THE GEOLOGICAL SOCIETY

The Geological Society of London (GSL) was founded in 1807. It is the oldest national geological society in the world and the largest in Europe. It was incorporated under Royal Charter in 1825 and is Registered Charity 210161.

The Society is the UK national learned and professional society for geology with a worldwide Fellowship (FGS) of 10 000. The Society has the power to confer Chartered status on suitably qualified Fellows, and about 2000 of the Fellowship carry the title (CGeol). Chartered Geologists may also obtain the equivalent European title, European Geologist (EurGeol). One fifth of the Society's fellowship resides outside the UK. To find out more about the Society, log on to www.geolsoc.org.uk.

The Geological Society Publishing House (Bath, UK) produces the Society's international journals and books, and acts as European distributor for selected publications of the American Association of Petroleum Geologists (AAPG), the American Geological Institute (AGI), the Indonesian Petroleum Association (IPA), the Geological Society of America (GSA), the Society for Sedimentary Geology (SEPM) and the Geologists' Association (GA). Joint marketing agreements ensure that GSL Fellows may purchase these societies' publications at a discount. The Society's online bookshop (accessible from www.geolsoc.org.uk) offers secure book purchasing with your credit or debit card.

To find out about joining the Society and benefiting from substantial discounts on publications of GSL and other societies worldwide, consult www.geolsoc.org.uk, or contact the Fellowship Department at: The Geological Society, Burlington House, Piccadilly, London W1J 0BG: Tel. +44 (0)20 7434 9944; Fax +44 (0)20 7439 8975; E-mail: enquiries@geolsoc.org.uk.

For information about the Society's meetings, consult Events on www.geolsoc.org.uk. To find out more about the Society's Corporate Affiliates Scheme, write to enquiries@geolsoc.org.uk.

BP
Centrica Energy
Chevron
ConocoPhillips
ExxonMobil
Hardy Oil and Gas plc
Hess
Maersk
MND Exploration & Production
Nexen
Petro-Canada
PA Resources
Schlumberger
Serica Energy
Sonangol Gas Natural
StatoilHydro
Venture Production plc

Preface

The Seventh Petroleum Geology Conference (PGC VII) was the latest in a prestigious series dating back to 1974. Over the years, this conference series and the associated proceedings volumes, commonly known as the 'Barbicans', have provided an important reference to NW Europe exploration and production, from its early life as an emerging world class petroleum province, through to its current mature stage. The previous conference opened the door to embracing selected other areas of the world, while still maintaining the tradition of the former five preceding conferences. The seventh conference, entitled: 'Petroleum Geology: from Mature Basins to New Frontiers', while also staying true to its roots, was a truly international conference, with sessions encompassing many of the petroleum provinces of the world, that is: Europe; Russia, the Former Soviet Union (FSU) and the circum Arctic; North Africa and the Middle East; and Passive Margins worldwide. As the world seeks new energy sources, it was most appropriate to have a session dedicated entirely to unconventional hydrocarbon resources. Regular features such as a core workshop were present. In addition, innovative new features, such as the geocontroversies debates and virtual field trips, both of which are described below, enhanced what was already a well established conference format.

The conference series has been distinguished by its high scientific quality; PGC VII is no exception. We are confident that these proceedings volumes will continue to be the standard reference for successive generations of petroleum geoscientists. The proceedings, in general, will follow the thematic format of the conference itself, and the majority of the papers presented in the conference appear as scientific contributions in the proceedings volumes. This preface attempts to provide an insight into the unifying themes of the conference.

The scene was set by a plenary address on 'Global Petroleum Systems' to place the various geographic-based sessions into their mega-regional plate perspective.

The geocontroversies debates, mentioned above, were designed to address certain broader challenges facing society and the petroleum industry today, in contrast to the highly scientific nature of the presentations in the other sessions. The format of the geocontroversies debates was one whereby two expert protagonists presented their case: one for and one against a motion. The three motions, one of which was presented on each of the three days of the conference, were entitled: 'This House believes that the North Sea is finished'; 'This House believes that National Oil Companies (NOCs) are the future of the petroleum industry'; and 'This House believes "Peak Oil" is no longer a concern'. Each debate was concluded with a poll in which the audience raised a yellow or red card to indicate their support or opposition to the motion. The results were, respectively, that the North Sea is not finished; NOCs are the future of the petroleum industry; and that 'Peak Oil' is indeed with us! The debates were a great success, enjoyed by all, and set a benchmark for the future.

The virtual field trips transcended all aspects of petroleum geoscience, using a medium whereby delegates could 'return to the rocks' and go on a field trip to various exotic parts of the world, but without leaving London. Significant advances over recent years in geoscience data acquisition, visualization and analysis now permit the construction of detailed digital outcrop models. In a visualization environment, these outcrop models can be viewed sequentially in 3D to simulate a geological field trip. While it is recognized that virtual field trips will not surpass the benefits of undertaking actual field work, they clearly have their place in the petroleum geoscientists' tool-kit. For example, digital outcrop mapping techniques, showing lateral and vertical facies associations and the distribution of fracture networks, can be transformed into a static geocellular model, the forerunner for reservoir simulation. Eight case studies are provided as video-clips on the accompanying DVD. The various localities visited include Ireland, France, Norway, Egypt, Greece and the USA. More widespread use of these technologies, and associated new developments, are undoubtedly a future trend in petroleum geoscience, as the keen interest in this session demonstrated.

The core workshop has been a successful regular feature of recent 'Barbican' conferences, enabling petroleum geoscientists to 'get their hands on the rocks'. This has, in large part, been due to the enthusiasm and dedication of Dr Colin Oakman. Colin sadly passed away at the time of preparing for PGC VII. It is most appropriate that this core workshop bears his name. Colin would have been duly proud. The core workshop focussed on reservoir sedimentology of the North Sea Basin and featured presentations by PhD students, academics and consultants that placed the reservoirs, as shown by the cores, into context. The cores illustrated a diverse range of 'classic' North Sea reservoirs. Cores were presented from the alluvial and fluvial clastics and carbonate turbidites of the Carboniferous of the southern North Sea. The central North Sea was represented by cores from Triassic aeolian and fluvial clastics, Jurassic (Fulmar Formation) shoreface sandstones and Cretaceous deepwater fan deposits. The northern North Sea was represented by cores from the deltaic sequences of the Jurassic (Brent group). In summary, the core workshop provided an impressive display of reservoirs of various ages, facies and geography across the North Sea Basin to complement the papers and posters of the Europe session.

Europe, in particular the North Sea, has been the cornerstone of the 'Barbican' conferences over the past 35 years, as summarized in the Europe section of these proceedings volumes. This conference confirmed that a high interest in Europe continues, manifesting itself as the most extensive session of the conference. This is depicted in the proceedings by the themes of exploration, field development and production, and new techniques in exploration and exploitation. The key issues addressed include small pool and high-pressure, high-temperature exploration, late-stage field exploitation, and field redevelopment. In addition, the North Sea has, for many years, provided copious high-quality, multidisciplinary subsurface datasets that permit tracking of plays and fields from discovery through to late life and, in some cases, rehabilitation; it is truly a world class 'laboratory' for future exploration and production activities around the world. This aspect is complemented by the pioneering of emerging technologies that also have applicability around the world.

The exploration theme has papers, regional, local and of a detailed case-study nature, that describe current exploration activity for small, deep pool, and complex structural and stratigraphic prospects in mature and frontier plays. The detailed integration of seismic, well and analogue-derived technologies to better understand structural evolution and sequence stratigraphic-based depositional systems are illustrated by case examples. The field development and production theme contains papers that describe the petroleum industry's responses to the challenges of low-permeability reservoirs and reservoir prediction. Finally, the theme on new techniques in exploration and exploitation contains papers that emphasize the need for integration across the spectrum of geoscience and petroleum engineering disciplines. Papers pertaining to recent advances in petrophysics, 3D and 4D seismic applications, and the targeting of drilling and completion technologies within integrated reservoir models complete this most rewarding section in the proceedings. For those readers searching for Atlantic margin papers in this section, these are placed more appropriately in the Passive Margins section. In this regard, we would encourage readers to look throughout the proceedings, as their particular subject of interest may be in a different section.

The Russia, FSU and circum-Arctic session covered vast, diverse regions, with some complex petroleum systems, ranging in age from the Neoproterozoic to the Cenozoic. These regions have attracted considerable interest from the petroleum industry over the past 20 years. The offshore Arctic, in particular, is perceived as a possible future world-class petroleum province with the likelihood of some new giant fields. It has, however, significant technological challenges in addition to important environmental considerations and its remoteness from markets. The series of regional papers addresses the geology of the Arctic basins, including their tectonic origin, and proposes models for their genetic evolution. It is truly a circum-Arctic regional section, with papers from Russia, Norway, Greenland, USA and Canada. In contrast, at a field scale, this section hosts two field development papers from the north Caspian Basin: the giant Karachaganak and Kashagan fields.

The North Africa and Middle East session is also strongly represented by papers addressing the regional geology. However, in this region, the emphasis was on the search for new older and deeper plays in known areas, and conventional plays in the frontiers. The North Africa petroleum systems of the Ghadames and Kufra basins are featured, including discussion of the glacio-eustatic controls on facies patterns. The impact of recent advances in seismic technology, in providing a step-change improvement in our understanding of basins, and their possible deeper potential, was demonstrated by papers from the comparatively well known Gulf of Suez and northern Red Sea areas. Moving to a field scale, a case study of the appraisal of the Taq Taq field in northeast Iraq provides insights into the technological approaches used to model fracture systems.

The session on Passive Margins was highly popular with delegates. Passive Margins have been the mainstay of global exploration success and fast-track field development over the past 25 years. Deepwater production now exists from Passive Margins as diverse as Angola, Nigeria, Brazil, US Gulf of Mexico, Egypt and India. A generation of petroleum geoscientists have now spent a significant part of their careers exploring Passive Margins using methodologies mostly based on direct hydrocarbon indicators.

It is welcoming now to see a more holistic approach to our understanding of Passive Margins, this being a key feature of the conference and proceedings. New insights are presented and old dogmas questioned. The evolution of Passive Margins is examined using exciting new information on the deeper structure of continental margins. New models are being developed that propose, for example, multiphase rifting events and a better understanding of the role and implications of volcanics. This diverse nature of Passive Margin geodynamics has resulted in different views regarding genetic basin evolution and architecture. This impacts our understanding of thermal history and subsequently the predicted level of maturation of source rocks. Further examples of a more holistic approach include discussion and integration of 'source to sink' concepts that address geomorphology, drainage systems, sediment supply and the influence of palaeoclimate. A principal benefit of these new approaches is a better understanding of the potential of a variety of play types, for example, deltaic depocentres, slope by-pass systems, carbonate platforms and margins, deepwater fold-belts, and pre-rift and syn-rift sections. Technology will continue to play a vital role. Papers were presented that demonstrate that improved seismic imaging techniques are having a profound effect in our understanding of the pre-salt plays offshore Angola. Will the latter mirror the conjugate margin offshore Brazil, the scene of many exciting, world class discoveries in recent years? The comprehensive Atlantic Margin section addresses new results in understanding the sub-volcanic geology of this extensive region. We are confident that further applications of these new approaches will breathe further life into Passive Margins worldwide and unlock new, deeper play potential.

Since the last conference in 2003, there has been a significant increase in interest in unconventional hydrocarbon resources to address, in part, the world's future energy needs. This has been particularly apparent in North America. It therefore appeared appropriate for this conference to address this important topic, and to assign a separate session devoted exclusively to unconventional oil and gas resources. These resources include oil sands, oil shale, shale gas, basin-centred gas, coal bed methane and gas hydrates. Unconventional oil and gas resources are commonly described as continuous or regionally pervasive and, although in-place volume estimates may be large, overall recovery is relatively low. These accumulations certainly challenge the paradigms associated with conventional resources, for example trap delineation is often problematic; reservoirs are developed in rocks formerly considered as sources and seals; and many unconventional oil and gas resources lack hydrocarbon–water contacts.

Pioneering research and technological innovation is underway. Many initiatives are focussed on North America, although other areas of the world are emerging. Aspects of this research are highlighted and complemented by some initial studies in Europe.

A spectrum of different examples from various parts of the world were presented. These include: the Bakken petroleum system, a tight oil play of the Williston Basin in North America; the basin-centred gas plays of the Western Canada Foreland Basin and the Pannonian Basin, Hungary; and the heavy oil deposits of the Athabasca Oil Sands in Canada.

The geological storage of carbon dioxide is rapidly gaining recognition as an important potential method for reducing carbon dioxide greenhouse gas emissions in the near future. These developments are driven by concerns to address climate change. However, these technologies are expected to also have future application to the petroleum industry and other parts of the energy sector. Recent findings from current commercial carbon capture and storage projects in the North Sea and North Africa are presented, and are complemented by major research programmes in North America.

The 'Seventh Petroleum Geology Conference; from Mature Basins to New Frontiers', and these proceedings, owed their success to the efforts of many dedicated individuals over a considerable period of time. We take this opportunity to thank each of them for their contributions, energy and enthusiasm, which have resulted in a complex job well done. We fully recognize that this success has been achieved at the same time as other competing demands for their skills and expertise. The willingness of many companies to release proprietary datasets and concepts, a hallmark of an up-to-date conference and scientific publication, is also gratefully acknowledged. We believe that the highest scientific standards have been attained in line with the tradition of the 'Barbican' conferences and proceedings of the past. In particular, we thank all members of the PGC VII Board, Organizing Committee, and Technical Committee, the latter as convenors for the conference, and subsequently as authors, referees and editors for the proceedings volumes. It has been an honour and a privilege to work with them. We also thank all our sponsor companies and universities for their support, whether this has been through direct funding, or indirectly through the provision of their staffs' valuable time. Finally, we thank the staff of The Geological Society Publishing House for preparation of a publication that will stand the test of time. We hope and trust that you, the reader, will enjoy the proceedings and use them extensively as a scientific standard reference, both as a book on your bookshelf and digitally on your desktop, in the global search for, and exploitation of, future energy resources.

Abstract: Each of the Earth's approximately 900 sedimentary basins is a unique result of geologic, hydrologic, atmospheric and biologic processes. The interaction of these processes results in complex histories that are palaeogeographically linked within tectonic provinces. Process-based genetic analysis provides the fundamental framework for predicting the distribution and character of petroleum systems. New technologies enable the exploitation of this predictability and are themselves the origin of new ideas and improved systems understanding. Petroleum geoscience embraces both forward modelling of processes as well as observation, calibration and inverse modelling. This approach of forward and inverse modelling promotes a general scientific methodology of simulation, prediction, testing and learning that allows us to describe the genetics of sedimentary basins. Genetic analysis can be applied to the spectrum of resource types from hydrocarbon to groundwater to mineral systems and across the range of scales from regional to play to prospect. Like the study of evolution through the fossil record, fundamental characteristics of petroleum systems can be recovered from the patterns of their distribution within the framework provided by plate motion, palaeogeography and palaeoclimate. These fundamental drivers control regional tectonics, subsidence, fill history and deformation that result in the phenotypic expression of individual basins and their fluid systems. Genetic analysis results in a taxonomic hierarchy that facilitates prediction and guides resource exploration. Although genetic analysis provides a framework for understanding the distribution and nature of petroleum systems, that framework itself is insufficient to address the challenges now facing the petroleum industry. New technologies are required to enable exploration in frontier settings, to identify new opportunities in mature basins, to maximize recovery from existing fields, and to unlock the potential of unconventional resources. Future success in all of these areas is fundamentally dependent on our ability to conceptualize new ideas.

Keywords: basin, petroleum system, palaeogeography, plate reconstruction, play element, genetic, tectonics, hydrocarbon

The objectives of this paper are threefold. Firstly, to provide a perspective on global petroleum systems including the global experience base and genetic thinking at a variety of scales from plates to pores. Secondly, to address the role of technology both in supporting identification of new opportunities and in maximizing value of existing assets, and thirdly to introduce the themes of the 7th Petroleum Geology Conference.

Our industry is currently facing a number of challenges. In the spring of 2008, the price for a barrel of oil was approximately US$90. By midsummer, it had exceeded US$140 and by March of 2009 it had dropped below US$40. The impact of such dramatic price fluctuation is clearly reflected in the news headlines. During the summer of 2008, many companies were announcing major new projects in what had been economically challenged opportunities such as Canadian tar sands. In the past few months, many of these same companies have announced decisions to delay or defer these same projects.

The asset portfolio of many major international oil companies is evolving through the inclusion of new asset types and a changing distribution of asset classes. To some degree, this has always been the case in our industry. For example, the same comments were made when the industry evolved from dominantly onshore in the 1940s–1950s to including significant offshore operations in the 1960s. The move into very deep water in offshore West Africa, Gulf of Mexico and elsewhere in the 1980s is another example. Now, as exploration for conventional hydrocarbons becomes increasingly challenged, the asset portfolio includes more and more hydrocarbon resources associated with what a decade ago were largely considered economically and technically unattractive opportunities.

The primary objective for most exploration activities is profitable acquisition of the best quality resources available. Recognizing both the difficulty in prediction of the price environment and the long-term nature of our projects, our industry has always relied on the development of new technology to make these resources profitable. Technology itself, however, presents an increasingly demanding challenge. Lienhard (1979) and others have demonstrated that the rate of technology change is exponential given that two criteria are met: (1) incentive/motivation exists to improve the technology; and (2) the technology is not limited by basic laws of science. Although Moore's law related to the exponential increase in the number of transistors placed on an integrated circuit is the most commonly cited example, many technologies exhibit this behaviour. Examples in our industry include LNG train capacity, heavy oil recovery, and controlled source electromagnetic imaging performance. The pace of technology development demands that companies are actively engaged in technology innovation just to keep up with the rapidly changing technology landscape.

A large number of organizations within our industry are now facing a demographic challenge that has been referred to as the 'crew change'. The experience profile of these organizations includes a large population of staff nearing retirement age, followed by an underrepresented population of 32–45 year olds, and then a population of young staff with limited experience. This has led to significant activity associated with efforts to capture and transfer knowledge within organizations.

Our industry has always faced challenges such as these and will continue to be faced with new challenges in the future. Success in

VINING, B. A. & PICKERING, S. C. (eds) *Petroleum Geology: From Mature Basins to New Frontiers – Proceedings of the 7th Petroleum Geology Conference*, 1–9. DOI: 10.1144/0070001

the face of such challenges depends in part on a few simple principles. From a business perspective, these principles might include such things as profitable volumes growth, operations integrity, effective knowledge transfer and commitment to research and development.

In addition to these extrinsic challenges, we are continually faced with the intrinsic challenges associated with sedimentary basins and their petroleum systems. All basins are unique. They represent complex systems with long histories involving multiple agents, numerous non-linear processes, feedback and emergent behaviour. Our ability to image, sample and measure these systems is limited, yet business success is dependent on our ability to predict the distribution and characteristics of these systems and, most importantly, how they will produce. In addition, especially in basins where we have our most mature knowledge through a history of exploration and production, the realization is increasingly common that future opportunities will be more subtle. Our ability to identify opportunities associated with new hydrocarbon resources as well as to maximize the value of existing resources also relies on fundamental principles such as genetic basin analysis and improvements in technology capability.

Genetic basin analysis

Genetic basin analysis has a long and colourful history. The Rover Boys are representative of an early phase of genetic analysis. They were a group of geologists who, during the 1940s through the 1960s, were sent out by Standard Oil management into the unknown basin areas in the world to make a quick assessment of hydrocarbon prospectivity. They developed an impressive understanding of global geology and hydrocarbon potential based on their widespread travels and fundamental field observations. Describing the history of the Rover Boys, Dave Kingston wrote: ‘By the mid-1960s, the best-looking onshore basins worldwide had been examined and surface field work had given way to a new frontier – the offshore. ... The roving days were over by the end of the 1960s’.

Although the quote from Dave Kingston carries more than a hint of sadness, the Rover Boys would reinvent themselves through a series of global studies groups and projects that were fundamentally based on genetic analysis. A report by Dave Kingston and others from 1973 on basin classification identified a series of ‘prime genetic parameters’ including basement composition (oceanic or continental), the type of past plate movement involved in basin formation (divergent, convergent), the present day plate position, the number of structural or subsidence events and the number of changes in the latter. This eventually became the Kingston basin classification that was published in 1983 and used by many geologists for a number of years (Kingston *et al.* 1983).

Similarly, some organizations within our industry were very early adopters of plate tectonic theory and quickly translated it into implications for understanding and predicting basin history. For example, in 1968 Temple and Nelson wrote a report entitled ‘Origin and Evolution of the Continental Margins’ that concluded: ‘Based on the hypothesis of sea floor spreading and continental drift, a model for the origin and evolution of continental margins is proposed. ... The type of margin and its predictable characteristics ... should lead to a better assessment of their petroleum potential’. This was 1968! Remember, the classic paper by Le Pichon on seafloor spreading was only just published in 1968 (Le Pichon 1968).

Within just a few years of the emergence of the plate tectonic paradigm, it was becoming common practice within regional studies groups to generate plate reconstructions as base maps for palaeogeography and to convolve that framework with models of subsidence and eustasy to predict the accommodation history, sedimentary fill patterns and play element distribution in frontier basins. This was genetic basin analysis being used as a framework to understand petroleum systems in space and time. Interestingly, even early on, the approach often addressed the entire Phanerozoic as recognition of inheritance associated with basin evolution and included more than just the region of interest as recognition of the necessity to look broadly within genetically related tectonostratigraphic provinces.

During the 1980s and 1990s, major advances were made in petroleum systems analysis that, when linked with genetic basin analysis, provided the foundation for modern approaches to understanding and predicting the time–space distribution of petroleum systems. For example, Waples (1980) drawing from the earlier work of Lopatin (1971) described the time–temperature behaviour of conversion of kerogen into liquid hydrocarbon and showed how this could be predicted from burial history. Welte & Yukler (1981) described what they called the ‘3D deterministic dynamic model’, which was essentially an early basin model that coupled descriptions of maturation and fluid migration within a 3D cellular model that evolved through time. Demiason & Huizinga (1994) defined an approach to genetic classification of petroleum systems based on consideration of charge, migration and trap characteristics. Magoon & Dow (1994) outlined an approach for integrated petroleum systems analysis, bringing clarity to the definition of petroleum systems, their constituent elements and the importance of understanding their temporal and spatial relationships.

Genetic basin analysis: overview

Now, genetic analysis embraces a full systems approach that addresses the fundamental processes associated with how basins form, fill and evolve (Fig. 1). This evolution includes both the rock and fluid systems and the goal is to identify the simple patterns that underlie fundamental relationships that in turn provide predictability. The process of genetic analysis causes one to move from a collection of observations such as simply listing the ages of play elements on a single chart to a systems-level understanding of the dependencies, feedback loops and inherent non-linearity. This increased ability to utilize complexity provides increased insight and ability to be predictive.

In addition to these aspects, genetic basin analysis also provides a framework for knowledge capture, which has been described as one of the key challenges facing our industry today and over the decade. The fundamental process relationships provide an architecture for both understanding and predicting the behaviour of basins and their associated petroleum systems. They also imply a structure for knowledge organization that is reflected in the hierarchy from tectonostratigraphic provinces, to terranes, to basins, to basin phases, to second and higher order accommodation cycles. Data and knowledge organized this way logically supports the notion of an integrated Earth model, reinforces the lessons learned through genetic analysis, and therefore transfers data, knowledge and understanding (Loutit 1996).

All basins are unique yet the processes that control how basin form, fill, deform and evolve fluids are common and predictable. These processes are ordered in a natural hierarchy that ranges from plate motion to pore and grain evolution. Plate interaction and interplate events drive intraplate deformation. Intraplate deformation creates both mountains and basins and provides a large-scale control on accommodation history. Intraplate deformation also controls the timing and style of some trap types and orogenic fluid movement. Accommodation space for sediment accumulation is modified by sea-level and climate process and influences the depositional systems and stratal geometry as expressed through local palaeogeography. Stratal geometry and

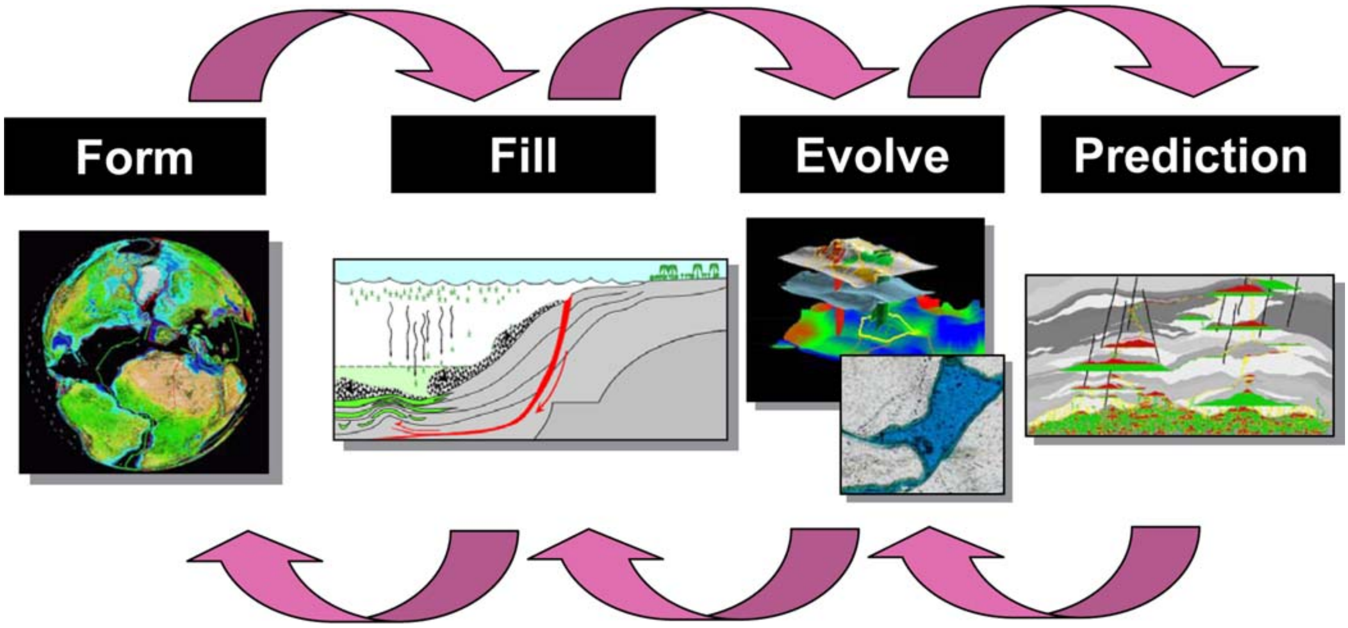

Fig. 1. Genetic basin analysis is a full-systems approach based on the fundamental processes of how basins form, fill and evolve, including both rock and fluid systems in order to make predictions about the distribution and character of global petroleum systems in space and time.

sediment distribution control the gross distribution and timing of petroleum system elements such as source, reservoir and seal. Post-depositional evolution associated with process such as burial, compaction, fluid expulsion and deformation can modify the previously developed elements and control HC migration (Fig. 2).

This hierarchy of process provides the fundamental underpinning of genetic analysis and is supported by an evolving suite of concepts, methods and tools. These include software for modelling plate motion, lithospheric deformation, subsidence, palaeogeography, sediment deposition, maturation, migration, fluid flow and diagenesis. These also include concepts and methods related to how basement architecture can provide controls on subsequent deformational behaviour, or how production, preservation and dilution control the distribution of organic-rich sediment in space and time. These also include analytical tools such as petroleum geochemistry, fluid inclusion analysis, microscopy and rock mechanics experiments. The value of genetic basin analysis is enhanced through advanced visualization and informatics technology and though a commitment to knowledge capture and knowledge organization as described previously.

As a basin forms and fills it is influenced by a variety of Earth processes and 'inherits' characteristics from all stages of its development. These stages are commonly expressed as basin phases that can be recognized or characterized by key attributes such as plate position, subsidence mechanism/rate and basin geometry. Even though all basins are unique due to the complex combination of these inherited characteristics, the Earth processes are common and therefore predictable. They possess characteristics that permit recognition with incomplete local data because of their predictability from global and regional patterns.

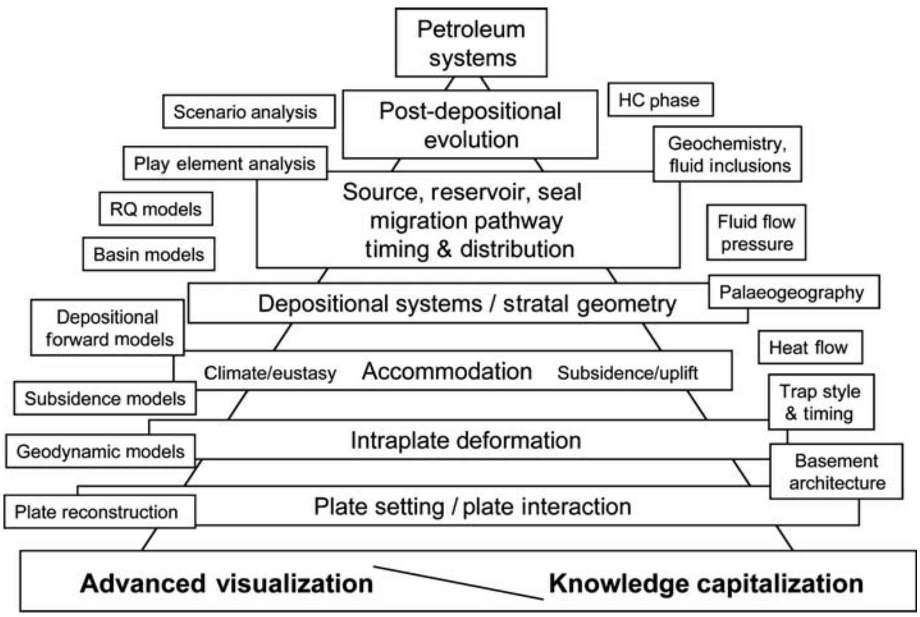

Fig. 2. Hierarchy of processes associated with genetic basin analysis.

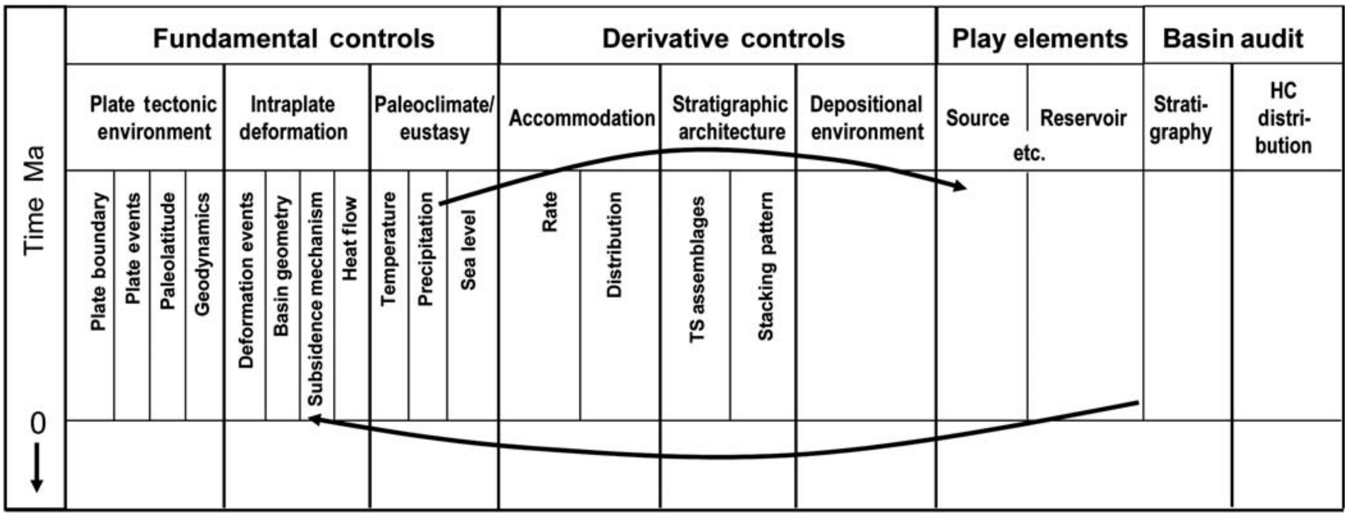

Fig. 3. Genetic analysis summary chart.

The viability of petroleum systems is a result of the combinations through time and space of these fundamental processes. A genetic analysis summary chart as shown in Figure 3 is one tool for capturing data and knowledge to assess and predict play element distribution, quality and hydrocarbon potential. This chart is organized to reflect the hierarchy of processes represented through fundamental controls such as plate tectonic environment, intraplate deformation and palaeoclimate, then the derivative controls of accommodation, stratigraphic architecture and depositional environment, then the timing of known play elements and finally the details of stratigraphy and hydrocarbon distribution. In this view, the latter are treated as an audit of the predictions from genetic analysis.

