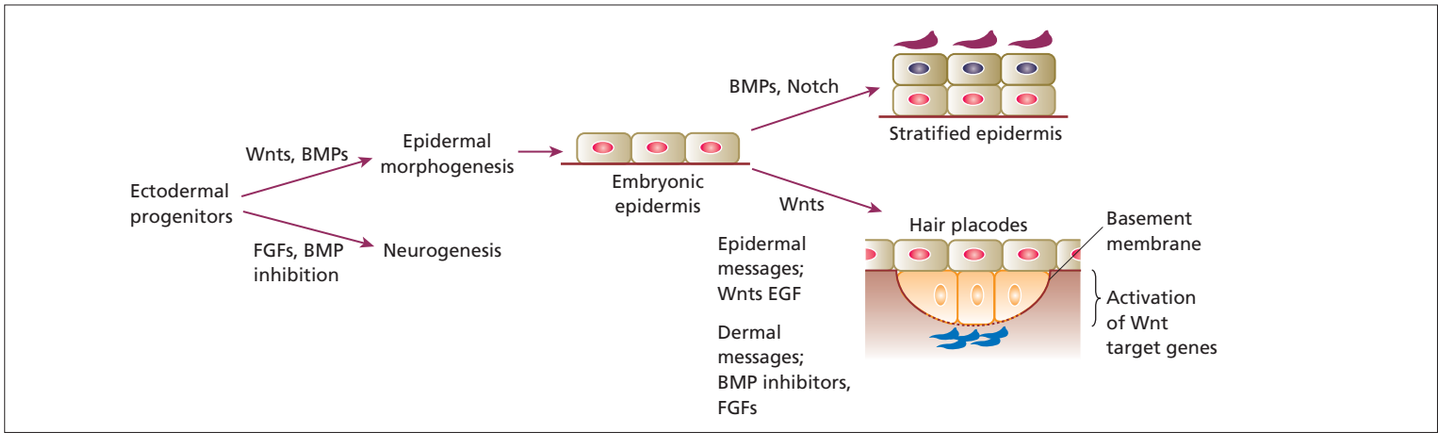

Fig. 3.2 Embryonic development of the skin depends on specific signalling molecules. Relative stimulation or inhibition by these signalling molecules also determines whether embryonic epidermis progresses to a stratified epidermis or whether formation of skin appendages is induced. BMP, bone morphogenic protein; FGF, fibroblast growth factor; EGF, epidermal growth factor.

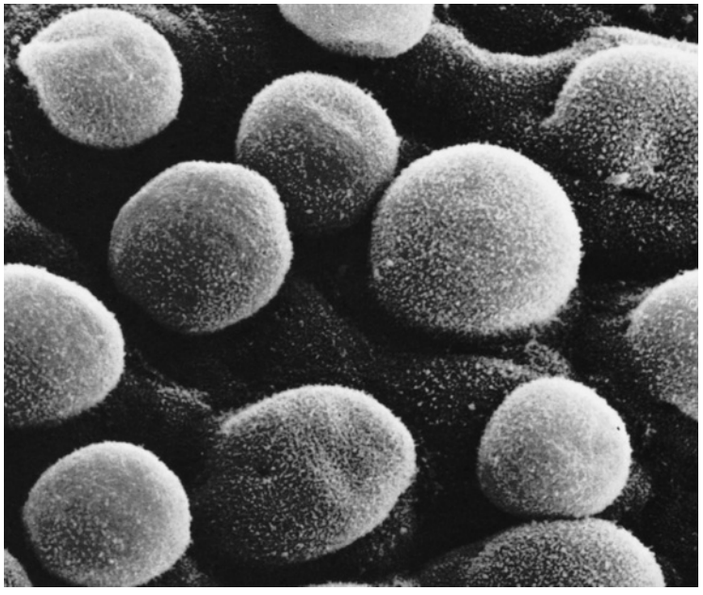

Fig. 3.3 Scanning electron micrograph of an 85–110 day (estimated gestation age) human embryo. Single globular blebs project from the periderm cells. (Courtesy of Professor K.A. Holbrook.)

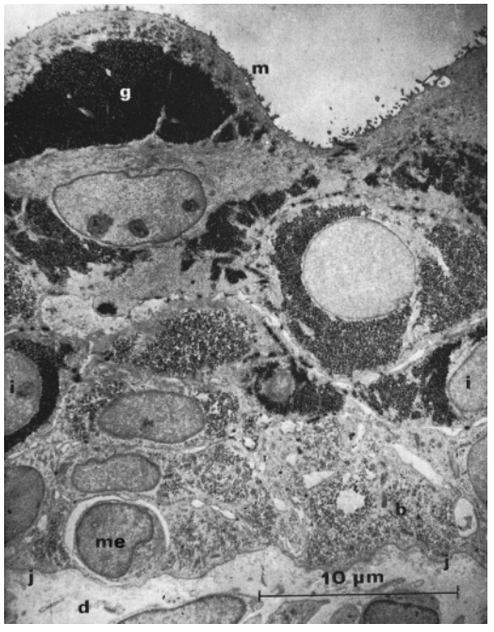

Fig. 3.4 Electron micrograph of the full-thickness epidermis from the back of a 14-week human fetus. Osmium fixation and lead staining. The periderm cells are full of glycogen (g) and have microvilli (m) at their amniotic border. Cells of the intermediate layer (i) also contain glycogen. Basal-layer cells (b) have lost glycogen by this stage. Just above the dermal–epidermal junction (j) there is a melanocyte (me); the surrounding space indicates that it is a recent immigrant from the dermis (d). (Courtesy of Professor A.S. Breathnach, St John's Institute of Dermatology, King's College London,UK.)

follicle density. The epidermal response to form the hair placode is generated by Wnt signals such as Wnt10b and sonic hedgehog (Shh) which also has a key role in the formation of the dermal papilla. After it is formed, the dermal papilla sends further signals to transform the placode into a hair follicle. At the centre of the signalling crosstalk is the bipartite transcription factor composed of LEF1 and stabilized β-catenin, which is essential for hair follicle formation. Hair follicle development is also influenced by Smads, a group of signalling mediators and antagonists of the transforming growth factor-β (TGF-β) superfamily: Smad-4 affects hair follicle differentiation by mediating BMP signalling; Smad-7 affects hair follicle development and differentiation by blocking TGF-β/Activin/BMP pathways [4].

Signalling responses differ between follicular and interfollicular epidermis: BMP signalling is active in the interfollicular epidermis and is both an epidermis-promoting signal as well as a follicle-inhibiting signal; epidermal growth factor receptor (EGFR) signalling may have a similar role in governing follicle density. As hair follicles mature to form inner and outer root sheaths, several signalling pathways are involved, including Wnt, Notch and BMP receptors. There are also marked changes in certain cell adhesion

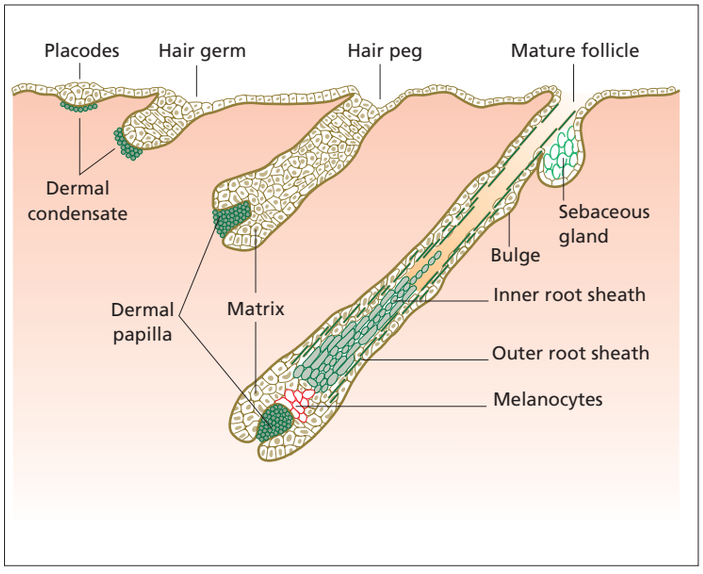

Fig. 3.5 Embryonic stages of hair follicle morphogenesis.

proteins, notably E-cadherin and P-cadherin. The hair follicles are arranged in patterns, usually in groups of three. It appears that the first follicles develop over the surface at fixed intervals of between 274 and 350 μm. As the skin grows, these first hair germs become separated, and new rudiments develop between them when a critical distance, dependent on the region of the body, has been reached. There is no large-scale destruction of follicles during postnatal development, only a decrease in actual density as the body surface increases; nor do any new follicles develop in adult skin. In interfollicular epidermis, the undersurface of the epidermis is smooth, but during the fourth month, at the same time as the hair follicle starts to develop, it becomes irregular.

Sebaceous glands first appear as hemispherical protuberances on the posterior surfaces of the hair pegs. The cells contain moderate amounts of glycogen, but soon the cells in the centre lose this, and become larger and foamy as they accumulate droplets of lipid. The sebaceous glands become differentiated at 13–15 weeks, and are then large and functional. The sebum forms part of the vernix caseosa. At the end of fetal life, sebaceous glands are well developed and generally large. After birth, the size is rapidly reduced, and they enlarge to become functional again only after puberty. The molecular signals that induce sebaceous gland differentiation involve the c-Myc transcription factor as well as the adipogenic transcription factor peroxisome proliferator-activated receptor γ (PPAR-γ) [5].

Eccrine glands start to develop on the palms and soles at about 3 months, but not over the rest of the body until the fifth month [6]. In embryos of 12 weeks, the rudiments of eccrine sweat glands are first identifiable as regularly spaced undulations of the developing epidermis. Cells that go on to form the eccrine sweat glands are oblong, palisading and lie closely together, but otherwise they do not differ from the rest of the developing basal epidermis. By 14–15 weeks, the tips of the eccrine sweat gland rudiments have penetrated deeply into the dermis, and have begun to form the coils. In the overlying epidermis, columns of cells that are destined to form the intraepidermal sweat ducts are recognizable. Each column is composed of two distinct cylindrical layers, comprising two inner cells that are elongated and curved so that they embrace the inner cylinder. The intraepidermal duct appears to form by the coalescence of groups of intracytoplasmic cavities formed within two adjacent inner cells. In the intradermal segment, the lumen forms by dissolution of the desmosomal attachment plaques between the cells that compose the inner core of the eccrine duct germ.

Nails begin to develop in the third month. Key signalling events in nail development involve the R-spondin family of transcription factors [7]. In fetuses at 16–18 weeks (crown to rump length 120–150 mm), keratinizing cells from both dorsal and ventral matrices can be distinguished. Melanocytes take their origin from the neural crest. This can be identified in early human embryos, but the elements arising from it soon lose themselves in the mesenchyme, and pigmented melanocytes cannot be identified, even in black skin fetuses, before 4–6 months of gestation. However, dopa-positive melanocytes can be demonstrated earlier. Langerhans' cells are derived from the monocyte–macrophage–histiocyte lineage and enter the epidermis at about 12 weeks. Merkel cells appear in the glabrous skin of the fingertips, lip, gingiva and nail bed, and in several other regions, around 16 weeks.

Although some cells of the dermis may migrate from the dermatome (ventrolateral part of the somite) and take part in the formation of the skin, most of the dermis is formed by mesenchymal cells that migrate from other mesodermal areas [8]. These mesenchymal cells give rise to the whole range of blood and connective tissue cells, including the fibroblasts and mast cells of the dermis and the fat cells of the subcutis. In the second month, the dermis and subcutis are not distinguishable from each other but distinct collagen fibres are evident in the dermis by the end of the third month. Later, the papillary and reticular layers become distinct and, at the fifth month, the connective tissue sheaths are formed around the hair follicles. Elastic fibres are first detectable at 22 weeks.

Skin maintenance

To maintain skin homeostasis, regenerate skin appendages and repair itself after injury, the skin contains stem cells which reside

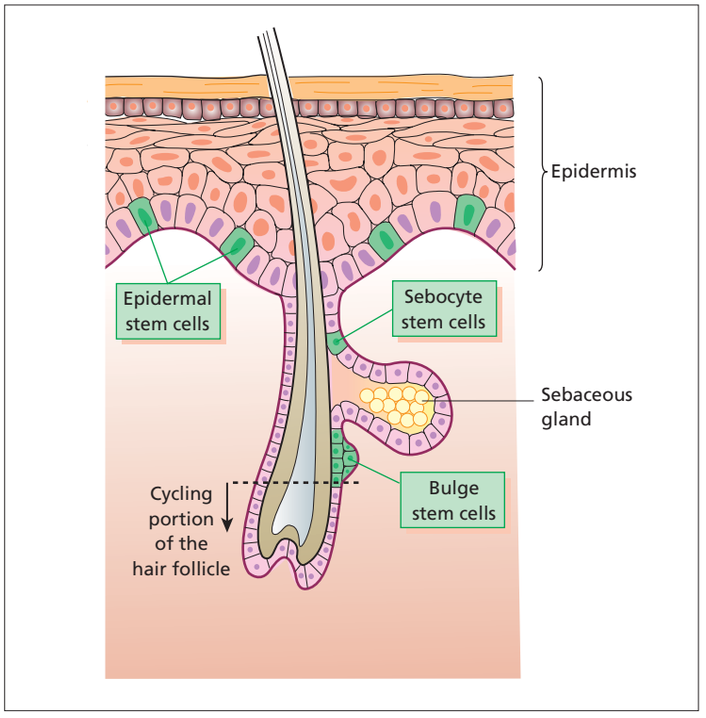

Fig. 3.6 Epithelial stem cells are found within the interfollicular epidermis, the base of sebaceous glands and in the bulge area of hair follicles.

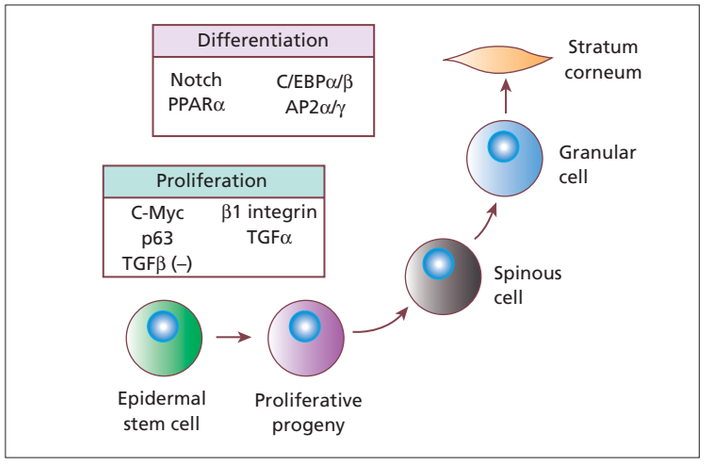

Fig. 3.7 Epidermal stem cell proliferation regulated positively by β1 integrin and TGF-α, and negatively (–) by TGF-β signalling; the transcription factors c-Myc and p63 also promote epidermal proliferation. Notch signalling and the transcription factors PPARα, AP2α/γ, and C/EBPα/β control the differentiation of epidermal cells.

in the bulge area of hair follicles, the basal layer of interfollicular epidermis and the base of sebaceous glands [1] (Fig. 3.6). These stem cells generate a proliferative progeny that can undergo differentiation. The molecular signals involved in regulating epidermal stem cell proliferation and differentiation are illustrated in Fig. 3.7.

Stem cells are able to self-renew as well as give rise to the differentiating cells [2]. In the epidermis, some basal cells can periodically withdraw from the cell cycle and commit to terminal differentiation. It is still not clear, however, whether every cell or only a proportion of cells in the basal layer is a stem cell. One long-established theory divides basal keratinocytes into epidermal proliferation units, which comprise one self-renewing stem cell and about 10 tightly packed, transient, amplifying cells (each capable of dividing several times and then exiting the basal layer to undergo terminal differentiation) [3]. This unit gives rise to a column of larger and flatter cells that culminates in a single hexagonal surface. Stem cells within epidermal proliferation units are associated with a profile of particular chemical, molecular and biological characteristics [4]. For example, stem cells retain labelling with injected ^{3}H-thymidine or Brdu after repeated cell division. In culture, actively growing clones present after serial passaging are considered to indicate an origin from stem cells. Potential markers of interfollicular epidermal stem cells are α6 and β1 integrin as well as p63, whereas sebocyte stem cells express Blimp1. Markers of hair follicle bulge stem cells include CD34, NFATc1, vitamin D receptor, TCF3, Sox9 and Lhx2.

In the epidermal proliferation unit concept of stem cell behaviour, the division of basal cells has been viewed as a symmetrical process in which equal daughter cells are generated; the basal cells progressively reduce their adhesiveness to the underlying epidermal basement membrane, delaminate and commit to terminal differentiation (Fig. 3.8).

However, recent data suggest that basal cells can also undergo asymmetrical cell division, shifting their spindle orientation from lateral to perpendicular [5]. Asymmetrical cell divisions provide a natural means of maintaining a proliferative daughter cell that retains the cell markers associated with stem cells, while the other daughter cell has reduced markers such as β1 integrin, increased expression of Notch signals, and is committed to terminal differentiation. Asymmetrical cell divisions, therefore, can bypass the need for transient amplifying cells.

The structural and biological composition of the dermal–epidermal junction also influences the proliferative properties of basal keratinocytes. Laminin-332 promotes anchorage as a ligand via α6β4 integrins in hemidesmosomes and signalling/migration via its association with α3β1 in focal adhesions. Signalling via α3β1 integrin stimulates the MAP-kinase pathway, turnover of focal adhesions and epidermal migration. The basement membrane is also a reservoir for growth factors that can promote epidermal proliferation (e.g. TGF-α, EGFs and insulin growth factors) or restrict it (e.g. TGF-β). EGFR signalling also enhances proliferation and migration in the epidermis, possibly by phosphorylating β4 integrin and promoting hemidesmosome disassembly. Thus the control of basal keratinocyte stem cell activity in maintaining homeostasis and responding to injury is through the regulation of at least two opposing tyrosine kinase pathways and two integrin structures.

A key transcription factor in regulating the self-renewal and long-term proliferative capacity of the stem cell is p63, a member of the p53 family of proto-oncogenes. However, the precise role of p63 is not clear; it may have a direct effect on stem-cell renewal, or lineage commitment, and/or an effect on switching from proliferation to terminal differentiation [6]. Notch signalling also appears to have an important gatekeeper function in the transition

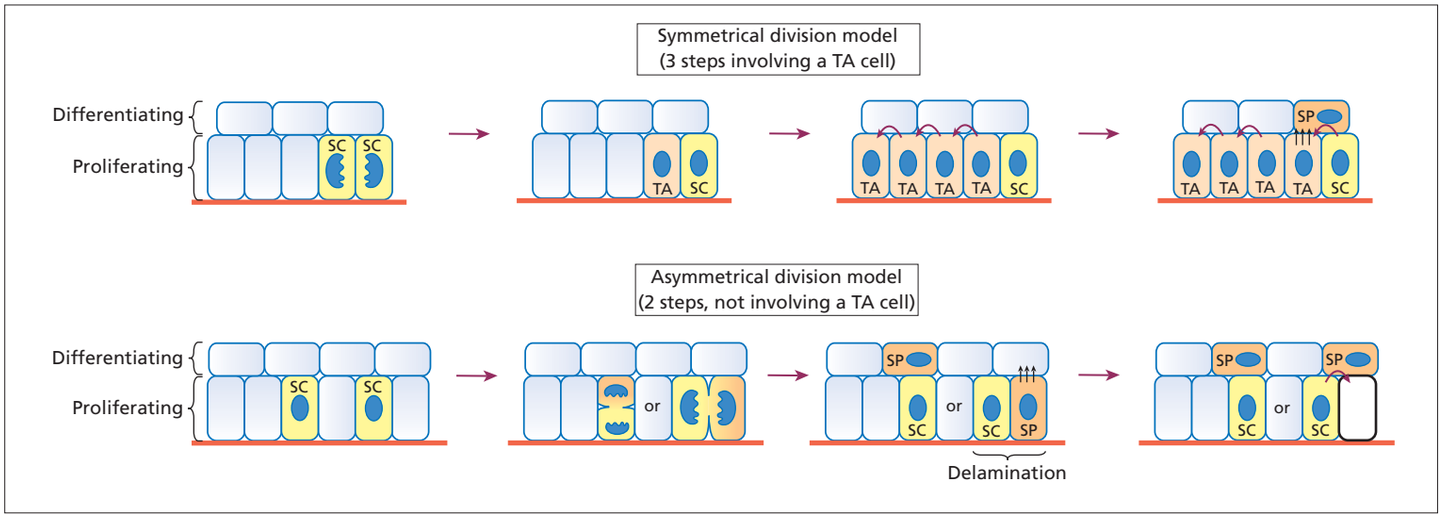

Fig. 3.8 Possible mechanisms for the proliferative potential of stem cells (SC) in the basal keratinocyte layer. In the symmetrical division model, two stem cells are produced. Some of these cells in contact with the epidermal basement membrane are transit-amplifying cells (TA). These cells are capable of dividing four to five times before leaving the basal layer (delamination, black arrows) to become a spinous layer cell (SP) and entering terminal differentiation. In the asymmetrical division model, there is preferential partitioning of proliferation-associated factors into the stem cell daughter cell and, conversely, preferential partitioning of differentiation-inducing components into the daughter cell that is destined to become a spinous layer cell. Depending on the orientation of the cell spindle, the daughter cell destined for differentiation can either become a spinous layer cell directly or delaminate from the basal layer to enter terminal differentiation. *In vivo*, both mechanisms may exist.

from basal to suprabasal cells; there is basal expression of Notch ligands such as Delta1 and suprabasal expression of Notch receptors and Notch downstream targets such as Hes1 [7].

Stem cells in hair follicles are located in the lowest permanent part of the follicle, within the outer root sheath. These cells cycle more slowly than other cells and have the capacity to migrate (e.g. to the base of the hair follicle in follicular regeneration), as well as to differentiate into diverse lineages (e.g. outer root sheath, inner root sheath, hair shaft, sebocytes and interfollicular epidermis). Despite this multipotency, however, the follicle stem cells only function in pilosebaceous unit homeostasis and do not contribute to interfolliclular epidermis unless the skin is wounded [8].

Hair follicles undergo cycles of degeneration and regeneration throughout life. During the growth phase (anagen), which requires activation of hair follicle stem cells, matrix cells proliferate rapidly but then undergo sudden apoptosis (catagen). The hair bulb and root shrivel to form an epithelial strand which forces the dermal papilla to rest at the base of the non-cycling part of the hair follicle [9]. The hairs then enter a resting phase (telogen). At a molecular level, inhibition of BMP signalling and activation of Wnt signalling converge to regulate stem cell activation. From microarray studies, *Sox9*, *Tcf3* and *Lhx2* appear to be markers of follicular stem cells whether they are quiescent or proliferative.

Apart from stem cells in the hair follicles and interfollicular epidermis, other cells in the dermis and subcutis may have stem cell properties. These include cells that have been termed skin-derived precursors (SKPs), which can differentiate into both neural and mesodermal progeny [10]. In addition, a subset of dermal fibroblasts can have adipogenic, osteogenic, chondrogenic, neurogenic and hepatogenic differentiation potential [11]. Moreover, dermal fibroblasts can be reprogrammed into cells bearing an embryonic stem cell (pluripotent) phenotype by the insertion of just four key transcription factors, *Oct4*, *Sox2*, *Klf4* and *Myc* [12].

Epidermal and adnexal structures

The normal epidermis is a terminally differentiated, stratified, squamous epithelium. The major cell, making up 95% of the total,

is the *keratinocyte*, which moves progressively from attachment to the epidermal basement membrane towards the skin surface, forming several well-defined layers during its transit [1]. Thus, on simple morphological grounds, the epidermis can be divided into four distinct layers: *stratum basale* or *stratum germinativum*, *stratum spinosum*, *stratum granulosum* and *stratum corneum*. The term *Malpighian* layer includes both the basal and spinous cells. Other cells within the epidermis include melanocytes, Langerhans' cells and Merkel cells (Fig. 3.9).

The stratum basale is a continuous layer that is generally only one cell thick but it may be two to three cells thick in glabrous skin and in hyperproliferative epidermis. The basal cells are small and cuboidal (10–14 nm in diameter) and have large, dark-staining nuclei, and dense cytoplasm which contains many ribosomes and dense tonofilament bundles. Immediately above the basal cell layer, the epibasal keratinocytes enlarge to form the spinous/prickle-cell layer or *stratum spinosum* (Fig. 3.10).

Fig. 3.9 Photomicrograph of a 1-μm-thick plastic section of normal human skin. The tissue was fixed with half-strength Karnovsky's medium and embedded in Epon. This technique allows the cellular components of the epidermis, including keratinocytes, melanocytes (straight arrows) and probable Langerhans' cells (curved arrows) to be clearly resolved. × 400. Basic fuchsin and methylene blue.

The stratum spinosum is succeeded by the *stratum granulosum* or granular layer, which contains intracellular granules of keratohyalin. At high magnification, the dense mass of keratohyalin granules from human epidermis has a particulate substructure, with particles of irregular shape, on average 2 nm in length, and occurring randomly in rows or lattices. The cytoplasm of cells of the upper, spinous layer and granular cell layer also contains smaller lamellated granules averaging 100–300 nm in size, which are known as lamellar granules or bodies, membrane-coating granules or Odland bodies. These are numerous within the uppermost cells of the spinous layer and migrate towards the periphery of the cells as they enter the granular cell layer (Fig. 3.11). They discharge their lipid components into the intercellular space, playing important roles in barrier function and intercellular cohesion within the stratum corneum [2].

The outermost layer of epidermis is the stratum corneum where cells (now corneocytes) have lost nuclei and cytoplasmic organelles. The cells become flattened and the keratin filaments align into disulphide cross-linked macrofibres, under the influence of *filaggrin*, the protein component of the keratohyalin granule, responsible for keratin filament aggregation. The key role of filaggrin in skin biology has been demonstrated by the discovery of very common loss-of-function mutations in the filaggrin gene as the cause of the genetic disorder ichthyosis vulgaris and as a major risk factor for the development of atopic dermatitis, atopic asthma and systemic allergies [3]. The corneocyte has a highly insoluble, cornified envelope within the plasma membrane, formed by cross-linking of the soluble protein precursor, *involucrin*, following the action of a specific epidermal transglutaminase also synthesized in the high stratum spinosum (Fig. 3.12).

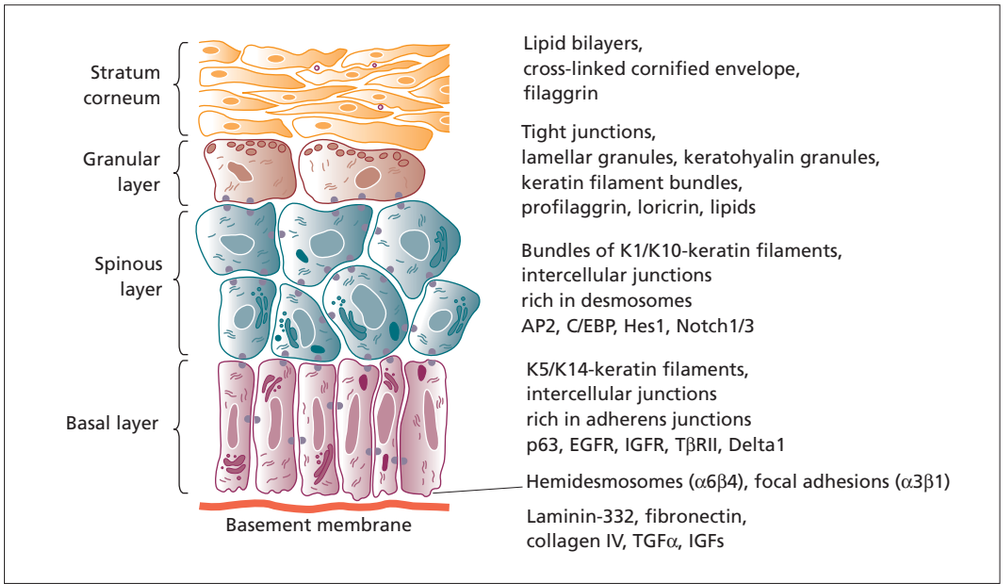

Fig. 3.10 The process of epidermal differentiation is associated with expression of different structures, macromolecules, transcription factors and other signalling molecules and their receptors in the different keratinocyte layers.

The process of desquamation involves degradation of the lamellated lipid in the intercellular spaces and loss of the residual intercellular desmosomal interconnections [4]. In palmoplantar skin there is an additional zone, also electron-lucent, the *stratum lucidum*, between the granulosum and corneum. These cells are still nucleated, and may be referred to as 'transitional' cells.

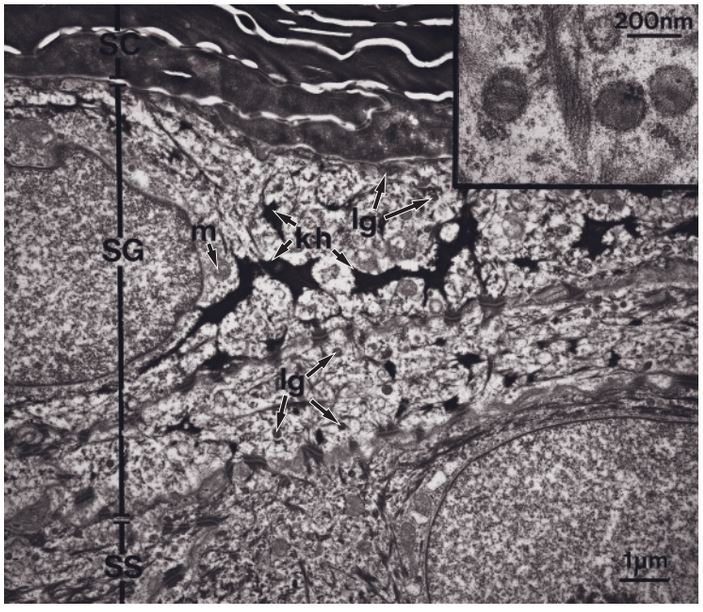

Fig. 3.11 Electron micrograph showing details of upper part of epidermis including stratum corneum (SC), stratum granulosum (SG) and the most superficial cell layer of stratum spinosum (SS). Note the irregularly shaped keratohyalin granules (kh) and the small, round lamellar granules (lg). The latter are present in both SS and SG and are smaller than mitochondria (m). Inset shows details of lamellar granules. Scale bar = 1 μm.

Keratinocytes

The filamentous cytoskeleton of all mammalian cells, including epidermal keratinocytes, comprises: actin, containing microfilaments approximately 7 nm in diameter; tubulin, containing microtubules 20–25 nm in diameter; and filaments of intermediate size, 7–10 nm in diameter, known as intermediate filaments. There are six types of intermediate filaments: keratins in epithelial cells; vimentin within mesenchymal cells; glial filament acidic protein (GFAP) in glial cells; neurofilaments in neurones; desmin in muscle cells; and peripherin in peripheral nerves. The nuclear matrix proteins, nuclear lamins A, B and C, are also intermediate filaments. The polypeptide building blocks of all intermediate filaments have a similar backbone structure of a classical α-helical region with heptad repeats, having four separate helical zones with interhelical linker sequences, and non-helical carboxy- and amino-terminals. There are 70 intermediate filament genes (including those encoding keratins, desmins, and lamins), which are now known to be associated with at least 72 distinct human diseases, including skin blistering, muscular dystrophy, cardiomyopathy, premature ageing syndromes, neurodegenerative disorders and cataract [1].

The human genome possesses 54 functional keratin genes located in two compact gene clusters, as well as many non-functional pseudogenes, scattered around the genome [2]. Keratin genes are very specific in their expression patterns. Each one of the many highly specialized epithelial tissues has its own profile

of keratin gene expression. Hair and nails express modified keratins, containing large amounts of the amino acid cysteine which forms numerous chemical cross-links to further strengthen the cytoskeleton. The genes encoding individual keratins fall into two gene families: type I (basic) and type II (acidic). Mapping the tissue distribution of keratins shows coexpression of particular acidic–basic pairs in a cell- and tissue-specific manner. Heterodimers are assembled into higher-order protofibrils and protofilaments by an antiparallel stagger of some complexity.

Simple epithelia are characterized by the keratin pair K8/K18, and the stratified squamous epithelia by K5/K14 (Fig. 3.13). In addition, stratified squamous epithelia express up to four other keratin pairs during epithelial differentiation. In skin, suprabasal keratins K1/K10 are characteristic of epidermal differentiation. In the stratum granulosum, release of filaggrin from the keratohyalin granules forms macrofibres. Retinoid levels, growth factors and hormones may regulate keratin gene expression. Mesenchymal signals may also direct or permit intrinsic patterns of keratinocyte differentiation. K15 is expressed in basal keratinocytes of the hair-follicle bulge region at the site of pluripotential stem cells. K9 and K2e expression is site restricted in skin: K9 to palmoplantar epidermis and K2e to superficial interfollicular epidermis. Apart from their structural properties, keratins may also have direct roles in cell signalling, the stress response and apoptosis [3]. In epidermal hyperproliferation, as in wound healing and psoriasis, expression of suprabasal keratins K6/K16/K17 is rapidly induced.

Currently, 21 of the 54 known keratin genes have been linked to monogenic genetic disorders, and some have been implicated in more complex traits, such as idiopathic liver disease or inflammatory bowel disease [4]. The first genetic disorder of keratin to be described was epidermolysis bullosa simplex, which involves mutations in the genes encoding K5 or K14. About half of the keratin genes are expressed in the hair follicle, and mutations in these genes may underlie cases of monilethrix as well as hair and nail ectodermal dysplasias [5].

Skin barrier

One of the key functions of the epidermis is to form a barrier against the external environment. To that end, terminal differentiation of keratinocytes leads to formation of the cornified cell envelope. The cornified envelope is rendered highly insoluble by the formation of glutamyl-lysyl isodipeptide bonds between envelope proteins, catalysed by transglutaminases [1]. There are at least three distinct transglutaminases, but TG1 (keratinocyte transglutaminase) can cross-link envelope proteins in the absence of other enzymes. Mutations in TG1 underlie some cases of lamellar ichthyosis or non-bullous congenital ichthyosiform erthroderma; mutations in TG5 result in autosomal recessive skin peeling syndrome [2,3]. Several different proteins contribute to the cornified envelope (Fig. 3.14).

Involucrin is the best-established envelope precursor although it is also a marker of differentiation in epithelia such as cornea. Other cytosolic envelope precursors include the family of small proline-rich proteins (SPR1) including *cornifin* or SPR1 and *pancornulins*. Other envelope proteins include *SKALP/elafin* and *keratolinin/cystatin*, a 36-kDa protein cross-linked by transglutaminase into a 150-kDa multimer.

Some precursors of the cornified envelope are delivered by granules. Small, smooth, sulphur-rich L granules contain the cysteine-rich protein *loricrin*, and accumulate in the stratum granulosum [4]. Loricrin is the major component of the cornified envelope. Expression of loricrin depends on a high calcium concentration and is down-regulated by retinoids. Profilaggrin in F granules may make a minor contribution to the envelope. Membrane-associated proteins that contribute to the cornified envelope include the plakin family members, periplakin, envoplakin, epiplakin, desmoplakin as well as plectin.

Formation of the cornified cell envelope is triggered by a rise in intracellular calcium levels [5]. This leads to cross-link formation between plakins and involucrin catalysed by transglutaminase. Other desmosomal proteins are then also cross-linked, forming a scaffold along the entire inner surface of the plasma membrane. Ceramides from the secreted contents of lamellar bodies are then esterified onto glutamine residues of the scaffold proteins. The cornified cell envelope is reinforced by the addition of a variable amount of SPRs, repetin, trichohyalin, cystostatin α, elafin and LEP/XP-5 (skin-specific protein). Although most desmosomal components are degraded, keratin intermediate filaments (mostly

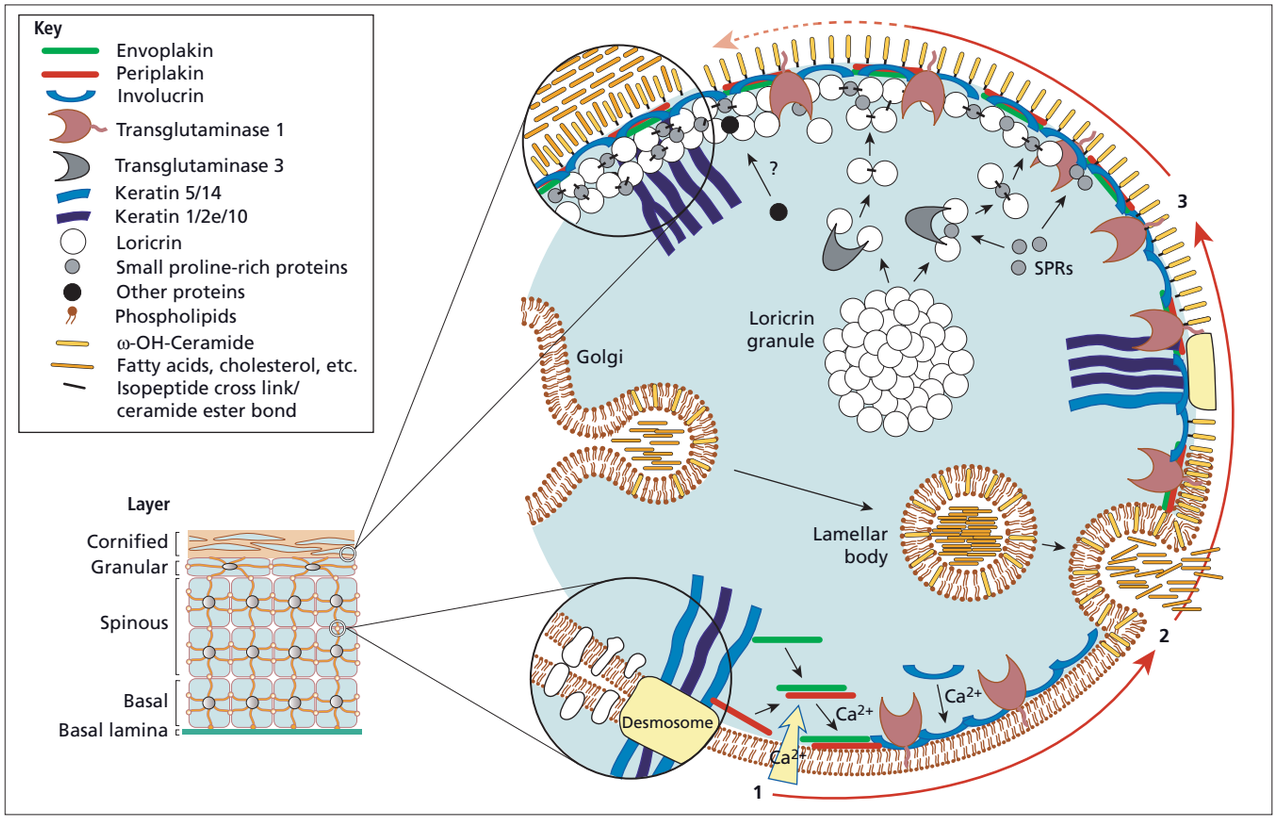

Fig. 3.14 Assembly of the epidermal cornified cell envelope. In response to increasing intracellular calcium, an internal scaffold of desmosomal proteins is made along the plasma membrane. The contents of lamellar bodies (ceramides and other fatty acids, cholesterol and cholesterol esters) are released into the extracellular milieu to form a lipid membrane. The developing envelope is then added to and reinforced by recruitment of various proteins, including loricrin, small proline-rich proteins (SPR1), other desmosomal remnants and attached keratin filaments. The resulting cornified cell envelope is durable and flexible and provides important mechanical and barrier functions.

K1, K10 and K2e) may be cross-linked to desmoplakin and envoplakin remnants. Together these assembly and degradation events result in durable, flexible but dead cells that have vital mechanical and water-permeability barrier functions.

During epidermal differentiation, there are profound changes in the composition of lipids; in the viable layers phospholipids, cholesterol and triglycerides predominate, but in the upper stratum spinosum and stratum granulosum lipid is synthesized and packaged into lamellated, membrane-bound organelles known as *membrane-coating granules*, lamellar granules or Odland bodies [6]. They are found adjacent to the cell membrane with alternating thick and thin dense lines separated by lighter lamellae of equal width, consistent with packing of flattened discs within a membrane boundary. Immunochemistry has confirmed the presence of phospholipids, glycolipids and free sterols. The organelles move towards the plasma membrane as the cells move through the granular layer and cluster at the cell membrane. They fuse with the plasma membrane, dispersing their contents into the intercellular space. Polar lipids from the lamellar granules are remodelled into neutral lipids in the intercellular space between corneocytes, forming an important barrier to permeability. The lamellar granules also contain hydrolytic enzymes, lipases and glycosidases, which are responsible for this remodelling. Thus, the stratum corneum is rich in ceramides, free sterols and free fatty acids. Linoleate appears to be essential for proper barrier function as an ester-linked residue in acyl ceramides; thus, in essential fatty acid deficiency, substitution of this linoleate by oleate causes a defect in barrier function. The skin is an active lipid-synthesizing tissue, with a daily production rate of 100 mg/day.

In human epidermis, nearly all sterol is present as cholesterol. In many cells, cholesterol biosynthesis may be modulated by uptake of exogenous cholesterol, mediated by low-density lipoprotein (LDL) receptors, but these are only present on the plasma membrane of basal keratinocytes, and are rapidly down-regulated on epidermal differentiation. Sterol synthesis is higher in the stratum granulosum, and is thus relatively autonomous and uninfluenced by dietary or circulating sterol levels. Cholesterol sulphate is highest in the stratum granulosum and corneum, where it is thought to play a role in cell cohesion. In X-linked recessive ichthyosis due to steroid sulphatase deficiency, scales contain high levels of cholesterol sulphate giving increased intercellular adhesion.

Eccrine and apocrine glands

Human sweat glands are generally divided into two types: apocrine and eccrine [1]. The eccrine gland is the primary gland responsible for thermoregulatory sweating in humans. Eccrine sweat glands are distributed over nearly the entire body surface. Sweat glands become identifiable in the palms and soles in the 16th fetal week, and in the rest of the body from the 22nd week onwards. The number of sweat glands in humans varies greatly, ranging from 1.6 to 4.0 million. The structure of the eccrine sweat gland consists of a bulbous secretory coil leading to a duct. The secretory coil is located in the lower dermis, and the duct extends through the dermis and opens directly onto the skin surface. The active sweat glands are present most densely on the sole, forehead and palm, somewhat less on the back of the hand, still less on the lumbar region, and the lateral and extensor surfaces of the extremities, and least on the trunk and the flexor and medial surfaces of the extremities. The uncoiled dimension of the secretory portion of the gland is approximately 30–50 μm in diameter and 2–5 mm in length. The size of the adult secretory coil ranges from 1 to 8×10^{-3} mm^3.

Human perspiration is classified into two types: insensible perspiration and active sweating. Insensible perspiration involves water loss from the respiratory passages, the skin and gaseous exchanges in the lungs. In the skin, the epidermis is supplied with water originating from blood in the skin microcirculation and interstitial spaces so that water can evaporate from its dry surface. Thus, the evaporation of water from the skin may depend on several environmental factors, such as ambient temperature and ambient humidity. Heat, mental stimuli, muscular exercise and carbon dioxide can all induce active sweating in human beings. Active sweating may be classified into two types: thermal and mental/emotional. Thermal sweating plays an important role in keeping the body's temperature constant and involves the whole body surface [2]. Mental or emotional sweating usually appears on the palms and soles. The physiological features of mental sweating differ considerably from those of thermal sweating. Mental sweating has a shorter latent period for its onset and immediately attains a certain rate of secretion that corresponds to the intensity of stimulation, remaining for the duration of the stimulation and subsiding quickly after it ends. Eccrine glands contribute to both types of sweating.

The secretory nerve fibres innervated in human sweat glands are sympathetic, which seem to be cholinergic in character as sweating is produced by pilocarpine and stopped by atropine [3]. Vasoactive intestinal peptide (VIP) coexisting in the cholinergic nerve fibres has been suggested as a candidate neurotransmitter that may control the blood circulation of the sweat glands. The sudorific nervous system is also separated into parts for thermal and emotional sweating, each being controlled by its own regulatory centre in the brain which is associated with the sweat glands in its respective region of the skin. The exact neurological pathways responsible for sweating are not entirely understood. Evidence from animal studies suggests that efferent signals from the preoptic hypothalamus travel via the tegmentum of the pons and the medullary raphe regions to the intermediolateral cell column of the spinal cord. From here, neurones emerge via the ventral horn, pass through the white ramus communicans, and then synapse in the sympathetic ganglia. Postganglionic nonmyelinated C fibres pass through the grey ramus communicans, combine with peripheral nerves and travel to sweat glands. Sympathetic nerve terminals cluster mainly around the secretory coil of the sweat gland, but a few projections extend to the sweat duct. Acetylcholine is the primary neurotransmitter released from cholinergic sudomotor nerves and binds to muscarinic receptors on the eccrine sweat gland, although sweating can also occur via exogenous administration of α- or β-adrenergic agonists. Released acetylcholine is rapidly hydrolysed by acetylcholinesterase, and this response may be one of a number of mechanisms by which the rate of sweating rate is regulated.

When acetylcholine binds to muscarinic receptors on the sweat gland, intracellular Ca^{2+} concentrations increase. This results in an increase in the permeability of K^+ and Cl^- channels, which initiates the release of an isotonic precursor fluid from the secretory cells [4]. This precursor fluid is similar to plasma but is devoid of proteins. As the fluid travels up the duct toward the surface of the skin, sodium and chloride are reabsorbed, resulting in sweat on the surface being hypotonic relative to plasma. When the rate of sweat production increases, however, for example during exercise or heat stress, ion reabsorption mechanisms can be overwhelmed due to the large quantity of sweat secreted into the duct, resulting in higher ion losses. The sodium content in sweat on the skin's surface, therefore, is greatly influenced by sweat rate.

Apart from eccrine glands, the skin also contains apocrine sweat glands [5]. Eccrine glands do not show cytological changes during secretion whereas apocrine glands are characterized by decapitation secretion, in which part of the cell is pinched off and released into the lumen. Apocrine glands are located only in genital, axillary and mammary areas, where they are always connected to a hair follicle. Apocrine glands have a low secretory output, and hence no significant role in thermoregulation. They are composed of a coiled secretory portion and an excretory duct. The inner layer of the secretory portion contains a single columnar secretory cell type containing numerous, large dense granules located at the apical aspect, which contribute to the lipid-rich secretion produced. The inner layer is also surrounded by a fenestrated layer of myoepithelial cells but the lumen is generally larger in diameter than that present in eccrine tissue. The apocrine excretory duct does not have any known reabsorptive function and consists of a double layer of cuboidal cells that merge distally with the epithelium of the hair follicle, resulting in emptying of the secretion into the hair follicle. The exact role of apocrine glands in humans is unknown. A third type of intermediate sweat glands, the apoeccrine glands, has also been described in axillary skin but their existence is not universally accepted.

Pilosebaceous unit

The pilosebaceous units develop from epidermal downgrowths under the influence of specific mesenchymal cell condensations between the 10th and 14th week estimated gestational age. They have complex groups of specialized cell layers with distinctive pathways of differentiation. There are four classes of pilosebaceous unit: terminal on the scalp and beard; apopilosebaceous in axilla and groin; vellus on the majority of skin; and sebaceous on the chest, back and face. The dermal papilla is located at the base of the hair follicle with a rich extracellular matrix. Around the papilla are germinative (matrix) cells that have a very high rate of division, and give rise to spindle-shaped central cortex cells of the hair fibre, and the single outer layer of flattened, overlapping cuticle cells. A central medulla is seen in some hairs, with regularly stacked, condensed cells interspersed with air spaces or low-density cores. The cortical cells are filled with keratin intermediate filaments orientated along the long axis of the cell, interspersed with a dense interfilamentous protein matrix. Terminal differentiation of cortical cells is associated with the appearance of a contiguous, laminated, intercellular layer, which appears critical for filament integrity. The cuticular cells are morphologically distinct; these are flattened, outward-facing cells, with three layers inside the cuticle of condensed, flattened protein granules: endocuticle, exocuticle and 'a' layer [1].

Around the cuticle is the inner root sheath (IRS), which is composed of three distinct layers of cells that undergo keratinization: the IRS cuticle, the Huxley layer and the outermost Henle layer [2]. Differentiation in the IRS involves the development of trichohyalin granules, with 8 to 10-nm filaments orientated in the direction of hair growth. The IRS moves up the follicle, forming a support for the hair fibre, and degenerates above the sebaceous gland. The outermost layer is the outer root sheath (ORS), which is continuous with the epidermis and expresses epithelial keratins, K5/K14, K1/K10 and K6/K16 in the upper ORS and K5/K14/K17 in the deeper ORS.

Normal growth of the hair fibre is 300–400 µm/day, generated by the high rate of proliferation of progenitor cells in the follicle bulb. Compartmentalization within the bulb gives rise to the different layers within the follicle, with the majority of bulb cells forming the IRS. There are three phases of cyclical hair growth: anagen, when growth occurs; catagen, a regressing phase; and telogen, a resting phase (Fig. 3.15). The follicle re-enters anagen, and the old hair is replaced by a new one.

Immediately above the basal layer in the hair bulb, cells undergo a secondary pathway of 'trichocyte' or hair differentiation, and express a further complex group of keratins, the hard keratins [3]. Two families of hair keratins, types I and II, are present in mammals, which have distinctive amino- and carboxyterminals with high levels of cysteine residues, and lack the extended glycine

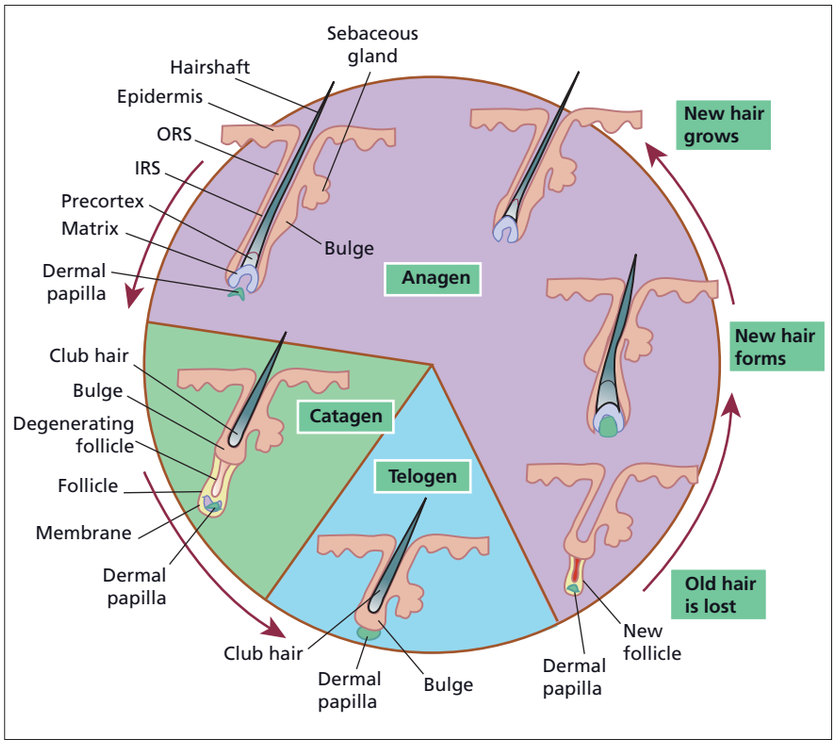

Fig. 3.15 The hair cycle. There are three components to the hair cycle: anagen (where new hair forms and grows), followed by catagen (regressing phase) and telogen (resting phase), and then loss of old hair. The hair cycle is associated with discrete changes in hair follicle anatomy, both in the shape of the follicle and in the subjacent dermal papilla. IRS, inner root sheath; ORS, outer root sheath.

residues of epidermal keratins. The proteins differ from epithelial keratins in their positions on two-dimensional gels but they can be grouped into acidic and basic families; there are four major proteins in each of these families and several minor proteins, Ha 1–4 and Hb 1–4. Recent cloning of the hair keratin genes, which cluster on chromosomes 12 and 17, has shown a greater number of hair keratin genes, *HaKRT1–6* (including 3.1 and 3.2) and *HbKRT1–6*. Mutations in hair keratin genes have been found to be causative for autosomal dominant forms of the human disease monilethrix. In addition, keratin 17 null mice also demonstrate varying degrees of alopecia, depending on the age and strain of the mice.

Over the last decade, several naturally occurring, human inherited disorders of hair have provided fascinating insight into hair development and growth. These include key signalling molecules such as ectodysplasin, as well as transcription factors, including hairless and the vitamin D receptor, structural hair keratins, desmosomal proteins, a G protein-coupled receptor, a serine protease and a copper transporter [4]. More common hair variants, such as curly hair, may be explained by dynamic changes during hair growth [5]. Curvature of curly hair is programmed from the very basal area of the follicle and the bending process is linked to a lack of axial symmetry in the lower part of the bulb, affecting the connective tissue sheath, ORS, IRS and the hair shaft cuticle.

Nails

The main purpose of the nail apparatus is to provide protection to the digit tips, enhance sensory discrimination, help increase dexterity, facilitate scratching or grooming, and, in some individuals, to function as a cosmetic accessory [1]. The earliest signs of finer nail development occur at 8–9 weeks' gestation: there is an invagination of the primitive epidermis to form an uninterrupted groove delineating a flattened surface at the end of each digit, known as the nail field. A key transcription factor in nail initiation is R-spondin 4, mutations in which underlie congenital anonychia [2]. A group of cells from the proximal part of the nail fold then grows proximally into the digit, stopping approximately 1 mm from the phalanx and giving rise to the matrix primordium. This site will eventually contribute to the epithelium of the proximal nail fold as well as the distal and intermediate matrix epithelium. From the distal part of the nail fold, a visible mound of cells emerges on the dorsum of the distal tip of each digit, which is known as the distal ridge [3]. At 13 weeks' gestation, the proximal nail fold is formed and the first signs of nail plate growth are observed from the lunula. At this stage, the stratum corneum and the stratum granulosum start to materialize from the nail field epithelium, beginning distally and advancing toward the proximal nail fold. At 18 weeks' gestation, the granular layer recedes, and the nail bed epithelium takes on a postnatal appearance. Likewise, at 20 weeks' gestation, the process of cellular differentiation and maturation within the matrix is similar to that seen in adult nails. By 32 weeks' gestation, virtually all the components of the nail can be recognized. Toe nail development is similar to that of finger nails but the stages occur about 4 weeks later.

The nail unit is comprised of the nail plate and four epithelial structures: the proximal nail fold, the matrix, the nail bed and the hyponychium [4] (Fig. 3.16). The nail plate is a rectangular, translucent and relatively inflexible structure, and contains calcium, phosphate, iron, zinc, manganese and copper, but it is mainly sulphur within the nail matrix that is responsible for the nail plate's physical qualities. The nail plate arises from beneath the proximal nail fold and is bordered on both sides by the lateral nail folds. The proximal aspect may contain white semicircular areas called lunulae, which are the visible portions of the distal matrix [5]. The dorsal surface of the nail unit appears pink in colour because of the enhanced vasculature of the underlying nail bed. The proximal nail fold has a dorsal and a ventral epithelial surface. It is a continuation of the skin of each digit (the dorsal surface) that folds underneath itself, resting above the nail matrix (the ventral surface). The dorsal proximal nail fold is devoid of hair follicles, sebaceous glands and dermatoglyphic markings and the ventral proximal nail fold also lacks rete ridges. At the junction between the dorsal and ventral surfaces is the eponychium (cuticle) which protects the matrix from damage. The lateral nail folds are extensions of the skin surface of the sides of the digits and join the nail bed medially.

The nail matrix forms the nail plate and is divided into three regions: the dorsal section of the matrix contributes to the most

superficial layers of the nail plate whereas the intermediate region of the matrix forms the deeper layers. The ventral subdivision is the most distal part of the nail matrix. The nail bed is the area underneath the nail plate (between the lunula and the hyponychium). It has a role in forming the deeper layers of the nail plate, as its thin epidermal layer represents the ventral portion of the nail matrix. The hyponychium is located underneath the free edge of the nail plate and denotes the transition of the nail bed to the normal epidermis of the fingers and toes. There is also part of the hyponychium, known as the onychodermal band, that reflects on to the ventral surface of the nail plate to protect the nail parenchyma from trauma.

The epithelium of the matrix is composed of at least two to three actively dividing, basal keratinocyte layers. These cuboidal cells have their vertical axes aligned in a diagonal manner, which allows the nail plate to develop in an upward and outward direction. As these cells differentiate and migrate they become flatter, losing their nuclei and becoming integrated into the developing nail plate as onychocytes, or nail plate cells. This process of cellular maturation is similar to stratum corneum formation within the epidermis but does not require keratohyalin. The matrix also contains melanocytes, which pigment surrounding keratinocytes and manifest as longitudinal bands across the nail plate; this may be a common racial variant in darker-skinned individuals. The nail bed is composed of a thin epidermal layer and a dermal layer, but there is no subcutaneous fat. As the epidermis is thin, the differentiation of keratinocytes to onychocytes occurs within one to two cell layers. The epidermis of the nail bed also contains parallel longitudinal ridges from the lunula to the hyponychium. These ridges interlock to provide strong binding between the nail bed and the nail plate. The dermal layer of the nail bed contains blood vessels to supply the nail unit, as well as lymphatics. Trauma to these vessels results in splinter haemorrhages.

Merkel cells

Merkel first gave the name *tastzellen* to certain cells that he found near the base of the rete-peg in the snout skin of the mole. As there were intraepidermal neurites with expanded tips (Merkel discs) adjacent to them, he believed them to be transducers of physical stimuli. Merkel cells are post-mitotic cells scattered throughout the epidermis of vertebrates and constitute 0.2–5% of epidermal cells [1]. They are located amongst basal keratinocytes and are mainly found in hairy skin, tactile areas of glabrous skin, taste buds, the anal canal, labial epithelium and eccrine sweat glands (Fig. 3.17).

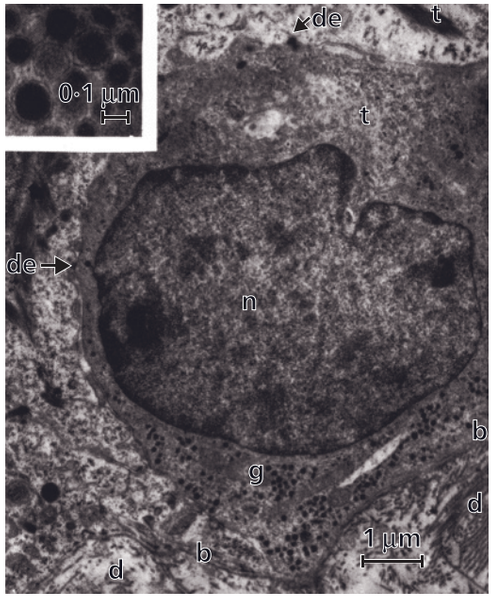

Fig. 3.17 Merkel cell in human epidermis. The dermis (d) with collagen fibres is seen in the lower part of the picture; b, basement membrane; de, desmosomes making connections with adjacent basal keratinocyte; g, spherical granules (see inset); n, nucleus of Merkel cell; t, tonofilaments. (Courtesy of Professor A.S. Breathnach, St John's Institute of Dermatology, King's College London,UK.)

Sun-exposed skin may contain twice as many Merkel cells as non-sun-exposed skin. They form close connections with sensory nerve endings and secrete or express a number of peptides. Human Merkel cells express immunoreactivity for various neuropeptides including *Met*-enkephalin and vasoactive intestinal polypeptide, in addition to neurone-specific enolase and synaptophysin-like and pancreastatin-like material. They also contain chromogranin A [2].

Merkel cells are easily identifiable on transmission electron microscopy. They are oval with a long axis of approximately 15 µm, orientated parallel to the basement membrane. They also have a large bilobed nucleus and clear cytoplasm, which reflects a relative scarcity of intracellular organelles. Merkel cells contain numerous neurosecretory granules, each 50–160 nm across; these are found opposing the junctions with the sensory nerve endings. The close contact between Merkel cells and nerve fibres represents a Merkel cell–neurite complex, but there is no clear evidence of synaptic transmission, although numerous vesicles can be identified in neurones apposed to Merkel cells [3].

Human skin contains an extensive neural network that consists of cholinergic and adrenergic nerves and myelinated and unmyelinated sensory fibres. The skin also contains several transducers involved in the perception of touch, pressure and vibration, including Ruffini organs surrounding hair follicles, Meissner's corpuscles, Vater–Pacini corpuscles located in the deep layer of the dermis, and nerve endings which pass through the epidermal basement membrane. Some of these contain Merkel cells, which form the Merkel cell–neurite complex, while others are free nerve endings. The cell bodies for all these neurones reside in the dorsal root ganglion. The Merkel cell–neurite complexes are thought to

serve as mechanoreceptors and to be responsible for the sensation of touch.

In glabrous skin, the density of Merkel cells is approximately 50 per mm^2. They are clustered near unmyelinated sensory nerve endings, where they group and form 'touch spots' at the bottom of rete ridges. These complexes are also known as hair discs, touch domes, touch corpuscles or Iggo discs. The complex is innervated by a single, slowly adapting type 1 nerve fibre. In hairy skin, Merkel cells also cluster in the rete ridges and in the outer root sheath of the hair follicle where the arrector pili muscles attach. The function of Merkel cells in hair follicles is unclear, although they may be involved in the induction of new anagen cycles.

There are two hypotheses for the origin of Merkel cells: one possibility is that they differentiate from epidermal keratinocyte-like cells and the other is that they arise from stem cells of neural crest origin that migrated during embryogenesis, in similar fashion to melanocytes [4]. A unifying view, however, could be that there is very early migration of the Merkel cells from the neural crest and population of the epidermis during the sixth or seventh embryonic week in humans and that these cells subsequently only undergo further differentiation once in the epidermis.

Circulating autoantibodies against Merkel cells have been described in pemphigus and graft-versus-host disease. Merkel cells are absent in vitiligo lesions, in keeping with an autoimmune destruction or neural involvement. Merkel cell hyperplasia is a common histological finding and may accompany keratinocyte hyperproliferation as well as being frequently seen in adnexal tumours such as naevus sebaceus, trichoblastomas, trichoepitheliomas and nodular hidradenomas [5]. Merkel cell hyperplasia is associated with hyperplasia of nerve endings that occurs in neurofibromas, neurilemmomas, nodular prurigo or neurodermatitis. It is not clear whether Merkel cell carcinoma originates from Merkel cell or their precursors but the latter may be more likely given that many dermal Merkel cell carcinomas do not connect with the epidermis.

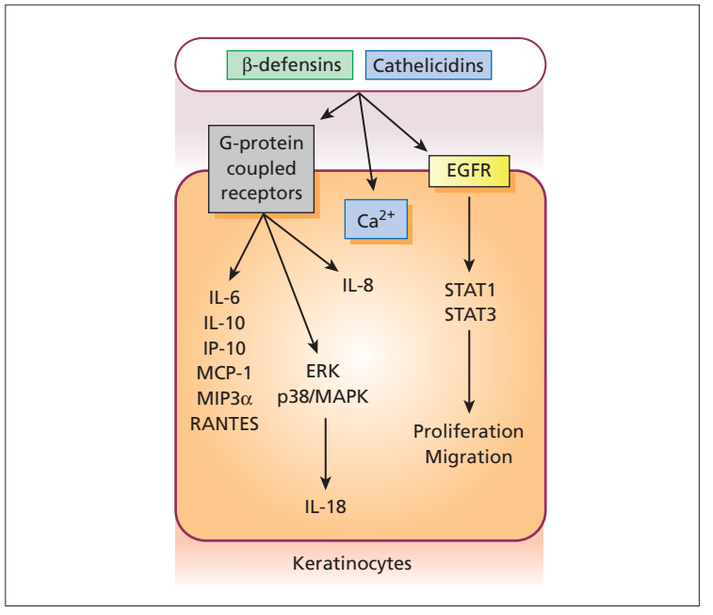

Fig. 3.18 As part of the innate immune defence system, antimicrobial peptides can stimulate G-protein coupled receptors to induce cytokine and chemokine release from keratinocytes as well as epidermal growth factor receptor (EGFR) signalling to influence cell proliferation and migration.

Skin as an immune system

Innate immunity

The skin continuously encounters microbial pathogens and to defend against this cells within the epidermis and dermis have evolved several innate strategies to prevent infection. One of the primary mechanisms used by the skin in the early stages of immune defence is the synthesis, expression and release of antimicrobial peptides [1]. There are more than 20 antimicrobial peptides in the skin, including cathelicidins, β-defensins, substance P, RANTES, RNase 2,3,7 and S100A7 (Fig. 3.18).

Many peptides have antimicrobial action against bacteria, viruses and fungi. The antimicrobial activity of most peptides occurs as a result of unique structural characteristics that enable them to disrupt the microbial membrane while leaving human cell membranes intact. Some may play a specific role against certain microbes in normal skin, whereas others act only when the skin is injured and the physical barrier disrupted [2]. Other peptides may play a larger role, signalling host responses through chemotactic, angiogenic, growth factor and immunosuppressive activity; these peptides are known as alarmins [3]. For example, some alarmins not only kill bacteria but also stimulate expression of syndecan-1 and -4 in dermal fibroblasts, which is critical to the process of wound healing. Alarmins may also stimulate elements of the host defence system, such as barrier repair and recruitment of inflammatory cells [4].

The production by human skin of antimicrobial peptides such as defensins and cathelicidins occurs constitutively but also greatly increases after infection, inflammation or injury. Some skin diseases, including atopic dermatitis or rosacea, show altered expression of antimicrobial peptides, partially explaining the pathophysiology of these diseases [5]. In atopic dermatitis there is decreased expression of multiple antimicrobial peptides, which contributes to an increased susceptibility to infections, and in rosacea there are excessive and abnormally processed cathelicidin peptides, which can reproduce elements of the disease in mice. Certain antimicrobial peptides can influence host-cell responses in specific ways. For example, the human cathelicidin peptide LL-37 can activate mitogen-activated protein kinase (MAPK) and

extracellular signal-related kinase in epithelial cells, and blocking antibodies to LL-37 hinder wound repair in human skin equivalents. Defensins and cathelicidins have immunostimulatory and immunomodulatory capacities as catalysts for secondary host defence mechanisms. At nanomolar concentrations they are chemotactic for distinct subpopulations of leukocytes as well as some non-leukocytes. Human β-defensins (hBDs) 1–3 are chemotactic for memory T cells and immature dendritic cells. hBD2 attracts mast cells and activated neutrophils, whereas hBD3–4 is also chemotactic for monocytes/macrophages. Cathelicidins are chemotactic for neutrophils, monocytes/macrophages and CD4 T lymphocytes. Epidermal keratinocytes stimulated with either β-defensins or cathelicidins release an array of cytokines through stimulation of G protein-coupled receptors. In addition, antimicrobial peptides induce keratinocyte proliferation and migration, which involves EGFR signalling and STAT activation.

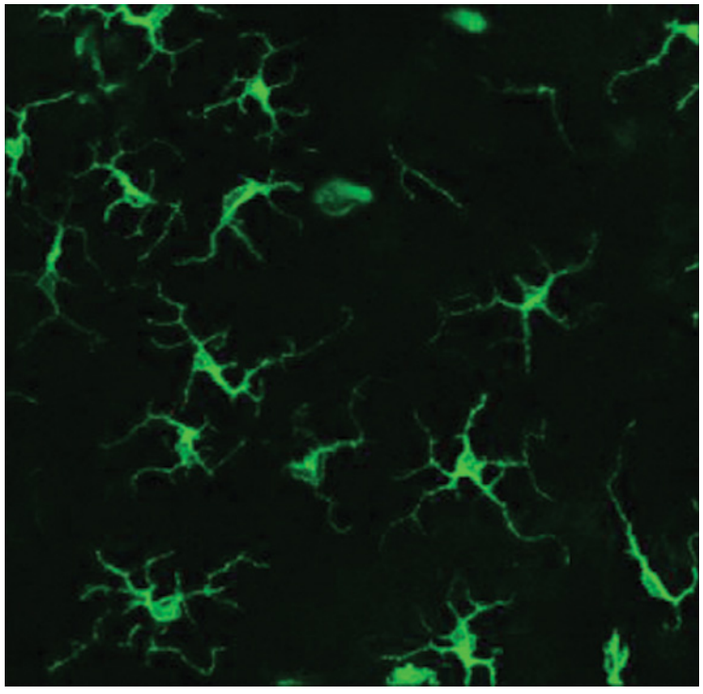

Fig. 3.19 Dendritic appearance of epidermal Langerhans' cells. Exposure to antigen provokes increased movement of Langerhans' cells as well as direct cell–cell contact between Langerhans' cells. (Courtesy of Dr R. Mohr, University of Toledo, Ohio, USA.)

Langerhans' cells

Dendritic cells of a form similar to melanocytes, but free from pigment and dopa negative, were first described by Langerhans, who demonstrated their existence in human epidermis by staining with gold chloride. More recently, the dynamic behaviour of epidermal Langerhans' cells has been investigated by combining time-lapse, intravital, confocal imaging technology and I-Aβ–enhanced green fluorescent protein (EGFP) knock-in mice in which Langerhans' cells can be identified by EGFP-associated fluorescence. Without stimulation, some Langerhans' cells exhibit a unique motion, which has been termed *dendrite surveillance extension and retraction cycling habitude* (dSEARCH), and which is characterized by rhythmic extension and retraction of dendritic processes between intercellular spaces. Topical application of an antigen such as dinitrofluorobenzene leads to greater dSEARCH motion and also triggers direct cell-to-cell contact formation between adjacent Langerhans' cells. It appears that, *in vivo*, dSEARCH motion allows for a more efficient antigen sampling through scanning of a wider area and it is also evident that, under pathological stimulation, adjacent Langerhans' cells may exchange antigens between cells [1] (Fig. 3.19).

Langerhans' cells, in combination with macrophages and dermal dendrocytes, represent the skin's mononuclear phagocyte system [2]. Langerhans' cells are capable of phagocytosis, antigen processing, antigen presentation and interactions with lymphocytes (Fig. 3.20).

They can also release cytokines, such as interleukin-1, to promote lymphocyte chemotaxis and activation [3]. Langerhans' cells are intraepidermal macrophages whose dendrites trap antigens among keratinocytes. The cells then leave the epidermis and migrate via lymphatics to a regional lymph node. In the paracortical region of lymph nodes, the Langerhans' cell (or 'interdigitating reticulum cell' as it is then known) expresses protein on its surface to present to a T lymphocyte that can then undergo clonal proliferation. There may be some selectivity in whether certain antigens are presented to lymph nodes by Langerhans' cells or by dermal dendrocytes. The timing of antigen presentation may also vary, with the possibility that sequential presentation of skin-acquired antigens may regulate cell-mediated immunity.

Langerhans' cells may contribute to several skin pathologies including infections, inflammation and cancer and they play a pivotal role in regulating the balance between immunity and peripheral tolerance [4]. Langerhans' cells appear, however, to have characteristics distinct from other dendritic cells in that they are more likely to induce Th2 responses than the Th1 responses that are usually necessary for cellular immune responses against pathogens. It has also been shown that Langerhans' cells are dispensable for contact hypersensitivity and that dermal dendrocytes can serve as antigen presenting cells in the absence of Langerhans' cells. Indeed, Langerhans' cells-deficient mice appear to have enhanced contact hypersensitivity. With regard to a specific function, Langerhans' cells, or a subset thereof, may have regulatory properties that counteract the proinflammatory activity of surrounding keratinocytes. It is plausible that under non-inflammatory steady-state conditions, Langerhans' cells carry skin-specific components to draining lymph nodes to prevent immunization and to induce peripheral tolerance against

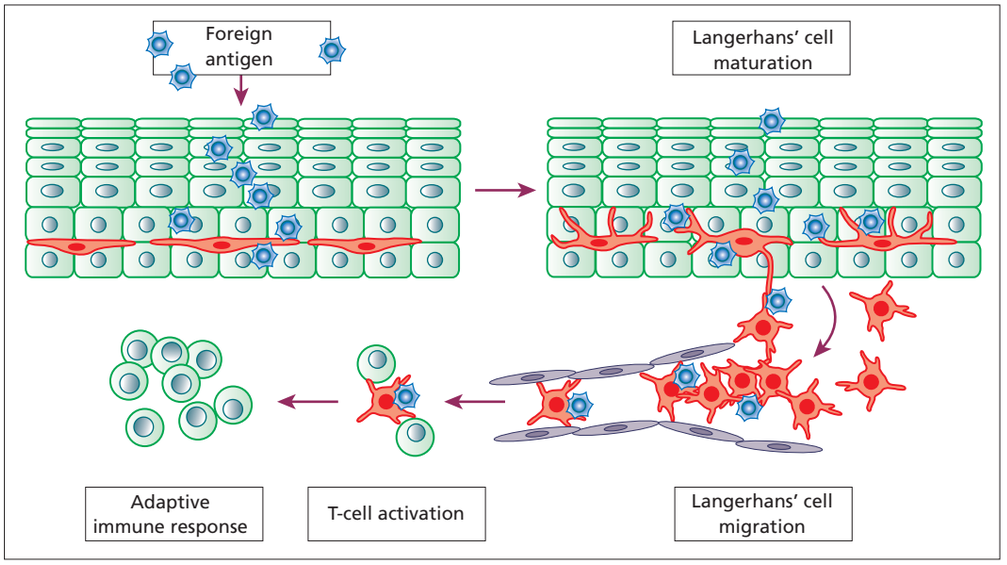

Fig. 3.20 When exposed to foreign antigen the activity of resting Langerhans' cells increases and the cells mature. Antigen is then processed and transported to the lymph nodes. T cells are then activated and an immune response is triggered.

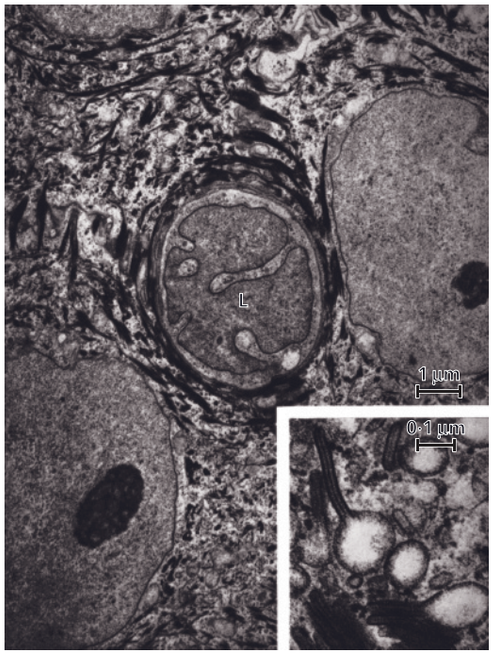

Fig. 3.21 Langerhans' cell (L) with its characteristically indented nucleus, situated between keratinocytes. Inset: Langerhans' cell granules showing racquet-shaped profiles. (Courtesy of Professor A.S. Breathnach, St John's Institute of Dermatology, King's College London, UK.)

epidermal self-determinants [5]. It also appears that Langerhans' cells may indeed consist of distinct subsets, since Langerhans' cells that repopulate the skin after inflammation have been shown to derive from monocyte precursors. Under the electron microscope, Langerhans' cells share with melanocytes a lobulated nucleus, a relatively clear cytoplasm and well-developed endoplasmic reticulum, Golgi complex and lysosomes (Fig. 3.21).

They differ in lacking melanosomes or premelanosomes, and in possessing a characteristic granule which is rod- or racquet-shaped. These 'Birbeck' granules have been shown to represent subdomains of the endosomal recycling compartment and form at sites where the protein Langerin accumulates.

Using ultrastructural evidence of the presence of the characteristic granules, Langerhans' cells have been identified in the outer root sheath of the human hair and the secretory duct of the sebaceous gland and in the epithelium of the crypts of the human tonsil. The discovery of similar granules in cells in the dermis in histiocytosis X resulted in the renaming of this condition as Langerhans' cell histiocytosis.

Immune surveillance

Besides the antigen detection and processing role of epidermal Langerhans' cells, cutaneous immune surveillance is also carried out in the dermis by an array of tissue-resident T cells, macrophages, and dendritic cells [1] (Fig. 3.22).

These immune sentinel and effector cells are able to provide rapid and efficient immunological backup to restore tissue homeostasis should the epidermis be breached. The dermis contains a very large number of resident T cells; remarkably, there are approximately 2×10^{10} skin-resident T cells, which is twice the total number of T cells in the circulating blood [2]. There are

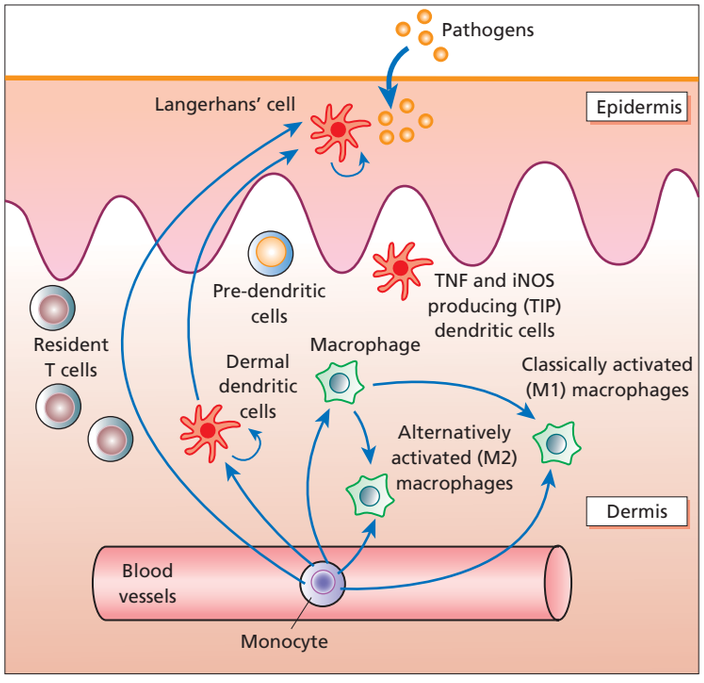

Fig. 3.22 Immune surveillance in normal skin is carried out by an array of skin-based dendritic cells, macrophages and resident T cells.

several distinct populations of dermal dendritic cells; some have potent antigen-presenting capacities, others have low antigen-presenting capacity but the potential to develop into $CD1a^+$ and Langerin-positive Langerhans' cells, while some are proinflammatory. Another recent addition to the family of skin immune sentinels is type I interferon-producing plasmacytoid predendritic cells, which are rare in normal skin but which can accumulate in inflamed skin [3]. A further component of the dermal immune system is the dermal macrophage. This cellular diversity of dermal immune sentinels is reflected in some flexibility or plasticity in function. For example, immature dendritic cells, including dermal dendritic cells, can be phagocytic, which is a cellular function usually attributed to macrophages [4]. Alternatively, macrophages, which normally are phagocytic cells, can also be potent antigen-presenting cells for $CD8^+$ T cells. This means that tissue-resident mononuclear sentinels of the dermis are likely to exist in a pluripotent state. Depending on microenvironmental factors and cues, they may acquire an antigen-presenting mode, a migratory mode or a tissue-resident phagocytic mode.

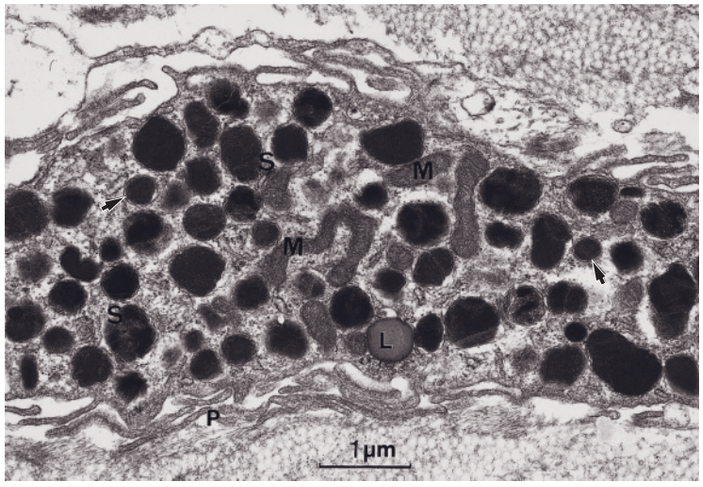

Fig. 3.23 Part of a human skin mast cell showing characteristic granules, some with scroll-like profiles (S). Arrows indicate perigranular membrane; L, lipid droplet; M, mitochondria; P, peripheral processes.

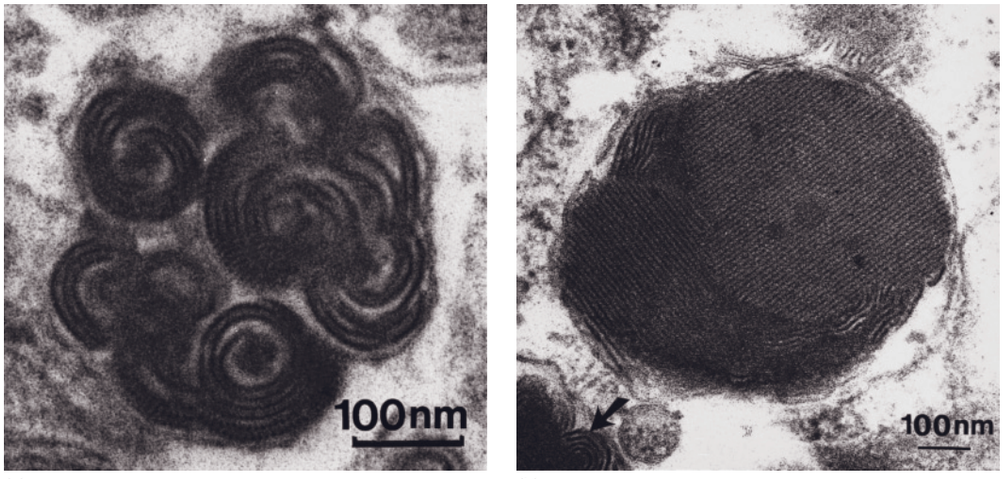
Mast cells



Mast cells were first described by Ehrlich in 1877, who distinguished them from other connective tissue cells by their ability to stain metachromatically with basic aniline dyes. Mast cells are larger than eosinophils and basophils. They occur in most tissues, but are particularly numerous in skin, bronchus, nasal mucosa and gut. In the skin, mast cells are distributed close to blood vessels, nerves and appendages, and are most numerous in the subpapillary dermis, in the region of the superficial dermal vascular plexus. There are about 7000 mast cells per mm^3 in normal skin.

Dermal mast cells are ovoid or spindle-shaped, mononuclear or occasionally binuclear, and only rarely show signs of mitosis in normal skin. Their major distinguishing feature is the presence of numerous, round cytoplasmic granules (Figs 3.23 and 3.24).

Mast cells are heterogeneous and fall into two main types—connective tissue and mucosal—which can be differentiated by their morphology, tissue distribution, histochemical characteristics and responses to degranulating agents. Solubility of the granules in formaldehyde and content of neutral proteinase, namely tryptase and chymase (chymotryptic proteinase) will vary according to the type of cell. For example, human foreskin mast cells contain both proteinases, whereas mast cells in intestinal mucosa and lung contain mainly tryptase [1].

Human mast cells arise from $CD34^+$ pluripotent stem cells in the bone marrow. They then circulate in the blood as precursors and home to tissues where they mature under the influence of stem cell factor (SCF) and local cytokines and other factors. Mast cell growth and differentiation are also influenced by several other cytokines, including IL-3, IL-4, IL-6, IL-9, IL-10 and nerve growth factor (NGF). Mast cells are long lived and may proliferate in association with IgE-dependent activation and in the presence of IL-4 [2].

Kit (CD117), expressed on haematopoietic stem cells and progenitor cells, is the tyrosine kinase transmembrane receptor for

(a) (b)

Fig. 3.24 High-magnification views of dermal mast cell granules. (a) Typical scroll-like configuration of lamellae, some of which show a cross-banding of regular periodicity. (b) The substructure of this granule is a highly organized lattice.

SCF which is involved in differentiation of both myeloid and lymphoid lineages. While Kit is down-regulated on other bone marrow-derived cells during their differentiation, Kit remains highly expressed on mast cells and is critical for many mast cell functions such as survival, differentiation, chemotaxis and enhancement of signalling events during mast cell activation. The importance of Kit is shown by the finding of activating mutations in the *KIT* gene in patients with urticaria pigmentosa [3].

Upon activation of mast cells via crosslinking of the high affinity IgE receptor (FcεRI) or non-IgE-mediated activation through complement receptors or toll-like receptor (TLR) activation, mast cells can release histamine, serotonin and proteases as well as newly synthesized leukotrienes, prostaglandins, cytokines and chemokines. In addition to IgE-mediated activation, human mast cells exposed to IFN-γ can be activated following IgG-mediated aggregation of FcγRI to release similar mediators. Additional IgE-independent mast cell triggers have been described, including SCF, complement (C3a and C5a), neuropeptides (substance P), adenosine, TLR and scavenger receptors.

Mast cell products may both induce an immediate reaction and contribute to a late-phase reaction. The immediate phase reaction occurs within minutes of FcεRI crosslinking and its consequences are referred to as an immediate hypersensitivity reaction. Late-phase reactions peak 6–12 h following antigen challenge and are associated with cytokine and chemokines from eosinophils, neutrophils and basophils that have been secondarily recruited. Mast cell activation results in increased vascular permeability and smooth muscle contraction, as well as fibroblast deposition of collagen, induction of B cells to class switch to synthesize IgE, basophil histamine release, recruitment of neutrophils and eosinophils, and promotion of T cells to a T helper 2 (Th2) phenotype.

Mast cells play an important role in both adaptive and innate immunity, and contribute to the skin pathology seen in contact dermatitis, atopic dermatitis (AD), immunobullous disease, scleroderma and chronic graft-versus-host disease [4]. In AD, there is an increase in mast cell numbers in lesional skin. Mast cells reside in the papillary dermis and undergo migration through the basal lamina into the epidermis. Although overall levels of histamine are not increased in AD, tryptase and activation of proteinase-activated receptor-2 (PAR-2) may contribute to the pruritus seen in AD, as tryptase is reported to be increased up to fourfold in AD patients and PAR-2 expression is markedly enhanced on primary afferent nerve fibres in skin biopsies from patients with AD. Chymase may play a role in eliciting and maintaining chronic inflammation in AD by increasing spongiosis and compromising the skin barrier. Mast cell–nerve interactions may also play a role in promoting inflammation in AD [5]. There is an increased number of contacts between mast cells and nerves in both lesional and non-lesional skin which may lead to inflammation mediated by neuropeptides such as substance P, calcitonin gene-related peptide, vasoactive intestinal peptide and NGF.

Melanocytes

Melanocytes are pigment-producing cells located in the skin, inner ear, choroid and iris of the eye. In skin and hair, two forms of melanin pigment are produced; brown/black eumelanin and yellow/red phaeomelanin (Fig. 3.25).

The melanin is subsequently transferred in melanosomes to neighbouring keratinocytes in the epidermis and into the growing shaft in hair follicles. Variations in the types of melanin pigment produced and their distribution within skin and hair contribute to the vast diversity in colour. A key protein involved in melanosome assembly is NCKX5, encoded by the gene *SLC24A5* [1]. Loss of expression of this gene in mice results in marked changes in

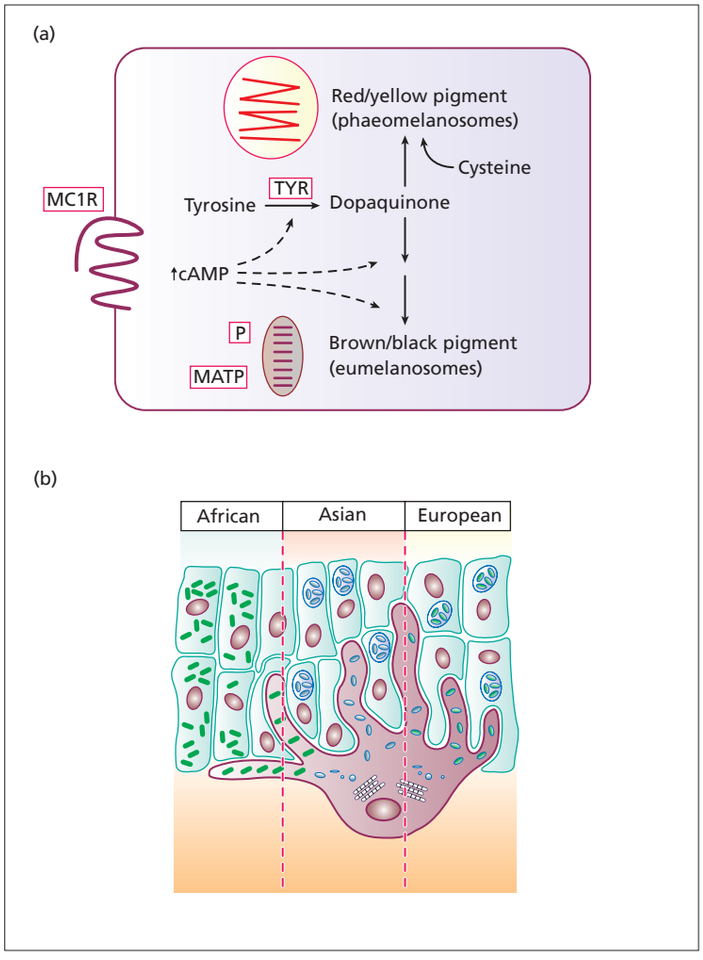

Fig. 3.25 (a) Activation of the melanocortin 1 receptor (MC1R) promotes the synthesis of eumelanin at the expense of phaeomelanin. Oxidation of tyrosine by tyrosinase (TYR), however, is required for synthesis of both pigment types. Melanosomal membrane components, including the membrane-associated transport protein (MATP) and the pink-eyed dilution protein (P), play a role in determining the amount of pigment synthesis within melanosomes. (b) In African, Asian and European skin there is a gradient of melanosome size and number; in addition, melanosomes in African skin are more widely dispersed.

skin colour with loss of pigment. Melanin production also provides skin protection by reducing damage from harmful ultraviolet radiation. In humans, alterations in melanocyte development and function can lead to various pigmentary disorders. These include disorders with reduced melanocytes in skin, such as Piebaldism and Waardenburg syndrome, and disorders with defective pigment production or processing, such as albinism, Hermansky–Pudlak and Chediak–Higashi syndromes.

The melanin-producing melanocytes in adult skin and hair develop from embryonically derived melanocyte precursors called melanoblasts. During development, melanoblasts emerge from a subset of neural crest cells and migrate to the skin and developing hair follicles. In the hair follicle, melanocytes are divided into two distinct populations: differentiated melanocytes, located in the hair matrix region, and melanocyte stem cells, located at the lower permanent portion of the hair follicle. The life cycles of the follicular melanocytes and melanocyte stem cells are closely related to the cyclical nature of the hair follicle and during anagen new melanocytes are generated from the pool of slow-proliferating melanocyte stem cells [2]. Differentiated melanocytes express *Sox10, Kit, Mitf, Pax3* and *Dct* but melanocyte stem cells only express *Pax3* and *Dct* [3]. Whether a subpopulation of melanocyte stem cells exists that may be relevant to the pathogenesis of melanoma is not yet known, although some of the melanocyte stem cells do express markers such as CD166, CD133 or Nestin which are found in stem cells from other lineages and may be multipotent in culture, capable of differentiating into various cell types (e.g. adipocytes, chondrocytes).

Alterations in melanocyte signalling pathways also contribute to common hair abnormalities such as hair greying. One particular pathway involves Notch signalling [4]. The Notch signalling pathway is an essential cell–cell interaction mechanism, which regulates processes such as cell proliferation, cell fate decisions, differentiation or stem cell maintenance. Notch signalling in melanocytes is essential for the maintenance of proper hair pigmentation, including regeneration of the melanocyte population during hair follicle cycling. Deletion of Notch1 and Notch2 or RBP-Jkappa in melanocyte lineages results in a gene dosage-dependent, precocious hair greying, due to the elimination of melanoblasts and melanocyte stem cells. Aberrant Notch signalling may also be relevant in the development or progression of melanoma.

Melanocytes possess melanocyte-specific receptors including melanocortin-1 (MC1R) and melatonin receptors [5]. The activation or the inhibition of melanocyte-specific receptors can augment normal melanocyte function, skin colour and photoprotection. Moreover, receptor polymorphisms are known to underlie red hair phenotypes. Receptor targeting may also be relevant to the treatment of melanoma. Notably, melanocytes also possess G-protein-couple receptors, such as Frizzled5, and receptor tyrosine kinases, including c-Kit and hepatocyte growth factor (HGF) receptor. These receptors activate two crucial cell-signalling pathways, RAS/RAF/MEK/ERK and PI3K/AKT, integral to melanoma cell survival, and could serve as targets for future therapies of disseminated melanoma.

Epidermal attachment complexes

Desmosomes

Desmosomes are the major adhesion complex in epidermis, anchoring keratin intermediate filaments to the cell membrane

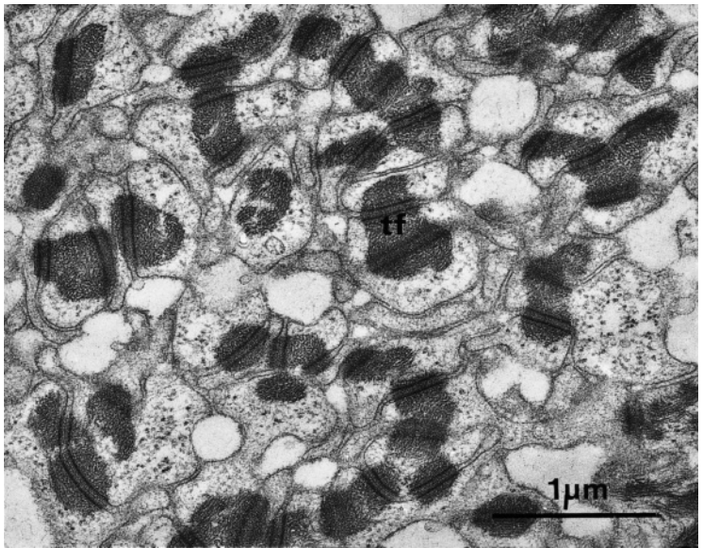

Fig. 3.26 Electron micrograph of desmosomes in the spinous layer. These intercellular junctions are closely associated with tonofilaments (tf), many of which, in this view, are cross-sectioned.

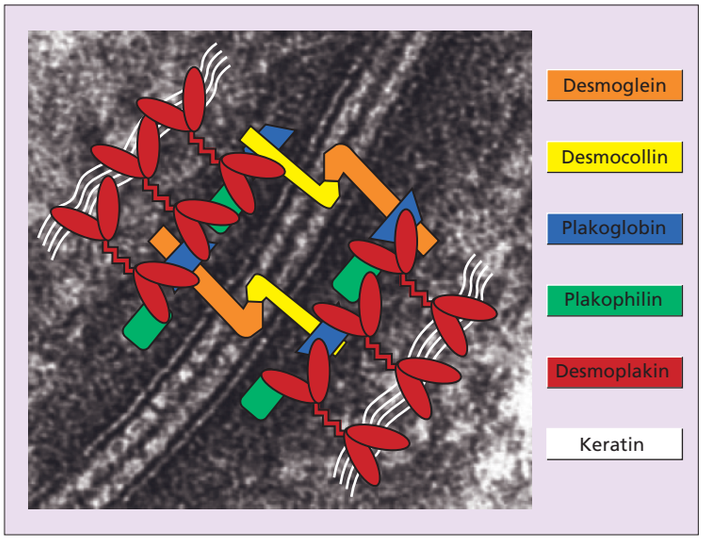

Fig. 3.27 Macromolecular composition of desmosomes linking adjacent keratinocytes. Cells are connected via transmembranous cadherin glycoproteins (desmogleins and desmocollins). Attachment of these molecules to the keratin filament cytoskeleton occurs via a network of desmosomal plaque proteins (desmoplakin, plakoglobin and plakophilin). The background to this figure is a transmission electron micrograph of a desmosome to highlight how the molecules function as an adhesive complex.

and bridging adjacent keratinocytes, and allowing cells to withstand trauma. Desmosomes are also found in the myocardium, meninges and cortex of lymph nodes. The desmosome has a characteristic ultrastructural appearance, in which the cell membrane of two adjacent cells forms a symmetrical junction with a central intercellular space of 30 nm containing a dense line (Fig. 3.26). Plaques of electron-dense material run along the cytoplasm parallel to the junctional region, in which three ultrastructural bands can be distinguished: an electron-dense band next to the plasma membrane, a less dense band and then a fibrillar area [1].

The main components of desmosomes in the epidermis consist of the products of three gene superfamilies: the desmosomal cadherins, the armadillo family of nuclear and junctional proteins and the plakins [2]. The transmembranous cadherins comprise mostly heterophilic associations of desmogleins and desmocollins. There are four main epidermis-specific desmogleins (Dsg1–4) and three desmocollins (Dsc1–3), all of which show differentiation-specific expression. For example, Dsg1 and Dsc1 are preferentially expressed in the superficial layers of the epidermis whereas Dsg3 and Dsc3 show greater expression in basal keratinocytes. The intracellular parts of these glycoproteins are attached to the keratin filament network via desmoplakin, plakoglobin and other macromolecules, including the armadillo protein, plakophilin 1, an important stabilizer of keratinocyte adhesion in differentiated keratinocytes, as well as other site-specific plakin cell envelope proteins, such as envoplakin and periplakin [3]. The network of the major interactive desmosomal proteins is depicted in Fig. 3.27.

Further clues to the biological function and *in vivo* contribution to keratinocyte adhesion of these desmosomal components have arisen from various mouse models and human diseases, both inherited and acquired [4,5]. Naturally occurring human mutations have been reported in nine different desmosome genes; these result in a spectrum of dominant and recessive diseases with variable skin, hair and heart abnormalities. A summary of recent gene mutation findings is represented in Fig. 3.28.

The desmosome proteins may also serve as autoantigens in several immunobullous blistering skin diseases [6]. The specific diseases linked to particular desmosomal target antigens are shown in Fig. 3.29.

Antibodies to multiple desmosomal proteins may develop in diseases such as paraneoplastic pemphigus, possibly through the phenomenon of epitope spreading [7]. Disruption of the extracellular domain of Dsg1 has also been demonstrated as the basis of staphylococcal scalded skin syndrome and bullous impetigo in which this desmosomal cadherin is cleaved by the bacterial toxin [8].

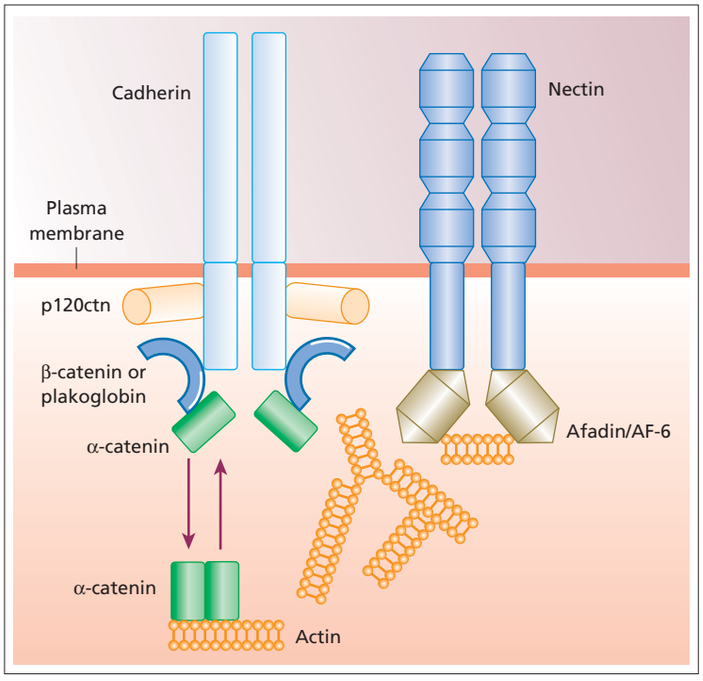

Fig. 3.30 Macromolecular composition of an adherens junction in keratinocytes. There are two main components, nectin–afadin and the classical cadherin–catenin complex, which can both attach to the actin cytoskeleton.

Adherens junctions

Adherens junctions are electron dense, transmembrane structures that engage with the actin skeleton [1]. They can associate with tight junctions and desmosomes or exist separately from these junction complexes. Adherens junctions contribute to epithelial assembly, adhesion, barrier formation, cell motility and changes in cell shape. They are characterized by two opposing membranes separated by approximately 20 nm and are 0.2–0.5 μm in diameter. Adherens junctions may also spatially coordinate signalling molecules and polarity cues as well as serving as docking sites for vesicle release. They comprise two basic adhesive units: the nectin–afadin complex and the classical cadherin complex [2,3] (Fig. 3.30).

There are several different nectins and cadherins and these may be variably incorporated into adherens junctions; the precise composition will impact on the adhesive specificity and other functions of the junction. The nectins form a structural link to the actin cytoskeleton via afadin (also known as AF-6) and may be important in the initial formation of adherens junctions. The cadherins form a complex with the catenins (α-, β-, and p120 catenin) and help mediate adhesion and signalling. Cell signalling via β-catenin can activate several Wnt pathways, which implicates adherens junctions in co-ordinating morphogenetic movements with cell fate determination. Adherens junctions are also associated with a variety of actin-binding molecules, suggesting multiple dynamic interactions with the cytoskeleton.

The first human gene mutation reported in a component of adherens junctions was in plakoglobin (also a component of desmosomes, see Fig. 3.10) in individuals with Naxos disease [4].

However, mutations have subsequently been reported in the *CDH3* gene, which encodes P-cadherin; these mutations result in autosomal recessive hypotrichosis with juvenile macular dystrophy [5]. P-cadherin mutations are also found in a different disorder, ectodermal dysplasia–ectrodactyly–macular dystrophy (EEM) syndrome, in which there is hypotrichosis, macular degeneration, hypodontia and limb defects, including ectrodactyly, syndactyly and camptodactyly [6].

Gap junctions

Gap junctions comprise clusters of intercellular channels, known as connexons, that directly form connections between the cytoplasm of adjacent keratinocytes (and other cells) [1]. Thirteen different human connexins have been described. Connexons originate following assembly of six connexin subunits within the Golgi network that are then transported to the plasma membrane. The connexins are divided into three groups (α, β and γ) according to their gene structure, overall gene homology and specific sequence motifs [2]. At the plasma membrane, connexons associate with other connexons to form a gap junction (Fig. 3.31).

Homotypic or heterotypic connexins (formed from one or more than one type of connexin, respectively) are possible and the formation and stability of gap junctions can be regulated by protein kinase C, Src kinase, calcium concentration, calmodulin, adenosine 3′,5′-cyclic monophosphate (cAMP) and local pH [3]. Apart from the connexins, vertebrates also contain another class of gap junction proteins, the pannexins, which are related to the innexins found in non-chordate animals. To date, however, no human abnormalities of pannexins have been reported. The function of gap junctions is to permit sharing of low-molecular-mass metabolites (<1000 Da) and ion exchange between neighbouring cells, thus allowing intercellular coordination and uniformity to maintain tissue/organ homeostasis in multicellular organisms [3]. Gap junction communication is essential for cell synchronization, differentiation, cell growth and metabolic coordination of avascular organs, including epidermis.

Inherited abnormalities in genes encoding four different connexins (Cx26, 30, 30.3 and 31) have been detected in several forms of keratoderma and/or hearing loss but non-dermatological disorders can also arise from mutations in the higher molecular weight connexins (Cx32, 40, 43, 46 and 50). The spectrum of diseases associated with connexin gene pathology is illustrated in Fig. 3.32.

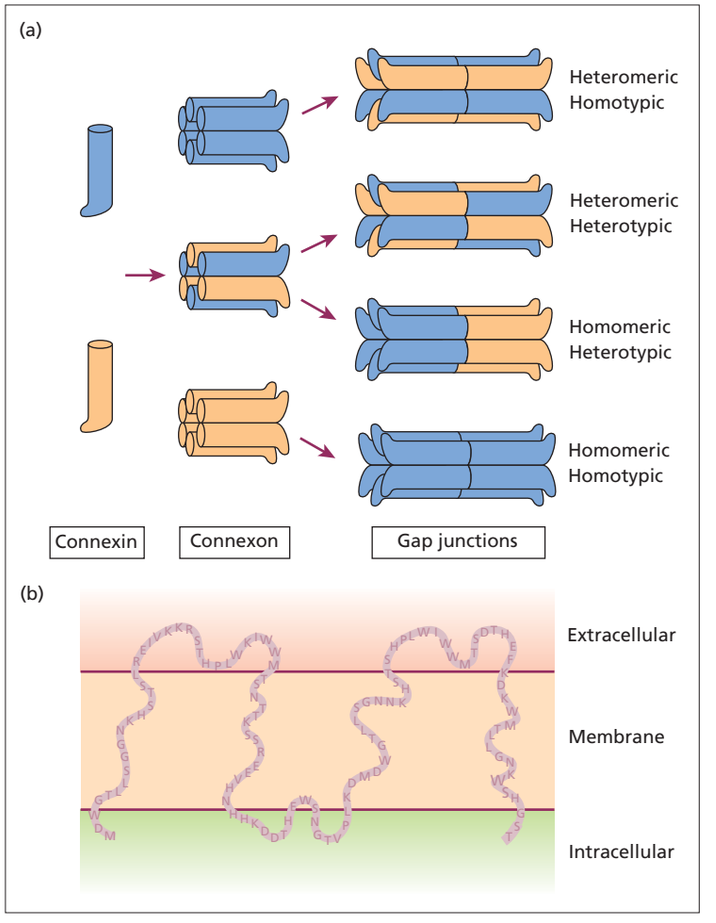

Fig. 3.31 Formation and structure of gap junctions in human skin. (a) In the Golgi network six connexin subunits assemble to form a connexon. The connexon is then transported to the plasma membrane. Other connexons then coaggregate to form homotypic or heterotypic gap junctions. (b) The gap junction protein is a transmembranous molecule with intracellular, transmembranous and extracellular domains (here illustrated for Cx26).

Tight junctions

Tight junctions are the major regulators of permeability in simple epithelia, but they are also present in skin, with a key role in skin barrier integrity and maintaining cell polarity [1]. Tight junctions regulate the paracellular flux of water-soluble molecules between adjacent cells [2]. The principal structural proteins of tight junctions are the claudins, of which there are approximately 24 subtypes. The other component transmembranous proteins are the IgG-like family of junctional adhesion molecules (JAMs) and the occludin group of proteins. The main claudins in the epidermis are claudin 1 and 4. These transmembranous proteins do not bind to one another but the claudins and occludins can bind to the intracellular zonula occudens proteins ZO-1, ZO-2, ZO-3; these proteins can also interact with actin thus providing a direct link

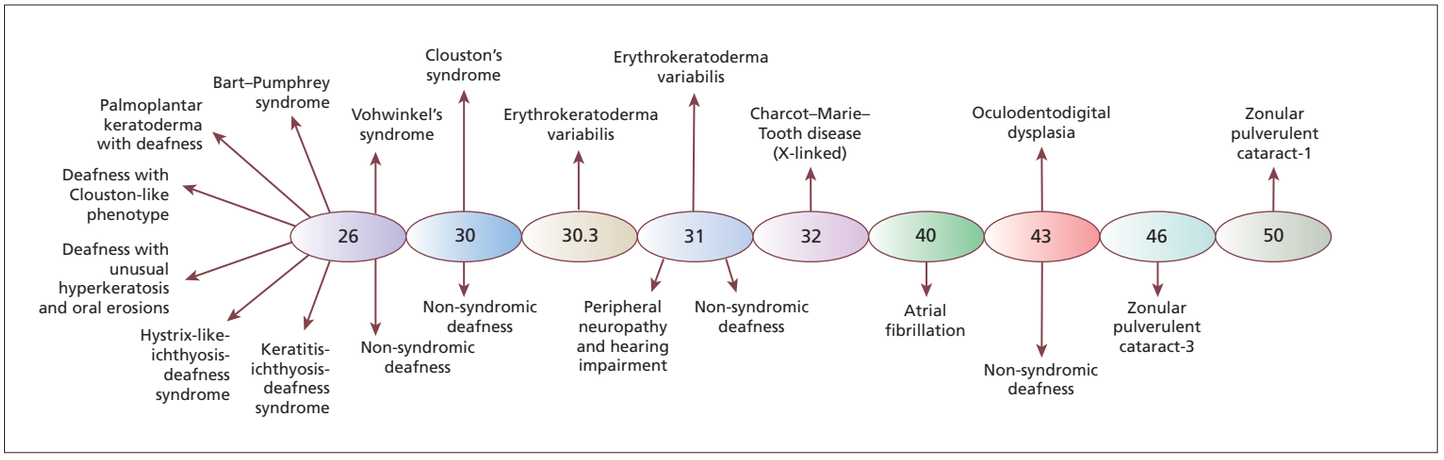

Fig. 3.32 Disease associations arising from gene mutations in the different molecular weight connexins.

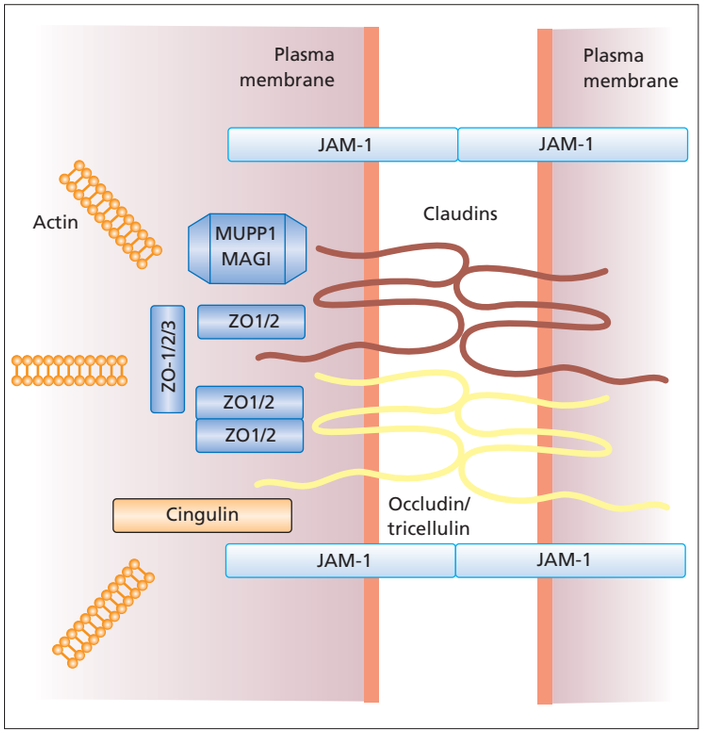

Fig. 3.33 Structural composition of a tight junction in human skin. There are three transmembranous families of proteins, the junctional adhesion molecules (JAMs), the claudins and the occludins, of which the latter two bind to zonula occludens proteins (ZO) and then directly to actin. with the cytoskeleton [1,3]. The structural organization of a tight junction is shown in Fig. 3.33.

Mutations in claudin 16 (also known as paracellin-1) result in familial hypomagnesaemia with hypercalciuria and nephrocalcinosis; mutations in claudin 14 underlie the autosomal recessive deafness disorder DFNB29 leading to cochlear hair cell degeneration; mutations in the gene encoding the ZO-2 protein have been found in some cases of familial hypercholanaemia. With respect to skin, mutations in claudin 1 have been demonstrated in one autosomal recessive pedigree with clinical features of diffuse ichthyosis with large scales, hypotrichosis, scarring alopecia and sclerosing cholangitis [4]. Collectively, these human disorders demonstrate the key role tight junctions play in the skin, kidney, ear and liver.

Dermal–epidermal basement membrane

The interface between the lower part of the epidermis and the top layer of the dermis comprises the dermal–epidermal basement membrane zone (BMZ), which consists of a number of extracellular matrix macromolecules [1,2] (Fig. 3.34 & Table 3.1).

Many of these components are glycoproteins, and the BMZ can be recognized histologically by positive labelling with PAS stain. Ultrastructural examination of the BMZ by transmission electron microscopy shows the presence of two distinct layers with different optical densities (Fig. 3.35).

The upper layer, the lamina lucida, is a less electron dense region which directly abuts the plasma membranes of the basal keratinocytes. Below the lamina lucida is the lamina densa, an electron-dense region which at the lower part interacts with the mesenchymal matrix of the upper dermis. The major biochemical components of the BMZ are type IV collagen and a number of collagenous glycoproteins, including laminin 322 [3]. Associated with the cutaneous BMZ are ultrastructurally recognizable attachment structures which form a contiguous network extending from the intracellular milieu of basal keratinocytes through the plasma membrane of the basal cells, traversing the dermal–epidermal basement membrane and extending to the upper papillary dermis (Fig. 3.34). The components of this network are the hemidesmo-

somes, anchoring filaments and anchoring fibrils. The biochemical components of the BMZ are synthesized by basal keratinocytes and dermal fibroblasts, which both contribute to the development and repair of the basement membrane [4]. The critical importance of this network structure in securing the adherence of the epidermis to the underlying dermis is reflected in the group of diseases, epidermolysis bullosa, in which components of the hemidesmosomes, anchoring filaments or anchoring fibrils are genetically altered or missing, and, as a result, fragility at the dermal–

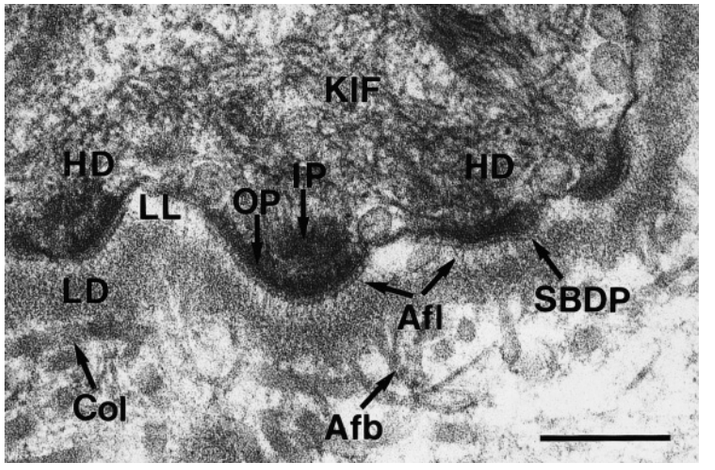

Fig. 3.35 Transmission electron microscopy of the dermal–epidermal junction in human skin recognizing hemidesmosomes (HD), anchoring filaments (Afl), and anchoring fibrils (Afb). The HD consists of an intracellular inner plaque (IP) and outer plaque (OP) as well as sub-basal dense plate (SBDP) in the upper lamina lucida (LL). The anchoring filaments traverse the lamina lucida appearing as thread-like structures which concentrate under the hemidesmosomes and merge with the lamina densa (LD). Anchoring fibrils extend from the lower part of the LD to the upper papillary dermis where they closely associate with interstitial collagen fibres (Col). Keratin intermediate filaments (KIFs) associate with intracellular components of HDs. Scale bar, 0.25 μm.

epidermal junction ensues, clinically manifesting as erosions and blisters following minor trauma [5] (Fig. 3.36).

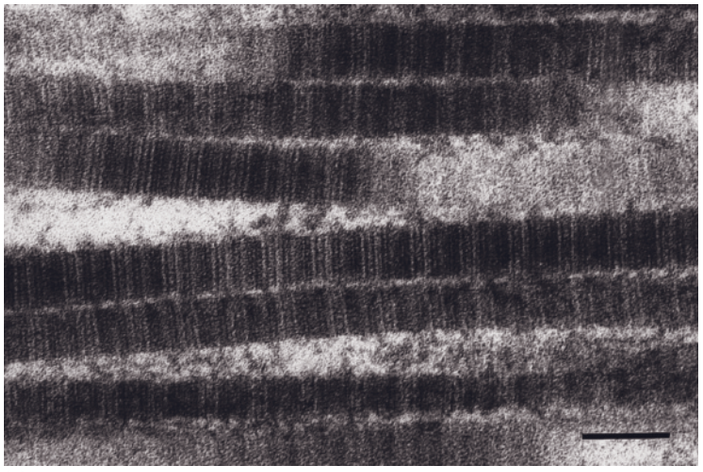
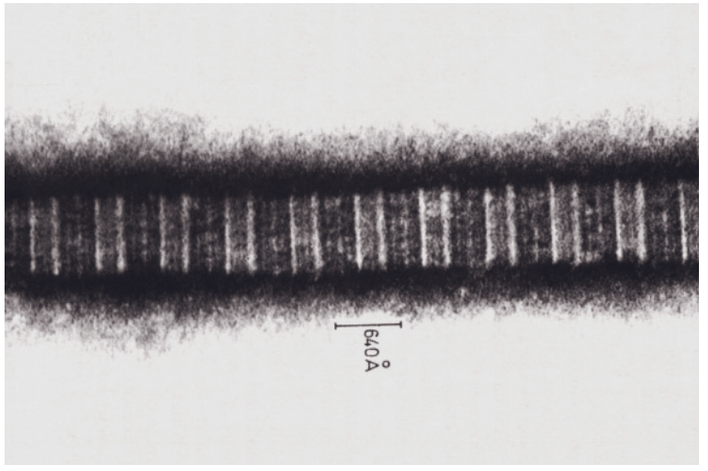
Type IV collagen

The major component of the dermal–epidermal basement membrane is type IV collagen, a heterogeneous group of macromolecules which are present in diverse combinations in various basement membranes [1] (Fig. 3.37).



Like all collagens, each type IV collagen molecule consists of three polypeptide subunits, known as α-chains. Some collagen molecules are homopolymers, that is the three α-chains are genetically identical, as in the case of type II, III and VII collagens, while others are heteropolymers so that there are two or even three different kinds of polypeptides, as for example in type I and type VI collagens. For type IV collagen, there are six genetically distinct but structurally related α-chains, and the precise composition of the α-chains varies with the tissue location of the basement membranes. In the case of the cutaneous basement membrane zone, the major type IV collagen consists of α1 and α2 chains, with the chain composition $[\alpha1(IV)]_2\alpha2(IV)$, although other type IV collagen subunit polypeptides are also present in lower quantities. The α3 chain of type IV collagen has been shown to be the antigen recognized by circulating autoantibodies characteristic of Goodpasture's syndrome, while structural aberrations in the α5 chain of type IV collagen are associated with Alport syndrome [2]. Autoantibodies against α5 and α6 chain epitopes have also been reported in patients with glomerulonephritis and subepidermal blistering [3].

The characteristic fibre structure of interstitial collagens results from the lateral aggregation of individual molecules in a quarter stagger array; this gives rise to a 64-nm cross-striation pattern, when examined by transmission electron microscopy (Fig. 3.38).



In the case of type IV collagen, the non-collagenous globular domains both at the amino- and carboxyl-ends of the individual collagen molecules interact to form dimers and tetramers which then assemble into lattice-like structures and associate laterally in a complex hexagonal arrangement (Fig. 3.39). This arrangement allows high flexibility to the basement membrane structure and makes interactions with other collagenous and non-collagenous basement membrane components possible [1].

Type*	Chain composition	Old designation	Distribution in basement membranes
111	α1β1γ1	1	Blood vessels, LD
332	α3β3γ2	5	LL/LD
311	α3β1γ1	6	LL/LD
511	α5β1γ1	10	LL/LD

* For the latest nomenclature, see [4].
LD, lamina densa; LL, lamina lucida.

The laminin family

Other components that contribute to the cutaneous basement membrane zone include members of the laminin family of multidomain proteins [1,2]. As many as 16 different laminins have been identified thus far and at least four of them are physiologically present in the skin in significant quantities (Table 3.2) [3]. Each laminin molecule consists of three polypeptide subunits, α, β and γ chains, which form a cruciform structure with three short arms and one long arm when visualized by rotary shadowing electron microscopy (Fig. 3.40).

The short arms represent the N-terminal segments of the α, β and γ chains. The long arm consists of an extended rod-like structure of the triple-stranded, coiled-coil domain of all three chains. This domain serves as the site of chain assembly of the three subunit polypeptides. The α-chain contains an additional C-terminal segment which contains five globular segments located at the tip of the long arm, known as the G domain. The major laminin within the cutaneous basement membrane zone is laminin 332, previously known as laminin 5 (for the most recent nomenclature see [4,5]) (Fig. 3.41). In addition, laminin 311 and laminin 511 are also integral components of the cutaneous basement membrane zone, while laminin 111 is present in basement membranes of the blood vessels in human dermis.

The cell binding of laminins is mediated by integrins, a family of cellular receptors, each consisting of two subunit polypeptides (Fig. 3.42). Integrins also mediate outside-in signal transduction elicited by laminins and regulate cell migration, proliferation, differentiation and adhesion [6]. The principal integrin in the cutaneous BMZ is the α6β4 integrin, which is critical for the adhesion of basal cells to the underlying BMZ.

The cruciform structure of laminins contains both globular and rod-like segments which have been individually implicated in various functions, including interactions with other extracellular matrix molecules, such as the hemidesmosomal components and type VII collagen, as well as in cell attachment and spreading, neurite outgrowth and cellular differentiation. Collectively, the laminins play vital roles in the development and maintenance of the supramolecular organization of basement membrane. The

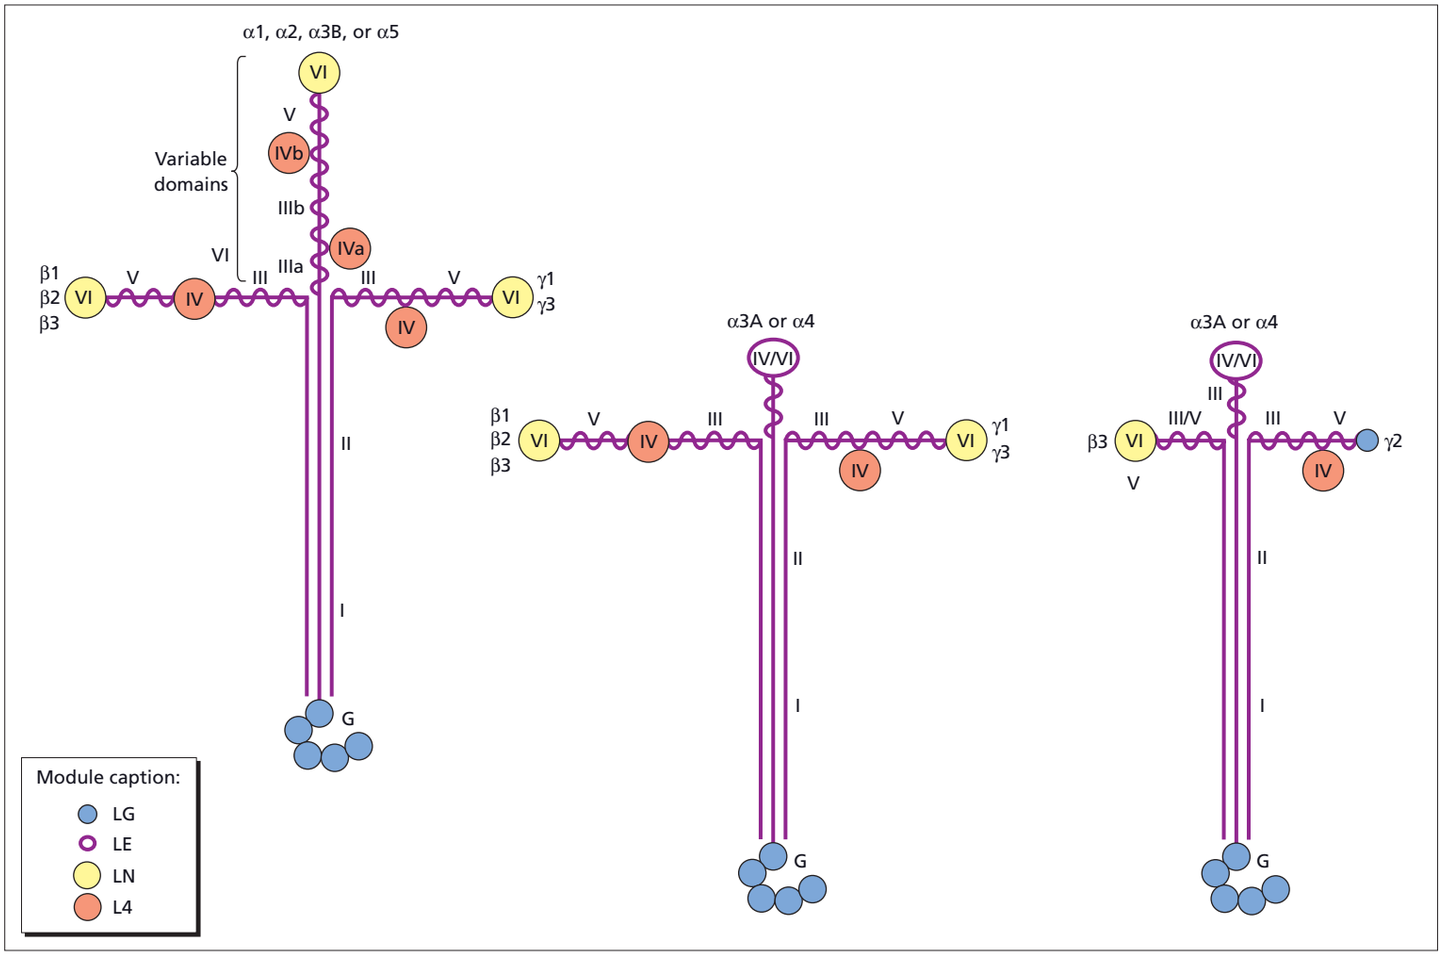

Fig. 3.40 Schematic representation of the different isoforms and the domain organizations of laminin, each consisting of three distinct subunit polypeptides, α, β, and γ chains. The LE modules are formed by approximately 60 residues each and have homology to epidermal growth factor. The LN and L4 modules are folded into globular structures located between LE modules (domain IV) or at the amino-terminus of each chain (domain VI). The coiled-coil central region, comprising all three polypeptides, is represented as vertical straight lines. Note the presence of a G domain consisting of five globular segments (LG) at the carboxy-terminus of the α chains. (Adapted from [10].)

critical role of laminin 332 in providing integrity to the cutaneous basement membrane zone is evident by observations that genetic mutations in any of the three polypeptide subunits, that is the *LAMA3*, *LAMB3* or *LAMC2* genes which encode the α3, β3, and γ2 chains, respectively, can result in junctional forms of epidermolysis bullosa (EB) with profound fragility of the skin (Fig. 3.42). Furthermore, mutations in the *ITGA6* and *ITGB4* genes (encoding the α6 and β4 subunit polypeptides of integrin, respectively) cause a form of junctional EB frequently associated with pyloric atresia [7].

Other basement membrane zone components at the dermal–epidermal junction include a glycoprotein known as nidogen (previously called entactin) which interacts with type IV collagen either alone or as a laminin–nidogen complex (Fig. 3.41) [8]. Nidogens are a family of highly conserved, sulphated glycoproteins within a spectrum of binding proteins. Although nidogens are an abundant component of various basement membranes, genetic analyses have shown that they are not required for the overall architecture of the basement membrane. Instead, nidogens appear to play a critical role in the development of basement membranes in tissues undergoing rapid growth or turnover [9].

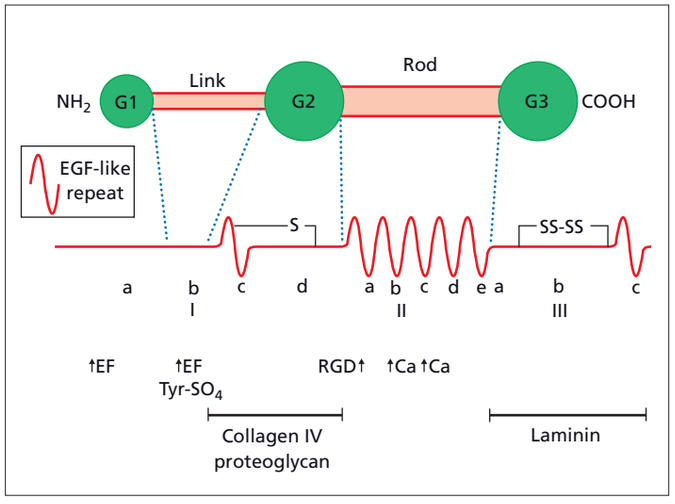

Fig. 3.41 Model of nidogen containing subdomains with predicted binding activities to type IV collagen, proteoglycans, and laminin 1. EF and Ca refer to putative calcium binding sites; RGD is a putative cell-binding sequence. EGF, epidermal growth factor. (Adapted from [11].)

Another class of integral basement membrane constituents is the heparan sulphate proteoglycans (HSPGs). These molecules consist of a core protein with different numbers of covalently associated heparan and sulphate chains which make these molecules highly negatively charged and hydrophilic. These proteoglycans are capable of interacting with a number of basement membrane components and they are likely to contribute to the overall architecture of the basement membrane. Specific cell surface HSPGs are found also on the surface of epithelial cells and possibly mediate cell-matrix interactions.

The hemidesmosome–anchoring filament complex

The dermal–epidermal junction of skin is characterized by the presence of specific structures that are critical for the functional integrity of the skin. These ultrastructurally recognizable components include hemidesmosomes, anchoring filaments and anchoring fibrils. The molecular composition and the specific domain organizations of the component macromolecules have been largely characterized (Fig. 3.44).

The hemidesmosomes are seen ultrastructurally as electron dense attachment complexes, which extend from the intracellular compartment of the basal keratinocytes to the lamina lucida in the upper portion of the dermal–epidermal basement membrane (Fig.

3.45). The intracellular component of a hemidesmosome within the basal keratinocytes attaches to the keratin intermediate filament network, while in the extracellular space within the lamina lucida the hemidesmosomes are contiguous with anchoring filaments, thread-like structures which traverse the lamina lucida and tend to concentrate below the hemidesmosomes; this unit is termed the hemidesmosome–anchoring filament complex.

Early biochemical studies identified at least five major components of hemidesmosomes, originally designated as HD1–HD5 with molecular masses of approximately 500, 230, 200, 180 and 120 kD, respectively. Various molecular and immunological approaches have subsequently identified HD2 and HD4 as the 230-kDa and 180-kDa bullous pemphigoid antigens (BPAG1 and BPAG2), respectively [1–3]; HD3 and HD5 correspond to the β4 and α6 integrin subunit polypeptides, respectively; and HD1 corresponds to plectin, a large intracytoplasmic adhesion molecule. The intracellular hemidesmosomal plaque contains the 230-kDa bullous pemphigoid antigen, a non-collagenous protein of the plakin family that serves as an autoantigen in bullous pemphigoid. The 180-kDa bullous pemphigoid antigen, a transmembrane collagenous protein, also known as type XVII collagen, interacts with α6β4 integrin and extends from the intracellular compartment of basal cells to the extracellular space, thus stabilizing the association of basal keratinocytes to the underlying basement membrane (Fig. 3.34 and 3.43).

Attesting to the critical importance of the hemidesmosomes in providing stability to the association of basal keratinocytes with the underlying BMZ is the finding that mutations in the genes encoding hemidesmosomal proteins (with the exception of *BPAG1*) have been shown to result in different forms of EB [4,5] (Fig. 3.36). For example, mutations in the *BPAG2* gene result in a relatively mild, non-Herlitz type of junctional EB; mutations in the α6β4 integrin genes (*ITGA6*, *ITGB4*) cause skin fragility associated with congenital pyloric atresia; mutations in the plectin gene (*PLEC1*) result in skin blistering disorder frequently associated with late-onset muscular dystrophy. The finding of skin and muscle manifestations as a result of mutations in the plectin gene can be explained by the fact that plectin is expressed not only in the hemidesmosomes in the epidermis but also in the sarcolemma and the Z-lines of muscle [6,7]. The causative nature of the mutations in these hemidesmosomal genes has been verified by development of targeted mutant ('knockout') mouse models, which

frequently recapitulate the clinical, genetic, histological and ultrastructural features encountered in patients with EB [8,9].

The hemidesmosomes are complexed with anchoring filaments, which are thread-like structures that tend to coalesce below hemidesmosomal outer plaques (Figs 3.34 and 3.45). Electron microscopy and immunohistochemical analyses have suggested that laminin 332 may be the major component of the anchoring filaments, although the presence of additional molecules has also been suggested, including ladinin, a recently characterized protein with currently unknown function. As indicated above, laminin 332 is a disulphide-bonded complex of α3, β3, and γ2 chains which associate into a trimeric, cruciform structure. After the initial assembly, the α3 and γ2 chains are proteolytically processed, and many of the conformational epitopes are recognized by specific antibodies. Complete absence of any of the three subunit polypeptides of laminin 332, due to loss-of-function mutations in both alleles of the corresponding gene, results in Herlitz junctional EB (Fig. 3.42) [5]. Since laminin 332 binds to α6β4 integrin in the hemidesmosomes and to type VII collagen in the anchoring fibrils, the severity of skin fragility in this form of EB apparently reflects the loss of its ability to bridge the hemidesmosomes and the anchoring fibrils, resulting in separation of the epidermis from dermis within the lamina lucida.

Anchoring fibrils

Anchoring fibrils are ultrastructurally recognizable, U-shaped structures which extend from the lower part of lamina densa to the upper reticular dermis [1] (Fig. 3.46).

Type VII collagen is the major, if not the exclusive, component of anchoring fibrils [2]. Individual collagen molecules are approximately 450 nm long, consisting of a central triple helical segment flanked by non-helical globular domains at each end of the triple helix: NC1 at the amino terminus and NC2 at the carboxy terminus of the molecule (Fig. 3.39). In addition, the triple helical segment of type VII collagen contains imperfections in the triple helix, including a central 39-amino acid non-collagenous segment. These interruptions in the glycine-X-Y sequence are thought to provide flexibility to the type VII collagen molecules [3].

The gene encoding type VII collagen (*COL7A1*) is extremely complex, consisting of 118 exons on the short arm of human chromosome 3 [4]. Type VII collagen is synthesized by both dermal fibroblasts and epidermal keratinocytes, although the basal cell appears to be the major source of type VII collagen during early prenatal development of skin. Upon secretion, two type VII collagen molecules align into an antiparallel dimer with overlapping NC2 domains, and after partial proteolysis of the NC2 domain, the dimer is stabilized by intermolecular disulphide bonds (Fig. 3.39). Subsequently, a large number of type VII molecules laterally aggregate to form anchoring fibrils in which the NC1 domains at both ends attach to the basement membrane. The U-shaped loops then entrap, and possibly interact with large interstitial collagen fibres consisting of type I, III, and V collagens [2,5] (Fig. 3.34).

The critical importance of the anchoring fibrils in securing the adhesion of the dermal–epidermal basement membrane to the underlying dermis is illustrated by the dystrophic forms of EB. Specifically, complete absence of type VII collagen results in severe, generalized, recessive dystrophic EB with fragility of the

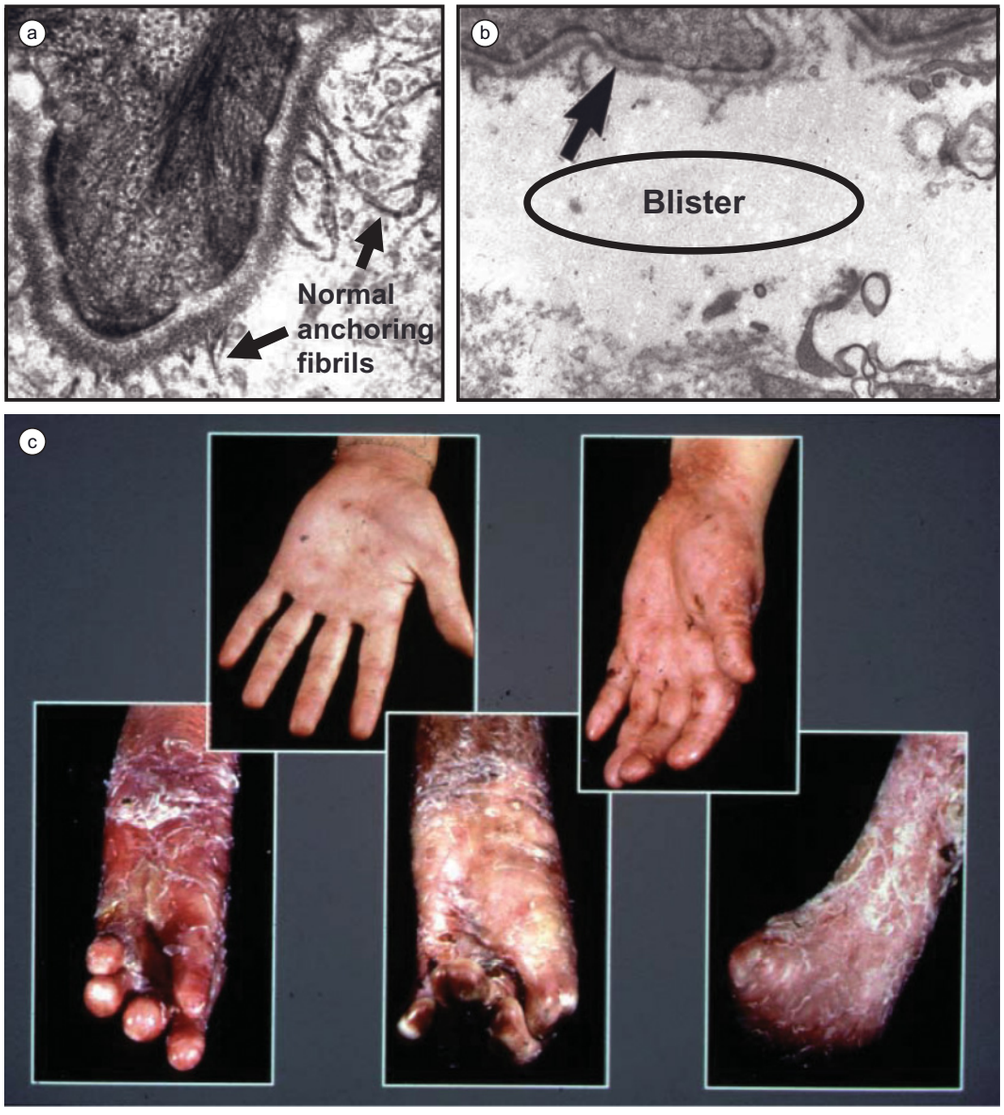

Fig. 3.46 (a) Anchoring fibrils extend from the lower part of lamina densa to the underlying upper dermis forming U-shaped loops which entrap and interact with the large collagen fibres consisting of type I, III, and V collagens. (b) In the absence of type VII collagen, the lamina densa detaches as a result of minor trauma from the underlying dermis and leads to blisters. (c) Chronic blistering and erosions result in variable scarring of the hands in recessive dystrophic EB.

skin and mucous membranes leading to mutilating scarring of the hands and feet (Fig. 3.46). Missense mutations, particularly glycine substitution mutations, can result in somewhat milder, dominantly inherited dystrophic EB [6].

Extracellular matrix of connective tissue

The major component of human skin is the dermis demarcated on the top by the lower border of the dermal–epidermal basement membrane interface and at the bottom by the subcutis. In contrast to the epidermis, the dermis is largely acellular and consists primarily of the extracellular matrix of connective tissues, a complex meshwork of various macromolecules. There are four major classes of extracellular matrix components: (a) collagen fibres, which provide tensile strength to allow skin to serve as a protective organ against external trauma; (b) elastic structures, which provide elasticity and resilience to normal human skin;

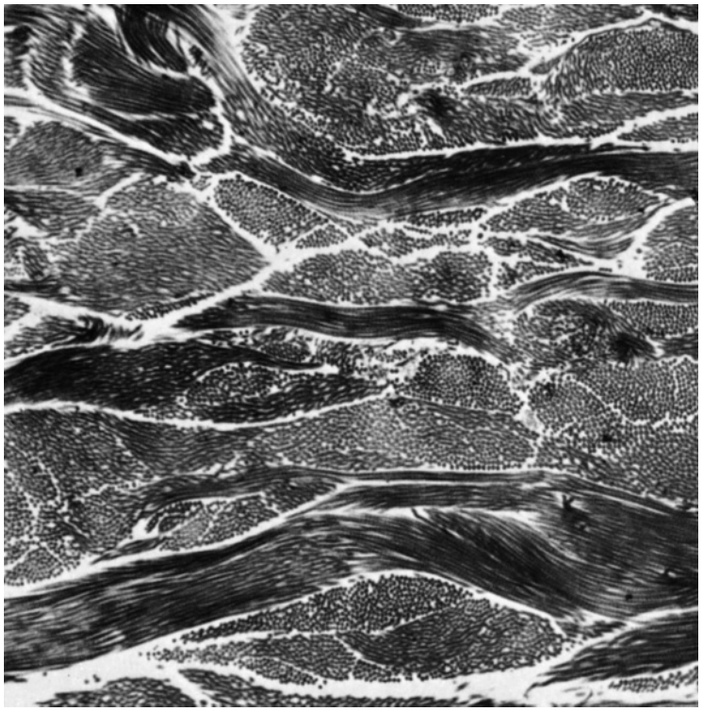

Fig. 3.47 Transmission electron micrograph of a section of dermis from the human forearm shows bundles of collagen fibres, both in transverse and longitudinal sections. Original magnification, ×4900. (c) non-collagenous glycoproteins, such as fibrillins, fibulins and integrins, which often serve as organizers of the matrix and facilitate cell-matrix interactions; and (d) proteoglycan/glycosaminoglycan macromolecules, which provide hydration to the skin. Maintenance of proper quantities and appropriate interactions between the extracellular matrix components is a prerequisite for the physiological homeostasis of the dermis.

The collagen family of proteins

The major extracellular matrix component in the dermis is collagen, which comprises a family of closely related yet genetically distinct proteins [1–4]. The major collagen fibres in the dermis provide tensile strength to the skin to serve as a protective organ against external trauma (Fig. 3.47).

A characteristic feature of all collagens is the presence of the triple-helical conformation, which is predicated upon the primary amino acid sequence of the subunit polypeptides, α-chains, depicting a repeating glycine-X-Y sequence. The collagens also demonstrate non-collagenous flanking segments at the ends of the individual molecules. Currently, 29 distinct collagens have been identified in vertebrate tissues, and have been characterized to the extent that they are referred to by Roman numeral designation (I–XXIX) in the order of their discovery, many of them being present in the skin (Table 3.3).

All collagen molecules consist of three subunit polypeptides which can either be identical as homotrimers or can consist of two or even three genetically different polypeptides in heterotrimeric molecules. Since the different subunits are all distinct gene products, there are over 40 different genes in the human genome that encode the different subunit polypeptides, the α-chains, of these distinct collagens [5].

Collagens in the skin

On the basis of their fibre architecture in tissues, the genetically distinct collagens can be divided into different classes [1,2]. Types I, II, III, V and IX align into large fibrils and are designated as fibril-forming collagens. Type IV is arranged in an interlacing network within the basement membranes, while type VI is a distinct microfibril-forming collagen, and type VII collagen forms anchoring fibrils. FACIT collagens (fibril-associated collagens with interrupted triple-helices) include types IX, XII, XIV, XIX, XX and XXI. Many of the latter collagens associate with larger collagen fibres and serve as molecular bridges, stabilizing the

AD, autosomal dominant; AR, autosomal recessive.

organization of the extracellular matrices. The major collagens significantly contributing to skin physiology and pathology are presented in Table 3.3. Other collagen types, including types II, IX, X, XI, XIX, XX and XXI, are not discussed in detail because they are not present in the skin to a significant extent or their participation in maintaining skin physiology is unclear.

Type I collagen, the most abundant form, is the predominant collagen in human dermis, accounting for approximately 80% of the total collagen. Type I collagen contains two different kinds of α-chain with an $[\alpha(I)]_2\alpha2(I)$ stoichiometry. A collagen consisting of three identical α1(I) chains has also been identified (so-called α1(I)-trimer), but it appears to be only a minor component of connective tissue in the skin. Type I collagen associates with type III collagen to form broad, extracellular fibres in the human dermis. Mutations in type I and III collagens, or in their processing enzymes, can result in connective tissue abnormalities in the different forms of Ehlers–Danlos syndrome (Table 3.4), and mutations in the type I collagen gene are responsible for the fragility of bones in osteogenesis imperfecta.

Type III collagen accounts for about 10% of the total bulk of collagen found in adult human dermis. It was originally shown to predominate in human skin during embryonic development, but during the early postnatal period, type I collagen synthesis accelerates, resulting in the ratio of type I to type III collagen in the adult human skin being approximately 8:1. Type III collagen is most prominent in vascular connective tissues, the gastrointestinal tract and the uterus. It consists of three identical α-chains, α1(III), and mutations in the type III collagen gene can cause the vascular type of the Ehlers–Danlos syndrome [3,4].

Type IV collagen is a basement membrane collagen present within the dermal–epidermal junction as well as in the vascular basement membranes (Fig. 3.37). The predominant form of type IV collagen in human skin is a heterotrimer of $[\alpha1[IV)]_2\alpha2(IV)$, although occasional homopolymers from these two chains may be assembled. The type IV collagen molecule is characterized by the presence of non-collagenous interruptions within the triple-helical domains, thus conferring flexibility to the molecule. In addition to α1 and α2 chains, four other polypeptides of type IV collagen have been identified [5]. Type IV collagen molecules containing these polypeptides are present primarily in the glomerular basement membranes, and their importance for renal physiology is attested by the fact that mutations in the gene encoding the α5(IV) polypeptide results in Alport syndrome. The α3(IV) chain harbours the epitopes recognized by antibodies in Goodpasture's syndrome, and the α5 chain of type IV collagen has been shown to be a target of circulating autoantibodies in a novel autoimmune disease with subepidermal blisters and renal insufficiency.

Type V collagen consists of interrelated collagens containing four different types of α-chains. Type V collagen is present in most connective tissues, including dermis, where it represents less than 5% of the total collagen. Type V collagen is located on the surface of large collagen fibres in the dermis, and its function is to regulate the lateral growth of these fibres. Thus, in the absence of type V collagen, the collagen fibre diameter is variable and the contour of the individual fibres can appear irregular, some of them having 'flower-like' morphology in cross-section. The importance of type V collagen in contributing to connective tissue stability is attested by the fact that mutations in the type V collagen gene underlie most patients with classic, autosomal dominant forms of Ehlers–Danlos syndrome [6].

Type VI collagen, as originally discovered, consists of three distinct α-chains, α1(VI), α2(VI) and α3(VI), which fold into a relatively short triple-helical domain and contain large globular domains at both ends. More recently, three additional α-chains have been suggested to belong to the type VI family of collagens [7]. Type VI collagen is a relatively minor collagen in human dermis where it assembles into thin microfibrils independent of the broad collagen fibres, which consist primarily of type I and type III collagens. The microfibrillar network has an anchoring function, stabilizing the assembly of collagen fibres as well as basement membranes. Mutations in the three type VI collagen genes can lead to different forms of muscular dystrophy with little effect on the physiology of skin [8].

Type VII collagen, the major if not the exclusive component of anchoring fibrils, consists only of one type of α1 chain, α1(VII). This polypeptide has a characteristic modular structure, with the central collagenous domain being flanked by amino-terminal (NC1) and carboxy-terminal (NC2) collagenous domains with homology to known protein sequences (Fig. 3.48). A large number of genetic mutations have been identified in the *COL7A1* gene, as shown in Fig. 3.48. The mutations above the type VII collagen polypeptide are associated with recessively inherited forms of dystrophic epidermolysis bullosa and are primarily premature termination-causing ones resulting in the synthesis of truncated,

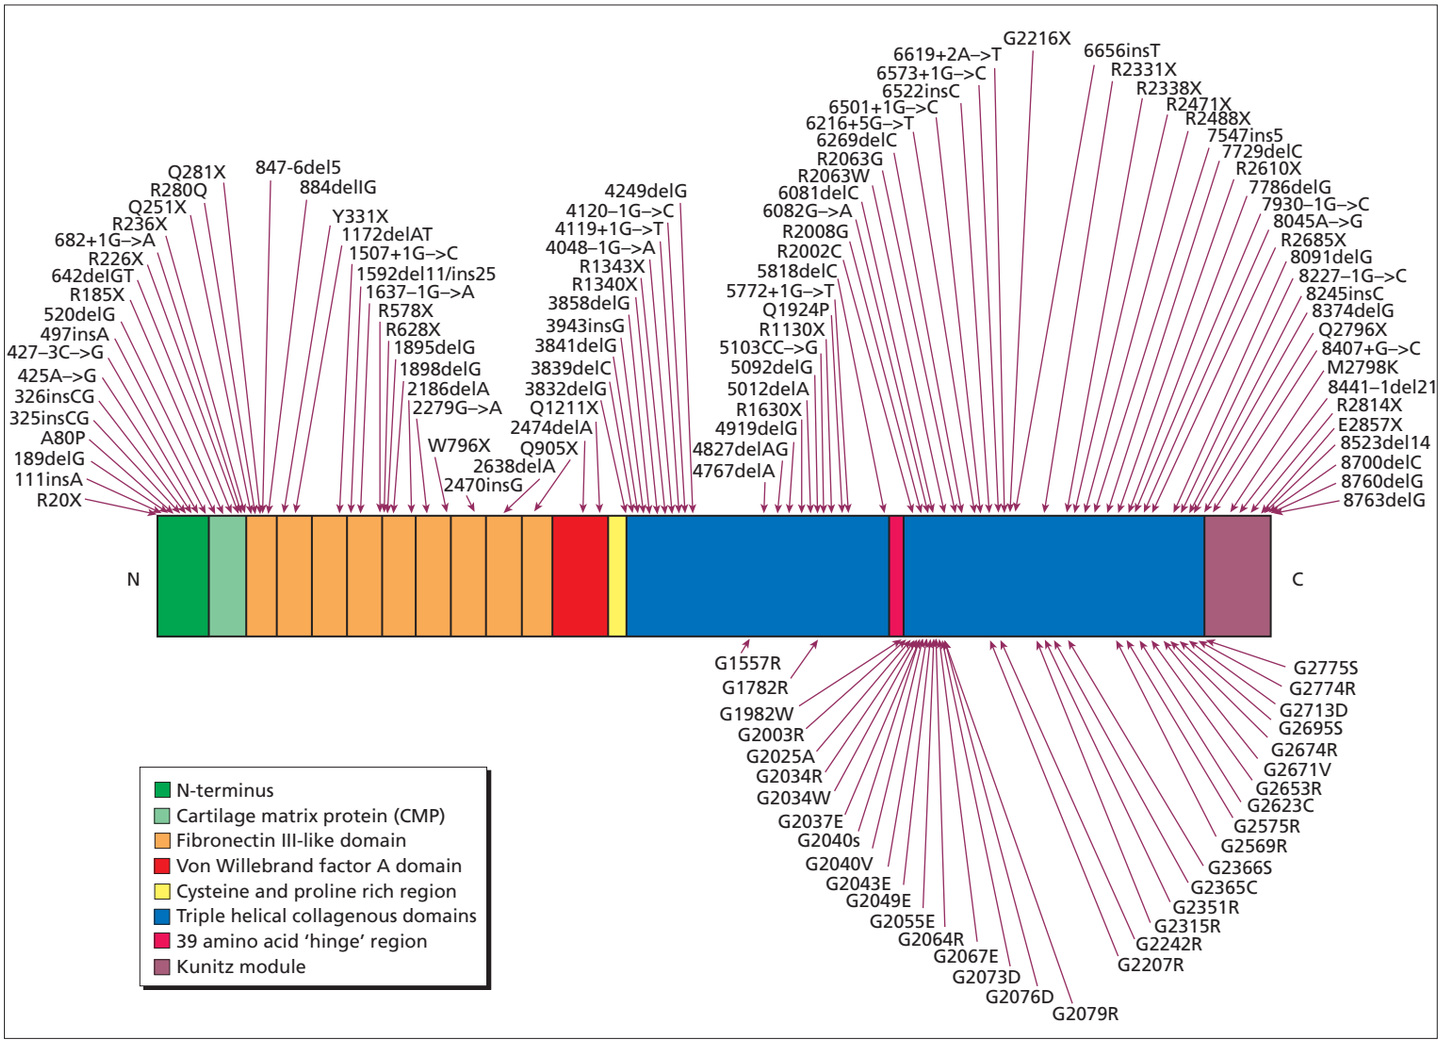

Fig. 3.48 Schematic representation of a type VII collagen monomer with its domain organization and illustration of mutations underlying the dystrophic forms of epidermolysis bullosa. (Adapted from [14].)

and therefore non-functional, polypeptides. The mutations depicted below the polypeptide are missense mutations causing substitutions of critical glycine residues in the triple-helical collagenous domain of the protein and are associated with dominantly inherited forms of epidermolysis bullosa [9].

Type VII collagen molecules become organized into anchoring fibrils through the formation of antiparallel dimers linked through their carboxy-terminal ends (Fig. 3.39). The large amino-terminal, non-collagenous NC1 domains interact with type IV collagen and laminin 332 at the dermal–epidermal basement membrane, forming U-shaped loops that entrap larger fibres in a manner that stabilizes the association of the lower part of the lamina densa to the upper papillary dermis (Fig. 3.46). Consequently, altered expression or changes in the molecular interactions of type VII collagen with other basement membrane components can result in skin fragility as exemplified by the dystrophic forms of epidermolysis bullosa [9]. In addition to the heritable forms of EB, type VII collagen serves as an autoantigen in the autoimmune blistering skin disease EB acquisita, the majority of antigenic epitopes residing within the NC1 domain [10].

Type XVII collagen was initially identified as the 180-kDa bullous pemphigoid antigen (BPAG2) recognized by circulating autoantibodies in the sera of patients with bullous pemphigoid or herpes gestationis. Subsequent characterization of the protein and the corresponding gene has indicated that BPAG2 is, in fact, a collagenous molecule consisting of 15 collagenous domains with characteristic Gly-X-Y repeat sequences which form triple-helices [11] (Fig. 3.49).

Type XVII collagen is a transmembrane protein in type 2 topography, that is the amino-terminal segment of the molecule is intracellular while the carboxy-terminal ectodomain, containing the collagenous segments, is in the extracellular space. The importance of type XVII collagen to the stability of the dermal–epidermal junction is attested to by the fact that mutations in the corresponding gene (*COL17A1*) result in a non-Herlitz variant of junctional EB, originally designated as generalized atrophic benign

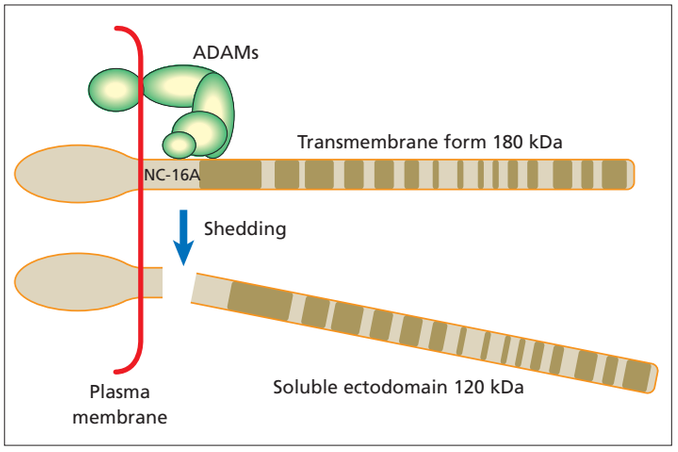

Fig. 3.49 Schematic representation of type XVII collagen, a transmembrane protein in type 2 orientation. Note that the ectodomain traversing the lamina lucida contains 15 distinct triple-helical collagenous segments (COL1–15). The non-collagenous segment between COL15 and the transmembrane domain, NC-16A, harbours the major epitopes recognized by autoantibodies in bullous pemphigoid. ADAMs, a disintegrin and metalloproteinase with thrombospondin motifs cleaves the protein at a sequence in the NC-16A, resulting in release of the ectodomain. (Adapted from [15].)

epidermolysis bullosa (GABEB), and circulating autoantibodies to type XVII collagen (BPAG2) are associated with bullous pemphigoid [12].

Type XXIX collagen is a putative epidermal collagen with a specific gene expression pattern; the highest level of expression is in the skin, lung and the gastrointestinal tract [13]. In the skin, expression is restricted to the epidermis with the highest level in suprabasal layers. This collagen was initially identified through genetic linkage of patients with atopic dermatitis to a locus on the short arm of chromosome 3q21. The locus contained a single gene encoding a collagenous segment flanked by multiple von Willebrand factor-A like domains, with a high degree of homology with the α3 chain of type VI collagen. Immunofluorescence staining of skin from patients with atopic dermatitis demonstrated a striking lack of collagen XXIX in the viable, outermost spinous and granular layers, suggesting a role in atopic dermatitis.

Collagen biosynthesis

The genetically distinct collagens demonstrate considerable tissue specificity, and, accordingly, they are synthesized by a number of different cell types, including dermal fibroblasts, epidermal keratinocytes, vascular endothelial cells and smooth muscle cells. The individual α-chains are initially synthesized as precursor molecules, pro-α-chains, with non-collagenous extensions at the ends of the collagenous domain (Fig. 3.50).

While in the rough endoplasmic reticulum, three individual pro-α-chains assemble into a trimeric molecule through their interactions of the non-collagenous sequences at the carboxy-terminal end. Upon completion of the prolyl hydroxylation reactions, the collagenous domains of the α-chains fold into triple-helical conformations, and the collagen molecules are then secreted through Golgi vesicles into the extracellular milieu. In the extracellular space, parts of the non-collagenous peptide extensions are cleaved by specific proteases, and the collagen molecules then assemble into their tissue-specific supramolecular organization. For example, the fibrillar collagens align into a characteristic quarter-stagger arrangement and form fibres, the growth occurring at the tip of the growing fibre. The coarse collagen fibres in the mid-dermis consist primarily of type I and type III collagens, and type V collagen associates with them on the surface of the fibre so as to regulate the diameter of the growing fibre (Fig. 3.38). Type VII collagen assembles into centrosymmetric anchoring fibrils within the dermal–epidermal basement membrane zone, and type XVII collagen assumes a transmembrane type 2 orientation as a component of the hemidesmosomes (Figs 3.36 and 3.40).