Building a summary chart in this way from left to right forces the mindset of genetic analysis and involves investigation of interactions between processes, feedback, non-linearity and emergent behaviours. This is a fundamental difference between genetic analysis and petroleum systems analysis as described by other authors where the summary chart is a series of columns for play elements against time (e.g. Magoon & Dow 1994) or the other common approach that shows stratigraphy on the left, play elements through the centre and tectonic events on the far right, as an afterthought.

Taking the analogy with genetics a step further, the basin or petroleum system genotype is expressed through the temporal convolution of processes such as palaeolatitude v. time, tectonic setting v. time, subsidence style v. time, palaeoclimate v. time, etc. The phenotype, or the material expression of this genetic sequence, is expressed through such attributes as play element distributions, field size distributions, hydrocarbon type distributions and creaming curves. For example, the Gippsland Basin offshore Australia is a basin with relatively simple genetics, and the creaming curve was nearly vertical in the late 1960s as the large structures with good top seal were all drilled over a short period of time. The main plays in the basin were tested and developed in a relatively efficient manner with about 350 total wells for a cumulative in-place volume of about seven billion oil equivalent barrels (GOEB). This is in sharp contrast to the Gulf of Mexico, with a creaming curve that climbed more or less steadily from 1950 to 2005, capturing about 60 GOEBs though about 50 000 cumulative wells. This is a basin with a complex genetic history, including multiple basin phases, a complex distribution of stacked play elements and salt tectonics. The continued exploration success in this basin has been enabled by numerous technology advances in both the geoscience and engineering domains.

Genetic basin analysis: global data and global plate motion

Genetic analysis of global basins and petroleum systems is now supported by a variety of global data sets some of which are publicly available and some of which have been developed by individual organizations. These include DEM/bathymetry, global geology, global tectonics, age of ocean crust, crustal thickness, total sediment fill and genetic analysis summary charts. The global data sets also include volume data such as seismic tomography (Van der Hilst *et al.* 1997). Advances in computer hardware including graphics and visualization tools allow these types of data to be manipulated and utilized for various kinds of analysis and at a variety of scales from global plate reconstruction to local basin geology.

Global plate motion models and associated palaeogeographic reconstructions provide a useful framework for understanding global petroleum systems in space and time. Global data sets can be integrated with the global plate model to illustrate the distribution of key petroleum system elements such as source, reservoir and seal (Fig. 4). Global plate motion models provide the foundation for a genetic framework that drives understanding and prediction of intraplate deformation, palaeogeography, palaeoclimate, basin history, play element distribution and quality. Plate reconstructions have long provided base maps for palaeogeographic models, but genetic analysis also requires an understanding of plate motion. Plate events can represent relatively instantaneous changes in plate motion or they can represent longer intervals of time during which a new plate boundary is organized. Changes in plate velocity, direction and boundary conditions correspond temporally and spatially with events of basin subsidence.

It is important to utilize global plate models that are internally consistent, but that also capture alternative scenarios. Given the common uncertainties associated with data used to constrain plate reconstructions (e.g. palaeomagnetic data, potential fields data, biogeographic data, etc.), alternative scenarios are almost always possible.

As an example of global genetic analysis, the Late Cretaceous (Turonian) is a time of widespread organic rich rocks including marine shales of the Cretaceous Interior Seaway in North America, the Gulf of Mexico, the North American Arctic, South America, West and South Africa, the Arabian Peninsula, Europe and East Central Australia. By this time, Pangea had been largely dismembered and most modern major ocean basins were growing

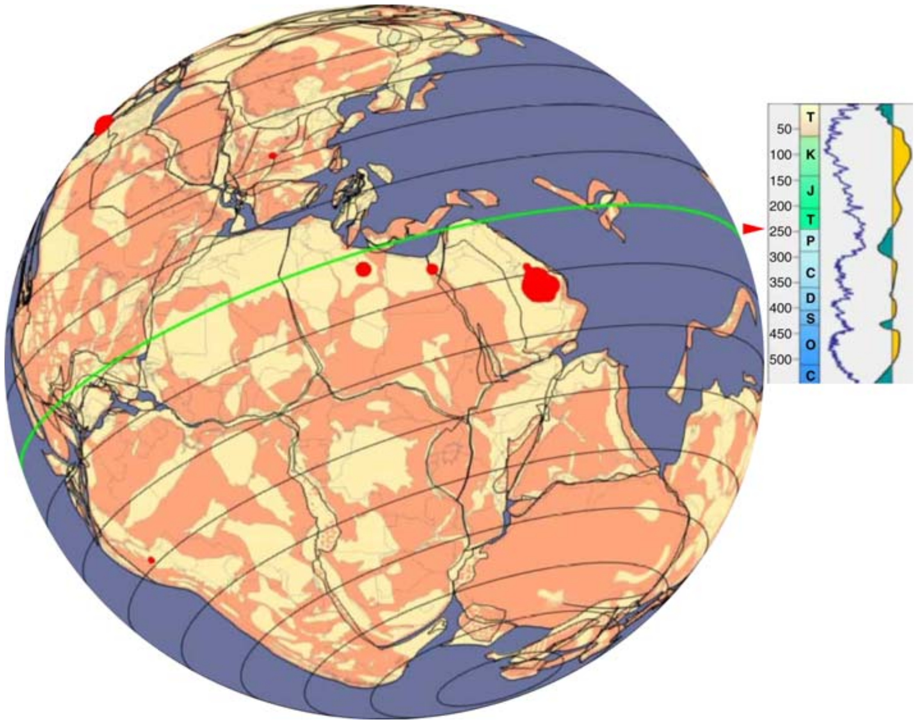

Fig. 4. Global plate reconstruction in the Late Jurassic illustrating plate geometry and basin location providing a time–space framework for genetic analysis of petroleum systems.

through seafloor spreading. Sea level was at its highest stand in the Phanerozoic and global climate was in a greenhouse period with very warm and equable conditions, including relatively low equator-to-pole gradients. Broad flooded shelves support deposition of reef building carbonates that become important reservoirs and the lack of polar ice is expressed through relatively low amplitude, high-frequency eustatic fluctuation. Palaeoclimate modelling predicts areas of significant marine upwelling and also significant restriction in the northern South Atlantic, the North American Interior Seaway, the North Atlantic, West Siberia and associated areas of the Arctic. The ability to analyse global datasets within a plate tectonic reference frame linked to other fundamental controls like eustasy and climate is essential for genetic analysis of petroleum systems in space and time.

Patterns emerge from this type of analysis that reflect fundamental controls on these elements and their interaction in space and time resulting in petroleum systems. For example, at the largest scales, there are clear relationships between global plate motion, eustasy, climate, the evolution of plant forms and the distribution of widespread source intervals. By the early 1990s, Klemme & Ulmishek (1991) and others recognized large-scale patterns controlling the distribution of key source rocks and parameters such as eustasy, subsidence and climate by generating global source rock distribution and type maps on plate reconstructions. Major periods of widespread, marine source rocks are correlated with first-, second- and third-order eustatic rises and periods of widespread basin formation associated with global plate tectonics. During these periods of widespread deposition, the organic characteristics, thickness and distribution of source rocks are controlled by regional palaeogeographic factors including the degree of oceanic circulation restriction, the evaporation–precipitation balance in each basin, and the degree of dilution associated with clastic influx in marginal marine settings.

Identification of these patterns that describe known petroleum system elements is only the first step towards what really matters – that is to utilize these patterns and fundamental relationships to identify new opportunities.

Genetic basin analysis: example

As a brief example of genetic analysis at the regional to basin scale, we will consider the Bighorn Basin in Wyoming. The Bighorn Basin contains more than 8 km of preserved Phanerozoic sediments that were deposited on Archaean crystalline basement of the Wyoming Craton (Snoke 1993). In the Early Palaeozoic, the basin is located in a proximal passive margin location in equatorial latitudes. By the Late Palaeozoic, that margin had become much more complex and was evolving into a convergent margin initially associated with the collision of offshore arcs and also probably influenced by the South America–North American collision to the south. By the Jurassic–Cretaceous, the Bighorn Basin was located in a proximal retroarc foreland setting with the arc to the west above a dominantly east-dipping subduction system. This foreland was disrupted during the Late Cretaceous–Early Cenozoic Laramide Orogeny that has been linked to a variety of convergent margin geometries or events with the currently favoured being flat-slab subduction during increased convergence rates (DeCelles 2004).

Plate events associated with the transition from passive to convergent margin temporally coincided with two events of intraplate deformation expressed as tectonic subsidence in the late Palaeozoic. In conjunction with second-order eustatic trends, these intraplate events controlled the timing of accommodation events that influenced the deposition of key reservoirs (carbonate and clastic). Later, after the convergent margin became better organized, the Bighorn Basin area was part of a broad retroarc foreland system that stretched from the Gulf of Mexico to Alaska. Tectonic subsidence, associated with this basin phase in conjunction with first- and second-order eustatic rises, resulted in deposition of source, seal and reservoir elements during the Cretaceous. Finally, the primary phase of rapid subsidence and sediment accumulation during the Laramide Orogeny drove all local source rocks into the oil generation window and produced the local basement-involved compressional structures that represent the major traps in the basin. The four main intervals identified by prediction from plate motion to intraplate deformation to accommodation do, in fact, control much of the distribution of hydrocarbons within the Bighorn Basin as well as the timing of key events such as trap formation and local maturation.

Application of genetic analysis over decades on a global scale reveals patterns of relationships as just described for the Bighorn Basin. For example, genetic analysis of numerous basins that include a foreland phase late in their evolution reveals that stacked source intervals commonly include both widespread pre-kinematic elements that are often oil-prone and somewhat more restricted syn-kinematic elements that can be both oil- and gas-prone. The foreland phase of subsidence and filling often drives maturation of the pre-kinematic source. Migration often includes both long-distance lateral migration and cross-stratal migration associated with encroaching compressional deformation. Such systems often include the potential for stratigraphic traps, hotelling and remigration.

Technology

Although genetic analysis provides a framework for understanding the distribution and nature of petroleum systems, that framework itself is insufficient to address the challenges now facing the petroleum industry. New technologies, including concepts, methods and tools, are required to enable exploration in frontier settings, to identify new opportunities in mature basins, to maximize recovery from existing fields, and to unlock the potential of unconventional resources. Future success in all of these areas is fundamentally dependent on our ability to conceptualize new ideas.

Concepts

Extensional systems

New concepts for extension of the lithosphere provide new ideas for the evolution of passive margins and the petroleum systems associated with them, especially in hyper-extended regions of outer continental margins. For many years, the pure shear model for lithospheric extension was the dominant model used for interpreting subsidence and heat flow on passive margins (McKenzie 1978). This 'classic' view led to a model of uniform thinning of the lithosphere from the hinge zone out to the continent–ocean boundary. A variety of alternative models including those of Wernicke (1985) and Lister *et al.* (1986) proposed that other mechanisms such as simple shear associated with major detachment faults and asymmetry may be important. Whereas these were largely kinematic models, advances in dynamical modelling that include realistic boundary conditions (e.g. strain rate), rheology and behaviour (e.g. strain softening) provide insights into the genetic processes that control architecture, subsidence and heat flow in extensional systems.

Most recently Manatschal and others (e.g. Manatschal 2004; Peron-Pinvidic *et al.* 2007) have proposed new models to describe the mechanisms by which continental lithosphere is thinned during formation of passive margins. These models have been driven by a combination of field work in the Swiss Alps, ODP drilling off the Iberian margin and geodynamic modelling. Removal of the entire crust is explained by a model where deformation is partitioned in the lithosphere and fault geometry changes as a function of the rheological evolution of the extending material. Initial stretching is accommodated by brittle deformation in the crust (e.g. North Sea). Crustal thinning evolves through deep faulting below a mid-crustal decoupling zone (e.g. Ivrea zone, Alps) and wholesale removal of the crust occurs after strain is localized on through-going detachment faults as sub-continental mantle rocks are exhumed. The continent–ocean transition is being redefined on the basis of these ideas and new observations from outcrop, drilling and reflection and refraction seismic data. On the Iberian margin, the zone of exhumation is >100 km wide and contains organized magnetic anomalies apparently related to serpentenization during extension rather than seafloor spreading (Sibuet *et al.* 2007).

The genetic implications of such models range from alternative reconstruction of conjugate margins, to reinterpretation of syn-rift and post-rift tectonostratigraphic assemblages, to alternative models for heat flow. The recognition of syn-extensional sag associated with preferential thinning of the lower crust without brittle upper-crustal deformation is a critical observation. These alternative models may result in new ideas about play element distribution and quality and associated hydrocarbon systems.

Methods

Detrital zircon geochronology

In addition to new concepts, there are a variety of new methods being developed that will impact our understanding of genetic controls on petroleum systems. U–Pb ages from detrital zircons are providing useful data for a variety of geoscience applications including plate reconstructions, regional tectonic models, palaeogeography, palaeodrainage evolution and sandstone composition. Although detrital zircon geochronology has been used for a number of years, recent advances in analytical techniques have improved the robustness and utility of this method. Modern laboratories utilize micromass isoprobe multicollector (ICP-MS) with a laser ablation system to date individual zircon grains that can be selected to represent all sizes and morphologies present in a sample (Miller *et al.* 2006). Some laboratories can now process more than 500 analyses per day, making it possible to efficiently and cost-effectively produce robust characterizations of the zircon age spectra for sediment samples.

Recent examples have demonstrated the value of this technique for characterizing source terrains for sandstones (e.g. Gehrels *et al.* 2008*a*). These authors sampled a large number of sediments from various terranes in the Tibetan region. Comparison of the zircon age spectra from these sediments suggests that the commonly accepted locations for major sutures separating terranes of different affinity and palaeogeographic proximity may be suspect. These new methods and the new data they produce can result in alternative plate reconstructions which, in turn, yield alternative palaeogeographies and potentially new models for play element distribution and quality.

A collaborative effort between the University of Arizona, the University of Kansas and ExxonMobil is developing a global database for detrital zircon dates that will be accessible to the global community to evaluate plate reconstructions and palaeogeography (Gehrels *et al.* 2008*b*).

Tools

Representation of genetic analysis in Bayesian Belief Networks

'New' tools are also impacting the genetic analysis of basins and petroleum systems. 'New' is used in quotes, because the fundamental theorem for the tool referenced here was published by Bayes in 1763. Nevertheless, a new application of this old theorem was recently published by Heins & Kairo (2007) as a model called SandGEM for predicting sand character through integrated genetic analysis. Although geoscientists have agreed on the fundamental processes that control sand generation for many years (Sorby 1880), the work of Heins and Kairo provides the first systematic approach to applying genetic analysis. To codify the relationships between genetic controls, they utilize a Bayesian Belief Network (BBN). In this approach, the primary genetic factors include tectonic setting and weathering processes, hinterland controls and erosion/transport processes, as well as basin controls including depositional processes. The BBN provides a useful technique for concatenating a web of conditional probabilities that represents the genetic relationships in the system. Relatively complex cause and effect relationships including single causes with multiple effects or even contradictory effects can be accommodated.

In SandGEM, as proposed by Heins & Kairo (2007), there are seven input nodes representing climate and weathering potential, climate flushing potential, regional topographic gradient, hinterland transport distance, basin subsidence rate, basin fluvial transport distance and depositional facies. The three output nodes include deposited sand composition, deposited grain size and sorting, and deposited matrix abundance. The SandGEM model has been calibrated in modern systems where the genetic factors are well constrained. In a series of validation studies in modern systems from South America and Australia, Heins & Kairo (2007) conclude that the BBN approach accurately predicts sand composition and texture across a range of different environments. SandGEM is just one example of how genetic analysis can be applied through probabilistic tools to understand and predict the behaviour of complex systems.

Similar approaches are being developed and tested for a variety of other petroleum system elements such as organic-rich rock. Genetic analysis of the controls on distribution and quality of source rocks has been an area of research for many years. Process-based models are now able to incorporate factors that control production such as in the case of marine upwelling, preservation such as in areas of palaeogeographic restriction and dilution such as is related to the inverse of clastic sediment supply (Bohacs & Heins 2007). As in the previous example for prediction of sandstone composition, BBNs are proving a useful approach for capturing complex relationships and generating probabilistic predictions about the likelihood of occurrence in time and space of organic-rich sediments.

Forward modelling

A variety of new tools are emerging for forward modelling of key genetic processes. These tools are enabled by advances in computing and visualization as well as the creative investigation of fundamental physics and geology.

For example, Miller *et al.* (2008) have reported on new approaches to develop full physics depositional models based on numerical description of fluid flow and sediment transport. Because these models can be developed to utilize multi-processor architecture, the time to run an interestingly large (space and time) model is becoming reasonable. There is a range of potential applications for such process-based models, from developing new insights into stratigraphic processes, to extraction of patterns and statistics for rule-based and geostatistical modelling, to full physics simulation of the erosion and deposition of a reservoir.

Other applications of new forward modelling capabilities include geodynamic modelling for improved understanding of lithospheric scale processes (e.g. Huismans & Beaumont 2007), mechanical modelling of crustal deformation in compressional settings, and models that attempt to incorporate deformation, development of topography through landscape evolution algorithms and sedimentation all within a single integrated model that includes feedback between the various processes (Braun & Yamato 2008). This is a glimpse of a future that will eventually evolve full-physics forward models of coupled Earth processes in order to simulate and test the fundamental controls on how basins form, fill and evolve – that is, genetic analysis.

Forward modelling is essential to calibrate and test process-based understanding and it provides a quantitative methodology to predict away from empirical data and evaluate alternatives. However, forward modelling is not a ‘silver bullet’ and model integrity is completely dependent on the validity of process description and the fidelity of input data.

Forward modelling provides an approach to predicting the subsurface through simulation of Earth history. Such predictions must be tested against and calibrated with our empirical understanding of the present state of the Earth through inversion of geophysical and well bore detection technologies and data. The return loop of test and learn is critical for the continuous evolution of the models. Both sides of this methodology must feed the integrated Earth Model that provides the common environment for the ‘simulate, predict, test, and learn’ process, for capturing our knowledge, and for identifying new opportunities (Fig. 5).

Opportunities

For a number of our organizations, offshore West Africa provides an example of how both genetic analysis and technology have supported a very successful series of ventures. Various West African basins including those offshore Angola, Nigeria and Equatorial Guinea, enjoy robust petroleum systems resulting in a prolific hydrocarbon province. The relatively rapid and efficient exploration was driven by continuing genetic analysis and by technology developments. Improvements in genetic understanding of deep water depositional processes and associated reservoir styles were key. Many intra- and extra-basinal variables and controls contribute to the development of a particular reservoir architectural style. Depositional styles observed in offshore West Africa include distributary systems, weakly confined systems, confined systems and bypass systems. The genetics of each of these styles influences reservoir architecture and performance.

Prediction from genetic models was effectively coupled with new technologies to image or detect the current subsurface state in offshore West Africa. Improvements in seismic data quality and DHI/AVO analysis played a significant role. For a robust suite of prospects, economic success rate increased from about 36% to over 60% for prospects with DHI support (Rudolph 2008).

Another opportunity where genetic analysis and technology are playing a key role is associated with unconventional resources, including heavy oil, tight gas, shale gas, coal bed methane and others. These types of resources are becoming increasingly important contributors to the asset portfolios of many organizations. Given experience with assets like Cold Lake heavy oil, we often think of these unconventional resources as requiring a long start-up time but also with a long asset life, heightened need for close integration of subsurface characterization, exploitation technology and commercial considerations and for their operational intensity. Conversely, the emergence of the unconventional gas play in the Barnett Shale has been dramatic, increasing from about 0.5 billion cubic feet per day (GCFPD) in 2002 to about 4.7 GCFPD at the end of 2007. The evolution of the Barnett play has been supported by improved genetic understanding of shale gas plays (Pollastro *et al.* 2007) and the controls on rock mechanics and gas distribution as well as a number of technology advancements primarily related to well architecture and reservoir stimulation.

Even though many of the unconventional resources require a different mindset when it comes to development and production strategies, they are still conducive to genetic analysis. Key

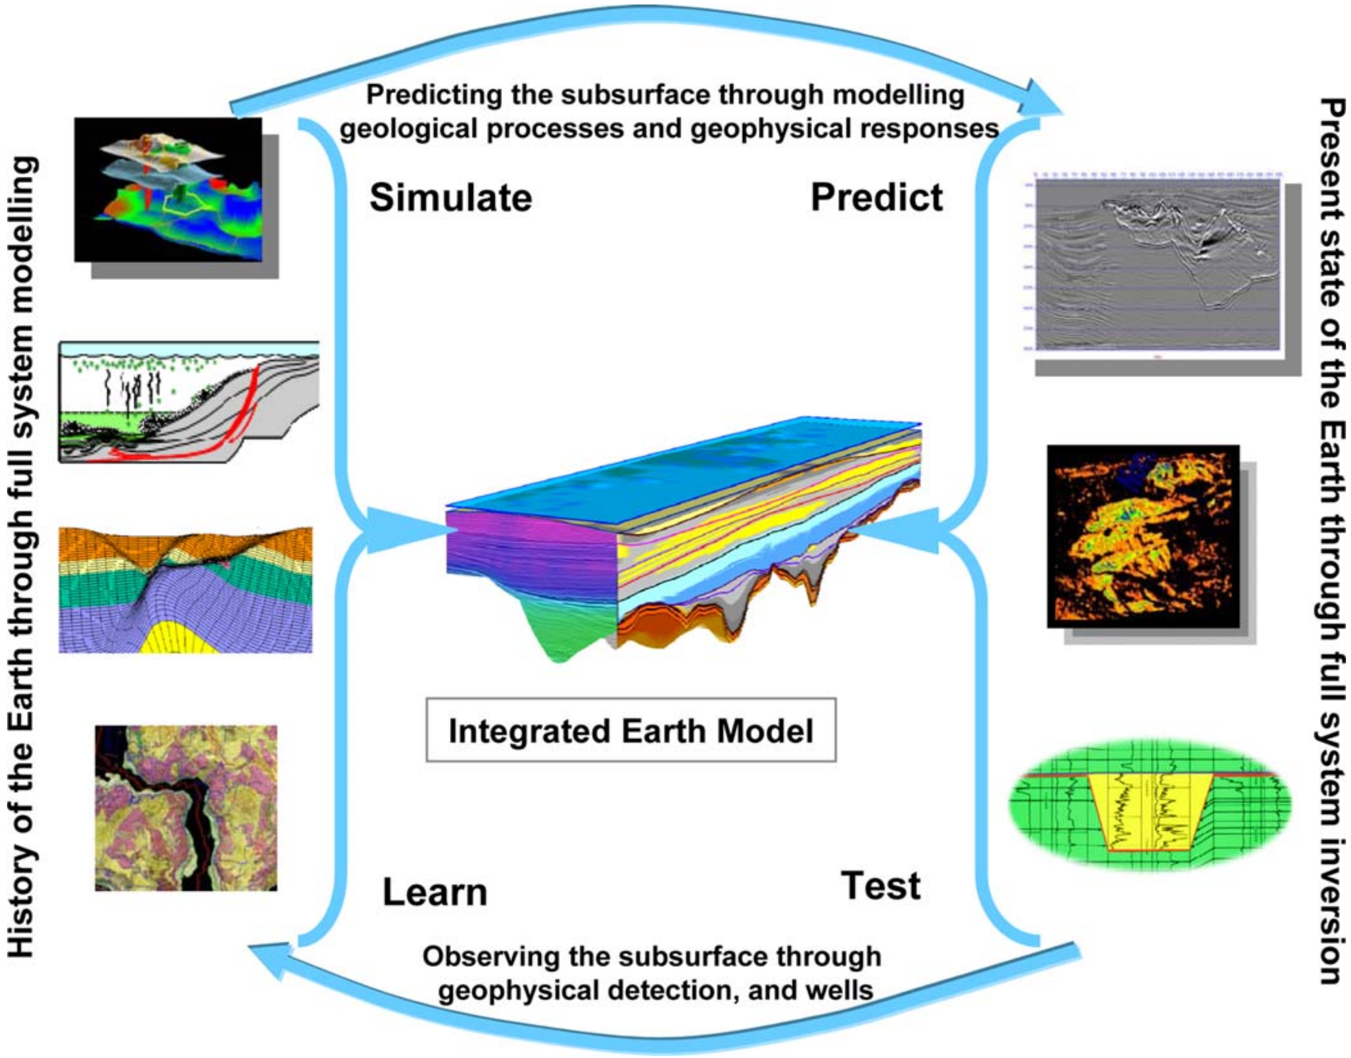

Fig. 5. Both forward and inverse models calibrated with appropriate data support the process of simulate, predict, test and learn that is fundamental to genetic analysis.

questions about the fundamental controls on sweet spots are now being studied with a genetic approach that spans plate-to-pore scales.

Summary

Genetic analysis encourages us to embrace systems thinking and complexity, to be aware that opportunities are often more unique than similar and to be very careful when attempting to use analogues. This is wise as the subsurface is almost always more complex than we initially predict. A case from the Gulf of Mexico illustrates this point. At the time of the development funding decision for this particular case, a simple model was based on a couple of exploration and delineation wells, poor quality seismic and a depositional model. The result was the pre-development cross-section with widespread 'sheet' sands and only modest variability. The narrow range of scenarios carried at this time did not include the potential for a highly channelized reservoir. With additional wells and improved seismic, a revised model now includes a highly channelized reservoir, with significantly more complex connectivity architecture demonstrated by well logs, higher resolution seismic, geochemistry and engineering data. Failure to embrace the potential complexity and failure to consider fundamental relationships, like the fact that continuous sheet sands are uncommon in this setting, can lead us down unfortunate paths.

As geoscientists, there is an easy way to reinforce the truism of the discussion above, and that is to spend as much time as possible observing the rocks. Getting on the rocks either in the field, in the core laboratory, or in the CAVE to make observations, develop interpretations and models and then test those models against the next outcrop or the next structure or the next core is always an educational and often a humbling experience. The complexity is what keeps it fascinating and discovering the patterns that underlie the genetic relationships is what keeps it rewarding.

The GeoControversies debates

J. R. UNDERHILL

Grant Institute of Geology, The School of Geosciences, The King's Buildings, University of Edinburgh, West Mains Road, Edinburgh EH9 3JW, UK (e-mail: jru@staffmail.ed.ac.uk)

Abstract: An opportunity to discuss and publically debate three critical issues of concern to oil company geologists was introduced into the Petroleum Geology Conference (PGC) programme for the first time in 2009. The debates selected focused on whether "peak oil" was already upon us; the relative role of National Oil Companies (NOCs) versus that of International Oil Companies (IOCs) and whether North Sea Exploration was finished. In each case, the arguments were delivered by two experts, who presented the case for and against each motion before answering questions and facing a vote by the audience, who showed coloured cards to indicate their support for what they had heard. All three debates proved to be extremely popular and were very well attended for all three days. The novel concept was deemed a great success and added significant value to the PGC.

Keywords: GeoControversy debates, peak oil, National Oil Companies, North Sea exploration

The Petroleum Geology Conference (PGC) – organized by the Geological Society, Petroleum Exploration Society of Great Britain (PESGB) and the Energy Institute – has a rich tradition of furthering the understanding of the geology of the North Sea basin. The series of seven conferences that have been held over the past 30 years or so have stressed the basin's important place in global oil and gas exploration and development through the delivery of technical presentations and poster displays. At the most recent PGC7, three innovative, hour-long debates were added to the conference programme, at which two expert protagonists presented their views for and against the three following motions of direct relevance to the petroleum industry:

- 'This House believes "peak oil" is no longer a concern'.
- 'This House believes that National Oil Companies (NOCs) are the future of the petroleum industry'.
- 'This House believes that the North Sea is finished'.

Each of the PGC debates ended with a poll at which the audience raised a yellow or red card (Fig. 1) to indicate their support for or opposition to the motions. The conclusions of the polls were that 'peak oil' was indeed with us; that oil power increasingly lay with NOCs; and the companies' North Sea exploration days were not yet numbered.

Debate 1: 'This house believes "peak oil" is no longer a concern'

'Peak oil' was a term originally coined in the mid-1950s by M. King Hubbert, a US Shell geologist, to describe the inflection point at the top of a production curve at which peak production is achieved and after which the rate of oil extraction inextricably declines. Whilst the term could arguably be applied to individual wells and fields, it is most commonly used in the evaluation of prospective sedimentary basins, countries and, more especially, in geopolitical circles to describe global production. 'Hubbert's Peak', as it has become known, was surpassed in the US in 1971 and in the late 1990s in the North Sea as major fields discovered in the 1970s entered a phase of terminal decline. However, controversy surrounds whether the balance and offset between the cumulative effect of basin maturity and exploration success in new frontier basins has already been achieved or will soon be reached.

The following section summarizes the debate, which focused upon whether 'peak oil' is already upon us. Whilst David Jenkins, a former Technical Director and Board Member at BP, argued that 'peak oil' is not of immediate concern, Jeremy Leggett of Solarcentury spoke against the motion.

For the motion: David Jenkins

"Historically the concerns about 'peak oil' have focused on the inability of supply to meet progressively increasing demand. The time of peaking relates to the degree of cumulative production from the resource base and, once it is passed, declining production is inevitable. 'Peak oil' concerns are entwined in a wistful recall for the days when cheap energy underpinned the Organization for Economic Cooperation and Development's (OECD) rapid economic growth. Those days are now over and will never return. The world needs to become accustomed to expensive energy. If the present concerns about carbon dioxide (CO_2) persist, the concomitant requirement to decarbonize carbon-based fuels will mean a further significant increase in costs. In fact, rather than the supply peak around which commentators have fretted, high energy prices could even engender a demand peak for oil, something which the environmental movement would applaud.

It is important to recognize that there is no near-term resource peak for oil, nor gas or coal. That is quite clear from the 2005 International Energy Agency's (IEA's) *World Energy Outlook*. This gave an assessment of 'available oil resources' at over 3.5 trillion barrels, and did not include any contribution from gas-to-liquid or coal-to-liquid technologies, which could become significant sources of liquid petroleum at prices above $100 per barrel.

The question of whether or when we experience peaks in production is fundamentally about market forces and definitely not related to a resource peak, as exemplified in the classic King Hubbert model. We had a production peak in 2008. It was caused by a very sharp speculative run up in price and led to the inevitable cut back in demand. Although the price has since come back, it remains high in historic terms and demand is continuing to decline. Investment, though, has also been cut back dramatically and we can certainly expect a supply shortfall sometime in the next four to seven years. This shortfall will also not be related to peak oil, but it will cause a further spike in price as occurred in 2008 and then, as last year, demand will again drop. The pattern

VINING, B. A. & PICKERING, S. C. (eds) *Petroleum Geology: From Mature Basins to New Frontiers – Proceedings of the 7th Petroleum Geology Conference*, 11–17. DOI: 10.1144/0070011

Fig. 1. The PGC7 audience were asked to raise a yellow or red card to indicate their support or opposition to each debated motion, the novelty of which was evidently enjoyed by all participants.

in the future is likely to be one of an extended irregular production plateau, punctuated by abrupt swings in prices leading to abrupt changes in demand.

Although at the moment we rely almost exclusively on liquid petroleum for road, marine and air transport fuels, and because mobility is so fundamental to our way of life and standard of living, we cannot conceive how we could change. This perceived dependence has underpinned our worries about global oil supply peaking. Decarbonizing energy because of the fear of climate change, however irrational that fear may actually prove to be, would have the effect of forcing such change. Moving away from the internal combustion engine to an electric drive train, associated with greatly increased production of biofuels, is soon to become technically feasible and could very plausibly produce a scenario that eliminated further growth in global demand for oil. Combine this with the production capacity available from the global resource base and a future world of expensive carbon-free energy, and then 'peak oil' clearly becomes an artefact of a prior economic world. In this somewhat bleak future it will definitely not be one of our many concerns."

Against the motion: Jeremy Leggett

"'Early peakers' like me fear that the oil industry has lapsed into a culture of over-exuberance about both the remaining oil reserves and prospects of oil yet-to-be-discovered, and about the industry's ability to deliver capacity to the market even if enough resources exist. In the corporate world, early peakers include the recently formed UK Industry Taskforce on Peak Oil and Energy Security (ITPOES), members of which include Virgin, Arup, Foster and Partners, Scottish and Southern Energy, Solarcentury, Stagecoach and Yahoo.

The first report of the ITPOES group of companies, released in November 2008 at the London Stock Exchange, presented evidence that total global oil production will begin declining early in the next decade. The main argument is that new capacity flows coming onstream from discoveries made by the oil industry over the preceding decade will begin dropping at that time. This problem will be compounded by other issues, including the accelerating depletion of the many old oil fields that prop up much of global oil production today, the probable exaggeration by OPEC countries of their reserves, and the failure of the 'price-mechanism' assumption that higher prices will lead to increased exploration and expanding discoveries.