A characteristic feature of collagen is the presence of hydroxyproline and hydroxylysine residues, two amino acids that are post-translationally synthesized by hydroxylation of proline and lysine residues, respectively [1] (Fig. 3.51).

These hydroxylation reactions are catalysed in the rough endoplasmic reticulum by prolyl and lysyl hydroxylases, respectively, enzymes that require ascorbic acid, molecular oxygen and ferrous iron as cofactors. The hydroxylation of prolyl residues is necessary for the stabilization of the triple-helical conformation at physiological temperatures, and hydroxylysyl residues are required for formation of stable covalent crosslinks. Thus, for example, as a

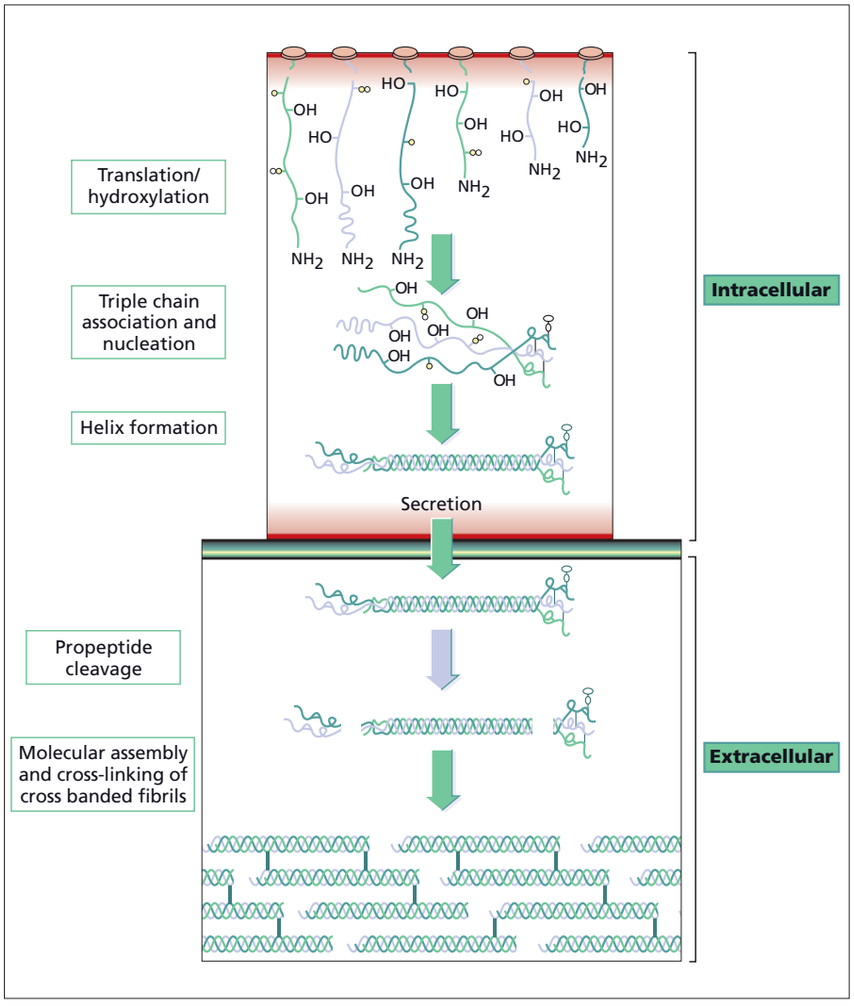

Fig. 3.50 Steps in the intracellular biosynthesis of triple-helical type I procollagen, its secretion into the extracellular space, and assembly and cross-linking of mature collagen fibres in the extracellular space.

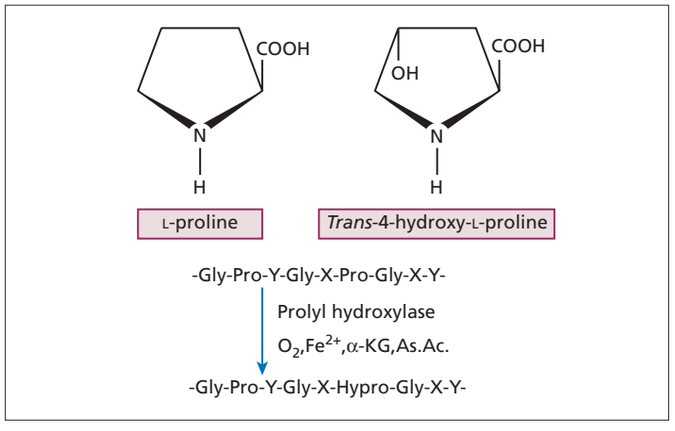

Fig. 3.51 Schematic representation of the enzymatic hydroxylation of prolyl residues in the Y-position of the repeating Gly-X-Y amino acid sequence to form hydroxyproline, an amino acid characteristic of collagen. Note that the reaction requires molecular oxygen, ferrous iron, α-ketoglutarate (α-KG) and ascorbic acid (As.Ac.) as co-factors.

result of ascorbic acid deficiency in scurvy, the hydroxylation reactions are suboptimal, the newly synthesized collagen is poorly functional, and clinically scurvy manifests with connective tissue weakness. Similarly, low oxygen tension in chronic ulcers and wounds due to poor circulation may impair collagen production, resulting in poor healing.

Hydroxylation of the lysyl residues is followed by *O*-glycosylation, catalysed first by galactosyltransferase, which adds a galactosyl residue to the hydroxyl group of hydroxylysine, followed by glucosyltransferase reaction to form glucosyl-galactosyl-hydroxylysine in *O*-glycosidic linkage. Additional glycosylation in *N*-glycosidic linkage will take place on the non-collagenous extensions at the end of the triple-helical molecule, but the functional significance of these glycosylation reactions is currently unclear.

Regulation of collagen gene expression

The regulation of collagen gene expression has to be tightly controlled in order to maintain normal amounts and ratios of genetically distinct collagens under physiological conditions. At the same time, regulatory mechanisms have to be responsive to the needs of rapid collagen synthesis in repair processes, such as wound healing. On the other hand, uncontrolled collagen synthesis can lead to excessive accumulation of collagen in fibrotic diseases, as exemplified by systemic sclerosis, keloids and hypertrophic scars [1,2].

An important control mechanism is at the level of collagen mRNA formation through regulation of the transcriptional activity of the corresponding genes. In general, there is a good correlation between the rate of collagen biosynthesis and the corresponding procollagen mRNA levels, as demonstrated in several *in vitro* models, including cultured fibroblasts. The transcriptional regulation of collagen gene expression involves a number of both *cis*-acting elements and *trans*-acting factors. The *cis*-acting elements, nucleotide sequences within the regulatory regions of the gene that serve as binding sites for *trans*-acting regulatory proteins, have been identified in most collagen gene regulatory regions [2]. Such factors can either up-regulate or suppress the transcriptional promoter activity. An example of such *trans*-acting factors are the retinoic acid nuclear receptors (RAR and RXR) that form a complex with the ligand (a retinoid) which then binds to the retinoic acid-responsive elements (RARE) in the target gene [3]. Retinoids, such as all-*trans*-retinoic acid, have been shown to modulate collagen gene expression both *in vitro* and *in vivo*, and quiescent non-proliferating cells can be stimulated by retinoic acid to activate type I collagen synthesis. These observations may have relevance to the elevated rate of collagen synthesis observed in photodamaged dermis treated by topical application of retinoids [4]. All-*trans*-retinoic acid has also been demonstrated to increase the density of anchoring fibrils along the cutaneous basement membrane zone in adult human skin, suggesting that retinoids are capable of up-regulating type VII collagen gene expression.

Collagen gene expression can also be modulated by a number of cytokines and growth factors, and one of the most powerful modulators of connective tissue gene expression is transforming growth factor-β (TGF-β) [1,5]. In general, TGF-β is pro-fibrotic and it has been shown to up-regulate the expression of a number of extracellular matrix protein genes, including those encoding collagen types I, III, IV, VI and VII. Elevated levels of TGF-β have also been demonstrated in various fibrotic lesions, including the skin in systemic sclerosis and keloids. The up-regulatory activity of TGF-β can be counteracted by other cytokines, including tumour necrosis factor-α and interferon-γ, which antagonize the TGF-β action [1]. These cytokines have been tested for their efficacy for the treatment of keloids and other fibrotic diseases, with variable results.

A number of hormones clearly regulate collagen gene expression, as certain endocrine disorders dramatically change the amount of collagen found in connective tissues, including the skin. Glucocorticosteroids also affect collagen biosynthesis; inhibition is much more pronounced with fluorinated steroids compared to hydrocortisone. The glucocorticosteroid inhibition of collagen biosynthesis occurs in lower concentrations at the transcriptional level through inhibition of the promoter activity. In higher concentrations and with more potent glucocorticosteroids, inhibition of prolyl hydroxylase activity also is evident, leading to deficient hydroxylation of collagen polypeptides and subsequently to reduced amounts of newly synthesized collagen. These mechanisms would explain the connective tissue side effects, such as dermal atrophy, associated with intralesional or prolonged topical application of fluorinated glucocorticosteroids.

Collagen cross-linking

The alignment of collagen molecules into their specific supramolecular organization occurs spontaneously, but these fibre structures do not attain the necessary tensile strength until the molecules have been covalently linked together by specific intra- and intermolecular cross-links [1,2]. The most common forms of cross-link in type I collagen are derived from lysine and hydroxylysine residues, and in some collagens there are also cysteine-derived disulphide bonds. The first step in the cross-linking process is enzymatic synthesis of aldehyde residues from lysyl and hydroxylysyl residues by removal of the ε-amino group of these amino acids (Fig. 3.52).

This oxidative deamination reaction is catalysed by lysyl oxidases (LOX), a group of enzymes that require copper as a co-factor. These enzymes act primarily upon native collagen fibrils and poorly, if at all, on denatured collagen (gelatin) or isolated α-chains. Similar deamination reaction catalysed by lysyl oxidase occurs also in elastin.

In addition to the classic human lysyl oxidase, four additional lysyl oxidase-like (LOXL1–4) genes/proteins have been identified. These lysyl oxidase-like enzymes have been postulated to play a role in a number of disease processes. For example, *LOXL1* gene sequence variants confer susceptibility to exfoliation glaucoma and elastin was found to be the major component of the ocular lesions in this disease [3,4]. The expression of lysyl oxidase-like 2 is increased in a number of cancers, and LOXL2 has been shown to be a marker for poor prognosis with decreased overall and disease-free survival in squamous cell carcinomas [5]. LOXL3 and 4 demonstrate structural features similar to LOX and have wide tissue distribution [6,7]. Alterations in lysyl oxidase activities have also been described in a number of experimental systems involving age-related changes in the cardiovascular system [8].

Collagen degradation

Collagen fibres, once fully matured by the cross-linking processes, are relatively stable and can exist in tissues under normal physiological conditions for long periods. However, there is continuous, yet slow, degradation and turnover of collagen in normal situations, as attested by continuous urinary excretion of hydroxyproline as a marker of collagen degradation. In addition, in certain physiological situations, as exemplified by reabsorption of the postpartum uterus, and in pathological conditions, such as tissue invasion and tumour metastases, degradation of connective tissues and particularly collagen is accelerated. There are a number of enzymes that comprise the family of matrix metalloproteinases (MMP), enzymes capable of degrading the extracellular matrix components. These proteinase families include the collagenases, gelatinases, stromelysins, matrilysins and the membrane-type MMPs [1–3] (Fig. 3.53).

Native collagen is resistant to nonspecific proteolytic degradation in physiological situations due to the fact that the triple-helical conformation is not readily degradable by general proteases. However, collagenases have the ability to degrade collagen triple-helix at physiological pH and temperature. The vertebrate collagenase was initially isolated from tadpole tails which, when cultured upon reconstituted type I native collagen substrate, exercise proteolytic activity, and similar techniques were subsequently employed to demonstrate the presence of collagenase in human skin. Interstitial collagenase (MMP1) was initially shown to be synthesized as a proenzyme by cultured fibroblasts, and later on, different cell types, including epidermal keratinocytes, were shown to express a similar or identical enzyme. The ability of interstitial collagenase to digest the type I collagen triple helix is based on its ability to specifically cleave the α1(I) chain at a particular glycine-isoleucine, or α2(I) chain at a glycine-leucine peptide bond. This initial cleavage results in two degradation products, three-quarters and one-quarter of the size of the original collagen molecule. These shortened triple-helical fragments have a lower helix-to-coil transition temperature (Tm) than the full-length molecule, and subsequently at temperatures below 37°C the triple-helix unravels, rendering the individual polypeptides susceptible to general proteolytic degradation. It should be noted that type I collagen has several additional glycine-isoleucine and glycine-leucine sequences, but these are not susceptible to

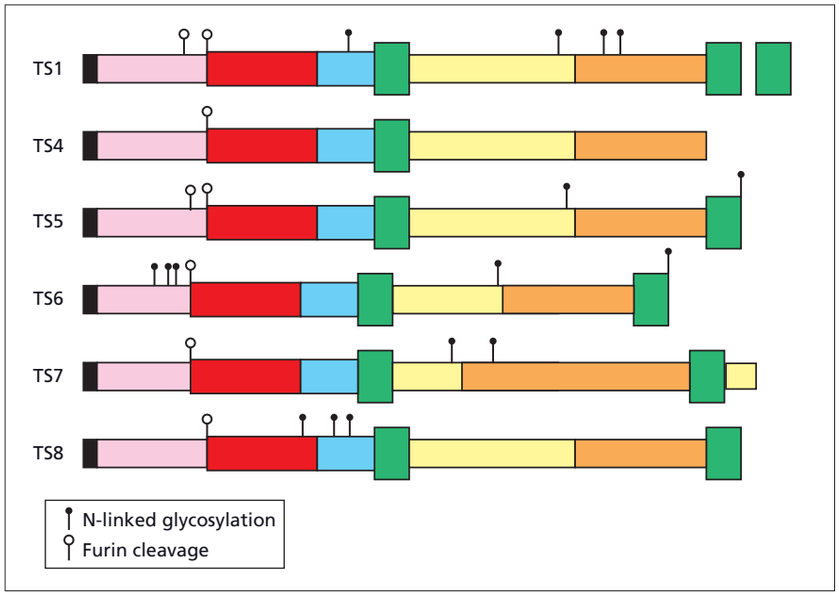

Fig. 3.54 Schematic representation of the main organization of various ADAMTS family metalloproteinases. The catalytic domain is shown in red, while other domains include the thrombospondin type I repeat sequences (green), disintegrin-like domain (blue), and cysteine domain (yellow). The signal peptidase is shown in black, the propeptide sequence is coloured pink, and the spacer domain is in orange.

collagenase degradation in this collagen when in the native triple-helical conformation. A similar enzyme (MMP8) has been identified in human neutrophils with comparable degrading characteristics. The neutrophil collagenase is stored in neutrophil granules and released upon stimulation. MMP1 and MMP8 can, in addition to type I collagen, degrade a number of other collagens, including types III and VII.

Another group of extracellular proteolytic enzymes is the gelatinases, which are able to degrade denatured collagen (gelatin) but can also cleave certain native collagens, such as types IV, V and VII, with certain interruptions or imperfections in their collagenous triple helices, thus allowing the proteolytic cleavage at these sites. The basement membrane collagen IV can also be degraded by MMP3 (stromelysin-1) and MMP10 (stromelysin-2).

In general, MMPs are synthesized and secreted as inactive proenzymes, which become activated proteolytically by removal of the propeptide. The MMPs are zinc metalloenzymes and require calcium for their activity. Consequently, the enzymes can be inhibited by chelators of divalent cations, and, pharmacologically, tetracyclines have been suggested to inhibit MMP proteolytic activity due to their ability to bind calcium. The MMPs also have specific, small molecular weight peptide inhibitors, so-called tissue inhibitors of metalloproteinases (TIMPs). These proteins stoichiometrically complex with MMPs preventing the degradative events.

In normal human skin, a number of MMPs are synthesized and secreted by fibroblasts and keratinocytes. The expression of these enzymes is activated in various pathological situations, including invasion and metastasis of cutaneous malignancies, as well as during dermal wound healing and epidermal regeneration [2,4]. Finally, proteolytic enzymes play a pathophysiological role in tissue separation in a number of blistering diseases, such as bullous pemphigoid, dermatitis herpetiformis and epidermolysis bullosa acquisita [5].

Another metalloproteinase family has been designated as ADAMTS (a disintegrin and metalloproteinase with thrombospondin motifs). The prototype, *ADAMTS-1* gene can be induced by interleukin-1 *in vitro* or by lipopolysaccharide injection in mice, and, thus, this metalloproteinase was initially associated with inflammatory processes [6]. Subsequently, a number of ADAMTS genes have been identified with similar domain organizations, consisting of a signal sequence, a propeptide, a metalloproteinase domain, a disintegrin-like domain, a cysteine-rich region and a variable number of thrombospondin type-1 molecules [7] (Fig. 3.54). These molecules are zinc-dependent proteases with a high level of expression in fetal tissues. ADAMTS proteases also have high levels of expression in tumour cells and tissues, including melanoma and colon carcinoma. Of particular interest in the context of collagen processing is ADAMTS-2, which serves as procollagen I/II amino-propeptide processing enzyme.

Regulation of extracellular matrix turnover and collagen degradation during postpartum involution of the uterus has been attributed to relaxin, a hormone initially implicated in pregnancy-related conditions. More recently, it has become clear that a number of tissues, including skin, can serve as targets of relaxin. These tissues contain a relaxin family peptide receptor-1 (RFPR1) which mediates the relaxin effects on connective tissue metabolism, contributing to the maintenance of tissue homeostasis. The critical role of relaxin and its receptor has been illustrated by targeted mutant mice in which the absence of relaxin leads to collagen accumulation in a number of tissues, similar to systemic sclerosis [8,9].

Elastic fibres

An integral component of the dermal connective tissue is the elastic fibre network which provides resilience and elasticity to the skin. Elastic fibres are a relatively minor component in normal sun-protected adult skin, being less than 2–4% of the total dry weight of the dermis. The elastic fibre system in the reticular dermis consists of horizontally oriented fibres which interconnect to provide a network structure. Extending from these horizontal fibres is a network of vertical extensions of relatively fine fibrils, which consist either of bundles of microfibrils (oxytalan fibers) or of small amounts of cross-linked elastin (elaunin fibres) (Fig. 3.55).

Elastic fibres have two principal components: (a) elastin, a well-characterized connective tissue protein which forms the core of the mature fibres; and (b) the elastin-associated microfibrils which consist of a family of proteins, some of them less defined [1–3]. Examination of mature elastic fibres by transmission electron microscopy reveals an electron-lucent core which consists of elastin (Fig. 3.56). Surrounding the elastin core are distinct microfibrillar structures, which appear electron-dense under routine electron microscopy staining. While elastin is the major component and the microfibrils are less conspicuous in fully mature elastic fibres, the relative proportion of these two components varies during the embryonic development of elastic fibres and/or connective tissue repair. The first elements of elastic fibres that form consist of bundles of microfibrils, which can be visualized by electron microscopy during the first trimester of gestation. These microfibrils form a scaffold, allowing alignment of the elastin molecules in parallel array so as to guide the growth of fibres with relatively uniform diameters [4]. During the second trimester of fetal development the elastic fibres remain immature, but with increasing fetal age maturation of the fibres occurs and the elastin component becomes more prominent. In fully developed elastic fibres, well over 90% of the total content is elastin with relatively few microfibrillar components, mostly confined to the outer surface of the fibres.

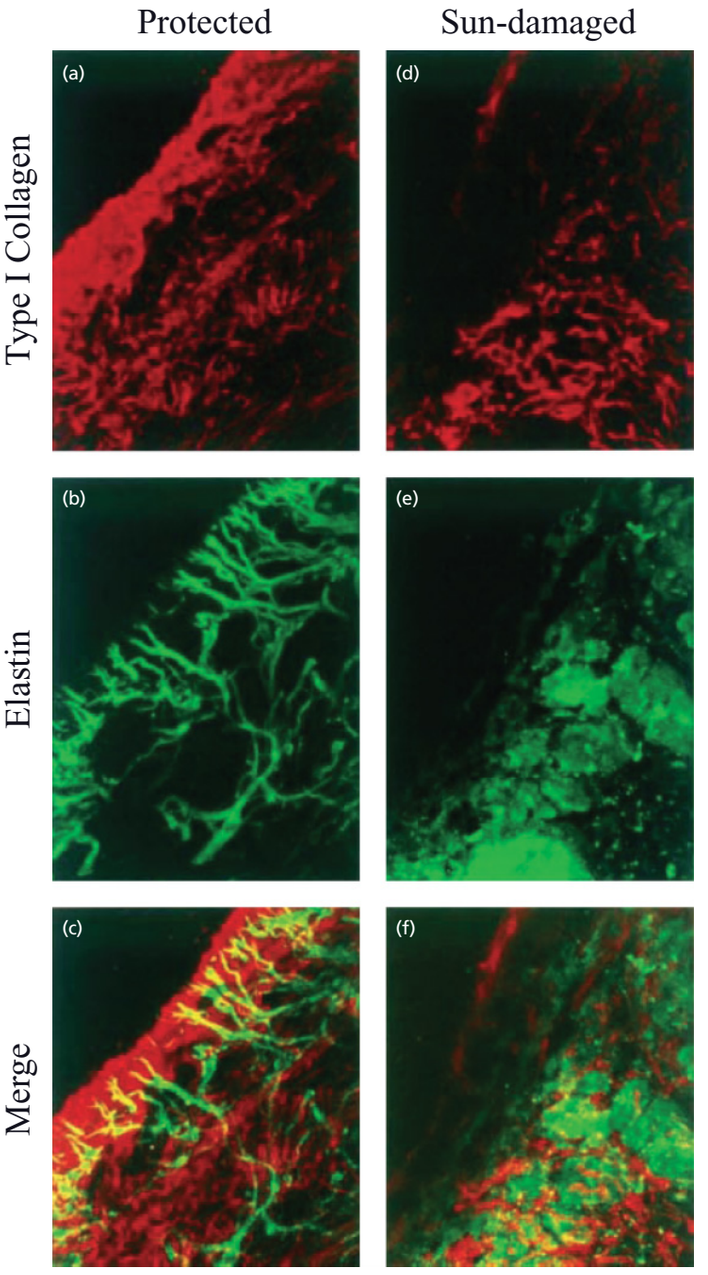

Fig. 3.55 Immunofluorescence staining of type I collagen (a,d) and the elastic fibre network (b,e) in the dermis of human skin visualized by confocal laser scanning microscopy. Merging of the images (c,f) reveals that the elastic fibres assume a horizontal orientation in the mid-dermis while vertical extensions (oxytalan and elaunin fibres) reach the upper dermis, terminating just below the dermal–epidermal junction. Note that in sun-damaged skin there is a dramatic decrease and disorganization of both collagen and elastic fibres in comparison with sun-protected skin. (Adapted from [5].)

Elastin

Elastin is initially synthesized as a precursor polypeptide, 'tropoelastin', which consists of approximately 700 amino acids with a molecular mass of approximately 70 kDa [1]. The amino acid composition of tropoelastin is similar to collagen, in that about one-third of the total amino residues consist of glycine. However, glycine is not evenly distributed in elastin in every third position as it is in a typical collagenous sequence. Instead, the tropoelastin primary sequence shows domains rich in glycine, valine and proline, alternating with lysine and alanine-rich sequences. A characteristic sequence motif in the latter setting is the presence of two lysine residues separated by two or three alanine residues (Fig. 3.57).

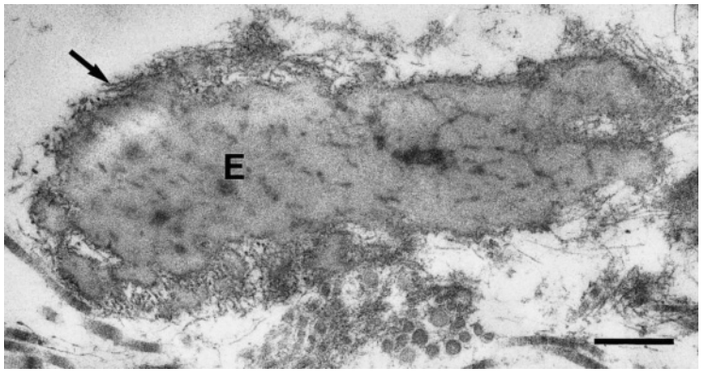

Fig. 3.56 Transmission electron microscopy of an elastic fibre in the reticular dermis. The central electron-pale core consists of elastin (E), while the electron dense areas represent the elastin-associated microfibrillar proteins which are particularly evident at the periphery of the fibre (arrow). Scale bar, 0.5 µm.

The lysine residues in tropoelastin are critical for formation of covalent cross-links, desmosine and its isomer, isodesmosine, that are unique to elastin. The first step in formation of these elastin-specific cross-links is oxidative deamination of three lysine residues to form corresponding aldehydes, so-called allysines. Three of these resulting aldehydes, together with a fourth lysine residue containing the intact unmodified ε-amino group, spontaneously fuse to form a stable desmosine compound which covalently links two of the tropoelastin polypeptides. Addition of desmosines to other parts of the molecule progressively converts tropoelastin molecules into an insoluble fibrous structure which can be stretched, but upon release the fibres recoil providing resilience and elasticity to the skin (Fig. 3.58). The content of desmosine in various elastin preparations is fairly constant, with approximately 1.5 residues per 1000 amino acids, and desmosine or isodesmosine

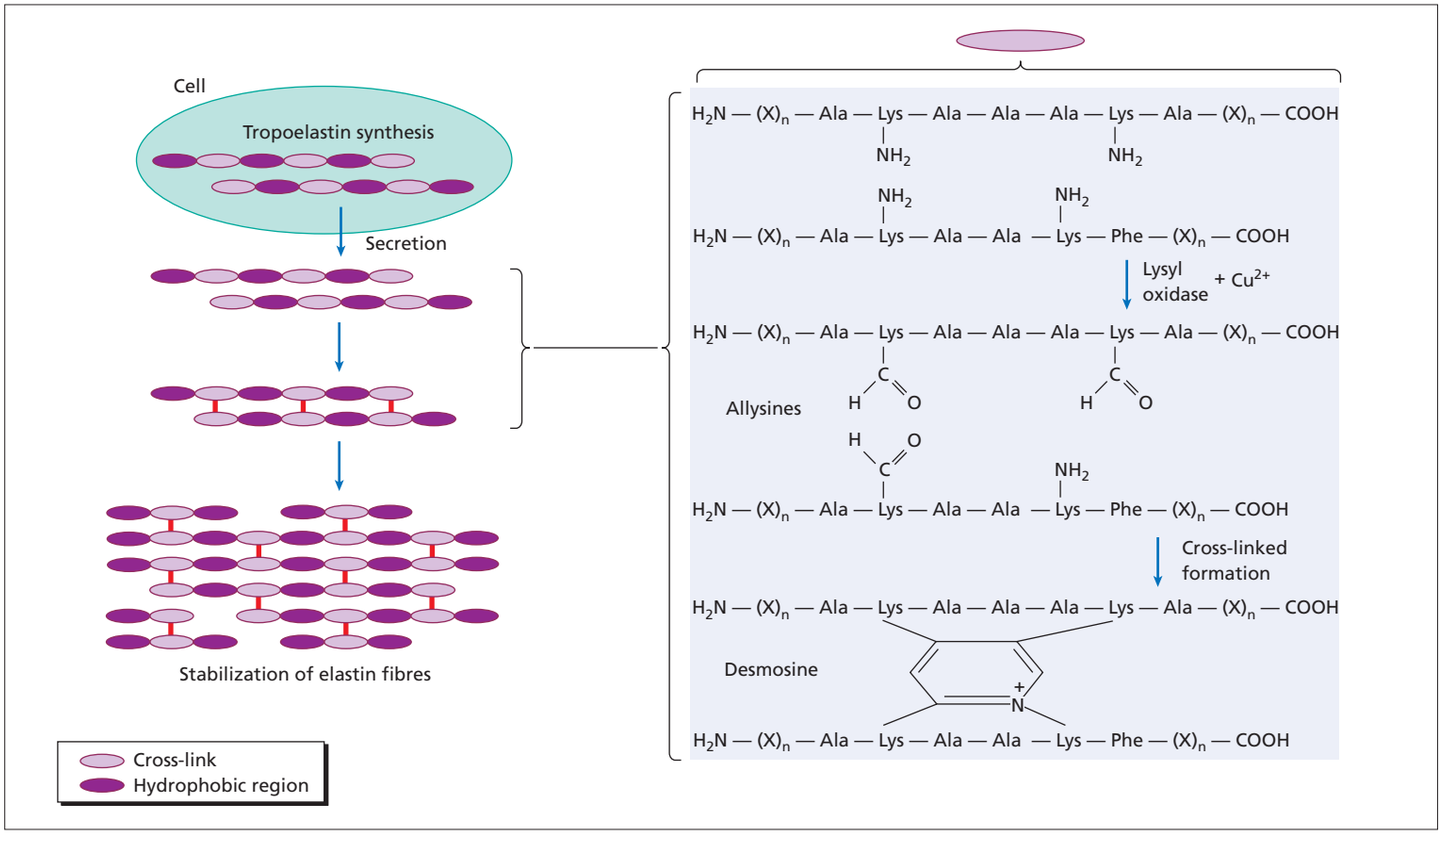

Fig. 3.57 Assembly and cross-linking of elastic fibres. Newly-synthesized elastin precursor polypeptides, tropoelastins, with alternating hydrophobic and cross-link regions are secreted into the extracellular milieu. Lysine residues in characteristic lys-ala-ala-lys or lys-ala-ala-ala-lys sequences in the cross-link region undergo oxidative deamination of the ε-amino groups catalysed by lysyl oxidase, an enzyme requiring copper as co-factor. Three resulting allysine residues fuse with an unmodified lysine residue to form desmosines, elastin-specific cross-link molecules. (Modified from [6].)

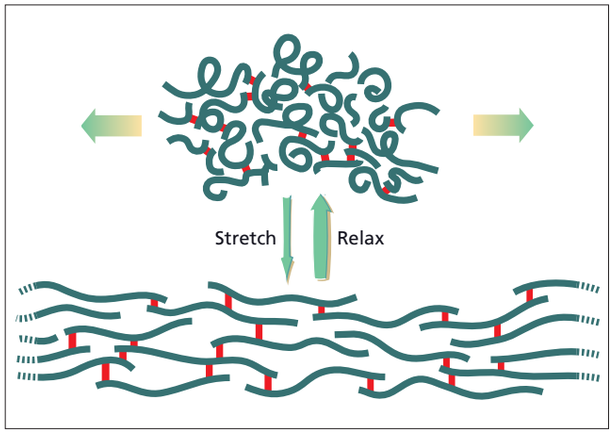

Fig. 3.58 Schematic representation of elastic fibres cross-linked by desmosines (red). In relaxed state, the fibres assume coiled-coil conformations. When the fibres are stretched and then released, they return to relaxed state, the contraction providing elasticity and resilience to the skin.

can therefore provide a quantitative measure of the insoluble elastin content in tissues.

The human elastin gene spans approximately 45 kb of genomic DNA on chromosome 7 and consists of 34 exons corresponding to 3.5 kb of human elastin mRNA sequences. Examination of the gene structure reveals that the alternating cross-link domains, characterized by presence of lysyl residues separated by two or three alanines, and the hydrophobic domains, are encoded by individual exons. The elastin mRNAs are synthesized in a number of cell types present in elastin-rich tissues, as for example, the vascular smooth muscle cells in arterial connective tissues. In the skin, the primary cell type responsible for elastin production appears to be the fibroblast which, under tissue culture conditions, expresses the elastin gene. Keratinocytes have also been suggested to express the elastin gene, but the level of expression is very low in comparison to dermal fibroblasts and the potential significance of elastin in the epidermis remains unclear.

Primary mutations in the elastin gene have been demonstrated in cutis laxa, a group of diseases that manifest with loss or fragmentation of elastic fibres [2]. It should be noted, however, that this group of heritable diseases is highly heterogeneous, and mutations in the fibulin-4 and fibulin-5 genes have also been observed. Williams syndrome is a contiguous gene deletion syndrome that also involves the elastin gene, with clinical manifestations predominantly in the cardiovascular system [3]. Finally, cutis laxa can develop as a post-inflammatory condition, probably mediated by proteolytic enzymes released from the inflammatory cells [4].

An interesting observation during the processing of elastin mRNA precursor molecules is that they undergo extensive alternative splicing, leading to formation of elastin molecules of varying primary sequences. In fact, at least six exons in the human elastin gene have been reported to be subject to alternative splicing, and this mechanism can provide significant variation in the primary sequence composition of elastin polypeptides, leading to different types of elastic fibres in different tissues. However, the physiological significance of the alternative splicing has not been established.

The oxidative deamination of lysyl residues to corresponding aldehydes is catalysed by a group of enzymes, lysyl oxidases, which require copper for their activity. Thus, copper deficiency can lead to reduced lysyl oxidase activity and synthesis of elastic fibres that are not stabilized by sufficient amounts of desmosines. In such a situation, the individual tropoelastin polypeptides remain soluble and susceptible to non-specific proteolysis, and the elastin-rich tissues are fragile. Clinical manifestations of copper deficiency can vary depending on the level of copper and its circulating transport protein, caeruloplasmin, as manifested by Menkes' syndrome and the occipital horn syndrome, two conditions allelic due to mutations in the copper transporter protein gene, *ATP7A* [5]. Copper deficiency can also occur in patients undergoing long-term treatment with high doses of D-penicillamine, a copper chelating agent, which can result in abnormalities in the elastic structures in the skin and other tissues.

The metabolic turnover of elastin is slow, but a portion of elastin in the body is continuously degraded as reflected by the continuous presence of desmosines in the urine. Thus, there may be an ongoing turnover and repair of elastic fibres in normal tissues. In addition, there are a number of pathological conditions in which degradation of elastin is the histopathologic hallmark, such as some forms of cutis laxa and cutaneous ageing. Elastic fibres are degraded by elastases, a group of elastolytic enzymes in different tissues and with different cleavage specificities [4]. The classic elastases, such as those originally isolated from the pancreas, are serine-proteases, and their activity can be inhibited by serum factors, such as α1-antitrypsin and α2-macroglobulin. In addition to these classic serine-elastases, there are a number of metalloenzymes that are capable of degrading elastic structures, particularly the microfibrillar components. These metalloelastases are present in the skin and originate from fibroblasts and monocyte-macrophages.

Elastin-associated microfibrils

The elastin-associated microfibrils consist of tubular structures of approximately 10–12 nm in diameter. Both ultrastructural evidence and biochemical analyses have confirmed that the microfibrils differ from elastin, and they may also be found in a number of tissues as individual microfibrillar structures without direct association with elastin. It is now known that the elastin-associated microfibrils consist of a number of proteins, which can be divided into several different categories based on their molecu-

lar characteristics [1]. Many of them form gene families with closely related structure and function, but clearly different from other groups in their structural features.

One of the microfibrillar protein families is the fibrillins, which are a critical part of the microfibrillar structure [2]. Two distinct, yet closely homologous, human genes encode fibrillin 1 (FBN1) and fibrillin-2 (FBN2), proteins characterized by multiple repeats of sequence motifs previously observed in the epidermal growth factor (EGF) precursor molecule, with each motif having six conserved cysteine residues. Electron microscopy has established that monomeric fibrillin molecules synthesized by fibroblasts show an extended flexible molecule, which is approximately 148 nm long and 2.2 nm wide. Multiple fibrillin molecules can then align in a parallel, head-to-tail fashion to form microfibrils associated with elastin in tissues, such as skin and the arterial connective tissues. It should be noted that fibrillin is also a major component of microfibrils in tissues such as the ocular ciliary zonule and the periodontal ligament, without microscopic or immunoreactive evidence of elastin. The importance of fibrillin 1 is illustrated by the fact that the mutations in the corresponding gene (*FBN1*) underlie Marfan's syndrome, manifesting with skeletal abnormalities, aortic dilatations, subluxation of the lens and cutaneous laxity [3]. Fibrillin 2 (*FBN2*) mutations cause congenital contractural arachnodactyly with some similarities, but also differences, to Marfan's syndrome.

The latent transforming growth factor-β binding family of proteins (LTBP) has some structural similarities with the fibrillins, including repeating EGF-like domains [4]. Transforming growth factor-β, a pro-fibrotic cytokine, is secreted as a latent complex bound to LTBP. There are at least four distinct proteins in the family, with a molecular weight ranging from 125 to 310 kD. One of the putative functions of LTBPs is to facilitate the secretion of TGF-β or binding of the inactive complex to the cell surface where activation takes place. However, LTBPs have also been found as free proteins associated with components of the extracellular matrix. LTBP1, a prototype of this subfamily of elastin-associated microfibrillar proteins, is clearly a component of the elastic fibres in human skin, and its levels are altered in solar elastosis.

Another family of the elastin-associated microfibrillar proteins consists of fibulins, extracellular matrix glycoproteins with characteristic calcium binding EGF-like domains. Five distinct fibulins have been characterized (fibulins 1–5; FBLN1–5), and at least four of them have been located within the elastic fibres in different tissues [5]. In addition, FBLN-5 has been shown to bind both muscle cells and elastin, thus apparently facilitating cell-matrix interactions. The importance of FBLN-4 and FBLN-5 in skin physiology is attested by demonstration of mutations in the corresponding genes in patients with cutis laxa, manifesting with loose and sagging skin and loss of recoil [6–8].

In addition to fibrillins, LTBPs and fibulins, a number of other proteins have been shown to be associated with elastic fibres in the microfibrillar network. Several of these proteins belong to the families of microfibril-associated glycoproteins (MAGP) or microfibril-associated proteins (MFAP), highly acidic, relatively small molecules, some of which have been characterized in detail [1]. In addition, interface proteins, so called emilins, as well as lysyl oxidases critical for the crosslinking and stabilization of elastic fibre structures, have been shown to be associated with elastic fibres [9,10].

Proteoglycan/glycosaminoglycan macromolecules

Proteoglycans form a number of subfamilies defined by a core protein to which polymers of unbranched disaccharide units, glycosaminoglycans (GAG), are linked by an O-linkage to serine residues (Fig. 3.59). There are a number of distinct core proteins, the number of attached disaccharides varies, and the molecular mass of GAGs is highly variable. Commensurate with variability in structure, different proteoglycans are of different functional importance as critical components of cell membranes and the extracellular matrix of the skin during development, homeostasis and disease [1].

GAGs are highly charged polyanionic molecules which attach to the core protein. The characteristic feature of GAGs is their primary structure, consisting of alternating pairs of different monosaccharides, glucose or galactose, joined in 1-3 or 1-4 linkage (Fig. 3.60). After the initial synthesis of GAGs, the polymers undergo complex post-assembly modifications catalysed by specific enzymes. Sulphatases catalyse replacement of *N*-acetyl by *N*-sulphate and epimerases convert D-glucuronic to L-iduronic acid. The linear GAG chains, consisting of linked disaccharide units, are highly variable in size, ranging from just a few to several thousands and, consequently, the molecular mass of naturally occurring GAGs can range from 5×10^3 to 5×10^7 Daltons.

The degree of post-assembly modifications is highly variable, and the control of this reaction depends on the specific characteristics of the GAGs, the associated core protein as well as the cell type and tissue environment (Fig. 3.61). The simplest GAG, hyaluronic acid, is not sulphated, while other GAGs show sulphation of varying degrees. Within the individual GAG chains, there are regions that show either low or high degree of sulphation, a

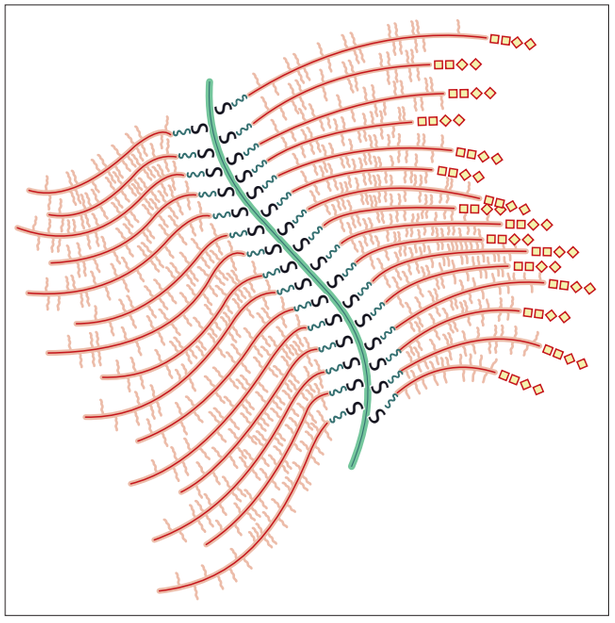

Fig. 3.59 Representation of a prototypic proteoglycan in which the central core (green) is hyaluronic and the link proteins are represented by S-shapes, joining the protein side-chains and carbohydrate polymers. (Adapted from [9].)

feature that may facilitate interactions of proteoglycans and GAGs with their numerous binding partners.

The core proteins of proteoglycans have been increasingly characterized through cloning and sequencing of the corresponding genes. These genes are expressed in a number of different types of cells, including dermal fibroblasts which are the principal cell type for proteoglycan synthesis in the dermis. Newly synthesized core protein polypeptides are transferred to Golgi vesicles where the attachment of GAG chains occurs. The final product, consisting of a core protein with attached GAG chains, allows classification of the proteoglycans. It should be noted that hyaluronic acid is a GAG produced without synthesis of a core protein; instead, this macromolecule is synthesized by a complex of enzymes at the plasma membrane, with subsequent extrusion into the extracellular space.

Known core proteins with their predominant tissue distribution and associated GAG components are listed in Table 3.5. The core proteins can be intracellular, reside on the cell surface or be part of the extracellular matrix. For example, serglycin shows an intracellular core protein present in secretory granules of haematopoietic cells, such as mast cells and eosinophils, associated with either heparan sulphate or chondroitin sulphate GAGs. This proteoglycan is found in the skin in areas infiltrated by mast cells or eosinophils, and, on subsequent release, serglycin is a major form of highly sulphated heparan sulphate GAG in the skin.

There are a number of cell-surface proteoglycans which function at the interface between the plasma membranes and the extracellular matrix. The mode of attachment to the cell surface is variable. For example, the glypican family of proteoglycans is attached to the cell surface by a phospholipid anchor, while the syndecans have membrane-spanning core proteins. Syndecans and glypicans are present in a number of cells and tissues, including abundant expression in the skin. Syndecan expression varies during development and maturation of tissues, and, for example, syndecan-1 is particularly abundant in keratinocytes. The nature of the attached GAG chains, however, changes as keratinocytes differentiate. Syndecans-1 and 4 are also induced in the dermis and granulation tissue, and it has been shown that deletion of syndecan-4 from mice greatly decreases the rate of wound repair. Furthermore, there are alterations in syndecan-1 expression as a result of malignant transformation [2–4].

The extracellular matrix contains a number of different proteoglycans as an integral component of the connective tissue meshwork. In the dermis, fibroblasts produce large proteoglycans, as exemplified by versican, consisting of a core protein with attachment sites for 12 to 15 GAG side chains (Fig. 3.62). The GAGs in versican are primarily chondroitin sulphate or dermatan sulphate, but versican can also bind hyaluronic acid, resulting in formation of large aggregates. In the skin, versican has been identified in the dermis and epidermis as a product of fibroblasts and keratinocytes, respectively.

Extracellular matrix contains a number of small proteoglycans, exemplified by the family of leucine-rich repeat motifs. The prototype of this family is decorin, abundantly present in the skin. The decorin core protein is relatively small in size and has a single dermatan sulphate side chain covalently bound to a serine residue at the amino acid position 4 of the core protein. This proteoglycan was designated 'decorin' due to the observation that it associates with collagen and 'decorates' the fibres *in vivo*. This binding is attributed to the availability of decorin core protein to bind type I collagen, but the single GAG chain of decorin also binds to tenascin-X, another extracellular component with affinity for collagen fibrils. Consequently, these interactions contribute to the connective tissue organization and architecture with functional consequences for normal skin physiology [4,5].

Proteoglycan/GAG complexes have a multitude of functions. For example, the proteoglycans containing heparan sulphate and dermatan sulphate have the ability to bind extracellular matrix components, including various collagens. In addition, these proteoglycans bind several growth factors, cytokines, cell adhesion molecules and growth factor binding proteins and they can serve as antiproteases. In addition to binding to a number of extracellular molecules, proteoglycans also play a role in the adhesion of cells to the extracellular matrix. For example, syndecan-4, which is selectively enriched in dermal fibroblasts, facilitates the adherence of the cells in conjunction with other extracellular matrix binding molecules, such as the integrins. Furthermore, the formation of focal adhesions requires heparan sulphate and subsequent activation of protein kinase C by a domain in the syndecan-4 core protein cytoplasmic tail [6].

Proteoglycans also interact with other extracellular matrix molecules besides collagen. In addition to decorin, which is known to associate primarily with type I collagen, chondroitin sulphate and dermatan sulphate bind fibronectin and laminin. The largest extracellular GAG, hyaluronic acid, plays an important role in providing physicochemical properties to the skin, mediated at least in part by its hydrophilicity and viscosity in dilute solutions.

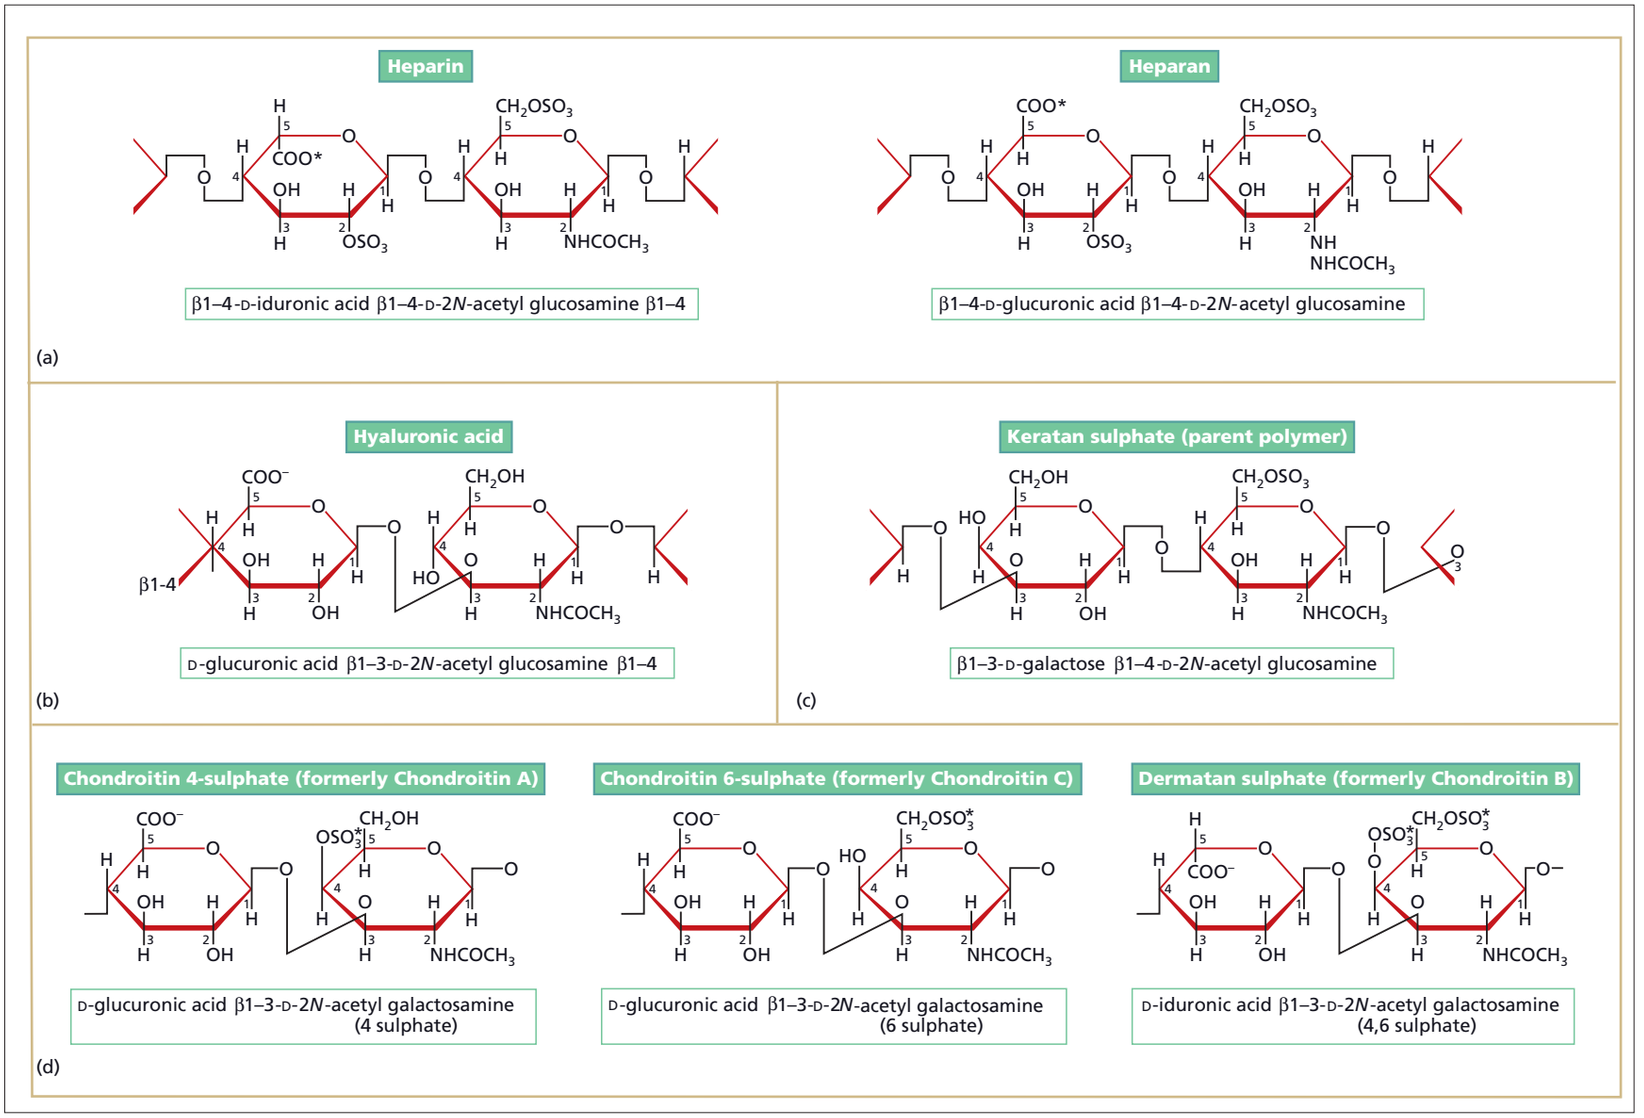

Fig. 3.60 Schematic representation of the glycosaminoglycan molecules which comprise the carbohydrate polymer side-chains of proteoglycan molecules, including (a) heparin and heparan, (b) hyaluronic acid, (c) keratan sulphate, and (d) various chrondroitin sulphates. Note the variants that include O-sulphation at the 6 position of both glucosamine and galactose.

Table 3.5 Molecular characteristics and tissue distribution of selected proteoglycans.

PG	Protein (kDa)	Glycosaminoglycan(s)	Gene location	Tissue distribution
Decorin	36	CS/DS	12q21–23	Connective tissue
Biglycan	38	CS/DS	Xq28	Cell surface
Fibromodulin	42	KS	1q32	Collagen matrix
Lumican	38	KS	12q21–22	Cornea, bowel, cartilage, muscle
Epiglycan	36	CS/DS		Epiphyseal cartilage
Versican	260–370	CS/DS (10–30)	5q13	Skin, blood vessel, cartilage, brain
Aggrecan	220	CS (100)	15q26	Cartilage, blood vessel, brain
Perlecan	400–470	HS/CS	1p36	Cartilage, bone marrow
Agrin	210	HS (3–6)	1q32	Cell membranes, kidneys, neuromuscular
Neurican	136	CS (3–7)		Brain
Brevican	100	CS (1–3)		Brain
Testican	44	HS/CS	21	Testis

CS, chondroitin sulphate; DS, dermatan sulphate; KS, keratan sulphate; HS, heparan sulphate.

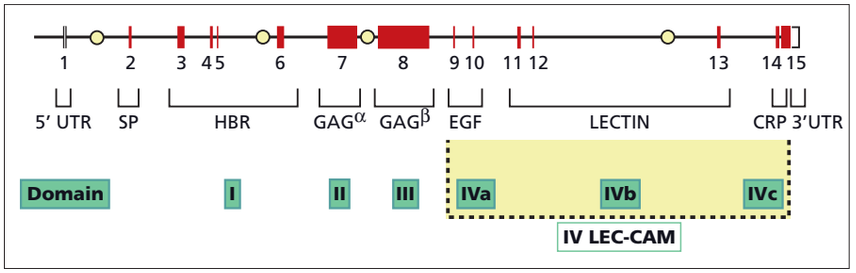

Fig. 3.62 The human versican gene: intron–exon organization (top) and deduced functional domains of the encoded protein. UTR, untranslated region; SP, signal peptide; HBR, hyaluronan-binding region; GAG, glycosaminoglycan; EGF, epidermal growth factor; CRP, complement regulatory protein. (Adapted from [11].)

Most notably, hyaluronic acid has an expansive water-binding capacity, providing hydration to normal skin. The expression of hyaluronan is developmentally regulated in the skin, and the gene required for its synthesis, hyaluronan synthase, has been characterized. During wound healing, the physicochemical properties of hyaluronan may serve to expand the matrix and thus aid cell movement. The relatively high content of hyaluronan may also explain the finding that wounds in fetal skin heal without scarring. Finally, other properties attributed to large proteoglycans complexes, such as those formed with versican or basement membrane proteoglycans, include their ability to serve as ionic filters, regulate salt and water balance and provide an elastic cushion [7].

Quantitative changes in the deposition of tissue proteoglycans have been encountered in a number of pathological processes. These include elevated hyaluronic acid synthesis in keloids and other fibrotic processes, as well as in pretibial myxoedema. In other skin conditions, including lichen myxoedematosus, systemic scleroderma and pseudoxanthoma elasticum, the lesional areas of skin have been reported to display abnormal amounts of proteoglycans. In most of these cases, the changes in proteoglycan/GAG content are secondary to an unrelated primary event. Finally, during innate cutaneous ageing in sunprotected areas of skin, the content of hyaluronic acid diminishes, possibly explaining the reduced turgor in aged skin [8].

Fibroblasts

The principal cell type responsible for the synthesis of connective tissue in the dermis is the fibroblast, which is of mesenchymal origin. The term fibroblast refers to a fully differentiated, biosynthetically active cell, while the term fibrocyte refers to an inactive cell. Biosynthetically active fibroblasts, as detected in developing or regenerating tissues, have an abundant cytoplasm, well-developed rough endoplasmic reticulum, and prominent ribosomes attached to the membrane surfaces, features characteristic of cells engaged in active synthesis and secretion of extracellular matrix macromolecules (Fig. 3.63). As indicated in the case of collagen, the polypeptides are first assembled in the cisternae of the rough endoplasmic reticulum, and the precursor polypeptides subsequently undergo extensive post-translational modifications. The newly-synthesized polypeptides are then transferred to the Golgi vesicles and secreted to the extracellular milieu.

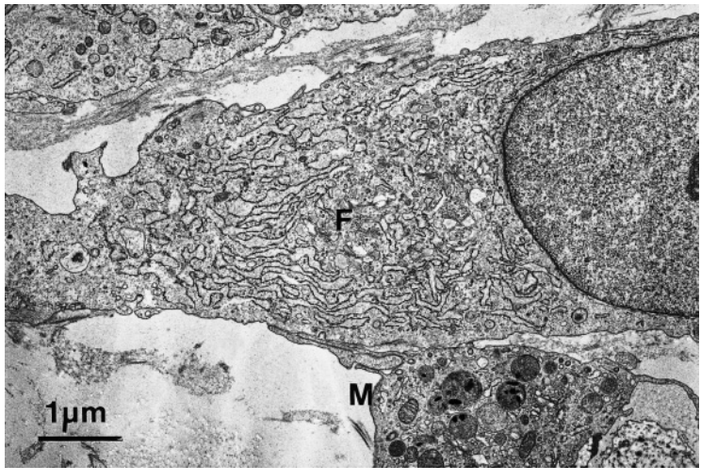

Fig. 3.63 Transmission electron microscopy of an activated dermal fibroblast (F) in a healing wound. Note the prominent rough endoplasmic reticulum in the cytoplasm of this cell. There is an adjacent macrophage (M) with characteristic phagolysosomes, some of which contain ingested melanosomes.

Human skin fibroblasts are the principal cell synthesizing collagen in the dermis. While the source of elastic fibres in the skin is less obvious, fibroblasts clearly have the capacity to synthesize elastic tissues *in vitro*, and they probably are the primary source of elastin within the dermis as well. Finally, fibroblasts are the primary, if not the exclusive, cellular source of proteoglycan/glycosaminoglycan macromolecules. There is, however, considerable heterogeneity within fibroblast populations, and it has been demonstrated that the ratio of type I/III collagen synthesis or fibronectin expression in any given fibroblast population can be variable. For example, fibroblasts isolated from the papillary versus reticular dermis of skin have higher rate of synthesis of type III collagen, and there can be as many as 30-fold differences in the level of fibronectin expression within individual cells [1].

The multiple functions of the stroma of vertebrate animals is dependent on the architecture of the extracellular matrix, which contains mesenchymal cells and provides a structural scaffold for blood and lymphatic vessels and nerves. Reciprocal interactions between the mesenchymal and epithelial cells are known to play a critical role in the development and morphogenesis of tissues, such as skin. More recently, the specific gene expression patterns in cultured fibroblasts derived from fetal and adult human skin at different anatomical sites have been explored [2,3]. Fibroblasts from different sites were shown to display distinct and characteristic transcriptional patterns, and groups of differentially expressed

genes include some involved in extracellular matrix synthesis, lipid metabolism and cell signalling pathways that control proliferation, cell migration and fate determination. Large differences in the gene expression programmes were also related to anterior–posterior, proximal–distal and dermal versus non-dermal anatomic divisions.

Remarkably, adult fibroblasts maintain key features of *HOX* gene expression patterns established during embryogenesis, suggesting that the *HOX* genes direct topographic differentiation and retain the detailed positional memory in fibroblasts. In that sense, fibroblasts from different parts of the skin should be considered distinct, differentiated cell types. Collectively, these findings suggest that site-specific variations in fibroblast gene expression programmes are systematically related to their positional identities relative to the major anatomical axes [2,3].

While fibroblasts demonstrate certain variability in their gene expression profile, they are considered fully differentiated cells with relatively little plasticity. Recent, remarkable observations suggest, however, that fibroblasts can be induced to become pluripotent stem cells (iPS), essentially indistinguishable from embryonic stem cells (ES) [4,5]. Specifically, transduction of cultured fibroblasts with four transcription factors, *Oct4*, *Sox2*, *Klf4* and *cMyc*, generated pluripotent stem cells, and similar protocols have been developed without the participation of the *Myc* retrovirus [6]. Furthermore, transduction of human skin cancer cell lines with mir-302, a member of the microRNA family, which is highly expressed in slow-growing human embryonic cells and which quickly decreases after differentiation and proliferation, rapidly converted the cancer cells into a pluripotent state with the expression of key embryonic cell markers [7]. Collectively, development of these technologies holds promise for the reprogramming of fibroblasts in a manner that allows development of patient- and disease-specific pluripotent stem cells for the treatment of diseases without a significant risk of immune rejection.

MicroRNAs (miRNAs) are short non-coding RNAs involved in post-transcriptional regulation of gene expression, and over 500 miRNAs have been identified so far in humans [8]. Their biological importance was initially demonstrated for a role in cancer and, subsequently, they have been suggested to play a role in a number of clinical conditions. Certain miRNAs have also been suggested to contribute to skin development, for example by invoking differentiation through suppression of 'stemness' of the stem cells [9,10]. Recent results have also suggested that miRNA deregulation may be involved in the pathogenesis of psoriasis by contributing to the dysfunction of the cross-talk between resident and infiltrating cells [11].

Fibroblasts in disease

Certain types of fibroblast may be associated with disease processes resulting from altered extracellular matrix production. For example, the fibroblastic cells in keloids, connective tissue tumours characterized by excessive deposition of collagen, depict large rough endoplasmic reticulum and have the characteristics of myofibroblasts with a well-developed intermediate filament network [1,2]. The keloid fibroblasts also appear to be less responsive to signals that normally regulate the homeostatic level of collagen gene expression and are necessary to maintain the regulated growth of normal collagen fibres. Another example of morphologically abnormal fibroblasts is those noted in the skin of patients with lipoid proteinosis. Transmission electron microscopy of the skin shows fibroblastic cells with peculiar cytoplasmic inclusions with characteristic duplication of basal lamina at the dermal–epidermal junction and surrounding the blood vessel walls [3]. This autosomal recessive disorder with protean cutaneous and neurological manifestations is now known to result from mutations in the extracellular matrix protein 1 gene (*ECM1*) [4].

Blood vessels and lymphatics

The arteries entering the skin form a deep plexus, the 'fascial' network, from which individual vessels rise to the border between the subcutaneous adipose tissue and the dermis to form a 'cutaneous' vessel network. These vessels then branch out towards various cutaneous appendages and provide ascending arterioles to generate a subpapillary plexus, which forms capillary loops entering the papillary dermis between the rete ridges. From these capillaries the blood is drained by venules which form intermediate plexuses. Thus, the cutaneous vasculature is rather elaborate and limited to the dermis, while the epidermis has no blood vessels [1–3] (Fig. 3.64).

In addition to providing nutrients and oxygen to the skin, the vasculature plays a major role in regulating the body temperature.

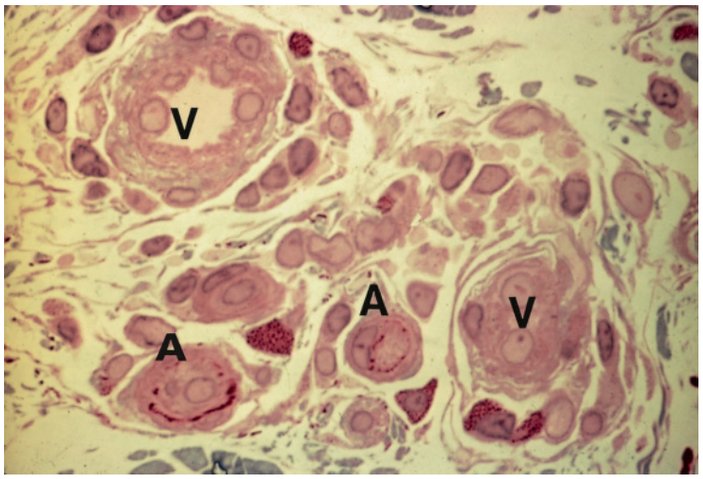

Fig. 3.64 Histology of microvessels in reticular dermis. Arterioles (A) can be distinguished from venules (V) by the presence of elastic lamina which stains red. Surrounding mast cells can be distinguished by their prominent red/blue cytoplasmic granules. (Basic fuchsin and methylene blue stain; original magnification, ×400.)

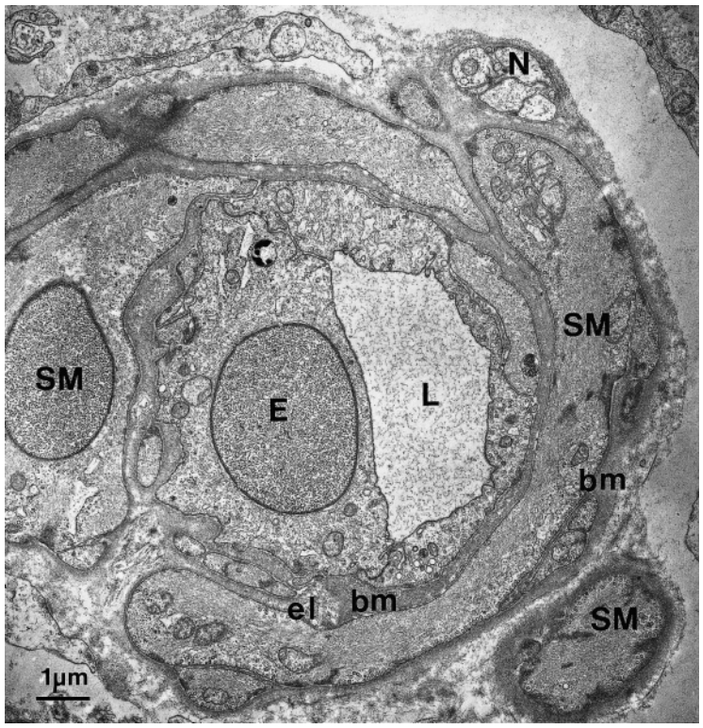

Fig. 3.65 Transmission electron microscopy of cross-section through a small arteriole in the skin. Note the relatively smooth surface of the endothelial cell (E) surrounding the lumen (L) and the presence of smooth muscle (SM) with an associated nerve (N). There is a small amount of elastic tissue (el) adjacent to the endothelial basement membrane (bm).

This is accomplished by controlling the blood flow through the capillaries in the upper dermis so that opening allows dissipation of excess heat while constriction of the blood vessels slows the blood flow to the skin and conserves the core energy. The amount of blood flowing through the superficial layers of the dermis can also be controlled by arterial–venous anastomoses, which act as shunts to short-circuit the flow.

The innermost component of the blood vessels is the endothelium, consisting of adjoining endothelial cells that surround the lumen. Arterioles are characterized by a subendothelial layer of elastic tissue, while venules generally do not have elastic tissue in their walls (Figs 3.65 & 3.66). The endothelium of capillaries and the small arterioles and venules is surrounded by pericytes, which appear to share certain characteristics with both endothelial and smooth muscle cells. Capillaries contain a single, discontinuous layer of pericytes, whereas venules may include more than one pericyte layer in their periendothelial investment. Smooth muscle cells are found chiefly in the walls of ascending arterioles but also within the arterioles of the superficial and deep plexus and in collecting venules. Smooth muscle cells and pericytes are surrounded by a basement membrane, which also encompasses the outer surface of endothelial cells. Veil cells are long, thin cells with an attenuated cytoplasm, and they more closely resemble fibroblasts than pericytes. They do not have a basement membrane investment and are located outside the vessel wall [4].

At the ultrastructural level, endothelial cells possess many of the common cellular organelles, including the rough and smooth endoplasmic reticulum, mitochondria and lysosomes, and micropinocytotic vesicles are also evident. Intermediate filaments containing vimentin are present and have been reported to be more abundant on the venous than on the arterial site. Dense bodies associated with actin-like filaments of 5–6 nm diameter are found in the endothelial cells of the larger arterioles, and they may have a role in endothelial contraction.

Weibel–Palade bodies are endothelium-specific inclusions that occur more frequently in the venous side of the microvasculature

Fig. 3.66 Transmission electron microscopy of a transverse section through a venule in the skin. The surface of the endothelial cells (E) in the lumen (L) is more convoluted than in its arteriolar counterpart (see Fig. 3.65). The endothelial cells are surrounded by pericytes (P), and not smooth muscle cells, and the basement membrane (bm) contains dense strands (arrows). The arrowheads indicate Weibel–Palade bodies.

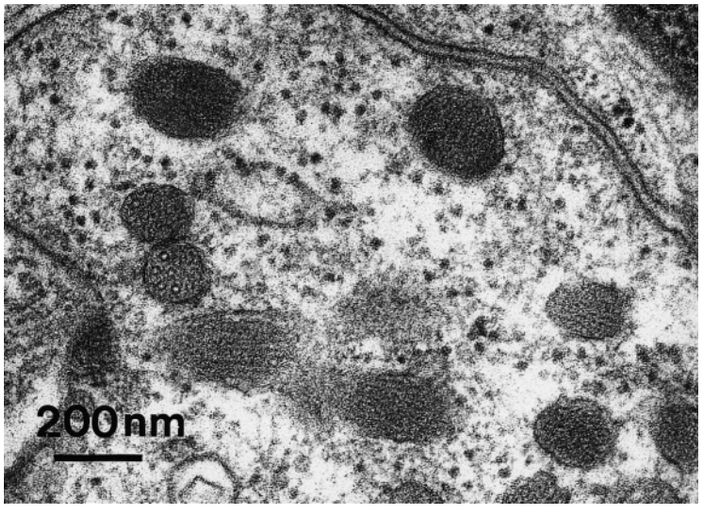

Fig. 3.67 High-magnification view of Weibel–Palade bodies revealing tubular profiles in cross-section.

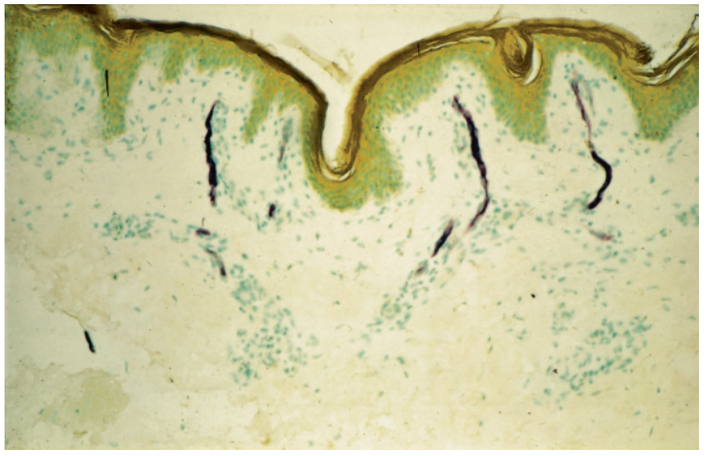

Fig. 3.68 Histochemical detection of alkaline phosphatase activity indicates the presence of arterial microvessels in the superficial dermis. Original magnification, ×160.

(Fig. 3.67). They are not found in dermal lymphatics but have been reported in larger lymph vessels. Weibel-Palade bodies contain factor XIII-related antigen, von Willebrand factor and GMP-140, a protein that was first described in platelet α-granules.

Fenestrations, which allow rapid passage of water and solutes between the circulation and the extravascular space, have been observed in capillaries, mainly in the vicinity of epidermal appendages but also in papillary dermis, facing the epidermis [5].

A major feature distinguishing arterial from venous microvessels is the ultrastructural appearance of the basement membrane. Venules and venous capillaries have a multilaminated basement membrane, whereas arterioles possess a more homogeneous matrix, lacking the electron-dense strands. Vascular basement membrane contains laminin 111, type IV collagen, fibronectin and heparan sulphate proteoglycans. It does not contain, however, bullous pemphigoid antigens, type VII collagen or laminin 332, components of the epidermal basement membrane zone.

A number of endothelium-specific antigens have been recognized, and they may have a special value in studies of cutaneous pathology. Endothelial cells are the major source of angiotensin-converting enzyme as well as various cytokines and adhesion molecules. The microvasculature is also a rich source of enzymes that may be involved in cellular processes, such as endocytosis and vesicular transport. Acid phosphatase has been localized to lysosome-like structures in the endothelium, and alkaline phosphatase reactivity has been used extensively to map the distribution and arborization of the arterial network in the upper dermis (Fig. 3.68).

The lymphatic network in the skin serves to transport particulate and liquid materials, such as proteins, from the extravascular compartment of the dermis. Interconnecting lymphatic spaces arise from terminal bulbs in the papillary layer and ultimately form the system that drains into the lymph nodes. The vessels have a broad lumen surrounded by a single endothelial layer, which is discontinuous in the terminal components and rests on an often discontinuous basal lamina. These processes are critical for the normal function of skin, as altered function and development of lymphatics can lead to diseases, including primary and secondary lymphoedemas [6–8].

Subcutaneous fat

Fat is a major component of the human body and approximately 80% of fat is in the subcutis; the rest surrounds internal organs. In non-obese males, 10–12% of body weight is fat, while in females the figure is 15–20%. Fat comprises white and brown adipose tissue. Brown fat is more common in infants and children and is characterized by different mitochondrial properties and increased heat production [1]. The function of fat is to provide insulation, mechanical cushioning and an energy store. In addition, fat may have an endocrine function, communicating with the hypothalamus via secreted molecules such as leptin to alter energy turnover in the body and to regulate appetite [2]. Adipocytes also have important signalling roles in osteogenesis and angiogenesis, and additional physical functions such as phagocytosis. Multipotent

stem cells have been identified in human fat, which are capable of developing into adipocytes, osteoblasts, myoblasts and chondroblasts. Molecular biological insight into genes, proteins, hormones and other molecules that influence fat deposition and distribution are gradually being realized, both from research on rare inherited disorders (such as the lipodystrophies or obesity syndromes) as well as population studies on more common forms of obesity [3].

Mechanical functions, 4.7
Immunological functions, 4.8
Sensory and autonomic functions, 4.9
Bioengineering and the skin, 4.10
Sociosexual communication, 4.11

Introduction

The skin is arguably the largest immunologically active organ in the body, and its relative accessibility for basic scientific research has allowed much progress in our understanding of its multiplicity of functions. The most obvious functions of the skin are to provide a protective physical barrier between the body and the environment, preventing the inward and outward passage of water and electrolytes, reducing penetration by destructive chemicals, arresting the penetration of microorganisms and external antigens, and absorbing radiation from the sun. The skin is important in the regulation of body temperature and is designed, to an extent, to respond to mechanical forces; the epidermis has a degree of mechanical strength to withstand damage and the ability to repair itself if damaged, and the dermis provides elasticity in response to mechanical insults.

The immunological functions of the skin depend both on cells in the epidermis and on dermal cellular constituents. Antimicrobial peptides (AMPs) are a diverse group of proteins that are involved as a first line of immune defence by many living things, including plants, insects, bacteria and vertebrates [1,2]. In human skin, AMPs provide a chemical barrier to potentially pathogenic microorganisms. The skin also contains sensory and autonomic nerves and several types of sensory receptor, which detect the incoming stimuli of touch, vibration, pressure, change in temperature (warmth and cold), pain (including heat pain) and itch. As in other animals, human skin has a role in sociosexual communication.

The aim of this chapter is to consider the functions of the skin in relation to its structure. It is important to understand physiological functions of the skin, so that one can plan a logical approach to the management of skin diseases. For example, if a patient has extensive areas of denuded skin, as seen following severe burns or in toxic epidermal necrolysis, the skin is unable to play its usual part in the maintenance of fluid balance and temperature regulation, a clinical situation referred to as 'skin failure' [3]. In addition, a knowledge of the skin as a barrier is important from the point of view of the delivery of topical treatments for skin diseases, and ceramide-dominant barrier-repair lipids have been reported to improve atopic dermatitis [4]. The contribution of bioengineering to present knowledge is also discussed.

It is beyond the scope of this chapter to provide a detailed account of skin biochemistry, and some biochemical functions of the skin are discussed in chapters referring to specific skin diseases. For example, androgen biochemistry is discussed in relation to disorders of the sebaceous glands in Chapter 42, altered cyclic nucleotide metabolism in atopic dermatitis [5] in Chapter 24, and phosphoinositide cell-regulatory abnormalities in psoriasis [6] in Chapter 20. Under the influence of sunlight, the skin is the site of vitamin D synthesis (see Chapter 59). In addition to its effects on calcium and bone metabolism, vitamin D_3 has antiproliferative and immunomodulatory effects, both of which are likely to be relevant to the treatment of psoriasis with vitamin D analogues (see Chapter 20).

Nails and hair are discussed elsewhere (see Chapters 65 and 66, respectively). Briefly, the scalp hair has a role in heat regulation and in display. Nails are mainly protective, aid in performing delicate tasks and are of cosmetic importance, a more noticeable feature when the nails are either absent or disfigured.

Barrier functions

The epidermis and stratum corneum as a physical barrier

The skin acts as a two-way barrier to prevent the inward or outward passage of water and electrolytes. The physical barrier is largely situated in the epidermis, isolated epidermis being as impermeable as whole skin, whereas once the epidermis is removed the residual dermis is almost completely permeable. The epidermal barrier is localized to the stratum corneum.

On routine histology, the stratum corneum shows a basket-weave structure, and early investigators therefore believed it to be porous, and considered the barrier must lie below it [1]. In 1953, Blank [2] found that the water permeability of excised full-thickness skin remained unchanged by successive stripping with adhesive tape until the lowest part of the stratum corneum was removed, and proposed that the barrier lay within a thin layer of the innermost region. Subsequently, these observations were considered to be consistent with the belief that there is a uniformly good diffusion barrier throughout all or most of the horny layer [3–5].

The barrier depends on both the cornified material of the keratinocytes and the intercellular material, particularly lipids, regional differences in permeability being related to lipid content and not to thickness of the stratum corneum. A two-compartment model of the stratum corneum as a barrier is currently accepted, in which protein-rich cells, the corneocytes, are embedded within a continuous lipid-rich matrix.

Within the keratinocytes are synthesized both the fibrous proteins of keratin and a histidine-rich protein known as keratohyalin, currently usually referred to as filaggrin (filament-aggregating protein, see below) [6,7]. Around each corneocyte is an envelope, formed by cross-linking of the precursors involucrin and keratohyalin, which forms an insoluble exoskeleton and acts as a rigid scaffold for the internal keratin filaments [8,9]. There is evidence that lipids are chemically bound to its surface [10].

The intercellular cement is the product of ovoid organelles, 0.2–0.3 μm in diameter, known as membrane-coating granules, Odland bodies or lamellar bodies [11]. They become identifiable in cells of the spinous layer, and migrate to the cell periphery and fuse with the plasma membrane in the granular layer. They then discharge their contents into the intercellular spaces, which expand to form 10–40% of the total volume of the tissue.

The lamellar bodies originally contain neutral sugars linked to lipids and proteins, hydrolytic enzymes and free sterols, but the composition of the secretion changes greatly as they migrate outwards. Phospholipids, present in the stratum basale, diminish in the stratum spinosum, and virtually disappear at the level of the stratum corneum. However, neutral lipids and sphingolipids, in particular ceramides, are increased in the stratum corneum [12–17]. Cholesterol sulphate increases from the spinous to the granular layer, but is decreased in the stratum corneum.

In parallel with these biochemical events, changes can be observed in the ultrastructure of the intercellular material (Fig. 4.1) [18]. Within the granules, bilayers become arranged to form discs, which represent flattened, unilamellar liposomes. The formation of such flattened liposomes has been demonstrated *in vitro* by exposing a mixture of ceramides, cholesterol, palmitic acid and cholesterol sulphate to a hypertonic medium [19,20]. After extrusion into the intercellular space, the discs become arranged parallel to the cell membranes and then fuse to form uninterrupted sheets [21].

In consequence of their origin by fusion of flattened vesicles, the intercellular lamellae of the stratum corneum consist of two lipid bilayers in close apposition [22]. The stratum compactum has been considered to form the principal diffusion barrier. It has also been proposed that in the stratum dysjunctum, the vesicular bodies maintain the patency of the intercellular space, and thus facilitate the absorption of applied substances by a form of shunt mechanism, as well as functioning as a reservoir. Vickers [23] first showed that the horny layer can retain topically applied corticosteroids, and such reservoir effects were later confirmed for hydrocortisone [24] and established for hexachlorophene [25].

In atopic dermatitis, the xerosis and permeability barrier abnormality seem to have a role in driving disease activity [26]. Both involved and clinically uninvolved skin in atopic dermatitis have impaired barrier function [27], which correlates with a reduction in the stratum corneum ceramide fraction [28]. Emollients do not usually correct the underlying stratum corneum lipid abnormality, but ceramide-dominant barrier-repair lipids have been shown to improve atopic dermatitis in children [29].

The function of filaggrin in the formation of the stratum corneum has been reviewed by Smith *et al*. [30] following exciting genetic findings in ichthyosis vulgaris and atopic dermatitis. Keratohyalin granules in the granular layer of interfollicular epidermis are predominantly composed of the 400-kD protein profilaggrin. Following a short, unique N-terminal domain, most of the profilaggrin molecule consists of 10 to 12 repeats of the 324-residue filaggrin sequence [31]. Upon terminal differentiation of granular cells, profilaggrin is proteolytically cleaved into filaggrin peptides of approximately 37 kD and the N-terminal domain contains an S100-like calcium-binding domain. Filaggrin rapidly aggregates the keratin cytoskeleton, causing collapse of the granular cells into flattened, anuclear squames. This condensed cytoskeleton is cross-linked by transglutaminases during formation of the cornified cell envelope.

Smith *et al*. [30] identified homozygous or compound heterozygous mutations in the filaggrin gene in individuals with moderate or severe ichthyosis vulgaris, loss or reduction of this major structural protein leading to varying degrees of impaired keratinization. Palmer *et al*. from the same group [32] showed that two independent loss-of-function genetic variants in the filaggrin gene are very strong predisposing factors for the development of atopic dermatitis.

Percutaneous absorption

The skin is considered to be a composite membrane, with three anatomically distinct layers [1]: the stratum corneum (10 μm), the viable epidermis (100 μm) and the uppermost papillary layer of the dermis (100–200 μm), each having a different diffusion constant. Even healthy adult human skin allows some permeation of almost every substance, and rates of penetration of different materials may differ by 10 000-fold.

Percutaneous absorption has been studied both *in vivo* and *in vitro*. The penetration *in vivo* of topically applied substances can be assessed by physiological or pharmacological means, or analysed by chemical or histological techniques. Thus, vasoconstriction has been utilized for corticosteroids, vasodilatation for nicotinates, wealing for histamine, sweating for pilocarpine and anaesthesia for local anaesthetics. The application of compounds labelled with radioisotopes and their location through time in layers of stratum corneum, successively stripped by adhesive tape, has been particularly useful. Body fluids, such as blood and urine, can similarly be analysed for substances that have traversed the skin.

In vitro methods usually utilize sheets of whole epidermis or stratum corneum rather than whole skin. Epidermal sheets can be prepared from skin removed surgically, or obtained from cadavers within 48 h of death. The epidermis can be separated by mild heat [2], ammonia vapour [3] or even distilled water. For removal of the Malpighian layer, digestion in 0.2% trypsin [2] or in dispase, a bacterial neutral protease, has been used [4]. The prepared skin material is mounted as a membrane in a diffusion cell between an upper compartment containing a substance, the penetration of which is under study, and a lower compartment containing a buffer solution, which is replenished as samples are removed for analysis at known time intervals, to determine the content of the test substance.

The properties of the skin barrier have a purely physicochemical basis, and do not depend upon the energy-requiring activities of living cells. They are essentially the same *in vitro* as *in vivo*, are unaffected by reversal of the membrane and are maintained long after the skin is removed from the body [5]. Penetrants in weak solutions (although not those at very high concentrations) obey Fick's first law of diffusion, which states that the rate of flow, or flux, is the product of the average concentration of the molecules and their average velocity. In simple terms, the permeability of the barrier for any given penetrant can be completely characterized by the ratio of the flux to the concentration applied, which is known as the permeability constant, and is expressed in length per unit time. The principles of skin permeability and percutaneous absorption have been reviewed in detail elsewhere [1,6–8].

Permeability constants of human and animal skins have been published for a large number of different molecules [6,8]. They vary considerably between species. For example, human skin, which is slightly permeable to water, is relatively impermeable to sodium, potassium and other ions in aqueous solution. In contrast, penetration of various ions through many animal skins is comparatively rapid. Most covalent substances in aqueous solution, such as glucose, urea and the macromolecular human serum albumin, have very low permeability constants in both human and rabbit skin. Others, such as certain aliphatic alcohols, have high constants. Solutes in organic liquids generally show a permeability similar to the solvents themselves. The presence of a solvent is not necessary, for solids dried on the skin continue to penetrate long after a volatile vehicle has evaporated [9]. Thus, for example, application to the scalp of corticosteroids in alcohol may be an effective therapy. In addition, vapours and permanent gases can penetrate skin [10].

The efficiency of the barrier differs between body sites. The scrotum is particularly permeable [11] and the face, forehead and dorsa of the hands may be more permeable to water than the trunk, arms and legs. The palms are particularly impermeable to nearly all molecules except water.

The barrier is affected by many other factors, such as age, environmental conditions and physical trauma, and permeability can be enhanced by various agents, permitting increased access of topically applied drugs.

By virtue of the stratum corneum being adapted to prevent excessive water loss from the body, there is an excellent barrier to the influx of polar molecules, such as water itself. However, many potentially destructive chemicals are non-polar, and the barrier function of the skin slows down penetration of such compounds rather than impeding penetration completely.

Microorganisms: antimicrobial peptides (AMPs) as a chemical barrier

An intact stratum corneum prevents invasion of the skin by normal skin flora or pathogenic microorganisms. However, both minor injury to the skin, as well as skin diseases, can provide portals of entry to microorganisms, particularly streptococci or staphylococci. The same organisms give rise to different patterns of infection depending, in part, on the nature of the injury. Cellulitis, a dermal and subcutaneous process, may follow a minor abrasion to the skin or tinea pedis affecting the toe webs. Larger abrasions of the skin, as one sees with the lesions of atopic dermatitis (atopic eczema), tend to be associated with superficial infections, such as the crusted lesions of impetigo. In addition, the appendages of the skin can provide a route for infection by some organisms, such as *Staphylococcus aureus* (as seen in folliculitis or a boil) or fungal infections. Colonization with microorganisms occurs more readily in moist areas (flexural sites), and the dryness of the skin surface and continuous shedding of corneal cells help prevent sustained growth of pathogenic organisms.

Sebaceous lipids have been reported to possess antibacterial properties [1], and glycophospholipids and free fatty acids of the stratum corneum have bacteriostatic effects [2], selective for pathogenic microorganisms.

AMPs are a diverse group of peptides that are present on epithelial surfaces, such as the epidermis and its appendages, as a first line of immune defence by many living things [3,4]. AMPs directly kill a broad spectrum of microbes, including Gram-positive and Gram-negative bacteria, fungi and certain viruses. In addition, these peptides interact with the host itself, targeting events that complement their role as naturally occurring antibiotics.

AMPs can be divided into several categories on the basis of their structures, and most of them include a cationic charge and the ability to interact with bacterial membranes through hydrophobic amino acids. Two major families of AMPs have been characterized in mammals: defensins and cathelicidins.

Defensins are a broadly dispersed family of gene-encoded antibiotics that are subdivided predominantly into the α-defensins and the β-defensins, according to the alignment of the disulphide bridges and their molecular structure [5]. Human neutrophils express a number of distinct defensins, six α-defensins having been identified [6]. Four of these are known as α-defensins 1, 2, 3 and 4 (also referred to as human neutrophil peptides (HNPs) 1–4). The other two α-defensins, known as human defensins 5 and 6 (HD-5 and HD-6), are abundantly expressed in Paneth's cells of the small intestinal crypts and in epithelial cells of the female urogenital tract [3].

In humans, four types of β-defensins have been identified, referred to as human β-defensins (HBDs) 1–4, but it seems that many β-defensins have yet to be discovered [7]. β-defensins have a broad spectrum of antimicrobial activity and act indirectly, being chemotactic for immature dendritic and memory T cells [8], promoting histamine release and prostaglandin D_2 production in mast cells [9,10], and acting as an adjuvant in enhancing antibody production [11]. Human neutrophil α-defensins (HNPs 1–3) also increase the expression of tumour necrosis factor-α (TNF-α) and interleukin-1 (IL-1) in human monocytes that have been activated by bacteria (*Staphylococcus aureus*) [12].

Cathelicidins have been found only in mammals, being limited to a single gene in humans. The human cathelicidin LL-37/hCAP18 was cloned from cDNA isolated from human bone marrow as FALL-39 [13]. The mature AMP is referred to as LL-37 because it begins with two leucine residues and is 37 amino acids long. The term hCAP18 was independently used, because the peptide is a cationic AMP whose mass before proteolytic processing is approximately 18 kDa [14]. The bactericidal activity of human cathelicidin peptide requires proteolytic activation from its precursor by enzymes including neutrophil elastase and proteinase [15]. LL-37 has a broad spectrum of antimicrobial activity and is a chemoattractant for various inflammatory cell types [16,17]. As with the defensins, LL-37 has the potential to participate in the innate immune response both by killing bacteria and by recruiting a cellular immune response.

HBD-2 is present in psoriatic scale [18] and HBD-2 and HBD-3 are increased in keratinocytes from patients with psoriasis [19]. Dermcidin and LL-37 have been found constitutively in sweat gland secretions [20] and HBD-1 and HBD-2 have been demonstrated in ductal epithelia of sweat glands and in normal hair follicles [21]. Other proteins with antibacterial activity in the skin include adrenomedullin [22], cystatin [23] and secretory protease inhibitor [24]. Impaired production of AMPs has been observed in the epidermis in atopic dermatitis, and Th2 cytokines inhibit the expression of HBD-2, one of the AMPs deficient in atopic skin [25].

In normal skin, potential sites of entry of bacteria such as hair follicles and sweat glands produce small amounts of AMPs that provide a chemical barrier to infection where a physical barrier is absent or limited. After injury, the skin responds rapidly with increased production of AMPs from the epidermis and recruited neutrophils (Fig. 4.2) [3]. Cutaneous defence mechanisms by antimicrobial peptides have been reviewed [26,27].

Ultraviolet radiation

The sun's radiation is made up of infrared, visible and ultraviolet (UV) light (see Chapter 29), and it is the UV rays that affect the skin. The shorter wavelength UVB rays penetrate the epidermis

and are the cause of sunburn and, in the long term, contribute to premature ageing of the skin and the pathogenesis of skin cancer. UVA rays penetrate the skin more deeply and are considered to have an important role in chronic sun damage, particularly skin ageing but also skin cancer development.

The skin has two barriers to UV radiation: a melanin barrier in the epidermis; and a protein barrier, concentrated in the stratum corneum. Both function by absorbing radiation, thereby minimizing absorption by DNA and other cellular constituents. Melanin is synthesized by melanocytes in the basal layer of the epidermis and transferred to surrounding keratinocytes in melanosomes. The partially protective mechanism of delayed tanning [1] is associated with an increase in the number of functional melanocytes, an increase in the number of melanosomes synthesized, and an increased rate of transfer of melanosomes to the keratinocytes. In the long term, there is thickening of the epidermis in response to chronic sun exposure.

Absorption of radiation by epidermal lipids may contribute to protection from UV radiation, in a similar way to that suggested for some low-molecular-weight degradation products of epidermal proteins, including urocanic acid [2]. The role of UV-induced cytokines in the regulation of melanin production is not yet clear [3,4].

Temperature regulation

The advantage of maintaining a constant body temperature is that the metabolic processes are not directly dependent on changes in the environmental temperature. However, at extremes of ambient temperature, heat may need to be lost or retained. The skin provides a sensory input to thermoregulation and functions to allow heat loss or conservation.

The thermoreceptor cells of the skin are distributed irregularly over the skin, there being warm- and cold-sensitive thermoreceptors. Information on changes in their stimulation in response to changes in temperature is sent to the hypothalamus, leading to either inhibition of sweating or stimulation of shivering [1]. However, the skin thermoreceptors have a relatively minor role in modifying core temperature, and skin temperature has a greater role in mediating behaviour, for example by turning on the heating or putting on extra clothing. At high temperatures, heat pain via nociceptors is perceived rather than warmth.

From an effector point of view, the skin has a major role in thermoregulation of the human body [2]. Heat can be lost through the skin surface by radiation, convection, conduction and evaporation. Of importance in these mechanisms is the rich blood supply of the dermis, which is much greater than that needed for nutrition. The cutaneous circulation is described elsewhere (see Chapters 3 and 47). The essential point about its function, however, is that a system of arteriovenous shunts, which are plentiful in the feet, hands, lips, nose and ears, enables the blood flow to an extensive and more superficial venous plexus to be considerably varied.

In high environmental temperatures, the process of evaporation is considerably enhanced by eccrine sweating.

Skin failure

Skin failure has been defined by Irvine [1] as 'a loss of normal temperature control with inability to maintain the core temperature, failure to prevent percutaneous loss of fluid, electrolytes and protein with resulting imbalance and failure of the mechanical barrier to penetration of foreign materials'. The term was initially used to bring to the attention of non-dermatologists the need for specialist care in this dermatological emergency. Apart from in thermal burns, skin failure can occur as a consequence of a number of dermatological diseases, including Stevens–Johnson syndrome, toxic epidermal necrolysis, pustular psoriasis and erythroderma of various causes. Depending on the extent of the disease, pemphigus vulgaris, graft-versus-host disease and epidermolysis bullosa are other potential examples.

Used in this specific sense, skin failure is an interesting concept that has not gained common usage. The term is sometimes used in a more general sense to reflect disability in dermatology [2].

Hence, Ryan [2] has included a wide range of skin diseases as examples of 'skin failure', such as hand dermatitis, the development of sunburn and skin cancer in the albino African, and failure of display because of disfigurement. He has emphasized the need for dermatologists and allied health professionals to use a language that can be understood by everyone, particularly patients, when referring to the consequences of skin disease [3].

Both authors [1,2] have drawn attention to the fact that skin failure represents severe loss of function as occurs in other organ systems, for example heart failure, liver failure, renal failure and respiratory failure.

Mechanical functions

Although the epidermis and subcutaneous fat each have a role in the protective function of the skin, the mechanical properties of the skin related to hard blows with blunt objects depend mainly

on the dermis. Skin is elastic to a degree and can, for a few seconds at a time, be stretched reversibly by 10–50%. Skin pulls easily at first. The initial response appears to involve a reorientation of collagen fibres towards the load axis and a decrease in their convolution [1]. The tonus of skin is probably maintained by the elastic fibres, and it seems likely that these fibres provide the small forces that restore the extensibility of slack skin.

Once the initial slack has been taken up, the skin becomes much more difficult to extend. It gradually stretches if it is maintained taut for a long time, as, for example, when using tissue-expanding techniques in skin surgery. This further extension under continued stress is referred to as 'viscous extension', 'viscous slip' or 'creep', and is irreversible. This slip depends on the collagen fibrils. It is unlikely that slipping occurs within the fibril itself; either the individual fibrils slip relative to each other, or whole fibrils do so within the related ground substance. The most probable hypothesis to explain the relative lack of slip is that slip is interfibrillar, that the collagen fibrils are very long and that the interfibrillar substance is highly viscous. It appears that dermatan sulphate is more closely connected to the collagen than hyaluronic acid, and it is probable that this material is the one responsible for restraining the viscous slip.

From these considerations it is clear that disorders in which the skin is hyperelastic, such as Ehlers–Danlos syndrome (see Chapters 3 and 45), must involve a breakdown of the collagen mechanism. The striae seen in adolescence, pregnancy and in situations of excessive systemic corticosteroids, whether administered or as part of Cushing's syndrome, are thought to involve a breakdown of the fibril overlap, so that there is no viscous force to limit further slip.

A further property of skin is that it can be compressed. If a small object is pressed into the skin, a depression is formed that remains after the object is removed; thus, skin becomes moulded round the object exerting the force, and the pressure on any one point is reduced. This compression is primarily because of a flow of ground substance through the dermis between the collagen fibres.

The epidermis itself is relatively strong and holds together under the pressure from blister fluids. On the other hand, the dermal–epidermal junction in human skin is relatively weak. The superficial collagen in the papillary layer appears to be particularly easy to weaken, and many blistering agents appear to act at this level.

By virtue of its protein and lipid constituents, the stratum corneum is a relatively strong elastic tissue. The network of structural proteins allows exogenous forces to spread throughout the tissue. The elasticity of the stratum corneum is also influenced by the degree of hydration of the corneal cell proteins, which in turn depends on the water content of the tissue, and by the humidity of the surrounding environment [2]. Stratum corneum proteins, lipids [3,4] and low-molecular-weight by-products of keratohyalin breakdown, referred to as natural moisturizing factors [5], bind and retain water in the stratum corneum, thus maintaining its elasticity.

Immunological functions

The immunological functions of the skin have been the subject of intense research in recent years, and it is clear that the skin has an important role in immunological host defence, particularly involving those cells residing in (keratinocytes, Langerhans' cells) or passing through (T lymphocytes) the epidermis (see Chapters 12 and 13). The role of AMPs as a first line of defence against microorganisms has been discussed above (see p. 4.5).

Antigens are from either the external environment (exogenous antigens) or are newly formed in the cell itself (endogenous antigens). T lymphocytes are able to recognize antigen only when it has been presented by specialized cells, termed antigen-presenting cells (APCs) or accessory cells [1–3]. The T cell recognizes the antigen in association with products of the major histocompatibility complex (MHC) gene region of the APC. In helper T cell (Th cell) activation, the antigen moiety is usually presented in the context of MHC class II molecules, whereas most cytotoxic T cells recognize the antigen in association with MHC class I molecules.

Any cell expressing the respective MHC gene product can act as an APC [4] and the predominant APC populations in the MHC class II-dependent antigen-presenting pathway are mononuclear phagocytes [3,4], Langerhans' cells [5–7], B cells [8] and lymphoid dendritic cells [9]. T-cell activation is preceded by interaction of surface molecules, including T-cell antigen receptor (TCR) occupancy by the antigen–MHC complex.

In human skin, most T cells are found in the dermis, usually grouped around postcapillary venules and the appendages. Intraepidermal T cells account for less than 10% of T cells in human skin. Langerhans' cells involved in antigen presentation in damaged epidermis undergo phenotypic and functional changes prior to leaving the epidermis, entering the dermal lymphatics and migrating to the paracortical areas of the draining lymph nodes. At this stage, they present the antigen–MHC complex on their surface to the TCR on either $CD4/CD8^-$ or $CD4^-/CD8$ naïve resting T cells, and elicit an antigen-specific T-cell response. The T-cell blasts thus generated then seem to preferentially return to the skin sites bearing the antigen.

It will be seen from this brief outline that epidermal cells are intimately involved in the afferent and effector limbs of the immune response. The broader principles of immunology, the mechanisms of immune responses and the implications for clinical dermatology are fully explored in Chapters 12 and 13. As discussed elsewhere, immunological dysfunction probably has a pathogenetic role in a wide range of skin diseases, including the immunobullous disorders, allergic contact dermatitis, atopic dermatitis, psoriasis and cutaneous T-cell lymphoma (mycosis fungoides).

Sensory and autonomic functions

The skin is innervated by a dense, three-dimensional network of highly specialized afferent sensory and efferent autonomic nerve branches. The sensory nervous system detects the sensations of touch, vibration, pressure, change in temperature (warmth and cold), pain (including heat pain) and itch [1,2]. The autonomic nervous system is innervated by postganglionic cholinergic parasympathetic nerves and adrenergic and cholinergic sympathetic nerves. The autonomic system has an important role in maintaining cutaneous homeostasis by regulating vasomotor functions, pilomotor activity and eccrine sweat gland secretion, and is discussed further in Chapter 63.

The sensory nerves are either myelinated A fibres or unmyelinated C fibres, the latter containing sensory and autonomic fibres. The rate of transmission of a nerve impulse is proportional to the diameter of the nerve, and the various types of A fibres are thicker (1–20 μm) than the slow-conducting unmyelinated C fibres (0.2–1.5 μm). The myelinated human cutaneous nerves have been divided into Aβ and Aδ types on the basis of their conduction velocities, corresponding to 35–75 m/s and 5–20 m/s, respectively [2]. In the upper dermis, small myelinated nerves lose their nerve sheaths, and together with the unmyelinated nerves end in either free nerve endings or as specialized sensory receptors, such as Meissner's corpuscles or Merkel's receptors [2].

Much of the research into the sensory functions of the skin was carried out from the 1950s to the 1970s but, since the discovery of neuropeptides with implications for potential pharmacological modulation, there has been renewed interest in this field. Electrophysiological studies showed the existence of functionally specific afferent units [3]. Two major categories of afferent unit have been clearly established: mechanoreceptors and thermoreceptors [4,5]. A third group of pain receptors (nociceptors) respond only to high-threshold stimulation, including mechanical, thermal (heat pain) or chemical stimulation. Within each of these categories some of the afferent units determined functionally can be clearly identified with morphologically distinct structures.

Touch is mediated by mechanoreceptors in the skin, there being two main functional groups [5] according to the way they respond to constant or persistent stimuli. *Slowly adapting* mechanoreceptors respond continuously to a persistent stimulus, whereas *rapidly adapting* mechanoreceptors respond at the onset and frequently at the end of the stimulus, but not throughout the duration of the stimulus.

Glabrous and hairy skins have different types of mechanoreceptor (Fig. 4.3). The predominant mechanoreceptor in hairy skin is the hair-follicle receptor. Glabrous skin (e.g. the hairless skin of the palmar surface of the hands) has two main types of superficial mechanoreceptor: a rapidly adapting receptor, the Meissner's corpuscle; and a slowly adapting receptor, the Merkel's receptor.

Subcutaneous tissue and the deeper dermis beneath both hairy and glabrous skin contain two types of mechanoreceptors: the Pacinian corpuscle, a rapidly adapting receptor; and Ruffini's corpuscle, a slowly adapting receptor. In contrast to the small receptive-field size of Meissner's corpuscles and Merkel's receptors in the upper dermis, the receptive fields of Pacinian and Ruffini's corpuscles are large. When Pacinian corpuscles are tested with uniform or constant-velocity displacement, no impulses result, but sinusoidal displacement (vibration) generates a regular stream of impulses.

The sensations of warmth and cold are mediated by thermal receptors. Two distinct kinds of thermoreceptor [3,6] have been identified in tongue, hairy and glabrous skin of a number of mammals, including humans. Such fibres show a steady discharge dependent on temperature, but no response to non-painful intensities of mechanical stimulation. Temperature sensitivity is punctate, each afferent fibre being connected with a few receptive spots with a diameter in hairy skin of less than 1 mm.

Cold and warmth spots correspond to discrete zones of innervation by cold and warmth receptors. Cold receptors show a frequency rise on sudden cooling, the frequency of firing being proportional to the rate and degree at which the temperature is lowered. Cutaneous cold receptors are activated from approximately 1–20°C below the normal skin temperature of 34°C. Warmth receptors show a steady discharge at constant temperatures in the range 32–45°C, an acceleration of the discharge on warming the skin, small receptive fields and a high sensitivity to temperature change. At temperatures greater than approximately 45°C, heat pain via nociceptors is perceived rather than warmth.

Pain is mediated by *nociceptors*, receptors that respond selectively to stimuli that can damage tissue. Three types of nociceptor can be distinguished. Mechanical nociceptors are activated by strong mechanical stimulation, such as sharp objects. Pricking of the skin gives rise to two kinds of sensation. The initially felt 'pricking' or 'fast' pain is punctate, superficial and local, and this is followed by a more diffuse 'burning' or 'slow' pain [5]. Thermal nociceptors respond to heat or cold. In humans, heat nociceptors respond when the temperature of their receptive field exceeds 45°C, the heat pain threshold. Cold nociceptors respond to cold noxious stimuli. In addition, there are polymodal nociceptors that respond to several different kinds of noxious stimuli, including mechanical, heat and chemical [5].

Itching [7–10] is closely related to pain and is discussed in detail in Chapter 21.

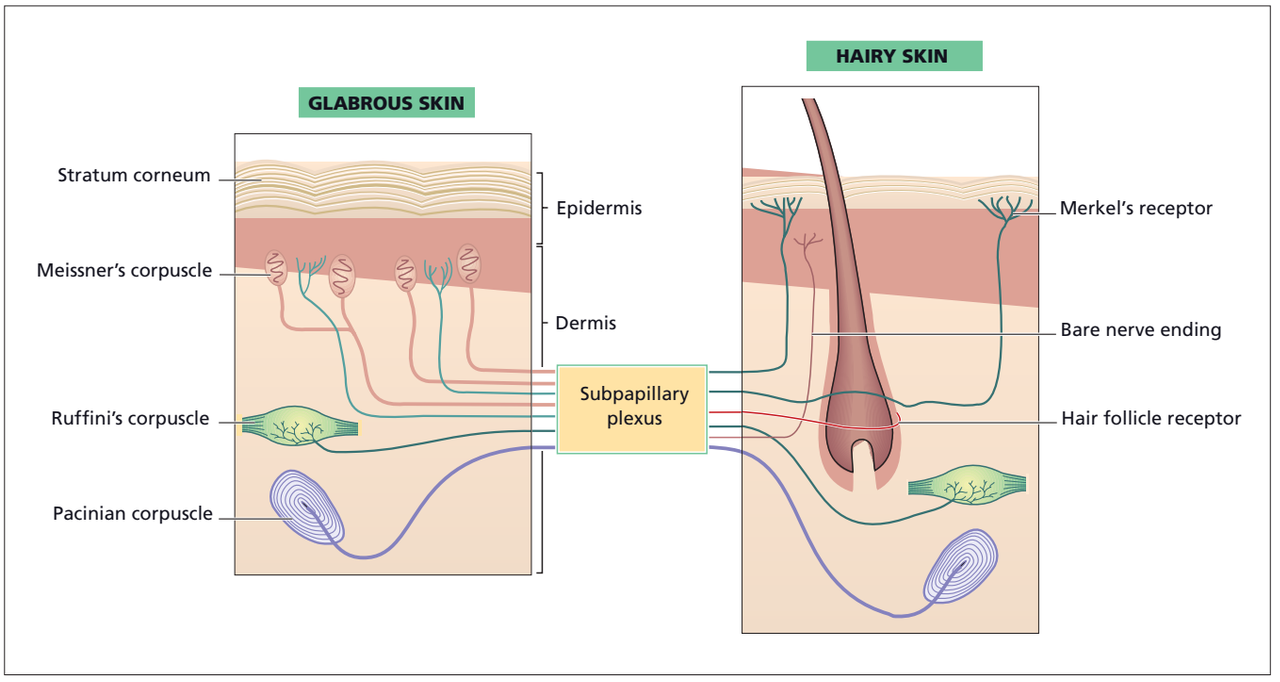

Fig. 4.3 Diagram to show the location of sensory receptors in hairless (glabrous) and hairy skin. The receptors of glabrous skin are Meissner's corpuscles and Merkel's receptors in the dermal papillae, and bare nerve endings. The receptors of hairy skin are hair-follicle receptors, Merkel's receptors, and bare nerve endings. Pacinian corpuscles and Ruffini's corpuscles are situated in the subcutaneous fat and deeper dermis in both glabrous and hairy skin.

In addition to classical neurotransmitters such as noradrenaline (norepinephrine) and acetyl choline, peripheral nerves contain neuropeptides. Neuropeptides are released from nerve terminals following depolarization, and have a role in regulating synaptic transmission. A number of neuropeptides have been demonstrated in human skin, including substance P, vasoactive intestinal peptide (VIP), somatostatin, calcitonin gene-related peptide (CGRP), neuropeptide Y and bombesin [11–13]. In addition to acting as neurotransmitters, neuropeptides have a role in the mediation of inflammation in the skin, and are discussed more fully in Chapters 12 and 63.

Bioengineering and the skin

In recent years, there has been much emphasis on the importance of objective measurement in dermatology and, driven in part by the cosmetics industry, there have been a number of advances in bioengineering technology. Relatively non-invasive bioengineering techniques can be used to assess the functions of the skin either in the resting state or in test conditions (e.g. the use of transepidermal water loss [TEWL] measurement in irritancy testing), or to quantify the response of clinical disorders to treatment (e.g. the use of ultrasound to assess therapeutic responses in chronic dermatoses). Selected aspects of bioengineering and the skin are discussed here. The importance of validation of and comparison between the plethora of similar techniques has been emphasized [1].

TEWL measurement is used to assess the barrier function of the stratum corneum, usually to predict irritancy of substances or to contribute to the assessment of clinical disorders. Various methods

have been used, but an open-chamber gradient-estimation method in the form of the *evaporimeter* is preferred, because it allows continuous measurement in ambient air, with little alteration of the microclimate overlying the skin surface [2].

In the past, TEWL was taken to indicate the water vapour passing through the stratum corneum by passive diffusion [3], but currently TEWL refers to the total amount of water loss through the skin, which includes sweating [2]. Many irritants, such as detergents and solvents, damage the skin by impairing the barrier function of the stratum corneum, and TEWL measurement has been reported to be more sensitive in assessing such irritancy effects than visual scoring [4,5], laser Doppler flowmetry, colorimetry and skin thickness by ultrasound A scan [5]. A higher TEWL has been demonstrated in lesional skin of various types of dermatitis [6,7], in psoriatic plaques [8] and in non-lesional skin of patients with atopic dermatitis [9,10].

Cutaneous gaseous exchange, a term preferable to cutaneous respiration, is the absorption of oxygen and the elimination of carbon dioxide through the skin surface [11]. In clinical medicine, transcutaneous oxygen tension (tcPo_2) measurement is used to quantify the adequacy of skin circulation, and to estimate the severity of leg ulceration, because tcPo_2 reflects the degree of oxygen supply by tissue perfusion.

The mechanical properties have been assessed by a number of techniques, designed either to induce a skin deformation and record the resisting force, or to place a load on the skin and measure the resulting deformation. The assessment of vertical forces to the skin is often avoided because this, in part, measures the contribution of the subcutaneous fat, which varies considerably between different subjects and different sites of the body in the same subject [12]. Non-invasive methods include twistometry [12], suction techniques [13], indentometry [14] and ballistometry [15].

TEWL decreases during the ageing process, becoming obvious after the fifth decade [16]. The decrease in TEWL with age is considered to be partly caused by an increased size of corneocytes and increased thickness of the stratum corneum, related to an elevated accumulation of corneocytes resulting from impaired desquamation [17]. Stratum corneum hydration is also decreased in elderly subjects [18,19], the 'dryness' of the skin in the elderly differing from pathologically dry skin, in which there is impaired barrier function.

Sociosexual communication

The skin, by virtue of its visual appeal, smell and feel, has an important role in social and sexual communication in humans, as it does in other animals. Cosmetics and clothes are used to enhance the appearance and sometimes (but not always) sexual attraction. There are many interesting parallels between humans and other animals, particularly primates, in terms of both visual communication and body odour. The reader is referred to Ebling's fascinating account for further information [1].

Fundamentals of diagnosis

As for any other organ system, diagnosis of skin disease involves a history, examination and sometimes additional tests. The visibility of skin allows an instant diagnosis in some cases, or at least a 'diagnostic label' for the type of disease process being considered, using a variety of visual clues which include not only the individual lesional morphology but other factors such as the body site distribution, colour, scaling and arrangement of lesions. Such apparently effortless pattern recognition is actually quite complex when the individual components are analysed separately [1]. Further history, histopathology examination of skin biopsies, and other investigations, may be needed to refine the diagnosis or, in some instances, to identify a cause. The concept often held by non-dermatologists, that dermatology just involves having a 'quick look' at a patient, ignores issues around investigation and successful management (Fig. 5.1).

Whilst visual aspects are of great importance in dermatology diagnosis, other sensory modalities are also used in examination; for example, palpation may help in determining induration, quality of scaling and temperature changes [2], and even smell may be diagnostic in some instances. Some conditions may lack objective signs or may just have secondary changes (for example, due to scratching); in several eruptions, a knowledge of internal disease is required in order to make a diagnosis. This chapter briefly introduces aspects of the history, examination and other diagnostic manoeuvres.

Disease definition

Most skin diseases do not have a cause which is both identified and unique to that disorder. Conversely, many known causes of skin disease may play a part in several different types of disorder (for example, ultraviolet light may cause or contribute to sunburn, skin cancers, skin ageing and various patterns of photosensitivity; chromate may cause irritant contact dermatitis, caustic burns or allergic contact dermatitis at various body sites). Current definitions of most skin diseases therefore rely on the presence of a constellation of clinical, histopathological and sometimes immunopathological or genetic features. Even common and important diseases such as psoriasis have no strict and unique diagnostic criteria; indeed, some feel (and genetic studies are perhaps starting to support the thesis) that what has been accepted as 'psoriasis' should actually be more tightly classified morphologically [1] in order to help understand phenotypic heterogeneity [2]; it may be that this common dermatosis is several different diseases or is expressed according to different pathomechanisms.

The diagnostic stringency required for day-to-day clinical management may differ from that required in epidemiological and therapeutic research, in which it is clearly important to be sure that all studies are actually describing the same entity [3]. In some disorders which remain difficult to classify, such as parapsoriasis [4], numerous names may have been applied over the years and it may be difficult to know exactly what was meant in a previous publication. This problem applies even in atopic eczema/dermatitis, a very common disorder and generally considered a fairly straightforward diagnosis, and has significant implications for epidemiological research. Similarly, treatments and prognosis may vary between different types of cutaneous T-cell lymphoma (CTCL), but it is impossible to be certain about the types of CTCL that have been assessed in some studies.

Scientific advances are resolving some of these diagnostic and terminology issues, but many disease definitions in dermatology are still based on a constellation of clinically determined,

Fig. 5.1 The distribution of eczema in this patient strongly suggests that a reaction to footwear is the prime culprit. Despite this immediately apparent clue, appropriate investigation, management and resolving schooling issues were time consuming.

morphological cutaneous features. Some of these have distinct anatomical correlates (e.g. myxoid cyst), a specific external cause (e.g. scabies), or have a known genetic or biochemical defect (e.g. many genodermatoses). Many will have characteristic histological features, although—particularly in the case of inflammatory dermatoses—there are often areas of overlap between disease entities.

In other cases, there may be a number of different cutaneous features or multiorgan involvement which are associated together as a syndrome, as in systemic lupus erythematosus (SLE) or Behçet's disease. A syndrome is usually defined by the simultaneous presence of a fixed combination of disease indicants, but these may not all be present in an individual case and may not require to be present concurrently; additionally, 'overlap' syndromes can occur where features of two or more related syndromes are present in the same patient. In such instances, making a diagnosis may rely on fulfilling a certain number of criteria—for example, the American Rheumatism Association (ARA) criteria for diagnosis of SLE [5]. This can be further refined by having major and minor criteria in order to achieve a given sensitivity and specificity. In some instances, such as the International Study Group diagnostic criteria for Behçet's disease, a single diagnostic criterion must be fulfilled (recurrent oral aphthae) together with a given number of minor criteria [6]. In other instances, the number of criteria in each category which need to be fulfilled may vary—for example, in the diagnostic criteria for streptococcal toxic shock, the number of minor criteria that need to be fulfilled depends on the strength of the major criteria that are achieved [7]. All such diagnostic criteria may need to be updated to take into account new diagnostic techniques. However, it should be noted that many such criteria have been derived for confirmation of diagnosis for epidemiological or research reasons, rather than being a prerequisite for clinical diagnosis and management of individual patients. Thus, even for the same disorder, different diagnostic criteria may exist, with different purposes, complexity, levels of sensitivity and specificity, and validity; in atopic dermatitis, the criteria of Hanifin and Rajka are fulfilled by having three (of four) major criteria and three (of 22) minor criteria [8], whilst those of Williams and Pembroke proposed a single obligatory criterion (itchy skin) together with three (of five) additional features [9]. Clearly, some of the 22 minor criteria will have greater discriminatory value than others. Validation of such diagnostic criteria has been discussed in more detail elsewhere, using these examples [10].

Observer experience may also influence how well diagnostic criteria work in practice; the UK 'seven-point' checklist for suggesting melanoma as a diagnosis in pigmented lesions, whilst a useful tool to generate suspicion by patients and non-specialists [11,12], does not have sufficient sensitivity or specificity to allow risk to be assessed from the score criteria when they are used in the clinical situation of a primary care physician deciding that urgent dermatological opinion is required [13]. However, it is only by recording, challenging and refining such diagnostic criteria that advances will occur. This is particularly important for trainees and non-experts; for example, a diagnostic algorithm designed for use by rural health workers in under-developed countries was tested and had about 80% accuracy [14], a major benefit for care providers with essentially no access to ongoing education. At the other end of the scale, more sophisticated computer-assisted diagnostic algorithms can be constructed from detailed morphological and body site descriptions [15].

It is also important not to view such diagnostic criteria as static; for example, in Sweet's syndrome (Chapter 50), proposed diagnostic criteria have been modified over a period of years, and criteria for drug-induced Sweet's disease have been added. In other areas, proof of genetic mutations is redefining disease diagnosis—for example, in the classification of different types of epidermolysis bullosa [16–18]. Careful correlation of genotype and phenotype enables large diagnostic systems to be constructed, which aid diagnosis for subsequent patients [19,20] as well as assisting epidemiological research [21].

Having an accurate diagnosis is obviously important for patients, for prognosis, and may become important for more precisely targeted treatment [22,23]. It also enables construction of diagnostic coding systems, which are widely used in determining the cost of skin disease (largely relating to reimbursements for periods of care in insurance-led health-care systems, termed 'diagnosis-related groups' (DRGs [24,25]) or 'health-related groups'), but which also aid epidemiological and therapeutic research. There is, however, concern about accuracy of coding, costing and case mix issues in such systems.

Diagnosis, and thus construction of valid databases, is influenced by many issues. Specifically, drug reaction surveillance generally relies on voluntary reporting [26,27], which may vary according to perceived severity, 'newness' or other unusual aspects. For example, searching the UK Committee on Safety of Medicines data for reports of toxic epidermal necrolysis (searched as TEN), most reports relate to lamotrigine [28] although historically this would not be the commonest cause of TEN—reporting may reflect increased use of a drug, 'newness' of the drug or severity of the reaction, active encouragement not to report well-known reactions, etc. Cutaneous reactions typically account for most adverse drug reaction reports, for example they comprise almost 30% in the French Pharmacovigilance database [27], but accurate

diagnosis of different types of drug eruption will often vary according to whether the reporting physician has dermatological experience or not. Similarly, in occupational reporting, the cases and situations encountered by occupational health physicians (mainly irritant dermatitis in larger industrial settings) will differ from those seen by dermatologists (more allergic contact dermatitis, including a greater emphasis on occupations such as hairdressing) [29–31]. Generally, systems that are designed to include other disciplines, such as the World Health Organization's International Classification of Diseases (ICD) system, have been felt to be dermatologist 'non-friendly', and unhelpful for clinical and epidemiological dermatology [32], so some national bodies have created their own diagnostic indexing systems (such as the British Association of Dermatologists Dermatological Diagnostic Index System, DDIS.)

The history

Clinical diagnosis is paramount in dermatology, a discipline where histopathological and other techniques are often not routinely used, and which may only support a clinical diagnosis rather than being specific in their own right. However, whilst not necessarily required for rashes, histopathology for confirmation of the diagnosis, and for assessment of adequacy of excision, is important in the case of skin neoplasms—an increasing part of the work of dermatologists. Histopathological support for a diagnosis is often appropriate for some rashes (especially if systemic therapy is being considered).

In most cases, a carefully directed history is important for refining the diagnosis, for identifying further investigations (both to confirm a diagnosis and to determine the investigations that might help to identify a cause) and to address issues that may be important for optimal management. The amount of history required, and the sequence of history-taking and examination, may vary depending on the condition and on the referral information already provided to the dermatologist from a primary care provider. For example, a patient with hand dermatitis, especially if it is of possible occupational causation (Chapter 27), may need a detailed history about agents handled, hand washing and protective gloves that are used (Fig. 5.2).

Several national committees, consensus conferences, workshops and therapeutic guidelines have suggested minimum data sets for the medical history and morphological findings in skin diseases [1,2] as well as the information and investigations that are suitable for (especially systemic) therapies [3–5]; these are likely to become an important part of the clinical history along with the more fundamental issues pertaining to diagnosis, that are discussed below.

Fig. 5.2 A selection of glove materials; knowledge of types of protective gloves is potentially of high importance in preventing industrial hand dermatitis.

Fig. 5.3 Herpes simplex. Itch typically precedes the visible cutaneous signs, and is often described as having a burning quality (note also the typical 'herpetiform' clustering and also that these lesions are pustules, implying a duration of a few days).

The presenting complaint

The following issues are likely to form part of the dermatological history, especially for dermatoses, in most consultations, although the emphasis on each will vary according to the diagnostic area.

Symptoms. Itch is the prime dermatological symptom, but may be variously described by different patients; there are individual differences in threshold and perception. Intense itch is typical in scabies, atopic dermatitis and lichen planus, whereas psoriasis and pityriasis versicolor usually cause less severe itch for the same degree of body surface involvement. Indeed, the degree of itch (as judged by the amount of scratching, and the general affect, and even without any other history), is potentially useful in distinguishing between atopic versus seborrhoeic dermatitis in infants.

Other symptoms include various qualities of pain, such as sharp pain (e.g. chondrodermatitis of the ear), burning (e.g. chilblains) or tenderness (e.g. erythema nodosum). The site may influence symptoms; for example, urticaria causes itch, but the same pathology affecting the palms often causes pain (because the oedema is deeper and the firmer tissues of the palm cannot distend easily). Both the quality and intensity of symptoms should therefore be recorded.

Symptoms usually parallel overt development of an eruption, but discordance can be diagnostically useful—for example, localized itch preceding herpetic vesicles (Fig. 5.3), or fever and malaise preceding erythema and swelling in cellulitis of the leg or erysipelas.

Duration, evolution, periodicity and previous episodes. The overall duration of a rash or localized lesion is usually apparent to the patient, although there are exceptions; basal cell carcinoma, for example, is often noticed only when it ulcerates, and the patient will therefore underestimate the duration of the lesion. Whether the onset of a rash was sudden or gradual may be diagnostically useful. The overall duration is also of diagnostic help for localized lesions. For example, a presumed keratoacanthoma that is still enlarging after a few months is probably a squamous cell carcinoma; lesions that turn black overnight do so due to intralesional bleeding, not as a result of becoming a melanoma.

More precise details may require carefully phrased questions. In urticaria, the diagnostic feature is that individual lesions change from day to day (usually over a few hours), but the overall duration of the process may be years. Asking the patient about the duration of the eruption needs to distinguish between these two aspects. Similarly, if lesions are not present, then diagnosis may depend on the patient's description, but there are pitfalls; weals are often described as 'blisters', a term which should not be taken at face value, and distinguishing between eruptions triggered by heat or sunlight often causes confusion. It is helpful to ask the patient whether any particular factors (e.g. dietary items, cosmetics, work chemicals, sunlight) appear to provoke (or alleviate) the condition.

Some dermatoses have a characteristic evolutionary sequence (e.g. pityriasis rosea, in which a solitary larger 'herald patch' precedes the widespread eruption by a few days, or 'pre-pemphigoid' eczematous lesions). Other disorders may demonstrate periodicity; for example, occupational contact dermatitis may improve at

weekends or holiday periods, and both photosensitivity and airborne contact allergy to plants may be seasonal.

Previous episodes of a similar type are likely to be relevant, but other skin problems may be important even if they do not appear to be the same process. For example, patients with type IV hypersensitivity to fragrance materials might at different times have eyelid rash due to cosmetics, axillary rash due to deodorants, widespread eczema due to soaps or clothing detergents or diffuse facial rash due to airborne perfume agents. In such cases the body site distribution may be confusing, but the sequence of sites affected should be determined, especially the site of initial involvement in the case of rashes.

Previous episodes are also potentially relevant for localized lesions (e.g. patients with two or three previous basal cell carcinomas have a high risk of another, so the level of suspicion may be greater in those with a positive previous history of these lesions).

Previous therapy. Previous treatment and response should be documented to guide future therapy, and to exclude the possibility of the diagnosis being obscured (for example, tinea incognito due to use of topical corticosteroids).

General history

Medical history, medications and dietary history. General medical conditions may have cutaneous features, and should be noted, especially in patients with rashes or generalized skin symptoms (see Chapter 62). Recent illnesses, even if apparently resolved, deserve special attention, as conditions such as urticaria, vasculitis, guttate psoriasis and erythema multiforme can be triggered by viral or bacterial infections in the weeks preceding the onset of the rash. Any recent or current systemic medication should be noted, including regular or intermittent self-medication or that received from relatives or friends, both as a possible cause of drug eruptions and to avoid interactions with treatment prescribed for the skin complaint. Topical therapies should also be considered, both in terms of their efficacy (or lack of), as well as because they may conceal or even cause a dermatosis. Allergies to medicaments or other agents may be important, as are drugs that might interact with anaesthetics or cause surgical bleeding.

Dietary history may be important in some individuals, especially those with intermittent urticaria or anaphylaxis. However, diet is often erroneously blamed for skin eruptions.

Family history. This may be important if a genodermatosis is suspected, in disorders with more complex inheritance (e.g. atopic dermatitis, psoriasis), and in some non-inherited disorders in which family contact is important (e.g. scabies, chickenpox).

Occupation and leisure activities. An occupational history may be of importance, both current and previous, particularly in individuals with eczema; a detailed account of processes and chemicals may be required, together with additional testing (Chapters 25–27). Hands are the most commonly affected site in occupational dermatitis, and it is useful to record details of hand protection (e.g. gloves, barrier creams) as well as the agents to which the patient is exposed. Hobbies less commonly cause problems, but may involve exposure to a variety of common allergens. Outdoor work or hobbies may also involve exposure to sun, cold or to plant allergens. An overview of some of these aspects is given in Table 5.1.

Ethnicity and cultural aspects (Chapter 9). Several disorders have a predilection to occur in specific racial groups—for example, the high frequency of sarcoidosis in black patients [1], or prurigo pigmentosa in the Japanese [2]. The morphology of common diseases may be altered by racial pigmentation, and normal pigmentary variations may be apparent. The severity of diseases may appear to be different between races or cultural groups; atopic eczema has been noted to be more frequent in children born in England of Asian or Caribbean origin [3,4]. Cultural differences may be diagnostically important, such as use of hair pomades and skin depigmenting agents, or may influence acceptance and understanding.

Geographical factors. Foreign travel, especially if recent, is a potentially important cause of dermatological disease. The place(s) visited may lead to specific likely diagnoses, and documentation should include any brief stopping-off countries. A long visit increases the risk of significant exposure to environmental agents, but dust-borne spores and insect vectors may be carried in aircraft and potentially alter the natural history of a disorder by allowing exposure outside the anticipated geographical distribution.

Social and psychological factors. The living conditions, economic status and standard of nutrition of the patient may be relevant both as a guide to diagnosis and to ensure compliance with the treatment advised. Specific examples of important social factors include the strong association between cigarette smoking and palmoplantar pustulosis, and the multiple influences of excessive alcohol intake on the severity and therapeutic options in psoriasis. A sexual history is also required in some instances. The effects of skin problems on lifestyle, relationships, costs to the patient and costs to the community from work days lost are important, and it is helpful to know the patient's main concerns. This applies particularly to chronic skin eruptions, but many patients with discrete lesions primarily want reassurance that they are not malignant. It is unlikely that many skin eruptions are due to 'nerves', but psychological factors can clearly be of importance in aggravating or perpetuating symptoms, and may be the primary abnormality in some instances (Chapter 64).

Activity	Examples of dermatological implications that may occur
Agricultural	Irritant dermatitis (e.g. to disinfectants, physical 'wear and tear') (Chapter 25) Contact allergy (e.g. rubber chemicals in gloves or footwear) (Chapter 26) Hazards from animals (e.g. tinea; Chapter 36) Hazards from plants (e.g. lichen allergy in forestry)
Gardening	Irritant or contact allergic dermatitis related to many plants Contact allergy to gloves Bites and stings; harvest mites etc. (Chapter 38)
Building trade and 'do-it-yourself'	Irritant dermatitis from cement (also causes chemical burns), plaster, solvents, preservatives, fibreglass Contact allergic dermatitis, especially from chromate in cement, epoxy resin, formaldehyde resins, colophony in soldering flux Mechanical—frictional palmar dermatitis from tools; vibration white finger related to use of some tools
Cars (trade or home)	Irritant dermatitis from solvents, paints, hand cleansers Contact allergic dermatitis from paints, resins, metals, rubber (gloves, tyres, tubing) Chemical leukoderma from rubber chemicals in tyre manufacture
Cooking (work or home)	Irritant dermatitis (detergents/hand washing, juices of meat, fruit and vegetables) Contact allergic dermatitis (or urticaria in some cases) from fruits, garlic, spices, meat, fish, gloves Physical—cuts, burns
Cleaning (work or home)	Irritant dermatitis from detergents Contact allergic dermatitis to fragrances or antimicrobials in detergents, polishes etc., or to gloves
Health workers	Irritant dermatitis from cleaning agents/hand washing Contact allergies—latex allergy (urticaria or dermatitis), medicament allergies (dentists—allergy to balsam flavourings, mercury, resins) Infections and infestations, e.g. scabies, especially nursing homes
Hairdressers	Irritant dermatitis from shampoos, bleaches etc. Contact allergic dermatitis from perfumes, dyes, bleaches, lanolin, antimicrobials; contact urticaria due to henna
Textiles (work or hobby)	Irritant dermatitis from solvents, bleaches, detergents/hand washing Contact allergic dermatitis—dyes, formaldehyde resins (finishes), mordants
Travel	Physical—photodermatoses, prickly heat Animals—bites, stings, seabather's eruption, swimmer's eruption, other marine invertebrate hazards Infections—cutaneous larva migrans, tungiasis, leishmaniasis, tropical viral exanthems Contact allergy—exotic plants, phytophotodermatitis

Examination of the skin

Most patients referred to the dermatologist have objective changes in the appearance or consistency of the skin. Even those who describe itch without rash often have dry skin or other features that can be elicited, such as dermographism. Most lesions and eruptions can either be diagnosed fully, or at least assigned to a diagnostic category, by clinical examination; indeed, clinical diagnosis is more precise than laboratory tests in many disorders. The ability to elicit and interpret cutaneous physical signs is therefore of fundamental importance in dermatological training.

The patient should always be examined in a good light, preferably daylight, and with magnification of lesions if necessary. Ideally, the entire skin should be examined in every patient, and particularly if the diagnosis is in doubt, as this may reveal lesions that are more easily identifiable and have not been modified by secondary changes. Adolescents and elderly people will often deny the existence of lesions other than those presented for examination, the former because they are unwilling to undress and the latter because they have not seen them.

In the examination of the skin, it is helpful to consider the morphology of individual lesions, their overall pattern and spatial relationship to each other, and their body site distribution. Each of these aspects is discussed more fully below. Specific attention to hair, nails and the mucous membranes is required. Careful description and use of nomenclature aids the monitoring of changes during follow-up, and any discussion with colleagues.

Touching the skin is important in most instances, and is discussed in more detail below. Gloves should be worn for examination of the mouth, genital/perineal region, or in the case of infective or infected dermatoses.

Additional, simple aids to clinical examination include use of Wood's light, diascopy, dermoscopy, starch iodine testing to identify sweat duct orifices and hair microscopy.

Individual lesions—nomenclature

The commoner descriptive terms applied to cutaneous lesions are listed below. These definitions are broadly in agreement with those recommended by the Nomenclature Committee of the International League of Dermatological Societies [1]. However, it is important to note that some of these definitions have been challenged subsequently [2–5]. A particular problem that many authors have glossed over is the dynamic aspects of skin disease. For example, some papules (less than 0.5 or 1 cm, depending on the source of the definition) are destined to grow larger and become nodules, whereas others (such as syringomas) rarely do so. Additionally, some eruptions may have essentially similar lesions but whose size may include both papules and nodules. Recording of actual size of lesions, or the range of sizes, is often a more useful clinical record [6].

Glossary

alopecia—absence of hair from a normally hairy area.
aphtha—a small ulcer of the mucosa.
atrophy—a loss of tissue from one or more of the epidermis, dermis or subcutaneous tissues. There may be fine wrinkling and increased translucency if the process is superficial.
burrow—a small tunnel in the skin that houses a parasite, such as the scabies acarus.
callus—a localized hyperplasia of the stratum corneum.
cellulitis—an inflammation of cellular tissue, particularly purulent inflammation of the deep dermis and subcutaneous tissue.
comedo (pl. comedones)—a plug of keratin and sebum in a dilated pilosebaceous orifice.
crusts (scabs)—crusts consist of dried serum and other exudates.
cyst—any closed cavity or sac (normal or abnormal) with an epithelial, endothelial or membranous lining and containing fluid or semisolid material.
ecchymosis (bruise)—a macular area of haemorrhage more than 2 mm in diameter.
en cocarde (or 'cockade')—a rosette pattern of concentric rings, usually applied to naevi.
erosion—a loss of epidermis, which heals without scarring. It commonly follows a blister.
erythema—redness of the skin produced by vascular congestion or increased perfusion.
excoriation—loss of skin substance, specifically produced by scratching.
exfoliation—the splitting off of the epidermal keratin in scales or sheets.
fibrosis—the formation of excessive fibrous tissue.
fissure—any linear gap or slit in the skin surface.
fistula—an abnormal passage from a deep structure, such as a hollow viscus, to the skin surface or between two structures. It is often lined with squamous epithelium.
gangrene—death of tissue, usually due to loss of blood supply.
guttate lesions—small round or oval lesions distributed as a 'shower' of droplets. Usually applied to a form of psoriasis.
haematoma—a localized tumour-like collection of blood.
keratoderma—a horny thickening of the skin.
lichenification—thickening of the epidermis (and to some extent also of the dermis) in response to prolonged rubbing.
macule—a circumscribed alteration in the colour of the skin. Authorities vary on the issue of scaling causing texture change within the definition.
maculopapular—rash consisting of both macules and papules.
milium—a tiny white cyst containing lamellated keratin.
nodule—a solid mass in the skin, which can be observed as an elevation or can be palpated. It is more than 0.5 cm in diameter. It may involve epidermis and dermis, dermis and subcutis, or subcutis alone. It may consist of fluid, other extracellular material (e.g. amyloid), inflammatory or neoplastic cells.
papilloma—a nipple-like mass projecting from the surface of the skin.
papule—a circumscribed palpable elevation, less than 0.5 cm in diameter. By careful examination it is often possible to determine whether the thickening involves predominantly the epidermis or the dermis and what type of pathological process is concerned. The only distinction between a papule and a nodule is the size, and this is artificial; some lesions characteristically occur at the smaller size of a papule, whereas others typically enlarge from a papule to become a nodule. Recording a finite size is more useful.
petechia (pl. petechiae)—a punctate haemorrhagic spot, approximately 1–2 mm in diameter.
plaque—an elevated area of skin, usually defined as 2 cm or more in diameter. It may be formed by the extension or coalescence of either papules or nodules as in psoriasis and granuloma annulare, respectively. Small plaque is sometimes used for such lesions 0.5–2 cm in diameter.
poikiloderma—the association of cutaneous pigmentation, atrophy and telangiectasia.
pustule—a visible accumulation of free pus. It may occur within a pilosebaceous follicle or a sweat duct or, less often, on glabrous skin. Most commonly due to infections (Fig. 5.3), but some eruptions typically cause sterile pustules.
pyoderma—any purulent skin disease.
scale—a flat plate or flake of stratum corneum. A *collarette* scale is a fine, peripherally attached and centrally detached scale at the edge of an inflammatory lesion. Annular scaling is also seen in porokeratosis (Fig. 5.4). *Furfuraceous or pityriasiform* scales are fine and loose. *Ichthyotic* scales are large and polygonal. Scaling may accompany or follow many inflammatory disorders. Silvery scales are characteristic of processes involving parakeratosis, especially psoriasis. The silvery colour is due to reflection of light at the many air–keratin interfaces and can be altered by wetting the skin.

Fig. 5.4 Annular scaling in porokeratosis; subtle atrophy is also visible centrally.

scar—replacement by fibrous tissue of another tissue that has been destroyed by injury or disease. An *atrophic* scar is thin and wrinkled. A *hypertrophic* scar is elevated, with excessive growth of fibrous tissue. A *cribriform* scar is perforated with multiple small pits.

sclerosis—diffuse or circumscribed induration of the subcutaneous tissues. It may also involve the dermis, when the overlying epidermis may be atrophic. It is characteristically seen in scleroderma, but may occur as a sequel to or in association with many different processes.

sinus—a cavity or track with a blind ending.

target lesions—these are less than 3 cm in diameter and have three or more zones, usually a central area of dusky erythema or purpura, a middle paler zone of oedema, and an outer ring of erythema with a well-defined edge.

tumour—literally a swelling. The term is used to imply enlargement of the tissues by normal or pathological material, or cells that form a mass. It may be inflammatory or non-inflammatory, benign or malignant. The term should be used with care, as many patients believe it implies a malignancy with a poor prognosis.

ulcer (of skin)—a loss of dermis and epidermis, often with loss of the underlying tissues.

vegetation—a growth of pathological tissue consisting of multiple, closely set, papillary masses.

vesicles and bullae—visible accumulations of fluid within or beneath the epidermis. Vesicles are small (less than 0.5 cm in diameter) and often grouped. Bullae, which may be of any size over 0.5 cm, should be subdivided as multilocular (due to coalesced vesicles, typically in eczema) or unilocular.

weal—a transient area of dermal or dermal and hypodermal oedema, white, compressible and usually evanescent. It is the characteristic lesion of urticaria. It is often surrounded by a red, axon-mediated flare.

Shape of lesions, linear and annular lesions

The shape of each lesion and the pattern in which neighbouring lesions are arranged in relation to each other is often of great significance and may provide an easily recognizable clue to a rapid visual diagnosis. The main shapes, with examples, are listed in Table 5.2 and illustrated in Figs. 5.5–5.10. The mechanism or anatomical factor dictating the shape can sometimes be inferred, as in the case of many linear lesions (Table 5.3) or the vascular patterning leading to livedo (Fig. 5.5); in other instances, such as many annular lesions (Table 5.4) and reticulate lesions (Fig. 5.6), the explanation for the pattern is less clear.

A specific cause of a linear lesion is the Koebner or isomorphic phenomenon [1]. This term is applied when localized, non-specific trauma locally provokes lesions of a dermatosis which is usually spontaneously present elsewhere, and usually in a relatively 'active' or eruptive phase. It is particularly characteristic of psoriasis (Fig. 5.9, see also Chapter 20) and lichen planus, but occurs in several other dermatoses (Table 5.3). Less common dermatoses in which this may occur include erythema multiforme [2], Sweet's disease and scleromyxoedema [3]. The trauma may be mild, and is usually a scratch or similar, although light or heat may do the same. Occasionally, one disease may be responsible for the localization of another, such as granuloma annulare developing at sites of herpes zoster, or psoriasis developing at sites of contact dermatitis; this has been termed the isotopic response [4]. Development of lesions of pyoderma gangrenosum or Behçet's disease at sites of injection of serum or saline (or even just pinprick or venepuncture) is known as pathergy.

Table 5.2 Main shapes of skin lesions. (Adapted from GM White and NH Cox, *Diseases of the Skin*, 2nd edn. London: Mosby, 2000: 6.)

Shape	Description	Examples
Discoid (nummular)	A filled circle	Discoid eczema, psoriasis
Petaloid	Discoid lesions which have merged together	Seborrhoeic dermatitis on the trunk
Arcuate	Incomplete circles	Urticaria
Annular	Open circles with different central skin compared with the rim	Tinea corporis, granuloma annulare
Polycyclic	Circles which have merged together	Psoriasis
Livedo	Chicken-wire criss-cross pattern	Erythema ab igne, polyarteritis nodosa, microvascular occlusion disorders
Reticulate	Fine lace-like pattern	Oral lichen planus
Target	Multiple concentric rings	Erythema multiforme
Stellate	Star-shaped	Lesions of meningococcal septicaemia
Digitate	Finger-shaped	Chronic superficial dermatosis
Linear	Straight line	Koebner reaction to a scratch in lichen planus or psoriasis (see also Table 5.3)
Serpiginous	Snake-like	Cutaneous larva migrans
Whorled	Swirling pattern	Epidermal naevi, late-stage incontinentia pigmenti

Some annular shapes result from centrifugal extension of an infection from the point of inoculation (e.g. tinea corporis with dermatophyte fungi or erythema chronicum migrans in *Borrelia burgdorferi* infection). In others, a spreading neoplastic or inflammatory process leaves central scarring or ulceration, for example superficial basal cell carcinoma and discoid lupus erythematosus. In eruptions in which an allergic process is probably involved, the annular configuration is attributed to the refractory state of the central area. In some conditions, annular shapes can be related to the vascular network (see livedo, Chapter 49, and Fig. 5.5). Some involve an iatrogenic component, for example warts recurring at the margin of a blistered cryotherapy site. However, in many diseases, such as lichen planus, sarcoidosis or psoriasis, there is no satisfactory explanation for the occurrence of annular lesions. In clinical evaluation of annular lesions, it is particularly helpful to consider surface features such as scaling as an aid to identifying epidermal involvement and thus narrowing the differential diagnosis.

Determinant of pattern	Examples
Blood vessels	Thrombophlebitis, Mondor's disease (linear thrombophlebitis on the trunk) Eczema related to varicose veins Temporal arteritis
Lymphatics	Lymphangitis Sporotrichosis, fish tank granulomas
Dermatome	Herpes zoster, zosteriform naevus, zosteriform Darier's disease, zosteriform metastases
Nerve trunks	Leprosy (thickened cutaneous nerves)
Developmental, Blaschko lines	Pigmentary demarcation line, linea nigra Epidermal naevi, incontinentia pigmenti, hypomelanosis of Ito Linear psoriasis, linear lichen planus, lichen striatus
Skin stretching	Striae due to growth spurt (on lower back)
Infestation	Scabies, larva migrans (both usually serpiginous)
External factors	
Plants	Phytophotodermatitis
Allergens	Elastoplast, nail varnish (neck), necklace, waistbands, etc.
Chemical	Caustics, e.g. phenol
Thermal	Burns
Physical	*Trauma to previously normal skin* Keloid scar, bruising, dermatitis artefacta, amniotic constriction bands *Trauma to skin with a pre-existing dermatosis* Purpura (cryoglobulinaemia, amyloid, vasculitis) Blisters (epidermolysis bullosa, porphyrias) *Koebner phenomenon* Psoriasis, lichen planus, lichen nitidus, vitiligo, lichen sclerosus, pityriasis rubra pilaris *Inoculation* Warts, molluscum contagiosum *Other mechanism* Scar sarcoid
Other determinants	Linear scleroderma (limb, central forehead) Senear–Caro ridge (on hands in psoriasis) Dermatomyositis (dorsum of fingers; Gottron sign) Interstitial granulomatous dermatitis (rope or cord sign) Flagellate pigmentation due to cytotoxic drugs (e.g. bleomycin)

Table 5.4 Examples of lesions that are characteristically annular or often include annular morphology (Fig. 5.10).

Infections
'Ringworm' dermatophyte infections
Impetigo
Erythema chronicum migrans
Syphilis (secondary, tertiary)
Leprosy
Inflammatory
Psoriasis
Seborrhoeic dermatitis
Atopic dermatitis (some)
Halo eczema (Meyerson's phenomenon)
Subacute cutaneous lupus erythematosus
Lichen planus
Sarcoidosis
Granuloma annulare
Actinic granuloma
Erythema multiforme
Urticaria
Serum sickness and serum sickness-like eruption
Linear IgA disease/chronic bullous dermatosis of childhood
Bullous pemphigoid
Subcorneal pustular dermatosis
Erythema annulare centrifugum
Jessner's lymphocytic infiltrate
Erythema marginatum rheumaticum
Pityriasis rosea (herald patch)
Vascular
Purpura annularis telangiectoides
Neoplastic
Superficial basal cell carcinoma
Mycosis fungoides
Other cutaneous lymphomas
Keratinization disorders
Porokeratosis

Pattern of lesions

The arrangement of individual lesions may create a characteristic pattern, such as the grouping of vesicles in herpes simplex—this pattern is so striking that it is applied to other lesions which do not share the same aetiology (herpetiform mouth ulcers).

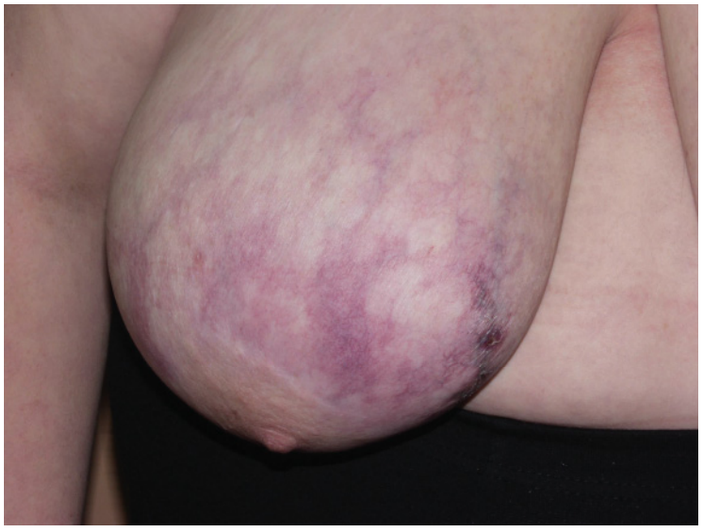
Useful terminology to describe patterns includes:

Agminate—clustered; used to describe lesions such as acne agminata, where granulomatous lesions cluster around the lids (Fig. 5.11), or agminate naevi, an unusual clustering of melanocytic naevi.

Grouped or clustered—characteristic of some infections (herpetic vesicles, molluscum contagiosum, plane warts), flea bites, as well as of endogenous lesions such as lichen planus, leiomyomata, lymphangioma circumscriptum (Fig. 5.12).

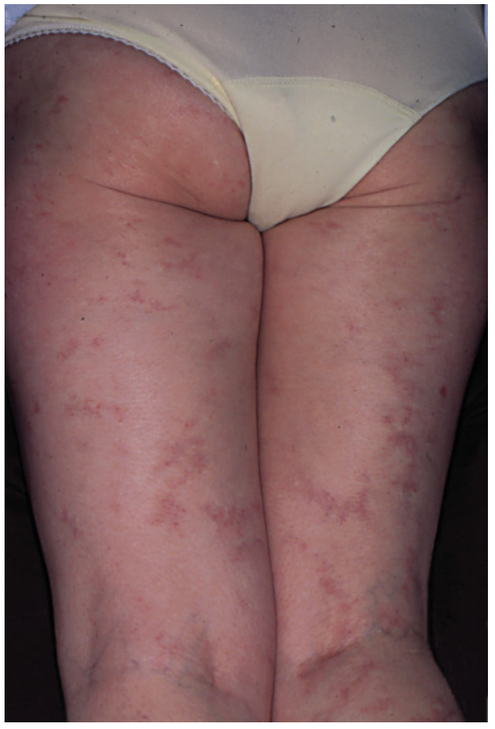
Satellite—a cluster of lesions around a larger central lesion. May occur due to local lymphatic spread of neoplasm such as melanoma (Fig. 5.13); may occur in chronic bullous disease of childhood/linear IgA disease.

Confluent—lesions merging together, locally or widespread, e.g. pityriasis versicolor.



Scattered, disseminated and exanthematous—for example, many drug eruptions, viral exanthemata, as well as some extrinsic causes (Fig. 5.14).

Spared—patterns of sparing may also be diagnostically important, e.g. islands of sparing occur within the otherwise often confluent orange–red erythema of pityriasis rubra pilaris, sparing within skin folds in papuloerythroderma of Ofuji, or areas shielded by clothing or a wristwatch may be overtly spared in photosensitivity (Fig. 5.15).



Symmetrical—often endogenous (e.g. psoriasis) and *asymmetrical*, often of exogenous cause (e.g. tinea).

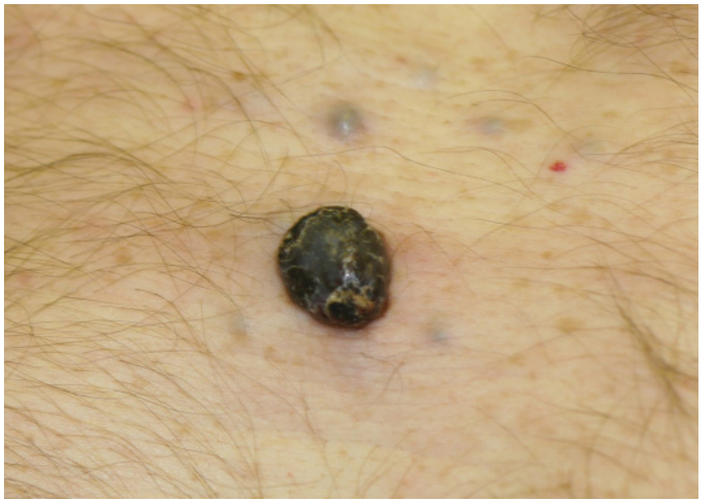

Fig. 5.13 Satellite lesions—in this case, local metastases around a primary nodular melanoma.

Fig. 5.14 Scattered lesions. The predominantly 'buckshot' pattern here is typical of 'strimmer' or 'weedwacker' dermatitis, in which photosensitizing plant products have been spattered onto the skin and produced localized photosensitivity. A useful clue to diagnosis is that, in addition, some of the individual lesions have a linear morphology (seen here as is a poorly defined linear band crossing the elbow joint) representing direct contact with a causative plant stem.

Fig. 5.15 A drug-induced phototoxic eruption. There is a striking pattern of sparing of skin covered by a sandal.

Distribution of lesions

The overall distribution of lesions in many common dermatoses may be so characteristic that it is of great assistance in clinical diagnosis, even though the mechanism in most instances is not understood. Examples of body site predilection of dermatoses are provided in Table 5.5. Some of these are explained by anatomy, sites of contact, etc. (see below), but even some demarcations that presumably have an anatomical basis are not fully understood, for example Wallace's line on the foot or the equivalent on the hand (Fig. 5.16). Some, for example those at flexural sites (Table 5.6), are often modified in appearance by moist occlusion. Important factors in determining the distribution of dermatoses include the following:

Anatomical factors

- blood supply, e.g. venous eczema
- skin appendages, e.g. acne, hidradenitis
- type of skin, e.g. eruptions may be localized to the glabrous skin of palms and soles
- neural, e.g. herpes zoster
- developmental, e.g. disorders which follow lines of Blaschko (Chapter 15)
- regional variation in the skin surface microenvironment, e.g. erythrasma is usually localized to flexures
- others, e.g. polychondritis is restricted to sites where there is cartilage, affecting ears, nose, joints (and trachea)

External factors

- solar exposure, e.g. photosensitivity disorders, squamous cell carcinoma
- chemical exposure, e.g. contact dermatitis
- infective, e.g. orf

Colour of skin and of lesions

Normal skin colour is due to melanin, phaeomelanin, haemoglobin, oxyhaemoglobin and carotenoids (Chapter 58). The colour of the skin is greatly modified by the scatter of light, which is responsible, for example, for the whiteness of scale and the blueness of any melanin deep in the dermis, although colour contrast with surrounding skin also alters perception of the colour of skin and subcutaneous structures [1]. The range of colours that may be seen

Table 5.5 Some examples of disorders that have predilection for specific body sites.

Body site	Type of disorder	Examples
Scalp	Hair disorders/alopecia	Alopecia areata, androgenetic alopecia
	Inflammatory dermatoses	Psoriasis, seborrhoeic dermatitis, lichen simplex
	Localized lesions	Pilar cysts, organoid naevus, squamous cell carcinoma, atypical fibroxanthoma, cutaneous metastases
Eyelids	Inflammatory dermatoses	Atopic dermatitis, contact allergy (cosmetics, nickel), seborrhoeic blepharitis, angiooedema, dermatomyositis
	Localized lesions	Basal cell carcinoma, xanthelasma
Ears	Inflammatory dermatoses	Seborrhoeic dermatitis, psoriasis, atopic dermatitis, relapsing polychondritis
	Infection	Pseudomonas ('malignant') otitis externa
	Localized lesions	Actinic keratosis, squamous cell carcinoma, chondrodermatitis nodularis, atypical fibroxanthoma, angiolymphoid hyperplasia with eosinophilia, gouty tophi
Face	Inflammatory dermatoses	Acne, atopic dermatitis, seborrhoeic dermatitis, rosacea, lupus erythematosus, lupus pernio, photosensitivity
	Infections	Herpes zoster, erysipelas, impetigo
	Localized lesions	Naevi and freckles, actinic keratoses, basal and squamous cell carcinomas, keratoacanthoma, lentigo maligna
Lips	Inflammatory dermatoses	Dermatitis (atopic, contact), cheilitis (angular, actinic), angiooedema, contact urticaria, erythema multiforme
	Infections	Herpes simplex, viral warts
	Localized lesions	Vascular lesions (venous lake, pyogenic granuloma), squamous cell carcinoma
Hands	Inflammatory and other dermatoses	Dermatitis (dyshidrotic, pompholyx, contact), psoriasis and palmoplantar pustulosis, keratodermas, erythema multiforme, photosensitivity (dorsal hand), collagen vascular disorders and vasculitis, granuloma annulare
	Infections	Paronychias, onychomycosis, scabies (especially fingerwebs), viral warts
	Localized lesions	Actinic keratoses, squamous cell carcinoma, subungual melanoma
	Nail disorders	Koilonychia, pachyonychia congenita, many others
Limbs	Inflammatory and other dermatoses	Psoriasis (elbows, knees), atopic dermatitis (limb flexures), discoid eczema, venous eczema and ulceration (lower leg), asteatotic eczema (lower leg), lichen simplex (lower leg), lichen planus (flexor forearms, shins), dermatitis herpetiformis (knee, elbow), granuloma annulare (elbows), erythema nodosum (legs), vasculitis (legs), papular urticaria/flea bites (lower leg)
	Localized lesions	Bowen's disease (lower leg), dermatofibroma
Feet	Inflammatory and other dermatoses	Dermatitis (pompholyx, contact, juvenile plantar), psoriasis and palmoplantar pustulosis, vasculitis and arterial disease, callosities/corns
	Infections	Dermatophyte fungal infection (skin and nails), pitted keratolysis, verrucae
	Localized lesions	Eccrine poroma, subungual exostosis
Axillae (see also Table 5.6)	Inflammatory dermatoses	Psoriasis, contact dermatitis, hidradenitis suppurativa, acanthosis nigricans, fibroepithelial polyps, freckles in neurofibromatosis (Crowe's sign)
	Infections	Staphylococcal boils, erythrasma
	Localized lesions	Apocrine hidrocystoma
Genital	Inflammatory and other dermatoses	Psoriasis/Reiter's syndrome, lichen planus and lichen nitidus (penis), lichen sclerosus (penis, vulva), lichen simplex (scrotum, vulva), fixed drug eruption (penis), Zoon's balanitis (glans penis), plasma cell vulvitis, other vulval dermatoses
	Infections	Sexually transmitted diseases, genital warts, molluscum contagiosum
	Localized lesions	Epidermoid cysts (scrotal), squamous cell carcinoma (penis, vulva)

Fig. 5.16 A keratoderma showing abrupt discontinuation at Wallace's line.

in individual skin lesions is enormous (Table 5.7). Although many red, scaly rashes tend to resemble each other, many dermatoses have their own distinctive colour which aids recognition—for example, the orange and yellow–orange palms of pityriasis rubra pilaris and carotenaemia, respectively. Some colours can be logically explained—for example, the purple of lichen planus is due to the redness of inflammation combined with the blue–brown of melanin within the dermis.

Examination of pigmented skin requires a degree of practice, as the physical signs may be modified. Erythema is seen as a dark area, macular or diffuse. Dermal oedema lightens the skin and weals appear pale. Papules may be pale or dark according to the degree of oedema or the presence of acanthosis or hyperkeratosis, which mask pigment. Purpura may be difficult to detect, but may appear jet-black in lighter-pigmented skin. Post-inflammatory depigmentation and hyperpigmentation are exaggerated

Table 5.6 Some disorders that have a predilection for flexural sites. (Adapted from GM White and NH Cox, *Diseases of the Skin*, 2nd edn. London: Mosby, 2000: 24. See also Chapter 71.)

Type of Disorder	Disorder	Comment (all refer to major flexures unless specified)
Inflammatory dermatoses	Psoriasis	Common in flexures, typically red and shiny rather than the usual white scale (Chapter 20); may be termed the 'inverse pattern' if mainly flexural distribution
	Seborrhoeic dermatitis	Usually with lesions elsewhere also; central face, scalp etc.
	Contact dermatitis	Irritant or allergic; may affect the vault of the axilla (e.g. deodorants) or axillary folds (e.g. clothing dermatitis) (Chapters 25 and 26)
	Intertrigo	Especially inframammary; may be due to simple maceration, but also secondary infection may occur (staphylococcal, streptococcal, candidal)
	Napkin rash	Many causes, the commonest are irritant and candidal (see Chapter 17)
	Lichen planus	Not often mainly flexural, but may cause confusion as flexural and genital lesions are often brown in colour and/or annular in morphology, rather than the usual purplish plaques, and may lack the anticipated pruritus
	Hidradenitis suppurativa	Affects axillae, groin, inframammary area (Chapters 30 and 42)
	Crohn's disease	Cutaneous lesions affect especially the perineum (Chapter 71)
	Atopic dermatitis	Affects elbow and knee flexures, uncommonly the major flexures other than in infants when the process may be generalized (Chapter 24)
Bullous diseases	Pemphigus vegetans	Rare, mainly flexural (Chapter 40)
	Hailey–Hailey disease	Inherited, variable (Chapter 39)
Infections	Dermatophytes	Especially male groin; usually associated with tinea pedis (Chapter 36)
	Erythrasma	Brownish colour, fluoresces under Wood's light (Chapter 30)
	Trichomycosis axillaris	Coated hair shafts (Chapter 66)
	Candidosis	Especially in napkin rash or bedbound elderly adults, commoner in diabetes; satellite pustules are characteristic (Chapter 36)
	Bacterial	Various types—follicular infections (furuncles), perianal abscesses, secondary infection of intertrigo, Gram-negative toe-web infections etc. (Chapter 30)
	Scabies	Multiple itchy flexural nodules are highly suggestive of the relatively chronic nodular variant—penile lesions are also common in this pattern (Chapter 38)
	Parvovirus B19	Often acral, but the laterothoracic type may include axillary involvement, and a bathing trunk pattern involves groin flexures; often purpuric
Localized lesions	Fibroepithelial polyps (skin tags)	A common normal variant
	Neurofibromatosis	Axillary freckling is seen (Crowe's sign) (Chapter 15)
	Fox–Fordyce disease	An apocrine occlusion dermatosis (Chapter 44)
	Pseudoxanthoma elasticum	Inherited defect of elastic tissue, most apparent on the neck and axillae (Chapter 45)
Miscellaneous	Hyperhidrosis and other sweat apparatus disorders	Mainly axillae (Chapter 44)
	Acanthosis nigricans	May be endocrine-related or paraneoplastic (Chapters 19 and 62)
	Acrodermatitis enterpathica/zinc deficiency	Severe napkin rash and perioral rash in an infant (Chapter 17); acquired version in adults; necrolytic migratory erythema of glucagonoma syndrome may have the same pattern (Chapter 62)
	Langerhans cell histiocytosis	May present as severe napkin rash (Chapter 17)
	Mycosis fungoides	Often affects shielded sites, may be limited to main flexures ± buttocks
	Granular parakeratosis	Rare—hyperkeratotic, mainly adult female axilla
	'Inverse' pattern of drug eruption	See Chapter 75

compared to paler skin—for example, after herpes zoster, syphilis, leprosy, lichen simplex and many other conditions. Normal pigmentary variation between body sites is also more apparent in darker skin, and may cause confusion (for example, dark crease lines on the relatively pale palms); pigmentary demarcation lines may also be visible (Futcher's and Voigt's lines) [2].

Palpation of the skin

Palpation of rashes or localized lesions imparts additional information about texture, consistency, thickness, tenderness and temperature [1]. It has been shown, using a trained 'blinded' observer, that the scaling of psorasis and eczema can be distinguished by palpation alone [2]. Gentle scratching or rubbing alters visibility of scaling and may elicit dermographism. The main 'touch' modalities in examining the skin are:

Simple palpation—to determine texture, etc., as above.

Blunt pressure—e.g. to detect oedema, assess capillary refill, identify the dermal defect that occurs in anetoderma.

Linear or shearing pressure—to elicit dermographism, or Nikolsky's sign in pemphigus (Chapter 40).

Squeezing or pinching—to determine localization and consistency of lesions, e.g. a pinch of skin can be lifted up over a subcutaneous nodule, whereas squeezing a tethered intradermal process such as a dermatofibroma produces dimpling (Fig. 5.17).

Table 5.7 Colours of skin lesions. (Adapted from CM Lawrence and NH Cox, *Physical Signs in Dermatology*, 2nd edn. London: Mosby, 2002: 21.)

Colour	Examples
Black	Melanin, e.g. some naevi, melanoma Exogenous pigments, e.g. tattoos, pencil/ink Exogenous chemicals, e.g. silver nitrate, gold salts Deeply situated blood or melanin, e.g. angiomas, blue naevus
Blue-grey	Inflammatory diseases, e.g. orf Drug-induced pigmentation, e.g. phenothiazines, minocycline
Dark brown	Melanin near the skin surface, e.g. most melanocytic naevi Exogenous pigments, e.g. dithranol (anthralin) staining
Pale brown	Melanin near the skin surface, e.g. lentigo, freckles
Muddy brown	Melanin in the superficial dermis, e.g. post-inflammatory pigmentation
Purple	Vascular lesions, e.g. angiomas Other disorders where telangiectasia is a prominent feature, e.g. lupus pernio (chronic sarcoidosis), dermatomyositis
Dusky blue	Reduced amounts of oxygenated haemoglobin, e.g. poor arterial supply, central causes of cyanosis, methaemoglobinaemia
Violaceous and lilac	Lichen planus, edge of plaques of morphoea, connective tissue disorders, e.g. dermatomyositis
Pink-red	Many exanthemata and common disorders, such as psoriasis
Red-brown	Inflammatory dermatoses, e.g. seborrhoeic eczema, secondary syphilis Haemosiderin, e.g. pigmented purpuric dermatoses
Scarlet-red	Lesions with a strong arterial supply, e.g. pyogenic granuloma, spider naevus Altered haemoglobin, e.g. carbon monoxide poisoning
Orange	Haemosiderin, e.g. lichen aureus Inflammatory disorders, e.g. pityriasis rubra pilaris
Yellow-white/ yellow-pink	Xanthomatous disorders
Yellow-orange	Carotenaemia (ingested carotene, myxoedema)
Yellow-green	Jaundice
Green	Exogenous pigment, e.g. copper salts
White-ivory	Lichen sclerosus et atrophicus, morphoea
White (or pale pink, depending on vascularity)	Vitiligo, naevus anaemicus, arterial insufficiency, chemical depigmentation on vascularity

Stretching—may produce blanching of vascular lesions, and helps in visualizing lesions such as 'submarine' comedones, the elastomas of Buschke–Ollendorf syndrome and the glassy edge of a superficial basal cell carcinoma.

Rubbing—may cause release of chemicals, e.g. rubbing a mastocytoma causes urtication and a flare due to histamine release (Darier's sign), rubbing a neuroblastoma causes surrounding pallor due to catecholamine release.

Scratching and picking—scratching scale in psoriasis makes the scale appear more silver in colour by introducing air–keratin interfaces; more vigorous scratching or picking off the scale produces small bleeding points (Auspitz's sign). Neither of these is specific to psoriasis. Removal of crusts overlying nodules may demonstrate the extent of the lesion, and additional diagnostic features, more accurately.

Fig. 5.17 Squeezing the skin adjacent to a dermatofibroma causes a dimpled appearance, also termed a positive 'pinch sign'.

Additional simple clinical examination

Wetting the skin with water or mineral oil (which lasts longer) fills air spaces in scale and allows underlying features to become more visible. In some instances, this just enhances underlying redness—for example, in psoriasis. In other instances, diagnostic features may become apparent to the naked eye (such as Wickham's striae in lichen planus) or with the aid of additional magnification (e.g. use of a dermatoscope to examine pigmented lesions). Soaking of the skin may make the lesions of pitted keratolysis more apparent.

Application of heat or cold may identify specific physical urticarias. Whole-body warming may confirm cholinergic urticaria. Even whole-body cooling has been used, to identify dysarthria as being due to Raynaud's phenomenon of the tongue.

Pinprick sensation may be lost in leprosy, and decreased *light touch sensation* (using specific graded monofilaments) can predict diabetes-related neuropathic ulceration.

Paring the skin allows distinction between a wart and a corn, or may confirm the presence of old blood in talon noir or a haematoma.

Smell may be useful—for example, in suspecting anaerobic wound infection, or in diagnosis of rarities such as trimethylaminuria.

Simple microscopy may be diagnostic for hair shaft abnormalities and for distinguishing between hair casts and head lice egg cases (nits), and is used to detect cutaneous fungal disease. Dermoscopy, an *in vivo* form of magnification, is discussed on p. 5.20.

Table 5.8 Uses of Wood's light.

Fungal infection	Tinea capitis—green fluorescence associated with *Microspora* species and favus (see also Chapter 36) Pityriasis versicolor—yellow
Bacterial infections	Erythrasma, acne—coral pink (porphyrins) *Pseudomonas pyocyanea*—yellowish green (pyocyanin)
Infestations	Scabies—fluorescein solution fills the burrows and can be viewed with Wood's light
Porphyrias (see also Chapter 59)	Urine, faeces and occasionally blister fluid fluoresce in porphyria cutanea tarda; teeth in erythropoietic porphyria; blood in protoporphyria
Pigmentary disorders	Vitiligo is accentuated (see text), dermal pigment becomes less apparent Detection of ash leaf macules in tuberous sclerosis
Drugs and chemicals	Detection in tissues, e.g. staining of teeth or sebum from tetracyclines and of the nails from mepacrine Detection of fluorescent contact or photosensitizers on the skin, or in cosmetics and industrial agents, e.g. ballpoint-pen ink, eosin, furocoumarins, halogenated salicylanilides, pitch ingredients Fluorescein can be added to topical medications to investigate sites of application or of manipulation (e.g. in the investigation of dermatitis artefacta)
Tumours	Red fluorescence can occur in some malignant tumours and other lesions of the skin, especially squamous cell carcinomas Conversion of aminolaevulinic acid to protoporphyrin IX occurs within tumours as the first step in photodynamic therapy and can be detected with Wood's light
Miscellaneous	Lipofuscins in sweat from patients with chromhidrosis can be identified by Wood's light examination of stained clothing Research use of fluorescent 'markers' for the investigation of cutaneous penetration and epidermal turnover Detection of mineral oil on the skin in the assessment of barrier creams

Additional clinical investigations

Diascopy

Pressing a glass slide or (more safely) a stiff, clear, colourless piece of plastic onto the skin compresses blood out of small vessels, to allow evaluation of other colours. Diascopy is of particular value in detecting granulomatous nodules, which have a translucent brownish colour known as 'apple jelly' nodules (e.g. in lupus vulgaris). In naevus anaemicus, a localized area of vasoconstriction, other pigments are unaltered—diascopy of adjacent skin therefore reveals an identical colour to that of the 'depigmented' area. By contrast, diascopy of skin adjacent to vitiligo, in which there is loss of melanin, demonstrates that the vitiligo remains paler. Application of medium pressure to a spider naevus can compress radiating arterioles and allow visualization of pulsatile flow in the feeding vessel.

Wood's light

This is a source of ultraviolet light from which virtually all visible rays have been excluded by a Wood's (nickel oxide) filter. Applications of Wood's light are listed in Table 5.8 [1,2].

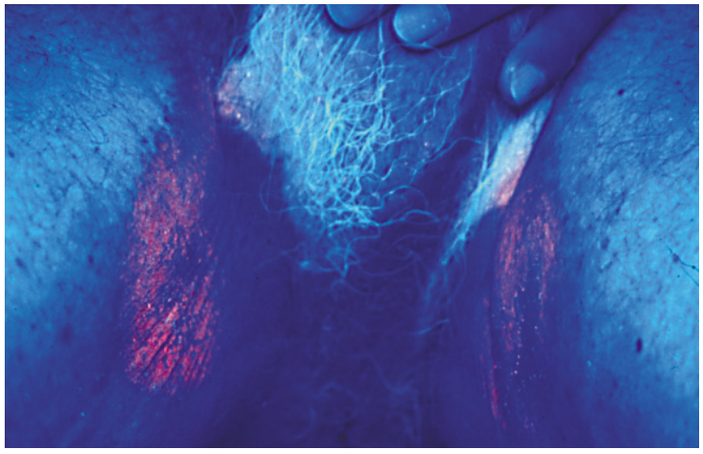

Fig. 5.18 Coral pink fluorescence of erythrasma in the groin creases, viewed with Wood's light.

Variations in epidermal pigmentation are more apparent under Wood's lamp than under visible light, whereas variations in dermal pigment are less apparent [3]. Thus, for example, it can be used to distinguish vitiligo from naevus anaemicus. Vitiligo is due to loss of epidermal melanin, and the depigmented areas are greatly exaggerated under Wood's light; naevus anaemicus is due to localized dermal vasoconstriction with normal overlying epidermal pigmentation, and the pallor completely disappears under Wood's light. The ash-leaf macules of tuberous sclerosis are much more prominent under Wood's lamp [3].

Many organisms produce chemicals that fluoresce under Wood's light [4,5] including *Propionibacterium acnes* [6], and *Corynebacterium minutissimum*, the bacterium responsible for erythrasma (Fig. 5.18), and conversion of aminolaevulinic acid to protoporphyrin occurs in several tumours and other skin lesions, leading to the technique of photodynamic diagnosis [7] as well as photodynamic therapy (Chapter 78). Fluorescein can be added to topical agents in studies of their use—for example, to detect areas that are missed during sunscreen application [8]. Wood's light can also be used to view *ex vivo* specimens, such as blood or urine in porphyrias [9], or even inanimate objects, such as clothing from patients with chromhidrosis [10].

There are pitfalls of using Wood's light:

- It is useful to diagnose tinea capitis acquired from cats or dogs, but most fungi do not fluoresce, so a negative test does not exclude the diagnosis.
- There is some reflection of light from any scaly dermatosis, which may be confused with the relatively subtle colour change of pityriasis versicolor.
- Optical brighteners in detergents fluoresce strongly—white shirts and coats may be a considerable distraction.
- Erythrasma fluoresces pink due to porphyrins—it is a reasonably frequent finding that the expected fluorescence is negative if the affected skin has been washed prior to a clinic appointment.

Clinical microscopy, dermoscopy and other imaging systems

Microscopy is an important laboratory technique, discussed briefly later. However, microscopy in a clinical setting also has several uses.

Dermoscopy

This technique, also known as dermatoscopy or epiluminescence microscopy, is an extension of the use of simple magnification. Dermoscopes have built-in illumination, and are applied to the skin surface with a film of oil on the lesion to enhance visibility of subcorneal structures. The technique is mainly used in the diagnosis of doubtful pigmented lesions (Chapter 54). The images may be viewed directly, photographed or recorded digitally for subsequent or sequential analysis. A structured system of analysing the colours and appearances of the structural elements (pigment network, globules and dots, horn cysts and pseudofollicular openings and the vascular patterns visualized) may increase the accuracy of diagnosing malignant melanoma [1]. Scoring systems such as the ABCD dermatoscopy score (assessing *a*symmetry, *b*order *c*olour and *d*ermatoscopic structures) [2] and a 'seven-point check list' [3] have been devised. Computerized image analysis is being developed to aid in distinguishing benign melanocytic lesions from melanoma [4]. Dermoscopes can also be useful in distinguishing haemangiomas, angiokeratomas, pigmented basal cell carcinomas and seborrhoeic keratoses from melanocytic lesions. More novel uses include the identification of scabies burrows and mites, diagnosis of tungiasis and other parasitic infections.

Other imaging systems for localized lesions

Spectrophotometric image analysis of pigmented lesions (SIAoscopy) allows the assessment of eight narrow-band spectrally filtered images of the skin over an area of 24 × 24 mm with radiation ranging from 400 to 1000 nm. The value of this technique as an adjunct to clinical examination and dermoscopy has produced differing opinions [1–3]; it has also been used in diagnosis of non-melanoma skin cancers [4], and used with an algorithmic approach to diagnosis [5].

In vivo confocal laser scanning microscopy (CLSM) represents a novel imaging tool that allows the non-invasive examination of skin cancer morphology in real time at a 'quasi-histopathological' resolution, viewing microanatomical structures and individual cells. It may show promise in the assessment of suspected melanoma [6].

Identification of scabies mites

Scabies mites can be extracted from the end of a burrow using a needle, with microscopy to confirm the diagnosis. The technique can be useful to convince sceptical sufferers of their infestation. Alternatively, application of mineral oil [1] or 5% potassium hydroxide to an affected interdigital space, followed by light scalpel scraping, reveals the acarus or its eggs. The faecal pellets (scybala) of the mite are also diagnostic, but are dissolved by potassium hydroxide; they remain intact in oil. Burrows can also be removed by a very superficial shave technique, and can be made more apparent by application to the skin of either black ink, or fluorescein with Wood's light visualization. Dermatoscopy (see above) can also be used—the mite appears as a dark triangle shape—or higher-resolution microscopy with a standard light microscope [2]. Outwith the scope of this section, scabies can also be identified using polymerase chain reaction (PCR) to detect mite antigens [3].

Other simple microscopy procedures

Simple light microscopy is helpful in evaluating hair shaft abnormalities (this, and more complex electron microscopy, are discussed in Chapter 66).

Microscopy of skin scrapings for fungi is discussed in Chapter 36. Scraping the base of a herpetic vesicle with simple Giemsa staining may reveal giant cells (Tzanck smear); molluscum contagiosum can be identified in a similar fashion. Examination of skin pustule smears after fixation and haematoxylin and eosin staining may be useful in the rapid diagnosis confirmation of infantile eosinophilic folliculitis and incontinentia pigmenti; in both conditions, the pustules are filled with eosinophils.

Skin surface biopsies using tape-stripping or adhesive microscope slides pressed onto the skin allow observation of cells of the stratum corneum and of bacteria, fungi such as *Pityrosporon* species, and *Demodex* mites [1–3]. Plastic polymer (Silflo) skin surface impressions may be useful for the study of eccrine gland pore size and numbers.

Fine-needle aspiration of lymph nodes (FNA)

Aspiration of lymph node tissue using a 25- or 27-gauge needle allows cytological assessment of lymph nodes and is useful in the staging of metastatic malignant melanoma and squamous cell carcinoma of the skin, as well as the assessment of lymph nodes in suspected lymphoma. In patients with palpable lymph nodes and melanoma, the technique has been shown to have high specificity and sensitivity [1] (Fig. 5.19). Combining the technique with flow cytometry can help in the differentiation of lymphoma from reactive and dermatopathic lymphadenopathy [2].

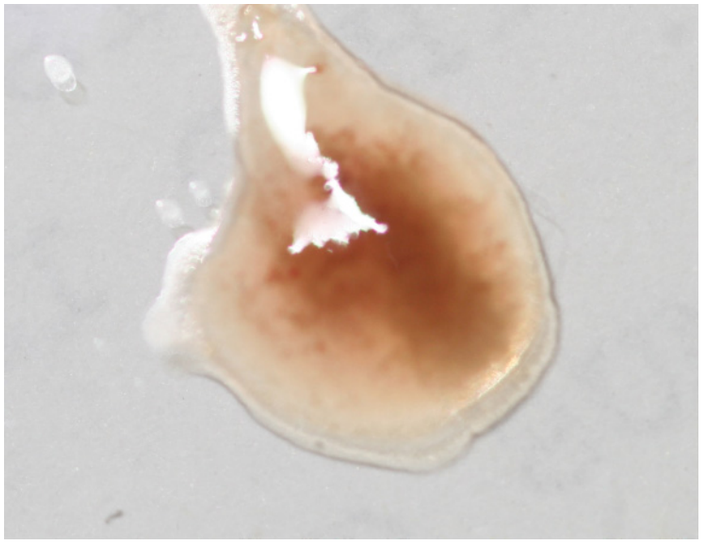

Fig. 5.19 Fine-needle aspiration. In this case, the fluid obtained on aspiration of a 5-cm lymph node in a patient with melanoma had a readily apparent black colour.

Commonly used laboratory tests

Numerous special investigations are used to refine a dermatological diagnosis, or for disease or therapy monitoring. Many of these are discussed specifically in relevant chapters—for example, testing for photosensitivity (Chapter 29) or for contact allergy (Chapter 26). The commonest tests which involve additional laboratory processing of samples are as follows:

- Blood tests for haematology or biochemistry. These are used in numerous situations, both diagnostically and for assessing the impact of a skin disease or for monitoring systemic therapy. Many infective disorders or acute inflammatory conditions are associated with neutrophilia or with abnormal results of inflammatory markers such as erythrocyte sedimentation rate or C-reactive protein; eosinophilia is also a feature of several dermatological conditions (briefly listed in Table 5.9, and discussed in more detail in Chapter 62).
- Blood tests for immunological studies. For example, in the diagnosis of connective tissue diseases (Chapter 51), IgE and radioallergosorbent test (RAST) in atopic and allergic diseases (Chapters 13 and 24).
- Histology of skin biopsy (Chapter 10). This may include special staining methods, direct immunofluorescence studies and immunocytochemistry. 'Rush' frozen sections may be necessary—for example, during micrographic surgery or in the urgent diagnosis of some blistering conditions [1].

Table 5.9 Some 'dermatological' causes of eosinophilia (more than 0.44×10^9/L eosinophils).

Atopic disorders, especially asthma and eczema
Parasitic infestations
Worms (intestinal or systemic)
Scabies
Allergy to food or drugs
Tryptophan myalgia syndrome
Collagen vascular disease (especially polyarteritis nodosa and variants), dermatomyositis and eosinophilic fasciitis
Malignancy, especially Hodgkin's disease and eosinophilic leukaemia
Bullous disorders
Dermatitis herpetiformis
Pemphigus
Pemphigoid
Erythema neonatorum
Hypereosinophilic syndrome

- Other immunological and microscopy studies for bullous diseases, e.g. immunoblotting (Chapter 40) and electron microscopy (Chapters 16 and 39).
- Bacteriology and mycology samples (Chapters 30–37). May include samples for microscopy and culture, serological tests, PCR tests (e.g. for mycobacteria).
- Cytological examination. Usually in the context of FNA from lymph nodes, discussed above.

Radiological and imaging examinations

These have an important role in dermatology, but less than in many other specialties, because the skin can so readily be seen and felt. Ultrasound [1,2], magnetic resonance imaging (MRI) [3–5], radio-isotope scans and even positron emission tomography (PET) [6,7], are all used in clinical dermatological practice, mainly in relation to detection of lymphadenopathy or other metastatic skin cancer. High resolution ultrasound is increasingly important in documentation of nodal enlargement and tumour infiltration, and can be used to guide biopsies. Other uses of radiological procedures in dermatology include, for example, for the accurate assessment of the thickness of lesions in scleroderma, the extent of infection in severe forms of cellulitis (and distinction, using MRI, from necrotizing fasciitis), and assessment of local invasion of tumours. Various imaging techniques are also important in the management of diseases such as neurofibromatosis, where there may be central nervous system involvement, or in the assessment of muscle change in dermatomyositis. Lymphoscintigraphy may be a useful functional assessment of the lymphatic system of the swollen lower limb (Chapter 48). Doppler assessment of the peripheral lower limb arteries is an essential bedside technique prior to the use of high-compression bandaging in the management of venous leg ulcers (see Chapter 47); use of standard electronic sphygmomanometer systolic pressure measurements is not accurate in measurement of peripheral arterial pressures [8].

Skin testing

Substances may be introduced into the skin by a variety of techniques to study pharmacological and immunological [1] reactions under controlled conditions. Such tests are extremely valuable, but details of the type of test and the time at which it is read must correspond to the pathological process under consideration. Interpretation of the relevance of tests, either positive or negative, must always be correlated with the clinical picture. All too often, evidence adduced from tests is either meaningless or misleading.

Absorption of many substances through the intact skin is poor and variable, but direct application to the surface of the skin is used for patch testing. The epidermal barrier may be overcome either by removing it or by introducing the material directly into the dermis. The following techniques for skin testing are most commonly used.

Techniques for skin testing

Epicutaneous tests—patch tests

Patch tests are usually used to detect contact allergy of the delayed hypersensitivity type. They are usually read at 48–72 h and again up to 1 week, but can also be read at 15–30 min to detect contact urticaria. At times, patch testing may usefully be combined with scratch testing. Details of these techniques are discussed in Chapter 26.

Intradermal injection

The injection is made into the superficial layer of the dermis through a fine-bore (26- or 27-gauge) needle with its bevel pointing upwards. The quantity that may conveniently be injected varies from 0.01 to 0.1 mL. Precise measurement of smaller quantities is difficult and requires syringes with especially well-fitting plungers and a micrometer screw gauge. For routine clinical purposes, an approximation is sufficient—either 0.05 mL or the amount that just causes a visible weal (0.01–0.02 mL).

The optimal time for reading the reaction naturally varies with the pharmacological agent or the type of immunological reaction. Most such tests are read at either 15–20 min or at 48 h, but it may be important to read the tests at other times, for example at 4–12 h or after 4 days. The response to be observed at 15 min—for example, after an injection of histamine or after immediate-weal allergy tests—is a weal with a surrounding flare (Fig. 5.20). The weal is a more accurate measure than the flare. When the test is read at 48 h—for example, in the tuberculin reaction—the sizes of the indurated papule and of the erythematous reaction should be observed.

The site of the test is of some importance [2,3]. In general, the whole skin surface is capable of responding to skin tests, but there are regional variations. The back and the flexor aspects of the forearms are most conveniently used. The skin on the ulnar aspect of the forearm is more sensitive than the radial, and the proximal

Fig. 5.20 A positive prick test reaction to latex allergen.

more sensitive than the distal. These differences are not of sufficient magnitude to affect routine testing, but must be taken into account by using symmetrical areas for controls in any accurate quantitative testing.

A test solution must always be compared with a control solution injected in a comparable site at the same time. A positive test may be taken as one that is significantly different from the control. Assessment of what is significant is difficult, and varies with the enthusiasm of the tester. If a difference of less than 5 mm is accepted, reproducible results may not be obtained on retesting [4].

The measurement of a weal is usually made by diameter, although more sophisticated methods, such as volume measurements and Doppler flow, have been used [5]. If the weal is not circular, an approximation may be made by averaging maximum/minimum diameters, or more accurately the area may be calculated by the formula $D_1 \times D_2 \times \pi/4$, where D_1 and D_2 are the maximum and minimum diameters [6]. For irregular weals, a tracing may be made on squared paper. Pseudopodia should be noted, but for measurement of diameter they are ignored. Attempts to assess the volume of a weal are less satisfactory for routine use.

The size of the weal is not directly proportional to the dose of the active agent, but varies also with the total volume of fluid injected. An approximation of a linear relationship may best be achieved, often only over a narrow range, by plotting the response against the log dose. For accurate quantitative observations, weal diameters below 4 mm or above 15 mm cannot be relied upon.

Antihistamines may greatly inhibit the immediate weal tests. In the case of very long-acting agents, this effect may last as long as 3 weeks. They have no appreciable effect on delayed hypersensitivity patch tests. Moderate to large doses of corticosteroids, in contrast, may somewhat inhibit patch tests, although smaller doses—for example, prednisone 10 mg daily—are not necessarily a contraindication to testing. Steroids do not greatly inhibit the immediate weal tests. When a patient feels faint, any immediate weal test may be completely inhibited.

Prick test

This is a modification of the intradermal injection. A small quantity of the test solution is placed on the skin and a prick is made through it with a sharp needle. This should be superficial and not sufficient to draw blood. The quantity has been estimated as 3×10^{-6} mL [3]. The size of the weal and flare are measured after 15 min (Fig. 5.20). This test gives reproducible results and is convenient for much routine allergy testing. Because of the discrepancy in quantities injected, the testing solutions are made up at different strengths for prick testing and intradermal testing. The intradermal injection of prick-test solutions may be dangerous.

Scratch test

The scratch test resembles the prick test. A linear scratch about 1 cm long, but not sufficient to draw blood, is made through the epidermis. This test gives less reproducible results than the prick test.

Modified prick test

Here, a drop of the test solution is placed on the skin. A needle is then inserted very superficially and almost horizontally into the skin and lifted to raise a tiny tent of epidermis. This test is slightly more sensitive than the ordinary prick test, but gives no more reproducible results.

Skin-window technique [7,8]

The surface of the skin over an area a few millimetres square is scratched off with a scalpel, the test solution applied and the area covered with a coverslip. This is removed at various intervals—for example, 3 h, 6 h, 12 h, 24 h and 48 h—and immediately replaced by another coverslip. The cells on the coverslip are stained with ordinary haematological stains. The cellular response at varying time intervals can be assessed.

Immediate weal tests

These tests are used for detecting IgE antibodies. The passive transfer test may be used to detect circulating IgE, but is not recommended because of the risk of serum hepatitis or human immunodeficiency virus (HIV). These antibodies play a role in hay fever, asthma, atopic dermatitis and anaphylactic reactions. They occur especially, but not exclusively, in patients with a personal or family background of atopy. Positive skin tests to a wide variety

of antigens are extremely frequent in these patients and must always be correlated with the history. They are principally used in the assessment of hay fever and asthma and have a limited place in the management of atopic dermatitis (Chapter 24). They are disappointing in the diagnosis of urticaria. False-positive and false-negative reactions are common.

Severe systemic reactions and, very rarely, fatalities may occur after correct use of standard testing solutions, and epinephrine (adrenaline) and hydrocortisone injections should always be at hand when skin tests are performed [1,2].

Alternative methods of detecting and measuring circulating antibodies are the RAST and the enzyme-linked immunosorbent assay (ELISA). RAST correlates well with skin testing [3,4]. It is particularly useful (i) in testing very young children; and (ii) with allergens associated with risk on prick testing (e.g. drugs).

The autologous serum test is a technique used in the investigation of chronic idiopathic urticaria whereby the patient's own serum is injected intradermally. It is regarded as being positive if at 30 min there is a weal 1.5 mm larger than at the saline control injection site. Positive reactions are indicative of functional autoantibodies against the high-affinity IgE receptor FcεRI, or against IgE [5] (Chapter 22).

Delayed (4–8 h) tests

The clinical interpretation of tests that are positive at 4–8 h can be difficult. Sometimes, these represent an Arthus reaction, but ideally this should be confirmed histologically. Other such tests represent a delayed variant of the immediate weal (15-min) test.

Intradermal tests for the detection of delayed sensitivity to bacterial, fungal and viral antigens

The tuberculin test. Testing for evidence of tuberculosis has achieved new importance in dermatology, in part because of an increasing incidence of tuberculosis associated with HIV infection, and also because screening is a necessary part of the work-up before use of antitumour necrosis factor biological drugs (for example, in psoriasis). A positive result to the standard strength (10 tuberculin units, TU) is an indication of previous mycobacterial infection, but not necessarily by *Mycobacterium tuberculosis* (especially if the reaction is weak or doubtful). Reactions to 1 TU (1/100 dilution of purified protein derivative (PPD)) are, however, significant. In sarcoidosis, reactions may be wholly negative, or only positive to 100 TU. The minimum size of a positive reaction is taken as 5 mm. An intermediate (24-h) reaction sometimes occurs.

Comparable doses of PPD may vary according to their source. Misleading negative reactions may occur in anergic patients. Tuberculin tests are discussed further in Chapter 31.

The Heaf test. Used in mass testing and in children. It is roughly equivalent to, or perhaps slightly more sensitive than, a dilution of 1:100 old tuberculin [6].

Candida antigen is used in a similar manner to the tuberculin test. Depressed reactivity occurs in sarcoidosis and other immunosuppressed conditions. Negative reactions in normal subjects are, however, not uncommon and depend on age and locality.

Trichophytin detects past infection by *Trichophyton* species. Its value is limited.

The lepromin test. This is discussed in Chapter 32.

Histoplasmin, coccidioidin and similar antigenic tests are of most value in areas where these diseases are not endemic. The Frei test and cat scratch fever antigen are of some value in the UK, where the relevant diseases are comparatively rare. A positive reaction is then significant. Conversely, Brucella antigen and toxoplasmin are of limited use in dermatological practice.

Delayed-type bacterial antigen tests [7–9]. These are not widely used, partly because their specificity and interpretation are difficult to assess. They consist of standard preparations of bacterial extracts, each probably containing a mixture of antigenic components, which may produce an immediate, or delayed 48-h reaction or an even later reaction. The normal 48-h response is a papule showing, histologically, a tuberculin-type reaction of lymphocytic type. Occasionally, however, especially in cases of vasculitis, an acute leukocytoclastic reaction occurs within 6–8 h [8] and is fully established at 24–48 h. Sometimes, the reaction is severe enough to produce a sterile abscess. It is tempting to believe that these reactions may be of some significance in conditions such as erythema multiforme, erythema nodosum (streptococcal), allergic vasculitis and, perhaps, pustular psoriasis. However, the antigens at present in use are relatively impure and the reactions may be non-specific. Further careful immunological studies are required.

Long-delayed (6-week) intradermal reactions. These comprise the Kveim test and the Mitsuda test. They are read at 6 weeks, but biopsy is essential with the Kveim test. Kveim test antigen is no longer available in the UK.

Oral provocation tests

The administration of a drug, food or chemical by mouth may sometimes be called for to confirm the diagnosis of an eruption or to establish its exact cause. Such tests are used in the following situations.

1 To determine the cause of a drug eruption or to isolate one from a number of drugs or ingredients of a compound drug. It is applicable only when the drug given and the dose chosen are unlikely to provoke a severe reaction in the patient. It may be a valuable method of proving the cause of a fixed drug eruption but should rarely, if ever, be used if the reaction has been of a generalized or acute nature. The subject is discussed in more detail in Chapter 75.

2 In the course of the investigation of food allergens [1–3]. The reintroduction of specific foods, one at a time, is an established part of exclusion, elimination and challenge diets. It is important that the role of the suspect food is subsequently confirmed by reintroducing it in a disguised form to avoid identification by the patient. The procedure is applicable to patients with atopic eczema (Chapter 24), chronic or recurrent urticaria (Chapter 22) and possibly to some other dermatological conditions that have an allergic basis. However, it must be carried out with care and is only valuable if the tests are properly controlled and the patient is cooperative and well motivated.

3 In establishing the role of additives in chronic urticaria or angio-oedema (Chapter 22). Tartrazine, benzoates and antioxidants have been especially implicated [4–6]. Although oral provocation with increasing test doses of these substances is theoretically simple, the same reservations apply, and the administration of the diets and the 'blind' challenge require time, patience and motivation. Audit has shown that these tests appear to benefit the patient at low cost, but their scientific validity remains uncertain [7].

The role of oral nickel and chromate in the behaviour of endogenous hand eczema has been studied [8,9]. Some authors have produced flares of vesicular hand eczema after oral administration of nickel, but others have been unable to reproduce these results when interspersing test doses with placebo capsules.

Oral provocation with balsam of Peru was used in a series of 221 patients [10]. Flares of an existing dermatitis occurred in 45 patients, only 17 of whom had shown positive patch-test reactions to this substance. Subsequent dietary restriction of flavourings was said to clear or 'markedly improve' the dermatitis in half the patients.

Sublingual food tests are unreliable [11].

Telemedicine

Considerable clinical experience is needed in order to make correct dermatological diagnoses, and since trained dermatologists are in relatively short supply even in many developed countries, telemedicine—remote consultation via an electronic link—may become an attractive option. It is particularly useful in remote or rural areas where there are no specialists.

Dermatologists have for many years conducted long-range consultations by telephone or by mailing histology slides or clinical photographs, but the unique feature of telemedicine is the two-way electronic network that now allows immediate interactive communication between the patient, the primary care physician and the specialist (so-called real-time teleconsultation). Different parts of the patient can be viewed at various magnifications, and the specialist can ask supplementary questions and advise on the most suitable biopsy sites if necessary. Such teleconsultations may be extremely valuable for obtaining international specialist opinion. A less satisfactory, but relatively time-efficient approach is the 'store and forward' system, whereby history details and images taken remotely are reviewed later by a distant specialist. Both for the primary care physician and specialist, teleconsultation time exceeds the duration of face to face consultation [1]. This does not allow simultaneous supplementary history and directed image choice, which may hamper appropriate management.

Several trials have shown that telemedicine can be effective, with high levels of satisfaction reported by patients, GPs and hospital specialists [2–4] though good photographic technique and lighting are essential for optimal results. It may be useful for tumour triage as well as assessing inflammatory dermatoses [5]. A personal encounter between specialist and patient may offer additional advantages, such as enhanced information about the patient's personality, with more patient participation in decisions and a placebo effect, which can lead to greater compliance [6]. The ability to palpate and smell can also give valuable diagnostic information (p. 5.17) but telemedicine clearly has considerable potential for dermatological diagnosis. With the ubiquity of high resolution mobile phone cameras, an increasing number of patients bring images of themselves, and this may be valuable in assessing evanescent eruptions. Mobile phone teledermatology may help in triage [7,8].

What is epidemiology and why is it relevant to dermatology?

> *Epidemiology is the simplest and most direct method of studying the causes of diseases in humans and many contributions have been made by studies that have demanded nothing more than an ability to count, to think logically and to have an imaginative idea.*
>
> (Sir Richard Doll, 1987 [1])

Many dermatologists still think of epidemiology in terms of describing the prevalence and the age, sex and geographical characteristics of a particular skin disease. Whilst it is true that epidemiology is often used in this fashion to describe the *burden* of disease in human populations, as Sir Richard Doll points out above, epidemiology also offers one of the most powerful and direct methods of evaluating the *causes* of skin diseases in human populations. One definition of epidemiology is therefore 'the study of the distribution and causes of diseases in human populations'. In addition to describing the burden and causes of skin diseases in populations, *clinical epidemiology* is concerned with describing the natural history and prognosis of diseases and with evaluating interventions which seek to prevent or treat diseases [2]. The term *dermatoepidemiology* refers to the study of the epidemiology of dermatological disorders [3]. Because epidemiological studies are often concerned with making observations about highly complex natural experiments, methods for minimizing bias or adjusting for confounding factors (see glossary) have had to be developed. These new methods, along with the high scientific rigour necessary for designing and interpreting epidemiological studies, are aspects from which all dermatological research can benefit. Epidemiology is therefore relevant to dermatology for the six reasons shown in Table 6.1.

Although epidemiology is still sometimes perceived as a novel aspect of dermatology, the first epidemiological discoveries in dermatology can be traced back to 1746, when James Lind [4] concluded that scurvy in sailors was related to dietary factors. He then showed, by means of a controlled study, that the disease readily responded to the addition of fresh oranges and lemons in the sailors' diet (the principles developed by Lind have resulted in the establishment of a library documenting the development of fair tests in treatments in health care [5]). In 1914, Joseph Goldberger [6] observed that 8% of 418 patients admitted to the Georgia State Sanatorium developed pellagra, compared with none of the 293 Sanatorium employees. He suggested that pellagra was due to an absence of 'essential vitamins', today recognized as nicotinic acid, and proceeded to test his suggestion in a community trial. Thus, dermatoepidemiology is not such a new subject, and with over 2000 skin disease reaction patterns described, the scope of the topic is vast. This chapter will therefore not deal with the epidemiology of specific skin diseases, which will be described where possible under the relevant disease sections. It will instead attempt to illustrate the relevance of modern epidemiology to dermatology by using specific examples. The principles of evidence-based dermatology, which relies heavily on methods developed from

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

Table 6.1 The relevance of epidemiology to dermatology.

To quantify the burden of skin disease in the community
To identify the causes or risk factors for skin diseases
To describe the natural history, prognosis and disease associations of skin diseases
To evaluate the effectiveness of dermatological treatments and organization of health care
To provide a methodological framework for underpinning evidence-based practice in dermatology
To provide appropriate methods for designing and interpreting clinical dermatological research

clinical epidemiology, are discussed in more detail in Chapter 7 by Bigby and Williams. A glossary of commonly used epidemiological terms and further reading sources are to be found at the end of this chapter.

Thinking in terms of populations rather than individuals

The community diagnosis

One of the first hurdles to overcome when considering the epidemiology of a skin disease is to think in terms of *populations* rather than *individuals*. Many physicians find this conceptual jump quite difficult, as they are used to dealing with *individual* patients on a daily basis, whereas epidemiological studies refer to *groups* of individuals. Just as molecules, genes and individuals exhibit various aggregate characteristics, entire groups or populations exhibit their own unique characteristics and problems that enable a *community diagnosis* to be achieved [1].

Interesting patterns can occur when one explores the potential implications of treating an entire community (the public health approach) rather than sick individuals who present themselves to doctors (the high-risk approach). Rose [2], for example, showed that a 10-mm lowering of blood pressure distribution as a whole (e.g. from reducing salt intake) would correspond to about a 30% reduction in the total attributable mortality, simply because of the shape of the change conferred on the distribution curve in relation to specific 'disease' cut-off points. In other words, a little bit of benefit spread across the entire population distribution may result in large population benefits in absolute terms.

Table 6.2 Prevalence of scabies among 756 Kuna Indians on the island of Ticantiki, Panama [3].

Date	Community treatment status	Prevalence of scabies (%)
July 1986	Conventional treatment	33.0
October 1986	Community control and surveillance instituted	0.7
July 1987	Breakdown due to supply problem	3.6
December 1988	Programme running again	1.5
March 1990	US invasion of Panama	12.0

During the scabies epidemics that occurred on the islands near Panama in the 1980s [3], it was found that even the best topical treatments when administered properly had no sustainable impact on the overall prevalence of scabies (which was very high in this population and which was associated with considerable morbidity from secondary pyoderma). When a *population* approach was adopted, that is treating all individuals with a programme of continuing surveillance, the prevalence of scabies fell dramatically to less than 2%, as shown in Table 6.2, and was sustained at that level until the US invasion of Panama interrupted these efforts. Thus, just as individuals become 'diseased', entire populations can become sick [2]. In these situations, whether it be an infestation such as scabies or a disease of modern society such as obesity, tackling the problem based on a population diagnosis is usually beneficial, cost-effective and appropriate [4].

Skin diseases as 'entities' in the population

The concept of considering the health of entire populations also applies to the classification of skin diseases. Typically, dermatologists are preoccupied with deviants who present themselves to secondary and tertiary care because of disease severity and/or chronicity and who are at the extreme end of the normal distribution curve of variations in skin health and disease. Such individuals usually have well-defined physical signs which prompt those studying them to declare them as discrete 'entities' [5,6]. Such distinctions often become blurred when community surveys are undertaken. In a community survey of atopic eczema, for instance [7], it was noticed that indeterminate or borderline cases who had limited areas of dry skin or a single patch of eczematous inflammation were quite common. In these circumstances, perhaps the more relevant question is not 'Has the person got eczema?' but 'How much eczema does the person have?'

The concept of a distribution of disease severity at a population level may also be helpful in evaluating different treatment policies. For example, it has been estimated that a small change in the treatment threshold of isotretinoin from severe to moderate cases of acne could result in a 15-fold increase in prescriptions in absolute terms, simply because moderate cases outnumber severe cases by so much [8].

Making comparisons and drawing inferences

Epidemiological reasoning usually progresses in an ordered fashion, starting with a hypothesis that has been suggested by

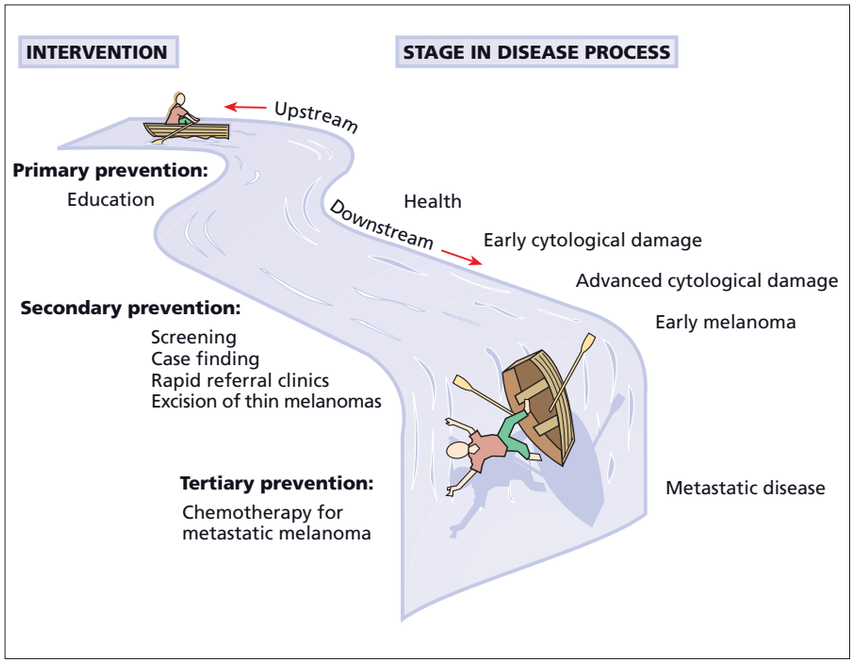

Fig. 6.1 Disease prevention in a serious condition such as melanoma is much more sensible than treating sick individuals with expensive drugs at the end of a long chain of irreversible pathological events.

good clinical observations (e.g. palmoplantar psoriasis seems to be commoner in smokers) or descriptive studies of populations. The hypothesis (that smoking is a risk factor for palmoplantar psoriasis) is then tested in an epidemiological study, which gathers and analyses data in a systematic fashion in relation to an appropriate comparison group to see if a statistical association exists. *Analytical epidemiology* is therefore concerned with making comparisons. These comparisons rely upon the uneven distribution of disease and risk factors within and between populations to shed light on possible causes of ill health. Thus, previous case–control studies [9] showed that smoking was far more common in patients with lung cancer—a finding which led to more sophisticated studies to establish disease causality [10]. If everyone had smoked, it is unlikely that smoking would have been identified as a cause of lung cancer.

In the simplest form of epidemiological study, a count is made of the number of cases with a particular skin disease (the numerator) within a catchment population (the denominator). The probability or frequency of disease occurrence may then be compared in two or more populations—for example, one exposed to a putative causative agent compared with another which is not. Inferences are then drawn based on the magnitude of the differences of disease frequency between the populations in light of possible alternative explanations such as chance, bias and confounding (see glossary). If such associations are genuine, further evidence is usually needed to determine whether they are causal in nature [11]. The whole process brings us one step nearer to the dermatoepidemiologist's ultimate goal—that of preventing skin disease, providing such causes are amenable to individual/public health manipulation. Prevention of skin disease is clearly more desirable than treating diseased individuals (Fig. 6.1).

When referring to an epidemiological study, it is important to make a distinction between the study population chosen for a particular study (e.g. those attending a hospital outpatient clinic) and the base population about whom one wishes to make inferences, as shown in Fig. 6.2. [12]

The prevention paradox

Interventions that confer large population health gains may not confer much benefit to individuals. Thus, in the example of scabies in Panama above [3], although the population's health as a whole benefited greatly, many apparently healthy individuals may have not appreciated being treated for scabies, as it was not known who would have developed scabies in the absence of the prevention programme. Similarly, it is difficult to say which child will benefit from being immunized for tuberculosis in a BCG immunization programme, because events have not yet occurred. This conflict between large gains in the health of entire populations versus small gains in individuals has been termed the 'prevention paradox' [4]. In the field of contact dermatitis, for example, eradication of a rare but potent contact sensitizer may have a great impact on affected individuals but little impact on the overall total burden of contact dermatitis in the general population. On the other hand, reduction in the amount of contact with formaldehyde, a less potent but far more common sensitizer in the general population, will result in a much larger reduction in the burden of contact dermatitis in that population, simply because far more people are exposed to formaldehyde [13]. As Table 6.3 illustrates, a little bit of harm affecting a lot of people can therefore add up to more than a lot of harm affecting a few people, in *population terms.* The first step when considering the epidemiology of skin disease is therefore to think about *populations* rather than *individuals*.

Table 6.3 The prevention paradox: a little bit of harm affecting a lot of people can add up to more than a lot of harm affecting a few people. From Williams [13] with kind permission from Karger, Basle.

	Eradication of exposure in:	
	The population	**The individual**
Rare—Exposure with high relative risk (e.g. contact sensitization to diphencyprone)	Small benefit	Large benefit
Common—Exposure with low relative risk (e.g. smoking and psoriasis)	Large benefit	Small benefit

How much of a public health problem is skin disease?

The need for a clear disease definition in epidemiological studies

A glance at the dermatological journals makes it clear that the subject matter of most current research is defined—wholly or in part—by diagnostic criteria. But if these criteria are not explicitly stated, are prone to vary from one patient to the next in unpredictable ways, and vary systematically from place to place and time to time, the usefulness of such research is gravely impaired. Although phrases such as 'diagnosed by dermatologists' or 'diagnosed independently by two experienced physicians' and 'all with typical symptoms' may be adequate for dealing with individual patients, they are hopelessly inadequate when describing groups of individuals in epidemiological studies [1]. For instance, it has been shown that even experienced physicians are perfectly capable of disagreeing with each other over the classical signs of atopic dermatitis [2], and when two agree, a third is capable of disagreeing. What is regarded as 'typical' in London may be nothing of the sort in Lourdes, Lima, Lhasa or Lusaka.

Diagnostic criteria that work well in hospital studies may perform poorly in community studies because of the effect of low disease prevalence on positive predictive value (see glossary) and an increase in borderline cases. The properties of good diagnostic criteria for use in epidemiological studies are summarized in Table 6.4.

Not only is it important to use diagnostic criteria of known validity and repeatability in epidemiological studies, but it is

Table 6.4 The attributes of a good disease definition for use in epidemiological studies. From Williams [3], with permission.

Validity: it measures what it purports to measure by including cases and excluding non-cases
Repeatability: good replication of the definition between and within observers
Acceptability: to the study population in order to ensure high response rates
Coherence: with prevailing clinical concepts
Easy to administer by field workers
Reflects some degree of morbidity
Comprehensiveness: applicable to a range of ages, ethnic groups and disease severities
Comparability: they should contain elements which allow some comparison with previous studies

sometimes important to qualify cases identified by such criteria by some measure of disease severity. For example, prevalence surveys of acne in the absence of severity measures are not very helpful in quantifying the disease problem, since physiological acne (non-inflammatory lesions) affects over 90% of adolescents [4]. Again, severity grading systems used in a hospital setting (which are usually non-linear and tend to favour severe and currently active disease) may not be so helpful in separating disease severity in milder community cases, where intermittent disease may be more common.

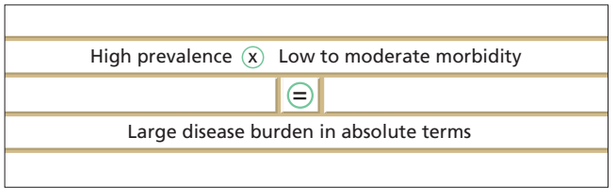

Fig. 6.3 Skin disease is a major public health problem: in public health terms, a little bit of misery affecting a lot of people can add up to more than serious illnesses which affect only a few people.

Burden, impairment, disability and handicap caused by skin disease

The burden of skin disease can refer to disease occurrence using terms such as prevalence or incidence (epidemiological burden), the effects of skin disease on a person's well-being (quality of life burden) or the direct and indirect costs associated with skin disease (economic burden). A working group affiliated to the US National Institute of Arthritis and Musculoskeletal Diseases (NIAMS) examined such conceptual frameworks in more detail, supplemented by thorough reviews of current data [5]. They concluded that further research is needed to reach consensus on how skin diseases and their associated burden should be defined. Burden of skin disease was also the theme of the 2008 International Dermato-Epidemiology Association Congress in Nottingham (http://www.nature.com/jid/journal/v128/n10/pdf/jid2008267a.pdf, accessed 28th July 2009), the findings of which will be summarized in a forthcoming publication.

In addition to the concept of burden, consideration of the three concepts of impairment, disability and handicap may be helpful in separating those effects which result from disordered function from those which are conferred on individuals by society. Impairment refers to the organic lesion produced by a disease, for example a broken limb; disability is the dysfunction that results from that impairment, for example not being able to walk; and handicap is the disadvantage that society confers upon the individual as a result of the impairment, for example unemployment. Handicap in skin disease may not be as explicit as that associated with a broken limb, but the psychological consequences of skin disease, which include 'failure of display' [6,7], may be just as important. It has been shown that relatively minor skin complaints often cause more anguish to people than other more serious medical problems [6]. Also, because skin disease is so common, a little bit of morbidity affecting a lot of people can add up to far more than a lot of morbidity affecting only a few people. It is this product of high prevalence times moderate morbidity that makes skin disease very important from the public health point of view (Fig. 6.3). Small changes in health policy can have large financial implications, simply because they affect so many people.

One population-based, cross-sectional study conducted in the USA on a random sample of 20 479 people examined by dermatologists in 1971 to 1974 [8] has pointed to the magnitude of disability and handicap from skin diseases; skin conditions were reported to limit activity in 10.5 per 1000 of the population aged 1–74 years, or 9% of those persons with such skin conditions. About 10% of those with skin complaints considered the condition to be a handicap to their employment or housework, and 1% considered themselves to be severely handicapped. About one-third of those persons with skin conditions indicated that the condition(s) were a handicap in their social relations. The dermatological examiners rated more than two-thirds of those with skin complaints as disfigured to some extent from the condition, and about one-fifth of those were rated moderately or severely disfigured. More than half of those with skin complaints reported some overall discomfort from the condition such as itching or burning. An estimated 62.8 per 1000 US civilians (or 56% of those with skin complaints) indicated that the conditions were recurrent, with 49% active in the preceding 7–12 months.

The 1989 UK General Household Survey estimated that 16 per 1000 persons were affected by a long-standing skin disorder sufficiently severe to limit their activities [9]. Another survey of disability, amongst 14 000 adults conducted in the mid-1980s, found that 1% of complaints causing disability in private households and 2% in communal establishments were due to skin disease [10]. A survey of self-reported skin problems in 8000 adults in Uppland, Sweden, found that 20.5% reported skin problems [11]. Those reporting skin problems scored lower on all eight dimensions of the SF-36, a generic quality-of-life instrument.

In addition to disability and handicap, some chronic skin diseases such as atopic eczema also incur considerable additional direct costs to families, such as that needed to purchase moisturizers, special soaps, extra laundry expenses, cotton clothing and bedding. The Lothian Atopic Dermatitis Study estimated that the mean cost to the patient was £25.90 per 2 months, while the mean cost to the Health Service was £16.20 in 1994 [12]. A systematic review of cost studies of atopic dermatitis in the US found very wide ranging costs estimates of 364 million to 3.8 billion US dollars per year, with very little information on indirect costs [13]. Another study estimated the direct cost of care for patients with psoriasis and psoriatic arthritis in the United States [14]. An ambitious project in the United States tried to estimate the direct and indirect costs of people with 22 of the commonest skin disease categories in 2004 and found that they accounted for around $29 billion in direct costs (medical care and products), $10 billion in lost productivity costs and a further $56 billion for loss of quality of life [15].

Routine data that describe the burden of dermatological disease

Generally speaking, routinely published medical statistics on skin disorders are sparse and, when available, are of limited use to the dermatologist in describing the burden of skin disease in the community. Special surveys are usually required to determine the

prevalence and morbidity of skin diseases in general or specific skin diseases.

Some routinely published data on skin disease morbidity have limited uses.

1 **Mortality**. Overall mortality is relatively low for skin diseases, accounting for at least 2578 deaths in 1992 in the UK [16] (or 0.46% of deaths from all causes and all ages). Melanoma alone accounted for a total of 1142 deaths in England and Wales in 1992, with 48% of deaths occurring in economically active adults [16]. Mortality statistics of melanoma and non-melanoma skin cancer may be useful in discerning trends over time, which may be related to the biology or treatment of these diseases.
2 **Morbidity**. Most routinely published morbidity data refer to those who seek medical help in the primary-care setting. With the exception of a few conditions, such as cellulitis, where incidence and demand are closely related, the extent to which routine morbidity data reflect the burden of dermatological need in the community is unclear. Despite these limitations, routine statistics, such as the UK morbidity surveys from general practice [17], are useful in that they provide an estimate of the magnitude and demographic determinants of those who seek medical care. Several important findings have already emerged from careful analysis of dermatological data from general practice databases [18–21].
3 **Skin cancer registration data** (i.e. cases presenting to physicians for the first time who are also reported) are of variable completeness and accuracy [22], but they have contributed some knowledge to understanding secular trends in reported cancer incidence and variations by sex, age and latitude. Special skin cancer registers, such as the Scottish Melanoma Group Database [23] and the German Central Malignant Melanoma Registry [24], are examples of more complete databases with stringent controls on data quality.
4 **Other special registers** maintained by groups of enthusiastic individuals exist and may be useful for certain types of epidemiological studies, for example the UK Epi-Derm surveillance system for monitoring occupationally acquired skin diseases, the US National Epidermolysis Bullosa Registry [25], the German *Dokumentationszentrum schwerer Hautreaktionen* for severe cutaneous drug reactions [26] and national registers of sexually transmitted diseases. The US PUVA cohort study has produced many useful findings related to subsequent skin cancer risks which have informed clinical practice [27]. Other sources of data, such as in-patient and outpatient statistics and prescription data, tell us something about those who present themselves to tertiary medical care. Record-linkage studies may provide useful insights into the determinants of in-patient versus outpatient care [28].

Special prevalence studies of skin disease in general

Self-reported skin disease

In 1986, the Proprietary Association of Great Britain commissioned a detailed, nationwide survey of 1217 adults and the parents of 342 children to determine how British people manage minor ailments and some chronic, recurring illnesses [29]. Skin complaints were the commonest ailment reported in the previous 2 weeks, comprising 25% of 6009 adult 'ailments' and 36% of 806 child 'ailments'. In addition to estimating the age- and sex-specific incidence of skin complaints over a 2-week period, the study provides a useful estimate of the proportion of skin complaints that are not considered by the public to be sufficiently severe to seek medical care, and the potential service implication should that threshold change. For example, of the 291 people complaining of acne/spots/greasy skin, 47% took no action, 34% used or bought an over-the-counter preparation, and 12% used medicines prescribed by a doctor, the remaining 7% using home remedies.

Similar proportions of self-reported 'skin disease in the last 2 weeks' have been recorded in two earlier studies [30,31]. A survey of 20 000 randomly chosen residents aged 20–65 years in Gothenburg, Sweden, found that 27% of females and 25% of males reported symptoms of skin disease in the previous 12 months [32]. Another survey of 8000 people aged 20–84 years in Sweden found that 20.5% reported a skin disease and/or use of topical dermatological drugs, with a higher frequency in women (23.3%) than men (17.3%) [11]. A survey of a representative sample of 18 137 people in France found that 86.8% reported some kind of skin problem since birth, and that in 28.7% of these it impaired their quality of life [33].

Examined skin disease

The Lambeth Study

Only one study in the UK has ever estimated the prevalence of skin diseases in the general population according to some form of physical examination. This study, conducted by Rea *et al*. in 1975 [34], was based on a questionnaire on skin symptoms which was sent to a stratified sample of 2180 adults in Lambeth, London. All positive respondents and one-fifth of those responding negatively were then interviewed and examined at home by a team of seven doctors and 11 nurses trained in the recognition of common skin disorders. Only exposed skin (face, scalp, neck, forearms, hands, knees and lower legs) was examined, and the overall response rate was 90.5%. Because of difficulties in agreeing on objective criteria for skin disease severity, skin disease was classified into trivial (not justifying medical attention), moderate (justifying medical attention) and severe (needing early medical attention because of severe symptoms or risk of progression), based upon the judgment of the examiner. The key findings of this study were as follows.

1 The overall proportion of the population found to have any form of skin disease was 55% (95% confidence intervals 49.6–61.3%).
2 The overall proportion considered to have skin disease worthy of medical care (i.e. moderate or severe) was 22.5% (95% confidence intervals 17.8–27.2%).

As shown in Table 6.5, the group containing tumours and naevi had the highest overall prevalence (20.5%), but 90% were considered as trivial by the examiners. In the eczema group, on the other hand, with an overall prevalence of 9%, more than two-thirds were graded as moderate/severe, so that the highest prevalence of conditions justifying medical care fell into this group (6.1%). Clear age trends emerged for specific disease groupings, for example acne and warts in younger age groups, although age, sex

Table 6.5 Prevalence of examined skin disease expressed as rates per 1000 in a survey of 2180 adults in Lambeth [34]. Prevalence rates have been rounded to the nearest whole number, and 95% confidence intervals for the main findings are shown in parentheses.

Skin condition	Both sexes		Male		Female	
	All grades	Moderate and severe	All grades	Moderate and severe	All grades	Moderate and severe
Tumours and vascular lesions	205	14	142	1	264	27
Eczema	90	61	100	80	81	43
Acne	86	35	109	35	64	35
Scaly dermatoses	85	29	118	39	53	19
Scalp and hair disorders	82	14	79	8	95	18.9
Prurigo and allied conditions	82	39	61	17	95	60
Erythematous and other dermatoses	75	21	31	21	117	22
Infective and parasitic conditions	46	7	48	11	44	3
Warts	34	2	36	–	33	3
Nail disorders	33	19	24	13	42	25
Psoriasis	16	6	24	4	8	8
Mouth and tongue disorders	9	1	15	–	3	1
Chronic ulcer	2	–	4	–	–	–
Any skin condition	555 (496–614)	225 (178–272)	479 (400–559)	213 (147–280)	607 (520–693)	236 (170–302)

and social class trends were not found when all forms of skin disease were considered together, since several conditions had trends in opposite directions.

HANES-1

Another detailed, cross-sectional study of skin diseases was conducted within the first US Health and Nutrition Examination Survey (HANES-1) [8]. This study, conducted on a representative population sample of 20749 persons aged 1–74 years from 65 primary sampling units throughout the USA during 1971 to 1974, included a detailed, structured skin examination by 101 dermatologists. Clinical findings were backed up by laboratory investigations, such as mycology culture and skin biopsy where possible. Key points emerging from this study were as follows.

1. Nearly one-third (312 per 1000 population) had one or more significant skin conditions which were considered by the dermatologist to be worthy of evaluation by a physician at least once.
2. The prevalence of significant skin pathology increased rapidly with age from 142 per 1000 children aged 1–5 years to 362 per 1000 youths aged 12–17 years and to 365 per 1000 young adults aged 18–24 years, due primarily to the increase in acne at puberty.
3. After a slight decline at age 25–34 years, the prevalence of skin pathology again increased steadily, reflecting the increase in chronic diseases such as psoriasis, vitiligo, malignant and benign tumours, actinic and seborrhoeic keratoses.
4. In this study, significant skin pathology was slightly commoner in males.
5. An additional 12.5% of the population was deemed to have a skin condition that was clinically inactive at the time of examination.

Both of these studies therefore suggest that significant skin disease is extremely common. Even though dermatology is characterized by an enormous range of disease-reaction patterns, prevalence surveys suggest that the bulk of the skin disease problem is made up of less than 10 disease groups [35]. The prevalence of skin disease documented in these two large population studies [8,34] also suggests that most individuals with skin disease do not seek medical help. Knowledge of this submerged section of the dermatological iceberg is important, as small changes in the population's perception of the need for medical help can have large effects on the delivery of health care.

Caution should be applied to prevalence studies with low response rates, as it cannot be assumed that respondents share the same characteristics as non-respondents. Indeed, a survey of non-respondents to a prevalence survey for skin disease in Australia found that people who did not respond to the initial survey were more likely to have skin cancers than respondents [36]. This important finding emphasizes the need to sample non-respondents in general prevalence surveys of skin diseases.

Surveys limited to children

A large, comprehensive survey of examined skin disease in 2491 schoolchildren was conducted in the state of Victoria, Australia, with specific reports published pertaining to warts, atopic dermatitis, acne and tinea pedis [37–40]. Another survey of 1006 primary and secondary schoolchildren in Hong Kong found that 31.3% had one or more skin disorders, 70% of whom did not seek medical attention [41]. A study of 2788 children from eight randomly selected schools in Amman, Jordan, found a similar prevalence of 19.23% [42], and a study that involved a dermatologist examining 1114 children aged 6–12 years in Bucharest, Romania, found a point prevalence of one or more skin diseases of 22.8% [43].

Collectively, these surveys suggest that, like adults, around one-fifth to one-quarter of schoolchildren in urban centres have one or more skin diseases. Skin examination surveys conducted

at one point in time (point prevalence surveys) are likely to underestimate the true burden of skin disease in children, since they will miss many children with infectious skin diseases of short duration, such as impetigo.

The burden of skin disease in developing countries

Table 6.6 summarizes studies of skin disease prevalence that have been conducted in developing countries compared with data from some developed countries [8,34,44–54]. Making comparisons between countries is difficult, as survey methods have differed in terms of population ages, method of sample selection and classification of diseases. The distinction between any form of skin disease and that which would benefit from medical care is particularly prone to vary according to the views of the dermatologist examiner and the availability of local services. Use of traditional healers is common in developing countries, especially amongst older community members [55]. Some general points can be made regarding the prevalence surveys in these countries: (i) skin diseases are very common; (ii) infections and infestations predominate; (iii) skin diseases are most common among the younger age groups; and (iv) most are easily treated and (v) knowledge of diagnosis and management and resources for treatment are usually very scarce in the public sector. Making such generalizations is always hazardous, as even within 'developing' countries, urban pockets may occur with a disease spectrum very similar to developed countries. A comprehensive review of skin diseases in developing countries covering prevalence and patterns at the community level, effective therapies, economic assessments and current status of community control measures is to be found in an excellent World Bank publication [56]. Scabies, bacterial and fungal infections including tinea capitis and tinea imbricata, tropical ulcer and HIV-related skin diseases and pigmentary disorders are covered in some detail.

What determines the frequency of skin disease in populations?

Risk factors, association and causation

In the first instance, epidemiological studies seek to establish *risk factors* for diseases, that is factors which are associated with an increased frequency of disease. When *associations* between skin diseases and risk factors are discovered (e.g. by demonstrating an increased risk of palmoplantar psoriasis in smokers [1]), it should be understood that such *associations* do not necessarily imply *causation*. The association between smoking and psoriasis may simply be a *chance* finding (around one in 20 studies with a *P* value of less than 0.05 in favour of rejecting the null hypothesis of no association will be wrong due to chance alone), or it could be due to *confounding* (i.e. a third factor such as alcohol, which is independently associated with both smoking and psoriasis [2]). The association could be due to a *bias*—for example, people with psoriasis in hospital may be more likely to recall antecedent events or seek reasons for explaining their illness in comparison with healthy controls [3]. Further analyses or new studies are usually needed to establish whether risk factors are *causative*—for example, by evaluating the strength of the association, biological gradient, relationship in time, the consistency between different studies, biological plausibility, coherence of evidence with external sources, experimental evidence, and specificity of findings as suggested by the Bradford-Hill criteria of causality [4].

The causes of some skin diseases are already established—for example, the herpes simplex virus causes cold sores—but for most dermatological conditions, the causes are unknown. Nevertheless, epidemiological research has already established many *risk factors* for skin diseases which maybe help to serve as pointers to specific causes. Direct manipulation of these risk factors may help in preventing or reducing disease even before the specific cause is found. For example, in the London cholera epidemics of the 1850s, John Snow [5] postulated that the disease was spread by some 'morbid matter' in the water supply and proceeded to intervene by removing the pump handle in Broad Street. This resulted in a dramatic fall in incident cholera cases. All of this occurred some 20 years before germ theory had become established in Europe. Snow's work illustrates one of the beauties of epidemiological research, which is that knowledge of pathophysiology is not a prerequisite for determining aetiology.

Even when a causative agent is discovered, for example *Vibrio cholerae*, exposure to this agent does not necessarily imply disease. Of those exposed to cholera during an outbreak, some will die from the disease, some will be very ill, some will be slightly unwell, some will be apparently healthy (but still carry the organism) and some will not be affected at all. The absence of disease in some individuals following exposure is probably due to a whole range of factors such as chance, infecting dose, genetic heterogeneity, and other constitutional and environmental factors which interact together to produce the final clinical picture. This phenomenon of apparent health in the presence of an established harmful exposure has been exploited by individuals in order to avoid modifying their behaviour. One often hears statements such as 'my grandfather smoked 40 cigarettes a day all his life and he did not get lung cancer'. In order to explain such phenomena, we return to the epidemiological concept of *groups* of people or *populations* and *probability* of disease [6]. On average, groups of people who smoke cigarettes are 10 times more likely to develop lung cancer when compared with those who do not smoke.

It is also important to separate risk factors associated with disease *incidence*, that is number of new cases in a given population occurring over a defined period, from those which determine disease *chronicity*, that is the determinants of how long a particular disease will last once an individual has it, as the risk factors for each of these aspects may be different. Many dermatoepidemiology surveys have measured the *prevalence* of skin disease when examining risk factors [7], but because prevalence is a function of incidence times chronicity, it is often difficult to say whether these risk factors are important in people developing a disease for the first time, or whether they maintain the disease once established.

Risk factors for skin disease may operate at many different levels. Some may predispose to disease (e.g. a mother with atopic eczema genetically predisposes her child to atopic eczema), some may precipitate disease (e.g. exposure to high levels of house-dust mite may precipitate atopic eczema for the first time), and some may be important in perpetuating that disease (e.g. failure to use prescribed treatments may worsen the course of atopic eczema).

Some of the commonest risk factors for skin disease are discussed below.

Genetics

In addition to a few rare diseases such as epidermolysis bullosa, where specific chromosomal mutations have been closely correlated with different disease phenotypes, several genes may be important in many of the major inflammatory skin diseases. Thus in atopic dermatitis, genes such as filaggrin mutations which play a key role in skin barrier function, as well as several other genes that code for inflammatory responses, may be important in explaining the variation in disease phenotype [8]. Genes such as those that predispose for melanoma may only express their beneficial or deleterious effects when individuals who carry them are additionally exposed to key environmental risk factors such as ultraviolet light [9]. Some genes may be responsible for disease predisposition and some may be responsible for disease severity and chronicity, as exemplified by molecular subsets in the gene expression signatures in the skin in scleroderma [10].

The early environment

There is evidence to suggest that the experience of the fetus *in utero* (e.g. in terms of nutrition) is critical in 'programming' adult diseases such as hypertension and diabetes [11], and *in utero* programming may well operate for many skin diseases such as atopic eczema [12].

The later environment

Age and sex are often included in the descriptive epidemiology of many skin diseases and may point to further risk factors. The marked female preponderance of lichen sclerosus, for example, suggests that hormonal factors may be important in this disease.

Ethnic group may account for some variations in disease rates. Thus, it has been shown that atopic eczema is twice as common in black Caribbean children in comparison with similar white children [13] and, conversely, that mortality from most cancers is less common in black ethnic groups in the UK [14]. Ethnic group, which refers to a way of life encompassing a whole range of dietary and cultural factors, must be distinguished from racial factors [15], which are often more difficult to define because of the considerable mixing of modern populations. Care also has to be taken in lumping many distinct ethnic groups together—for example, combining the diverse cultures of black Africans and black Caribbeans into 'blacks' may be totally inappropriate, both in terms of respecting the identity of the separate cultures and because such lumping together may obscure important epidemiological associations [16]. The term 'race' should not be used in epidemiological studies, as it has no scientific meaning [17]. Migration itself may be an important factor in determining skin diseases; for example, individuals who migrated from China (where atopic eczema is not very common) developed much higher rates of disease (similar to the rates in the local population) after migration to Hawaii [18]. Migrants may not be totally representative of their indigenous peoples, but they may nevertheless show the effect of the environment in determining the frequency of skin disease.

Secular factors may reflect changes in the natural history of skin disease or of transient environmental exposures. Thus, the epidemic of melanoma skin cancer has been attributed by some to increased exposure to sunlight over the last 40 years [19]. There is reasonable evidence to suggest that the prevalence of atopic eczema has increased two- to threefold over the last 30 years, but the reasons for this change are less clear [20].

Socioeconomic factors may also be crucial in accounting for the distribution of skin disease. In many poorer countries where overcrowding and poor sanitation may occur, infectious or ectoparasitic skin diseases such as secondarily infected scabies or pediculosis are commoner [21,22]. In wealthier countries where such infectious dermatoses are less common, new 'diseases' such as concern regarding the cosmetic appearance of sun-damaged skin or thread veins may preoccupy the population in their quest for a perfect skin. Some skin diseases, such as atopic eczema, also demonstrate a genuine positive social class trend, that is higher prevalences in more wealthy groups [7]. Some of this increase in reported eczema may have been due to differences in reporting between socioeconomic groups, but other genuine environmental factors such as hygiene, carpets, central heating, family size, or differences in treatment also probably play a part.

Geography and climate are important considerations in describing the frequency of skin disease. Thus, consideration of the marked latitude gradient of melanoma in white-skinned peoples has supported the concept that exposure to sunlight is an important risk factor for this disease [23]. Paul [24] has drawn attention to the concepts of *macroclimate*, which in the ordinary geographical sense refers to temperature, rainfall and humidity, and *microclimate*, which refers to the immediate domestic and occupational environment a given individual finds himself or herself in. These are discussed further by Marshall [25] and Canizares [26]. The combination of temperature, rainfall and humidity may be crucial to sustain certain infectious disease vectors such as the *Simulium* fly in onchocerciasis, and may for example account for seasonal fluctuations in pyoderma secondary to scabies during the wet season in Lilongwe in Malawi [27].

Occupational factors are occasionally a very important factor for skin disease. Thus, exposure to irritants and contact sensitizers in light and heavy industry accounts for a very large burden of hand dermatitis and lost revenue for both individuals and the state. Certain occupations, for example mining, where workers are constantly exposed to damp conditions, may predispose to fungal infections. Some diseases may occasionally occur in outbreaks from work-related substances, for example chloracne due to dioxins, vinyl chloride disease, and hydroquinone-induced leukomelanoderma. The reader is referred to standard texts of occupational dermatoses and to Chapter 27 for further reading [28,29].

Infective agents may directly cause or be suspected to cause many skin diseases. Thus, for a long time, it was suspected that fifth disease was caused by an infectious agent, but it was not until 1983 that human parvovirus B19 was identified as the causative

organism [30]. Similarly, there is reasonable circumstantial evidence to suggest that diseases such as pityriasis rosea are caused by infectious agents, even though no specific agents have yet been consistently isolated [31].

Dietary factors may be crucial in some skin diseases. As the examples of Lind and Goldberger in the opening section showed, vitamin deficiency states may directly cause skin diseases. Other deficiency diseases with skin manifestations, such as acrodermatitis enteropathica, are completely reversible with administration of the appropriate agent, in this case zinc. Some diseases, such as phenylketonuria and dermatitis herpetiformis, may be transformed by restricting substances that affected individuals cannot handle—for example, phenylalanine and gluten, respectively. Some skin diseases, such as atopic eczema and acute urticaria, may be modified by avoidance of dietary allergens in a proportion of cases. Leisure activities such as gardening or habits such as smoking cigarettes and drinking alcohol may be important risk factors for many skin diseases including contact dermatitis, psoriasis and porphyria cutanea tarda. Medicines, although intended to alleviate human disease, are a very common cause of cutaneous eruptions, some of which (e.g. toxic epidermal necrolysis) can be fatal.

Describing the natural history and associations of specific skin diseases

Questions commonly asked by patients with a skin disease are 'How long will it last?' and 'Will it come back again?' Special studies are required to answer these questions, which ideally involve following, over many years, individuals with typical and well-defined disease in terms of morphology and severity [1]. Such prospective studies are rare in dermatology. Another approach is to identify cases with a specific skin disease from old hospital records and then to trace them in order to find out what has happened to them since they were seen [2]. Studies on the natural history of disease are often difficult to interpret because of incomplete follow-up, the intermittent nature of many skin diseases (leading to the need to distinguish between 'real' and 'apparent' clearance rates) [3] and because the treatment of many diseases has improved with time. Guidelines regarding the attributes of what makes a good follow-up study are summarized elsewhere [4].

Disease associations of specific skin diseases may also give insight into possible causative factors. Thus, the high incidence of laryngeal carcinoma in psoriasis patients might be evidence for the possible role of cigarette smoking in psoriasis [5]. Many publications have emerged over the last 7 years linking psoriasis with the metabolic syndrome, suggesting that it is a systemic disease and that patients with psoriasis should be screened for cardiovascular risk factors [6]. Establishing disease co-occurrence, for example atopic eczema and psoriasis, may also shed light on shared or opposed immunopathological mechanisms [7,8]. Great care has to be exercised in interpreting disease associations generated from hospital sources because, in the absence of an appropriate denominator, many types of bias may occur [9,10].

Table 6.7 A guide to the number of persons per 100 000 per year using dermatology services. From Williams [4] with permission.

Number with a skin complaint	25 000 (at least 25% of total population) [5]
Number who will self-treat	7500 (30% of those with skin complaint) [6]
Number who will seek advice from GP	14 550* (15% of total population or 19% of all GP consultations) [7]
Number referred to dermatologist	1162 (8% of those attending their GP for skin problems, or 1.2% of the total population) [8]
Number admitted to hospital	24–31 (2–3% of all new dermatology referrals) [9]
Number of deaths due to skin disease	5† (0.4% of all new dermatology referrals) [10]

* Excludes skin neoplasms, viral warts, herpes simplex and scabies.
† Includes people dying from cellulitis, chronic ulcer of the skin and severe drug reactions who might not have been admitted under a dermatologist's care.

Health-services research in dermatology

Broadly defined, dermatological health-services research is concerned with studying how dermatological health care is delivered with the ultimate aim of benefiting patients. Dermatological health services research thus covers a wide variety of service aspects, such as determinants of referrals to hospital departments, evaluation of cost-effectiveness of alternative treatment strategies, quantifying the dermatological needs of the community, evaluating the role of dermatological nurses and exploring economic aspects of screening and other prevention strategies. These diverse studies require a range of quantitative and qualitative research methods, such as focus groups, comparative studies, randomized controlled trials and health economic modelling. Research establishes which treatments or services should be used, whereas audit seeks to establish whether health-care providers perform these services to a required standard [1]. As in any other branch of epidemiology, health-services research requires meticulous attention to be given to aspects of study design. A useful introduction to health-services research in dermatology is given elsewhere [2].

Needs assessments in dermatology

When evaluating dermatological health services, certain steps need to be followed [3].

1 Establish the size and nature of the dermatological need based on epidemiological data
2 Summarize currently available supply of services for that problem
3 Appraise the evidence for effectiveness of those services
4 Propose models of care which best fit the epidemiological data and evidence of effectiveness of care within current resources
5 Propose outcome measures and targets which can be monitored after implementation.

Such an assessment has been attempted for UK dermatological health services by the author [4], and a comprehensive update of the assessment will be available on the Centre of Evidence-Based Dermatology website in 2009 (see Resources at the end of this chapter).

Services available for people with skin diseases

People with skin problems obtain help from various sources, including self-help, advice from pharmacists, advice and treatment from the primary-care team and specialist services. Little research has been conducted to clarify the relative health gain and appropriateness of the various health-care settings for different subgroups of skin disease. The estimated number of people using current dermatology health services in the UK at various entry points, for a population of 100 000 over a 1-year period, is summarized in Table 6.7 [5–10].

Self-help

Although self-help/medication is not traditionally regarded as a health service, the range and availability of over-the-counter skin products is an important element in the equation of balancing need, supply and demand. Around 30% of those with a skin complaint decide to self-medicate, and this proportion is similar for trivial and for moderate to severe disease [6]. Many effective skin treatments are available over the counter in the UK, such as 1% hydrocortisone for mild eczema, topical aciclovir cream for cold sores, topical benzoyl peroxide for acne, and numerous antifungal preparations and wart removers. Pharmacists occupy a key role in advising the public on the use of these products, but whether this advice is beneficial or whether it simply delays appropriate medical consultation has not been studied adequately in the UK [11]. Self-help groups are often a useful source of advice to those with chronic skin diseases [12].

Primary care

The majority of those with a skin complaint who seek medical help are treated by their general practitioner (GP). In the UK, around 6–8% of all GP diagnoses involve the skin [13,14]. Morbidity statistics from General Practice in the UK from 1995 [7] suggest that 1455 people per 10 000 person-years at risk (approximately 15% per year) consult their GP because of a skin condition (excluding benign and malignant skin neoplasms and some skin infections). In the USA, it has been estimated that around 36.5% of patients attending their family practitioner over a 2-year period had a skin complaint [15].

Table 6.8 The nine categories of skin disease which account for over 70% of dermatological diagnoses in primary and secondary care. From Williams [4].

Skin cancer (including melanoma)
Acne
Atopic eczema
Psoriasis
Viral warts
Other infective skin conditions
Benign tumours and vascular lesions
Leg ulceration
Contact dermatitis and other eczemas

The range of skin disorders seen in general practice is similar to that in the general population, with relatively few subcategories accounting for the majority of consultations [13,16]. As one would anticipate, proportionally more incident diseases such as skin infections (e.g. impetigo, herpes simplex and viral exanthems) are seen in general practice than in secondary care [7,16].

Secondary care

Although dermatology covers around 2000 disease-reaction patterns, over 70% of specialist activity is concerned with fewer than 10 main disease categories, as shown in Table 6.8 [4]. Age-specific attendance rates are more common in female patients and also increase with increasing age. Around 12% of referrals were considered inappropriate by dermatologists in one UK study [17]. Another UK study showed that even a relatively junior physician with 3 months' dermatology training considered that 26% of 490 consecutive referrals were probably unnecessary [18], and that 75% of these unnecessary referrals belonged to just seven disease categories (warts, eczema, naevi, basal cell carcinoma, acne, psoriasis and seborrhoeic warts). There is considerable variation in referral rates to specialist care within the UK and there is some evidence to suggest that much of the regional variation in referral rates may be governed by established patterns of care and the number of available consultants, rather than by any objective dermatological need [4]. Roland and Morris [19] showed no relationship between referral rates for dermatology services and medical need as suggested by standardized mortality ratios or mean number of prescriptions issued by GPs (standardized regression coefficient of 0.1). It should be emphasized, though, that mortality ratios are not a suitable surrogate measure for dermatological need. A strong relationship between dermatology referral rates and the number of dermatology consultants per 100 000 population was present, however, in their study (standardized regression coefficient of 0.82, $P < 0.001$).

Traditional boundaries between what might be considered as primary and secondary care have become blurred over the last 5 years, and the relationship between the two in terms of cost-effectiveness is far from straightforward. Thus, specialists from secondary care might conduct work in a primary-care setting and general practitioners might develop an interest in skin diseases and work partly in a secondary-care setting. Specialist dermatology nurses might work across both settings. Thus it is more appropriate to separate skill mix and practice setting when considering the pyramid of dermatological care from generalist to specialist services in the UK and elsewhere. A recent report found that transfer of some activities and professional behaviour change strategies targeted at primary care are generally effective in reducing demand on secondary care, whereas relocation of specialists into a community setting and better liaison strategies do not, although they may improve quality of care [20]. Another randomized, controlled study has shown that, despite widespread adoption of minor surgery for skin problems in primary care, minor surgery is more cost-effective in the secondary care sector [21]. Another report found that the general practitioner with a special interest service for dermatology is more costly than hospital outpatient care, but this additional cost needs to be weighed against improved access and broadly similar health outcomes [22].

The relationship between need, supply and demand for dermatological care

Unlike commerce, which aims to balance supply with demand, caring for sick human beings requires consideration of a third factor—that of medical need. Medical need may be defined as the ability to benefit from medical care, demand as that which people ask for, and supply as what the service does or could provide [3,4]. Not all dermatological need is demanded (e.g. a person may be unaware that he or she has an early melanoma), not all that is demanded is needed (e.g. cosmetic removal of all moles), although all that is supplied is usually needed or demanded. The division between what constitutes reasonable need (e.g. somebody worried that a mole may be cancerous) and demand (e.g. somebody requesting removal of an 'ugly' mole) is especially blurred in dermatology. Defining 'need' in dermatology is therefore quite difficult, and is a process which requires participation of society so that appropriate policies can be set in the light of finite resources.

Two population surveys conducted in the 1970s have produced useful data on the relationship between the need, supply and demand for dermatological care. In a study of 2180 adults in Lambeth who were examined for skin disease [6], it was shown that for those with moderate/severe skin disease, only 24% had made use of any medical service in the previous 6 months. A further 30% had used self-medication. Medical usage was still considerable for those with trivial skin disease, with 10% using medical services and 33% self-medicating.

In the US HANES-1 study [23], there was a considerable mismatch between what the dermatologists considered to represent medical need and what the population were concerned about. Only one-third (31%) of persons with significant skin pathology diagnosed by the dermatologists expressed concern about these specific skin conditions, whereas nearly 18% of those who complained about their skin conditions were not considered to have serious conditions by the dermatologists.

Thus, both of these population studies suggest that, at any one time, around one-quarter to one-third of the population have a skin problem which could benefit from medical care, yet around 80% do not seek medical help. As Savin points out [24], with increased public and professional awareness of effective treatment, this submerged sector of the population is likely to surface and place heavy demands on the current system.

The relationship between need, supply and demand for dermatology services in developing countries may be very different from those in developed countries. Many surveys have shown a high prevalence of need, mainly due to infectious dermatoses [25,26]. There is marked maldistribution of care for people with skin diseases throughout the world, with meagre to absent dermatological services in many countries [27]. Leprosy, onchocerciasis and leishmaniasis are probably the commonest skin diseases worldwide, but the epidemiological research afforded to these diseases is usually scanty. Groups such as the International Foundation for Dermatology work to remedy such inequalities, with the ultimate aim of a healthy skin for all [24]. Getting the right people to the right services is a major challenge. In the state of Guerrero in Mexico, for instance, skin complaints represent the second commonest reason for referral to rural clinics, resulting in a detrimental effect on other important activities such as immunization programmes and antenatal care [28]. In addition to such opportunity costs, this study also showed how much family income is wasted on ineffective treatments for skin infections and scabies. An excellent report on skin diseases in developing countries has been commissioned by the World Bank [29]. This report points out that, although few die from skin diseases, the population needs for effective services must be met because: (i) skin diseases are extremely common, with the result that patients present in such large numbers in community settings that ignoring them is not a viable option; (ii) disfigurement from diseases such as filariasis leading to lymphoedema, or hypopigmentation from leprosy, often lead to significant morbidity and social isolation; (iii) the costs of treating even minor skin diseases can be high; and (iv) screening for skin diseases such as leprosy is an important strategy, yet a basic knowledge of diagnosis and management of such diseases is often missing at a primary-care level.

Systematic reviews and the Cochrane Collaboration

Reviewing the effectiveness of services in the light of an epidemiologically based needs assessment helps health-service planners to distinguish those interventions which confer maximum health gain (e.g. establishment of community leg-ulcer clinics) from those where services are ill-deployed (e.g. specialists involved in the routine treatment of viral warts) [4]. Using published evidence to inform everyday clinical decisions on disease treatment is something that most physicians aspire to, yet with over 240 specialist journals in dermatology alone [30], keeping abreast of important therapeutic developments in dermatology is difficult. Even enthusiastic teachers place their median reading time at about 2 h per week [31]. Most physicians therefore rely on reviews of the primary research in order to help them make therapeutic decisions in their daily practice. Unfortunately, the quality of traditional expert reviews is often suspect, because reviewers have not conducted their review in a systematic fashion with regard to the scientific principles of considering bias and sampling error [32]. Expert therapy reviews, published in the top medical journals, have been shown to miss important studies and to be far more biased in their conclusions when compared with systematic reviews [33]. Lessons from general medicine have suggested that deficiencies in reviews have meant that advice on some highly effective forms of care have been delayed for many years and other forms of care have continued to be used long after research has shown them to be ineffective or even harmful [34].

Over 30 years ago, the late Professor Archie Cochrane drew attention to our great collective ignorance on the effects of health care and explained how collated evidence from randomized, controlled trials could help the use of resources more rationally, and proceeded to criticize the medical profession for not producing a critical summary, by speciality, of all relevant trials, which is periodically updated [35]. The worldwide Cochrane Collaboration—groups of individuals dedicated to preparing and maintaining systematic reviews of health care—has evolved in response to this challenge [36]. Unlike traditional reviews, systematic reviews employ a structured methodology, which includes: (i) defining the primary objective of the review; (ii) predefining the clinically important outcome measures; (iii) the systematic retrieval of all (published and unpublished) relevant material; (iv) abstracting the quantitative information; (v) summarizing and quality appraisal of the retrieved evidence; and (vi) interpreting the results. In addition to the benefits of reducing bias by inclusion of unpublished data and by giving more weight to high-quality studies according to predefined criteria, the increased statistical power afforded by the quantitative pooling of many small studies (meta-analysis) can often provide a clear answer to many small studies that appear at first to be 'conflicting' in their recommendations [37].

Summarizing the effectiveness of various dermatological interventions (be these aimed at preventing new disease, treating established disease or preventing disability) is a time-consuming process. Like any scientific methods, techniques such as meta-analysis have their limitations [38,39]. Many systematic reviews of dermatological intervention have already been conducted, although the poor quality of dermatology trials in terms of unclear entry criteria [40], diversity of outcome measures [41] and inadequate details [42] have served as an obstacle for some reviews. The quality of reporting clinical trials in dermatological journals is generally poor [43,44]. The adoption of the CONSORT guidelines for better clinical trial reporting by several of the top dermatology journals should help to improve the situation [45–47]. An international Cochrane Skin Group formed in 1997 in response to the challenge of providing an up-to-date summary of dermatological health-care interventions [48,49]. Reviews produced by the Cochrane Skin Group have been shown to be more methodologically rigorous than non-Cochrane reviews [50]. The editorial base of the Cochrane Skin Group coordinates a worldwide, voluntary effort in preparing, maintaining and disseminating systematic reviews of health-care interventions in relation to skin diseases and maintains its own specialized register of dermatological clinical trials. Further information about the Cochrane Skin Group is available on the website indicated at the end of this chapter. Epidemiological principles that underpin the theory and practice of evidence-based medicine are discussed more fully in Chapter 7.

Conclusions

This chapter has demonstrated the fundamental importance that the discipline of epidemiology plays in understanding skin diseases in context, from the clinic to the population. Not only is epidemiology concerned with issues such as describing the incidence, prevalence and human and financial cost of skin disease, but it is also one of the most direct ways of finding out the causes of skin diseases. Finding out causes is important because it may lead to prevention of skin disease on a massive scale. For example, it has been found through a number of epidemiological studies that atopic eczema is less common in large, less economically advantaged families [1,2]. This observation gave rise to the hygiene hypothesis, which postulated that increased exposure to microbes and infections in early life might protect against atopy [1,3]. The

hygiene hypothesis led to a full-scale, randomized, controlled trial of lactobacilli cultures given to pregnant mothers and infants, a study which suggested that around 50% of atopic eczema could be prevented by such a measure in infants [4]. Even though this particular study had some potential flaws [5], it nevertheless demonstrates the power of prevention.

Epidemiological principles have been key to developing the principles of evidence-based medicine and of health services research in relation to dermatology. Although traditional epidemiology may be superseded by genetic epidemiology and other new hybrids as biomedical knowledge develops, there will always be a need for a thorough understanding of the principles of assessing risk and the roles that the 'big three' factors of chance, bias and confounding may play in any study. Similarly, the principles of critically appraising published literature using a framework derived from epidemiology are as basic to dermatological clinical practice as diagnosing skin rashes [6,7].

Glossary of epidemiological terms

Measures of disease frequency

Prevalence. The proportion of people with a disease at any one time. *Point* prevalence refers to prevalence at one point in time. *Period* prevalence refers to proportion with a disease (existing and new cases) over a longer period, for example 1 year.

Incidence. The rate of new cases developing over a specified time period, for example the incidence of melanoma in the USA in men in 1983–1987 was 6.9 per 100 000 per year [1].

Measures of disease associations

Risk factor. A factor that increases the risk of disease. This could be a specific exposure, for example asbestos giving rise to mesothelioma, or an attribute such as gender or social class which is indirectly associated with an increased frequency of disease.

Relative risk. This is the *ratio* of the risk of disease occurring in those exposed to the agent under investigation divided by the risk of those not exposed. It is a measure of the strength of the risk factor.

Attributable risk. This is the *difference* between the incidence rate in those exposed to a factor and the incidence rate in those unexposed. It is a measure of the absolute effect of the exposure.

Odds ratio. An approximation of relative risk used in case–control studies. It is the ratio of the odds of exposure in cases to the odds of exposure in controls.

Hazard ratio. This a special form of relative risk that is used in studies that examine survival to express the relative risk of an endpoint or 'hazard' occurring at any given time.

Interpreting results

Sampling error. This refers to the variation in values that a given sample could be expected to show by chance alone.

P-value. When referring to the association of a disease with a particular exposure, a *P*-value of <0.05 means that a value as extreme as that obtained by the study would be expected to be observed by chance in less than one in 20 such studies (or <5% of the time). It is convention at this level of significance to reject the null hypothesis of no difference between the compared groups.

*Confidence interval*s. This refers to the range of plausible values for a main study finding. It is based on the size of the sample and the size of the difference between compared groups. For example, the 95% bounds of a relative risk of 2.0 for smoking in a sample of psoriasis sufferers was 1.5–2.5. If the association is a genuine one, this means that the reader can be 95% confident that the true population relative risk resides between the values of 1.5 and 2.5.

Bias. Bias is a systematic error resulting in an incorrect conclusion about the association between an exposure and an outcome. Over 30 types of bias have been described [2], but they fall into two main groups: (i) *selection*, that is the two groups to be compared are not comparable in terms of factors in addition to the exposure of interest; and (ii) *information*, that is collection of information about the disease and exposure in a fashion that could bias response—for example, those evaluating a new drug were aware of the treatment allocation when assessing patients' response to treatment. An excellent description of the main forms of bias in epidemiological research is to be found elsewhere [3].

Confounding. This is where the association between an exposure and disease is mixed up with a third factor which is independently associated with both the exposure and the disease, for example the protective effect of prolonged breastfeeding (the exposure) on the development of atopic eczema (the disease) may be due to confounding by parental atopy. The risk of atopic eczema is increased in children born to atopic parents, and atopic parents are more likely to practise prolonged breastfeeding in their infants because they may be more aware of a possible protective effect of breastfeeding.

Association and causation. Association between an exposure and disease does not necessarily imply causation. Other factors such as chance, bias and confounding may explain that association.

Validity and repeatability

Internal validity, for example of a diagnostic test, refers to the extent to which the test measures what it is meant to measure. This is normally measured in terms of sensitivity (proportion of

true cases correctly identified) and specificity (proportion of non-cases correctly identified).

External validity refers to the extent to which findings from one particular study (the study population) can be generalized to the target population—for example, to what extent are the favourable results of a clinical trial to test a new oral agent for children with severe atopic eczema attending hospital applicable to children with milder eczema in the community?

Predictive value. When comparing the performance of a test or diagnostic criterion to a gold standard (e.g. clinical diagnosis of melanoma against histological diagnosis), the positive predictive value refers to the probability that someone is a genuine case given a positive test result. Negative predictive value refers to the probability that a person does not have that disease given a negative test result. In addition to sensitivity and specificity, predictive value is dependent on the overall prevalence of the disease being studied [4].

Repeatability. This refers to the extent to which two observations agree with each other. This may be between two observers (inter-observer agreement) or between replicate measurements in one observer (within-observer agreement). Repeatability is measured by chance-corrected agreement measures such as the κ statistic [5], or by differences between two observers plotted against corresponding means of observations and *not* correlation coefficients [6].

Types of epidemiological study

Observational or descriptive studies. These are studies where the frequency of a disorder is described in terms of its association with various background attributes such as age, sex and ethnicity.

Analytical studies. These set out to test specific hypotheses on the relationship between a potential exposure and disease. These may be *cross-sectional*—for example 'Is atopic eczema more common in black Caribbean children in London compared with white children?'; *case–control*—for example 'Is a history of preceding infection more common in people with pityriasis rosea than in controls?'; or *cohort*—for example 'Are people who are exposed to diesel fumes more likely to develop asthma than those who are not?'

Intervention studies. These are studies in which groups of individuals are allocated to an experimental treatment prospectively. Clinical trials are the commonest examples. Occasionally, such trials are conducted at a community level—for example, vaccine trials.

Screening. This refers to the examination of healthy people who would not otherwise have sought medical help for the presence or absence of disease. Principles for evaluating the usefulness of screening are described elsewhere [7].

Checklist for reading 'epidemiological studies' in dermatology

This checklist represents a general approach to exploring key elements that should have been included in an epidemiological study. For recommendations on what to include when reporting case–control, cohort and prevalence studies, please refer to the STROBE checklist (STrengthening the Reporting of OBservational studies in Epidemiology) at http://www.strobe-statement.org/Checklist.html (accessed 15th December 2008).

1 Is there a clear objective(s)?
2 Is the study design appropriate and efficient for the question posed?
3 Have cases (numerators) been clearly defined?
4 Is there a population denominator?
5 Have the main hypotheses and outcome measures been stated *a priori*?
6 Is there a rationale for the study's sample size?
7 Have potential confounders been considered and measured?
8 Has the study attempted to minimize selection and information biases?
9 Have the data been analysed appropriately?
10 Are the main results clearly presented with confidence intervals?
11 Have subgroups or *post hoc* findings been treated appropriately?
12 Have the authors discussed alternative explanations such as chance, bias and confounding?
13 Are the study's conclusions supported by the main results?
14 Who sponsored the study? Could sponsorship have affected the choice of data and the way they were presented?

The need for evidence-based medicine

Distinguishing effective treatments from those that are ineffective or harmful [1]

Distinguishing effective treatments from those that are ineffective or harmful has been a problem facing medical practitioners since medicine has been practised. Prior to the 1940s, determination of treatment efficacy was based on expert opinion, trial and error, uncontrolled observation and small case series. The only treatments that could be distinguished as effective were those that produced dramatic increases in survival, such as streptomycin for tuberculosis meningitis [1]. The publication of the randomized, controlled clinical trial (RCT) that demonstrated that streptomycin was effective in the treatment of pulmonary tuberculosis was a landmark event in determining treatment efficacy [2]. Since then, the RCT has become the gold standard for determining the efficacy of therapeutic interventions. Hundreds of RCTs were conducted between 1950 and the 1970s. However, their results were not catalogued or used systematically to inform medical decision-making.

Evidence-based medicine is a framework designed to help practitioners distinguishing interventions that are effective from those that are ineffective or harmful. The origin of evidence-based medicine is most often traced to Pierre Charles Alexander Louis who introduced the teaching of statistical methods into the study of medicine in post-revolutionary France. However, a strong case can be made that its modern originator was Archie Cochrane, a British epidemiologist and physician who, in 1971, published his response to being asked to evaluate the effectiveness of the British National Health Service in delivering health care to the population of the UK. In his analysis he concluded that medical science was poor at distinguishing interventions that were effective from those that were not and that physicians were not using available evidence from clinical research to inform their decision-making [1,3].

Like-minded epidemiologists and physicians responded to Archie Cochrane's challenge by examining the methods by which medical decisions and conclusions were reached, and proposed an alternative method of summarizing evidence based on finding, appraising and utilizing available data from clinical research performed on patients. In 1985, Sackett and colleagues published a landmark book entitled *Clinical Epidemiology: A Basic Science for Clinical Medicine* that detailed the rationale and techniques of this evidence-based approach [4]. These authors and others reduced the rules of evidence to a small subset of principles that were easier to teach and to understand, and reintroduced the concept in 1992. They named this technique 'evidence-based medicine' (EBM). It was defined as the conscientious, explicit and judicious use of the best current evidence in making decisions about the care of individual patients [5]. The definition was expanded to include the integration of independent, clinical expertise, the best available external clinical evidence from systematic research, and patients' values and expectations [6]. Others, such as Ian Chalmers, were instrumental in setting up the Cochrane Collaboration, a global network of individuals, mainly volunteers, who were tasked with preparing and maintaining unbiased systematic reviews of all randomized controlled trials, organized according to specialty [7]. Whereas making decisions about therapy has been the primary focus of EBM, its principles have been extended to diagnosis, prognosis, harmful effects of interventions and economic analyses [1].

It has been estimated that physicians need evidence (e.g. about the accuracy of diagnostic tests, the power of prognostic markers,

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

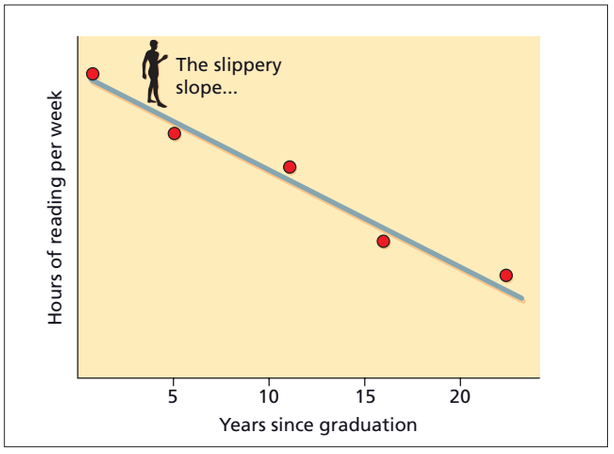

Fig. 7.1 Relationship between reading and years from graduation from medical school. Based on Sackett [11].

the comparative efficacy and safety of interventions) about twice for every three outpatients seen (and five times for every inpatient). In reality, we get less than a third of this evidence [1,8,9].

Keeping up with the literature

The best external evidence that informs patient care comes from clinical research involving patients. It has a short doubling time (10 years) and replaces currently accepted diagnostic tests and treatments with new ones that are more powerful, more accurate, more efficacious and safer [1].

In the field of medicine the amount of data published far exceeds our ability to read it. Keeping up by reading the literature is an impossible task for most practising physicians. It would require reading around 19 articles a day, 365 days a year. The average practising physician spends one half hour per week reading the medical literature related to the patients whom he or she sees (Fig. 7.1) [1,6,8]. The burden of literature for dermatologists is no less daunting, since there are now more than 200 journals devoted to dermatology worldwide [10]. This expansion in the biomedical literature has been one of the main reasons for developing secondary research synthesis summaries (systematic reviews) of all available evidence, so that the busy physician can go to just one place for an up-to-date summary.

Even if he or she had the time, the best clinical evidence published in journals is often inaccessible to the average practising physician. Most are not adequately trained in clinical decision-making, clinical research, epidemiology or statistics to adequately read and critically evaluate many articles published in the primary medical literature. Commonly used techniques and concepts, such as odds-ratio, confidence interval, utility, Yates' correction or fixed-effects model, as examples, are often poorly understood. Evidence-based medicine provides a systematic method to evaluate the medical literature that allows the average practising physician not only to understand the medical literature but also to apply it to the care of individual patients.

Table 7.1 The five steps of practising evidence-based dermatology.

1. Formulating a well-built clinical question generated from a patient encounter
2. Searching for valid external evidence
3. Critically appraising that evidence for relevance and validity
4. Applying the results of that appraisal of evidence back to the patient
5. Recording the information for future use

Practising evidence-based medicine

What then is evidence-based medicine? Practising EBM consists of five steps (Table 7.1). Once learned, the techniques of EBM can be performed rapidly and efficiently to use available external evidence from the medical literature combined with clinical experience and patient preferences in order to make clinical decisions.

Formulating questions and finding evidence

Formulating well-built clinical questions [1]

A central issue in practising EBM is that of trying to find answers to clinically relevant questions that arise in caring for individual patients. Asking *well-built clinical questions* may be the most important step in practising EBM. A well-built clinical question has four elements: a patient or problem, an intervention, a comparison intervention (if necessary) and an outcome. These are encompassed in the acronym PICO (patient, intervention, comparator and outcome). Well-built clinical questions about individual patients can be grouped into several categories, relating to issues such as aetiology, diagnosis, therapy, prevention, prognosis and harm.

A well-built clinical question has two strong advantages. One major benefit of careful and thoughtful question forming is that it

makes it easier to search for, and critically appraise, the available evidence. The well-built question makes it relatively straightforward to determine and combine the appropriate search terms needed to obtain relevant information from whichever database(s) you choose (e.g. Medline, EMBASE or the Cochrane Library). Second, having to formulate well-built clinical questions will also train you to clearly define your patient, to be specific about the interventions used and to choose carefully described outcomes that are important to your patient and to yourself.

What is 'the best evidence?' [2]

Practising evidence-based medicine is dependent on finding and utilizing the best evidence. Potential sources of evidence include having an understanding of the aetiology and pathophysiology of disease, application of logic and personal experience, views of colleagues or experts, and information from textbooks, articles published in journals and systematic reviews. An important principle of EBM is that the quality (strength) of evidence is based on a *hierarchy of evidence* (Fig. 7.2). The order of the hierarchy of evidence is dependent on the type of question being asked (Table 7.2). The hierarchy of evidence consists of results of well-designed experimental studies such as RCTs (especially if the studies have results of similar magnitude and direction, and if there is homogeneity among studies), results of observational studies such as case series, expert opinion and personal experience, in descending order. The hierarchy was created to encourage the use of the evidence that is most likely to be true and useful in clinical decision-making. The ordering of this hierarchy has been widely discussed, actively debated and sometimes hotly contested [3]. It is important to consider study quality when referring to the evidence hierarchy. For example, a well-designed cohort study may provide more

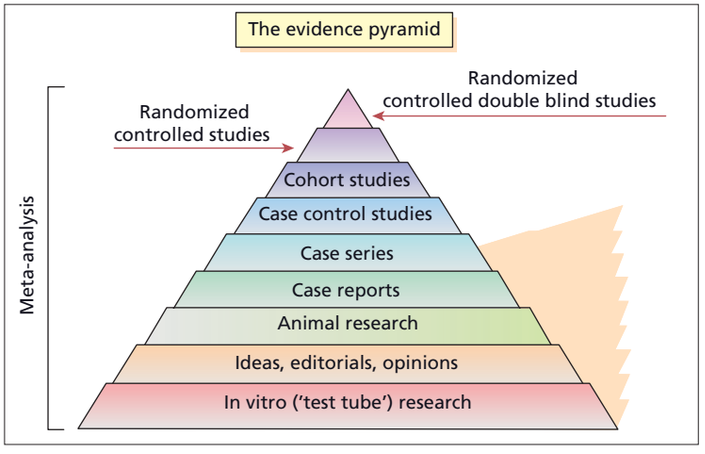

Fig. 7.2 The hierarchy of evidence. Permission to reprint granted by SUNY Downstate Medical Center, Medical Research Library of Brooklyn Guide to Research Methods, The Evidence Pyramid. SUNY Health Sciences, Evidence Based Medicine Course. http://servers.medlib.hscbklyn.edu/ebm/2100.htm.

Table 7.2 Levels of evidence.

Level of evidence	Type of study	Other studies reaching this evidence level
1a	Multiple RCTs* with homogeneity†	Multiple level 1b (see immediately below) diagnostic studies with homogeneity; or CDR‡ with 1b studies from different clinical centres
1b	Individual RCT (with narrow confidence intervals)	Independent blind comparison of an appropriate spectrum of consecutive patients, all of whom have undergone both the diagnostic test and the reference standard
1c	All or none§	Very high sensitivity or specificity¶
2a	Cohort studies with homogeneity	Multiple level ≥2 (see below) diagnostic studies with homogeneity
2b	Individual cohort study (including low-quality RCT, e.g. <80% follow-up)	Independent blind comparison but either in non-consecutive patients or confined to a narrow spectrum of study individuals (or both), all of whom have undergone both the diagnostic test and the reference standard; or a diagnostic CPG not validated in a test set
2c	'Outcomes' research**	
3a	Case–control studies with homogeneity	Multiple 3b and better studies (see below) with homogeneity
3b	Individual case–control study	Independent blind comparison of an appropriate spectrum, but the reference standard was not applied to all study patients
4	Case series (and poor quality cohort and case–control studies)	Reference standard was not applied independently or not applied blindly
5	Expert opinion without explicit critical appraisal, or based on physiology, bench research or logical deduction	

Modified from: Ball C, Sackett D, Phillips B, Haynes B, Straus S. NHS R&D Centre for Evidence-Based Medicine. http://www.cebm.net/index.aspx?o=1025 (last accessed 30 October 2007).

* RCT, randomized controlled trial.

† Homogeneity, lacking variation in the direction and magnitude of results of individual studies.

‡ CDR, clinical decision rule. These are algorithms or scoring systems that lead to a prognostic estimation or a diagnostic category.

§ All or none, interventions that produced dramatic increases in survival or outcome such as streptomycin for tuberculosis meningitis.

¶ A diagnostic finding with a specificity so high that a positive result rules in the diagnosis or a diagnostic finding with sensitivity so high that a negative result rules out the diagnosis.

** Outcomes research includes cost–benefit, cost–effectiveness and cost–utility analyses.

reliable evidence than a small, poorly conducted RCT (even though the RCT theoretically provides a stronger design for minimizing bias).

A systematic review is an overview of available evidence that answers a specific clinical question, contains a thorough, unbiased search of the relevant literature, explicit criteria for assessing studies and structured presentation of the results. When there are similar studies in a systematic review (e.g. RCTs using the same interventions and outcomes), the authors of a systematic review may use a statistical technique, called meta-analysis, to combine quantitative data from several studies in order to provide a more precise and informative overall estimate of treatment effects.

Meta-analysis is credited with allowing recognition of important treatment effects by combining the results of small trials that individually lacked the power to demonstrate differences among treatments. For example, the benefits of intravenous streptokinase in acute myocardial infarction was recognized by the results of a cumulative meta-analysis of smaller trials at least a decade before it was recommended by experts and before it was demonstrated to be efficacious in large clinical trials [4]. Meta-analysis has been criticized for the discrepancies between the results of meta-analysis and those from large clinical trials [5]. For example, results of a meta-analysis of 14 small studies of calcium to treat pre-eclampsia showed benefit of treatment, whereas a large trial failed to show a treatment effect [6]. The frequency of such discrepancies ranges from 10% to 23% [6]. Discrepancies can often be explained by differences in treatment protocols, heterogeneity of study populations or changes that occur over time [6].

The type of question being asked determines the type of clinical study that is likely to provide the best evidence. Questions about therapy and interventions for disease prevention are best addressed by RCTs. Questions about diagnosis are best addressed by cohort studies. RCTs are usually a good source of evidence for the harmful effects of interventions for adverse events that occur frequently, but are not always reliable for identifying rare but potentially important adverse events. For adverse effects that occur infrequently, cohort studies, case–control studies, or post-marketing surveillance studies are best. Case reports are often the first line of evidence for rare adverse events and sometimes they are the only evidence.

Over half a million RCTs have been conducted in medicine. Studies have demonstrated that failure to use randomization or adequate concealment of allocation results in larger estimates of treatment effects, predominantly caused by a poorer prognosis in non-randomly selected control groups compared with randomly selected control groups [7]. However, some studies comparing randomized and non-randomized clinical trials of the same interventions have reached disparate and conflicting results [8,9]. In some instances, observational studies find stronger treatment effects than RCTs [7]. Other studies have demonstrated that the results of well-designed observational studies (with either a cohort or a case–control design) do not systematically overestimate the magnitude of the effects of treatment as compared with RCTs on the same topic [8,9]. Sifting through the controversy leads to the following limited conclusions: (i) trials using historical controls result in larger estimates of treatment effects compared with randomized controlled trials; and (ii) large, inclusive, fully masked RCTs are likely to provide the best possible evidence about effectiveness [3].

Whereas personal experience is an invaluable part of becoming a competent physician, the pitfalls of relying too heavily on personal experience have been widely documented. Nisbett and Ross extensively reviewed people's ability to draw inferences from personal experience and document several pitfalls [10]. They include:

1. over-emphasis on vivid, anecdotal occurrences and under-emphasis on significant statistically strong evidence
2. bias in recognizing, remembering and recalling evidence that supports pre-existing knowledge structures (e.g. ideas about disease aetiology and pathogenesis) and parallel failure to recognize, remember and recall evidence that is more valid
3. failure to accurately characterize population data because of ignorance of statistical principles including sample size, sample selection bias and regression to the mean
4. inability to detect and distinguish statistical association and causality, and
5. persistence of beliefs in spite of overwhelming contrary evidence.

Nisbett and Ross provide numerous examples of problems associated with recall from controlled clinical research. Physicians may remember patients who improved, often assume that patients who did not return for follow-up improved, and conveniently forget the patients who did not improve. A patient treated with a given medication may develop a severe life-threatening reaction; on the basis of this single undesirable experience, the physician may avoid using that medication for many future patients, even though, *on average,* it may be more efficacious and less toxic than the alternative treatments that the physician chooses. Few physicians keep adequate, easily retrievable records to codify results of treatments with a particular agent or of a particular disease; and even fewer actually carry out analyses. Few physicians make provisions for tracking those patients who are lost to follow-up. Therefore statements made about a physician's 'clinical experience' may be biased. Finally, for many conditions, a single physician sees far too few patients to enable reasonably firm conclusions to be drawn about the response to treatments. For example, suppose a physician has treated 20 patients with lichen planus with tretinoin and found that 12 (60%) had an excellent response. The confidence interval for this response rate (i.e. the true response rate for this treatment in the larger population from which this physician's sample was obtained) ranges from 36% to 81%. Thus the true overall response rate might well be substantially less (or more) than the physician concludes from personal experience.

Expert opinion can be valuable, particularly for rare conditions in which the expert has the most experience or when other forms of evidence are not available. However, several studies have demonstrated that expert opinion often lags significantly behind conclusive evidence. Experts may rely too heavily on bench research, pathophysiology and treatments based on logical deduction from pathophysiology and from the same pitfalls noted regarding reliance on personal experience.

It is widely believed that clinical decisions can be made on the basis of understanding the aetiology and pathophysiology of disease and logic [11]. This paradigm is problematic since the

accepted hypothesis for the aetiology and pathogenesis of disease changes over time. For example, in the last 20 years, hypotheses about the aetiology of psoriasis have shifted from a disorder of keratinocyte proliferation and homeostasis, to abnormal signalling of adenosine cyclic monophosphate, to aberrant arachidonic acid metabolism, to aberrant vitamin D metabolism, to the current favourite: a T-cell-mediated autoimmune disease. Each of these hypotheses spawned logically-deduced treatments. The efficacy of many of these treatments has been substantiated by rigorous, controlled clinical trials, whereas others are used even in the absence of systematically collected observations. Therefore, many options are available for treating patients with severe psoriasis (e.g. UVB, narrow-band UVB, the Goeckerman regimen, psoralen–UVA, methotrexate, ciclosporin and biological agents) and others for mild-to-moderate psoriasis (e.g. dithranol, topical corticosteroids, calcipotriol and tazarotene). However, we lack a clear sense of which is best, in what order they should be used or in what combinations.

Treatments based on logical deduction from pathophysiology may have unexpected consequences. For example, the observation that antiarrhythmic drugs could prevent abnormal ventricular depolarization after myocardial infarction logically lead to their use to prevent sudden death after myocardial infarction. However, an RCT showed increased mortality of patients treated with antiarrhythmic drugs compared with placebo [12].

In the field of dermatology, it was postulated that thalidomide might be a useful treatment for toxic epidermal necrolysis based on the observation that thalidomide showed antitumour necrosis factor-alpha properties, yet an RCT of thalidomide was stopped early because it was found that mortality was significantly higher in the thalidomide group than in the placebo group [13].

Textbooks can be valuable, particularly for rare conditions and for conditions for which the evidence does not change rapidly over time. However, textbooks have several well-documented shortcomings. They tend to reflect the biases and shortcomings of the experts who write them. By virtue of how they are written, produced and distributed, most are at least 2 years out of date at the time of publication. Most textbook chapters are narrative reviews that do not consider the quality of the evidence reported.

Finding the best evidence [2]

The ability to find the best evidence to answer clinical questions is crucial for practising EBM. Finding evidence requires access to electronic searching, searching skills and available resources. Evidence about therapy is the easiest to find. The best sources for finding the best evidence about treatment include:

1. the Cochrane Library
2. searching the Medline and EMBASE databases
3. primary journals
4. secondary journals
5. evidence-based dermatology and evidence-based medicine books
6. the National Guideline Clearinghouse (http://www.jcaai.org)
7. the National Institute for Health and Clinical Excellence (NICE) (www.nice.org.uk)

The Cochrane Collaboration developed in response to Archie Cochrane's challenge to organize a critical summary, by specialty or subspecialty, adapted periodically, of all relevant RCTs. The Cochrane Library contains the Cochrane Database of Systematic Reviews, the Database of Abstracts of Reviews of Effectiveness (DARE), the Cochrane Central Register of Controlled Trials (Central) and the Health Technology Assessment Database (HTA). It is the most complete and best index database of systematic reviews of therapy, RCTs and controlled clinical trials, and is the best and most efficient place to find evidence about therapy.

The Cochrane Database of Systematic Reviews is the most comprehensive collection of high-quality, systematic reviews available. Volunteers, according to strict guidelines developed by the Cochrane Collaboration, write the systematic reviews in the Cochrane library. Systematic reviews conducted within the Cochrane Collaboration are rated among the best [14]. The last issue of the Cochrane Library (2008, issue 1, accessed 31 March 2008) contained 5171 completed systematic reviews. The number of reviews relevant to dermatology is around 200 and is steadily increasing.

Central is a database of over 527 885 controlled clinical trials. It is compiled by searching the Medline and EMBASE databases, and additionally by hand searching many journals. Hand searching of journals to identify controlled clinical trials and RCTs was undertaken because members of the Cochrane Collaboration noticed that many trials were incorrectly classified in the Medline database. As an example, Adetugbo and William hand searched the *Archives of Dermatology* from 1990 to 1998 and identified 99 controlled clinical trials; 19 of the trials were not classified as controlled clinical trials on Medline and 11 trials that were not controlled clinical trials were misclassified as controlled clinical trials on Medline [15].

DARE is a database of abstracts of systematic reviews published in the medical literature. It contained abstracts and bibliographic details on over 7048 published systematic reviews. DARE is the only database to contain abstracts of systematic reviews that have been quality assessed. Each abstract includes a summary of the review together with a critical commentary about the overall quality.

HTA consists of completed and ongoing Health Technology Assessments (studies of the medical, social, ethical and economic implications of health-care interventions) from around the world. The aim of the database is to improve the quality and cost-effectiveness of health care.

The Cochrane library can be easily searched using simple Boolean combinations of search terms as well as by more sophisticated search strategies. The Cochrane Database of Systematic Reviews, DARE, Central and HTA can be searched simultaneously. The Cochrane Library is available on a personal or institutional subscription basis on CD, and on the world wide web from Wiley InterScience (http://www3.interscience.wiley.com). Subscriptions to the Cochrane Library are updated quarterly. The Cochrane Library is offered free of charge in many countries by national provision and to faculty and students by many medical schools in the USA.

The second best method for finding evidence about treatment, and the best source for finding most other types of best evidence,

in dermatology is by searching the Medline or EMBASE databases. Medline is the National Library of Medicine's (NLM) bibliographic database covering the fields of medicine, nursing, dentistry, veterinary medicine, the health-care system and the preclinical sciences. The Medline file contains bibliographic citations and author abstracts from approximately 5000 current biomedical journals published in the USA and 80 other countries. The file contains approximately 15 million records dating back to the 1950s.

Medline searches have inherent limitations that make their reliability less than ideal [2]. For example, Spuls *et al*. conducted a systematic review of systemic treatments of psoriasis [16]. Treatments analysed included UVB, PUVA, methotrexate, ciclosporin and oral retinoids. The authors used an exhaustive strategy to find relevant references including Medline searches, contacting pharmaceutical companies, polling leading authorities, reviewing abstract books of symposia and congresses, and reviewing textbooks, reviews, editorials, guideline articles and the reference lists of all papers identified. Of 665 studies found, 356 (54%) were identified by Medline search (range 30% to 70% for different treatment modalities). The 17 of 23 authorities who responded provided no references beyond those identified by Medline searching.

Specific search strategies, known as 'filters', have been developed to help find relevant references and to exclude irrelevant references for systematic reviews and for evidence about aetiology, diagnosis, therapy and prevention, prognosis, and clinical prediction guides (http://www.ncbi.nlm.nih.gov/entrez/query/static/clinicaltable.html#ClinicalQueries). These filters have been incorporated into the PubMed Clinical Queries search engine of the NLM and are available at http://www.ncbi.nlm.nih.gov/entrez/query/static/clinical.shtml. PubMed Clinical Queries is the preferred method for searching the Medline database for the best clinically relevant evidence. It can be freely used by anyone with Internet access.

EMBASE (http://www.embase.com/) is Excerpta Medica's database covering drugs, pharmacology and biomedical specialties. EMBASE has better coverage of European and non-English language sources, and may be more up to date than Medline. The overlap in journals covered by Medline and EMBASE is about 34% (range 10% to 75% depending on the subject) [17]. EMBASE contains over 11 million records from 1974 to the present. EMBASE.com performs simultaneous searches of EMBASE and Medline databases and eliminates duplicate records. Personal and institutional subscriptions are available.

Structured abstracts of articles are published in secondary journals (e.g. the Evidence-based Dermatology section of the *Archives of Dermatology*). The articles are strictly selected on the basis of methodological quality and are accompanied by commentary putting the information in clinical perspective. The Evidence-based Dermatology section is published quarterly in the *Archives of Dermatology*. *Clinical Evidence* is a 6-monthly-updated compendium of evidence on the effects of common clinical interventions. Twenty-four skin-related diseases were included in the latest issue (last accessed 30 October 2007). It is available through the American College of Physicians and the British Medical Association (http://clinicalevidence.org/ceweb/index.jsp).

Full text versions of many primary journals are now available on the Internet. Available vendors include DataStar, DIALOG, DIMDI, Ovid Online and STN, among others. The National Guideline Clearinghouse maintains a database of guidelines for the treatment of disease written by panels of experts following strict guidelines of evidence. The database is accessible through the Internet (http://www.guideline.gov). However, current coverage of dermatological topics is limited.

The UK National Institute for Health and Clinical Excellence (NICE; www.nice.org.uk) produces guidance on public health, health technologies and clinical practice based on the best available evidence. It includes guidance for treating atopic eczema, a final appraisal determination on the use of calcineurin inhibitors for atopic dermatitis and on the use of biologics for psoriasis, and a full set of guidelines for skin cancer, including melanoma. The Skin Disorders Specialist Library provides a 'one-stop shop' of reliable Internet resources on skin diseases including guidelines, patient information resources, evidence sources and updates of systematic reviews; part of the UK National Library for Health, and directed at UK health professionals, it is freely available anywhere in the world (http://www.library.nhs.uk/skin/) [18].

Critically appraising evidence and applying it to individual patients

Critically appraising the evidence [1]

After finding evidence, the next step in practising EBM involves *critically appraising the evidence*. The criteria to critically appraise systematic reviews are listed in Table 7.3 (other lists for appraisal of other types of study are provided later in Tables 7.5–7.7). Papers that meet defined appraisal are more likely to provide information that is true and useful in the care of patients. Detailed explanation of each criterion and examples using a patient with a dermatological complaint are available [2].

Critically appraising evidence consists of three steps, determining whether the results are:

1 valid (i.e. as unbiased as possible)
2 clinically important and
3 applicable to the specific patient being seen.

Determining the validity of evidence centres on ascertaining whether the evidence was produced in a manner most likely to eliminate and avoid bias. Clinical importance is determined by looking at the magnitude of the effect of the intervention (e.g. treatment effect for systematic reviews, meta-analyses and RCTs; likelihood ratio for diagnostic studies; and relative risk or odds ratios for studies of harm) and its corresponding precision (usually expressed as the 95% confidence interval). To determine whether the evidence is applicable to a specific patient requires physician expertise, knowledge of the patient's preferences, and an evaluation of the availability, risks and benefits of the intervention.

Critically appraising systematic reviews [3]

Are the results of the systematic review valid?

Not all systematic reviews and meta-analyses are equal. A systematic review should be conducted in a manner that will include all of the relevant trials, minimize the introduction of bias, and synthesize the results to be as truthful and useful to clinicians as possible. Systematic reviews should be reported fully according to the Quality of Reporting of Meta-Analyses (QUOROM) guidance [4].

In general, the criteria to critically appraise systematic reviews and meta-analyses are similar to the criteria used to appraise the individual studies that make up the systematic review. Like the well-built clinical question for individual studies, a focused clinical question for a systematic review should contain four elements:

1 a patient, group of patients or problem
2 an intervention
3 comparison intervention(s) and
4 specific outcomes.

The patient populations should be similar to the majority of patients likely to be seen in the population to which one wishes to apply the results of the systematic review. The interventions studied should be those commonly available in practice. Outcomes reported should be those that are most relevant to physicians and patients.

The overwhelming majority of systematic reviews involve therapy. Therefore, RCTs should be used for systematic reviews of therapy if they are available. The quality of included trials is assessed using the criteria that are used to evaluate individual RCTs. The quality criteria commonly used include concealed random allocation, groups similar in terms of known prognostic factors, equal treatment of groups, masked (also known as blinded) evaluation of treatment outcomes and accounting for all patients entered into the trial in analysing results (intent-to-treat design).

Systematic reviews of treatment efficacy should always include a thorough assessment of common and serious adverse events, as well as of efficacy, in order to come to an informed and balanced decision about the utility of a treatment. A thorough assessment of adverse events should include data from RCTs, case–control studies, post-marketing surveillance studies and some of the other sources shown in Table 7.4.

Publication bias (i.e. the tendency that studies that are easy to locate are more likely to show 'positive' effects) is an important concern for systematic reviews; Sterne *et al*. have written a useful review of this subject [5]. It results from allowing factors other than the quality of the study to influence its acceptability for publication. Several studies have shown that factors such as sample size, direction and statistical significance of findings, or investigators' perception of whether the findings are 'interesting', are related to the likelihood of publication [6].

Language bias may also be a problem, i.e. the tendency for studies that are 'positive' to be published in an English language journal, and additionally may be published more quickly than inconclusive or negative studies (a factor that applies to any journal, whatever the language). A thorough, systematic review should therefore include a search for high-quality, unpublished trials, and should not restrict itself to journals written in English.

Studies with small samples are less likely to be published, especially if they have negative results. By emphasizing only those

studies that are positive, this type of publication bias jeopardizes one of the main goals of meta-analysis (that of achieving an increase in power when pooling results of small studies). Chan and colleagues have also documented selective reporting of outcomes with positive results, a feat that is easily accomplished since most RCTs use multiple outcomes that are not prespecified in the public domain [7]. Creation of study registers (e.g. see http://clinicaltrials.gov/) and advance publication of research designs have been proposed as ways to prevent publication bias (see http://prsinfo.clinicaltrials.gov/icmje.html).

Publication bias can be detected by several methods, such as using a simple graphic test (funnel plot), by calculating the 'fail-safe' N, using Begg's rank correlation method or the Egger regression method, and others [8]. These techniques are of limited value when fewer than 10 RCTs are included. Testing for publication bias is almost never possible in systematic reviews of skin diseases, because of the limited number and sizes of trials.

For many diseases, the studies published are dominated by drug company-sponsored trials of new, expensive treatments. This bias in publication can result in data-driven systematic reviews that draw more attention to those medicines. This problem underlines the need to develop a protocol for a systematic review before the data are explored, as is the current practice with Cochrane reviews. Question-driven systematic reviews answer the clinical questions of most concern to practitioners. In many cases, studies that are of most relevance to doctors and patients have not been done in the field of dermatology due to inadequate sources of independent funding. Systematic reviews that have been sponsored directly or indirectly by industry are also prone to bias by over-inclusion of unpublished 'positive' studies that are kept 'on file' by that company [9]. Until it becomes mandatory to register all clinical trials conducted on human beings in a central register, and to make all of the results available in the public domain, distortions may occur due to selective withholding or release of data.

Generally, reviews that have been conducted by volunteers in the Cochrane Collaboration are of better quality than non-Cochrane reviews [10]. However, potentially serious errors have even been noted in up to a third of such reviews [11]. In general, the studies included in systematic reviews are reviewed by at least two reviewers. Data such as numbers of people entered into studies, numbers lost to follow-up, effect sizes and quality criteria are recorded on predesigned data abstraction forms by at least two reviewers. Differences between reviewers are usually settled by consensus or by a third arbitrator. A systematic review in which there are large areas of disagreement among reviewers should lead the reader to question the validity of the review.

Are the results of the systematic review important?

Results in the individual clinical trials that make up a systematic review may be similar in magnitude and direction (e.g. they may all indicate that treatment A is superior to treatment B by a similar magnitude). In this situation, assuming that publication bias can be excluded, the systematic review should provide results that are most likely to be true and useful. However, it may be impossible to draw firm conclusions from systematic reviews in which studies have results of widely different magnitude and direction.

The magnitude of the difference between the treatment groups in achieving meaningful outcomes is the most useful summary result of a systematic review. The most easily understood measures of the magnitude of the treatment effect are the difference in response rate and its reciprocal, the number needed to treat (NNT) [1,12]. The NNT represents the number of patients that one would need to treat, on average, to achieve one additional cure. Whilst the interpretation of NNT may be straightforward within an individual trial, interpretation of NNT requires some caution within a systematic review, as this statistic is highly sensitive to baseline event rates. For example, if a treatment 'A' is 30% more effective than treatment 'B' for clearing psoriasis, and 50% of people on treatment B are cleared with therapy, then 65% will clear with treatment A. These results correspond to a rate difference of 15% (65 – 50) and an NNT of 7 (1/0.15). This difference sounds quite worthwhile clinically. But if the baseline clearance rate for treatment B in another trial or setting is only 30%, the rate difference will be only 9% and the NNT now becomes 11 and, if the baseline

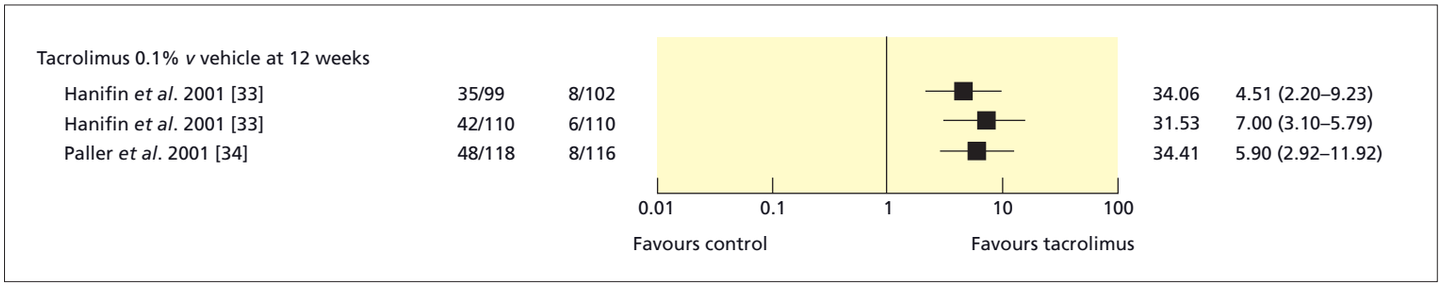

Fig. 7.3 Typical Forest Plot showing the results of a meta-analysis of trials of tacrolimus 0.1% ointment versus vehicle in the management of moderate to severe atopic dermatitis. The X-axis represents the rate ratio of the investigator global assessment of response. From Ashcroft *et al.* [32].

clearance rate is 10%, then the NNT for treatment A will be 33, which is perhaps less worthwhile. In other words, it does not make sense to provide one NNT summary measure within a systematic review if 'control' or baseline event rates differ considerably between studies. Instead, a range of NNTs for a range of plausible control event rates that occur in different clinical settings should be given, along with their 95% confidence intervals.

The precision of the estimate of the differences among treatments presented within a systematic review should always be estimated. The confidence interval provides a useful measure of the precision of the treatment effect [1,13]. The calculation and interpretation of confidence intervals are described below.

The point estimates and confidence intervals of the individual trials and the synthesis of all trials when a meta-analysis is performed are typically displayed graphically in a Forest Plot, an example of which is shown in Fig. 7.3. Results are most commonly expressed as the odds ratio of the treatment effect (that is, the odds of achieving a good outcome in the treated group divided by the odds of achieving a good result in the control group). An odds ratio of 1 (null) indicates no difference between treatment and control and is usually represented by a vertical line passing through 1 on the x-axis. An odds ratio of greater or less than 1 implies that the treatment is superior or inferior to the control respectively. The point estimate of individual trials is indicated by a square whose size is proportional to the size of the trial (i.e. number of patients analysed). The precision of the trial is represented by the 95% confidence interval that appears in Forest Plots as the brackets surrounding the point estimate. If the 95% confidence interval (represented by the brackets) does not cross null (the vertical line representing an odds ratio of 1), then the individual trial is statistically significant at the $P = 0.05$ level. The summary value for all trials is shown graphically as a parallelogram whose size is proportional to the total number of patients analyed from all trials. The lateral tips of the parallelogram represent the 95% confidence interval and if they do not cross null (odds ratio of 1), then the summary value of the meta-analysis is statistically significant at the $P = 0.05$ level. See the section below on Critically Appraising a Study about Adverse Events (Case Control and Cohort Studies) for a discussion of the relationship between odds ratio, relative risk, risk difference and NNT.

Certain conditions must be met when meta-analysis is performed to synthesize results from different trials. The trials should have conceptual homogeneity (i.e. they must involve similar patient populations, have used similar treatments and have measured results in a similar fashion at a similar point in time). There are two main statistical methods by which results are combined: using random effects models or fixed effects models. Random effects models assume that the different studies' results may come from different populations with varying responses to treatment. Fixed effects models assume that each trial represents a random sample of a single population with a single response to treatment. In general, random effects model are more conservative (i.e. they are less likely to show statistically significant results than fixed effects models). When the combined studies have statistical homogeneity (i.e. when the studies are reasonably similar in direction, magnitude and variability), the random effects and fixed effects models give similar results.

The key principle when considering combining results from several studies is that conceptual homogeneity precedes statistical homogeneity. In other words, results of several different studies should not be combined if it does not make sense to combine them; for example, if the patient groups or interventions studied are not sufficiently similar to each other. Although what constitutes 'sufficiently similar' is a matter of judgement, the important thing is to be explicit about one's decision to combine or to not combine different studies. Tests for statistical heterogeneity are typically of very low power, so that failure to detect statistically significant heterogeneity does not 'prove' homogeneity. When there is evidence of heterogeneity between studies, the reasons for the heterogeneity (such as different disease subgroups, intervention dosage or study quality) should be sought.

Sometimes, the robustness of an overall meta-analysis is tested further by means of a sensitivity analysis. In a sensitivity analysis the data are re-analysed but exclude those studies that are suspect because of quality or patient factors, in order to see whether their exclusion makes a substantial difference to the direction or magnitude of the main, original results. In some systematic reviews in which a large number of trials have been performed, it is possible to evaluate whether certain subgroups (e.g. children versus adults) are more likely to benefit than others. Subgroup analysis is rarely possible in dermatology because few trials are available.

The conclusions in the discussion section of a systematic review should closely reflect the data that have been presented within that review. The authors should make it clear which of the treatment recommendations are based on the review data and which reflect their own judgements. In addition to making clinical recommendations of therapies when evidence exists, many reviews in dermatology find little evidence to address the questions posed.

This lack of conclusive evidence does not mean that the review is a waste of time, especially if the question addressed appears to be an important one. For example, a systematic review of antistreptococcal therapy for guttate psoriasis provided the authors with an opportunity to call for primary research in this area, and to make recommendations on study design and outcomes that might help future researchers [14].

Can the results of the systematic review be applied to your specific patient?

Applying evidence summarized in a systematic review to specific patients requires the same processes used to apply the results of individual controlled clinical trials to patients (see below).

Critically appraising individual clinical trials [1,2,15,16]

Are the results of the trial valid?

To determine whether an individual clinical trial is valid, pay particular attention to the features that strengthen clinical trials and that help to validate their conclusions (Table 7.5). The 'big three' that should always be assessed are:

Table 7.5 Critical appraisal of a paper about therapy.

Are the results of this single preventive or therapeutic trial valid?
Was the assignment of patients to treatments randomized?
—and was the randomization list concealed?
Were all patients who entered the trial accounted for at its conclusion?
—and were they analysed in the groups to which they were randomized?
Were patients and clinicians kept 'blind' to which treatment was being received?
Aside from the experimental treatment, were the groups treated equally?
Were the groups similar at the start of the trial?
Are the valid results of this trial important?
Calculations:
Intervention Response Rate (IRR)
Comparison (Intervention) Response Rate (CRR)
Difference in Response Rates (DRR (IRR – CRR))
Number Needed to Treat (NNT (1/DRR))
What is the 95% confidence interval of the difference in response rates (DRR)?*
What is the 95% confidence interval of the NNT?**
Can you apply this valid, important evidence in caring for your patient?
Do these results apply to your patient?
Is your patient so different from those in the trial that its results can't help you?
How great would the potential benefit of therapy actually be for your individual patient?
Do the regimen and its consequences satisfy your patient's values and preferences?
Do your patient and you have a clear assessment of your values and preferences?
Do this regimen and its consequences meet them?

From http://www.cebm.net/index.aspx?o=1157.

* The 95% confidence interval of the difference in response rates (DRR) is from:

$$\text{DRR} - 1.96x\text{SE to DRR} + 1.96x\text{SE where SE} = \sqrt{\frac{IRR(1-IRR)}{\#\,\text{Intervention Patients}} + \frac{CRR(1-CRR)}{\#\,\text{Comparison Patients}}}$$

** The 95% confidence interval of the NNT = 1/limits on the confidence interval of its DRR.

1 Is the method of generating the randomization sequence and subsequent concealment of allocation of participants clearly described and appropriate?
2 Were participants and study assessors masked to the intervention?
3 Were all those who originally entered the study accounted for in the results and analysis (i.e. was an intention-to-treat analysis performed)?

Ideally, patients should be randomly assigned to treatment groups to avoid the introduction of biases and to distribute intrinsic prognostic factors equally among treatment groups. Randomization controls patient selection and evaluation bias by physicians and study personnel. Non-randomized studies have limited value in distinguishing useful from useless or even harmful therapy. When compared with RCTs, studies in which patients are not allocated randomly more commonly show larger effects, many of which are false positive. For example, the belief that use of azathioprine reduced the dose of corticosteroids necessary to treat bullous pemphigoid was suggested by several uncontrolled or non-randomized studies. However, a randomized trial of the effects of azathioprine on corticosteroid dose in patients with bullous pemphigoid indicated that azathioprine had no or negligible effects on remission or corticosteroid doses [17].

Randomization has the disadvantage of depending on chance for an equal statistical distribution of prognostic factors among groups. Therefore, it is always important to identify known prognostic factors such as disease severity, and to compare their distribution among treatment groups at baseline. The common practice of assigning *P* values to differences in characteristics at baseline is inappropriate. Although demographic and known prognostic factors may not be equally distributed among treatment groups when patients are randomly assigned to them, the impact of the unequal distribution of prognostic factors on treatment results should be assessed. Inequality of groups in randomized trials is a more significant problem in studies with few patients but can usually be adjusted for in appropriate analyses.

When patients are assigned randomly, the method used to randomize should be reported. The most widely accepted and unbiased methods are using sealed random numbers obtained from tables, or random numbers generated by computers. In this method, patients are assigned a random number after they are admitted to a trial. That number has been previously assigned to a treatment group and the assignment is unknown to the patient and the investigator. Correct randomization or concealment of assignment is often not done in published studies, and the methods of randomization are rarely reported. Many commonly encountered methods of randomization (for example, on the basis of admitting team, alternative assignment, odd or even days of entry, birth dates, social security numbers, or day of the week), can lead to significant introduction of selection bias. For example, a physician who would like a new treatment to be superior in efficacy to an older treatment may be able to enter patients most likely to respond to treatment on even days and patients least likely to respond on odd days if he or she knows that the new treatment is assigned on even days and the older treatment is assigned on odd days.

Concealment of treatment allocation refers to the steps taken by the trialists to conceal the allocation of participants to the intervention groups from those recruiting the trial participants. Concealing the allocation of interventions from those recruiting participants is a crucial step in the progress of an RCT. Concealing the sequence from recruiters is adequate if investigators and patients cannot foresee the assignment to intervention groups (e.g. using numbered and coded identical sealed boxes prepared by central pharmacy, or sealed opaque envelopes); conversely, it is inadequate if the allocation schedule is open for the recruiting physician to view beforehand (e.g. using unsealed envelopes).

The randomization list should be kept away from enrolment sites (for example by a central clinical trials office or pharmacy). Internet randomization by a third party, whereby details of a new potentially eligible trial participant are entered irrevocably onto a trial database before an allocation code is offered, is another very secure way of concealing allocation.

It is important to make the evaluation of the outcome of a trial as masked as possible to avoid the introduction of bias. Masking can refer to at least four groups of people: those recruiting patients, the study participants themselves, those assessing the outcomes in study participants and those analysing the results. Masking of physicians and patients is especially important when subjective outcomes such as pain are being measured. Masking of patients and evaluators also ensures that ancillary therapies and outcome evaluations are applied equally, thus minimizing performance bias. A patient who is known to be receiving a new treatment may be observed more closely, may receive better ancillary care and may have different expectations compared with a control patient. Changes in disease status may receive greater (or lesser) emphasis, and adverse events may similarly receive more (or less) attention. Masking is less of an issue for some studies that use very objective outcomes such as death.

However, masking is often not possible. In dermatology, many treatments produce skin changes that make it apparent what treatment is being used. For example, the drying effects of topical and systemic retinoids and the tanning effects of UVB therapy make the recipients of those therapies readily apparent. An unmasked study may still be valid but the designers of an unmasked study must make allowances for the possibility that bias may have been introduced and should increase the statistical rigor for demonstrating differences.

The whole purpose of randomization is to create two or more groups that are as similar to each other in as many respects as possible, the only difference between them being the intervention under study. In this way the additional effects of the intervention can be assessed. A potentially serious violation of this principle is the failure to take into account all those who were randomized when conducting the final main analysis, for example participants who deviate from the study protocol, those who do not adhere to the interventions and those who subsequently drop out for other reasons. People who drop out of trials tend to differ from those who remain in them in several ways; for example, they may drop out because they encounter adverse events, get worse (or no better), or simply because the proposed regimen is too complicated for them to follow. They may also drop out because the treatment is working so well. Ignoring participants who have dropped out in the analysis is not acceptable, as their very reason for dropping out is likely to be related in some direct or indirect way to the study interventions. Excluding participants who drop out at any stage after randomization potentially biases the results. One way to reduce such bias is to perform an intention-to-treat (ITT) analysis, in which all those initially randomized are included in the final analysis.

Unless one has detailed information on why participants dropped out of a study, it cannot be assumed that an analysis of those remaining in the study to the end is representative of those randomized to the groups at the beginning. Failure to perform an ITT analysis may inflate or deflate estimates of treatment effect. Performing an ITT analysis is often regarded as a major criterion by which the quality of an RCT is assessed.

It may be entirely appropriate to conduct an analysis of all those who remained at the end of a study (a 'per protocol' analysis) alongside the ITT analysis. Discrepancies between results of ITT and per protocol analyses may indicate the potential benefit of the intervention under ideal compliance conditions, and identifies a need to explore ways of reformulating the intervention so that fewer participants drop out of the trial. Discrepancies may also indicate serious flaws in the study design. A good discussion of when and where it might be appropriate to exclude trial participants from the main analysis may be found in [18].

Other features that strengthen the validity of trials [1,2,15,16]

In evaluating a clinical trial in dermatology, look for clinical outcome measures that are clear cut and clinically meaningful to you and your patients. For example, in a study of a systemic treatment for warts, complete disappearance of warts is a meaningful outcome, whereas a decrease in the volume of warts is not. Historically, three principal methods are used to determine patient outcomes in dermatological clinical trials. The first involves examining patients before, during and at the conclusion of treatment, and reporting how the patients appear at the various time points. The second involves determining the degree of improvement during treatment [19]. A third method, determining the impact of therapy on the quality of the patient's life, is being increasingly used in dermatological trials.

An example of the first method is commonly encountered in therapeutic trials of psoriasis. A common practice is to assign numerical values to the amount of erythema, scaling and degree of infiltration, to determine the area of the body surface involved, and to formulate an 'index' by calculating a derivative of some product of these four numbers. The overall condition of the patient can then be represented by this index. A common example is the psoriasis area and severity index (PASI) that ranges from 0 to 72 [20]. The major problem with such indices is that they presume that area of involvement corresponds with severity of disease. For example, a patient with thick plaque-type psoriasis of the knees, elbows and scalp may have the same index (score) as a patient with diffuse but minimal psoriasis of the trunk and arms. Whereas the former patient is notoriously difficult to treat, the latter will generally respond rapidly and easily to many forms of therapy.

The second problem with indices is that they lend an air of accuracy to the analysis and presentation of data that are not warranted. For example, Tiling-Grosse and Rees demonstrated that physicians and medical students were poor at estimating the area of skin disease and, therefore, some of the components that make up indices may be inaccurate [21]; this potential inaccuracy is magnified in severity indices such as PASI, where scores for surface are multiplied with scores for erythema and scaling. Finally, calculating the means, differences in means and percentages of change in indices in response to treatment often do not convey an accurate clinical picture of the changes that have occurred.

The second method of assessment groups patients according to their degree of improvement. Treatments are then compared by their ability to move patients to higher degrees of improvement. There are two major problems with this form of assessment. The first is that the categories of improvement are often not well defined. The second problem is that the categories are not additive. That is, 60–80% improvement is often assumed to be twice as good as 20–40%, although no such numerical relationship exists between these subjectively defined categories.

To be most useful, the outcome variables to measure must be clearly defined, as objective as possible and should have clinical and biological significance. The best indices and scales are the ones that accurately reflect the state of the disease and the ones with validity and reliability that have been verified by previous work. The development of scales and indices for cutaneous diseases, and testing their validity, reproducibility and responsiveness, has been inadequate. Therefore a lack of clearly defined and useful outcome variables remains a major problem in interpreting dermatological clinical trials.

Until better scales are developed, trials with the simplest and most objective outcome variables are the best. They lead to the least amount of confusion and have the strongest conclusions. Thus, trials in which a comparison is made between death and survival, patients with recurrence of disease and those without recurrence, or patients who are cured and those who are not cured, are studies with outcome variables that are easily understood and verified. For trials in which the outcomes are less clear-cut and more subjective in nature, a simple ordinal scale is probably the best choice. The best ordinal scales involve a minimum of human judgement, have a precision that is much smaller than the differences being sought and are sufficiently standardized that they can be used by others and will produce similar results.

In addition to being clearly defined, outcome variables should have clinical and biological significance. For example, in a therapeutic trial of patients with severe acne, treatment was associated with a decrease in lesion count from a mean of 400 to a mean of 350. This numerical difference may be of statistical significance, but it does not convey what the clinical significance of the change in lesion number represents. This result may mean that some patients with severe acne cleared completely whereas other patients remained the same or got worse. It could also mean that most patients got slightly better. Furthermore, does an individual patient look better when their lesion number has been reduced from 400 to 350? Are scarring and complications less?

To strengthen clinical trials and to help validation of their conclusions, the outcome variables should be few in number and should be chosen before initiation of the study. All trial protocols should be registered in clinical trial registries in the public domain. Having many outcome variables increases the likelihood that spurious, chance differences will be detected. An ineffective treatment may be claimed to be efficacious when tested using poorly designed outcome assessment tools. Conversely, an effective therapy may be found ineffective by an insensitive scale.

Special precautions are recommended when dealing with 'substitute or surrogate endpoints', especially when no differences are detected in clinically important outcomes. Examples of such endpoints include CD4:CD8 ratios instead of survival in studies of treatments of AIDS, ANA levels or sedimentation rates instead of clinical measures of disease activity in lupus erythematosus, and volume of warts instead of proportion of patients cleared of warts. Carefully chosen and validated surrogate endpoints often allow studies to provide answers to questions that would typically require much larger or longer trials if the targeted clinical endpoint were utilized. For example, a well-designed, short clinical trial may be sufficient to demonstrate that a new drug effectively lowers serum cholesterol or that another drug is effective in controlling hypertension. In both cases much longer and larger studies would be required to demonstrate that the cholesterol-lowering drug and the antihypertensive drug reduced morbidity and mortality from atherosclerotic and hypertensive cardiovascular diseases, respectively. Surrogate endpoints must, however, correlate with clinical outcomes, and their validity must be demonstrable in earlier studies.

Are the results of the clinical trial important? [1,2,15,16]

Once sound, clinically relevant outcome measures are chosen, the magnitude of the difference between the treatment groups in achieving these meaningful outcomes, the NNT and the precision of these estimates should be determined.

A trial comparing placebo, aciclovir, prednisone and aciclovir–prednisone in the treatment of herpes zoster [22] provides good examples of the application of the concepts of NNT and confidence intervals. At day 30 of the trial, 48 of 52 patents treated with aciclovir were totally healed compared with 22 of 52 patients who received placebo. The response rates for aciclovir and placebo were 0.92 and 0.42 respectively, and the difference in response rates was 0.5. The NNT was therefore 2.0 (1/0.5). This result means that, for every two patients treated with aciclovir instead of placebo, one additional patient would be totally healed by day 30. The 95% confidence interval for the difference in response rates is from 0.35 to 0.65, and the 95% confidence interval for the NNT is 2 to 3.

Misinterpreting trials that fail to show statistically significant differences among treatments is a common error of interpretation in dermatology clinical trials. It is important to remember that 'not statistically significant' means that a difference has a reasonably high probability of having been due to chance; it does not mean that there is no difference or that treatment is necessarily ineffective. Significant differences in treatment effects in comparison trials may be missed if the number of subjects tested is small. For example, in a 1978 survey of 71 published trials with negative

results, Freiman *et al*. found that a 25% or 50% improvement in outcome might have been missed in 57 (80%) and 34 (48%) of the studies respectively [23]. A follow-up study conducted by Moher *et al*. in 1994 indicated that 25% or 50% improvements in outcome might have been missed in 84% and 64% of 102 negative studies, respectively [24]. The sample sizes of many dermatological trials are often inadequate to detect clinically important differences. For example, 58 clinical trials with negative conclusions, published in three British dermatological journals over 4 years, were reviewed to determine the risk of their having missed an effective treatment. All but one of the 44 evaluable trials had a greater than 1 in 10 risk of having missed a 25% relative treatment difference (median risk 81%), and 31 of the trials (70%) were so small that they had a greater than 1 in 10 risk of having missed a 50% relative treatment difference (median risk 42%) [25].

Can the results of the trial be applied to your specific patient?

Applying external evidence to the patient in front of you is one of the most difficult steps of EBM. Having identified some relevant and valid information from clinical trials in relation to a clinical question generated by a patient encounter, four questions now need to be asked in order to guide the application of such information to that patient. They are listed in Table 7.4.

When faced with the task of determining whether the results of a particular study are applicable to a specific patient, physicians should ask themselves whether there are any compelling reasons that the results should not be applied to the patient, rather than expecting a perfect match of the study participants and patient. Only if the answer is 'yes' should the study's results be considered not applicable to the patient. Whilst participants in clinical trials may be different from the patient who originally prompted you to ask an evidence-based question in obvious biological ways, such as age, sex and clinical disease type, in most circumstances these differences do not prevent you from making some useful generalizations from the literature. Perhaps one of the most frequent problems encountered is that of having to generalize trials of adult therapy to children, in whom RCTs are rarely performed. Yet, children can suffer almost all of the 'adult' skin diseases, and practitioners frequently have no choice but to use adult-based data as a means of informing treatment decisions.

Critical appraisal of a study about a diagnostic test [1,2]

Are the results valid?

To be valid, studies about diagnostic tests should include masked comparison with a criterion ('gold') standard, evaluation in an appropriate spectrum of patients and consistent application of the criterion standard (Table 7.6). Few studies in dermatology meet this standard.

Are the results important?

Important terms and concepts that must be understood to determine whether the results of a paper about a diagnostic test are clinically important include the likelihood ratio, the pre-test probability, the post-test probability, and the threshold for action. The likelihood ratio is the percentage of people with the disease who have a positive test divided by the percentage of people who do not have the disease but who have a positive test. The likelihood ratio is traditionally taught as the (sensitivity/[1 – the specificity]); it provides an estimation of how much higher the likelihood of the disease is, given a positive test (post-test probability), compared with the probability before the test is done (pre-test probability). An ideal test is one that will almost always be positive when the disease is present and negative when the disease is absent. Thus, it is one with a high sensitivity and specificity. Such a test would have a very high likelihood ratio.

In order for the likelihood ratio to be useful, one has to have an idea of how likely the disease is to be present before the test is done (i.e. the pre-test probability) and a sense of how certain one needs to be to conclude that the patient has the disease and to act on it (i.e. the threshold for action) [26]. The pre-test probability is determined from available published data or is based on physician experience and judgment. Once the pre-test probability is known or estimated and the likelihood ratio determined, a nomogram can be used to estimate the post-test probability (Fig. 7.4).

If the nomogram is not available, the calculations can be done manually, but require conversion of probabilities to odds. The

Table 7.6 Critical appraisal of a paper about a diagnostic test.

Are the results of this diagnostic study valid?

- Was there an independent, blind comparison with a reference ('gold') standard of diagnosis?
- Was the diagnostic test evaluated in an appropriate spectrum of patients (like those in whom it would be used in practice)?
- Was the reference standard applied regardless of the diagnostic test result?

Are the valid results of this diagnostic study important?

Calculations:

		Target disorder	
		Present	Absent
Diagnostic test result	Positive	a	b
	Negative	c	d

Sensitivity = a/(a + c) Specificity = d/(b + d)

Likelihood ratio for a positive test result = [a/(a + c)]/[b/(b + d)] = sensitivity/(1 – specificity)

Likelihood ratio for a negative test result = [c/(a + c)]/[d/(b + d)] = (1 – sensitivity)/specificity

Can you apply this valid, important evidence about a diagnostic test in caring for your patient?

- Is the diagnostic test available, affordable, accurate and precise in your setting?
- Can you generate a clinically sensible estimate of your patient's pre-test probability (from practice data, from personal experience, from the report itself or from clinical speculation)?
- Will the resulting post-test probabilities affect your management and help your patient? (Could it move you across a test-treatment threshold? Would your patient be a willing partner in carrying it out?
- Would the consequences of the test help your patient?

From http://www.cebm.net/index.aspx?o=1157.

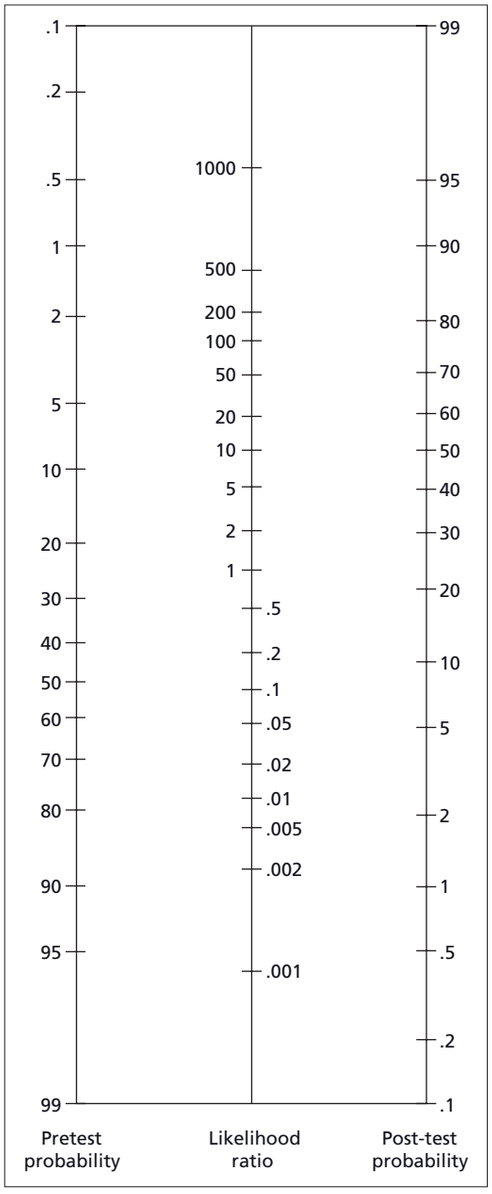

Fig. 7.4 Nomogram for determining the post-test probability. To determine the post-test probability, draw a straight line through the pre-test probability and the likelihood ratio and read the post-test probability on the right.

odds of disease is defined as the probability of disease divided by one minus the probability (odds = probability/[1 − probability]). For a defined group of individuals or patients, it can be also calculated as the ratio of the number of those with disease to those without disease. Thus, if the probability (proportion) of a disease is 0.20 (20%), the odds of that disease are 0.20/(1 − 0.20) = 0.20/0.80, that is 1 : 4. This result means that for every person with the disease, there are four people without the disease. The post-test odds are equal to the pre-test odds times the likelihood ratio (post-test odds = pre-test odds × LR). The formula (probability = odds/[odds +1]) is used to convert odds back to probability.

For example, suppose that based on clinical judgement the estimated probability that a patient with a cluster of vesicles on his cheek has herpes zoster is 0.6 (60%), then his odds of having herpes zoster are 1.5 : 1 (calculated from 0.6/[1 − 0.6]). Assume, for this example, that the sensitivity and specificity of a direct fluorescent antibody (DFA) test for herpes zoster are 80% and 96% respectively. Therefore, the likelihood ratio for a positive DFA is 0.80/[1 − 0.96] = 20. If this patient's DFA test is positive, his post-test odds are 30 (calculated from 1.5 × 20) and the post-test probability of herpes zoster is 0.97 (97%) (calculated from 30/[30 + 1]). This probability is certainly high enough to act upon.

Whether formally or informally, physicians develop thresholds of certainty at or above which they are comfortable with establishing a diagnosis and acting on the diagnoses. Action may take the form of communicating the diagnosis or prognosis to the patient, prescribing treatment or referring the patient. When history and physical evidence lead a clinician to suspect a diagnosis, but the degree of certainty does not exceed the threshold for establishing a diagnosis, a test is done to increase the probability that the disease is present above the clinician's threshold for action [26]. Studies reporting diagnostic tests in dermatology should adhere to established, international reporting standards [27].

Can the results of the diagnostic study be applied to your specific patient?

The key questions to ask to determine whether the results of a diagnostic study can be applied to a specific patent are shown in Table 7.5.

Critically appraising a study about adverse events (case–control and cohort studies) [1,2]

Are the results valid?

To be valid, studies about the harmful effects of exposures should include cohorts with comparable groups of exposed and unexposed individuals (or cases and controls), objective outcome measures and adequate follow-up. In addition, the results should make clinical and biological sense (Table 7.7). Few dermatological studies meet these criteria.

Are the results important? [1,2,28]

Important terms and concepts that must be understood to determine whether the results of a paper about harmful effects of exposures are clinically important include case–control and cohort studies, risk ratios and odds ratios. In a cohort study, a group of individuals who are exposed to an agent is compared with an appropriately selected unexposed control group, and both groups are followed either until an event of interest occurs or for a prespecified length of time. The association of exposure to the harmful outcome is expressed as the relative risk (Table 7.6). A relative risk of 1 implies that there is no association. If the relative risk is greater than unity, then the result implies a positive association between exposure and the harmful outcome. If it is less than unity, then the implication is of an inverse association. However, in order to infer a causal association reflected by either an increase in risk (relative risk of more than 1), or a protective effect (relative risk less than 1), it is important to evaluate the validity and precision of the relative risk estimate. The precision can be readily assessed by means of the 95% confidence interval. A confidence interval that does not include 1.0 denotes a statistically significant association. Because

Table 7.7 Critical appraisal of a paper about harm.

Are the results of this harm study valid?

- Were there clearly defined groups of patients, similar in all-important ways other than exposure to the treatment or other cause?
- Were treatment exposures and clinical outcomes measured in the same ways in both groups (e.g. was the assessment of outcomes either objective (e.g. death) or blinded to exposure)?
- Was the follow-up of study patients complete and long enough?
- Do the results satisfy some 'diagnostic tests for causation'?
  - Is it clear that the exposure preceded the onset of the outcome?
  - Is there a dose–response gradient?
  - Is there positive evidence from a 'de-challenge–re-challenge' study?
  - Is the association consistent from study to study?
  - Does the association make biological sense?