In the same week as the ITPOES report was released, the IEA published its latest weighty annual report, the *World Energy Outlook*. In 2008, for the first time, the IEA conducted an oilfield-by-oilfield study of the world's existing oil reserves. It revealed that the fields currently in production are running out alarmingly fast. Crude oil production from all the world's existing fields climbs unevenly from just below 60 million barrels per day in 1990 to a peak – more exactly a brief plateau – of just over 70 million barrels per day between 2005 and 2008. In 2009, however, crude production begins a steep descent, falling steadily all the way below 30 million barrels per day by 2030. To meet the projected demand figure by 2030, up to 64 million barrels per day of totally new production capacity would be needed onstream within 22 years. That, the IEA points out, is fully six times the production of Saudi Arabia today.

The oil industry is not discovering giant oil fields at anything like the rate it did in the 1960s – the peak decade for discoveries. This is the case despite much better equipment for exploration today, and even after four years of rising oil prices from 2004 into 2008, when exploration was not hampered by lack of funds for investment. When the oil companies do make big discoveries, the lead times from discovery to first new oil delivered to market are long – often more than 10 years. In addition, the oil industry has profound infrastructure problems, and major issues with under-skilling and under-investment.

Many drilling rigs, pipelines, tankers and refineries were built more than 30 years ago, and according to some insider experts the physical state of the global oil infrastructure is a major problem even at current rates of oil production, much less the significantly higher levels anticipated in the future. The average age of personnel in the oil industry is 49, with an average retirement age of 55 – little less than a human-resources time-bomb.

To add to the challenges, the industry's overall exploration budget has actually fallen in real terms in recent years. The ITPOES fears that these issues will synergize to compound the 'peak oil' crisis, thus gravely impairing society's collective ability to respond.

In conclusion, this debate is all about the risk of a mighty global industry having its asset assessment systemically overstated, due to an endemic culture of over-optimism, with potentially ruinous economic implications. That couldn't possibly happen could it?"

Debate 2: 'This house believes that National Oil Companies are the future of the petroleum industry'

Whilst the UK has long since lost its very own national oil company (BNOC) and even its private successor, Britoil, NOCs have become increasingly important around the globe. This has happened rapidly; as recently as the mid-1970s the seven oil majors controlled around 80% of the world's oil supplies. Today, the five majors that remain control just 5% of reserves and national interests prevail in most of the petroleum producing nations.

The following article summarizes the debate which focused on whether the rise of the NOCs were a threat or an opportunity. Whilst Marlan Downey, an American Association of Petroleum Geologists (AAPG) past President and former Technical Director and Board Member at Arco, argued that NOCs are the reality and future, Peter Gaffney of the Society of Petroleum Engineers (SPE) and co-founder of the consultancy Gaffney, Cline & Associates (GCA) spoke against the motion.

For the motion: Marlan W. Downey

"For me, as someone whose career was mainly as a representative of the international oil companies (IOCs), it's like speaking at a funeral. I mourn the weakening of the IOCs to a point where they are near-to-death. Once, they controlled nearly 100% of all oil produced. Now, ExxonMobil, the world's largest IOC, controls only about 1% of the world's oil reserves. The hydrocarbon energy business (exploration and production) has shifted into the hands of the NOCs. Things have changed forever.

Once, the IOCs and their clients, the great powers, imposed their will on the penniless, powerless countries where oil was found. The great powers, economically allied with the IOCs, divided much of the world up into 'spheres of influence' and agreed not to compete with one another. British Petroleum was formed to give the UK government control of Persian oil via the 60-year D'Arcy concession.

Once, the IOCs boycotted oil producing countries that asked to retain a share of their oil. Shell refused the strange new concept of production-sharing contracts when they were introduced in Indonesia. In other words, the IOCs controlled the production, transportation, refining and marketing of nearly all the oil in the world, outside the United States. Now their share of that production has shrunk to total less than 10%.

Once, the IOCs alone had the capital, the technology and the project management skills to undertake large oil development projects. They provided all the capital, the technology, the project management skills and, fairly enough, took most of the oil.

Once, oil producing countries courted IOCs, rolling out the red carpet for international investors. Now, IOCs are coming (hat-in-hand) to plead to work with NOCs in oil producing countries.

Once, oil importing countries closely supported the interests of the IOCs – no longer. The UK won't do battle on the part of BP. NOCs, in contrast, are totally supported by their host countries. Now, we see a total asymmetry of contract sanctity. A producing country can abrogate its oil production contract, citing such legal fictions as 'the doctrine of changing circumstances', and face no consequences.

Once, IOCs were *needed*; now they are, sometimes, reluctantly *accepted* – accepted to do the difficult and risky projects that are on the bottom of the value order list of NOCs. We see an extraordinary shift in relationships – IOCs are no longer needed, only accepted, to supply low-cost risk capital. That's dangerous. During the 1990s I declined many opportunities to invest in the Former Soviet Union (FSU), as it was clear that they did not *need* my staff, my technology – they only wanted me to bring capital.

Once, NOCs were simply a local politician's dream, a way to provide costless patronage and thousands of jobs to kith and kin, with cities, hospitals and schools clustered like satellites around the oil fields. They siphoned off a tiny bit of the oil field's revenue as it was transmitted to the uses of the producing state. They had no real or useful function. These embryonic NOCs were staffed with civil servants, functionaries and accountants, and had few or no qualified engineers, geologists or geophysicists.

Today, the NOCs, two generations old, are benefiting from staff that have had 50 years of training on the job, and are making use of wise graduates from the greatest universities of the world. Now, the negotiating power, the control of oil, belongs to the NOCs in oil producing countries. Now, and in the future, producing nations and their petroleum operating arms, the NOCs, are awash with capital, possessed of great staff and rich in technology. That is the current status of relationships – where will it take us in the future?

Wisdom is recognizing life as it is – not as it once was. The IOCs gave up their dominance in technology by gutting their laboratories and research staffs in the 1980s and 1990s to save a few dollars. How stupid was that? Today, Petrobras doesn't need any help from Shell to develop in the deepwater. Saudi Aramco doesn't need any help from Chevron to manage large oil field projects in Saudi Arabia.

There is a golden rule for international business that needs to be kept in mind; I saw it expressed recently in the *Financial Times*: 'Them that has the gold makes the rules'. IOCs have been relegated to the leavings of exploration and production, and (should they ever approach success) are likely to have the prize taken from them. The exporting countries, with their surrogate NOCs, with an abundance of capital, manpower and technology, will make the rules.

Forget the myth of contractual third party arbitration. Does anyone doubt that courts in the FSU will rule on petroleum contract disputes in a manner favourable to the FSU? Does anyone doubt that Abu Dhabi can purchase whatever technology they need from service companies?

Now the future exploration and production business belongs to the NOCs – we taught them well . . . as foster parents and former partners, we wish them well. NOCs are the future of the hydrocarbon energy business – it *is* their century."

Against the motion: Peter Gaffney

"We originally agreed to this debate over a year ago when the oil price was $130 per barrel and increasing, and the world economy hadn't yet heard the bad news. On the day of the debate – 1 April 2009, April Fools' Day! – the price was about $50 per barrel, the Henry Hub gas price was down at $4/million cubic feet (mn cf) and we remain in the worst recession since the 1930s if not before. So, perhaps the question addressed in this debate has become less relevant as many governments fight to mitigate unemployment and economic security by pumping billions of dollars into, among other things, alternative fuels and possibly eventually changing the relative importance of petroleum at some point in the foreseeable future.

The NOCs themselves can be divided into two groups – the producers and the consumers, with almost equal and opposite objectives. While they often work together, the consumers are always looking to both reduce their import costs and secure their long-term sources across as wide a variety of suppliers as is reasonably practical.

The exporting NOCs themselves are facing much of the same suffering as the rest of the industry. Indeed, for the first time in several years, they are looking for partners on a broader front than previously, also curbing their plans for new plants and/or production capacity. The last few months have clearly shown that the market is a more powerful influence than the exporting NOCs – as much as they wished to stem the price fall tide, they were largely powerless to stop it.

I believe that, regardless of how important petroleum is to the world economy, particularly as a basic transportation fuel, it is still a commodity and as such will continue to oscillate in price through its foreseeable life. Commodity prices tend to be determined by a combination of perception and reality – and that perception is largely that expressed by the consumers.

Part of the basis of the belief that the NOCs are the future of the industry is linked to the concerns that many larger companies have regarding their ability to work with today's NOCs. The reality is that many of the larger companies have found it difficult to accept the realities of the modern day world – that is, that NOCs have matured and graduated into worthy competitors in their own right and that the deals available today need to be structured in today's real world, not that of the 1950s.

The NOCs themselves are widening their net to be international competitors across a broad front and look to work with others to mitigate their own risks. It is perhaps relevant to quote one of the renowned earlier petroleum industry experts – A. I. Levorsen, who wrote *Geology of Petroleum* many years ago: 'The petroleum geologist is the centre piece in the foundation of the petroleum industry. The industry is completely dependent upon a continuing discovery of new pools, or extension of old pools, for maintenance of its supply of crude oil and thereby of itself; and most certainly the discovery and production of oil is a geological enterprise'. This is still true today and the centre and fountain of such thoughts and ideas is not necessarily in the NOCs but exists, and will continue to exist, in the challenging minds of the professionals in our industry throughout the world – be it in NOCs or elsewhere.

However, let us consider this position in another context. China and India are key driving forces in the world economy today. In the future they will also be substantial and growing consuming nations and, as such, have a capability to influence the market from a very different perspective from that of the exporting countries.

Returning to the current situation, the industry already has spare capacity in excess of some 7 million barrels per day. Even with the expected declines in existing production sources, with possibly even lower operating levels we can anticipate that it will take some considerable time to take up this spare capacity to the point where capacity alone – rather than sentiment, hedge funds and/or politics – encourages significant increases in the price of oil and gas.

Peter Tertzakian, in his 2006 book *A Thousand Barrels a Second*, forecast the 'coming breakpoint', as he called it, in petroleum's tightening supply demand environment and he suggested that such a breakpoint may come about in different ways. What we have seen in the recent economic turndown is the very sort of event that helps to realize the breakpoint that he anticipated. Perhaps fortunately we will get a softer landing than might have been anticipated previously, as the supply limitations will now not materialize quite as early as it looked like they would just one year ago.

New technology itself is changing our situations too. Who could have imagined 10 years ago the huge new resources of natural gas that have become available in the United States through coal bed methane and the very successful shale gas developments? These natural gas developments alone are likely to materially change the energy dynamics not only of North America but also that of the rest of the world's energy position over the decades ahead. So, yet another factor which is completely independent of the effects of the NOCs has provided and will continue to provide a level of alternative investment opportunities.

To summarize, it is likely that whereas the NOCs will continue to have an effect on the way the petroleum industry addresses the future, there are many other factors which will also have a significant impact – as they have repeatedly done in the past. While I remain extremely optimistic about the opportunities for the oil and gas business, I remain enough of a realist to believe that no one group of organizations holds the key to the future and that people in general, the professionals within our business, including those in the NOCs, happenstance will continue to fashion our industry to provide the lowest cost supplies to meet the demands of the future."

Debate 3: 'This house believes that the North Sea is finished'

North Sea oil and gas provided the financial basis for Britain's economic recovery in the 1980s and 1990s. Phenomenal exploration success boosted Treasury income and provided the platform for stable government and prosperity. Recent years, however, have seen many changes with mergers and acquisitions leading to new mega-nationals seeing the North Sea as a less attractive exploration province now that the most obvious large structures have been drilled and the very largest fields have been exploited. Given those changes, the debate centred upon whether the North Sea had any form of future or not.

The following summarizes the debate, which focused upon determining whether the end of North Sea exploration is nigh. Whilst Richard Hardman, Director and Technical Adviser to the Board of FX Energy and former North Sea Exploration Manager of Amerada Hess, argued that North Sea exploration was in terminal decline, Jim Hannon, a Managing Director at HannonWestwood, spoke against the motion (Fig. 2).

For the motion: Richard Hardman

"One of the most successful companies of recent years, OILEXCO, has filed for bankruptcy despite having a 40% interest in Huntington, perhaps a 150 million barrel field and the biggest discovery for some time. Was it just bad luck, bad timing, bad management or is it a feature of the North Sea today? I will leave it to you the audience to decide after you have heard the arguments for and against the proposition.

Some years ago at an art fair I bought a large slate engraved with the words 'For he has hold not of an image but reality' – an apt aspiration for an oil and gas explorer. Only when the drill bit hits the horizon where pay should be found do we know if our ideas are based on reality. Explorers are true artists and, like artists, the only test is 'do their dreams make money?' A pessimistic explorer is a contradiction in terms – an oxymoron. One without creativity is like an artist who only paints pictures by numbers. To explore satisfactorily you have to think creatively, use ideas based on all the knowledge available and then take the risk you may have got it all wrong. Keeping this in mind there is always a risk the creative mind wanders off into the fictional domain, particularly as by trade, training and inclination we are optimists. And it is my contention that this is what is happening with the North Sea today.

An analysis of risk in exploration has shown that the biggest risk an explorer faces is not failing to find oil or gas but the risk of losing the job. Looking at the North Sea as a whole it is difficult to find disinterested parties who can appraise its merits clinically. The other day the UK Oil Minister, Mike O'Brien, joined in the optimism. On the *Today* programme, referring to the latest round of licensing, he said the undiscovered resources in the UK offshore

Fig. 2. The GeoControversies debates led to robust questioning and lively debate chaired superbly by Julian Rush (on the left), as exemplified here, where Jim Hannon was put on the spot in 'the North Sea is finished' debate.

amounted to 20 billion boe. He did not mention the risk and seemed to assume that this was the bounty to be found. He had no choice but to be up-beat.

The thought that these riches are at an end is unbearable at a time of the greatest economic downturn since the 1930s, and it is better politically to be unrealistic than tell a sober truth. Where many people's livelihoods and several political futures depend on a mature basin, its potential will always be overstated.

To recap today's presentations [at PGC7], the biggest single item in this analysis is the basins and their capacity to contain additional reserves. In the UK, new plays are either of moderate risk and small, or large and very risky involving new and untested ideas. Only west of Shetland is there running room – and costs are so high that this is a big company playground and is not the North Sea. Norway is over red-taped – attractive for exploration when you have qualified, but procedures are cumbersome and the authorities never allow speed to be of the essence. Meanwhile, Denmark has too small a prospective area and is largely explored out. The Netherlands still has potential, but how much of an open door policy is pursued is debateable. It is a very complex area and, hence, as new technology develops more subtle traps are identified.

Consequently, as far as exploration goes, the North Sea is finished – at least for anything except the very smallest of companies. I wish it were otherwise."

Against the motion: Jim Hannon

"The UK continental shelf (UKCS) was projected to hold some 60 billion boe, of which perhaps 35 billion have been produced – leaving some 20–25 billion boe potentially available. But can it be recovered and is there the technical, political and business resolve to pursue the remaining opportunity?

The key components to consider are, first, the geology – the remaining resource potential; secondly, recent drilling activity and results; third, the commercial hurdle; and fourth, the present structure of the industry – the number and composition of oil companies that are currently participators on the UKCS.

A review of the North Sea's remaining resource potential suggests that there are around 430 undeveloped discoveries with a total unrisked potential of 8 billion boe – giving an average discovery size of 21 million boe. The database also contains details on over 1500 prospects, with total unrisked potential of 65 billion boe, an average prospect having around 40 million boe.

In the past five years, around 60 exploration and appraisal wells have been drilled in each year – a total of over 250 wells. Hannon-Westwood have calculated a success rate of 86% for appraisal wells and, for exploration wells, 42% discovered oil or gas. The planned well database contains some 190 wells in planning for the remainder of 2009 until 2011, suggesting that enthusiasm for the basin remains undiminished. It is worth noting that, although the average discovery size has been around 20 million boe, the majors have access to west of Shetland and central North Sea high pressure/high temperature prospectivity, enabling them to drill prospects well in excess of 60 million boe.

Using economic models tailored to test the quality of the undeveloped discoveries and undrilled prospects, and taking conservative parameters, numbers were reduced by 10% for discoveries and by 25% for prospects, while capex and opex were inflated. A discounted profitability index was calculated to measure the capital efficiency of each project at a range of oil and gas prices. The results show that at $40 per barrel only 18 of the undeveloped discoveries are commercial – being just 4% of the total, but at $60 per barrel around 200 discoveries become viable. On analysing the prospects, a similar outcome unfolds.

At $40 per barrel, only some 85 prospects would be fit for consideration for drilling – representing about 6% of the population, but at $60 per barrel, the number rises to 700 prospects (45% of the total). In total, at $60 per barrel, some 900 structures merit drilling, targeting 9 billion boe and potentially delivering a business net present value of $100 billion after a capital investment of $105 billion. A low commercial hurdle and a very substantial business opportunity, by any measure. However, is the industry optimally structured to seize this opportunity?

HannonWestwood consider that the scale of the resource outlined is optimally fit for a licensee population of perhaps 40–50 companies, but there are currently 168 licensees on the UKCS. While the weakest players will go, funding has to be secured for the best of the prospects developed by the Promote licensees; their expectations, if realistic, have to be met. Economic success is more likely to be delivered through a significant drilling programme, scheduled in a cost-effective way, than through participation in one or two wells per year with a likely 80% failure rate. Companies need a good business plan to recognize the risk and to be able to tolerate the North Sea cost base. The majors will continue to target high value prospects; for others, the key for success will be some consolidation and the innovative alignment of funding to talent."

Summary: Julian Rush

"It was a privilege to chair the well attended debates. The idea had always been to challenge and to provoke discussion (Fig. 2). That the GeoControversies debates succeeded in doing that, and more, with rigour and good humour, is a tremendous tribute to the organizing skill and hard work of all concerned and to the way in which the conference embraced the concept and engaged in the discussion.

During the first debate on 'peak oil' between Jeremy Leggett and David Jenkins, I was reminded of the furore surrounding *The Limits to Growth* from the *Club of Rome* in the early 1970s. It was published while I was an undergraduate studying Engineering and Economics, and I recall it prompted considerable debate. Much maligned for predictions it didn't actually make, not least the infamous 'forecast' that oil would run out in 1992, it did serve to start a debate that continues to this day about the way Earth's growing human population uses and exploits the planet's resources.

The discussion is rightly wider now than the narrow issue of supply and demand, as both speakers in the 'peak oil' debate implicitly recognized. It is no longer a debate based on the assumption that resources are infinite and demand enduring and inflexible, but one coloured by the realization that peak oil must happen; it is a necessary precondition for the successful adaptation of humanity to climate change.

The issue, then, is not a matter of if, but when? And the timing is critical, especially if you accept the latest warnings from IPCC (Intergovernmental Panel on Climate Change) scientists of the need for greenhouse gas emissions cuts way beyond those currently contemplated in international negotiations.

Can 'peak oil' be managed so there is a smooth transition to replacement technologies or fuel sources with urgency but without excessive societal disruption? Both contributors agreed oil prices will rise in the next few years; the trick for the world's leaders is to put in place timely policy responses to use such rising prices so they act as a driver to accelerate the switch to a low-carbon economy and infrastructure. Arguably, they have been dismally slow to do so. Or will unfettered market forces drive up oil prices so quickly, as oil companies seek to recover the costs of extraction from increasingly difficult environments like the deep sea or tar sands, that wealthy western societies, at least, are left with difficult choices about unaffordable lifestyles? For the politicians, that is a distinctly uncomfortable scenario, one likely to be made of their own reluctance to act. The problem is, as both David Jenkins and Jeremy Leggett make clear, particularly acute when it comes to transport.

Then there are the oil companies. 'Business as usual' is a superficially attractive option for those unwilling or unable to adapt. Already we see many of the majors retrenching to their core businesses. But by adopting strategies designed to delay peak oil in order to protect their short-term vested interests, they risk not only exacerbating climate change – for which they are unlikely to be forgiven – but their very survival as well when their bluff is eventually called.

As for the second NOC debate, I found it interesting to see an audience largely comprising individuals dependent in one way or another upon private sector IOCs willingly persuaded their benefactor's time was up.

As someone whose job is to report for a daily TV news programme, it is rare to get the opportunity to step back from the immediate to consider a bigger, strategic picture. The changing financial and corporate structure of a global industry is pretty dry stuff – not, I'll admit, the bread and butter of a jobbing hack, unless, like the banking sector, it suddenly implodes. Not that the NOC debate was dry – far from it. This PGC debate offered that opportunity and both speakers and the audience embraced it vigorously.

The world's oil and gas industry has clearly changed in the last three decades as it has evolved to meet new global political realities as wealth, power and influence ebb and flow across the planet. Geopolitics is an ecosystem and at the heart of this debate was a question about which structure – NOC or international private sector oil company – is best fitted to evolve further. A company is like an organism, and it fights for its survival. (How else to view the millions of dollars spent by the fossil fuel industry lobbying against action to limit the effects of climate change?) The 21st century will see huge changes in the geopolitical ecosystem as the economies of China, India, Brazil and others grow to equal and surpass the western economies.

NOCs, both speakers agreed, are now the dominant life-form in the petroleum industry. By their very nature they are intimately bound to their political masters, masters whose ambition is the growth of their economies, a symbiotic relationship that currently benefits both. But will they survive to be the future of the petroleum industry? To my surprise the audience thought they would – Marlan Downey's was overwhelmingly voted the more persuasive argument. That assumes, of course, that the NOCs' political masters see oil and gas as part of their plans for growth. Is there a future of any kind for the petroleum industry in the sort of low-carbon geopolitical ecosystem that may evolve if developed and developing countries do actually agree action to limit the effects of climate change? One was left pondering the key question as to whether all oil companies, both private and national, face extinction before the first half of the 21st century is out.

It was a brave challenge in the final, North Sea debate to ask a conference of petroleum geologists to look over the edge of the abyss and ask them to consider if they still had a purpose. There can't have been many in the auditorium at the QEII Centre who had not looked out over the grey waters of the North Sea at some stage in their career as they pondered what lay beneath. The North Sea has been the nursery of a generation of geologists, their geo-playground and their workplace. They looked over the edge in the North Sea debate though and decided the explorers' days were not yet numbered. But, reflecting on the debate between Richard Hardman and Jim Hannon, I wonder if they reached the right answer for the wrong reasons.

The debate, of course, was about exploration for oil and gas – were the glory days of the past over yet? But we are heading into a low-carbon future, one that seeks not to praise carbon, but to bury it. The North Sea is routinely promoted as the ideal location to store carbon dioxide (CO_2) when it is eventually captured from power stations and industry.

Carbon capture technology is in its infancy, but the engineering problems are not insurmountable. I have little doubt it will succeed – it has to. Storage, though, is usually taken for granted; where there was methane, so there can be CO_2. It may not be that easy – CO_2 is not CH_4. Their geochemistry is different. While CO_2 has been successfully sequestered for over a decade in Statoil's Sleipner field, or used to enhance oil recovery in depleted oil fields in Canada, it cannot be taken for granted that formations that stored methane for millennia will do the same for CO_2. Finding the reservoirs where CO_2 can be safely sequestered for the significant time-scales required, in formations that don't leak, is a geological challenge of a different kind that will need considerable 'exploration'.

North Sea exploration, then, does have a future, as the audience decided – but I would not be surprised if the young geologists in the audience who will be doing the exploring find themselves using their considerable skills and knowledge as petroleum geologists to look for something other than petroleum products."

Conclusion

The introduction of the novel new series of debates was a huge success, being well attended and a subject of lively debate and discussion long after the lunchtime sessions were concluded. The debates spawned articles in *Petroleum Review* and *GeoEnergy*, and have even led to the instigation of Petroleum Group GeoControversy debates at Burlington House on subjects like the formation of the 'Silverpit Crater' and the like. In so doing, the PGC has demonstrated flexibility and yet again led the way to leave a legacy for the geoscientific community. Hopefully, when PGC8 comes around, it will be ripe for a new series of debates on those GeoControversies of the moment.

I wish to acknowledge the help and support of Bernie Vining, Graham Goffey and Al Fraser, whose enthusiasm for the notion of the GeoControversies Debates and unstinting enthusiasm for the concept materially contributed to their success. Thanks are given to the conference photographer for providing the photos used in the paper.

Abstract: Significant advances in geosciences data acquisition, visualization and analysis now allow highly detailed outcrop models to be constructed for a range of petroleum industry purposes. From a given field locality, a virtual outcrop is created from a centimetre-scale digital elevation model and colour photographs with geological information overlaid as appropriate. In a visualization environment, these datasets can be viewed sequentially to simulate undertaking a fieldtrip. These *virtual fieldtrips* allow geoscientists to improve and expand the traditional fieldwork experience in a number of ways, ranging from planning and health and safety considerations for management, to providing live supplemental technical content on a mobile device to the fieldtrip participant. The fieldtrips are easily archived and content can be reviewed in the office to provide analogue information during technical work. Examples of virtual fieldtrips are provided on the DVD that accompanies this volume.

Keywords: virtual outcrops, fieldwork, laser scanning, lidar, analogue model

Over the last 10 years there have been significant advances in geoscience data acquisition and visualization techniques. These advances have revolutionized geological fieldwork, primarily with the emergence of the *virtual outcrop* (VO), where a high-resolution copy of the outcrop is recreated on a computer in 3D. While 'virtual fieldwork' is unlikely to surpass the experience gained during real fieldwork, it is now clear that digital outcrops can provide significant insights that can supplement the traditional field experience.

Despite high costs and an increasingly stringent health and safety culture, the petroleum industry still sees clear benefits from subsurface technical personnel undertaking fieldwork and spending time at outcrops. There are a number of different types of fieldwork that geoscientists working in the petroleum industry may carry out, including:

(1) Multidisciplinary excursions, typically involving all the technical staff (geoscientists, reservoir engineers, drillers, etc.) within an asset. Such trips will normally be to outcrops that are analogous to a particular licence block or field and will be designed to increase understanding of the subsurface challenges faced by the team.
(2) High-level training for expert geoscientists to increase knowledge of geological processes and products, especially in sedimentology, stratigraphy and structural geology. Such trips may also include a component of fieldwork in which data are collected to address specific challenges (e.g. Dreyer *et al.* 1993; van Wagoner & Bertram 1995 and numerous other examples).
(3) Geoscience training for non-geologists, typically reservoir engineers and geophysicists, in order to improve understanding of geology and how it impacts their respective disciplines.
(4) Collection of field data to build analogue models for reservoir flow or forward seismic modelling. Such work is commonly focused on collecting data to address a specific reservoir or exploration-related issue (e.g. Howell *et al.* 2005).
(5) Pioneering field survey in frontier petroleum provinces, where fundamental new data from the outcropping part of a basin are collected to support petroleum exploration (e.g. Reynolds *et al.* 1998).
(6) Calibration and validation of numerical modelling of reservoir processes (e.g. Jones *et al.* 2008).

In this paper we explore the way in which VO datasets can be utilized in almost all of these different types of fieldwork setting. This paper also serves as an introduction to the eight case study examples that are provided as video clips on the accompanying DVD. These have been selected to communicate different aspects of the data capture, visualization and the range of applications that are being developed for virtual fieldwork datasets.

Creation of virtual fieldtrips

Virtual reality technology allows the user to interact with an artificial computer-simulated 3D environment. In the context of geological fieldwork, this generally means a geoscientist being able to interact with a digital representation of a field-site projected onto a screen or series of screens. A minimum requirement would be that the user can change their vantage point and gain a different view of an object as opposed to a fixed vantage point that is gained from viewing a photograph. This means that the digitized field-site or outcrop must be embedded in a 3D world and that the user has a means of moving around it in a virtual sense.

VINING, B. A. & PICKERING, S. C. (eds) *Petroleum Geology: From Mature Basins to New Frontiers – Proceedings of the 7th Petroleum Geology Conference*, 19–26. DOI: 10.1144/0070019

The basis for virtual fieldwork is a VO. These are models which are created from raw data acquired using a combination of satellite positioning, remote sensing and laser-based mapping survey (see McCaffrey *et al.* 2005; Pringle *et al.* 2006 for a summary of these technologies). The VO is generated in vector formats, generally georeferenced to global or local coordinate systems and viewed using 3D visualization hardware and software. In geology, the first VO datasets were created by Xu *et al.* (2000) and quickly followed by many others (e.g. Pringle *et al.* 2001; Pringle 2004*a*, *b*; Jones *et al.* 2004; Hodgetts *et al.* 2004; Bellian *et al.* 2005; Clegg *et al.* 2005; Trinks *et al.* 2005; Tomasso *et al.* 2006; Enge *et al.* 2007; Redfern *et al.* 2007; Janson *et al.* 2007; Buckley *et al.* 2008; Fabuel-Perez *et al.* 2009; Wilson *et al.* 2009). In addition to the VO, most virtual fieldtrips will also include other data that supplement the basic outcrop, including sedimentary logs, structural measurements, projected bedding and fault surfaces and even geocellular models of the outcrops (Pringle *et al.* 2006; Labourdette & Jones 2007).

The basic workflow to create a virtual fieldtrip is summarized in Figure 1. Underlying all other components is the topography digitized as a detailed digital elevation model (DEM). The resolution of a DEM is dependant on how the underlying data were acquired. There is worldwide coverage at 90 m resolution (size of each pixel) created from the Shuttle Radar Topography Mission (SRTM) and freely available to download (http://srtm.csi.cgiar.org/). Increasingly, 30, 25 and 10 m data is available in many countries. The large scale (100×100 km) of the San Rafael Swell in central Utah included in this publication was built entirely from free, publicly available data including the USGS 10 m DEM and 1 m resolution aerial photo from the Utah Geological Survey. Similar image resolution can commonly be found in Google Earth and other free GIS applications and has been used for the Lofoten and western Ireland models summarized later. For higher-resolution topography, a bespoke capture process is usually undertaken. This usually involves a ranging device, generally a laser, being scanned across the target, although photogrammetric methods can be used for the same purpose (e.g. Pringle *et al.* 2001, 2004*b*). Airborne laser scanner or lidar (light detection and ranging) topography datasets have a resolution of 50 cm^{-1} m and are flown over areas in the region of 10 s km^2. For topographic models of individual outcrops a ground-based (terrestrial) laser scanner is generally used (Fig. 1) and these systems have the capability to generate centimetre resolution topography over distances up to a kilometre. These systems are coupled with high-resolution digital cameras and together manage to capture the type of micro-topographic features that are found in outcrops such as bedding, sedimentary and tectonic structures.

Once the topography has been captured the next step is to create a VO, also called a digital outcrop model (DOM) (Bellian 2005). This generally involves creating a meshed patch from the DEM and rendering it with images from the fieldsite (see Bonnaffé *et al.* 2007; Buckley *et al.* 2008 for reviews of the process). These images are derived from satellite images, aerial photographs or high-resolution digital outcrop photographs depending on the resolution required. These surface patches provide a good virtual representation of the field site or outcrop when inspected from various vantage points in a 3D viewer. At this stage other related data can be added as point, line or polygon features (Fig. 2). For example, orientation data could be plotted as a 3D symbol inclined in the correct direction or the results from geochemical analysis of samples as a proportional symbol. Lines are used to represent the traces of logs, bedding planes or other structural features and polygons to define areas on outcrops. Georeferencing is critical and field data that are to be included in the VO will ideally be mapped with a GPS (global positioning system) receiver and the location coordinates converted to the same scheme as the topographic model.

The paucity of geoscientific interpretation software for virtual models has made it difficult to unlock the full power of a VO. Many of the existing software packages for lidar data are designed for land surveying or civil engineering purposes, and so do not provide the tools needed by geologists. Recently a variety of software has been developed by different groups to aid visualization, interpretation and modelling of lidar data. These new software approaches have allowed better use of lidar, DEM and satellite image data in a variety of applications (Redfern *et al.* 2007; Bates *et al.* 2008; Fabuel-Perez *et al.* 2009; Wilson *et al.* 2009). The objective is to place points onto the 3D surface of the outcrops and to build those interpretations into surfaces. These interpretations can be guided by traditional field measurements, such as orientation data or existing boundary correlations, in either an algorithmic or a heuristic manner. The interpreted surfaces can then be constructed into data volumes using geomodelling tools designed for subsurface work (e.g. Petrel, RMS, Gocad, etc.).

The final step is to assemble the fieldtrip so that the outcrop models can be viewed in a logical and pedagogical manner. A number of software packages are emerging that support participation in the virtual fieldtrip. Typically it has been the practice to load separate models sequentially in the preferred viewer. More recently, systems such as Google Earth allow a large-scale overview, with individual localities nested inside, allowing the entire multiscale virtual fieldtrip to be undertaken from a single platform. These systems have the advantage that they are already widely used, intuitive and freely available. The VO models and interpretations for each outcrop can be assembled and loaded individually as Google Earth KML (Keyhole Markup Language) files. They can then be successively viewed by selecting in the 'My Places' listing and the software will move automatically between locations, preserving the geographical context and giving a real 'trip experience'. An exciting result is that multiple fieldtrip itineraries to address specific issues can be constructed using the same base of fundamental data.