Are the valid results from this harm study important?

Calculations:

		Adverse outcome	
		Present (case)	Absent (control)
Exposed to the Treatment	Yes (Cohort)	a	b
	No (Cohort)	c	d

In a randomized trial or cohort study: relative risk = [a/(a + b)]/[c/(c + d)]

In a case–control study: odds ratio (or relative odds) = ad/bc

Should these valid, potentially important results of a critical appraisal about a harmful treatment change the treatment of your patient?

- Can the study results be extrapolated to your patient?
- What are your patient's risks of the adverse outcome?
- What are your patient's preferences, concerns and expectations from this treatment?
- What alternative treatments are available?

From Sackett *et al.* [31].

the most likely result of a study is the point estimate (i.e. the reported result), the observed association (expressed by the point estimate) may be causal, even if the confidence interval includes 1.0 due to a small sample size. Other criteria, such as dose–response effect, consistency, biological plausibility and specificity, need to be considered when inferring causality from observational data [29].

Case–control studies can be used when the undesirable outcome (e.g. lymphoma) is recognized but the causative agent has not yet been discovered. Case–control studies are also used when there is a very long time period between exposure and outcome, or when the frequency of adverse events is very small. In a case–control study, patients with a disease of interest are compared with appropriately selected controls. The odds of exposure to suspected causative agents are ascertained in cases and controls (Table 7.6). The odds of an event are the ratio of the number of events to the number of non-events. Events are exposures to potentially harmful risk factors in case–control studies. The odds of exposure of the cases are divided by the odds of exposure among the controls to derive the 'odds ratio', which is a good estimate of the relative risk when the outcome (e.g. disease or death) is relatively rare (i.e. when it occurs in less than 5% of the exposed subjects). The association between exposure and outcome is expressed as the odds ratio in case–control studies. An odds ratio of 1 implies no association. If the odds ratio is greater than 1, then the result implies a positive association between exposure and the harmful outcome. If the odds ratio is less than 1, then the result implies a protective effect of the exposure. As noted above, it is important to evaluate the validity and precision of the odds ratio estimate by examining the 95% confidence interval.

For example, suppose a case–control study was performed to study the relationship between limb deformity and exposure to thalidomide. The results of the study indicated that patients with limb deformities were more likely than controls to have been exposed to thalidomide *in utero*. The odds ratio for thalidomide exposure was 3.5 and the confidence interval was from 1.8 to 6.6. Thus the odds that patients with limb deformities were exposed to thalidomide *in utero* were 3.5 times the odds of thalidomide exposure in controls. Since the odds ratio is greater than 1, and its 95% confidence interval does not include 1, the result implies that the positive association between thalidomide use and limb deformities was not likely to have been due to chance. These results (an odds ratio of 3.5 and confidence interval of 1.8 to 6.6) were actually the results of a study by Wolf *et al.* who studied the relationship between sunscreen use and melanoma in a case–control study in Austria [30]. Their results indicated that patients with melanoma were more likely than controls to have used sunscreen often. In order to infer causality it is important to assess whether the results could have resulted from confounding (i.e. the association between exposure and outcome could have been explained by other factors, such as age or sex), whether there might have been any bias (for example, people with melanoma may have been more likely to recall sun protective behaviour), and whether the results are biologically plausible.

To add confusion to an already difficult area, clinical researchers will often report results of meta-analyses, cohort studies and RCTs using odds ratios. Odds ratios are used because they have stronger statistical properties than other measures [28]. For example, odds ratios can take any value between zero and infinity, are symmetrical in a log scale and can be used to make adjustments for confounding factors (using multiple regression analysis). Unfortunately, they are the least intuitively understood measure of association. If a meta-analysis, controlled trial or cohort study is reported using odds ratios, the relative risk, the difference in response rates or the NNT can often be calculated if the primary data are provided. Alternatively, these more readily understandable measures can be derived if the number of subjects in each group, odds ratio and overall event rate are provided (http://www.cebm.net/index.aspx?o=1044).

Can the results be applied to your specific patient?

The key questions to ask to determine whether the results of a case–control or cohort study can be applied to a specific patent are shown in Table 7.6.

Conclusions

EBM is the use of the best current evidence in making decisions about the care of individual patients. It relies on asking clinical

questions, finding the best evidence to answer the questions, critically appraising the evidence, applying the evidence to specific patients and saving the critically appraised evidence. The EBM approach is most appropriate for common, frequently encountered conditions.

Results from well-designed clinical studies on patients are at the pinnacle of the hierarchy of evidence used to practise evidence-based medicine. Recommendations about treatment, diagnosis and harm made in this textbook and in other sources should take into account the validity, magnitude, precision and applicability of the evidence upon which it is based.

Shortcut method and evaluating the data in clinical research papers

Shortcut method for appraising clinical research papers [1]

The EBM criteria for appraising evidence represent subsets of other schemes for appraising the quality of clinical research. These method include QUOROM (Quality of Reporting of Meta-Analyses), AMSTAR (Assessment of Multiple Systematic Reviews), CONSORT (Consolidated Standards of Reporting Trials), STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) and the methods of DerSimonian, Evans and Pollock, Poynard, Nyberg and many others [1–5]. What is common to all of these methods is that they require reading the entire paper, especially the methods section. Doing so is often not possible for busy clinicians trying to find answers to specific problems. Nor is it the most efficient use of his or her time. Instead, a shortcut method for evaluating the literature is available (Table 7.8). A shortcut method to evaluate clinical trials will enable you to use your time efficiently. It allows you to decide not to read the majority of poorly conceived, designed, executed or reported trials, or those trials with insignificant results. After each step you should re-ask the questions, 'Am I still interested in this trial?' and 'Is it worth spending my valuable time on it?'.

First read the title. If the title holds interest for you, read the abstract. If after reading the abstract you still feel that the article

Table 7.8 Shortcut method.

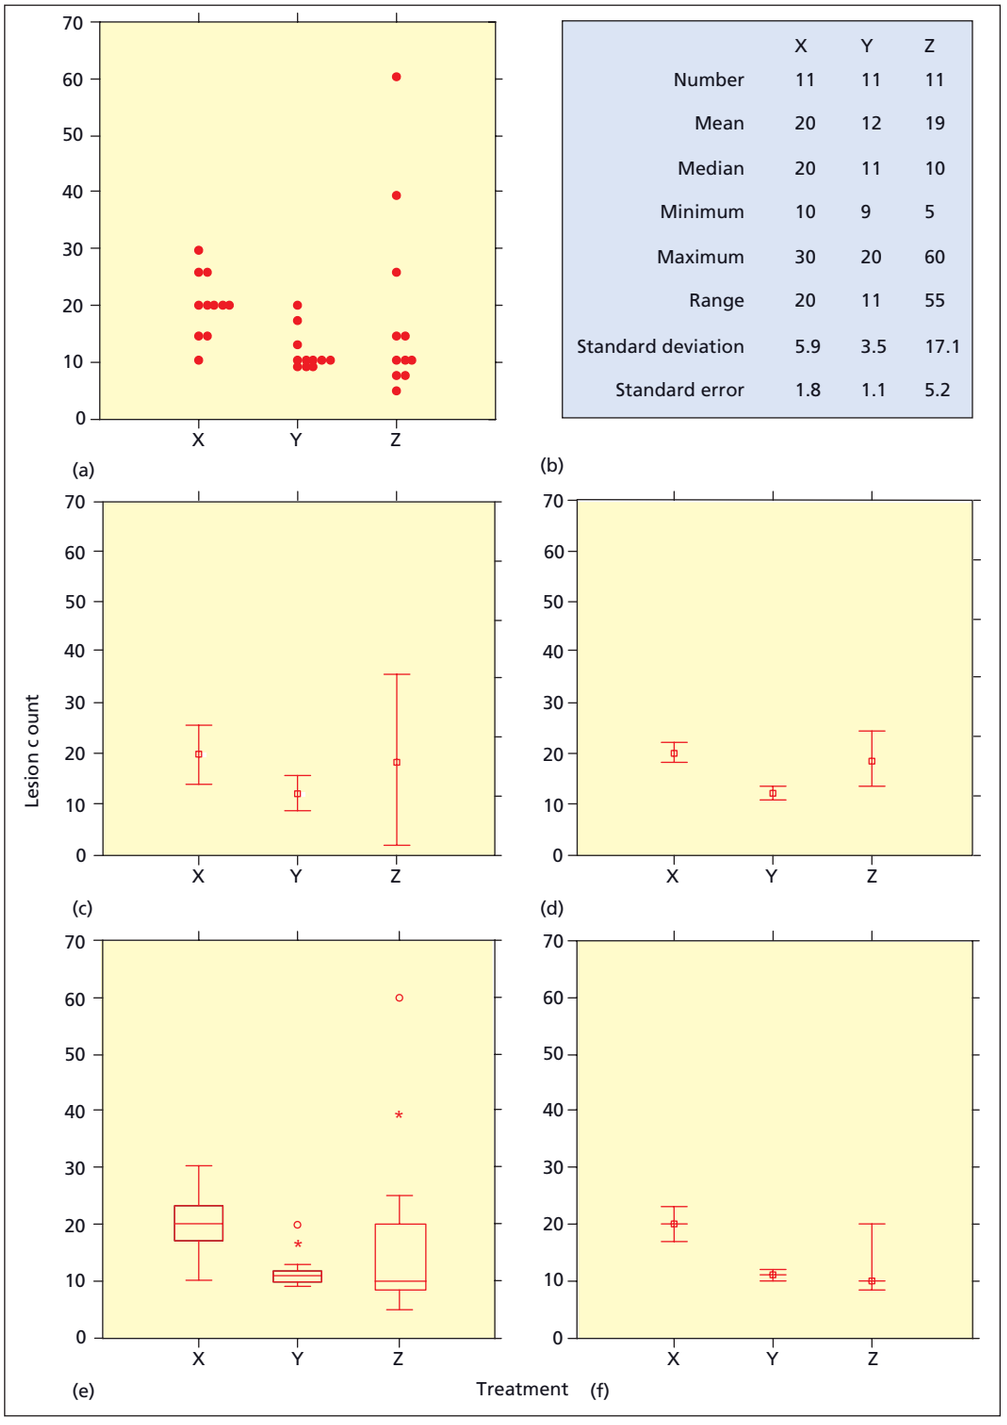
Step	Comments
Read title	If interesting, continue.
Read abstract	If still worthy of your time, continue.
Look at figures and tables	Find most important data. Are the data adequately reported? Is there a control group? Are outcomes clinically important? Are data subjected to statistical testing and are tests used correctly? If still worthy of your time, continue.
Read results	Are complications reported? Are compliance and lost patients considered? Ask yourself 'If everything the authors say is true, is it important for my patients, my practice or for the field of dermatology?' If 'no,' stop reading; if 'yes' or 'possibly,' continue.
Read methods	How were patients chosen and allocated? Are outcomes clearly defined and assessed blindly? Are the conclusions valid? If yes, continue.
Record citation	Note authors, citation and conclusions of the study for easy retrieval later.
Read discussion	
Read introduction	

is worthy of your time, look at the figures and tables. Authors generally display their best or most convincing data in figures and tables [6]. In a well-written study, you should be able see the important results in summary figures and tables. Try to pick out the one or two figures or tables that hold the most important data. Look at the data to see whether they are summarized and displayed correctly (see section Evaluating the data in clinical research papers, below). Determine whether there is an appropriate control group, whether the outcomes are clinically and biologically important, whether the data are subjected to statistical analysis and whether the correct statistical methods were used. *It is important that you examine and assess the data yourself.* If you are still convinced that the article is worthy of your time, then read the results. Determine whether complications are reported, and whether compliance and lost patients were considered. After reading the results ask yourself the question, 'If everything the authors say is true, is it important for my patients, for my practice or for dermatology as a whole.' If the answer is an emphatic 'no', stop reading; if 'yes or possibly', continue to the methods.

While reading the methods pay particular attention to the features that strengthen clinical trials and that help in validating their conclusions. In particular, determine the eligibility criteria, whether patients were randomly allocated, and whether the outcome is clearly defined and assessed masked. Make an effort to find out who paid for the study and whether all possible conflicts of interest were declared [7]. If your conclusion is that the trial was conducted in a reasonable manner and the conclusions are valid, then make some notation of whom the authors are and the conclusions of the study. Several software packages for cataloguing and managing references are available for most computer platforms (e.g. EndNote and Reference Manager). Finally, if you still have time and interest, read the discussion and introduction, in that order.

Evaluating the data in clinical research papers [1]

Are the data adequately reported?



The authors of a study should present their results in sufficient detail to allow the reader to perform his or her own preferred analysis of the data. At a minimum, the presentation of interval data (i.e. discrete or continuous data such as lesion counts or area of involvement) should include a summary measure of the centre of the data for each group (usually the mean and/or median) and a measure of the variability of the data.

The mean is simply calculated as the sum of the data points divided by the total number of data points. The mean is the most appropriate choice for normally distributed data (i.e. data that are distributed in the shape of the bell curve). The median is a better choice for data that are skewed or that contain outliers (Fig. 7.5a,b). The median for an odd number of data points is the value in the middle when the data are ordered from lowest to highest. The median for an even number of data points is determined by taking the mean of the two numbers in the middle when the data points are ordered from lowest to highest. Thus, half of the data points fall above and half fall below the median. The magnitude of the difference between the mean and the median is a crude indicator of the degree of skewing. If the difference is none or small the data are or approach normal (i.e. are symmetrically distributed); if the difference is large the data are skewed.

The standard deviation, range, inter-quartile range, and 95% confidence intervals are commonly used to indicate the variability or spread of the data (Fig. 7.5b,f). The standard deviation (SD) is the square root of the average squared deviation of values from the mean. That is:

$$\mathrm{SD} = \sqrt{\sum \left(X - \bar{X}\right)^2 / (n-1)}$$

The SD is an important summary statistic for normally distributed data only. For normally distributed data, approximately 68% of the data points will lie within the range from the mean minus one SD to the mean plus one SD (mean ± 1 SD); and 95% of the data points will lie within the range from the mean minus two times the SD to the mean plus two times the SD (mean ± 2 SD). These relationships do not apply to skewed data or to small data sets that contain outliers. Note in Fig. 7.5c that the mean and SD do not adequately describe the centre of the data or its distribution for skewed data, or for data with outliers (treatments Y and Z). The range is the interval from the highest to the lowest data points. The range may be a good indicator for variability for data that are tightly arranged around the mean and for small data sets. The range is greatly influenced by outliers and may not give adequate indication of skewed data. Therefore the range is not a good descriptive statistic for skewed data sets or for data with outliers (Fig. 7.5a,b). The inter-quartile range is the interval that contains the middle 50% of the data points. It excludes the highest 25% of the data points and the lowest 25%. The inter-quartile range is a reasonable descriptive statistic to describe skewed data and data with outliers (Fig. 7.5e). Confidence intervals are the best way to present the degree of uncertainty of normally distributed data as well as skewed data or data with outliers (see discussion of confidence intervals below). The 95% confidence interval around the mean can be calculated for normally distributed data using the

	X	Y	Z
Number	11	11	11
Mean	20	12	19
Median	20	11	10
Minimum	10	9	5
Maximum	30	20	60
Range	20	11	55
Standard deviation	5.9	3.5	17.1
Standard error	1.8	1.1	5.2

Fig. 7.5 Hypothetical final lesion counts in a clinical trial of treatments X, Y and Z. The same data are displayed or summarized in each panel. A graphical display of all of the data points (a) gives an accurate description of the magnitude and distribution of the results. Commonly used summary statistics are given in (b). The mean with error bars consisting of one standard deviation (c) or one standard error (d) provide little useful information even for the normally distributed response to treatment X, and are totally misleading for treatment Y and for treatment Z which has outliers. A box plot of the data (e) shows the median (line within the box), the interquartile range (top and bottom of the box), and adequately represents skewed data (note asymmetry of median within the box in the Y plot) and the presence of outliers (note asymmetry of median within the box in the Z plot and the outliers indicated by asterisk and open circle). The 95% confidence interval about the median (f) adequately represents skewed data and the presence of outliers. If the 95% confidence intervals around two means or medians do not overlap, you can be confident at about the 95% level that the two population means or medians are different.

sample mean, standard error and the *t* distribution. For skewed data, the confidence interval around the median should be used (Fig. 7.5f). The confidence interval provides a range of values in which the 'population' or true response to treatment lies. For example, the population or true mean has only a 1 in 20 (5%) chance of lying outside the 95% confidence interval. If the 95% confidence intervals around two means or medians do not overlap, you can be confident at the 95% level that the two population means or medians, from which the samples were drawn, are different.

The standard error (SE) is the standard deviation divided by the square root of the number of data points ($SE = SD/\sqrt{n}$). Unfortunately, the SE is commonly, but incorrectly, used to summarize the variability of data. This choice is made partly because of tradition

and partly because the SE is always smaller than the SD and 95% confidence interval and, therefore, looks better (Fig. 7.5c,f). The SE is correctly used to analyse normally distributed data in inferential statistics (see discussion of the *t*-test below). The common practice of reporting the mean ± SE is firmly ingrained in the medical and scientific literature but is often misleading and inappropriate, and should be discouraged. The SE is an important and useful statistic only for normally distributed data sets. It is used to make predications or inferences about the population from which the sample is chosen. That is, for large, normally distributed data sets, the chance that the true or population mean (from which the sample was drawn) will lie outside the range [mean ± 2SE] is only 5%. The relationship between the sample mean, the population mean and the SE does not apply to skewed data or to small data sets that contain outliers.

Descriptive statistics are at best incomplete summaries of the data; considerably more information may be conveyed by graphic displays (see Fig. 7.5). The production and interpretation of graphic displays is well reviewed by O'Brien and Shampo [8]. Figures that show individual observations are an excellent tool for presenting small datasets, and for data that are skewed or have outliers (Fig. 7.5a). Unfortunately, such diagrams are under-utilized in the scientific and medical literature. Graphic displays of data using 'error bars' showing 1 SD or 1 SE depict at best 68% of the sample or 68% confidence intervals respectively and, therefore, are misleading and should be avoided or approached with scepticism (Fig. 7.5c,d).

Categorical data are preferably presented in tables in which treatments and outcome are represented in rows and columns. Examples of categorical outcomes include cured and not cured, survived and died, and minimal, moderate and marked improvement. Categorical outcomes should be clearly defined, limited in number, clinically important and declared before the trial is begun.

Are data subjected to statistical testing and are tests used correctly?

Observed differences in outcome in clinical trials may be due to chance alone. It is therefore imperative that statistical analyses be performed to verify that the results are from treatment and not from chance. This admonition is especially true for trials containing few patients, which includes many published dermatological trials.

Statistical methods

Understanding P

Understanding the meaning of *P* is fundamental to understanding and interpreting statistical testing. In the simplest terms, all clinical trials begin with the null hypothesis that the treatments are the same. If the results of the trial indicate that the outcomes of treatment are different, then a statistical test is performed to determine whether the difference can be from chance or from sampling variation alone. If chance is not a likely explanation of the difference, the null hypothesis that the treatments are the same is rejected. '*P*' represents the probability that a difference as large as the observed difference might arise by chance if the treatments are the same. The error of believing that a difference in treatments exist, when in fact there is no difference in treatments and the observed differences were from chance or sampling variation alone, is referred to as a Type I (or Type α) error. The statement that 'the difference was statistically significant ($P = 0.05$)' means that the probability that a difference as large as the observed difference might have arisen by chance is 1 in 20, and that the author will accept this degree of chance as being sufficiently unlikely that the null hypothesis that the treatments are the same can be rejected. Conversely, the statement that 'the difference was not statistically significant ($P = 0.10$)' means that the probability that a difference as large as the observed difference might have arisen by chance was 1 in 10, and that the author will not accept this degree of chance as being sufficiently unlikely that the null hypothesis that the treatments are the same can be rejected. It is important to remember that 'not significant' means that a difference is not proven; it does not mean that there is no difference.

The acceptance of a significance level of 0.05 as the cut-off for rejecting the null hypothesis is a tradition based on quality control standards and is not an absolute truth. At times, more stringent standards are required and, paradoxically, tests that do not meet the $P = 0.05$ standard may sometimes be significant. For example, in a trial of a new chemotherapeutic agent involving 30 randomized patients with metastatic melanoma, 7 of 15 patients treated with the new agent survived 5 years compared with 3 out of 15 control patients treated with conventional surgery, chemotherapy and radiation. Whereas the result does not achieve statistical significance when compared by chi-squared testing (see below) (Yates corrected chi-squared = 1.35; $P = 0.25$), the result is, nonetheless, potentially significant. If the therapy is beneficial and the estimated difference in response rates is the true difference in response rates, it might result in the saving of 2072 lives annually (based on 7770 deaths from melanoma annually and the degree of survival advantage in this hypothetical example). Because of the biological and clinical importance of the results suggested by the study, the treatment should be subjected to study in a larger patient population with more power to detect a difference if one exists (see discussion of power below). Others might argue that the adherence to the 95% standard ($P = 0.05$) should be relaxed in cases such as this. The potential benefit of the treatment may be revealed by the use of confidence intervals (see discussion of confidence intervals below).

Investigators should indicate what statistical procedures were utilized to compare results. Simply stating that the difference was statistically significant ($P < 0.05$) does not constitute an adequate description of the statistics used. The exact procedure used (e.g. *t*-test or chi-squared test), and the results obtained, must be specified. The *t*-test and the analysis of contingency tables (e.g. chi-squared and Fisher's exact test) are the most commonly employed procedures, and should be understood by all physicians.

The t*-test*

The *t*-test is the most commonly used statistical test in the biomedical literature. The *t*-test is used to determine whether the difference in the means of two samples is from chance (sampling

variation) alone. It should be emphasized that the *t*-test at a significance level of 0.05 is designed to compare the difference in the means of only two samples or populations. The *t*-test has additional important restrictions. It should only be used to compare the means of interval data that are normally distributed. Additionally, the data analysed by the *t*-test should be sufficiently large, should not contain outliers, should be statistically independent and the variability of the two treatment groups should be similar. In most instances a two-sided *t*-test is appropriate. When a one-sided *t*-test is performed the reasons should be specified. The unpaired *t*-test should be used to analyse two different groups (e.g. patients receiving alternative treatments). The paired *t*-test should be used to analyse the effects of two different treatments on the same patients (e.g. in a cross-over or left–right comparison study).

Statistical analysis using the *t*-test will be illustrated using data from a study comparing calcipotriol and betamethasone ointments in the treatment of stable plaque type psoriasis [9]. In this multicentre RCT, 201 and 200 patients were randomized to treatment with calcipotriol and betamethasone respectively. Outcomes were measured by changes in PASI scores. At the end of 6 weeks of treatment the improvement (decrease) in PASI scores were 5.50 and 5.32 for calcipotriol and betamethasone respectively. The statistical significance of the small difference in the change in PASI scores was evaluated using an unpaired *t*-test. The *t* value and corresponding significance level can be determined using computer programs or calculated using a *t*-distribution table and the formula. Not surprisingly, the result indicated that the difference was not statistically significant ($P = 0.76$). Thus, the trial failed to demonstrate a difference between the two treatments.

Misuse of the *t*-test was one of the most commonly encountered errors in the use of statistics found by Gore *et al*. in his review of the use of statistical methods in the *British Medical Journal* [10]. They found that 52% (32/62) of analytical reports that utilized statistical analyses contained at least one error in the use of statistics. Eleven of the errors were misuse of the *t*-test. The errors included using the *t*-test to analyse data that were not normally distributed (non-parametric), had different variability or had used an unpaired *t*-test to analyse paired data. Another commonly encountered error in the use of the *t*-test is its use to compare the means of more than two samples. This error in the use of the *t*-test occurred in 61% and 44% respectively of articles that used statistical analyses published in *Circulation Research* and *Circulation* in 1977 [11].

The *t*-test should not be used to analyse data that are skewed, or data in which the variability (SD) are very different between treatment groups. Nor should it be used to analyse small data sets, because it is impossible to verify that small data sets are normally distributed. In these situations, the Mann–Whitney U test, the distribution-free equivalent of the *t*-test, may be used for unpaired data and the Wilcoxon test can be used for paired data. The *t*-test should also not be used to compare more than two groups because it ignores possible associations among groups and thus increases the likelihood that spurious results will be obtained. Comparison of means of more than two groups can be performed with different forms of analysis of variance.

Table 7.9 Format of a fourfold contingency table.

	Good response	No or poor response	Total
Treatment A	a	b	H1
Treatment B	c	d	H2
Total	V1	V2	N

The chi-squared for unpaired data is calculated using the formulas:

$$\text{chi-squared (uncorrected)} = \frac{|a \times d - b \times c|^2 N}{H1 \times H2 \times V1 \times V2}$$

$$\text{chi-squared (Yates' corrected)} = \frac{|a \times d - b \times c| - 0.5 \times N|^2 N}{H1 \times H2 \times V1 \times V2}$$

in which $|a \times d - b \times c|$ indicates the absolute value of $a \times d - b \times c$.

Contingency tables

Chi-squared is the most commonly used test to determine whether the categorical data in contingency tables differ because of chance alone. The format of a typical fourfold (2×2) contingency table is shown in Table 7.9. The numbers in the table (indicated by a, b, c and d) are the numbers of patients in each treatment group that fall into each outcome category. The assumption made to formulate the null hypothesis that the treatments are the same is that the overall response rate (i.e. the total number of patients with good responses divided by the total number of patients; V1/N in Table 7.9) is the same for both treatments. Chi-squared is then used to determine how likely it is that the actual numbers observed could be obtained by chance or sampling variation if the response rate for the two treatments were the same. A continuity correction in the chi-squared is recommended to analyse smaller data sets (20 to 40 patients). This correction is used to account for the use of continuous curves to approximate the discrete frequencies in contingency tables. The Yates correction is most commonly used (Table 7.9). Chi-squared should not be used to analyse small trials (trials with less than 20 patients) or when the predicted number of patients in any cell (positions a, b, c or d in Table 7.9) is less than five. In such circumstances, the Fisher exact test should be performed. Chi-squared is used to analyse unpaired data and McNemar's test is used to analyse paired contingency table data. Contingency table analyses can be easily modified and used to compare more than two treatments and more than two outcomes.

Like the *t*-test, the chi-squared test is frequently used incorrectly in published clinical trials. In their analysis of the use of statistics in medical papers published in the *British Medical Journal*, Gore *et al.* found that chi-squared was used incorrectly in 12 of 62 published papers [10]. The errors included omission of the continuity correction for studies with few patients, omission of a clearly stated hypothesis to be tested, lack of consideration of degrees of freedom and misuse of the test to study paired data.

Confidence intervals

Standard statistical hypothesis testing generally results in a determination of a *P* value that represents the probability that a differ-

ence as large as the observed difference might arise by chance. If this probability is equal to or less than a predetermined 'critical value' (usually 0.05), then the null hypothesis is rejected and the difference is considered statistically significant. If the *P* value exceeds the predetermined value, the null hypothesis is not rejected and the difference is considered not statistically significant. This dichotomous treatment of the results of clinical trials as being significant or not significant may sometimes be misleading and may hide meaningful estimates in the differences between the treatments. What matters most in a therapeutic trial is whether investigators have been able to detect a medically significant difference in treatments and how large the difference is likely to be, as described above in the hypothetical study of treatment for melanoma. The conventional significance levels are useful guides to the interpretation of trial results but they should not be considered strict rules. The absurdity of the dichotomous significance testing approach is best appreciated by considering two trials, one of which has a *P* value of 0.05 and the other a *P* value of 0.06. The difference in the level of significance is very small, yet the former is considered statistically significant and the latter is not.

Reporting results with confidence intervals is an alternative or complementary way to present the results of clinical trials. Many believe that it is far preferable. In simple terms, the reported result provides the best estimate of the treatment effect and the confidence interval provides a range of values in which the 'population' or true response to treatment lies. For example, the population or true mean has only a 1 in 20 chance of falling outside the 95% confidence interval. Alternatively if the trial is repeated many times, 95% of the confidence intervals produced will contain the true or population mean response to treatment. The true response rate will most likely lie near the middle of the confidence interval and will rarely be found at or near the ends of the interval.

The confidence interval provides a direct, numerical measurement of the imprecision of the estimate of the response to treatment that is due to sampling variability. The width of the confidence interval is determined by the sample size (the larger the sample the narrower the interval), the variability of the response being measured (the larger the variability the wider the interval) and the degree of confidence desired (the higher the confidence desired the wider the interval) (Fig. 7.6). Confidence intervals can be determined for means and their differences, and for proportions and their differences, by looking them up in tables, by calculating them with formulas or by using computer software. It is important that, in comparative studies, confidence intervals should be reported for the differences between groups, not for the results of each group separately.

There is a close relationship between the results of a test of a hypothesis and the associated confidence interval; if the difference between treatments is significant at the 5% level, then the associated 95% confidence interval excludes the zero difference. The advantage of using confidence intervals instead of, or in addition to, *P* values is that confidence intervals provide an indication of size of the differences in treatments and give numerical measurements of the inexactness in our knowledge of the real differences in treatments.

Confidence intervals can be valuable in interpreting data from trials in which the difference is not statistically significant (i.e. the

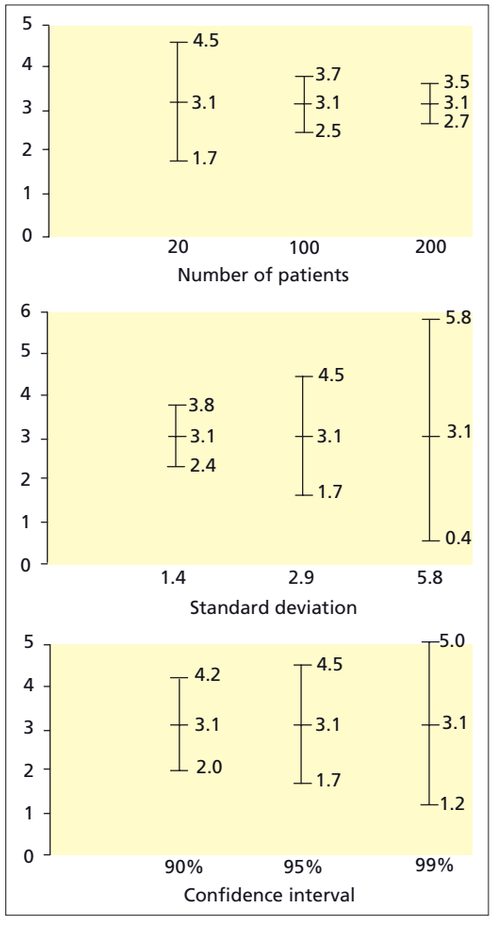


Fig. 7.6 The confidence interval is dependent on the sample size, sample variability and confidence level desired. In the top panel, the mean change in PASI score was 3.1 with a standard deviation of 2.9. The 95% confidence interval is shown and narrows as the number of patients studied increases from 20 to 200. In the middle panel, the mean change in PASI score of 20 patients was 3.1. The 95% confidence interval is shown and widens as the sample variability (standard deviation) increases. In the lower panel, the mean change in PASI score of 20 patients was 3.1 with a standard deviation of 2.9. The confidence interval widens as the degree of confidence desired increases from 90% to 99%.

P value is greater than 0.05). To determine whether a treatment effect may have been missed in a study reporting negative results, one should look at the upper boundary of the 95% confidence interval. If this value would be clinically important if it were the true response, then an important treatment effect may have been missed in the study. In the calcipotriol and betametasone trial as an example, the upper boundary of the difference in PASI scores was 0.78. As the range of possible PASI scores is 0–72, this small degree of difference in PASI scores would be unlikely to have much clinical significance and therefore it is unlikely that a significant treatment advantage for calcipotriol was missed in this study.

In contrast, consider our hypothetical new treatment for metastatic melanoma that had a 5-year survival rate of 7/15 versus 3/15 for conventional treatment. The cure rates for the new treatment and for conventional treatment were 47% and 20% respectively, and the difference between them was 27%. The 95% interval

for the difference in proportions was –10% to 51%. The upper boundary of the difference in cure rates was 51%. This difference would clearly have a significant impact on the treatment of patients with metastatic melanoma and, therefore, a significant treatment advance may have been missed in this study. Also note that the 95% confidence interval of the difference in proportions does not exclude the zero difference; therefore, we cannot be 95% certain that the response rates of the two treatments are different.

Confidence intervals also may be useful in interpreting the response to a single treatment. Ninety-five per cent confidence intervals for the response rate of a single treatment can be determined using formulas, tables, nomograms and computer programs. An important point can be made from determining the confidence interval of a single proportion. There is a degree of uncertainty in reported response rates that can be expressed in exact numerical terms by determining the confidence interval.

Confidence intervals also may be useful in interpreting the rate of side-effects observed in a clinical trial. For example, in the calcipotriol study 40 out of 201 patients (20%) treated with calcipotriol developed lesional or perilesional irritation. The 95% confidence interval for this adverse reaction would be 14% to 26%. Thus a high rate of local irritation can be anticipated with calcipotriol and the rate may be as high as 26%. If no untoward reactions occur in a study, it is still possible to determine the 95% confidence interval of adverse reactions. Accurate upper limits of the reaction rate can be obtained by referring to available tables. A reasonable approximation of the rate of adverse reactions in this situation can be obtained by dividing 3 by the number of patients who were exposed to the studied treatment.

Power

Significant differences in treatment effects in comparison trials may be missed if the number of subjects tested is small. For example, in a 1978 survey of 71 published trials with negative results, Freiman *et al.* found that a 25% or 50% improvement in outcome might have been missed in 57 (80%) and 34 (48%) of the studies respectively [12]. The importance of this observation, and the importance of determining the power of studies to detect clinically significant differences in treatments, is illustrated by the fact that this study has been cited more than 700 times. Despite the recognition of the importance of power, a follow-up study conducted by Moher *et al.* in 1994 indicated that 25% or 50% improvements in outcome might have been missed in 84% and 64% of 102 negative studies respectively [13].

Power is an expression of the ability of a trial to detect a difference in treatments, if one exists. The investigators in a well-designed clinical trial should have an estimate or prediction of the anticipated differences among treatments and knowledge of the magnitude of differences that would be clinically important. The trial should then be designed to enrol sufficient patients to ensure, with reasonable certainty, that a statistically significant difference would be obtained if the anticipated or clinically important differences between the treatments existed. The error of believing that there are no differences between treatments, when in fact there are differences, is a Type II (Type β) error.

The power of a trial to detect a significant difference is determined by the response rates of the treatments, the significance level desired by the investigators and the number of patients treated. The power of a trial to detect differences between treatments can be calculated using formulas, nomograms, programmable calculators or computer software. Conventionally, a power of 80% with a significance level of 0.05 is considered adequate. The choice of a power of 80% means that, if the anticipated or clinically important difference in treatments really exists, four of five trials with the specified number of patients in the treatment groups will show a statistically significant difference. However, higher power sometimes may be desirable. For example, increasing the power to 90% means that 9 of 10 trials would detect a statistically significant difference between treatments if the difference really exists. The power of a study design to detect clinically significant differences in treatments is best considered before the trial is initiated. However, studies that fail to demonstrate statistically significant differences among treatments should always include a discussion of power.

The sample size needed to detect a difference is small when the difference in treatments is large. Conversely, the sample size needed to detect differences is large when the difference in treatments is small or when the response rate of the comparison treatment is high.

As noted by Moher *et al.* [13], 'If a trial with negative results has a sufficient sample size to detect a clinically important effect, then the negative results are interpretable—the treatment did not have an effect at least as large as the effect considered to be clinically relevant. If a trial with negative results has insufficient power, a clinically important but statistically insignificant effect is usually ignored or worse, is taken to mean that the treatment under study made no difference. Thus, there are important scientific reasons to report sample size and/or power calculations.'

The importance of statistical analyses must be kept in proper perspective. Statistics are a tool for trying to ensure that results of clinical trials are not due to chance or sampling variation alone. The combination of hypothesis testing and the use of confidence intervals give a measure of the likelihood that results of a trial are due to chance, and the precision of the estimated difference in treatments, respectively. Statistical analyses cannot tell you the medical significance of differences in treatments. In other words, statistically significant should not and cannot be equated with medically significant. Conversely, a trial the results of which indicate that the difference in treatments was not statistically significant does not necessarily mean that there is not a medically important difference between treatments. It may simply mean that too few patients were used to detect the difference that does exist.

Introduction

Human life is a continuum, but within which are several identifiable phases. Life passes through a period of development to 'maturity', which is then followed by a process of intrinsic ageing leading inexorably to senescence. Throughout life, alterations take place in the structure and function of the skin and there are important differences in the range, presentation, prognosis and treatment of skin disorders at various ages. Indeed, some of the physiological events that accompany puberty, pregnancy, the menopause and old age can, of themselves, be sufficient reason for a patient to seek specialist dermatological advice.

This chapter provides an overview of the skin during these stages in life. The dermatological problems of the neonatal period and infancy have been dealt with elsewhere (see Chapter 17). This chapter deals principally with the skin and its disorders during puberty, the menstrual cycle, pregnancy, childbirth and the puerperium, mid-life, the menopause and old age.

Birth to puberty

Somatic growth

Growth, defined as an increase in size, occurs in most tissues, including the reproductive system. In particular, the changes in the skeleton, which can be monitored radiologically, and in the visible teeth, have traditionally been used as indices of maturity [1]. However, there is increasing evidence that there is no connection between skeletal maturity and onset of puberty [2].

Between birth and maturity the skeleton and body keep in step with increases in weight of 20- to 25-fold, whereas the somatic muscles increase by 30- to 40-fold and the nervous system by less than fivefold. The surface area of the skin increases sevenfold. In the first year after birth the body length increases by approximately 50% to around 75 cm and another 12–13 cm are added in the second year. Subsequently, growth remains steady at 6 cm/year until the spurt associated with puberty. Weight follows a similar pattern [1].

Five highly related genes encode human growth hormone (GH). One of these is expressed solely in the anterior pituitary somatotrophs and the rest in placental villous syncytiotrophoblasts. The initiation of *GH* expression during development depends upon epigenetic modifications at the *GH* locus under the control of its distal locus control region [3]. The expression of certain other developmental genes, such as *Pit1,* is necessary to produce GH [4].

Postnatal growth is dependent on GH, secreted by the anterior pituitary gland, although other hormonal interactions may also be necessary. GH is a protein with 191 amino acids, which exerts an effect on a number of tissues, including the viscera and bone. In particular, it affects stature by stimulating proliferation of cartilage cells at the epiphyseal plates until the point when the epiphyses of the long bones have fused. GH also antagonizes the actions of insulin, possibly by reducing its binding at target sites, or by interacting with a second-messenger system. Some of the effects of GH are indirect, in the sense that they are mediated through the production of polypeptide growth factors in the target

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

tissue. The most important of these are insulin-like growth factor 1 (IGF-1) and IGF-2 [5].

The secretion of GH from the pituitary is mediated primarily by the interaction between hypothalamic GH-releasing hormone and somatostatin, a 14-amino acid polypeptide that has numerous regulatory and neuromodulatory effects. Negative feedback both by IGF-1 and GH itself may also be involved, as may cell–cell interactions, between somatotrophs and between somatotrophs and folliculostellate cells respectively in the anterior pituitary [4]. The basal concentration of GH in the plasma is below 1 mIU/L, but it can reach peaks of up to 60 times this amount in adolescence. Bursts of GH secretion occur every 1–2 h during sleep, but can also be provoked by physiological and psychological stresses.

Excessive GH secretion before puberty gives rise to gigantism, but once the epiphyses of the long bones have fused it results in thickening of the bones and enlargement of the hands and feet, known as acromegaly. Acromegalics also have, on average, abnormally high sebum secretion, mediated by the increased activity of GH and IGF-1 [6]. The range of skin manifestations in acromegaly is discussed in Chapter 62.

Deficiency of GH, either in isolation or as a component of general hypopituitarism, is one cause of short stature [7].

Sexual development

The period between infancy and puberty that we call childhood is, in relation to sexual development, a hiatus in hormonally controlled events that have already been initiated in the fetus. While the dermatological problems of the neonatal period are so distinctive and of such practical importance as to merit a separate chapter, an understanding of the hormonal status of the fetus and the neonate and of the cutaneous implications, is an essential starting point in this journey.

Sex determination as a mechanism equates to a binary switch that locks the embryonic gonads, at a molecular level, into either future testes or ovaries. The initial event in both sexes is the formation of a bipotential primordium. Several genes are involved in this initial stage including *LIM1* (*LHX1*), *SF1* (*ZPF162*), *WT1*, *EMX2* and *LHX9* [1]. Males become differentiated from females by their possession of a Y chromosome, which causes the undifferentiated gonads to become testes. A number of genes are involved in this process, including *SRY*, *SOX9*, *DAX1 (NROB1)*, *SF1* and *ATRX* [1,2]. Anti-Müllerian duct hormone (AMH) is a 560-amino acid glycoprotein secreted from the Sertoli cells of the testis [3]. AMH causes the degeneration of the Müllerian duct between the seventh and eighth weeks of gestation [3]. When fragments of fetal testes or isolated Sertoli cells are placed adjacent to cultured tissue segments containing portions of the Wolffian and Müllerian ducts, the Müllerian duct atrophies even though no change occurs in the Wolffian duct. AMH is thought to bind to the mesenchyme cells surrounding the Müllerian duct and to cause them to secrete a paracrine factor that induces apoptosis in the Müllerian duct epithelium [3]. Oestrogen is needed for the complete development of both the Müllerian and the Wolffian ducts. In females, oestrogen secreted from the fetal ovaries appears sufficient to induce the differentiation of the Müllerian duct into its various components: the uterus, oviducts and cervix [3]. Testosterone, which causes virilization of the Wolffian duct, is needed to form most of the male system. Conversion of testosterone to 5α-dihydrotestosterone is necessary for the development of the prostate from the urogenital sinus and of the external genitalia. In the latter trimesters of intrauterine life, the testicles descend to their position in the scrotum in response to gonadotrophin from the fetal pituitary, as well as testosterone.

The fetal testis continues to secrete testosterone even after birth [4]. At 50 days of age the level of plasma testosterone (250 ng/100 mL) is more than seven times that in umbilical cord blood (35 ng/100 mL) and is unlikely to be of maternal origin. By about the age of 6 months the plasma level of testosterone falls, and is maintained at a low concentration for the rest of childhood.

In males, the production of testosterone appears at first sight to correlate with activity of the sebaceous glands, which become functional by 17 weeks of gestation. The glands are large at birth and the skin surface lipid is high, approximately 400 g/cm^2, remaining so for approximately 3 months [5]. The level throughout the rest of childhood is maintained at approximately 100 g/cm^2. Neonatal skin-surface lipid is, however, as high in females as in males, although the hormonal pattern is quite different; the maximum plasma testosterone occurs immediately after birth and falls very rapidly [4]. The pattern of dehydroepiandrosterone, however, very closely follows that of sebum levels in both sexes [6]. For these reasons, it seems possible that the production of sebum in the neonatal period and the occurrence of acne in prepubertal children may be related to adrenal activity.

Sebaceous activity starts to increase again towards the end of childhood, in advance of other signs of approaching puberty [7]. Dramatic changes take place between the ages of 8 and 9 years, in both males and females and it seems possible that these are related to an increase in output of adrenal androgens. Comedones may develop around this period [7].

The skin in childhood

The skin, along with other organ systems, undergoes some degree of maturation during the hiatus of childhood, before the resumption of sexual development at puberty and the transition to adulthood. The skin disorders seen in children in part reflect these physiological changes, but many of the most troublesome cutaneous problems encountered result from intrinsic genetic abnormalities conditioned by environmental influences. Perhaps the best example is atopic eczema (see Chapter 24), which has now reached very high levels of prevalence in some societies [1–3]. The ways in which the environment affects the child changes, as he or she becomes more mobile and travels further afield, thus becoming exposed to potential antigens.

School years bring exposure to a wide variety of infections and contagions, such as measles, chickenpox, impetigo, warts, molluscum contagiosum, scabies and head lice. There is also a gradual increase in contact with potential irritants: at school during lessons, in sporting activities such as swimming and team games and in hobbies. The wearing of jewellery and cosmetics and exposure to sensitizers such as rubber chemicals in footwear and preservatives in medicaments, bring a further range of dermatological problems in the form of allergic contact dermatitis, which is not as rare before puberty as is often suggested [4]. One disorder that appears to have a definite predilection for the prepubertal period in girls is lichen sclerosus [5], which may, but does not always, improve and disappear as puberty approaches [6]. In boys, the same pathological changes are frequently found in prepuces removed to relieve phimosis.

There is an increasing awareness in recent years that both girls and boys may present to the dermatologist with symptoms and signs that indicate sexual abuse [7]. Vulval or perianal soreness and inflammation for which no other cause can be found should be considered suspicious, as should the presence of anogenital warts [8], although these may be acquired innocently. Proof of sexual abuse is always difficult unless there has been disclosure or confession from within the family unit. Furthermore, the social and legal implications of formal investigations for the child and his or her family are enormous. Inquiries must therefore be undertaken with care, although there is a well-established framework in many countries to deal with the problem, generally involving paediatricians, social workers and the police [7]. It is important to note that the changes associated with lichen sclerosus and Crohn's disease in childhood can be mistaken, by non-dermatologists, for evidence of sexual abuse [7], although their presence does not exclude it.

Syndromes of short stature

There is no uniformly agreed definition of short stature, although a reasonable cut-off would seem to be below the third centile for the child's community [9]. There are several disorders in which abnormal or delayed growth and development are accompanied by cutaneous changes. Some lead to short stature (a term preferred to 'dwarfism'), which is a common feature of chromosomal abnormalities. In others, delayed sexual development (infantilism) is also present and this will be discussed briefly in relation to premature and delayed puberty. It is important to note that due allowance must be made for parental height in assessing possible delayed growth in a child [10]. Some of the more important of the disorders in which skin changes accompany short stature are listed in Table 8.1.

Table 8.1 Disorders in which short stature may occur with cutaneous changes.

Often severe	Moderate
Rothmund–Thomson syndrome	Turner's syndrome
Bloom's syndrome	Hypohidrotic ectodermal dysplasia
Cockayne's syndrome	Marinesco–Sjögren syndrome
Bird-headed dwarfism	Xeroderma pigmentosum
Progeria	Trichorhinophalangeal syndrome
Cornelia de Lange syndrome	Focal dermal hypoplasia
Cartilage–hair hypoplasia	Werner's syndrome
Conradi's disease	Darier's disease
Polydysplastic epidermolysis bullosa	Atopic dermatitis
Ataxia–telangiectasia	
Leprechaunism	
Growth retardation, alopecia, pseudo-anodontia, optic atrophy (GAPO)	
Short stature, alopecia and macular degeneration	

Furthermore, it is well known that severe skin disease of any kind in childhood can have a considerable impact on general physical development. Atopic eczema is a good example, short stature being very common in severely affected individuals, at least until puberty [11], although the assessment of this may be complicated by systemic or topical steroid therapy.

Puberty and adolescence

Hormonal events and cutaneous changes

Puberty is the attainment of the ability to reproduce. The term adolescence embraces these events, but is also used in a wider sense to include the phase of psychological and social adjustment to the physical changes. Thus, depending on the society, adolescence may be prolonged well beyond the completion of puberty [1].

Puberty occurs physiologically because the hypothalamus begins to secrete one key decapeptide, gonadotrophin-releasing hormone (GnRH). The release of GnRH is under the permissive control of the kisspeptin neuropeptide, acting on its GPR54 receptor on the GnRH neurones [2,3]. Glutaminergic input from glial cells may also be important in triggering the increased pulsatility of GnRH secretion [4]. Activated transiently during the first months of postnatal life, the GnRH system remains dormant until its reactivation signals the onset of puberty [5]. Its pulsatile release into the hypothalamohypophyseal portal system then stimulates the production and release of the pituitary gonadotrophin hormones follicle-stimulating hormone (FSH) and luteinizing hormone (LH). These gonadotrophins induce the maturation of the testis and the ovary, which then produce sex steroid hormones and mature sperm and eggs. It should be noted that production of oestrogens at puberty is important for sexual development in both girls and boys. GnRH release is inhibited by negative feedback of the gonadotrophins, neuropeptide Y, opiate peptides, gamma amino butyric acid and, prior to the pubertal surge, steroid hormones and a peptide called inhibin, which is produced by the gonads [4–6].

In the male, initiation of spermatogenesis requires both LH and FSH, but secretion of testosterone by the Leydig cells needs only LH. Levels of serum FSH and LH rise between the ages of 6 and 17 years in both sexes [6]. As puberty develops, LH is released in pulses, at first only at night but later also during the day [6]. The onset of puberty in the male is heralded by an increase in testicular volume resulting from the appearance of a lumen in each seminiferous tubule and an increase in the size and number of the testosterone-producing Leydig cells [1]. Testosterone is responsible for most of the secondary changes such as enlargement of the penis and larynx, growth of pubic, axillary and beard hair and also for a rise in sebum excretion and increased axillary sweating. Slight growth of pubic hair, at around 8 or 9 years and probably provoked by adrenal androgens, may precede other secondary characteristics [1]. Facial hair usually only starts to appear about 2 years later. A full account of the patterns of hair development is given in Chapter 66.

The age at which these changes occur is highly variable but Tanner's data on white British boys give some guidance [7–9]. In 95% of boys, the genitalia started to enlarge at between 9.5 and 13.5 years (mean 11.6 ± 0.9 years of age) and functional maturity, indicated by the ability to ejaculate, was achieved between the ages of 13 and 17 (mean 14.9 ± 1.1) years. The adolescent growth spurt, when the average gain in height reached a peak of 10 cm/year, a velocity of growth similar to that at the age of 2 years, usually occurred between 12.5 and 15 (mean 14.1 ± 0.9) years, approximately 3 years after the first signs of genital enlargement.

In girls, one of the first signs of puberty is the onset of breast development (thelarche), indicated by the elevation of the breast and papilla to form a small mound known as the breast bud [8,10]. The average age in white North American girls is 9.96 ± 1.82 years and 8.87 ± 1.93 years in their African American compatriots [11], but the breasts continue to enlarge for approximately 2 more years. The secretion of ovarian oestrogens promotes breast growth, with the further development of the secretory alveoli during pregnancy requiring the action of progesterone as well. Pubic hair also starts to develop at about age 9, probably as a result of stimulation by androgens from the adrenal cortex, the so-called adrenarche, and is thus dependent on an output of pituitary adrenocorticotrophic hormone (ACTH) [6,12] (see Chapter 66). The most obvious feature of puberty, namely first menstruation or menarche, occurs at an average age of 13 years, but within an age range of 10–16.5 years. The early menstrual cycles do not usually involve ovulation, so full reproductive function is generally delayed for a further year or two. The growth spurt, with a peak height gain of 8 cm/year, occurs between 10.5 and 13 years of age in white British girls [10]; approximately 2 years earlier than in boys. It is also noteworthy that rapid somatic growth precedes the major events of sexual maturation in girls but accompanies or succeeds them in boys.

Both the age at which puberty begins in childhood and the duration of the process vary enormously between individuals, irrespective of gender. The pubertal growth spurt appears, in both sexes, to be dependent on androgenic steroids as well as on growth hormone. Boys with growth hormone deficiency respond less well to testosterone than do normal subjects, not only in relation to acceleration of growth but also for development of the secondary sexual characteristics [13]. In recent decades, the age at which puberty begins has decreased in many countries [1,14,15]. Puberty starts when adequate growth and energy storage has occurred, so the earlier age of puberty may reflect recent trends in increasing adolescent obesity [14,15]. One important signal is the hormone leptin, produced by adipocytes. If fat reserves are low, circulating leptin levels are low and reproductive activity is stopped. Puberty will not begin unless adequate metabolic fuels are available, so leptin levels may act as a 'gate' for puberty [16]. As modern lifestyles are becoming increasingly sedentary, it is little surprise that the prevalence of obesity is increasing in children. Perhaps this increased availability of metabolic fuels and fat reserves, with consequent hyperleptinaemia and hyperinsulinaemia, is opening the puberty 'gate' earlier? In children born small for gestational age, puberty is significantly advanced in girls, but not boys, suggesting that nutritional influences on the onset of puberty are complex [17].

Premature and delayed puberty and hypogonadism

Although it must be acknowledged that the measurement of the onset and progress of puberty remains somewhat controversial [1], the dermatologist will occasionally see patients with what is clearly an abnormally early or delayed puberty, or with various hypogonadal syndromes. The appearance or non-appearance of sexual hair, or the onset of acne lesions in late childhood are the usual reasons for such referrals. Premature and delayed puberty are matters for endocrinological investigation, but the dermatologist should at least be aware of the range of diagnostic possibilities.

Premature puberty

Signs of puberty before the age of 10 years are generally held to be abnormal. This may result from an early onset of complete (or true) puberty, in which the changes are triggered by early activation of the normal hypothalamo–pituitary–gonadal axis. In some instances, early signs of puberty are caused by false (or pseudo-) puberty, in which sex hormone secretion is independent of normal control mechanisms. Partial or incomplete puberty is also recognized and there are two forms: thelarche (isolated breast development) and pubarche (isolated development of pubic and axillary hair). The former may be unilateral and be confused with tumours.

Table 8.2 Classification of premature puberty. (From Rayner [4].)

Complete (true)	False (pseudopuberty)
Constitutional	Adrenal lesions
Sporadic	Congenital adrenal hyperplasia
Familial	Tumours
Cerebral/neurogenic	Cushing's syndrome/hyperplasia
Tumours	Ovarian tumours
Development defects	Testicular tumours
CNS infections	Iatrogenic (sex hormones)
CNS trauma	Extrapituitary gonadotrophin secreting tumours
McCune–Albright syndrome	Teratoma
Neurofibromatosis	Chorionepithelioma
Tuberous sclerosis	Hepatoblastoma
Silver's syndrome	
Hypothyroidism	
Pineal lesions	
Incomplete	
Premature thelarche, pubarche	

CNS, central nervous system.

It is not clear what causes isolated breast enlargement, although tissue hypersensitivity to oestrogen has been suggested (see Chapter 70). Pubarche is often associated with adrenal androgen secretion and this may be a priming phenomenon in the early phases of normal pubertal development [2]. Indeed, the very early, isolated appearance of sexual hair may presage a true early puberty and the distinction can be a very fine one. Table 8.2 gives a clinical classification of early puberty.

Most instances of premature, complete puberty are constitutional. Although this may be sporadic, there is often a strong family history. Indeed, it seems likely that many families never present at all, accepting that it is quite normal for them. This is particularly true for girls, in whom approximately 80% of premature puberty is thought to be constitutional [3]. There is no difference in the order of events, but mental and emotional development may lag behind the physical changes. In boys, where the event is rarer, there is more often an underlying pathological condition [3].

The investigation of complete premature puberty is obviously a complex process, especially if a neurogenic origin is suspected, but the dermatologist should always look for other features of the specific syndromes listed in Table 8.2: McCune–Albright syndrome, neurofibromatosis, tuberous sclerosis and Silver–Russell syndrome (short stature, craniofacial disproportion and clinodactyly), as well as hypothyroidism [3].

Cystic fibrosis
Thalassaemia major
Diabetes mellitus
Hypothyroidism
Gluten intolerance
Anorexia nervosa
Excessive exercise
Hypergonadotrophic hypogonadism
Klinefelter's syndrome
Ullrich–Turner syndrome
Dystrophia myotonica
Trisomy 21 (Down's syndrome)
17β-Hydroxylase deficiency
Androgen insensitivity (testicular feminization syndrome)
Surgical accidents (e.g. during herniorraphy)
Testicular torsion
Anorchia and bilateral cryptorchidism
Irradiation and cytotoxic drugs
Orchitis (e.g. mumps)
Polycystic ovarian disease

Delayed puberty and hypogonadism

Puberty can be considered delayed if there is no sign of sexual development by the age of 15 years in boys and 14 years in girls [1]. There are a number of important causes, listed in Table 8.3. Constitutional delay accounts for at least 50% of male cases and is much more common than in girls [1].

As with premature puberty, pubertal delay requires endocrinological investigation. However, a dermatologist can make a useful contribution if the patient presents first in the skin clinic. Examination can reveal the obesity, short stature and mental retardation of the Prader–Willi syndrome, the polydactyly of the Laurence–Moon–Biedl syndrome, or the increased height and gynaecomastia of Klinefelter's syndrome.

Many extraneous factors can also affect the onset of puberty. Malnutrition and extreme forms of exercise, such as long-distance running and ballet training, may markedly delay onset of puberty, probably by interfering with hypothalamic triggering mechanisms [2,3].

Dermatoses of puberty and adolescence

Adolescence is a difficult period for most people. It is a time when the whole emphasis of relationships is supposed to change from the herd bond of the 'gang' to the pair bond of courtship and sexual involvement, but this does not happen all at once or completely. Most of us retain a need for the approbation of our peers throughout life, as well as a desire to develop a close one-to-one relationship. The tensions involved in this are at their most acute during adolescence and, for this reason, many skin diseases, which first presented during childhood, only begin to exert their most damaging influences after the onset of puberty. Adolescence is a bad time to have skin disease, especially on the face or on the extremities.

The physiological changes that occur in the skin during puberty and adolescence also have several effects and may result in sufficient distress to cause the individual to seek medical advice. There are several examples of this: the increase in sebum production frequently results in unacceptably greasy hair, on which many hours and much money is expended; teenagers often present with secondary sexual hair that they perceive to be abnormal, largely as a result of the pressure exerted by the media; young men become anguished when androgenetic, male-pattern balding begins in the teenage years; members of both sexes become disturbed by the onset of 'body odour'.

It has been pointed out that the pressures of coping with a maturing skin are particularly acute for a girl who is persuaded by advertisers that she should have plenty of hair on her head, but none on her face, under her arms or on her legs. Her skin should be free from grease, acne and, moreover, should be odourless [1]. Puberty makes this ideal image virtually impossible to achieve. Several disorders cause special problems or make their first appearance in adolescence. The classic example is acne vulgaris but there are several others (Table 8.4).

Table 8.4 Disorders that present in or cause particular problems during adolescence.

Acne vulgaris
Acne excoriée and neurotic excoriation
Self-mutilation and dermatitis artefacta
Seborrhoeic dermatitis
Pityriasis versicolor
Hyperhidrosis
Axillary bromhidrosis (body odour)
Hidradenitis suppurativa
Fox–Fordyce disease
Polymorphic light eruption
Epidermolysis bullosa simplex (Weber–Cockayne syndrome)
Psoriasis
Atopic dermatitis

Fig. 8.1 Self-inflicted lesions on the cheek of a teenager.

Teenagers may present with a variety of skin disorders in which self-inflicted injury is an important component (Fig. 8.1), varying from mild excoriated acne to severe habitual mutilation. The mental state of these individuals ranges from simple mild anxiety to gross personality disorder, psychotic disturbance and instability. Extreme forms of deliberate self-harm almost invariably begin in adolescence, but most continue for many years [2].

Seborrhoeic dermatitis is generally seen only from adolescence onwards, as is pityriasis versicolor in temperate climates. An explanation for this may lie in the alterations in sebum that appear to occur at puberty [3], especially if it is accepted that yeast organisms have a role in seborrhoeic dermatitis (see Chapter 23). This alteration in sebum is also said to be responsible for the virtual disappearance of scalp ringworm after puberty.

Teenagers may seek help for a number of different axillary problems. Severe eccrine hyperhidrosis can be a very distressing complaint, but usually responds well to treatment (see Chapter 44) [4], as does axillary odour (bromhidrosis). More difficult to deal with are abnormalities of the apocrine glands (hidradenitis and Fox–Fordyce disease).

Polymorphic light eruption often presents for the first time in adolescence [5] and can ruin summer holidays. So does psoriasis [6]; 25% of 5600 patients with psoriasis dated the onset of their disease to between the ages of 10 and 20 years [7]. The impact of the appearance of psoriasis on a teenager should not be underestimated. The patient will be told that psoriasis is probably genetic, that it is likely to continue to be a lifelong problem and that there is no satisfactory cure. All this has to be assimilated during a period of increasing awareness of the importance of being attractive.

Atopic eczema can also be a major problem for the teenager and his or her family. It may present for the first time in adolescence, but this is rare. More commonly, children do not grow out of it as they have been led to believe, or atopic eczema may disappear during childhood only to reappear in adolescence. In this situation, the skin changes and pruritus are often severe and usually have already affected the enjoyment of childhood. The adolescent is then quite abruptly faced with the prospect of the skin problem continuing for an apparently indefinite period into adult life. Many, if not all, affected teenagers become increasingly depressed and frustrated and a sense of hopelessness can descend on the whole family. Many patients completely lose faith in orthodox medicine and seek advice from homeopaths, herbalists, naturopaths and others. A truly sympathetic and holistic approach is therefore required if the dermatologist is to retain the confidence of his or her young patient and their relatives through this difficult period. Good communication needs to be cultivated and maintained. Professional counselling facilities can be very helpful, but are often either neglected or are unavailable.

Another troublesome aspect of atopic eczema in adolescence is that there is a greater tendency to develop involvement of the hands (and feet) as the years go by. This can lead to difficulties in choosing a suitable occupation (see below). Furthermore, treatment parameters usually differ in adolescents and adults from those in childhood atopic eczema [8]. In particular, the information and support needs differ and, in practical therapeutic terms, steroid-sparing strategies may become more important.

Some congenital and genetic diseases, such as tuberous sclerosis and neurofibromatosis, may progress during the teenage years, causing increasing physical and cosmetic disability. Others (e.g. ichthyotic disorders, pigmentary anomalies and port-wine stains), even though largely static, may exert a greater effect because of the social and psychological tensions of adolescence.

However, some disorders improve at puberty. For example, atopic eczema clears in many individuals and autosomal dominant ichthyosis tends to improve.

Skin disease and career

Young people with skin disease are often not aware that they may be at a major disadvantage in pursuing some occupations.

The armed forces medically examine all recruits and are unlikely to accept anyone with either psoriasis, significant atopic eczema or severe acne. It is therefore preferable for acne to be eradicated before rather than after application.

Psoriasis and dermatitis of the hands can be troublesome for those hoping to work in catering. Although they may be accepted by colleges to study, such individuals often find it difficult to obtain subsequent employment.

Hand dermatitis among hairdressers is a far greater problem in those with active or inactive atopic eczema than in those who are unaffected [9]. A teenager with atopic eczema may work in a hair salon for months or even years suffering with hand dermatitis before eventually giving up. The same applies to nursing, where many committed individuals are rejected at the occupational health screen because of dermatitis. Any teenager with a chronic skin disease, especially of the hands, should therefore be made aware of the potential difficulties that he or she may face in the choice of occupation.

The menstrual cycle

Hormonal influences

The menstrual cycle involves changes in the genital tract, which are brought about by two hormones from the ovary. At the start of each cycle, after menstruation is completed, the rising secretion of oestradiol induces the repair and proliferation of the endometrium and the synthesis of receptors for progesterone and oestradiol within its cells. Following ovulation and the formation of the corpus luteum, the rise in progesterone causes the endometrium to double in thickness and the tubular glands to become tortuous and sacculated. The maintenance of this secretory phase is dependent on both oestradiol and progesterone and the breakdown of the endometrium that causes menstrual bleeding is a consequence of the withdrawal of these hormones. The cyclic hormonal changes also affect the vaginal epithelium, which can be monitored through desquamated cells in vaginal smears, the consistency and pH of the cervical mucus and several features of the skin [1].

Synthesis of oestrogens in the ovary first involves the production of the androgens androstenedione and testosterone, in the theca interna cells of the follicle and then their conversion to oestrone and oestradiol in the granulosa cells. Luteinizing hormone (LH) derived from the pituitary gland stimulates these processes. However, the increased production of oestradiol between the eighth and tenth days of the cycle is also dependent on FSH in the sense that this is responsible for the development of numbers of primary follicles in the early follicular phase, which increases the number of granulosa cells [1].

Ovulation in the middle of the cycle is associated with surges in both LH and, to a lesser extent, FSH. The surge in LH lasts for approximately 36 h and is affected by pulsatile output of GnRH from the hypothalamus. It appears that feedback by oestradiol is responsible; in the early follicular phase, oestradiol acts to inhibit secretion of gonadotrophin but, as the follicle ripens, a threshold is exceeded which switches the feedback from negative to positive [1].

Cutaneous changes

Many women notice changes in their skin and hair during the course of the monthly cycle. For example, 70% of Scottish women reported a few acne papules during the premenstrual phase of their cycle and a significant number of others experienced textural variations. Some found the skin and hair greasier (35%), others drier (16%) [1], despite the fact that sebum production has not reliably been shown to alter significantly. Pre-existing skin disorders, other than acne, may also undergo premenstrual exacerbation; examples are psoriasis, rosacea, atopic eczema, lupus erythematosus, anogenital pruritus, recurrent aphthae and herpes simplex [2,3].

Some women experience premenstrual flushing identical in quality to that associated with the menopause. In one study of 120 women with classical features of the so-called premenstrual syndrome, 72% were observed to have such flushing episodes [4]. This phenomenon may be related in part to the general increase in cutaneous vascularity during the second half of the menstrual cycle [5], but detailed investigation of one of these women revealed that each flush (recorded using skin resistance and finger temperature) coincided with a measurable pulse of LH. Identical findings are reported in menopausal flushes (see p. 8.20), suggesting a common pathogenesis.

Other cutaneous disturbances described in the 'premenstrual syndrome' include minor non-specific abnormalities and recurrent boils. Premenstrual oedema has also been described, most commonly of the feet and ankles, but occasionally involving the hands and even the face. In rare individuals this may be very marked.

It is not at all clear what causes most of the symptoms associated with the 'premenstrual syndrome', but there have been many suggestions, including hormonal influences, abnormalities of fluid balance, nutritional changes (including essential fatty acid deple-

Fig. 8.2 Autoimmune progesterone dermatitis. (Courtesy of Dr J.D. Wilkinson, Amersham Hospital, Amersham, UK.)

tion), neurotransmitters and psychological factors. It seems most probable that the syndrome is a complex of interrelated problems, each with a different basic cause or causes [6].

Autoimmune progesterone dermatitis (Fig. 8.2)

There are also patients in whom the regular appearance of skin changes in the premenstrual period is associated with evidence of hypersensitivity to progesterone. This has generally been established by skin testing, deliberate challenge with progesterone or the presence of antibodies and the term autoimmune progesterone dermatitis has been coined for this syndrome [7]. The cutaneous lesions that have been described are very variable, resembling eczema, particularly the pompholyx type, urticaria, erythema multiforme, dermatitis herpetiformis or anaphylaxis [7]. Many patients develop the eruption after receiving exogenous synthetic progesterone preparations.

Treatment of autoimmune progesterone dermatitis can be difficult. Most patients are unresponsive to topical steroids and antihistamines, but some respond to oestrogen or tamoxifen therapy [7]. One resistant patient required bilateral oophorectomy [7].

Pregnancy, childbirth and the puerperium

Pregnancy, childbirth and the puerperium are associated with profound physiological endocrine upheavals. Many of the consequent cutaneous changes should be considered normal, although not every woman is happy to accept them in this light. The physiological events of pregnancy and its resolution can also modify a number of cutaneous disorders and there are also some pathological skin conditions that are virtually pregnancy-specific.

Endocrine background

Pregnancy is characterized by the advent of a new and unique endocrine organ, the placenta. The hormonal changes of pregnancy start soon after the fertilized ovum becomes implanted in the endometrium, when the developing trophoblast begins to secrete chorionic gonadotrophin. This, in turn, stimulates production of oestrogen and progesterone by the corpus luteum. The increase in the concentration of these steroids suppresses pituitary FSH production and thus prevents further ovulation. At about the ninth week of pregnancy the fetoplacental unit begins to synthesize pregnenolone and progesterone. Pregnenolone crosses to the fetus and is converted to dehydroepiandrosterone by the developing fetal adrenal. This, in turn, returns to the placenta to be aromatized to oestriol. From about the 12th week there are increasing amounts of oestriol and progesterone and the corpus luteum of pregnancy regresses.

The placenta also produces lactogen (hPL) in quantities as great as 1 g/day by late pregnancy. This hormone has some somatotrophic as well as lactogenic properties. A human chorionic thyrotrophin (hCT), structurally different from pituitary thyroid-stimulating hormone (TSH), has also been isolated.

Placental hormones partly facilitate the physiological adaptations that occur in pregnancy including, for example, a considerable increase in blood volume. The thyroid enlarges and takes up more iodine. The pituitary also enlarges and increases its output of ACTH, prolactin and gonadotrophins. Circulating cortisol rises, caused mainly by a decrease in its clearance rate combined with increased cortisol-binding globulin.

The breasts enlarge during pregnancy, most noticeably towards term. In the early phases of a first pregnancy there is a rapid growth and branching of the terminal portions of glandular tissue, together with an increase in the vascularity of the breast as a whole. Later, true acini appear for the first time and alveolar secretion begins during the second trimester. In the last weeks there is considerable parenchymal cell enlargement and the alveoli become distended with colostrum [1].

The state of pregnancy is ended, at least in part, by an alteration in the balance of the antagonistic actions of oestrogen and progesterone. This is probably fine-tuned by the fetal pituitary–adrenal axis and its effect on oestrogen production [1]. Thus, abnormalities of the fetal brain, such as anencephaly, may lead to abnormally early or late onset of parturition. The tendency of labour to be delayed in mothers bearing children with X-linked ichthyosis is caused by a reduction in the processing of hormones by the placental enzyme steroid sulphatase (see Chapter 19).

After birth, the mother's hormonal status changes yet again. Levels of prolactin rise steadily towards the end of pregnancy and at childbirth the apparently inhibitory effect of the fetoplacental steroid hormones is suddenly lost, leaving prolactin acting unopposed. This initiates lactation [1].

Physiological skin changes related to pregnancy

Pigmentation (see Chapter 58)

Most women notice a generalized increase in skin pigmentation during pregnancy and the change is more marked in dark-haired than in fair-haired women. Areas that are already pigmented become darker, in particular the nipples, areolae, genital areas and the midline of the abdominal wall. In consequence, the 'linea alba' ('white line') may become brown. The pigmentation usually fades after delivery, but seldom to its previous level. Many women also notice an increase in the size, activity and number of melanocytic naevi [1].

In approximately 70% of women, especially those of dark complexion, chloasmal pigmentation also develops during the second half of pregnancy. Its intensity is not necessarily proportional to that of the general melanosis. Irregular, sharply marginated areas of pigmentation develop in a roughly symmetrical pattern either on the forehead and temples, or on the central part of the face, or both. It usually fades completely after parturition, but may persist [1].

The extent to which human pigmentary changes are brought about by oestrogen and progesterone, or by melanocyte-stimulating hormones derived from pro-opiomelanocortin and other factors (see Chapter 58), is uncertain [2,3].

Hair and nail changes

Many women maintain that hair growth on the scalp is more vigorous during pregnancy. In the latter part, the proportion of follicles retained in anagen rises, but a compensatory decrease after parturition associated with shedding of hairs may result in noticeable postpartum, telogen alopecia [1]. Spontaneous recovery is usual. Mild frontoparietal recession may also occur [4].

Minor degrees of hypertrichosis are not uncommon. Hirsutism, accompanied by acne and, in severe cases, by other evidence of virilization, occurs rarely, usually during the second half of pregnancy. It may result from an androgen-secreting tumour, luteoma, lutein cysts or polycystic ovary disease [1,5,6]. All cases should be thoroughly investigated. A female fetus may be masculinized. In the absence of a tumour that can be eradicated, the problem tends to recur in subsequent pregnancies. Hirsutism may regress between pregnancies, but this is not always complete.

Pregnant women often report brittleness of the nail plate and some develop distal onycholysis, similar to that seen occasionally in thyrotoxicosis [4].

Eccrine, apocrine and sebaceous gland activity

Eccrine activity may be noticeably increased during pregnancy [4], although palmar sweating diminishes [1,4]. This may be responsible for the recognized increased frequency of miliaria. It is often said that apocrine gland activity is reduced during pregnancy, but the evidence is conflicting. There is no increase in apocrine sweating immediately postpartum, but Fox–Fordyce disease usually improves in pregnancy, which suggests that apocrine activity has been reduced [1].

Although there is considerable individual variation, the rate of sebum excretion tends to increase during pregnancy and return to normal after delivery [7].

The rise in sebum excretion during the last trimester of pregnancy, at a time when oestrogens, which suppress sebum secretion, are being produced in large quantities, suggests that a powerful sebotrophic stimulus is released. The sebum excretion rate in women with twins or triplets is no greater than the rate in women with a single fetus, suggesting that the sebotrophic factor comes from the pituitary rather than the placenta [3,8]. Sebum excretion does not fall in women who are lactating [9] and suckling presumably promotes secretion of pituitary factors, such as prolactin, which either stimulate sebaceous glands directly or enhance their response to androgens.

Vascular changes

The vascular changes of pregnancy do not differ qualitatively from those in hyperthyroidism or cirrhosis. All are thought to be due to sustained high levels of circulating oestrogen. Vascular 'spiders' are very common in white women but are said to be less so in black women [1]. They usually disappear postpartum. Palmar erythema is also common, affecting at least 70% of white women and 30% of black women [1]. In some, it takes the form of a diffuse pink mottling of the whole palm, whereas in others the changes are confined to the thenar and hypothenar eminences [1]. Palmar erythema and vascular spiders commonly occur together.

Less commonly, pregnant women develop small haemangiomas [1]. These usually affect the head and neck (Fig. 8.3) and occur in approximately 5% of pregnancies [1].

Varicose veins of the legs and haemorrhoids are frequent complications of pregnancy. A rarer but more serious event is the

Fig. 8.3 Pyogenic granuloma in a port-wine stain during pregnancy. This woman had similar lesions in three successive pregnancies.

development of deep-vein thrombosis, which can lead to permanent damage to the veins of the legs and, occasionally, death from pulmonary embolism. Many pregnant women (possibly 50%) also develop non-pitting oedema of the face, eyelids, feet and hands [2]. The swelling is usually most pronounced in the early morning and disappears during the course of the day. There is no known treatment, but it is important to recognize and differentiate the condition from cardiac, renal or pre-eclamptic oedema.

Gingivitis and pregnancy 'epulis'

Eighty per cent or more of pregnant women develop some gingival oedema and redness [2,3]. This can become painful and ulcerative, especially if oral hygiene is poor. In approximately 2%, the gingival changes are associated with the appearance of a small vascular lesion similar to a pyogenic granuloma, known as a pregnancy epulis or granuloma gravidarum [1]. This may bleed profusely on contact. These phenomena, like palmar erythema and vascular spiders, are probably brought about by the general increase in vascularity associated with high oestrogen levels.

In most women, gum changes resolve after parturition. Vitamin C has been used to try to improve the symptomatology [3].

Porphyria cutanea tarda	Acne
Acrodermatitis enteropathica	Hidradenitis suppurativa
	Fox–Fordyce disease

Dermatoses modified by pregnancy

Some dermatoses worsen during pregnancy, some improve and many are unpredictable. Table 8.5 lists those dermatoses and tumours that are commonly modified by pregnancy and the puerperium. The details of most of these are discussed elsewhere in this book; however, some specific points should be noted here.

Infections and immunity in pregnancy

Cell-mediated immunity is depressed during normal pregnancy [1], which probably accounts for the increased frequency and severity of certain infections such as candidiasis. Condylomata acuminata too can be exacerbated, growing very rapidly and occasionally obstructing the birth canal. *Candida*, genital warts and herpes simplex can be transmitted to the baby during childbirth. In babies of very low birth weight, candidiasis and herpes simplex can be life-threatening [2,3]. In view of the known oncogenic potential of some strains, there is a debate about whether mothers infected with human papillomavirus should routinely be offered caesarean section, as generally practised for active herpes simplex infection. However, there is doubt whether this practice prevents neonatal infection [3] either by herpes virus or by genital warts [4]. Bowenoid papulosis (see Chapter 71), a condition closely linked with wart virus infection, may appear for the first time or deteriorate during pregnancy [5].

Podophyllin should never be used in the treatment of warts during pregnancy because of potential maternal and fetal toxicity; physical treatments are preferable [6].

The immune alterations of pregnancy, childbirth and the puerperium have an adverse effect on leprosy in more than one-third of patients [7]. Leprosy reactional states are more common and the decline in immune reactivity may also lead to an increase in drug resistance [7]. Furthermore, there are specific problems with some antileprosy drugs: thalidomide cannot be used because of its teratogenicity and clofazimine has been associated with unexplained fetal deaths [8].

Autoimmune disorders

The outcome of most pregnancies in women with systemic lupus erythematosus is undoubtedly better than was once thought, although a few develop renal damage and disease exacerbation may be severe enough to cause death [9]. Lupus in the mother may affect the baby (neonatal lupus; see Chapter 17). Cutaneous lupus does not appear to be affected by pregnancy [9].

Most women with scleroderma do not experience major problems and some appear to improve [10]. Occasionally, however, there is severe progressive deterioration of renal function, with hypertension and pre-eclampsia. This may lead to fetal loss or even maternal death [10].

Dermatomyositis and polymyositis are generally unaffected by pregnancy, but some patients may deteriorate and it can be associated with a poor fetal outcome [11].

Metabolic disease

There is no consensus about the effects of pregnancy on porphyria cutanea tarda. Some women experience few problems. However, some cases do show clinical and biochemical deterioration and on one occasion this may have been parallel to the physiological rise in oestrogen [12]. Acrodermatitis enteropathica is said always to deteriorate in pregnancy [13].

Disorders of connective tissue

Women with Ehlers–Danlos syndrome types I and IV often have major problems, including bleeding, wound dehiscence and uterine lacerations (see Chapter 45) [14]. They should probably be counselled to avoid pregnancy altogether. Some patients with pseudoxanthoma elasticum have suffered major gastrointestinal bleeds necessitating blood transfusion [14].

Tumours

The relationship between malignant melanoma and pregnancy (and, indeed, exogenous oestrogens) has been discussed for many years [1]. One large series suggests that melanoma developing during pregnancy carries a slightly worse prognosis, but that pregnancy following excision of a tumour does not affect prognosis [15]. Epidemiological studies from the USA have failed to show significant associations between melanoma and reproductive and other hormonal factors in women [16]. Neurofibromata may grow during pregnancy, or appear for the first time. Rupture of major blood vessels in neurofibromatosis has also been reported [17,18] and hypertension is a common complication. Pregnancy may exacerbate mycosis fungoides [19] and the eosinophilic granuloma form of Langerhans' cell histiocytosis [20].

Miscellaneous dermatoses

Atopic eczema often improves in pregnancy, but this is unpredictable; in some patients it is exacerbated. Breastfeeding is often a problem for those suffering from atopic eczema because of nipple eczema and the puerperium may herald deterioration in hand eczema because of exposure to irritants.

Pregnancy may trigger erythema multiforme and vaginal stenosis has been described in severe Stevens–Johnson syndrome occurring in pregnancy [21].

Marked deterioration in erythrokeratoderma variabilis occurred during pregnancy in two related women [22].

The effects of pregnancy on psoriasis are variable, although often consistent in the same individual. On balance psoriasis is more likely to improve during pregnancy with relapse postpartum [23]. A rare occurrence is the sudden eruption of acute pustular psoriasis. This used to be considered as a distinct entity called *impetigo herpetiformis*, but this term is probably best discarded.

AIDS and pregnancy

AIDS is a worldwide problem and there have now been many pregnancies in women infected by human immunodeficiency virus (HIV). The infection has often only become apparent after birth when the children developed AIDS. Although it appears that pregnancy may subsequently accelerate the development of AIDS symptoms [1,2], there does not seem to be a tendency for HIV disease to progress during pregnancy itself [3]. If opportunistic infections, such as *Pneumocystis* pneumonia or listeriosis, develop in a pregnant woman with AIDS, the outcome is generally fatal [4,5]. This contrasts with the more usual 70% recovery rate in non-pregnant AIDS patients and suggests that the immune suppression of pregnancy may be additive to that of HIV infection. Kaposi's sarcoma has also been reported in AIDS in pregnancy [6]. The effects of maternal HIV infection on the child can be devastating [7].

The dermatoses of pregnancy

Irritation, rashes and other skin changes are common in pregnancy [1]. The possibility that the patient has an unrelated skin condition such as scabies must not be overlooked. However, there are several skin changes that appear to be specifically related to pregnancy and the puerperium, distinct from physiological events and not caused by exacerbation of a pre-existing condition [2].

Pruritus gravidarum

Itching in pregnancy is dealt with here because it is uncertain whether it is an extension of the physiological changes or a specific dermatosis. As many as one-fifth of pregnant women experience itching [3]. In most, this can be attributed to some identifiable skin disorder such as scabies, eczema, urticaria, a drug eruption or one of the specific pregnancy-related inflammatory dermatoses discussed below. However, there is also a small group of women who experience intense pruritus without evident primary cutaneous changes and it is to these patients that the term pruritus gravidarum is applied.

It is generally considered that pruritus gravidarum is a mild variant of recurrent cholestasis of pregnancy and occurs in 0.02–2.4% of pregnancies [4]. The itching begins in the second or third trimester and is often localized to the abdomen, or the palms and soles, although it may also be very widespread. The patient may be mildly icteric. Liver function tests are occasionally abnormal, with a raised alkaline phosphatase [5].

The cause is thought to be multifactorial [2,6], although it is probable that the irritation itself results from abnormal hepatic excretion of bile acids induced by metabolites of both oestrogen and progesterone, both of which have been shown to affect the handling of bile acids [2,6]. The condition also occurs more commonly in mothers of patients with rare inborn cholestatic syndromes [6].

The itching usually subsides rapidly after childbirth, but may persist for some weeks into the puerperium. It may also recur with subsequent pregnancies and the use of oral contraceptive pills. Recurrent attacks increase the liability to cholelithiasis [3]. Treatment with ursodeoxycholic acid is effective in reducing itch and abnormal liver function tests [6].

Striae

Striae distensae (striae gravidarum) are a common and striking feature of most pregnancies. They are dealt with fully in Chapter 45 [7].

Skin tags

Synonym

- Molluscum fibrosum gravidarum

Multiple tags often appear in the second half of pregnancy. These are most common on the face, the side of the neck, in the axillae and under the breasts. The histological features are those of ordinary skin tags. They are usually small, but may reach 5 mm in size. They generally regress in the puerperium and it has been suggested that they are probably a result of hormonal factors [8].

'Cracked' and sore nipples

Many women experience discomfort, irritation and fissuring of the nipples, especially early in the puerperium as they are trying to establish breastfeeding. Anatomical features, such as relatively flat nipples, contribute to the development of this problem. Mastitis and deep abscesses may occur because of penetration of the broken skin by pyogenic bacteria. The problem is, in essence, one of friction and irritation and can be eased considerably by the judicious use of gentle cleansing and emollients [5].

Inflammatory dermatoses specific to pregnancy

Classification. The older literature is confusing. Dermatoses considered distinct by some authors are lumped together by others. Holmes and Black [9] have suggested a rationalization of the terminology and have proposed a classification that seems the most logical for practical use (Table 8.6), even though alternatives are still employed. Ackerman *et al*. [10] argue that there really are only two dermatoses in this category: pruritic urticarial papules and plaques of pregnancy (PUPPP) and pemphigoid gestationis.

Table 8.6 Specific dermatoses of pregnancy. (From Shornick [11].)

Pemphigoid (herpes) gestationis
Polymorphic eruption of pregnancy
Prurigo of pregnancy
Pruritic folliculitis of pregnancy

However, some of the other dermatoses that have been reported as being pregnancy-associated are discussed here, drawing attention to those descriptions that appear to be at least clinically distinct from PUPPP or pemphigoid gestationis and reviewing whether others are really distinct entities or not.

Pemphigoid (herpes) gestationis

This rare and highly characteristic disorder affects approximately 1 in 10 000 to 1 in 150 000 pregnancies and is considered in detail in Chapter 40. The disease usually appears in the second or third trimester and presents with an intensely itchy urticarial or vesiculobullous eruption. Immunofluorescence reveals a linear band of immunoglobulin G (IgG) at the basement-membrane zone, identical to that seen in bullous pemphigoid. The histopathological features resemble bullous pemphigoid too [12]. Recent studies involving tissue typing have supported earlier suggestions of a genetic predisposition [13]. The disease is often associated with other organ-specific autoimmune diseases and tends to recur in subsequent pregnancies, although this is not always the case [14].

Polymorphic eruption of pregnancy

Synonym
- Pruritic urticarial papules and plaques of pregnancy

In addition to the above designations, these skin changes have been known as toxaemic rash of pregnancy, toxic erythema of pregnancy and 'late-onset' prurigo of pregnancy. It is probable also that some patients with this condition have been recorded in the literature as prurigo gestationis (see below), erythema multiforme and pemphigoid (herpes) gestationis [15,16].

If there is agreement that all these disorders are one and the same, there is still no consensus on which name to use. In the UK, as proposed by Holmes and Black [9], the term polymorphic eruption of pregnancy is favoured. Elsewhere, the lengthy descriptive phrase 'pruritic urticarial papules and plaques of pregnancy' or 'PUPPP', still finds favour, especially in the USA [15,16].

Incidence. Polymorphic eruption of pregnancy occurs in approximately 1 in 160 pregnancies [16]. The eruption begins in the third trimester, usually of a first pregnancy, but is occasionally delayed until a few days postpartum. It rarely recurs in subsequent pregnancies, but when it does it is often less severe [15,16].

Aetiology. The cause remains obscure, although the condition has been related to abnormal weight gains in the mother and to twin pregnancy [16]. Although this study found no link with high fetal birth weight [16], this has previously been thought to be an association [17]. As the disorder occurs predominantly in primigravidae in the third trimester, it has been postulated that excessive abdominal distension may act as a trigger for the skin changes. The typical distribution (see below) may lend some credence to this view. It has also been shown that serum cortisol levels are low in patients with polymorphic eruption of pregnancy, while human chorionic gonadotrophin (hCG) and oestradiol are normal [18]. Unlike pemphigoid gestationis, there is no HLA-association [15].

Pathology. The histology of this condition is non-specific and there are many similarities with the early prebullous phase of pemphigoid gestationis. Most biopsies show epidermal and upper dermal oedema, with a perivascular infiltrate of lymphocytes and histiocytes. There may be a striking number of eosinophils (as there may be in pemphigoid gestationis). Spongiotic vesicles are also seen, as is patchy parakeratosis [15].

Immunofluorescence is generally negative, even by immunoelectron microscopy, and this provides the best means of distinguishing this disorder from pemphigoid gestationis, should there be any diagnostic doubt [19]. There are occasional reports of equivocal immunofluorescence findings with polymorphic eruption of pregnancy, such as minimal C3 deposition along the basement membrane, perivascularly in the dermis or in the epidermis [15]. In these rare situations of equivocal immunofluoresence, a BP180 NC16a enzyme-linked immunosorbent assay has been shown to be highly sensitive and specific in distinguishing pemphigoid gestationis from polymorphic eruption of pregnancy [20].

Clinical features. The patient usually complains of intense itching. The skin lesions closely resemble the very early stage of pemphigoid gestationis. The eruption consists predominantly of urticated papules and plaques. Less commonly, vesicles, target lesions and polycyclic erythematous areas are seen. The most striking feature, however, is the distribution of the lesions. They usually begin and predominate on the abdomen, often closely following the lines of the striae, where present (Fig. 8.4). The umbilicus is frequently spared. Lesions often also appear on the upper arms and thighs.

Despite the outdated term toxaemic rash of pregnancy, there is no suggestion that polymorphic eruption has any adverse effect on the outcome of the pregnancy [15,16].

Treatment. Some patients improve with topical emollients or steroids. Most women are relieved to learn that the condition is not serious, that all should be well with them and their baby and that the rash will disappear at or soon after childbirth [15,16].

Prurigo of pregnancy

Synonyms
- Early-onset prurigo of pregnancy
- Prurigo gestationis of Besnier

The main differences between this disorder and polymorphic eruption of pregnancy are that it begins earlier (usually between 25 and 30 weeks' gestation) and that there are no urticated lesions. It occurs in 1 in 50 to 1 in 200 pregnancies. Clinically, there are

(a)

(b)

Fig. 8.4 Typical lesions of polymorphic eruption of pregnancy: (a) on the arm and (b) on the abdomen. (Courtesy of Dr D.A. Burns, Leicester Royal Infirmary, Leicester, UK.)

multiple excoriated papules over the abdomen and on the extensor surfaces of the limbs. Histology reveals acanthosis and parakeratosis, with perivascular lymphocytic infiltration around upper dermal vessels. Immunofluorescence is negative. The lesions tend to persist throughout pregnancy and may continue well into the puerperium, although the pruritic element often settles shortly after delivery. As with polymorphic eruption of pregnancy, the mother and fetus are unaffected, but prurigo of pregnancy may recur in successive pregnancies, which can cause significant distress to the pregnant woman. It has been suggested that cases labelled 'prurigo of pregnancy' may, in fact, have been eczema.

Only symptomatic treatment is available and this is often rather unsatisfactory [1,2,21].

Pruritic folliculitis of pregnancy

This disorder begins in the second or third trimester and usually resolves within 2 weeks of delivery. The eruption consists of masses of itchy red follicular papules. It strongly resembles steroid-induced acne. Histology reveals a non-specific folliculitis. Immunofluorescence is negative. There is no adverse effect on mother or baby [1,2,21].

Less well-defined dermatoses

Papular dermatitis of pregnancy

Considerable controversy surrounds this entity. It was first described by Spangler *et al*. [22] in 1962, who reported a widespread papular eruption, which they estimated to occur only once in every 2400 pregnancies. In the original description, the rash consisted of widespread, 3–5 mm, intensely itchy papules with a smaller central crust. There were several laboratory abnormalities, including markedly raised urinary chorionic gonadotrophin levels and low urinary oestriol. Of most significance was the observation that there appeared to be a 30% fetal mortality with this eruption. However, there have been no other convincing reports and a recent review of 85 patients found no evidence of increased fetal loss [23]. The confusion may have arisen because Spangler *et al*. [22] included fetal deaths in pregnancies unaffected by a rash and spontaneous abortions, without qualifying these by gestational age [2].

It is now generally accepted that the changes reported as papular dermatitis of pregnancy are probably those of pregnancy prurigo and that the fetal loss in Spangler *et al*.'s series was overestimated.

Autoimmune progesterone dermatitis of pregnancy

There is a single case report of a patient who developed an odd acneiform rash on the extremities and buttocks in two successive pregnancies [24]. There was an associated arthritis and a positive skin test reaction to progesterone. The author used the term autoimmune progesterone dermatitis to describe this phenomenon, thereby leading to confusion with the condition of the same name that is not pregnancy-associated. However, the clinical features of the two disorders are quite distinct.

Prurigo annularis

Two reported cases [25] had annular scaly lesions that persisted for years postpartum. Whether it really had anything to do with the pregnancy must be in doubt.

Mid-life, obesity and the skin

Introduction to obesity

Where energy intake exceeds expenditure, the storage of excess energy in adipocytes leads to obesity. This may present at any age from early childhood onwards, but tends to develop most commonly in mid-life. Obesity can be measured by population means, waist circumference, percentage body fat or body mass index (BMI = weight kg/height m^2). BMI, the most commonly used measure, was first used nearly 150 years ago [1], but one criticism is that it neglects differences in density between muscle and fat, so bodybuilders and children are arbitrarily defined as obese [2]. In 1980, 8% of women and 6% of men in England were obese, with BMIs more than 30 kg/m^2. By 1998, 21% of women and 17% of men were obese [3]. What might be the reasons for this increase?

Individual psychological factors are clearly important [4] and may have a genetic basis, such as the extreme food-seeking behaviour of leptin-deficient humans [5]. Both in developing and developed economies alike, spending on food advertising is increasing greatly. Within a few years of their introduction, 65% of the Chinese population recognized the Coca Cola brand, 42% recognized Pepsi and 40% recognized Nestlé, whilst in North America, fat and sugar form more than half the daily intake of calories, as available food is now both more processed and more energy dense [6]. Fast food consumption, in particular, positively correlates with weight gain and insulin resistance [7]. Watching television, the third major activity after work and sleep in the USA [8], is associated with frequency of meals, obesity and diabetes [9,10]. This modern, obesity-prone living environment may thus be a result of dietary and activity changes induced by strong commercial pressures. A consequence of this is that obesity increases the risk of many systemic illnesses, such as diabetes, hypertension, coronary heart disease, sleep apnoea and osteoarthritis [11], and cancer of breast, endometrium, prostate and bowel [12].

Physiological function of adipose tissue

In adults, subcutaneous fat consists almost entirely of white adipose tissue. This provides insulation and acts as an energy source. Additionally, white adipose tissue produces many peptide hormones, cytokines and paracrine transmitters. These include leptin, tumour necrosis factor α, transforming growth-factor β, interleukins 1 and 6, acylation stimulating protein, adiponectin, resistin, visfatin, plasminogen activator inhibitor and non-esterified fatty acids among others [1–3]. In contrast, brown fat is most prominent in the newborn where it is likely to have a different metabolic role [4].

Cutaneous pathophysiology in the obese

Obesity alters the natural physiology of the skin. Obese individuals have increased transepidermal water loss, dry skin and erythema compared with controls, suggesting a fundamental alteration in the epidermal barrier. Obesity correlates with increased cutaneous blood flow, which may explain the erythema. The obese have larger skin folds and tend to sweat more profusely when overheated than controls. Obesity impairs lymphatic flow, and alters both collagen formation and wound healing [1]. Delayed-type hypersensitivity, to a range of antigens injected intradermally, was reduced in obese women following weight reduction [2]. Conceivably, this could relate to an alteration in the balance of cytokine production by the adipocytes [3]. It is interesting that there is no data so far with regard to potential differences in the activity of sebaceous, apocrine or eccrine glands in the obese compared with the non-obese [1].

Obesity changes the shape of the foot, for example obese children have a lower footprint angle. Obese individuals have a wider forefoot width and also higher plantar pressures during standing and walking. These pressure effects may be the cause of plantar hyperkeratosis, which is thought to be a cutaneous sign of severe obesity [4].

Cutaneous disorders in the obese

Many skin disorders are associated with obesity. Obesity is associated with insulin resistance and type 2 diabetes mellitus. Therefore, there will be a secondary association with all the cutaneous associations of that disorder. These are detailed elsewhere. Specific dermatological associations with diabetes and obesity include fibroepithelial polyps and acanthosis nigricans [1,2]. Many infections are found with increased frequency in the obese, including candidiasis, candida folliculitis, intertrigo, tinea cruris, erythrasma, cellulitis, furunculosis and folliculitis. Less common infections include necrotizing fasciitis and gas gangrene [1,2].

Occasionally, severe obesity is associated with the development of massive necrosis of both subcutaneous fat and the overlying skin. This may lead to secondary infection and ulcer formation [3]. The obese have increased intra-abdominal pressure, which in women may predispose to urinary incontinence, exacerbating any tendency to infection and ulceration in the groins and genital area [4]. Obesity may result in a range of respiratory complications. This may necessitate a tracheostomy being performed. Cutaneous complications of this procedure include bleeding, erosions, ulceration and infection [4].

Excess adiposity affects sensitivity to pressure and pain. Obese persons have a higher pain threshold than the non-obese. This decreased pain sensitivity might be the reason for the development of distal venous and pressure ulcers in obese individuals. Lymphoedema presents as a soft, pitting swelling most commonly over the shins and results from poor lymphatic return. It is often associated with obesity [1,2].

As stated earlier, obesity is associated with a number of non-cutaneous cancers [5]. Also, a number of epidemiological studies have found a link between excess adiposity and malignant melanoma [6–10]. Others have found no significant association with melanoma [11,12].

Other conditions that may be associated with or aggravated by obesity include varicose eczema, hidradenitis suppurativa, acne, hirsutism, androgenetic alopecia, psoriasis, keratosis pilaris, striae, seborrhoeic dermatitis, scleroedema, livedo reticularis, cutis verticis gyrata, lichen myxoedematosus, lipodermatosclerosis and lichen sclerosus [1,2,13–18].

Obesity is linked with a number of rarer conditions. Keratosis follicularis squamosa is a condition consisting of scaly patches, symmetrically scattered over the trunk, buttocks and thighs. Histopathological examination shows a dilated hair follicle with a follicular plug, surrounded by lamellar orthohyperkeratosis. There may be an association with obesity [19]. Granular parakeratosis is a recently recognized disorder of keratinization that is confined to intertriginous body sites, which may explain the connection with obesity. The histological features are distinctive, a parakeratotic stratum corneum, with the presence of keratohyalin granules. These granules are normally confined to the stratum granulosum. The underlying pathophysiological defect is thought to be a failure in the normal degradation of profilaggrin and is responsive to topical corticosteroids [20]. Pretibial mucin deposition on the shins, associated with autoimmune thyroid disease, is known as pretibial myxoedema. A recent report found a similar condition (both clinically and histologically) in three morbidly obese patients, without thyroid disease. This paper proposed a new entity ‘chronic obesity lymphoedematous mucinosis’ as a subtype of pretibial myxoedema [21]. Dercum’s disease (adiposis dolorosa) is a rare disease characterized by multiple, painful, subcutaneous lipomata that usually occurs in obese, postmenopausal women. It may have a familial basis [22].

Treatments for obesity can have cutaneous complications too. Jejunoileal bypass surgery is no longer performed regularly for weight loss, as there are newer, less invasive techniques (e.g. gastric banding) and also because a considerable proportion of patients suffer side effects such as polyarthritis, tenosynovitis, myalgia, fever, anaemia and renal failure. This condition often responds to antibiotic therapy [23–26]. Cutaneous features are found too with post-jejunoileal bypass surgery, including a pustular erythematous macular eruption, with a neutrophilic infiltrate similar to Sweet’s syndrome [23,25], a non-pruritic papular eruption, with IgG and C3 deposition [24] and erythema nodosum

Table 8.7 Genetic disorders in which obesity may occur with cutaneous changes.

Disorder	Cutaneous features	Accompanying other features
Prader–Willi syndrome [3]	Hypopigmentation	Learning difficulties
Fragile X syndrome [4]	Regional hyperpigmentation	Learning difficulties, prominent mandible, macro-orchidism, large ears
Proopiomelanocortin deficiency [5]	Red hair, fair (type 1) skin	Tall stature, hypoadrenalism
MOMES syndrome [6]	Atopic eczema	Learning difficulties, ocular abnormalities, maxillary hypoplasia, prognathism
Hyperostosis frontalis interna [7]	Hypertrichosis	Thickening of the frontal bone
Ulnar-mammary syndrome [8]	Hypohidrosis, nipple hypoplasia to absent breasts, absent axillary hair, nail duplication	Malformed digits, hypogonadism, delayed growth
McCune–Albright syndrome [3]	Atypical café-au-lait patches, linear epidermal naevi, Cushing's syndrome, acromegaly	Polyostotic fibrous dysplasia, gigantism, thyrotoxicosis, precocious puberty
Carney complex [9]	Lentigines, oral pigmentation, Cushing's syndrome, schwannomata	Cardiac myxoma, multiple endocrine tumours, precocious puberty

MOMES, mental retardation, obesity, mandibular prognathism with eye and skin anomalies.

[23,26]. Pharmacological therapies for obesity can also have cutaneous side effects. For example, orlistat, lipoprotein lipase inhibitor, therapy may be linked with the development of a lichenoid drug eruption [27].

Syndromes of obesity with cutaneous features

Obesity presents in children as well as adults [1]. A tiny percentage of these cases will be the result of single gene mutations resulting in a severe obesity phenotype [2]. Some of these genetic syndromes also have a cutaneous phenotype and they are summarized in Table 8.7. A few may have the typical central obesity and other features of Cushing's syndrome.

The menopause

Hormonal and physiological changes

Strictly speaking, the term *menopause* defines the fixed single point in a woman's life characterized by her last menstrual period [1,2]. This is established formally after 12 months of amenorrhoea in the middle years of life [2]. The surrounding years, or climacteric, are a time of change and readjustment to the new phase heralded by the menopause and its loss of fertility; literally, *climacteric* means a step up the ladder. It is a crucial phase for a woman, preparing her for the years to come which, in modern societies at least, may now represent at least 30 years, or one-third of her life [2]. It has been estimated that by 2030, there will be 1.2 billion postmenopausal women worldwide [3].

The age of onset of menopause has been the subject of much study. Some of the data have been criticized because of flaws in their collection and interpretation [4,5]. However, the menopause occurs between the ages of 45 and 55 years in 65–70% of women and the median age in most Western populations is around 50 years. Factors that may influence menopausal age include heredity (age of mother's menopause is highly predictive), smoking, parity, socioeconomic factors, exposure to toxins and nutrition [4]. The onset appears to occur a little earlier in developing countries than in Western societies [5].

True premature menopause before the age of 40 years occurs in less than 1% of women [6], but can follow surgery, irradiation, viral infections (especially mumps), accompany various enzymatic and hormonal defects, or be associated with a number of systemic disorders such as Addison's disease, rheumatoid arthritis, diabetes or myasthenia gravis [1].

During the reproductive years, oestrogen is produced mainly by ovarian follicles, but at the menopause there are major changes. There are very few follicles left, the ovaries become atrophic and the level of ovary-derived oestrogen falls. The endocrinology of this period of a woman's life results from the interrelationship of reduced ovarian function and resultant changes in gonadotrophins. Although there may be intermittent bursts of oestrogen in the immediate postmenopausal period because of residual follicular activity, the level of plasma oestradiol ultimately falls to less than 20 pg/L and remains there for the rest of the woman's life [5]. The ratio of oestradiol to oestrone changes, with oestrone becoming the more abundant hormone [2] and most oestrogens being derived from the direct peripheral conversion to oestrone of androstenedione, which has been produced by the adrenals. Some oestrone may arise through the alternative pathway via testosterone and oestradiol [7]. The pituitary–gonadal feedback loop is virtually absent and levels of gonadotrophins are elevated in consequence. In addition, a number of granulosa cell-derived peptide hormones influence FSH levels [8].

These hormonal changes are reflected in a number of physiological alterations [1]. In the breast, glandular tissue decreases and fibrous tissue increases. The body of the uterus becomes smaller and its muscle is partly replaced by fibrous tissue and the endometrium regresses and becomes atrophic. However, it still retains the capacity to respond to exogenous hormones. The vagina becomes shorter and narrower and the vaginal epithelium atrophies. The pH of the vagina rises and infections become more frequent. The external genitalia atrophy, with a loss of vulval subcutaneous fat and thinning of the vulval epithelium. Pubic hair diminishes.

The epithelium of the lower urinary tract also atrophies and this, together with the increased tendency to prolapse, increases the frequency of urinary tract infections. There is a loss of elasticity in the pelvic supporting ligaments, contributing to prolapse and urinary incontinence [9].

There are no structural cutaneous changes that are specifically associated with the menopause, but there are oestrogen receptors in the skin, suggesting that the skin is a target organ for oestrogen and that its withdrawal may be important [2]. It is interesting that there is a far greater concentration of oestrogen receptors in facial skin than in skin on the breasts or thigh. Some of the changes seen after the menopause, such as dryness, epidermal thinning and loss of dermal elasticity, may result, in part, from lower circulating oestrogen levels. Certainly, administration of oestrogen to castrated animals leads to thickening of the dermis and decreased breakdown of collagen. Oestrogen given to postmenopausal women also increases dermal thickness and has been shown to improve skin elasticity and deformability [2]. The application of topical oestrogens to the face in menopausal women has also been reported to improve various parameters, including reduction in the depth of wrinkles [10]. However, the picture is not as clear-cut with regard to the epidermis. Hormone replacement therapy (HRT) may increase the skin's water-holding capacity [11].

Skin disorders of the menopause

Atrophic vulvovaginitis

It has been known for many years that the atrophic changes in the female external genitalia described above respond, at least partially, to topical oestrogens [1].

Menopausal flushing

The most consistent and distressing complaint associated with the menopause is flushing [2]. This is usually described as a sudden feeling of intense heat in the face, neck and chest, often accompanied by discomfort and sweating. Although the intensity and duration vary, it typically lasts 3–5 min. Visible changes occur in approximately 50% of women and generally consist of a blotchy erythema on the face, neck, upper chest and breasts. Some women also develop palpitations, throbbing in the head and neck, headaches, waves of nausea and anxiety attacks. Sleep disturbance is not uncommon [2]. Physiological changes occurring during hot flushes include increased temperature, pulse rate and respiratory rate [3,4], which are body functions regulated centrally by the hypothalamus.

Neurokinin B (*NKB*) gene expression is elevated in the hypothalamus in postmenopausal women. Oestrogen replacement decreases both the number of *NKB* mRNA-expressing neurones and the level of expression within individual cells. Similarly, *NKB* gene expression is elevated in ovariectomized rats and reduced after oestrogen treatment [5]. NKB is involved in GnRH release from the median eminence [6], which ultimately controls LH release from the pituitary. Flushes are associated with pulsatile release of LH [7], presumably because of failure of the normal feedback mechanisms. However, flushing can occur after hypophysectomy [8] and so LH itself cannot be responsible for the observed vasomotor instability. One suggested mechanism involves alteration of hypothalamic catecholamine levels and a failure of normal central thermoregulatory centres through a GnRH-dependent mechanism. Flushes similar to those seen in the menopause can be induced by an enkephalin analogue and blocked by naloxone infusions [9], indicating that menopausal hot flushes may also be mediated by an opiate-dependent mechanism [10].

The consensus is that oestrogen therapy is the most effective treatment for symptomatic hot flushes [2], although not all authorities have always agreed [4]. Alternatives that can be considered when oestrogens are contraindicated include various progestins [11], clonidine, paroxetine, venlafaxine, gabapentin and the phytooestrogen, black cohosh [12]. Other therapies have been considered ineffective in a systematic review [12].

Keratoderma climactericum

This term has been used to describe the appearance of hard skin on the palms and soles, especially around the heels. Although originally reported as a specific association with the menopause [13], the same changes are seen in men and women at other ages, many of whom are obese [14]. It may therefore be a non-specific effect. There has been a report of a therapeutic response to systemic retinoids [15].

Lichen sclerosus

This disorder is considered in detail in Chapters 51 and 71 but is mentioned here because of its frequent presentation at or around the menopause and because of the significant symptomatology it may cause.

Complications of HRT

The increasing use of HRT, largely to prevent osteoporosis and cardiovascular disease, has revealed a number of problems associated with this treatment. Apart from the ongoing debate regarding the relationship between HRT and cancers of the breast and genital tract, HRT may be responsible for a number of cutaneous problems. Oestrogen therapy may trigger or exacerbate, amongst others, increased skin sensitivity, chloasma (melasma), spider angiomas, darkening of naevi, the skin changes of porphyria cutanea tarda or lupus erythematosus, photosensitivity, pompholyx, erythema multiforme, urticaria and acanthosis nigricans [2,16]. Allergic reactions have been reported to the transdermal patches frequently used as delivery systems for HRT. These may be to the adhesives or to the oestrogens themselves [17].

Old age

Introduction

Senescence in the skin is a gradual process that ultimately results in the appearances and functional differences that we associate with old age. However, by no means all of these changes are purely intrinsic. The skin is particularly vulnerable to the ageing effects of a number of environmental insults, especially UV radiation [1]. In women there are additional hormonal changes at the menopause (see p. 8.19). These factors are superimposed on the background changes of intrinsic ageing and care needs to be exercised in interpreting which are most important in determining any particular aspect of the appearance and function of the skin in an elderly person. There have been increasing efforts to disengage the roles of these intertwined and contemporaneous processes.

Biology of ageing

Ageing is a complex process that has been defined as the accumulation of molecular damage over time [2]. It is controlled by both genetic and environmental factors [1,3]. Intrinsic factors that may be under genetic control include skin colour [4], antioxidant mechanisms to prevent free-radical damage, telomere shortening, mutations in the mitochondrial genome [5], hormone systems [6] and the absolute length of the continuous cell cycle [1,7].

Clearly, not all age-related change is due to genetic factors alone. For example both excess calories and lack of micronutrients may accelerate the physical changes associated with senescence [8].

In the skin, gravitational forces or traction can activate phospholipase A2, an enzyme involved in the generation of prostaglandins and leukotrienes. These can lead to cytokine release, neutrophil recruitment and free-radical generation [2]. Intercellular adhesion molecule-1 (ICAM-1) is a ligand for lymphocyte function-associated antigens. Anoxia induces ICAM-1 synthesis, which facilitates cell movement out of blood vessels, and thus macrophage migration [2]. Electromagnetic radiation from computers and mobile phones induces histamine, interleukin (IL) 1 and IL-6 release [1]. Cutaneous neuropeptides regulate the expression of cell-surface adhesion molecules on immune cells and endothelial cells in response to neurogenic inflammation [2]. The non-enzymatic glycosylation of blood vessels, a normal feature of ageing and accelerated in diabetes mellitus, also induces ICAM-1 expression [2]. All of these triggers can lead to a self-sustaining inflammatory and ageing process, involving the cyclical synthesis and expression of ICAM-1, with immune cells invading the dermis [2].

Photoageing

If the ageing of most of the bodily organs has, however reluctantly, to be accepted, the ageing of the facial skin appears to be a matter of widespread concern. The reason is that the skin plays a major part in our social and sexual interactions; the concern is not so much to do with physiological functions, which may remain adequate in old age, but about continuing effectiveness, particularly of the facial skin, in communication. To display sexuality or assert social status it is necessary to have skin and hair that look, feel and smell attractive.

The most obvious signs of an ageing skin are atrophy, laxity, wrinkling, sagging, dryness, yellowness, a multiplicity of pigmented and other blemishes and sparse grey hair. Some of these stigmata clearly have genetic components, as some are mimicked by heritable disorders. The abnormal skin in cutis laxa makes young children look old; in progeria, on the other hand, the connective tissue remains evenly dense, although the epidermis shows mottled pigmentation [9]. Of particular relevance to the skin, it is thought that more than 90% of age-associated cosmetic problems are caused by ultraviolet (UV) radiation on exposed skin, which damages telomeres, generates free-radicals and whose effects are largely proportionate to skin type [10].

Ultraviolet (UV) radiation has several direct and indirect effects on the skin. About 50% of UV induced damage is from the generation of free radicals, with direct cellular injury and other mechanisms accounting for the rest [9]. DNA damage induced by UV radiation has been studied extensively in relation to skin cancer (see Chapter 29). These UV-related DNA mutations may be of relevance to specific signs of photoageing such as wrinkling and increased elastin and collagen damage. However, it is not known specifically how DNA photoproducts lead to the photoaged phenotype [10]. Ultraviolet A, and to a lesser extent UVB, may damage DNA indirectly through the generation of free-radicals, which damage cellular DNA as well as lipids and proteins [1,10].

A 4977 base-pair deletion in mitochondrial DNA is found in dermal fibroblasts of photoaged skin. This may be a marker for UVA damage. The mitochondrion has the highest turnover of free-radicals in the cell and is responsible for cellular energy production. Many of the genes involved in this process are encoded in mitochondrial DNA, so mutations in its genome could be associated with the changes seen with photoageing [11].

The transcription factor nuclear factor NF-κB is activated by UV radiation and this leads to elevated levels of the proinflammatory cytokines IL-1, IL-6, vascular endothelial growth factor (VEGF) and tumor necrosis factor (TNF)-α [10]. This attracts neutrophils which increase oxidative damage through their production of free-radicals.

Increased VEGF levels favour angiogenesis, aided by reductions in thrombospondin-1, an angiogenesis inhibitor, and increases in platelet-derived endothelial cell growth factor, an angiogenesis activator. These UV-induced changes in gene expression may contribute to the telangiectases seen in sun-exposed areas, as well as contributing to photocarcinogenesis in elderly people [10].

Within 15 min after UV exposure epidermal growth factor, IL-1 and TNF-α receptors are activated in keratinocytes and fibroblasts. This ultimately leads to the expression and activation of the nuclear transcription factor activator protein 1 (AP-1). AP-1 regulates transcription of matrix metalloproteinases (MMPs), enzymes responsible for degradation of the extracellular matrix [9]. MMPs are found in both epidermal keratinocytes and dermal fibroblasts. Iron is required for the activation of MMP-1, the major metalloproteinase responsible for collagen degradation [10]. The

transcription factor NF-κB is also activated by UV radiation via an iron-dependent mechanism. It amplifies the UV response by stimulating the transcription of inflammatory cytokines and attracting neutrophils that contain preformed neutrophil collagenase (MMP-8). NF-κB is also able to increase expression of MMPs [9].

Up-regulation of MMP can occur after only a minimal dose of UV, well below that required to produce erythema and there is a dose–response relationship between UV exposure and MMP induction. Minimal repetitive exposures to UV radiation at a dose equivalent to 5 to 15 min of exposure to midday sun every other day is enough to maintain these elevated levels of MMP. Exposure to UV radiation insufficient to cause sunburn can lead to the degradation of skin collagen and eventual photoageing [10].

UV irradiation may produce both local and systemic immunosuppression. This is partly mediated by DNA damage and also by altered cytokine expression. UV-induced immunosuppression may have arisen evolutionarily to prevent autoimmunity resulting from UV-mediated DNA damage. It also predisposes the individual to photocarcinogenesis [9]. This subject is covered in greater detail in Chapter 29.

The ageing skin

Dermis

Wrinkling of ageing skin is almost entirely the result of changes in the dermis. The debatable questions concern the nature of these changes and to what extent they are intrinsic or environmentally caused [1].

The dermis diminishes in bulk and in absolute terms the collagen per unit area of unexposed skin decreases with age. This is exaggerated in exposed skin, as after UV irradiation, the procollagen pool is markedly decreased and may be absent by 24 h after exposure *in vivo*. AP-1 and transforming growth factor (TGF)-β are involved in this UV-mediated down-regulation of collagen synthesis. Also, damaged collagen itself may down-regulate new collagen synthesis [1].

Mechanical effects also contribute to decreased collagen synthesis in the photoaged dermis. Cells produce collagen most effectively under high mechanical tension. Impaired distribution and attachment of fibroblasts onto degraded collagen may contribute to inhibition of collagen synthesis. A cycle forms whereby decreased new collagen production due to poor adhesion of fibroblasts to damaged collagen, leads to worsening photoageing [1].

There also appears to be a steady increase in the number of mast cells, mononuclear cells and neutrophils. The fibroblasts show a stellate phenotype and, ultrastructurally, a highly activated endoplasmic reticulum, reflecting increased biosynthetic activity [2]. Although it is often assumed that the lax skin of the aged results from lack of water, there is evidence that water content increases in photoaged skin. Intrinsically aged skin has a similar water content to non-aged skin [3].

Gross morphological changes, especially in the collagen and elastin fibres, have been revealed by electron and light microscopy. Their relationship to molecular changes as determined by physical and chemical methods requires interpretation. Moreover, it has long been clear that such changes are largely the result of exposure to solar radiation, photoageing [1].

Accumulating evidence indicates that intrinsically aged skin shares a number of features with photoaged skin. Commercial interests have dictated a more detailed interrogation of the mechanisms underlying photoageing. However, the same research techniques are now being applied to intrinsically aged skin. There is an age-related loss of fibroblast frequency and size, coupled with a decrease in their synthetic ability [1]. Over the age of 70 years, there is loss of collagens I and III in the papillary dermis with an associated increase in MMPs [1]. Reactive oxygen species and free radicals are key drivers of the degeneration that is so characteristic of aged skin. This oxidative damage is produced in part by the action of mitogen-activated protein (MAP) kinases. In aged skin, stress-activated MAP kinase activity is elevated [4].

In the dermis of young adults, the collagen bundles are well organized. They form a rhomboid network with the individual bundles lying at angles to one another. Intertwined among the collagen bundles lie single branching elastic fibres, apparently aligned haphazardly, in planes parallel with the surface at all levels beneath the dermal–epidermal junction. The network of collagen bundles, although composed of inextensible fibres, is itself extensible as the bundles rotate relative to one another to form parallel alignments. It seems likely that the return of the network to its unstretched state is brought about by the interwoven elastic fibres [1]. Thus, in cutis laxa, an uncommon disorder in which the skin hangs in folds, the elastic fibres appear to be reduced in number and are degenerate (see Chapter 45).

The various descriptions of changes in ageing based on histological staining techniques are often confusing. In general, it appears that the collagen bundles become fragmented and disorientated and elastin fibres become progressively reduced [5]. However, in senile skin from exposed areas there may, paradoxically, be a striking increase in fibres that take up elastin stains in actinic elastosis [1].

Elastic fibres gradually disintegrate with age, even in protected skin and after the age of 70 years most fibres appear abnormal [5,6]. These changes are most probably a combination of reduced synthesis and elastolysis. Similar changes can be produced in protected buttock skin within hours by incubating it with pancreatic elastase and bovine chymotrypsin [6].

Epidermis

Many differences between a senile and young epidermis have been described, but a consistent interpretation of the ageing process has proved difficult. In part, this is because the epidermis varies from site to site. Young skin from the back, like that from the scalp and axilla, has deep and complex rete ridges, whereas that of the face [7] has a fairly flat dermal–epidermal junction. It is widely agreed that in areas where the junction is corrugated in youth, it becomes flattened in the aged [8].

Similarly, there are differences in epidermal thickness, even in young skin. On the face or on the dorsum of the hand, for example, it is considerably greater than on the arms, legs or trunk [8]. In many areas, the whole epidermis becomes thinner with age and the cells become less evenly aligned on the basement membrane and less regular in size, shape and staining properties [8]. There is now some consensus that the cell turnover rate is halved between the third and seventh decades of life [9]. The evidence that the rate of epidermal repair and wound healing declines with age [10] is consistent with the view that the rate of epidermal turnover is decreased.

The permeability of the skin also changes with age. The capacity of the isolated horny layer *in vitro* to restrict water loss does not differ between young adults and persons over 70 years of age, but the aged skin is decidedly more permeable to chemical substances [11]. However, percutaneous absorption of testosterone appears *in vivo* to be reduced in old age. A possible explanation is that, although substances enter aged skin more easily than young skin, they are removed more slowly into the circulation because of changes in the dermal matrix and reduction in the vasculature [11,12]. The response to blistering agents, such as 50% ammonium hydroxide, is initially quicker in elderly than in young subjects, but the formation of the full blister takes longer [13]. These physiological differences must be largely related to changes in the stratum corneum [14]. However, the surface area of individual corneocytes from unexposed areas of the arms, thighs and lower abdomen increases with age, which may reflect an increased transit time [15]. A change in the nature of the corneocytes is also indicated by the tendency of the ageing epidermal surface, especially that of the lower legs, to become dry, flaky and sometimes itchy. Apart from reduced function of the skin glands, the water-binding capacity of the stratum corneum appears to be reduced [14], coupled with an increase in renewal time if damaged [1].

Pigmentation

The most obvious senile changes in white skin are pigmentation irregularities. Yellow or brown macules, known as 'liver spots' or 'age spots' (lentigos), develop on the backs of the hands and exposed parts of the face in more than 50% of persons over 45 years of age. They consist of a localized proliferation of melanocytes at the dermal–epidermal junction. Very rarely, such lentigos appear to develop into *lentigo maligna*, which is a precancerous condition, although it progresses very slowly [16]. Even heavily pigmented skin darkens. A study of 578 adult natives of New Guinea revealed that pigmentation increased with age in skin exposed to the sun, but not in axillary skin and that males darkened more than females [17].

Greying of hair

Greying of the hair in a white population, starts at an average age of 34 and half the population will have 50% grey coverage by age 50. It should be noted that these statistics may not hold for all populations [18]. Interestingly, there is an association between premature greying with both cigarette smoking and osteoporosis [18,19]. It is interesting that sudden onset of white hair seems to be a separate phenomenon to greying and is associated with alopecia areata and vitiligo [20].

The bulbs of grey or white hairs show various abnormalities, but it is uncertain which are critical. In general, the bulbs appear to lack or be deficient in tyrosinase, the enzyme necessary for the first stages of melanin synthesis [21]. Structurally, the follicles of grey hairs still have melanocytes placed normally over the dermal papilla, but the cytoplasm may contain large vacuoles and the melanosomes may be only lightly melanized [21]. The follicles of fully white hairs may completely lack melanocytes. However, among grey or white hairs, there may be a few normal bulbs producing dark hairs. An unexplained fact is that at all ages from their appearance on the chest in males and probably elsewhere, grey hairs tend to be thicker and longer than pigmented ones.

Hair follicles

Scalp hair also becomes finer with age, especially in those with alopecia. Androgenetic alopecia is an extremely common disorder affecting both sexes, with a greater incidence in males than females. The density of hair follicles in the scalp steadily decreases with age, more rapidly in bald than in non-bald persons. This disorder results from the progressive conversion of terminal hairs into indeterminate hairs and then finally into vellus hairs. Patients therefore have a reduction in the terminal-to-vellus hair ratio. Fibrous tracts remain, following miniaturization of the follicles. Patients with this disorder usually have a typical distribution of alopecia, with hair becoming sparse on the vertex while it is still luxuriant on the occiput [22,23]. Genetic variation in the androgen receptor gene is thought to be the principal pathogenic factor in early-onset androgenetic alopecia. The androgen receptor gene is located on the X-chromosome, stressing the importance of the maternal line in the inheritance of androgenetic alopecia. It is not known whether this gene mutation is of significance in women or in men with minimal baldness [24]. Although baldness is mainly a cosmetic issue, some epidemiological studies have linked it with important conditions of old age, such as hypertension [25] and prostate cancer [26].

The weight of beard grown per day reaches a peak in the fourth decade and starts to decrease slightly in the seventh decade [27]. As the density of the hairs remains constant, the decrease in weight must be accounted for by a reduction in the rate of growth, in diameter, or in both. Evidence that the linear growth of beard hair is correlated solely with levels of 5α-dihydrotestosterone (DHT) in

the plasma, not with testosterone, whereas hair density is significantly correlated solely with testosterone, not with DHT [28], suggests that the age changes may result not so much from reduced production of testosterone as by lessened peripheral metabolism.

Chest hairs, which are also androgen-dependent, reach a maximum in number, breadth and length around the fifth decade and then start to diminish markedly [29].

Axillary hair reaches a peak in mass and in rate of production towards the end of the third decade in males and females alike and this is followed by a rapid decline, somewhat more severe in females [30]. Pubic hair appears to follow a similar pattern.

If most of the changes with ageing involve reductions in the amount of hair, this is not true of all sites. In the male, the eyebrows may become bushier and visible hairs develop around the external auditory meati. In the female, hirsutism may occur as a result of endocrine changes associated with the menopause.

Sebaceous and apocrine glands

Sebum production is at its greatest in early adulthood and lessens in old age, remaining unchanged until past the age of 70 years in men, but falling after the menopause in women [31].

Measurements of the sustainable rate of wax ester secretion after depletion of the sebum reservoir by absorption with bentonite clay suggest that sebum secretion declines steadily through each decade by approximately 23% in men and 32% in women [32]. The fatty acid composition also changes [33].

The predominant belief is that, in spite of their decreased output, the sebaceous glands increase in size because turnover of cells is slower in senility [34,35]. However, in one study in 14 women the glands appeared to become smaller and the sebocytes flatter with age [36].

The axillary apocrine glands also regress with age and produce less odour [8].

Eccrine glands

Spontaneous sweating on the fingertips declines in old age, as a result of a combination of a reduction in the number of glands [37] and of the output per gland [38]. The response of the forearm sweat glands to adrenaline declines with age equally in men and women, suggesting an intrinsic deterioration of the glands. This interpretation is supported by histological evidence. In contrast, the effect of age on the response to acetylcholine is much greater in the male than in the female, suggesting that ageing affects cholinergic sweating indirectly through the hormonal balance in the blood [38]. Such a hypothesis is borne out by the evidence that the maximum rate of cholinergic sweating is much greater in adult males than in females or in juveniles and is thus probably androgen-dependent [39].

Nail growth

The rate of linear nail growth increases until well into the third decade. From about the age of 25 years it starts to decrease. Until the age of 70 years, nail growth is greater in men than in women, but thereafter the situation appears to be reversed [40]. Nails are more brittle in the elderly and are characterized by beaded ridging, sometimes called 'sausage links'. Brittleness may be caused by a reduction in the nail content of lipophilic sterols and free fatty acids [41].

Nerves and sensation

Age often decreases sensory perception and increases the threshold for pain [42]. There is evidence for progressive disorganization or loss of some sense organs; for example, the density of Meissner corpuscles in the little finger falls from over 30/mm^2 in young adults to approximately 12/mm^2 by the age of 70 years [43].

Langerhans' cells and immune functions

Langerhans' cells become considerably reduced in number in elderly people, even in light-protected areas [44]. There is a reduction in number of epidermal Langerhans' cells with age, coupled with a reduced ability to migrate from the epidermis in response to TNF-α [45]. Exogenous IL-1β improves the impaired Langerhans' cell migration in aged skin [46].

Peripheral immune function is altered in the elderly. The responses of both T and B cells to specific mitogens are altered in the over 80s, despite the fact that the absolute numbers of T and B cells remain within normal limits [47]. The decreased intensity of delayed hypersensitivity reactions [1,47], the increased risk of photocarcinogenesis and the greater susceptibility to chronic skin infections are some of the consequences of the ageing of the immune system [1,47].

Skin disease in old age

The demography of most nations is changing. Higher standards of housing, hygiene and nutrition, together with improvements in health-care services, have meant that the average lifespan has increased considerably over the last century. Added to this, many couples are now limiting their families to two or three children at most. Virtually every Western society is therefore experiencing an increase in the average age of its population. The provision of health care for elderly people is consequently becoming more and more important. Disease of the skin is no exception to this [1]. Elderly patients present to dermatologists with a wide variety of skin problems; a few are more or less specific to old age, but most are familiar skin disorders whose clinical expression, physical and emotional consequences and management may be altered by the age of the patient and the problems that increasing age bring with it.

The reasons an individual seeks advice for skin changes in old age may be as much influenced by personality and social conditioning as by the absolute severity of the problem. Although some societies are still said to view the outward signs of age, such as wrinkles and grey hair, as marks of distinction, it is clear that in much of the world 'Westernization' is resulting in an increasing degree of social stigmatization associated with looking old. Furthermore, it is recognized that, contrary to the popular belief of the young, elderly people are often anxious to look attractive [2].

Thus, particularly in rich and highly developed societies, there is an increasing reluctance to accept the physiological consequences of old age and the effects of environmental exposure. Some may consider these ageing changes to be abnormal and many older people with plentiful spare time and financial resources have become obsessed with the pursuit of an eternally youthful appearance (Fig. 8.5). One reason for this is that the pharmaceutical and cosmetic industries have invested heavily in the promotion of the concept that 'young is beautiful'. A great deal of money is being, and will continue to be, devoted to the study of compounds that may arrest or reverse the visible effects of ageing. Some are claiming success, most notably with all-*trans* retinoic acid and other retinoids for wrinkles [3]. Such research is also increasingly gaining credence in mainstream medical circles and dermatologists are becoming more involved in this area of practice (see Chapter 80).

However, most people accept (albeit increasingly reluctantly) that ageing is a natural process and only seek medical advice when skin changes are particularly troublesome or severe, or

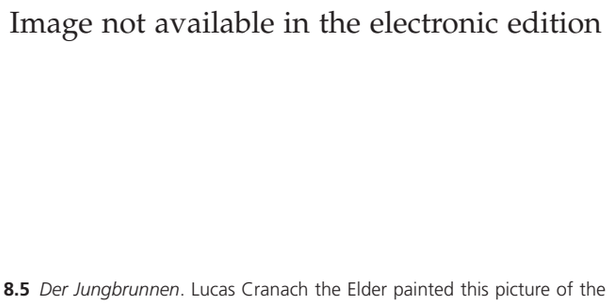

Fig. 8.5 *Der Jungbrunnen*. Lucas Cranach the Elder painted this picture of the Fountain of Youth in 1546, when he was 72 years of age. On the left, a succession of aged and decrepit women are brought to the fountain by an interesting variety of primitive transport. As they move through the basin they are transformed into lovely young maidens. The eternal desire for and, indeed, the possible advantages of rejuvenation are wonderfully expressed. (Courtesy of Staatliche Museen zu Berlin, Gemäldegalerie, Berlin, Germany.)

develop earlier than might otherwise have been expected. Skin changes of sufficient severity to warrant medical attention in elderly patients may result from the interplay of several factors:

1. Alterations in structure and function of the ageing skin
2. Cumulative effects of exposure to a variety of environmental insults, especially UV radiation
3. Cutaneous consequences of ageing or age-related disease in other organ systems
4. Changes in the environment—decreasing occupational exposure, increasing leisure exposure to potential irritants and sensitizers
5. Social circumstances, with poor nutrition, home care and mobility often contributing to the expression, perpetuation of and failure to resolve skin problems
6. Physiological problems, such as dementia, increasing rigidity of attitude and refusal to accept advice
7. Increasing physical frailty, resulting in a relative incapacity to carry out tasks correctly.

Of particular practical importance are the latter three problems, which are frequently ignored. An elderly patient may be too proud to point out that physical incapacity prevents the twice-daily application of a cream, or may deliberately refuse or forget to relate relevant facts about the home situation. The onus is very much on the dermatologist to consider these factors when dealing with skin disease in the elderly patient.

Incidence of skin problems in old age

It is hard to estimate the true frequency of skin disease in the population as a whole, let alone specifically in older age groups. One problem is that the line between that which is physiological and that which is 'truly' pathological, becomes increasingly difficult to draw with advancing years. Another is that studies of skin problems in the elderly have used different types of population and diagnostic groupings that are not directly comparable (Table 8.8). It is probably better therefore to think of skin problems rather than just skin disease in this age group.

Table 8.8 Studies on the incidence of skin disease in elderly people.

Reference	No. of patients	Population studied
Droller [6]	476	Random; at home
Young [9]	330	Ambulatory outpatients from skin clinic; chosen 'at random'
Epstein [10]	687	US private practice
Tindall & Smith [7]	163	Volunteers; at home; black and white people
Verbov [13]	170	Mainly outpatients; some in-patients
Weisman *et al*. [8]	584	Residents of old people's homes
Beauregard & Gilchrest [5]	68	Volunteers: housing projects, geriatric home visits, medical centre employees
McFadden & Hande [11]	257	Dermatology outpatients

However, the vast majority of people over 70 in the USA have at least one troublesome skin condition. Approximately 10% of the over 70s have three or four significant skin conditions [1]. Many studies on elderly individuals selected randomly and not from skin clinics give much the same impression [4–8]. For example, of 68 volunteers aged between 50 and 91 years, living in Boston, USA, two-thirds of the entire group and 83% of those aged over 80 years complained of skin problems of some kind [5]. In a European study, 77.4% of a population of 584 elderly residents of a municipal old people's home in Denmark were found to have a skin problem [8].

Many of the skin problems that are found most commonly on random examination of elderly people are not those for which elderly patients necessarily seek attention from specialist or non-specialist doctors. Although eczemas, pruritus, easy bruising and dryness (under various headings) are certainly seen in skin clinics, tumours, both benign and malignant, tend to figure more prominently than inflammatory problems [9–13].

Specific skin problems in old age

Most of the skin disorders that are particularly troublesome in the elderly patient are described elsewhere in this book. However, one or two points should be emphasized about certain specific disorders.

Wrinkles and elastosis

These changes, together with greying of the hair, are most readily associated with an aged appearance. The different clinical forms of wrinkles and the clinical syndromes associated with elastosis, are described in Chapter 45 and the histological changes of the ageing dermis are discussed above. Plastic surgeons and dermatologists are becoming increasingly involved in their management. Topical retinoids, botulinum toxin injections, chemical peels, dermabrasion, ablative or non-ablative laser techniques, collagen implants and facelift operations are in widespread use in the treatment and prevention of wrinkling [1,2], described in detail in Chapter 80.

Pruritus

Itching in old age can be so severe that it ruins quality of life [3]. The itch may be localized or generalized and may or may not be accompanied by skin changes. It is crucial to examine an itching elderly person carefully for primary cutaneous disease. In one study, 142 of 162 elderly patients had an identifiable cause for their itching (including xerosis), leaving only 20 to whom the term senile pruritus was applicable [4]. Diagnoses that are particularly easy to miss are scabies [5] (often caused by the inadequate examination facilities in residential homes for the elderly) and bullous pemphigoid, which often begins with a non-specific or even no rash [6]. Non-specific skin changes in anogenital itch may also conceal important diagnoses: candidiasis in undiagnosed diabetes, lichen sclerosus, the classical signs of which may easily be obscured by secondary excoriation and inflammation.

If a primary skin disorder has been ruled out, it is important to investigate any elderly patient with generalized itching for systemic causes: renal disease, cholestasis (especially chronic liver disease), thyroid disease, anaemia or cancer. The relationship between carcinomas and pruritus in the elderly patient is controversial, but there is no doubt that lymphomas, leukaemias and other myelodysplastic disorders may present in this way [7]. The frequency with which a systemic cause is found varies, but is high enough to justify a routine search [7].

When all these causes have been excluded, there remains a small core of elderly patients with intractable pruritus. In some, the itching is accompanied by xeroderma, but in others the skin feels relatively normal to the touch. The management of such patients is extremely difficult and is often totally unsatisfactory for all concerned. The topical use of emollients, soothing preparations such as menthol in calamine and potent topical steroids may be helpful. However, many of those with the worst pruritus are quite unable to manage topical therapy by themselves and it is necessary to resort to relatively sedative systemic drugs, such as phenothiazine-type antihistamines. These, too, have their drawbacks, not the least of which is the development of confusion and disorientation [7].

Senile xerosis and asteatotic eczema

Synonym
- Eczéma craquelé

Ageing skin often feels 'dry' to the touch, although the reason for this is not clear. Water loss is not increased in aged skin [8], but the water content of the epidermis appears to be somewhat reduced [9]. Dryness is often worse in the winter, a fact that has given rise to many of the alternative names used for these changes: winter eczema, prurigo or pruritus hiemalis. The changes are often most pronounced on the legs. In some patients, the surface texture of the skin assumes a cracked appearance resembling crazy paving. This is known as asteatotic eczema or eczéma craquelé (Fig. 8.6). Frequent washing is certainly a causative factor in susceptible individuals [10] and central heating may also play a part by reducing atmospheric humidity. Perhaps it is not surprising that this problem is commonly seen in geriatric in-patients.

The use of emollients to reduce requirements for soaps and detergents will improve xerosis in most patients and, because high water temperature appears to increase the tendency to irritant reactions [11], so will reducing the bath temperature. Moisturizing preparations in the bath are generally held to be effective [3], but bath oils can make the bath very slippery, which has its risks in the elderly and frail patient.

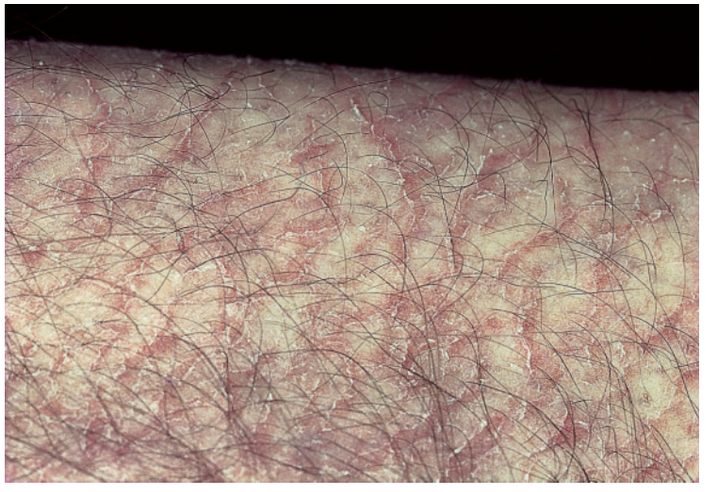

Fig. 8.6 Asteatotic eczema.

Eczema

The aged may suffer from any of the clinical types of eczema. Atopic eczema, for example, occasionally continues into old age or even appears for the first time. However, certain patterns such as asteatotic eczema are more common and more troublesome in elderly subjects.

Seborrhoeic dermatitis may be more common in the elderly infirm and in those confined to bed [12]. In the aged patient, especially the obese, a flexural pattern is often encountered, which may mimic intertrigo and flexural psoriasis.

Some elderly patients present for the first time with a discoid or nummular eczema and gravitational eczema is much more common in the elderly patient (see Chapter 23) and may be complicated by contact sensitivity.

Contact dermatitis of irritant or allergic origin is generally considered to be less common in elderly people, partly because of decreased occupational exposure [13]. This may also reflect the decline in immune reactivity that occurs with age [14] and the fact that irritant responses to some substances are reduced in intensity [15]. However, patch-test positivity remains quite common, presumably from exposure earlier in life. Allergic contact dermatitis remains a significant problem in elderly people, especially resulting from local medicaments, such as aminoglycosides, lanolin, parabens, antihistamines and anaesthetics. Other sensitizers that continue to cause trouble in old age include rubber in gloves and shoes, plastics in hearing aids and spectacle frames, plants and hair dyes [13].

Marked secondary lichenification and chronic lichen simplex are also often seen in older patients.

Bullous disorders

Pemphigoid (see Chapter 40) is much more frequent in the elderly than in other age groups. Old age modifies the management of all blistering diseases because of unwanted effects of drugs, or because of physical and social circumstances. Steroids precipitate glucose intolerance more often in the elderly and sulfapyridine or sulfamethoxypyridazine may be better first-line drugs than dapsone for dermatitis herpetiformis because of the tendency for dapsone to cause haemolysis [16]. Drug regimens should be kept simple and written down where necessary.

Psoriasis

There is a distinct peak of onset of psoriasis in later life, between the ages of 55 and 60 years, that is not as clearly associated with a family history as in patients whose disease begins earlier. This is reflected in different human leukocyte antigen (HLA) associations [17].

Psoriasis causes increased problems in the elderly patient. Disease of lesser extent and severity may be relatively more disabling in old age than in youth and the systemic effects of widespread or acute pustular psoriasis are less well tolerated than in younger individuals. Flexural psoriasis is a particular problem in the elderly patient [17], but other patterns are also seen. Eruptive guttate disease, however, is rare in old age.

Treatment can be difficult. The patient may be unable to apply topical therapies and there may be problems in travelling to and from the hospital for outpatient dithranol treatment, or in standing for psoralen and UVA (PUVA) therapy. One solution is the use of systemic therapy, especially methotrexate. There is less reason for concern over long-term methotrexate toxicity in the elderly patient, relatively small doses may keep the patient comfortable (perhaps because of diminished renal clearance) and the drug is generally well tolerated. The use of etanercept has been found to be well tolerated by the over 65s, with equal clearance rates, when compared with younger patients [18].

Leg ulcers (see Chapter 47)

Leg ulcers are a major problem. Most are caused by venous hypertension, but arterial disease becomes increasingly important with advancing years. Poor wound healing in elderly people, perhaps associated with other illnesses and poor nutrition, may also have a role in the perpetuation of some ulcers [19].

In managing chronic leg ulcers in the elderly patient it is important to take an overview of the whole situation. Strenuous efforts to heal a stable ulcer in someone who is coping independently at home may be inappropriate in some cases if long-stay in-patient treatment will be required [20].

Decubitus ulcers [21]

See Chapter 28.

Varicella zoster and post-herpetic neuralgia

Shingles is much more common in old age, the relative incidence in those over 60 is 11.2 per 1000 patient years. Post-herpetic neuralgia is also much more common in elderly people [22]. Recently, a vaccine has been developed for varicella zoster, which should reduce the population frequency of post-herpetic neuralgia [22].

Skin tumours

Most skin tumours are more common in elderly people: benign, such as seborrhoeic keratoses, senile lentigines and skin tags; dysplastic, such as actinic keratoses; and cancers, especially basal and squamous cell carcinomas. Lentigo maligna is seen predominantly in the elderly [23] and the highest age-specific incidence rates for invasive malignant melanoma are also in those over 60 years.

Fig. 8.7 A large, neglected basal cell carcinoma on the back of an elderly lady.

There is also an association between increasing age and decreasing 5-year survival in malignant melanoma [24]. It is not clear why this should be, but elderly patients seem to present with thicker lesions [24,25] and recent evidence suggests that the proportion of nodular melanomas may rise with increasing age [25]. The tendency to wait longer before presenting for treatment also extends to other tumours and lesions such as that shown in Fig. 8.7 are essentially restricted to elderly people.

Infections with ectoparasites

Outbreaks of scabies in residential homes for the elderly are not uncommon and are usually attributable to one individual with a heavy infection, perhaps with crusted scabies. Clothing lice (see Chapter 38) are, in the UK, almost exclusively seen in elderly vagrants.

Introduction

This chapter aims to describe the normal variants of different 'racial' groups as well as to consider the impact of biological racial variation and cultural racial influences on the expression of skin disease. Specific tropical infections are not covered. Instead, this chapter focuses on racial susceptibility/variation in disease rather than the influence of geographic location, although inevitably the two are sometimes linked.

What is race?

In biology, 'race' refers to a subpopulation or variety of a species that differs in gene frequencies from other members of the classification group.

Many anthropologists do not think 'race' can be usefully applied to humans, because humans do not fall into geographic populations that can readily be distinguished in terms of different sets of biological or physical traits. Thus, classifications of 'race' in humans (Table 9.1) only represent a variation in DNA of 0.1% [1]. Emerging views of 'race' recognize the role of biological or anthropological definitions of the term, but also assert that 'race' reflects a social construct [2], that is a product of historical relationships amongst groups rather than just an inherited trait. Whilst this might be overlapping, 'culture' or 'ethnicity' (distinctive customs, achievements, products, outlooks, etc. of a society or group; the way of life), describing this broader construct and including the social landscape that influences a population group makes sense when considering the skin. Study of dermatological patterns in health and disease should include focusing on the cultural aspects of race, as well as the biological.

Racial variants in the structure and function of the skin

The degree of pigmentation is one of the most obvious and immediate factors in distinguishing the main races. Other differences in the structure and function of the skin are less obvious and not so well studied but have some relevance [1] and are discussed below. Where there is little evidence of difference between the races, no further comment is made.

Melanosomes (see Chapter 3)

The density of melanocytes is known to be identical amongst different racial groups, although it varies across body sites. It is variability in the amount and type of melanin that accounts for the intrinsic complexion. There is also variation in melanosome size with race—Africans having the largest melanosomes and European Caucasians having the smallest [1]. Furthermore, the patterns of melanosome distribution in keratinocytes of human skin vary. In Caucasian skin the melanosomes are predominantly clustered (84.5%) and membrane-limited, whereas in African skin they are individually distributed (88.8%) over the nucleus of the keratinocyte. In Asian skin the melanosomes are distributed as a combination, some being individually placed and others in clusters [2].

The epidermis

Although the stratum corneum is of equal thickness between races, there are more layers in black skin, and more extensive tape stripping is required to remove it, compared to Caucasian skin [3]. Desquamation in black skin is reported to be 2.5 times greater than in Caucasians and Mongoloids [4]. Additionally, black skin shows higher transepidermal water loss than Caucasian skin [5].

Racial differences in hair (see also Chapter 66)

Human scalp hair is categorized into three distinct forms: African, Asian and Caucasian. However, there are limited data on the influence of racial origin on hair characteristics.

Diameter. Asian hair is thicker in diameter and generally circular in cross section, whereas African hair tends to be more elliptical in cross section with a variable diameter along its shaft. The Caucasian hair-shaft seems to lie somewhere between the two.

Fibre shape. Caucasian and Asian hair shafts are generally cylindrical whereas the African hair shaft resembles a twisted, oval rod [1].

Telogen counts tend to be higher in Afro-Caribbeans than in Caucasians, whereas hair density is lower; mean ± SD: 190 ± 40; 227 ± 55 hairs/cm^2, respectively [2].

Male Caucasoids show more androgenic balding over the vertex with age than Afro-Caribbeans [3]. Black hair colour predominates amongst Asian, African and Amerindian races; however, hair can also be red in these races. European or Caucasoid hair colour varies widely from black in southern Europe to blond in northern countries [4].

Amerindian, Polynesian, Micronesian and Melanesian (collectively known sometimes as Mongoloid) races have less body, beard and axillary hair than Caucasoids [5].

Normal variants

Voight's lines

Synonym

- Futcher's lines

These are sharply demarcated borders between areas of darker pigmentation on the dorso-lateral and ventral aspects of the limbs [1]. They are bilateral and most obvious on the proximal part of the limb, especially on the upper arms (Fig. 9.1). The line of demarcation corresponds to innervation within a dermatome; however, histologically, there is no alteration in the distribution or amount of melanin [2]. Occasionally a second such line may be seen postero-medially on the lower part of the limb [2]. Although infrequently seen in other racial groups [3], they are very prevalent in black races. Estimates of their frequency vary, being reported in up to 30% of black individuals [1,3,4]; their occurrence is proportional to the degree of pigmentation. More rarely, a line of hypopigmentation may occur in the midline of the anterior chest wall [1]. It is most prominent in children. Although entirely benign, reassurance may sometimes be required as such lines can be thought to be pathological or may be a source of cosmetic concern.

Hyperpigmentation of the palms and soles

Patchy and rather mottled pigmentation on the palms and soles (Fig. 9.2) is a common finding in black individuals [1]. The lesions are usually multiple, vary in size and have rather indistinct borders but should be easily distinguished from solitary melanocytic naevi, malignant melanoma or lesions of secondary syphilis [4].

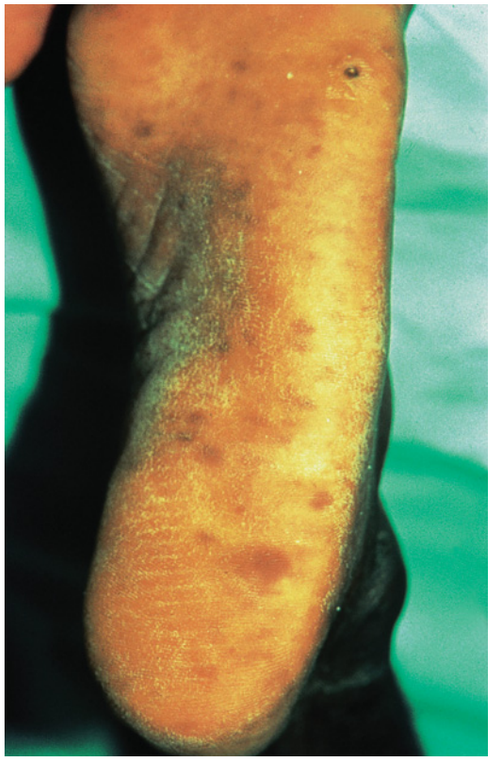

Fig. 9.2 Mottled hyperpigmentation of the soles. (Courtesy of Dr D.J. Barker, Bradford Royal Infirmary, Bradford, UK.)

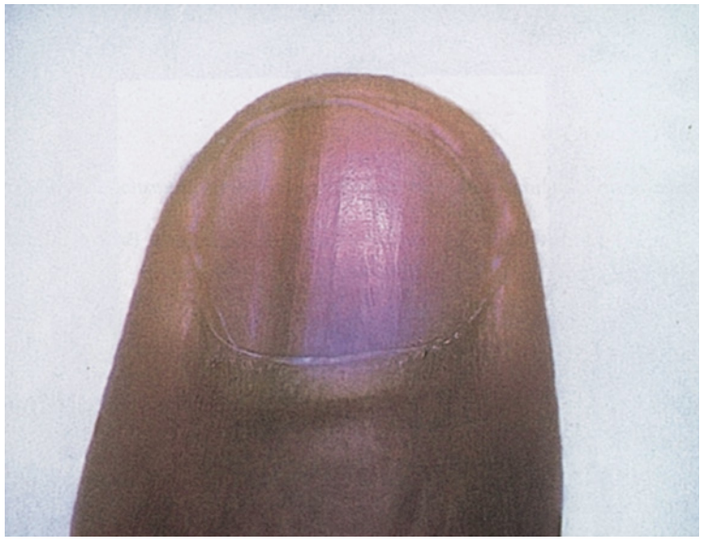

Fig. 9.3 Melanonychia: nail pigmentation.

Melanonychia

Nail pigmentation is quite variable in people with skin types 5 and 6. While some individuals have quite pink nails, in others diffuse pigmentation may occur and there is quite wide inter-family variation. Discrete, longitudinal bands of hyperpigmentation are common, particularly on the first and second digits [4]. Such changes are found in at least 50% of all black Africans, but more so in those with darker skin. They may be noted in childhood, but appear to increase in frequency with age. They are due to increased melanin deposition in the nail plate and matrix [5]. Trauma has been implicated in their development [6]. In children, benign melanocytic hyperplasia is the most common cause [7]. Concern regarding the possibility of malignant melanoma may arise [8], but the pigmented bands of longitudinal melanonychia are static, usually multiple or bilateral, and are not associated with pigmentation extending onto the surrounding skin (Fig. 9.3).

Oral pigmentation

Oral pigmentation is common in darker races [1]. It most frequently affects the gingivae, but may involve the hard palate, buccal mucosae and tongue [2].

Table 9.2 Some causes of hypopigmentation.

Division	Disorders
Congenital or genetic	Albinism, piebaldism, achromic naevus
Infections	Leprosy, onchocerciasis, pinta, pityriasis versicolor, herpes zoster
Papulosquamous disorders	Pityriasis alba, pityriasis rosea, pityriasis lichenoides chronica, psoriasis, seborrhoeic dermatitis, lichen striatus
Other inflammatory disorders	Discoid lupus erythematosus, systemic sclerosis, sarcoidosis, some eczematous eruptions
Physical or chemical agents	Burns, cryotherapy, ammoniated mercury, hydroquinone products, fluorinated corticosteroids
Miscellaneous	Vitiligo, idiopathic guttate hypomelanosis

Table 9.3 Some causes of hyperpigmentation.

Division	Disorders
Congenital or genetic	Voight's lines, congenital melanocytic naevus, epidermal naevus, Becker's naevus, neurofibromatosis, McCune–Albright disease
Infections	Tinea corporis, herpes simplex, chickenpox, herpes zoster
Papulosquamous disorders	Eczema, lichen simplex, lichen planus, pityriasis rosea
Post-inflammatory	Fixed drug eruption, erythema multiforme, trauma
Physical or chemical agents	Thermal burn, contact dermatitis, ochronosis
Miscellaneous	Melasma, idiopathic macular hyperpigmentation, ashy dermatosis

Follicular prominence

Follicular accentuation is a frequent finding in black skin, especially in young children. While slightly more common in those with an atopic diathesis, it is not in itself pathological, although it may be mistakenly thought to represent a skin disease. The term 'disseminate and recurrent infundibulofolliculitis' [1] may simply describe accentuation of such a normal variant, or may represent a low-grade eczematous reaction. Follicular reaction patterns are generally more prevalent in black skin [2]. Emollients may be helpful in making the appearance less pronounced, but over-treatment of what is essentially a normal variant should be avoided.

Common diseases that show racially dependent variations

Studies show that the spectrum of common inflammatory skin disease is not dissimilar in black and white populations living in Western communities, with acne and eczema predominating [1–4]. However, common dermatoses may appear different in black skin and may pose diagnostic difficulty for clinicians unfamiliar with cutaneous reaction patterns in black skin [5]. Erythema is harder to discern, follicular and annular reaction patterns are more common and altered pigmentation, as a post-inflammatory phenomenon (Tables 9.2 & 9.3), may dominate the clinical picture (Fig. 9.4).

Inflammatory and lichenoid conditions

Acne (see also Chapter 44)

Although the prevalence of acne may be similar across most races, apart from in the Japanese where it has been reported to be less

common [1], there is evidence that it is more severe in white skin [2]. However, the traditional measures of severity do not give weighting to pigmentary changes. Post-inflammatory hyperpigmentation following acne in a deeply pigmented skin can be devastating and may persist for months, if not years. Thus, earlier and more aggressive intervention in acne in pigmented skins often is justified. Secondary acne, induced by the use of hair oils (pomade acne), has been reported to occur commonly on the forehead of Afro-Caribbeans [3]. Skin lightening products can lead to steroid-induced acne (Fig. 9.5) (see p. 9.8).

Fig. 9.5 Acne exacerbated by the use of 'skin lighteners' containing topical steroids.

Lichen planus and lichen nitidus (Chapter 41)

The typical violaceous colour of lichen planus is not so easily identifiable in a deeply pigmented skin. Instead a dark purple colour may be appreciated (Fig. 9.6a). As with any disorder disrupting the dermo-epidermal junction in skin types 5 and 6, intense post-inflammatory hyperpigmentation is particularly striking following lichen planus and is often very persistent (Fig. 9.6b). Hypertrophic variants of lichen planus appear more common in Afro-Caribbeans (Fig. 9.6a), whereas oral lesions may be less so [1]. Lichen nitidus, in which minute, pale papular foci of lichenoid inflammation occur, particularly around the umbilicus, is much more common in black skin [2].

Lichen striatus

This linear eruption, more common in children, is often more obvious in black patients [3]. The disorder is characterized by small papules clustered in a linear configuration, following Blaschko's lines and predominantly affecting the limbs. In white patients the papules are pinkish, but in black individuals the lesions are usually hypopigmented, with no discernible erythema. The condition is often asymptomatic and usually self-limiting, resolving over 18 months.

Pityriasis lichenoides chronica (Chapter 57)

This chronic papulo-squamous eruption may begin insidiously, but often becomes extensive. Crops of lesions occur in a relapsing and remitting manner, and the disease course can be very prolonged. Although the characteristic distribution on the inner aspect of the limbs is the norm, facial involvement is not infrequent in black patients [4]. The subsequent post-inflammatory

(a)

(b)

Fig. 9.6 (a) Hypertrophic lichen planus. (b) Post-inflammatory hyperpigmentation following lichen planus may be very striking and persistent.

Fig. 9.7 Pityriasis rosea: small urticated papules occur in the characteristic distribution.

hypopigmentation is usually pronounced and can be devastating [3]. Long-term antibiotics and phototherapy are the mainstay of treatment, but low-dose methotrexate has been shown to be very helpful in recalcitrant disease [5].

Pityriasis rosea (Chapter 33)

Although pityriasis rosea is twice as common in black individuals as white, occurring with a frequency of 6% [1], the same seasonal peaks and preceding herald patch occur [2]. However, in black skin, individual lesions are smaller and more papular (micropapular), often urticated (Fig. 9.7) and may even be vesicular [3].

An inverse distribution of pityriasis rosea is more frequent in black skin [3] and involvement of the face is seen in 30%, especially in children [2]. The scalp is also more often affected [2]. Lesions in black patients tend to be quite pruritic and more persistent [3], and are known as the 'eczematide' reaction. Post-inflammatory hyperpigmentation occurs in almost half of black patients, but hypopigmentation may also occur [2]. Symptomatic treatment with antihistamines and topical steroids is often required and in severe cases UVB has sometimes been used [3].

Seborrhoeic dermatitis (Chapter 23)

The erythema of seborrhoeic dermatitis is often masked in black skin, especially on the face, and the scale may be very fine. The dominant feature is usually the post-inflammatory hypopigmentation, which may be very sharply demarcated and in an annular configuration [1,2]. Hypopigmentation can be very pronounced in infants with seborrhoeic dermatitis, although it recovers quickly [3].

Infections

Pityriasis versicolor (Chapter 36)

This disorder is more prevalent in tropical climates. The hypopigmentation associated with this pityrosporum-related dermatosis is often more obvious in black skin [1], but the disorder itself does not occur with any increased frequency in different ethnic groups living in the same country [2]. However, extension onto the neck and face is more common in black patients [2].

Syphilis (Chapter 34)

Primary disease is similar in all races, but the manifestations of secondary syphilis vary. Macular lesions are common in Caucasians, but follicular, papular and annular forms are more frequent in black Africans [3,4]. Lesions are often hyperpigmented, and corymbose forms (a cluster of satellites around a central lesion) may occur in black patients [3]. Palmoplantar lesions may be keratotic in black Africans.

Pigmentary disorders

Vitiligo (Chapter 58)

Although vitiligo occurs in all ages and races, the clinical effects of the disease are more obvious in a dark skin (Fig. 9.8) and are

Fig. 9.8 Vitiligo.

generally associated with a higher impact on quality of life. Furthermore, in areas where infectious diseases associated with pigment loss occur, cultural stigmatization of leucoderma can be a problem. This is especially problematic in India [1].

Neoplastic disorders

Mycosis fungoides (Chapter 57)

Hypopigmented mycosis fungoides (MF) is more frequently associated with skin types 5 and 6 than with types 1–4 [1], and appears to occur at a younger age than classical MF [2]. Differentiation from pityriasis versicolor, vitiligo or post-inflammation hypopigmentation is important. In MF, the skin involvement tends to be more centripetal and pruritus is frequent [3].

Histologically, immunohistochemistry of hypopigmented MF shows loss of $CD7^+$ cells [2]. Hypopigmented patch stage MF responds well to phototherapy, and usually follows an indolent course, but in tumour stage MF, black patients often present late, with more aggressive disease and consequently a poorer prognosis [3].

Diseases with a distinct racial or ethnic predisposition related to cultural practices/lifestyle

Diseases that have a greater clinical impact due to variation in cultural practices or beliefs are also considered in this section.

Hair and scalp

Hairstyling practices

It has not been established definitively what role hair styling practices have in the various hair complaints suffered by patients of Afro-Caribbean origin. The problems include easy breakage, itching, flaking, and hair loss over the crown and also of the temporal areas.

Follicular degeneration syndrome (FDS) or central centrifugal scarring alopecia, describing hair loss associated with scarring over the crown in Afro-Caribbean women, was initially attributed to the use of hot combing [1]. However, causality has never been established and the term FDS was coined in 1992 [2] to suggest that pathogenesis is multifactorial and not just attributable to hair styling practices, whether chemical (relaxers) or physical (tight mechanical braiding). However, raising awareness of the possible risks of excess use of cosmetic hair products is advocated, as a smaller series correlates misuse with the onset of scarring alopecia [3]. Frontotemporal scarring alopecia is seen commonly in women of Afro-Caribbean extraction and has been attributed to traction from tight braiding practices, but is probably also multifactorial (Fig. 9.9).