Applications in the petroleum industry

There are a number of ways in which the virtual fieldtrip can add value to the industry (see Table 1 for specific examples and references).

As an additional training tool on a traditional fieldtrip

Virtual fieldtrips can supplement real fieldtrips by providing easily digestible technical content such as orientation context before and during a real excursion and opportunities for customized follow-up work afterwards. In this case the virtual fieldtrip may be used to show the participants where they will visit prior to going on the trip and also can act as a refresher on return. A morning or evening classroom session with a virtual fieldtrip can provide opportunities on the day to expand the discussion to encompass other datasets such as synthetic seismic, geocellular models and flow simulation results.

To provide additional field time outside scheduled fieldtrips

While real fieldtrips happen once or twice a year and involve significant logistics and travel time, the virtual fieldtrip can happen at any time. This enables the geoscientist working on a reservoir model to be able to take a 20 min virtual trip to an analogue without leaving his/her desk. Another example is a seismic interpreter trying to understand which model to push through a data volume. Here, having easy access to analogue material can be an invaluable aid to encourage interpreters to consider a range of

(**c**) Lidar-derived DEM overlain by Quickbird Satellite image showing bedding orientation, horizon interpretations and scan positions in the VRGS software.

possible models. Virtual fieldtrips can also be used to illustrate specific points in meetings between partners and between disciplines.

Multiscale model context

Our understanding of the way in which some geological processes operate across a wide range of scales remains relatively poor. For example, processes operating in rifted margin and foreland fold/thrust belts can span up to eight orders of magnitude in length. The main advantage is the facility for researchers to view individual outcrops in their correct relative position at a variety of zoom settings, allowing simultaneous appreciation of fine-scale structure and overall geometry of the feature of interest.

Table 1. Use of virtual fieldwork in petroleum geosciences

Use	Detail	Study

Constraints on geobody dimensions, geometry and properties

Outcrop analogue studies are a key way of improving understanding of reservoir facies architecture, geometry and facies distributions. Subtle surfaces with very low bedding dip that are very difficult to measure in the field can be mapped and correlated over large areas. The VO also provides a very efficient method of producing quantitative data on subseismic scale facies and reservoir architecture. Bed geometries that are below seismic resolution can be measured very quickly, providing large volumes of tightly constrained data, often from inaccessible cliff sections. These data can be used to populate subsurface models with facies objects away from the borehole and also to model the outcrop directly and test the impact of heterogeneities on flow.

The integration of lidar technology with standard outcrop data collection techniques has led to a step-change in the analysis of 3D outcrops, enabling workers to interrogate the outcrop in much more detail (e.g. Pyles *et al.* 2010). Three-dimensional reservoir models generated from these outcrops, populated with petrophysical parameters from analogue producing reservoirs, enable issues such as connectivity to be studied. To bridge the gap in scale between the outcrop resolution and subsurface data collection, forward seismic models can be generated, in either 2D (e.g. Sullivan *et al.* 2000; Bakke *et al.* 2008) or 3D (e.g. Tomasso *et al.* 2006; Janson *et al.* 2007). Forward seismic models can be generated at specific frequencies, or the frequency spectrum tailored to a specific subsurface seismic image (Tomasso *et al.* in press). Seismic architectures can then be compared back to the known outcrop architecture, and the forward seismic model investigated for attribute combinations that can increase the resolution and interpretability of the stratigraphic architecture.

Constraints on discontinuity dimensions and geometry

Building fractured reservoir models has in the past involved laborious digitizing work on remote sensed images and outcrop photographs and the resulting models are usually dimensionally limited by the original input media (2D images). VO datasets provide input data that has a 3D component gained from the intersection of fracture surfaces with the microtopography. The development of automated fracture picking methods allows the geologist to better focus on the interpretation and analysis of outcrop analogue data and to extract parameters for the building of discrete fracture network models. If the fractures define the topography, as is often the case in an opencast pit or quarry, automated surface fitting algorithms can be used to build a fracture model. Where the fractures intersect the topography edge, detection methods used with seismic data may be employed.

Knowledge and training

VOs and fieldtrips can offer an efficient way to provide training for personnel. The training for many specialist disciplines involves fieldwork and virtual datasets can assist with pre-fieldwork preparation, presenting supplementary data during a course and post-excursion follow-up exercises (e.g. forward seismic models draped on to the outcrop). VOs could offer a useful mechanism to provide orientation for non-geoscientists and a vehicle for improving communication between disciplines. Finally, pre-fieldwork health and safety requirements can also be addressed using a virtual fieldtrip.

Planning and logistics

Virtual fieldtrips are also valuable for planning and logistics for fieldtrips in the real world. The amount of time a petroleum industry geologist spends in the field is typically limited by time or budget constraints, and making the most of that time is essential. Virtual models are frequently used in seismic survey planning, where understanding topography, surface obstructions and surficial geology is essential for a successful field campaign. Additionally, they are an increasingly essential part of planning fieldwork campaigns and keeping track of personnel working in a field area via the use of real-time GPS tracking devices. This means that health and safety issues are addressed through the use of virtual models both by shifting some ‘fieldwork’ back to the office, and also by adding to the safety of individuals while in the field.

Examples on DVD

In the accompanying DVD there will be short video clips to illustrate the following eight virtual fieldtrips.

1. Shannon Basin, West of Ireland (Thurmond et al.*)*

The Carboniferous Shannon Basin in western Ireland is approximately 100 km wide and filled with a sedimentary succession of up to 2200 m thick. The fill is an overall deepening to shallowing-upwards succession from shallow-water clastics to deepwater carbonates through a source-rock quality deep basinal shale (Clare Shale), followed by a 460 m thick sand-rich turbidite unit (the Ross Formation), a 550 m thick overall fine-grained, complex slope succession (the Gull Island Formation) and capped by a 900 m thick succession of deltaic cyclothems of the Central Clare Group.

Outcrops of the Shannon Basin have been extensively studied, and provide both a testing ground for new ideas and a frequently visited location for fieldtrips and schools. There have been several studies aimed at collecting 3D data from the better-exposed outcrops, and these data have been used for various types of analyses, including sedimentological interpretation, structural measurement and construction of synthetic seismic profiles. The virtual fieldtrip provides an overview of Statoil's efforts in the Shannon Basin, including integration of several 3D outcrop models (photorealistic models), interpretations and advanced synthetic seismic within the framework of Google Earth and proprietary extensions to it. This illustrates how a wide variety of scales can be visualized simultaneously – from centimetre-scale features on a VO to basin-wide synthetic seismic lines and cross-sections.

2. Grès d'Annot Formation, SE France (Tomasso et al.*)*

Salt withdrawal minibasins contain significant petroleum reservoirs in many petroleum provinces around the world, such as the deep northern Gulf of Mexico and offshore Brazil. These minibasins are typically connected by large canyon-like channels that serve as conduits for sediment gravity flows bypassing from proximal basins into adjacent distal basins. The Grand Coyer sub-basin of the Eocene–Oligocene Grès d'Annot Formation of the southwestern French Alps provides an excellent outcrop analogue of an interbasinal conduit that connects the proximal southern Annot sub-basin to the distal northern Trois Evéchês sub-basin. Stratigraphic columns, palaeocurrent, photomosaic and lidar data were collected to address the stratigraphy of the conduit.

This virtual fieldtrip visits several of the key exposures around the Grand Coyer sub-basin, illustrating and analysing the stratigraphic packaging moving from lower to upper fill, from axis to margin, and from proximal to distal deposition. Using a detailed, outcrop-based geological model of the conduit, large (field) scale forward seismic models are used to contrast the geometries that we see in the outcrop with those that we would resolve on seismic images. Lessons learned from these exposures could be used to better predict sand distribution and reservoir geometry within interbasinal conduits.

3. Nukul syncline, Gulf of Suez (Hodgetts et al.*)*

The authors have developed bespoke software called Virtual Reality Geological Studio (VRGS) which can be used for the interpretation and integration of traditional forms of data with the lidar scan data (Fig. 2). The development of this software was driven by the lack of geoscience-specific software that allows full use of the scan data. In outcrop data it is often difficult to constrain geometries in 3D. Data is usually high-density in some areas, and sparse in others, leading to increased uncertainty. This may be the case for sediment bodies, faults or surfaces. In order to constrain these geometries as much information from the outcrop must be used as possible. In this study a large lidar dataset (over 100 linked and georeferenced scan positions) is used to derive information in addition to traditional fieldwork to help constrain hanging wall morphology (Fig. 2) in a syn-rift fault block comprising early Miocene strata in the Gulf of Suez. The resulting integrated dataset of both lidar and field-based observations has been used to build and condition a reservoir model in Petrel.

4. Deltaic reservoir analogues from central Utah (Howell et al.*)*

This virtual fieldtrip illustrates the utilization of outcrops and VOs to build geometrically accurate geocellular models that have been used to address oilfield production challenges at a variety of scales. VOs from two Cretaceous deltaic units, the Panther Tongue sandstone and the Ferron Sandstone that crop out in the northern Book Cliffs and the San Rafael Swell, are presented. This involved creating a large-scale VO covering 10 000 km^2 from publicly available DEM and aerial photo data. This was used to build a geocellular model that captures the very large-scale stratigraphic architecture of the Mesaverde Group clastic wedge, including the Panther Tongue and Ferron sandstones. Detailed lidar studies of selected outcrops from the Panther Tongue and Ferron Sandstone have captured the detail of individual delta front clinothems and bedsets. The data have been used to capture statistics that describe clinothem bed thickness and downdip bed thinning trends. The VOs have also been used as the basis for a series of geocellular models that were flow-simulated to investigate the effects of shale-draped clinoforms as barriers in deltaic reservoirs.

5. Lofoten, Norway (McCaffrey et al.*)*

The Lofoten–Vesterålen offshore continental margin is a narrow shelf with a relatively steep slope and crustal thickness up to *c.* 30 km. The area has a prolonged post-Caledonian history of intermittent extension and basin formation documented from the Devono-Carboniferous to Cenozoic times (Bergh *et al.* 2007). The Lofoten archipelago is composed mainly of high-grade metamorphic Precambrian rocks which have been uplifted in the footwall to a Mesozoic normal fault (west Lofoten boundary fault). The exposed rocks are mainly Palaeoproterozic migmatitic gneisses that have been intruded by mangeritic and charnockitic plutons. Using a combination of Google Earth and laser scanned outcrops, the Lofoten virtual fieldtrip provides an opportunity to examine Mesozoic faulting in crystalline basement and allows us to directly study faults and fractures onshore, placing kinematic constraints on the early evolution of parts of the margin that are located in the subsurface offshore. In addition the fieldtrip provides an opportunity to study faults/fractures developed in basement crystalline rocks which are generally not well imaged in seismic data sets. Thus this virtual fieldtrip can provide a potential analogue for basement-hosted reservoirs, for example, Clair field, Faero-Shetland basin where Mesozoic faults cut crystalline basement rocks.

6. Arkitsa fault, Greece (Jones et al.*)*

This VO dataset shows complex fault geometries developing in an area of active extension, and also illustrates how an enhanced view of the outcrop can be presented by superimposing quantitative geometrical analyses on top of the VO topography. The outcrop is an important analogue for studying the development of 3D fault zones and associated fault damage, and the likely effects on connectivity and reservoir performance. It is located on the eastern shore of Gulf of Evia in central Greece, an area that is currently undergoing active north–south to NE–SW regional extension, with rates on the order of 1–2 mm/year, in response to the complex tectonic interplay between subduction beneath the Hellenic Arc, back-arc extension in the Aegean, and the westward movement of the Anatolian plate. The Arkitsa fault has a throw of >500 m and is part of an array that extends for over 100 km along-strike. The footwall rocks are Upper Triassic–Jurassic platform carbonates and the hanging-wall rocks are Pliocene to Quaternary sediments. The Arkitsa fault is best exposed in an outcrop 450 m south of the main Athens–Lamia national road, where recent quarrying activity during the last 20 years has removed hanging-wall colluvium to reveal clean, fresh exposures of the upper 65–70 m of three large fault panels.

This virtual fieldtrip, created using a terrestrial laser scanning (lidar) workflow, shows that it is a powerful and versatile tool that is highly suitable for acquisition of very detailed, precise measurements of slip-surface geometry from well exposed faults (Kokkalas *et al.* 2007; Jones *et al.* 2009*a*). Quantitative analysis of the lidar data, combined with 3D visualization software, allows the spatial variation in various geometrical properties across the fault surface to be clearly shown. Properties such as variation in orientation and curvature (normal, mean and Gaussian) allow culminations and depressions, fault corrugations, and fault splays and bifurcations to be easily identified.

7. Moab fault, Utah (Imber et al.*)*

The Moab Fault is a steep normal fault which cuts and exposes a sequence of interbedded sands and argillaceous units ranging from Late Permian to Mid Cretaceous age. Throws of up to 960 m are observed in surface exposures. The footwall and hanging-wall strata are deformed into a series of long-wavelength normal drag folds of variable amplitude that trend NW, approximately parallel to the strike of the Moab Fault. The Moab virtual fieldtrip has been created using terrestrial laser scanning methods to illustrate the sizes and shapes of normal drag zones and the effect of normal drag on fault throw distributions and juxtapositions. From the fieldtrip we can quantify the along-strike variability which places constraints on how to model in flow simulators. In the Moab fault example, drag accounts for *c*. 30–50% of total throw with a steep inner drag zone (bed dip $< 50^\circ$) up to 150 m wide, and a more gently dipping outer drag zone (bed dip $< 15^\circ$) up to 350 m wide. The along-strike 'drag wavelength' of at least 800 m is larger than the grid cell size of a typical flow simulator, implying that normal drag zones should be modelled explicitly to capture their effect on across-fault juxtapositions.

8. Carbonates, Alpine foreland (Viseur et al.*)*

Carbonate architectures can be complex, reflecting spatial and temporal changes and the interaction between biological, physical and sedimentary processes. In such cases, it can be difficult to characterize the 3D geometry of sedimentary or diagenetic bodies at a range of different scales. Laser scanning technology offers a new approach to determine these geometries from outcrops. We present a case study located near Marseilles (France) and corresponding to the 'La Marcouline' formation. These deposits are particularly interesting to model as: (1) they are located in the transition zone between the northern Provence platform and the South Provence Trough; (2) the passage between the carbonate platform deposits (north to south prograding) and the clastic deposits ranging from marginal to deeper marine sediments can be easily followed thanks to continuous outcrops. This study shows how it has been possible to combine classical field data with digital outcrop data in order to construct a high-resolution model of carbonate architectures. The workflow involved (1) data acquisition and building and construction of a VO model; (2) the integration of logs and maps; and (3) the use of automated pattern extraction for the picking of geological strata. The virtual fieldtrip shows the application of the automated tools for the detection of geological information from the VO. Finally, the 3D model of the 'la Marcouline' carbonate architecture, built from the outcrop interpretations and our evolutionary 4D model displaying the carbonate bodies in chronological order, is shown.

Future trends

- VOs and fieldtrips technologies are not yet standard tools for the industry geoscientist but we expect their widespread adoption in the next 5–10 years. A combination of hardware and software advances, both on the acquisition and also on the visualization side will ease the transition into mainstream activities.
- A variety of custom software tools are being created to interpret VO data. These will continue to be developed with particular emphasis on intuitive interpretation and quantitative data extraction.
- The latest generation of smart mobile devices (such as the iPhone) are powerful enough to be visualization platforms in their own right. This means that virtual fieldtrips can be made 'portable', and therefore be used directly in conjunction with real-world field excursions. Many of these devices also have integrated GPS systems, allowing a fieldtrip participant to more actively follow a virtual field guide, and also have direct access to a wide variety of data to provide context to what they are seeing in real time.
- More sophisticated laser scanners are moving beyond simple ranging devices, the latest instruments offering full-waveform capabilities that will allow surface characteristics (e.g. water content) to be determined. On-board inertial systems mean that instruments can be used from boats and helicopters, increasing the range and size of outcrops that can be captured.
- Google Earth is the obvious platform to deliver seamless virtual fieldtrips that will be available to a range of users.
- We expect increasing use of standards in VOs datasets. The Open Geospatial Consortium (http://www.opengeospatial.org/) has recently added KML to their list of approved formats – thereby making it easier to construct virtual fieldtrips that comply with open standards for use and interchange.
- We finish by calling for access to shared datasets to avoid groups/companies having to acquire the same primary datasets and welcome the development of databases and repositories with the support of industry.

The authors thank Tony Reynolds for reviewing an earlier draft of this paper. Production of the video clips on the DVD was sponsored by Statoil. K. J. W. McCaffrey acknowledges receipt of a Royal Society Industry Fellowship.

Colin Oakman core workshop

G. J. HAMPSON,[1] J. D. COLLINSON[2] and P. GUTTERIDGE[3]

[1]*Department of Earth Science and Engineering, Imperial College London, South Kensington Campus, London SW7 2AZ, UK (e-mail: g.j.hampson@imperial.ac.uk)*
[2]*John Collinson Consulting, Delos, Knowl Wall, Beech, Staffordshire ST4 8SE, UK*
[3]*Cambridge Carbonates Ltd, Meadow Barn, Mill Lane, Brailsford, Ashbourne, Derbyshire DE6 3BB, UK*

The core workshop followed the format of the three core events at previous Petroleum Geology Conferences (e.g. Oakman & Martin 1993), although it was smaller in scale and its focus was on the reservoir sedimentology of the North Sea. The workshop was organized by the British Sedimentological Research Group (BSRG) with the cooperation of the Petroleum Exploration Society of Great Britain (PESGB) and British Geological Survey (BGS), who provided and transported all of the cores on display. BSRG exists to promote and support the work of young researchers in sedimentary geology (including stratigraphy, diagenesis, process sedimentology and geochemistry), many of whom go on to successful careers in the oil industry. Within this context, the workshop featured presentations by PhD students, academics and consultants that put the reservoirs illustrated by the cored intervals into context, from both a depositional and a commercial standpoint.

Fig. 1. Colin Oakman (1955–2008).

Colin Oakman (Fig. 1), a leading force in organizing core workshops at previous Petroleum Geology Conferences, sadly died prior to the conference. The workshop was dedicated to Colin's memory in appreciation of his enthusiasm and hard work.

Sedimentology is a key component in understanding the character and distribution of hydrocarbon reservoirs, and its application continues to play a major role in exploration and production activities in the North Sea. Despite new and ever more sophisticated remote-sensing technologies, cores continue to provide the direct rock samples that are critical to many aspects of reservoir geology, and ultimately to the efficient extraction of hydrocarbon resources. On display were about 320 m of core from 15 wells, selected to illustrate a diverse range of reservoirs and plays, including the 'classic' reservoir intervals that have been the engine of North Sea production over the last 30 years, and less conventional, emerging plays that may sustain future development. The cored intervals represented Lower Carboniferous shelfal and resedimented carbonates, Upper Carboniferous deltas and alluvial plains, Permian brecciated carbonates, Permo-Triassic marginal aeolian and dryland river deposits, a range of Middle–Upper Jurassic deltaic and shallow-marine systems, and Cretaceous–Cenozoic deepwater fans (Table 1). The workshop highlighted the challenges of interpreting sedimentary processes and environments from core data and emphasized the role that core sedimentology has played, and continues to play, in reservoir characterization, development and management.

During the conference, over 300 delegates attended the scheduled presentations for each of the cores and associated posters, and many more delegates browsed the core displays outside of these presentations. Both presenters and visitors appreciated the opportunity to discuss geological concepts and models against

Session: Europe

Europe overview

G. GOFFEY

PA Resources UK Limited, 4th Floor Waterfront, Winslow Road, Hammersmith, London, UK (e-mail: ggoffey@paresources.uk.com)

Abstract: Over 35 years, the Petroleum Geology Conference series has been the leading UK conference dedicated to making public the scientific advances and findings of some four decades of NW European hydrocarbon exploration and production. Leading edge issues in the NW European province after four decades include small pool and high pressure high temperature (HPHT) exploration, late-stage field exploitation and field redevelopment. The rich subsurface datasets and pioneering of emerging technologies provide a stream of valuable models, lessons, techniques and ideas which have both local and international applicability. Papers grouped under the exploration theme contain regional, local and detailed studies which illustrate the nature of current exploration activity for small, deep and complex structural and stratigraphic prospects. Closer and more comprehensive integration of seismic-derived understanding of structural evolution and seismic, well and analogue-derived depositional and sequence stratigraphic constraints are probably the most fruitful approaches and are shown by a number of papers. Papers on field development and production themes describe the industry's response to challenges such as low permeability and reservoir prediction through the use of multiple 3D and 4D seismic datasets and the exploitation of advances in drilling, well logging and completion technologies to drain progressively smaller per well reserves. Again, integration is the watchword, here between interpretations and analyses of subsurface data with well planning and construction. Finally, a number of papers describe current techniques in petrophysics, 3D and 4D seismic applications and remote sensing approaches.

History of the Petroleum Geology Conference series from 1974 to date: from NW Europe to international

The first conference in 1974 was described in the foreword to the proceedings as 'the most important and significant geological conference ever presented in the European area, and possibly in the world, in view of the great importance of the North Sea development in the total world energy picture'. The conference was seen as unique because most of the presentations were previously unpublished findings of the oil industry, rather than from academia. Publication of the proceedings of the conference (Woodland 1975) initiated a series that have become essential reference works for geoscientists working the NW European hydrocarbon basins.

The second conference was held in 1980 (Illing & Hobson 1981) and more than 1000 delegates from 12 countries listened to papers describing the emergence of the North Sea as a major oil province. The Right Honourable David Howells, then UK Secretary of State for Energy, commented on how the discovery of new oil reserves would depend on new ideas and a fresh approach. His talk anticipated the licensing of previously unexplored deepwater areas west of the UK and highlighted the need for new discoveries to sustain UK hydrocarbon self-sufficiency into the 1990s.

The third conference (Brooks & Glennie 1987) took place in 1986 in arguably the first major downturn experienced by the modern petroleum industry. In his opening address, the Right Honourable Alick Buchanan-Smith, UK Minister of State for Energy, presciently observed the cost in human terms of the industry downturn, with the great loss of skilled personnel from the industry.

The fourth conference was held in 1992 (Parker 1993) and attracted 1230 delegates including 350 from 15 overseas countries. This was the first event to feature a Core Workshop displaying some 600 m of cored rocks. Conference Chairman Jim Brooks observed in his introduction that whilst the *major* companies had dominated in the early days of North Sea exploration, *independents* were increasingly involved in the exploration, development and production of offshore fields.

Held in 1997, the fifth conference (Fleet & Boldy 1999) was the last to be focused exclusively on NW Europe. Highlights of this conference were the increasing integration of disciplines within the geosciences and of geosciences with other disciplines, the development of reservoir modelling and 3D/4D seismic techniques, and the ongoing refinement of sequence stratigraphic approaches.

The sixth conference in 2003 (Doré & Vining 2005) was the first to explicitly broaden its perspective to encompass international activities. Entitled *North West Europe and Global Perspectives*, the conference aimed to both import ideas and concepts from the international arena as well as exporting to other parts of the world ideas and concepts developed in the North Sea 'laboratory'. New themes for the NW Europe industry were infrastructure-led exploration, tail-end production and field rejuvenation. The emergence of gas as a fuel for the future was marked by a section dedicated entirely to gas.

The Right Honourable John Smith, then UK Under-Secretary of State for Energy, commented in his opening address to the First Conference in 1974 that 'the successful exploitation of North Sea hydrocarbon resources with the new data and technological innovation it will produce, will lead ... to worldwide development of offshore petroleum in waters that have until now seemed impossible to work'. In 2009, the seventh conference was inspired by Smith's prescient observations to build upon the NW European roots of the series to develop into a truly international conference, sharing insights, techniques and success stories on a global basis 'from mature basins to new frontiers'.

Overview of the Europe proceedings

The NW European province continues to mature and break new ground, particularly in small pool exploration, development

VINING, B. A. & PICKERING, S. C. (eds) *Petroleum Geology: From Mature Basins to New Frontiers – Proceedings of the 7th Petroleum Geology Conference*, 31–33. DOI: 10.1144/0070031 © Petroleum Geology Conferences Ltd. Published by the Geological Society, London.

and exploitation. The extensive subsurface datasets prevalent in NW Europe and the response of the industry to the challenges it faces provide a rich stream of valuable models, lessons, techniques and ideas which have both local and international applicability. Equally, the importance of new ideas and a fresh approach as noted in 1980 are as important as ever and the industry needs to look to the international arena as a source of such ideas and approaches.

The Europe session at the 7th Petroleum Geology Conference was the most extensive session at the conference and, in addition, the core workshop contained core exclusively from reservoirs of the North Sea and adjacent petroliferous basins. Given the history of the conference series as a NW Europe conference, this emphasis on Europe was to be expected. Papers and posters contained within this proceedings volume have been grouped into three sub-themes: exploration; field development and production; and techniques in exploration and production.

Exploration

A number of authors contributed regional-level papers on European petroleum provinces, represented here by papers from Erratt, Milton-Worsell *et al.*, Petersen, Knutz and Bertello. Erratt draws attention to the interplay between tectonics and sedimentation in hydrocarbon play development. Whilst Milton-Worsell uses an extensive regional dataset of well and in particular long-offset seismic data to draw attention to a potential Palaeozoic basin in an underexplored area of the Central North Sea flanks, Knutz examines the development of Mio-Pliocene ‘channel’ features in the main body of the rift and their linkage to deeper structure, hydrocarbon leakage and potential contourite depositional processes. Further south, a poster by Petersen examines the controlling influence on exploration outcomes of source rock quality in the NW Danish Central Graben. Finally Bertello provides an overview of hydrocarbon occurrence in fold belt to foreland settings in Italy – by a considerable degree the most important hydrocarbon province in southern Europe and not widely appreciated by northern European geoscientists.

The depositional, sedimentological and sequence stratigraphic setting of Middle and Upper Jurassic reservoirs is explored in papers and posters by Johannesen *et al.*, Kieft and Sansom. Johannessen *et al.* draw together a revised palaeogeographic understanding of Late Jurassic deposition in the Danish Central Graben utilizing recent exploration results, whilst the poster of Johannesen *et al.* develops a Recent analogue for the depositional architecture of a deep Upper Jurassic barrier and shoreface sandstone reservoir in the Danish offshore. A poster from Kieft explores the use of an extensive core database to understand reservoir development within an overall transgressive interval of marine and marginal marine sandstones of the Middle Jurassic Hugin Formation in the Norwegian South Viking Graben. Finally Sansom constructs a detailed understanding of the shallow marine, Late Jurassic Fulmar reservoir and highlights the previously unrecognized controlling role of intra-Volgian tectonic reconfiguration events on basin morphology and reservoir distribution and preservation. Taken together, these papers illustrate the insights possible in the data-rich North Sea setting when reservoir models are built or critically challenged through analysis at various levels from detailed regional reviews, through to core-based studies and the use of Recent analogues.

Several papers look at recent discoveries and soon to be drilled prospects. Hollywood and Olsen examine the Paleocene and Upper Jurassic Fulmar discoveries at Huntington in the UK Central North Sea, where the oil columns discovered exceeded the pre-drill predictions due to stratigraphic trapping elements. Similarly, Ward *et al.* review the HPHT Jasmine discovery, also in the UK Central North Sea, and where again the discovered hydrocarbon column exceeded pre-drill predictions, in this case by some 1100 feet, for reasons not yet fully understood but assumed to relate to fault seal. Rodriguez described the extensive de-risking of what was at the time an undrilled seismic anomaly/stratigraphic prospect West of Shetlands.

These papers and several unpublished oral presentations at the Conference illustrate the nature of exploration activity after four decades of North Sea exploration. Structural traps tend to be small and larger finds tend to occur in stratigraphic traps and complex or deep structural traps. The rich North Sea database lends itself to reworking and to the generation of new insights from comprehensive regional evaluation and the development of models which better integrate seismic-derived understanding of structural evolution and seismic, well and analogue-derived depositional and sequence stratigraphic constraints. It is not clear that such work is undertaken with the frequency, perspicacity and creativity that are justified.

Field development and production

Several papers typified the techniques which have been evolved to understand and tackle the reservoir complexities which pose challenges in the appraisal and development of North Sea fields in the fourth decade of activity in the basin. Challenges include low permeability, reservoir development and prediction, and modelling and understanding of the dynamic behaviour of the reservoir to permit continued commercial development.

Seismic methods including improved 3D data and the use of AVO techniques during appraisal and in a 4D sense during production have become routine and are substantial value drivers. Similarly, drilling, well logging and completion technologies are allowing new field development and the exploitation of progressively smaller per well reserves. The careful evaluation of all subsurface data and integration with well planning and construction are fundamental in realizing the value offered by these technologies.

The value of seismic methods is shown by Gordon *et al.* in the evaluation of gas-condensate reservoirs in Laggan and Tormore Fields, West of Shetlands, aided by the use of AVO techniques to reduce uncertainty on reservoir development. Witt *et al.* report on the start-up of the naturally fractured Clair Field, West of Shetlands, the drainage and completion strategies adopted and the use of permanent ocean bottom cables to assess the 4D response of the reservoir and improve production history matching.

Drilling and completion techniques are fundamental to the papers of Tringham *et al.* and Purvis *et al.*, who both describe the use of long-reach horizontal wells with multistage hydraulic fracturing to dramatically improve reservoir deliverability in low permeability gas-bearing sandstones in the Southern North Sea. Hampson and Walden provide an update on the two large producing heavy oil fields, Alba and Captain. Here intensive data gathering through multiple 3D surveys, the drilling of pilot holes and logging while drilling (LWD) techniques have allowed long horizontal development wells to be carefully placed to optimize recovery and commercially drain small in-field targets of the order of 1 to 2×10^6 bbl.

Several additional papers examined the continued exploitation of some of the North Sea’s largest fields. Gill and Shepherd describe the geological and reservoir management workflows used to identify field infill drilling targets and optimize field management in Nelson Field, themes continued by Brook *et al.* in their description of late stage infill drilling in the Scott–Telford field complex. Ray *et al.* describe the evolved geological understanding of the Buzzard Field sediment gravity flow reservoir and the insights achieved through integration of core, log and dynamic field data.

The challenges of HPHT field appraisal and development are elegantly captured in papers by Kape *et al.* and Quin *et al.* The former highlight the importance of careful geological evaluation and modelling given the inevitably under-appraised nature of HPHT fields. This carrying through of risk to the development phase is exemplified by Quin *et al.*'s paper, which demonstrates how the excellent reservoir encountered in appraisal drilling in Kristin Field on the Halten Terrace, NCS, was found through development and production to be unrepresentative of the appreciably poorer reservoir away from the appraisal wells.

Finally, and in a sense coming full circle, Reekie *et al.* review the redevelopment of Donan Field and the way that many of the field development techniques which have evolved in the last 20 years have allowed commercial redevelopment of a prematurely abandoned field.

Techniques in exploration and exploitation

This section covers a suite of papers which describe the use of a variety of geological, petrophysical, seismic and remote sensing techniques in exploration and production applications. The role of careful petrophysical evaluation is underlined by papers by Worthington and by Fabricius and Rana. Worthington describes a modus operandi for the recognition of bypassed pay, whilst Fabricius and Rana provide a case history evaluation of the post-fill tilted oil–water contact in the Danish chalk field, Tyra, through analysis of capillary pressure data. Staying with the chalk, Hampton *et al.* illustrate the development and use of a fully calibrated biostratigraphic zonation with particular intra-field applicability to aid well placement and reservoir management.

O'Connor *et al.* explore the use of well-derived pressure profiles to predict overpressure distribution and development and infer the development of topseal capacity whilst Purves *et al.* use 3D seismic data to map fault damage zones as a contribution to the assessment of fault-sealing potential.

With the rich North Sea datasets, seismic techniques continue to be instrumental in field exploitation in particular. A number of papers provide illustrations of current seismic applications. Rushmere *et al.* analyse the relative impact of acquisition and particularly processing improvements in increasing 4D signal-to-noise ratios, whilst Herwanger *et al.* examine the application of 4D techniques and their integration into dynamic field models at South Arne Field in Denmark. Abramowitz *et al.* expand the use of 3D integrated with well data and 2D seismic inversion into a regional study of intra-chalk porosity variations.

Finally, in the remote sensing domain, Hardy and Jones show how deepwater seismic data has unexpectedly revealed temperature and salinity stratification on the water column, whilst Olesen *et al.* publish results of the Geological Survey of Norway's aeromagnetic data acquisition and modelling, constrained by some 40 000 measurements of magnetic susceptibility and remnance to increase the utility and insight available through the modelling of magnetic data.

Abstract: A review is given of the development of the understanding of the structure and stratigraphy of a classic petroleum province through 35 years of NW European Petroleum Geology Conferences, using new examples to illustrate the interplay between tectonics and sedimentation in the development of some of the major hydrocarbon plays. Cimmerian tectonics is discussed, with regard to the evidence for regional-scale truncation beneath the Mid Cimmerian unconformity, and the stratal motifs characteristic of rifting associated with the Early and Late Cimmerian events. New data revealing the structural geometries associated with polyphase rifting in the East Shetland Basin are presented. The seismic and sequence stratigraphy of Jurassic and Cenozoic sequences are reviewed and new data presented, with a discussion of generic play controls in North Sea Jurassic deepwater reservoirs. The development of integrated hydrocarbon system studies is reviewed, and the remaining challenges to predictive capabilities discussed. The impact of advances in geoscience and technology on North Sea creaming curves is discussed.

Keywords: North Sea, hydrocarbon systems, Jurassic, Cenozoic, tectonics, seismic and sequence stratigraphy

The exploration of the North Sea has spanned over 40 years, and has paralleled significant advances not only in the quality and quantity of subsurface data, but also in the Earth sciences generally. Many aspects of North Sea geology we now take for granted developed as a result of the application of new and sometimes controversial geological concepts, the pioneering application of new technologies and many years of passionate debate.

This paper discusses the development of key geological concepts underpinning our understanding of North Sea geology in the 34 years since the publication of the first NW European Conference volume (Woodland 1975), illustrating the part played by the North Sea in the development of our understanding of fundamental geological processes and rift basins, specifically the structural and stratigraphic consequences of polyphase Mesozoic extension and uplift (the 'Cimmerian' tectonic pulses), and parallels in the sequence stratigraphic context of shallow to deepwater reservoir transitions in the Jurassic and Palaeogene. Developments in basin modelling studies are discussed. Throughout the paper, historical references to earlier North West European/'Barbican'/'PGC' conferences are made by way of reference to the date, editor or position of the conference in the sequence.

Regional setting

The geological evolution and exploration history of the North Sea has been comprehensively documented elsewhere, most notably in the precursors to this volume (Woodland 1975; Illing & Hobson 1981; Brooks & Glennie 1987; Parker 1993; Fleet & Boldy 1999; Doré & Vining 2005) and the North Sea Millennium Atlas (Evans *et al.* 2003). Figures 1 and 2 summarize the tectonic and stratigraphic architecture of the North Sea rift system, and highlight the location of the examples drawn on in this paper. The rift basin results principally from several phases of extension commencing in the Permian, climaxing in the Late Jurassic (the principal trap-forming event), with minor, more localized reactivation in the Albo-Aptian. Permian extension was superimposed on Carboniferous and Devonian strata subcropping the Base Permian 'Saalian Unconformity'. Coal-bearing Carboniferous provides the source to the Southern North Sea Gas Province, and both Carboniferous and Devonian reservoirs occur in traps on the rift flanks. Regional subsidence was punctuated by early Mid Jurassic uplift. Varying degrees of mild regional compressive pulses result in local basin inversion, most notably in the Late Campanian, and salt diapirism throughout the Cenozoic. With regards to the basin fill, a broad continental to marine transition occurs from Triassic to Late Jurassic. Reservoir-prone Triassic and Jurassic sequences are pervasive throughout the rift system, with the Triassic becoming shale prone in its lower parts towards the south. The Jurassic reservoirs give way to widespread Jurassic shales with generally increasing organic content towards the Jurassic–Cretaceous boundary, culminating in the world-class Kimmeridge Clay source rock. With the cessation of rifting at the end of the Jurassic, effective Cretaceous seals to much of the future hydrocarbon system were deposited across the abandoned rift topography. Locally developed Albo-Aptian sandstones were deposited basinally in response to hinterland rejuvenation resulting from extension switching to the proto-Atlantic margin. This critical phase in the history of the NW European margin was responsible for leaving the pre-Cretaceous plays of the North Sea largely intact. Widespread Late Cretaceous chalk deposition preceded the influx of significant quantities of Cenozoic coarse clastics in response to the emplacement of the Iceland plume and the corresponding uplift of the Scottish mainland. Post Palaeogene deposition is predominantly shale prone into a gently subsiding thermal sag basin.

North Sea tectonics, main themes and historical milestones

'Cimmerian' events and the North Sea Dome

The rift basin architecture of the North Sea rift was apparent on early vintages of seismic data, although not prior to the First

VINING, B. A. & PICKERING, S. C. (eds) *Petroleum Geology: From Mature Basins to New Frontiers – Proceedings of the 7th Petroleum Geology Conference*, 37–56. DOI: 10.1144/0070037

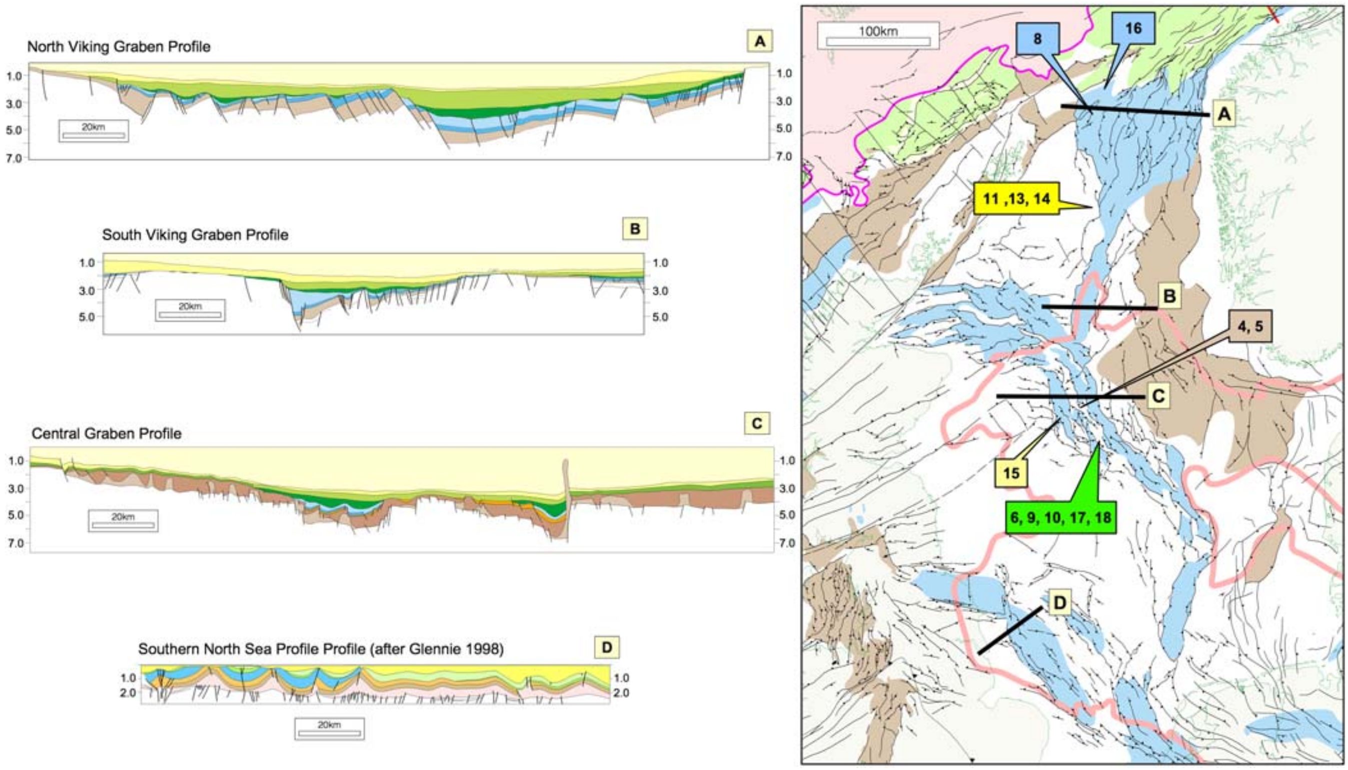

Fig. 1. Structural elements of the North Sea Rift. Map shows principal fault trends at the Base Cretaceous. Colour scheme on map shows timing of principal rift events, migrating westward towards ultimate Atlantic break-up in the early Cenozoic. Colour scheme for map corresponds to cross-sections. Zechstein salt on sections C and D in light pink. Locations of figures in text are numbered.

Licence Round in 1964 (e.g. Erratt *et al.* 2005), at which time only the Cenozoic sag basin was imaged. Ultimately, the major rift-related unconformity acquired a varied nomenclature, the terms Base Cretaceous, Late Cimmerian or 'X' becoming largely synonymous and interchangeable. The use of the term 'Cimmerian' was the subject of some debate, as evidenced by the discussion of P. Ziegler's paper in the proceedings of the first conference (Woodland 1975). The early regional syntheses of the Ziegler brothers led to the development of a model of a regional strain ellipse to describe the regional context of the Jurassic rift (Ziegler W. H. 1975*b*), and eventually to the appreciation of regional-scale uplift during the early Jurassic, Peter Ziegler's 'mid Cimmerian dome' (Ziegler 1981). In time, these studies were to prove prescient, demonstrating the importance of understanding regional-scale tectonics to provide rational models of rift evolution and play development (Fig. 3).

The 'Mid Cimmerian' and controls on effective Triassic reservoir distribution

The absence of Lower Jurassic strata via regional truncation led to Ziegler's interpretation of the regional 'Mid Cimmerian' unconformity, centred on the Rattray igneous province, as described in the 1981 volume (Illing & Hobson 1981). Detailed correlation and mapping of the truncation and onlap patterns by Underhill & Partington (1993) documented the areal extent of the dome. They considered the amount of uplift associated with the transient mantle plume to have been in the region of 400–500 m, somewhat less than earlier estimates. Davies *et al.* (1999) highlighted the minimal impact of the deflating dome on the stratigraphic architecture of the succeeding Late Jurassic rift.

Underhill and Partington's (1993) detailed stratigraphic correlations and analyses demonstrated the regional overstep of the Middle and Late Jurassic across the unconformity, truncation patterns to the north and west, facilitated by the well-constrained stratigraphies of the Viking Graben and Inner Moray Firth respectively. The progressive subcrop of the Mid Cimmerian Unconformity towards the dome centre from the south was not as extensively documented as those from the north and west, hampered by the lack of deep well data from the Central Graben, the absence via truncation of a readily correlatable Liassic sequence, and the lack of a sufficiently detailed Triassic stratigraphy in the Central Graben to facilitate recognition of a regional subcrop pattern.

At the first conference, a review of the Triassic by Brennand (1975) shows a heavily truncated Triassic section present across the Central Graben region, comprising only the basal Triassic Bunter Shales (later named Smith Bank Formation). This interpretation reflected both the paucity of well control and the inevitable bias introduced by wells drilled on eroded structural highs (see comparison in Fig. 5).

The field of Triassic stratigraphy has witnessed one of the more notable advances in our understanding of North Sea geology. The work of Phil Goldsmith (e.g. Goldsmith *et al.* 2003) showed that in the Central North Sea, in particular, sequences are correlatable over a wide area, in spite of being deposited in a continental setting in which bio-stratigraphic control is scarce, and where active basement extension and accompanying salt tectonics resulted in significant lateral thickness variations. Nonetheless, climatically controlled signals represented by repeated lacustrine transgressions still enable a relatively high degree of confidence in well correlation.

Following Brennand's initial foray into the Triassic, further drilling in the Central North Sea area, especially in the high pressure/high temperature domain (McKie & Audretsch 2005; Erratt *et al.* 2005) revealed a sand-prone section of regional

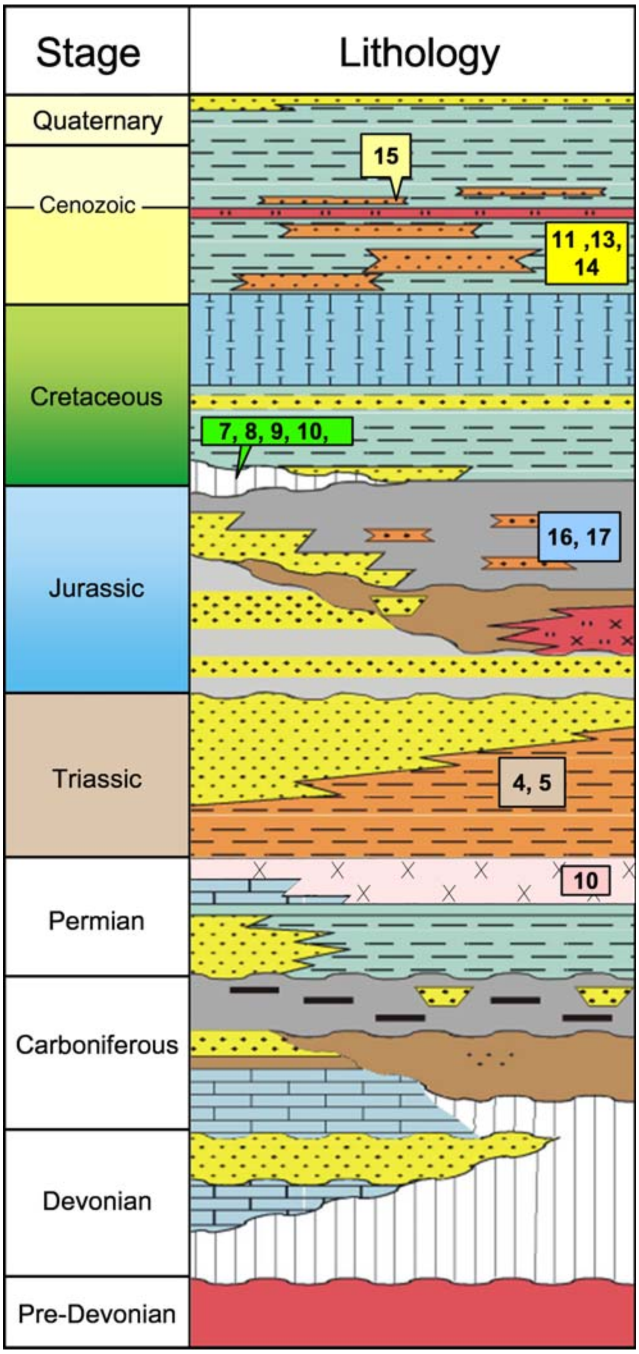

Fig. 2. Generalized stratigraphy of the North Sea Rift (after Vining *et al.* 2005). Location of figures in text are numbered.

extent succeeding the Smith Bank/Bunter shales (the Skagerrak Sandstones), and a regionally extensive unconformity at the base of the Middle Jurassic which cuts progressively further downsection towards the north and the centre of the mid Cimmerian 'dome'. The Triassic stratigraphy of the North Sea Rift is summarized in Figure 4. The refinement of the standard two-fold nomenclature of the Smith Bank Shale and Skagerrak Sandstone Formations into a regionally correlatable section based on the 'J' Ridge area (Goldsmith *et al.* 1995, 2003) moved the stratigraphy of the Central North Sea closer to the classic Germanic three-fold subdivision of the Bunter, Muschelkalk and Keuper. Coupled with improved regionally extensive 3D seismic data, the resulting higher resolution litho and seismic stratigraphy (Fig. 5), enabled the recognition of a subcrop pattern of the Triassic beneath the Mid Cimmerian unconformity to the south of the dome, further reinforcing the models of Ziegler (1981) and Underhill & Partington (1993). This regional truncation, which on structural highs is further accentuated by the later Base Cretaceous/Late Cimmerian unconformity, controls the northern limit of high quality Triassic reservoirs of the upper units of the Judy Member of the Skagerrak Formation. Tests north of this truncation line are uniformly disappointing until younger section re-occurs on the northern flank of the 'dome'.

Late Cimmerian tectonics and fault geometries

Since the initial 1975 volume, the application of the 'Cimmerian' nomenclature to the North Sea, the precise timing of the multiple phases of extension associated with Mid Jurassic to earliest Cretaceous tectonics, and the origin of the structural events in terms of the dominant structural processes have been the subject of extensive and long running debate (see discussion of Ziegler's 1975 paper). Subsequent accounts describe the complexities of the stratigraphy of the Jurassic/Cretaceous boundary in the North Sea, particularly Rawson & Riley (1982), Partington *et al.* (1993) and Rattey & Hayward (1993). All of these have run alongside the development of the paradigm established by McKenzie (1978) in the evolution of sedimentary basins, and failed rifts of the North Sea type in particular, which ushered in a parallel debate about the quantitative modelling of subsidence, thermal history and the evolution of hydrocarbon systems.

The single most telling factor in the advancement of our collective understanding of the dominant structural processes has been the acquisition of a regionally extensive blanket of 3D seismic data. Interpretation of these data, combined with dense high-quality well control and detailed quantitative structural analyses, eventually resulted in a regionally coherent picture of the structural evolution of the North Sea Rift, reconciled with the tectonic evolution of NW Europe and the European Atlantic Margin. For the purposes of the following account, the terms Mid Cimmerian will refer to the Base Mid Jurassic unconformity as described by Ziegler (1981) and Underhill & Partington (1993), whilst the Late Cimmerian will be used synonymously with the Base Cretaceous seismic event and group of related surfaces forming the regional surface of passive onlap.

Crustal scale deformation: pure and simple shear, basin forming mechanisms

Early contributions to the debate on the structural evolution of the North Sea rift built on the early regional syntheses by the Zieglers, describing the interaction of the predominantly extensional tectonic regime with the pre-existing Palaeozoic structural fabrics (e.g. Threlfall 1981). By the mid 1980s the acquisition of deep reflection profiles around the UK Continental shelf, in particular the BIRPS programme (e.g. McGeary *et al.* 1987), had been extended to the North Sea, and ushered in a new debate around the role of crustal scale detachments (e.g. Wernicke 1985) in the formation of the basin. The third conference (Brooks & Glennie 1987) contained significant contributions from Gibbs (1987) and Beach (1987) which interpreted the crustal scale structural development of the basin in light of these new models. By the 1990s models invoking both pure and simple shear were emerging (e.g. Kusznir *et al.* 1991). The debate expanded by the time of the fourth conference to encapsulate the observations by a number of workers (e.g. Ziegler 1983) that extension measured from fault heaves or the dip of fault blocks could not be reconciled with that predicted by subsidence analysis (see discussion in Roberts *et al.* 1993). The difficulties in applying their techniques were highlighted at the time, in particular those associated with halokinesis in the Central Trough region of the North Sea. These may present issues to revisit given both the extent and quality of the regional 3D coverage

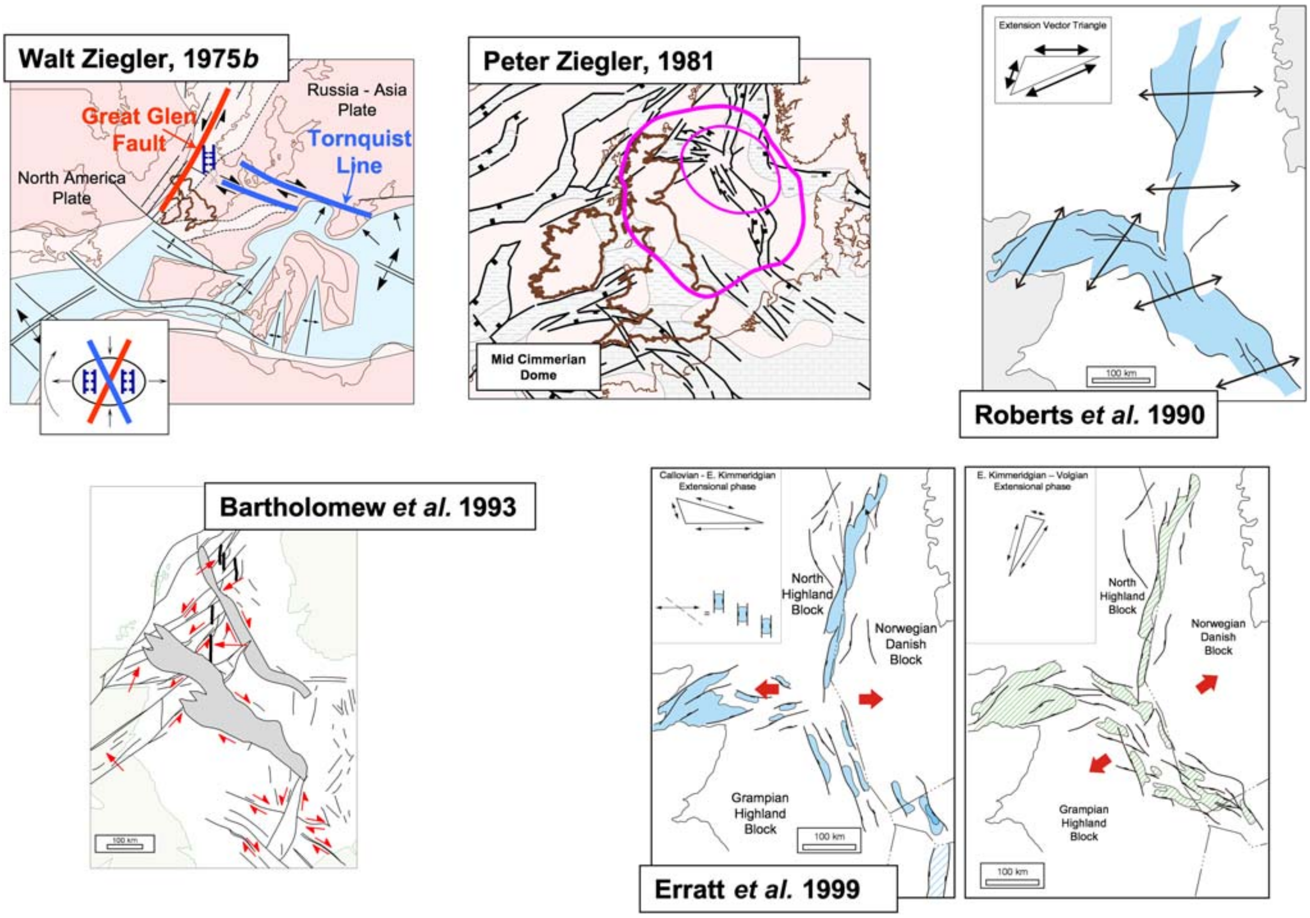

Fig. 3. The evolution of North Sea tectonic models. A regional strain ellipse to describe the regional context of the rift (after Ziegler 1975*b*), Peter Ziegler's 'mid Cimmerian dome' (after Ziegler 1981; Underhill & Partington 1993). Extensional models (e.g. Roberts *et al.* 1990; Erratt et al. 1999) competed with strike-slip (e.g. Bartholomew *et al.* 1993) as databases and imaging improved.

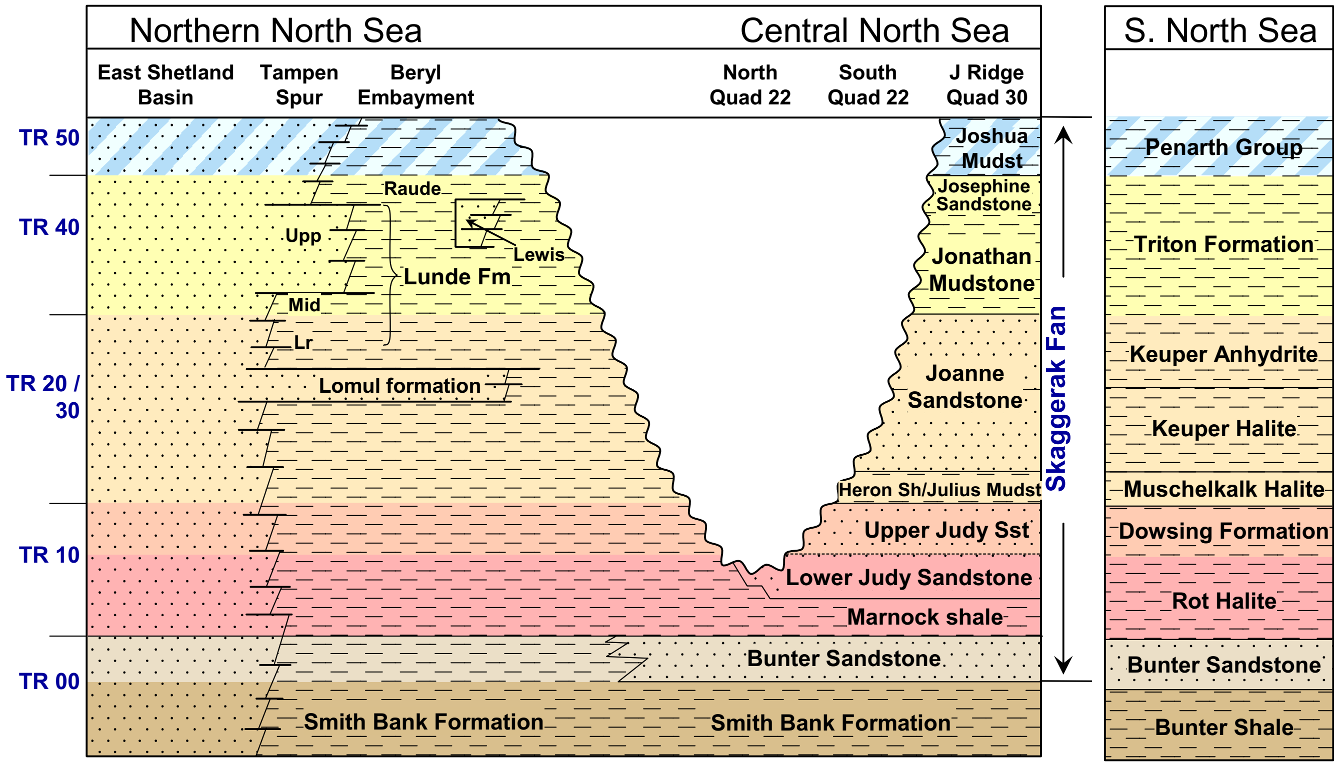

Fig. 4. The Triassic stratigraphy of the North Sea Rift (after Goldsmith *et al.* 2003).

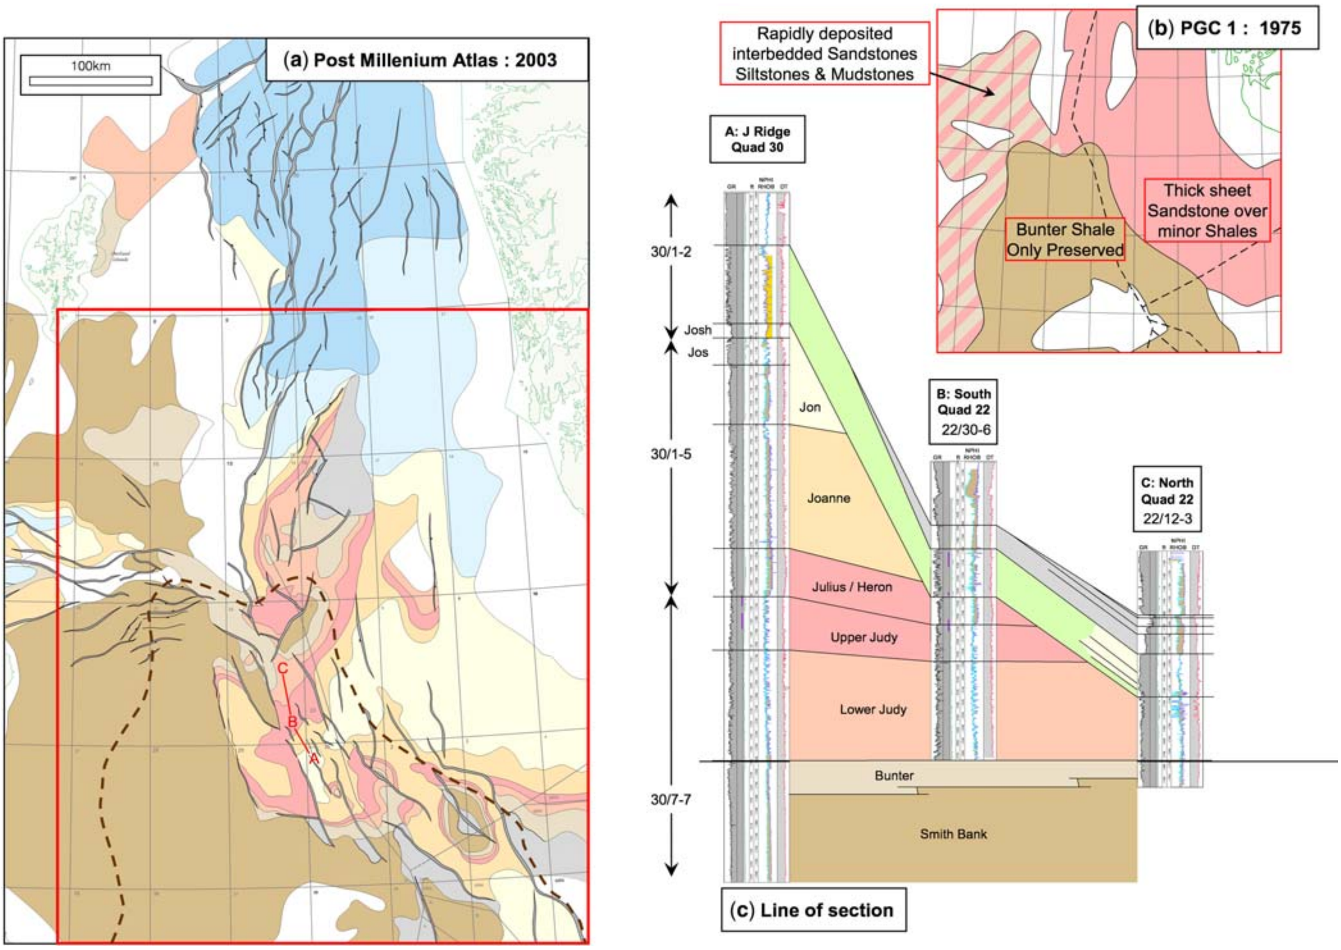

Fig. 5. (**a**) Truncation of Triassic strata beneath the 'Mid Cimmerian' unconformity in the Central North Sea, and the Jurassic subcrop of the unconformity in the Viking Graben. (**b**) A comparison with early models based on considerably less well data (after Brennand 1975). (**c**) Well data from the Central North Sea illustrating truncation of the Triassic beneath Middle Jurassic. Colour code for Triassic as in Figure 4. White areas are structural highs with no presumed deposition; cross-hatched areas interpreted as Triassic eroded beneath Base Cretaceous Unconformity.

now available and new interpretations of the kinematics of Jurassic rifting. The relative merits of the pure shear and simple shear models are captured by Zanella *et al.* (2003), and as indicated by them, the application of new insights resulting from concepts of depth-dependent extension (e.g. Karner & Kusznir 2007) suggests potentially important developments in understanding the history of North Sea extension and subsidence.

Structural processes at a trap scale: strike- v. dip-slip and salt tectonics

Addressing the linkage between the deep crustal structure and the prevailing structural style in the prospective Mesozoic basin fill required 3D data of regional extent. Its arrival ushered in an alternative pervasive regional control for structural geometries on a trap scale, in the form of strike-slip tectonics. One of the main talking points of the fourth conference (Parker 1993) was the debate surrounding the merits of this model, largely superceding the discussions of pure v. simple shear and large-scale basin geometries in the context of the PGC conferences.

Basement-involved strike-slip faulting had been invoked as a dominant process in the Southern North Sea/Zechstein basin. In this basin, two dominant fault orientations are apparent, with localized inversions along the WNW trend. The pattern of two dominant fault trends with a preferential inversion of the WNW trend is repeated in the Central Trough area of the main North Sea rift, and was documented by Erratt *et al.* (1999). Jurassic age strike-slip faulting as the dominant structural process in the main rift system, however, was somewhat more contentious. Possible examples of strike-slip-related structures were presented from a number of North Sea domains. Whilst all were drawn from 3D seismic data, two prevailing issues required reconciliation. Firstly, in the Central Trough, were structural geometries the result of pervasive strike-slip faulting (e.g. Bartholomew *et al.* 1993), or the interplay between salt tectonics and basement extension? Secondly, how were structural geometries throughout the North Sea impacted by the multi-phase extensional history recorded across the entire region?