Mudi-chood

This is an unusual lichenoid dermatosis of the nape of the neck and upper back seen almost exclusively in young women from the Kerala province of India [1]. The disorder is characterized by small pruritic pustules, which evolve to form pigmented macules and plaques with a hyperkeratotic rim (Fig. 9.10). It is thought to be related to the occlusive effect of plant oils used in the traditional

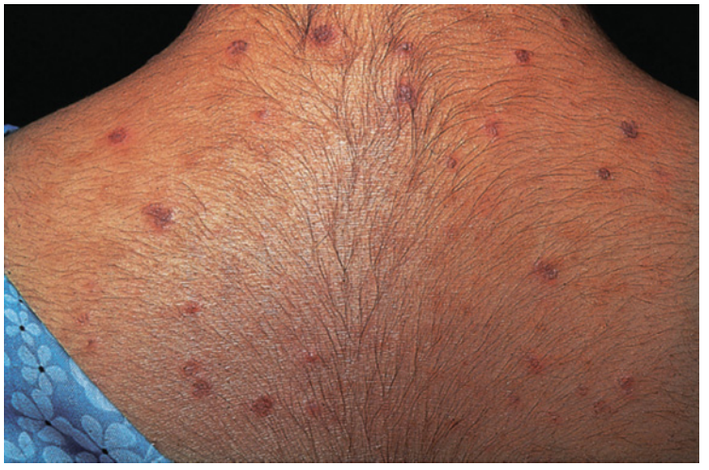

Fig. 9.10 Mudi-chood. (Courtesy of Dr P. Sugathan, Baby Memorial Hospital, Calicut, India.)

grooming of hair, compounded by the heat and humidity of the climate [4,5]. Reducing the use of oils, or cutting the hair shorter, are curative.

Tinea capitis (Chapter 36)

Scalp ringworm (tinea capitis) is an infection caused predominantly by the dermatophyte group of fungi affecting scalp hair follicles and the surrounding scalp skin. Tinea capitis in the UK and France is currently most frequent in urban areas and appears to be more common in children of Afro-Caribbean extraction than in Caucasians and other races [6,7]. This is thought to be due to hair styling practices which render the hair more vulnerable to infection; these include close-cropped styles, tight plaits and sharing clippers, which facilitate transmission of anthropophilic spores [6].

Other applications to the skin

Effects of skin bleaching

In certain parts of the world, it is common practice for individuals with dark skin tones to use agents to lighten the skin; 52.7% of women attending a skin clinic in Senegal had used skin lightening products [1]. The reasons for doing so are complex. The agents used are wide ranging and include hydroquinone, steroids, mercury iodide and caustic agents, but often the ingredients are unknown. Skin lighteners have other less desirable effects on the skin, including steroid-induced acne, tinea facei, striae, macular hyperchromias and telangiectasia. Treatment involves cessation of use of the skin lightening product, but this can be difficult to achieve when admission to its use in the first place is often not forthcoming.

When treating acne related to the use of bleaching products, not only withdrawal of the skin lightener, but also aggressive concomitant treatment of the acne, is required to minimize permanent scarring (Fig. 9.5).

Traditional therapies

Traditional medicinal practices such as cupping, coin rubbing or moxibustion are popular in Eastern cultures, and may result in eccymoses, purpura, circular areas of post-inflammatory hyperpigmentation or, occasionally, true burns [2].

Miscellaneous

Podoconiosis (Chapter 48)

Synonyms
- Mossy foot
- Big foot disease
- Non-filarial elephantiasis

Podoconiosis is a non-communicable disease first described by Price [1], which produces lymphoedema of the legs. It is caused by exposure of bare feet to irritant, alkalic clay soils. It is thus a geochemical dermatosis confined to communities of bare-foot subsistence farmers. It has been found recently in at least 10 countries in tropical Africa, central America and north-west India where the culprit soils prevail together with low income, high rainfall and high altitude. The disease becomes apparent in susceptible individuals by the third decade. Colloid-sized silicate particles penetrate the skin and are taken up by macrophages in the leg lymphatics, leading to endolymphangitis and obliteration of the lymphatic vessels. Susceptibility is highly inheritable [2], and the economic impact can be catastrophic in affected areas, where communities are dependent on subsistence farming.

With relatively simple measures, such as vulnerable individuals wearing shoes at all times when in contact with irritant soils, this non-communicable disease is entirely preventable. Early stages are reversible with good foot hygiene and the wearing of shoes, but later stages lead to significant economic and social difficulties, and may require interventions such as prolonged episodes of leg elevation and even surgical nodulectomies.

Diseases with a distinct racial or ethnic predisposition

Some dermatoses are almost exclusive to certain races. Others may occur more widely, but have varied prevalence in different racial groups.

Diseases characteristic of specific racial groups

Hair and scalp disorders

Pseudofolliculitis barbae

Shaving tightly curled hair creates a sharp residual point, which either retracts under the skin and embeds, or curls over and ingrows, to produce a foreign body inflammatory reaction with papule and pustule formation. Mild cases may be transient, but severe cases are very destructive with subsequent scarring. Initial inflammation is sterile, but secondary infection is not uncommon. Estimates of prevalence vary between 45 and 85% of African Americans [1]. The problem may occur on any part of the body that is repeatedly shaved [2]. It is most common in men, but may be seen in women, related to repeated plucking or shaving of hairs on the chin and neck [3]. The treatment is to allow the hair to grow, reduce inflammation with topical steroids and then use specialized shaving techniques and avoid close shaving [3].

Acne nuchae keloidalis

Synonyms
- Folliculitis keloidalis
- Lichen keloidalis nuchae

This is a scarring process related to ingrown hairs producing a folliculitis, which becomes chronic and scars, in a hypertrophic manner, with associated alopecia. Initially papular, the lesions may coalesce to form large plaques (Fig. 9.11), usually confined to the central occipital area, which are both tender and unsightly. It is one of the most common reasons for black patients to attend dermatology clinics [4]. It is a post-pubertal phenomenon, but onset is rare after age 50 years [2].

The pathogenesis is believed to be multifactorial and exacerbated by secondary infection [2]. Although close-cropped hair styles appear to be the main pathogenetic factor, friction from shirt collars and helmets [5] has also been implicated. The condition is much commoner in black men than in other races, but a similar process occurs in Caucasians. In particular, it has recently been described in transplant recipients taking ciclosporin [6], presumably related to the combined effects of the pro-fibrotic state and concurrent infection and therefore giving further clues about the pathogenesis.

Treatment of early disease has the most impact [7,8], and centres on reducing the inflammatory response with topical steroids, and treating any secondary infection. Late disease presents a treatment challenge, involving intra-lesional steroids, surgery, cryotherapy and laser ablation.

Fig. 9.11 Nuchal acne keloidalis.

Fig. 9.12 Dissecting cellulitis of the scalp.

Dissecting cellulitis

Synonym
- Perifolliculitis capitis abscediens et suffudiens

This is an uncommon, chronic inflammatory condition of the scalp, and may form part of the follicular occlusion tetrad. It occurs in both men and women, but is most common in black men [1]. It tends to begin at the vertex and spread posteriorly, but severe cases may involve the whole scalp. Large, tender fluctuant swellings develop, which progress to produce extensive destruction of hair follicles and permanent scarring alopecia (Fig. 9.12).

Swabs from the affected areas are usually sterile [9]. Treatment involves long-term antibiotics (for their anti-inflammatory effect), oral steroids and retinoids, but disease control is often difficult [1].

Keratodermas and ichthyoses

Keratodermas and focal acral hyperkeratosis (Chapter 19)

Synonyms
- Marginal papular acrokeratoderma
- Acrokeratoelastoidosis

Keratodermas are often very pronounced in black skin, particularly on the dorsum of the distal hands and feet [1,2]. The cutaneous changes become more pronounced with time and may be of great cosmetic concern, but rarely require any intervention other than emollients and avoiding excess friction.

Crateriform keratotic papules along the border of the hands and feet are a frequent finding in black patients [3]. They represent a genodermatosis, and are thought to be related to the breakdown and extrusion of dermal elastic material by fibroblasts [4], but the nosology of this and related conditions has become confused. Over time, a wide variety of names have been applied to this process [4]. Histologically, when elastorrhexis is present, the term acrokeratoelastoidosis of Costa has been used, but when absent, the lesions have been classified as focal acral hyperkeratosis [5].

However, it has now been suggested that they should all be considered variants of the same process [3]; the collective term marginal papular acrokeratodermas has been proposed [6], although no consensus on nomenclature has been agreed.

Keratosis punctata (keratotic pits) of the palmar creases

Small conical pits, confined to the creases of the palms (Fig. 9.13) and volar aspects of the fingers, occur exclusively in black races [7], particularly in men, with a prevalence of about 3% [8]. The aetiology is unknown, but the condition is familial, with apparent autosomal dominant inheritance [9]. Trauma seems to play a part, and the disorder is more frequent in those with manual occupations [8]. It may occur in association with punctuate keratoses of the palms and soles, but there is debate about whether this should be considered a variant of keratosis punctata [9] or a distinct entity [8].

Fig. 9.13 Keratosis punctata of the palmar creases. (Courtesy of Dr D.J. Barker, Bradford Royal Infirmary, Bradford, UK.)

Pityriasis rotunda

This relatively rare disorder, seen in individuals with skin type 6, is a form of acquired ichthyosis in which large, discrete circular patches appear, mainly on the trunk [10,11]. Some lesions coalesce to produce a petaloid appearance. Patches are usually lighter in colour than the surrounding skin, but may be darker. It is usually idiopathic, and is sometimes observed in newly arrived immigrants (possibly due to the effect of change in climate), but has also been reported in association with serious illness or as a paraneoplastic phenomenon [12]. Rare reports in Europeans [10] have described occurrence at a younger age, and are typically familial, so they probably represent a separate, distinct disorder.

Pigmentary disorders

Dermatosis papulosa nigra

This is a very common condition with a familial basis. Small, deeply pigmented, papules appear on the face (Fig. 9.14), neck and upper torso from the early twenties. The condition is estimated to affect up to 77% of black individuals, and is progressive with more lesions appearing over time [1]. It is more frequent in women than men, and women tend to have more lesions than men [1]. Lesions vary from pin-point to several millimetres in diameter. Histologically, they are identical to seborrhoeic keratoses, and should be considered a variant of such [2]. The main concern is usually cosmetic, but occasionally larger lesions may become inflamed by trauma. Light cautery or hyfrecation may be effective [2], but it is important to acknowledge the potential risk of scarring related to surgical intervention and it is often impractical to remove numerous lesions.

Idiopathic guttate hypomelanosis (Chapter 58)

Myriads of small, pale macules, 1–2 mm in diameter, appear on the distal limbs, particularly the legs and gradually extend over time. Although mild forms may occasionally be seen in other racial groups, it is characteristic of skin types 5 and 6 [1]. Lesions appear later in life and are progressive with age, being most prevalent after the seventh decade [2]. They are often a cause of great cosmetic concern, and patients may be worried that they are developing vitiligo, but histologically the two conditions are quite distinct, and hairs within the affected areas are not depigmented [3]. Histology shows epidermal atrophy with flattening of the dermo-epidermal junction and reduction in the number of melanin granules within the basal layer [1]. There may be a familial basis to the disorder, but actinic factors and ageing are also implicated [2]. The condition is much more prevalent in women [1]. It is benign and asymptomatic, but there is no effective treatment [4].

Childhood and inherited disorders

Mongolian blue spot (Chapters 17 and 54)

Synonym
- Congenital dermal melanocytosis

Mongolian spots are macular areas of bluish-grey pigmentation, occurring over the lower back and present at birth (Fig. 9.15). They are observed in 100% of Mongoloid babies, up to 96% of black African infants but only 10% of Caucasians [1]. The pigmentation is most common in the sacral region, but may extend to cover a large area from the buttocks to upper trunk. They vary considerably in size from a few centimetres diameter to involving the majority of the back. The pigmentation tends to increase initially, reaching a peak by the age of 2 years, and then gradually fades through childhood [2]. Rarely, it may persist into adulthood [2].

Fig. 9.16 Facial Afro-Caribbean childhood eruption. (Courtesy of Professor H.C. Williams, Queen's Medical Centre, Nottingham, UK.)

Transient neonatal pustular melanosis (Chapter 17)

A transient eruption of sterile vesico-pustules is seen during the neonatal period in 4.4.% of black infants [1]. Individual pustules have a rim of surrounding erythema and, as the lesions progress, the pustules rupture to leave pigmented macules, which gradually fade over a few weeks. Pustules are sterile, but a skin smear shows a mixed inflammatory infiltrate with neutrophils. The most common sites are the face and shins [2]. It probably represents a variant of erythema toxicum neonatorum, but is associated with fewer eosinophils in lesions. No treatment is required as the condition resolves spontaneously, but it can persist for up to 3 months [2].

Facial Afro-Caribbean childhood eruption (FACE)

First recognized by Marten in the early 1960s, the acronym FACE was coined two decades later [1,2]. Multiple, small, pale, flesh-coloured papules appear on the face of children, especially boys. The eruption tends to be concentrated centrally and is often most prominent periorally, but may extend onto the whole face (Fig. 9.16). The condition is pre-pubertal, with an onset around 8 years, and it tends to resolve spontaneously after 3–5 years. The histology is rather non-specific, but appears quite distinct from acne. Topical antibiotics are often given in response to demand for treatment, but have limited effect. The cause is unknown, but it is the authors' impression that the condition may be becoming less frequent.

Sickle cell disease

This haemoglobinopathy is unique to those of African or Caribbean heritage, and the cutaneous complications, particularly ulceration [1], are therefore only seen in black patients. Sickle cell ulcers, secondary to cutaneous ischaemia compounded by trauma and secondary infection, are the most common complication, and are often seen in young patients, but rarely before the teenage years [1]. They are very painful and recalcitrant, and present a difficult therapeutic challenge. Hand–foot syndrome, in which painful, non-pitting acral oedema develops as a consequence of infarctions of the small bones of the hands and feet, may be the initial manifestation of the disease in children [2].

Infections

Mould infections (Scytalidosis) (Chapter 36)

Cutaneous mould infections, for example with *Scytaldium* or *Hendersonula* spp., are endemic in parts of West Africa and the Caribbean. Such infections are being seen more commonly in temperate climates, but, apart from rare cases, only occur in immigrants born in the tropics [1]. A fine, white, powdery scale is seen on the palms and soles, most prominently within the skin creases [2]. Nail involvement is common, but the disease is resistant to most standard antifungal agents.

2 Hay RJ, Moore MK. Clinical features of superficial fungal infections caused by *Hendersonula toruloidea* and *Scytalidium hyalinium*. *Br J Dermatol* 1984; **110**: 677–83.

HTLV-1 associated infective dermatitis

This variant of eczema is common in the Caribbean [1] as well as in South America [2]. It comprises recurrent infective eczema, especially in children and adolescents, which is usually infected/colonized with either *Staphylococcus* or *Streptococcus* species, as a manifestation of underlying infection with HTLV-1. Other sequelae of HTLV infection are likely [2].

Miscellaneous

Ainhum

Ainhum describes the development of a fibrotic band around a digit, usually the fifth toe, which causes severe constriction and may progress to spontaneous amputation of the affected digit [1]. It is generally observed in the indigenous black population of

tropical countries. Trauma and infection related to walking barefoot are thought to stimulate the fibrotic reaction.

Dermatosis pustulosa cruris et atrophicans

A condition usually seen in African women, due to the occlusive effect of certain moisturizers, in which large superficial lakes of pus develop on a background of taut shiny skin, on the thighs and lower legs [2]. Lesions are always centred on a follicle, which can be seen as a dark spot within the lake of pus. Although relatively rare in the West [3], milder folliculitis as a pomade effect of excess emollient use is common, especially in adolescent girls. Short courses of antibiotics may be required, but the condition clears on stopping the causal emollient.

Adult T-cell leukaemia lymphoma (ATLL) (Chapter 57)

Cutaneous involvement, with small pale papules resembling sarcoid or large tumid nodules, may be the presenting sign in patients with ATLL [4].

Papuloerythroderma of Ofuji

An unusual eruption, of unknown aetiology, characterized by firm papules, which coalesce into erythroderma, with characteristic sparing of the folds of the body. First described in elderly Japanese men [5], it has now been reported in other races.

Diseases with varied racial prevalence

Dermatitis

Atopic dermatitis (Chapter 24)

Atopic dermatitis (eczema) is commoner in London-born black Caribbean children compared to their white counterparts [1]. Furthermore, black children with atopic dermatitis have a sixfold increased risk of having severe disease. It can be difficult to appreciate erythema in a dark skin (Fig. 9.17), so there may be failure to recognize the severity of the eczema [2].

Follicular accentuation is recognized to be more common in Afro-Caribbean dermatoses, and can occur as a finding in normal skin [3]. Follicular eczema is not uncommon in Afro-Caribbeans. It is managed in the usual way; however, it is the authors' observation that excessive use of greasy emollients in such cases can lead to an occlusive folliculitis.

Contact dermatitis (Chapters 25 and 26)

Several reports suggest that black skin may be more resistant to skin irritants than white skin. Tape stripping eradicates this difference, suggesting that this might be due in part to the qualities of the stratum corneum, which it is thought possesses an increased intercellular cohesiveness in black skin. Measurement of early inflammatory reactions to application of irritants, using confocal microscopy, showed that white subjects had more severe inflammatory reactions and also higher transepidermal water loss after application of 4% sodium lauryl sulphate than black skin, in contrast to the situation in non-irritated skin where black skins lose more water [4].

Fig. 9.17 Lichenified eczema.

Capsaicin dermatitis, caused by handling chilli peppers, is a particular problem in the Hispanic population because of their frequent use of this spice in cooking. Symptoms can be quite severe, with burning pain and erythema, requiring topical anaesthetics and topical corticosteroids for symptomatic relief [5].

Allergic contact dermatitis is generally thought to occur less frequently in the black population [6]. Fragrance sensitivity, in particular, is most prevalent in Caucasians [7]. The exception may be hair dye allergy [8], which appears more prevalent in black and Asian populations, probably reflecting increased usage. Cultural variations in exposure probably account for reported differences in prevalence of allergic contact dermatitis. There is some evidence that the incidence of contact dermatitis in Africans is increasing in relation to improved socio-economic conditions and urbanization [9]. Traditional pigments, for example bindi, applied for religious and social reasons, may produce an allergic contact dermatitis in Indian women [10].

Lichen simplex chronicus (Chapter 23)

Hyperpigmented lichen simplex is a common disorder in darkly pigmented skins. It can be associated with repetitive trauma of

any kind. Prayer nodules of the devoutly religious represent an example. Lichen simplex of the scrotum is especially common in African males [9].

Other inflammatory dermatoses

Psoriasis (Chapter 20)

The prevalence of psoriasis is quoted as about 2% in Northern Europeans, but is much less frequent in the black population, probably reflecting genetic/HLA differences. It is more prevalent in East Africans [1] and rare in West Africans [2]. However, when psoriasis does occur in patients with pigmented skin, it is often extensive, quite resistant to therapy and therefore more likely to require systemic treatment.

Rosacea (Chapter 43)

Rosacea is rare in black individuals but may be under-reported [1], as the diagnosis may be masked by natural skin pigmentation [2]. However, steroid-induced acne and rosacea are frequent, due to the wide availability of unlicensed skin products containing potent steroids, which are often used as cosmetics [3].

Morphoea and systemic sclerosis (Chapter 51)

Morphoea is less common in black than in white individuals [1]. Systemic sclerosis is also less prevalent in black patients [2] but when it does occur, inflammatory complications (e.g. pericarditis) are more frequent and occur earlier in the disease process [2]. In contrast, digital infarcts are less common in black patients [2]. Overall, the disease in black patients tends to be more aggressive, with a worse overall prognosis than in white patients [2].

Sarcoidosis (Chapter 61)

This chronic, granulomatous disease occurs three to four times more commonly in the black population in the United States compared to the white population, with a prevalence reaching 64 per 100 000 [1]. The highest incidence of all is in black women in the fourth decade of life [1]. Although the disease may present in many ways, cutaneous involvement occurs in 25% [2]. Papular sarcoid is the most frequent form in blacks, but hypopigmented and annular forms are also often seen [2]. Although nasal involvement is common, the violaceous plaques of classical lupus pernio are rare in black individuals [2]. Instead, reddish brown translucent nodules around the nares are common. Erythema nodosum as a presenting feature of sarcoidosis is also less frequently seen in black patients [3].

Pemphigus (Chapter 40)

Pemphigus vulgaris is more common in the Indian subcontinent than in the West [1] and tends to occur at a younger age [1]. In contrast, pemphigus foliaceus is rare in Asians [1,2], but is seen more commonly amongst black Africans [2]. An endemic form of pemphigus foliaceus, fogo selvagem, is seen in parts of Brazil [3]. Environmental factors are thought to precipitate disease in immunogenetically susceptible individuals [3].

Lupus erythematosus (Chapter 51)

Lupus erythematosus (LE) is increasingly being recognized as an autoimmune disorder whose incidence is closely associated with certain genetic markers. A study of African American families has

Fig. 9.18 Large spontaneous keloids in an African.

shown significant evidence of linkage at chromosomal location 11p13 [1].

Both depigmentation and hyperpigmentation are seen following lesions of discoid lupus erythematosus (DLE). It is the observation of the authors that depigmented scarring is more common in East Africa, whereas hyperpigmentation is more prominent following DLE in Afro-Caribbeans living in London.

Keratinization and fibrotic disorders

Keloid scarring (Chapter 14)

Keloid scarring represents a pathological response to cutaneous injury, and creates disfiguring results (Fig. 9.18). Medical literature suggests a greater frequency of keloid scar formation in Afro-Caribbean, Malaysian and Indian skin compared with Caucasians; however, many of these references are observational statements, published over 30 years ago, and address spontaneous keloids rather than post-procedural scars. The reported incidence ratios for Afro-Caribbeans : Caucasians have ranged from Brenizer's 2 : 1 [1] to Fox's 19 : 1 [2]. This literature has contributed to the practice of adopting a cautious approach to biopsying Afro-Caribbean skin, because of the perceived increased risk of keloid scar formation. Management continues to be challenging and a recent meta-analysis review demonstrates no statistically significant treatment option likely to guarantee a superior outcome [3].

Fig. 9.19 Prayer nodule.

Knuckle pads

These well circumscribed thickenings of the skin over the proximal interphalangeal joints, and occasionally the metacarpophalangeal joints, are much more frequently, but not exclusively, seen in black individuals. Most cases appear to be idiopathic [4], although there is often a familial basis. Some cases are associated with Dupuytren's contracture [1] and repeated trauma has been implicated in the aetiology [5,6].

Prayer nodules

Thickening of the skin with hyperpigmentation, or the formation of true callosities, may be seen in deeply religious individuals as a result of sustained and repetitive kneeling during prayer. Prayer nodules are most frequently seen in Moslem men [7], and may occur on the knees or forehead (Fig. 9.19), but have also been reported in devout Catholic women from central America [8], in whom they are confined to the knees because of the different posture adopted in prayer.

Acanthosis nigricans (Chapter 19)

Although this is a relatively common disorder across all races, it has been considered to be particularly prevalent in Asians. Some authors report a higher incidence in Afro-Caribbean youths, compared with their Caucasian counterparts. It is associated with insulin resistance [9].

Pigmentary disorders

Albinism (Chapter 58)

Oculocutaneous albinism is a worldwide hereditary disease. Although prevalence is globally reported to be 1:20 000 [1], data is emerging to suggest that it is more common in parts of Africa [2] with figures as high as 1/1000 in the Tonga tribe in Zimbabwe [3]. Not only is it more common but the adverse impacts on health can be devastating. These can be divided into actinic, ocular and social. Long hours of sunshine and the high intensity of ultraviolet radiation (UVR) in equatorial regions expose the albino person to large amounts of UVR, and actinic keratoses can develop in children as young as 8 years of age. People affected with albinism living in the tropics are sunburned most of the time and also suffer from actinic cheilitis, premature solar elastosis and numerous solar lentigines. In one survey of 164 albino patients in Tanzania, 19% of <21 year olds and 91% >21 year olds had solar keratoses, whereas 25% of 20 year olds and 34% of the over 30s were found to have overt skin cancers [4].

Ocular problems limit the educational opportunities for the albino child in the Third World. This, coupled with poor resources, lack of employment opportunities and social prejudice, result in severe economic hardship and social isolation for affected individuals. Although more than 50% of albino persons will have an affected relative, the majority of native Africans do not understand the inherited nature of the disease. The Albino Outreach programme in Moshi, Tanzania, attempts to address these issues through education and by providing practical help for sufferers [5].

The Hermansky–Pudlak syndrome, a triad of albinism, platelets lacking dense bodies and storage of ceroid-like material in tissues, occurs with a population frequency of approximately one in 2000 in north-western Puerto Rico [6].

Progressive macular hypomelanosis (Chapter 58)

Synonyms
- Creole dyschromia
- Idiopathic macular hypomelanosis of the melanodermic halfcast of Guillet–Helenon

This disorder has been noted to be especially common in the Caribbean [1] but has also been found in Asians [2]. It presents with extensive round areas of macular hypopigmentation on the back, especially in young women; individual lesions may coalesce. One study suggests a role for *Propionibacterium acnes* [3], a theory supported by the observation that clearance is faster following antimicrobial regimens than with application of topical steroids [4]. It is mostly unresponsive to therapy, but tends to regress spontaneously over 3–4 years.

Melasma (Chapter 58)

There is an absence of detailed epidemiological data regarding the prevalence of melasma, but general observation suggests that the condition is more prevalent in Asian populations [1] and in those of Central and South American origin [2]. Indeed, the frequency of melasma in Thai women has been reported to be as high as 40% [1], and at least 50% of Mexican women are thought to develop melasma during pregnancy [2]. Estimates of the general prevalence in Hispanic populations range from 4.1 to 8.2% [2]. The distribution is usually centro-facial or malar [2], but in older patients it tends to be mandibular. Although there is a strong female preponderance, 10–20% of cases of melasma occur in men [1,2]. There is usually histological evidence of significant solar damage in affected individuals [3]. Treatment with combination topical regimes can be very effective, provided they are used in conjunction with rigorous sun protection [3].

Erythema dyschromicum perstans (ashy dermatosis) (Chapter 58)

Originally described in El Salvador, this acquired cutaneous disease is also well recognized in the Asian population. It is characterized by asymptomatic, irregularly shaped, macular areas of greyish pigmentation, particularly on the trunk. It is the distinctive colour [4] that gives rise to the term ashy dermatosis. However, it is true pigmentation and not just the ashy hue seen in black skin in winter, secondary to xerosis [5]. The cause is unknown, but there is strong genetic susceptibility and the condition is thought to have an immunological basis [6]. Recent studies in Mexican Mestizo Indians show that the disease is strongly associated with HLA-DR4 [5]. Reactions to chemical ingestion [2,7] and an association with intestinal parasites have also been postulated [2]. Some cases have been attributed to lichen planus, but there is no consensus view on whether lichen planus and ashy dermatosis represent a spectrum or are distinct. The borders of individual patches may be erythematous. Histologically, there is increased pigmentation of the basal layer of the epidermis, with a mild

perivascular lymphohistiocytic infiltrate and pigmentary incontinence in the papillary dermis. The differential diagnosis includes lichen planus pigmentosus, idiopathic macular hyperpigmentation, macular amyloidosis and fixed drug eruption, although in the latter the preceding inflammatory component is usually obvious and the subsequent post-inflammatory pigmentation much darker. The disease tends to be chronic, but may resolve over time. Improvement with clofazamine has been reported [8].

Primary cutaneous amyloidosis (Chapter 59)

Primary cutaneous amyloidosis is rare in Western populations, but has a high incidence in South-east Asia and some South American populations [1,2]. Two main forms, macular amyloidosis and lichen amyloidosis, are seen, but other rare variants exist [2]. Histologically, both of the main types appear similar; deposition of amyloid protein is seen in the papillary dermis, although meticulous sectioning and special stains may be required to confirm the diagnosis if the changes are subtle [2,3]. Clinically, macular amyloidosis is characterized by areas of rippled pigmentation, particularly on the upper back. In lichen amyloidosis, the pigmented lesions are smaller and more papular, and are localized on the shins and lower limb. There is no involvement of internal organs. Macular amyloidosis seems to be more prevalent in Indians [4], but is less common in Chinese individuals, in whom lichen amyloidosis predominates [2]. Macular amyloidosis is more common in females, and has an earlier onset in those with paler skin [3]. Both conditions tend to be pruritic and features of both types may co-exist [2]. Most cases of primary cutaneous amyloidosis are sporadic [2], but familial cases account for about 9% [4]. Friction, particularly from vigorous towelling, is thought to be contributory in some cases [5]. A rare form, ano-sacral cutaneous amyloidosis, has been reported in Oriental patients, particularly men; this may be difficult to distinguish clinically from lichen simplex [6], and indeed there may be an aetiological link, secondary to scratching [7].

Naevus of Ota and naevus of Ito (Chapters 18 and 54)

Naevus of Ota is a form of dermal melanosis [1], producing macular pigmentation on the side of the cheek, adjacent to the eye and involving the sclera, within the distribution of the first two branches of the trigeminal nerve [2] (Fig. 9.20). It is most common in Oriental populations, but can occur in other races. It is five times more common in women than in men [1], and accounts for 0.8% of all dermatological consultations in Japan. Naevus of Ota is congenital in 50% of cases; the acquired form usually develops in the second decade [1]. Although usually unilateral, it is bilateral in 5%.

A similar pigmented naevus, naevus of Ito, occurs around the neck and shoulder region, within the distribution of the posterior supraclavicular and lateral brachial nerves. Histologically the two lesions are identical and may co-exist. Treatment with the Q-switched laser can be very effective [2].

Melanocytic naevi (Chapter 54)

Caucasians have more melanocytic naevi than other races. The number of naevi is inversely proportional to the degree of pigmentation of the skin, and increases with age [3]. The median number of melanocytic naevi in white children is 17 compared with 2.5 in those with skin type 5 and 6 [3]; for young adults, the median number of naevi rises to 61 and 16 respectively [3].

Infections

Cellulitis

In Africa, infections are much the commonest skin disease [1]. As populations urbanize or migrate to developing countries, patterns of skin disease begin to change and to mirror those of Western populations, with eczema and acne predominating and the frequency of cutaneous infections becoming lower [2]. Cellulitis, in particular, appears relatively less frequent in black adults [3], possibly due to immunity acquired in childhood.

Candida paronychia (Chapter 36)

Although this chronic fungal infection is well recognized in association with diabetes and occupations in which the hands are repeatedly immersed in water, it also appears to be more common in black individuals [4].

Viral warts (Chapter 33)

Far fewer black than white patients present to UK dermatology departments with viral warts (12% vs. 75% respectively) [4]. Other studies corroborate the relatively low incidence in black clinic attendees [5], but the true prevalence in the community is unknown. Whether this reflects socio-economic factors for attendance at hospital or a genuine difference in disease susceptibility is unclear.

Lyme disease (Chapter 38)

Reported incidence rates for Lyme disease in the Eastern United States are higher for white subjects than for African Americans [6]. However, black patients are more likely to present late, less likely to have erythema chronicum migrans, but more likely to have an associated arthritis [6].

Neoplasia

Skin cancer (Chapters 52 and 54)

Not surprisingly, both photoageing [1] in general, and UV-related skin cancer, are far more common in skin types 1–4, particularly those living in the Southern hemisphere [2], than in those with darker skin [3]. In particular, squamous cell carcinoma (SCC) is rare in skin types 5–6, although it can be seen as a complication of scars in discoid lupus erythematosus [4] and it presents a particular problem in patients with albinism living in the tropics. However, in contrast to white populations, there is no increase in the incidence of immunosuppression-related, non-melanoma skin cancer in non-white renal allograft recipients [5]. Additionally, there does not appear to be an increased risk of PUVA-associated SCC in black patients [6].

Basal cell carcinomas are generally less frequent in patients of skin type 4–6 than in fair skinned individuals, but when they do occur, they are more common in women, particularly those from the Orient and Asia, and are often the pigmented variant [7].

Bowen's disease is also relatively rare in non-Caucasians but, when it does occur, it tends to be pigmented, is often on non-sun-exposed skin and may be clinically atypical [3].

Melanoma is predominantly a disease of fair skin [8]. Non-white patients tend to present later, with more advanced tumours [9]. This discrepancy accounts for the poor outcomes reported in ethnic minorities. However, stage for stage, outcomes are similar for all racial groups [9].

Kaposi's sarcoma (Chapter 56)

Kaposi's sarcoma (KS) is a tumour of uncertain aetiology but probable endothelial origin [1]. It can be classified into four distinct types depending on the population affected: classical in those of Ashkenazi Jewish or Mediterranean origin; endemic in Africans; epidemic in association with AIDS; and iatrogenic in those treated with immunosuppressive regimens. All types are more frequent in men and all have been shown to have an association with human herpes virus 8 [1,2].

The annual incidence of classical KS in Greece is 0.47/100 000 population [3]. Classic KS tends to affect the legs and run a chronic indolent course in the elderly. In contrast, endemic KS may affect children. African Bantu have the highest incidence of endemic KS [4]. Iron exposure from volcanic soils has been linked to the development of classical and endemic KS [1]. The disease tends to be more aggressive in African children with endemic KS and in

those with epidemic KS, in whom multiple lesions, internal organ involvement and secondary lymphoedema occur.

Miscellaneous

Photodermatoses (Chapter 29)

Racial pigmentation has a photoprotective effect. However, even a pigmented skin may become sunburnt, although the erythema may be masked [1]. Conditions such as polymorphic light eruption and chronic actinic dermatitis occur in all races [2]. However, in black skin polymorphic light eruption may be atypical and pin-point in morphology [3].

One condition with a strong racial predilection is actinic prurigo, seen in Native Indian and Mestizo populations of Central and South America, particularly those who live at higher altitudes [4]. Intensely pruritic, polymorphic lesions, with papules, plaques and vesicles, appear on sun-exposed skin. Lesions become excoriated and may heal with scarring. Conjunctival and labial involvement is common [4]. Unexposed skin may be affected and symptoms tend to be chronic, and can persist through the winter months [4].

Introduction

As well as clinical examination, microscopic examination of skin tissue is probably the single most important diagnostic ancillary technique used by dermatologists in the management of patients with skin disorders. The correlation of clinical appearances with the dermatopathological findings is not only of direct benefit to individual patients, but has also led to the recognition of many new skin disorders and increased our understanding of the mechanisms of skin disease. The science and art of dermatopathology had its beginnings in early 19th-century Europe with the writings of pioneers such as Simon, von Baerensprung, Unna and Gans. It is interesting that these individuals were dermatologists, and this tradition of dermatologists writing about histopathological aspects of skin disease was carried on by researchers such as F. Pinkus, A. Civatte, J. Darier, H. Montgomery, H. Pinkus, W. Lever, and in the last half of the 20th century by R.K. Winkelmann, E. Wilson-Jones and A.B. Ackermann. During the last 20 years, the definition of numerous new disease entities and great advances in histopathological and related techniques have led to a wealth of publications on the histopathology of skin disease. Many major reference texts are now available [1–4].

Close cooperation between the clinician and the diagnostic dermatopathologist is not only desirable, but also essential. The spectrum of skin disease, including rare genetic disorders, infectious diseases, neoplasms and a wide range of inflammatory disorders, is huge, and although in many conditions the histological features are relatively distinctive of a particular skin disorder, in others the changes may be fairly non-specific. Only by close liaison between the disciplines of clinical dermatology and histopathology can the usefulness and limitations of skin biopsy examination be appreciated. The clinician who reviews the histology of his or her own biopsies appreciates the problems of interpretation of an inadequate biopsy, a biopsy from an inappropriate or unrepresentative lesion, and the effects of artefact caused by undue trauma at the time of biopsy. The pathologist in turn can learn, for instance, that epidermal spongiosis, exocytosis of lymphocytes and mild dermal inflammatory changes are the hallmark of a spongiotic process and that a wide variety of clinical entities may show a similar histological picture. Using the term 'chronic non-specific dermatitis' to denote this picture is unhelpful and misleading. What the pathologist should do is to closely correlate the clinical picture with the histological findings and try to reach a more specific diagnosis. Even if this is not possible, the clinical often finds it very useful if a number of differential diagnoses are ruled out.

Dermatopathology as a medical specialty is a rapidly expanding discipline, as witnessed by the plethora of recent publications, the development of many national societies for dermatopathology and the many international meetings currently taking place. In the UK for more than a decade, the Diploma in Dermatopathology of the Royal College of Pathologists has assessed proficiency in dermatopathology for both pathologists and dermatologists. In Europe, a similar exam has been set in recent years by the European Union of Medical Specialists/Sections of Dermatovenereology and of Pathology [5]. This initiative has been received enthusiastically by physicians in both specialties not only throughout Europe but also worldwide. The exam has been so successful that it now also takes place in Latin America under the auspices of the Ibero-Latin American Society of Dermatopathology.

Biopsy of the skin

A thorough understanding of both the indications for skin biopsy and the various biopsy techniques and their limitations is essential if the histopathologist is to provide the maximum useful

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

Table 10.1 Indications for skin biopsy.

Excision of epidermal or dermal neoplasm, whether benign or malignant. Clear margins are required in a malignant neoplasm.
An incisional biopsy (shave or punch biopsy) for confirmation of diagnosis of a lesion too big for removal, which will be treated by alternative methods, e.g. more complex surgery (Mohs), radiotherapy or cryotherapy. Most useful for basal cell carcinoma or *in situ* squamous cell carcinoma (Bowen's disease); avoid in melanocytic lesions, particularly lesions suspected of malignant melanoma.
An incisional biopsy of a hard-to-categorize skin eruption. Most will be inflammatory and a punch biopsy is often performed; sometimes cutaneous T-cell lymphoma is suspected and more than one biopsy may be necessary.
Fresh-tissue incisional skin biopsies for immunopathological study, especially immunofluorescence, in suspected autoimmune dermatoses, e.g. blistering disorders (perilesional skin) or lupus erythematosus (lesional skin).
Simultaneous processing of contiguous incisional biopsies for pathology and for culture of fresh, unfixed tissue when infection is suspected. The tissue can be cultured for various organisms including mycobacteria, deep fungi or examined for protozoa or filarial worms.

information from the study of biopsy sections [6–8]. In addition to light-microscopic examination of paraffin-embedded tissue, material obtained from skin biopsy may be used for a variety of investigative procedures. These include ultrastructural examination (only very seldom used nowadays), immunofluorescence studies, antigen mapping in congenital bullous disorders, immunohistochemistry, microbiological studies, tissue culture and molecular biological methods such as *in situ* hybridization (including FISH: fluorescent i*n situ* hybridization) and polymerase chain reaction, mainly for immunoglobulin and T-cell-receptor gene rearrangement studies. These various investigative techniques often require specific specimens and transport conditions. The individual undertaking skin biopsy should have a clear idea, before carrying out the procedure, of the studies that are to be performed on the specimen obtained. It should be borne in mind that division of the specimen into many small portions for various techniques such as culture, direct immunofluorescence studies and light microscopy may lead to specimens too small, too unrepresentative or too traumatized to provide useful results. It is often better to perform two biopsies or more to guarantee enough tissue to maximize the amount of information from the samples obtained.

Of the various indications for skin biopsy (Table 10.1), a diagnostic skin biopsy is frequently used to confirm a clinical diagnosis or to aid in the establishment of a diagnosis where a clinical diagnosis is not apparent. An excisional biopsy is the method of choice in treatment of skin lesions, particularly malignant neoplasms. It is less often used to remove lesions for cosmetic reasons.

The type of biopsy, the selection of the site to be biopsied and the type of lesion to be biopsied, where there is a widespread eruption, are of utmost importance. Ideally, the lesion biopsied should be an early and untreated lesion and representative of the skin disorder as a whole. Avoiding secondary changes is crucial to obtain adequate information. Excoriated lesions and areas where secondary changes may obscure the primary features should be avoided. If lesions are present at all stages of evolution, such as may be seen in pityriasis lichenoides, it may be appropriate to biopsy more than one lesion. Multiple biopsies are also often helpful in conditions such as early cutaneous T-cell lymphoma, where definite histopathological diagnosis is often difficult. Normal skin should be included with a diagnostic biopsy wherever possible, and the inclusion of perilesional skin is essential when submitting biopsies for direct immunofluorescence studies. In certain conditions, such as connective tissue naevi, the changes may be very subtle and comparison with normal neighbouring skin may be very helpful. When this is done the clinician should mark the area of normal skin with a stitch to facilitate comparison. It is equally important to ensure that the biopsy is deep enough. It is frustrating for the pathologist and clinician alike to receive a specimen with a request form suggesting a diagnosis of panniculitis where sections from the biopsy show only a portion of epidermis and superficial dermis. The general tendency in cases suspected of panniculitis is to perform a punch biopsy. However, not infrequently, the information obtained from this type of biopsy in the setting of panniculitis is minimal and, ideally, a large deep incisional biopsy should be performed to obtain maximum yield. If lesions are widespread and there is a choice of biopsy sites, it is sensible to avoid areas liable to heal badly, such as areas over bony prominences and the lower limbs, and to avoid cosmetically important areas. Secondary changes in some areas of the body, such as changes of venous stasis in biopsies from the lower legs of older people, may be confusing to the inexperienced diagnostic dermatopathologist, and such sites are also best avoided.

Prior to skin biopsy, written informed consent is normally obtained from the patient, and in all but the smallest biopsies, local anaesthetic—usually 1% or 2% lidocaine (lignocaine) with or without epinephrine (adrenaline)—is injected around the biopsy site. Superficial blebs resulting from injecting local anaesthetic into the skin itself should be avoided. Injection of too much local anaesthetic into one area of the skin can cause a prominent distortion artefact in sections that are prepared from biopsy tissue. The effect of epinephrine on dermal blood vessels and mast cells has probably been overemphasized in the past. However, when biopsying conditions such as urticaria pigmentosa, it may be prudent either to avoid the biopsy site itself and inject the anaesthetic in a circle around it or to use an anaesthetic not containing epinephrine. Epinephrine and other vasoconstrictors should not be used in biopsies taken from the fingers or toes, as occasional intense vasospasm can result in tissue necrosis. Recently, topical anaesthetic gels have been developed as an alternative to injections for removal of superficial skin lesions. These topical anaesthetics are particularly helpful with biopsies performed in children. The main topical anaesthetic used is a combination of lignocaine and prilocaine (EMLA). Although this topical preparation is extremely useful, it is important to know that it may cause secondary histological changes that may alter the interpretation of the biopsy. This is probably due to an irritant contact dermatitis and seems to be associated with the time of exposure to the medication and is more common in samples taken from patients with inflammatory dermatoses [9,10]. The histological changes consist of vacuolar change of keratinocytes in the upper layers of the epidermis and clefting at the dermoepidermal junction.

There are circumstances when skin biopsy is best avoided unless absolutely essential (Table 10.2).

Table 10.2 Relative contraindications to skin biopsy.

Infants	Although local anaesthetic creams/gels make this easier
Upper trunk	In order to avoid keloid formation
Lower legs in elderly patients	Poor healing may occur
Cardiac patients	Valvular disease means there is a potential risk of subacute bacterial endocarditis Aspirin/anticoagulants can produce extensive bleeding
Melanoma (incisional) biopsy	Primary excision is preferable to allow proper evaluation and an accurate diagnosis In large lesions on acral sites and face, incisional biopsies are sometimes performed to confirm the diagnosis and plan definitive treatment

Table 10.3 Skin biopsy techniques.

Excision	For removal of a single lesion; an elliptical or fusiform-shaped area of skin is removed
Incision biopsy ('wedge')	Similar to excision, but narrower; to include fat in suspected panniculitis; some normal perilesional skin is included for comparison
Punch biopsy (3–6 mm)	Useful if tissue available is limited, but accurate sampling is essential; a rapid procedure sometimes useful in children
Curettage	For hyperkeratotic lesions, e.g. seborrhoeic keratoses, viral warts, basal cell carcinomas; usually accompanied by cautery
Shave biopsy	For facial protuberant lesions, e.g. benign intradermal naevi
Snip	For skin tags; skin snips also for onchocerciasis

Techniques of skin biopsy (Table 10.3) [6–8]

Elliptical surgical biopsy [8]

This is one of the most commonly used diagnostic skin biopsy techniques. Equipment required includes scalpel, fine-toothed forceps, needle holder, scissors and eyeless needle with suture (Fig. 10.1). The use of a skin hook greatly facilitates manipulation of the biopsy specimen and avoids undue trauma. A reasonable size for an elliptical biopsy is about 5 mm, but smaller specimens may be adequate where indicated for cosmetic reasons. Small lesions may be totally excised, but a biopsy of a larger lesion should be at right angles through the margin to include adjacent normal skin. The long axis of the wound should, where possible, follow the natural crease lines of the skin. For suspicious melanocytic lesions, a simple excision with narrow margins is performed and this is followed by a wider excision on confirmation of the diagnosis. A full discussion of surgical techniques and suture materials is beyond the scope of this chapter, but there are several excellent reviews [7,8] and aspects of cosmetic dermatological surgery are discussed in Chapter 80.

Punch biopsy [11]

The biopsy punch is a metal cylinder of variable diameter with a sharp cutting edge at one end, usually attached to a plastic handle (Fig. 10.2). The punch is pushed into the skin with a downward twisting movement, and then removed. The tissue specimen is lifted and separated from the underlying tissue, and removed from the biopsy punch. The wound may be left to heal without suturing, the base of the wound being cauterized by electrocautery or some other haemostatic agent. Many operators, however, prefer to insert one or two sutures to secure haemostasis.

Punch biopsies are convenient and quick to use, but it is preferable to use at least a 3-mm punch to obtain a satisfactory specimen. Biopsy punches blunt easily, and therefore disposable punches are recommended. Another problem with small punch biopsies is that the specimen is often difficult to orientate, and most pathologists greatly prefer elliptical excision biopsies for diagnostic interpretation. In general, a punch biopsy should not be used for the diagnosis of cutaneous tumours, and this is particularly true for

Fig. 10.1 Instruments for skin biopsy, including scalpel, scissors, needle holder and skin hooks.

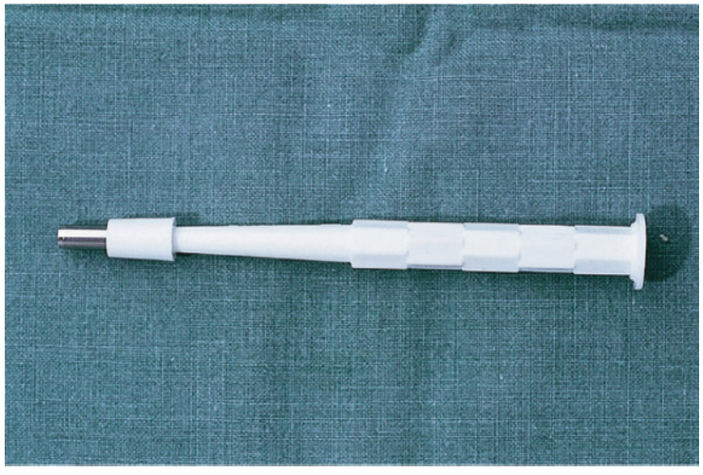

Fig. 10.2 Disposable punch for cutaneous biopsy.

melanocytic lesions. Nevertheless, punch biopsies do have a place in busy outpatient departments and office practices, particularly for diagnosis and management of small cutaneous lesions.

Curettage [12,13]

The technique of curettage with a sharp-edged Volkmann's spoon or disposable curette followed by cautery is often used for the treatment of small benign and malignant skin lesions, such as viral warts, solar and seborrhoeic keratoses, and basal cell carcinomas. The resulting specimen is often badly fragmented, and it is often impossible to comment on adequacy of removal. A combination of curettage and shave excision has been proposed to overcome this problem. Curettage alone is more useful as a therapeutic procedure than as a technique for providing ideal specimens for histopathological diagnosis. It must be emphasized that all specimens should be submitted for histopathological examination. Haemostasis may be achieved by electrocautery, alginate dressings or using aluminium chloride hexahydrate solution on a cotton bud rolled over the wound. It is important to mention a further haemostatic agent, Monsel's solution (ferric subsulphate) that is no longer widely used but may cause problems in the histological interpretation of re-excision specimens. The pigment coats the collagen bundles and induces a histiocytic reaction with numerous siderophages [14]. This may make the interpretation of biopsies very difficult, particularly in the setting of melanocytic lesions.

Shave biopsy

Certain superficial, benign papular or nodular lesions may be treated by shaving off the lesion flush with the surface of the surrounding skin. Many sorts of superficial skin lesion may be treated in this way, in particular melanocytic naevi. Although often a useful cosmetic result may be obtained, this technique has several drawbacks. The whole lesion is rarely removed, and recurrence of the lesion is sometimes a problem. In the case of melanocytic naevi, it is known that lesions that recur following partial excision may often demonstrate atypical histopathological features, sometimes leading to an erroneous diagnosis of a malignant lesion [15]. As with the techniques of curettage and punch biopsy, the wounds resulting from the procedure of shave biopsy normally require some form of cauterization or use of aluminium chloride hexahydrate to achieve haemostasis.

Other biopsy techniques

Various other ways of obtaining portions of skin tissue for diagnostic purposes have been described, including needle biopsy, similar to that used for tissue diagnosis of liver disease and lymph-node pathology (see section on cytodiagnosis). The results from such a technique are generally unsatisfactory for skin lesions, and in no way compare with those achieved using more conventional surgical procedures. Techniques for slit-skin smears for leprosy and skin snips for oncho-cerchiasis are discussed in Chapters 32 and 37, respectively.

Information to be provided with the specimen

For the clinician to obtain the optimum help from the pathologist, it is essential that full clinical details be provided. A fully completed histopathology request form should include the following details for each specimen. The patient should be identified by name, sex, age and usually a hospital reference number, or some other identification record number. It is useful to know the patient's racial group, as prominent epidermal basal layer melanin pigmentation may be pathological in some situations, and represents normal skin for other individuals. A brief clinical history of the duration of the skin condition should be provided, together with details of any treatment including topical and systemic therapy. The site of each biopsy taken should be clearly identified on the request form, and accompanied by specimens in separate, individually labelled containers. Unfortunately, it is not uncommon to receive several biopsies from what are thought to be trivial lesions from the same patient in one container. Sometimes it turns out that one of these lesions is histologically malignant and the others are benign, and in these circumstances it may be impossible to determine the site of the malignant tumour.

Details of previous biopsies, and where possible the histopathology report reference numbers, should always be included on a request form, and finally a suggested clinical diagnosis or list of differential diagnoses is helpful. Where possible, abbreviations should be avoided. It may be that many pathologists will recognize the letters PLC as standing for pityriasis lichenoides chronica, but perhaps there would be fewer who would immediately recognize the letters TMEP as representing a form of urticaria pigmentosa.

Finally, but most importantly, the dermatologist or surgeon sending the biopsy material to the pathologist should give some clear indication on the request form from whom the biopsy is being sent, or to whom the report should be forwarded. If some of the simple advice above were more often heeded by clinicians performing biopsies, it would make the life of a dermatopathologist very much easier.

Care of the specimen

Care is required throughout the biopsy procedure, to avoid trauma to the specimen with forceps or any of the other instruments used during biopsy. The use of skin hooks in manipulating the specimen during biopsy is helpful in this respect [16] and, in order to avoid trauma artefact, division of small specimens into multiple smaller portions of tissue for different diagnostic purposes should be avoided. If a specimen is needed for four separate studies—such as paraffin embedding, direct immunofluorescence studies, electron microscopy and microbiological culture—it is often better to take two separate specimens and divide each of these into two portions than to attempt to divide one specimen into quarters. Biopsies taken for ultrastructural studies should be small (of the order of 1–2-mm cubes) to allow for adequate fixation. Once the biopsy specimen has been taken, it should be placed epidermal side uppermost on a small portion of filter paper, to prevent curling, and transferred promptly to the appropriate transport medium.

For routine diagnostic microscopy of paraffin-embedded material, 10% neutral buffered formalin is still the most widely used fixative and is satisfactory for most purposes [17]. Many other fixatives [17] and transport media such as Michel's [18] (Table 10.4) are available, and these are indicated for either the

study of specific diseases or tissue components, or for the application of specific diagnostic techniques such as immunofluorescence [19]. The use of Michel's medium allows the preservation of antigens for immunofluorescence studies for up to 6 months [20]. By using Michel's medium, specimens may be sent safely without the need for immediate freezing. This medium is also useful for fixation of samples used in immunoelectron microscopy studies [21] and also seems to preserve the antigens relevant for investigation of genetic blistering skin diseases [22]. The specimen has to be washed thoroughly on receipt before freezing it to avoid artefacts. Sodium chloride 0.9% has been proposed as an alternative transport medium to Michel's medium [23]. However, preservation of antigens only lasts for 24 hours and frequent artefacts, including hydropic degeneration of keratinocytes and splitting of the dermoepidermal junction, are seen. Furthermore, this method is not suitable for samples obtained for immunoelectron microscopy or antigen mapping. Table 10.5 gives some details of the more important fixatives and transport media.

Table 10.4 Michel's transport medium for fresh cutaneous tissue.

Ammonium sulphate	55 g in 100 mL buffer
Buffer	1 mol/L potassium citrate (pH 7), 2.5 mL 0.1 mol/L magnesium sulphate, 5 mL 0.1 mol/L ethyl maleimide, 5 mL Distilled water, 87.5 mL Mix 1 : 2 with 1 mol/L potassium hydroxide to pH 7.0

Table 10.5 Fixatives and transport media for skin biopsy specimens. (Details of most methods are given in Bancroft and Gamble [17].)

Investigative technique	Fixative/transport medium	Comments
Most routine diagnostic studies on paraffin-processed material	10% neutral buffered formalin solution (pH 7) 10% aqueous formalin (unbuffered)	Most useful fixative for general use H&E staining generally better than with buffered preparation Formalin pigment a nuisance
	Carnoy's solution (pH 2.8)	Good preservation of nuclear chromatin Haemolyses red blood cells; use small specimens
Where rapid fixation required	Place specimen in the oven in alcohol	Microwave fixation
When good preservation of mucopolysaccharides is required	Formal saline solution (pH 3.8)	Nuclei badly distorted Not satisfactory for routine purposes
Demonstration of leprosy bacilli	FMA fixative or Zenker's fluid	Good results for acid-fast bacilli with Wade–Fite stain Mercury deposits must be removed
Transmission electron microscopy and some electron immunocytochemistry	Karnofsky's solution or 2.5% buffered glutaraldehyde solution Post fixation with osmium tetroxide	Small specimens required, normally no more than 1-mm cube
Immunofluorescence and immunoenzyme techniques	Various; periodate lysine paraformaldehyde fixation and cold processing useful for some endothelial cell markers	Various fixatives suitable depending on technique and antigen/substance to be identified Frozen tissue may be required
Transport of specimens for immunofluorescence studies	Michel's medium	Specimen must be thoroughly washed in phosphate-buffered saline before immersion in Michel's medium
Microbiological studies, studies on fat tissue and some immunohistological investigations	Fresh or frozen tissue	Specimens for microbiological examination should be placed in sterile containers and transported to the laboratory as soon as possible

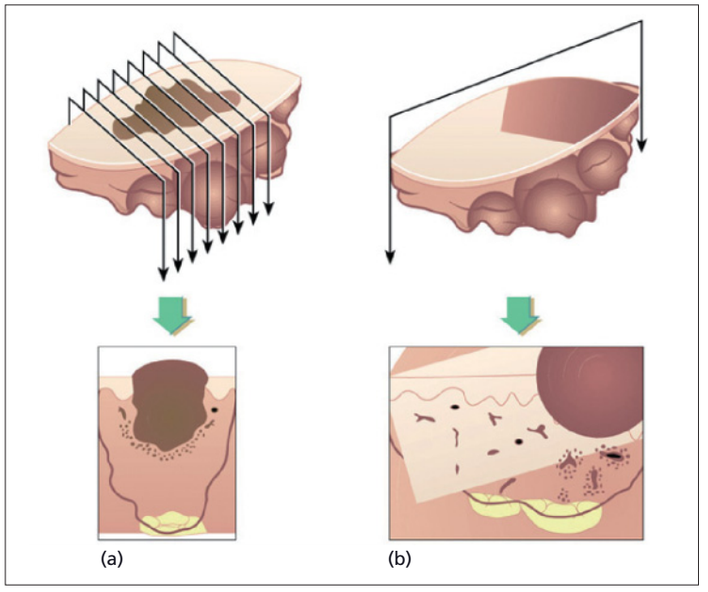
Laboratory methods

Specimen preparation

Frozen sections are not used routinely in dermatopathology, except for Mohs micrographic surgery (described in Chapter 77) and immunofluorescence. Most antibodies used in diagnostic dermatopathology work adequately in samples fixed in formalin, and except in the context of research, frozen sections are therefore not used on a regular basis for immunohistochemical studies. Frozen sections are used for the diagnosis of autoimmune blistering disorders and also for the diagnosis of blistering genetic skin diseases (antigen mapping, see Chapter 39). Although it has been advocated that autoimmune blistering disorders may be diagnosed with immunohistochemistry performed on samples fixed in formalin, the results are often of inferior quality and interpretation is difficult, leading to false-negative and false-positive results. This method is therefore not recommended.

Careful identification and preparation of tissue specimens prior to processing is most important. The first requirement is that the biopsy specimen be placed immediately into a fixative solution. Various routine fixatives are employed; most contain 10% formalin. Because a stock solution of formalin consists of 40% formaldehyde, 10% formalin is really 4% formaldehyde. A minimum of 12 h fixation is recommended for most specimens, but small specimens may only need 6 h, and larger specimens a longer period of fixation, to produce optimal results. After fixation, the biopsy tissue is removed from its container, double-checking that the specimen corresponds with details given on the request form, and the pathologist produces a macroscopic description together with details of 'the cut up'.

Special care should be taken where multiple fragments of tissue are present, for example, in specimens obtained by curettage. It may be necessary to pass the contents of the biopsy container through a filter paper to ensure that all relevant portions of tissue are processed and examined. After orientating the specimen, a description should be made of the size and shape of the specimen, and a note made of whether subcutaneous or other tissue is included. A careful description of surface changes is then made, with particular reference to changes of colour and surface texture, such as erosion or ulceration. Any obvious clinical lesion present on the gross specimen should be described. In some surgical specimens, an identification label, such as a skin suture, is left in place in the biopsy specimen by the surgeon, to enable precise orientation of the specimen. This is particularly important when dealing with neoplastic lesions, where clearance of tumour in the margins of the biopsy specimen needs to be assessed.



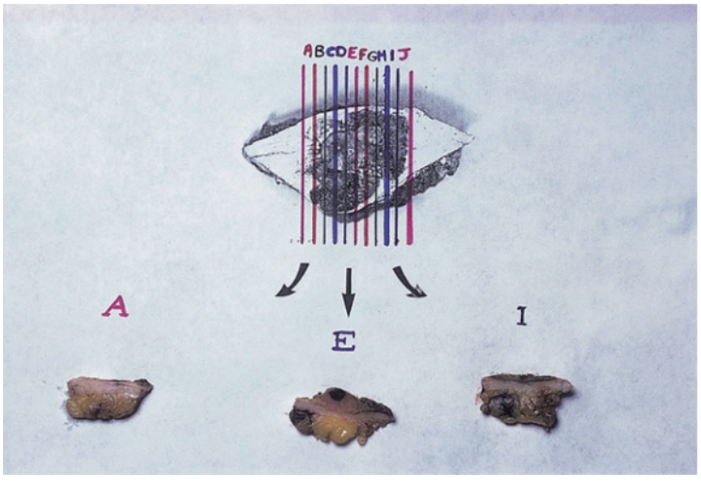


Fig. 10.3 Blocking of elliptical skin biopsy specimens. (a) Neoplastic lesions. Multiple transverse blocks through the whole lesion allow for histopathological examination of the tumour at all levels, and assessment of the narrowest excision margins. (b) Incisional biopsy of inflammatory lesion. Longitudinal blocking is recommended. This allows optimal visualization of the affected and adjacent normal skin.

Prior to sectioning of a gross specimen, especially excised tumours, it is good practice to paint the margins of the biopsy specimen with coloured dyes that are resistant to tissue processing. Various commercial preparations are available, and one or several colours may be used. If the dye is visible on the final tissue section examined by the pathologist, this implies that no tissue has been lost in processing, and that the edge of the section corresponds to the genuine margin of the biopsy. After painting of the biopsy margins, the gross specimen is then sectioned prior to the preparation of histological blocks. There are various techniques for cutting up a standard elliptical skin biopsy. The ideal method depends to some extent on the nature of the suspected diagnosis. A specimen from an excision biopsy of a benign or malignant skin tumour is better handled by taking transverse blocks through the specimen, so that the narrowest excision margins may be examined. For malignant lesions, particularly for suspected malignant melanoma, ideally transverse blocks should be taken at 2-mm intervals throughout the whole length of the lesion (Fig. 10.3a) [1]. An elliptical biopsy, taken, for instance, from the margin of a patch of an inflammatory dermatosis, is best sectioned longitudinally, so that both normal and abnormal skin can be visualized (Fig. 10.3b). With larger specimens, examination of a selection of transverse blocks made from various portions of the tumour may be adequate for diagnostic purposes. Any biopsy tissue not processed should be labelled, and returned to the fixative in the container and stored. Laboratories have different

(a)

(b)

Fig. 10.4 Photocopy procedure for recording the preparation of blocks. (a) The appearance of a macroscopic specimen of malignant melanoma. (b) Transverse blocks are taken from the specimen, and their exact position is recorded on a photocopy made from the surface of the gross specimen.

policies regarding the retention of fixed tissue specimens. Ideally, all specimens should be retained, but limitations of space often mean that most routine specimens can be discarded after a period of a few weeks after the histopathological report has been approved and signed.

In addition to a written description of the gross specimen, and how it has been prepared for blocking, a rough diagram of the specimen is very useful, particularly with larger specimens. This enables clear identification of the portion of the specimen from which various blocks have been taken. An alternative approach for larger specimens, especially when dealing with neoplastic lesions, is either to photograph the specimen or to wrap the specimen in clear cling-wrap film and take a photocopy of the surface. This produces an image the same size as the gross specimen, and details of the blocks taken can be recorded directly on the photocopy image (Fig. 10.4).

Very small specimens may be blocked in their entirety after trimming. Other blocking techniques may be used for specific purposes. An example is the blocking of transverse sections of cylindrical punch biopsies (at least 4 mm in diameter) of scalp disorders [2–5]. This technique is particularly useful in the assessment of various forms of inflammatory alopecia, and facilitates the quantitative morphometric analysis of pilosebaceous follicles and the hair itself. The technique also provides a useful method of studying the morphological details of the normal transverse anatomy of follicular structure, including the various phases of the normal hair cycle. Ideally, when investigating a condition presenting with alopecia, two biopsies should be provided: one for vertical sectioning and one for horizontal sectioning. It has been shown that the interpretation of both horizontal and vertical sections in scalp biopsies is better than each method on its own to obtain a high diagnostic yield [4]. If immunofluorescence studies are required, the specimen for vertical sectioning can be divided into two portions.

Routine tissue processing

Although the skin biopsy specimen may be examined with various techniques, at least a portion of most skin biopsies is routinely processed for light microscopic evaluation of sections from paraffin-embedded tissue. In most modern histopathology departments, the tissue processing is carried out by the use of automated machines. Although it is maintained that superior results may be possible by manual means, this often involves the changing of processing fluids at inconvenient times, and is a time-consuming and labour-intensive procedure. Two main types of automated tissue-processing machine are in use: the traditional carousel type and the enclosed pumped fluid type. Both types of machine have the facility for multiple separate stages in processing. Whether tissue processing is carried out by machine or by hand, after completion of fixation the same basic steps of dehydration, clearing and embedding are involved. The process of dehydration removes aqueous fixative and any tissue water. Clearing refers to the use of a substance such as xylene, which is totally miscible with both the dehydrating agent that precedes it, and the embedding agent that follows it.

For embedding, paraffin wax at 56°C remains by far the most popular material; it is cheap, large numbers of tissue blocks may be processed in comparatively short times, and later sectioning and staining are straightforward. The use of vacuum impregnation in modern and automated tissue-processing machines considerably reduces the overall processing time. At the end of the embedding procedure, paraffin blocks are cut and stained and are then ready for microscopic examination. The dermatopathologist should be aware of relatively common potential artefacts that can cause confusion and misinterpretation (Table 10.6) [6]. When urgent preparation of tissue specimens is required, various processing steps can be shortened. The use of very thin portions of tissue, increasing the temperature of the fixative, microwave-fixation techniques [7,8] and shortening the time used for clearing, can all facilitate rapid processing. Alternatively, cryostat sections can be examined.

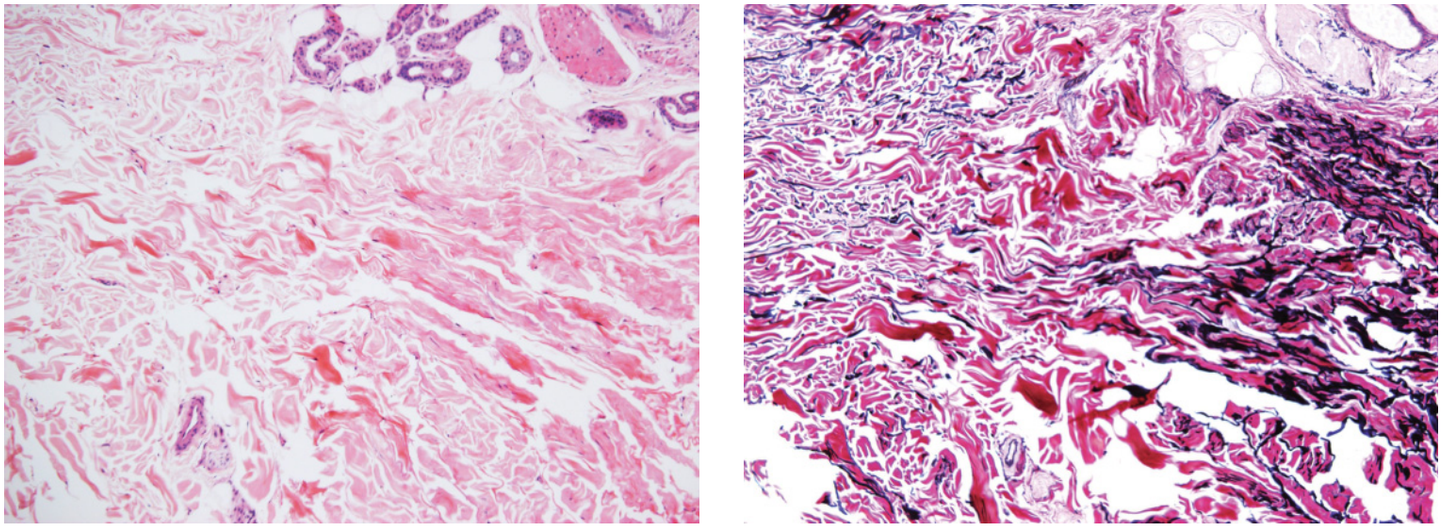
Table 10.6 Potential dermatopathological artefacts.

Poor orientation: cross-sectioning making it difficult to evaluate the epidermis and dermis
Sometimes this results in complete loss of the epidermis
Formaldehyde fixation: vacuolation of epidermis
Fixation in non-buffered formaldehyde: pigment deposition
Freezing artefact: prominent intracytoplasmic vacuoles in keratinocytes
Scratch marks across tissue due to nick in microtome knife
Tissue carry-over from microtome knife
Foreign bodies, e.g. formaldehyde pigments, suture, *Alternaria*, spores, starch
Polarization of cell nuclear material by electric current in curetted specimens
Clumped mitoses in podophyllin-treated warts
Pyknotic prickle cells from methotrexate- or hydroxyurea-treated patients

Table 10.7 Some tinctorial stains used in dermatology.

Special stains	Tissue constituent	Appearance
Periodic acid–Schiff (PAS)	Glycogen	Magenta red (diastase sensitive)
	Mucopolysaccharides	Red (fungal wall red)
Van Gieson	Collagen	Red
	Muscle, nerve	Yellow
Congo red	Amyloid	Red with green birefringence
Acid orcein–Giemsa	Elastic fibre	Dark brown
	Collagen	Pink
	Melanin	Black
	Haemosiderin	Green/yellow
	Amyloid	Light blue
	Mast cell granules	Purple
Masson's trichrome	Collagen	Green
	Muscle + fibrin	Red
Aldehyde fuchsin	Elastic fibre	Purple
Gomori's	Reticulin	Black
Alcian blue (pH 4.5, 0.5)	Acid mucopolysaccharides	Blue
Toluidine blue	Acid mucopolysaccharides	Metachromatic purple including mast cells
Perls' Prussian blue	Iron (haemosiderin)	Blue
Masson's Fontana	Melanin	Black
Von Kossa	Calcium salts	Brown/black
Grocott's	Fungus wall	Black
Methenamine silver	Bacteria	
	Gram+	Blue/violet
	Gram–	Red/pink
Ziehl–Neelsen/Wade–Fite	Acid-fast bacilli	Red

Routine staining techniques, including histochemistry (Table 10.7)



By far the most widely used stain for section from skin biopsies used in histopathology laboratories is haematoxylin and eosin (H&E). This staining technique gives good definition of many cellular and tissue structures in the skin, and is sufficient for the diagnosis of most skin diseases. This stain, however, does not clearly demonstrate certain tissue components, such as elastic fibres (Fig. 10.5a & b), and does not allow differentiation between melanin, haemosiderin and other skin pigments. Special stains are required for these purposes, and also for confirming the nature of abnormal dermal deposits, such as calcium, mucin and amyloid. Another important indication for special staining techniques is the demonstration of microorganisms. Full details of the techniques and applications of special stains used in diagnostic dermatopathology are given in standard reference texts [9–11]. Examples of commonly used staining techniques that are useful in the diagnosis of specific conditions are given below.

The periodic acid–Schiff (PAS) stain demonstrates the presence of carbohydrates, particularly some polysaccharides such as glycogen, and mucoproteins containing neutral mucopolysaccharides. These substances are stained reddish purple by the PAS reaction. Because the cell walls of fungi and yeasts contain neutral polysaccharides, they also stain positively with the PAS reaction (Fig. 10.6). This is a cheap and reliable diagnostic method and it has been advocated that a PAS stain should be routinely used in all biopsies of inflammatory dermatoses [12]. The reasoning for this proposal is based on the fact that the clinical and histological appearances of tinea may be fairly non-specific. The technique is also useful in demonstrating blood-vessel walls, basement membrane (Fig. 10.7), fibrin deposition and the presence of glycogen deposits, for instance in certain sweat gland tumours, such as clear cell hidradenoma, trichilemmoma and some epithelial lesions of uncertain histogenesis, such as the clear cell acanthoma of Degos. The identification of glycogen can be further confirmed by removal by enzyme digestion with diastase in 1% aqueous solution at 37°C for 30 min. Positive staining after the use of diastase indicates the presence of neutral mucopolysaccharides.

The Alcian blue reaction produces a blue coloration in the presence of acid mucopolysaccharides. In addition to demonstrating the presence of mucin in cutaneous mucinoses, the technique is also of value in some cases of extramammary Paget's disease, and occasionally in the demonstration of goblet cells in metastatic carcinoma of the gut. There are small amounts of acid mucopolysaccharide present in the ground substance of normal dermis, and the Alcian blue reaction is very pH-dependent. Care should therefore be exercised in the interpretation of a positive result.

Acid orcein and Giemsa stain was popularized by Pinkus and Mehregan, who recommend its use as a second routine stain [13]. It is a valuable technique which demonstrates, in addition to structures normally visible with H&E stain, the presence of mast cells, eosinophils, metachromatic substances and elastic fibres. The routine use of the orcein–Giemsa stain often avoids recutting of blocks for other special stains. Orcein itself is a constituent in other staining methods, particularly those used to demonstrate elastic fibres.

Special staining techniques are often essential to differentiate between epidermal and dermal deposits of melanin, haemosiderin and other substances. Masson's ammoniacal silver nitrate technique produces a densely black reaction product with melanin. Melanin deposits appear greenish black with the acid orcein–

(a) (b)

Fig. 10.5 (a) Connective tissue naevus. The section stained with H&E only shows focal condensation of the collagen. (b) An elastic van Gieson stain shows marked focal increase in the number of elastic fibres.

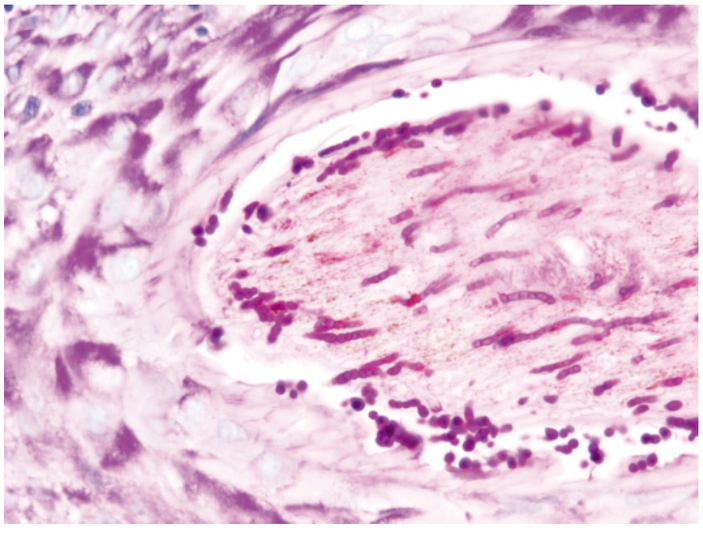


Fig. 10.6 Periodic acid–Schiff (PAS) stain, showing numerous hyphae within the hair shaft in an endothrix infection.

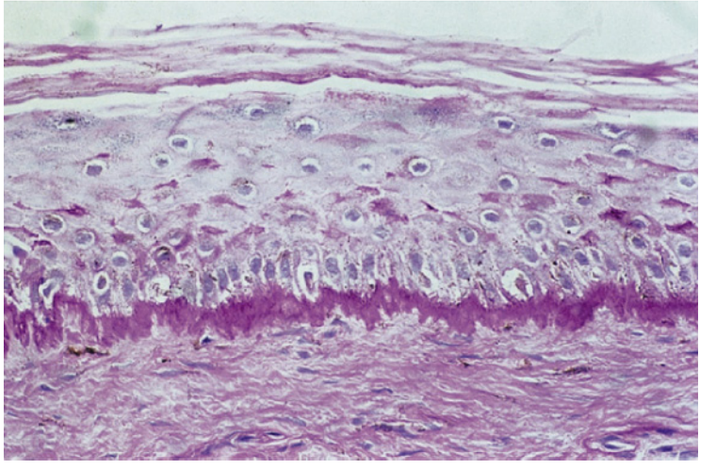

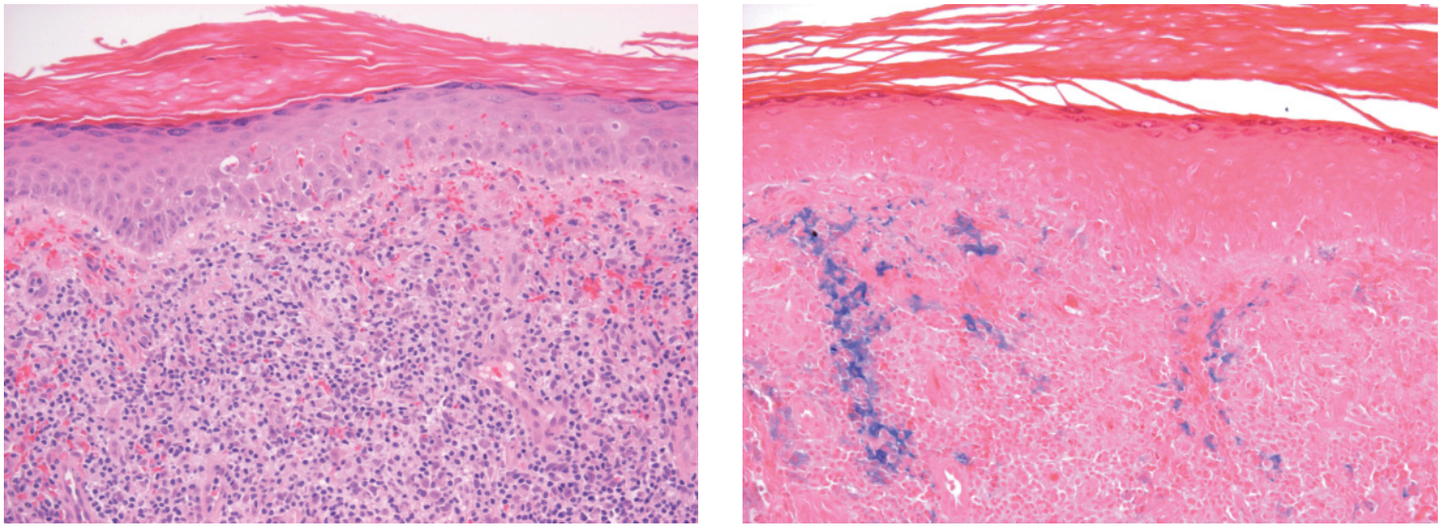

Fig. 10.7 Periodic acid–Schiff (PAS) stain, showing thickening of the basement membrane zone in cutaneous lupus erythematosus.

Giemsa stain referred to above. Iron, which in the context of skin biopsy material normally means haemosiderin pigment, is demonstrated by Perls' Prussian blue reaction, which yields a deep-blue reaction product in the presence of ferric and ferrous iron (Fig. 10.8a & b).

Trichrome stains can demonstrate various elements of connective tissue. Common examples are the van Gieson stain, in which collagen appears red and muscle and nerves yellow, and Masson's trichrome stain, in which collagen is green and muscle red. The latter stain is seldom used nowadays.

Reticulin fibres are demonstrated by Gomori's silver impregnation technique. This technique is particularly useful in the study of certain cutaneous tumours, including vascular tumours and malignant melanoma. The application of this method to melanocytic lesions may reveal foci of expansile growth undetectable in normal H&E-stained preparations.

Certain types of cell present within the skin may be difficult to recognize on conventional H&E-stained material. Mast cells are best demonstrated either by the use of a metachromatic staining technique, such as toluidine blue, or with one of the few enzyme histochemical methods that may be carried out on paraffin-embedded tissue, such as the chloroacetate esterase reaction. The use of this technique applied to formalin-fixed paraffin sections was described by Leder [14], and mast cells and myeloid white cells are easily identified by their bright pinkish red staining (Fig. 10.9). Other histiocytic and dendritic cells that are difficult to visualize on routinely stained material are best visualized with immunohistochemical methods.

(a) (b)

Fig. 10.8 (a) A prominent lymphocytic infiltrate which is focally lichenoid and is associated with extravasation of red blood cells in a case of lichen aureus (H&E). (b) Perls' stain highlighting numerous haemosiderin-containing macrophages, a useful technique to confirm the diagnosis of lichen aureus.

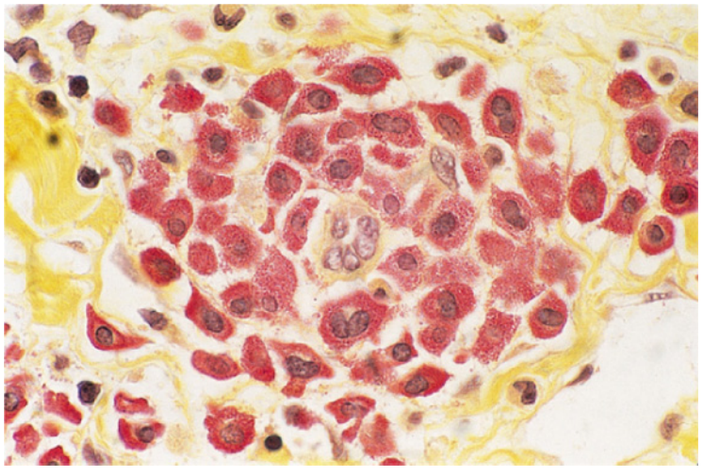

Fig. 10.9 The chloroacetate esterase stain. Mast cells appear red with this technique.

Cutaneous deposits of various naturally occurring and foreign substances often require special staining techniques for their demonstration. The von Kossa method produces a black coloration in the presence of calcium salts, and amyloid deposits may be demonstrated using crystal violet or Congo red. With this latter technique, amyloid deposits stain pinkish red, and under polariscopic examination there is a green birefringence. Another technique useful for the demonstration of amyloid deposits is the thioflavine T method, yielding green fluorescence on examination with a fluorescence microscope. Unfortunately, several of the staining techniques recommended for the demonstration of amyloid are technically unreliable, and none is absolutely specific for amyloidosis. Some cotton dyes other than Congo red, such as pagoda red, have been claimed to be as sensitive as Congo red while being more specific [15]. It is recommended that more than one special stain be used if amyloid is suspected. Occasionally, even with the use of several special stains, amyloid cannot be demonstrated and electron microscopy is necessary for this purpose.

A wide range of techniques is employed for the demonstration of microorganisms in the skin. Reference has already been made to the usefulness of the PAS stain in the demonstration of yeasts and fungi. The silver staining technique of Grocott is also very helpful in the identification of fungal hyphae and yeast bodies. These structures stain black on a pale-green background. Other silver techniques, including the Warthin–Starry technique, are useful in demonstrating spirochaetes, *Bartonella henselae* (the organism that causes bacillary angiomatosis) and *Borrelia* in tissue sections. *Bartonella* may also be demonstrated by the use of a Giemsa stain. The traditional Gram stain demonstrates coccal and bacillary organisms in the skin. Several techniques are available for the demonstration of acid-fast bacilli. The Ziehl–Neelsen method is widely used for the demonstration of mycobacteria, particularly *Mycobacterium tuberculosis.* It is based on the capacity of the lipid-rich cell wall of mycobacteria to take up strong phenol-dye solutions. This dye is retained after differentiation in acid or alcohol. Mycobacteria stain magenta and the background is blue. Auramine–rhodamine is also a sensitive method for demonstrating mycobacteria in tissue sections. Its main drawback is that it requires the use of a fluorescence microscope for interpretation [16]. The Ziehl–Neelsen method should not be used for the demonstration of leprosy bacilli. The use of this technique often leads to a false-negative result. The reason for this is that the leprosy bacilli are less acid- and alcohol-fast. The Wade–Fite stain, or a modification of this technique, is more appropriate for identification of leprosy bacilli and atypical mycobacteria because it uses minimal treatment with alcohol and acid. In fact, in cases with very few organisms, if Ziehl–Neelsen is used instead of Wade–Fite, the diagnosis may be missed.

Even with the above techniques, demonstration of small numbers of microorganisms in the skin may be very difficult, and may require the examination of very many sections. Thankfully, since the last decade of the last century, increasing numbers of newer tests for the detection of microorganisms in paraffin embedded tissue have become available, simplifying the task of pathologists and dermatopathologists. These techniques include *in situ* hybridization, polymerase chain reaction (PCR) and immunohistochemistry and are used for the detection of a wide variety of microorganisms, including bacteria, mycobacteria, viruses and leishmania [17–29]. PCR is a very valuable tool for confirming the diagnosis in these infections, but very stringent conditions are required to avoid false-positive results, especially in the setting of mycobacterial infections. PCR is particularly useful in cases with suspicious histology in which special stains and cultures have been negative. It is important to highlight that mycobacterial DNA has been found in cutaneous lesions of nodular vasculitis and papulonecrotic tuberculid [30,31]. While this confirms the relationship between these two entities and tuberculosis, it does not necessarily mean that the finding may be interpreted as evidence of tuberculous infection in the affected sites. A polyclonal antibody for BCG is very useful as a screening technique for the presence of fungi and bacteria in tissues and this is based on the presence of wide cross-reactivity of this antibody between different species [32,33,34]. The antibody is, however, not useful to detect viruses, leishmania or spirochaetes.

Immunopathology

There are some situations where even after careful biopsy of an appropriate lesion, expert tissue processing and sectioning, and the use of several special staining techniques, a specific histological diagnosis is still not possible. The use of immunological methods permits the identification of antigens, antibodies and various other cell and tissue components, and has greatly facilitated our ability to achieve a specific diagnosis. Hybridoma monoclonal antibody technology paved the way for the development of numerous antibodies to cell and tissue structures. Further refinement and experimentation with immunohistological techniques has brought this powerful new diagnostic tool within the reach of most histopathology laboratories, particularly with increasing commercial availability of diagnostic cell markers that label routine paraffin sections (Table 10.8).

Immunofluorescence methods

Immunofluorescence is a technique for detecting the presence and position of antigens, antibodies, other cell secretions and cell components in cells or tissue sections. The principle of the technique is that certain fluorochrome dyes exposed to ultraviolet (UV) light emit fluorescent radiation, the colour of which depends upon the particular fluorochrome. When these dyes are conjugated to proteins that are subsequently added to tissue sections, or injected into an animal, the position of the proteins can be traced microscopically by the fluorescence they emit under illumination with UV light with suitable filters.

Two fluorochromes are generally available. Fluorescein is most commonly used. It is best conjugated to protein in the form of fluorescein isothiocyanate, which emits an apple green fluorescence. The second dye is rhodamine RB200, which is conjugated to protein as rhodamine isothiocyanate or sulphonyl chloride; it emits an orange fluorescence.

Preparation of tissues

Tissues to be examined are usually snap frozen in liquid nitrogen, cut in a cryostat at about –20°C, dried and stained without fixation. Sections can be fixed, before staining, in cold acetone or

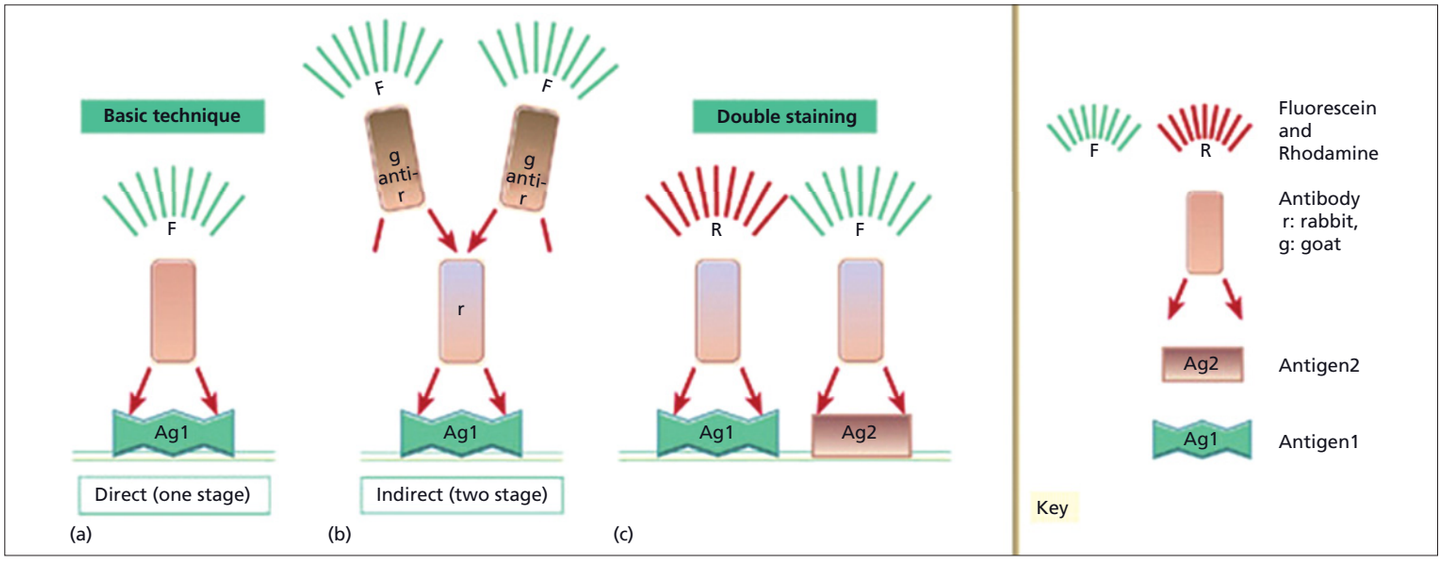

Fig. 10.10 Diagrammatic representation of immunofluorescence techniques.

methanol, provided that these agents do not alter the antigenicity of, or dissolve, the substances to be detected [1]. This provision also applies to the technique of cold formaldehyde [2] or alcohol fixation of tissues, and embedding in paraffin for cutting on a microtome at room temperature. The use of acetone, ethanol and methanol enhances tissue preservation, but sometimes increases non-specific staining.

Many antigens can be detected in routine paraffin tissues; others are masked after fixation in formalin, para-formaldehyde or glutaraldehyde and paraffin embedding. Such antigens can be 'retrieved' or revealed, and detection improved, by heat in strictly controlled conditions [3–8]. Heat treatment is by pressure cooker or by microwave. The heat retrieval solution is citrate buffer, 10 mmol/L sodium citrate made pH 6.0 by HCl. When heated in a pressure cooker, the slides in open metal racks, well spaced, are placed in hot buffer in the pressure cooker and as quickly as possible heated to 15 lb pressure for 1 min only. Then the pressure cooker is plunged into a sink of cold water. In the more often used microwave method, the slides are placed in Coplin jars containing the same buffer; the jars are placed in an open dish. The dish may contain water but this is not essential. The tissues are heated for variable periods; 15 min is usually adequate. Antigens in skin should not require more than 10 min. After the first and every 5 min after, the fluid in the Coplin jar is replenished with water to replace that lost by evaporation. Unfortunately, the dermis is susceptible to disintegration if heating is excessive, though eccrine and sebaceous glands and larger blood vessels remain. The treated sections are stained by standard methods of immunofluorescence or by immunoenzyme techniques.

Some antigens require protease treatment instead of heat; this is usually indicated on the leaflets accompanying vials of commercial antibodies.

Labelling procedures

Tissue sections must be wetted and treated with protein to block or reduce non-specific binding for at least 30 min. The diluent is phosphate-buffered saline (PBS) +0.1% Triton X100 and protein, which may be 0.5% chick albumin, or 0.5–2.0% bovine serum albumin or, rarely, 2–5% of the serum of the same species as the primary antibody. The diluent for the antibody is PBS with 0.1% Triton X100 and 0.5% chick or bovine albumin.

The two principal labelling techniques are direct staining (Fig. 10.10a), in which sections are incubated with fluorochrome-labelled antibody to detect substances (i.e. the corresponding antigen) in tissues, and indirect staining (Fig. 10.10b), in which unconjugated antibody is incubated with the section, and any bound antibody is detected by the subsequent addition of fluorochrome-conjugated antiglobulin sera. These simple techniques may be modified for more sophisticated investigations by using double staining (Fig. 10.10c) on the same section, one with a fluorescein-labelled antibody, the other labelled with rhodamine or some other fluorochrome-conjugated antibody. Thus, it is possible to detect antigen and antibody in an immune complex (Fig. 10.10c) or a secreting cell and its secretions. Usually, the two labelled antibodies are derived from different species.

Direct labelling. Direct staining is used to detect substances, including antibody immunoglobulins in tissues (e.g. *in vivo* bound immunoreactants as in pemphigus and pemphigoid), by the addition of fluorochrome-conjugated antibodies (Fig. 10.10a) with subsequent washing to remove from the preparation all the conjugated antibody except that fixed to the particular substance. The details of the method are as follows.

1 For critical examination to detect small amounts of antigen, sections treated with the conjugated antibody are maintained in humid conditions overnight at 4°C. For more routine procedures, antibody treatment is for 2–4 h at room temperature in a humid container. The containers must be light-proof.
2 Wash tissue in PBS pH 7 with three changes for a total of 20 min.
3 Mount in commercial antifade mountant fluids.

Indirect labelling. The unconjugated antibody, or primary antibody, is incubated with the specimen to bind to the test antigen; the uncombined surplus is removed by washing, and the preparation stained by a fluorochrome-conjugated antiglobulin serum, i.e. this is the secondary antibody which binds to the primary antibody (Fig. 10.10b). The details of the indirect staining method are as follows.

1 Incubate the tissue with the antibody to the test antigen. This is the primary antibody.
2 Wash in PBS with three changes for at least 20 min.
3 In a light-proof humid container, incubate the sections for 30–45 min at room temperature with the conjugated antiglobulin antibody; this is the secondary antibody, to bind to and label the primary antibody.
4 Wash in PBS for 20 min (three changes) with the least exposure to light.
5 Mount.

Indirect staining with conjugated antiglobulin sera is more sensitive than direct staining with conjugated antibodies, because more conjugated antiglobulin molecules are fixed to antibody in the second stage than are antibody molecules fixed to antigen in the first stage. The method has, however, the disadvantage that it increases the likelihood of non-specific staining.

Results are dependent upon the quality of the antibodies. Monoclonal antibodies, which bind to a small sequence of antigen determinants (epitopes), may have weak affinity and be eluted during washing. False-negative results also occur when the particular epitopes are not exposed; thus monoclonal antibodies to different epitopes of the same antigen vary in their ability to detect the antigen.

Technical limitations

All that glows is not specific fluorescence. The two major sources of error are autofluorescence and non-specific binding.

Control tests. In routine use, the specificity of the conjugated antisera and optimal washing dilution is established and blocking tests are not required, except perhaps in sites of severe inflammation. For critical or experimental studies, blocking tests may be required to prove antibody specificity. Before addition of the conjugated antibody, sections may be treated with normal serum of the same species, or unconjugated specific antibody of the same subclass but against an irrelevant antigen, or unconjugated specific antibody, although this is usually expensive. If the selected pretreatment does not block the binding of the subsequent addition of the test-conjugated antibody, the staining is considered to be antigen-specific. Labelled antisera should be centrifuged before use, to remove any particulate matter, and the glass slides, sections and washing solutions should be free of dust, which readily adsorbs conjugates.

Autofluorescence. Tissues exposed to UV light emit their own fluorescence. In skin, this is not quenched by fixation, and is best controlled by appropriate filters.

Antigen non-specific staining. Non-specific staining refers to fluorescent staining of a section by a labelled antibody, not resulting from a specific antigen–antibody reaction. The causes of non-specific staining and the methods available for removing it are described in detail by Nairn [9].

Appropriate blocking before antibody treatment is essential (see above). The use of optimal dilutions of labelled antibody avoids excess fluorochrome application to the tissue, thus reducing potential non-specific staining. Neutrophils, eosinophils and histiocytes are particularly prone to absorb globulins non-specifically, which accounts for much of the apparently specific fluorescence of inflammatory lesions.

The antigen non-specific binding of fluorescein conjugates by eosinophils can be inhibited by prior treatment of the sections with diaminobenzidine in hydrogen peroxide [10,11].

Another source of confusion is the presence of 'natural' antibodies in the labelled antiserum that combine with sites other than those containing the antigen under examination. This does not apply to monoclonal antibodies and rarely to commercial polyclonal antibody, but they may be present in laboratory-prepared polyclonal antibodies. Natural antibodies are removable by absorbing the antisera with tissue powder from the same species as the tissue under test. Aggregated IgG in the conjugate will also bind non-specifically. Aggregation will occur in conjugates frozen and thawed repeatedly; therefore, conjugates should be stored as small samples and discarded after use. It is advisable to centrifuge the antibody before use.

A peculiarity of immunofluorescence tests on skin is the affinity of the stratum granulosum for antibody–fluorescein conjugates. The nature of this antigen non-specific binding has not been ascertained. Tests on the basic protein or filaggrin peculiar to stratum granulosum cells have not shown this to be the binding substance. However, careful preparation of the conjugates provides reagents with little or no affinity for the stratum granulosum.

Counterstaining. Identification of the particular cells or structures binding labelled antibody may be difficult if there is poor contrast with the background, if there is much autofluorescence and if the specific fluorescent binding is weak. Procedures to identify sites of specific binding are combined phase contrast and immunofluorescence, counterstaining for all the background tissue, or selective stains for nuclei. Counterstains have been used successfully but no one technique is applicable to all preparations. The emission from the counterstain may swamp the specific immunofluorescence if the preparation is thick or the charge affinity is strong, as may occur following the addition of Evans blue or brilliant cresyl violet [9] or of unconjugated rhodamine isothiocyanate to provide contrast to the green specific immunofluorescence. Instead of staining all the structures in a tissue, another counterstain procedure is to use dyes that selectively bind to nuclei to identify cells, for example propidium iodide [12,13], ethidium bromide [14] or *p*-phenylenediamine [15], the latter having the additional advantage of reducing fading of the immunofluorescence.

Photobleaching. Fading or photobleaching is a technical limitation of immunofluorescence. Prolonged or repeated examination reduces the intensity of emission, which also decays if prepara-

tions are exposed to sunlight. This fading can be reduced by the addition of *p*-phenylenediamine to the buffered glycerol mounting fluid [16]. This dye was subsequently found to be a useful nuclear counterstain.

Immunoenzyme methods [1,2]

The immunoenzyme (immunoperoxidase) methods have several advantages over immunofluorescence:

1 Standard microscopes and illumination are used.
2 The preparations are permanent, and the reaction products do not usually fade on repeated examination.
3 Counterstains enable cells containing antigen to be identified with more certainty than using immunofluorescence with dark-ground illumination.
4 Examination is less tiring for the microscopist.
5 The preparations may be examined by electron microscopy.

Technical limitations

Inflammatory lesions may contain endogenous peroxidase activity, and such sections have to be pretreated to remove it [3]. Furthermore, it is possible for the antigen to be modified by the pretreatment, with the result that it is more difficult to detect. This mainly applies to examination of lesions. Normal tissues, for example those used as a substrate to detect antibodies in a patient's serum, rarely require pretreatment. The problem with endogenous peroxidase is analogous to the disadvantage of autofluorescence in the immunofluorescence preparations.

There is less contrast with immunoperoxidase methods than in slides treated by the immunofluorescence technique, and fine stippling or cytoskeletal structures seen by immunofluorescence are not quite so easily detected by immunoperoxidase. Although immunofluorescence may be more discriminating in detecting small amounts of antigen in cryostat-cut sections, the immunoperoxidase methods, used on paraffin-embedded tissues for antigens that are stable during preparation, provide more definite resolution of the tissue and sites of antigen.

Immunoperoxidase methods have another advantage in being the preferred method to re-examine tissues stored in paraffin blocks after routine histology, provided that the antigens are stable in the fixative and dehydrating agents.

Recent improvements in immunoenzyme techniques have resulted in their application to many investigations. The reagent antibody is conjugated with an enzyme, usually horseradish peroxidase, and the antibody conjugate combines with the antigen in the test preparation. The site of binding is detected by adding a substrate for the enzyme: the degradation of many molecules of substrate leaves a deposit confined to the site of binding. Sites of peroxidase activity appear as dark-brown granular deposits that are seen distinctly in contrast to suitable counterstains, for example methyl green or Mayer's haemalum.

Although the application described is the detection of antigen in tissue sections and cell suspensions or monolayers, the principle of the method is the same as that of the enzyme-linked immunosorbent assay (ELISA).

Chemical conjugation of peroxidase to antibody

Antiglobulins conjugated with peroxidase, and peroxidase–antiperoxidase (PAP) complexes, described below, are available commercially.

Use of conjugates

The horseradish peroxidase, conjugated to antibody or to globulin, may be applied to sections to detect antigen by procedures similar to those used for immunofluorescence. There are, however, modifications that increase the sensitivity of the method so that it is equal to, or possibly more sensitive than, indirect immunofluorescence.

The diagrammatic representation of the procedures seen in Fig. 10.11 shows the different forms of conjugate. Antibody against the antigen to be detected may be conjugated directly with the enzyme (Fig. 10.11a). This is not a very discriminating procedure. The indirect or two-stage procedure, whereby the unlabelled antibody bound to the antigen is detected by antiglobulin conjugated to enzyme (Fig. 10.11b), increases sensitivity by increasing the

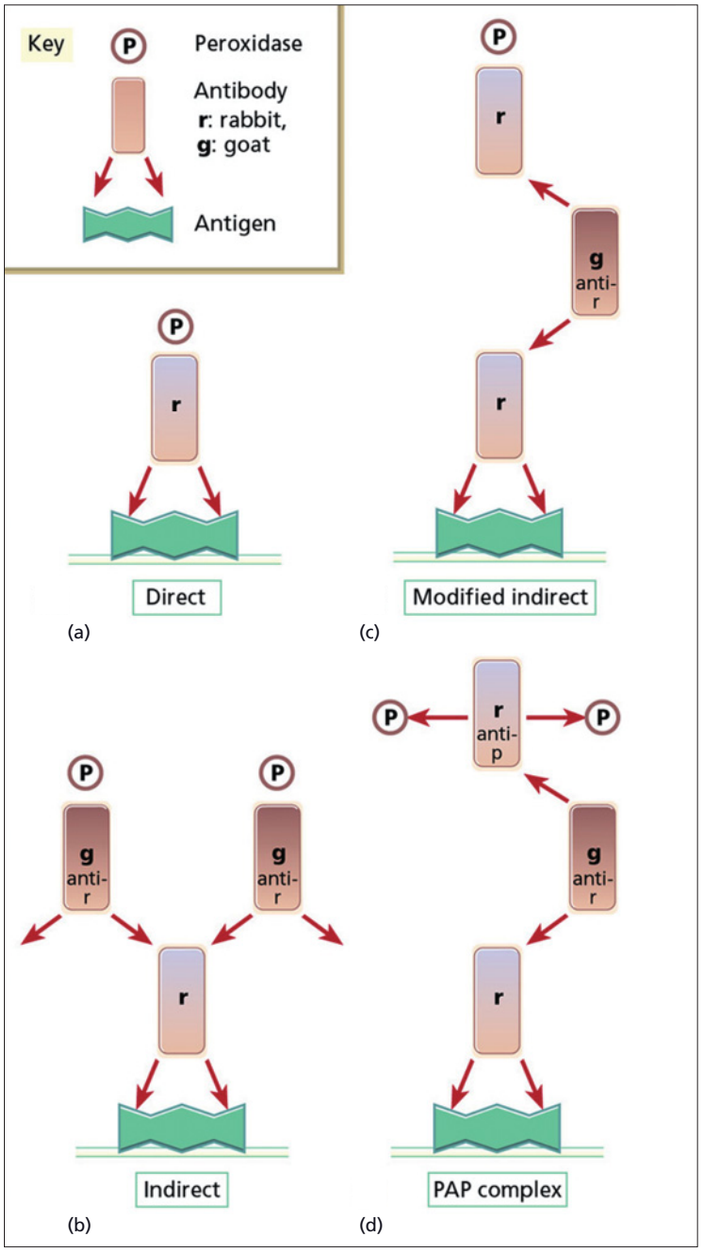

Fig. 10.11 Diagrammatic representation of immunoperoxidase techniques.

number of conjugated antibodies binding to the site, and is more versatile, because one conjugated antiglobulin can detect any antibody of that species.

Two other procedures increase the sensitivity of the technique. The antibody bound to the antigen is treated with unconjugated antiglobulin, which in turn is treated with normal globulin of the same species as the first antibody (Fig. 10.11c), for example, a sequence of rabbit antibody, goat anti-rabbit globulin and then rabbit normal globulin conjugated with peroxidase.

In the second modification, instead of using globulin conjugated chemically with enzyme in the third stage, a PAP complex is added (Fig. 10.11d), for example, rabbit antibody to peroxidase, which gives a more discrete, intense reaction product than chemically prepared conjugates of normal globulin–peroxidase, possibly because chemical treatment tends to alter the antigenic determinants of the normal globulin, and to polymerize the peroxidase.

The enzyme most frequently used is horseradish peroxidase, which forms a dark-brown product from its substrate. Alkaline phosphatase may also be used, and the reaction product with its substrate is red. The two enzymes may be used with appropriate antibodies on the same tissue or cells to detect different antigens, and the relationship of one antigen to another (i.e. double staining). A further enzyme may be used to obtain a more permanent red product that is preferable in cases where interpretation of the results may be hampered by the presence of pigment (haemosiderin and particularly, melanin). This is 3-amino-9-ethylcarbazole [4].

Examination of fixed frozen sections

There are three stages in the procedure:

1 The preparation of the tissue sections.
2 Treatment of the sections with the peroxidase-labelled antibody.
3 Chemical reaction to detect the peroxidase in the tissue.

Preparation and fixation of sections. Sections may be prepared from routine cryostat-cut samples or paraffin-embedded material, and may be treated for antigen-retrieval as described above. Some improvement in cryostat-prepared sections may be achieved by short-term fixation in dilute formalin, as follows.

1 Fix thin slices (2 mm thickness) with 1% formaldehyde in 0.1 mol/L phosphate buffer pH 7.2–7.4 for 30 min.
2 Wash in three changes of 15% sucrose in 0.1 mol/L phosphate buffer pH 7.2–7.4 for 18–24 h at 4°C.
3 Snap freeze in isopentane at the temperature of liquid nitrogen.
4 Cut sections 4–6 µm in a cryostat. Mount on slides, and dry under a fan at room temperature.

Treatment of the sections with antibody. Control for antibody specificity is as described for immunofluorescence. Sections may be treated by the methods described above (Fig. 10.11). The indirect method is probably the most suitable for general use, applying unlabelled antibody, followed by labelled antiglobulin.

1 Moisten section in PBS.
2 Treat with suitable dilution of specific antibody in PBS in a moist chamber at room temperature for 30 min–2 h.
3 Rinse well in PBS: then in two washes of PBS, each for 5 min with gentle agitation. (As the tissues are fixed they are less likely to be washed off the slides than unfixed tissues in the immunofluorescence technique.)
4 Treat with peroxidase-conjugated antiglobulin specific for the antibody applied in Step 2. Use at optimum dilution in PBS for 30 min.
5 Rinse well: wash in PBS for 15 min.

Detection of the peroxidase reaction product by staining. The substrate is a carcinogen and should be handled in small quantities with appropriate precautions. It is made up as follows:

- 3′,3′–diaminobenzidine tetra-HCl (DAB), 25 mg
- 0.05 mol/L pH 7.6 Tris–HCl buffer, 50 mL
- 3% hydrogen peroxide (H_2O_2), 0.15 mL

Dissolve the DAB in the buffer and add the H_2O_2 immediately before staining.

1 Slides treated with conjugated antibody or antiglobulin and washed are incubated with the substrate solution for 5–15 min (the longer period is not always an advantage).
2 Wash in tap water for 5 min. (If required, the reaction products may be intensified by 2% osmium tetroxide for 1 h, and the slides then washed.)
3 If required, the slides may be counterstained with methyl green, or Mayer's haemalum.
4 Treat for about 1 min each with 70%, 90% and twice with 100% industrial spirit, followed by two treatments with xylol.
5 Mount with DPX or Permamount.

Controls

It is necessary to confirm that the reaction observed reflects antibody-conjugated peroxidase and not endogenous peroxidase, and that the antibody binding is specific for antigen.

One section should be stained with DAB only; another section with DAB–methanol–H_2O_2, to confirm the absence of endogenous peroxidase.

Paraffin sections

If the antigens to be detected are stable in the fixatives and dehydrating agents, the immunoperoxidase methods may be applied to sections from paraffin-embedded tissue. The paraffin is removed from the sections with xylol and alcohols; sections are subsequently treated as for frozen sections.

The identity of the cells and tissues containing the antigen is much more easily determined by this method than by cryostat-cut sections, or by immunofluorescence. Immunoglobulins and hormones may be readily detected, but some antigens, such as those of bacteria in vasculitic lesions, tend to be extracted during processing.

Conjugates involving avidin–biotin coupling of antibody and enzyme

Instead of chemical covalent binding of antibody to enzyme to prepare conjugates, the two reagents may be linked non-covalently by the very strong affinity between biotin (a vitamin widely distributed in mammalian tissues) and avidin (a glycoprotein of egg white). Biotin is coupled to the reagent antibody through formation of an intermediate biotin derivative, and the avidin is coupled to the selected enzyme by glutaraldehyde [5]. Each biotin molecule has one combining site for avidin, and avidin has four sites for biotin, although not all of these would combine in a test system. Guesdon *et al*. [5] described two procedures.

1 The antibody–biotin conjugate is incubated with and combines with antigen in the test section or cell. This is followed by addition of peroxidase conjugated with avidin. The avidin binds the peroxidase to any biotin, and subsequent treatment with the substrate for the enzyme reveals the antigen sites (Fig. 10.12a).
2 The antibody–biotin conjugate is used as above to bind to any antigen. Avidin is then added, which becomes strongly linked to the biotin. Then biotin-labelled enzyme is added and the avidin bridges the biotin molecules. As the avidin has a potential four valencies for biotin, there is an enhancement or amplification of the enzyme binding, and therefore greater discrimination of the sites of antigen (Fig. 10.12b).

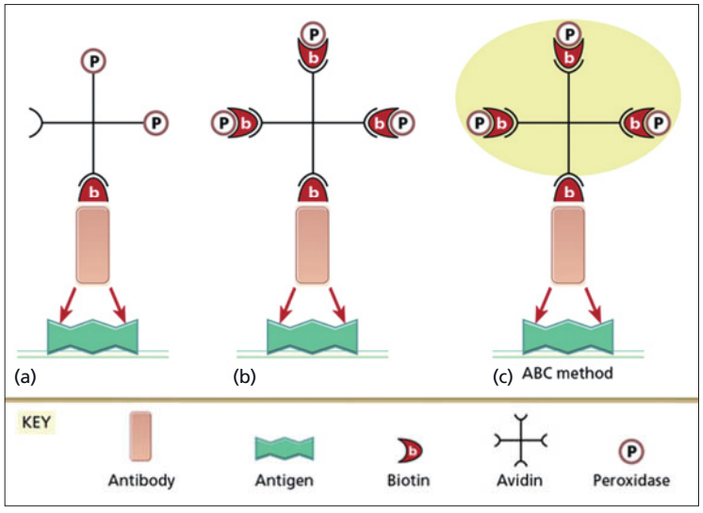

Fig. 10.12 Avidin–biotin staining methods. (a) Antibody coupled with biotin binds with the antigen in tissue. Avidin coupled with peroxidase binds to the biotin on the antibody. Treatment with enzyme substrate reveals the bound peroxidase, and therefore site of antigen. (b) Antibody coupled with biotin binds with the antigen in tissue. Avidin will bind the biotin–antibody complex. Biotin coupled with peroxidase will then bind to the free avidin-combining sites. Finally, treatment with enzyme substrate reveals the bound peroxidase. (c) Complexes (shown within yellow circle) are formed of biotin, coupled with peroxidase, incubated with moderate excess of avidin (ensuring some free avidin combining sites). Antibody coupled with biotin binds to antigen in tissue. The complexes are added to the tissue and the free avidin sites bind to the biotin on the antibody. Finally, treatment with enzyme substrate reveals the bound peroxidase.

A further modification is the avidin–biotin–peroxidase complex (ABC) method (Fig. 10.12c), similar to the PAP method already described. A prepared ABC follows the use of biotin-labelled antiglobulin (to detect unlabelled reagent antibody, or tissue-bound antibody in the tissue). The complex binds through the avidin bridge to biotin on the antiglobulin; the method results in greater intensity of staining.

As in the other immunodetection techniques, it is necessary to ensure that there is no autologous tissue background activity that will cause confusion when interpreting results. In the avidin–biotin methods, it is necessary to eliminate the possibility of endogenous peroxidase activity as in any peroxidase method. It is also necessary to inactivate endogenous biotin present in tissues that would bind the avidin-labelled reagents. However, overcoming any endogenous activity is a complex multistep activity and is not necessary if the appropriate controls (e.g. tissue treated with the avidin conjugates) show no binding.

Applications of immunopathology techniques [1–3]

The immunopathological methods described above have revolutionized diagnostic histopathology, and have helped us to recognize, classify and understand the pathogenesis of a wide variety of cutaneous disorders. Although there are many antigens of diagnostic value that are not stable following formalin fixation and paraffin-embedding of tissue, there is still a wide range of antigens that are stable. A few of the more important areas of diagnostic dermatopathology that highlight the usefulness of immunopathological techniques are described below (Table 10.9).

Immunopathological techniques for the diagnosis of connective tissue diseases and autoimmune blistering diseases mainly rely on the use of immunofluorescence methods. Although some have suggested that immunoperoxidase methods are equally reliable in this setting, formalin fixation results in poor preservation of the antigens of interest and false-negative results are frequent. In the last decade, immunofluorescence studies (antigen mapping) have been increasingly used with success in the diagnosis of genetic blistering diseases, particularly epidermolysis bullosa (see Chapter 39). Samples are fixed in Michel's medium and frozen sections are processed in the same way as samples submitted for the diagnosis of autoimmune blistering disorders.

Lupus erythematosus

The deposition of immunoglobulins and complement at the dermal–epidermal junction is of diagnostic value in patients with lupus erythematosus (Fig. 10.13) and is known as the lupus band test. The presence of immunoglobulins, particularly those other than IgM, at the dermal–epidermal junction in normal non-sun-exposed skin correlates to some extent with the presence of systemic lupus erythematosus and renal involvement [4]. Sequential biopsies may demonstrate the disappearance of a positive lupus band during periods of disease inactivity, and may aid the clinician in the management of the disease. However, this approach is hardly ever used, as it implies repeated invasive procedures and disease activity may be monitored in a simpler way with blood tests. A positive lupus band is usually seen in involved skin in cutaneous lupus erythematosus [5], but false-positive results may be seen in sun-exposed skin from patients who do not have lupus. Immunofluorescence studies, in conjunction with other serological investigations, have led to the recognition of various important subsets of lupus erythematosus. Examples of this include the high incidence of anti-Ro/SSA and anti-La/SSB antibodies in the sera of patients with subacute lupus erythematosus and neonatal systemic lupus erythematosus.

Bullous disorders (see also Chapter 40)

The histological diagnosis of the various cutaneous autoimmune blistering diseases should always be confirmed with immunofluorescence studies. Although in many non-autoimmune blistering diseases a diagnosis can be made on the basis of light microscopic features in biopsies from formalin-fixed tissue, in immunological diseases a specific diagnosis is often not possible. In these circumstances, immunofluorescence studies are essential. Other techniques including immunoelectron microscopy and immunoblotting are extremely helpful. The classification and understanding of the

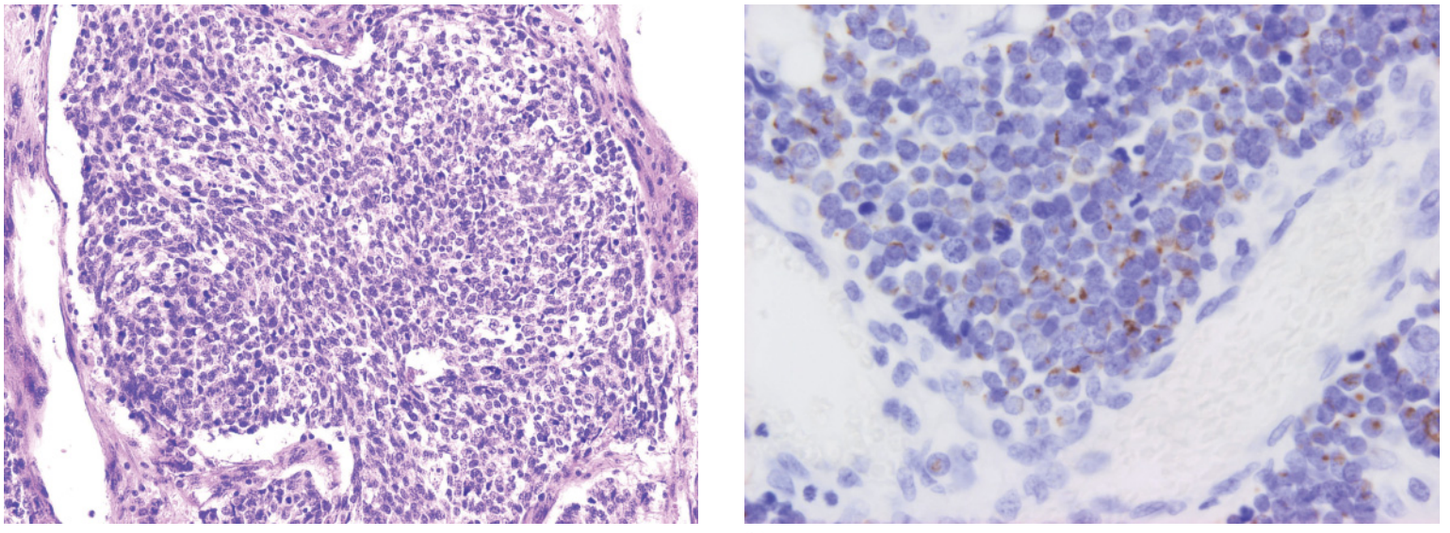
pathogenesis of numerous bullous disorders has been greatly facilitated by advances with these techniques. Ideally, tissue for immunopathological examination and serum for indirect immunofluorescence studies should always be taken at the time of a skin biopsy in a patient with an acquired blistering disorder. The biopsy submitted for immunofluorescence should be from perilesional or clinically normal skin. If lesional skin is submitted for immunofluorescence studies, a false-negative result is often obtained. The results of direct immunofluorescence studies on skin biopsies vary considerably depending on the disease being investigated, and the site of the biopsy. Intercellular epidermal deposition of IgG is present in almost all cases of pemphigus (Fig. 10.14). Complement is also frequently present, and IgA and/or IgM may be seen in a smaller percentage of cases. The additional presence of basement-membrane-zone IgG, or the C3 component of complement, points to a diagnosis of pemphigus erythematosus. Linear basement-membrane-zone IgG and complement deposition, and less commonly IgA or IgM, is associated with bullous pemphigoid (Fig. 10.15). Identical results are usually obtained in epidermolysis bullosa acquisita. The differential diagnosis is greatly aided by the use of the split-skin technique. In this technique, the exposure of the specimen to 1 mol/L NaCl induces a subepidermal blister [6]. In epidermolysis bullosa acquisita, the immunoreactants line the floor of the blister, and in bullous pemphigoid, the immunoreactants line the roof of the blister. With the indirect immunofluorescence technique using patient serum, the detection of linear basement-membrane-zone immunoglobulin antibodies is much more common in the classical form of bullous pemphigoid than in the cicatricial form of the condition, where positive results are obtained in approximately only 10% of cases. The diagnosis of other blistering diseases such as herpes gestationis (pemphigoid gestationis) and dermatitis herpetiformis is also greatly facilitated by immunopathological studies. In addition to direct immunofluorescence examination of skin biopsy material, and indirect immunofluorescence studies carried out on patient serum, the split-skin technique is valuable in the study of most of the subepidermal blistering disorders, enabling localization of the antibody-binding sites to be visualized [6]. Data obtained from such research has shed considerable light on the pathogenesis of many blistering diseases [7,8]. Since the advent of immunopathological techniques, several blistering diseases have been categorized and known entities have been further refined. Immunoblotting and related techniques enable specific antigens to be categorized more precisely.

Cutaneous neoplasms [1–3,9]

One of the most useful applications of immunopathology is in helping to determine the line of differentiation of poorly differentiated benign and malignant neoplasms that may arise from the various cellular components within skin and related tissues. The development within the last few years of increasing numbers of antibodies and other labels that can be utilized on formalin-fixed paraffin-embedded material has increased the usefulness of this application. All the antibodies discussed below work well in formalin fixed paraffin-embedded material.



Keratins and other epithelial markers

Cytokeratins represent a group of intermediate filaments, known as tonofilaments, of variable molecular weight that may be demonstrated in keratinizing and non-keratinizing epithelia [10,11]. They represent the main structural component of the cytoskeleton of epithelial cells. About 30 different keratins have been demonstrated in humans by the use of double-diffusion gel electrophoresis. Their molecular weight ranges from 40 to 68 kDa. Keratins are divided according to molecular weight and their charge

properties into acidic (type I) and neutral-basic (type II) [10,11]. They associate as pairs of one acidic and one basic keratin polypeptide molecule with each epithelial cell containing at least one keratin pair. The antibodies against keratins most commonly used in dermatopathology include AE1/AE3, MNF116 (Fig. 10.16a & b) and CAM 5.2. They are all cocktails containing several monoclonal antibodies of different molecular weight. CAM 5.2 is a low-molecular-weight keratin antibody, which labels most epithelia, with the exception of stratified squamous epithelia [12]. CAM 5.2 is usually negative in squamous cell carcinoma. It should therefore not be used in the diagnosis of poorly differentiated squamous cell carcinoma, as a negative result is the norm. Positive staining however may be seen in sebaceous carcinoma, and this is an aid in the distinction between this tumour and squamous cell carcinoma. The main use of CAM 5.2 in dermatopathology is in the diagnosis of Merkel cell carcinoma (primary cutaneous neuroendocrine carcinoma), as tumour cells in this lesion display a typical perinuclear dot-like positivity for this antibody. Cytokeratin 20 (CK-20), a low-molecular-weight cytokeratin, expressed usually only in urothelium, gastrointestinal epithelium and Merkel cells, is also very useful in the diagnosis of Merkel cell carcinoma [13,14]. The staining pattern is identical to that of CAM 5.2 (perinuclear dot-like, Fig. 10.17a & b), and a positive result strongly suggests a primary cutaneous origin rather than a metastatic neuroendocrine carcinoma originating in another organ. Only Merkel cell carcinoma and salivary gland small cell carcinoma tend to be

positive for this marker, while neuroendocrine tumours from other organs are consistently negative.

Cytokeratin 7 (CK-7) is a very useful antibody for confirmation of the diagnosis of mammary and extramammary Paget's disease [15] (Fig. 10.18a & b). Tumour cells in the latter stain consistently for this antibody while the surrounding epidermis is negative. However, staining for keratin 7 is not specific for mammary and extramammary Paget's disease as positivity has been described in pagetoid Bowen's disease and in rare cases of actinic keratoses [16,17].

It is important to remember that keratin and also EMA expression (see below) is commonly seen in various sarcomas, including epithelioid sarcoma, synovial sarcoma, epithelioid angiosarcoma, and more rarely in other tumours such as leiomyosarcoma and rhabdomyosarcoma [18–21].

Epithelial membrane antigens (EMA) [22] are derived from human milk fat globulin membrane, and consist of high-molecular-weight glycoproteins. Antibodies to EMA and related labels react with a range of normal and neoplastic epithelia, and positivity may be found in squamous and ductal epithelia as well as eccrine, apocrine and sebaceous glands. EMA tends to be at least focally positive in squamous cell carcinoma, sebaceous carcinoma, perineuroma and a wide variety of adnexal carcinomas. It is also positive in plasma cells, in epithelioid sarcoma, synovial sarcoma, epithelioid angiosarcoma and in systemic and much less commonly, primary cutaneous $CD30^+$ large-cell anaplastic lymphoma [23].

Carcinoembryonic antigen is a protein that is normally found in the goblet cells of the small and large intestine. It is found in many adnexal carcinomas, particularly tumours displaying ductal differentiation [24]. It is also expressed in many glandular carcinomas arising in other organs. Its main use in dermatopathology is to highlight ductal differentiation in adnexal tumours.

Neuroendocrine markers

Besides CK-20, whose use in the diagnosis of Merkel cell carcinoma has been described above, markers of neuroendocrine differentiation include neurone-specific enolase, chromogranin and synaptophysin. Neurone-specific enolase is an enzyme described in the brain but also found in neuroendocrine cells [25]. Its use in diagnostic pathology is very limited because of the lack of specificity. Chromogranin A is part of a family of calcium-binding proteins present in the secretory granules of neuroendocrine cells. This protein is very specific but poorly sensitive for neuroendocrine differentiation [26]. Synaptophysin is a transmembrane glycoprotein with a molecular weight of 38 kDa and is a specific marker of neuroendocrine differentiation [27]. CD56 (neural cell adhesion molecule, NCAM) is expressed in neural tissues, natural killer cells and a subset of T cells, among other tissues [28]. This protein is often expressed in tumours with neuroendocrine differentiation and is sometimes included in the immunohistochemical panel used to diagnose Merkel cell carcinoma. However, it is important to highlight its relative lack of specificity.

Melanocytic markers

Over the years, a wide array of markers for melanocytes have been described including S-100, HMB45, Melan-A, Mel-5, tyrosinase and MIFT-1 (microphthalmia transcription factor-1).

It is important to emphasize that no marker allows distinction between benign and malignant melanocytes and that the sensitivity and specificity of different markers is variable. S-100 protein is very sensitive but much less specific than other markers including HMB45, MelanA and MIFT-1. Melanocytic markers are particularly useful as part of a panel in the differential diagnosis of poorly differentiated malignant tumours. Desmoplastic melanomas are usually positive for S-100 but negative for melanocytic markers such as Melan-A, HMB45 and MIFT-1.

S-100 protein is an acidic protein, originally derived from ox brain, and named because of its solubility in 100% ammonium sulphate. It is a sensitive marker of melanocytes [29–31]. Antibodies to S-100 protein, however, also react with Schwann cells, glial cells, adipocytes, chondrocytes, Langerhans' cells and cells of the eccrine sweat coil, and therefore tumours and hamartomas derived from these cells. S-100 also stains the cells in Rosai–Dorfman

disease. S-100 protein is particularly useful in the study of suspected malignant melanoma, as the great majority of, but by no means all, melanomas are positive for this marker [32]. In this context, the technique is particularly valuable in the differentiation of melanoma from other spindle cell neoplasms, and in identifying small deposits of melanoma that may be present in deep dermal tissues, as in determination of accurate Breslow thickness and/or intravascular spread, or the evaluation of spread to sentinel lymph nodes. S-100 is less reliable when used to delineate the epidermal component of a melanocytic lesion. The reason for this is that it also stains Langerhans' cells. More specific markers of melanocytes such as Melan-A should be used for this purpose (see below). S-100 is also often focally positive in a number of soft-tissue tumours and should therefore be used as part of a panel of markers in the diagnosis of poorly differentiated tumours.

HMB-45 (gp100) [33–35] recognizes a 10-kDa antigen localized in premelanosomal vesicles. The antibody was developed from an extract of a lymph-node metastasis of melanoma. This antibody does not stain normal adult melanocytes or intradermal naevi. It is a very specific antibody, which is usually negative in desmoplastic melanoma. Around 90% of primary and metastatic melanomas are positive for this marker.

Melan-A (MART-1) [36,37] is a melanocyte marker that recognizes an antigen present in melanoma cells and recognized by $CD8^+$ cytotoxic T lymphocytes. It is a fairly specific marker of melanocytes. Melan-A stains naevi and melanomas, but it tends to be negative in desmoplastic melanoma, spindle cell melanoma and neurotized naevi. Although Melan-A is a useful melanocytic marker, its usefulness in distinction between *in-situ* melanoma arising in sun-exposed skin and pigmented actinic keratosis has been challenged [38]. The reason for this is that Melan-A may also occasionally stain melanocytes probably as a result of transference of the protein from melanocytes to keratinocytes.

Mel-5 is a monoclonal antibody developed against a 75-kDa glycoprotein present in melanocytes, naevus cells and melanoma cells [39]. As for Melan-A, it does not tend to be expressed in desmoplastic melanoma, spindle cell melanoma and neurotized naevi.

MIFT-1 is the latest addition to the armamentarium of melanocytic markers [40]. This is a nuclear protein involved in the development of melanocytes and in the regulation of melanin synthesis. It stains naevi and melanoma but is usually negative in desmoplastic melanomas. Although it was initially regarded as fairly specific, it has been found to be expressed in macrophages, mast cells, fibroblasts, lymphocytes, Schwann cells and even smooth muscle cells [41]. Its utility as part of a panel for the diagnosis of difficult tumours has proven to be limited.

Cocktails consisting of a mixture of different monoclonal antibodies against melanocytes have been developed and advocated as being effective particularly in the detection of low volume melanoma cells in sentinel lymph node biopsies. One of the main cocktails used consists of a mixture of Mart-1, Melan-A and tyrosine (MCW) [42].

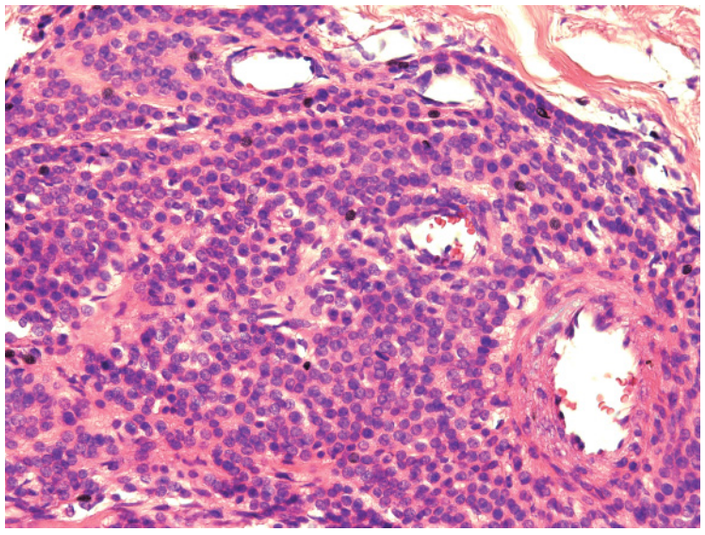
Mesenchymal markers

There are many markers of mesenchymal differentiation that are useful in the differential diagnosis of neoplasms, particularly those that are poorly differentiated. As with many of the other antibodies discussed so far, the specificity and sensitivity of each of these markers is very variable. What this means is that they should always be used as part of a wider panel of markers. Commonly used markers include vimentin, desmin, smooth muscle actin, muscle-specific actin, calponin, h-caldesmon, S-100, CD34, CD31, factor VIII-related antigen and Fli-1.

Vimentin has a molecular weight of 57 kDa and it is found in all mesenchymal cells and their tumours. It has a very low specificity and can be found in melanomas, lymphomas and even carcinomas. Its value is therefore very limited [43].

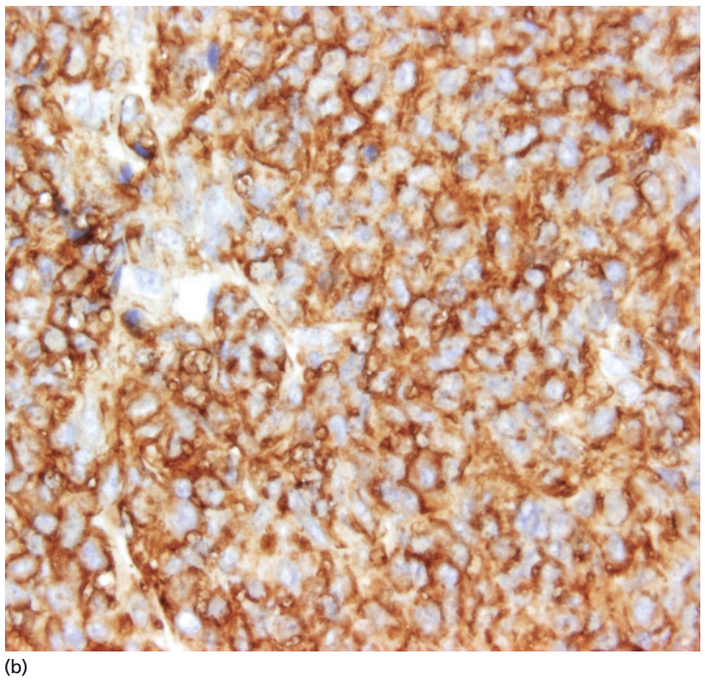
S-100 has already been described above. It is a very useful marker for neurofibroma and Schwannoma. While the latter tumour tends to be uniformly positive for S-100, the percentage of tumour cells positive for this marker varies in neurofibroma.

Desmin is a polypeptide with a molecular weight of 53 kDa, and is characteristic of smooth, skeletal and cardiac muscle [44]. In skeletal muscle desmin filaments are found in association with the Z-discs of the sarcomeres and the sarcolemmal attachment plaques. In smooth muscle cells, desmin filaments interconnect the fusiform dense bodies with the plasmalemmal dense bodies. Desmin is very specific for muscular differentiation and it is a useful marker only occasionally reported in other tumours such as Schwannoma and epithelioid sarcoma [45,46].



Actin represents a family of intermediate filaments present in the cytoskeleton of eukaryotic cells. They are contractile proteins involved in the control of motility of muscle cells and non-muscle cells. Actin proteins are classified according to their amino acid sequences, and six major isoforms have been described. Of the monoclonal antibodies used in diagnostic pathology the most useful ones are HHF35 (muscle-specific actin) and 1A4 (alpha-smooth-muscle actin) [47–49]. The former reacts with skeletal and smooth muscle and the latter only reacts with smooth muscle. Both types of antibody stain myofibroblasts, pericytes, glomus cells (Fig. 10.19a & b) and myoepithelial cells [48].

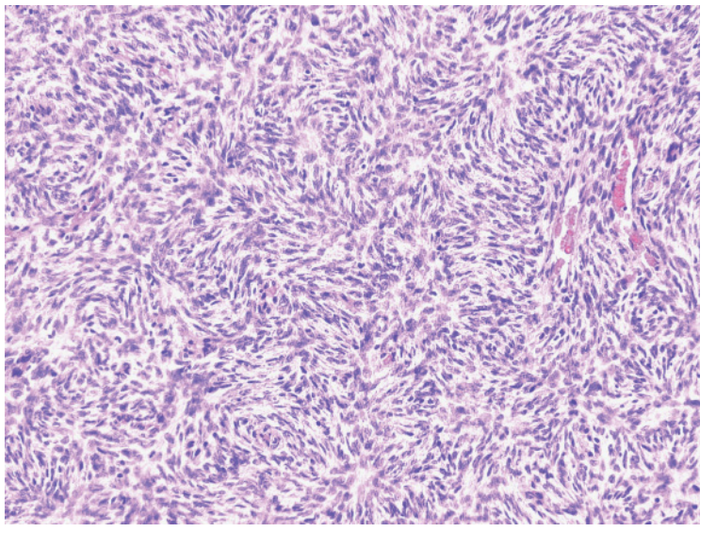
Calponin is a basic troponin-T like protein that modulates the interaction between actin and myosin and it is a good marker of smooth muscle and myofibroblastic differentiation [50].



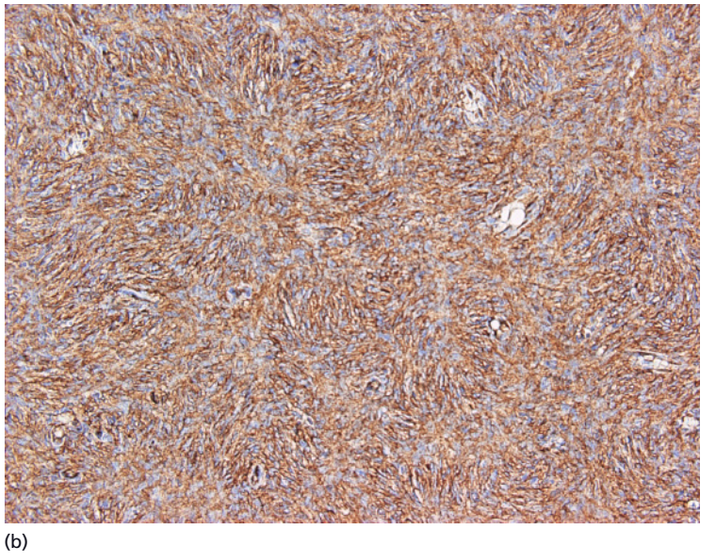
H-caldesmon is a protein combined with actin and tropomyosin that regulates cell contraction. It is fairly specific for smooth-muscle differentiation and less often stains myofibroblasts [51,52].

CD34 is a glycosylated transmembrane protein with a molecular weight of 110 kDa. It is normally present on haematopoietic progenitor cells and vascular endothelial cells [53,54]. This marker, however, is fairly non-specific and it is expressed in a wide number of soft-tissue tumours including dermatofibrosarcoma protuberans (DFSP) (Fig. 10.20a & b), neurofibroma and spindle cell lipoma. Its main use in dermatopathology is as an endothelial cell marker and in the differential diagnosis between DFSP and fibrous histiocytoma and its variants, particularly cellular fibrous histiocytoma. CD34 tends to be diffusely positive in the former and negative or only focally positive, mainly in the periphery of the tumour, in the latter [55,56].

One large group of soft-tissue tumours where useful markers are badly needed is the group of fibrohistiocytic tumours. So-called markers of histiocytic cells, including α-1-antitrypsin and α-1-antichymotripsin, are very non-specific and have no role in the diagnosis of these tumours. Besides, it appears clear that



(a)



(b)

the so-called fibrohistiocytic tumours usually do not show true histiocytic differentiation. Another interesting polyclonal antibody produced against the blood coagulation transglutaminase, factor XIIIa, seems to be a cell marker for a particular subpopulation of dermal dendritic mononuclear macrophage cells termed dermal dendrocytes [57]. A number of positive cells may be identified in very many different types of soft-tissue tumours. However, combined with other markers, FXIIIa is useful in the differential diagnosis between benign fibrous histiocytoma and DFSP. The former is normally rich in factor XIIIa positive cells particularly at the periphery, in contrast to DFSP which is negative.

A wide range of endothelial markers now available are useful in the histological diagnosis of vascular tumours. The most useful of these markers are CD31, CD34, FVIII-related antigen and Fli-1. There is also an expanding range of markers of lymphatic endothelium, some of which are quite specific (see below).

CD31 refers to a glycoprotein that belongs to the immunoglobulin supergene family and has a molecular weight of 130 kDa. It is also known as platelet-endothelial cell adhesion molecule type I (PECAM-1) and it stains endothelial cells and some haematopoietic cells. CD31 is the most sensitive marker of endothelial cells [58–60]. However, interpretation should be cautious as CD31 also stains macrophages [61].

Antibodies to factor VIII-related antigen label normal and neoplastic endothelium in routine paraffin sections [62]. This marker, however, may be negative in lymphatic capillaries, and because of the presence of factor VIII-related antigen in plasma and tissue exudates, false positive labelling may be encountered.

Fli-1 (friend leukaemia virus integration 1) is a DNA binding transcription factor member of the ETS gene family. Most cases of Ewing's sarcoma (90%) show a translocation t(11;22)(q24;q12) indicating fusion of EWS with Fli-1. Fli-1 is also expressed in endothelial cells and is a useful and fairly specific marker of endothelial cell differentiation [63]. The positive product displays nuclear staining.

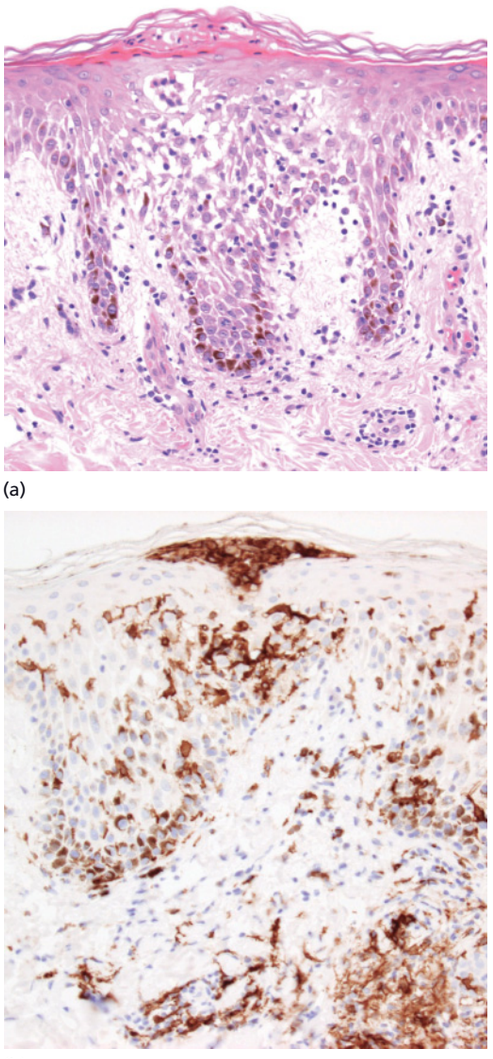
None of the previously described endothelial cell markers allows distinction between lymphatic and vascular endothelium. In recent years, a number of antibodies have been described with claims as to their specificity for lymphatic endothelium. These antibodies include vascular endothelial growth factor receptor-3 (VEGFR-3), podoplanin, LYVE-1 (lymphatic vessel endothelial hyaluronan receptor) and Prox-1 (a nuclear transcription factor important in lymphangiogenesis) [64–70]. Some of these markers are not very specific of lymphatic differentiation, particularly VEGFR-3 [64].

Metastatic cutaneous tumours

It is important to remember that all tumours that are present in the skin are not necessarily of cutaneous origin. Reference has already been made to several epithelial markers, many of which may be useful in diagnosing metastatic adenocarcinoma. Immunohistochemistry, however, does not usually allow determination of the site of the primary tumour except in a few instances. The latter include prostate-specific antigen in prostatic carcinoma and thyroglobulin in thyroid carcinoma. Markers for oestrogen and progesterone receptors are not useful in the diagnosis of metastatic breast carcinoma, because adnexal carcinomas may also be positive for one or both markers. Combination of a number of markers may often be useful, however, in determining whether a tumour is primary or metastatic. Thyroid transcription factor-1 (TTF-1) is a 38-kDa nuclear protein expressed in epithelial cells of lung and thyroid. TTF-1 is therefore a useful marker in the diagnosis of cutaneous metastatic tumours [71]. p63, a homologue of the p53 gene, has been demonstrated to be useful in the differential diagnosis between primary and metastatic adenocarcinomas in the skin. Metastatic adenocarcinomas to the skin are usually negative for p63 while primary adnexal adenocarcinomas tend to be positive for this marker [72,73]. Similar findings are obtained in adnexal carcinomas metastatic to other organs. The same finding has been recently reported with podoplanin as metastatic adenocarcinomas to the skin tend to be negative in tumour cells while tumour cells in primary adnexal carcinomas are positive for this marker [74].

Histiocytic markers

CD68 (KP1) is the main marker used to demonstrate histiocytic differentiation in paraffin-embedded material [75,76]. It is an antibody raised against a 110-kDa glycoprotein present in pulmonary macrophages. This antibody stains normal histiocytes, granulocyte precursors, tumour cells in myelomonocytic neoplasms and true histiocytic lymphomas. KP1, however, is not specific for histiocytic differentiation, and expression may be seen in many tumours, including carcinoma, melanoma, granular cell tumours and a variety of sarcomas [77–79]. A more specific marker of histiocytic differentiation is PG-M1, a member of the CD68 group of proteins, which is present only in macrophages and not in myeloid cells [80,81]. Further markers of histiocytic differentiation that are poorly specific are lysozyme and Mac387.



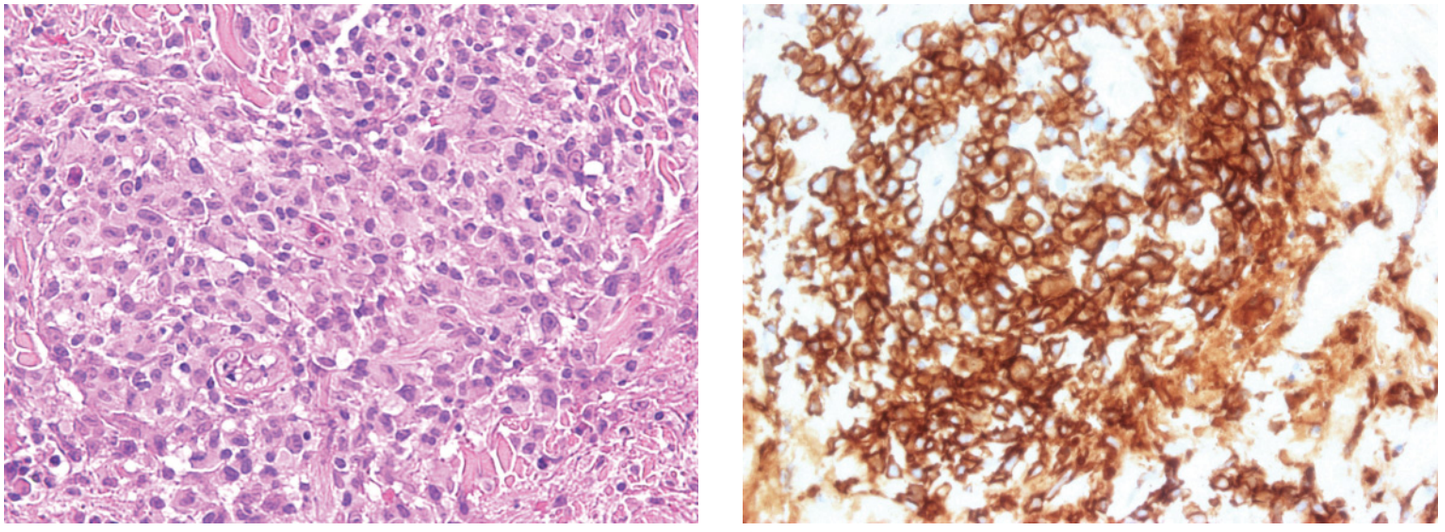


Fig. 10.21 (a) Subacute spongiotic process (eczema) with hyperplasia of Langerhans' cells presenting in a large nest within the epidermis mimicking a Pautrier microabscess (H&E). (b) Staining for CD1a highlighting the nature of the nested cells within the epidermis.

Langerhans' cell markers

The main markers of Langerhans' cells are S-100 and CD1a. More recently, langerin (CD207, a Langerhans' cell specific lectin) has been introduced as a sensitive and specific marker of Langerhans' cells as is CD1a [82,83]. S-100 is very sensitive but poorly specific, particularly as it stains melanocytes. Both the latter and Langerhans' cells are present in healthy and abnormal epidermis. Often, in inflammatory conditions, there is hyperplasia of Langerhans' cells within the epidermis and they are often arranged in nests. This may lead to the erroneous diagnosis of mycosis fungoides as the nests of cells are confused with Pautrier microabscesses. In this setting, immunohistochemistry for Langerhans' cells (Fig. 10.21a

(a) (b)

Fig. 10.22 (a) Sheets of large, atypical lymphoid cells with pleomorphic nuclei and pink cytoplasm. (b) Positive staining of atypical cells in a case of CD30-positive, anaplastic, large T-cell lymphoma. Note the typical strong cytoplasmic membrane positivity and dot-like perinuclear staining.

& b) and other histological parameters, are useful to make the distinction.

Lymphoid markers

One of the most difficult areas in diagnostic dermatopathology is the interpretation of heavy lymphoid infiltrates in cutaneous biopsies. The wide range of conditions that may produce a histological picture simulating lymphoma ranges from insect bites and viral infections through syphilis, to reactive lymphoid hyperplasia where an aetiological factor cannot be demonstrated. Furthermore, recognition of the number of different varieties of malignant lymphoproliferative disorders that may be encountered in the skin continues to increase. Very many different markers for lymphocytes and their subsets are now available, and are particularly useful when used as a battery. It should be remembered that histological and antibody-labelling patterns of cutaneous lymphomas do not necessarily mirror their nodal counterparts, and that very few markers are absolutely specific for cells of one lineage. Furthermore, it has to be realized that in the course of a disease process, many lymphoid cell types may lose their antigenic determinants and label in an anomalous fashion. This is particularly common in some forms of advanced cutaneous lymphoma. Nevertheless, with careful interpretation and the use of antibody panels, considerable information can be derived from the use of monoclonal antibodies [3].

The rationalization of nomenclature in relation to human leukocyte antigens, the CD (or cluster of differentiation) nomenclature, has been a great advance, enabling useful comparison of numerous different monoclonal antibodies developed in different laboratories, and facilitating their classification [3,84,85]. As in other areas of immunopathology, a further bonus for the diagnostic dermatopathologist is the possibility of using many of these leukocyte antigen markers in paraffin processed tissue [85–87]. A full discussion of the applications of immunopathology to the recognition of subsets of lymphocytes in skin biopsies is beyond the scope of this chapter. Useful antibodies available for use on routinely processed material include CD45 (leukocyte common antigen), pan-B-cell markers such as CD20 (L26) and CD79a, and pan-T-cell markers such as CD3, CD2, CD5 and CD7 [88,89]. Determination of the subset of T cells in paraffin-embedded skin biopsies is also possible, as there are commercially available antibodies to CD4 (helper T cells) and CD8 (cytotoxic T cells) T cells [3,90,91]. Immunohistochemistry is also very useful in the determination of clonality, particularly in B-cell infiltrates. Antibodies against kappa and lambda light chains can be used in paraffin-embedded material to demonstrate clonality [3,92,93]. Monotypic Ig light chain expression is very suggestive of a B-cell lymphoma.

Other markers of interest include determinants closely associated with T-cell activation, such as the CD30 antigen. An example of an antibody to the CD30 epitope is Ber-H2, which identifies activated T cells, B cells and Reed–Sternberg cells. In cutaneous biopsies, it is commonly present in examples of CD30-positive lymphoproliferative disorders, including lymphomatoid papulosis types A and C, and CD30-positive anaplastic large cell lymphoma [94–96] (Fig. 10.22a & b).

Anaplastic lymphoma kinase (ALK) is a marker of the protein that results from translocation 2;5 between the ALK and nucleophosmin. Its usefulness resides in the fact that this protein is expressed in systemic large-cell anaplastic lymphoma, but it is usually not expressed in primary cutaneous large-cell anaplastic CD30-positive lymphomas [97,98].

CD56 (neural cell adhesion molecule) is expressed in the central and peripheral nervous system, and it is also a marker of natural killer (NK) cells. Its main use in dermatopathology is in the diagnosis of cutaneous NK/T-cell lymphoma [99,100]. Some subcutaneous panniculitis-like T-cell lymphomas may also express this marker [101].

TIA-1, granzyme and perforin are cytotoxic proteins present in the cytoplasmic granules of NK and cytotoxic T cells. Expression of these proteins can be demonstrated in paraffin-embedded material and this is useful in the diagnosis of NK or cytotoxic lymphomas [102,103].

Markers of B follicle-centre cells such as CD10 and bcl-6, although not entirely specific, are useful in demonstrating the presence of these cells in the skin. Positive staining does not indicate that the cells are neoplastic but that they are of follicle-centre origin [104–106]. Reactive cutaneous germinal centres are positive for these markers. On the other hand, an infiltrate with follicle-centre cells which are positive for bcl-2 is very suggestive of a follicle-centre cell lymphoma, and usually indicates the presence of a 14;18 chromosomal translocation [5,107]. Many primary cutaneous follicle-centre cell lymphomas, however, do not stain for this marker and the t(14;18) chromosomal translocation is often absent [108]. It is worth remembering that normal reactive T lymphocytes are usually bcl-2 positive and these tend to be prominent in B-cell infiltrates. Normal mantle B cells are also bcl-2 positive.

More recently, further markers of B-cell differentiation have been described including MUM-1/ITRF4 (multiple myeloma 1/interferon regulatory factor 4) and FOXP-1. MUM-1 is a protein expressed by late centrocytes and post-germinal germinal centres and FOXP-1 is an essential transcriptional regulator of B-cell development [109]. Cutaneous follicle centre cell lymphomas do not tend to express either MUM-1 or FOXP-1 while diffuse large B-cell lymphoma leg-type tends to be diffusely positive for both markers [109]. In cutaneous marginal zone lymphoma, MUM-1 is only expressed by the neoplastic plasma cells. This pattern of staining, coupled with the other commonly used immunohistochemical markers, is helpful in differential diagnosis [110].

The field of immunopathology in general, and in relation to the study of lymphoid proliferations in particular, continues to grow apace. In addition to the techniques discussed above, it is likely that within the next few years further information of use to the diagnostic pathologist will be gained from studies of cytokines, adhesion molecules and similar substances. The correlation of immunophenotypic studies with immunogenotyping using the latest molecular biological techniques is likely to contribute further to our understanding of cutaneous and systemic lymphomas.

Other special laboratory techniques

Cytodiagnosis and Tzanck smears [1] (Fig. 10.23)

Cytodiagnosis in dermatopathology should not be regarded as a substitute for formal biopsy. The technique has been used as an aid to rapid diagnosis of numerous skin conditions, including epithelial tumours, Paget's disease, malignant melanoma, cutaneous lymphomas and skin metastases. In most of these conditions, a diagnostic surgical biopsy rather than fine needle biopsy, is always preferable. Examination of cytological specimens from skin lesions is of most value in bullous disorders, vesicular virus eruptions and basal cell epithelioma.

In blistering disorders, a small, early, uninfected lesion should ideally be selected. The roof of the blister is removed with scissors, and the base of the blister gently scraped with a blunt scalpel so as not to produce bleeding. The material obtained is spread thinly on a glass slide. This is called a Tzanck smear. However, herpes simplex infections cannot be differentiated from herpes zoster using such a simple technique. For cytodiagnosis of suspected basal cell epitheliomas, any surface crust should be removed from ulcerated tumours, and non-ulcerated tumours should be incised with a sharp, pointed scalpel. The incision should be superficial enough to avoid undue bleeding. A sample of tumour is then obtained with either a blunt scalpel or a small curette, and the tissue obtained is pressed between two glass slides. Smears from blisters and basal cell epitheliomas should be fixed immediately for 2 min in absolute alcohol, and stained with H&E. Following rinsing and drying, the smears are cover slipped for microscopic examination.

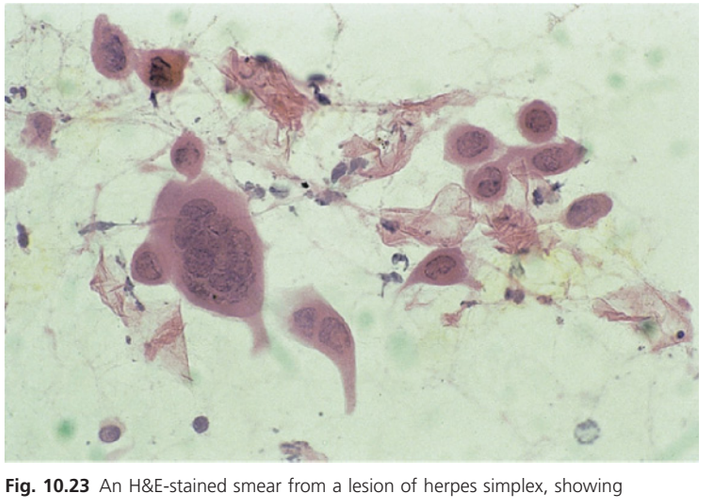

Fig. 10.23 An H&E-stained smear from a lesion of herpes simplex, showing multinucleate giant cells and degenerative nuclear changes.

Microscopic appearances

Bullous disorders. Cytodiagnosis is of most value in pemphigus in its various forms, and in Hailey–Hailey disease, because of the presence of numerous acantholytic keratinocytes. In pemphigus vulgaris, pemphigus vegetans and Hailey–Hailey disease, the cells obtained in the skin smear are usually rounded, and more or less uniform in size, with a relatively large nuclear cytoplasmic ratio. There may be a perinuclear pale halo, with the peripheral part of the cell staining more darkly. In the more superficial forms of pemphigus, including pemphigus foliaceus and Senear–Usher pemphigus, the keratinocytes tend to be more cuboidal in shape, with a small nucleus and more prominent cytoplasm. The cells may contain keratohyalin granules and show evidence of keratinization. Occasional giant cells may be seen, but are quite unlike virus giant cells, which show ballooning degeneration. In addition to the acantholytic disorders mentioned above, occasional acantholytic cells may be obtained in Darier's disease, where dyskeratosis may also be present, and in bullous impetigo. In this latter condition, normally in addition to acantholytic cells there are numerous neutrophil polymorphs and bacteria. The usefulness of cytodiagnosis in subepidermal bullous eruptions is limited, the smear in most instances containing only inflammatory cells. Eosinophils are commonly found in bullous pemphigoid, but may also occur in dermatitis herpetiformis.

Viral disorders. The cytology of herpes simplex, herpes zoster and varicella is often diagnostic because of the presence of characteristic multinucleated giant cells. Keratinocytes of varying size are seen, and as the cell enlarges the nucleus shows some blurring of chromatin pattern and loss of staining. Some of the cells may show condensation of chromatin of the nuclear membrane. The multinucleate giant cells often contain eight or more nuclei, and these nuclei show great variation in size and shape (Fig. 10.23).

Eosinophilic inclusion bodies are very occasionally identified in the herpes virus group of disorders, but commonly examination of many smears may fail to reveal any evidence of this change. Typical ballooning degeneration and giant cell formation as described above does not normally occur in vaccinia or cowpox, but occasionally somewhat enlarged acantholytic cells may be found, and sometimes eosinophilic intracytoplasmic inclusion bodies may be detected. In molluscum contagiosum, characteristic molluscum bodies are easily identified. These are large, rounded, eosinophilic bodies, and may be identified without H&E stain in a potassium hydroxide preparation.

Basal cell carcinoma. In smears obtained from basal cell carcinoma, clumps of closely set, oval or round, deeply basophilic cells are found. The cytoplasm is usually very scanty and in some cases may not be detectable. The nuclei are finely granular with poorly defined nucleoli, and the cells in the smear are very regular in size and shape. In the presence of significant cytological atypia, an alternative diagnosis, such as squamous cell carcinoma or Bowen's disease, should be considered.

Electron microscopy

Electron-microscopic examination of cutaneous tissues is performed much less often than light microscopy, and is nowadays rarely used in diagnostic dermatopathology. Electron microscopy has been replaced by antigen mapping by immunohistochemistry in the diagnosis of many genetic disorders, particularly those in the epidermolysis bullosa group. This technique and its applications are described in Chapter 39. Transmission and scanning electron microscopy have greatly increased our understanding not only of the microanatomy of normal skin, but also of many disease processes. The use of newer embedding material has enabled ultrastructural examination to be carried out on single blocks of tissue prepared primarily for light microscopy. With care, even routinely fixed and paraffin-embedded material may produce electron micrographs that provide useful diagnostic information. In recent years, the combination of electron microscopy with immunopathological techniques, autoradiography and cytochemical methods, has greatly enhanced our knowledge of tissue and cell pathophysiology. The contribution of ultrastructural studies to our understanding of normal microanatomy of skin structures and their variants has been referred to in Chapter 3. Below are listed some of the cutaneous disorders where electron microscopy may be of diagnostic help.