Polyphase rifting

The interaction of the multiple phases of Mesozoic extension on a regional scale was persuasively demonstrated by Doré *et al.* (1999). This regional-scale overprinting placed the evolution of the North Sea structural fabrics in a consistent regional framework, and with the availability of regionally extensive 3D coverage within the North Sea, was able to place some of the more problematic 2D structural and stratigraphic geometries in an appropriate context (Fig. 6). The 3D coverage provided the necessary vertical and areal resolution to overcome difficulties in fault aliasing and reliable seismic stratigraphic correlation. Much of the debate in the 1990s revolved around the Central Trough. However, data from elsewhere in the North Sea does not suffer from the ambiguities presented by the overprint of salt tectonics. Figure 7 illustrates

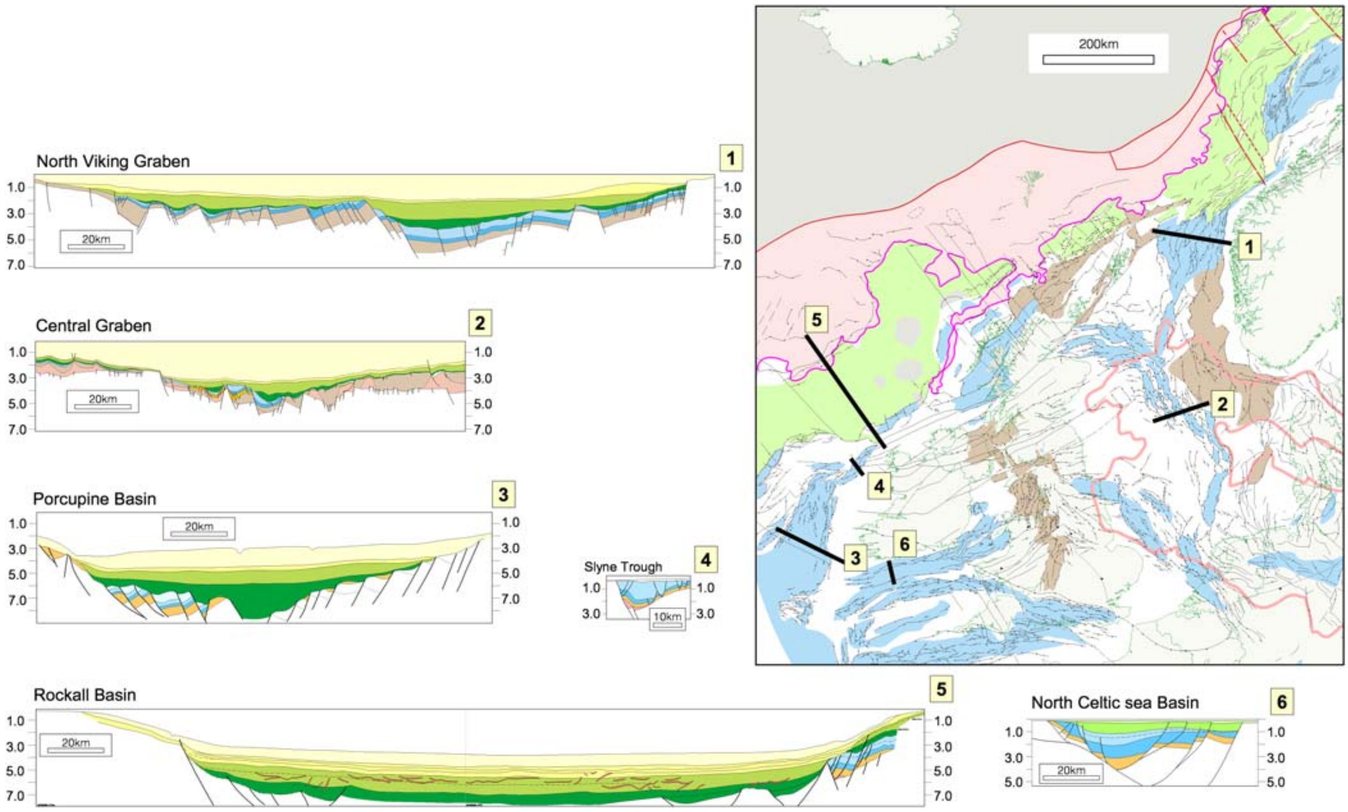

Fig. 6. Comparative NW European basin architectures illustrating regional-scale polyphase rifting. Colour scheme for map and sections as in Figure 1.

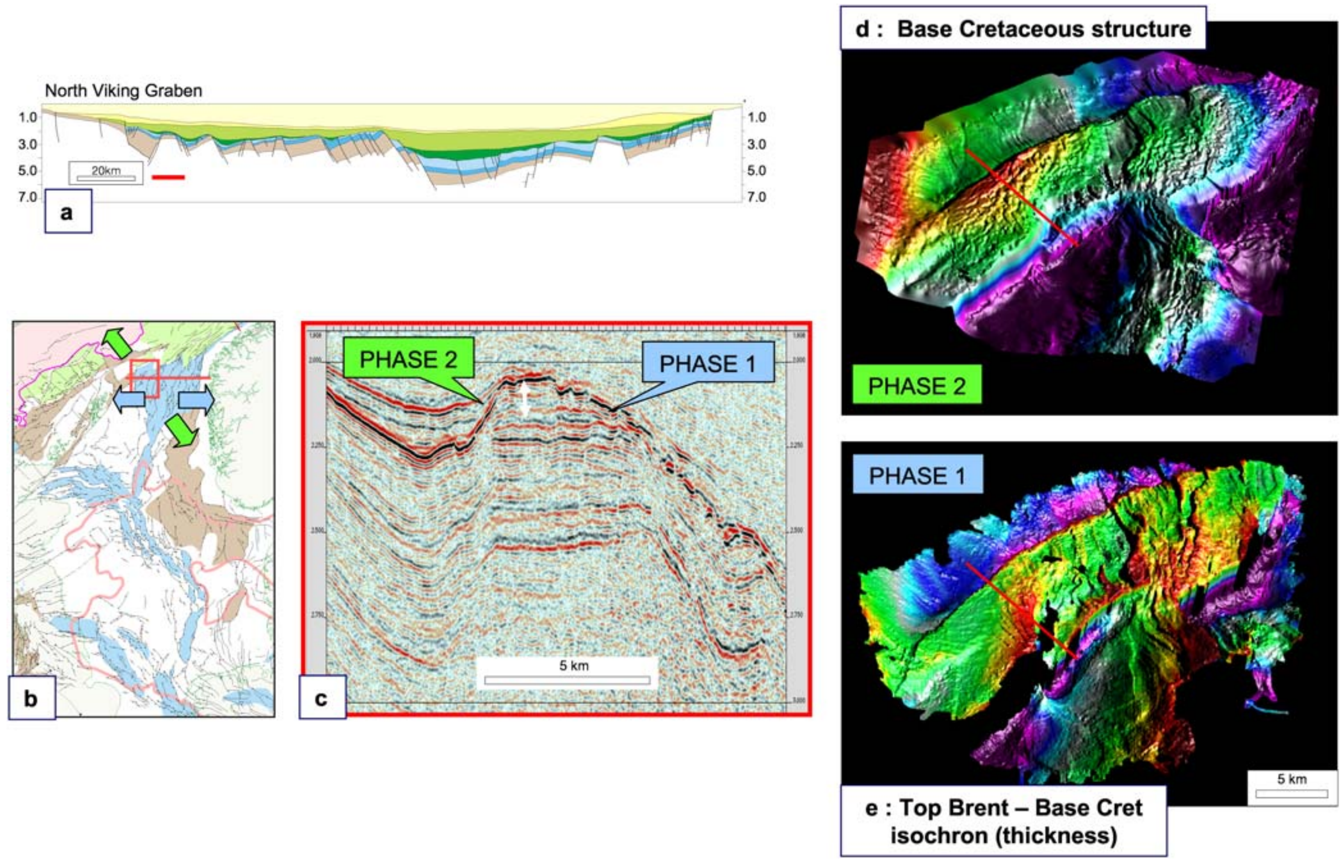

Fig. 7. The interplay of multiple phases of Late Jurassic extension in the evolution of the Tern Horst, ESB, UK Quad 210. Seismic line (**c**) is located on regional cross-section (**a**) and shaded relief images (**d** and **e**) by red lines. Shaded relief images illustrate the two phases of rotation of the feature, resulting in the unusual erosional profile of the feature beneath the Late Cimmerian. Upper image (d) is TWT structure to Base Cretaceous (red, highs; purple, lows), lower (e) is Base Cretaceous to Top Brent TWT thickness (red, thins; purple, thicks, arrowed on seismic section) draped on the Top Brent time surface. Two phases of rotation denoted by green and red arrows and cross-referenced to extension directions shown on structural elements map (**b**).

the interplay of multiple phases of Late Jurassic extension in the evolution of the Tern Horst, a prominent feature towards the western margin of the East Shetland Basin (ESB) in UK Quad 210. The seismic section illustrates a long-observed peculiarity of the Tern Field. The crest of the structure at Base Cretaceous/Late Cimmerian level is underlain by a section of Upper Jurassic Kimmeridge and Heather Shale, which thins downflank towards the east, towards the axis of the Viking Graben. The thinning is clearly the result of truncation at a horizon at or just beneath the Late Cimmerian surface. This trend is counter to the more commonly observed thinning towards the crest of a westerly dipping structure, which dips away from the axis of the graben at all pre- and syn-rift stratigraphic levels, exemplified by structures such as the Brent Field. A shaded relief image of the Late Cimmerian surface shows two main fault trends, a NE–SW trend defining the Tern Horst, and a lesser north–south trend superimposed on top of the horst and extending beyond it. Coupled with the stratal relationships evident on seismic, the horst block can be seen to be the result of at least two phases of extension post-deposition of the Brent reservoir section. The first rotated structures along north–south faults away from the axis of the graben, resulting in truncation of a structural crest on the east side of the present day horst. The second event, resulting in faults along the NE–SW trend, re-orientates and overprints the earlier fabric and rotates structures away from the axis of the proto-Atlantic rift. The re-utilization during Late Jurassic rifting ('Late Cimmerian') of earlier Triassic faults ('Early Cimmerian') in the ESB is sporadic, a characteristic also illustrated by the Tern Horst and the interplay between the Jurassic margin of the ESB and the Triassic Unst Basin (Fig. 7). The eastern bounding fault of the Unst Basin constitutes the northwestern bounding fault of the Tern Horst as the former continues on a northeasterly trend beneath the Jurassic fault block terrane of the ESB. This fault is reactivated as described above and forms a receiving half-graben to Upper Jurassic deep-water sands, broadly equivalent in the context of the first-order tectono-stratigraphic evolution of the basin to the reservoirs at the Magnus Fields. These sands, like those at Magnus, are themselves rotated and truncated by end Jurassic/earliest Cretaceous movement along the northerly trending western margin of the ESB.

Examples of poly-phase rifting in the Central North Sea and Moray Firth have been documented elsewhere (e.g. Hibbert & Mackertich 1993; Erratt *et al.* 1999), which built on the work of Roberts *et al.* (1990), and continued to compile a compelling body of data in support of dip-slip models. By the time of the fifth conference, the completion of the emerging regional blanket of 3D seismic data, and the appearance of the elegant reconciliation of basement extension and salt withdrawal by Helgeson (1999), had gone a long way to resolving the questions raised by the strike-slip v. dip-slip debate of the fourth conference (Figs 8 & 9).

Implications of trap scale salt-related geometries for regional tectono-stratigraphy

The role of salt tectonics in determining the structural fabric of the Mesozoic section of the Central Trough, and the platform areas in particular, surfaced during the 1980s, partly in response

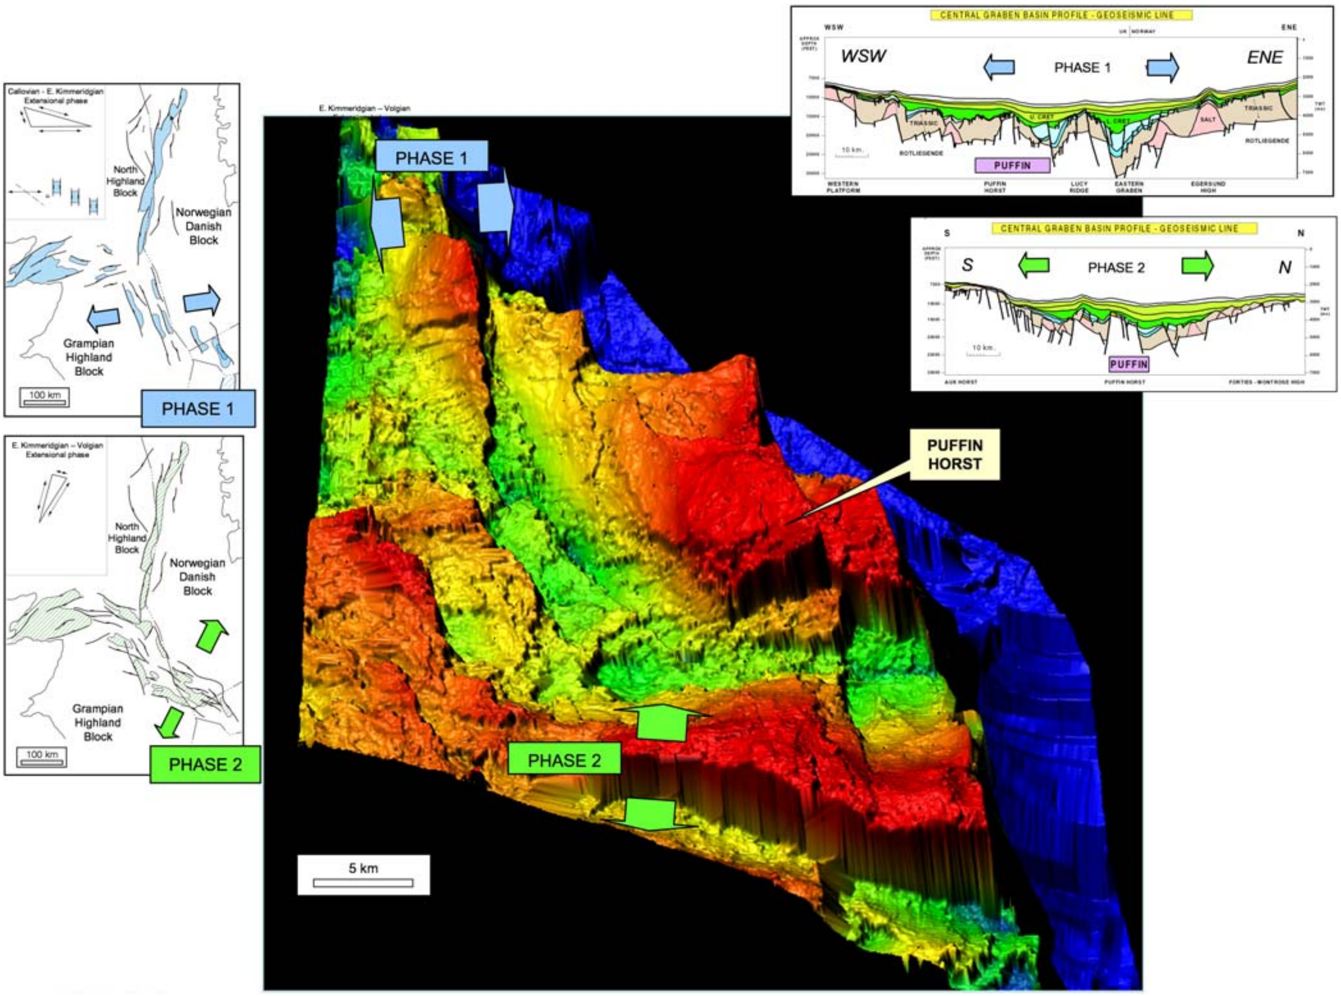

Fig. 8. Shaded relief image of the Base Zechstein surface on the Puffin Horst area of the Central North Sea (red, highs; blue, lows). Two dominant fault trends are apparent, corresponding to the polyphase model of Erratt *et al.* (1999) as shown on maps. The regional sections locate the horst within the wider graben area.

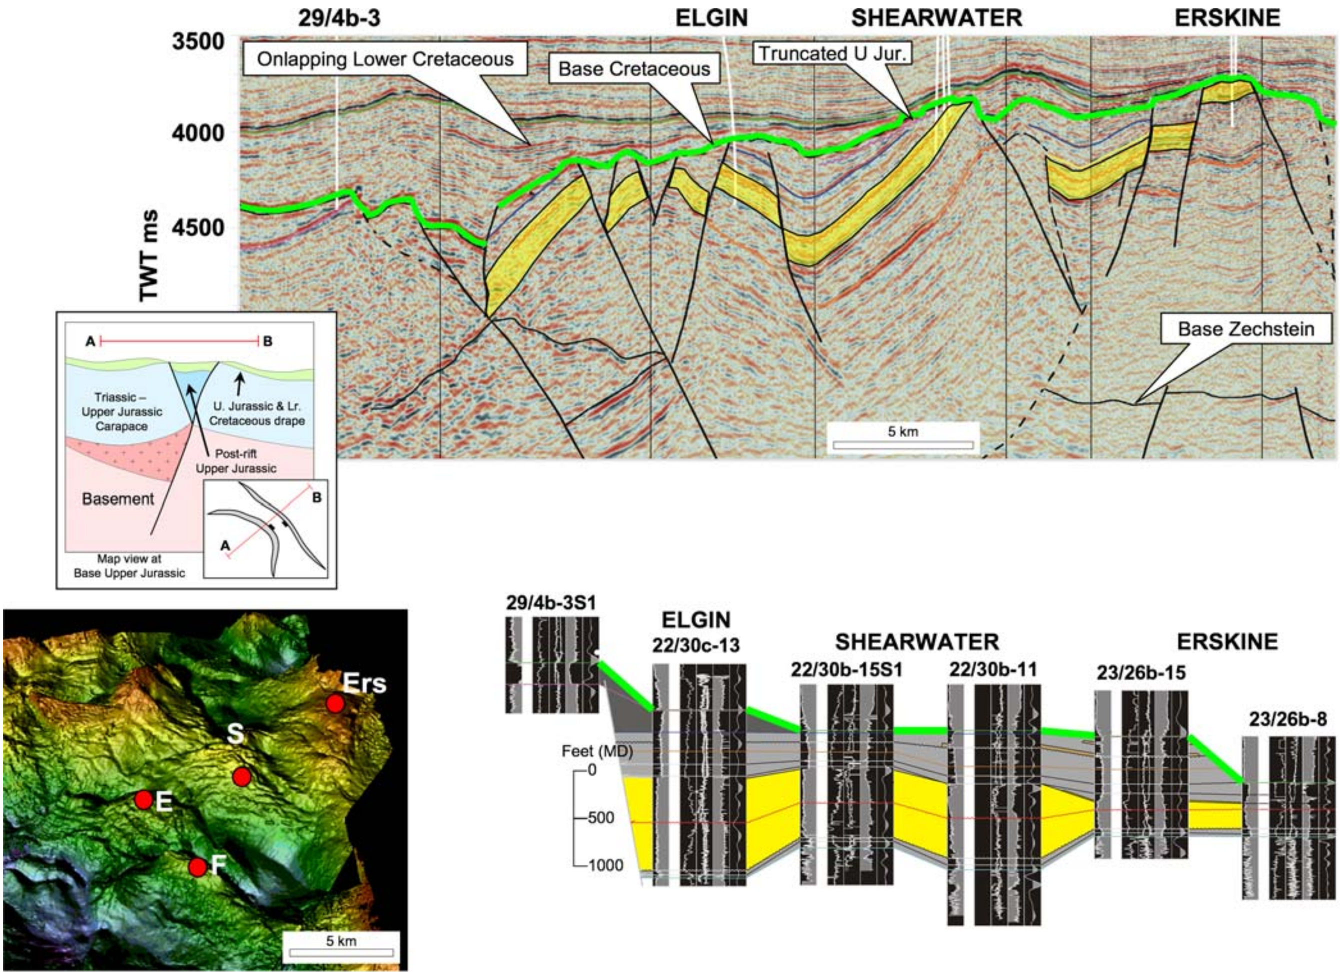

Fig. 9. Seismic line illustrating Helgeson's (1999) model of interaction between pre- and post-salt sections during Cimmerian rifting and the impact of polyphase rifting on the stratal relationships above and below the Base Cretaceous surface.

to structural models invoking gravity driven processes (e.g. Gibbs 1984). Smith (1987) in the third, and Wakefield *et al.* (1993) and Erratt (1993) in the fourth conferences illustrated the alternative salt withdrawal hypothesis, the latter introducing the 'pod'/'interpod' terminology to describe areas of complete salt withdrawal and grounding of the Triassic section, and areas of preserved Zechstein salt respectively. Stewart (1993) described similar features from the Norwegian sector (e.g. the Ula Field), whilst Stewart & Clark's (1999) paper in the fifth conference was a thorough synthesis of the previous studies in the light of new examples. These debates took place against a backdrop of considerable uncertainty in the amount of Zechstein salt underpinning the Mesozoic section of the Central Trough, apparently acting as a regional-scale decollement between the Mesozoic carapace and the underlying rifted basement. Initial models of the basin, and resulting regional transects (e.g. Glennie 1998) indicate a relatively thick, continuous salt section across the main graben areas (Fig. 10). Conversely, the platform areas, having given rise to the development of the pod–interpod model and consequent total salt withdrawal, point to a pattern of frequent welding of the Triassic section with the Palaeozoic of the rift floor. Stewart & Clark (1999) demonstrated that much of the salt withdrawal had taken place as early as the Triassic. Regional considerations of poly-phase rifting indicated that, for the most part, the main locus of Triassic rifting was offset relative to the main Jurassic graben (e.g. Erratt *et al.* 1999). As such, it was unlikely that the thick salt invoked in earlier models would be accommodated by an age model invoking Permian rifting providing the necessary accommodation for the thick Zechstein sequence. Helgeson's model, which invoked frequent welding of the pre- and post-salt section, pointed towards a much thinner regional salt layer beneath the graben, and for the first time provided consistency in interpretation of the structural fabrics of graben and platforms.

The Late Cimmerian: fundamental change in rift architecture and stratal geometries

The debate over the applicability of the 'Cimmerian' nomenclature to some extent clouds the fundamental observation that the Late Cimmerian event in the North Sea rift marks a fundamental change in rift architecture and accompanying structural geometries relative to earlier rift events.

Sinclair *et al.* (1994) drew attention to the changing stratal geometries throughout the Jurassic in their consideration of the Jean d'Arc, Outer Moray Firth and Porcupine Basins. The stratal patterns described in the Porcupine Basin, in the sequences onlapping the Late Cimmerian unconformity, mimic those in the North Sea, showing passive onlap, which contrasts markedly with the classic 'syn-rift', fanning stratal geometries of the bulk of the Upper Jurassic section (e.g. Figs 7 & 9). The polyphase rift model of Erratt *et al.* (1999) describes the overprint of the latter by the former, although their account does not explicitly describe this fairly obvious phenomenon. Similarly, their published cross-sections show the overprint of the two basin types in both the ESB (Fig. 7), where the Late Cimmerian 'Tern Horst' overprints the Triassic Unst Basin and earlier Late Jurassic structures, and in the Central North Sea, where the 'strike lines' to the earlier phase rifts become 'dip lines' to the last ('Late Cimmerian') phase as

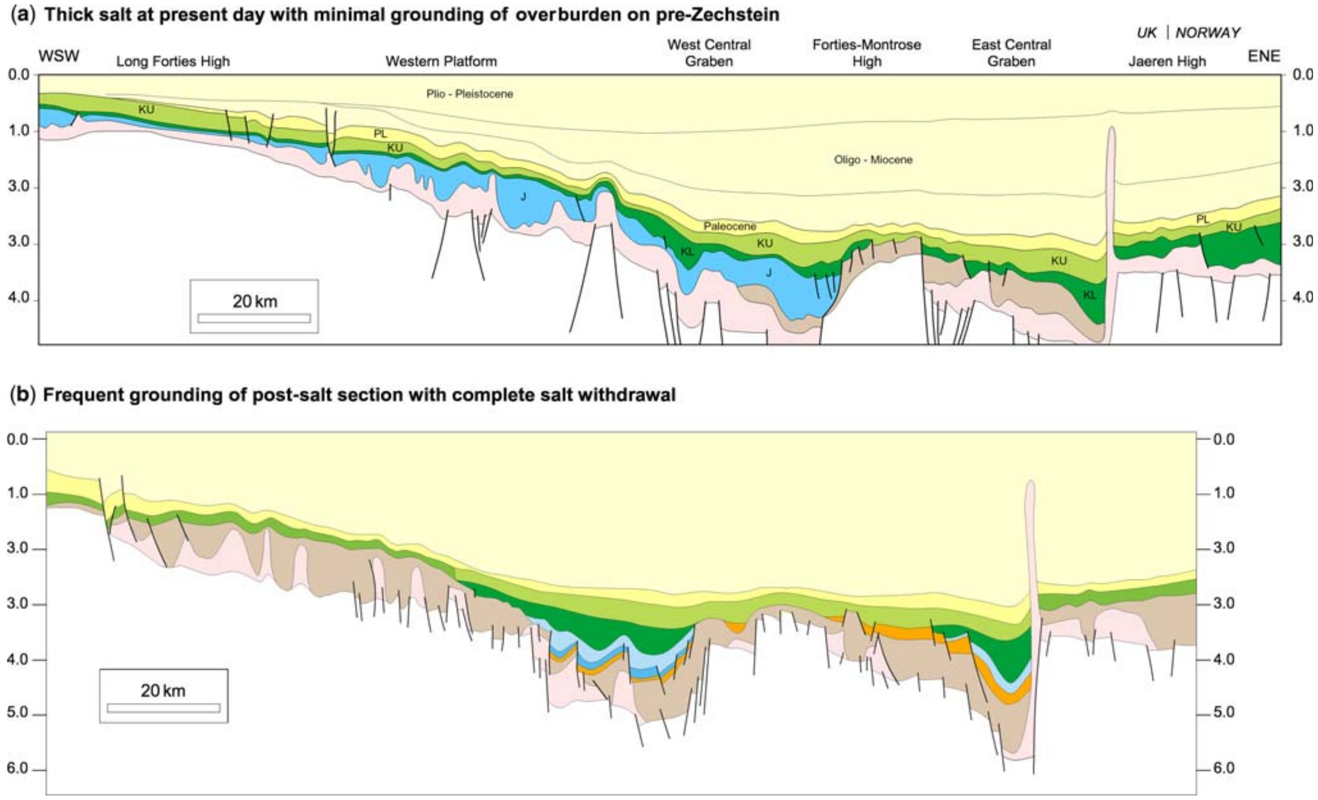

Fig. 10. Comparison regional traverses. (**a**) Early models (e.g. after Glennie) of the basin indicate a relatively thick, continuous salt section across the main graben areas. Later models (**b**) indicate a hard linkage via a thinner initial salt thickness. Colour scheme as in Figure 1.

extension vectors change (see figures in Erratt *et al.* 1999). New perspectives on basin architecture and rift timing, coupled with the application of robust sequence stratigraphic models, leads to an appreciation of the spatial distribution of Jurassic basin floor reservoirs. A possible explanation for the relative lack of success in this play in certain parts of the rift system results, and is discussed in a subsequent section.

North Sea deepwater reservoirs: some comparisons between the Palaeogene and Late Jurassic

The ground-breaking regional studies published by geoscientists from BP in the fourth conference (Parker 1993) marked a major milestone in the wider understanding of the interplay between North Sea tectonics and stratigraphy, and more generally, the application of sequence stratigraphy in a syn-rift setting (e.g. Partington *et al.* 1993; Rattey & Hayward 1993; Underhill & Partington 1993). The early seismic stratigraphic analysis by Vail & Todd (1981) of the Northern North Sea Jurassic sequences appeared in the proceedings of the second conference, the landmark 1977 AAPG Memoir 26 (see Fig. 12) having appeared between the first and second conferences. Data quality and limited seismic resolution were barriers to the application of the technique throughout much of the Brent province and the Jurassic sequences of the entire rift. Subsequently, however, the Upper Jurassic 'Troll delta' presented some well-imaged progradational geometries, and these are presented and discussed in the Millennium Atlas (Fraser *et al.* 2003).

Cenozoic examples and play considerations

Cenozoic sequences in the North Sea present better subjects for seismic stratigraphic analysis than their Jurassic counterparts, being thicker, shallower and preserving complete, largely undeformed shelf to basin transitions, as evidenced by the early examples published by Vail and his co-workers in the aforementioned AAPG memoir. The stratal relationships typical of progradational highstand sequences can be observed even on the earliest vintages of 2D seismic coverage. Subsequently, regional-scale 3D seismic coverage revealed a higher-order stratal architecture internal to the shelfal, highstand sequences, as well as a detailed picture of the distribution and architecture of basin floor, lowstand reservoir sequences (e.g. Fig. 11). Figure 13 illustrates the higher-order architecture of the Late Paleocene ('Sele/Hermod') shelf. Well 9/18-30 penetrated a thick sandstone section, with a distinctive blocky gamma ray signature. Seismic data indicates a high-amplitude planar, gently basinward dipping reflector at the base of this sequence. This unit is interpreted as an example of a lowstand 'shelf margin wedge'; the basal reflector marks a sequence boundary, possibly an example of the early 'Type 2 Sequence Boundary' of the type described by the Exxon group in their early publications. This represents a basinward shift in facies without significant bypass of the shelf and corresponding deposition of sand on the basin floor. The blocky signature of the sandstone section in 9/18-30 shows a predominantly aggradational stacking pattern, itself indicative of deposition during a relative lowstand of sea-level (e.g. Van Wagoner *et al.* 1990). The association of these phenomena in a relatively subtle manifestation of the sequence stratigraphic model may serve as a template for certain aspects of Upper Jurassic shallow marine depositional systems in other parts of the North Sea which do not benefit from direct seismic imaging of stratal geometries by virtue of depth and consequent limited seismic resolution. The application of this template to the Upper Jurassic is discussed in a subsequent section.

The latest Paleocene shelfal 'Hermod' sequences are succeeded by isolated, mounded deepwater basin floor sands of the Early Eocene Balder Formation. These are very well sorted sands

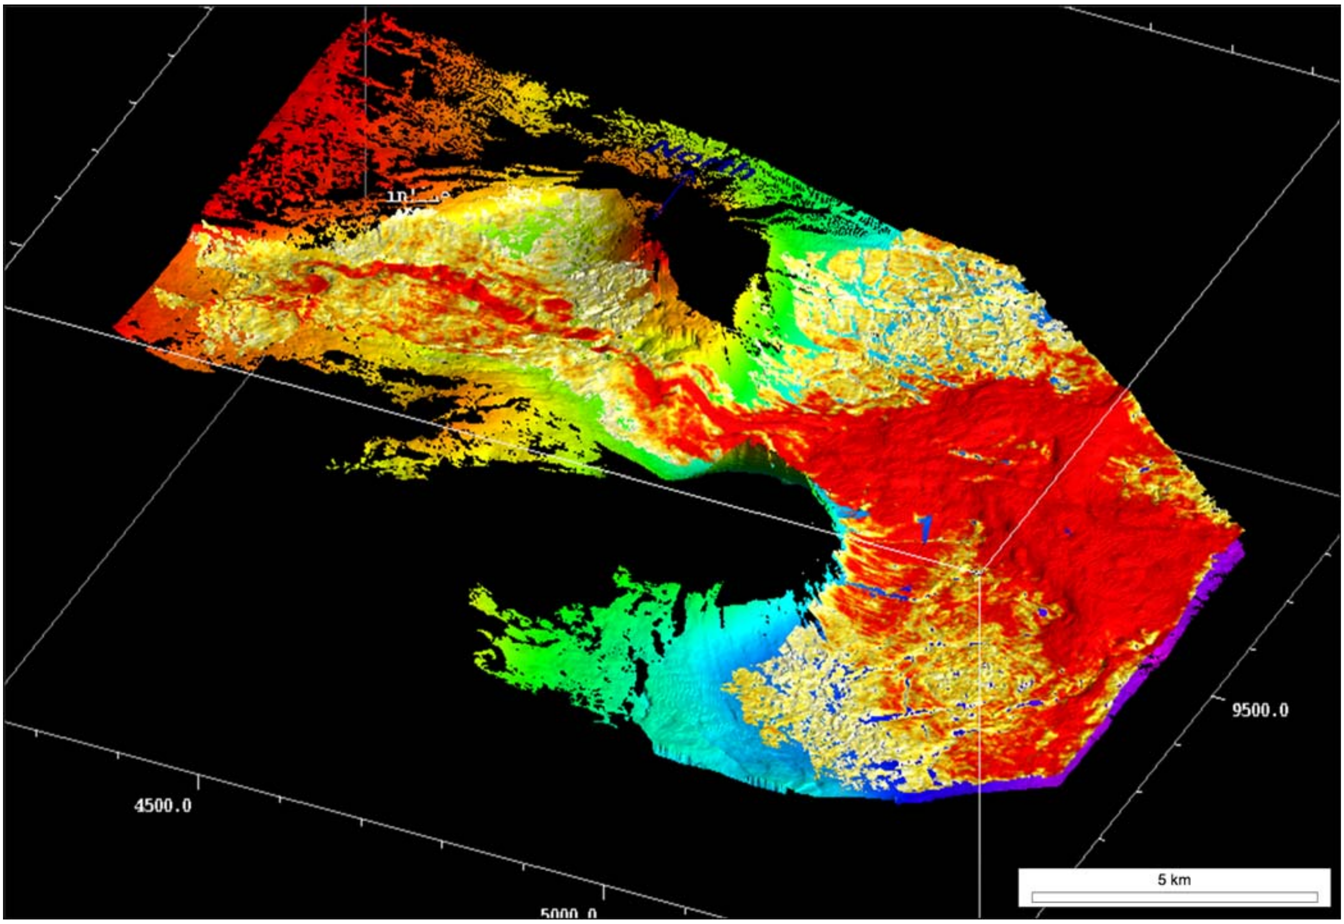

Fig. 11. Eocene Tay formation fan system, Gannet Area, Central North Sea. The distribution of Eocene sands is shown in red derived from seismic amplitudes, draped on the top Paleocene time structure (red, high; purple, low). The shorter face of the reference box is 10 km wide.

re-deposited from a shallow marine setting (e.g. Dixon & Pearce 1995), probably indicating the widespread collapse of a shelf margin system similar to the underlying Hermod system.