Bullous disorders. The classification and subdivision of bullous disorders has been dramatically advanced by electron microscopy and immunoelectron microscopy. With the electron microscope, it is much easier to separate the varieties of epidermolysis bullosa. In epidermolysis bullosa simplex, the plane of cleavage is within the basal cells. Additionally, tonofilament clumping may be seen. Junctional epidermolysis bullosa has various clinical forms, and, although with the electron microscope there is separation in the lamina lucida zone, junctional epidermolysis bullosa is probably a heterogeneous group of disorders. In some forms of this condition, hemidesmosomes are reduced in number, and this may represent a primary defect. In other forms of junctional epidermolysis bullosa, however, hemidesmosomes may be apparently normal. In dystrophic epidermolysis bullosa, again, various abnormalities are observed, but in this case the split is below the lamina densa. Immunoelectron microscopic techniques provide further information in epidermolysis bullosa, and also in some of the other idiopathic blistering disorders. In cicatricial pemphigoid, for instance, immunoreactants may be identified at a lower level in the lamina lucida than in classical bullous pemphigoid. In linear IgA disease, immunoreactants may be found either in the lamina lucida or below it. Sublamina densa deposits of immunoreactants are also seen in epidermolysis bullosa acquisita.

Pigmentary disorders. The quantitative and qualitative evaluation of melanocytes and melanosomes at ultrastructural level can be of great value in the examination of disorders of hyper- and hypopigmentation. In albinism, normal numbers of melanocytes are present, although melanosomes are immature. In vitiligo, a biopsy from affected skin shows either a complete absence or greatly diminished population of melanocytes. In early stages of

vitiligo, some vacuolar degeneration of epidermal melanocytes may be identified.

Cellular identification. In addition to the demonstration of melanocytes, various other cells, both in inflammatory and neoplastic disorders, can be identified clearly with the aid of the electron microscope. The shape of the convoluted nucleus in the peripheral blood from patients with Sézary syndrome is diagnostic. Annulate lamellae, large, dense granules and decapitation secretion are all found ultrastructurally in apocrine secretory cells. Other cellular substructures that may be of diagnostic value are the identification of desmosomes in various epithelia, myofilaments in tumours of muscular origin, the Birbeck granule characteristic of Langerhans' cells, and the Weibel–Palade body found in the endothelial cells of blood vessels.

Identification of dermal deposits. Ultrastructural examination of various forms of amyloidosis shows characteristic deposits of straight, non-branching, non-anastomosing filaments of approximately 6–7 nm in diameter. The apparent increased electron density at their periphery produces a superficial appearance of hollow cylinders. Colloid milia of both the adult and juvenile type may on occasions be confused with amyloid deposition at the light-microscopic level. Ultrastructurally, however, the fibres of colloid milia are of a different thickness to those seen in amyloidosis, and are wavy rather than straight. Other conditions where amorphous hyaline deposits may be seen with the light microscope, such as forms of porphyria and lipoid proteinosis, also have characteristic electron-microscopic appearances.

Viral diseases

Many of the conventional techniques for confirmation of a diagnosis of virus infection, such as virus isolation and culture and the various serological tests, are slow, and the patient has often recovered by the time the diagnosis is established with certainty. Conventional histology either from biopsy or from the scraping of the base of blisters, for instance in herpes simplex or zoster infections, can be useful in experienced hands, but there is quite a high rate of false-negative results. Molecular biological techniques including PCR are more specific, especially for identification of human papillomavirus (HPV) infection, but are not widely available. Direct visualization of virus particles with the electron microscope, using a negative staining technique, can give a positive result within half an hour of a lesion being sampled. This technique has become invaluable for confirmation of diagnosis in disorders caused by many of the main families of viruses, particularly lesions such as herpes simplex and zoster, and hand, foot and mouth disease. Immunohistochemical stains are widely available for various viruses including herpesvirus 1 and 2 and also for cytomegalovirus, and are quite useful in establishing a diagnosis in paraffin embedded sections. Human herpesvirus 8 is a novel type of herpes virus that can be detected in all tumours in patients with Kaposi's sarcoma [1]. A monoclonal antibody raised against the nuclear latent antigen of the virus is very sensitive and specific.

Immunogenotyping

In most inflammatory disorders, the lymphocyte population in skin tissue is normally polyclonal, containing progeny of many different parent lymphocytes. In contrast, most lymphomas are monoclonal, with cells being derived from the same parent cell. With the development of DNA probes to detect rearrangements of genes encoding for immunoglobulin and T-cell receptor molecules, it is now a routine technique to assess clonality of T- and B-cell populations by immunogenotyping [1–4]. Refinements in technique mean that significant results can now be obtained from relatively small portions of tissue. The PCR technique is now widely used for the study of clonality in cutaneous lymphoid infiltrates. This subject is discussed in detail in Chapter 57.

Artefacts (Table 10.6)

The microscopic appearance of the end product produced by processing a tissue specimen is in many ways an artificial representation of what is going on in a complex organ at one point in time. The procedures of biopsy fixation and tissue processing produce significant alterations in size, shape and structure of tissue constituents. We tend to think of fat cells as large, round, empty cells with peripheral nuclei, because this is how we are used to visualizing them microscopically. Cysts that normally contain lipid-rich substances, such as those of steatocystoma multiplex, appear relatively empty when sections from paraffin-embedded material are viewed. The clear halo often seen around melanocytes in the lower layers of the epidermis is at least in part an artefactual change. Some routinely observed tissue artefacts are useful for diagnostic purposes. The so-called separation artefact, where dermal connective tissue separates away from islands of basal cell carcinoma, aids us, for instance, in differentiating a basal cell carcinoma from a trichoepithelioma. In addition to these everyday artefacts, there are a wide range of other changes that may be induced accidentally or by poor processing technique. These changes may in some instances mislead the diagnostic pathologist.

Artefacts due to poor biopsy technique

Undue squeezing of the specimen with forceps can produce a marked artefact, causing the connective tissue to become amorphous and basophilic. Considerable distortion of cellular

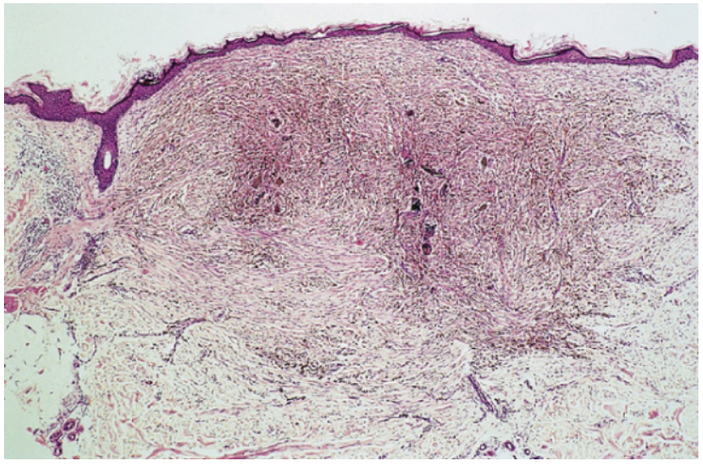

Fig. 10.24 Extensive dermal pigmentation as a result of the application of Monsel's solution.

infiltrates is also seen. Toothed forceps can produce a hole within the tissue specimen, which, although rarely causing diagnostic confusion, is aesthetically unpleasing. When a small tissue specimen is cut up into even smaller pieces, the pressure produced by the knife at the edge of the smaller biopsy portions may lead to connective tissue and cell distortion. It is far better to carry out several small separate biopsies, perhaps with a punch, from the same area than to try and divide a single specimen after it has been removed from the patient. Various techniques of cautery used to secure haemostasis following either a shave biopsy or curettage can lead to unusual histological appearances. Diathermy produces a bizarre alteration of cellular and nuclear morphology, as well as producing a stringy eosinophilic and homogenized appearance to connective tissue. The haemostatic agent, Monsel's solution (20% aqueous ferric subsulphate), can occasionally produce extensive ferrugination of fibrin, dermal collagen and even striated muscle in skin biopsies [1]. The iron pigment deposition can be very confusing and simulate melanin (Fig. 10.24). Particular problems are encountered where this technique is used following shave biopsy of melanocytic naevi. The deposition of this pigment could lead to an erroneous diagnosis of a malignant melanoma [2]. Artefacts may occasionally be induced by local anaesthetic. The epinephrine contained in some local anaesthetics may result in some degranulation of mast cells, and have minor effects on dermal blood vessels, but these are not normally important problems. A large quantity of local anaesthetic, particularly when injected directly into a lesion or superficially in the dermis, can cause appearances simulating marked tissue oedema, or in the case of a cellular naevus, disruption of the normal architecture of the tumour.

Artefacts related to fixation media

It has already been stressed that adequate fixation of skin-biopsy tissue specimens is needed for optimum histological interpretation. Specimens that have been fixed for an insufficient time show poor definition of cell structure and connective tissue. Cells may appear swollen, and staining of such poorly fixed specimens often produces a rather smudged appearance. Similar results may be seen when the specimen has not been placed in the correct fixative, but rather in some inappropriate solution such as normal saline. Formalin pigment may be precipitated out into the tissues in some skin biopsies, particularly where the biopsies have been fixed in a formalin-containing fixative with an acid pH. Formalin pigment artefact is particularly common in biopsies from tissue containing large amounts of haemorrhage, or tissues heavily congested with blood. Even in neutral buffered formal saline, a long fixation may increase the tendency to formalin pigment production. There are some fixatives, such as Zenker's fluid and Heidenhain's Susa, that contain mercuric chloride. Tissues fixed in these media may develop a granular, brownish black deposit. This deposit can be removed, normally by treatment in Lugol's iodine followed by sodium thiosulphate.

Artefacts due to blocking and sectioning

One of the most commonly encountered problems is with the orientation of the specimen. Oblique blocking can give a very misleading picture—for example, suggesting that there is pseudoepitheliomatous hyperplasia of the epidermis or psoriasis, when one is in fact dealing with normal skin. Correct and accurate vertical sectioning and blocking is particularly important where measurements are to be made, such as in the assessment of Breslow thickness and Clark's level of malignant melanoma. Occasionally, fragments of a biopsy adhere to the microtome blade and 'knife carry' may occur, with the result that, for instance, a fragment of basal cell carcinoma may be seen just above the epidermis in a section from a histiocytoma. Normally this artefact is easy to spot, but occasionally it can give rise to confusion. Partial blunting of the microtome knife causes uneven thickness of the histological section. This can give a false impression, both of the density of cellular infiltrates and of the qualities of the connective tissue. Irregularities in the microtome knife edge can cause an unaesthetic artefact known as shatter marks. In the presence of very hard or dense foreign material in the tissues, such as calcium, the foreign material may be drawn through the tissue, forming a tear in the resulting sections.

Artefacts due to staining techniques

It should be remembered that the various staining solutions have a very short shelf-life once made up, and that staining solutions that are old produce a very unsatisfactory end-result. It is also quite common for staining solutions to be contaminated with various foreign materials, such as plant hairs [3] or microorganisms, which may appear to be present within the tissue biopsied, when viewed in the finished mounted preparation.

The approach to microscopic examination of tissue sections

Some understanding of the basic principles of microscopy and careful microscope maintenance are essential for optimal visual-

ization of tissue sections, and ultimately therefore for achieving a correct histopathological diagnosis. Knowledge of the techniques and applications of fluorescence microscopy, interference microscopy and polarized light microscopy is also recommended.

Preparing for microscopy

Before using the microscope, some attention should be given to various practical points. Are all the optical surfaces clean? Greasy fingerprints and dust may seriously impair the quality of the image, and before using the microscope all lens surfaces should be cleaned. This may be done with an optical lens tissue. Petroleum spirit is recommended by some manufacturers. Cleaning of objectives with a concave shape can be difficult. A recommended method is to use a small, freshly broken-up piece of expanded polystyrene. It is important that there is no trace of xylene or other organic solvent on an objective treated in this way, or there is a risk of a film of dissolved plastic being left behind.

The microscope light source should be centred, and on most modern microscopes this is easily achieved by a pair of centring screws acting against a spring, or by loosening a screw column and orientating the lamp holder.

The condenser is then adjusted. The aperture diaphragm in the base of the microscope should be closed, and the condenser height adjusted, until the image of the field diaphragm is in focus. The diaphragm should then be centred with adjusting screws. After centring, the field diaphragm should be opened until it just disappears from view. The aperture (substage iris diaphragm) is then adjusted. With experience, this can be done while viewing the image on the slide. Alternatively, an eyepiece can be removed, and while looking down the eyepiece tube the diaphragm is opened until it occupies approximately one-third of the field of view. In this position, the numerical aperture of the condenser is approximately that of the objective in use, and optimum resolution is achieved.

The slide to be examined should then be viewed with the naked eye. Is the specimen a section of solid tissue, or uniformly spread across the slide, like a tissue or cell smear? The size and shape of sections on the slide should be noted, and it may be possible with naked eye examination to identify several tissues. It is important to note the number of sections mounted on one slide, and whether these are likely to represent sections from the same block, or different blocks mounted together. Finally, before putting the slide on the microscope stage, the name or identification number carried by the slide should be correlated with the details on the clinical request form. When inserting the slide into the microscope, make sure that it is the right way up, otherwise it may be impossible to focus the image with higher power objectives.

Microscopic interpretation

Examination of sections

The normal and recommended procedure is to start with lower power examination of the sections and gradually move up to higher power, detailed examination. Low-power scanning examination with a ×2.5 or ×4 objective provides a wealth of information. Identification of tissues is made, orientation of the specimen is possible, and the main site of any pathological changes is often identified. The basic nature of the pathological changes may also be recognized—for example, whether the main pathology represents a neoplastic or inflammatory process. Low-power scanning of all the material on the slide makes it clear whether all sections are from the same block, or whether they represent different portions of tissue. Low-power examination of biopsy material is the first step in the problem-solving exercise, and is the key to good diagnostic dermatopathology. During low-power examination, the site of biopsy and whether this correlates with the clinical information should be evaluated and, secondly, some attempt at pattern diagnosis should be made.

When a foreign body is suspected it is very useful to examine the section under polarized light. This is a quick method of confirming the presence of foreign material within the tissue. However, it is important to emphasize that some endogenous substances polarize and that not all external particles polarize.

Site of biopsy and normal histological variation

Without a working knowledge of the differences in skin microanatomy in the different regions of the body, it is very easy to come to a wrong diagnostic conclusion. For instance, the prominent sebaceous glands seen on facial skin, particularly the nose, may lead to a diagnosis of sebaceous hyperplasia, and the normally thick stratum corneum present on the palms and soles may be interpreted as hyperkeratosis. The following notes describe some of the more typical features seen in skin biopsies from specific sites.

Skin from the palms and soles. In biopsies from these sites, there is a fairly thick Malpighian layer with a thickened basket-weave stratum corneum, and a very prominent epidermal rete ridge pattern. Occasionally, specialized nerve endings (Meissner's corpuscles) may be seen in the dermal papillae. Eccrine sweat glands are fairly numerous, but no pilosebaceous follicles are identified. Vater–Pacini corpuscles are characteristically found in the subcutis. They are large, specialized nerve endings and have an ovoid or round shape with a typical onion ring appearance.

Skin from the areola of the nipple and the scrotum. In these sites, papillomatosis is a common finding, and in the upper dermis there are often numerous small fascicles and fibres of smooth muscle. In biopsies from the areola and nipple, occasional lactiferous ducts may be identified.

Mucous membranes. Histology of mucosal surfaces often shows fairly thick epithelium lacking well-defined keratinization. Focal mild parakeratosis is often seen. The rete ridge pattern normally associated with glabrous skin is not marked, and the cells of the Malpighian layer are large, pale and typically vacuolated.

Axillary skin. In skin from the axillae, papillomatosis of the skin surface is often marked. Abundant hair follicles are present, as are numerous apocrine glands, which are seen in addition to eccrine glands commonly present in other sites.

Scalp skin. Biopsies from the scalp are normally readily identified by the presence of numerous, large hairs (terminal hair follicles) with the hair bulbs frequently in the subcutaneous fat.

Facial skin. Facial skin is characterized by the presence of smaller hair follicles than in the scalp and, particularly in the central facial area, large numbers of mature sebaceous glands. The epidermis is very thin and melanocytes are numerous. The rete ridge pattern at the epidermodermal junction is often very poorly developed, which makes a distinction between papillary and reticular dermis often difficult to assess. *Demodex* organisms may be seen in the ostia of hair follicles and deeper within the sebaceous glands. Muscle may be identified relatively close to the epidermis in certain areas of the face, such as round the eyes or mouth.

Truncal skin. Skin from the trunk shows no very specific histological hallmarks. However, it is normally quite thick, with the distance between the epidermis and the subcutaneous fat being much greater than in biopsies from other sites. Eccrine sweat glands are normally identified at the junction between the dermis and the subcutaneous fat, and may, in skin from the trunk, appear within the reticular dermis itself. The skin from the back contains a very thick dermis with thick collagen bundles in which the ground substance is minimal. This normal pattern is often confused with evidence of a sclerosing dermal process such as morphoea.

Low-power histological pattern diagnosis

Having attempted to recognize the site of the biopsy, and having correlated this with the clinical information, the next task is to interpret any abnormal findings and attempt to come to some diagnostic conclusions. Sometimes, the site of the abnormality in the section is immediately obvious on scanning magnification. This then leads one to examine the appropriate area in more detail. When there is no obvious pathology in the section, a useful approach is to examine each identifiable cutaneous structure in turn. For instance, starting outwards with the stratum corneum and working inwards. Is it increased or decreased in thickness? Is parakeratosis present? Is the pattern of keratinization normal producing a basket-weave pattern, or is the stratum corneum compacted? Examination of the epidermis may reveal atrophy or acanthosis, spongiosis or cell atypicality, and may also reveal colonization of the epidermis by inflammatory or other abnormal cells. Various forms of epidermal degeneration may be noted. Some variants of these are described below. A vesicle or bulla may be present within the epidermis or below it.

Moving on to the dermis, is the arrangement of connective tissue fibres in the papillary and reticular dermis normal, or are the collagen fibres thickened and hyalinized? Is there an increase in interstitial oedema fluid, or is there evidence of increased amounts of mucin separating the collagen bundles? Is the elastic pattern normal? Careful examination of all adnexal structures should be made, and then, finally, any dermal infiltrate should be assessed. The density of the infiltrate, the pattern of the infiltrate (diffuse and interstitial and/or focal and localized) and the composition of the infiltrate are important. The position of the infiltrate in the dermis, whether it is predominantly deep or predominantly involves the epidermis, is also worth noting, as is the relationship of the infiltrate to adnexal structures and blood vessels. The blood vessels themselves should also be examined carefully for evidence, for example, of any vasculitic change or dilatation, increased tortuosity or thickening. A search should be made for any abnormal deposits or pigments such as amyloid, calcium or tattoo pigment. When one has some experience in assessing the different structures in a skin biopsy, one soon learns to recognize certain patterns of neoplastic change and inflammation. Ackerman has described a method of pattern diagnosis appropriate for the study of inflammatory diseases [1]. He suggests recognition of nine major patterns of inflammatory change in the skin, ranging from superficial perivascular dermatitis to panniculitis. Having classified the appearances in the section according to one of these patterns, closer examination enables one to come to a more precise diagnosis. Other authors have described similar schemes of microscopy. The system of pattern analysis can be recommended to those new to dermatopathology. More experienced pathologists have almost always developed their own pattern analysis system.

High-power microscopical examination

By the time one has examined a histological section with a ×2.5 objective, a ×4 to ×8 objective depending on personal preference, and a ×10 objective, one should have some idea in most cases of a differential diagnosis. High-power examination with ×25, ×40 or ×50 and sometimes with a ×100 oil-immersion lens provides an opportunity to confirm one's initial impressions.

Under high-power examination, one examines carefully cells and other structures in the skin in various specific ways. When dealing with neoplastic disorders, the cytology of individual tumour cells, with particular reference to nuclear detail and the variation in size and shape between cells of the same population should be studied. The number of mitotic figures and the number of abnormal mitoses are noted. The pattern of relationship of tumour cells to each other is also an important feature. Loss of polarity of keratinocytes in squamous epithelium is a characteristic feature associated with premalignant epithelial dysplasias, such as Bowen's disease and actinic keratoses, although it can of course also occur in invasive epithelial tumours. The relationship of tumour cells to neurovascular bundles is also important, and the pattern of neoplastic cells in relation to dermal connective tissue should also be evaluated. The so-called Indian-filing pattern of tumour cells lining up one behind another, sandwiched between collagen bundles, is in some contexts suggestive of malignant disease.

In inflammatory conditions under high-power examination, there is an opportunity to try and categorize the different types of cells in the infiltrate. It is important to look over the whole section, as in some areas the infiltrate may be composed of one cell type and in other areas another cell type may predominate. Some infiltrates are composed of almost pure populations of, for example, lymphocytes, and are described as monomorphic, whereas other infiltrates are composed of plasma cells, histiocytes, lymphocytes and eosinophils, and are described as polymorphic. It is only with experience that one becomes confident in recognizing the cytology of cutaneous infiltrates, and one must remember that in some biopsy material, cells may be seen that are impossible to classify by conventional criteria. The following notes describe the more typical appearances of commonly seen inflammatory and related cells, and describe some of the situations where they may be encountered.

Lymphocytes

Lymphocytes originate in the bone marrow and mature through a series of stages both in the bone marrow and the thymus gland, before being released into the peripheral blood and body tissues. The family of lymphocytes is a very heterogeneous one, with many subtypes of lymphocytes. T lymphocytes and B lymphocytes are indistinguishable by normal light microscopy, although on scanning electron microscopy *in vitro* B lymphocytes appear to have rather rougher surfaces than T lymphocytes, and show villous projections. On light-microscopic examination of sections stained with H&E, lymphocytes are roughly 7–12 µm in diameter, and possess small, round, deeply basophilic nuclei, surrounded by a thin rim of cytoplasm, which is usually very difficult to visualize. Numerous immunohistochemical methods are available that readily distinguish T and B lymphocytes, and most of these methods can be carried out using paraffin-embedded sections. In the majority of inflammatory conditions affecting the skin where a significant dermal infiltrate is seen, T cells outnumber B cells. Mature T and B cells are, of course, not the only lymphoid cells that may be found in the skin. In addition to plasma cells (see below), various follicular centre cells and T and B immunoblasts may be seen under certain conditions.

Plasma cells

Plasma cells are responsible for immunoglobulin production. They are a variety of B lymphocyte, approximately 10 µm in diameter, that have a distinct appearance in H&E-stained sections. They have abundant basophilic cytoplasm with a round, eccentrically placed nucleus. The nuclear chromatin is scattered in coarse clumps at the periphery of the nucleus giving it a 'clock face' appearance. Closely adjacent to the nucleus there is a zone of pallor in the cytoplasm, sometimes called the perinuclear hof. This area corresponds to the site where the Golgi apparatus is located. Older plasma cells often contain homogeneous eosinophilic globules of varying size within their cytoplasm, known as Russell bodies. Plasma cells are seen in many situations in the skin, particularly in inflammatory conditions affecting hairy areas, near mucous membranes and in the late stages of some granulomas.

Neutrophils

Neutrophils are the most numerous of the circulating white blood cells, comprising in normal individuals 50–70% of the blood leukocytes. They have a multilobed nucleus (three to four), with the lobes connected by narrow bridges of nucleoplasm. The slightly basophilic cytoplasm contains many smallish granules, many of which ultrastructurally correspond to membrane-bound lysosomes. Neutrophils function primarily as phagocytes, and are directed by chemotactic factors, including the complement cascade to noxious materials present in tissue. Such foreign materials include bacteria, fungi and tissues that have been injured. Collections of neutrophils may be seen in the skin in various infectious conditions, such as impetigo and staphylococcal folliculitis, in various inflammatory disorders of unknown cause, such as pyoderma gangrenosum and Sweet's syndrome, and in various vasculitic disorders, including leukocytoclastic vasculitis, granuloma faciale and erythema elevatum diutinum.

Eosinophils

Eosinophils, like neutrophils, originate in the bone marrow, but are rather larger than neutrophils, being 12–17 µm across. The nucleus of the eosinophil is usually bilobed, and the cytoplasm is filled with eosinophilic granules that are larger than the granules found in neutrophil leukocytes. Eosinophils are highly phagocytic, capable of ingesting various bacteria, fungi, immune complexes and inert particles and, like neutrophils, eosinophils contain hydrolytic and proteolytic enzymes contained in membrane-bound granules. Eosinophils are seen in skin biopsies in certain infections, in reactions to insect bites and other foreign bodies, in some drug reactions, and in bullous eruptions such as bullous pemphigoid, and some forms of pemphigus. They are of major importance in the condition known as eosinophilic cellulitis, and may also occur in association with proliferations of cells of the lymphoid series in certain cutaneous T-cell lymphomas.

Histiocytes/monocytes/tissue macrophages

The term histiocyte is used by different authors to mean different things, and is an unsatisfactory term. Monocytes circulating in the blood may be attracted into the skin for the purposes of phagocytosis. They are then called histiocytes or tissue macrophages. However, many other mesenchymal cells and cells of the granulocyte series are also capable of phagocytosis. The appearances of a histiocyte vary considerably. Many of the cells are fairly large with a lightly staining, sometimes vesicular, elongated nucleus. The cytoplasm is usually pale and cell margins may be indistinct. The cells may be dendritic, spindle-shaped or epithelioid, taking on the latter form particularly in epithelioid cell granulomas. The size of histiocytes is also very variable, ranging from 15 to 25 µm. Compared with some of the cells described above, they are less easy to identify, particularly for the novice, in skin biopsies, and immunohistological methods are often necessary to demonstrate histiocyte subsets. Several factor XIIIa-positive, dendritic phagocytes (dermal dendrocytes) are seen in close proximity to the superficial microvascular plexus. These cells, together with other immune cells, mast cells and endothelial cells, probably collaborate to coordinate antigen presentation, induction of cellular inflammation, wound healing and haemostasis in this microenvironment. Various histiocytes are found in a wide range of inflammatory and neoplastic disorders, but are particularly important in the production of granulomatous inflammation, both in conditions such as granuloma annulare, and in response to cutaneous infection such as mycobacteria.

Giant cells

Many types of giant cell may be recognized in skin tissues. The three best known are the Langhans' giant cell, the foreign-body giant cell and the Touton giant cell. All these giant cells are derived from tissue macrophages, and forms intermediate between the different characteristic types are sometimes seen. The size of these cells varies greatly, but is usually of the order of between 40 and 120 µm. Langhans' giant cells show a characteristic horse-shoe distribution of the nuclei arranged at the cell periphery. They are most characteristically seen in sarcoidosis and tuberculosis.

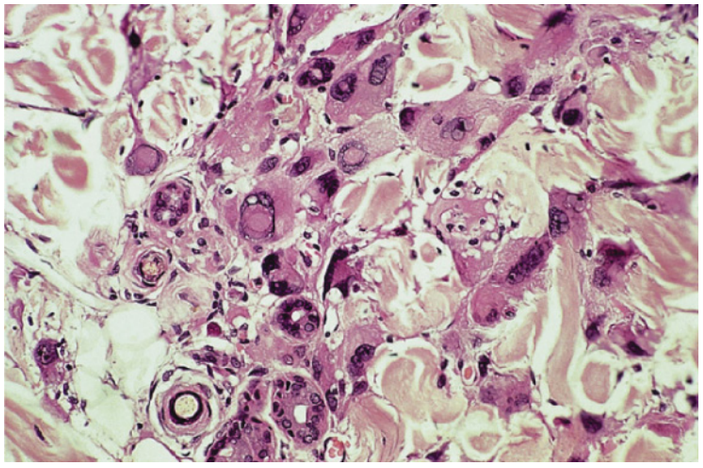

Fig. 10.25 Bizarre multinucleated giant cells from a Spitz naevus.

Foreign-body giant cells contain a haphazard arrangement of nuclei scattered throughout the cell cytoplasm, and may also contain foreign material. Although typically seen in foreign-body granulomas, they are common in other forms of granulomatous inflammation and in situations where there is disruption of pilosebaceous follicular structures with keratin release into the dermal connective tissue. Touton giant cells have a central ring of nuclei enclosing a layer of ground-glass cytoplasm, with a peripheral zone of clearer cytoplasm. They are typically seen in some xanthomas and juvenile xanthogranuloma.

It should be noted that many other forms of giant cell are seen, such as the fairly typical giant cell with scattered nuclei, prominent nucleoli and PAS-positive cytoplasm in multicentric reticulohistiocytosis. Not all giant cells are derived from cells of the macrophage series. Multinucleate cells derived from infected keratinocytes may be seen in various virus infections such as herpes and poxvirus infections, and multinucleate cells derived from melanocytes are quite typical of epithelioid and spindle cell (Spitz) naevi (Fig. 10.25).

Mast cells

Mast cells, unlike the white blood cells and some histiocytes, all of which probably originate from the bone marrow, are likely to arise from undifferentiated mesenchymal cells. In normal skin, they are present around small blood vessels in the dermis. They are approximately 9–16 μm in diameter, and they possess a central round to ovoid, dark-staining nucleus. The cytoplasm contains small granules that stain metachromatically with such stains as toluidine blue. The granules contain vasoactive substances such as heparin, histamine, and eosinophilic and neutrophilic chemotactic factors of anaphylaxis. Mast cell activation may be triggered by neuropeptides derived from unmyelinated axons that surround perivascular mast cells. This in turn triggers adhesive events between leukocytes and endothelial cells, resulting in angiocentric inflammation.

Although in normal skin the cells tend to have a dendritic morphology, in various pathological conditions, including some forms of urticaria pigmentosa, the cells are larger and polygonal with a central, rounded nucleus. In addition to being found in increased numbers in the mastocytoses, they are also commonly seen in various benign and malignant nerve tumours, and in association with some melanocytic naevi.

Fibroblasts

Fibroblasts are often difficult to identify on routine light microscopy. Their nuclei tend to be oval or spindle-shaped, and with moderately basophilic staining. They are usually found between collagen bundles, and may be prominent in conditions where there is an increase in the production of dermal connective tissue or ground substance, such as morphoea and scleromyxoedema. They may also contribute to the histogenesis of the wide range of so-called fibrocytic tumours that may occur in the skin.

Myofibroblasts

These cells are mainly defined by their electron microscopic appearances and display features intermediate between those of fibroblasts and smooth muscle cells. They are mainly seen in reactive reparative processes and in neoplasms. Histologically, they have indistinct cytoplasmic margin, pink pale cytoplasm and vesicular tapering nuclei with a single inconspicuous nucleolus. Myofibroblasts can only be identified with certainty by electron microscopy.

Smooth muscle cells

Smooth muscle cells occur normally in the skin in the arrector pili muscles, in the tunica dartos of the external genitalia, in the areola of the nipple and in the walls of blood vessels. They are easy to identify by recognizing the normal structures in which they occur and also by their cytomorphology, which consists of abundant bright eosinophilic cytoplasm and vesicular nuclei with a single inconspicuous nucleolus.

Rhabdomyocyte (striated muscle cell)

Skeletal muscle occurs in the skin of the neck and of the face. The constituent cells are arranged in bundles and have characteristic cross striations and abundant, bright pink cytoplasm.

Schwann cells

Schwann cells are the main constituent cells of nerves. They envelop the neuroaxons and are characterized by a slender hyperchromatic thin nucleus and inconspicuous cytoplasm.

Endothelial cells

A single layer of endothelial cells lines all types of vascular channels in the skin. These cells usually appear flat with inconspicuous cytoplasm and small histiocyte-like vesicular nuclei. However, in most pathological processes, they become more prominent and may appear somewhat hyperchromatic. This, coupled with an increase in mitotic activity, may lead to confusion with malignant cells, particularly in cross-sections, where the normal architecture of the vascular channel is often not apparent.

Pericytes

Pericytes occur as a single layer of indistinct cells around small dermal blood vessels. They are recognized by their location and by positive staining for actin.

Miscellaneous

In addition to closely examining cytology under the high-power objective, the opportunity should also be taken to look carefully for organisms, foreign bodies or deposits of foreign material such as amyloid. Special staining techniques will often be needed to confirm suspicions, and with these stains bacterial, fungal and protozoal organisms may be identified as well as various forms of parasite. The presence of viral organisms can also be inferred by the presence of characteristic cytopathic changes, such as occur for instance with herpesvirus infections and infections with cytomegalovirus. Close examination of nerves and blood vessels should be carried out, particularly in relation to the presence of any organisms or tumour deposits. After examining adnexal structures and the subcutaneous tissues, it is useful to return to low-power examination and attempt to be certain one has not missed any pathology. It is not uncommon to discover more than one abnormality in a tissue section. Patients who develop solar keratoses may also have seborrhoeic warts, naevi and basal cell epitheliomas. Biopsies from patients with acquired immune deficiency syndrome (AIDS) often have multiple pathologies, and one may, for example, see a biopsy of perianal tissue in which there is evidence of cytomegalovirus infection in the endothelial cells, HPV infection of the overlying epithelium and the presence of Kaposi's sarcoma.

The importance of carefully assessing both the low-power pattern of changes in a skin section, as well as a more detailed examination of the cytology of the pathological changes, cannot be too strongly emphasized.

How to produce a histopathology skin report

After carefully carrying out the recommended procedure for low scanning power and high-power examination of a skin biopsy slide, the pathologist will either need more information, or will be in a position to provide a microscopic histopathological report to supplement the report on the gross pathological appearance of the biopsy specimen before processing. If there is very little obvious abnormality, it may be appropriate to cut deeper levels from the tissue block, or even consider blocking any remaining wet tissue that is in storage. If the specimen has been blocked obliquely or, for instance, the epidermis is missing, reblocking will be necessary. Serial sections may be required to determine pathological features that are only focal, such as changes affecting pilosebaceous follicles in a biopsy from the scalp. Special stains may be required for the evaluation of abnormal dermal deposits, to detect the presence of organisms, or to elucidate the nature of various pigments in the biopsy material. Immunohistochemical studies may also be requested in, for example, cases of cutaneous lymphoma or malignant spindle cell tumours. If there is going to be undue delay in these various extra investigations, a preliminary report should always be issued.

Although reporting of histopathology is to some extent a subjective art, and every pathologist will have his or her own idea of what is an appropriate report, a description of the objective histological changes, and either a suggested diagnosis or a differential diagnosis, are always desirable. In a description of the pathology, it is important never to describe features that are not present, even though they may be consistent with the correct diagnosis. The differential diagnosis suggested by the pathologist should fully take into account the clinical information supplied by the clinician. If the clinician suggests on the request form chronic superficial scaly dermatitis, it would be churlish to sign out the report as subacute eczema without further qualification. In addition to a description of the objective pathological changes and a diagnostic suggestion, it is quite legitimate to add a further comment in certain situations. If the clinician suggests a tumour has been excised, then a comment on the adequacy of excision is obviously useful. Conversely, if the clinician states that this is a diagnostic/incisional or superficial biopsy, it is irritating for the clinician to receive a report stating that tumour extends to one margin of excision.

In some situations where the various histopathological parameters need to be recorded repeatedly in biopsies from specific skin disorders, for example malignant melanoma, specially designed forms facilitate both the recording of information and subsequent computer analysis.

There is some degree of disagreement as to whether it is the role of the histopathologist under any circumstances to make recommendations for treatment, and no general rule can be given on this. If one knows one's clinical colleagues well, it is quite appropriate under certain circumstances to recommend a modest re-excision of the biopsy site, for instance in early superficial spreading melanoma. Some pathologists prefer to make such comments in a separate covering note. With some rarer conditions, particularly if they have serious implications for the patient, a telephone call to the clinician, or again a covering note, may be a reasonable approach. An offer from the pathologist to discuss any interesting case in more detail is often a good idea, and is usually taken up. It is always in the best interests of the patient for there to be a close working relationship between the histopathologist and the clinician.

Finally, it is most important always to appreciate one's own limits of ability. One should never be afraid of asking for a second opinion from a colleague. It has been said that sections from skin biopsies fall into three groups. Firstly, there are those sections where the histological appearances are easy for anyone to interpret and diagnose. Secondly, sections from biopsies, for instance of a very poorly differentiated spindle cell tumour, where one does not know what the diagnosis is, but knows that it is likely that no one else will either. Thirdly, sections where one does not know how to interpret the histological appearances oneself, but does know it is likely that someone else will! Once one is able to divide histological material into one of these three groups, one is already on the way to becoming an accomplished diagnostic dermatopathologist.

Commonly used descriptive terms in dermatopathology, and their diagnostic significance

Acantholysis

Acantholysis is the term used to describe loss of cohesion between keratinocytes, due to breakdown of intercellular bridges. It results in the formation of intraepidermal clefts, vesicles and bullae. It appears to be the primary pathological change in a group of diseases including pemphigus and its variants, Darier's disease, transient and persistent acantholytic dermatosis and warty

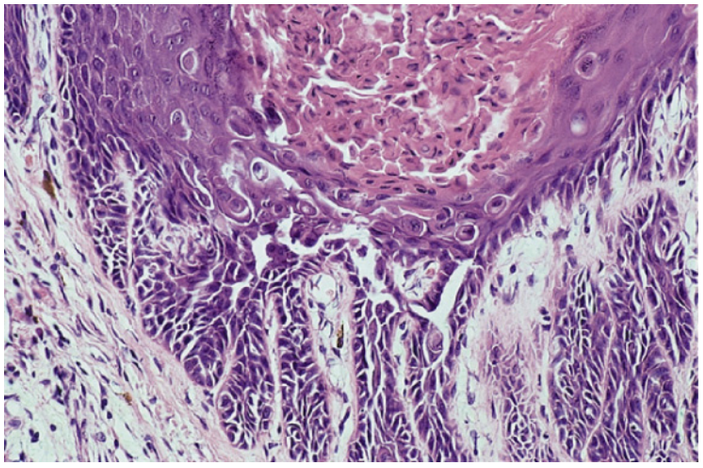

Fig. 10.26 A biopsy from a case of Darier's disease, showing the histological features of parakeratosis, dyskeratosis, acantholysis and formation of villi.

dyskeratoma. The site of acantholysis in these disorders is important. In pemphigus foliaceus and pemphigus erythematosus, acantholysis is usually confined to the upper portion of the epidermis, whereas in pemphigus vulgaris the split is formed at a lower level in the epidermis. In benign familial pemphigus (Hailey–Hailey disease), although acantholysis is often focal or incomplete, where it does occur it tends to affect the full thickness of the epidermis.

Acantholysis may also be seen secondary to some other pathological change, where there is alteration or damage to epidermal cells. It may occur, for example, in bullous impetigo, viral disorders, solar keratoses and some forms of squamous cell carcinoma. When acantholysis occurs in these disorders, the term secondary acantholysis is often used to distinguish the process from primary acantholysis, which occurs in pemphigus and related diseases (Fig. 10.26).

Acanthosis

This term is used to describe an increase in number of cells in the Malpighian or prickle cell layer of the epidermis (from the Greek for prickle or thorn). Sometimes, a distinction is made between increased thickness of the epidermis due to enlarged keratinocytes (pseudoacanthosis) and true acanthosis due to increased numbers of keratinocytes. In practice, acanthosis is commonly used to cover both senses. Increased thickness of the epidermis may result from increased length of rete ridges, as in a psoriasiform tissue reaction, or may affect the whole epidermis, such as in lichenification. Acanthosis is commonly accompanied by other histological changes such as hypergranulosis, hyperkeratosis and papillomatosis.

When reactive epidermal proliferation is marked, the process may simulate an epithelial carcinoma, and in this situation is referred to as pseudoepitheliomatous hyperplasia. Acanthosis may be seen in a wide variety of inflammatory and neoplastic disorders. Some of the common situations where this feature may be seen include the following:

1 Naevoid conditions and localized benign epidermal tumours—for example, keratodermas, epidermal naevi and seborrhoeic keratosis.
2 Virally induced papillomas—for example, viral wart, molluscum contagiosum.
3 Secondary to inflammatory conditions affecting the epidermis, particularly where chronic—for example, persistent friction, lichenification, prurigo and chronic eczema, psoriasis and lichen planus.
4 Secondary to conditions associated with loss of keratinocyte adhesion—for example, the pemphigus group of disorders and Darier's disease.
5 Secondary to conditions associated with the presence of foreign cells within the epidermis, such as malignant melanoma, Paget's disease, mycosis fungoides and Langerhans' cell histiocytosis.
6 Acanthosis is commonly seen overlying a variety of abnormalities in the dermis:
   (a) dermal tumours such as fibrous histiocytoma and granular cell tumour;
   (b) certain forms of cutaneous infection such as lupus vulgaris and blastomycosis;
   (c) overlying dermal deposits of substances such as amyloid, abnormal elastic tissue or in association with foreign bodies; and
   (d) in association with chronic oedema, such as chronic lymphoedema of the lower limb and myxoedema.

Anaplasia

This is a term used to describe variations in nuclear size, dense and clumped heterochromatin, and nuclear contour angulation typical of malignant cells, as in metastatic melanoma.

Apoptosis

This is a morphologically distinct type of cell degeneration and death, usually applied to keratinocytes that become homogeneous and eosinophilic and are extruded into the underlying upper dermis. These eosinophilic bodies (known as Civatte or colloid bodies), and the process of apoptosis, occur characteristically in lichenoid tissue reactions. A similar process may be observed in many other processes, for example, following UV light exposure, in graft-versus-host disease and in cutaneous lupus erythematosus.

Basal lamina (Chapter 3)

This structure, also known as the basement membrane, is a submicroscopic structure approximately 40 nm in thickness, which extends along the undersurface of the epidermal basal cells. It is not visible with light microscopy. The term basement-membrane zone is sometimes applied to the area that may be visualized with the PAS-staining technique (see Fig. 10.7). The basement membrane is a very complex structure composed of large numbers of proteins with important functions in maintaining the structure of the skin. Many of these proteins are of great importance in genetic (epidermolysis bullosa) and acquired diseases (autoimmune blistering diseases).

Bullae

Bullae represent fluid-containing cavities occurring within or below the epidermis. Small bullae are known as vesicles. Determination of the site of bulla formation is most important in

histological assessment of skin biopsies. Intraepidermal bullae may arise as the result of spongiosis, as in acute eczema, from reticular and ballooning degeneration seen in association with viral disorders, or from acantholysis or epidermal cell necrosis. Subepidermal blisters usually result either from a defect in the basement membrane region, such as occurs in some forms of epidermolysis bullosa and porphyria, from a disruption of the basement membrane from intense liquefaction degeneration or necrosis of the basal cell layer, such as may occur in bullous lichen planus or bullous lupus erythematosus, or as a result of dermal inflammatory processes involving the upper dermal connective tissue and basement membrane region. In some conditions, such as erythema multiforme, both subepidermal and intraepidermal factors seem to be involved in bulla formation.

Colloid body

This term, usually regarded as synonymous with Civatte body, describes the homogeneous eosinophilic rounded body resulting from degeneration and death of keratinocytes, particularly in the lower layers of the epidermis. This structure is found in various lichenoid tissue reactions and is involved in the process of apoptosis.

Crust

This term is used to describe collections of inflammatory cells, red blood cells, plasma and fibrin in the superficial portion of the epidermis. A crust may also contain microorganisms, and often replaces a partial or total loss of the epidermis itself.

Curlicue (storiform) pattern

This descriptive term refers to the twisting and curving of dermal fibrohistiocytic cells around collagen bundles, often at the margins of a dermal tumour. The pattern is mainly observed in dermatofibrosarcoma protuberans. The pattern described by this term is the same as that referred to by the term storiform (Fig 10.20a).

Degenerations

Dermal

Colloid degeneration. Colloid degeneration refers to the deposition of extracellular homogeneous gelatinous material of variable composition. It is typically seen in colloid milium, but may also be found in certain epithelial tumours.

Elastotic degeneration. This describes the degenerative changes that develop with increasing age, particularly in the upper part of the dermis in sun-exposed skin. Early changes include an increase in the number and size of connective tissue fibres staining with elastic stains. In advanced stages of the condition, there are masses of disorganized elastotic fibres occurring particularly in the upper third of the dermis, and appearing to replace the normal collagen. This elastotic degeneration is normally separated from the epidermis by a narrow band of normal-staining connective tissue. In sections stained with H&E, the elastotic material is basophilic.

Fibrinoid degeneration. This term describes the deposition in tissue of eosinophilic, granular or fibrillary material resembling fibrin. The composition of the eosinophilic amorphous material may vary in different situations, but fibrinogen, plasma proteins, immunoglobulins and dermal ground substance may be components of the material. It is most typically seen in forms of necrotizing vasculitis, and is also found in disorders such as lupus erythematosus and the collagen diseases.

Hyaline degeneration. This term refers to the presence of homogeneous eosinophilic degenerative material in dermal connective tissue, or in relation to blood vessels. The material has a glassy and refractile appearance. Hyaline degeneration occurs in forms of porphyria, lipoid proteinosis and sometimes in lichenoid tissue reactions. Epithelial structures may also show a similar type of change, for instance the tumour cells of cylindroma frequently undergo hyaline change.

Myxoid degeneration. This indicates the deposition or replacement of dermal connective tissue by amorphous, stringy, basophilic material. This pattern of degeneration is seen in localized myxoedema, papular mucinosis, scleredema and dermatomyositis, as well as being seen in various neural, epithelial and adnexal neoplasms.

Epidermal

Ballooning degeneration. This form of degeneration of keratinocytes is associated with marked swelling and pallor of individual cells, with loss of intercellular bridges. A blister forms as a result of the consequent acantholysis. Ballooning degeneration along with reticular degeneration is characteristic of virus disorders affecting epithelia, such as herpesvirus infections.

Hydropic degeneration. This is also known as liquefaction degeneration, and refers to a vacuolar change that affects the basal cell layer of the epidermis. Small droplets and vacuoles develop within and in between basal cells. The process is commonly associated with pigmentary incontinence, and when marked may lead to subepidermal blister formation. It occurs typically in the whole range of lichenoid tissue reactions, including lupus erythematosus, lichen planus, dermatomyositis, poikiloderma atrophicans vasculare and lichen sclerosus (Fig. 10.27).

Reticular degeneration. This indicates the development of large, multiple, intraepidermal vesicles, where there remains a ragged network of epidermal cell remnants. As mentioned above, reticular degeneration often occurs in association with ballooning degeneration in acute virus infections of the herpesvirus and poxvirus groups. This pattern of epidermal degeneration may also sometimes be seen in the acute bullous reaction of contact dermatitis.

Desmoplasia

This term describes a pattern of fibrosis or sclerosis of dermal connective tissue, usually in association with an epithelial or melanocytic proliferative lesion. Examples of the use of this term are in desmoplastic trichoepithelioma and desmoplastic malignant melanoma.

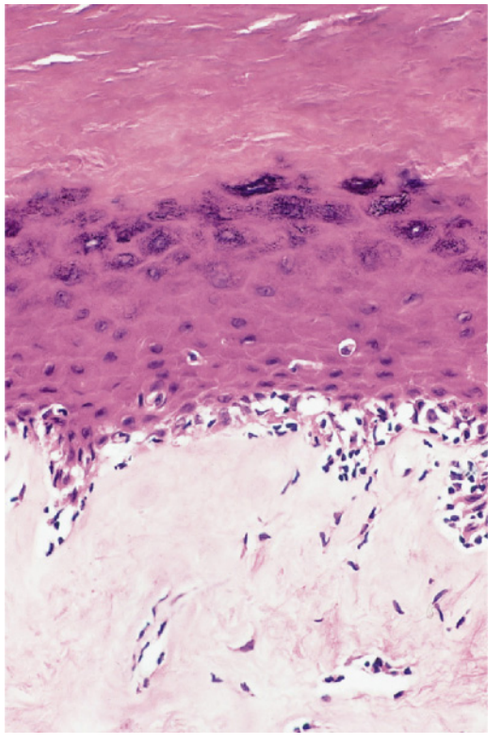

Fig. 10.27 Prominent liquefaction degeneration from a case of lichen sclerosus.

Dyskeratosis

This term relates to some abnormality in the process of epidermal cell keratinization. The changes usually consist of nuclear pyknosis and bright pink condensation of the cytoplasm of keratinocytes. The process occurs in two main contexts. Firstly, in malignant and premalignant epithelial lesions, such as squamous cell carcinoma, Bowen's disease and solar keratosis. Secondly, in various forms of acantholytic disorder such as Darier's disease. In this latter condition, specific types of dyskeratotic cell include corps ronds and grains (see Fig. 10.26).

Dysplasia

This term is a confusing one, especially when used to describe atypical melanocytic naevi, because if communication with the clinician is inadequate, it may be interpreted to mean different things. Its use normally reflects some abnormality in cell maturation, cytomorphology or the relationship between cells in epithelial structures. It has the connotation of possible progression to neoplastic disease.

Exocytosis

This term describes the migration of inflammatory cells from the blood vessels of the dermis into the overlying epidermis. The process may be associated with spongiosis, as in eczema, or occur in the absence of spongiosis, such as may be seen in mycosis fungoides. In the later setting, the word epidermotropism is usually preferred.

Granuloma

A granuloma describes circumscribed foci of inflammation containing monocytes, macrophages, lymphocytes and epithelioid cells. Multinucleated giant cells of foreign body, Langhans or Touton type may also be observed. Varying degrees of epidermal hyperplasia, capillary proliferation and dermal fibrosis are common accompanying changes. Granulomatous inflammation occurs in a wide variety of infectious and non-infectious conditions. Many different types of organism ranging from viruses through bacteria to fungi can produce a tissue granuloma. The presence of granulomas in a skin biopsy may indicate a systemic disease, such as sarcoidosis, or a localized dermatosis of unknown cause, such as granuloma annulare or acne agminata. The precise histological appearance of a dermal granuloma depends not only on the underlying cause, but on the period over which the disease has been active, and the immune status of the host.

Grenz zone

This comes from the German word for border, and in dermatopathology is applied to a narrow zone of normal dermis between the epidermis and pathological changes in the underlying dermis.

Hypergranulosis

This refers to an increase in thickness of the granular layer of the epidermis, and is commonly accompanied by hyperkeratosis and acanthosis. It is often seen in chronic lichenification and lichen planus and related disorders.

Hyperkeratosis

Hyperkeratosis refers to increased thickness of the stratum corneum, and may be associated with acanthosis of the Malpighian layer. Hyperkeratosis may occur in various disorders of keratinization, such as the keratodermas and some ichthyotic disorders, and relative hyperkeratosis is quite common in chronic discoid lupus erythematosus. In certain conditions, such as in Flegel's disease, in addition to increased thickness of the stratum corneum there is a change from the normal basket-weave pattern to a compact arrangement of the stratum corneum cells. When assessing the thickness of the stratum corneum, it is important to correlate the histological appearances with the site of the biopsy. The stratum corneum is normally thick on the palms and soles, and very thin, or even absent, around the eyelids and near mucous membrane junctions.

Epidermolytic hyperkeratosis

This particular change, also sometimes referred to as granular degeneration, is a peculiar and characteristic change seen in a number of skin disorders. There is an increase in the thickness of the granular layer, where keratinocytes appear to contain an increased number of keratohyalin granules. Perinuclear vacuolization occurs in this area, and the cell boundaries may be indistinct. The vacuolization may be marked, in some cases appearing to lead to intraepidermal vesicle formation. Although this change is best known as the characteristic histopathological feature of bullous ichthyosiform erythroderma (Fig. 10.28), it also occurs in many other inherited and acquired conditions, including a form of palmoplantar keratoderma, so-called epidermolytic acanthoma,

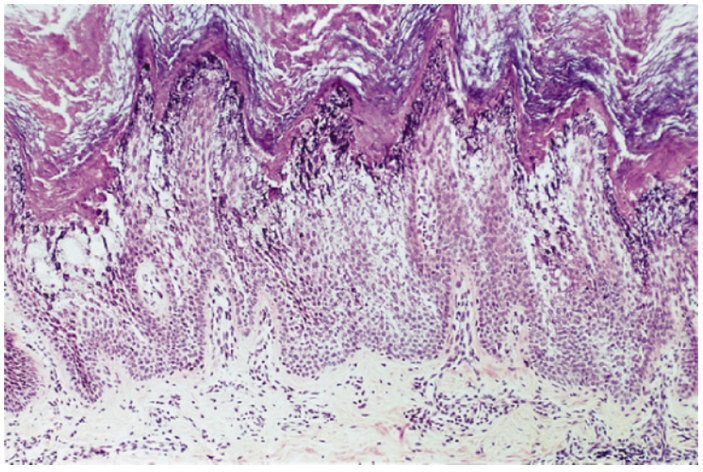

Fig. 10.28 Epidermolytic hyperkeratosis seen in a biopsy from a patient with congenital bullous ichthyosiform erythroderma.

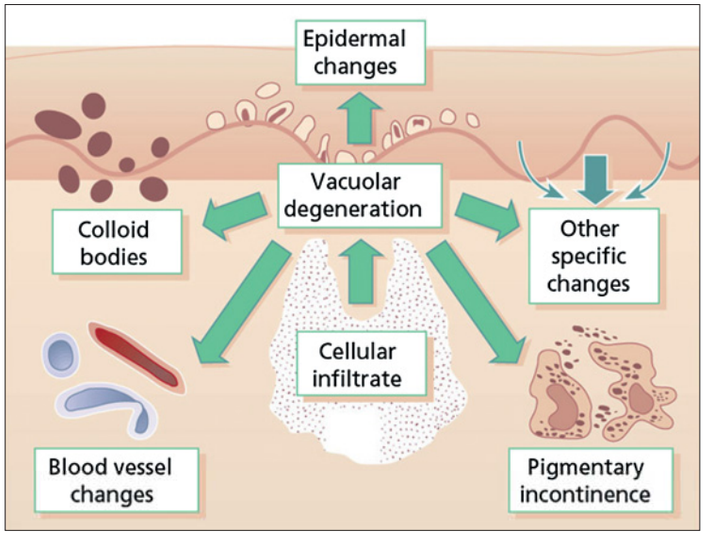

Fig. 10.29 The lichenoid tissue reaction. Various histopathological consequences follow damage to the dermal–epidermal junction. These histopathological changes are seen in a wide variety of lichenoid reactions, ranging from lichen planus to lupus erythematosus, poikiloderma atrophicans vasculare, lichen sclerosus and lichenoid drug eruptions.

and some forms of linear epidermal naevus. It is also occasionally seen as an incidental finding, either in normal skin or in association with a lesion, such as a naevus, a viral wart or a seborrhoeic keratosis.

Follicular hyperkeratosis

This describes varying degrees of hyperkeratosis and plugging of the ostia of hair follicles, and this change may be associated with the rupture of the follicular wall. It occurs in many conditions including pityriasis rubra pilaris, lupus erythematosus, lichen planopilaris and lichen sclerosus.

Kamino bodies (eosinophilic globules)

This term describes the eosinophilic globules seen in the epidermis or in the region of the dermal–epidermal junction in spindle- and epithelioid-cell (Spitz) naevi. They are almost always found in Spitz naevi but may also be seen in some cases of melanoma.

Karyorrhexis

This refers to the fragmentation of cell nuclei, and the process may be seen in various forms of neutrophilic dermatoses and cutaneous pyoderma. It is commonly seen in necrotizing vasculitic processes. The term leukocytoclasis specifically refers to the fragmentation of nuclei of neutrophil polymorphonuclear leukocytes. However, the term is sometimes used to refer to fragmentation of other inflammatory cells such as lymphocytes.

Lichenoid tissue reaction

This is a pattern of changes occurring both in the epidermis and especially the dermis, seen in a wide variety of conditions, ranging from lichen planus itself to lupus erythematosus, lichen sclerosus and the poikilodermas. Lichenoid changes may also be seen in some examples of cutaneous drug eruptions. In the upper dermis, there is a band-like infiltrate consisting predominantly of mononuclear cells. This is closely related to the dermal–epidermal junction, which itself may have a saw-toothed pattern. Liquefaction degeneration of the basal cell layer is seen, and colloid body formation may be present. There is often an increase in thickness of the overlying epidermis, affecting both the Malpighian layer and the stratum corneum (Fig. 10.29).

Metaplasia

This term is used to indicate an alteration of one type of tissue into another, such as the formation of bone in certain epithelial tumours, for example pilomatricoma.

Necrobiosis

Necrobiosis is an unsatisfactory term derived from words for life and death. It is applied to certain granulomatous disorders where the dermal connective tissue becomes homogenized and loses its normal staining characteristics, resulting in mucinous, fibrinoid or sclerotic alteration. The outlines of the normal architecture are usually still present, and the amount of inflammation varies. Changes of necrobiosis are normally surrounded by a palisading histiocytic granuloma. The condition is seen in association with granuloma annulare, necrobiosis lipoidica, rheumatoid nodule and acne agminata.

Necrolysis

This is used to describe the separation of tissue constituents as a consequence on cell death. Epidermal changes of necrolysis are seen in various inflammatory reactions such as erythema multiforme, toxic epidermal necrolysis and necrolytic migratory erythema seen in association with the glucagonoma syndrome.

Necrosis

This term describes the death of cells or tissue.

Papilloma

This term indicates a tumour or tumour-like proliferation exhibiting both papillomatosis and hyperkeratosis. Acanthosis is also

present. Examples of skin papillomas include viral warts, seborrhoeic keratoses and some epidermal naevi.

Papillomatosis
This change is characterized by elongation upwards of the dermal papillae, giving an accentuated and sometimes irregular, undulating configuration to the dermal–epidermal junction. The feature is commonly seen in psoriasis, and a wide variety of other inflammatory and neoplastic cutaneous disorders.

Parakeratosis
Parakeratosis can be defined as the retention of keratinocyte nuclei within the horny cell layer. It represents a disturbance of keratinization, and is normally associated with an absence or reduction in thickness of the granular cell layer. The histological feature of parakeratosis is commonly seen in many different forms of inflammatory dermatosis, and is closely associated either with increased epidermal cell turnover or with inflammatory changes in the epidermis itself. It is commonly seen in psoriasis and subacute eczematous reactions, and in conditions such as pityriasis lichenoides where the change reflects an earlier disturbance in the underlying epidermis. In chronic inflammatory conditions where epidermal turnover is unaffected, such as in lichenoid reactions, parakeratosis is rarely seen. Dysplastic epithelial changes, such as those occurring in actinic keratoses and Bowen's disease, are normally accompanied by parakeratosis.

Pigmentary incontinence
This refers to the loss of melanin from cells of the basal layer of the epidermis, and the accumulation of melanin, both free and within dendritic macrophages, in the underlying dermis. It is associated with damage to keratinocytes of the lower epidermis, and is commonly seen in lichenoid tissue reactions. Small amounts of melanin may be seen in the upper dermis in normal pigmented skin.

Pleomorphism
This describes variability in the appearance of cells, and in particular the nuclei of cells of the same type. Although it may be seen in malignant and premalignant conditions, marked pleomorphism may also be seen in benign lesions such as Spitz naevi.

Polymorphism
Conventionally this is used to describe a variation in types of cells in a cutaneous lesion. This term is not the same as pleomorphism.

Pustules and abscesses
These terms are used to describe cavities within the epidermis or dermis formed by collections of neutrophil or eosinophil polymorphonuclear cells. Occasionally, the term is used to describe collections of other leukocytes, as in the term Pautrier microabscesses (see below). Cutaneous pustules may be sterile, or associated with an infectious microorganism. Certain specific types of microabscess and pustule are of diagnostic value in dermatopathology.

Kogoj's spongiform pustule. This describes the multilocular micropustules that form in the superficial portions of the epidermis in pustular psoriasis. They form in a similar manner to Munro microabscesses but the process is more extensive.

Munro microabscesses. These lesions are small collections of neutrophil polymorphs usually found within the stratum corneum. They are normally seen in lesions of chronic established psoriasis, and the other histological features of the psoriatic reaction, such as irregular epidermal thickening and parakeratosis, are normally present.

Papillary tip microabscesses. These are small focal collections of neutrophil polymorphs or occasionally eosinophils, in the tips of dermal papillae. Although they are characteristic of dermatitis herpetiformis, they may occur in other bullous eruptions such as epidermolysis bullosa acquisita and the bullous form of lupus erythematosus.

Pautrier microabscesses. These small, intraepidermal collections of lymphoid cells in the absence of marked spongiosis are characteristic of mycosis fungoides. The cells within the epidermis may show some degree of nuclear hyperchromatism or atypia. Single cell colonization of the epidermis is more commonly seen than true Pautrier microabscess formation in many cases of early mycosis fungoides.

Subcorneal pustules. Large, subcorneal collections of neutrophil polymorphs usually represent either impetigo or subcorneal pustular dermatosis. Sometimes, the distinction of either of these two conditions from pustular psoriasis may be difficult.

Pyknosis
This term is used to refer to hyperchromatism and shrinkage of the cell nucleus. It is normally associated with cell death, and may be seen in a wide variety of conditions, including epithelial dysplasias, drug reactions and reactions to UV light.

Saw-toothing
This refers to an alteration in the pattern of the dermal–epidermal junction where dermal papillae are expanded and the tips of the rete pegs are pointed. The resulting pattern bears a superficial resemblance to the teeth of a saw and the change is seen in lichen planus and other lichenoid reactions.

Spongiosis
Spongiosis is also known as intercellular oedema, and describes the widening of intercellular spaces between keratinocytes due to fluid accumulation. Spongiosis is the characteristic histopathological change seen in acute and subacute eczematous reactions, but is also seen in a wide variety of other conditions; when spongiosis is marked it leads to intraepidermal vesiculation. Spongiosis of follicular epithelium may be associated with increased mucin deposition in the histopathological reaction pattern known as follicular mucinosis.

Storiform patterning
This is a pattern of proliferation commonly seen in various dermal and soft-tissue tumours, where strands of spindle-shaped tumour

cells or even collagen bundles are arranged so as to resemble the pattern seen in woven cloth. The term is also sometimes applied to the presence of strands of spindle-shaped tumour cells or connective tissue cells that appear to extend radially from a central hub, similar to the spokes of a wheel. Cartwheel patterning is probably a better term to describe this particular appearance. Storiform and cartwheel patterning, although commonly referred to in DFSP, are by no means specifically diagnostic (Fig. 10.20a).

Theque

This term is derived from French and Greek words for a box (*thèque*, θηκη) and is conventionally used in dermatopathology to describe small aggregates or nests of cells, particularly the collections of naevus cells at, and in the region of, the dermal–epidermal junction.

Villi

This term refers to elongated dermal papillae covered usually with a single layer of epidermal cells, and which form the base of a blister cavity that has resulted from the process of suprabasal acantholysis. Villi are seen in the various forms of pemphigus and Darier's disease (see Fig. 10.26), warty dyskeratoma, and transient and persistent acantholytic dermatosis.

Special problems that may be encountered in skin biopsies

Histological sections that reveal little or no abnormality

It is not uncommon for the diagnostic dermatopathologist to come across histological sections where at first sight the appearances resemble normal skin. It may be that the pathological changes have been missed. This can be the fault of the clinician who has perhaps taken too superficial a biopsy from a lesion of suspected panniculitis, or it can be the fault of the pathologist who has inappropriately blocked the biopsy specimen, or taken too few sections from the material. The importance of studying numerous serial sections in this situation cannot be overemphasized. There are a number of conditions, however, where subtle pathological abnormalities are present, but where a high index of suspicion is needed to make a correct diagnosis. The following list includes some of the more important of these.

Epidermal lesions

Fungal infections. In the presence of patchy epidermal spongiosis and focal overlying parakeratosis, it is always important to exclude the presence of a fungal infection with a PAS stain. Occasionally, a few neutrophil polymorphs may be seen in the upper Malpighian layer of stratum corneum, and this may provide a clue to the correct diagnosis. Pityriasis versicolor may be present in the absence of spongiosis, and is frequently missed.

Ichthyotic disorders. The dominant form of ichthyosis vulgaris is usually characterized by some degree of compact hyperkeratosis, and an absent or attenuated granular layer. If the hyperkeratosis is not significant, the diagnosis may be overlooked. When assessing the stratum corneum, it is always important to look at not only the thickness, but also the quality of the corneocytes. An alteration from the normal basket-weave pattern to a compact cornified layer usually indicates some pathological abnormality.

Porokeratosis. The epidermal changes, usually of atrophy, in the various forms of porokeratosis are often not striking, and the diagnostic cornoid lamella may not be seen on the first sections cut from the block. In diagnostic biopsies, the cornoid lamella may not be present. All forms of porokeratosis may be misdiagnosed, but the disseminated actinic form of the disorder is the most commonly overlooked.

Actinic keratoses. Some flat actinic keratoses may show very little evidence of keratinocyte atypia, and unless a reasonable amount of normal skin is included the biopsy material may be signed out as non-diagnostic.

Pigmentary disorders

Various disorders of epidermal pigmentation may be difficult to diagnose with certainty, particularly if one is not certain of the skin colour of the patient from whom the biopsy has been taken. The loss of pigment in established vitiligo is normally associated with absence or reduction in number of melanocytes. However, in café-au-lait spots and ephelides, melanocytes are normal in number. A melanin stain may reveal a difference between lesional and adjacent skin. In post-inflammatory hypo- or hyperpigmentation, the number of melanocytes remains normal with increase or decrease in melanin in basal cells. Often, melanophages are seen in the papillary dermis particularly in post-inflammatory hyperpigmentation.

Dermal deposits

The small amounts of amyloid seen in macular amyloidosis are often difficult to visualize with H&E stain. Special stains are indicated, but the presence of slightly expanded dermal papillae, together with a hint of lichenoid tissue reaction, may alert the pathologist to this possibility. A further useful clue is the presence of scattered apoptotic keratinocytes. The presence of iron pigment in small quantities in the dermis is easily missed, either in common conditions, such as bruising, or in rare situations, such as idiopathic haemochromatosis. A Perls' stain usually highlights iron deposits that have not been detected in slides stained with H&E. The deposits of silver in argyria are often best seen around the basement-membrane zone of dermal sweat ducts.

Connective tissue diseases

Scleroderma, particularly in the late stages, often shows little histopathological abnormality. The coarsening and hyalinization of collagen bundles, with a reduction in the space between them, is often not prominent particularly in the superficial form of morphoea. In the early stages of the condition, there is normally some increase in cellularity around dermal blood vessels. It is always important to try and assess normal skin if there is some present in the biopsy. Similar problems may be encountered with various forms of connective tissue naevi, and abnormalities of elastic tissue such as anetoderma. In atrophoderma, the elastic pattern is more or less normal, but there is a reduction in total thickness of the dermis, which may be difficult to evaluate. A solution to this

problem is to obtain an ellipse of skin in which half of the specimen represents clinically normal skin. To indicate the clinically normal skin, the clinician marks the specimen with a stitch.

Dermal infiltrates

Urticaria. In biopsies from urticarial lesions, there may be very little more than slight dermal oedema, which is often difficult to evaluate on processed tissue, together with a slight increase in inflammatory cells around upper dermal blood vessels. It should be remembered that, in normal skin, a few mononuclear cells, fibroblasts and other cells are present in the dermis. A clue to the diagnosis of urticaria is the presence of at least a few eosinophils.

Blue naevus and related disorders. The dendritic melanocytes seen in the dermal melanocytoses, particularly Mongolian spot, are often difficult to recognize without the use of special stains such as the S-100 immunohistochemical marker. The main problem resides in the distinction between melanophages and melanocytes, as most dermal melanocytoses excluding blue naevus contain only few scattered dermal pigmented melanocytes. The use of an immunohistochemical marker for melanocytes such as S-100 is useful, but the product obtained in the detection of the final peroxidase product is usually brown and this is very similar to melanin. This problem can be overcome by bleaching the slide before immunohistochemistry, or by changing the diaminobenzidine for amino-ethyl carbazole, which results in a red product.

Granuloma annulare. In the majority of cases this diagnosis is straightforward, with evidence of a dermal palisading granuloma with necrobiosis. However, in the disseminated form of the condition the changes are often very slight, and may be represented by just a few mononuclear cells dissecting bundles of collagen.

Mast cell disorders. The adult form of urticaria pigmentosa, and particularly its variant telangiectasia macularis eruptiva perstans, frequently shows only a relatively slight increase in numbers of mast cells within the dermis. In these forms of urticaria pigmentosa, the mast cells tend to be rather dendritic or short spindle-shaped. Their granules may not be obvious, and they may resemble normal connective tissue cells, such as fibroblasts. In mastocytoma and some juvenile forms of mastocytosis, the mast cells are larger, rounded cells with central nuclei and are easier to recognize.

Scalp disorders

Unless an adequate biopsy is available for examination, many disorders of the scalp may be difficult to evaluate. Conditions such as telogen effluvium and long-standing alopecia areata show very little sign of inflammation, and diagnosis may have to be made purely on the number of pilosebaceous structures, and the relative number of follicles in different phases of the hair cycle. The study of horizontally sectioned biopsies is the ideal method to study hair follicles with regards to their cycle, pathological alterations and numbers (see Chapter 66).

Conclusion

As mentioned at the start of this chapter, histopathological examination of a skin biopsy taken from an appropriate lesion is a great help in assisting the clinician to come to a correct diagnosis, and therefore to come to a decision regarding management of the patient. Light microscopic examination of sections from skin-biopsy tissue fixed in formalin and embedded in paraffin is likely to remain the single most useful diagnostic technique for the foreseeable future. The wide range of tissue and cytological changes that may be encountered within normal skin and inflammatory and neoplastic conditions mean that considerable experience is required for the dermatopathologist to contribute helpfully to patient management. Many excellent texts are now available on the histopathology of the skin, but there can be no substitute for personal study on a day-to-day basis of as much material as possible under the supervision of an experienced guide. Feedback and communication between clinician and pathologist is essential, and has been perhaps one of the most important factors in the advances in dermatopathology in the last decade. The light microscopist already has a very wide range of additional techniques available to assist in diagnosis and to study the anatomy and physiology of normal and diseased tissues, some of which are outlined above. The numerous new areas of investigation that have developed over the last few years, including molecular biological techniques, such as PCR, *in situ* hybridization and studies on biological response modifiers, cytokines and adhesion molecules, will no doubt continue to further major advances in our understanding of skin in health and disease.

Introduction

There is no single, all-embracing definition of molecular biology. However, it is possible, certainly with hindsight, to plot and recognize the growth of a unique blend of biochemistry, genetics and cell biology—the subject we now call molecular biology—which is having a revolutionary impact on all areas of biology, not least clinical medicine. The Nobel Laureate James Watson and colleagues, writing in a preface to one of the standard texts of molecular biology, commented that whereas only 25 years ago it was possible for one individual to know all the important topics in molecular biology, this was no longer the case [1]. This explosion of knowledge is not just due to a revolution in our conceptual understanding, but owes as much to an astonishing expansion in our technical facility to characterize and manipulate nucleic acids (both DNA and RNA) and the resulting proteins. Several features of the organization and structure of nucleic acids go some way to explaining the power of this gene-centred approach to biology. Genetic information is conveyed in a *linear* sequence of only four bases; genes are *collinear* with proteins; and genes themselves are arranged in chromosomes in a fixed *linear* sequence, without which cloning of genes on the basis of position (so-called positional cloning or reverse genetics) would be impossible. What is still extraordinary, and was once not obvious, is how much biologically meaningful information can be revealed by merely understanding the linear base sequence of a particular gene [2].

The development of molecular biology as a discipline has not been a gradual, step-by-step process but, by contrast, has faltered at several stages [1–5]. Intellectual landmarks include Avery's work with *Pneumococcus*, demonstrating that nucleic acids (rather than protein) carry genetic information; Watson and Crick's Nobel Prize-winning description of the structure of DNA; and subsequent work by Crick, together with Brenner and others in the late 1950s and early 1960s, describing how information encoded by DNA was realized in protein structure [1–5]. In the early 1960s, however, there was a hiatus lasting until perhaps the mid 1970s. At this stage, many of the ground-breaking discoveries, whilst having a general applicability, were experimentally limited to simple organisms such as bacteriophages or bacteria. There were not the experimental tools to allow human genome analysis and, consequently, genetic approaches to disease were still beyond reach. In the 1970s, a number of fundamental advances in an area that would later become known as biotechnology changed this situation. The identification and experimental manipulation of plasmids and the identification of restriction, and other DNA-modifying, enzymes heralded a new era in our ability to study the human genome and start utilizing genetic approaches to human disease. In particular, combinations of techniques, together with considerable insight, led to the ability to study those rare but important differences between individuals' protein-coding DNA, which are the cause of most inherited disease. Perhaps counter-intuitively, the detection of variation in non-coding DNA (so-called 'junk DNA') was also to have a great influence; virtually all present-day mapping of disease-causing genes relies on such variation. In addition, an ever-enlarging armamentarium of techniques allowed the increased experimental manipulation of DNA, including the reintroduction of DNA into cells, firstly in culture and later into animals, leading to the development of transgenic technology. This new biology now permeates all areas of clinical medicine, and dermatology is no exception; there has been astonishing progress in identifying the genes for a host of skin disorders. As well as providing and hinting at explanations for the underlying pathophysiology of these diseases, these advances promise an increase in the speed of development of new therapeutic approaches, either those based on genes themselves, such as gene therapy, or by allowing a quickening of the pace of drug discovery. Finally, the Human Genome Project, an international effort using high throughput sequencing started in 1990 and completed in 2007, has led to sequence information on the estimated 3.1 billion base pairs of DNA and approximately 25 000 genes in the human genome [6].

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

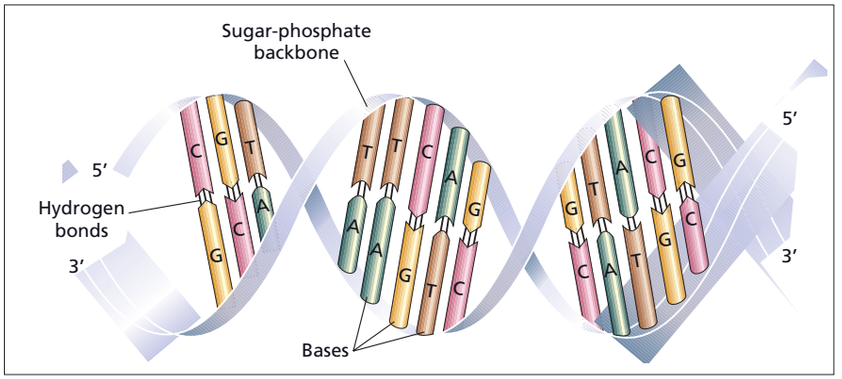

Fig. 11.1 Schematic of the DNA double helix. The backbone of the helix is made up of sugar and phosphate moieties that run in opposite directions (5′→3′ and 3′→5′). The strands are linked by the bases, which pair via hydrogen bonds in a particular fashion, cytosine with guanine, and adenine with thymine. Because of the specific nature of the base pairing, if the hydrogen bonds are broken, each strand can act as a template for the other, such as occurs at transcription of DNA into RNA or when DNA is replicated. It is also evident that because each strand of DNA is complementary to the other, then one strand can be used as a probe for the other.

It is not possible within this chapter to give a comprehensive or even fair treatment of the whole of molecular biology as it applies to dermatology. For those interested, there are some unusually readable (and exciting) books on molecular biology/genetics to which the reader is directed [1,2,4,6–8]. Nor can the chapter be viewed merely as a catalogue of genetic disorders of the skin; review of the Online Mendelian Inheritance in Man (OMIM) database suggests that up to one-third of the listed disorders may involve the skin. However, what I will try to do is: (i) briefly review the structure of nucleic acids; (ii) explain how the structure of DNA allows the development of a number of techniques, which in turn permits further analysis of the relation between genes and organisms; and (iii) give examples of how molecular biological approaches have been informative for the study of skin disease, including a section on cancer genetics. Finally, a brief summary is given of the use of molecular biological techniques in diagnosis and therapy.

Basic molecular biology of the cell

Structure of nucleic acids (DNA and RNA) [1–3]

DNA is an antiparallel double helix in which the backbones of the helix are made from sugar and phosphate groups; these are linked by one of four bases (cytosine, guanine, thymine and adenine) that form hydrogen bonds with a complementary base on the opposing backbone (Fig. 11.1). The primary genetic information is coded by the pattern of these bases. Importantly, and central to the Watson and Crick model, cytosine always binds with guanine, and adenine with thymine. Because these base pairings are held together by hydrogen bonds only, one can imagine how, if the bonds are broken (such as by treatment with heat), each strand of DNA could act as a template for the opposing strand. Each cell in the human body contains 3.3 billion base pairs of DNA packaged into 46 chromosomes (22 pairs of autosomes and 2 sex chromosomes, X and Y). If DNA were unravelled, the length of DNA in each cell would be 2 m; that from a human body would stretch further than to the moon and back!

Surprisingly, perhaps 90% of the DNA on chromosomes does not appear to code for protein, and is therefore often referred to as 'junk DNA'. Much of this DNA is made up of repeated sequences of DNA, the function of which is unclear. It has, however, been experimentally fortuitous, in that this 'junk DNA' is a rich source of genetic variation between individuals, and forms the basis for genetic mapping of disease traits. Thus for any one chromosome, the genes residing on that chromosome will be diluted by a much larger volume of DNA that does not appear to code for protein. Finding genes is therefore sometimes like searching for a needle in a haystack, even when the area of a chromosome harbouring a gene for a particular disorder has been closely localized by mapping of the disorder in affected kindreds. Not only are genes arranged on chromosomes in an intermittent way, but while genes and proteins are collinear, the DNA that directly codes for particular groups of amino acids is in itself discontinuous on the chromosome, being arranged into introns and exons (Fig. 11.2).

With certain important exceptions (which are not central to this description), DNA in every cell in the body is identical in terms of its primary structure. The keratinocyte's DNA is the same as that in a red-cell precursor or a neurone. This immediately raises the problem of how a keratinocyte knows how to make keratins, a red-cell precursor globins and a neurone synapses. How do the different types of cells produce different proteins if they carry identical DNA? DNA is transcribed into RNA, which is then translated into protein. If one were to examine the RNAs produced in these different cell types, one would detect differences. A major area of interest in molecular biology has therefore been in understanding the control of such differences in *gene expression*. This control occurs at two main levels: first, transcription—whether particular RNAs are copied from a particular gene; and second,

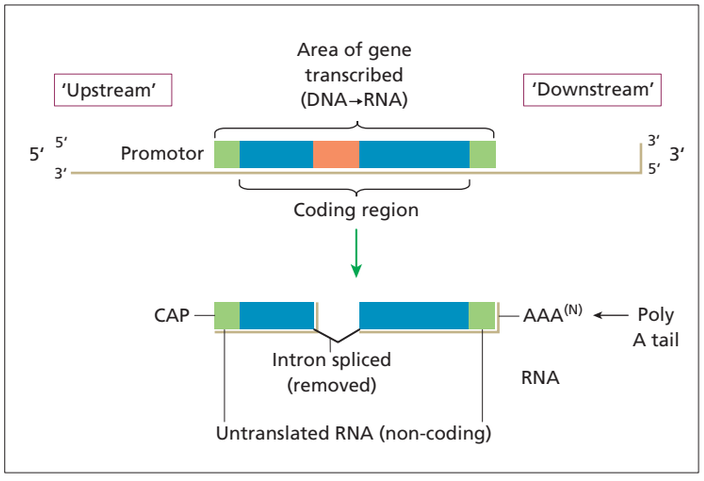

Fig. 11.2 Schematic of a gene and transcription to, and processing of, RNA. The gene comprises the transcribed region, which largely consists of the coding region (including the introns, which will be spliced out and do not code for protein) and the upstream and downstream regions. The promoter region is upstream, although sequences important in determining the level of gene expression in response to a variety of stimuli can be located upstream or downstream. DNA is transcribed into RNA by a DNA-dependent polymerase and the resulting RNA strand processed by removal (splicing) of introns, addition of a string of adenines at the 3′ end (polyA tail) and 'capping' of the 5′ end. Some of the RNA that is transcribed and not spliced out (the untranslated 5′ and 3′ sequences) does not code for protein, but appears to be important for RNA stability and translation into protein. The number of introns is extremely variable: some genes have no introns, whereas others have hundreds of introns, with the length of the introns greatly exceeding the length of the region that directly codes for protein.

translation—whether proteins are then made from any particular RNA molecule. Whether a particular gene is transcribed into RNA is determined by the interaction between a variety of proteins in the cell, and by extracellular signals mediated through a number of pathways that interact with RNA polymerases (enzymes that copy DNA into RNA) via the promoter region of the gene. The promoter, located (usually entirely) 5′ to the coding region of the gene ('upstream'), functions akin to an on/off and volume control on a CD player, controlling whether, and how much, gene transcription takes place in response to instructions received from a myriad of pathways. Transcription factors are proteins that bind to the promoter region of a gene to activate transcription. Various signalling pathways control the transcription of a gene, depending on the transcription factor that binds to the specific gene promoter, and this is a complex area of molecular biology. As mentioned above, the gene itself is likely to be discontinuous, such that the RNA produced may contain what are called introns (areas that do not code for protein), which are cut or spliced out once the RNA is made (see Fig. 11.2). The spliced version of the RNA then proceeds to the ribosome (in the cytoplasm) where protein synthesis occurs. Other changes to the RNA also occur, including the addition of a string of adenines (the so-called polyA tail, which appears to be important for the stability of the RNA) and a process termed capping at the 5′ end of the RNA (see Fig. 11.2). The structure of a protein from the same gene may therefore differ in different cells, depending on the splicing and any other changes to the RNA. Throughout this transfer of information, however, it is the linear sequence of bases within and around the gene that appears important in determining the structure of the protein. Within the coding region of the gene, each group of three adjacent bases ('triplet') specifies a particular amino acid. Outside the coding region, although the DNA may not code for protein directly, the pattern of bases, particularly that before the start of a transcription site in the promoter of the gene, is also important in determining the level of transcription (in response to a variety of stimuli). Primary sequence is therefore more than just a shorthand for the three-dimensional structure of the resulting protein.

Table 11.1 Differences between nuclear and mitochondrial genome (adapted from [5]).

Characteristic	Nuclear genome	Mitochondrial genome
Size of genome	3.3×10^9 bp	16569 bp
Number of genes	25000–30000	37 (13 encoding proteins, 22 transfer RNAs and 2 ribosomal RNAs)
Introns	Frequent	Absent
Transmission	Mendelian	Maternal
Transcription	Genes transcribed individually	Genes transcribed as large polycistrons
Coding DNA	Approximately 3%	93%

Mitochondrial DNA

Mitochondria are intracellular organelles that are involved in cellular aerobic respiration, including generation of ATP, and in cell signalling, particularly cell death pathways. Mitochondria contain their own DNA, which is inherited from an individual's mother [4]. Some of the differences between mitochondrial and nuclear DNA are given in Table 11.1.

Mitochondrial DNA mutations can contribute to ageing and associated disease such as type 2 diabetes, neurological disorders, photoageing and skin cancer [5,6].

Molecular techniques

Extraction of nucleic acid is straightforward. Take a few millilitres of blood, or a small skin biopsy, treat with a proteinase overnight, separate the nucleic acid from protein using phenol and chloroform, and then precipitate the several hundred micrograms of DNA with cold alcohol. This procedure is straightforward but

time consuming and so kits, available from several manufactures, are now commonly used to extract DNA in as little as 30 min. The resulting DNA can be easily pelleted in a microcentrifuge, and appears as a slightly yellow, sticky substance that can subsequently be dissolved in water and assayed on the basis of its absorption of UV radiation. This isolated DNA is made up of the 3 billion bases of genomic DNA from each cell, multiplied by the 100 million or so cells from which the DNA has been extracted. However, at this level of analysis, the DNA from different individuals would look much the same. Mere examination with the eye does not provide any insight into the primary base sequence. The technical revolution in the last quarter century allows such analysis. While whole volumes are devoted to describing the techniques of molecular biology, the principles involved are usually straightforward, and it is often possible intuitively to appreciate how and why they work, and to see how they take advantage of the basic structure of DNA.

Restriction enzymes are naturally occurring enzymes that cleave DNA in a sequence-specific manner. They have been identified in a variety of bacteria, where their principal function seems to be to defend bacteria against particular forms of bacteriophage infection (the principle being that particular sequences might occur in an invading organism but not in the host, and that enzymes specific for these sequences would be able to defend the host from invasion). If the DNA isolated from blood or skin, which consists of pieces upwards of 50 kilobases (kb) in length, is suspended in buffer and incubated with a restriction enzyme, the DNA is cleaved into much smaller fragments. The exact size of the fragments depends on the particular restriction enzyme chosen; some might be expected to cut the DNA every few hundred base pairs, whereas others whose target sequence is not so common might only cut once every million base pairs or so. It is therefore possible to characterize the DNA in terms of its primary sequence structure based on the pattern of fragments obtained following restriction enzyme digests. Furthermore, differences between DNA from different individuals (which are particularly common in the non-coding region of DNA) may show up as differences in the size of the fragments following digestion with particular restriction enzymes (Fig. 11.3). An important feature of many restriction enzymes is that although their action depends on the presence of a particular sequence of bases, DNA is cleaved in such a way that, with another enzyme known as DNA ligase and a source of energy, it can be stuck together again—'cut and paste' in word-processing terminology. This 'cut-and-paste' facility allows small pieces of DNA (say a couple of kilobases long) that have been cut with the enzyme to be inserted into a vector such as a plasmid. The subject of vectors may appear confusing but, for present purposes, molecular biologists have identified and created a whole range of experimental vehicles that allow the propagation of DNA; very much the workhorses underlying the phrase 'cloning of DNA'. A commonly used vector is a plasmid. Plasmids are naturally occurring, extrachromosomal, circular pieces of DNA found in bacteria. Their medical importance is that they may carry antibiotic-resistance genes and transmit these from one bacterium to another. Experimental manipulation makes it possible to 'cut and paste' a piece (an 'insert') of DNA into a plasmid, *transfect* the plasmid back into a bacterium, and wherever the bacterium divides, the plasmid and insert will also be copied. Because bacteria can grow in an exponential fashion, this technique allows large amounts of the insert to be produced (cloned).

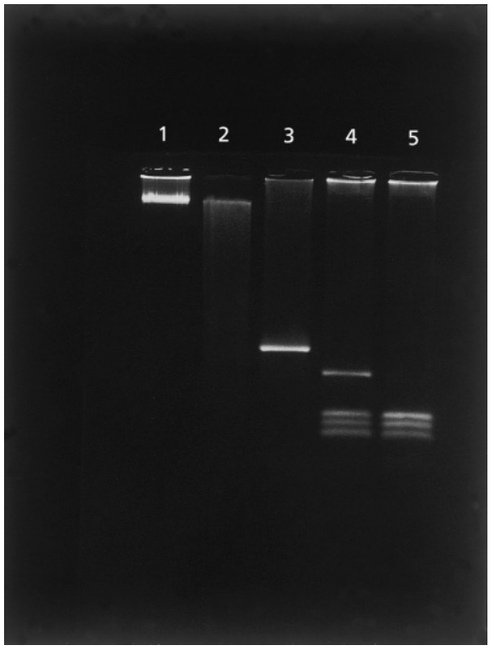

Fig. 11.3 DNA labelled with ethidium bromide and run through an agarose gel and examined under a UV radiation source. Ethidium bromide intercalates into DNA and fluoresces in response to short-wave UV radiation. The first two tracks show a sample of genomic DNA before and after digestion with a restriction enzyme (note the smearing present in track 2). Track 3 shows the human melanocortin 1 receptor (melanocyte-stimulating hormone receptor) amplified using the polymerase chain reaction (PCR). Tracks 4 and 5 show the PCR, shown in track 3, from two individuals digested with a restriction enzyme which reveals a polymorphism due to a mutation at codon 84 of the melanocortin receptor gene.

Additionally, it is possible to restrict (in other words, digest with a restriction enzyme) the DNA isolated from a cell, and 'paste' many of the resulting small pieces of DNA into plasmids (or other suitable vectors), such that each vector will contain only one insert of DNA and that the majority of plasmids would be expected to contain a unique insert. These plasmids can then be transfected back into bacteria, and the resulting collection of bacteria containing many different plasmids comprises a *DNA library*—a representation of a cell's DNA, now in a form that can be cloned, promulgated and used experimentally. An analogous technique can be used to make a complementary DNA (cDNA) library, that is a library that represents the RNA species expressed by a particular cell, in which each 'book' corresponds to a particular RNA molecule (Fig. 11.4). Unlike DNA, RNAs are not ordered in the cell in linear arrays like genes on chromosomes, but rather the RNA from a particular cell consists of hundreds of thousands of individual RNA molecules, each of which can be translated into a particular protein. Unlike DNA, RNAs are expected to differ dramatically between different cell types: keratinocytes will produce a large number of RNAs coding for keratins, whereas these would not be seen in a red-cell precursor, which by contrast will be rich in globin RNAs, and vice versa. Because RNA is diffi-

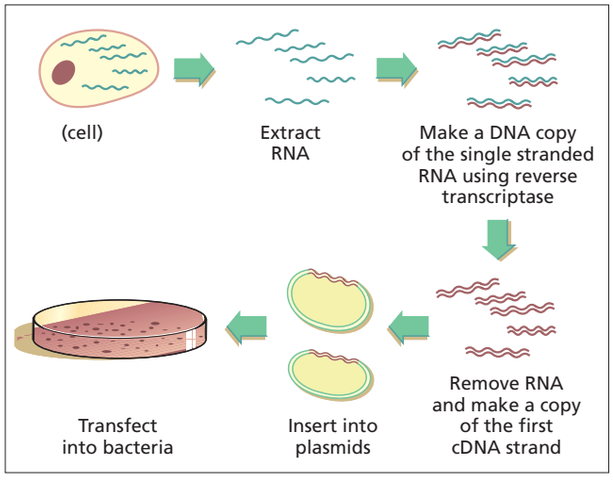

Fig. 11.4 Making a complementary DNA (cDNA) library. RNA (single stranded) is extracted and a cDNA copy of the RNA made using reverse transcriptase. The RNA is then removed, and the first strand of cDNA acts as a template for the second strand of DNA. The short fragments of double-stranded DNA (inserts) are then 'pasted' into plasmids, transfected into a suitable bacterial host, cultured and plated out on agarose. Each bacterial colony will contain a clone of bacteria that contains only one insert. The number of colonies expressing the same insert should reflect the frequency of the RNA species in the cells the library has been made from. Libraries can also be made from genomic DNA, in which case no cDNA synthesis is necessary, but because the desired fragments to be cloned are larger, a variety of other vectors (rather than plasmids) are used.

cult to manipulate experimentally, the RNA species can be converted using reverse transcriptase into a cDNA—very much the reverse of normal transcription, which converts DNA into RNA—and the resulting DNA inserted into a plasmid, such that the population of plasmids now represents the RNA species in any one cell. The resulting library is known as a cDNA library, 'c' because it is complementary to the RNAs in the original cell.

Southern and northern blotting

If the DNA extracted from a eukaryotic cell is cut with a particular restriction enzyme, the resulting fragments might be expected to differ between different individuals, the organization of the fragments therefore providing information about any DNA sequence differences. In order to display the DNA, it is possible to order the resulting fragments of DNA by passing them through an agarose gel within an electric field. The charged DNA molecules will migrate through the gel depending on their mass, with the smallest fragments travelling furthest. However, once the nucleic acid has migrated through the gel, it can be conveniently transferred to a nitrocellulose (or better still a nylon) membrane, in a process called Southern transfer (Fig. 11.5). The DNA is then fixed (cross-linked) to the membrane (which, while looking like a piece of paper, has similar tensile properties to a plastic carrier bag) using UV radiation. Importantly, although the nucleic acid is now covalently bound to the membrane, it is still free to take part in hydrogen-bond reactions. This transfer of DNA from an agarose gel to a membrane is known as Southern blotting, after its inventor Ed Southern; northern blotting (a pun on Southern!) refers to the transfer of RNA and western blotting to the transfer of proteins.

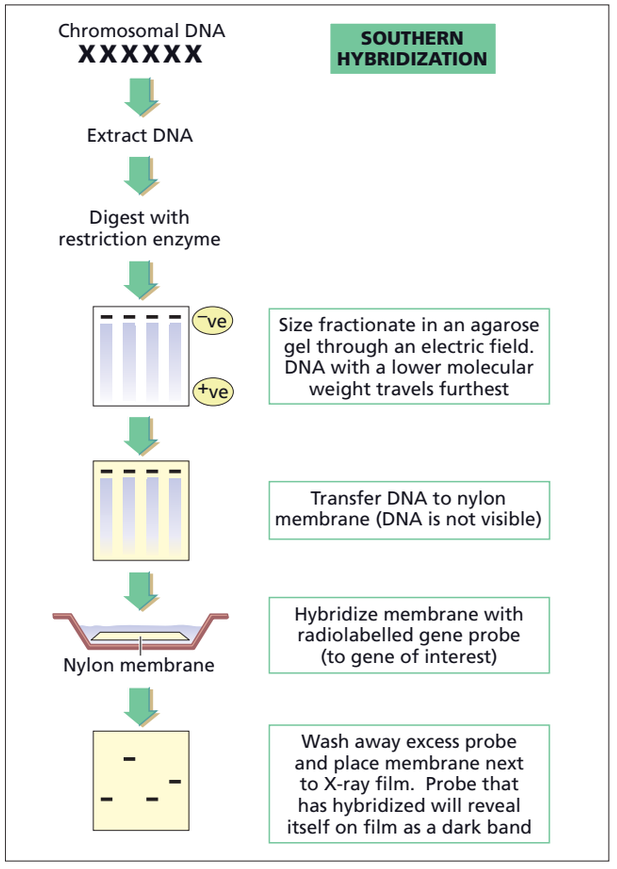

Fig. 11.5 Southern hybridization. Genomic DNA extracted from cells can be cut with a suitable restriction enzyme and then size-fractionated through an agarose gel within an electric field. The DNA in the gel can then be transferred (or blotted) to a nylon (or nitrocellulose) membrane, which is then hybridized with a radiolabelled probe complementary to the target sequence. Following hybridization, the membrane is washed to remove excess probe and sequences that have bound non-specifically. The membrane is then placed next to radiation-sensitive film overnight. Wherever the radiolabelled probe has bound to a complementary sequence, a band will be visible on the film. In this example, DNA from four individuals was run on the gel and hybridized. The differences in the position of the black bands on the autoradiograph reflect that the size of the DNA fragment containing the gene of interest differs between individuals. The most likely explanation for this polymorphism is that the restriction enzyme has cut the DNA differently because of variations in the DNA between the individuals close to, but probably not within, the gene of interest (see text). A similar procedure can be carried out to examine RNA expression and is called northern (as compared with Southern) blotting. Because RNA molecules exist individually rather than as large chromosomes (as for DNA), no restriction digestion is necessary; the details of the transfer of RNA to a nylon membrane also differ from that needed for DNA. When the membrane is placed next to film, the intensity of the resulting band will reflect the amount of that RNA species in the target cell of interest. More than one band may be seen in a single track, reflecting differences in how the RNA is spliced (there may be more than one splice variant in a particular cell).

Because RNAs exist as individual molecules rather than as long arrays on chromosomes like DNA, RNA extracted from cells is fractionated immediately, and does not have to be first digested with restriction enzymes.

Following Southern blotting, the DNA attached to the membrane will not be visible to the naked eye, although it is possible to see the DNA when it is size fractionated through an agarose gel

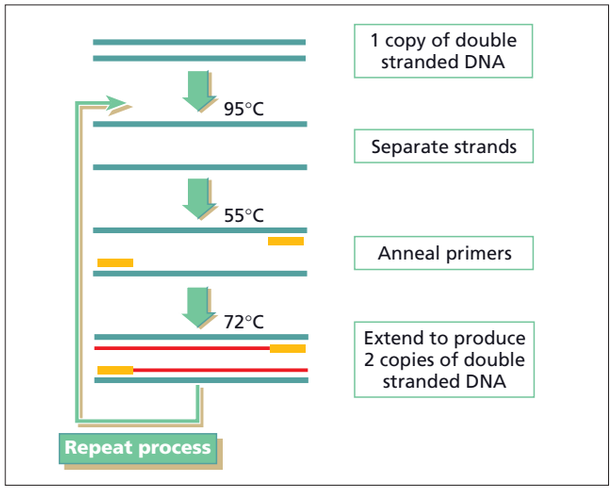

Fig. 11.6 Polymerase chain reaction (PCR). A double-stranded molecule of DNA is denatured into two complementary strands using heat (95°C). Primers are short stretches of DNA, usually 18–25 base pairs in length, complementary to sequences on the separated strands of DNA. For the primers to anneal, the temperature needs to be approximately 55°C, and the presence of a primer is essential for the polymerase (plus the necessary bases and energy) to make complementary copies of each strand of DNA ('extension'). The two double-stranded molecules that are produced can then act as templates for further rounds of replication; hence the term 'chain reaction'. The technical breakthrough that has made PCR so successful was the discovery of polymerases that are so heat stable that they are not destroyed during the denaturation (strand separation) step (such polymerases were found in bacteria that inhabit hot springs).

by virtue of the fact that dyes such as ethidium bromide intercalate in DNA and fluoresce under UV radiation (see Fig. 11.3). If such a gel or membrane is examined, a long smear comprising millions of molecules of DNA will be evident; for most purposes it will be necessary to characterize the DNA further, so that individual genes or stretches of DNA can be examined (see Fig. 11.3). This is usually accomplished by using a labelled gene probe that is complementary to the target of interest, which will bind to the target nucleic acid located somewhere within the smear (and which will comprise only a tiny fraction of the total DNA, for instance one gene out of 25 000).

Polymerase chain reaction (PCR)

Mention has already been made of the use of DNA or RNA polymerases, enzymes that allow copies of a nucleic acid to be made. For example, a DNA-dependent DNA polymerase will make complementary DNA copies of a DNA molecule, whereas reverse transcriptase is an RNA-dependent DNA polymerase and will therefore make DNA copies of RNA. As well as an energy source and the necessary nucleotide bases, most polymerases require a primer or short sequence of DNA complementary to the strand to be copied, from which to start the synthesis of the complementary copy. The most celebrated use of DNA polymerases is *PCR* (Fig. 11.6), application of which has revolutionized much of molecular biology and more recently clinical diagnostics. The principle underlying PCR is that if primary sequence information is available for a primer area (usually 15–25 bases long) outside the target area of interest, then once a copy of both strands is made using a DNA polymerase and the resulting daughter strands reanneal, heating the DNA to near 100°C causes the daughter strands to separate again and in turn act as templates for further rounds of replication. The technical breakthrough has been the identification of thermally stable DNA polymerases that are not destroyed by the high temperature needed to separate the complementary strands. Intuitively, one can see that this replication is logarithmic, and therefore PCR allows the amplification of DNA many millionfold. In practice, there are some constraints: amplifying short sequences of 400–500 bases is straightforward but the limit is reached at around 10–15 kb; the extreme sensitivity of the technique can also be a disadvantage, as laboratory contamination can be a major hazard, a drawback which should not be forgotten when PCR is used to diagnose infectious agents in clinical biopsies.

In *reverse transcription PCR* (RT-PCR), RNA is extracted from tissue or cells, converted to its corresponding cDNA and then this cDNA is subjected to PCR. The amplified PCR product is then run on an agarose gel (as in Fig. 11.3). The technique is extremely sensitive and has been of great use in the study of gene expression patterns in skin pathophysiology. Its utility in skin disease has partly been because of the difficulty of extracting high-quality RNA in large amounts from intact skin (as compared with cell culture). The main disadvantage of PCR is that because it is so sensitive, DNA species of little biological purpose may be amplified. *Real-time PCR* is identical except the progress of the reaction is monitored in real time. A fluorescent probe (e.g. Taqman-type probe), complementary to the gene of interest, binds to the DNA and fluorescence increases with the number of copies of DNA allowing quantitation of gene expression. A major advantage of real-time PCR is that running a gel is not necessary.

DNA sequencing

DNA-dependent polymerases also play a central role in the commonest method of sequencing DNA. As long as there is a cloned source of DNA, either from the gene being cloned in a plasmid or from PCR, it is possible to determine the primary base sequence. This makes use of a DNA polymerase and the four nucleotide bases, only one of which is labelled; in the original method a radioactive label was used. As well as bona fide bases, particular nucleotides ('terminators') are added to the mix; these cause the DNA polymerase to fall off the template, resulting in complementary strands that have terminated prematurely. These aborted transcripts will therefore reveal themselves as shorter fragments when the products of the reactions are run on a polyacrylamide gel, resulting in a ladder of lines that will reflect the primary sequence. If separate terminator bases are used in each of the four reactions, one for cytosine, one for guanine, one for thymine and one for adenine, and the resulting four reactions are run out side by side on a gel, then the resulting pattern of radiolabelled, prematurely terminated bands will correspond to the primary sequence (Fig. 11.7).

For large-scale sequencing, such as was necessary to sequence the human and mouse genomes, new technology had to be developed. In dye-terminator sequencing, each of the four dideoxynucleotide chain terminators is labelled with a different fluorescent dye, which emits fluorescence at a specific wavelength. This is

Fig. 11.7 An example of a DNA sequence obtained using the dideoxy method of sequencing for which Sanger was awarded a second Nobel prize. Essentially, copies of the template are made using a DNA polymerase only. The presence of dideoxynucleotides (instead of deoxynucleotides as in normal DNA) in the reaction causes the template copies to terminate prematurely. Four such copying reactions are carried out, one for each dideoxy base, such that the reaction terminates where the base was being added. When the products of all four reactions are run out on one gel, then reading across the bands reflects the order of premature termination products, which in turn reflects the primary sequence of the DNA strand being copied. This method is now mainly of historical interest only. (Courtesy of M. Birch-Machin, Department of Dermatology, University of Newcastle, Newcastle, UK.)

analysed by computer and the data output is a fluorescent peak trace chromatogram (Fig. 11.8). This technology reads about 67 000 base pairs per hour. However, newer higher-throughput sequencing technology is now available, such as 454 (Roche) or Solexa (Illumina) sequencing [1].

RNA interference

RNA interference (RNAi) is a mechanism that inhibits gene expression through degradation of specific mRNA molecules. This phenomenon of gene-specific silencing was described initially in petunia plants before its recognition as a widespread, possibly universal, mechanism. The discovery that RNAi is active in mammals opened the gates for the possibility of effectively silencing virtually any gene with a known sequence, either for basic scientific interest or for therapeutic purposes [2]. The RNAi pathway is triggered by double stranded RNA (dsRNA) molecules sharing sequence-specific homology to particular 'target' mRNAs. The RNase III enzyme, Dicer, is a key molecule in the RNAi pathway as it binds and cleaves long dsRNA molecules into short fragments, known as small interfering RNAs (siRNAs). siRNA duplexes are small, 19-bp dsRNA molecules, bearing two-nucleotide (nt) 3′ overhangs at each end. siRNA duplexes mimic the structure of mature *microRNA* (miRNA) duplexes, which are genomically encoded RNAs that do not code for proteins and are involved in regulating gene expression, particularly during development. It is estimated that there are about 500 miRNAs in mammalian cells, regulating about 30% of genes [3]. The RNA-induced silencing complex (RISC) (Fig. 11.9) incorporates one of the two strands of the siRNA duplex, known as the antisense or guide strand, where it acts as a guide RNA to direct the RISC to complementary mRNAs, while the second strand is degraded. A critical component of the RISC, the Argonaute-2 (Ago2) protein, then cleaves the targeted mRNA at a defined position; the targeted mRNA is then degraded by cellular RNAses, thereby preventing it from being used as a translation template. The exogenous introduction of synthetic siRNA duplexes (19–25 bp in length) directly into the cell is a simple and effective technique to induce transient RNAi. These siRNAs act catalytically at non-toxic, low nanomolar concentrations and are capable of cleaving up to 95% of the target mRNA in the cell (Fig. 11.9).

Genomics

Human genomics is the large-scale study of the entire human DNA sequence. Studying the human genome has required the development of appropriate technology to manipulate and sequence DNA and appropriate computer software to analyse the large amounts of information generated. A single nucleotide polymorphism (SNP, pronounced snip) is a single nucleotide substitution in DNA. There are over 10 million SNPs listed in the dbSNP database. A haplotype is a set of SNPs on a single chromosome that are likely, statistically, to be inherited together. The emergence of microarray chips has facilitated both the study of SNPs and gene expression, at the transcriptional level. A gene expression 'chip' has thousands of DNA probes at high density on silicone slides or beads on a slide. Target RNA is reverse-transcribed, fluorescently labelled and hybridized to the slides and the signal read as fluorescent intensity. Because more than one fluorescent label can be used, the relative intensity of RNA from different tissues or cells that have undergone an experimental intervention can be hybridized at the same time and the readout quoted as the ratio of expression in one sample to that in another (based on the ratio of fluorescence for each probe). This allows the characterization of gene expression from cells in culture or from tissue.

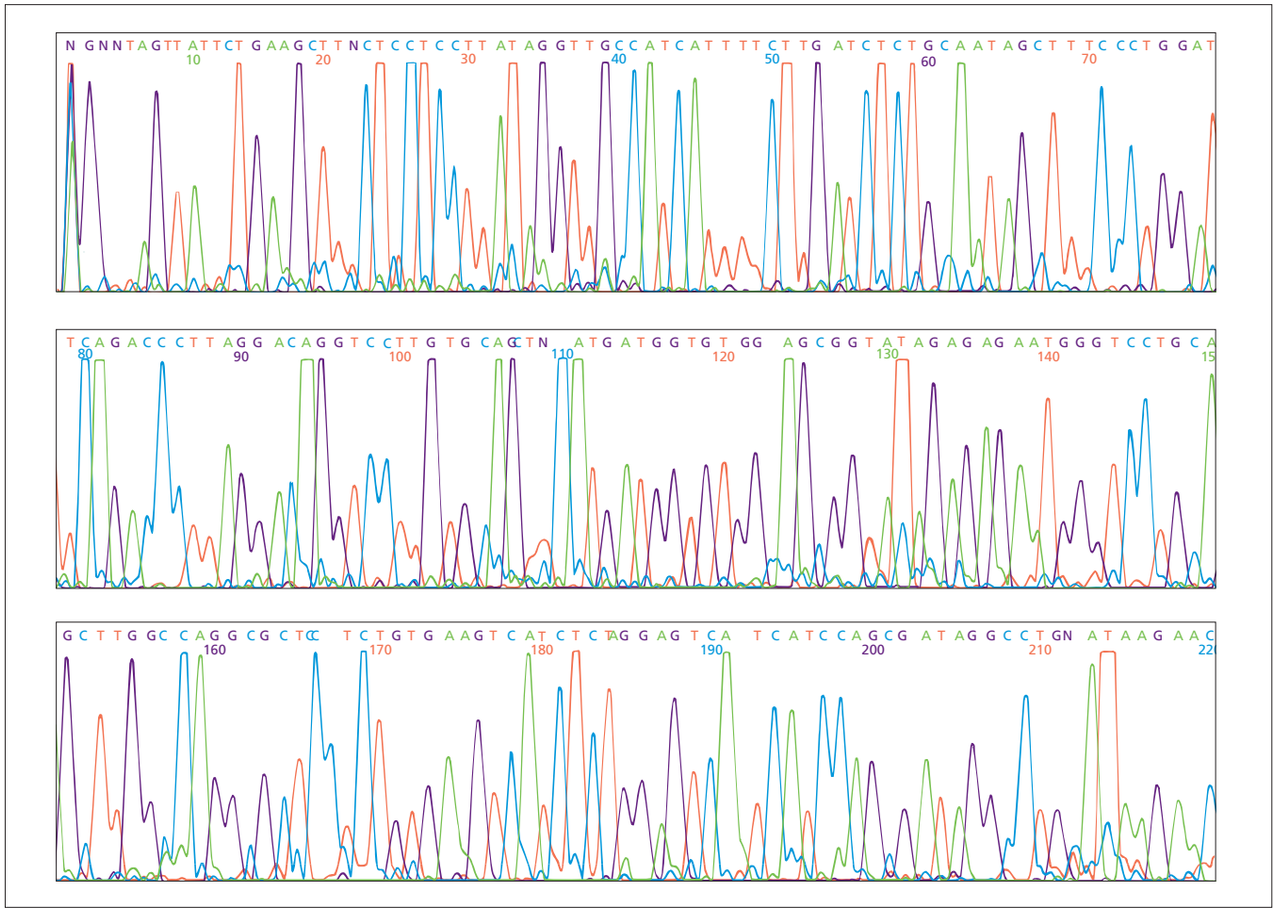

Fig. 11.8 An example of an automated sequence output using fluorescent primers. In this method, each base or primer pair is labelled with a fluorescent dye, the sequencing reaction carried out as described in Fig. 11.7, and the products run in one lane of a gel. A laser beam directed at one point of the gel causes the dyes to fluoresce as the DNA fragments move past, and because the maximum fluorescence occurs at a different wavelength for each of the four dyes, the sequence can be read by computer. (Courtesy of M. Birch-Machin, Department of Dermatology, University of Newcastle, Newcastle, UK.)

Pathway analysis can then be used to examine the patterns of gene expression under various conditions. Other microarray applications are outlined in Table 11.2.

Proteomics

The field of proteomics encompasses the study of all proteins expressed in a tissue at a given time, including their various isoforms, identification of post-translational modifications (for example, phosphorylation and glycosylation) and protein–protein interactions [4]. When a new gene is sequenced, it is of interest to find out where the gene-encoded mRNA transcripts and proteins are expressed and to find out their function. Interestingly, there is poor correlation between mRNA expression levels and protein expression. Genes can be variably expressed, gene splicing and mRNA editing are frequent and post-translational modification of the protein occurs, making proteomics a challenging field [5]. Also, although the genome of a cell is relatively constant, the proteome is in a constant state of change in response to the cell cycle, drug exposure, age, etc. Proteomic analysis can be simplified by isolation of a class of proteins with similar chemical properties. For example, proteins that are tyrosine phosphorylated can be immunoprecipitated with a phosphotyrosine antibody. An initial approach usually involves separation of the protein using one-dimensional (1-D) or two-dimensional (2-D) gel electrophoresis followed by excision of the band of interest and identification of peptides using mass spectrometry.

Bioinformatics

Bioinformatics is a science that combines molecular biology, computer science and information technology. This involves analysis of nucleotide and amino acid sequences, protein domains and protein structures [6]. In Table 11.3, some web resources are listed.

Application of molecular techniques

The utility of the techniques described above has in the recent past been extended in two particular directions. Firstly, it has been possible to marry the approaches of classical genetics and molecular biology to such a degree that mapping of human diseases characterized by a Mendelian pattern of inheritance is now very straightforward, and this will be discussed in the next section. Secondly, it has become possible to manipulate genes experimentally, such that they can be overexpressed or inhibited in either living cells in culture or, more recently, living organisms (transgenic animals).

When a gene for a particular disorder has been identified, it is frequently possible to obtain a good idea of the function of that gene, based on either sequence similarity to genes previously identified, or knowledge about similar genes in model organisms such as *Drosophila*, mouse or yeast. For example, *patched*, the gene underlying the naevoid basal cell carcinoma syndrome, once identified, was shown to have a homologue in *Drosophila*, and work in this 'model organism' had already provided important insights into the protein's cellular localization and participation in various signalling pathways [1,2].

Once a gene is identified, either through genetic linkage or candidate gene approaches, as described below (p. 11.11), a number of techniques facilitate studies of the gene's expression and function. A technique called *in situ* hybridization is used to examine expression of RNA in tissue and this is widely used in dermatology. In some instances, a gene can be transcribed into RNA but, perhaps surprisingly, little protein may be made. By contrast with *in situ* hybridization, immunohistochemistry detects protein expression, and therefore the two techniques can be considered complementary. For *in situ* hybridization tissue sections are prepared and exposed to a cDNA or RNA probe, which is tagged with either a radioisotope or a colour label (as used in immunocytochemistry), and the experimental conditions manipulated such that where there is base pairing between the probe and the target, the RNA signal is detected. Radioactive methods were popular historically, but colour detection methods such as digoxigenin are generally used today. The R-spondin 4 gene (*RSPO4*) is mutated in inherited anonychia and Fig. 11.10 elegantly demonstrates expression of *RSPO4* in nail using whole-mount *in situ* hybridization in a mouse embryo [3].

Cloned genes may be manipulated *in vitro* to elucidate the gene function. Although one may associate a particular change in DNA sequence with a particular disease state, at some stage it may be necessary to prove functionally how the mutation leads to disease. The ability to clone DNA in vectors such as plasmids allows the possibility of transferring these plasmids containing the target gene into human cells in the laboratory. If the plasmids are engineered with appropriate regulatory sequences (promoter and related upstream sequences) that will be recognized by eukaryotic cells, the cells may proceed to transcribe genes from the plasmid in a temporary fashion (*transient transfection*) or, if particular selection markers are encoded by the plasmid, the plasmids may stably

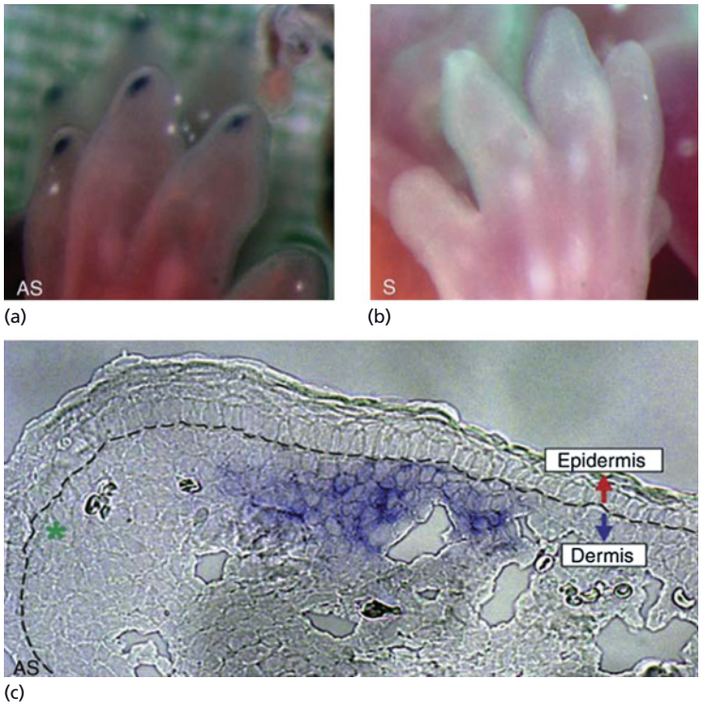

Fig. 11.10 Whole-mount *in situ* hybridization of E15.5 mouse embryos showing specific expression of Rspo4 at the sites of nail development. (a) Detection of Rspo4 expression (blue) using an antisense probe (AS). (b) The negative control using a sense probe (S). (c) A section through the nail region shows that expression is confined to the nail mesoderm. The boundary between dermis and epidermis is marked with a broken line, and the green asterisk denotes the tip of the finger (From Blaydon *et al.* [3]).

integrate into the host nuclear DNA (*stable transfection*). Genes can also be cloned into viral vectors, such as retroviral or lentiviral vectors, the plasmid DNA transfected into a packaging cell, and the secreted viral particles used to stably transduce cell lines or primary keratinocytes [4]. Use of such experimental systems allows examination of the effects of any cloned gene on cellular functions such as proliferation, migration, adhesion and apoptosis. A cDNA of interest may also be transfected into cultured cells simply to obtain large amounts of the resulting protein for further analysis. Mutated genes, either spontaneously occurring or constructed in the laboratory (usually using PCR-based site-directed mutagenesis), can also be transfected, and the influence of these mutations used to map out important domains of the protein's function [5]. A similar assay can be used to study the upstream regulatory regions that are important in controlling a gene's expression. Key regulatory sequences upstream of a gene's start site can be placed in a plasmid vector and transfected into cells. The gene's product itself can be assayed, or more often the gene of interest can be replaced with a gene called a 'reporter' that lends itself to experimental analysis. For instance, if one is interested in studying the regions upstream of a gene that are important in determining its expression (i.e. the regions of the promoter that mediate binding to a variety of other cellular proteins and signalling pathways), then one can clone this particular region of the genomic DNA, attach it to a reporter gene that codes for a fluorescent material such as luciferase, and transfect this into cells. The cells can then be treated with a variety of agents to discover whether they are able to induce, or alter, transcription of the reporter gene acting through the promoter sequence being studied.

The development of siRNA technology has allowed transient or stable knockdown of target mRNA using siRNA duplexes or short hairpin (sh) RNAs in retroviral vectors, respectively, followed by functional studies [6]. Microarray technology can be applied using very small amounts of RNA. As an example, cDNA libraries were generated from 50 pg of RNA from single putative epidermal stem cells. Gene expression profiling was performed using expression chips and a new putative stem cell marker was identified, called *Lrig1*, a known antagonist of the epidermal growth factor receptor (EGFr). Down-regulation of *Lrig1* increased EGFr expression and cell proliferation, consistent with the role of this gene in stem cell biology [7].

Techniques that allow the production of transgenic animals, which either carry an additional copy of the gene or, by taking advantage of the presence of endogenous recombinases, allow a particular gene to be deleted, are very powerful. Readers are directed to standard textbooks of molecular and cell biology for further details. For instance, imagine one wanted to examine the effects of a particular mutant form of a human keratin gene that had been associated with a particular skin disease. The mutated human gene, once identified, can be cloned and inserted into a plasmid with the appropriate upstream regulatory sequence (promoter), which means that the gene will only be expressed in a particular target situation. Obviously, for this particular experiment one would only wish to express the mutant gene in a physiologically appropriate manner and so ideally its own promoter should be used. Of course it is not necessary to wait for a spontaneous mutant in a human population from which to make a transgenic mouse. One could mutate a normal human gene and then insert this into a mouse to see what happens. In fact, it was this approach that first suggested that mutations of *K14* or *K5* cause epidermolysis bullosa; transgenic mice in which a mutated *K14* gene was expressed in the basal layer of skin showed a phenotype corresponding to that of epidermolysis bullosa simplex [8].

An added twist to these sorts of experiment is that it is possible, by using the appropriate regulatory regions that determine where a gene is expressed, to express a gene in an unphysiological context. This can be experimentally revealing. For instance, β1 integrin is normally expressed in the basal layer of skin, but when transgenic mice are produced in which β1 integrin is expressed suprabasally, by expressing the gene under the involucrin promoter, a phenotype resembling psoriasis is seen [9]. Because of the specificity of expression patterns of the various keratin genes, their promoters have been frequently used to regulate the expression of a variety of other genes within skin, including various cytokine genes.

An alternative transgenic experimental design is that of homologous recombination, in which endogenous recombinases allow wild-type sequence and a mutated vector sequence to be interchanged in embryonal stem cells. These cells can then be used to create chimeric mice, which later can be bred so that they are null for the relevant gene (i.e. they do not have any functional gene on

either chromosome) [10]. If a gene is necessary for normal development, then the null mouse may die *in utero*. The technique of Cre/*lox* recombination allows a focal knock-out of the gene product (i.e. not in the whole animal) such that frequently the mutation is not embryonically lethal and that some animals will survive into adulthood where a phenotype may be seen in at least part of the animal [11]. A more sophisticated approach to controlling gene expression has also been developed by combining Cre/*lox* with a tetracycline-regulated transcriptional system. In this combination system, expression of Cre occurs only when the drug tetracycline is administered, allowing scientists to switch gene expression on and off. A further approach is the generation of a hypomorphic mouse that expresses just enough of the gene of interest to be viable, but still has the disease phenotype [12]. A good example is the recessive dystrophic epidermolysis bullosa hypomorphic mouse that expresses about 10% of wild-type type VII collagen and survives, in contrast to the collagen VII null mouse that dies in the neonatal period [10,12]. Despite the expense and time required, these approaches are extremely powerful, and can go a long way to determining the function of a certain gene is at the physiological or whole-animal level, or how mutations of a gene contribute to a particular phenotype. However, perhaps the most striking observation in 'knock-out' animals made using homologous recombination is how often such animals are grossly normal. This has inevitably prompted re-examination of the amount of redundancy, and the biological significance of this redundancy, in various biological pathways.

Strategies for identification of disease-causing genes

The spectacular advances in the application of molecular biology to the genetics of human disease have largely been confined to disorders characterized by a simple Mendelian inheritance pattern (such as autosomal dominant or autosomal recessive). Examples include the discovery that mutations in keratin genes can cause a range of skin diseases [1] and the identification of *patched* as the tumour-suppressor gene underlying Gorlin's syndrome and sporadic basal cell carcinoma [2,3]. There are two approaches to identifying the causative gene for a disorder that shows a Mendelian pattern of inheritance: genetic linkage (genome-wide analysis) and candidate gene approaches. In many instances, the successful identification of a disease-causing gene relies on a combination of these approaches, and such examples are discussed below.

In the candidate gene approach, a starting point is the suspicion that a particular gene may be implicated in a particular disorder. Clues may arise from the phenotype of affected individuals, histology, other similar diseases where the gene is known, etc. The candidate gene is then examined for the presence of mutations in an affected kindred. The obvious limitation of this approach is that it only works if understanding of the pathophysiology of a disorder is sufficient to allow a candidate to be identified, and if the relevant gene has been cloned. For instance, once the tyrosinase and tyrosinase-related genes were identified, they were obvious candidates to examine for mutation in individuals with albinism or other pigmentary disorders [4]. Mutation detection can be undertaken using a number of strategies, but the gold standard is DNA sequencing. Often, however, particularly when large genes are examined or a large number of individuals need to be studied, screening techniques are used that, while not providing full sequence information, can detect many, if not all, changes in comparison with the known sequence (e.g. PCR amplification of exons followed by conformational change analysis such as single-stranded conformational polymorphism or heteroduplex and melt-curve analysis) [5]. A possible strategy for searching for a mutation in a known or candidate gene is illustrated in Fig. 11.11. The disadvantage of the candidate gene approach is that, for many skin disorders, our knowledge of the underlying pathophysiology is so limited that we are unable to identify suitable candidates. A genomic approach can also be taken, for example microarray technology comparing gene expression from fibroblasts or keratinocytes from a normal and an affected individual, particularly in recessive conditions, might reveal a single gene with markedly reduced expression in the affected individual.

When little is known about the underlying pathophysiology of the disorder, the only viable strategy is that based on genetic linkage or genome-wide analysis. This requires a suitable kindred, preferably showing Mendelian inheritance of the trait, and traditionally the use of polymorphic microsatellite markers. A standard, commercially available panel consists of 400 microsatellite

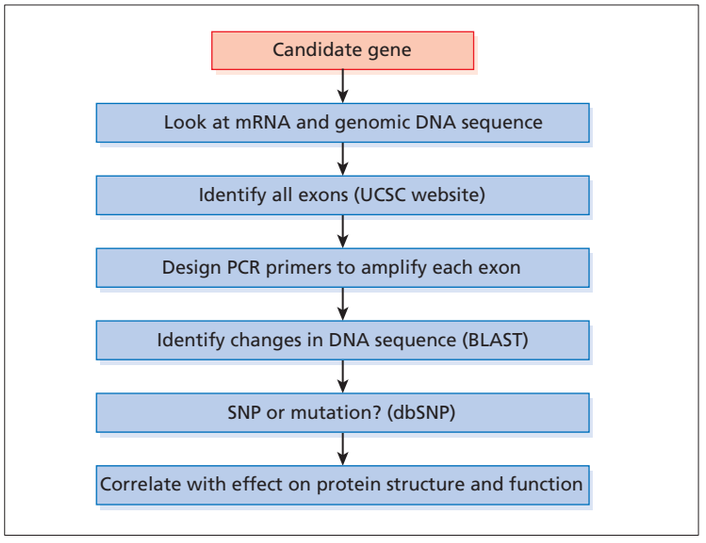

Fig. 11.11 Strategy for finding a mutation in a gene.

markers (fluorescently tagged primer pairs) covering the entire genome. Evidence of linkage may then be confirmed by selecting further microsatellite markers, at closer intervals, spanning the chromosomal area of interest. Genetic mapping compares the inheritance pattern of the trait with the inheritance pattern of a chromosome region, allowing one to find a chromosomal region that all the affected but none of the unaffected have in common. Ideally, large kindreds are needed, but if these are not available, then it may be possible to analyse several different kindreds, assuming that the same gene causes the disorder in the respective kindreds. This assumption is not always warranted; for instance, mutations of *K5* and *K14* located on different chromosomes both cause epidermolysis bullosa. When numerous loci are examined for linkage to a particular trait, statistical tests are required to determine whether the association between a particular trait and a particular chromosomal position could have occurred by chance. This is conventionally quoted as the log of the odds ratio (lod score), and as a rule of thumb a lod score of at least 3, and preferably higher, is required. (A lod score of 3 approaches a similar level of significance as that seen with a conventional statistical test with a value of $P = 0.05$.)

Although candidate gene approaches and genetic linkage/positional cloning have been described as alternative approaches, in practice they are often combined, and dermatology has already provided some pertinent examples of such experimental synergism, notably the identification of mutations in keratin genes as the cause of a range of cutaneous disorders. Keratin genes were among the first human genes identified, largely because their expressed RNA represents such a major proportion of the RNA species of a keratinocyte; early cDNA libraries from keratinocytes consisted predominantly of keratin cDNA clones. Despite the high levels of keratin expression in keratinocytes, the raising of antibodies, and numerous studies trying to relate keratin gene expression to disease states, the exact function of keratins remained uncertain. One can imagine two experimental approaches: (i) what disease would result from a mutated keratin ('gene looking for a disease'); and (ii) knowing that keratins are highly expressed in skin, would positional cloning of various skin diseases centre on the known clusters of keratin genes located on chromosomes 12 and 17 ('diseases looking for a gene')? As it turned out, for keratins and epidermolysis bullosa the answer to both these questions was the same, and arrived at within weeks of each other. Mice that had been born harbouring an experimentally mutated keratin showed a phenotype strikingly similar to that seen in epidermolysis bullosa simplex [6]. Almost simultaneously, positional cloning in kindreds mapped the cause of the same disorder literally on top of *K14*, a coincidence too good to ignore [7]. Because *K14* combines with *K5*, it was predicted and subsequently shown that the same phenotype could be produced from mutations in *K5* (even though *K5* and *K14* are located on different chromosomes). Because many keratin genes are clustered on chromosomes 12 and 17, it took little effort to examine whether other inherited blistering disorders might involve other keratin genes. Analysis of kindreds with bullous ichthyosiform erythroderma showed that this disorder also mapped to the keratin cluster and subsequently was found to be due to mutations of *K1* or *K10* [8]. It has been possible to extend this 'phenotypic walking' (by analogy with chromosome walking) even further. Given that bullous ichthyosiform erythroderma is the result of *K1* or *K10* mutations, it was no surprise when ichthyosis of Siemens, a condition with many similarities to bullous ichthyosiform erythroderma, was found to be due to mutations of *K2e* (expression of *K2e* is similar to that of *K1* or *K10*, but more superficial, in keeping with the histological features) [9]. Similarly, some of the cases of palmoplantar keratoderma, where the pattern of blistering is restricted to sites of maximal expression of *K9*, were shown to be secondary to *K9* mutations [10]. However, this process can be taken even further. Patients with pachyonychia congenita show similar involvement of the palms, and a collection of other phenotypic features suggestive of defects in *K17*. Candidate-directed mapping in several kindreds showed linkage to the keratin clusters [11], and pachyonychia congenita has subsequently been shown to arise (depending on the clinical subtype) from mutations of *K17*, *K16* or *K6* [12,13]. Patients with pachyonychia may also show changes in the mouth akin to those of white-sponge naevus and, on the basis of this overlap, mutations of *K4* or *K13* were found to underlie white-sponge naevus syndrome [14]. Similarly, some patients with pachyonychia have cysts like those seen in steatocystoma multiplex, which in turn can also be caused by mutations of *K17* [15]. Abnormal hair is also a feature of pachyonychia congenita and suggested to some that monilethrix might be secondary to a keratin mutation. Subsequently, mutations were found in monilethrix in the hair cortex keratin, hHb6 (Keratin 86) [16]. A mutation in the V1 domain of *K5* was found in the rare epidermolysis bullosa simplex with mottle pigmentation [17]. Mutations in the V1 domain of *K14* were recently found to cause Naegeli–Franceschetti–Jadassohn syndrome (NFJS) and dermatopathia pigmentosa reticularis (DPR), two closely related autosomal dominant ectodermal dysplasia syndromes with similar features, including complete absence of dermatoglyphics (fingerprint lines), a reticulate pattern of skin hyperpigmentation, palmoplantar keratoderma and abnormal sweating, providing a further link between altered skin pigmentation and keratin mutations [18]. The speed at which researchers

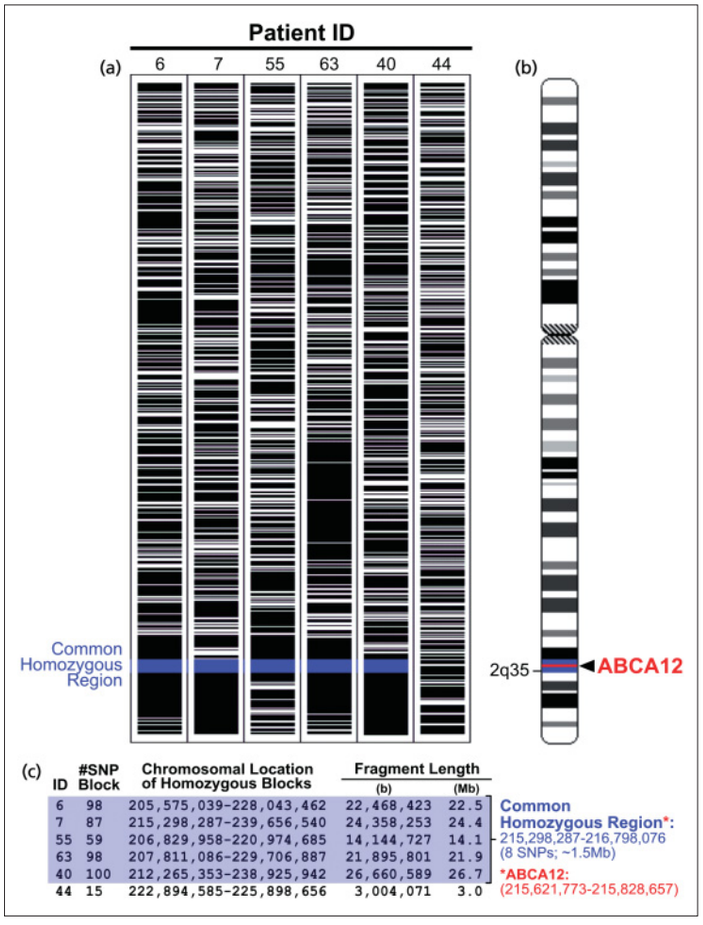

Fig. 11.12 Localization of the harlequin ichthyosis (HI) gene to chromosome 2q35 by the use of SNP-array mapping. (a) Homozygous SNP profiles of chromosome 2 in six patients with HI. Black bars indicate homozygous SNP call data. Blue bars indicate the minimal common region of homozygous SNPs in patients 1–5, a genetic distance of approximately 1.5 Mb. (b) Ideogram of chromosome 2 showing the position of *ABCA12* (red bar), located within the minimal common region of homozygous SNPs (blue) identified in panel (a). (c) The genetic interval of the homozygous SNP 'blocks' in each patient with HI, with clear indication that the *ABCA12* gene maps within the common homozygous region for five of the six patients. (From Kelsell *et al.* [19]).

have uncovered the genes responsible for so many cutaneous disorders attests to the power of the combination of mapping and candidate approaches.

Until recently, in the absence of a candidate gene, one of the bottlenecks in the identification of disease-causing genes was the difficulty moving from chromosomal position, which might encompass up to 10 million bases, to identification of the disease-causing gene. For autosomal recessive disorders in consanguineous families, arrays of 10 000 to 500 000 SNPs, available commercially from Illumina and Affymetrix, provide a rapid method of disease mapping. Finding the gene for harlequin ichthyosis (HI), the most severe congenital ichthyosis, was hampered by neonatal mortality and very few kindreds with more than one affected child. The HI gene, *ABCA12*, was identified in 2005 using SNP arrays, which showed an area of shared homozygosity on chromosome 2 in five out of six affected individuals (Fig. 11.12). Microsatellite markers were then used to confirm and refine the minimal region [19]. Of the six genes in this region, *ABCA12* was an obvious candidate, as missense mutations in *ABCA12* had been shown to underlie the less severe non-bullous ichthyosiform erythroderma/lamellar ichthyosis [20]. Sequencing confirmed *ABCA12* as the major genetic cause of HI [19]. Recently, SNP array technology was also used to map the genes for autosomal recessive anonychia and woolly hair [21,22].

Another array technique, high-resolution comparative genomic hybridization, was used to localize deletions on the X-chromosome in focal dermal hypoplasia, an X-linked dominant condition characterized by defective development of mesodermal and ectodermal tissues. Sequencing of genes in the area of deletion revealed mutations in *PORCN*, encoding a putative *O*-acyltransferase, involved in Wnt signalling, an important developmental pathway, as the cause of this condition [23].

If there are multiple, complex deletions or duplications in a gene, this may be difficult to identify with standard sequencing techniques. A truncated message (mRNA) may indicate a large deletion. In a recent study, several patients with harlequin ichthyosis appeared to have mutations on one allele only [24]. Multiplex PCR and copy number array analysis confirmed exon deletions on the other allele (Fig. 11.13).

Complex traits

The term 'complex trait' describes any pattern of inheritance of a phenotype that does not fit a classic Mendelian pattern. Examples in dermatology include atopic eczema and psoriasis. Although these disorders are inherited in families, gene–environment and gene–gene interactions, low penetrance, genetic heterogeneity and statistical power pose challenges for researchers. In an absolute sense, the distinction between complex and simple traits is artificial, as even a disorder with an apparently straightforward pattern of inheritance, such as epidermolysis bullosa simplex or Darier's disease, may show variations of clinical phenotype between

affected individuals that are the result of other modifying genes or differences in environmental exposure.

Whereas positional cloning, candidate gene analysis and linkage of Mendelian traits have had considerable success, genetic analysis of complex traits is a relatively new, but burgeoning area [1]. One can see that if a disorder is due to mutations at a number of different loci (i.e. it is polygenic), the influence of any one particular locus will tend to be modest, and conventional linkage analysis may be of limited utility. Allele-sharing methods tend to be more robust than linkage analysis, because no underlying model of inheritance is assumed. In allele-sharing methods, one tries formally to demonstrate that the inheritance pattern of a chromosomal region is *not* consistent with random Mendelian segregation (by showing that affected relatives inherit identical copies of the region more often than one would expect by chance). Examples of allele-sharing methods include affected sibling-pair analysis, where the frequency of sharing of particular regions is only compared in siblings affected with the disease (avoiding the problems of incomplete penetrance). Of course, for complex disorders the problem of moving from a highlighted chromosomal region to the actual gene is considerably more difficult than in highly penetrant disorders. This is because co-segregation of a marker and the disease may not be absolute; rather, one has to work with statistical confidence intervals. This raises the question of the number of individuals that need to be examined, because of the absence of the all-or-nothing principle of a gene that is both necessary and sufficient for a particular disease. In this situation, a variety of other strategies, such as linkage disequilibrium mapping, may be needed. Alternative strategies include association studies, which are in effect case–control studies based on the presence of a particular allele in affected and unaffected individuals, for example as in recent genetic studies on psoriasis [2,3]. Low power can be a limiting factor in case–control studies.

The use of genetically homogenous populations such as founder populations or isolated, island populations can increase statistical power considerably. A good example of this is the work of the biopharmaceutical company, deCODE (www.decode.com). Based in Iceland, with unique genealogical data and DNA samples from over half of the adult population, scientists are able to study very large, extended pedigrees. Genes are mapped by linkage analysis of affected large pedigrees, focusing in on chromosomal areas and using high-density markers to find which haplotypes are associated with disease.

Many research groups are now performing whole-genome association studies using DNA chips, which can genotype over a million SNPs in the human genome, encompassing about two-thirds of the common genetic variants. Using the typed SNPs and HapMap data, the statistical technique of imputation can be used to deduce genotypes at untyped SNPs [4]. The Wellcome Trust Case–Control Consortium using DNA SNP chips, with 3000 controls and 2000 cases of each of seven complex diseases, including Crohn's disease and diabetes, doubled the number of known genetic variants associated with these complex diseases in an initial study [5]. These findings have now been replicated in other populations. The deCODE group in a similar whole-genome study in the Icelandic population recently identified novel genetic determinants of hair, skin and eye colour [6,7]. Importantly, this study replicated the previous association of *MC1R* variation with hair colour. In a subsequent paper, they showed that variation in two of these genes, *TYR* (encoding tyrosinase) and *ASIP* (encoding agouti signalling protein), were associated with increased risk of basal cell carcinoma and malignant melanoma [8].

Genetics studies of Mendelian disorders can give clues to the pathogenesis of complex disease. Dermatologists know that ichthyosis vulgaris is more common in atopic individuals. Ichthyosis vulgaris was recently shown to be due to loss-of-function mutations in filaggrin, an important component of the epidermal barrier [9]. Subsequently, loss-of-function variants of filaggrin were shown to be a major risk factor for atopic eczema in Northern European white populations [10]. A further example is the finding of mutations in the gene coding for an exonuclease, *TREX1*, causing Aicardi–Goutières syndrome, a condition comprising encephalopathy with spasticity associated with chilblain lupus [11]. Mutations in *TREX1* were subsequently found to associate with systemic lupus erythematosus [12].

Copy number variation can also contribute to complex disease. This is where a segment of DNA, at least 500 bases in length, is found at different copy numbers in different individuals. This may be because of deletion or duplication [13]. It had been thought that individuals have two copies of each gene, but it has now been shown that about 12% of the human genome has variability in copy number [14]. A recent study found increased β-defensin copy number in psoriasis. β-defensins play a major role in innate immunity in the skin and an 'increased dose' of defensins could account for some of the inflammation seen in psoriatic skin [15].

Pharmacogenetics

The field of pharmacogenetics encompasses the study of how genetic variation affects an individual's response to drugs. Both side effects and therapeutic failure of drugs may have a genetic component. A good example in dermatology is thiopurine methyl transferase (TPMT) genotyping prior to starting individuals on azathioprine [1]. Patients with TPMT alleles causing low enzyme activity are at high risk of myelotoxicity and azathioprine is avoided, whereas in patients with intermediate activity, the dose of azathioprine can be reduced. Identification of the patient's genotype, therefore, enables the decision that it would be safer to use an alternative drug or tailoring of the dose to suit the patient and this practice is now widespread.

The use of methotrexate in psoriasis can be limited by toxicity and lack of efficacy in a proportion of patients. Methotrexate is a potent inhibitor of dihydrofolate reductase and produces its toxic effect through inhibition of synthesis of purines and pyrimidines. Specific polymorphisms in thymidylate synthase have been associated with poor clinical response or increased toxicity in patients with psoriasis on methotrexate [2]. Furthermore, genetic variation within the ABC-binding cassette family genes, *ABCC1* and *ABCG2*, is associated with a favourable response to methotrexate therapy [3]. Genetic variation may also explain the poor response of some patients with psoriasis to anti-TNF therapy. Variations in the TNF gene, its receptor and associated cytokines have been demonstrated in patients with rheumatoid arthritis and Crohn's disease, which may explain the altered pharmacodynamics and lack of response in a subgroup of patients [4]. Stevens–Johnson syndrome and toxic epidermal necrolysis are very severe skin reactions that may develop in some individuals after administration of carbamazepine. There is a strong association of the HLA-B*1502 allele in Han Chinese individuals with carbamazepine-induced Stevens–Johnson syndrome [5].

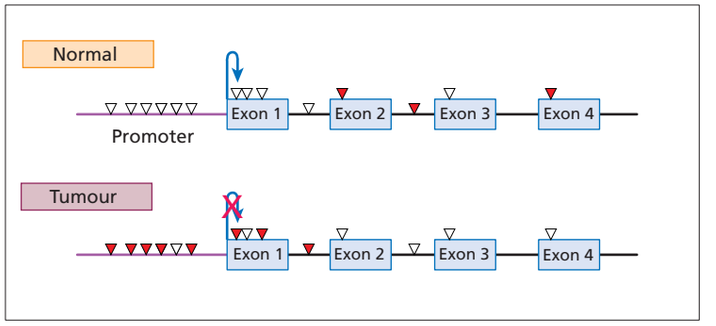

Fig. 11.14 Differences in methylation between normal and cancer cells. A sample human gene is shown, with exons 1–4, a continuous line representing gene introns, and a purple line representing the promoter region. Putative CpG islands are represented by triangles (red, methylated; white, unmethylated). In simple terms, in normal cells, the unmethylated state of CpG sites within the promoter permit active transcription, whereas the opposite is true in cancer cells.

Epigenetics

Epigenetic change is a modification to DNA or associated histone proteins, without variation in the DNA sequence [1]. This may be caused by environment, ageing or disease. The epigenetic state of cells and tissue varies depending on internal and external cues. There are two main mechanisms of epigenetic modification, *DNA methylation* (addition of a methyl [CH_3] group) and *chromatin* or *histone modification* [2]. DNA methylation occurs in cytosines that precede guanines, known as dinucleotide CpGs or CpG islands, which occur in the promoter regions of many genes (Fig. 11.14). DNA hypermethylation has been regarded as a mechanism of gene silencing (switching off gene expression); however, in cancer, DNA hypomethylation may also inactivate gene expression. The second major mechanism of epigenetic change is histone modification. Histones are the main proteins in chromatin that forms the core around which the DNA double helix is formed. Changes may involve methylation or covalent modifications of serine or lysine, such as phosphorylation or acetylation. Both monogenic and complex diseases may be modified by epigenetic change. The genetic skin disease, incontinentia pigmenti, and other X-linked disorders, may show variability in phenotype because of X-chromosome inactivation (XCI), a process in which females silence either the wild-type or mutant X-chromosome during embryogenesis [3,4]. In systemic lupus erythematosus, lymphocyte DNA hypomethylation can occur. Procainamide and hydralazine can both cause DNA hypomethylation and drug-induced lupus [5]. Current major areas of research include the epigenetics of cancer and development [2,6]. Unlike changes in the DNA sequence, epigenetic changes are reversible. The epigenome can be modified globally by drugs that inhibit DNA methylation or histone deacetylation. The histone deacetylation inhibitor (HDI), panobinostat, is well-tolerated and induces a clinical response in cutaneous T-cell lymphoma [7].

Cancer genetics

Molecular biological approaches to understanding the mechanisms underlying cancer are increasingly fruitful [1,2]. Interest in the molecular biology of cancer not only reflects the importance of the disease to human health overall, but also the intrinsic interest in many of the physiological processes that are deranged in the cancer cell, including cell-cycle control, cell proliferation, invasion and differentiation, and the control of cell death. Molecular biological approaches have led to a new conceptual understanding of the genetic contribution to cancer, which can be summarized as follows. First, cancer is a genetic disease in which the accumulation of multiple genetic abnormalities, coupled with the selection of cells for a more and more malignant phenotype, leads to, and correlates with, the clinical behaviour of the tumour. Second, the underlying defective pathophysiological mechanisms in a wide range of human cancers are similar, and increasingly can be seen to relate to a few key cellular pathways, many of which appear to influence whether a cell cycles or not. Third, the same genes are often involved in sporadic tumours as in inherited tumours; for instance, the same gene *patched* is important in Gorlin's syndrome and in sporadic basal cell carcinomas [3,4].

Genetic abnormalities in cancer cells can be classified into two types: oncogenes and tumour-suppressor genes [5]. Oncogenes are mutated forms of cellular genes called proto-oncogenes that normally control how a cell divides and differentiates. When a proto-oncogene mutates into an oncogene through a point mutation, amplification or translocation, the gene becomes permanently activated, pushing the cell towards the adoption of a malignant phenotype. In genetic terms they are dominant, and therefore only one mutated copy per cell is enough to observe a different phenotype. Oncogenes were originally identified in animal models in which host genes had been hijacked by viruses and mutated. When these viruses infected animal cells, they contributed towards the adoption of a malignant phenotype. Although this is an interesting experimental paradigm, and within animal models of cancer viruses are not infrequently implicated, in humans the association between viruses and cancer is weaker, and, where it exists, it may not be because viruses harbour oncogenes. Early functional assays for oncogenes relied on extraction of DNA from a tumour, and then transfection of this DNA into cells that had been manipulated experimentally such that they were on the verge of neoplasia. If an oncogene were present, clones of these cultured cells would progress and adopt a malignant phenotype, which could be assayed on the basis of phenotypic characteristics (such as colony formation in soft agar). This sort of assay system is cumbersome, and many more oncogenes in human cancers have been identified either on the basis of homology to known oncogenes in other animal systems or by candidate approaches based on their physiological role.

A tumour-suppressor gene is a gene that, when functioning normally, acts so as to protect against the development of the malignant phenotype—the product of the gene possesses *tumour-suppressing* activity. These genes slow down cell division, repair mutations in DNA and trigger cell death to prevent cancer. As with oncogenes, many of these genes appear to be involved in interactions with regulatory proteins controlling the cell cycle. Unlike oncogenes, tumour-suppressor genes are (at the level of the cell) recessive, in that a homozygous mutation is required for them to lose their normal physiological role. Of particular importance has been the discovery that the same tumour-suppressor genes are frequently implicated in sporadic and familial tumours; mutations of *patched* are the cause of Gorlin's syndrome and sporadic basal cell carcinoma [6].

One aspect of tumour-suppressor genes that is not self-evident is that, although these genes are recessive at the level of the cell, when examined in a kindred the trait appears dominant. Based on observations of the epidemiology of retinoblastoma, Knudson [7] proposed a model in which a critical step in the development of tumourigenesis required the inactivation of both maternal and paternal alleles of a particular gene. Importantly, he showed that in an individual inheriting one faulty gene, a second 'hit' leading to loss of the remaining allele (in any particular gene) was far more likely to occur than in an individual who had inherited two wild-type genes. Implicit in this hypothesis was that the same genes were involved in familial and sporadic cancer [7]. This model is illustrated in Fig. 11.15. In Gorlin's syndrome, for instance, those with a family history inherit one abnormality in every cell in the body. If a second hit or mutation occurs (hence the name 'two-hit hypothesis') and if other genetic events are also present, then a tumour may result. In an individual who does not inherit one abnormal copy, a tumour may still result, but in this case both maternal and paternal alleles would have to be somatically inactivated, an event far less likely to occur. This explains why tumours are more common in those who inherit one faulty allele through the germ line. It is of interest to dermatologists that the origin of this idea was first proposed over 50 years ago in order to explain certain aspects of experimental skin carcinogenesis in the mouse [8].

There are a number of mechanisms by which a tumour-suppressor gene can be inactivated: the gene may be mutated; viral proteins may interact with the tumour-suppressor gene product, targeting it for degradation (as happens with some human papillomaviruses); or, quite commonly, the area of the chromosome harbouring the gene may be lost (for example by deletion) [9]. Researchers are now also focusing on epigenetic change as a further mechanism of tumour suppressor gene inactivation causing loss of protein expression [10]. Loss of genetic material can be easily detected using polymorphic PCR microsatellite markers identical to those used in positional cloning, so that instead of two bands—one representing the maternal chromosome and the other the paternal chromosome—being visible in the

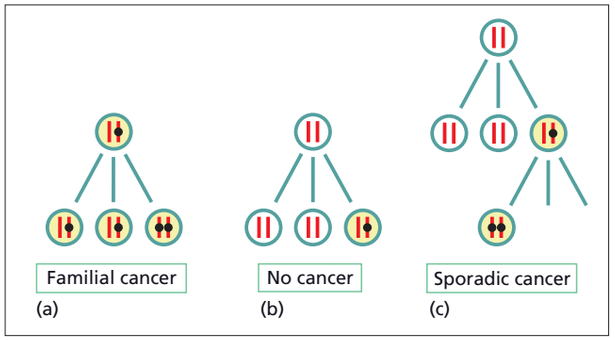

Fig. 11.15 Knudson two-hit hypothesis. Based on the epidemiology of retinoblastoma, Knudson hypothesized that the same genes are involved in familial cancer as in sporadic cancer and that they are recessive at the cellular level—two hits are required to observe a phenotype. Gorlin's syndrome appears to fall into this tumour-suppressor paradigm. A member of a Gorlin's kindred inherits one abnormal germ-line allele (*patched*) in every cell (a). Because tumour-suppressor genes are recessive at the cellular level, the phenotype of all the somatic cells is normal until the remaining wild-type allele is mutated. Once both alleles are inactivated, a rate-limiting step for cancer development has been passed. By comparison, in an individual with no cancer predisposition (b), both germ-line alleles are normal; if an occasional cell undergoes inactivation of one allele, no phenotype will be seen. For a tumour to develop without an inherited predisposition (c), both alleles would have to be inactivated somatically, an event orders of magnitude less likely to occur. This model explains why the frequency of basal cell cancer (in this example) is so much higher in a Gorlin's kindred than in other individuals. Note that despite the gene being recessive at the cellular level, the trait is inherited as a dominant.

tumour, loss of one allele will be evident as loss of one band. Rarely both alleles will be lost, although it is more common for both alleles to be inactivated by different mechanisms. This loss of genetic material, which is referred to as *loss of heterozygosity* (LOH), is one of the major methods by which tumour-suppressor genes may be identified. *Uniparental disomy* (UPD) occurs when two copies of a chromosome or a portion of a chromosome originate from one parent. If a parent is heterozygous for a mutation, the offspring will be recessive. Identification of areas of LOH and UPD can now be performed rapidly using SNP array technology, as recently demonstrated in non-melanoma skin cancer [11,12]. Online genetic databases can then be used to find genes of interest in the affected chromosomal region. Recently, sequencing of over 18000 genes in 11 breast and 11 colon tumours has identified 280 new possible cancer genes, some of which will be of interest in dermatology [13].

Besides oncogenes and tumour-suppressor genes, a third category of gene, the mismatch repair gene, is of relevance to human skin cancer. There are well-known associations between sebaceous carcinoma and a variety of systemic malignancies, particularly colorectal cancer (Muir–Torre/Lynch syndrome) [14]. Molecular studies showed microsatellite instability (MSI) in sebaceous gland tumours and colon carcinoma from Muir–Torre patients [15]. The microsatellite sequences were frequently abnormal in length, with additional bands being seen following PCR, caused by mutations in *MLH1* and *MSH2*. Subsequently, MSI and mismatch repair gene mutations have been found in sebaceous hyperplasia and sebaceous tumours from immunosuppressed transplant patients [16,17].

Efforts have intensified over the last 5 to 10 years to understand the molecular basis of melanoma and non-melanoma skin cancer. *Basal cell carcinoma* (BCC) is genetically quite homogeneous. About 90% of sporadic BCCs have identifiable mutations in the *PTCH1* gene, resulting in upregulation of hedgehog signalling [11]. In addition, about 10% have activating mutations in the *SMO* gene, encoding smoothened, another member of the hedgehog pathway [18]. About 40% of BCCs have UV-induced transition mutations in *TP53*, a tumour suppressor gene which repairs UV-induced mutations in DNA [19]. Polymorphisms in genes activated by exposure to UV, such as reactive oxygen species (*GST, CYP450*) or DNA repair (xeroderma pigmentosum genes) and genetic variants in *MC1R*, associated with fair skin, are also significantly associated with risk of BCC development (reviewed in [6]).

Squamous cell carcinoma (SCC) is very heterogeneous. Ultraviolet radiation-induced *TP53* mutations are found in up to 90% of SCCs [20]. Mutations in $p16^{INK4A}$ and $p14^{ARF}$ (genes controlling the cell cycle), and hypermethylation without mutation, have also been documented in SCC, as well as activating mutations in *HRAS* and *KRAS* [21–23]. A recent SNP array analysis examined genome-wide allele imbalance in SCC [12]. Loss of heterozygosity on chromosome 9p was observed in 13 out of 16 tumours. Other recurrent events included LOH on 3p, 2q, 8p and 13 in approximately 50% of the SCCs. This study also identified deletions within the protein tyrosine phosphatase receptor type D locus in three out of 16 tumours, with a possible association with metastasis.

The *NRAS* gene, encoding for a small guanine-nucleotide binding protein involved in activation of the mitogen-activated protein kinase pathway was the first gene found to be mutated in about 20% of malignant melanomas [24]. Subsequently mutations were found in *BRAF*, a downstream effector of *RAS*, in about 70% of malignant melanoma and benign naevi [25,26]. Melanocortin-1 receptor variants that cause red hair and freckling are associated with a small increase in melanoma risk (two- to threefold) and an increased risk of melanoma with *BRAF* mutations [27]. The growth factor stem cell factor binds to a receptor called KIT, which is mutated in 5–10% of melanomas, mainly from acral and mucosal sites [28]. There are at least four other genes that underlie predisposition to familial melanoma. The commonest is a gene on chromosome 9, *CDKN2A*, which codes for $p16^{INK4A}$, an inhibitor of the cyclin-dependent kinases 4 and 6 [29]. Fifty per cent of British families with three or more melanoma cases have *CDKN2A* mutations. There is also a rare, dominant, activating mutation in the *CDK4* gene rendering it insensitive to p16 inhibition [30]. Very rare deletions in $p14^{ARF}$, a second product of the *CDKN2A* locus, have also been shown to underlie susceptibility to melanoma and neural tumours [31].

Putting it all together and future trends

Perhaps one of the most astonishing aspects of the growth in technical prowess of molecular biology has been the way in which, from initial 'boot-strapping' methodology, there has been a roller-coaster of more powerful experimental techniques, allowing increasingly precise and ambitious questions to be answered. For instance, when a gene for a particular disorder has been identified using SNP array technology, it is frequently possible to obtain a good idea of the function of that gene, based on either sequence similarity to genes previously identified or knowledge about similar genes in model organisms such as *Drosophila*, mouse or yeast. Identification of new genes that do not bear some sequence similarity to known genes is becoming increasingly rare. The availability of sequencing data from the Human Genome Project now allows analogous prediction, based on what is described as *in silico* experimentation; human sequences can be screened using a variety of bioinformatic techniques in which expressed sequences can be predicted and similarities to known gene products scored and putative functions suggested.

In the 'post-genome era', the availability of genomic and proteomic technology allows scientists to catalogue changes in genes and proteins in disease pathophysiology. There is also optimism that even those disorders that show a more complex pattern of inheritance, such as atopic eczema, psoriasis and acne vulgaris, will also fall to currently available technologies. However, perhaps the most pressing force driving change is the desire to narrow the gap between the identification of disease-causing genes and the development of therapeutic agents.

In some instances, however, cloning of the gene does have immediate clinical implications; identification of the genes underlying the inherited bullous disorders and harlequin ichthyosis means that prenatal and even preimplantation diagnosis is now a reality [1,2]. For carriers of highly penetrant genes, modification of lifestyle may be appropriate, as for carriers of *p16* mutations who are at high risk of malignant melanoma. It is likely that better clinical and genetic data on the heterogeneous group of congenital ichthyosiform erythrodermas (there are now six known genes, including *TGM1, ABCA12, ichthyin, ALOXE3, ALOX12B* and *CYP4F22*) will eventually allow classification on a more rational basis [3].

Understanding the biological mechanism of both common and rare cutaneous disorders may also lead to new therapies. For example, acral and mucosal melanoma frequently have mutations in *KIT*. Inatamib mesylate is a receptor tyrosine kinase inhibitor that inhibits *BCR-ABL* and *KIT* and is effective in treating chronic myeloid leukaemia and neurogastrointestinal tumours [4]. Clinical trials of inatamib are currently in progress for patients with acral and mucosal melanomas who have *KIT* mutations. Rosacea is a common skin disorder characterized by inflammation and vascular abnormalities. A recent study identified two new features of this disorder: increased expression of cathelicidin antimicrobial

peptides and a related serine protease, molecules involved in innate immunity, which may be future specific targets [5]. Also, identification of abnormalities in vascular endothelial growth factor signalling have been found in infantile haemangioma, suggesting that this pathway may be a target for new topical therapies [6]. Merkel cell tumour, a rare cancer occurring in elderly individuals, were hypothesized to have an infectious aetiology. A recent study, using digital transcriptome subtraction, a high-throughput DNA sequencing method, identified a novel polyomavirus in these tumours, confirming this possibility [7]. Finally, cloning of human genes allows the production of recombinant pharmaceuticals, such as interferons, new monoclonal antibodies and vaccines, by genetic engineering.

From genetics of disease to treatment

Future work relating to the development of new therapeutic strategies lies in three directions: first, the detailed characterization of differences in gene expression; second, gene-based therapies; and finally, high-throughput screening of pharmacological compound libraries to identify drugs that modulate expression of the mutant gene, or related genes, and thus may compensate functionally for the mutant gene. In the 'post-genome era', automated approaches such as microarray chips are facilitating identification and description of gene expression in different cell types.

Thinking specifically of therapy, there are clear alternative, and perhaps complementary, strategies being pursued. For instance, the development of new, small-molecule pharmacological agents is now heavily dependent on molecular biological techniques. The identification of genes, the ability to study gene expression and the ability to produce large amounts of a protein experimentally, all facilitate functional studies of protein activity, identification of key domains and characterization of protein structure by crystallography. The identification of the myriad of isoforms for many receptors offers new targets for small-molecule design.

Gene therapy

Gene therapy traditionally describes a range of technologies that have in common the treatment of disease based on the introduction of genes or nucleic acids (including oligonucleotides), usually employing viral vectors expressing the DNA of interest. The virus can integrate into the human genome giving stable, long-term expression of the gene. Despite considerable media attention, success has been limited, and most work has concentrated on the development of the technology, toxicity assessment and *in vitro* work. In initial clinical trials of gene therapy for X-linked severe combined immunodeficiency, two children who were treated with retroviral vectors developed leukaemia [1]. It seemed likely that there was a causal relationship between integration of the virus and the development of the leukaemia, and this finding caused concern and a slowing down of clinical trials of similar approaches. In 2008, two groups reported safe administration of *RPE65* cDNA in an adenoviral vector to retinal epithelium in patients with Leber's optic amaurosis, the most severe form of inherited blindness, with subtle improvements in vision [2,3].

The approach to genetic therapy of skin disease can be summarized as follows. In recessive or compound heterozygous disorders, there is complete or almost complete absence of the protein, so replacement of the protein is necessary. This can be approached in two ways. The gene can be replaced by gene therapy (in the traditional sense) or the protein can be replaced by injection of recombinant protein or transplantation of cells expressing normal amounts of protein from a related donor. Examples of disorders that might benefit from this approach include recessive dystrophic epidermolysis bullosa (RDEB) and non-lethal forms of junctional epidermolysis bullosa. In dominant disorders, although generally less severe, gene therapy requires a different approach, as the patient has both mutant and wild-type copies of the gene. The mutant gene disrupts the function of the normal gene (dominant-negative effect). We know from parent and sibling carriers of recessive disorders that having 50% of the normal gene expression is sufficient. Therefore, inhibition of the mutant gene, using a small molecule or a molecular genetic approach such as a specific siRNA, could be sufficient to correct the problem. *In vitro* studies of siRNA for the skin disorder pachyonychia congenita have shown considerable promise (Fig. 11.16) and a clinical trial is currently in progress [4,5].

Many genetic diseases, including some forms of epidermolysis bullosa and neurofibromatosis, are due to nonsense mutations causing a premature stop codon in the messenger RNA, which results in a truncated protein. An American company, PTC Therapeutics (www.ptcbio.com), is developing small molecules that induce ribosomes to selectively read-through premature stop codons, resulting in production of full-length, functional protein. An example of this is PTC124, a new oral treatment for cystic fibrosis, which produced modest improvements in pulmonary function and chloride transport [6]. An understanding of how genes compensate and interact with each other may also facilitate development of therapy. In the keratin 14 null mouse model of epidermolysis bullous simplex (EBS), treatment with sulfurophane, a natural product derived from broccoli, improved blistering by increasing keratin 17 expression. Topical application of sulfurophane may be of value in EBS [7].

Genetic material may be passed to the cell of interest either *in vivo* or *in vitro*. With *in vitro* gene therapy, cells from the individual are cultured and genetic modification is carried out *in vitro*, before returning the cells to the patient. This is feasible in skin as kerati-

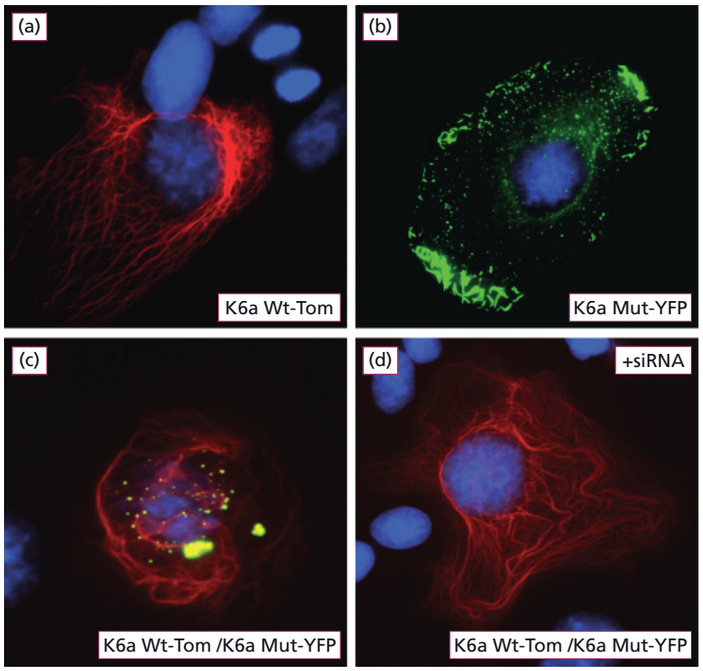

Fig. 11.16 Development of siRNA targeting of the mutant K6a present in pachyonychia congenita. Cells were transfected with fusion constructs coding for either (a) wild-type K6a and a red fluorescent reporter protein (K6a Wt–Tom), or (b) mutant K6a and a yellow/green fluorescent reporter protein (K6a Mut–YFP), or (c) both. Wild-type keratins produced intracellular filaments (red) and mutant keratins produced aggregates (yellow/green). (d) Transfection of cells with a specific siRNA targeting the single nucleotide mutation in K6a, in addition to K6a Wt–Tom and K6a Mut–YFP, resulted in loss of mutant K6a Mut–YFP. (Courtesy of R. Kaspar and R. Hickerson, TransDerm, CA, USA.)

nocytes and fibroblasts can be cultured relatively easily. With *in vivo* gene therapy, the gene of interest is applied to the skin using a delivery system such as a 'genecream' containing liposomes. Gene replacement can be achieved using various viral vectors that integrate their genome into the human genome. Retroviral particles generally only infect dividing cells; however, lentiviral vectors infect both dividing and non-dividing cells very efficiently, and are possibly the current vector of choice. A major success in genetic skin disease gene therapy was the successful treatment of a young man with junctional epidermolysis bullosa caused by a homozygous mutation in the *LAMB3* gene encoding the beta3 chain of laminin 332 [8]. A retroviral vector with a *LAMB3* gene insert was used to infect stem cells derived from the patient's palm and these cells were grafted onto surgically prepared regions on the patient's leg. The epidermis remained stable at 1-year follow-up. Small clinical trials are also planned in RDEB. Several RDEB patients in the USA have undergone allogeneic stem cell bone marrow transplant, after successful murine experiments [9], and this approach is promising for the future as a means of correcting both wounded epidermis and mucosae in RDEB (www.clinicaltrial.gov, identifier NCT00478244). A recent clinical trial of fibroblast therapy in five patients with RDEB achieved increased production of type VII collagen at the basement membrane zone [10]. Donor fibroblasts were injected into a small area of dermis, and although the fibroblasts were no longer present in skin after 2 weeks, significantly increased deposition of type VII collagen protein was seen up to 3 months in several of the patients. In a mouse model of RDEB, injection of human recombinant type VII collagen protein prolonged survival significantly, and this is also a possibility for future human clinical trials [11].

Molecular biology has allowed a genetic engineering approach to malignant melanoma. Peripheral blood lymphocytes from patients with melanoma were transduced with genes encoding the alpha and beta chains of the anti-MART-1 T-cell receptor. MART-1 is a tumour-associated antigen. These genes were cloned from a tumour-infiltrating lymphocyte (TIL) clone obtained from a patient who demonstrated almost complete regression of metastatic melanoma after adoptive cell transfer of TILs. Two patients out of 15 had sustained regression of their metastases 1 year after treatment and both had persisting, high, circulating engineered lymphocytes [12].

A final consideration with gene therapy is how generic the techniques can be made. This assumes importance because although studies on cancer using gene therapy have been well funded, to take gene therapy approaches through to the clinic, industrial-scale funding is probably necessary. For many rare dermatological disorders, as for development of new drug-based strategies, it is not clear that the size of the market will justify the necessary investment. A second limitation on application, particularly with respect to dermatological therapy, may be concern about safety. However, as stem-cell transplant and vector technology improve, this will be less of a concern. Obviously, since the vast majority of cutaneous diseases are not life-threatening, these sorts of approaches will, in the short term, be restricted to disorders that are potentially fatal, such as melanoma or some of the inherited blistering disorders.

Conclusion

Molecular biology and the application of molecular biological techniques to the study of disease have come an astonishingly long way in a short period of time. Disease-causing genes continue to be identified at a significant pace. Molecular biological technology has opened up the study at increased speed of whole areas of medicine, because of both DNA-based diagnostics and an increased facility to carry out high-throughput biochemistry and pharmacology. In genetic skin disease, molecular biology is beginning at last to yield treatments that are likely to be successful. In psoriasis, genetic engineering of new monoclonal antibodies targeting important immune drivers of the disease is now routine.

New therapies do not always work in every patient, but this sometimes allows a further hypothesis to be generated in the laboratory, which eventually results in a better drug [1].

High-throughput technology is already producing thousands of biomarkers and putative targets in various cancers, including melanoma. Skin cells can be reprogrammed to behave like embryonic stem cells by transfection with four genes and subsequently directed to a tissue-specific lineage, for example cardiomyocytes [2]. Sequencing of an individual's genome may soon become more widely available. The majority of drugs may in the future be adjusted after examining an individual's genotype. However, the real skill will be translating all of this information into clinically useful tools for the dermatologist [3]. That is why it is important that some dermatologists remain as close to the bench as they do to the clinic.

Introduction [1–18]

Inflammation can be defined as a complex body defence mechanism to respond to dangerous endogenous or exogenous stimuli. From a very early stage in phylogenesis, inflammation is associated with the host defence against infectious agents or injury. A variety of exogenous and endogenous mediators are capable of inducing inflammatory responses, such as microbial agents, toxins or pH changes, resulting in an acute dermatitis. Exogenous physical stimuli, such as heat, cold, UV radiation or mechanical irritation, may also affect skin homeostasis and activate the release of inflammatory mediators such as radical oxygen species, nitric oxide derivates, cytokines, chemokines, eicosanoids, neuropeptides, etc. [19].

The inflammatory response consists of various cellular and molecular mechanisms that enable reconstitution of body integrity. The acute reaction is characterized by successive phases. An initial, clinically 'silent' phase involves release of immediate inflammatory mediators from resident cells of the damaged tissue, thereby initiating the tissue (activated tissue cells) and immune responses (early components include: macrophages, mast cells, platelets, basophils, dendritic cells; and later: neutrophils, eosinophils, lymphocytes, etc.) [20]. In a second phase, a vascular reaction, characterized by vasodilatation and increased permeability, can be observed, followed by a cellular phase, where inflammatory cells infiltrate the injured microenvironment. As will become apparent, many skin diseases involve inappropriate regulation of the inflammatory response.

Early inflammatory cells, such as mast cells or macrophages, release a variety of mediators including cytokines, chemokines or proteases, to remove or inactivate dead cells, detritus, microbiological organisms and toxins. Upon activation, endothelial cells release a plethora of cytokines, chemotactic agents or radical oxygen species, important mediators which orchestrate the subsequent inflammatory mechanisms, such as leukocyte recruitment, extracellular matrix reorganization, and stimulation of epithelial cells, and fibroblasts; they are also crucial to the control of intravascular mediators such as coagulation factors and proteases. Leukocytes closely interact with activated endothelial cells expressing cell adhesion molecules, to allow emigration into the inflammatory environment. In addition, other important mediators, such as kinins, biogenic amines, neuropeptides, nitric oxide

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

and other radical oxygen species (ROS), haemoxygenase (HO), growth factors, complement compounds, prostaglandins, leucotrienes and ADP, are released to fine tune the inflammatory response. Moreover, several cutaneous cells are capable of generating inflammatory mediators and their receptors in order to regulate the cellular response to released pro-inflammatory molecules, ultimately leading to tissue repair. Under normal circumstances, inflammatory effects are rapidly attenuated by anti-inflammatory mechanisms to protect the body from uncontrolled stimulation, which might otherwise result in prolonged activation and possibly disease. As a consequence of uncontrolled conditions, an inflammatory response may become chronic, resulting in chronic eczema, impaired wound healing or autoimmune disease, for example [21].

The molecular mechanisms underlying the acute and chronic phases of inflammation are different, and are only partly understood. During the last few years, however, our knowledge of the pathophysiology of inflammation and the mediators involved has expanded substantially. This chapter highlights some of the important recent advances in our understanding of the mechanisms of inflammation with special regard to the skin, and discusses the impact of modern therapeutic strategies on the treatment of cutaneous inflammation. Cellular constituents of the adaptive immune system (T cells, B cells, antigen presenting cells) are described in detail elsewhere (Chapter 13). Therefore, the main focus of this chapter is on the cells and mediators of the innate immune system and their role during inflammation.

Clinical characteristics of inflammation

Five characteristic signs of inflammation were described by Celsus centuries ago: redness, heat, pain, swelling and loss of function. However, not all signs may be necessarily observed in all skin lesions during a given inflammatory response.

Redness (rubor). This reflects the presence of red blood cells or haemoglobin in the skin. Increased redness may follow increased blood flow through superficial dilated vessels, resulting from stimuli leading to vasodilatation, or from obstruction in deeper vessels causing diversion or 'shunting' of blood through more superficial vessels. Redness in the skin may also result from stasis and congestion without increased flow of blood. Such partial stasis increases the chances for leukocytes to emigrate from vessels.

Heat (calor). This is a usual consequence of increased blood flow through the skin. In acute lesions, the temperature of the skin may increase as a direct result of an elevated local metabolic rate. In chronic inflammation, neither local metabolism nor blood flow may be increased, and the skin may feel cool. Heat loss cannot be correlated exactly with redness, because areas of fast flow may be on the border of a more congested and slow-flowing system. Thus, conduction of heat to the surface of the skin may be considerable over a large, deep arteriovenous fistula, while the upper dermis may show all the effects of severe stasis as a consequence of the raised venous pressure.

Pain (dolor). The sensations that accompany inflammation of the skin may vary in the various diseases and include pain (sunburn), burning (rosacea), stinging, itching (atopic dermatitis) and/or tenderness, and are thus more variable than in most internal organs. Which of these sensations predominates depends in part on the site, depth, intensity and duration of the inflammatory process. Thus, in urticaria stinging may accompany transient superficial lesions. Itching is the usual sensation in prurigo, atopic dermatitis or papular urticaria or in weals due to mediator release from mast cells (such as histamine, tryptase) or keratinocytes. Pain and tenderness may accompany deeper lesions of long duration, as observed in delayed pressure urticaria. Other mediators such as cytokines (e.g. interleukin-31), nerve-growth factor (NGF), bradykinin and proteases may also induce pain by activating specific receptors on primary afferent neurones.

Swelling (tumor). Rapid tissue swelling is due to extracellular oedema, the increased leakage of water and mineral salts (transudate), or proteins (oedema fluid) as a consequence of plasma extravasation from post-capillary venules. In acute forms of inflammation, fluid accumulates at the site of inflammation when the rate of exudation from venules and capillaries is greater than the rate of clearance by the lymphatic vessels. This process is normally transient and stops after 4–6 h. Here, neuropeptides, peptides, nitric oxide, cytokines and other vascular active mediators play a crucial role. In most lesions, swelling is mainly due to oedema, or to plasma constituents, for example fibrin in delayed hypersensitivity reactions. In chronic inflammation, swelling is also caused by an increase of extracellular matrix components. Even a dense leukocytic infiltration usually does not substantially contribute to swelling, except in the case of abscess or granuloma formation. Neutrophils may accumulate at a site in large numbers within 4 h, but macrophages and lymphocytes, which contribute to a firmer, more persistent swelling, usually accumulate more slowly over 48–72 h. The persistence of the leukocyte infiltration depends upon the nature of causative agent and the kinetics of the clearing process. Tissue hypertrophy with acanthosis, fibroblast proliferation and angiogenetic factor-induced formation of new vessels may also contribute to more persistent swelling and dysregulated termination of the inflammatory process.

Phases of inflammation

Inflammation induced by exogenous or endogenous stimuli can either occur as an acute response or develop into a chronic condition. Normally, the acute inflammatory response is terminated by several negative feedback mechanisms, such as receptor-antagonists for cytokines or protease inhibitors. Under certain conditions, however, an imbalance of the inflammatory response can lead to a persistence of pro-inflammatory stimuli, resulting in a chronic disease state (Fig. 12.1).

The acute phase (first 6 h) of inflammation consists of a vascular reaction, including vasodilatation, oedema formation, plasma extravasation, activation of endothelial cells and release of early inflammatory mediators from the injured tissue site. Subsequently, this site becomes a target for inflammatory cells aiming to

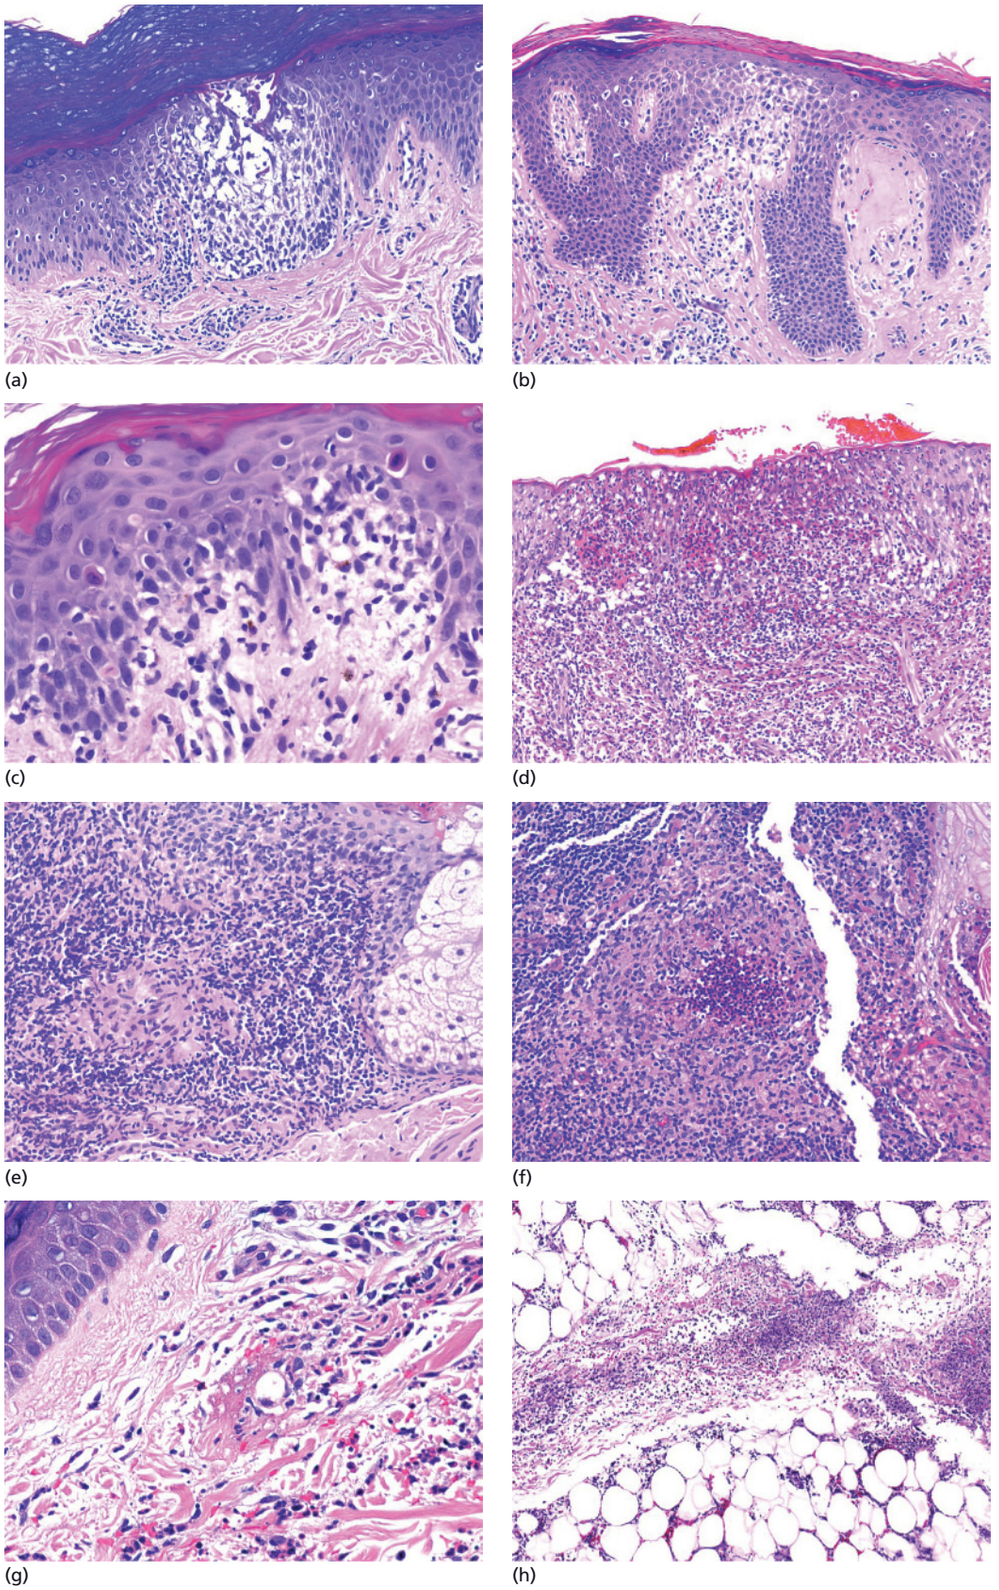

Fig. 12.1 Histopathological features of skin inflammation. (a) Subacute dyshidrosiform dematitis with intraepidermal intercellular oedema (spongiosis), and accumulation of inflammatory cells in the upper dermis around blood vessels. (b) Spongiotic dermatitis combined with regular epidermal hyperkeratosis (psoriasiform reaction pattern), as often observed in chronic inflammatory skin lesions. Note, epidermal hyperparakeratosis due to scratching, spongiosis, and in the dermis marked infiltration of T lymphocytes. In contrast to (c), there is no impairment of the basal membrane. (c) 'Interface' dermatitis in which inflammatory cells (e.g. T cells and eosinophils as here in graft-versus-host reaction) invade the damaged epidermal basal layer or above ('vacuolation'), closely associated with apoptotic ('eosinophilic') keratinocytes. (d) Eosinophilic dermatitis: high density of invading eosinophils in the superficial dermis, as observed in eosinophilic dermatitis of infancy. (e) Granulomatous dermatitis pattern: many lymphocytes surround a perifollicular granuloma consisting of macrophages, as observed in granulomatous rosacea. (f) Tuberculoid granuloma: masses of macrophages, epitheloid cells, giant cells as well as lymphocytes surrounding the granuloma, accumulation of acid mucopolysaccharides between collagen bundles, a loosened extracellular matrix, and occasional degeneration of fibroblasts due to apoptosis, as seen in tuberculosis. (g) Vasculopathic inflammatory tissue pattern: fibrinoid endothelial cell swelling, and increase in fibrohistiocytic cells. Leukocytes invade the connective tissue after transmigration through inflamed endothelial cell walls, as seen in leukocytoclastic vasculitis. (h) Septal panniculitis: inflammation of the deeper skin, and subcutaneous fat. Here, infiltrating neutrophils fill the septa in a patient with erythema nodosum.

eliminate the noxious agent. Vasodilatation of small vessels may be caused by several mediators, such as kinins (bradykinin), amines (serotonin), prostaglandins (PGE_2), and neuropeptides (e.g. calcitonin gene-related peptide, CGRP), which may be released by platelets, mast cells, endothelial cells or sensory nerves. Subsequently, plasma extravasation leads to oedema. Most of these effects are exerted via the up-regulation of specific receptors, such as the bradykinin-2 receptor, or the prostaglandin E_2-receptor. Conversely, peptidases released in the vicinity of the vessel wall may inhibit, and thereby effectively terminate, the vasodilatatory response to neuropeptides or endothelin. Nitric oxide (NO) synthase inhibitors may also block the effects of NO, thereby establishing tissue homeostasis.

Macrophages and neutrophils represent the first line of the host defence against microorganisms [19]. Sensors on these cells that recognize PAMPs (pathogen-associated molecular patterns), such as toll-like receptors (TLR) and nucleotide-binding oligomerization-domain protein-like receptors (NOD), play an essential role in the recognition of 'outside danger' molecules from pathogens [21]. By their recruitment, activation, phagocytosis and killing, the cells rapidly respond to infectious agents until the adaptive immune response is initiated. Subsequently, activated immune cells release cytokines and other mediators to direct the immune system towards the provision of a capable and effective host defence. Moreover, chemokines, which recruit leukocytes to the site of inflammation, can be released by most cutaneous cells. Infectious agents and the local inflammatory response activate the complement system, which initiates the production of plasma proteins capable of destroying pathogenic agents. Finally, the innate immune system also contributes substantially to activation of the adaptive immune response [22] and to resolution of inflammation [23].

The chronic phase of inflammation is characterized by a dysregulation of the homeostatic inflammatory–anti-inflammatory machinery, leading to a cellular phase with prolonged recruitment and enhanced immigration of inflammatory as well as immunocompetent cells to the site of inflammation. Finally, the resident and infiltrating cells are responsible for cell activation, phagocytosis, killing of pathogens, removal of debris, necrosis, apoptosis and modulated restoration of the tissue. The outcome of the inflammatory response is crucially determined by the removal of the primary pro-inflammatory stimulus. Thus, the progression of the acute into the chronic state of inflammation is due to the persistence of the stimulating agent. Exogenous factors may consist of toxins or pathogens, whereas endogenous factors could be autoantigens, for example. Microorganisms, via escaping immunosurveillance, can induce chronic inflammatory states, as observed in leishmaniasis or mycobacterial disease. On the other hand, chronic inflammation in autoimmune-mediated diseases, such as pemphigus vulgaris or lupus erythematosus, may be driven by defective down-regulatory mechanisms. The fine-tuned mechanisms of non-infectious chronic inflammation are poorly understood.

One of the intriguing recent findings which has increased our understanding of the endogenous-mediated processes of inflammation is the description of the NALP-3 inflammasome by ATP, K^+ ions, HMGB1 and S100 proteins, amongst others [24–28]. This is at least in part mediated by caspase-1 [29].

Innate defence mechanisms

Innate immunity consists of a complex defence system which is highly conserved throughout the species and already present at birth. The response generated by the innate defence system to injurious agents is immediate, not antigen specific and not activated by pathogen molecular patterns (PAMPs) [1]. In contrast to the adaptive immune response, the innate defence response is not enhanced upon a second exposure and, most importantly, has no memory. The major components of the innate defence system are antimicrobial peptides, toll-like receptors, type 3 complement receptor (CR3), scavenger receptors (SR), mannose receptor (MR) and other C-type lectins [2,3]. In a broader sense, radical oxygen species, nitric oxide and its derivatives, and certain neuropeptides (truncated neuropeptides) may be regarded as components of the innate defence system.

Antimicrobial peptides

Antimicrobial peptides or proteins (AMPs) constitute a novel family of effector molecules with an important contribution to host defence, inflammation or cytotoxicity, and with substantial potential benefit for the treatment of infectious and inflammatory skin diseases. In humans, peptide antibiotics of three families have been identified, and defined as defensins, cathelicidins and histatins. All of the characterized antimicrobial peptides share the capacity to kill and/or to inactivate bacteria, fungi and enveloped viruses *in vitro*. They apparently kill mammalian target cells and microorganisms by a mechanism involving initial electrostatic interactions with negatively charged surface molecules on target cells, followed by insertion into the cell membranes, permeabilization and formation of voltage-regulated channels. In addition to their antimicrobial and cytotoxic properties, some defensins act as opsonins, while others inhibit signal transduction pathways such as protein kinase C, competitively inhibit receptor activation (e.g. ACTH receptor), block steroidogenesis, or act as selective chemoattractants for monocytes. Thus, in addition to their capacity for killing microbes, endogenous AMPs may also contribute to both innate host defence and adaptive immune responses. Many of these AMPs can be induced *in vitro* by pro-inflammatory cytokines, bacteria or fungi. They are rapidly released and synthesized during inflammation; some are also locally expressed in the skin in the absence of inflammation. This suggests that non-inflammatory stimuli of endogenous and/or exogenous origin can also stimulate AMP synthesis without inflammation. Thus, AMPs may become useful therapeutic tools for regulation of immune defence without causing inflammation [4].

Defensins

Defensins are antimicrobial and cytotoxic peptides which consist of 29–35 amino acids, including six invariant cysteines whose intramolecular disulphide bonds cyclize and stabilize them in a triple-stranded beta-sheet configuration. They are generated by proteolytic processing from 93–95 amino acid precursor prepropeptides and can be detected in plants, insects and various mammals [5,6]. The prosegment keeps the peptide in an inactive state and subsequently activation occurs by proteolysis. Matrilysin (MMP-7) was identified as the enzyme responsible for the generation of mature defensins in mice by proteolytic cleavage.

In general, defensins maintain body integrity when the skin is challenged by microbial agents. The generation of antimicrobial peptides is one of the first-line protective systems of the skin. For example, cathelicidins protect the skin through two distinct pathways: (i) direct antimicrobial activity and (ii) initiation of a host response resulting in cytokine release, inflammation, angiogenesis and re-epithelialization [7]. Cathelicidin and proteases have been implicated in the pathophysiology of skin diseases such as psoriasis, atopic dermatitis and rosacea and, as vitamin D_3 may be a key regulator of human cathelicidin, this has implications for the treatment of certain inflammatory and infectious diseases [8–11]. For example, rosacea patients express abnormally high levels of cathelicidin in their facial skin, and the proteolytically processed forms of cathelicidin peptides found in rosacea are different from those in normal individuals. These cathelicidin peptides are the result of a post-translational processing abnormality associated with an increase in stratum corneum tryptic enzyme (SCTE) in the epidermis. Addition of SCTE, and increasing protease activity and deletion of the serine protease inhibitor gene *Spink5*, increase inflammation in mouse skin. Thus, antimicrobial peptides and proteases may be involved in an exacerbated innate immune response in inflammatory skin diseases, including rosacea.

Interestingly, defensins make up to 5% of the total protein content in human neutrophils and are also produced by macrophages, keratinocytes and mucosal epithelial cells of the cutaneous, respiratory, digestive, urinary and reproductive systems [12–15]. In mammals, neutrophils are capable of generating and releasing all three classes of defensins. The antimicrobial spectrum of defensins includes Gram-positive as well as Gram-negative bacteria, mycobacteria, *T. pallidum*, many fungi and some enveloped viruses. Defensins exert non-specific cytotoxic activity against a wide range of normal and malignant targets, including cells resistant to tumour necrosis factor alpha (TNF-α) and natural killer (NK)-cytolytic factor.

α-defensins contain three disulphide bridges, and reveal a triple-stranded β-sheet structure with a β-hairpin that contains cationic amino acids. The first human α-defensin was isolated from neutrophils [16]. Six human α-defensins (termed human neutrophil peptide (HNP)-1 to -6) have been identified. Human neutrophils generate four α-defensins, HNP-1 to -4. They all are localized in the azurophilic granules of neutrophil granulocytes, where they are the principal proteins and contribute to the oxygen-independent killing of phagocytized microorganisms. In contrast, mouse neutrophil granules do not contain α-defensins. HNP-5 and -6 are primarily found in Paneth's cells of the small intestine and epithelial cells of the female urogenital tract.

*β-defensin*s were first isolated from cow tongue in 1991 and originally named tracheal antimicrobial peptide (TAP). They contain six cysteine residues connected by three disulphide bridges but spaced differently from those in α-defensins. The genes encoding β-defensins are localized in the same chromosomal region as α-defensins. They consist of 36–42 amino acids, and possess a different disulphide alignment as compared to other defensins.

Human β-defensin-1 (hBD-1) is expressed constitutively in epithelial cells of the skin, the gastrointestinal as well as urinary and respiratory tracts. Human β-defensin-2 (hBD-2) was also isolated from psoriatic skin [17]. hBD-1 and hBD-2 are diffusely expressed throughout different epithelial organs, as well as glandular cells of different tissues. hBD-3 was isolated from psoriatic keratinocytes, and has potent antimicrobial activity against many skin-pathogenic bacteria [18].

The expression of defensins is tightly regulated. While the expression of hBD-1 has been found to be constitutive, hBD-2 expression seems to be inducible by infectious and pro-inflammatory stimuli. In the skin *in vivo,* hBD-2 transcripts and peptide are found to be up-regulated during infectious diseases [19]. *In vitro,* pro-inflammatory cytokines such as IL-1α, IL-1β and TNF-α, but also lipopolysaccharide (LPS) and microorganisms (Gram-positive and Gram-negative bacteria, and *Candida albicans*) are able to induce hBD-2 production. hBD-1, hBD-2 and hBD-3 are expressed in human skin and immune cells. The expression of hBDs are differentially regulated. For example, hBD-3 up-regulation is mediated by transactivation of the epidermal growth factor receptor (EGFR). The expression of hBD-2 is IL-1-dependent [20], and hBD-3 can be induced by histamine [21]. hBD play a role in keratinocyte migration and cytokine production [22], barrier function and *Staphylococcus aureus* protection [23,24].

θ-Defensins constitute a novel class of defensins that have been isolated from Rhesus monkey neutrophils. The peptide Rhesus θ-defensin-1 is produced by the post-translational ligation of two truncated α-defensins, and demonstrates salt-independent antimicrobial activity. So far, θ-defensins have not been detected in the skin.

Cathelicidins

Peptide antibiotics of the cathelicidin ('cathe-lin' = cathepsin L inhibitor) family contain a highly conserved signal sequence, but show substantial heterogeneity in the C-terminal domain encoding the mature peptide, which can range in size from 12 to 80 amino acid residues. The only human cathelicidin, LL-37/hCAP-18, was originally isolated from human bone marrow [5,6] but expression of LL-37/hCAP-18 is up-regulated in inflamed skin and colocalizes with IL-6. LL-37/hCAP-18 has been found to be regulated by various inflammatory stimuli such as cytokines [19]. Interestingly, the LL-37/hCAP-18 gene contains several potential binding sites for transcription factors (acute-phase response factor and nuclear factor for IL-6 expression (NF IL-6)) that are possibly involved in the regulation of inflammation. However, the mechanisms that induce antimicrobial peptides and the corresponding signalling pathways are speculative at present.

As described above, cathelicidins interact with serine proteases and protease inhibitors, thereby regulating immune defence mechanisms in rosacea [11].

Histatins

Histatins are a family of histidine-rich peptides present in human saliva [25], consisting of about 38 to 32 amino acid residues. The five members of the histatin family are modulated by post-translational processing. A specific role for histatins in humans, however, is still under debate. Histatins seem to play an essential role in the antiviral defence of human saliva and in wound closure [26,27], as well as in gingivitis [28]. Their antimicrobial activity includes strong effects on *Candida albicans* [29]. Histatins may also play a role in experimentally induced sepsis in rats.

Role of antimicrobial peptides in immunity and skin pathophysiology

Antimicrobial peptides, including defensins, cathelicidins and histatins, have a broad spectrum of activity against Gram-positive and Gram-negative bacteria as well as against fungi and enveloped viruses. Antimicrobial peptides show synergistic activity with other host defence molecules such as lysozyme and lactoferrin. The microbicidal activity of defensins is based on permeabilization of anionic lipid bilayers and the subsequent release of cellular contents and the destruction of the cell membrane electrode potential. A second model of action describes the aggregation of peptides into positively charged patches, resulting in the formation of transient gaps. Additionally, defensin-related cell death has been linked to interference with protein synthesis or DNA damage.

Thus far, the evidence that defensins contribute to innate immunity in humans *in vivo* is largely indirect. Evidence for the host defence function of antimicrobial peptides includes a study involving MMP7-knockout mice with an increased susceptibility for infections. In addition to their antimicrobial activity, defensins and cathelicidins can bind to lipopolysaccharide and inactivate the biological functions of this endotoxin. Bacterial resistance to antimicrobial peptides is a rare phenomenon. Mechanisms that result in the development of resistance involve modifications of outer cell wall components, such as lipopolysaccharide, teichoic acids or phosphocholine, and the modulation of efflux pumps [6].

Beside their role as endogenous antibiotics, antimicrobial peptides have other functions in inflammation, wound repair and regulation of the adaptive immune system. Human neutrophil defensins have been described to be cytotoxic for various cell types and to induce cytokine synthesis in epithelial cells, monocytes and T cells. Further, they increase the binding of bacteria to epithelial cells and induce the liberation of histamine from mast cells. Finally, α-defensins are involved in the chemotaxis of monocytes and T cells, the modulation of cell proliferation and B-cell production, and the inhibition of complement activation and proteinase inhibitors [9,30,31]. The human β-defensins have recently been identified as potent ligands for the chemokine receptor CCR6 that is present on dendritic and T cells, suggesting a close functional link between the innate and adaptive immune systems [32].

There is strong evidence that antimicrobial peptides serve as mediators of host defence not only by direct antimicrobial activity, but also by their function as modulators of the inflammatory process. Defensins induce the release of pro-inflammatory mediators such as IL-8, IFN-γ, IL-6, IL-10 and LTB4. On the other hand, defensins might also exhibit anti-inflammatory activities by inducing the secretion of IL-10 [33]. Furthermore, defensins attract inflammatory cells such as neutrophils, B cells, T cells and macrophages, and activate epithelial cells, including keratinocytes, to release cytokines and chemokines. Neutrophil-derived defensins, for example, stimulate IL-8 production, which also helps to recruit

more neutrophils to the site of inflammation. This is in accordance with the report that *in vivo* administration of human neutrophil defensins increases the ability of mice to resist local infection by enhancing neutrophil recruitment to infected tissues. Human neutrophil defensins are reported to bind to complement component 1q [34]. Therefore, it is possible that defensins may participate in the regulation of complement activation. Human neutrophil α-defensins also enhance the antigen-specific humoral immune response. For example, $CD4^+$ T cells isolated from mice immunized with antigen in the presence of α-defensins displayed a higher antigen-specific proliferative response and an elevated production of IFN-γ, IL-5, IL-6 and IL-10 as compared to T cells from mice immunized with antigen alone. HNP1 enhances phagocytosis by cultured mouse peritoneal macrophages. Human defensins can degranulate mast cells, resulting in the release of histamine and tryptase, leading to the recruitment of more neutrophils to the site of inflammation. Conversely, mast cells release the cathelicidin LL-37 which is involved in the killing of bacteria [35].

Antimicrobial peptides are also involved in the induction and regulation of adaptive immune responses [6,14,30,31,36]. Defensins have been shown to modulate the cytokine profile of T cells; HNP-1 and HNP-2 are T-cell chemoattractants and induce the recruitment of T cells to sites of inflammation *in vivo*. Defensins also modulate dendritic cell function. Human α- and β-defensins are selectively chemotactic for human immature, but not mature, dendritic cells. Although *in vivo* neutrophil defensins are stored in azurophilic granules, they can be released into the extracellular environment by neutrophil disruption or degranulation [37]. Murine BD2 has been demonstrated to directly modulate dendritic cell function and maturation, indicating that defensins are involved in immunosurveillance. Thus, defensins, presumably present at sites of inflammation, form chemotactic gradients for immature dendritic cells. Since dendritic cells are crucial for the induction of adaptive immune responses, defensins may directly contribute to antigen-specific immune responses.

In the skin, defensins such as hBD2 are up-regulated in psoriasis [17], acne [38] and folliculitis [39]. In contrast, decreased expression and release of hBD2 and LL-37 was found in lesional skin of atopic dermatitis patients [40]. Interestingly, antimicrobial agents such as LL-37 and hBD1 are up-regulated in the inflamed skin of newborn infants during erythema toxicum neonatorum [41]. Moreover, growth factors such as insulin-like growth factor-1 (IGF-1) and transforming growth factor-α (TGF-α) enhance the expression of hCAP/LL-37 and hBD3, indicating an up-regulation of antimicrobial peptides during wound healing [42]. Accordingly, HNP1 increases the expression of pro-α-(I)-collagen and decreases MMP-1 release, supporting a role of defensins in wound repair [43]. Moreover, IL-1 seems to be an important inducer of hBD2 synthesis in human keratinocytes [44]. One of the defensins most recently described in the skin is hornerin (S100A16) a new calcium-binding, profilaggrin-related protein, which may play an important role in epidermal barrier function [45]. In summary, defensins play an essential role in inflammatory skin diseases such as rosacea, atopic dermatitis and psoriasis, and wound healing, as well as in bacterial, viral and fungal infections [46], and are important antimicrobial peptides in human tongue [47].

Table 12.1 Potential use of toll-like receptor (TLR) agonists in various diseases.

Disease/condition	TLR involved	Therapeutic approach	Comments and expected outcome
Acne	TLR-2	Antagonist	Suppression of *P. acnes*-induced cytokine production
Atopic dermatitis	Many	Bacterial vaccine Agonists	Shifting of a Th2 into a Th1 response
Pathogen invasion	TLR-7	Agonist	Reinstatement of cytokine-induced host defence and elimination of viruses
Acute inflammation	TLR-2, -4	Antagonist	Reduction in inflammation by inhibiting TLR-2, -4 expression and HSP-70 release
Chronic inflammation	TLR-2, -4	Antagonist	Reduction in TLR-induced release of inflammatory mediators (heat shock proteins, fatty acids, hyaluronic acids)
Autoimmune disease	TLR-9	Antagonist	Blocking of production of autoantibodies and proliferation of B cells induced by immune complexes containing DNA
Sepsis	Many	Soluble TLRs Antagonists Signalling inhibitors	Ligand neutralization Mediator blockade Receptor blockade

Toll-like receptors

Toll-like receptors (TLRs) are key receptor molecules critically involved in microbial recognition by the immune system. At present, 12 members of the TLR family have been identified in mammals (Table 12.1). They recognize microbial structures such as bacterial lipopolysaccharides, bacterial DNA, viral double-stranded DNA as well as drugs or endogenous inflammatory molecules (S-100 protein MRP) [1]. There is also evidence that some probiotics which appear to be effective in allergy prevention may function via interaction with TLRs. Knowledge of the number of ligands for these receptors is growing, and it appears that multiple ligands exist for each receptor. TLRs activate common signalling pathways leading to the activation of the transcription factor nuclear factor-kappa B (NF-κB), as well as mitogen-activated protein kinases (MAPKs), which results in the production of pro-inflammatory cytokines and modulation of inflammatory processes, apoptosis or cell growth. On the other hand, individual TLRs, via their specific signalling systems, may induce immune responses to a single microbial agent. Thus, TLRs are crucial components of both the innate and adaptive immune responses.

TLRs are defined by the presence of a Toll/IL-1 receptor (TIR) domain in their cytosolic region and an extracellular domain comprising leucine-rich repeats. A key question concerns the signal transduction pathways, and whether different responses induced by different TLRs are important for the tailoring of the host defence against different microbes. In this regard, two TIR domain-containing adapter proteins, MyD88 and TIRAP/Mal, are of great interest. There is evidence from MyD88-deficient mice that MyD88 is an universal adapter for a wide range of the TIR domain-

containing receptors tested thus far [2], while TIRAP/Mal is implicated in signalling by the LPS sensor TLR-4, but not the bacterial cytosine-phosphate-guanine (CpG) DNA sensor TLR-9 or IL-1 [3,4]. Thus, TLRs are widely expressed on immunocompetent cells and thereby involved in the activation, as well as differentiation, of dendritic cells and T cells [5]. While undoubtedly important in downstream signalling responses and NF-κB activation, TLRs have not been shown to bind directly to ligands such as LPS or their complexes with LPS-binding protein (LBP) [6]. Instead, they bind to CD14, also implicated in apoptotic cell, heat shock protein and fibrinogen clearance. TLRs have recently been found to be expressed on various resident skin cells, including keratinocytes, in addition to immunocompetent cells.

The ligands so far identified that signal through TLR are mainly exogenous, but there are reports of drugs or endogenous ligands and of intracellular rather than surface engagement, through which selected TLRs may act. For example, imidazoquinolones such as imiquimod and resiquimod were found to bind to TLR-7 and TLR-8, respectively, and thereby activate macrophages. The resultant secretion of pro-inflammatory cytokines, predominantly IFN-γ, TNF-α and IL-12, was found to be responsible for an immunodeviation towards a T helper 1 (Th1) mediated response required for cytotoxicity and effective antiviral or antitumoral activity. Accordingly, topical imiquimod is successfully used for the treatment of anogenital warts and several types of skin tumour. A similar Th1-inducing effect has been observed for CpG oligodeoxynucleotides (ODN), and was found to be mediated via TLR-9. The efficacy of CpG ODN in the treatment of allergic diseases, or as an adjuvant immunotherapy for tumours, is currently under investigation. The potential for using TLRs for therapy of various inflammatory disorders is shown in Table 12.1.

TLRs play an essential role in many skin diseases such as mycobacteriosis and Wegener's syndrome. *Mycobacterium ulcerans* causes Buruli ulcer. Keratinocyte-derived toll-like receptors-2 and -4, as well as dectin-1, actively participate in the innate immune response to *M. ulcerans* by regulating internalization of bacteria, production of reactive oxygen species (ROS), and the expression of chemokines and the defensin LL-37 [7]. TLRs may be also involved in the pathophysiology of psoriasis, atopic dermatitis [8] and pityriasis rubra pilaris, which can be triggered by the TLR-9 agonist imiquimod [9]. Thus, the skin forms the outermost part of the innate immune system, by sensing danger from pathogen-associated molecule patterns (PAMPs) through toll-like receptors and other pattern-recognition receptors (PRRs). Hence, the skin may prevent inflammation by producing antimicrobial peptides or other antimicrobial intermediates before mediator release of cytokines, ROS or proteases can occur. For example, low-molecular weight hyaluronic acid induces TLR-2 and -4 activation, thereby regulating immune defence [10]. Secondly, TLRs communicate with the adaptive immune system, for example through activation of Langerhans' cells, dermal dendritic cells or T cells by TLR activation on keratinocytes. TLRs can influence the immune system in either stimulating or suppressing the immune response. For example, TLR-12 regulates susceptibility to contact hypersensitivity in mice [11]. Glucocorticoids induce TLR-2 activation on keratinocytes, suggesting that steroid-induced TLR-2 together with *P. acnes* plays a role in the exacerbation of acne vulgaris as well as corticosteroid-induced acne [12]. TLR-3 appears to be involved in antiviral defence in the skin [13].

NBS-LRR (nucleotide-binding site and leucine-rich repeat) proteins

While toll-like receptors are involved in detection of microbes in the extracellular compartment, a newly discovered family of proteins, the NBS-LRR (nucleotide-binding site and leucine-rich repeat) proteins (e.g. NODS, NALPS and NAIP) are involved in intracellular recognition of microbes and their products. Furthermore, NBS proteins may be involved in autoimmune diseases and atopic dermatitis. The NBS-LRR 'microbial-sensing' proteins participate in innate immune responses by recognizing conserved, often structural, components of microorganisms. NBS-LRR proteins are characterized by three structural domains: a C-terminal leucine-rich repeat (LRR) domain able to sense a microbial motif; an intermediary nucleotide binding site (NBS) essential for the oligomerization of the molecule, necessary for signal transduction induced by different N-terminal effector motifs, such as a pyrin domain (PYD); and a caspase-activating and recruitment domain (CARD) or a baculovirus inhibitor of apoptosis protein repeat (BIR) domain. Two of these family members, NOD1 and NOD2, play a role in the regulation of pro-inflammatory pathways through NF-κB induced by bacterial ligands. Recently, it was shown that NOD2 recognizes a specific peptidoglycan motif from bacteria, muramyl dipeptide (MDP). A surprising number of human genetic disorders have been linked to NBS-LRR proteins. For example, mutations in Nod2, which render the molecule insensitive to MDP and unable to induce NF-κB activation when stimulated, are associated with susceptibility to a chronic intestinal inflammatory disorder, Crohn's disease. Conversely, mutations in the NBS region of NOD2 induce a constitutive activation of NF-κB and are responsible for Blau syndrome, another autoinflammatory disease which includes inflammation of joints and the skin. NALP3 has been implicated in rare autoinflammatory disorders. In conclusion, NBS-LRR molecules appear as a new family of intracellular receptors of innate immunity, able to detect specific bacterial compounds and induce all inflammatory response; the dysregulation of these processes due to mutations in the genes encoding these proteins is involved in numerous autoinflammatory disorders [14].

NOD (nucleotide-binding oligomerization domain) proteins are members of a family that includes the apoptosis regulator APAF1 (apoptotic protease activating factor 1), mammalian NOD-LRR (leucine-rich repeat) proteins and plant disease-resistance gene products. Several NOD proteins have been implicated in the induction of NF-κB activity and in the activation of caspases. Two members of the NOD family, NOD1 and NOD2, mediate the recognition of specific bacterial components. Notably, genetic variation in the genes encoding the NOD proteins NOD2, cryopyrin and CIITA (MHC class II transactivator) in humans and Naip5 (neuronal apoptosis inhibitory protein 5) in mice is associated with inflammatory disease or increased susceptibility to bacterial infections. Mammalian NOD proteins seem to function as cytosolic sensors for the induction of apoptosis, as well as for innate recognition of microorganisms and regulation of inflammatory responses [15].

Type 3 complement receptor

Type 3 complement receptor (CR3) is a myeloid cell phagocytic receptor for complement-opsonized particles, responsible for direct interactions with pathogens such as *Mycobacterium tuberculosis* or yeast-derived zymosan, as well as for host ligands [16]. It is a β2-integrin also known as CD18/CD11b, critical to myelomonocytic cell recruitment to sites of inflammation, irrespective of the host or the microbial origin. The expression of CR3 by macrophages is tissue-selective, and is thus not generated by all immune cells. CR3 is promiscuous in its range of binding of ligands, including intercellular adhesion molecule-1 (ICAM-1) on endothelial cells or platelets, indicating a role at early stages of inflammation and wound healing. Moreover, CR3 contributes to clearance of apoptotic cells. Of note, the opsonic phagocytic mechanism differs from that mediated by Fc receptors, and CR3-mediated uptake by macrophages triggers cytokine release but does not trigger the release of prostaglandins or reactive oxygen species, indicating specific regulation of inflammatory processes.

Scavenger receptors

Scavenger receptors (SRs) represent a family of structurally unrelated membrane molecules expressed by macrophages and selected endothelial cells, with a broad specificity for polyanionic ligands such as low-density lipoprotein (LDL), suggesting a role in host defence and inflammation. SR-A, for example, contributes to the resistance of the host towards Gram-positive microbial infection *in vivo*. SR-A is also involved in the phagocytic uptake of unopsonized *Neisseria meningitidis* [17]. In contrast, LPS, a previously known ligand of SR-A, is not required for the uptake of *Neisseria* by macrophages, but is responsible for the TLR-4-mediated induction of pro-inflammatory responses. This is associated with an overproduction of TNF-α and other pro-inflammatory mediators, perhaps resulting from an imbalance between SR-A-dependent clearance of LPS and TLR-4-dependent pathways of secretory stimulation. Thus, the role of SRs during inflammation and infection has many interesting features. First, they are able to function as adhesion molecules, but can also mediate endocytosis and phagocytosis of modified-host components and of exogenous ligands (LPS, lipoteichoic acid, and others). The structural basis for receptor–ligand interactions remains unclear. Additionally, the signalling pathways induced by SR-A in the infected cell are poorly defined, and the ligands utilized in many studies can bind to a wide range of SR molecules. Future studies, with the availability of knockout mice for various SRs, will help to clarify their role within innate and adaptive immunity, as well as cutaneous diseases or skin homeostasis. Two novel surface scavenger receptors, SCART1 and SCART2, are related to CD5, CD6 and CD163 in developing and mature gamma delta T cells. SCART2 positive gamma delta T cells belong to a new IL-17-producing subset with distinct homing capabilities [18]. CD163 is a haemoglobin scavenger receptor and is a highly specific marker for monocytes, macrophages and histiocytes. Thus, CD163 expression is helpful in distinguishing between dermatofibroma, cellular fibrous histiocytoma and dermatofibrosarcoma protuberans [19]. Peroxisome proliferator-activated receptors (PPARs) and NF-κB may be involved in the pathophysiology of psoriasis, because deficient NF-κB activation permits unabated PPARδ-mediated transactivation, which may contribute to the pathological phenotype of psoriasis [20].

Mannose receptor and other C-type lectins

The mannose receptor (MR) is expressed by macrophages, dendritic cells and some endothelial cells. It is a multilectin, which binds mannosyl/fucosyl or GlcNAc-glycoconjugate ligands through its Ca^{2+}-dependent carbohydrate recognition domains (CRD) [21]. The ligands are present on several bacteria, fungi, virus-infected cells and parasites. Endogenous self-ligands for CRD include L-selectin, implicated in cell migration, and a number of mannose-terminal lysosomal hydrolases [22]. Recent data also suggest novel ligands for MR in peripheral lymphoid organs. Interestingly, macrophages are capable of releasing a soluble form of MR into the plasma. Thus, MR participates in complex functions related to tissue clearance, homeostasis, immunomodulation and host defence. The role of MR in inflammatory skin diseases is still obscure. MR is expressed by macrophages and dermal dendritic cells, and regulates the release of cytokines, transcription factors and receptors involved in inflammation [23] and *Candida albicans* infection [24]. MR also regulates the function of lymphatic vessels [25].

In other organs, such as the lung, it has been demonstrated that selective targeting of glucocorticoids to alveolar macrophages by applying mannosylated liposomes offers efficacious pharmacological intervention with minimal side effects, by inhibiting TNF-α, IL-1β, and cytokine-induced neutrophil chemoattractant-1 levels, suppression of neutrophil infiltration and myeloperoxidase activity, and inhibition of NF-κB [26].

Cell apoptosis and inflammation

Apoptosis (Greek: falling, as of leaves from a tree) is a physiological and programmed form of cell death that is characteristic for all nucleated cells, in plants, animals and humans. Apoptosis regulates the function of all skin cells and leukocytes by directly regulating various effector subtypes. It has to be substantially differentiated from the process of necrosis [1].

Apoptosis is the most common form of cell death in both innate and adaptive immunity. Central to the apoptotic process is a family of intracellular cysteine proteases with aspartate-specificity, defined as caspases. Caspases are intracellular proteases which are counter-regulated by multiple antiapoptotic molecules, and the expression of the latter in skin cells and immune cells is mainly dependent on survival factors. Thus, the steady state of apoptosis changes under different pathological conditions. During inflammation, the expression of survival factors is usually elevated, resulting in increased cell survival and consequently in the accumulation of the involved immune cells. In many inflammatory diseases, apoptosis is delayed, contributing to enhanced recruitment and survival of leukocytes at the site of inflammation. In keratinocytes, accelerated cell death can often be observed, a mechanism which amplifies or maintains chronic inflammatory reactions.

The first step of this fine-tuned cellular process is the induction of endogenous endonuclease activation and proteolysis. The intracellular activation machinery is very similar in all cells. Keratinocytes, for example, undergo apoptosis when irradiated with supraoptimal doses of ultraviolet light (UV light), during infection or in acute or chronic inflammation as well as in autoimmune diseases.

The pathways, regulators and counter-regulators of apoptosis are incompletely understood as of yet. In healthy tissues, cells that are no longer needed are rapidly eliminated without affecting the overall function of the tissue. In this process, cells undergo an active and spontaneous suicide, defined as programmed cell death. Most physiological cell death involves apoptosis. The morphological correlates of apoptosis include decrease of cell volume and condensation of the nucleus. However, intracellular organelles such as the mitochondria or lysosomes retain their normal morphology at this stage and are still active. Later, blebbing of the plasma membrane occurs, and the nucleus becomes fragmented. Finally, the cell itself fragments to form apoptotic bodies that are engulfed by nearby phagocytes. With respect to biochemical changes, it is known that the chromosomes become fragmented into nucleosome units.

At the cell surface, apoptosis is regulated by various receptors such as the TNF-α receptor or Fas receptor (so-called 'death signal' receptors). Survival factors include IL-3 and erythropoietin. The tumour suppressor gene *p53* plays a very important role in apoptosis induced by damage to DNA. This has been demonstrated by studying resistance to apoptosis of cells derived from *p53* knockout mice. Other molecules which have been strongly implicated as major players in apoptosis include the caspases, the Bcl-2 family proteins and the IL-1 converting enzyme (ICE). These proteins are highly conserved during evolution. Apoptosis occurs during viral, bacterial or fungal infections, neurogenic and non-neurogenic inflammation, physical trauma (e.g. UV radiation), etc. In contrast, inhibition of apoptosis in the immune system enables the survival of autoreactive B cells and T cells, and is therefore a cause of autoimmune disorders [1–3].

Fas ligand (FasL) causes apoptosis of epidermal keratinocytes and triggers the appearance of spongiosis in eczematous dermatitis. FasL also aggravates inflammation by triggering the expression of pro-inflammatory cytokines, chemokines and adhesion molecules in keratinocytes. FasL also triggers caspase activity, stimulates autocrine production of epidermal growth factor receptor (EGFR) ligands, and activation of EGFR and ERK1 and ERK2 mitogen-activated protein kinases. Subsequently, FasL regulates expression and release of CXCL8/interleukin-8, ICAM-1, IL-1α, IL-1, CCL20/MIP-3α and TSLP. Thus, FasL is involved in the regulation of epidermal inflammation [4,5]. FasL also triggers an NF-κB-dependent mRNA accumulation of inflammatory cytokines (such as TNF-α, IL-6, and IL-1β), chemokines (CCL2/MCP-1, CXCL1/GROα, CXCL3/GROγ, and CXCL8/IL-8), and the adhesion molecule ICAM-1. In the presence of caspase inhibitors, but not in their absence, FasL also triggers release of CCL5/RANTES mRNA. These findings identify a novel pro-inflammatory role of FasL in keratinocytes that is independent of caspase activity and is separable from apoptosis. Thus, in addition to causing spongiosis, FasL may play a direct role in triggering and/or sustaining inflammation in eczema [5].

In terms of the inflammatory process, recent knowledge indicates that inflammatory cells such as neutrophils, macrophages and dendritic cells are capable of directing the inflammatory response in both pro- or anti-inflammatory directions, depending on the signals which they receive. Thus, apoptosis may be either a pro- or anti-inflammatory process, depending on the microenvironment in which this interaction occurs [6].

During the past few years, it has become evident that apoptosis is not a 'passive' process in inflammatory terms, but is rather an active event in which apoptotic cells become phagocytosed, thereby inducing inflammatory responses. Thus, clearance of apoptotic cells can result in subsequent efficacious anti-inflammatory and immunosuppressive effects [7]. For example, the apoptosis of neutrophils infiltrating damaged tissue may contribute to the termination of inflammation or progression of wound healing. In the perturbed epidermis, particularly after ultraviolet (UV) light irradiation, physical trauma or certain cutaneous autoimmune diseases, apoptotic cell residues are known as Civatte cells (colloid bodies or sunburn cells) [8]. Recent data indicate that the clearance of apoptotic cells can also result in the generation of pro-inflammatory stimuli, which may ultimately lead to the amplification of chronic inflammation and also immune-mediated diseases [9].

During early stages of apoptosis in keratinocytes, the cell nuclei become convoluted and chromatin aggregates on the nuclear membrane, and cells shrink and separate from the contiguous cells (disaggregation). Subsequently, fragments of the nucleus and small apoptotic bodies become released from the cell surface ('apical blebbing'). Anatomically, apoptotic cells are composed of nuclear remnants, particles of organelles and the cytoplasm within a capsule of transglutaminase cross-linked proteins resembling differentiated involucrin in keratinocytes. Finally, the apoptotic cell residues may be ingested by professional phagocytes, such as macrophages or neutrophils [10,11].

Apoptosis differs from necrosis in that in necrosis single or very small groups of cells are affected. There is nuclear pyknosis, condensation of the cytoplasm and phagocytosis of the residual material without excitation of inflammation; resolution of the organized tissue without major structural change can occur. Nuclear pyknosis occurs in coagulative necrosis, but the change in apoptosis is caused by endonuclease splitting of the DNA, resulting in a 'ladder' pattern on separation in agarose gels, whereas necrotic cell DNA forms an amorphous smear [9].

In the skin, cell apoptosis of almost all resident or invading immune cells is induced during organ development, hypoxia, tissue injury, allergic reactions, exposure to toxins and drugs, after skin radiation with ions or UV light, and during autoimmune processes (e.g. pemphigus vulgaris). Thus, cell apoptosis can be regarded as a physiological defence mechanism against 'danger signals' threatening the skin, with the aim of clearance of the 'danger-induced' effects on tissue integrity. For example, distinct subsets of hapten-specific T cells are capable of inducing apoptosis in autologous keratinocytes. Moreover, nickel-specific $CD8^+$ and $CD4^+$ T-cell subsets can exert cytotoxic activity against keratinocytes. Finally, glucocorticoids and other immunosupressants, such as calcineurin inhibitors (tacrolimus, pimecrolimus), induce apoptotic pathways in several immune cells, thereby contributing to healing during inflammation or autoimmune diseases. Whether the induction of anti-apoptotic processes seen as a side effect during treatment with anti-inflammatory drugs is of importance for the observed amplification of infection by certain of these agents is currently unclear [10–14]. The mechanism of UV-light induced skin damage and exacerbation of lupus erythematosus has been a puzzle. Recent results demonstrate that sunlight triggers a colony stimulating factor (CSF-1)-dependent, macrophage-mediated destructive inflammation in the skin leading to cutaneous lupus erythema (LE) in LE-susceptible FAS-ligand mice but not LE-resistant mice [15]. Certain molecules have been identified in the last few years which regulate apoptosis in keratinocytes and skin immune cells. For example, Bid (BH3-interacting death domain protein) resists apoptosis and induces amplified immune responses after UVB exposure in Langerhans' cells and keratinocytes [16]. Matrix-metalloproteinases such as MMP21 are capable of inducing apoptosis in keratinocytes [17]. Thus, the skin contains an armada of proapoptotic as well as antiapoptotic instruments releasable in response to inflammatory stimuli, and which may endanger body integrity during infection or injury as well as during chronic inflammation and autoimmune diseases. Pemphigus foliaceus (PF) is an organ-specific autoimmune skin disease characterized by subcorneal epidermal cell detachment (acantholysis) and pathogenic autoantibodies against desmoglein 1. Apoptotic mechanisms in keratinocytes may be involved in PF, because proapoptotic factors such as caspases-3 and -6 as well as Bax are up-regulated, while antiapoptotic factors such as Bcl-x(L) are found to be down-regulated. Of note, caspase inhibitors such as Bok-D-fmk inhibit this effect. Thus, caspase activation and other apoptotic factors may contribute to apoptotic processes and therefore acantholytic blister formation in PF [18]. These mechanisms, however, may not be true for all subtypes of pemphigus [19].

Nucleotide-binding and oligomerization domain 2 (NOD2) belongs to the emerging NOD-like receptor (NLR) family, considered important in innate immunity. Mutations in NOD2 cause Blau syndrome, an inherited inflammation of eye, joints and skin. Mutations in a homologous region of another NLR member, NALP3, cause auto-inflammation, wherein IL-1β plays a critical role [20].

Other proteins, such as the cathelicidin LL-37, for example, may exert antiapoptotic effects on keratinocytes, thereby protecting the epidermal compartment during infection or inflammation [21].

Major histocompatibility complex and inflammation

The genetic loci responsible for the rejection of non-self tissues are located in a region known as the major histocompatibility complex (MHC) on chromosome 6. The MHC genes encode for highly polymorphic cell surface structures termed MHC antigens or human leukocyte antigens (HLA). MHC antigens are critically involved in many immune processes and skin diseases such as genodermatoses, psoriasis, and various autoimmune diseases. Three classes of molecules (I–III) have been identified. The class I and II glycoproteins share a similar overall structure and are involved in antigen presentation. There are three main class I genes (HLA-A, HLA-B and HLA-C) and three main class II genes (HLA-DP, HLA-DQ and HLA-DR). The class III proteins, although encoded by genes residing in the same chromosomal region as those for the class I and II molecules, consist of components of the complement system and molecules that are involved in the processing of antigens, such as the proteasome-like genes and transporter genes [1–3].

Each class I MHC protein is expressed on the cell surface as a dimer composed of two non-covalently-linked polypeptide chains (heavy or α-chain associated with a non-MHC-encoded β_2-microglobulin). The peptide-binding capacity of the class I MHC is enormous because each individual carries six different HLA-A, HLA-B and HLA-C alleles, and each allelic gene product is capable of generating a variety of different peptides [2,3].

The class II MHC is highly polymorphic, with the polymorphic residues concentrated in the α_1 and β_1 domains, which are involved in peptide binding. Multimeric receptor forms are also possible for other molecules involved in cognate recognition (e.g. class I MHC, T-cell receptor), and probably increase the avidity of interaction of juxtaposed cells [1–3].

Class I MHC molecules bind cytoplasmic proteins (e.g. viral proteins from infected cells) that are degraded into peptides by a large cytoplasmic proteolytic complex derived from at least two genes in the HLA class II region [4]. Class II MHC molecules bind peptides derived from exogenous proteins that have been internalized in antigen-presenting cells in a coated pit into the endocytic pathway, where antigen degradation generates functional peptides. The resulting peptide–protein complex is then translocated to, and expressed on, the antigen-presenting cell surface [5].

Under normal circumstances, self-proteins are displayed, leading to a state of tolerant inactivity. However, deleterious intracellular events lead to the display of MHC class I molecules complexed with foreign peptides, fostering the activation of $CD8^+$ T cells and the generation of cytotoxic T cells. Similarly, extracellular exposure to foreign substances results in the cell-surface display of class II MHC molecules complexed with foreign peptides, leading to the activation of $CD4^+$ T cells, the induction of B cells through helper T-cell activity, or immunoglobulin production.

The $CD8^+$ class I pathway of T cells is associated with internal cellular events. Because virtually all nucleated cells express class I molecules, essentially all cells can act as antigen-presenting cells for $CD8^+$ T cells, providing an important protection against harmful intracellular processes such as inflammation, infection or tumour development. The $CD4^+$ class II pathway is responsive to external cellular events, but the relative restriction of constitutive class II expression and antigen-presenting capacity to B cells, macrophages, dendritic cells, venular endothelial cells and probably keratinocytes limits the possibilities and consequences of activating $CD4^+$ T cells.

Dysfunction or genetic alteration of MHC alleles has been found in various skin and immune diseases. MHC class I-restricted $CD8^+$ T cells play an important part in the pathophysiology of contact hypersensitivity (CHS). Class I-restricted $CD8^+$ T cells are sufficient for the induction of CHS, supporting the idea that MHC class II-restricted $CD4^+$ T cells down-regulate this inflammatory response. Moreover, $CD8^+$ T cells mediate the skin inflammation through their cytotoxic activity using either the perforin or the Fas–Fas ligand pathway. Thus, cytotoxic $CD8^+$ T cells directly contribute to delayed-type hypersensitivity reactions [6]. Inflammation-associated regulation of MHC function appears also to be crucial in microvascular endothelial cells (HDMEC). Thus, cytokines such as TNF-α or IFN-γ, but not IL-1α, increase MHC class I expression on HDMEC [7].

Skin diseases. MHC class II antigens have been implicated in the pathophysiology of lichen planus, graft-versus-host disease and

Behçet's disease. Histopathological analysis of the skin revealed marked hyperkeratosis of the epidermis and dramatic thickening of the granular layer, with slight infiltration of inflammatory cells in the dermis, in transgenic mice carrying MHC class I chain-related gene B (MICB) [8]. Moreover, the absence of MHC class II permitted the development of systemic autoimmune effects in a mouse model of acute graft-versus-host disease [9]. In general, variation among individuals in a cluster of genes encoding inflammation-related proteins, along with MHC genes, seems to be crucial for the development of MHC-associated diseases and their susceptibility to a variety of autoimmune disorders [10].

Modern anti-inflammatory therapeutic strategies appear to be effective in the treatment of MHC-associated inflammatory diseases. For example, recombinant human IL-11 therapy was associated with suppression of mucosal inflammation, and concomitant improvement of epithelial resistance and neurally mediated secretion, in a model of chronic HLA-B27 colitis; oral treatment of HLA-B27 rats with rhIL-11 reduced myeloperoxidase (MPO) activity in the colon and suppressed clinical signs of diarrhoea [11]. For detailed information on the role of MHC in the adaptive immune response see Chapter 13.

The expression of MHC Class II is differentially regulated in epithelial cells during bacterial infection [12], and varies markedly in different chronic inflammatory skin diseases, such as allergic or atopic dermatitis and psoriasis. Among different known psoriasis susceptibility loci (*PSORS*), *PSORS1* on chromosome 6 has the strongest association to this disease as of yet. Altered expression of some *PSORS1* candidate genes has been reported, but little is known about HLA-C expression in psoriasis. Although HLA-C is abundant in protein extracts from both eczema and psoriasis, a consistent and intriguing difference in the expression pattern can be found. In psoriasis, strong HLA-C immunoreactivity occurs in the basal cell layer, polarized towards the basement membrane, whereas HLA-C immunostaining is present mostly in suprabasal cells of eczema patients and in normal healthy skin. A similar pattern can be observed for HLA class Ia expression. The difference in the HLA-C expression patterns in psoriasis and eczema suggests different functional roles in the specific immune response in different chronic inflammatory skin diseases [13–15].

Cellular components of cutaneous inflammation

Epidermis

To avoid repetition, the function of cellular constituents belonging to the adaptive immune system, such as lymphocytes and dendritic antigen-presenting cells (Langerhans' cells, dermal dendritic cells) will not be discussed here, as they are described in depth in Chapter 13.

Keratinocytes

In the past, the keratinocyte was viewed as a passive 'brick' in the defensive wall surrounding the body. However, beside their role in producing cytokeratins and lipids, keratinocytes are capable of generating and releasing an armada of different inflammatory and immunomodulatory mediators. Upon stimulation during inflammation, keratinocytes actively secrete large amounts of cytokines, chemokines, peptides and growth factors, and express receptors for these mediators, as well as several co-stimulatory molecules (Table 12.2).

The formation of the epidermal barrier is one of the mainstays of keratinocyte function. The skin forms an effective barrier between the organism and the environment, preventing invasion of pathogens and defending against physical or chemical injuries, and regulates the loss of water, molecules and solutes. The physical barrier is mainly located in the stratum corneum and consists of protein-enriched cells (corneocytes with cornified envelope and cytoskeletal elements, as well as corneodesmosomes) and lipid-enriched intercellular spaces. The nucleated keratinocyte also contributes to the barrier through tight, gap and adherens junctions, as well as through desmosomes and cytoskeletal elements. During epidermal differentiation, lipids are synthesized in the keratinocytes and extruded into the extracellular space, where they form extracellular lipid-enriched layers. The cornified cell envelope, a tough protein–lipid polymer structure, resides below the cytoplasmic membrane on the exterior of the corneocytes. Ceramides A

Table 12.2 Some important human keratinocyte cytokines and pro-inflammatory mediators (a non-exhaustive list).

Agent	Abbreviation
Interleukins	
Interleukin-1α and β	IL-1α and β
Interleukin-3	IL-3
Interleukin-6	IL-6
Interleukin-8	IL-8
Interleukin-18	IL-18
Interleukin-23	IL-23
Interleukin-33	IL-33
Interferons	
Interferon-α	IFN-α
Interferon-β	IFN-β
Pro-inflammatory mediators	
Tumour necrosis factor-α	TNF-α
Macrophage migration inhibitory factor	MIF
Prostaglandin E_2*	PGE_2
Leukotriene B_4*	LTB_4
12-Hydroxyeicosatetraenoic acid	12-HETE
Epidermal proteases	Cathepsins
Serine protease	Trypsinogen
Lysozyme	—
Neuropeptides	SP, NKA
Chemokines †	
Monocyte chemotactic protein-1	MCP-1 (CCL2)
Cutaneous T-cell-attracting chemokine	CTACK (CCL-27)
Macrophage inflammatory protein-3	MIP3a (CCL20)
Stromal cell-derived factor-1	SDF1a (CXCL12)
Inducible protein-10	IP-10 (CXCL10)
Monokine induced by γ interferon	MIG (CXCL9)
Growth-regulated oncogene-α	GRO-α (CXCL1)
Regulated on activation normally T-cell expressed, secreted	RANTES (CCL5)
Anti-inflammatory mediators	
α-Melanocyte stimulating hormone	α-MSH
IL-1 receptor antagonist	IL-1RA
Interleukin-10	IL-10
Colony-stimulating factors	
Granulocyte–macrophage colony-stimulating factor	GM-CSF
Granulocyte colony-stimulating factor	G-CSF
Macrophage colony-stimulating factor	M-CSF
Growth regulators	
Transforming growth factor-α	TGF-α
Transforming growth factor-β	TGF-β
Platelet-derived growth factor	PDGF
Basic fibroblast growth factor	bFGF
Vascular endothelial growth factor	VEGF
Endothelin-1	ET-1

† Note that chemokines are now properly referred to by their CXC/CC etc. abbreviation rather than by names describing biological activity.

* Detection in skin *in vivo*, presumably from the epidermis.

and B are covalently bound to cornified envelope proteins and form the backbone for the subsequent addition of free ceramides, free fatty acids and cholesterol in the stratum corneum. Filaggrin is cross-linked to the cornified envelope and aggregates keratin filaments into macrofibrils. Formation and maintenance of barrier function is influenced by cytokines, 3′,5′-cyclic adenosine monophosphate and calcium. Changes in epidermal differentiation and lipid composition lead to a disturbed skin barrier, which allows the entry of environmental allergens, immunological reaction and inflammation in atopic dermatitis. A disturbed skin barrier has been implicated in many skin diseases such as contact dermatitis, ichthyosis, psoriasis and atopic dermatitis [1–3].

Lipid metabolism plays an essential role in the maintenance of epidermal homeostasis and skin inflammation. The keratinocyte is a very active producer of various lipids and a key regulatory pathway in this process is that of peroxisome proliferator-activated receptors (PPARs) and their ligands. Activation of PPARα, -β/δ, or -γ or the closely related liver X-receptors (LXRs), stimulates keratinocyte differentiation and induces an armada of transcription factors involved in inflammation and metabolic regulation of cells. This leads to stimulatory signals for lipid synthesis, lamellar body formation and secretion. Accordingly, the activity of proteases and enzymes required for the extracellular processing of lipids in the stratum corneum leads to the formation of lamellar membranes that mediate permeability barrier function. The stimulation of keratinocyte differentiation and permeability barrier formation also occurs during fetal development, resulting in accelerated epidermal development. PPAR and LXR activation regulates keratinocyte mediator release, regulation of adhesion molecules, and proliferation and apoptosis. With respect to inflammation, PPAR and LXR activation is anti-inflammatory as shown in animal studies of allergic and irritant contact dermatitis. Moreover, in both psoriatic epidermis and atopic dermatitis, the expression of both PPARα and PPARγ is decreased. PPARs suppress proliferation and induce differentiation of keratinocytes, growth arrest, apoptosis and terminal differentiation. Of note, clinical trials using gemfibrozil, a PPARα ligand, resulted in a significantly lower occurrence of melanoma as compared to controls. Thus, PPARs and LXRs may be targets for anti-inflammatory therapies for diseases such as psoriasis, atopic dermatitis and others [4–6].

Keratinocytes respond to both external stimuli and endogenous trigger factors. External stimuli include bacteria, fungi, house-dust mites, viruses, antigens, mechanical stress, UV light or temperature change. Moreover, endogenous inflammatory mediators such as cytokines, neuropeptides, proteases, eicosanoids, nitric oxygen or other free radicals may directly modulate keratinocyte function. Thus, cytokines and other factors derived from keratinocytes may play a crucial regulatory role in many physiological and pathophysiological conditions in the skin such as inflammation, immune defence and wound healing.

The response of keratinocytes to injury may be separated into two phases. In the first phase, pro-inflammatory mediators are released (e.g. IL-1 and TNF-α) that initiate immediate host defence, for example by induction of adhesion molecules on endothelium and inducing migration of Langerhans' cells to draining lymphatic tissue. In the second phase, keratinocytes induce cutaneous regeneration by activating fibroblasts and proliferation of endothelium in order to repair tissue damage and restore integrity to the skin.

One of the prototypic keratinocyte-derived cytokines is IL-1. In the skin, IL-1 is constitutively synthesized in basal, and also

suprabasal, keratinocytes, and is released upon various injurious stimuli. IL-1 release can be induced in an autocrine or paracrine fashion by IL-1 itself, or by other cytokines such as TNF-α or IL-6 [7]. Not only does IL-1 release lead to local endothelial activation with leukocyte recruitment, keratinocyte-derived IL-1 can stimulate the release of secondary cytokines such as granulocyte–macrophage colony-stimulating factor (GM-CSF), which serves as a crucial mediator for the activation and differentiation of Langerhans' cells, a key part of the adaptive immune response. Keratinocyte-derived cytokines such as TNF-α, IL-1 or IL-6 may enter the circulation and subsequently exert systemic effects such as fever and acute-phase protein production. Although resting keratinocytes do not constitutively synthesize TNF-α, this important cytokine can be induced by various stimuli. At low concentrations it may regulate keratinocyte proliferation and the maturation and migration of Langerhans' cells. During inflammation and wound repair, keratinocyte-derived TNF-α also participates in the modulation of T-cell activity and dendritic cell function [8]. Moreover, keratinocyte-derived cytokines such as TNF-α are involved in the regulation of dermal microvascular endothelial cells, via stimulation of the production of cytokines as well as chemokines, and up-regulation of cell adhesion molecule expression, such as E-selectin, ICAM-1 and vascular cell adhesion molecule (VCAM). Other growth factors generated by keratinocytes include transforming growth factors (TGF-α, TGF-β) and colony-stimulating growth factors (G-CSF, M-CSF, GM-CSF), which exert multiple functions in the skin.

Keratinocytes also release a range of chemokines such as CCL-8 (MCP-2), CCL-27 (CTACK), CCL-5 (RANTES), CXCL-1 (GRO-α, CCL-2 (MCP-1), CXCL-10 (IP-10), CCL-11 (eotaxin) and others, which regulate trafficking of lymphocytes, neutrophils, eosinophils, dendritic cells and mast cells. Thus, being able to initiate endothelial activation and then direct migration of inflammatory cells through the skin, keratinocytes are likely to actively participate in the regulation of many inflammatory skin diseases including psoriasis and atopic dermatitis. These pro-inflammatory effects, however, may be inhibited by regulatory molecules such as the suppressors of cytokine signalling (SOCS). SOCS1, SOCS2 and SOCS3 proteins are up-regulated in the epidermis of psoriasis and allergic contact dermatitis but not in atopic dermatitis patients [9]. They exert multiple anti-inflammatory effects on keratinocytes, such as down-regulation of HLA-DR, ICAM-1, IP-10 and MCP-1.

Growth factors, such as epidermal growth factor (EGF), also modulate keratinocyte function during inflammation and tissue repair. Recently, an autocrine loop of keratinocyte proliferation and migration was observed during wound healing, and found to be regulated by the receptor for EGF [10]. Increased TGF-β, basic fibroblast growth factor (bFGF) and vascular endothelial growth factor (VEGF) expression levels can be also observed in keratinocytes after injury and inflammatory stimuli, indicating that keratinocytes are autocrine and paracrine key regulators of growth factors during skin inflammation and remodelling.

In addition to these non-antigen-specific pathways, keratinocytes may also participate in antigen-specific immunological responses. For example, keratinocyte expression of co-stimulatory molecules such as CD80, an important signal for professional antigen-presenting cell and T-cell interactions, is up-regulated by allergens or irritants [11]. In addition, various inflammatory stimuli up-regulate the expression of MHC molecules such as MHC II or CD1d on keratinocytes, suggesting a potential role for keratinocytes in antigen presentation [12], though this remains controversial. Keratinocytes also provide a source of antigenic proteins to which chemical haptens can conjugate. Lymph node cells from hapten-sensitized mice were found to proliferate in the presence of a keratinocyte extract without hapten [13]. Keratinocyte-derived chemokines also have an essential role during the induction, regulating Langerhans' cell egress from epidermis, as well as the elicitation phase, of contact hypersensitivity [14].

UV radiation is an important factor that modulates keratinocyte function during inflammation. UV causes DNA damage and, via the activation of the transcription factor NF-κB, induces the production of cytokines, growth factors, proteases and matrix metalloproteinases, which regulate keratinocyte function. Keratinocyte- as well as mast cell-derived cytokines such as TNF-α have been demonstrated to be involved in UV-mediated cutaneous immune responses [15,16]. It was observed that UV failed to induce tolerance in mast cell-deficient mice, and that tolerance occurred if mast cells were triggered to degranulate after activation of the IgE receptor [13]. NF-κB target genes (IL-1, IL-6, TNF-α, VEGF) also have a role in sunburn reactions after UV [17]. Finally, UV also induces the production of suppressor factors, such as IL1-RA, IL-10, TGF-β and melanocyte-stimulating hormone (α-MSH), which exert an anti-inflammatory and immunosuppressive action. The secretion of these signals following UV usually occurs later, after the initiation of pro-inflammatory mediators, and may therefore reflect mechanisms for the down-regulation of inflammation and the prevention of chronic inflammation [18]. Up-regulation of adhesion molecules such as intercellular adhesion molecule 1 (ICAM-1) on the surface of keratinocytes may play an important role in the recruitment of monocytes and activated T cells into the epidermis during UVB-induced inflammation. Recent data suggests that UVB-induced reactive oxygen species (ROS) is involved in the translocation of NF-κB, which is responsible for expression of ICAM-1 and subsequent increased monocyte adhesion to human keratinocytes [19], probably alongside MAP kinases [20].

Various microbiological agents such as viruses, bacteria, fungi or house-dust mite antigens, via multiple mechanisms including proteases, proteins and glycoproteins, may also affect keratinocyte functions, ultimately resulting in an inflammatory response. For example, human papillomaviruses (HPV) are known to modulate the expression of signals in keratinocytes that regulate their proliferation, as well as the release of mediators of inflammation. HPV-16 down-regulates IFN-responsive genes and up-regulates NF-κB-responsive genes in keratinocytes, resulting in a modified immune response. Moreover, an HPV-16 protein was found to induce the secretion of chemokines such as IL-8, RANTES, macrophage inflammatory protein-1α (MIP-1α) and IFN-γ-inducible protein. IFN-inducible genes and STAT1 (an important interferon responsive transcription factor) appear to be crucial target genes for keratinocyte-targeting viruses [21]. Thus, keratinocytes may directly alter gene expression in response to pathogens, and thereby influence host resistance to infection and inflammation.

Bacterial infections of the skin are another example of the interaction of microbes with keratinocytes. Although keratinocytes express antibacterial molecules such as defensins, streptococci and staphylococci may infect the skin by using strategies to overcome keratinocyte defence mechanisms. For example, CD44 appears to have an important role as a receptor for the colonization of keratinocytes by group A streptococci. Thus, receptor-blocking strategies on keratinocytes (e.g. TLRs, CD44 or activation of anti-inflammatory systems such as PPARs) may prove to be novel tools for the treatment of cutaneous infections as well as inflammation [22]. In summary, keratinocytes, via the release of mediators and the expression of surface molecules, subserve multiple important functions in the skin during inflammation and infection, tissue repair and autoimmunity.

Cytokines and chemokines regulate the function keratinocytes, which are an abundant source, but also targets for, these inflammatory mediators. Pro- as well as anti-inflammatory molecules have been described, and are 'hot topics' with respect to the treatment of skin inflammation. They contribute to mediator release, and activation of critical signalling pathways involved in inflammation (e.g. NF-κB, MAP kinases), as well as regulation of epithelialization, migration and cell growth. In human skin explants, recent studies have demonstrated that the chemokine CXCR2 is expressed in wounded keratinocytes, and its expression correlates well with the modulation of the Th1/Th2 ratio in the inflammatory state during wound healing, and proliferation of keratinocytes [23]. Furthermore, keratinocytes generate 'homing factors' for T helper cells to recruit those to the site of inflammation [24].

A recently described illustration of the interaction between genetic and inflammatory mechanisms in the pathogenesis of genodermatoses is Kindler's syndrome [25]. This autosomal recessive disease is characterized by trauma-induced blistering, poikiloderma, skin atrophy, mucosal inflammation and varying degrees of photosensitivity. Kindler syndrome involves loss-of-function mutations in a newly recognized actin cytoskeleton-associated protein, defined as fermitin family homologue 1, encoded by the gene *FERMT1*. This protein mediates anchorage between the actin cytoskeleton and the extracellular matrix via focal adhesions, and thus the structural pathology differs from other forms of epidermolysis bullosa in which there is a disruption of the keratin intermediate filament–hemidesmosome network and the extracellular matrix. In the skin, fermitin family homologue 1 is mainly expressed in basal keratinocytes and binds to the cytoplasmic tails of β1- and β3-integrins, as well as to fermitin family homologue 2 and filamin-binding LIM protein 1. It also plays a crucial role in keratinocyte migration, proliferation and adhesion. Consequently, dysregulation of this gene leads to epidermal blistering and inflammation.

Lymphocytes

T- and B-lymphocytes play a pivotal role in the pathogenesis and pathophysiology of many immune-mediated and inflammatory skin diseases, including psoriasis, atopic dermatitis, contact dermatitis and lichen planus. The role of T- and B-cells during

inflammation and the immune response is extensively discussed in Chapters 13 and 17, and these cells will not be discussed further here. However, the NK cell, a lymphocyte subset not discussed elsewhere, will be considered here.

Natural killer cells

Natural killer (NK) cells or large granular lymphocytes are bone marrow-derived lymphocytes that were initially characterized by their ability to lyse a variety of tumour targets and infected cells. Originally referred to as null cells, because they display neither T- nor B-cell-specific characteristics, NK cells typically express CD56, which is homologous to neural cell adhesion molecule, and sometimes express CD16, a low-affinity receptor for the Fc portion of IgG. CD16 is often associated with the CD3-ζ homodimer found in the T-cell receptor–CD3 complex. NK cells comprise approximately 10% of peripheral blood lymphocytes, and express neither B-cell-specific membrane immunoglobulins nor the T-cell receptor–CD3 complex. However, they may express some T-cell differentiation antigens, such as CD2 and CD8 (as an α/α homodimer), and myelomonocyte differentiation antigens, such as CD11b, CD11c, CD14 and CD15 [1].

It is well known that NK cells are able to secrete significant amounts of cytokines (IFN-γ and TNF-α) as well as chemokines. However, in contrast to T- and B-cell responses to antigen, which typically require a proliferation phase, the innate NK-cell response is immediate, implying that NK cells are involved in curbing pathogens during the initial hours and days of an infection. Indeed, there is strong evidence that NK cells contribute to the defence against intracellular bacteria and parasites and that they are crucial for controlling several types of viral infection. Moreover, their antitumour capacity is well established *in vitro* as well as *in vivo* [2–4].

Although NK cells do not possess the specialized gene rearrangement machinery that assembles T- and B-cell antigen receptor genes, they exhibit a clear capacity to discriminate between host and target cells. In the case of cellular targets, sensitivity to NK cells is correlated in many instances with decreased levels of MHC expression. NK cells are also able to reject MHC-incompatible bone marrow grafts. These observations led to the formulation of the 'missing self' hypothesis, by which NK cells ignore potential targets expressing normal levels of autologous class I molecules and attack cells that do not. However, 'missing self-recognition' is only one of several modes of NK cell–target cell discrimination [5–9].

NK cells preferentially kill target cells that lack surface expression of MHC class I molecules. This implies the existence of triggering receptors that recognize non-MHC ligands on these target cells. Unlike T lymphocytes that recognize MHC–peptide complexes using clonally distributed T-cell receptors generated by gene rearrangement, NK cells appear to use triggering receptors that do not require this genetic process. These triggering receptors can initiate NK-cell activation and target cell lysis, provided that NK cells are not turned off by activation of MHC class I-specific inhibitory receptors. These data suggest that triggering NK receptors involved in natural cytotoxicity recognize non-MHC ligands expressed not only by abnormal but also by normal cells [10,11].

NK receptors. NK cell activity is regulated by opposing signals from receptors that activate and inhibit their effector functions. Three distinct receptor families, Ly49, CD94/NKG2 and KIR (killer cell-inhibitory receptors), are involved in NK-cell recognition of polymorphic MHC class I molecules. Recent studies suggest these inhibitory NK-cell receptors are members of a larger superfamily containing immunoreceptor tyrosine-based inhibitory motif (ITIM), defined as the inhibitory receptor superfamily (IRS). Thus, NK cells are regulated by a balance of signalling via stimulatory receptors, specific for diverse ligands, and inhibitory receptors, specific for MHC class I molecules [12].

Three novel NK-specific triggering surface molecules that are involved in natural cytotoxicity have been identified (NKp46, NKp30 and NKp44). They represent the first members of a novel emerging group of receptors, collectively termed natural cytotoxicity receptors (NCRs) [13]. Interestingly, there exists coordinated surface expression of the three NCRs, their surface density varying in different individuals and also in the NK cells isolated from a given individual and altered expression or function of NCR or NKG2D is being explored as a possible cause of immunological disorders. Upon activation of NCRs, NK cells undergo blastogenesis, generate cytokines, enhance cytotoxicity and migrate. In contrast, inhibitory receptors prevent killing of normal cells and limit the production by NK cells of inflammatory cytokines, including TNF-α, IFN-γ and GM-CSF.

Other NK-cell receptors include the low-affinity receptor for IgG, CD16 (Fc RIII). The transmembrane-anchored CD16 isoform is expressed on the majority of (but not all) NK cells, as well as on activated monocytes and a subset of T cells. Upon CD16-mediated activation, NK cells secrete cytokines [14], mediate antibody-dependent cellular cytotoxicity and may undergo apoptosis as a consequence of Fas ligand-induced cell death [15]. CD2 may be a co-stimulatory receptor that augments primary activation of NK cells. NK specificity is derived from expression of a variety of MHC-specific receptors, such that each NK cell expresses several inhibitory and stimulatory receptors. Together these mechanisms ensure a self-tolerant and maximally discriminating NK-cell population.

Upon stimulation, NK cells produce high levels of certain cytokines and chemokines. They have a crucial role in the defence against a number of different infectious agents and tumours. The first evidence of this function came from observations that virus-induced interferons (IFN-α and -β) are potent inducers of NK-cell-mediated cytotoxicity, and that NK cells are important contributors to innate defence against viral infections. Subsequently, a wide range of other innate cytokines have been detected that mediate biological functions regulating the NK-cell responses of cytotoxicity, proliferation and IFN-γ or TNF-α production. For example, certain viral infections induce IL-12, which elicits IFN-γ production by NK cells, thereby inducing antiviral mechanisms. Thus, after microbial stimulation, NK cells have immediate effects resulting in host defence, especially with regard to viruses. In addition, chemokines such as MIP-1α are capable of stimulating migration of NK cells, probably via binding of the CCR5 chemokine receptor. Other chemokines that activate NK cells are CCL-4 (MIP-1β), CCL-2, CCL-8, CCL-7 (MCP-1, -2, -3) and CCL-5 (RANTES). In addition, numerous cytokines have been found to modulate

NK-cell function, including IFN-α and -β, which induce cytotoxic activity, stimulate proliferation and inhibit IL-12 production [13,16].

Unlike T and B cells, NK cells develop normally in scid mice or mice with disrupted rearrangement genes, indicating that gene rearrangement is not required for their differentiation or function. NK cells are clearly instrumental in innate immune responses, in particular providing for the early production of IFN-γ and possibly other cytokines necessary to control certain bacterial, parasitic and viral infections. The factors responsible for activation of NK cells during infection have remained elusive, but probably involve soluble factors such as IFN-α and -β, cytokines (TNF-α, IL-12, IL-15) and chemokines, as well as the presence of certain membrane-bound molecules on surrounding tissues. Although positive stimuli are required to activate NK-cell migration and effector function, the process is tightly regulated by inhibitory receptors and cytokines that limit and potentially terminate the response [17–19].

Signalling lymphocytic activating molecule (SLAM) family receptors and SLAM-associated protein (SAP)-related adapters play several important roles in the immune system. Natural killer (NK) cells express at least three members of the SLAM family. They are 2B4, NK, T- and B-cell antigen (NTB-A), and CD2-like receptor-activating cytotoxic cells (CRACC), which recognize their respective ligands CD48, NTB-A, and CRACC on target cells and possibly on other NK cells. In mature human NK cells, SLAM family receptors appear to have activating functions. In mature mouse NK cells, however, the only available information is for 2B4, which reportedly has the capacity to either stimulate or inhibit NK cell activation. The ability of SLAM family receptors to regulate NK cell functions seems to be largely dependent on their capacity to associate, by way of their cytoplasmic domain, with members of the SAP family of adapters, including SAP, Ewing's sarcoma-activated transcript-2 (EAT-2), and EAT-2-related transducer (ERT). By binding to SAP, SLAM family receptors are coupled to the Src kinase FynT, thereby evoking protein tyrosine phosphorylation signals. In human NK cells, SAP is likely to be crucial for the activating function of 2B4 and NTB-A, but not of CRACC, and SAP is also crucial for the activating function of 2B4 in mouse NK cells. Thus, SAP proteins and SLAM receptors have important functions in NK cell biology [20]. Mutations that affect the adaptor molecule SAP underlie the primary immunodeficiency disease X-linked lymphoproliferative syndrome. SAP is required for mediating signals from members of the SLAM family of immunomodulatory receptors. Recent data have highlighted a role for SAP in the development of innate-like T-cell lineages, including natural killer T cells, and in the regulation of the interactions between B cells and T cells that are required for germinal-centre formation and long-term humoral immunity. These data have revealed that SLAM family members and SAP have crucial roles in regulating lymphocyte interactions and adhesion, which are required for the normal development, homeostasis and function of the immune system [21].

In the skin, recent investigations have revealed that NK cells are involved in the pathophysiology of atopic dermatitis [22], contact dermatitis [23], sarcoidosis [24], transplant rejection [25] and infection [26].

Thus, NK cells serve as sentinels in the immune system, which is constantly assailed by pathogens as well as antigens, and where the achievement of a balance is crucial to permit elimination of pathogens but avoid autoimmunity. The potential for self-aggression is dramatically illustrated by the phenotype of mice with disrupted cytotoxic T-lymphocyte antigen 4 (CTLA-4) genes. In these animals, CD28 stimulation via CD80 or CD86 in the absence of negative regulation by CTLA4 [27,28] leads to a catastrophic T-cell lymphoproliferative disease that results in death. Receptors that possess the consensus ITIM (CD22, LAIR-1, gp49, LIR1, gp91/PIR, ILT1/2, ILT3) sequence seem to be crucial in this context [13,17,27,28].

Polymorphonuclear granulocytes

The polymorphonuclear granulocytes, basophils, eosinophils and neutrophils, are the mobile attack forces of the human body defence system to infection and injury as well as being involved in allergy. All cells arise from haematopoietic precursors, undergo maturation within the bone marrow and are released into the blood as mature leukocytes. Eosinophils and basophils are thought to arise from a common mononuclear stem cell, which is stimulated to divide by the cytokines IL-3 and GM-CSF acting in concert with stromal factors. While the production of these cells is limited under normal conditions, in allergy, increased levels of GM-CSF and IL-5 result in their increased production. Both eosinophils and basophils are primarily tissue cells with a very limited lifespan in the blood. For eosinophils, the lifespan in the blood is approximately 24 h and during injury the tissue:blood ratio is about 100:1. In contrast, neutrophils are constitutively generated by the bone marrow in large numbers. Because of the large number produced and the relatively short lifespan (less than 24 h), more than half of the work done by the bone marrow is dedicated to the production of neutrophils. In inflammation, increased levels of inflammatory cytokines stimulate enhanced neutrophil production. IL-3, IL-6, GM-CSF and TNF-α are the cytokines that are most likely to be involved.

Basophils

Although representing less than 1% of the circulating leukocytes, basophils can be purified from the blood and have been studied extensively *in vitro*. Like mast cells, basophils stain metachromatically with aniline dyes but can be distinguished from mast cells by their bilobed nucleus.

Structurally and functionally, basophils have a lot in common with mast cells. Perhaps the most important similarity is the presence of FcεRI, the high-affinity receptor for IgE, on their surface. Basophils derived from allergic patients contain up to 500 000 IgE receptors per cell [1]. However, they can be activated by cross-linkage of only approximately 1% of this number [2], making them exquisitely sensitive to allergen stimulation. It has been suggested that IgE on basophils may be in one of two forms, IgE^+ or IgE^- cells, with the former form being activated by IL-3 and histamine-releasing factors [3,4]. Furthermore, like skin mast cells, basophils are activated by the complement fraction, C5a. Other receptors on basophils are for IL-3, IL-4 and GM-CSF, which prolong their survival, and a histamine H_2 receptor, which down-regulates their function. The ease with which basophils can be obtained from patients has led to their widespread use *in vitro* in research and diagnosis of allergic disease (e.g. to detect circulating histamine-releasing autoantibodies in chronic urticaria [5]).

Basophils contain about 1 pg/cell of histamine, which, as in mast cells, is stored in modified lysosomal granules in combination with proteoglycans, predominantly chondroitin sulphate in the case of the basophil. Basophils contain very small amounts of tryptase, but no chymase. On stimulation, basophils generate relatively large amounts of the leukotrienes (LT) LTC_4, but not LTB_4 or the prostaglandin (PG) PGD_2 [6]. Another important function of the basophil is the generation of IL-4 and IL-13, which are critical for switching the B lymphocyte to IgE production [7,8].

In allergic diseases, basophils migrate from the bone marrow, enter the circulation as mature cells and infiltrate tissues in response to inflammatory stimuli. Knowledge of their role within the tissues is largely circumstantial. One reason is that basophils infiltrating an area of active allergic disease are likely to undergo degranulation quite rapidly and therefore be difficult to detect. Another is that until recently it has been difficult to distinguish tissue basophils from mast cells. However, monoclonal antibodies to a basophil granule protein have been described [9,10], which revolutionized basophil research; for example, evidence for basophil recruitment during late-phase allergic response is now unequivocal [11].

Eosinophils

The idea of an association between eosinophils and allergic disease, particularly asthma, has long history. Until the 1980s, it was thought that eosinophils might be anti-inflammatory. However, with the realization that eosinophil granule proteins are highly toxic, this view changed to one of eosinophils being considered as pro-inflammatory cells. Indeed, many of the features of asthma and related allergic diseases were considered to be mediated by eosinophil products. However, recent studies with anti-IL-5 and IL-12, which ablated eosinophils but failed to relieve asthma [12,13], have thrown doubt on the pivotal role ascribed to eosinophils in allergic diseases.

Coming from a common precursor, eosinophils and basophils are closely related. Eosinophils, like basophils, are approximately 8 μm in diameter, have a bilobed nucleus and use the blood merely as a transport system to reach the tissues. The eosinophil cytoplasm contains two types of granule, the most characteristic of which is the core-containing specific granule, which contains the basic proteins. Such granules avidly take up acidic dyes (e.g. eosin), giving eosinophils their characteristic microscopic appearance. The other granule is the so-called 'primary granule', which lacks a core and is of variable size. Also present in the cytoplasm are a number of lipid bodies, thought to be a store of arachidonic acid for eicosanoid synthesis.

The eosinophil membrane is particularly rich in receptors for adhesion proteins, chemokines and cytokines. For example, the coordinated action of IL-5, CCR3 binding chemokines and the adhesion molecules P-selectin and VCAM-1, acting in concert, cause selective recruitment of eosinophils into allergic tissue [14]. Once in the tissues, GM-CSF, IL-5 and eotaxin serve to both prime eosinophils for chemotactic and degranulatory responses and adhesion and cytotoxicity, and to prolong survival. Interestingly, eosinophils produce large quantities of GM-CSF and IL-5, so

ensuring their own survival [15]. Eosinophils also possess immunoglobulin receptors for IgA, IgG and IgE, and therefore have wide interactions with the immune system.

The major proteins of the eosinophil granule are major basic protein (MBP), eosinophil cationic protein (ECP), eosinophil peroxidase (EPO) and eosinophil-derived neurotoxin (EDN). To explain their presence, it must be remembered that the allergic response was originally developed as an immune defence system against helminth parasite infestation. All the above proteins are highly toxic to helminths. As they are also potentially toxic to mammalian cells, they may cause tissue damage in allergic responses. In addition, the peroxidase actions of EPO may lead to the generation of toxic oxygenated free radicals.

Eosinophils are probably the major producers of LTC_4 in allergic inflammation. Although this has profound implications for asthma, the importance in allergic responses in the skin is less clear. However, the beneficial effects of leukotriene receptor antagonists in atopic dermatitis [16] and urticaria [17] suggest an involvement.

In peripheral blood and non-inflamed tissue, eosinophils are in a resting state to prevent unwanted tissue damage from eosinophil-derived mediators. Thus, basophils are important regulators of immune cells such as eosinophils [18,19], and are critically involved in anaphylaxis [20]. In order to become activated, eosinophils must first be primed by exposure to the cytokines IL-5, GM-CSF and IL-3, or the lipid products platelet-activating factor (PAF) and LTB_4. As the majority of these substances are also chemoattractants, the end result is large numbers of degranulating eosinophils and heavy granule protein deposits at sites of allergic inflammation. Such a strategy would be ideal if the target was the surface of a large helminth parasite. However, in allergic skin disease, the stimulus is allergen and not a parasite. Even so, large deposits of extracellular eosinophil granule proteins are found in both urticaria [21] and atopic dermatitis [22,23], with raised MBP levels being found in the circulation [24].

Neutrophils

Neutrophilic polymorphonuclear leukocytes (or neutrophils) are approximately 7 μm in diameter and are easily recognized in conventional cytological preparations by their pinkish cytoplasm and distinctive polymorphic nuclei. When neutrophils are viewed under the electron microscope, a number of heterogeneous granules are obvious. The larger of these, the so-called primary or azurophilic granules, are peroxidase-positive, whereas the smaller ones, the so-called secondary or specific granules, are peroxidase-negative. Other subcellular structures, such as Golgi apparatuses, are scarce.

Neutrophils are the most numerous of the blood leukocytes and represent the first line of defence of the immune system against infection and tissue injury. As a consequence, it is necessary for them to be able to reach an inflammatory site very rapidly. Once released from the bone marrow, the majority of neutrophils are 'stored' intravascularly by the process of margination. It has been calculated for a 70-kg male that the number of marginated neutrophils is approximately 3×10^{10} [25]. The expression of a high density of adhesion proteins on their cell surface allows large numbers of neutrophils to move rapidly from their marginated sites into inflamed tissues. Indeed, evidence of their accumulation may be seen within minutes of a tissue stimulus. Several adhesion proteins have been identified on the neutrophil, the most important being the integrin LFA-1 (CD11a/CD18), which is the ligand for ICAM-1 [26]. In order to move rapidly to an inflammatory site once in the extravascular compartment, neutrophils must also express high levels of receptors for a wide range of chemotactic agents, such as IL-8 and LTB_4 (Fig. 12.2). Neurotrophins are also capable of modulating neutrophil function [27].

Like the other granulocytes, neutrophil mediators may either be preformed and stored in granules or be synthesized *de novo* on cell activation. The preformed mediators are mainly enzymes that facilitate the primary function of the neutrophils—to phagocytose and digest bacteria and other foreign particles. Neutrophil lysosomal granules contain more than 20 enzymes, including proteinases, elastase, gelatinase, collagenase, lysozyme, cathepsin G and defensins [28]. These enzymes may act either intracellularly to digest ingested bacteria or be released into the extracellular environment during inflammation. A further enzyme, myeloperoxidase, facilitates the bactericidal respiratory burst, which is characteristic of neutrophil activation [29]. In this reaction, oxygen radicals, hydrogen peroxide (H_2O_2) and superoxide (O_2^-) generated by the peroxidase converted into the even more toxic hypochloric acid (HOCl) and hydroxyl ($OH^\bullet$) radicals.

Evidence of the capacity of neutrophils to cause tissue damage is, for example, the tissue degradation around an implanted foreign body, such as a splinter, in order to facilitate its rejection as part of the healing process. Pus is an extreme example of neutrophil activity resulting from severe degradation of tissue and of dead leukocytes. However, the potential for neutrophils to cause overt tissue damage is limited by the presence of antiproteinases, such as α_2-antiproteinase, α_2-macroglobulin and antielastins, which penetrate the tissues from plasma during inflammation. Therefore, it is unlikely that neutrophils cause overt tissue damage in the presence of normal levels of antiproteinases. However, in antiproteinase deficiency, as has been suggested is the case in emphysema, the potential for neutrophil-induced tissue damage is enhanced [28]. Neutrophils also play an important role in *Staphylococcus aureus* infections and the onset of methicillin-resistant *S. aureus* infection [30,31].

The primary role of the newly generated mediators appears to be directed to the recruitment of more neutrophils. In the short term, this is facilitated by the synthesis and release of large quantities of LTB_4, a potent neutrophil attractant. *In vitro*, neutrophils certainly have the capacity to synthesize the cytokines IL-1β, TNF-α and IL-8, which would serve to recruit and activate further neutrophils, and IL-6, IL-12 and GM-CSF, which stimulate haematopoiesis of neutrophil precursors. However, bearing in mind that the peak production time for cytokines is often 12–24 h after cell stimulation, the clinical significance of their production in a cell with a tissue lifespan often less than 6 h is questionable.

The potential role(s) of neutrophils in inflammatory diseases is even less clear than that of basophils and eosinophils. In many situations when the neutrophils are present microscopically, it is difficult to evaluate whether their presence is a cause or consequence of the condition. Moreover, there is evidence that damage to the blood vessel wall in cutaneous leukocytoclastic vasculitis is

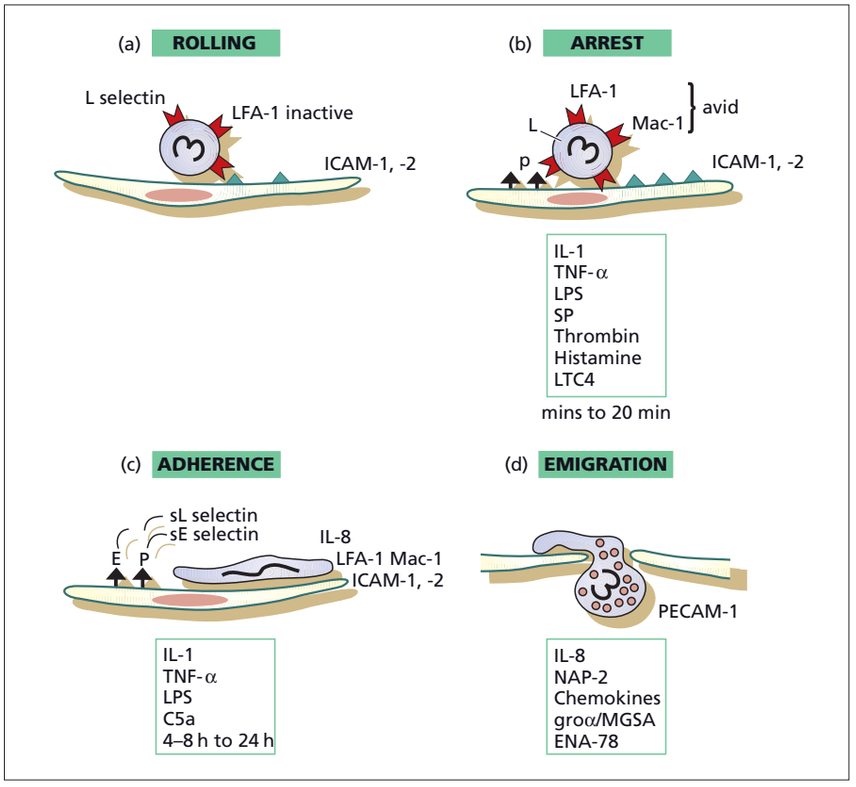

Fig. 12.2 Neutrophil emigration. (a) Rolling: cells roll over the endothelium by brief non-adherent contacts via the selectins, particularly L-selectin. The integrins are non-binding. (b) Arrest: on contact with activated endothelium, selectin binding briefly increases, integrins become avid and intercellular adhesion molecule 1 (ICAM-1) increases on the endothelial surface. (Monocytes and eosinophils also bind via α4β1 to vascular cell adhesion molecule 1 (VCAM-1).) (c) Adherence: the neutrophil flattens on the endothelium, affinity increases and motility response to chemokines is initiated. (d) Emigration: neutrophil leaves vessel through interendothelial cell junction, regulated by integrins, platelet/endothelium cell adhesion molecule 1 (PECAM-1) and chemokines.

caused by enzymes from activated neutrophils [32]. It has also been suggested that neutrophil elastase is involved in the dermal–epidermal cleavage observed in bullous pemphigoid [33].

The L-selectin molecule is localized to neutrophil microvilli and is cleaved or 'shed' during neutrophil activation, possibly permitting neutrophils to migrate from the intravascular lumen into sites of inflammation. After activation, P-selectin facilitates and supports neutrophil degranulation, superoxide (O_2^{2-}) production, and polarization in response to PAF and bacterial formylated peptides, such as formyl-methionyl-leucyl-phenylalanine (fMLP) [34]. In response to chemoattractant, cross-linking of L-selectin on neutrophils primes cells for increased O_2^{2-} production and calcium influx, and stimulates adhesion. Interaction of neutrophils with endothelial cells also results in increased mRNA levels for TNF-α and IL-8.

Many chemokines, including IL-8 and other chemoattractants such as formyl peptides, complement C5a, LTB_4 and PAF, cause rapid neutrophil adhesion, thereby supporting their emigration from the vasculature [35]. In contrast, the role of various mediators and chemokines in activation of the process of rolling of neutrophils in inflamed venules is still unclear. In certain *in vitro* systems, neutrophil arrest from rolling can be attributed to a single chemoattractant. For example, human umbilical vein endothelial cells (HUVEC) treated with histamine or thrombin support P-selectin-dependent neutrophil rolling and PAF-dependent activation [36]. However, in most inflammatory models *in vivo*, PAF synthesis or receptor antagonists have little or no effect.

Inflammatory or bacterial substances in sufficient amounts may depress the activities of neutrophils, as observed in patients with extensive leg ulcers, for example. Acquired defects in neutrophil chemotaxis are also observed in diabetes mellitus, which may be corrected *in vitro* by the addition of potassium, glucose and insulin. Thus, reduced random movement and response to chemotactic substances may be induced in previously normal neutrophils by severe bacterial infection, without obvious granule changes. This is reversible, because the reduced responsiveness of neutrophils returns to normal during effective treatment. In such cases, it is necessary to differentiate diminished activity induced in mature cells from the normal, lesser activity of immature cells mobilized as a result of the infection.

Abnormalities in neutrophils can have profound effects on resistance to disease. Several defects in enzyme activity have been observed. A deficiency in the H_2O_2–myeloperoxidase–halide system impairs the bactericidal activity of leukocytes. A very good example is chronic granulomatous disease, characterized by recurrent granulomas of skin and lymph nodes, which is associated with defective ability of neutrophils to kill bacteria [37]. An impairment in nicotinamide adenine dinucleotide (NADH) oxidase results in a failure to form H_2O_2 [38], which is critical for effective bactericidal activity. Moreover, deficiency of glucose-6-phosphate dehydrogenase (G6PD) results in the inability to kill catalase-active bacteria.

Several diseases have been revealed to be associated with defects in neutrophil function. In leukocyte adhesion deficiency-I (LAD-I),

patients lack CD18 and therefore all β2 integrins; their neutrophils can neither tightly adhere to endothelium nor exit from the circulation in response to infection. LAD-I patients have recurrent skin and mucosal infections, with most patients dying before the age of 10 years [39]. However, qualitative activation rather than quantitative expression of β2 integrins seems to be critical for stimulated neutrophil adhesion [40,41]. Another class of patient has defective carbohydrate fucosylation and lack of expression of sialyl Lewis X (sLex) ligands [42]. These 'LAD-II' patients have decreased neutrophil motility *in vitro*, neutrophilia and recurrent bacterial infections. Interestingly, classic drugs such as colchicine have been shown to decrease E-selectin density on endothelial cells and to down-modulate L-selectin expression on neutrophils [43]. Methotrexate inhibits neutrophil adhesion to connective tissues [40]. Corticosteroids lower adhesion molecule expression on both endothelium [44] and neutrophils [45]. Salicylates also inhibit neutrophil adhesion, probably by blocking activation of CD11b/CD18 [46].

Chédiak–Higashi disease is a rare autosomal recessive disease affecting neutrophils and all other lysosomal granule-containing cells in the body. The disease is secondary to mutations in *Lyst*, a gene encoding a cytoplasmic protein involved in lysosomal trafficking [47,48]. The neutrophils contain giant granules resulting from specific and azurophilic granule fusion. Patients have recurrent bacterial infections, neurological disease, partial albinism, platelet dysfunction and early death [39].

Another inherited granule disorder characterized by recurrent bacterial infection is specific granule deficiency, marked by the absence of neutrophil-specific granules and defensins. The disorder is probably secondary to the deficiency of transcription factor CCAAT/enhancer binding protein E, which has a critical role in normal myeloid cell development. Recently, a mutation in the gene encoding this protein has been characterized, and a knockout mouse for the gene has been engineered, showing impaired nicotinamide adenine dinucleotide phosphate (NADPH) oxidase activity [49], phagocytosis, intracellular killing and migration [50–52].

Mast cells

Mast cells (MC) are a heterogeneous group of multifunctional, tissue-dwelling cells with roles in conditions as diverse as allergy, parasite infestation, inflammation, angiogenesis and tissue remodelling. The cells were named 'Mastzellen' (Greek *mastos*, breast) in 1876 by Paul Ehrlich because he believed that the intracellular granules, which appeared purple in colour when stained with aniline blue dyes, contained phagacytosed materials or nutrients [1]. This change in colour, or metachromasia, we now know to represent the interaction of the dyes with the highly acidic heparin contained within mast cell granules. Mast cells are haematopoietic in origin, entering the circulation from the bone marrow as mononuclear cell precursors that both express mRNA for stem cell factor (SCF) and have SCF receptors (SCFR, CD117) on their cell membranes [2]. From the blood, the precursors migrate into the tissues where, under the influence of local microenvironmental factors, they undergo their final phases of differentiation and maturation into recognizable mast cells. It is pertinent at this stage to distinguish mast cells from basophils, which were originally thought to be circulating mast cells, but are actually related more closely to eosinophils, developing in the bone marrow from granulocyte precursors and entering the circulation only when fully mature [3]. Mast cells and basophils differ in their repertoire of mediators released (Table 12.3).

Table 12.3 Comparison of mediators formed by human mast cells and basophils.

Mediator/product	Mast cells	Basophils
Histamine	+	+
Leukotriene C_4	+	+
Leukotriene B_4	–	(+)
Prostaglandin D_2 (PGD_2)	+	–
5-HETE	+	–
Thromboxane A_2 (TXA_2)	+	–
Platelet-activating factor (PAF)	+	–
Interleukin-1β	+	
Interleukin-3	+	
Interleukin-4	+ +	+
Interleukin-5	+	?
Interleukin-6	+	?
Interleukin-8	+	+
Interleukins-9, -10, -13, -14	+	
MCP-1α (chemokine)	+	
TNF-α	+ +	–
Tryptase/chymase	+	–
Carboxypeptidase	+	–
Heparin	+	–
Nerve growth factor (NGF)	+	
Eosinophil chemotactic factor	+	+
Neutrophil chemotactic factor	+	?

Mast cells are distinguished immunocytochemically by their neutral protease content, the MC_T phenotype containing only tryptase and the MC_{TC} phenotype containing both tryptase and chymase [4]. MC_T and MC_{TC} mast cells also express different receptors (Table 12.4). Initially, these respective subtypes were suggested to be the equivalents of the 'mucosal' and 'connective tissue' types previously described in experimental animals. However, it is now realized that variable amounts of both mast cell subtypes are present within any given tissue, their relative abundance changing with disease (e.g. in allergy or fibrosis). MC_T appear to be 'immune system-related' mast cells with a primary role in host defence, whereas MC_{TC} appear to be 'non-immune system-related' mast cells with functions in angiogenesis and tissue remodelling rather than immunological protection. However, it should be remembered that both phenotypes express Fc, εRI and may therefore participate fully in IgE-dependent allergic reactions.

In addition, there appears to be a functional heterogeneity between mast cells of different tissues, which is largely unrelated to immunocytochemical heterogeneity. For example, human skin mast cells alone express CD88, the receptor for the anaphylatoxin C5a, allowing them to be activated in a complement-mediated

Table 12.4 Receptors identified on the mast cell and basophil membrane.

Receptors	Mast cells		Basophil	Ligand/agonist
	MC_{TC}	MC_T		
FcεR1	+	+	+	IgE
CD32 FcγRI	–	–	+	IgG
CD88				
C5aR	+	(–)	+	C5a
C3aR	–	–	+	C3a
CD25				
IL-1R	+	–	–	IL-1
IL-2R	–	–	+	IL-2
IL-3R	–	+	+	IL-3
IL-5R	–	–	+	IL-5
CDw128 IL-8R	–	–	+	IL-8
GM-CSFR	–	–	+	GM-CSF
Toll-like receptor (TLR)				
TLR1	+	(–)	–	
TLR2	+	–	+	Bacterial peptides
TLR4	+	–	+	LPS
TLR6	+	–	–	Bacterial peptides
Chemokine receptors				
CCR1	+	(–)	(+)	MIP1-α
CCR2	–	–	+	MCP
CCR3	+	(–)	+	MCP
CCR4	+			
CD40L	+	–	+	CD40 : B cells
CD117 c-*kit* (KL)	+	+	(+)	Stem cell factor c-*kit* ligand

GM-CSF, granulocyte–macrophage colony-stimulating factor; IL, interleukin.

disease [5,6]. Also, skin mast cells alone respond to a variety of basic non-immunological secretagogues, including neuropeptides and drugs, such as morphine, codeine and muscle relaxants [7,8]. Interestingly, activation by these agents is incomplete, in that eicosanoid generation does not accompany degranulation [7]. The ability of human skin mast cells, but not those from other tissues, to respond to anaphylatoxins and basic non-immunological secretagogues explains the flushing reactions observed in sensitive individuals in the absence of overt rhinorrhoea or bronchoconstriction. Such responses may also be involved in physical urticarias.

The secretory granule of the human mast cell contains a crystalline complex of preformed inflammatory mediators ionically bound to a matrix of heparin proteoglycan. The mediator most readily associated with the mast cell, the simple diamine histamine, is present in the granules at approximately 100 mmol/L, equivalent to about 1–4 pg/cell. Histamine exerts many effects pertinent to the immediate phase of allergic responses, including initiation of the wheal and flare response [9]. However, these effects are normally of relatively short duration as histamine is rapidly metabolized, usually within 1–2 min, by histamine-*N*-methyltransferase (approximately 70%) and by diamine oxidase (histaminase) (approximately 30%). Interestingly, reduced diamine oxidase activity has been associated with recurrent urticaria [10].

The other 'early phase' mediators released from the skin mast cell are PGD_2 and LTC_4 [11]. While there is little evidence for a role of the former in skin inflammation, the success, particularly in individuals with a variant LTC_4 synthase allele [12], of leukotriene receptor antagonists in atopic dermatitis [13] and urticaria [14] suggests that this eicosanoid may be more important in skin disease than considered previously.

The major mast cell protease is tryptase, an approximately 130-kDa serine protease that is stored in a fully active form in the granule [15,16]. When released into the extracellular environment, the neutral pH allows tryptase to become enzymatically functional as a tetramer bound to heparin. The properties of tryptase pertinent to the skin include cleavage of the vasodilator calcitonin gene-related peptide (CGRP); a kallikrein-like activity; cleavage of matrix components, including 75-kDa gelatinase/type IV collagen, fibronectin and type VI collagen, and activation of stromelysin, which may, in turn, cleave other matrix components; and mitogenic activity for fibroblasts. While there appear to be no endogenous inhibitors of tryptase, it is likely to have very local effects because, in the absence of heparin, the biologically active tetrameric form of tryptase rapidly dissociates into inactive monomers. In addition to acting as an enzyme in the extracellular space, tryptase and other serine proteinases have been demonstrated to activate specific receptors by proteolytic cleavage. In the skin, tryptase activates proteinase-activated receptor-2 (PAR-2), which is constitutively expressed by keratinocytes and myofibroblasts. Upon inflammatory stimuli, endothelial cells, nerves and immune cells up-regulate PAR-2 expression. Interestingly, tryptase mimics various effects of histamine via activation of PAR-2 such as oedema, plasma extravasation, recruitment of neutrophils, and induction of pruritus. Thus, alongside histamine, tryptase is an important mediator of inflammatory responses, suggesting a role in inflammatory skin diseases such as atopic dermatitis, urticaria and angio-oedema [17,18].

Chymase is a 30-kDa monomeric protease stored in the same secretory granules as tryptase in the MC_{TC} subset of mast cells. Chymase degrades the neuropeptide neurotensin, but not substance P or VIP, cleaves angiotensin I to angiotensin II more effectively than angiotensin converting enzyme (ACE), and may also contribute to the splitting of the dermal–epidermal junction in bullous pemphigoid [15,19]. Two other proteinases, carboxypeptidase and cathepsin G, have been associated with the MC_{TC} subset of human mast cells. Carboxypeptidase is a unique 34.5-kDa metalloproteinase that removes the carboxyl terminal residues from a range of peptides, including angiotensin, leu^5-enkephalin, kinetensin, neuromedin N and neurotensin. Cathepsin G is a chymotryptic enzyme with a structure seemingly identical to that of neutrophil cathepsin G. When mast cells are activated, chymase, carboxypeptidase and cathepsin G are released together in a 400–500-kDa complex with proteoglycan, and are likely to act in concert with the other enzymes to degrade proteins.

With the discovery that polymorphisms in *SPINK5*, a gene encoding for a serine protease inhibitor, are associated with Netherton's syndrome and other allergic diseases [20], the potential role for proteases in skin disease seems to be extending.

Cytokines are responsible for the initiation and coordination of allergic inflammation. It is logical, therefore, that the mast cell is

a source of such cytokines. Of particular note are the NF-κB-dependent cytokines, TNF-α, GM-CSF and IL-8 [21,22] and the Th2 cytokines, IL-4, IL-5 and IL-13 [23,24]. Thus, not only have mast cells the capacity to initiate immediate phase allergic and anaphylactic reactions and tissue damage, they also have the capacity to stimulate allergic inflammation, which is characterized by the influx of basophils, eosinophils and neutrophils [25].

Histamine released by mast cells binds to and activates histamine receptors. Four of them (H1R to H4R) have been cloned so far. Besides its effects on sensory nerves and endothelial cells, histamine also modulates keratinocyte function directly, such as MMP-9 production and cell migration. Thus, histamine may contribute to epidermal dysregulation during the acute or chronic phase of inflammation [26].

The fact that many pathological processes affect the activation of mast cells in the skin and that the number of mast cells varies in different skin and allergic diseases, tumours and fibrotic diseases, indicates an important regulatory role of these cells in many diseases. Indeed, mast cells are capable of releasing more than 30 mediators with diverse roles, including pro- as well as anti-inflammatory cytokines/chemokines, TNF-α, growth factors, proteases and prostanoids [27]. In mutant mice which are profoundly mast-cell deficient or genetically altered, mast cells revealed features usually seen during inflammatory or immune responses, tissue remodelling, host defence and skin homeostasis [28,29].

Monocytes and macrophages

The monocyte–macrophage system, formerly known as the 'reticuloendothelial system', represents a heterogeneous family of cell types that vary within different tissues. The range of functions of monocytes and macrophages is summarized in Table 12.5, and their receptor expressing and mediator repertoire is shown in Table 12.6. They all derive from identical progenitors in the bone marrow, where they mature from monoblasts to pro-monocytes. The maturation time is approximately 16 h in the rat and 19–25 h in humans. As mature cells, monocytes may remain in the blood for approximately 2–5 days. Following inflammatory stimuli, monocytes adhere to the endothelium and subsequently migrate into the site of inflammation where they differentiate into macrophages or dendritic cells (antigen-presenting cells). During acute inflammation, the rate of monocyte formation may be dramatically increased. This is important because resident macrophages show only a poor ability to divide [1,2].

Table 12.5 List of major functions of monocytes and macrophages, their receptors and secretory products.

Antitumour activity
Atherogenesis
Control of T and B lymphocytes
Control of dendritic cell function
Coagulation and fibrinolysis
Detoxification
Granuloma formation
Host defence
Metabolism and storage of lipids and iron
Mediation of acute and chronic inflammation
Modulation of keratinocyte function
Processing of antigens
Recruitment of leukocytes
Regulation of haematopoiesis
Release of enzymes for degradation
Scavenging of necrotic debris and effete cells
Wound healing

Table 12.6 List of major products released and receptors expressed by monocytes and macrophages.

Receptors (R)
IgG, IgE, IgA
C-reactive protein
C1q
C3b, C3bi
Fibrin
Fibronectin
Laminin
Transferrin
Heparin
IFN-α, -β, -γ
TNF-α
GM-CSF
Insulin
Insulin-like growth factor
Platelet-activating factor (PAF)
HLA-DR (class II MHC)
Macrophage inhibitory factor (MIF)
IL-2, -3, -4, -8, -10, -13, -16, -19, -23, -26
LTC, LTD_4, LTB_4
PGE_2
Histamine H_1, H_2
CCR4, CCR5
Angiotensin II
Toll-like receptors
α-adrenergic agents
β-adrenergic agents
Cholinergic agents
Products secreted
Atrial natriuretic peptide (ANP)
Lysozyme
Neutral proteases
Acid proteases
Lipases
Collagenase, elastase
α_2-Macroglobulin
α_1-Antiprotease
Complement C1, C2, C4, C3, C5
Factors B and D
NO
Prostaglandins E_2, $F_{2\alpha}$
Leukotrienes B, C, D, E
Thromboxane (TXA_2)
Glutathione
IL-1α, -1β, -1ra, -6, -8, -10, -12, -18
MIF
PAF
TNF-α
IFN-α/β
TGF-β
PDGF
GM-CSF, M-CSF, G-CSF
Respiratory burst reactive oxygen radicals

Macrophages rapidly recognize pathogens and 'danger signals' in the connective tissue by means of cell surface receptors [3] such as CD14, the mannose receptor, the SR, RAGE, protease-activated receptors [4] and TLRs (see above). These receptors recognize specific ligands released by microorganisms, leading to intracellular signal transduction pathways and ultimately initiating an inflammatory response. Macrophages also represent an important link to the adaptive immune system by generating immunomodulating cytokines such as interferons. In addition, they release IFN-γ and express MHC class II antigen HLA-DR, and may thus stimulate lymphocytes.

Macrophages have also been shown to utilize molecules from the complement system to interact with pathogens, and may subsequently undergo apoptosis or become degraded. Under pathophysiological conditions, macrophages may become incorporated into a granuloma or be converted into an epithelioid cell, with an increased ability to synthesize enzymes or other mediators of inflammation. Moreover, macrophages can also be incorporated into a giant cell by fusion with other macrophages. Such pathophysiological chronic inflammatory processes are observed in diseases that may affect the skin, such as tuberculosis, leprosy and sarcoidosis.

Macrophages are professional phagocytes; they recognize pathogens by specific receptors and subsequently phagocytose them. During this active, energy-driven process, macrophages generate acidic phagosomes and lysosomal mediators such as oxygen radicals. Macrophage-derived proteolytic enzymes, cathepsins D and G, acid phosphatases or matrix metalloproteinases are released during inflammation. Under normal circumstances, this network of defence molecules is a very effective barrier in the maintenance of tissue homeostasis. Under pathophysiological conditions, however, when defence mechanisms are impaired, these mediators may also have deleterious effects on the host, resulting in tissue destruction and fibrosis, as observed in various diseases such as arthritis.

Macrophage migration inhibitory factor (MIF) was originally described as a T-cell-derived lymphokine with the potential to inhibit the random migration of macrophages. However, recent reports have shown a much broader tissue distribution of

production, including the skin. Recently, an MIF has been localized to many skin cells such as keratinocytes [5], fibroblasts [6] and endothelial cells. An important role for MIF has been reported in several skin diseases such as lupus erythematosus [7], contact hypersensitivity [8], atopic dermatitis [9], psoriasis [10,11], wound healing [12], systemic sclerosis [13], graft-versus-host disease [14] and sepsis [15,16]. Thus, MIF may represent an important target molecule for the treatment of skin diseases in which macrophages are involved.

The production of arachidonic acid derivatives appears to be crucial for macrophage-mediated responses during inflammation. PGE_2, for example, is involved in lymphocyte activation by macrophages and also inhibits macrophages in an autocrine manner, indicating a negative-feedback system via specific prostaglandin receptors.

Macrophages are major targets for infection by human immunodeficiency virus type 1 (HIV-1). In addition to their role as productive viral reservoirs, inappropriate activation of infected and uninfected macrophages appears to contribute to pathogenesis. These responses establish a complex cytokine network, which may enhance or suppress HIV-1 replication. In addition, dysregulation of macrophage function by gp120–chemokine receptor signalling may contribute to local inflammation and injury and further recruit additional inflammatory and/or target cells [17].

Other receptors expressed by monocytes/macrophages are the peroxisome proliferator-activated receptors (PPARs). These are ligand-activated transcription factors that form a subfamily of the nuclear receptor gene family. This subfamily consists of three isotypes, PPARα (NR1C1), -γ (NR1C3) and -β/δ (NRC1C2) with a heterogeneous tissue distribution. PPARs are activated by ligands, such as naturally occurring fatty acids, which are activators of all three PPAR isotypes. In order to be transcriptionally active, PPARs need to heterodimerize with the retinoid-X-receptor (RXR). PPARs have a critical role in lipid and glucose homeostasis, but lately they have been implicated as regulators of inflammatory responses including in the skin. The first evidence of the involvement of PPARs in the control of inflammation came from PPARα knockout mice, which showed a prolonged inflammatory response. PPARα activation results in the repression of NF-κB signalling and inflammatory cytokine production in different cell types. A role for PPARγ in inflammation has also been reported in monocytes–macrophages, where ligands of this receptor inhibited the activation of macrophages and the production of inflammatory cytokines (TNF-α, IL-6 and IL-1β), although part of the anti-inflammatory effects of these ligands seems to be mediated by a mechanism not involving PPARγ. PPARs also regulate the gene expression of key proteins involved in vascular inflammation. By modulating transcription of pro-inflammatory genes such as cytokines, chemokines, endothelial cell adhesion molecules and metalloproteinases, PPARs directly affect inflammatory events. Together, these findings suggest a role of PPARs in the control of the inflammatory response, with potential therapeutic applications in inflammatory diseases such as acne, atopic dermatitis and psoriasis [18–22].

A novel family of monocyte-derived receptors has been described, which seems to be important in the regulation of inflammatory responses. This family of triggering receptors expressed by myeloid cells (TREMs) belongs to a rapidly expanding family of monocyte-derived receptors that include activating and inhibitory isoforms encoded by a gene cluster linked to the MHC. TREM1 and TREM2 activate myeloid cells by signalling through the adaptor protein DAP12. TREM1 triggers phagocyte secretion of pro-inflammatory chemokines and cytokines, amplifying the inflammation that is induced by bacteria and fungi [23].

Macrophages can remain within the tissue in a quiescent resting phase for months until stimulated through ligand binding to one or more of their numerous receptors (Fig. 12.3). They express receptors for IgG (FcγRI, FcγRII, FcγRIII) and complement components C3b and C3bi [24]. They also express receptors for C-reactive protein (CRP), which in blood monocytes induces synthesis of IL-1β and IL-1 receptor antagonist (IL-1RA).

There is evidence for a close interaction between T lymphocytes and macrophages. T-cell-derived IFN-γ both primes macrophages for an enhanced response to other cytokines and activates them to increase oxygen utilization and H_2O_2 formation. It also induces nitric oxide formation, increases phagocytic and tumouricidal activities, initiates or enhances MHC class II membrane antigen expression, and stimulates the synthesis of several cytokines and receptor expression. T-cell IL-2 stimulates macrophages, particularly if they are primed by IFN-γ. Macrophages also synthesize many cytokines such as IL-1, a potent pro-inflammatory signal.

Macrophages serve as an effective component of innate immunity by their ability to recognize, engulf and kill potential pathogens through lysosomal degradation. They also coordinate additional host responses by synthesizing a range of inflammatory mediators that can activate the adaptive immune response and establish protective immunity. Although they are a key component of the mammalian defence system, macrophage activity is not always beneficial to the host. The centrality of macrophages in disease processes makes macrophage regulation a major target in the prevention, control and cure of inflammatory processes. Consequently, macrophage-restricted genes may be crucial targets for therapeutic intervention. Large-scale cDNA microarrays have been used to compare macrophage inflammatory genes differentially expressed in two distinct macrophages populations (bone-marrow-derived macrophages and inflammatory thioglycolate-elicited peritoneal macrophages) with those in non-macrophage cell populations, such as primary embryonic fibroblasts and splenic non-adherent cells. Expression profiles indicate that macrophage inflammatory genes are associated with expected functional categories, such as lysosomal degradation, phagocytosis, host defence and homeostasis.

With respect to the molecular regulation of cytokine signalling in macrophages during inflammatory skin diseases, the Jak–Stat–Socs pathway has been shown to regulate all cell types involved in the initiation, propagation, and resolution of skin inflammation. The Jak–Stat pathway is negatively regulated by the suppressor of cytokine signalling (Socs) protein pathway. Thus, Jak–Stat–Socs signalling modulates developmental, pro- and anti-inflammatory outcomes depending on the cytokine receptor activated and which genes are accessible at the current state of inflammation [25].

Macrophages have been implicated in the regulation of T-cell function in the pathophysiology of psoriasis [26–30], atopic dermatitis, sarcoidosis, wound healing and Kawasaki disease [31], as

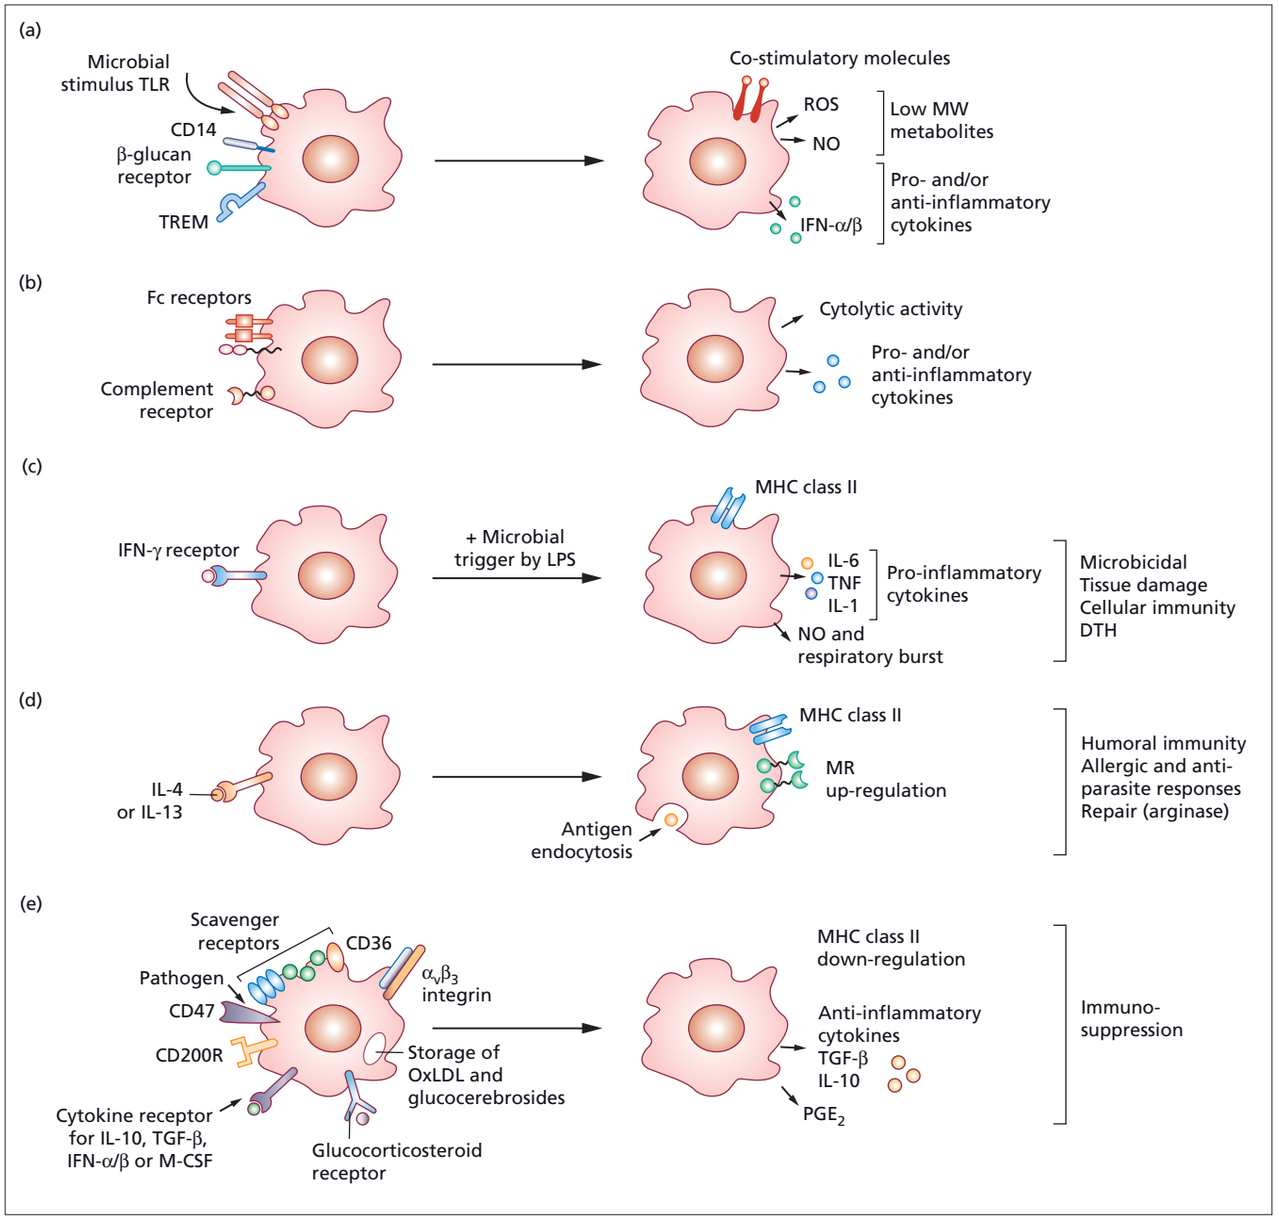

Fig. 12.3 Role of macrophages in innate and acquired immune function. (Modified from Gordon S. Alternative activation of macrophages. *Nature Rev Immunol* 2003; **3**: 23–35.) (a) Macrophages recognize pattern-recognition receptors such as toll-like receptors (TLRs), CD14–LPS-binding protein and others. These stimuli induce production of pro-inflammatory cytokines such as interferons, nitric oxide and reactive oxygen species. This is followed by a well-tuned anti-inflammatory response. Scavenger receptor (SR-A) and mannose receptor (MR) promote phagocytosis and endocytosis of host and of exogenous ligands. (b) Humoral activation and phagocytosis are mediated by some Fc and complement receptors, whereas other receptors down-regulate these responses. (c) Classical activation is triggered by the priming stimulus IFN-γ, followed by a microbial trigger (e.g. LPS). (d) Alternative activation is mediated by IL-4 and IL-13, acting through a common receptor chain (IL-4Rα). (e) Inactivation can be of innate as well as of acquired origin. Uptake of apoptotic cells or lysosomal storage of host molecules generates anti-inflammatory responses. Cellular activity is modulated by interactions of macrophages with T cells, fibroblast or extracellular matrix by activating specific receptors. Glucocorticoids and anti-inflammatory agents can suppress macrophage function. Pathogens can deactivate macrophages thereby contributing to infection. DTH, delayed-type hypersensitivity; M-CSF, macrophage colony-stimulating factor; OxLDL, oxidized low-density lipoprotein; PGE_2, prostaglandin E_2, TGF-β, transforming growth factor-β; TREM, triggering receptor expressed on myeloid cells.

well as in autoimmune diseases such as lupus erythematosus [32].

Fibroblasts

Under physiological conditions, fibroblasts are part of the connective tissue and the source of most of the extracellular matrix protein elements in the dermis. Intercellular substrates in the dermis are mainly composed of collagens, fibronectin, laminins, syndecans, decorin, hyaluronic acid, heparan sulphate and glycosaminoglycans (GAGs) (see Chapter 3). GAGs covalently bind to proteins to form proteoglycans, which are able to bind proteins such as cytokines, chemokines or growth factors in the extracellular space. Fibroblast-derived matrix molecules such as collagens, laminins and fibronectin are capable of modulating cell–cell interactions between fibroblasts and inflammatory cells. For example, migrating T cells or mast cells interact with extracellular matrix proteins via β2-integrin activation to regulate cell migration during inflammation or wound healing.

After stimulation, fibroblasts are able to transform into several types of specialized cell such as myofibroblasts, smooth-muscle cells, chondrocytes and osteocytes. It is not known if the different phenotypes arise from pluripotential stem cells or from subtypes with restricted properties of differentiation. Some differentiated fibroblasts can revert to the original mesenchymal state, whereas others persist as mature, committed cells. Therefore it is not surprising that fibroblast-derived cartilage and bone may occasionally be found in scar tissue induced by thus far unknown stimuli. Under normal circumstances in the skin, fibroblasts mature into dermal fibrocytes. After maturation, their function is merely restricted to the synthesis of extracellular matrix proteins such as collagens, elastin, hyaluronic acids and glycosaminoglycans. In the skin, collagens I, III, IV, VII, XVII, fibronectin and laminins are of special interest, due to their capability of regulating dermal–epidermal interactions via modulation of the basal lamina composition at the dermal–epidermal border, around vessels, and skin appendages. Thus, fibroblasts are critical cells for skin homeostasis but are also involved in inflammatory responses.

Under pathophysiological conditions, fibroblasts or fibrocytes can be involved in many diseases, such as connective tissues diseases (e.g. scleroderma, scleromyxoedema), vasculitis, graft-versus-host disease, wound repair, fibrosis, skin ageing, scar formation, keloids, autoimmunity and tumourgenesis.

During inflammation, the morphology and properties of fibroblasts are strictly dependent on the surrounding microenvironment. Dermal fibroblasts grown *in vitro* on different substrates, such as collagens or laminins, but maintained in the same medium, show differences in morphology, integrin expression and cytokine synthesis. Moreover, dermal fibroblasts cultured in contracting collagen gels form sixfold more PGE_2 than do cells cultured on plastic [1]. Fibroblasts in floating collagen gels are stellate with long cytoplasmic processes [2]. After gel contraction, the DNA synthesis is reduced [3] and collagenase synthesis is increased [4]. In contrast, fibroblasts grown on anchored (non-contracting) gels become elongated, bipolar and lie along lines of tension, similar

to fibrocytes [5]. They synthesize DNA, proliferate [3,6] and do not exhibit increased collagenase synthesis.

Alterations of the extracellular matrix generated by fibroblasts may depend on stimulation by certain cytokines, chemokines, proteases or growth factors. For example, the expression of β1-integrin chains α2, α3 and α5 in fibroblasts on fibronectin and fibrin substrates is regulated by platelet-derived growth factor (PDGF) and similar to that observed in fresh wounds. Moreover, PDGF also modulates the integrin synthesis in fibroblasts, resembling that of the granulating tissue of wounds [7]. Moreover, differences in the matrix composition alter PDGF-receptor phosphorylation [8]. Therefore, the responsiveness to PDGF is one of the most potent mediators controlling fibroblast proliferation and collagen formation.

During wound healing and scar formation, the surrounding environment of fibroblasts modulates freshly damaged tissues with fibrin clots (coagulation at early stages) to organized extracellular matrix at later stages. Moreover, hypertrophic scars are characterized by a stable phenotype of fibroblasts which differ from normal fibroblasts and exhibit a reduced response to epidermal growth factor (EGF) as well as an increased synthesis of collagens [9].

Inflammation plays an important role in the initiation and progression of scleroderma. In a study of systemic scleroderma, collagen formation was increased as the α2 chain of the α2β1 integrin was reduced [10]. Similarly, the down-regulation of collagen mRNA expression in fibroblasts of systemic scleroderma patients tended to be less than that in controls. This increased potential to form collagen was associated with a decrease in the α1β1 integrin [11]. Both α1β1 and α2β1 integrins, but particularly α2β1, recognize collagen-1 in the dermis, and the reduced integrin expression associated with increased collagen synthesis may reflect defective signalling between fibroblasts and their collagen matrix environment.

Dermal fibroblasts synthesize prostaglandins, leukotrienes and several cytokines or chemokines. As resident cells, fibrocytes release pro-inflammatory mediators as an early response to skin injury, and growth factors to promote subsequent healing. The production by fibroblasts *in vitro* of leukocyte activating/attracting agents is somewhat in contradiction to the *in vivo* histological findings, which rarely reveals accumulation of leukocytes round fibroblasts. Therefore, it is possible that proteoglycan binding of some of the cytokines results in a more diffuse leukocyte infiltration. Fibroblast proliferation is stimulated mainly by PDGF, TGF-β and fibroblast growth factor (FGF). The growth factor TGF-β may either stimulate or reduce proliferation, depending upon the state of cell activation [12]. Finally, synthesis of collagens or other connective tissue elements is induced by PDGF or TGF-β. In contrast, TNF-α may stimulate or repress synthesis depending on the state of activation [12]. In normal skin as well as during disease, a close interaction exists between fibroblast and keratinocyte activation which is regulated by cytokines, chemokines and growth factors.

Several *in vitro* studies suggest that eosinophils may have a role in fibrosis, remodelling and repair processes associated with IgE-mediated hypersensitivity. Eosinophil-derived TGF-β and IL-13 is temporarily associated with myofibroblast formation and deposition of tenascin and pro-collagen I, suggesting that both inflammatory mediators may contribute to repair and remodelling events of inflammatory skin diseases by modulating fibroblast function [13]. There is also evidence of a role for neuropeptides in the modulation of fibroblast functions. Thus, it has been shown that expression and cellular levels of SCF are up-regulated in fibroblasts by substance P (SP) [14]. In summary, fibroblasts contribute crucially to the interaction of epidermal and dermal components to maintain skin integrity.

In wounds involving the dermis, activated fibroblasts migrate on structures of the extracellular matrix such as collagens, fibronectin or fibrin, where they proliferate and synthesize new matrix proteins including collagens and elastin to form new granulation tissue. During this process, fibroblast (myofibroblast) proliferation becomes gradually reduced as the collagens mature and the wound contracts [6,15]. In the granulation tissue, the fibroblasts are transformed into myofibroblasts, with several morphological, chemical and antigenic differences as compared to resident mature fibroblasts [16,17]. Myosin in the activated cell is phosphorylated to expose actin-binding sites, to form actin–myosin contractile or stress fibres across the cell. Focal contacts or integrins exert tension forces on the extracellular matrix components. The first formed collagen gel is compacted and modified to form strands of dermal tissue fibres. The fibroblasts migrate to lie along the fibres as seen in normal dermis, at which time they lose their myosin stress fibres, although they continue to contribute to the overall tension of the skin.

Platelets

Platelets are derived from megakaryocytes in the bone marrow and are the major components involved in blood clotting and homeostasis. Upon injury and inflammation, platelets regulate leukocyte aggregation and adherence to the endothelium, reflected by cell arrest and emigration into the tissue. Using video microscopy, transient platelet rolling on endothelium has recently been observed. Platelets accumulate in the vicinity of an injury, making them available for an immediate response [1]. Moreover, platelets contain a variety of potent inflammatory mediators and growth factors that contribute to normal homeostasis of blood cells, acute inflammation, tissue repair and immune responses. Accordingly, platelets release mediators such as eicosanoids, ADP, amines, proteolytic enzymes and cationic proteins. They are also a source of serotonin (5-HT), which is released during vascular injury, resulting in enhanced deposition of immune complexes on the endothelium. Thus, the formation of platelet aggregates and the subsequent release of mediators appear to have a role in tissue damage during cutaneous small vessel vasculitis [2].

In contrast to their classical role in coagulation, platelet production and activation appears to be a critical cell type at early stages of inflammation, injury and immunity. Platelets become activated and interact with endothelial cells, thereby stimulating the increase of inflammatory transcription factors and mediators such as NF-κB and interleukin-6. Thus, continuous activation of platelets leads to the perpetuation of inflammatory signalling and amplification of the inflammatory response, as observed in vasculitis.

Platelets are functionally closely associated with all types of leukocytes. Activated platelets secrete chemotactic substances, facilitate the binding of leukocytes to the endothelium as well as their subsequent extravasation, and may influence the inflammatory responses of leukocytes by both stimulation and inhibition. However, platelets also contain an array of potent pro-inflammatory substances, and are therefore effector cells of inflammation. Because of the role of platelets in IgE-dependent killing and eosinophil infiltration, they are currently considered to be directly involved in allergic IgE-mediated reactions [3].

Platelets express several receptors and can be activated by plasma products, immunoglobulins, complement, extracellular matrix components, leukocytes (particularly neutrophils) and endothelial cells. Receptors for soluble agonists include ADP [4], FcγRII [5,6] and complement component C3a [7]. They also express PARs belonging to a novel subfamily of G-protein-coupled receptors with seven transmembrane domains activated by serine proteases [8,9]. PAR-1, -3 and -4 are thrombin receptors in mice (PAR-3, PAR-4) and humans (PAR-1 and PAR-4). During inflammation, PARs become activated by thrombin on platelets, leading to mediator release and regulation of endothelial cell and leukocyte function. PAR-1 is critically involved in angiogenesis and leukocyte transmigration [8].

α11bβ3 (also designated glycoprotein 11b–111a or GP11b–111a) represents an important platelet-specific integrin. Upon activation, it is recruited to the cell surface, where it is capable of binding to thrombin, collagen or laminin [10]. The platelet integrin α2β1 (GP1a–11a) binds collagen [11], α5β1 and α6β1 (GP1c–11a) bind to fibronectin, collagen and laminin, while CD36 (GPIV) binds thrombospondin and possibly collagen [12]. Complement binds to the granule membrane protein 140 (GMP-140). Upon activation, GMP-140 expression is induced on platelets and endothelium, resulting in up-regulation of E-selectin and the promotion of leukocyte adherence [13].

Some receptors may bind to several ligands, and the activating potential of distinct ligands varies. Whereas 'strong agonists' (thrombin, collagen, thromboxane A_2 [TXA_2] and PAF) elicit a direct response, 'weak agonists' (9-ADP, adrenaline [epinephrine], vasopressin and serotonin) depend upon secretion to mediate a full response. Antagonists include PGI_2, PGD_2, endothelium-derived relaxing factor (EDRF) and nitric oxide [14]. Several of these are generated as the result of platelets activating other platelets (TXA_2, ADP and serotonin).

Receptors of normal platelets are either intracellular or, if on the cell surface, do not contact their ligands in undamaged tissue. On activation, rapid exposure and realignment of receptors stimulates second-messenger G proteins, protein tyrosine kinases and phospholipases [14]. The platelets change shape to develop numerous microspicules, which leads to aggregation of platelets and binding to other cells [15]. Platelets are reported *in vitro* to release microparticles that preferentially bind, activate and aggregate neutrophils, increasing expression of the CD11b receptor [16]; *in vivo* this would increase neutrophil–endothelium binding. Platelet–neutrophil interaction promotes formation of leukotrienes and lipoxins, the precursors of which are derived from both cells. Di-HETE is formed by the interaction of platelet 12-lipoxygenase (12-LO) and neutrophil 5-LO; neutrophils release LTD_4 and LTC_4 [17,18]. Such transcellular mediator synthesis results in concentrations of pro-inflammatory lipoxins and leukotrienes at the site of vascular damage. Using 12-LO-deficient mice, a role for platelet-type 12-LO in normal transepidermal permeability barrier function in mice was shown [16]. Other platelet pro-inflammatory mediators include TGF-α and -β, PDGF and prostaglandins; platelet aggregates in clots are the source of most prostaglandins in the blood during inflammation [19]. PDGF is both a pro-inflammatory mediator by virtue of activating neutrophils and monocytes, and a growth factor inducing tissue repair by regulating fibroblast proliferation, chemotaxis and collagen synthesis.

The expression receptors for immunoglobulins and complement on platelets may contribute to inflammation and to the removal of potential agonists. Thus, via signalling through IgG as well as IgE receptors [3,5,6], the release of pro-inflammatory mediators is enhanced, and the activation of C3a receptors induces release of serotonin and synthesis of thromboxane [5]. The IgG receptors bind IgG–antigen complexes, which are removed from

the circulation when the platelet complex is subsequently ingested by phagocytes in the spleen, liver and elsewhere.

Thrombospondin 1 (TSP-1), an adhesive glycoprotein expressed by endothelial cells, fibroblasts and macrophages, has an important role in platelet adhesion, inflammation and cell–cell interaction [20,21]. TSP-1 is up-regulated early during tissue injury, and is involved in angiogenesis, inflammation and vascular skin diseases by directly interacting with endothelial cells.

Recent data strongly suggest platelets to be directly involved in immune responses. Thus, blood platelets participate actively in immune defence and inflammatory processes. Upon activation via adenosine-triphosphate (purinergic receptors) or protease-activated receptor-1 (PAR-1), platelets release a variety of mediators, including cytokines, chemokines such as thymus and activation-regulated chemokine (TARC/CCL17) or RANTES, platelet factor 4 (PF-4), PDGF, β-thromboglobulin, serotonin, proteases, and arachidonic acid metabolites (prostanoids) [22,23]. Platelets also induce the expression of immunomodulatory and cell adhesive molecules such as CD154 and P-selectin. Conversely, inflammatory processes in the skin induce platelet activation, which contributes to acceleration and modulation of many inflammatory processes including vasculitis. Activated platelets are capable of facilitating leukocyte rolling in the skin and the release of inflammatory mediators in the skin. Platelets might be an important effector cell of the skin immune system, with modifications of platelet function contributing to the pathophysiology of certain inflammatory skin disorders such as urticaria or psoriasis [24,25]. The changes in platelet activity and reactivity have been demonstrated to impact on the pathophysiology of wound healing [26,27], urticaria, atopic dermatitis and psoriasis [3,28,29].

Mediators of inflammation

The main role of the inflammatory response is the elimination of external noxious stimuli such as irritants, allergens and pathogens, or of endogenous stimuli such as toxic or infectious agents. There is also a necessity to avoid tissue disruption and cell destruction, and to restore tissue homeostasis. Balance between these potentially opposing requirements is achieved by generating a variety of inflammatory mediators, which may exert their effects in an autocrine, paracrine, juxtacrine or endocrine manner.

A wide variety of distinct mediators, including cytokines, phase proteins, kinins, prostanoids, leukotrienes, neuromediators, oxygen, nitrogen and carbon products, are involved in the orchestration of inflammation. Importantly, these mediators are not only released by leukocytes and lymphocytes, but also upon activation

during injury by almost any cell residing at the site of inflammation. The final outcome depends on the nature, severity and duration of the injurious stimuli, and reflects a cascade of well-tuned interactions between several mediators released by different cell types. Furthermore, the activation and up-regulation of specific receptors for each of these mediators is crucial for the outcome of any inflammatory reaction. Occasionally, some mediators can activate more than one receptor and, vice versa, some receptors can be activated by several ligands.

Acute-phase proteins

During the acute phase of inflammation, cytokines such as TNF-α, IL-1 and IL-6 rapidly stimulate the release of proteins from hepatocytes to coordinate tissue integrity. Acute-phase proteins (APPs) are defined as plasma proteins if their serum concentration increases by more than 25% after tissue destruction. They are released by the liver to opsonize pathogens, inhibit protease function and clear cell detritus. APPs such as CRP, mannan-binding lectin, complement proteins, fibrinogen, α_1-antitrypsin, α_1-antichymotrypsin, haptoglobin, serum amyloid A and acid α-glycoprotein may have several pro- or anti-inflammatory activities. Moreover, hormones (e.g. glucocorticoids) are capable of stimulating APP synthesis within hours.

CRP is an APP that can be detected in the serum during infection and tissue damage within 24–48 h. Because CRP correlates well with disease progression, it is a reliable activity marker for inflammatory or infectious processes. It binds phosphorylcholin of LPSs in the cell membrane of bacteria and fungi, activates the classical complement pathway [1], stimulates leukocyte chemokinesis and phagocytosis, and induces a spontaneous vasculitis [2]. It is proposed that one function of CRP is to mobilize cells rapidly to counteract infection, before specific antibody is formed.

Another APP that activates the complement pathway is mannan-binding lectin. Together with the pulmonary surfactant proteins, mannan-binding lectin belongs to the family of 'collectins' that contain a globular lectin-like domain which is able to bind the membrane of pathogens [3,4].

The classic complement pathway is initiated by CRP, heparin, protamine sulphate and DNA, and also by plasmin or trypsin action on C1s. The alternative pathway is initiated by bacterial and endogenous endotoxin and cell debris. Complement C5 is cleaved by leukocyte enzymes, particularly neutral proteases, neutrophil elastase and acidic protease cathepsin G [5]. Epidermal cells contain serine proteinases active at neutral pH, which appear to cleave C5, resulting in a greater neutrophilia than seen in similar tests with plasmin and trypsin [6]. C3 is activated by trypsin and neutrophil elastase. The processes of clotting, generation of kinins and fibrinolysis all activate complement. The pro-inflammatory properties of C5a, C3a and C4a on mast cells and basophils, as anaphylatoxins releasing cell mediators and, in the case of C5a, attracting and activating leukocytes, are described in Chapter 13.

Serum factors such as complement, DNase I, pentraxins (e.g. CRP) and IgM contribute to efficient opsonization and uptake of apoptotic and necrotic cells. Defects in these factors may impact the development of systemic lupus erythematosus (SLE) in humans and mice and may represent a central pathogenic process in the development and acceleration of SLE [7]. The status of acute phase proteins can be dramatically modified during cytokine therapy [8].

Cytokines

Cytokines are structurally related polypeptides or glycoproteins that exert their effects at concentrations within the pico- or nanomolar range. Originally, they were regarded as immunocompetent cell-derived immunomodulators. However, recent knowledge demonstrates that a clear-cut differentiation between cytokines, growth factors, neurotransmitters and hormones is not possible. The predominant role of cytokines is to mediate inflammatory and immune responses. Cytokines determine the direction of immune responses and control tissue integrity during injury. Thus, the quality and quantity of cytokine production within the injured tissue determines whether the immune system is directed into a humoral or cytotoxic cell-mediated allergic response. Moreover, cytokines (along with other mediators) determine the switch of the immune system from a pro- to an anti-inflammatory state.