Sandstone injectites

Before turning to Jurassic depositional systems, the Cenozoic sequences of the Northern North Sea and their high-quality seismic images merit further attention with regards to the definition of play fairways and the role of sandstone injectites.

Our understanding of the importance of sandstone remobilization in modifying the configuration of North Sea Cenozoic reservoirs has evolved dramatically since the availability of 3D seismic data (e.g. Lonergan *et al.* 2000) and was discussed by Hurst *et al.* (2005) at the sixth conference. The Cenozoic basin floor sequences of the Northern North Sea area display large, mounded geometries, typified by the Eocene Harding/Gryphon fields of the UK Beryl Embayment area, and the Paleocene/Eocene Balder Field in the Norwegian sector. Although occurring in different parts of the stratigraphy, and in markedly different locations, these fields have in common their location above the flanks of underlying westerly dipping rift elements, counter to the regional west–east sediment input direction of the Cenozoic sequences.

On a first-order scale these opposing dips account for the location of the two principal fairways in the Cenozoic play in this sector of the North Sea. The example of the Balder trend against the eastern flank of the underlying rift shoulder is repeated further south in the Sleipner and Everest complexes. The block diagrams of the UK Quad 9 play area in Figure 14a illustrate this setting.

The Balder Field and Harding/Gryphon complexes are further characterized by injectite complexes, occurring at all scales from core to seismic. Injectite complexes on a field scale present opportunities for near-field exploration. However, the relative lack of exploration success in many apparent four-way top reservoir closures, amongst mounded basin floor features away from the main play fairways, is probably due to the regional-scale effects of sandstone injections. Such areas are typified by failure to encounter hydrocarbon columns in the main massive reservoir sequences in structures displaying apparent four-way dip closure, and the occurrence of hydrocarbons in overlying injectites (e.g. 9/15-3 in Fig. 14b). This suggests that closure height at base of the ultimate top seal, effectively at the crest of the injectite 'swarm', is the key element in defining the relationship between closure height and the likelihood of encountering hydrocarbons in the massive 'primary depositional' reservoir section. Structures in the two main play fairways described above benefit from the inherited 'counter-depositional' dip relative to regional facies trends, allowing the build-up of hydrocarbon columns through the injectite swarm and into the massive reservoirs.

Upper Jurassic deepwater depositional systems

The Upper Jurassic depositional systems of the North Sea have been the subject of extensive regional studies, and multiple generations of stratigraphic schemes, summarized by Fraser *et al.* (2003) in the Millennium Atlas. In the BP studies published in the proceedings of the fourth conference, Partington *et al.* (1993) referenced the Upper Jurassic deepwater reservoirs of the Central North Sea as one of the remaining underexplored exploration plays of the

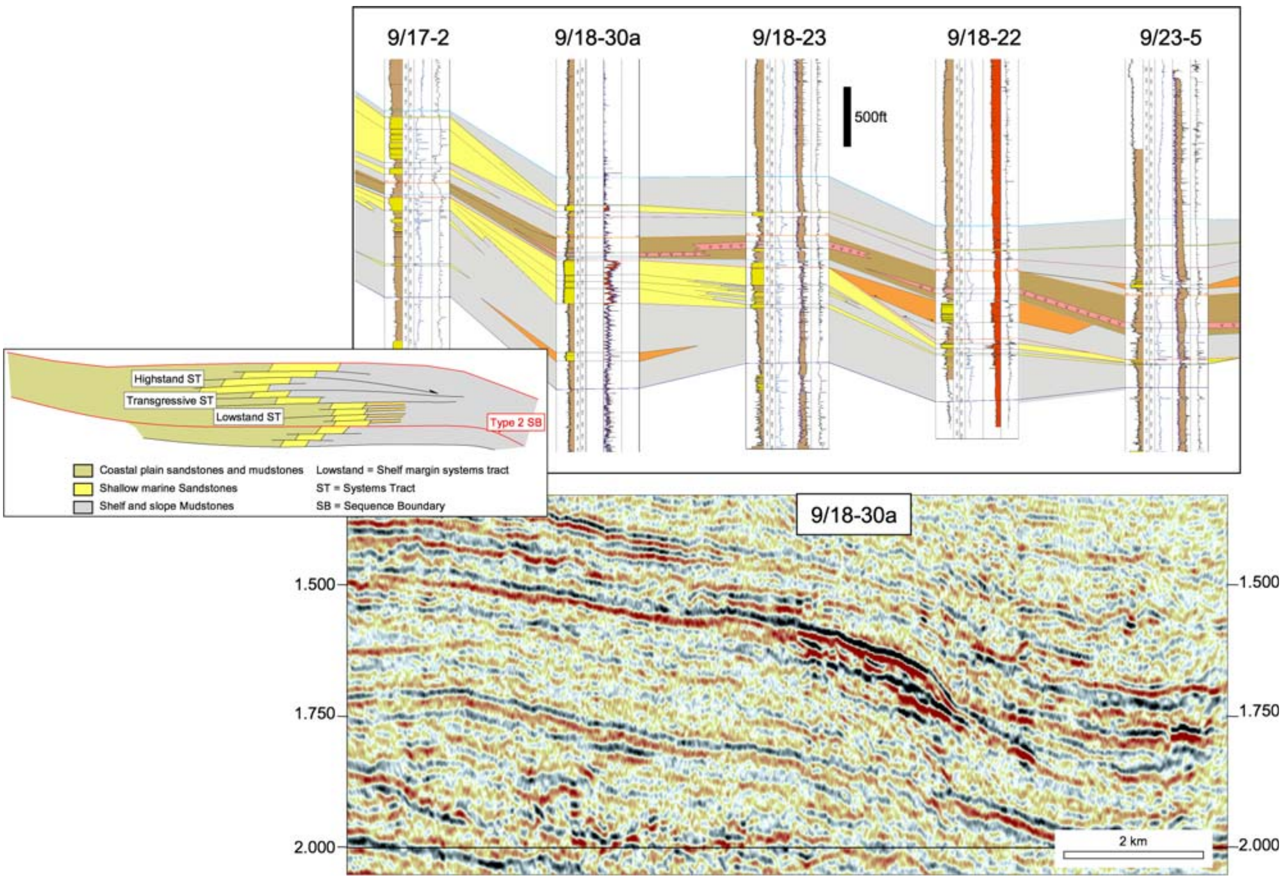

Fig. 13. Seismic and well log expression of the higher-order architecture of the Late Paleocene ('Sele/Hermod') shelf, UK Quad 9, and a type 2 sequence. Red and blue horizons reference the type 2 sequence boundary at the top and base of the 'shelf margin wedge'.

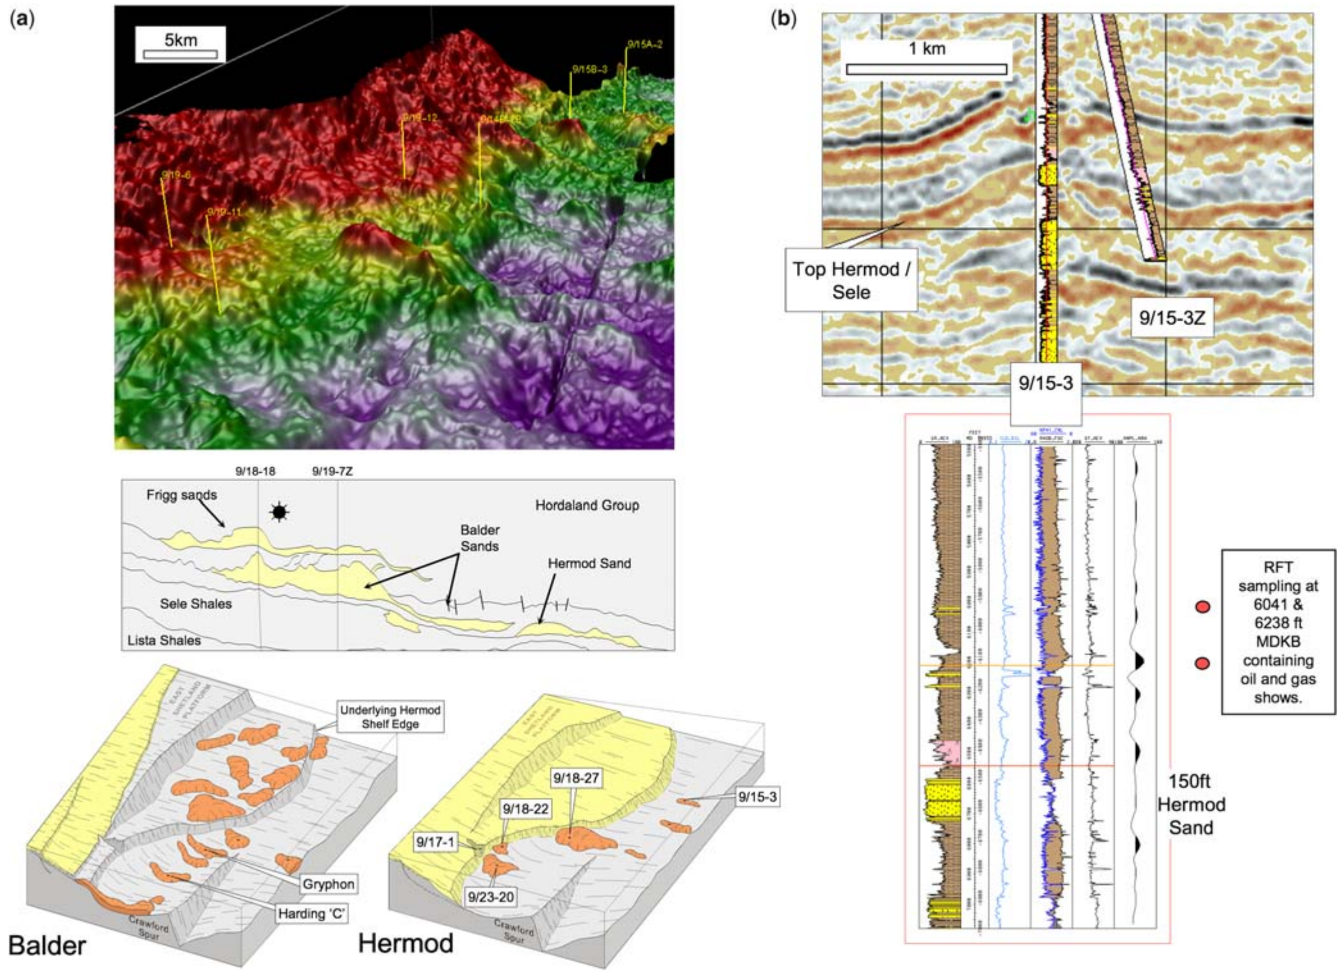

Fig. 14. The importance of basement structure in overcoming the risk posed by regional sand connectivity to effective trapping of hydrocarbons in compaction drape closures on the basin floor. Success cases exemplified by Gryphon (block diagram in **a**). Failure cases exemplified by the cross-section in (a) (9/19-7 well) and the 9/15-3 well (**b**). The shaded relief image is of the Top Hermod surface, UK blocks 9/14 and 15 (red, high; purple, low). Seismic line courtesy of Lundin.

North Sea. Some 16 years later, this play (especially in the Kimmeridgian/Volgian of the Central North Sea) remains enigmatic, in spite of success in the Moray Firth in the form of the Buzzard discovery in 2001 (Doré & Robbins 2005). The Moray Firth and the South Viking Graben are the two principal fairways for the Upper Jurassic deepwater play and have been the subject of numerous detailed accounts of their stratigraphy and depositional processes. Less widely discussed in the literature are the Upper Jurassic reservoirs of the ESB in the Northern North Sea, the Magnus Sandstone and its equivalents. In spite of this, Magnus, with production in excess of 750 mmboe (MacGregor *et al.* 2005), was the last giant field to be brought on stream in the UK North Sea. These three areas stand in marked contrast to the Central North Sea with regards to the Upper Jurassic deepwater reservoir play, in spite of a proven Upper Jurassic shoreface play in the latter (the Fulmar and Ula Formation reservoirs). This section compares and contrasts these systems to address the relative lack of success in the Central North Sea.

Sandstone provenance and reservoir fairway development

The deepwater systems of the South Viking Graben and Moray Firth owe their origin principally to the prolific sediment provenance areas of the Fladen Ground Spur and the Scottish mainland. Here, first cycle Devonian sediments derived from the denudation of the Caledonides subcrop extensively around the basin margins and provide a significant sediment source for Jurassic basin fill.

The ESB and Central Trough do not show similar occurrences of such prolific coarse clastic successions in their Upper Jurassic sections, with perhaps the exception of the Tail End Graben. However, deepwater Magnus Sands of the ESB constitute the reservoir section for the Magnus and Penguin Fields. The Magnus Sandstone reservoir is considered to be the lateral equivalent of the thick Upper Jurassic reservoirs drilled on the western flank of the basin in blocks 210/19 and 20 in the 1970s.

In spite of its inclusion in the regional accounts of North Sea Jurassic stratigraphy by the BP group in the fourth conference (e.g. Partington *et al.* 1993; Rattey & Hayward 1993), the significance of this fairway as an analogue for deepwater exploration has perhaps been lost due to being overshadowed by its illustrious counterparts in the Cenozoic, and the more prolific Jurassic fairways. 3D seismic coverage completed during the 1990s displays a network of amplitude phenomena associated with the development of the Upper Jurassic reservoirs along this flank of the basin. Reservoirs on the Magnus Field are similarly derived from the west (De'Ath & Schuyleman 1981), the depositional architecture of the complete basin floor system having been disrupted by faulting along a SW–NE proto-Atlantic trend described in an earlier section (Fig. 15). Published accounts by Surlyk (1987) of the Jameson Land Upper Jurassic outcrops reveal similar sand body geometries to those imaged west of Magnus.

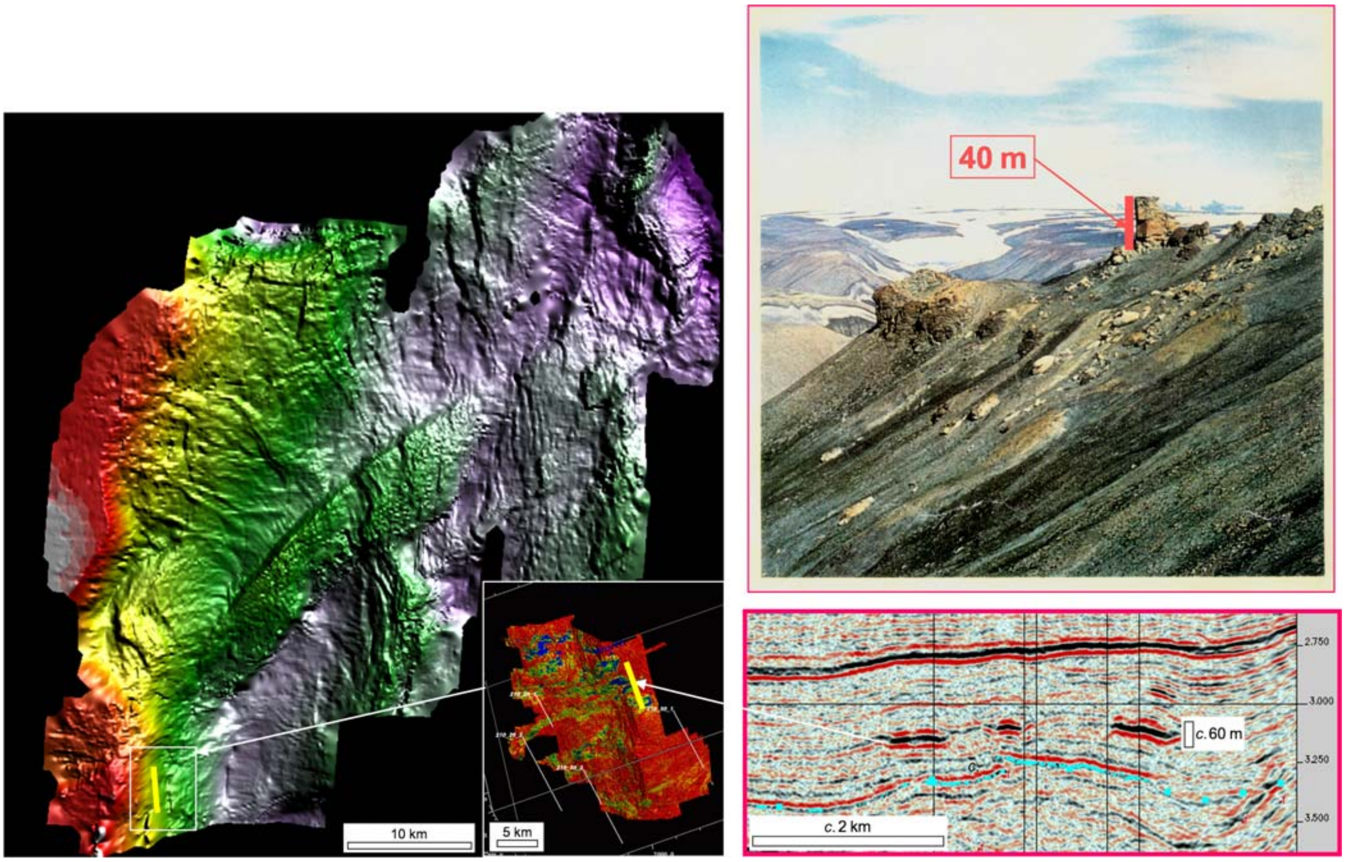

Fig. 15. Upper Jurassic deepwater reservoirs of the ESB and Jameson Land, East Greenland. Shaded relief image is of the Base Cretaceous, illustrating compaction drape over basin floor fans and feeder systems. Amplitude extraction is of events illustrated in the seismic line A–A′, of a comparable scale to 'gully sandstones' described by Surlyk (1987) in the Hareelv Formation of Jameson Land. Photograph courtesy of Finn Surlyk, seismic courtesy of Schlumberger.

Bio-stratigraphic data reveals that the Magnus sands were probably derived from a re-worked shallow marine section. In this respect they are analogous to the Cenozoic Hermod and Balder sands. These observations point towards a key control in delivery of sand to the basin floor in the absence of a significant, proximal first-order provenance, namely the oversupply of sand to the shelf and the collapse of shelf margin sequences to be re-deposited in deeper water, a mechanism similar to that already described in relation to the Eocene Balder Sand Formation of the UK Quad 9 area (see Figs 12 & 13, e.g. Jennette *et al.* 2000).

Comparing the Upper Jurassic of the Central Trough

The Fulmar and Ula Formations of the Upper Jurassic of the Central Trough (Fig. 16) are significant plays in the UK and Norwegian sectors respectively, and developed in shallow marine facies. They occur in fields in both deep graben settings, where the reservoirs are predominantly Oxfordian in age, and the marginal platforms, where they are largely Kimmeridgian to Volgian (e.g. Donovan *et al.* 1993; Partington *et al.* 1993; Wakefield *et al.* 1993; Jeremiah & Nicholson 1999; Fraser *et al.* 2003).

Although hydrocarbon-bearing deepwater equivalents have been encountered in the Oxfordian at the Jacqui discovery, Kimmeridgian at Shearwater, Erskine and Fulmar (the Ribble Member), and still younger at the Selkirk discovery, none are as significant as their counterparts in the Jurassic or Cenozoic sections in either the Central North Sea or elsewhere. Indeed, even comparing the Central North Sea Jurassic to the relatively minor Magnus play described above, there are no comparable occurrences of the seismic signatures associated with this fairway in the UK sector of the Central Trough. Consideration of the likely controlling mechanisms of these counterparts may point to an explanation of these significant differences.

Provenance/hinterland

Howell *et al.* (1996) offered a convincing account of the relationship between Fulmar Formation depocentres and the hinterland, with shoreface fairways forming at entry points in the relays in the graben system. This model offered a compelling fit with the recognition that the Oxfordian fairways were in turn located at the northern and southern limits of a series of en-echelon graben developing during the Oxfordian, with gradual retreat of these fairways away from the basin centres and ultimately onto the platforms in the Kimmeridgian (Erratt *et al.* 1999; Jeremiah & Nicholson 1999). Heavy mineral analysis of the Fulmar sands indicates a progressive un-roofing of the hinterland, with sediments derived from finer-grained and mixed lithologies in Triassic and Middle Jurassic sequences, indicating a less effective reservoir provenance than those feeding the South Viking Graben and Moray Firth systems.

Basin setting/response to sea-level

The early Oxfordian fairways are considered to have been deposited in a ramp-type setting. Fulmar sand reservoir log signatures are characteristically blocky, indicating deposition during relative sea-level lowstand conditions. The predominance of this log signature in the Fulmar Fm. suggests that much of the sediment deposited during the lowstands was in fact captured in the shallow marine shore-face realm, with relatively little by-pass to the offshore. Such a setting would be comparable to the Late Paleocene 'Hermod' system described earlier, in which sea-level falls result in large-scale exposure and incision of the shelf, with a basinward

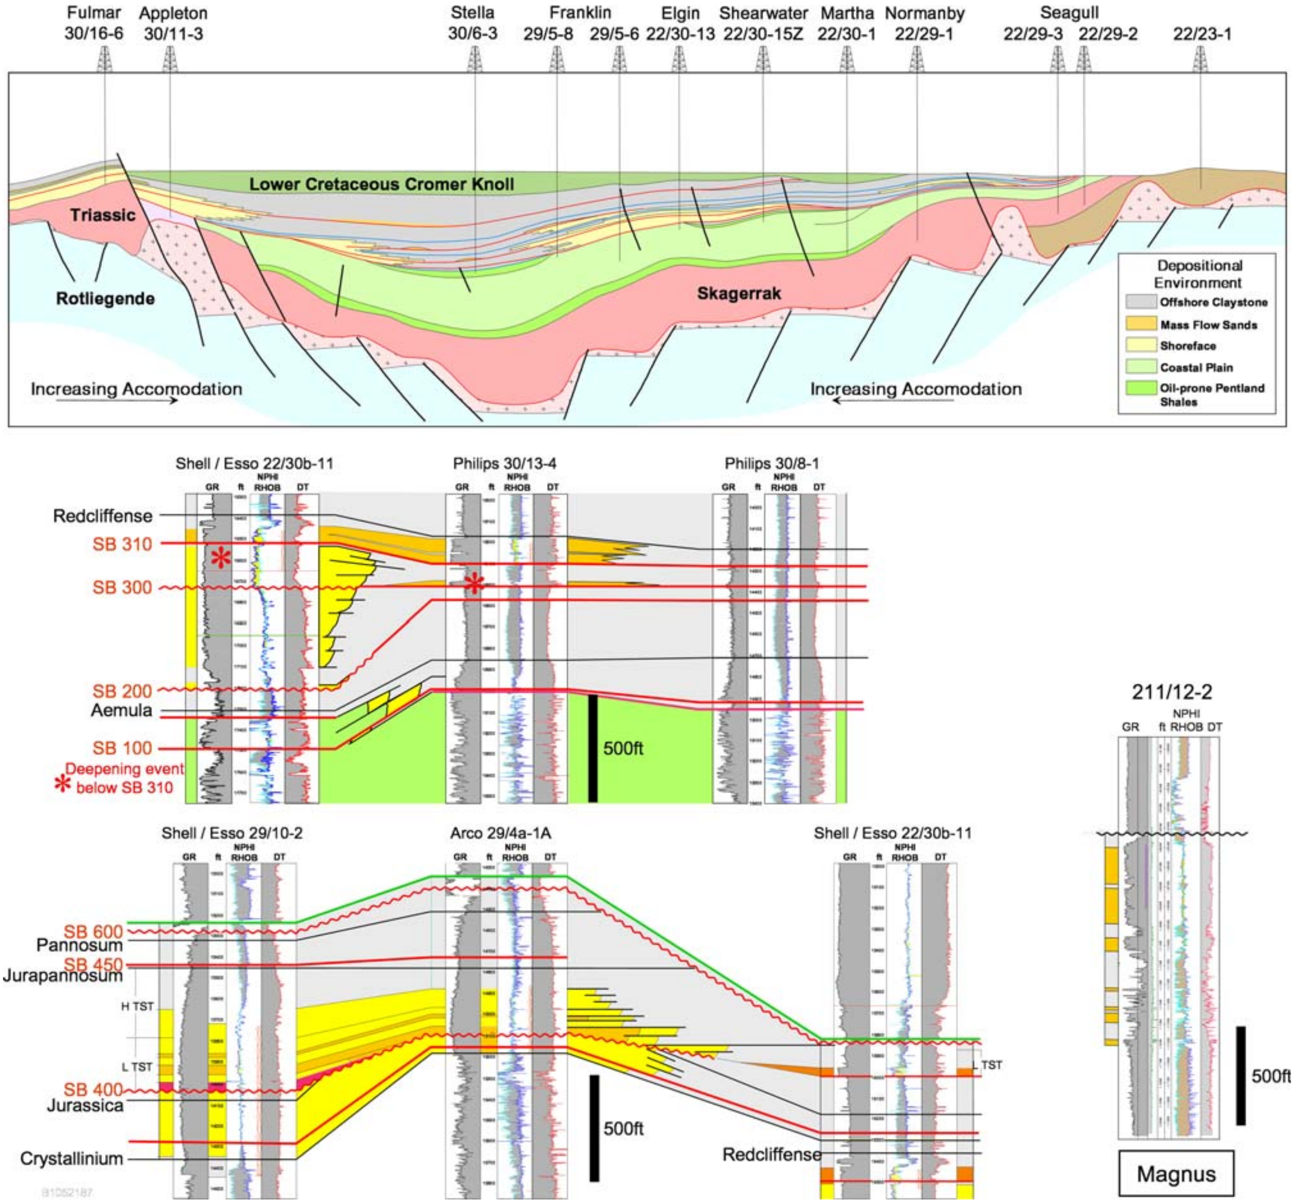

Fig. 16. Upper Jurassic deepwater reservoirs in the Central North Sea (well log sections after Jeremiah & Nicholson 1999). These reservoirs are relatively thin compared with their ESB counterparts (Magnus Field well log for comparison). Sands are likely to have remained stored in or close to the shallow marine environment in type 2 sequences, illustrated on the accompanying schematic cross-section (see also Fig. 13 for cross-reference to Cenozoic example.)

shift in facies above a 'Type 2 Unconformity' (Van Wagoner *et al.* 1990). Type 2 unconformities are considered to be typical of ramp-type shelf-basin transitions.

Basin architecture

The comparison of profiles from the Central Trough and South Viking Graben (Fig. 1) demonstrates a significant first-order difference in basin architectures, which, given that the Upper Jurassic is a syn-rift succession deposited during the formation of these basins, should be expected to have exerted a significant control on sediment dispersal and fairway development.

The South Viking Graben is essentially a single half-graben with the formation of one principal depocentre, with major footwall uplift across its main bounding fault resulting in significant erosion of the Palaeozoic floor of the rift, in this instance coincident with a Devonian basin containing the key first-order products of Caledonide denudation. The receiving basin is relatively narrow. This compares closely to the sub-basins of the Moray Firth, and both display significant vertical stacking of lowstand reservoirs (e.g. Partington *et al.* 1993; Fraser *et al.* 2003). Although lacking the spectacular half-graben geometry of the South Viking Graben, the Moray Firth benefits from close proximity to the Scottish mainland and significant sources of Palaeozoic sediments. By comparison with these close neighbours, the Central Trough comprises a number of smaller sub-basins. With extension effectively dissipated across a network of en-echelon bounding faults, the corresponding footwall uplift in these locations is reduced, such that occurrences of truncation sufficient to expose the Palaeozoic to erosion at these locations are relatively rare (e.g. Embla High adjacent to the Feda Graben).

The role of salt withdrawal

A further factor inhibiting the delivery of sand to deeper water environments may be salt withdrawal during the deposition of the Fulmar Fm. sequences, forming local sediment traps, thereby reducing the potential for sediment bypass.

Hydrocarbon systems

Comprehensive accounts of source rock development, maturation and migration appear in the Millennium Atlas (Kubala *et al.* 2003; Moss *et al.* 2003), and in particular, Cornford (1990). Relative to the fields of tectonics and reservoir stratigraphy, source rocks and the dynamic aspects of the North Sea hydrocarbon system were relatively under-represented in the early conferences, perhaps as a consequence of the realization that Kimmeridge Clay and its equivalent is a highly effective source rock throughout the basin (e.g. Barnard & Cooper 1981). This is not altogether surprising, since it is generally the case that, once proven, marine source rocks tend to be relatively widespread in lightly structured basins. Consequently, the search for new hydrocarbons in the maturing North Sea tended to focus on the search for new reservoir targets and subtle stratigraphic traps. By comparison with its NW European counterparts, the North Sea was already proven as a 'forgiving' hydrocarbon system with plays from the Palaeozoic to the Neogene.

The development of our predictive capabilities with regard to the more dynamic aspects of hydrocarbon systems, such as the maturation and migration of hydrocarbons, diagenesis and overpressure has, perhaps not surprisingly, tracked the development of computing technology in a fashion not dissimilar to the field of seismic technology.

As such it was only by the time of the fifth and sixth conferences in 1997 and 2003, well into the era of 3D seismic and routine, desk-top computer-based petroleum geoscience, that quantitative and computationally intensive basin modelling studies started to appear. [Compare the discussions of Fleet & Cordey (1993), Burley & Scotchman (1999) and Fries *et al.* (2005) from the fourth, fifth and sixth conference proceedings, respectively.] However two authors in particular, Goff (1983) and Cayley (1987), pre-empted this era with seminal papers on the maturation and migration of hydrocarbons in the Viking and Central Grabens, respectively. Cayley's paper drew attention to the dynamic aspects of the highly prospective multi-tiered hydrocarbon system of the Central North Sea, which by virtue of the development of drilling technology and demonstrated prospectivity in the deep overpressured parts of the graben (in contrast to the Northern North Sea), was taking exploration activity into the high pressure/high temperature domain (Erratt *et al.* 2005). This paper was the first to present a basin-wide map of overpressure at Cenozoic and Mesozoic levels, and ushered in a new generation of hydrocarbon system studies that addressed the important aspects of overpressure, top seal integrity and, most importantly, operational imperatives in this challenging subsurface environment. Gaarenstrom *et al.* (1993) built on the work of Cayley and his co-workers to provide an attempt at a quantitative analysis of top seal failure in the Central North Sea, a significant aspect of migration into Upper Cretaceous chalk reservoirs. This seal failure permitted formation of the vertical migration pathways, without which this locally prolific interval would have failed due to its normally poor regional horizontal permeability. As data quality and density increased, Cayley and Gaarenstrom's early maps gave way to more detailed descriptions of discrete pressure cells in the deep graben areas, with cell boundaries capable of leading to differences in overpressure of up to 2000 psi (e.g. Nicholson & Cayley 1998; Erratt *et al.* 2005; Winefield *et al.* 2005) (Fig. 17). On a first-order scale, the 'Golden Zone' concept of Nadeau *et al.* (2005) provides an integrated perspective on the temperature and pressure controls on the distribution of the bulk of the world's recoverable hydrocarbons. Meanwhile, in basins such as the North Sea where the, albeit relatively high-risk, high-pressure, domains remain prospective, predicting overpressure remains challenging, given the various contributing mechanisms in its generation: rapid Cenozoic burial, late gas generation and oil to gas cracking (Swarbrick *et al.* 2005). These factors, coupled with the limits to resolution in the mapping of the critical facies distributions and fault juxtaposition relationships, will continue to make overpressure prediction challenging, along with its dependent risks of top seal integrity and reservoir quality. Inevitably, studies in this realm have encapsulated efforts to predict the occurrence of the high-quality reservoirs at depths beyond those commonly encountered in the Northern North Sea and Moray Firth (see discussions in Fries *et al.* 2005, and Erratt *et al.* 2005). Here again, prediction remains challenging with the various controlling mechanisms operating across the scales from basin-wide (e.g. rapid Cenozoic burial leading to disequilibrium compaction; Moss *et al.* 2003; Jones *et al.* 2005) to pore-scale (chlorite and micro-crystalline quartz grain coats as inhibitors to quartz cementation; e.g. Paxton *et al.* 1995; Ajdukiewicz *et al.* 2001). Whilst the former might lend itself to some relatively high degree of predictability, the latter, being critically dependent on a detailed understanding of facies distributions, will remain a challenge in the face of insufficient well control or seismic resolution. Recent wells in the UK Central Trough have been at the limits of predictive capabilities with regards to pore pressure, deep reservoir quality and trap integrity (both with regards to top seal integrity and fault seal). Results in what is by now a mature exploration setting have been mixed, and these elements remain difficult to reliably predict. Erratt *et al.* (2005) and Winefield *et al.* (2005) presented the results of some of these wells with regards to top seal integrity.