Over the last decades, a large body of knowledge has accumulated on the role of cytokines in cutaneous inflammation. They are ultimately involved in all phases of inflammation. While pro-inflammatory cytokines induce the body response to external or internal danger, anti-inflammatory cytokines are capable of restoring tissue homeostasis by suppressing inflammatory processes. Various molecular biology and modern immunological techniques have been applied to cytokine research, and the genes for many of these factors have been cloned and characterized in the skin. Together, these studies clearly demonstrate that many cytokines exert pleiotropic functions. For example, IL-1 was originally described as a leukocytic pyrogen, endogenous pyrogen, B-cell-activating factor and lymphocyte-activating factor. Today it is well known that various skin cells, including keratinocytes, use IL-1 to communicate with neighbouring cells in the skin during inflammation [1]. Thus, the IL nomenclature was introduced to replace the older descriptive and often misleading names.

To understand fully the role of cytokines in skin inflammation, one has to collate information from human and animal studies as well as *in vitro* and *in vivo* data. The availability of recombinant cytokines and cytokine antagonists was of tremendous benefit in the verification of the specific effects of cytokines *in vivo*. Modern techniques, such as genomic and proteomic approaches, have given new insights into the regulatory mechanisms underlying the actions of cytokines. Moreover, the use of cytokine and cytokine receptor gene-deficient mice have helped in our understanding of the specific role of these molecules during cutaneous inflammation. It must be appreciated that *in vivo* a cocktail of several cytokines acts simultaneously or sequentially upon the inflammatory microenvironment. Thus, the biological activities of cytokines during inflammation are the sum of well-tuned synergistic and antagonistic processes.

Cytokines use different cell biological mechanisms to modulate inflammation. Some cytokines (e.g. IL-1, IL-2 or IL-4) exert their effects by exclusively binding to cell surface receptors. Others (e.g. TGF-β or IL-6) may additionally interact with components of the extracellular matrix to modulate skin function during inflammation.

Interleukins

Interleukins are polypeptides participating in all normal and reactive cell functions. So far, 35 interleukins have been described and characterized. Some prime cells, making them responsive to other agents, and most act in a synergistic way (see p. 12.28).

IL-1. The first cytokine detected in the skin was IL-1, originally named epidermal thymocyte-activating factor. Cytokines of the IL-1 family are key players in immunity and inflammation in virtually every organ of the body. Members of the IL-1 family discovered so far include IL-1α, IL-1β, IL-1 receptor antagonist (IL-1RA), IL-1H, IL-1F7b, IL-18 and IL-18-binding protein (BP). They may function as agonistic or antagonistic ligands for the members of the IL-1 receptor (IL-1R) family. IL-1 and IL-18 are structurally very closely related and both are synthesized as biologically inactive precursor molecules lacking a signal peptide. Almost all cells of the body, including keratinocytes, have been found to synthesize many of the IL-1 family members (see Table 12.2) upon stimulation. In some cells, such as macrophages, fibroblasts, endothelial and dendritic cells, IL-1 may also exist in a membrane-bound form.

The currently known 12 members of the IL-1R family are defined as membrane-spanning molecules that consist of at least one immunoglobulin-like domain exterior to the cell and, except for the IL-1RII, a Toll/IL-1R (TIR) domain in the cytoplasm. Type I IL-1R (IL-1R) binds both IL-1α and IL-1β. In addition, a homologue of the IL-1R, known as IL-1R accessory protein (AcP), which has no affinity on its own for either of the IL-1 forms, is required for IL-1 signalling. The second natural IL-1 binding protein is IL-1RII, which has a high affinity for IL-1α, but a much lower affinity for IL-1β or IL-1RA. IL-33 is a new member of the IL-1 family which exerts its effects in an autocrine and paracrine fashion, as does IL-1.

IL-1RI is expressed on keratinocytes, fibroblasts, endothelial cells, lymphocytes and other cells. IL-1RII can be detected on B lymphocytes and neutrophils. An endogenous soluble IL-1RA type I was found to act as a competitive IL-1R inhibitor. There is evidence of differences in responses mediated via each receptor. Cultured keratinocytes predominantly express mRNA for IL-1β, but *in vivo* in normal epidermis IL-1α is also detectable. IL-1 is present in the stratum granulosum, and considerable amounts have also been detected in psoriatic scales [1]. However, this is confined to IL-1β, which is functionally inactive, while active IL-1α is reduced [3].

IL-1 is a pro-inflammatory cytokine, stimulates repair and differentiation, and is an important mediator of immune regulation. It is mitogenic for thymocytes and T cells, induces IL-2 synthesis and receptor expression, proliferation and release of lymphokines (see Chapter 13). Furthermore, IL-1 is a growth factor for B cells, inducing proliferation and enhancing antibody formation, and it also increases NK cell activity. IL-1 also activates macrophages and neutrophils as well as the release of their enzymes, and induces prostaglandin synthesis.

It has been contended that, despite the large amounts of IL-1 being detected in epidermis, it is largely inactive and contributes little to the inflammatory response. Nevertheless, injection of keratinocyte IL-1 and recombinant IL-1 (rIL-1) into mice and rabbits induces oedema, erythema and neutrophil infiltration. There is also evidence that during wound healing, human keratinocyte IL-1 stimulates the synthesis of PGE_2 by subpopulations of human fibroblasts, which feeds back to result in the stimulation of keratinocyte proliferation and differentiation.

IL-1 is increased in the early phase of numerous skin diseases and induces the release of further cytokines and growth factors, and the recruitment of T lymphocytes, into the inflammatory tissue. IL-1 participates in the regulation of microvascular dermal endothelial cells by the up-regulation of cell adhesion molecules such as ICAM-1 or E-selectin. IL-1 also regulates the expression of ICAM-1 on keratinocytes, thus participating in the recruitment of lymphocytes into the epidermis, and activates IL-6 or NF-κB [3], which may be of considerable relevance in inflammatory dermatoses.

IL-1 is considered to be a key cytokine in the pathogenesis of autoimmune diseases such as pemphigus vulgaris. Increased levels of IL-1α and TNF-α have been detected in lesional skin of patients with pemphigus. Acantholysis of keratinocytes was found to be inhibited by antibodies directed against IL-1α and TNF-α. Furthermore, in IL-1-α and TNF-α receptor-deficient mice, a decreased susceptibility for pemphigus was observed. IL-1 also plays a crucial role by inducing keratinocyte apoptosis in pemphigus patients [4], and may be involved in vitiligo [5].

IL-2. IL-2, or T-cell growth factor, is an essential mediator for developing an immune response. Activated T lymphocytes secrete IL-2 and express IL-2 receptors, resulting in their proliferation and clonal expansion. IL-2 is also an important mediator for the proliferation of B lymphocytes and the activation of NK cells. Furthermore, IL-2 participates in the regulation of T-cell functions in Th1-mediated skin diseases such as psoriasis and cutaneous T-cell lymphoma [6–8]. The role of IL-2 in these diseases has recently been proven by the successful therapeutic use of specific anti-IL-2 strategies [7]. Another important regulator of memory

T-cell proliferation seems to be clofazimine, which inhibits Kv1.3 potassium channels, which has implications for the pathophysiology of autoimmune diseases and psoriasis [9]. Protein kinase C (PKC) isoforms (α, β, τ) play an essential role in the regulation of IL-2 expression levels. An oral PKC inhibitor (AEB071) blocked IL-2 mRNA expression and T-lymphocyte proliferation and achieved a significant decrease in the psoriasis severity score index, supporting the role of IL-2 and PKC in psoriasis [10].

IL-3. This belongs to the group of haematopoietic colony-stimulating factors (CSF), and promotes growth of T-cell lines and mast cells. It is synthesized by T lymphocytes, myeloid cell lines and keratinocytes. The IL-3 receptor (IL3R), like the IL-5R and the GM-CSFR, consists of two distinct chains of which the β-chain is identical for all three cytokine receptors. Although IL-3 has multi-CSF activity, in the skin it may activate both mast cells, contributing to fibrosis, as seen in scleroderma, and neutrophils, to release oxygen radicals cytotoxic for microorganisms. Moreover, monocyte proliferation, adherence to endothelium, secretion of IL-8 and the expression of LYVE-1 on lymphatic endothelial cells [11] is induced or enhanced by IL-3, as is eosinophil chemotaxis and phagocytosis [12,13]. IL-3 also regulates the activation status of human basophils [14]. Epidermal–dermal application of plasmid-encoded IL-3 by a gene gun resulted in enhanced infiltration of B cells, accumulation of dendritic cells, increase of TNF-α and IL-1β [15]. A ceramide derivate was able to inhibit skin inflammation and atopic dermatitis by suppressing IL-1 production [16].

IL-4. Originally named B-cell growth factor, IL-4 acts mainly on immunocompetent cells, and induces proliferation of activated mature T cells, and enhances T-cell cytotoxic properties, but suppresses cytokine formation by Th1 cells, thereby reducing delayed hypersensitivity responses. IL-4 stimulates MHC class II expression, and expression of the low-affinity IgE receptor (CD23) on B cells. IgE synthesis is regulated by IL-4 together with IL-13, and is inhibited by IFN-γ and TGF-β. Cytokines such as IL-2, IL-5, IL-6 and IL-9 synergize with IL-4 and IL-13 to enhance IgE production. On macrophages, however, IL-4 decreases CD23 expression. Mast cell growth is stimulated by IL-4, as is the growth of precursor haematopoietic cells, both directly and indirectly, by stimulating G-CSF and M-CSF production in monocytes. IL-4 is important for the differentiation towards a Th2 T-cell subtype. In contrast, cytokines such as IL-12, IL-18 and IL-23 inhibit the differentiation of IL-4-producing T cells. Although IL-4 is generated in high amounts by T cells, there is also evidence that IL-4 is released in the skin by keratinocytes or mast cells. The IL-4 receptor was detected on T and B cells, macrophages, dendritic cells, mast cells, fibroblasts and keratinocytes. IL-4 proved to be an essential mediator for the differentiation of dendritic cells [17]. *In vivo*, IL-4 has been found to mediate immunodeviation towards Th2 responses, and in preliminary studies has been successfully used for the treatment of Th1-mediated skin diseases such as psoriasis.

IL-5. IL-5, a helper T-cell lymphokine, induces growth and differentiation of activated B cells, and is a key mediator for the switching of immunoglobulin class synthesis. It is the most important promoter of eosinophil formation and differentiation. Mature eosinophils are activated and their survival is prolonged in parasitic infestations. IL-5 works synergistically with IL-3 and GM-CSF on eosinophils.

IL-6. This is mainly generated by monocytes, bone marrow cells, fibroblasts, endothelial cells, some T cells, B cells and keratinocytes [13]. IL-6 is involved in the regulation of the function of T, B and NK cells, which express both of the IL-6 receptor chains. It has an essential role in the maturation of B-cells, antibody production, and also participates in inflammation by inducing the formation of acute phase proteins (APP) by hepatocytes. In T cells, IL-6 mediates activation, growth and differentiation. Thus, IL-6 is an 'early' pro-inflammatory cytokine, which induces APP production, and the increased formation of IL-6 by fibroblasts, endothelial cells and keratinocytes stimulated by IL-1 and TNF-α may represent a significant amplifying process in inflammation [12,18]. Despite the finding of increased IL-6 serum levels in autoimmune diseases such as SLE, systemic scleroderma and pemphigus vulgaris, a specific role for IL-6 in any skin disease has not been established.

IL-7 and thymic stromal lymphopoietin (TSLP). IL-7, synthesized by monocytes and T cells, is a haematopoietic growth factor, stimulating T- and B-cell proliferation. Moreover, immune functions such as the proliferation of cytotoxic T and NK cells, as well as the activation of monocytes and macrophages, can be triggered by IL-7. Therefore, administration or neutralization of IL-7 may allow the modulation of immune functions in patients with lymphocyte depletion, tumours or autoimmune diseases [19].

Two different IL-7R have been characterized mainly on lymphoid and myeloid cells. There is evidence that mainly IL-7Rα but not IL-7Rβ expression is required for T-lymphocyte proliferation. Recently, an IL-7 like cytokine, TSLP, was described, which binds to a heterodimer consisting of the IL-7Rα chain and a common γ-like receptor chain also named TSLP receptor [20]. TSLP was found to be highly expressed in suprabasal keratinocytes from patients with inflammatory skin diseases such as atopic dermatitis. TSLP activates $CD11^+$ dendritic cells to migrate and to initiate a Th2 immune response [20,21]. TSLP activation is probably regulated synergistically by pro-inflammatory (TNF-α or IL-1α) and Th2 (IL-4 or IL-13) cytokines [22,23]. OX40 ligand was found to be the TSLP-induced molecule on dendritic cells that triggers inflammatory T(h)2 differentiation in the absence of IL-12. TSLP also regulates the innate phase of allergic immune responses through activating mast cells. Therefore, TSLP and OX40 ligand may be targets for therapeutic intervention in blockade of the initiation of allergic inflammatory responses [24].

IL-8. This is a member of the CXC subfamily of chemokines.

IL-9. This is produced by $CD4^+$ T lymphocytes and was originally described in the murine system as P40, T-cell growth factor III

(TCGF III) and mast cell growth enhancing activity (MEA). IL-9 is a growth factor for T-helper lymphocytes, mast cells and megakaryoblastic leukaemic cells, and stimulates the development of erythopoietic colonies as well as IL-4-induced IgE production by B lymphocytes. IL-9 transcripts have been detected in Hodgkin's lymphoma and large cell anaplastic lymphoma, suggesting a role for IL-9 in the pathogenesis of these tumours.

IL-10. This was originally described as a cytokine secreted by Th2 cells, which inhibits the release of cytokines from Th1 cells [25,26]. Later it was found that IL-10 can be synthesized by Th1 as well as Th2 lymphocytes, and also by cytotoxic T cells, mast cells, B cells and monocytes, the latter being the major source of IL-10 in humans [27]. There is now evidence for an IL-10 family of related cytokines, comprising different members of viral or cellular origin, including IL-19, IL-20, IL-22 (IL-10-related T-cell-derived inducible factor), IL-24 (melanoma differentiation-associated antigen 7) and IL-26 (AK155). The different receptors for the IL-10 family belong to the cytokine receptor family type 2, resulting, through the activation of signal transducer and activator of transcription (STAT) factors, in diverse biological effects [26].

IL-10 diminishes IFN-γ and IL-2 production by Th1 cells, as well as IL-4 and IL-5 generation by Th2 cells. IL-10 inhibits release of IL-1β, IL-6, IL-8, IL-12 and TNF-α in monocytes, as well as IFN-γ and TNF-α in NK cells. In monocytes or dendritic cells, IL-10 also down-regulates the expression and the release of MHC class II molecules, CD23, ICAM-I and the accessory B7 molecule. Thus, IL-10 is an important cytokine for the regulation of antigen presentation and suppression of Th1 as well as Th2 cytokine production.

The anti-inflammatory effect of IL-10 is a result of the inhibition of pro-inflammatory cytokines such as IL-1, IL-2, IL-6, TNF-α and IFN-γ, and the inhibition of chemokines (IL-8) and chemokine receptors such as CXC-2. In eosinophils, IL-10 inhibits eosinophil survival and IL-4-induced IgE synthesis, indicating an important role for this cytokine in allergic responses. In contrast, IL-10 activates the proliferation of, and immunoglobulin production by B cells. Thus, IL-10 is also a survival and differentiation factor for B cells. IL-10 contributes to inhibition of cellular and allergic immune responses while stimulating humoral and cytotoxic immune mechanisms [27].

Increased expression of IL-10 occurs in patients with allergic contact dermatitis [28], and IL-10-deficient mice show a delayed contact hypersensitivity immune response [29]. Stimulators of keratinocyte IL-10 synthesis include contact allergens and UVB light. The effect of IL-10 is mediated via a specific IL-10 receptor expressed on numerous skin cells. IL-10 has been proposed as a therapeutic target for the treatment of inflammatory diseases such as psoriasis, atopic dermatitis and asthma, and other autoimmune diseases [30,31].

IL-11. IL-11 stimulates precursor/progenitor haematopoietic blast cell mitosis, and synergizes with GM-CSF, IL-3 and IL-4. It also promotes an immunodeviation towards Th2, induces the formation of APPs by the liver, stimulates fibroblast functions, supports differentiation of lymphocytes but depresses differentiation of adipocytes, and inhibits abnormal keratinocyte differentiation. Accordingly, first clinical trials have shown that IL-11 appears to be effective in the treatment of psoriasis. Moreover, a role of IL-11 in tissue remodelling during severe asthma has been suggested [32].

IL-12. This cytokine is generated by monocytes, macrophages, dendritic cells, B cells, neutrophils, mast cells and keratinocytes. The active form is a heterodimer consisting of a p40 and a p35 subunit. Interestingly, homodimers and monomers of p40 serve as competitive antagonists by binding to the IL-12 receptor without activating the signal transduction cascade. There is now evidence for an IL-12 family of heterodimeric cytokines which share similar functions in innate as well as adaptive immunity but also have differentiated effects. Currently, the IL-12 family consists of five members, including IL-23, IL-27, cardiotrophin-like cytokine/soluble cyliary neutrotrophic factor receptor (CLC/sCNTFR) and CLC/cytokine-like factor 1 (CLC/CLF-1) [33].

IL-12 is an important activator of NK cells. It further increases IFN-γ production, modulates T-cell functions and inhibits tumour angiogenesis [34]. Stimulators of IL-12 secretion in skin include bacterial products or UV light. A protective effect of IL-12 on UV-induced DNA damage has been detected in keratinocytes [35].

IL-13. This is a cytokine with effects similar to IL-4, and was found to be released by T cells, mast cells and keratinocytes [36]. It affects the function of B cells as well as monocytes, and decreases production of pro-inflammatory cytokines in keratinocytes and endothelial cells. IL-13 also reduces chemokine-induced chemotaxis of T cells. IL-6 expression on monocytes is inhibited by both IL-4 and IL-13.

IL-14. IL-14 (high molecular weight [HMW], B-cell growth factor [BCGF]) is a cytokine implicated in the generation and maintenance of normal memory B cells. It is produced by malignant B cells and normal as well as malignant T cells [37].

IL-15. IL-15 shares many of the activities of IL-2 but is characterized by the use of a unique α-chain of its receptor. Both receptors use a common β- and γ-chain. The major sources of IL-15 are macrophages and epithelial cells, including keratinocytes and fibroblasts, whereas T cells do not express IL-15. Major stimuli for IL-15 production include IFN-α and -β. Like IL-2, IL-15 functions as a T-cell growth factor, is chemotactic for T cells, activates NK cells, stimulates B-cell growth as well as differentiation, and plays a role in the maturation of dendritic cells [38,39]. In human keratinocytes, IL-15 inhibits the anti-Fas and methylcellulose-induced apoptosis [40]. Because of its IFN-γ and IgE-synthesis-modulating function, a relevance in the pathophysiology of atopic dermatitis is attributed to IL-15.

IL-16. This is secreted from keratinocytes and Langerhans' cells amongst others, and is an important chemokine for the recruitment of $CD4^+$ T cells, monocytes, eosinophils and Langerhans' cells into inflamed skin. Serological levels of this cytokine correlate positively with the severity of atopic dermatitis [41].

IL-17. This is expressed by numerous immunocompetent cells. In keratinocytes, IL-17 initiates the release of growth-related oncogene-α (GRO-α), GM-CSF, IL-6 and the IFN-γ-induced expression of ICAM-1. In dermal endothelial cells, IL-17 induces IL-1 secretion and up-regulation of cell adhesion molecules. IL-17 activates skin fibroblasts [42] and results in increased IL-6 secretion and collagen synthesis. A pathophysiological role for IL-17 in systemic scleroderma has been proposed [43].

New evidence strongly supports the idea of an involvement of IL-17-producing T cells (TH_{17} T cells) in the pathophysiology of autoimmune diseases, psoriasis and contact dermatitis [44,45]. TH_{17} cells also express the hydrocarbon receptor which can be activated by dioxin derivates, linking TH_{17} T cells to environmental stimuli during immune responses and inflammation [46].

Although IL-17F is highly homologous to IL-17A and binds the same receptor, their functional roles are different. IL-17F plays only a marginal role in the development of delayed-type and contact hypersensitivities, autoimmune encephalomyelitis, and arthritis. Both IL-17F and IL-17A are involved in host defence against mucoepithelial infection by *Staphylococcus aureus* and *Citrobacter rodentium*. IL-17A is produced mainly in T cells, whereas IL-17F is produced in T cells, innate immune cells, and epithelial cells. Although only IL-17A efficiently induces cytokines in macrophages, both cytokines activated epithelial innate immune responses [47].

IL-18. The production of IL-18 has been described in dendritic cells, macrophages, keratinocytes, osteoblasts, microglia cells and fibroblasts, and IL-18 mRNA expression can be stimulated by LPS, GM-CSF and Fas ligand. IL-18 is also synthesized by human keratinocytes and was found be significantly up-regulated in inflammatory skin diseases. The receptor for IL-18 is expressed by keratinocytes, which implies an autocrine regulation by IL-18 [48]. Functional IL-18 requires activation by an IL-18 converting enzyme (ICE or caspase-1) or proteinase-3 [49].

Together with IL-12, IL-18 significantly stimulates the production of IFN-γ. IL-18 also induces the maturation of T cells and NK cells, and stimulates the release of cytokines and chemokines. It increases Fas-mediated NK-cell cytotoxicity, induces IgE production by B cells and synergizes with IL-2 to enhance IL-4 production. However, the effects of IL-18 on T cells seem to vary, dependent on endogenous and exogenous factors such as the maturation state and the micromilieu. In basophils, IL-18 contributes to IL-4 and IL-13 production and in macrophages IL-18 induces the production of cytokines such as IL-6 and IFN-γ, TNF-α and IL-1β. Moreover, IL-18 stimulates the synthesis of IL-6, IL-8, ICAM-1 and matrix metalloproteinases by endothelial cells.

IL-18 binds to a unique heterodimer receptor which is up-regulated by IL-12. IL-18-binding protein (IL-18BP) is a secreted protein able to bind IL-18 with high affinity, leading to inhibition of IL-18-induced IFN-γ and IL-8 production and NF-κB activation. Recently, another secreted protein, IL-1H, was observed also to have IL-18R antagonist activity.

In the skin, IL-18 modulates the migration of Langerhans' cells, the activity of T-helper cells and wound healing [50]. IL-18 also regulates ICAM-1 expression on microvascular endothelial cells, indicating a role in leukocyte–endothelial interactions during inflammation. The pathophysiological relevance of IL-18 for diseases such as atopic dermatitis [49] is currently debated. Enhanced expression of IL-18 was found in patients with lupus erythematosus and psoriasis. Finally, IL-18 also seems to be an important regulator during host defence in infections by viruses, bacteria, fungi and protozoa.

IL-19. This is a member of the IL-10 family that is released by monocytes and macrophages upon stimulation by LPS and GM-CSF. It can also be released by B cells. IL-19 exerts its effects by stimulating the receptors of IL-20 or IL-22.

IL-20. IL-20 shares a distinctive homology with IL-10, and is expressed in the skin and trachea. Overexpression of IL-20 in transgenic mice causes skin lesions similar to those of psoriasis. Two putative receptors for IL-20 were identified on keratinocytes. Moreover, IL-20 receptors are highly expressed in psoriatic skin, further providing evidence for a role of this cytokine in the disease [51].

IL-21. IL-21 is a new member of the type I cytokine superfamily which is mainly produced by activated T cells and has close structural similarities with IL-15, IL-2 and IL-4. It has a unique receptor chain, IL-21R, that pairs with the common γ-chain. The multiple biological functions of IL-21 include activation of NK cells, T cells and B cells, and it has also been found to inhibit the activation and maturation of dendritic cells [52].

IL-22. This IL-10-related, T-cell-derived inducible factor is synthesized by $CD4^+$ T and mast cells amongst others, and can be stimulated by IL-9 and LPS [51]. The IL-22 receptor has also been detected in the skin. There are two soluble IL-22 receptor antagonists (IL-22RA1 and -RA2). The IL-22RA2 is expressed by immunocompetent cells as well as epithelial cells. In contrast to other members of the IL-10 family of cytokines, IL-22 mediates acute-phase responses in inflamed tissue and hepatocytes.

IL-23. This cytokine is structurally closely related to other mediators such as IL-6, G-CSF and IL-12. Transgenic mice overexpressing IL-23 show an intense inflammatory infiltrate of lymphocytes and macrophages in numerous organs including the skin [53]. There is also evidence that IL-23, by increasing the number of Langerhans' cells with a more mature phenotype, enhances cutaneous immunity [33].

IL-24. IL-24 (melanoma differentiation-associated antigen 7) is a member of the IL-10 cytokine family, which is generated by Th2 cells in an IL-4 inducible manner. It is also produced by differentiated melanoma cells and LPS-stimulated monocytes. IL-24 has been shown to inhibit the proliferation of tumour cells, including melanoma, via the induction of apoptosis.

IL-25. Two new members of the IL-17 cytokine family, IL-17F and IL-25, have recently been described. IL-25 is produced by Th2 cells as well as mast cells, and by inducing the production of IL-4, IL-5 and IL-13 is capable of amplifying allergic-type inflammatory responses [54].

IL-26. IL-26 (AK155) is generated by monocytes and various T-cell types, and is involved in the transformed phenotype of human T cells after infection by herpes virus [55,56].

Our knowledge of its receptor expression, signalling mechanisms, biological effects and relevance to diseases is scant.

IL-27. This is a member of the IL-12 family of heterodimeric cytokines [57]. As an early product of activated antigen-presenting cells, IL-27 is able to induce the clonal expansion of naive $CD4^+$ T-cells. It synergistically with IL-12 induces the production of IFN-γ by Th1 and NK cells. IL-27 probably binds to the orphan-receptor WSX-1/TCCR belonging to the IL-6/IL-12 receptor family, identified as the IL-27R [58]. IL-27 is probably important for the proliferation and activation of naïve T cells [33].

IL-28 and IL-29. Three cytokines designated IL-28A, IL-28B and IL-29 [59] are induced by viral infection and are distantly related to type I interferons and the IL-10 family because of their antiviral activity. IL-28 and IL-29 bind to a heterodimeric class II cytokine receptor, consisting of IL-10Rβ, and an orphan class II receptor chain IL-28Rα.

IL-31. This has been found to be expressed mainly by Th2 lymphocytes. The IL-31 receptor (IL-31R) complex is composed of a heterodimer including the IL-31 RA and the oncostatin Mβ receptor (OSMRβ). Dimerization of IL-31RA and OSMRβ leads to IL-31-induced signalling (calcium, STAT3) in keratinocytes, macrophages and sensory neurones, suggesting a role in adaptive and innate immunity as well as neurogenic inflammation [60–62]. IL-31 is involved in inflammatory processes in the skin, gastrointestinal tract and lung [63]. Investigations in mice overexpressing IL-31 revealed this cytokine to be critically involved in dermatitis and pruritus [64]. Genetic and immunological studies support this also to be true for human skin, especially in atopic dermatitis and prurigo nodularis [65].

IL-32. IL-32 induces various cytokines/chemokines such as TNF-α, IL-8 and MIP-2. It activates the NF-κB and p38 mitogen-activated protein kinase pathway which is involved in inflammatory responses. IL-32 mRNA is highly abundant in immune tissue compared with other tissues. IL-32 can be induced in human peripheral lymphocyte cells after mitogen stimulation, in human epithelial cells by IFNγ, and in NK cells after exposure to the combination of IL-12 plus IL-18. IL-32 has been shown to play a role in viral infections and Wegener's granulomatosis, by interacting with neutrophil-derived proteinase-3 and proteinase-activated receptor-2; it may be involved in inflammatory, infectious and autoimmune diseases [66–69].

IL-33. IL-33 belongs to the IL-1-like cytokine family, and activates mast cells, Th2 lymphocytes and fibroblastic reticular cells of lymphoid tissues. It induces the production of Th2-associated cytokines such as IL-4, IL-5 and IL-13. IL-33 can activate immune cells in an autocrine or paracrine fashion. Of note, IL-33 is also a nuclear factor (NF-HEV) which is abundantly expressed in high endothelial venules from lymphoid organs, thereby acting as a nuclear transcriptional regulator. In the skin, IL-33 is also expressed in dermal endothelial cells and keratinocytes. It is abundantly expressed by skin vascular tumours. Thus, IL-33 receptor may act as a 'danger signal' receptor on keratinocytes, endothelial cells, T cells and mast cells during inflammation, trauma and infection [70,71].

IL-34. This is a novel cytokine which regulates monocytes via activation of an IL-34 receptor (known as macrophage colony-stimulating factor, M-CSF), followed by ERK1/2 activation [72].

IL-35. IL-35 is a heterodimeric novel cytokine of the IL-12 family, consisting of Ebi3 (Epstein–Barr virus induced gene-3) and IL-12α /p35. IL-35 is produced by specific subtypes of murine regulatory T cells (Tregs) and suppresses T-cell proliferation, making it a novel cytokine regulating adaptive immune responses during inflammation, autoimmune diseases and transplantation in mice [73]. This may not apply to humans, in which the role of IL-35 remains to be elucidated [74].

Interferons

Interferons (IFNs) were originally described as factors that 'interfere' with the replication of virus replication. They comprise a family of cytokines thought to be critical to the defence against cancer cells and viral infections. Moreover, IFNs are key regulatory agents with many activities in normal tissue physiology, inflammation and the immune responses, enhancing or depressing the activities of other cytokines.

IFN-α and IFN-β are rapidly released after viral infections upon stimulation by double-stranded RNA. In contrast, IFN-γ is induced indirectly during the inflammatory response against pathogens, but also contributes to host defence. The major cellular sources of IFN-α are macrophages and B cells, whereas IFN-β is produced by fibroblasts and IFN-γ is synthesized by activated T cells. A further member of the type I interferon family is defined as IFN-κ [1]. It induces the release of several cytokines from monocytes and dendritic cells, and inhibits IL-12 release from monocytes. The synthesis of IFN-κ is induced by IFN-γ in monocytes as well as dendritic cells. It also can be detected in these cells in lesional skin of atopic dermatitis and psoriasis.

The IFNs have specific receptors and different properties, which may act in a synergistic or antagonistic fashion. IFN-α and IFN-β exert their effects by inhibiting virus replication in host cells. Additionally, via binding to IFN receptors, both molecules not only affect infected cells, but also activate defence mechanisms in neighbouring 'healthy' cells in a paracrine manner. Activation of the receptor by IFN-α and IFN-β leads to the induction of intracellular signalling pathways involved in inflammation and host defence. For example, IFN-α and IFN-β activate STATs, P1-kinase and Mx-protein, all factors that increase the resistance of cells to viral replication [2].

IFN-γ alone induces the formation of MHC class II molecule HLA-DR on membranes of monocytes and keratinocytes [3–5], while IFN-α and IFN-β up-regulate expression of the MHC class I antigens on many cell types. This leads to optimal antigen presentation to cells of the adaptive immune system such as T cells. IFNs activate NK-cell activity, leading to the successful killing of infected cells. In contrast, IFNs save non-infected cells from destruction by NK cells by inducing MHC class I molecules on these cells. In addition, IFN-γ stimulates the activity of a proteinase, cathepsin S [6]. The release of VEGF is induced in keratinocytes and suppressed in fibroblasts by IFN-γ indicating that this cytokine is involved in the regulation of angiogenesis [7].

IFN-γ also augments monocyte secretion of TNF-α and TNF-β, which contribute to the antiviral and antiproliferative properties of IFNs [8], and increases the expression of IL-2R and ligand binding on human leukaemic and normal lymphocytes [9]. The IFNs augment activity of NK lymphocytes and macrophages [10], and stimulate macrophage synthesis of arachidonic acid products [11]. IFN-α may also stimulate the formation of IgG and IgM by B cells [12]. Thus, interferons directly function as important mediators of both the innate and the adaptive immune responses.

In inflammatory skin diseases such as atopic dermatitis, a beneficial effect of IFN-γ treatment has been reported. In mice, mast cells appear to contribute to the regulation of IFN-γ in the inflamed skin [13]. INF-γ has been implicated in autoimmune diseases such as lupus erythematosus; overexpression of IFN-γ in the epidermis leads to SLE-like skin alterations [14].

The pro-inflammatory effects of keratinocyte activation by IFN-γ can be inhibited by regulatory molecules defined as suppressors of cytokine signalling (SOCS). SOCS1, SOCS2 and SOCS3 proteins are up-regulated in the epidermis of psoriasis and allergic contact dermatitis but not in atopic dermatitis patients [15]. They exert multiple anti-inflammatory effects on keratinocytes, such as down-regulation of HLA-DR, ICAM-1, IP-10 and MCP-1.

Interferons are also involved in the response to infections, injury or exogenous triggering, such as UV-light leading to inflammation. Cells of the innate immune system activate adaptive immunity by means of multiple immunostimulatory cytokines including IFNs. IFNs can also induce specialized dendritic cells (DCs) expressing the tryptophan-catabolizing enzyme indoleamine (IDO), which confers potent T-cell suppressor activity. DCs also promote differentiation of naïve CD4 T cells into regulatory T cells (Tregs), and stimulate mature Tregs to acquire potent suppressor activity. pDCs up-regulate IDO by means of a mechanism that depends on cell-autonomous IFN type I signalling in response to CD80/86 (B7.1/2).

In summary, interferons not only act as antiviral agents but are also important mediators of inflammatory and immune responses within the skin.

Tumour necrosis factor

Tumour necrosis factor (TNF), also defined as cachectin or endogenous pyrogen, is a protein of approximately 17 kDa that exists in a secreted and transmembrane form, and builds dimers or trimers after being released [1]. It is secreted by monocytes and macrophages, mast cells, fibroblasts, smooth muscle cells, endothelial cells, keratinocytes, T cells and certain NK cells. It has multiple pro- as well as anti-inflammatory activities, and is also a growth factor in normal physiological regeneration and wound healing [2,3]. Upon stimulation by exogenous factors such as bacterial LPS, staphylococcal toxin, viruses and other organisms, or by endogenous mediators such as C5a, IL-1, IL-2, GM-CSF, substance P, bradykinin and TNF itself, large amounts are released within minutes, and the synthesis is rapidly increased. The rate of synthesis is controlled by IFN-γ [4], but several other cytokines may antagonize and influence further release (e.g. TGF-β, IL-6, PGE_2 or vitamin D_3). TNF-α is activated after processing at the cell membrane by a transmembrane enzyme, TNF-α converting enzyme.

Three types of TNF receptors have been identified: TNF-R1 (CD 120a, p55) and TNF-R2 (CD 120b, p75), which are expressed by almost all cells and bind both TNF-α and TNF-β; and TNF-R3 which is only synthesized by human hepatocytes and which binds TNF-α. Each receptor appears to mediate different cellular responses [5]. TNF receptors also belong to the superfamily of death receptors which are able to induce apoptosis (e.g. in keratinocytes and leukocytes during cutaneous inflammation).

The soluble forms of the receptors, released from cell membranes, neutralize both forms of TNF, thereby preventing systemic effects resulting from local inflammation [6]. The soluble receptors occur in the blood and urine of normal persons, and were found to be markedly increased during various inflammatory disorders and sepsis [6–8]. TNF-binding proteins (TBPs) are also capable of regulating TNF function after release into the extracellular space.

TNF has many biological properties, similar to those of IL-1, which synergistically may enhance TNF activity. It induces septic shock and fever [9], cachexia [10] and is a potent mediator of inflammation, increasing macrophage and neutrophil chemotaxis, phagocytosis, cytotoxicity and respiratory burst activity [11–16]. The protective role of TNF is supported by the observation that mice that lack the gene for TNF do not develop septic arthritis but otherwise are lacking an efficient defence against systemic infection [17]. Thus, an important role of TNF is to protect tissues by localizing inflammation. On the other hand, once infection becomes systemic, TNF may have deleterious effects leading to sepsis and shock [16]. Some of these effects may be aggravated by the TNF being able to stimulate synthesis of many other cytokines and mediators, including IL-1, GM-CSF, PDGF, TGF-β, prostaglandins and leukotrienes.

In the skin, TNF-α has been found to exert numerous effects. Toxins, haptens as well as UV light are potent inducers of TNF-α release from keratinocytes. TNF receptors are involved in the regulation of keratinocyte apoptosis [18]. TNF-α also induces intense expression of ICAM-1 in keratinocytes. Via activation of NF-κB and C/EBPβ TNF-α regulates the synthesis of cytoskeletal proteins participating in epidermal responses to inflammation or wound healing. In contrast to its tissue-damaging properties, TNF is also a growth factor, stimulating fibroblast proliferation and synthesis, and exhibits synergy with EGF, by increasing the EGF receptor, PDGF and insulin [2].

In endothelial cells, TNF promotes leukocyte adherence by increasing the expression of E-selectin, ICAM-1 and VCAM, probably via activation of the transcription factor NF-κB. TNF-α is also a potent activator of neutrophils, leading to the regulation of cell recruitment, chemotaxis, degranulation and release of cytokines and oxidative burst mediators. TNF-α has been identified as one of the cytokines required for the maturation of DC and therefore also plays a role in the initiation of an immune response. The pathophysiological relevance of TNF-α has been demonstrated in various models of infection, inflammation and autoimmune disease [19,20]. This is further supported by the successful use of biologics targeting TNF-α for the treatment of T-cell mediated skin diseases such as psoriasis [21,22]. Moreover, diseases associated with mutations within the TNF-receptor type I have been described. Thus, the TNF-receptor-associated periodic syndrome (TRAPS) is a rare hereditary disease characterized by prolonged periodic fever attacks and severe, localized inflammatory reactions [23].

The observation that TNF-α appeared to be a crucial protein in many skin diseases, including psoriasis, led to novel therapeutic strategies aimed at blocking TNF-α function and/or TNF-α receptor activation. Several different agents that neutralize the pro-inflammatory cytokine TNF-α such as a humanized antibody (infliximab), a full human antibody (adalimumab) and a protein containing the TNF-α receptor (TNFαRII) fused with a humanized immunoglobulin fragment (etanercept) are available for the treatment of inflammatory diseases, with psoriasis or psoriatic arthritis as an approved indication in addition to rheumatoid arthritis and Crohn's disease. A pegylated form of a recombinant soluble human TNF-α receptor is currently under investigation (pegsunercept). By contrast, patients have developed atopic dermatitis

lesions after infliximab therapy. TNF-α does not appear to play an essential role in the pathophysiology of atopic dermatitis or even ameliorate this disease, but TNF-α blockers do seem to be beneficial in the treatment of psoriasis, lichen planus and forms of panniculitis.

Cytokine suppressors and inhibitors

In addition to pro-inflammatory cytokines, certain cytokines including IL-1RA, TGF-β and members of the IL-10 family exert potent anti-inflammatory effects. The physical state of cytokines in body fluids has rarely been determined. Detection of a cytokine by immunological techniques allows only conclusions concerning its presence, but not about its potential activity. The cytokine may be coupled to another molecule that prevents binding to the specific receptor. Coupling may occur as: (i) dissociable complexes with a protective lipoprotein that releases the cytokine to react with its receptor; (ii) firmly bound complexes of cytokine and a carrier protein that interferes with receptor linkage [1,2]; or (iii) complexes of cytokine with its specific soluble receptor that blocks interaction with cell receptors [3].

Anti-inflammatory cytokines exert their effects by:

1 Regulation of cytokine secretion
2 Regulation of cytokine receptor expression
3 Receptor competition
4 Soluble binding factors and/or inhibitors
5 Regulation of proteases that activate the cytokine pro-form (converting enzymes).

This has led to novel therapeutic strategies in inflammatory and allergic diseases.

IL-1RA and IL-18RA

Two types of specific blocking agent for IL-1 activity have been identified. The first is a soluble receptor without a transmembrane structure that binds to free IL-1, inactivating its binding site. The second, IL-1 receptor antagonist (IL-1RA), is an inactive IL-1 homologue that blocks receptor sites on cells. IL-1RA is normally secreted during inflammatory reactions. Its production and release is modulated by many cytokines such as IL-4, IL-6, IL-13 or TGF-β. The important function of IL-1 RA is to potentially inhibit the deleterious effects of IL-1 during inflammation. Keratinocytes, fibroblasts and monocytes are also capable of generating an intracellular form of IL-1RA, the function of which is not understood [3].

IL-1α or IL-1β activity normally follows binding of the cytokine to the IL-1R type I receptor on all responding cells [4]. Other cells, such as B cells and neutrophils, express another IL-1R, the IL-1R type II [5]. It has been suggested that the IL-1RII can be shed from the cell surface and bind with free IL-1, thus ultimately blocking its ability to couple to cell-bound IL-R1. An alternative inhibitory molecule is an inactive homologue of IL-1, IL-1RA, which binds to cellular receptors without inducing a signal. The inert homologue therefore blocks the receptor, and subsequently prevents later binding of active IL-1 [6–9]. This type of antagonist is peculiar to IL-1. It is secreted mainly by monocytes and macrophages, but also by neutrophils and fibroblasts. It has been designated secreted interleukin-1 receptor antagonist (sIL-1RA).

Both the IL-1α and the IL-18 precursor require cleavage into an active mature molecule by an intracellular cysteine protease called IL-1α converting enzyme (ICE), also known as capsase-1. Thus ICE inhibitors may limit the activity of IL-1α as well as IL-18. IL-1RA is a physiological antagonist which has a similar structure to IL-1α as well as IL-β, and thus competes with the binding of the natural ligand to the receptor. IL-18BP is a naturally occurring

antagonist which is able to bind IL-18 with high affinity and to neutralize its activity, but not that of IL-1. Another IL-18 antagonist, IL-1H, has sequence homology with IL-1RA and binds the IL-18R but not the IL-1R. IL-1F7b shares sequence homology with IL-18, and binds the IL-18Rα but has no IL-18-like agonistic or antagonistic activity. IL-F7b binds to IL-18BP and subsequently may block the IL-18Rα, which ultimately results in the inhibition of IL-18 activity.

A non-receptor soluble protein that may function as a protective carrier protein or inhibitory substance is α_2M [10]; it is a carrier for IL-1, IL-6 and PDGF [11,12], but inactivates IL-2 and FGF [10]. Other soluble inhibitors, mainly against IL-1, have been found in the medium of UV-exposed keratinocyte cultures, and in the sera of UV-exposed mice and humans. The identity of this substance, and a related epidermal cell contra-IL-1, which blocks the activity of IL-1, is still to be determined [13].

TGF-β

TGF-β belongs to a family of peptides involved in growth and differentiation in almost all cells. It is involved in the regulation of fibroblasts and keratinocytes, as well as extracellular matrix proteins, in pathophysiological processes such as fibrosis, wound healing and scar formation. TGF-β is crucial to the transformation of fibroblasts into myofibroblasts, thereby promoting fibrosis.

Within the immune system, TGF-β is a potent anti-inflammatory molecule. It down-regulates the function of T cells, B cells, monocytes and NK cells. T cells undergoing apoptosis release TGF-β, leading to immunosuppressive effects in the inflammatory micromilieu [12]. TGF-β also diminishes mast cell function by inhibiting mast cell proliferation and IgE synthesis. TGF-β reduces the synthesis of IL-1 and IL-2. TGF-β, secreted in an inactive form, can bind weakly after exposure to acid pH in wound fluid to epidermal growth factor receptor (EGFR) on keratinocytes and endothelium, and compete with the stimulating molecules EGF and TGF-β thereby reducing keratinocyte and endothelial proliferation.

It is also critically involved in T-cell regulation and thus adaptive immunity. Furin cleaves TGF-β, thereby down-regulating the function of regulatory and effector T cells. Thus, furin might activate immune responses, and may result in a breakdown in peripheral tolerance [14].

IL-10 family of cytokines

Because of their similarity to IL-10 function, interleukins IL-10, IL-19, IL-20, IL-22, IL-24 and IL-26 have been grouped together as the IL-10 family. IL-28 and IL-29 share similarities to both type I interferons and IL-10 cytokines. Their function and role during inflammation and immune response are as described above.

Chemokines

Chemokines constitute a large family of soluble chemotactic cytokines with four conserved cysteines linked by disulphide bonds. Four subfamilies, CXC, CC, CX3C and C chemokines, are distinguished according to the position of the first two cysteines. More than 40 chemokines have been defined and characterized (Table 12.7). Most chemokine genes encode for proteins of approximately 90–125 amino acids. The different chemokine subfamilies are clustered on different chromosomes [1].

The main characteristic of chemokines is their potential to activate and attract leukocytes to the site of inflammation. Thus, chemokines have a pivotal role during inflammation and immunity. Interestingly, while CXC chemokines mainly attract neutrophils and lymphocytes, CC chemokines are capable of attracting monocytes, eosinophils, basophils and lymphocytes, but not neutrophils.

The classic role of chemokines is to attract leukocytes to the site of inflammation. For instance, $CD34^+$ dendritic cells (DCs) express ligands for chemokine receptors such as CCR1, CCR5, CCR6, CXCR4 or CCR9 to enter the target tissue. After maturation in epithelial tissues such as the epidermis, DCs change their phenotype by up-regulating CCR7, to traffic to lymph nodes [2]. In the skin, specific chemokines such as CCL27 attract a special subset of memory T cells normally expressing a cutaneous lymphocyte-associated antigen (CLA) which selectively traffics these cells to the skin. The CLA protein seems to be crucial for T-cell interaction with the endothelium, the extracellular matrix and other cell types in the skin [3].

In addition to attracting leukocytes, chemokines may also modulate leukocyte–endothelial interactions. They promote transendothelial emigration by supporting the binding of cell adhesion molecules with integrins (e.g. linkage of VCAM with α4β1 integrin on monocytes, eosinophils and basophils) or the binding of L-selectin to E-selectin on neutrophils. CC chemokines such as RANTES and MIP-1α may also induce the synthesis and release of inflammatory mediators such as histamine or leukotrienes from basophils [4–6].

Table 12.7 Nomenclature for human chemokines. (From Keystone Chemokine Conference, Keystone, CO, USA, January 18–23, 1999.)

Systematic name	Human ligand	Mouse ligand	Chemokine receptor(s)
CC chemokine/receptor family			
CCL1	I-309	TCA-3, P500	CCR8
CCL2	MCP-1, MCAF	MCP-1, JE	CCR2
CCL3	MIP-1α, LD78α, LD78β, AT464.1, AT464.2, GOS19-1, GOS19-2	MIP-1α	CCR1, CCR5
CCL4	MIP-1β, AT744.1, AT744.2, Act-2, G-26, HC21, H400, LAG-1	MIP-1β	CCR5
CCL5	RANTES	RANTES	CCR1, CCR3, CCR5
CCL6	Unknown	C10, MRP-1	Unknown
CCL7	MCP-3	NC28, FIC, MARC	CCR1, CCR2, CCR3
CCL8	MCP-2, HC14	MCP-2	CCR2, CCR3
CCL9, CCL10	Unknown	MRP-2, CCF18, MIP-1γ	Unknown
CCL11	Eotaxin	Eotaxin	CCR3
CCL12	Unknown	MCP-5	CCR2
CCL13	MCP-4, NCC-1, CKβ-10	Unknown	CCR2, CCR3
CCL14	HCC-1, HCC-3, NCC-2	Unknown	CCR1
CCL15	HCC-2, MIP-1δ, NCC-3, MIP-5, LKN-1	Unknown	CCR1, CCR3
CCL16	HCC-4, NCC-4, LEC, LMC	LCC-1	CCR1
CCL17	TARC, dendrokine	TARC	CCR4
CCL18	DC-Ck1, PARC, MIP-4, AMAC-1	Unknown	Unknown
CCL19	MIP-3β, ELC, exodus-3, CKβ-11	MIP-3β	CCR7
CCL20	MIP-3α, LARC, exodus-1	MIP-3α	CCR6
CCL21	6Ckine, SLC, exodus-2, TCA-4	6Ckine	CCR7
CCL22	MDC, STCP-1, DCtacin-β	ABCD-1	CCR4
CCL23	MPIF-1, MIP-3, CKβ8, CKβ8–1	Unknown	CCR1
CCL24	Eotaxin-2, MPIF-2, CKβ-6	Unknown	CCR3
CCL25	TECK	TECK	CCR9 (GPR9-6)
CCL26	Eotaxin-3	Unknown	CCR3
CCL27	CTACK/ALP	CTACK, ALP	Unknown
CXC chemokine/receptor family			
CXCL1	GRO-1, GROα, MGSA-α	GRO (KC)	CXCR2 > CXCR1
CXCL2	GRO2, GROβ, MIP2α, MGSA-β	GRO (KC)	CXCR2
CXCL3	GRO3, GROγ, MIP-2β	GRO (KC)	CXCR2
CXCL4	PF4	PF4var1, PF4alt	Unknown
CXCL5	ENA-78	LIX	CXCR2
CXCL6	GCP-2	CKα-3	CXCR1, CXCR2
CXCL7	NAP-2	Unknown	CXCR2
CXCL8	IL-8, MDNCF, NAP-1, NCF	Unknown	CXCR1, CXCR2
CXCL9	Mig, Humig	Mig	CXCR3
CXCL10	IP-10	crg-2, mob-1	CXCR3
CXCL11	I-TAC, H174, b-R1	Unknown	CXCR3
CXCL12	SDF-1α, SDF-1β, PBSF	SDF-1α/β	CXCR4
CXCL13	BLC, BCA-1	BLR1L, Angie	CXCR5
CXCL14	BRAK/bolekine	BRAK	Unknown
CXCL15	Unknown	Lungkine	Unknown
XC chemokine/receptor family			
XCL1	Lymphotactin, SCM-1α, ATAC	Lymphotactin	XCR1
XCL2	SCM-1β		XCR1
CX3C chemokine/receptor			
CX3CL1	Fractalkine, neurotactin	Fractalkine	CX3CR1

MDC, macrophage-derived chemokine; TARC, thymus and activation-regulated chemokine.

The effects of chemokines are mediated via binding and activating heptahelical G protein-coupled receptors. Chemokine activation instantly leads to rearrangement of the cell cytoskeleton, and activation of intracellular second messengers and integrins. Chemokine activation in neutrophils or monocytes results in the generation of inflammatory agents such as lipid mediators, NO, prostaglandins, amines, proteases and oxygen radicals [7].

Besides their specific ligand–receptor interaction, chemokines may also adhere to extracellular matrix proteins and the apical surface of endothelial cells. This appears to be crucial for the

migration of leukocytes to sites of inflammation. For example, CXCL8 and CCL19 attach to the endothelial cell surface, thereby stimulating transmigration [8]. In contrast, glycosaminoglycans such as heparan sulphate are capable of inactivating chemokine effects on endothelial cells [9].

Chemokine receptors are expressed by numerous cell types and modulate not only inflammation, but also embryogenesis and innate as well as adaptive immune responses. Chemokine receptors have been implicated in the pathophysiology of several diseases such as HIV infection, malaria, psoriasis and wound healing [10]. Moreover, viruses such as herpesvirus and poxvirus encode for chemokine receptors, thereby entering their hosts, indicating an important role for chemokines in certain infectious diseases [11].

CC chemokines

The CC-chemokine family currently comprises 28 members. Therefore, only those with a strong relation to skin inflammation will be briefly described here.

RANTES (CCL5). RANTES, an acronym for regulated upon activation, normal T cell expressed and secreted, is chemotactic for basophils, eosinophils, lymphocytes and monocytes. It induces granule release and leukotriene synthesis in basophils and eosinophils, and histamine release from basophils. The activity is enhanced by priming with IL-5. It is formed by macrophages, fibroblasts and T cells. RANTES is one of the more potent chemokines in inflammation and allergy, and is believed to be an important mediator of tissue eosinophilia. RANTES mRNA has been detected in skin of atopic subjects 6 h after challenge by antigen, and the secreted protein is present in atopic dermatitis skin scales [12].

Macrophage inflammatory protein 1a (CCL3). This is formed by monocytes, fibroblasts, activated T and B cells, and attracts monocytes, lymphocytes, basophils and eosinophils. When bound to endothelial cells, it is reported to increase binding of $CD8^+$ T cells. In mice, it releases histamine from mast cells and basophils, but histamine release from human basophils is little above control amounts.

Macrophage inflammatory protein 1b (CCL4). This is closely related to the α-form and shares many of its properties. It has been reported to increase the adhesion to endothelium of $CD8^+$ or $CD4^+$ T cells, via α4β1 integrin–VECAM binding.

Monocyte chemotactic proteins. MCPs are chemotactic for T cells, DCs and NK cells. They are also potent attractants of monocytes and modulate the expression of adhesion molecules. MCP-2 and MCP-3 (CCL7 and CCL8) also attract eosinophils, whereas MCP-1 (CCL2) and MCP-3 attract basophils, and induce histamine release and synthesis of LTC_4. Recently, MCP-2 has been reported to be as potent as MCP-3 in activating eosinophils and basophils [13]. These proteins contribute to leukocyte infiltration of damaged tissue, possibly especially in atopic disorders. Antibodies against MCP-1 rendered animals less susceptible to delayed-type hypersensitivity, indicating that they may provide a potential therapeutic strategy for the treatment of allergic reactions in the skin.

Eotaxin (CCL11). Eotaxin, a potent chemokine for eosinophils [14], has more than 50% amino acid homology MCP. It has been detected in the epithelium of nasal polyps and possibly contributes to the eosinophilia of allergic inflammation. Eotaxin attracts T cells and eosinophils to the skin in patients with atopic dermatitis. In eotaxin-deficient mice, allergen-induced attraction of eosinophils seems to be impaired; this effect, however, appears to be compensated for by other chemokines at later stages [15].

CCL18. CCL18 is constitutively present at high levels in human plasma and probably contributes to the physiological homing of lymphocytes and DC, as well as to the generation of primary immune responses. Increased CCL18 production is observed in several diseases, including inflammatory skin, joint and lung diseases or malignant tumours [16].

CCL27. This is a skin-associated CC chemokine member that binds the receptor CCR10 with high affinity. CCL27–CCR10 interactions are critical for skin-homing CLA-bearing memory T cells [17,18]. Data suggest that CCL27 directly contributes to cutaneous inflammation. For example, patients with psoriasis, atopic dermatitis and contact dermatitis express CCR10 on $CD4^+$ T cells, fibroblasts and endothelial cells. Intracutaneous application of CCL27 was found to attract lymphocytes into the skin [19].

CXC chemokines

IL-8. Among the 16 members of the CXC chemokine family, IL-8 was the first chemokine to be defined and is the most potent mediator for attracting neutrophils. IL-8 binds to and activates CXCR-1 and CXCR-2. CXCR-1 (IL-8R1) is exclusively activated by IL-8, while CXCR2 (IL-8R2) can also be activated by GRO-α (CXCL1), GRO-β (CXCL2), GRO-γ (CXCL3), NAP-2 (CXCL7), ENA-78 (CXCL5) and GCP-2 (CXCL6).

GRO-α (CXCL1). This product of a growth-regulated gene, which also has melanoma growth-stimulating activity (MGSA), attracts and activates neutrophils. It is formed by monocytes, fibroblasts, platelets, endothelial cells and melanoma cells. Increased amounts occur in psoriatic scales, together with IL-8 [20].

NAP-2 (CXCL7). This is a product cleaved from a basic protein derived from platelet granules. It attracts neutrophils, and induces influx of calcium ions, degranulation and the respiratory burst [21].

Interferon-inducible protein 10 (CXCL10). IP-10 is induced by IFN in monocytes, activated T cells, fibroblasts, endothelial cells and keratinocytes. It also attracts monocytes and T cells and promotes T-cell binding to endothelium; it may contribute to the cell changes of delayed hypersensitivity [22].

Epithelial neutrophil activating peptide 78 (CXCL5). ENA-78 attracts and activates neutrophils, resulting in the release of their granules and mediators. It is synthesized by platelets, type II alveolar epithelial cells stimulated by IL-1, as well as neutrophils, monocytes, endothelial cells, and vascular smooth-muscle cells stimulated by IL-1 or LPs. ENA-78 also has been detected in

lungs infiltrated by neutrophils in adult respiratory distress, and increased amounts are found in the sera of patients with rheumatoid arthritis [23].

Chemokine receptors

So far, five CXC receptor subtypes have been defined. Most receptors can be activated by more than one chemokine, and several chemokines bind to more than one receptor. Thus, a high variability can be observed following chemokine release leading to receptor redundancy which makes CRs relatively inaccessible to therapeutic intervention [1,10,16].

The first chemokine receptors for IL-8, defined as CXCR1 and CXCR2, are expressed by T cells, activated eosinophils, mast cells, basophils and dendritic cells, suggesting a role for IL-8 during acute inflammation and innate immunity. Both CXCR1 and CXCR2 can be activated by IL-2. CXCR1 appears to be the dominant receptor for chemotaxis, phospholipase D production and superoxide generation after IL-8 or NAP-2 activation. CXCR2 mediates neutrophil chemotaxis in response to low-concentration NAP-2 and GRO-α. Interestingly, human herpesvirus (HHV) and HHV8 both express functional CXCR2 receptors, although the significance of this remains unclear [24]. CXCR3 is a receptor for T-cell activation. It binds I-TAC (CXCL11), Mig (CXCL9) and IP-10 (CXCL10). CXCR3 is expressed mainly by Th1 cells and $CD45RO^+$ memory T cells. Interestingly, in sarcoidosis, virtually all T cells express CXCR3. CXCR4 has been detected on most hematopoietic cells such as B cells, dendritic cells, Langerhans' cells, macrophages and T cells. Moreover, CXCR4 has also been identified as an HIV virus co-receptor, in that the glycoprotein gp120 from the HIV envelope binds to CXCR4 in the presence of CD4 [25]. However, CD4 independent association of gp120 to CXCR4 has also been shown. Thus, CXCR4 may be involved in HIV infection and HIV neurotoxicity. CXCR5 is a B-cell chemokine receptor. After T-cell activation, CXCR5 is up-regulated on memory and/or effector T cells via the chemokine BCA-1 (CXCL13), suggesting a role in T–B cell interaction.

CCR1. This is a receptor for several chemokines such as MIP-1α, RANTES, MCP-2, MCP-3, MIP-5, MPIF-1 (CCL23) and HCC-1 (CCL14). MIP-1β and MCP-1 are also weak agonists. CCR1 is expressed by T cells, especially memory $CD45RO^+$ T cells. CCR1 knockout mice do not acquire spontaneous infections, but they exhibit increased mortality when infected with *Aspergillus fumigatus*, indicating a role for CCR1 in neutrophil-mediated diseases [26]. This receptor also appears to regulate granuloma formation and the Th1–Th2 cytokine balance. Data indicate that CCR1 is a receptor that can modulate inflammatory responses either positively or negatively, depending on the microenvironment.

CCR2. This is a leukocyte MCP-1 receptor expressed by monocytes, dendritic cells, NK cells and T cells, B cells and basophils. Mice lacking CCR2 develop normally but do not recruit macrophages in an experimental inflammation model. They fail to clear infections, have smaller granulomas and show defective recruitment of monocytes–macrophages to the site of inflammation. These results indicate a role for CCR2 in macrophage functions. Moreover, CCR2 also appears to be involved in HIV infection [1,5,10,25].

CCR3. This mediates the chemotaxis of eosinophils and may thus be important during allergic inflammation and hypersensitivity. This receptor can be activated by MIP-1α, MIP-1β and eotaxin, RANTES, MCP-3, MCP-4, MIP-5 and the TAT protein of HIV. Eotaxin appears to be the most potent agonist of CCR3. CCR3 can also be detected on basophils, mast cells, Th2-lymphocytes as well as DCs. Eotaxin knockout mice showed only weak responses after ovalbumin challenge. Using animal models, neutralization of eotaxin resulted in a partial blockade of eosinophilia after allergen challenge [27].

CCR4. This is expressed by Th2 cells and can be activated by macrophage-derived chemokine (MDC = CCL22) and thymus and activation-regulated chemokine (TARC = CCL17). This receptor may also be involved in dendritic cell functions, trafficking of T cells to the lymph nodes and T cell transmigration, as well as homing of memory T cells to inflamed skin [28].

CCR5. This has become well known as a major HIV-1 co-receptor that controls susceptibility to HIV-1 infection and disease [10]. CCR5 is expressed by T lymphocytes and macrophages as well as Langerhans' cells. CCR5 can be activated by MIP-1α, RANTES, MIP-1β and MCP-1. MCP-3 however, appears to be a CCR5 antagonist. Under normal conditions CCR5 knockout mice appear healthy. A role for CCR5 in down-modulating T-cell-dependent immune responses has been suggested. CCR5 is one of the first receptors for which use of receptor antagonists has been advocated in clinical trials in humans, in HIV infection [29].

CCR6. This mediates responsiveness of memory T cells to the chemokine LARC (CCL20). CCR6 seems to be important for the migration of memory T cells and DCs to secondary lymphoid organs. The chemokine MIP-3α has been shown to regulate the homing of Langerhans'-type dendritic cells to the epidermis by activating CCR6. The CCR6 ligand LARC can be released by macrophages, dendritic cells and endothelial cells. However, the human β-defensin 2 (HBD-2) has also been shown to functionally bind CCR6. HBD-2 is produced by enterocytes during infection and functions as an antimicrobial factor. It also attracts DCs and memory T cells via CCR6 activation. Together, these results indicate a role for this receptor as a link between the innate and adaptive immune systems [30].

CCR7. This is a homing receptor for B cells, T cells and DCs across high endothelial venules. CCR7 is activated by the chemokines ELC (CCL19) and SLC (CCL21), which are expressed in the T-cell area of lymphoid tissues but not in the B-cell area. This is supported by the finding that CCR7 knockout mice show defective B- and T-cell homing, whereas defective T-cell development is not found.

CCR8. This is critically associated with the function of Th2 lymphocytes. Reports of the activation of CCR8 by various agents such as TARC and MIP-1β are controversial. Interestingly,

CCR8 can be activated by viral chemokines from molluscum contagiosum [31]. CCR8 has also been described as an HIV-1 co-receptor.

CCR9. This is a recently described receptor that can be activated by TECK (CCL25), a chemokine for dendritic cells, T cells and activated macrophages. It also appears to be involved in the development of T cells within the thymus.

CCR10. This is a receptor for the skin-associated CC chemokine CCL27 (CTACK) that attracts skin-homing memory T cells to the site of inflammation [17].

CCR11. This is a receptor for MCP-1, MCP-2 and MCP-4. It has been described in the heart, small intestine and the lung.

CX3CR1. This is a receptor that is crucially involved in cell–cell adhesion and leukocyte trafficking. Its ligand fractalkine is a transmembrane protein that activates CX3R1 on neutrophils, monocytes, NK cells and T lymphocytes. This receptor has also been described as a co-receptor for HIV-1. Its role in the skin, however, is currently unknown.

A crucial role for chemokines and chemokine receptors in cutaneous inflammation has been demonstrated in several studies in which the relevant genes have been deleted by homologous recombination. For example, CXCR2 gene-deficient mice are incapable of mobilizing neutrophils *in vivo* [32]. Further results showing that CXCR2 ligand neutralization leads to impaired reactions during skin inflammation suggest a potential therapeutic potential for the use of chemokine receptor antagonists in inflammatory skin diseases such as psoriasis. CXCR2 knockout mice show defective neutrophil recruitment, an altered temporal pattern of monocyte recruitment and altered secretion of IL-1β, indicating a role for this chemokine receptor in wound healing [33].

Data suggest a role for chemokines in angiogenesis. IL-8 (CXCL8) has been shown to act as a growth factor in malignant melanoma. Melanoma cells overexpress certain chemokines that activate CXCL8, indicating an autocrine tumour-promoting effect of this chemokine. Many chemokines, including CCL20/MIP-3α, have been demonstrated to display antimicrobial activity comparable to defensins.

Chemokines may also be involved in the modulation of angiogenesis during tumour growth. For instance, CXCL8 (IL-8) and CXCL10 (IP-10) are angiostatic factors, while CXCL12 (SDF-1) has been shown to act as an angiogenic factor *in vivo* [2,8,10,34]. Interestingly, CXCL12 and VEGF appear to act synergistically to regulate angiogenesis. Other chemokines such as CXCL4, CXCL9 and CXCL10 decrease angiogenesis, and thereby may inhibit tumour growth. A role for chemokines in regulating blood vessel formation during chronic inflammation and injury awaits further clarification.

In summary, recent data indicate a crucial role for various chemokines in cutaneous inflammation, and receptor antagonists may prove useful in the treatment of several skin diseases including inflammation, autoimmunity, allergy, infection and tumour growth.

Proteases

Proteases constitute the largest family of enzymes, and comprise approximately 5% of the human genome, making them the largest protein family in humans. Although not known to be involved in multiple processes, proteases have in the past been regarded purely as destructive enzymes that merely degrade peptides. Proteases are in fact involved in almost all biological processes, such as embryogenesis, cell cycling, growth and differentiation, coagulation, inflammation, tumourigenesis, hair growth, secretion and tissue repair, and they also assist in cell–cell communication [1–4].

Proteases can be divided into five groups, depending on the type of molecule that mediates catalytic work (serine, threonine, cysteine, aspartyl, metalloproteinases). It is important to realize that the effect of a protease is irreversible, because hydrolysis cannot be reversed. Therefore, proteases are maintained in a precursor state (zymogen) and become activated only when needed. Proteinases are involved in inflammatory processes that are not appropriately regulated. Significant tissue destruction and impairment of repair mechanisms may occur after proteinase activation, or dysfunction of protease inhibitors. One of the best examples of a crucial part played by a protease-regulated system is the blood coagulation cascade. Another example is programmed cell death (apoptosis) in which cysteine proteases (caspases) are critically involved [5].

In the skin, exogenous proteases such as Der p3 or Der p9 from house-dust mite, bacterial (e.g. V8 protease from staphylococci) or fungal proteinases (aspartyl proteases) are capable of triggering the inflammatory response in the epidermis or dermis. Among the keratinocyte-derived enzymes that may contribute to inflammation are acid phosphatase, cathepsins (acid proteases) B, C and D, mainly distributed in lysosomes with acid phosphatase, and neutral serine proteinases such as squamous cell tryptic enzyme (SCTE), squamous cell chymotryptic enzyme (SCCE) and trypsin IV. Interestingly, enteropeptidase, the enzyme that cleaves trypsinogen and thereby activates trypsin, can be functionally expressed by keratinocytes. Keratinocytes also respond to protease inhibitors, indicating a complete proteinase-regulated machinery within the epidermis. Another enzyme, plasminogen activator, is generated throughout the epidermis, with some predominance within the granular layer.

Hereditary angio-oedema, characterized by episodic, localized angio-oedema of the skin or mucosa, results from heterozygous deficiency of a protease inhibitor from the plasma, C1 esterase inhibitor (C1INH). C1INH seems to be involved in preventing excessive vascular permeability, and is an important modulator of inflammatory responses via regulation of complement activation.

Converting enzymes, such as IL-1 converting enzyme or prohormone convertase, are important proteinases in the switching of a pro-form of a molecule to the active state. They are especially important during the inflammatory process, where dysfunction of such enzymes may result in a disease state.

Acid phosphatase occurs in large amounts, relative to other acid hydrolases, particularly in the upper keratinizing layers of the epidermis. It probably participates in nucleic acid degradation. Hyperplasia of human skin induced by UV radiation and vitamin A application is associated with an up-regulation of acid phosphatase. This increase, which also occurs in the stratum corneum, has found applications as a test for weak irritants; severe irritants result in a loss of acid phosphatase. Mild irritation of rat skin results in an increase of acid phosphatase, maximal on the third day, coinciding with acanthosis and thickening of the stratum granulosum.

Acidic protease cathepsins B, C and D occur in the human epidermis. In rabbits, cathepsin D was found to play a major role in intracellular protein digestion, and if released may degrade extracellular protein. Following irritation, proteases first degrade damaged cells via releasing lysosomal enzymes. Subsequently, via the activation of complement, Hageman factor, and cleavage of fibrin, the infiltration of leukocytes is initiated resulting in inflammation. Neutral protease in human skin, also present in fibroblasts, neutrophils and lymphocytes, has been shown to cleave complement and stimulate neutrophil chemotaxis in mice [6]. Thus, damage to the epidermis will initiate the generation of chemotactic substances by release of proteolytic enzymes and by activation of other acute phase proteins, resulting in infiltration by neutrophils and further inflammation.

Tryptase is released by mast cells during inflammation, allergic reactions and tissue repair, and stimulates the release of pro-inflammatory cytokines (IL-6, IL-8, GM-CSF) and other inflammatory mediators (NO, prostaglandins) [7–9]. Another protease released by mast cells during inflammation is chymase. This enzyme seems to be important as a regulator of vascular responses, leukocyte recruitment and the regulation of extracellular matrix proteins. Thus, chymase may be involved in the pathophysiology of allergic reactions, inflammation and tissue repair [10].

Many proteases are integral components of vital signalling networks. Besides their role as catalysts for extracellular matrix proteins, certain serine proteases have been demonstrated to activate specific receptors. The first protease-mediated receptor system identified was the thrombin receptor (PAR-1) [11]. Subsequently, two other thrombin receptors were characterized: PAR-3 and PAR-4 [12]. Thrombin not only plays an essential part in the coagulation cascade, but additionally activates platelets and

endothelial cells, thereby contributing to inflammation and tissue repair. PARs are G protein-coupled receptors with seven transmembrane domains. After activation, they mediate several inflammatory reactions, such as the release of cytokines, prostaglandins, NO or chemokines. Up-regulation of cell adhesion molecules on microvascular endothelial cells can also be mediated via PARs, indicating a direct role of proteases on leukocyte–endothelial interactions during inflammation [7]. *In vivo*, PAR-2 can be activated by skin-derived proteases such as tryptase and trypsin IV, leading to pruritus, oedema, plasma extravasation, and up-regulation of cell adhesion molecules followed by transendothelial migration of neutrophils [13–15]. Thus, activation of PARs appears to be a crucial event involved in many aspects of acute and chronic inflammation.

Plasminogen activation on the cell surface depends on the activation of urokinase type plasminogen activator (uPA) and its receptor. Such protease receptor families are defined as plasminogen activator receptors (also abbreviated PAR receptors). In contrast to the other PARs, these receptors are single-transmembrane receptors with protein kinase activity. One receptor, uPAR (urokinase receptor), can be activated by binding of urokinase and vitronectin [16]. Upon activation on endothelial cells, urokinase receptors mediate adhesion, proliferation and migration of inflammatory cells. For example, uPAR has been demonstrated to be highly expressed on leukocytes during HIV infection, and soluble uPAR (suPAR) in the serum is an effective predictor of survival in HIV infection [17]. In the skin, uPAR has been implicated in the pathophysiology of acantholysis in pemphigus [18]. uPA also activates metalloproteinases, thereby contributing to vascular damage [19]. The uPA–uPAR system is completed by the existence of plasminogen activator inhibitors (PAIs). Together, the orchestrated interaction of uPA, uPAR and PAI appears to have an essential role during inflammation, angiogenesis and cancer [20]. It is well known that protease inhibitor deficiency, or dysfunction, such as with α_1-antitrypsin, may result in airway disease [21]. An important finding has been that certain protease inhibitors are involved in cutaneous inflammation and disease. *SPINK5*, encoding the putative multidomain serine protease inhibitor LEKTI, has been identified as the gene defective in Netherton's syndrome [21]. LEKTI is strongly expressed in the granular and uppermost spinous layers of the epidermis, and in differentiated layers of stratified epithelia. Loss of LEKTI expression in the epidermis seems to be a diagnostic feature of Netherton's syndrome.

Protease inhibitors also have been identified as useful therapeutic agents. For example, inhibitors of angiotensin-converting enzyme are widely used for the treatment of hypertension but, via their pro-inflammatory capacity, may also cause the exacerbation of inflammatory skin diseases such as psoriasis. Moreover, HIV protease inhibitors recently have been introduced for the treatment of AIDS. The key role proteases play in the pathophysiology of many diseases makes them attractive targets for future drug development [22–25].

Matriptase is a trypsin-like proteinase which is produced by all types of epithelia, and was shown to be overexpressed in several carcinomas of epithelial origin. In human epidermis, matriptase is mainly produced by keratinocytes from the stratum granulosum and the first cornified layer. It is an important enzyme within the epidermis, allowing for the correct processing of profilaggrin. Filaggrin aggregates keratin inside the keratinocytes and facilitates cornified envelope as well as lipid matrix formation. Thus, matriptase may be involved in skin homeostasis, barrier function, inflammation and cancerogenesis. Indeed, mice lacking matriptase die shortly after birth due to fatal water loss. Moreover, hair follicle growth is impaired. Hepatocyte growth factor activator inhibitor-1 (HAI-1), the matriptase inhibitor, counteracts the enzyme activity of matriptase. There is strong evidence that the matriptase/HAI-1 ratio is dysregulated in epithelial cancers as well as under inflammatory conditions. Thus, protease/protease inhibitor systems may be involved in the development of cancer in chronic inflammatory conditions [26]. Kallikreins may play an essential role in epidermal homeostasis, Netherton's syndrome and barrier dysfunction [27–32].

Ectopeptidases such as dipeptidyl peptidase IV (DP IV) and aminopeptidase N (APN), as well as endopeptidases (NEP, neutral endopeptidase; ACE, angiotensin converting enzyme; ECE, endothelin-converting enzyme), and their related enzymes, have been considered as possible targets for the treatment of various inflammatory skin diseases [33–35].

Skin cells express dipeptidyl peptidase IV (DP IV) and aminopeptidase N (APN), and their related molecules of the DP IV-like family, DP2, DP6, DP8, DP9 and fibroblast activation protein (FAP), as well as the cytoplasmic alanyl aminopeptidase (cAAP). Inhibitors of DP IV-like activity, Lys(Z(NO2))-thiazolidide (LZNT) and Lys(Z(NO2))-pyrrolidide (LZNP), and the APN inhibitors actinonin and bestatin, affect proliferation, differentiation and cytokine production in keratinocytes as well as sebocytes, which are involved in the initiation of acne. Furthermore, they suppress proliferation of *Propionibacterium acnes*-stimulated T cells *ex vivo* and induce an anti-inflammatory cytokine profile. The inhibitors also suppress skin fibroblast proliferation, whereas only inhibition of DP IV-like activity decreases TGF-β1 expression, and abrogates the TGF-β1-mediated stimulatory effects on TGF-β1 and fibronectin production, collagen synthesis and matrix deposition in these cells [36].

In summary, proteases along with their inhibitors and receptors have an essential role in skin homeostasis and pathology. A well-tuned orchestra of these enzymes seems to be crucial for the maintenance of many inflammatory responses in the skin such as oedema, plasma extravasation, recruitment of leukocytes, cell–cell communication, extracellular matrix degradation, angiogenesis, cytoprotection, post-inflammatory pigmentation, spongiosis and keratinocyte desquamation. The significance of proteases to the treatment of skin diseases will be better understood once effective protease inhibitors, protease-receptor antagonists (or agonists) are available in the future.

Matrix metalloproteinases

Matrix metalloproteinases (MMPs) constitute a family of multidomain zinc endopeptidases that contain a catalytic domain with a common metzincin-like topology (Table 12.8). They are involved not only in extracellular matrix degradation, but also in a number of other biological processes. Classically, MMPs are known as key players in the regulation of the extracellular matrix (ECM), by mediating the responses of cells to their environment. By causing the proteolytic degradation or activation of a cell and the ECM, these proteases influence cell migration, proliferation and cell survival. They have overlapping activities, principally on collagen, fibronectin, laminin and elastin. The activity is tightly controlled, being stimulated by inflammatory mediators or growth factors such as IL-1, TNF-α, TGF-β, EGF, FGF as well as PDGF, and repressed by TGF-α and IL-4. The extracellular activity is inhibited by four different tissue inhibitors of metalloproteinases (TIMP-1–TIMP-4) and by the less selective α_1-antitrypsin (α_1-proteinase inhibitor) and α_2-macroglobulin [1–4].

Twenty-eight matrix metalloproteinases (MMP-1 to MMP-28), grouped according to domain structure as gelatinases, collagenases, stromolysins and matrilysin, are zinc-dependent endopeptidases present in small amounts in resting tissue, which are increased in normal tissue remodelling, and pathological changes including tumour infiltration and tissue repair. Secreted forms can be distinguished from transmembrane forms. Both forms have been implicated in proteolytic regulation of cell communication. TIMP-3 seems to be an inhibitor of the function of so-called ADAMs (adamalysin-like proteinases with metalloproteinase and desintegrin-like domains). Moreover, matrix-associated ADAMs exist that have a thrombospondin-like domain (ADAM-TS). In addition to TIMPs, ADAMs appear to be crucial regulators of MMP activity during skin homeostasis and disease. For example, TACE, ADAM-10 and ADAM-9 have been shown to be functionally expressed in keratinocytes. Activation of these ADAMs resulted in increased shedding of transmembrane collagen XVII from keratinocytes, indicating that it represents a substrate for ADAMs, thereby regulating extracellular matrix function in the skin during various subtypes of inflammation, wound healing,

Table 12.8 Vertebrate matrix metalloproteinases (MMPs).

MMP	Name	Group	Substrate
MMP1	Collagenase-1	Collagenases	Collagens I, II, III, VII, VIII, X, gelatine
MMP2	Gelatinase-A	Gelatinases	Collagens I, II, III, IV, V, VII, X, XI
MMP3	Stromelysin-1	Stromelysins	PG core protein, laminin, fibronectin
MMP7	Matrilysin-1	Matrilysins	Collagens I and IV, elastin, fibronectin, entactin, tenascin, aggrecan, vitronectin, decorin, versican, osteopontin, E-cadherin, Fas ligand, pro-TNF-α
MMP8	Neutrophil collagenase	Collagenases	Collagens I, II and III, aggrecan
MMP9	Gelatinase-B	Gelatinases	Collagens IV, V, XI and XIV, gelatine, elastin, fibronectin, vitronectin, laminin, aggrecan, versican, decorin
MMP10	Stromelysin-2	Stromelysins	Collagens III, IV and V, gelatine, elastin, fibronectin, aggrecan
MMP11	Stromelysin-3	Stromelysins	Collagin IV, gelatine, fibronectin, laminin, insulin-like growth factor-binding protein (IGFBP)
MMP12	Macrophage elastase	Metalloelastases	Collagens I, IV and V, gelatine, elastin, fibronectin, vitronectin, laminin, entactin, osteonectin, aggrecan
MMP13	Collagenase-3	Collagenases	Collagens I, II, III, IV, VI, IX, X and XIV, gelatine, fibronectin
MMP14	MT1-MMP	MT-MMPs	Collagens I, II and III, gelatine, fibronectin, tenascin, vitronectin, laminin, entactin, aggrecan, perlecan
MMP15	MT2-MMP	MT-MMPs	Fibronectin, tenascin, entactin, laminin, aggrecan, perlecan
MMP16	MT3-MMP	MT-MMPs	Collagen III, gelatine, fibronectin, vitronectin, laminin
MMP17	MT4-MMP	MT-MMPs	Gelatine, fibronectin, fibrillin
MMP18	Collagenase-4 (*Xenopus*)		
MMP19	RASI-1	Other MMPs	Collagen IV, gelatine, tenascin, fibronectin, aggrecan, entactin, laminin
MMP20	Enamelysin	Other MMPs	Amelogenin, aggrecan
MMP21	XMMP (*Xenopus*)		ND
MMP22	CMMP (chicken)		ND
MMP23	CA-MMP	Other MMPs	ND
MMP24	MT5-MMP	MT-MMPs	ND
MMP25	MT6-MMP	MT-MMPs	Collagen IV, gelatine, fibronectin
MMP26	Endometase, matrilysin-2	Matrilysins	Collagen IV, gelatine, fibronectin
MMP27			ND
MMP28	Epilysin	Other MMPs	ND

ND, not determined.

skin ageing or blistering diseases [5–9]. They are also involved in skin ageing which has an inflammatory component [10].

MMP activity seems to be enhanced in patients with inflammatory skin diseases such as psoriasis [11], and MMP-9 activity can be enhanced in human keratinocytes by UV irradiation [12] or even histamine from mast cells [13,14]. Moreover, matrix metalloproteinase gelatinase B (MMP-9) coordinates and effects epithelial regeneration during healing, as demonstrated in a mouse model [15]. MMP-1 also directly influences its own up-regulation by elastin peptides in cultured fibroblasts [16], and fibroblasts themselves are capable of generating MMP-2 and MMP-9 [17]. MMP-9 and -13 appear to modulate inflammatory responses during cutaneous inflammation, for example by regulating collagen function [18]. Increased levels of MMP-1, MMP-2 and MMP-13 were observed in lesional skin of inflammatory skin diseases such as stasis dermatitis. In contrast, TIMP-1 and TIMP-2 levels were diminished, indicating that MMPs are directly involved in the regulation of skin remodelling and inflammatory responses during stasis dermatitis [19]. MMP-2 seems to play a role in acne since the expression levels correlate with *Propionibacteria* infection [20]. Moreover, increased inflammation delays wound healing in mice deficient in collagenase-2 (MMP-8) [21].

MMP19 is important for cell proliferation, cell adhesion and migration. In mice, MMP-19 appears to be an important factor in cutaneous immune responses and influences the development of T cells [22]. Similar TNF-α, MMP-1, -9, -10 and -26 alterations are seen in both pyoderma gangrenosum and inflammatory bowel disease ulcers, suggesting a similar pathogenesis for cutaneous and mucosal inflammation in these two diseases, which may coexist in certain patients [23].

There is little difference in the enzymes present in tissues in acute and chronic wounds, the major enzymes being MMP-2 and MMP-9 (gelatinases and pro-collagenase) and MMP-1 (collagenase) [24,25]. Keratinocyte formation of collagenase occurs rapidly (within 4–6 h) during wound healing, reaching a maximum in uncomplicated wounds on days 3–5, and then declining by about day 9 when repair is complete. Collagenase digests native collagen to short peptide chains, which become susceptible to degradation by other non-specific proteases. At the wound edges, collagenase prepares the extracellular matrix bed for keratinocytes, and may contribute to keratinocyte migration [26–29]. In addition a decrease in the amount of TIMPs, the inhibitors of MMPs, in chronic wounds has been detected [27,30]. Fluid from acute wounds stimulates fibroblast proliferation, proteinase expression, matrix element formation and also was found to contain cytokines such as PDGF and βFGF [31,32].

MMPs may also play an important role in the mediation of UV-light-induced autoimmune diseases such as lupus erythematosus. Different subtypes of cutaneous lupus erythematosus are fairly similar in their MMP expression profile. MMP-3 and -10 mediate

both epidermal changes and dermal tissue remodelling but are not present in lymphocytes. Furthermore, the low expression of TIMP-1 suggests that lupus skin is characterized by proteolytic events, and targeted action using selective MMP inhibitors may reduce lupus-induced damage in inflamed tissues [33]. This needs to be further explored in more detail.

In patients with psoriatic arthritis, decreased levels of MMP-9 and angiogenic factors can be observed after anti-TNF-α treatment, strongly suggesting that MMP-9 may play a key role in the skin inflammatory process in psoriasis [34].

Thus, targeting MMPs and/or TIMPs may be beneficial for the treatment of various inflammatory skin diseases, Sjögren's syndrome and impaired wound healing. The anti-inflammatory effects of agents including glucocorticoids or antibiotics are only partly understood [35,36]. Tetracycline effects in various inflammatory skin diseases such as acne, rosacea, scleroderma, bullous dermatoses and pyoderma gangrenosum may be—at least in part—due to their inhibitory action on MMPs [37].

Lysosomal mediators

The role of lysosomes in skin inflammation—although underestimated—was highlighted by Winkelmann and Lazarus decades ago [1,2]. Recent research indicates lysosomal proteins to be involved in inflammation, wound healing, fibrosis, ageing and autoimmune diseases [3,4]. Many mediators of inflammation, particularly tissue-destructive enzymes, are derived from cellular lysosomes, which on release into the cytoplasm result in autolysis. Extracellularly, they degrade tissue elements (e.g. collagen and elastin) and dead cells [5,6]. These enzymes may also activate further mediators of inflammation in the plasma or tissue fluids

(e.g. the generation of kinins from kallikrein is induced by the trypsin-like activity of lysosomal proteases). Such proteases can also cleave complement C3 to activate the alternative pathway of complement.

Lysosomes are found in nearly all living cells, and comprise a semipermeable membrane surrounding a small vacuole, which contains acidic hydrolases and other enzymes and substances. There is some variation in the lysosomal components to be found in each type of cell [5,6]. In the developing neutrophil, lysosomes are derived from the Golgi complex; in macrophages and some other cells including keratinocytes, it is believed that they are derived from the rough endoplasmic reticulum and are transferred to special areas of the smooth endoplasmic reticulum situated within the Golgi complex.

Epidermal cells have lysosomes that contain acid phosphatases, aryl sulphatase, several proteases including the acidic protease cathepsin D, and other enzymes [7–9]. One of the difficulties in examining these enzymes is the presence of inhibitors, which inactivate enzymes of the epidermal cells, as well as of the dermis and plasma.

The lysosomes participate in the phagocytic functions of epidermal cells, particularly active during regeneration after wounds. They are also involved in pigmentation, as melanosomes are transferred to keratinocytes by a process analogous to phagocytosis. Epidermal cell derived lysosomes are involved in keratinization, responses to UV light and neoplasia [7,10]. Lysosomes also appear to be involved in sebum secretion, as they enlarge and rupture in the process of cell disintegration.

During inflammation the increase in extracellular acid phosphatase and protease is attributed to the release of epidermal lysosomes, because it occurs before leukocyte infiltration and is predominantly concentrated at the site of inflammation rather than in the serum. Leukocytes, particularly neutrophils, entering the lesion may be attracted by chemotactic factors generated by the activity of acid or neutral proteases, which cleave complement, kallikrein or Hageman factor. Accordingly, a neutral proteinase extracted from rabbit skin induced wealing within 15 min and acute neutrophil infiltration within 18 h when injected into the skin, indicating the possible participation of epidermal cell lysosome enzymes in inflammation [11].

Lysosomal proteins are also involved in the regulation of lymphatic vessel function [12], wound healing [4], regulation of T cell–Langerhans' cell interactions [13], keratinocyte function [14], granulomatous slack skin disease [15], mycobacteriosis [16] and Wegener's disease [3,17].

Radical oxygen species (ROS)

Radical oxygen species (ROS) are critically involved in many processes during acute and chronic inflammation such as ageing, cell differentiation, apoptosis, release of inflammatory mediators, etc. They monitor oxygen tension for the control of cell homeostasis and mediator production, and are involved in many signal transduction pathways involving membrane receptors during various physiological and pathophysiological processes. Activation is caused by membrane stimulation, phagocytosis, immune complexes or aggregated immunoglobulins (IgG and IgA) as well as IFN-γ. Oxygen radicals may exist following generation only for seconds; they potentially act as toxic agents, although their effects may not always be significant, and depend on the availability of intracellular control mechanisms [1–4].

NO and ROS are typically generated by tightly regulated enzymes such as NO synthase (NOS) and NADPH oxidase, or from less well-regulated sources such as the mitochondrial electron-transport chain. The massive production of antimicrobial and tumoricidal ROS in an inflammatory environment is known as the 'oxidative burst' and plays an important role as first-line defence against environmental pathogens. The physiological relevance of NADPH oxidase as a defensive agent is suggested by the observation that mice lacking the NADPH oxidase components gp91phox or p47 exhibit reduced resistance to infection [5–7].

Various forms ('species') of activated oxygen and intermediates exist: superoxide anion O^-, a precursor of toxic products, H_2O_2, MPO particularly formed in phagocytes, and hydroxyl ($HO^\bullet$) and singlet oxygen ($^\bullet O_2$) radicals, which give rise to chemiluminescence. Oxygen (O_2) alone is not toxic, and H_2O_2 in small amounts is a normal cell signal molecule; both may be converted to reactive

factors. H_2O_2, particularly in the presence of iron, is converted to the very reactive hydroxyl radical HO•. The HO• mediates a chain reaction with lipid and cyclic peroxides as the end-products, and causes cell death and membrane lysis. Furthermore, the superoxide anion of the human monocyte oxidizes low-density lipoprotein and converts it into a cytotoxin, which damages fibroblast cell lines [8].

In mitochondria, ROS are generated as undesirable side products of the oxidative energy pathway. An excessive and/or sustained increase in ROS production has been implicated in the pathogenesis of UV damage, skin ageing, autoimmune diseases, cancer, injury and wound healing, and many other diseases. ROS have been implicated in the pathophysiology of skin ageing as there is increasing evidence that free radical-mediated events may alter the expression of genes coding for proteins such as NF-κB. Finally, a crucial role for oxygen-dependent cytotoxicity in cutaneous cancerogenesis, as well as in decreased control of DNA synthesis and cell division, has been described [9,10].

There is growing evidence that oxidative stress has a pivotal role in various diseases such as inflammation, tumour growth, metabolic diseases, atherosclerosis and thrombosis, and infections such as HIV. 'Mitochondrial oxidative stress' seems to be crucial in metabolic diseases and cancer, resulting in a pro-oxidative shift in the systemic thiol–disulphide redox state and elevated ROS production. In these cases, increased ROS levels or changes in the intracellular glutathione levels are often associated with pathological alterations. Accordingly, this may result in a dysregulation of signalling or gene expression in inflammation in relation to cell adhesion molecules or cytokines [11,12].

During inflammation, NO and ROS are capable of killing microorganisms, thereby contributing to host defence. The generation of their activity is associated with the respiratory burst when cells are exposed to foreign agents. In the skin, UV radiation may—alone or following exposure to phototoxic or photoallergic chemicals as in PUVA therapy—induce activation of NO and ROS species, leading to the production of various inflammatory mediators, including cytokines and kinins. Similar effects are observed in patients with porphyria who have been exposed to UV light. The poly (ADP-ribose) polymerase (PARP) pathway appears to have an important role in the regulation of inflammatory reactions in the skin [13]. Some of the inflammatory activities of monocyte–macrophages, neutrophils and eosinophils are the result of free radicals. There is growing evidence that the biochemical basis for the mechanism of action of dithranol at the molecular level is related to redox activity leading to the production of active oxygen species, including singlet oxygen, superoxide anion and hydroxyl radical [14]. ROS molecules have been implicated in regulating leukocyte–endothelial interactions. Thus, adhesion of neutrophils to endothelial cells involves the stimulation of ICAM-1 and L-selectin via ROS activation [15,16].

There also exist important physiological aspects of redox regulation. The enzyme-mediated production of superoxide and NO, respectively, is strictly regulated by cytokines and other inflammatory mediators. Subsequently, the resulting oxidative species act as secondary messengers to control a variety of physiological responses such as vascular relaxation or hormone production [17].

Enhancement of signal transduction pathways by stimulation of ROS leads to up-regulation of expression or receptors involved in inflammation, such as the angiotensin II receptor and the EGF receptor. Furthermore, H_2O_2 has a relatively long half-life and may directly cross the cell membrane to modulate cell function. For example, ROS from activated macrophages and neutrophils may contribute to the activation of antigen-specific immune responses to pathogens. Signalling pathways involving JNK, p38 MAPK, and the transcription factors AP-1 and NF-κB, are particularly responsive to redox regulation. Thus, various intracellular signalling cascades are modulated by ROS molecules [18–20].

The production of ROS by non-phagocytic NADPH oxidase isoforms also plays a part in the regulation of intracellular signalling within non-phagocytic cells, including fibroblasts. Moreover, activated macrophages and neutrophils can produce large amounts of superoxide and its derivatives via the phagocytic isoform of NADPH oxidase. Stimulated neutrophils and macrophages generate singlet oxygen by reactions that involve either MPO or NADPH oxidase, respectively. Importantly, physiologically relevant ROS concentrations can modulate redox-sensitive signalling cascades and enhance immunological functions of lymphocytes [20,21].

With regard to achieving a balanced inflammatory response, the activity of free radicals has to be rapidly terminated. Therefore, various endogenous and exogenous molecules rapidly inactivate the function of extracellular oxygen species, such as superoxide dismutase, catalase and glutathione peroxidase, free α-tocopherols and antioxidants.

In summary, ROS generated by many cells in the immune system and the skin can modulate inflammation and infection. Clinical interventions with ROS-modulating agents may help to attenuate oxidative stress that is directly attributable to inflammation.

Nitric oxide

Over the last few years, NO has been established as a versatile factor in the immune system. NO is involved in the pathophysiology and control of inflammation, infectious diseases, autoimmune processes, tumourigenesis and chronic degenerative diseases, and may be of considerable importance in a variety of skin diseases (Table 12.9). Originally, NO was perceived as a product of macrophages activated by cytokines and generated from the amino acid L-arginine by the enzymatic activity of inducible NO synthase (iNOS or NOS2). It is now known that NO functions are considerably more complex. NO has a wide distribution in immune cells such as dendritic cells, eosinophils and neutrophils, Kupffer cells, macrophages, mast cells, microglial and NK cells, as well as in other cells that may be involved in immune reactions, such as chondrocytes, endothelial cells, epithelial cells, hepatocytes, mesangial cells, Schwann cells and vascular smooth muscle cells [1,2]. Furthermore, additionally to iNOS, different isoforms of NO synthase have been identified—endothelial NOS (eNOS or NOS3), neuronal NOS (nNOS or NOS1), both also known as constitutive NOS (cNOS)—that all operate within the immune system and catalyse the same reaction, conversion of L-arginine to NO [2]. Importantly, the activity of NO is not restricted to the site of production. It is highly diffusible, and the ability of NO to form complexes allows it to bridge long distances. Circulating nitrite (NO_2^-), a stable product of the NOS reaction, can be reduced to $^{\bullet}NO$, which is the substrate for the peroxidase pathways of eosinophils and neutrophils, leading to the formation of novel NO-derived oxidants at distant sites [3,4]. Therefore, NOS-negative immune cells can both produce NO and become targets of NO action.

Table 12.9 Pathophysiological role of nitric oxide in human skin.

Disease	Functions
Contact dermatitis (CD)	Modified expression in allergic and irritant contact dermatitis NOS expression in irritant CD: focal staining in epidermis and dermis
Atopic dermatitis	Clinical application of NOS inhibitor for atopic dermatitis Enhanced staining in the spongiotic area of the epidermis and of the perivascular region (inflammatory cells?)
Acute urticaria	NOS expression co-localized with inflammatory cytokines and CD23
Psoriasis	iNOS mRNA and IL-8 mRNA co-localize in keratinocytes of psoriatic skin Overexpression of iNOS in keratinocytes of psoriatic lesions NO may account for reduced incidence of infections in psoriasis
Lupus erythematosus (LE)	iNOS expression in cutaneous and systemic LE. Aberrant timing of UVA-induced iNOS expression in LE patients Enhanced NO production, endothelial and keratinocyte iNOS production in LE patients
Systemic sclerosis (SSC)	Increased iNOS and eNOS expression by endothelial cells in SSC Enhanced iNOS synthesis in SSC patients Increased NO production and iNOS synthesis in mononuclear cells, endothelial cells and fibroblasts in lesional skin of SSC
Stevens–Johnson syndrome (SJS)/toxic epidermal necrolysis (TEN)	Expression of iNOS in inflammatory cells of SJS and TEN
Sunburn erythema	Topical application of NO inhibitors protects against UVB-induced erythema UVB acts as a potent stimulator of eNOS and xanthine oxidase in human keratinocytes
Leg ulcers	Increased NOS expression in chronic leg ulcers Increased NOS activity in diabetic foot ulcers (macrophages)
Burn injury	Enhanced NO production in skin lesions Expression of iNOS in burn wounds (keratinocytes, capillary endothelium)
Tinea pedis	Successful treatment with an NO-liberating cream (acidified nitrate)
Molluscum contagiosum	Successful treatment with an NO-liberating cream (acidified nitrate)

eNOS, endothelial nitric oxide synthase; iNOS, inducible nitric oxide synthase; NO, nitric oxide; NOS, nitric oxide synthase.

The expression of iNOS is regulated by cytokines, while nNOS and eNOS, constitutively expressed in the cell, are activated by elevation of intracellular Ca^{2+} concentration and binding of calmodulin. All three NOS isoforms are only active as homodimers. In low concentrations, NO itself activates NF-κB and upregulates iNOS, whereas high concentrations exert the opposite effect and therefore may help to prevent NO overproduction.

Another factor that determines NOS activity is the availability of its substrate, arginine. Generation of NO (e.g. by macrophages) depends on extracellular L-arginine even when an adequate level of intracellular arginine is present [2,5].

The use of NOS inhibitors, NO donors and NOS knockout mice has provided evidence that NO triggers a broad spectrum of reactions. Accordingly, NO inhibits the adhesion of platelets and leukocytes to endothelium [6], via down-regulating the expression of adhesion molecules such as E-selectin, P-selectin, ICAM-1 and VCAM-1 [7,8]. Moreover, NO can inhibit the expression of integrins such as LFA-1 on neutrophils [6–8] and influence the chemotactic response of leukocytes by modulating the production and activity of chemokines [2,9–11]. Additionally, differentiation, proliferation and apoptosis of immune cells is mediated by NO. In the thymus deletion of T-cell receptor-activated double-positive thymocytes is dependent on thymic stromal cell released NO [12–16].

There is also evidence for a complex role of NO in autoimmune diseases such as experimental autoimmune arthritis (EAA), encephalomyelitis (EAE), uveitis (EAU) and nephritis (EAN). According to animal studies, iNOS appears to function as a negative feedback regulator of autoimmune Th1 cell response and thereby protect the host against immunopathological sequelae [1,17]. However, it has to be pointed out that results obtained with iNOS knockout mice, and mice treated with NOS inhibitors, do not support this view [17–19]. A possible explanation derives from work by McCartney-Francis *et al*. [19] on the streptococcal cell wall-induced arthritis model in rats, in which eNOS and nNOS appear to mediate the acute and chronic erosive joint disease, whereas iNOS helped to limit inflammation. Furthermore, a protective anti-inflammatory function of iNOS has been demonstrated in a T-cell-dependent and B-cell-mediated myasthenia gravis-like autoimmune disease [20], in local carrageenan-induced pleurisy [21] and in TNF-induced shock in mice [22]. In humans, a role of NOS has been demonstrated in pemphigus vulgaris [23].

Histamine

Histamine (2-[4-imidazolyl]ethylamine) was the first mediator of anaphylaxis to be identified, in 1932. Its pharmacological description as an endogenous substance was even earlier, in 1910 [1]. Histamine is synthesized from histidine by the specific enzyme L-histidine decarboxylase (HDC). It can be generated by some neurones, mast cells, basophils and platelets, where it is intracellularly stored in vesicles, and rapidly released upon stimulation. However, it has been shown that HDC is inducible in a variety of tissues by a mechanism coupled with the cytokine network, leading to non-classical histamine generation. Histamine, like tryptase, is one of the mediators rapidly released from mast cells during inflammation and hypersensitivity. However, recent knowledge clearly indicates that histamine is not the only inflammatory mediator released by mast cells.

Histamine exerts a powerful effect on blood vessels, causing smooth muscle contraction, vasodilatation and plasma extravasation from capillaries. Classically, histamine is released upon an antigen–antibody reaction with IgE bridging on the cell surface of mast cells. Further studies have shown that histamine release can

be also triggered in an IgE-independent manner (e.g. by direct interaction of molecules with cell membrane-associated G proteins or transmembrane lipid mediators). Release of high concentrations of histamine, as during immediate-type hypersensitivity, leads to systemic shock symptoms such as vasodilatation, oedema, smooth muscle contraction, decreased blood pressure and subsequent cardiopulmonary dysfunction.

Histamine mediates itch responses, especially at the beginning of an inflammatory response by activating histamine receptors on cutaneous sensory nerves. However, histamine does not appear to be the crucial mediator of itch in inflammatory skin diseases such as atopic dermatitis. Thus, a variety of distinct mediators seem to be responsible for mediating pruritus in different inflammatory skin diseases. For example, cytokines or proteinases released during the inflammatory response also have been found to activate itch mediating nerve fibres [2].

Additionally, histamine can exert direct effects on immune cells, endothelial cells and primary efferent nerve fibres via activation of histamine receptors. Four histamine receptors (HRs) have been cloned and characterized so far, which belong to the G protein-coupled receptor family with seven transmembrane domains (H_1–H_4). Except for H_3R, which is exclusively expressed in the brain, histamine receptors are widely distributed throughout the body. Thus, H_4R is located in the thymus, small intestine, liver, spleen, colon, bone marrow and on peripheral blood leukocytes [3]. H_1R is found to be expressed by tissues including mammalian brain, retina, airway, skin [4], genitourinary tract, vascular smooth muscle, adrenal medulla, liver, endothelial cells, astrocytoma cells, cerebral microvessels and lymphocytes [5]. H_2R shows a similar expression pattern to H_1R, being detected in mammalian brain, pulmonary system, cardiovascular system, intestine, skin [4], endocrine as well as exocrine glands [6] and the immune system, in T cells [7,8], macrophage–monocytes and lymphocytes [9].

In the skin, H_1R is localized on fibroblasts [10] and endothelial cells [11], and both H_1R and H_2R are expressed on keratinocytes [12,13]. After histamine activation, H_1R mediates several vascular responses, such as increased vascular permeability, vasodilatation and constriction of smooth muscle cells. H_2R exerts various effects on immune cells, such as mediator release from basophils, neutrophils and lymphocytes. Interestingly, H_2R augments T-suppressor cell activity, whereas H_1R activates regulatory T cells with contradictory effects. H_3R function is implicated in neuroregulation in the central nervous system.

Immune cells (mast cells, basophils and probably others) as well as neurones serve as cellular sources of histamine in the human body, albeit with a large difference in respect to active molecule levels. H_4R is activated by histamine at relatively low concentrations (5 nM) and, notably, by synthetic agonists (4-methylhistamine, OUP16 and some others). H_4R function can be selectively antagonized by a small molecule: JNJ7777120 and its benzimidazole analogue VUF6002. H_4R is able to cause signs of inflammation (oedema and leukocyte recruitment), and pruritus. H_4R participates in histamine-induced chemotaxis of these cells. Moreover, histamine-induced effects on the expression of cell adhesion molecules appear to be mediated via H_4R. H_4R is also involved in histamine-induced scratching in mice [14]. Thus, H_4R may be involved in the pathophysiology of skin inflammation, allergy and pruritus.

Histamine action can be terminated by receptor down-regulation, enzymes and suppressor factors. One of the latter is histamine suppressor factor (HSF), synthesized for example by activated lymphocytes. In monocytes histamine also was found to induce the production of mediators inhibiting lymphocyte migration [15]. Apart from these direct activities of histamine, it enhances expression of cell receptors, and depending on the concentration either may inhibit or stimulate the outgrowth of epidermis from skin slices *in vitro* [16]. Thus, depending on the concentration of degrading enzymes and the receptor repertoire on the cells involved histamine may contribute to pro-inflammatory as well as regenerative changes in the tissue.

Histamine formation and release is regulated by several factors other than IgE, such as cytokines, prostaglandins, leukotrienes and neuropeptides. In contrast, histamine activity regulates the formation of cytokines. Accordingly, some cytokines and chemokines such as IL-1, IL-3, IL-5, IL-8 and MCP-1, are potent inducers of histamine synthesis and release. Histamine, through the H_2 receptor, reduces the production of IL-1, IL-6 and TNF-α from endotoxin-stimulated monocytes [17,18]. Histamine also inhibits the formation of IL-2, and possibly indirectly through IL-2 inhibition also reduces IFN-γ activity [17].

Histamine regulates T-cell and B-cell functions by differential expression of H_1 and H_2 receptors [8]. Accordingly, histamine enhances Th1 responses by triggering the H_1R, whereas both Th1 and Th2 responses are negatively regulated by H_2R via the activation of different intracellular signalling pathways. In mice, deletion of H_1R resulted in the suppression of IFN-γ and the dominant secretion of Th2 cytokines (IL-4 and IL-13) associated with an increased specific antibody response (IgE, IgG1, IgG2b and IgG3). Mutant mice lacking H_2R showed up-regulation of both Th1 and Th2 cytokines [8]. These findings indicate an important regulatory mechanism in the control of inflammatory and immune functions through release of histamine. Finally, histamine also modulates MMP-9 production by keratinocytes [19].

Platelet-activating factor

PAF (1-*O*-alkyl-2-acetyl-sn-glycero-3-phosphocholine) is a phospholipid with diverse biological functions, particularly during inflammation. It is rapidly synthesized on stimulation, probably by activation of phospholipase A_2 hydrolysing fatty acid acyl groups as in arachidonic acid, followed by reacetylation. PAF binds to and activates a specific PAF receptor that is expressed by many inflammatory cells. Inactivation of PAF is regulated primarily by the rate of degradation, which is catalysed by PAF-acetylhydrolase. Beside its role as an inflammatory mediator, PAF is also capable of functioning as a hormone and transmitter in the nervous system. PAF is formed concomitantly with other arachidonic acid derivatives, the prostaglandins and leukotrienes.

In humans, PAF is synthesized by monocyte–macrophages, neutrophils, eosinophils, endothelial cells, mast cells, basophils and platelets, in response to immunological, infective or acute inflammatory mediators. PAF stimulates platelet aggregation, as well as synthesis and release of mediators [1], such as serotonin, thromboxane and PAF, within minutes of activation. In neutrophils, PAF induces chemokinesis (activated mobility), chemotaxis (attraction), secretion of lysosomal products, synthesis of 12-HETE and LTB_4 and initiation of the respiratory burst [2,3]. In monocytes PAF induces NF-κB activation and alterations in gene expression [4]. Eosinophils and endothelial cells are particularly responsive to PAF, especially *in vivo*. Moreover, PAF mediates the contraction in postcapillary venules with transient increased vascular permeability, followed by a late phase of erythema. In humans, intradermal injection of PAF has been shown to induce local eosinophilia [5] and a significant neutrophilia with a late-phase erythema [6]. In the skin, PAF is involved in growth of melanocytic tumours, and is known to mediate skin inflammation. In PAF-transgenic animals, an increased mortality was observed upon challenge with endotoxin. In addition these animals developed melanocytic tumours of the skin, and had increased bronchial hyperreactivity [7].

PAF signals the priming and activation of leukocytes at the cell surface of activated human microvascular endothelial cells. Moreover, PAF and the cell adhesion molecule P-selectin are coordinately displayed on stimulated human endothelial cells. P-selectin tethers the leukocyte to the endothelial cell, which allows PAF to bind to its receptors on the endothelial cell and on the polymorphonuclear leukocyte. This constitutes a form of juxtacrine signalling that may be a general way to spatially restrict the actions of a potent pleiotropic mediator such as PAF [8]. The PAF-receptor belongs to a subfamily of G protein-coupled receptors with seven transmembrane domains. It is expressed by many immune cells as well as epithelial cells. PAF-induced signalling is mediated via NF-κB and protein kinase C.

Dysregulated signalling by PAF may result in disease states. For example, developmental deficiency of PAF acetylhydrolase may lead to unregulated pro-inflammatory signalling by PAF in infants with neonatal necrotizing enterocolitis [9]. Dysregulated signalling by PAF also contributes to the severity of asthma in patients genetically deficient in PAF acetylhydrolase. Recently, strategies with exogenous recombinant PAF acetylhydrolase or PAF receptor antagonists demonstrated that PAF is a juxtacrine signalling molecule at the surfaces of activated human platelets, which—like endothelial cells—are critical in cell–cell interactions in inflammatory and thrombotic responses [10].

A role of PAF in inflammatory skin diseases is well documented. For example, PAF is involved in inflammatory response and pain transmission during UV-induced dermatitis [11], contact hypersensitivity [12], psoriasis [13], pruritus [14] and probably acne [15].

Prostaglandins and leukotrienes

Prostaglandins and thromboxanes

Prostaglandins (PG) and thromboxanes (TX) comprise a diverse family of autacoids, whose synthesis is initiated by cyclo-oxygenase-mediated metabolism of the unsaturated 20-carbon fatty acid arachidonic acid to the endoperoxide intermediates, PGG_2 and PGH_2 [1]. Prostaglandins were first discovered in the 1930s by Von Euler, who investigated the blood pressure lowering potential of compounds from semen. Prostaglandins are products of the cyclo-oxygenase activity on arachidonic acid, and to a much lesser extent other unsaturated fatty acids, and through intermediate products release PGE_2 and PGD_2 by different isomerases, and $PGF_2\alpha$ by a reductase. They are synthesized by many cell types leading to the generation of five bioactive prostanoids: TXA_2, PGD_2, PGE_2, PGF_2 and PGI_2. They function as mediators of inflammation, tumour growth and cardiovascular homeostasis. Each of the prostanoids is generated via activation of specific synthetases. Because prostanoids are either chemically or metabolically unstable, it is believed that they exert their effects very locally [2].

After being released, prostanoids exert their effects by binding and activating a subfamily of eight heptical G protein-coupled receptors, defined as EP (four subtypes for PGE_2) and FP, DP, IP or TP for PGF_2, PGD_2, $PGI_2\alpha$ and TXA_2, respectively [3]. Although each receptor subtype shows the highest affinity to the prospective ligand, cross-reactivity between the family members can be observed [4]. Moreover, splice variants of certain PG receptors can be observed, leading to altered receptor function and probably disease. PG receptors signal via stimulation of IP-3, diacylglycerol, and inhibition of adenylyl cyclase or Gi. In addition to PG transmembrane receptors, the nuclear peroxisome proliferator-activated receptor γ (PPARγ) has been identified as a prostanoid receptor. Interestingly, PPARγ can inactivate NF-κB, thereby modulating inflammatory responses [5].

Prostanoids and their receptors are widely distributed and have a biological role in many cell types. They may exert synergistic but also contradictory effects on specific cell types, such as epithelial cells or smooth muscle cells. In the airways, for example, PGE_2 has a relaxing effect, whereas $PGI_2\alpha$ is a potent vasoconstrictor. PGE_2 shows strong immunosuppressive effects on T cells and facilitates IgE switching in B cells by synergistically acting with LPS or IL-4. $PGI_2\alpha$ induces contraction of smooth muscle cells, and thereby mediates broncho- and vasoconstriction. Moreover, $PGI_{2\alpha}$ also inhibits PGE_2-mediated cutaneous permeability.

Thus, $PGI_2\alpha$ counteracts PGE_2 activity. In normal tissues, concentrations of both mediators seem to be balanced. Under pathophysiological conditions, however, the vasodilator PGE_2 is increased, resulting in pro-inflammatory effects. However, the balance is normalized during tissue regeneration.

In the skin, PGE_2 induces vasodilatation, and potentiates the pro-inflammatory effects of histamine, serotonin as well as bradykinin, and thus induces oedema, plasma extravasation, pruritus and pain [6]. Moreover, PGE_2 has important immunoregulatory functions in decreasing the proliferation of Th1 cells or stimulating the synthesis of IFN-γ [7]. This has clinical implications in patients with atopic dermatitis, who show increased synthesis of PGE_2 in peripheral blood monocytes, decreased Th1 lymphocyte proliferation and reduced synthesis of IFN-γ. PGE_2 also contributes to the synthesis of IL-4, thereby regulating IgE synthesis and affecting the Th1/Th2 balance [8,9]. *In vivo*, prostaglandins also contribute to cutaneous inflammation, such as contact dermatitis or UV-induced inflammation, and they potentiate the itch induced by histamine.

Prostacyclin (PGI_2), the common designation of epoprostenol, is the main metabolic product of arachidonic acid in vascular tissue, particularly in the endothelium [10]. It is an unstable substance with a half-life time of 2–3 min. PGI_2 is the most potent endogenous inhibitor of platelet aggregation, and also disperses aggregated platelets, inhibits thrombus formation, increases cutaneous bleeding time and is a strong vasodilator.

12-HETE and 15-HETE are products of arachidonic acid, converted by the 12- and 15-lipoxygenase enzymes via intermediate peroxy forms. Both are formed by fibroblasts and keratinocytes. 12-HETE is pro-inflammatory, attracting neutrophils, eosinophils as well as monocytes *in vitro*, and aggregates leukocytes [11]. It also stimulates epidermal DNA synthesis. When applied to skin, 12-HETE induces erythema followed by neutrophil and monocyte infiltration, but not eosinophil infiltration [12]. Physiological amounts occur in psoriatic skin and after UV irradiation. As it is much less potent than LTB_4 and other chemoattractants, the significance of 12-HETE in lesional skin is unknown. 15-HETE is the main arachidonic acid metabolite in homogenized dermis, and is almost certainly derived from fibroblasts; it inhibits mitogen-induced DNA synthesis by T lymphocytes and 12-HETE formation by platelets and keratinocytes. It is therefore anti-inflammatory, regulating the pro-inflammatory changes mediated by 12-HETE. Keratinocytes also form 15-HETE, but the significance of this in the control of 12-HETE production is unknown [13–15].

Pharmacological and genetic approaches have further defined the role of prostaglandin receptors in inflammation and the immune response. EP2-deficient mice show a loss of PGE_2-induced bronchodilatation, and EP3-deficient mice demonstrate impaired febrile responses to pyrogens and mucosal integrity. A decreased inflammatory response can be observed in EP4- and IP-deficient mice, indicating a direct role of this receptor during inflammation [16,17]. PGI_2, via IP activation, seems to be critically involved in acute oedematous responses [18]. PG receptors such as IP, EP1,

EP3 and EP4 are expressed by sensory neurones and contribute to pain during inflammation.

In addition, allergic reactions are associated with an increase in prostanoid secretion. Thus PGD_2 is a major PG released by mast cells during allergen challenge, and is abundantly produced in atopic diseases such as atopic dermatitis and asthma.

Prostanoid synthesis critically depends on the action of cyclo-oxygenase. Two isoforms exist: COX-1 and COX-2. Whereas COX-1 is localized in the endoplasmic reticulum close to the plasma membrane, COX-2 can be found in the perinuclear region. COX-1 is constitutively expressed by most cells but can be slightly increased by growth factors, cytokines or tumour-promoting agents [5]. Although COX-1 was not thought to be involved in inflammation, COX-1-deficient mice display reduced experimentally induced inflammation, such as ear oedema and allergic airway disease. COX-2 expression is inducible by various factors such as cytokines, growth factors and endotoxins. Surprisingly, COX-2-deficient mice do not exhibit marked differences in inflammatory responses as compared to wild-type mice. Thus, COX-1 may contribute more to inflammation than previously thought. Overexpression of the COX-2 gene in epithelial cells resulted in increased adhesion to the extracellular matrix, diminished E-cadherin expression, enhanced Bcl-2 levels and enhanced resistance to butyrate-induced apoptosis. Moreover, COX-1 appears to be essential for endothelial tube formation, whereas COX-2 is essential for the production of angiogenic factors. Thus, cyclo-oxygenases exert several effects on endothelial cells during inflammation and tumour growth [19].

Recently, a number of PG receptor compounds and COX-2 inhibitors have been developed. Most of these compounds are not selective, but activate or inactivate several receptor subtypes [20,21]. The classic COX-inhibitor, aspirin, blocks both, but preferentially COX-1 over COX-2. In contrast, COX-2 inhibitors such as rofecoxib and celecoxib are effective anti-inflammatory agents, while showing considerably less gastrotoxicity than COX-1 inhibitors and other non-steroidal anti-inflammatory drugs.

Leukotrienes

Cleavage of arachidonic acid by 5-lipoxygenase (5-LO) followed by further degradation results in several chemically related leukotrienes. They are generated by many cell types and may be divided chemically and biologically into two substances: LTB_4 and LTC_4 [20–23]. These may be further transformed into metabolites LTD_4 and LTE_4. LTB_4 stimulates chemokinesis of polymorphonuclear leukocytes, and induces exudation of plasma. Leukotrienes induce prolonged contraction of smooth muscle, and hence constriction of small airways. They stimulate mucus secretion and induce post-capillary oedema. LTB_4 has also been isolated from the skin of patients with psoriasis and atopic dermatitis.

The 5-LO pathway leading to leukotriene formation plays a pivotal part in the pro-inflammatory cascade during inflammation [21]. For example, LTB_4 promotes neutrophil chemotaxis and adhesion to vascular endothelium through specific integrins. The cysteinyl leukotrienes cause plasma leakage from postcapillary venules and enhance mucus secretion. LTD_4 and another 5-LO-derived eicosanoid, 5-oxo-ETE, are eosinophil chemoattractants. The use of murine models in which specific genes such as '5-lipoxygenase' of the leukotriene pathway have been deleted by homologous recombination firmly support their crucial role in allergic inflammation.

5-LO has been identified as an inducer of ROS production in lymphocytes. However, our knowledge on the physiological relevance of this in redox signalling is still incomplete. The oxidized metabolites generated by 5-LO have been found to change the intracellular redox balance and to induce signal transduction pathways and gene expression. LTB_4 controls cytotoxic effector T-cell recruitment to inflamed tissues [22]. Moreover, Th2 cytokines coordinately regulate IgE-dependent cysteinyl leukotriene production by human mast cells; IL-4 induces leukotriene C4 synthase expression, and thereby regulates T-cell–mast cell interactions [23–25].

Leukotrienes exert their effects by binding and activating specific heptical G protein-coupled receptors (GPCRs). Four receptor subtypes have been cloned and characterized. The high-affinity B-LT1 receptor on leukocytes binds LTB_4 in the subnanomolar range, and stimulates neutrophil secretion. Two subtypes of cysteinyl leukotriene receptors, CysLT1 and CysLT2, mediate the actions of LTC_4 and LTD_4. CysLT1 is found on airway smooth muscle cells and vascular endothelial cells, and promotes bronchoconstriction and up-regulation of endothelial cell adhesion molecules. However, our knowledge of the role of leukotrienes receptors under physiological and pathophysiological conditions in these tissues is far from complete.

The lipoxins are chemically and functionally different from the leukotrienes. Although LXA_4 and LXB_4 are similar in structure, these mediators display biological activities that are quite distinct. LXA_4 interactions with neutrophils involve binding sites that are not recognized by LXB_4 [26,27]. LXB_4 is a potent agonist for stimulating the proliferation and differentiation of granulocyte–monocyte colonies from human mononuclear cells [28], and increases the S-phase in the cell cycle and enhances nuclear protein kinase C activity [29]; such effects have not been reported for LXA_4. However, both LXA_4 and LXB_4 selectively stimulate human peripheral blood monocytes [30] and enhance growth of myeloid progenitor cells [31].

There is increasing interest in a potential therapeutic effect of leukotriene modifiers or antileukotrienes such as 5-LO inhibitors (zileuton [Zyflo]) and CysLT1 receptor antagonists (zafirlukast [Accolate] or montelukast [Singulair]). They have been used clinically in long-term studies in asthma therapy [32]. However, there is still much debate about their clinical efficacy. Their efficacy in exercise-induced asthma and aspirin-intolerant asthma is well documented. Clinical trials show bronchodilatory effects beyond those provided by β-agonists, as well as reduced eosinophil numbers in the sputum. On the other hand, a number of non-responding patients have been observed. This may be explained—at least in part—by non-leukotriene-dependent mechanisms involved in different forms of asthma or by pharmacogenetic factors. Thus, leukotriene-modulating agents may provide novel tools for the treatment of certain inflammatory diseases. For instance, a steroid-sparing benefit in mild to moderate asthma was described. However, whether antileukotriene agents may be of help for the treatment of inflammatory skin diseases such as urticaria and allergic reactions is still unclear [33].

Thus, targeting various pro-inflammatory or anti-inflammatory prostanoid receptors may be beneficial for treating inflammatory dermatoses including psoriasis or eczema. Administration of a small molecule antagonist, Compound A (Cmpd A), effectively blocked oedema formation and greatly reduced the inflammatory infiltrate in an allergic contact dermatitis model by down-regulating IL-4, IL-1β, TNF-α, TNF-β, GRO-α, MIP-2 and thymic stromal lymphopoietin (TSLP) [34,35]. In contrast, PGE_2 is a major soluble factor released by fibroblasts which suppresses inflammatory cytokine production from dendritic cells [36].

Neuromediators

Accumulating evidence indicates the existence of an interactive network between the cutaneous neuronal system, the neuroendocrine axis and the immune system. Neurocutaneous interactions influence a variety of physiological and pathophysiological biological functions in the skin, such as development, growth, differentiation, immunity, inflammation, pruritus and wound healing (Table 12.10). Different types of cutaneous nerve fibre release neuromediators and activate specific receptors on target cells in the skin, such as keratinocytes, mast cells, Langerhans' cells, microvascular endothelial cells, fibroblasts and infiltrating immune cells, thereby modulating inflammation [1–4].

Neuropathic pain is defined as symptoms associated with a primary lesion, or a dysfunction of the central or peripheral system. The neurophysiological base of neuronal signalling occurs exclusively in skin sensory endings, cutaneous nerves or central nervous tissue, as a consequence of an adequate sensory stimulus, and depends on the induction of an electric potential difference at

Table 12.10 Neuromediators in the skin; sources and target cells of neurotransmitters/neuropeptides.

Neuromediator	Receptor	Source	Target cells/function
Acetylcholine	Nicotinergic and muscarinergic acetylcholine receptors	Autonomic cholinergic nerves, keratinocytes, lymphocytes, melanocytes	Innervation of sweat glands and arteriovenous anastomoses; keratinocyte and lymphocyte differentiation; proliferation, adhesion; migration
Catecholamine, norepinephrine	Adrenergic receptors	Autonomic adrenergic nerves, keratinocytes, melanocytes	Innervation of blood vessels, arrector pili muscles; pain transmission; regulation of activity of natural killer cells and monocytes; apoptosis induction in lymphocytes
Substance P	Tachykinin (neurokinin) receptors (NK1-, NK2-, NK3R)	Sensory nerve fibres	Mediates skin erythema, oedema, pruritus; up-regulates cell adhesion molecule expression on keratinocytes and endothelial cells; release of IL-8, TNF-α, histamine, leukotriene B4, prostaglandin D_2
Neurokinin A	Tachykinin (neurokinin) receptors	Sensory nerve fibres	Up-regulation of keratinocyte nerve growth factor expression
VIP	VPAC receptors	Sensory nerve fibres, Merkel cells	Sweat secretion, vasodilatation; proliferation, migration of keratinocytes; histamine release from mast cells
PACAP	VPAC receptors	Autonomic and sensory nerve fibres, lymphocytes, dermal endothelial cells	Vasodilatation, immunomodulatory effect on T cells and macrophages; modulates mast cell function, inhibits antigen-induced apoptosis on mature T lymphocytes, down-regulates pro-inflammatory cytokines and chemokines in T cells, up-regulates cytokines and cell adhesion molecules in dermal microvascular endothelial cells
CGRP	CGRP receptors	Sensory nerve fibres	Keratinocyte and endothelial cell proliferation, stimulates cytokine production
POMC	Melanocortin receptors	Melanocytes, keratinocytes, endothelial cells, Langerhans' cells, mast cells, fibroblasts, monocytes, macrophages	Antagonizes effects of pro-inflammatory cytokines (IL-1α, IL-1β, IL-6, TNF-α, endotoxins); up-regulates Il-10; releases histamine from mast cells; regulates dendritic cell function

the nerve endings, mediated—at least in part—by induction of ion channels. A nerve action potential begins after depolarization involving transient membrane modification. In addition, calcium channels contribute to depolarization processes through activation of protein kinases. Thus, understanding the role of ion channels will lead to novel therapeutic strategies for the treatment of inflammation, pain and/or pruritus [5].

Hair follicle unit. The human hair follicle is a unique miniorgan, capable of life-long cycles of massive growth (anagen), regression (catagen) and resting (telogen). Recent work has identified complex, stringently localized signalling mechanisms between skin neuroectoderm and mesoderm that drive the hair cycle. Pilosebaceous units are both prominent targets and sources of stress mediators. Thus, the nervous system plays an essential role in the regulation of the hair cycle and melanogenesis [6].

Stress. Stress is linked to exacerbation and amplification of inflammation, allergic reactions, pruritus, sensitive skin, stinging and burning and delayed wound healing. Neuropeptides such as substance P (SP) may play a role in these processes. Stress, probably via SP and other mediators, is associated with neurogenic inflammation and increased apoptosis in the murine hair follicle. After exposure to sonic stress, for example, the number of SP-positive nerve fibres is significantly increased. There was strong association of nerve fibres to mast cells; the percentage of degranulated mast cells increased significantly, associated with a rise in apoptotic cells in the skin. Increased numbers of peptidergic nerve fibres correlated with increased numbers of growth-associated protein 43 $(Gap\text{-}43)^+$ nerve fibres, a marker for growing nerves. Thus, neuronal plasticity and increased neuroimmune interaction occur under stress and may alter the state of inflammatory skin diseases [7].

Atopic dermatitis and allergic reactions. Similarly, exposure to sonic stress in murine atopic dermatitis-like allergic dermatitis (AD) equipotently raised the number of SP^+ cutaneous nerve fibres. Stress increased AD histological parameters (eosinophil infiltration, vascular cell adhesion molecule-positive blood vessels, epidermal thickness) by at least 30%, associated with increased neurogenic inflammation (degranulated mast cells, interstitial neuropeptidergic dense core granules, mast cell apoptosis, endothelial gaping). Key features of AD exacerbation could not be induced in mice lacking the neurokinin-1 SP receptor (NK1). Interestingly, stress had no significant additional effect on $CD4^+$ cell number, but shifted the cytokine profile toward Th2 in the skin. Thus, stress primarily exacerbates AD via SP-dependent cutaneous neurogenic inflammation [8,9]. The number of sensory as well as autonomous nerves appears to be enhanced in chronic inflammation [10].

Cutaneous neuropeptides and neurohormones include a large family of small peptides such as substance P, CGRP, somatostatin, vasoactive intestinal peptide (VIP), pituitary adenylate cyclase activating peptide (PACAP), melanocyte-stimulating hormone (MSH) and β-endorphin. Moreover, neurotrophic factors such as

nerve growth factor may affect the skin. Such neuromediators can be released from both sensory and (rarely) autonomic nerve fibres, which terminate predominantly in the dermis but also in the epidermis, and thus are in close anatomical proximity to a variety of different cutaneous cell types during inflammation. Additionally, several skin cells generate neuropeptide receptors during the inflammatory response. Most of these belong to the G protein-coupled heptical transmembrane receptor family coupled to heterotrimeric G proteins. Because sensory neurones also express specific receptors for neuropeptides, prostaglandins, histamine, neurotrophins, proteases and cytokines, an interactive communication network between sensory nerves and immune cells probably exists during cutaneous inflammation [1,11,12]. Some neuropeptides have been demonstrated to be also capable of direct activation of intracellular G proteins. Endopeptidases such as neutral endopeptidase (NEP), endothelin-converting enzyme (ECE) or angiotensin-converting enzyme (ACE) are transmembrane molecules that regulate neuropeptide function by extracellular degradation or intracellular endosomal receptor-ligand control, thereby leading to the inhibition of neuropeptide function [13]. NEP appears to be an essential mediator both of pain and acute or chronic inflammation [14]. They have also been shown to modulate neurogenic inflammation by limiting the effects of neuropeptides in the skin [15]. Hence, a complex network of neuromediators, neurotransmitter receptors and peptidases exists to regulate cutaneous inflammation.

The axon reflex response in the skin is complex, and is dependent on the anatomical distribution of the cutaneous axon reflexes and release of different types of neuropeptide [15]. In the skin, at least 30% of the cutaneous afferent nerves belong to a subtype of sensory nerves with dual sensory afferent and efferent function, which mediate neurogenic inflammation. Capsaicin-sensitive C-fibres, and to a lesser extent Aδ–fibres, are not only capable of transporting impulses to the central nervous system (orthodromic signal) but also release neuropeptides (antidromic signal), which result in inflammatory activities in the skin. Neuropeptides released from cutaneous nerves are capable of acting on target cells via a paracrine, juxtacrine or endocrine pathway. These target cells express specific neuropeptide receptors that are appropriately coupled to an intracellular signal transduction pathway, or ion channels that, when activated, may result in activation of biological responses such as erythema, oedema, hyperthermia and pruritus. Because of their anatomical association to cutaneous nerves, mast cells and their released products appear to play an important part in mediating neuronal antidromic responses in the skin, although the precise role of these cells in cutaneous inflammation remains to be determined.

The tachykinin substance P strongly induces inflammatory responses and pruritus. Accordingly, SP is capable of mediating the release of the pro-inflammatory cytokine TNF-α, as well as the secretion of histamine from mast cells, which results in vasodilatation via activation of H1 receptors on vascular smooth muscle cells. SP may also induce the release of leukotrienes and prostaglandins. Acute immobilization stress triggers skin mast cell degranulation via SP, corticotropin releasing hormone and neurotensin [16]. This could be the explanation for the frequent observation that stress, via release of certain neuropeptides, may trigger skin mast cell degranulation and influence cutaneous inflammation and pruritus. Previous studies using antagonists against the SP receptor (neurokinin 1R, NK1R) indicate that cutaneous oedema can be modulated by SP via NK1R activation, independently of histamine effects [17].

Neuropeptides may also regulate vascular responses in the skin during inflammation. For example, PACAP is a potent vasodilatator and oedema potentiator in rabbit skin, and mediates plasma extravasation in rat skin [18,19]. PACAP is a relatively newly recognized member of the VIP–secretin-peptide family, present in autonomic and sensory nerve fibres of the spinal cord and dorsal root ganglia, where it may influence inflammation and nociception [20]. PACAP was detected in cutaneous nerve fibres co-localized with VIP, substance P or CGRP, respectively, all of which may play a part during cutaneous inflammation. PACAP produces a long-lasting depression of a C-fibre-evoked flexion reflex in rats [21]. PACAP may also be involved in immunomodulation via down-regulating pro-inflammatory responses such as IL-2 or IL-6 production, and up-regulating anti-inflammatory mediators such as IL-10 [22], indicating that PACAP may have a role in neurogenic inflammation of the skin.

Substance P and nerve growth factor (NGF) may be also involved in neurogenic inflammation, and its regulation, in hair follicle epithelial stem cells (HFeSC) [23]. The neuropeptide CGRP has been shown to modulate immune responses and inflammation *in vitro* as well as *in vivo*. It is one of the most potent vasodilatators in humans [24], and is critically involved in vasodilatation during neurogenic inflammation and acute inflammatory responses such as sunburn and acute contact dermatitis. In general, CGRP predominantly mediates anti-inflammatory and neurotrophic effects. CGRP was found to regulate Langerhans' cell function [25], and increases the phagocytotic ability of macrophages, indicating a regulatory role of CGRP on monocyte–macrophage–dendritic cell function. CGRP also stimulated adhesion of human neutrophils and monocytes to HUVEC and dermal microvascular endothelial cells [26]. In addition, CGRP potentiated the accumulation of neutrophils and oedema formation induced by IL-1 [27], and induced mast cells to release TNF-α which resulted in inflammatory effects on surrounding skin cells [28]. On the other hand, CGRP induced the production of IL-10 and blocked sensitization in a murine model of CHS, and induced specific immune tolerance [25]. In Langerhans' cells, CGRP inhibited the production of Th1-associated chemokines (CXCL9, CXCL10), but stimulated the generation of Th2-associated chemokines (CCL17, CCL22). Thus, neuronal derived CGRP drives LC to stimulate T cells towards a Th2 phenotype, as observed in atopic dermatitis [29].

Somatostatin (SOM) is an inhibitor of immunity and inflammation [30]. Somatostatin exerts its affects through five distinct subtypes of G-protein-coupled receptors (SSTR1–5). While SSTR1–3 are strongly expressed in the epidermis of healthy skin, and in the skin of patients with psoriasis or atopic dermatitis, SSTR4 and 5 were strongly expressed in the epidermis of psoriasis patients, but weakly expressed in the epidermis of those with atopic dermatitis and normal skin. The intensity of the staining also varied considerably between the different layers of the epidermis, especially in psoriasis patients. Dendritic cells, found mostly in the papillary and upper reticular dermis, showed strong expression of SSTR1–4,

but weak expression of SSTR5. SSTR1–5 were strongly expressed in the sweat glands in all skin biopsies. Hair follicles and sebaceous glands expressed all five subtypes. Striated muscle fibres showed intense expression of SSTR1–4, but weak or negative expression of SSTR5 [31]. SSTRs are rapidly internalized and recycle, where they can be reactivated [32]. Somatostatin is regarded as a predominantly antiproliferative molecule, having cancer-inhibiting properties mediated by tyrosine phosphatases, and inhibitory effects on the proliferation of T lymphocytes [33]. The inhibitory effects of SOM may not be generalized, because SOM also stimulates histamine release of human skin mast cells. SOM, and the SOM analogue angiopeptin, also decrease adhesion by monocytes to unstimulated and IL-1-stimulated endothelial cells by a cyclic adenosine monophosphate (cAMP) dependent mechanism that does not involve ICAM-1. SOM may therefore attenuate recruitment of distinct leukocyte subpopulations during the initial phase of inflammation [34]. There is evidence for the participation of SOM in the pathophysiology of atopic dermatitis and mastocytosis [35–37].

Proopiomelanocortin (POMC) peptides are widely distributed in the skin and are expressed by melanocytes, keratinocytes, microvascular endothelial cells, Langerhans' cells, mast cells and fibroblasts, as well as by immune cells such as monocytes and macrophages. Post-translational processing of a POMC prohormone generates up to eight different POMC peptides after cleavage by prohormone convertase 1 and 2 (PC1, 2).

α-MSH belongs to the family of POMC peptides. α-MSH is a tridecapeptide derived from proopiomelanocortin, with marked body-protective and anti-inflammatory effects. These effects can be elicited via centrally expressed melanocortin receptors that orchestrate descending neurogenic anti-inflammatory pathways. α-MSH modulates various signalling pathways, such as NF-κB activation, expression of adhesion molecules and chemokine receptors, production of pro-inflammatory cytokines and mediators, IL-10 synthesis, T-cell proliferation and activity, inflammatory cell migration, expression of antioxidative enzymes, and apoptosis. The anti-inflammatory effects of α-MSH have been validated in animal models of experimentally induced fever; irritant and allergic contact dermatitis, vasculitis, and fibrosis; ocular, gastrointestinal, brain, and allergic airway inflammation; and arthritis, as well as in models of organ injury. Due to its anti-inflammatory effect without pigmentary activity, the C-terminal tripeptide of α-MSH, KPV, has been proposed as an anti-inflammatory therapeutic agent in skin diseases [4]. In particular, α-MSH antagonizes the effects of pro-inflammatory cytokines such as IL-1α, IL-1β, IL-6 and TNF-α [38], suggesting that the immunomodulating capacity of α-MSH is also mediated through its effects on monocyte and macrophage functions. α-MSH down-regulates the production of pro-inflammatory cytokines and accessory molecules on antigen-presenting cells, while production of suppressor factors such as IL-10 is up-regulated by α-MSH [39]. It is well established that α-MSH ameliorates contact hypersensitivity, leading to hapten-specific tolerance by inducing anti-inflammatory cytokines. Moreover, α-MSH recently was found to exert anti-inflammatory activity in a murine model of asthma.

The neurotransmitters acetylcholine (ACh) and norepinephrine (noradrenaline) are also involved in inflammatory processes in the skin. ACh is released by autonomic nerves, but can be also produced by melanocytes, keratinocytes [40] and lymphocytes. It regulates different activities in keratinocytes such as proliferation, adhesion, migration and differentiation. ACh was shown to be crucial to sustain the viability of keratinocytes *in vitro*, and cholinergic drugs were capable of modulating keratinocyte function such as adhesion and motility. Both choline acetyltransferase and acetylcholinesterase appear to regulate the function of ACh in keratinocytes. Intracutaneous application of ACh has been demonstrated to modulate various inflammatory responses [41].

ACh and its derivatives exert their effects by activating nicotinergic or muscarinergic cell surface receptors. The nicotinic receptors for ACh are transmembrane ion channels. Muscarinic receptors belong to a subfamily of G protein-coupled heptical receptors, defined as m_1, m_2, m_3, m_4 and m_5 receptors. Muscarinergic as well as nicotinergic receptors are widely expressed and are involved in epithelial differentiation, cell survival of keratinocytes, and inflammation [42–44]. As expected, nicotine leads to marked effects on microcirculation (vasoconstriction) via activation of nACh receptors [45] but also influences inflammatory responses [46]. The precise role of Ach and smoking on inflammation in the skin, however, remains to be elucidated.

Catecholamines, their regulating enzymes and adrenergic receptors (ARs), have been detected in nerve fibres, keratinocytes [47] and melanocytes [48,49]. Certainly, the classic function of norepinephrine and other pharmacologically active derivatives is vasoregulation. Iontophoresed norepinephrine causes vasoconstriction, and it partially restores vascular reactivity in heat-induced vasodilated human skin [50]. Catecholamines also regulate the activity of certain lymphocytes (NK cells) and monocytes, and induce apoptosis in lymphocytes. In contrast, catecholamine release may be induced by lymphocytes such as T and B cells. During delayed-type hypersensitivity, norepinephrine may also serve as an immunoenhancing agent. α- and β-ARs have been detected in human skin. AR agonists inhibit TNF-α release from mast cells [51], and are potent inhibitors of the IgE-mediated release of tryptase mediators from human mast cells *in vitro* [52]. α- and β-ARs may also regulate important vascular responses in the skin such as vasoconstriction. Decreased levels of β-ARs were observed in lesional and non-lesional psoriatic skin [53], whereas increased levels of α-ARs were observed in arterioles of patients with scleroderma [54]. Norepinephrine is able to increase LPS-induced IL-6 production in human microvascular endothelial cells via ARs. Data suggest that catecholamines, in addition to CGRP, regulate Langerhans' cell function in the skin [55]. Taken together, these results clearly indicate a role for classic autonomic neurotransmitters during inflammation and the immune response.

Capsaicin (*trans*-8-methyl-*N*-vanillyl-6-nonenamide), a vanillyl-alkaloid found in chilli peppers and other solanaceae, has been used as an anti-inflammatory agent for many years. Topically applied, capsaicin elicits a rapid sensation of burning pain by selectively activating sensory C-fibres, and triggers a cascade of inflammatory events such as erythema, and the release of pro-inflammatory mediators in skin and mucosa. While capsaicin at lower concentrations activates sensory nerves to release neuropeptides, repeated application renders nerves in the treated area insensitive to further stimulation at higher concentrations. This is

probably caused by capsaicin receptor-mediated depletion of neuronal-derived neuropeptides within a certain subdivision of sensory nerves [56].

Chronic application of capsaicin leads to neurotoxic effects in sensory nerves, causing nerve desensitization and decreased release of neuropeptides to the site of inflammation. Thus, constant application may have an anti-inflammatory and anti-pruritic effect in the skin. These effects are at least partly mediated by activation of the capsaicin (vanilloid) receptor, TRPV1 [57]. TRPV1 is a non-selective cation channel with six transmembrane domains, now defined as the first member of the TRPV (transient receptor potential of vanilloid type) superfamily, TRPV1. To date, six members exist; these play a role in pain transmission induced by temperature, chemicals and inflammatory mediators (e.g. lipids, endocannabinoids) and chemicals. TRPV1 can be directly activated by exposure to heat, protons and the cannabinoid anandamide, conditions which participate in inflammation and injury. In the skin, TRPV1 is expressed by sensory nerves and keratinocytes and may induce the release of neuropeptides, prostaglandins (PGE_2) and cytokines such as IL-8. Of note, TRPV1 is up-regulated in keratinocytes of patients with atopic dermatitis, indicating a role for TRPV1 and its ligands (certain prostanoids, endocannabinoids, etc.) in cutaneous inflammation. Other important TRPV effects on skin homeostasis and inflammation may be subserved by TRPV2 (expressed by nerves and lymphocytes), and TRPV3, -4 and -6 (expressed by nerves and keratinocytes). TRPV3 appears to be involved in pruritic inflammatory skin diseases in mice [58]. This effect may be mediated by TRPV3-induced PGE_2 activation in keratinocytes [59].

Data suggest that proteases as neuromediators contribute to cutaneous inflammation, pruritus and barrier function by activating PARs. Activation of PARs by thrombin or mast cell tryptase results in vasodilatation, extravasation of plasma proteins and infiltration of neutrophils [60], by releasing neuropeptides such as CGRP and SP from sensory nerve endings. Thus, mast cells may regulate inflammatory responses in the skin by communicating with sensory nerves, not only via histamine receptors but also via PARs. Neutrophils release proteinase-3 which activates PAR-2, thereby playing a potential role in the exacerbation of the autoimmune disease, Wegener's syndrome [61]. In the skin, PARs are localized in keratinocytes, endothelial cells, nerve fibres and myoepithelial cells of sweat glands. Mast cells themselves express PAR-2, indicating a potential autocrine regulatory role for tryptase in cutaneous neurogenic inflammation via activation of PAR-2. *In vivo*, PAR-2 mediates oedema, plasma extravasation and up-regulation of cell adhesion molecules, and promotes the transendothelial migration of neutrophils [62], in part by a neurogenic mechanism. PAR-2 mediates pro-inflammatory responses and itch, indicating a role of PAR-2 during the pruritic response in inflammatory skin lesions [63]. Finally, PAR2 is involved in barrier function and probably ichthyosis [64,65].

The role of nociceptive processes in relation to chronic, tissue-damaging self-injury among individuals with neurodevelopmental disorders is poorly understood. Recent evidence strongly suggests implication of the sensory nervous system in injury, wound healing and self-destructive behaviour (artefacts, self-mutilation). Scientific investigation has been limited, in part, by the clinical reality that the majority of individuals with severe intellectual impairment have co-morbid communicative impairment, making it difficult to ascertain information regarding pain, pruritus and other sensations. Of note, there exists an abnormal pattern of peripheral epidermal nerve fibre innervation and increased neuropeptide (substance P) content, and modified neural neuroimmune activity, specific to a subset of individuals with chronic self-injury. These individuals had significantly more degranulated mast cells and were more responsive to tactile stimulation during a sensory testing procedure. Thus, nociceptive mechanisms and peripheral afferent sensitization may play a part in mediating and maintaining chronic self-injury [66,67].

Table 12.11 Integrin β1 and β2 families regulating cell–cell and cell–extracellular matrix binding.

	Family	α: CD number	Ligands	Integrin occurrence/responding cells
VLA-β1				
α1β1	VLA-1	CD49a	Laminin, type IV collagen	Fibroblasts
α2β1	VLA-2	CD49b	Laminin, collagens	Keratinocytes (basal), fibroblasts, platelets
α3β1	VLA-3	CD49c	Laminin, collagen, fibronectin	Fibroblasts, keratinocytes (basal)
α4β1	VLA-4	CD49d	Fibronectin VCAM-1	Fibroblasts, leukocytes (not neutrophils), Langerhans' cells
α5β1	VLA-5	CD49e	Fibronectin	Fibroblasts, endothelium, platelets, macrophages, keratinocytes
α6β1	VLA-6	CD49f	Laminin	Fibroblasts, keratinocytes
α7β1			Laminin	
α8β1				
α9β1			Fibronectin, VCAM-1	Fibroblasts, leukocytes, Langerhans' cells
α10β1			Collagens	Fibroblasts
α11β1			Collagens	Fibroblasts
αvβ1		CD51	Fibronectin, vitronectin	Fibroblasts, keratinocytes
LEUCAM-β2 (mainly cell–cell)				
α1β2	LFA-1	CD11a/CD18	ICAM-1, -2, -3	Leukocytes
αmβ2	Mac-1	CD11b/CD18	ICAM-1, fibrinogen, C3bi	Leukocytes
αxβ2	p150.95	CD11c/CD18	Fibrinogen, C3bi	Leukocytes, endothelium
αdβ2			ICAM-3	Macrophages

See text for abbreviation definitions. β1 integrins stated to bind to basal keratinocytes may be expressed weakly in suprabasal cells of normal epidermis; expression is increased during inflammation.
LEUCAM, leukocyte (cell) adhesion molecules.

Vasculature and inflammation

Cell adhesion and adhesion molecules

Cell–cell and cell–substrate adhesion is an essential function of cell membranes. Adhesion molecules participate in every cell activity, although they may be latent, that is not expressed until the cell is stimulated, as in platelets, or expressed very transiently, as for the selectins, between leukocytes and endothelium, for example. Over a longer duration, integrins can be up-regulated or down-regulated, thereby controlling interactions between basal keratinocytes and the basement membrane, skin cells and leukocytes or leukocyte–leukocyte interactions during inflammation. Tissue growth, differentiation and repair are tightly regulated by adhesion molecules, because leukocyte recruitment and function is critically dependent upon adhesion molecule functions. Practically, a leukocyte sequentially up-regulates several different surface molecules during its passage through the endothelium to the site of inflammation or injury. Accordingly, endothelial cells have to up-regulate their counterpartners on their cell surface, suggesting a close communication between leukocytes and endothelial cells through inducing mediators such as cytokines and chemokines. Thus, adhesion molecule expression is a complex process, associated with, or induced by, the contiguous cells or substrate. Adhesion molecules can be subdivided as members of the integrin family, the selectin family and the immunoglobulin superfamily.

The recruitment of immunocytes to cutaneous tissues, a complex multistep cascade mediated by a large variety of cytokines, chemokines, and adhesion molecules, is thought to be a pivotal process in the pathophysiology, development, perpetuation or termination of skin inflammation. Thus, defining the mechanisms and molecules, and targeting leukocyte trafficking, remains an attractive approach for the treatment of skin diseases. It is increasingly recognized that during the pathogenesis of psoriasis, for example, multiple interactions between T cells, dendritic cells, macrophages, mast cells, endothelial cells and keratinocytes play a role in the outcome of the inflammatory response. Biologics specifically inhibiting key molecules involved in cutaneous leukocyte recruitment have been approved for the treatment of various skin diseases [1]. However, the existence of certain redundant and/or functional overlaps limits their therapeutic success [2–4].

Integrins

Integrins, first recognized by Hynes in 1987 [5], are the best studied members of the cell adhesion receptor superfamily. Integrins and their ligands are key to embryogenesis, tissue development and differentiation, immune responses, leukocyte trafficking, cancer metastasis and tissue homeostasis. However, integrins are not only binding partners but also regulate release of mediators during inflammation [6]. Integrins also modulate T-cell function [7], contact hypersensitivity [8], recruitment of eosinophils [9], psoriasiform dermatitis in mice [10] and impaired wound healing [11].

Integrins are α- and β-heterodimers but are of considerable diversity, there being eight β chains and 18 α subunits; one α subunit non-covalently links with one β subunit [12], assembling into 24 distinct integrins (Table 12.11). Some α subunits (e.g. αv) may link with more than one β chain, enabling binding to different substrates (e.g. vitronectin, fibronectin or collagens). Partner recognition is specific for the tripeptide sequence Arg-Gly-Asp (RGD) [13]. Ligand substrates have been identified experimentally. *In vivo*, it is probable that there is diversity in adhesion molecules; a

cell may vary expression of integrins depending upon the nature either of the substrate or the stimulus [12].

In addition to their roles in adhesion to extracellular matrix ligands, integrins act as links between the intracellular cytoskeleton and extracellular milieu. All integrins, apart from α6β4, link to actin, whereas the β4 subunit with its large (1000 amino acid compared to 50 amino acid) cytoplasmic domain links to intermediate filaments. Ligation of integrins initiates a plethora of signal transduction events which serve to modulate cell behaviour, including proliferation, apoptosis, up-regulation of genes involved in inflammation, cell polarity and migration [14]. Many integrin-stimulated cell signalling pathways are similar to those triggered by growth factor receptors and cytokine/chemokine receptors.

Knockout mice studies have helped to elucidate the specific, non-redundant function of each of the 24 integrins. Indeed, genes for all β subunits and α subunits which have been knocked out reveal that the role of each integrin is markedly distinct. The phenotypes range from perinatal lethality (α3, α6, α8, αv, β4 and β8) to defects in leukocyte function (αL, αM, αE, β2 and β7), inflammation (β6) and angiogenesis (α1 and β3) [15].

The β1 chain integrins, also known as VLA (very late antigens of activation, being late in appearance on T-cell activation) bind cells to cell substrates (Table 12.11). The β1 integrins have important cell–cell and cell–membrane linking functions in the epidermis. The distribution of integrins in epidermal cultures is fairly consistent. The α2, α3, α5 and β1 chains are present in basal cells, particularly at cell–cell junctions; α6β4 integrin tends to be most strongly expressed on the base of the basal cells, as is αvβ1, which is weakly and irregularly expressed. These two integrins bind to fibronectin, laminin and vitronectin of the basement membrane [13–18]. If the culture substrate in the initial stages of development is changed from laminin to collagen, the dominant integrin in the basal–substrate zone changes from α3 to α2β1 [16]. The half-life of integrins in culture is 12–15 h. Disappearance of integrins in suprabasal cells occurs because they are not replaced, and is associated with terminal differentiation. Upward cell migration from the basal layer involves loss of adhesion to the basement-membrane proteins, which precedes the decrease and loss of the α5β1 integrins and fibronectin [19,20].

In normal epidermis *in vivo*, the highest expression of integrins is on basal cells, either at cell–cell contacts, where α2 and α3β1 are particularly found, or the basal cell–basement-membrane interface, with α3β1 being strongly expressed and αvβ1 and α1β1 being less evident [16,21,22]. Integrin α6β4, a laminin receptor, is strongly expressed in hemidesmosomes [23]. Opinion varies about the presence of α5 on normal basal cells, or the persistence of integrins in the suprabasal layers; discrepancies in the literature may be a result of different epitope specificities of the test antibodies, or to activation of the skin before or during sampling. The β1 chain persists on the cell surface in suprabasal layers, but at a lower level than on basal cells [13,16]. Reported identification of α2β1 and α3β1 on suprabasal cells of normal epidermis [16] may be caused by recognition of the β1 chain rather than the α chains. As described in the culture studies on α5β1, there is first loss of binding to the extracellular matrix components and then loss of the integrin during differentiation [20], with possibly greater persistence of the β1 cell–cell links.

During epidermal wound healing, there is increased expression in the wound of α2β1, α3β1, α5β1, αvβ4 and α6β4 integrins [21,24,25]; some differences in relative expression have been reported during repair of punch-biopsy wounds [25] as compared with suction blisters [21]. The migrating keratinocytes in punch-biopsy repair strongly express α3 and β1, α6 and β4, while after day 2 α5 activity is increased. The α3 and β1 pattern extends into the unwounded peripheral tissue [25]. In suction-blister repair, the blister roof expresses clusters of several α chains and β1 and β4 chains. On day 2, the migrating keratinocytes express the normal basal cell pattern. By day 6 in the healed hyperproliferative suprabasal epithelium, α2, α3, α6 and β1 are present, and there are low amounts of αv. The α5 and β4 integrins are confined to the basal layer, and in the case of β4 also to the next layer. The staining pattern distal to the wounds is normal [21]. These changes reflect the more rapid upward and lateral migration of hyperproliferative keratinocytes, and synthesis of extracellular substances (e.g. fibronectin and vitronectin). Changes in the granulating basement membrane of full epidermal thickness wounds [25] stimulate formation of the corresponding integrins. In 7-day wounds, formation of fibronectin and tenascin is associated with expression of αvβ6, and of the specific integrins beneath the basal cells at the dermal interface [26]. Hyperproliferation of epidermal keratinocytes in psoriasis is associated with discrete clusters of suprabasal α6 and β1 [18], and also with α3 and α5, particularly at the rete ridges [27].

Human Thy-1 is a receptor on endothelial cells which binds the interin Mac-1 on neutrophils. Thus, Mac-1 may contribute to neutrophil recruitment to sites of inflammation. Binding of neutrophils to human Thy-1 also stimulates release of MMP-9 and CXCL8 from neutrophils, resulting in enhanced migration, indicating that integrins are not only binding partners but also active drivers of mediator release [28], TNF-α blockers [29] and 1α,25-dihydroxyvitamin D_3 (vitamin D_3) [30].

Avidity of integrins (β2)

Cell migration, and cell–cell or cell–substrate binding in tissue repair, are associated with increased cell adhesion, integrin avidity and cytoskeleton actin polymerization. Members of the β2 integrin leukocyte cell adhesion molecule (LEUCAM) subfamily (also known as CD11/18) are expressed on most leukocytes, becoming inactive when they are 'resting'. Leukocyte function associated antigen-1 (LFA-1) (CD11a/CD18; α1β2) illustrates the changes in conformation and increase in binding sites after activation of the cell. The adhesion molecules of mobile non-activated leukocytes do not bind to endothelial cell ligands, thus avoiding spontaneous cell aggregation and vascular damage. On leukocyte activation, rapid changes in LFA-1 promote binding to the endothelial ligands (immunoglobulin superfamily members) ICAM-1 and ICAM-2, resulting in leukocyte arrest at the site, emigration or local inflammatory change [1,2]. New epitopes appear in the α and β chains [3,4] and there is an influx of calcium ions resulting in an increase in expression of the binding sites [2,5]. Strong support for the importance of β2 to leukocyte trafficking and inflammation comes from the phenotypes of mice lacking one or more β2 integrins on their ligands (e.g. skin infections), and the genetic disease leukocyte adhesion deficiency (LAD), which results from mutations in the gene for β2 integrin. LAD patients suffer from leukocytosis and failure to recruit leukocytes to sites of infection [6]. Blockade of β2 integrins is a highly promising line of biological therapy for skin inflammation, particularly psoriasis [7].

Low-avidity integrins are not closely associated with the cytoskeleton, but upon ICAM-1 contact stimulation, membrane protein kinase C (PKC) initiates phosphorylation of the cytoskeletal proteins, and the α and β chains of LFA-1. This results in reorganization of the vinculin, talin and α-actinin molecules that link actin fibrils to the cell membrane and the integrin, and induces polymerization of the actin fibrils, thereby increasing the cytoskeleton matrix essential to the adaptation of the cell to its environment. The changes in conformation result in increased avidity of the integrins [1,2]. Leukocyte activation results in high-avidity transformation of LFA-1, coupling to the actin intermediate proteins, and polymerization of the actin fibrils, which stabilizes binding to ICAM-1 and promotes adherence to the endothelium. Activation of integrins also stimulates cell synthesis of cytokines and receptors to chemokines, contributing to cell emigration.

Mac-1 (CD11b/CD18) on the membranes of neutrophils, eosinophils and monocytes has a wider range of ligand binding than LFA-1 although it has the same β2 chain (Table 12.11). In normal cells it is inactive but, like LFA-1, the binding affinity for the endothelial cell membrane and other ligands becomes expressed on leukocyte stimulation.

Selectins

Selectins are calcium-dependent transmembrane glycoproteins with an amino-group terminal portion that binds to sialylated carbohydrate counter-receptors on other cells. Selectin binding is a key transient link between leukocytes and vascular endothelium, thereby mediating the initial steps of leukocyte tethering

Table 12.12 Selectin family.

Molecule	Cells	Function	Activation
P-selectin			
CD62P GMP 140 PADGEM LECAM-3	Platelets, endothelial cells	Links neutrophils and monocytes to platelets and endothelium	Thrombin, histamine oncostatin M, IL-4, IL-13, free radicals, peroxides
E-selectin			
CD26E ELAM-1 LECAM-2	Endothelial cells	Links neutrophils, monocytes, and CLA^+ T-cell subsets to endothelium	IL-1β, TNF-α, LPS, substance P
L-selectin			
CD62L LAM-1 LECAM-1 $Gp90^{MEL}$ DREG	Neutrophils, basophils, eosinophils, monocytes, lymphocytes	Leukocyte rolling on endothelium; transient arrest	Constitutive activation by endothelium

and rolling. The selectin family comprises three members: P-, E- and L-selectin—the genes for which are clustered on chromosome 1 (Table 12.12) [1]. Each selectin has a lectin-like domain at the amino (NH_2) terminal followed by an EGF-like domain and consensus repeats.

P-selectin. P-selectin (CD62P, GMP-140, PADGEM, LECAM-3) is stored intracellularly in the α-granules of platelets and Weibel–Palade bodies of endothelial cells [2,3]. Surface expression of P-selectin on endothelium follows fusion of Weibel–Palade bodies with the plasma membrane. This follows stimulation by histamine, IL-4, IL-13, oncostatin M or thrombin [4–6]. Expression of P-selectin occurs rapidly, within 30 min. Transient expression on endothelium contributes to early leukocyte recruitment [7]. More sustained expression of P-selectin occurs when platelets and endothelium are activated by thrombin, histamine or free radicals, resulting in adhesion of platelets to neutrophils or monocytes and further adhesion of leukocytes, which is enhanced by PAF [8–10]. Once expressed on the cell surface, P-selectin is rapidly internalized by endocytosis [11].

The main ligand for P-selectin is P-selectin glycoprotein ligand-1 (PSGL-1) expressed on myeloid, lymphoid and dendritic cells [12]. P-selectin–PSGL-1 binding is crucial to neutrophil rolling, in that targeted gene disruption of PSGL-1 abrogates this process [13]. The other P-selectin ligand is CD24, which can mediate cell rolling on inflamed endothelium independent of PSGL-1 [14]. Recently, it has been shown that adhesion of P-selectin to leukocytes activates intracellular signalling pathways [15]. For instance, adhesion to T lymphocytes leads to tyrosine phosphorylation of proteins including paxillin [16].

Soluble P-selectin has been detected in plasma but its role is uncertain.

E-selectin. E-selectin (CD62E, ELAM-1, LECAM-2) is synthesized and expressed solely by endothelium and, unlike P-selectin, is not constitutively expressed. Expression is transcriptionally regulated by TNF-α, IL-1 LPS and substance P [17–19]. Following stimulation, peak expression of E-selectin occurs within 4 h and wanes in 24–48 h [17]. E-selectin ligand-1 (ESL-1), the main receptor for E-selectin, is expressed only on myeloid cells [20]. Both PSGL-1 and L-selectin are able to bind E-selectin [21,22]. Leukocytes do not require activation to bind to E-selectin, but as a result of binding there is activation of the β_2 integrin LFA-1 receptors on neutrophils [23]. E-selectin differentiates between neutrophil and eosinophil binding through differences in amount and dimeric form of ESL-1; eosinophil binding is about half that of neutrophils [24].