A retrospective view of the petroleum geology of the North Sea

The ultimate goal in the exploration of conventional hydrocarbon resources in the subsurface is reliable remote sensing of hydrocarbons and the accurate estimation of their recoverable volumes. In the absence of reliable remote sensing either of hydrocarbons directly, or of any of the component parts of a working hydrocarbon system, we have to rely on forward models based on our understanding of the available data and the fundamentals of geology. The latter is largely dictated by the prevailing paradigms of the day. This is the wider context of any consideration of our progress in understanding the petroleum geology of the North Sea and in our predictive capabilities. It seems reasonable therefore to assess advances in the understanding of North Sea hydrocarbon systems in the context of three factors: data, technology and fundamental geological principles.

Two fundamental paradigm shifts in geological thought have broadly paralleled the exploration of the North Sea which dates from the early 1960s, namely plate tectonics and sequence stratigraphy. Plate tectonics provided a predictive framework for regional syntheses such as those of the Zieglers and their contemporaries, and set the stage for decades of constructive development of regional models and new play concepts. To appreciate the impact, one need look no further than the parallel and contemporaneous new models of the evolution of orogenic belts, and the revolution in thought (e.g. Dewey & Bird 1970) ushered in by plate tectonics. Furthermore, it provided a unifying framework within which the parallel disciplines of structural mapping and subsidence analysis would ultimately lead to predictive models of the evolution of heat flow through time (McKenzie 1978). These would in turn underpin the development of hydrocarbon system analysis and quantitative basin modelling.

In the fields of stratigraphy and sedimentology, the impacts of first seismic and subsequently sequence stratigraphy (Vail *et al.* 1977; Van Wagoner *et al.* 1990) were no less dramatic. These disciplines, again evolving in parallel with the exploration of the North

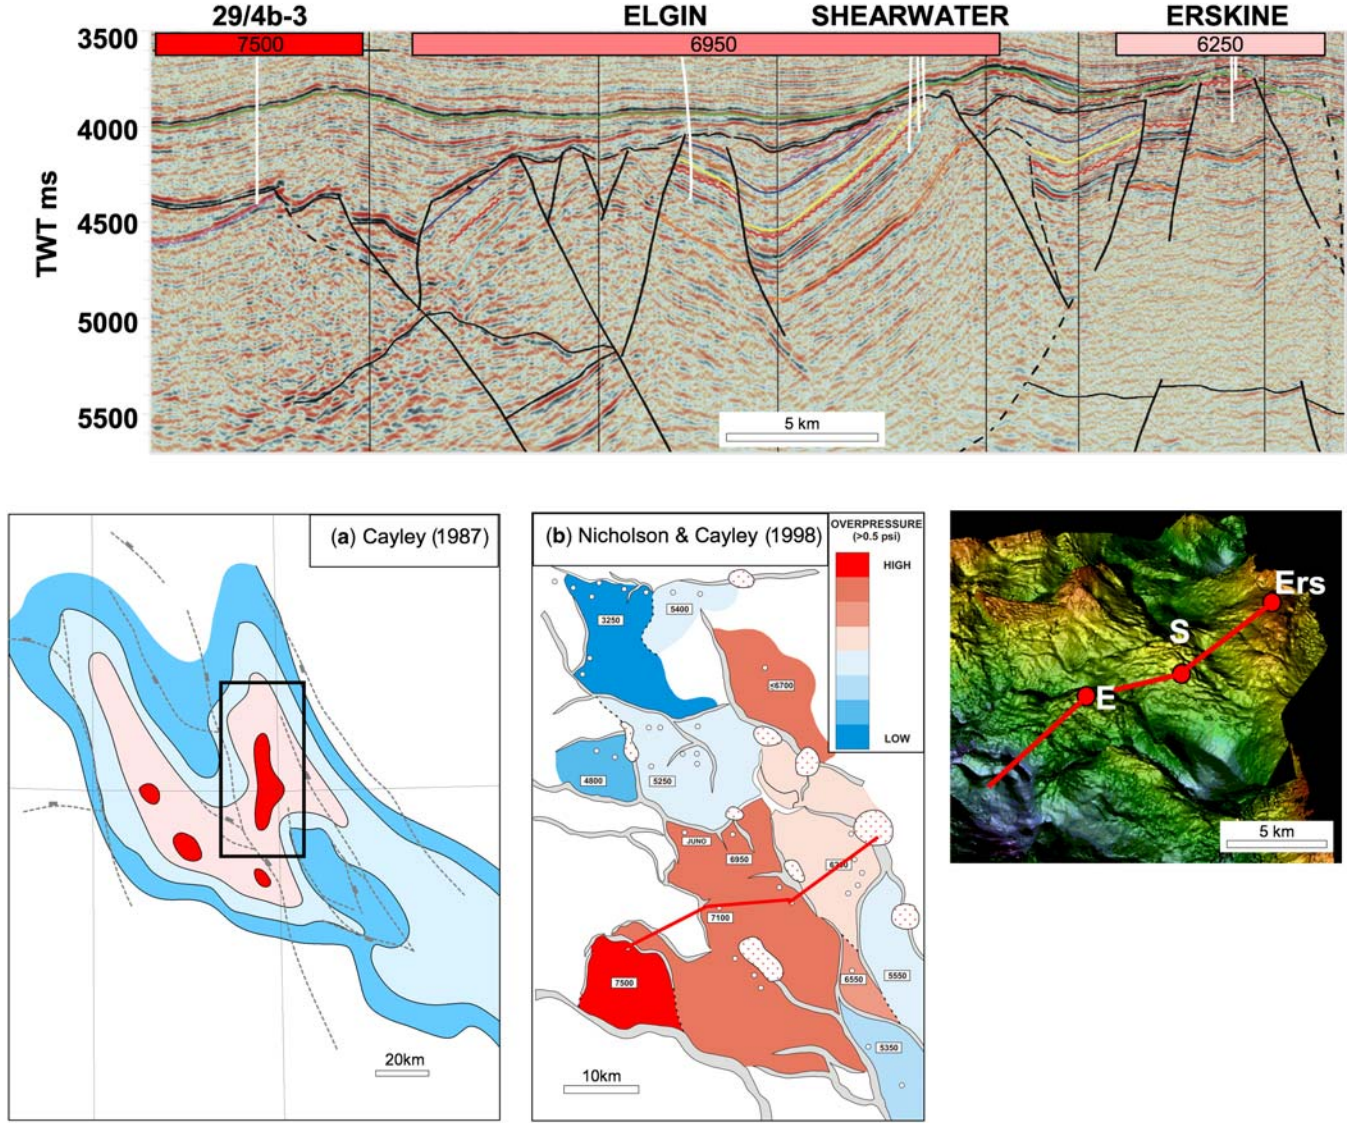

Fig. 17. Pressure distribution in the Central North Sea. Early mapping of pressure distribution (after Cayley 1987) based on 2D seismic, compared with Nicholson & Cayley's (1998) mapping based on closer well spacing and 3D seismic mapping (location shown on map **a**). The pressure cells are illustrated on the seismic traverse repeated from Figure 9.

Sea and the availability of increasingly high-resolution multi-channel seismic data, moved stratigraphy away from a largely descriptive discipline based on *ad hoc* local models towards a unifying, predictive theory. Despite early and widespread resistance, based largely around concerns that sequence stratigraphic models developed for the most part in the relatively unstructured Cretaceous Interior seaway of the USA were inappropriate in active rift settings, by the early 1990s and the fourth conference the discipline was firmly cemented at the core of North Sea geoscience (Donovan *et al.* 1993; Partington *et al.* 1993). Furthermore, seismic and sequence stratigraphy shifted the emphasis of stratigraphic and sedimentological research to outcrops that could be readily compared with standard seismic reflection data. This trend started in the Book Cliffs of Utah in the shallow marine domain and continued through to the Karoo Group of South Africa in deepwater settings. Importantly, Surlyk's work on North Sea analogues in East Greenland was a pioneering effort in this regard (Fig. 15).

With regards to technological advances, in the seismic realm the advent of multi-channel data, increasingly sophisticated processing algorithms, and ultimately of large-scale 3D surveys, have directly improved our ability to accurately describe and map stratigraphy and move structural analysis from the qualitative to quantitative. This transition has been driven to a great extent by advances in computing technology allowing the processing of huge seismic datasets. The same advances have facilitated the use of computationally intensive 3D basin modelling algorithms to enable prediction of the dynamic elements of the hydrocarbon system. All three subdisciplines – structural geology and tectonics, stratigraphy and sedimentology, and hydrocarbon systems analysis – have advanced on the back of regional-scale high-resolution subsurface imaging, to a degree unimaginable in the late 1970s and early 1980s. No less significant have been the advances in drilling technology that have enabled effective exploration and data gathering from high-pressure, high-temperature domains, largely off limits prior to the 1980s.

All of the advances described above pose the questions: 'What was the impact of these revolutions on the success or otherwise of the North Sea exploration venture?' and 'What are the implications for future exploration?' A review of the creaming curves presented by Vining *et al.* (2005) and Erratt *et al.* (2005) is an appropriate backdrop against which to address this question (Fig. 18). Removing the steep part of the curves prior to 1980

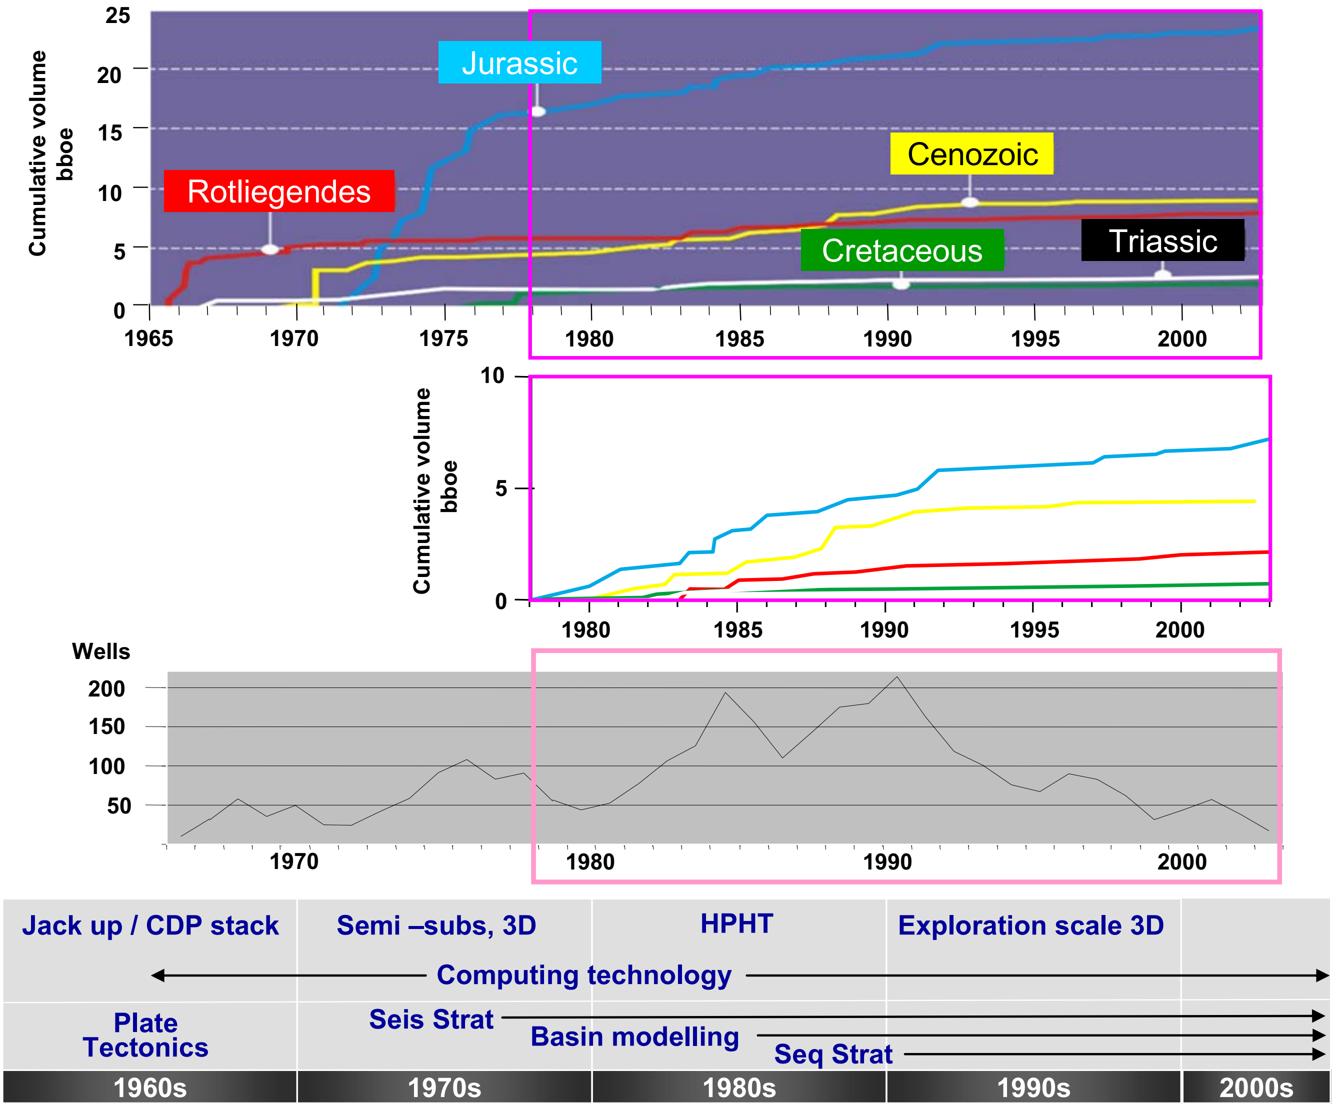

Fig. 18. Creaming curves (after Vining *et al.* 2005), drilling activity and milestones in geology and exploration technology. The arrested flattening of the Jurassic curve is illustrated by the expanded cumulative volume scale, and explained by high levels of activity in high pressure/high temperature domains. The approximate coincidental jump in the Cenozoic curve marks the discovery of the Nelson Field.

provides a more realistic perspective on the impact of these factors. Clearly, the breakthrough in high-pressure, high-temperature drilling technology opened up significant new fairways in the deep grabens. Intriguingly, most of the discoveries in this domain came before the advent of exploration-scale 3D seismic. Indeed, the significant impacts of the application of both 3D seismic data and sequence stratigraphy in the North Sea have tended to be in the production realm, with the widespread application of sequence stratigraphic techniques post-dating the bulk of the exploration success. It can be reasonably argued that in the 1980s and early 1990s, the advances in drilling technology in a forgiving hydrocarbon system were the trigger for any kick in the creaming curve. The historical tendency in the North Sea has been that readily identifiable structural traps are likely to be drilled, and, only after repeated failures with a clearly identifiable fatal flaw will structures in a trend remain undrilled (e.g. Triassic Smith Bank Pods on platform areas; Fig. 1). Stratigraphic trapping concepts have been and will continue to be pursued, especially when in the shallower, less operationally challenging subsurface environments. An example of such a play that indeed owed much to the availability of exploration-scale 3D is the Albo-Aptian Kopervik Sandstone trend of the Outer Moray Firth (Wilson *et al.* 2005). The value of reprocessing 3D data to help mature a sound geologically based play model was highlighted by Doré & Robbins (2005) on the Buzzard Field. It might be reasonably argued that the Alba/Chestnut Eocene discoveries would have been quickly revealed even on conventional low-fold 3D, and mapping of the play would not have been subject to the confusion that reigned following their discovery (see Bain 1993). However, the development of new trapping concepts in future will almost certainly depend heavily on continued improvements in seismic imaging technology, as will advances in basin modelling given its critical dependency on the fidelity of the input models.

On a concluding note, the impact of advances in technologies, data and paradigms, developed in part or in whole in the North Sea, is difficult to overestimate. The quality of North Sea datasets now widely available to both industry and academia alike is likely to keep the region at the forefront of geoscience research for the foreseeable future.

We would like to thank the management of ExxonMobil International Ltd and Shell UK for permission to publish this paper. Thanks to Graham Muckle and Finola Williams for assistance in drafting the figures, and Mike Thomas and Tom McKay for their constructive reviews of the paper.

Abstract: This paper integrates interpretations of modern long-offset seismic datasets with potential field anomalies derived from dense grids of 2D gravity and magnetic data to present a regional-scale synthesis of Devonian, Carboniferous and Early Permian basin development beneath the UK Central North Sea. The 95 000 km^2 study area has had little modern exploration for petroleum systems beneath the Upper Permian. Seismic interpretation and potential field modelling confirm that along the southern fringe of the Central North Sea, as in northern England, Lower Carboniferous basin development was strongly influenced by the disposition of granite-cored Lower Palaeozoic basement blocks – Farne Block, Dogger Block and Devil's Hole High. This study adds a previously unidentified WNW–ESE trending pre-Devonian basement block, the Auk–Flora Ridge, that exerted a profound control on Late Devonian to Mesozoic structural evolution of the south-Central North Sea. From the Flora Field, where it is overlain by relatively thick mid-Devonian to earliest Permian strata, the sub-Permian relief of this block becomes progressively shallower towards the NW. On its southern flank lies a parallel half-graben, akin to the Stainmore Trough in northern England, and interpreted as also containing several thousand feet of Lower Carboniferous strata. As indicated by the coal measures section in well 39/7-1, these strata are likely to include prolific source rocks, which have been modelled as being fully mature for oil generation in Quadrant 29. Potential field modelling extends this interpretation beyond the current seismic coverage, and suggests that Carboniferous to earliest Permian basin development in the Central North Sea was strongly influenced by an underlying Scottish–Norwegian SW–NE trending Caledonoid structural fabric. An earliest Permian, Lower Rotliegend unit thickens southwards towards the Auk–Flora Ridge, and rests unconformably on one or more undrilled NE–SW trending Carboniferous basins. Red-bed fluvial facies akin to those at Flora are likely to dominate the substantial post-Dinantian fill of these basins, but significant thicknesses of Westphalian coal-measure source rocks may also be present locally. As in central Scotland, the Dinantian strata underlying a widespread mid-Carboniferous unconformity in these basins are likely to contain further coal-measure intervals and local developments of oil-shale source rocks. These Westphalian and Dinantian source rocks are key elements of a Carboniferous petroleum system that remains largely untested across large areas of the Central North Sea.

Keywords: Central North Sea, Devonian, Carboniferous petroleum system, Rotliegendes, basin morphology, potential field modelling

This paper presents a regional-scale synthesis of Devonian to Early Permian basin development beneath the UK Central North Sea. The Carboniferous of the Central North Sea is one of the last remaining underexplored play fairways on the UK North Sea. It has been probed by only 25 exploration wells, of which 11 confirmed the potential for source rock intervals within both Dinantian and Westphalian-age coal measures. Until the recent advent of long-offset seismic data acquisition, it has remained poorly imaged on conventional seismic data. Nevertheless, an Exploration of Unproven Plays study (Hay *et al.* 2005) highlighted the possibility for expulsion of significant volumes of gas from these coal measures, where mature, into intra-Carboniferous, Lower Permian and Mesozoic traps remote from the traditional Central Graben Jurassic source kitchen. This hypothesis is supported by their recognition of prominent gas chimneys in the Mesozoic and Cenozoic strata of southern Quadrant 29 (Fig. 1), up to 50 km SW of the Jurassic source kitchen, but directly overlying a Dinantian coal-measure basin interpreted by Hay *et al.* (2005) and modelled by them as being fully mature for gas generation.

This study is based on interpretation of modern long-offset 2D and 3D seismic data of 2003–2008 vintage (Fig. 1), tied to the 117 wells that have drilled through the base of the Permian, and integrated with and validated by 3D inversion of potential field anomalies derived from dense grids of BGS and government-released industry 2D gravity and magnetic data. The interpretation of pre-Permian basin morphology has been made largely by analogy with the structural framework of the equivalent, more clearly imaged strata in onshore Britain. In England, the Carboniferous strata are now known to be disposed about a mosaic of clearly defined ramps, tilted blocks and half-graben structures (Grayson & Oldham 1987; Kirby *et al.* 1987; Smith & Smith 1989; Fraser & Gawthorpe 1990; Fraser *et al.* 1990). By contrast, the Midland Valley of Scotland was a tectonically complex area of Late Palaeozoic rifting, strike-slip faulting and prolonged volcanism (Ritchie *et al.* 2003).

Sub-Zechstein well sections

Unlike in onshore England and the Southern North Sea, the majority of deep Central North Sea wells have proved Upper Devonian continental red-bed facies rather than Carboniferous strata directly beneath a regional base Permian unconformity. We acknowledge that Upper Devonian and Late Carboniferous red-bed sections are not easily distinguished in all wells. Thirty-four of the interpreted Upper Devonian well penetrations are near or beneath the Auk and Argyll oil fields in the south of Quadrant 30 (Fig. 2). Six wells in this area proved Middle Devonian shallow-marine limestones, evaporites and mudstones of the Kyle Group,

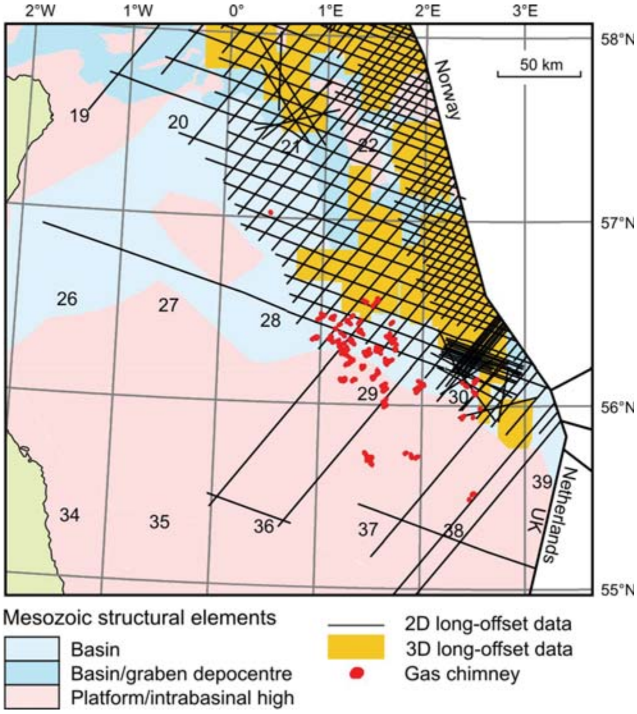

Fig. 1. Location of long-offset seismic data used in the study and of gas chimneys mapped in the Cenozoic section by Hay *et al.* (2005).

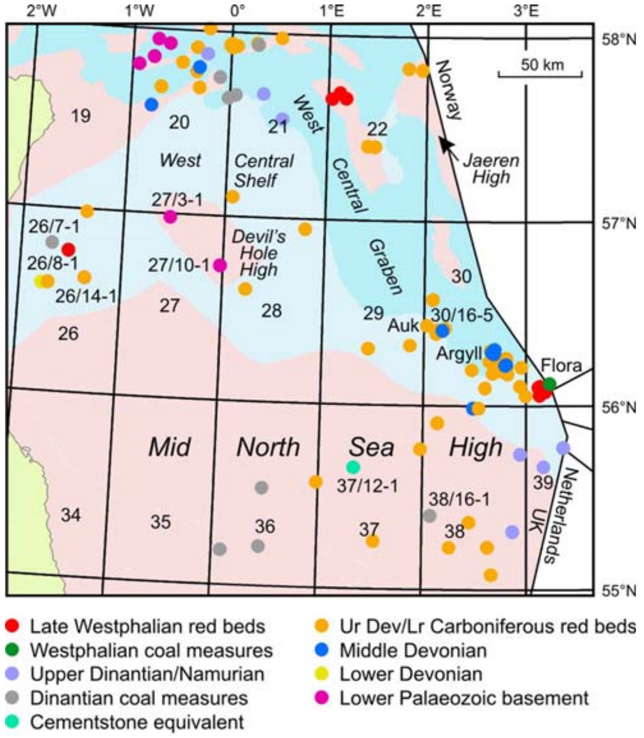

Fig. 2. Pre-Permian stratigraphy recorded in Central North Sea wells (Mesozoic structural elements as in Fig. 1).

subcropping the base Permian unconformity in four wells and lying below the Upper Devonian in two. Key well 30/16-5 (Fig. 2) drilled through the base of the Middle Devonian strata into mildly metamorphosed Lower Palaeozoic basement of Scottish Southern Uplands affinity. A summary of Permian and pre-Permian lithostratigraphy and of potential source rock and reservoir intervals in the region is shown in Figure 3. Initial indications from the well data are that pre-Middle Devonian strata may rise to relatively shallow levels beneath much of the Auk–Argyll region.

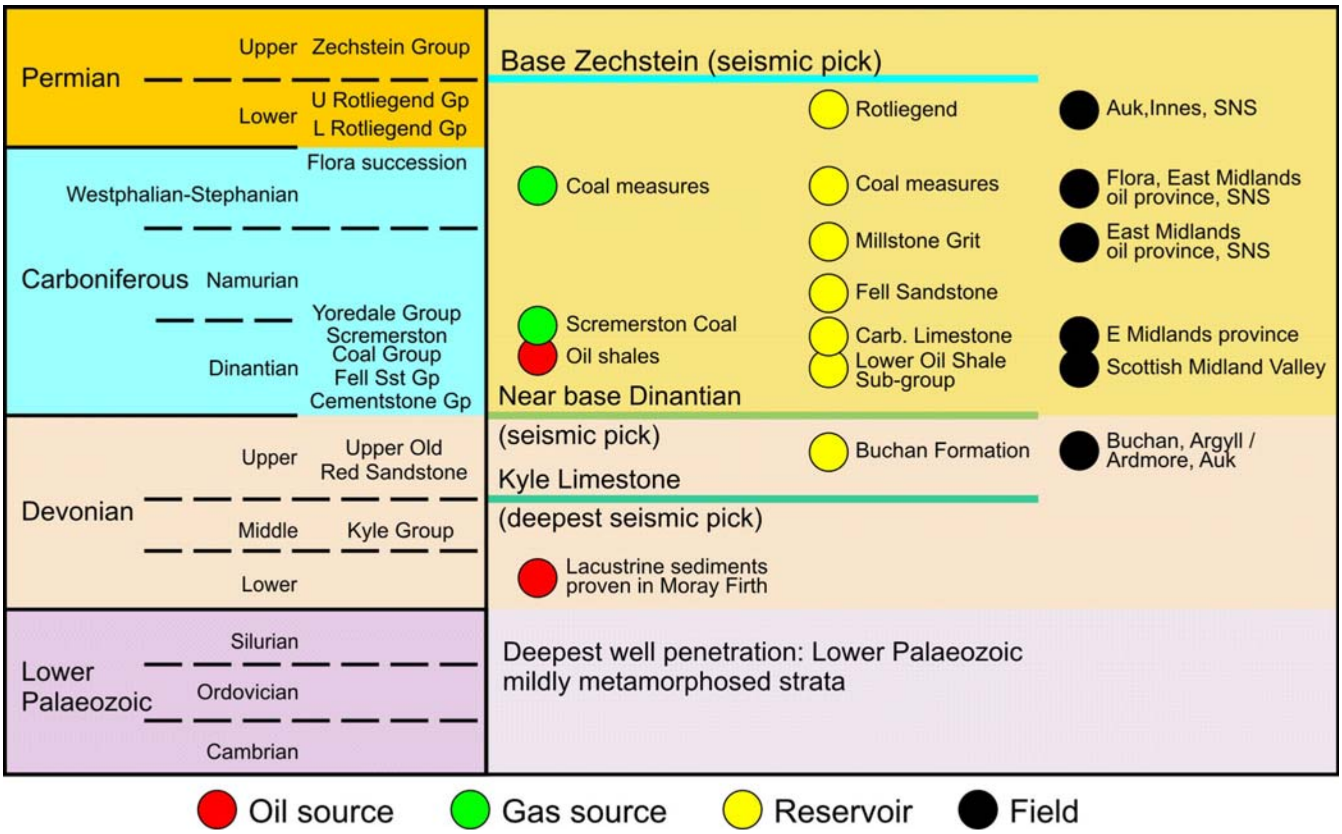

Fig. 3. Summary of Permian and pre-Permian lithostratigraphy and of potential source rock and reservoir succession in the region. The lithostratigraphy is after Cameron (1993*a*, *b*).

Drilling has revealed that the Mid North Sea High was not a uniformly positive feature in Carboniferous times. Directly beneath the Permian, nine of its wells proved Upper Devonian strata, whereas another five wells encountered Lower Carboniferous strata of Northumberland Trough affinity (Fig. 2). These wells include 37/12-1, which drilled 476 m of unfossiliferous mudstones, limestones and minor anhydrites in a succession resembling the largely Courceyan (Tournaisian)-age Cementstone Group in Northumberland. The three wells in Quadrant 36 and well 38/16-1 drilled Dinantian strata, including coal measures, which we correlate with Northumberland's Scremerston Coal Group.

In and adjacent to the Flora Field on the eastern fringes of the Mid North Sea High, six wells have provided key information on Upper Carboniferous to Lower Permian stratigraphic relationships. Westphalian B to Stephanian age Lower and Upper Flora Sandstone units here (Fig. 3) are separated by a Lower Volcanic unit, 250 m thick in Flora well 31/26a-12. The sandstone units show close lithological affinity to Late Westphalian red-bed sequences in the Southern North Sea (Martin *et al.* 2002). These strata are unconformably overlain by an argillaceous Grensen Formation and an Upper Volcanic unit, radiometrically dated as Stephanian or Asselian (basal Permian) in age. Correlated by Martin *et al.* (2002) with the Lower Rotliegend Group of onshore Europe, these strata have no equivalents in the UK Southern North Sea. Hence two regional base Upper Rotliegend Group (base Auk Formation equivalent) and base Lower Rotliegend Group unconformities are represented in these wells. The extent of the latter unconformity and of the Lower Rotliegend Group in the Central North Sea has been poorly reported up to now.

The Devil's Hole High wells 27/3-1 and 27/10-1, along with well 26/14-1, terminated in Lower Palaeozoic mildly metamorphosed basement. Well 26/7-1 drilled 1090 m of Holkerian to Chadian-age Lower Carboniferous coal measures that have closer affinity with equivalent sediments in the Midland Valley of Scotland than with the Scremerston Coal Group of the Northumberland Trough. In nearby well 26/8-1 these coal measures and the Lower Permian Auk Formation are separated by 899 m of dominantly arenaceous red beds. At least the lowest 306 m of these red beds were ascribed to the Westphalian. If correct, this provides the possibility for another significant unconformity within the Carboniferous section that is perhaps equivalent to the unconformity separating Late Namurian and younger from Early Namurian and older strata in the Midland Valley of Scotland.

Four wells in the NW of Quadrant 20 proved shallow-buried Caledonian granite beneath the base of the Permian. Remaining wells in this region record a progression from Late Devonian to earliest Carboniferous continental red-bed facies (Buchan Formation) through a transitional unit comprising cyclic alternations of sandstone and mudstone units (Tayport Formation) to Dinantian coal measures (Firth Coal Formation). The boundaries between these units are demonstrably diachronous (Cameron 1993*a*, *b*), suggesting that palaeorelief may have influenced facies development at least in this region during early Carboniferous times.

Seismic interpretation

In the Central North Sea the quality of information on sub-Zechstein geology that can be derived from seismic interpretation is influenced strongly by the structural complexity of its Zechstein to Cenozoic overburden. The information is best imaged on seismic profiles in the Auk–Argyll area, where the top of the Middle Devonian Kyle Limestone forms a conspicuous, high-amplitude and continuous reflector between and beyond the six wells that have drilled this unit. To the north, the Forties–Montrose High and Jaeren High provide windows of good-quality sub-Zechstein information also, showing many features in common with the Auk–Argyll area, but with limited well control. By contrast, the seismic data yield little or no information on the Middle Devonian to Lower Permian section beneath the Mesozoic Central Graben of the North Sea, but this section is inferred to have undergone significant stretching during creation of the Graben in any case.

Beyond the limit of the Kyle Limestone reflector, the seismic interpretation of Lower Carboniferous strata relies heavily on comparison of seismic facies with the equivalent drilled strata on the southern flank of the Mid North Sea High and in the Northumberland Trough in northern England (Chadwick *et al.* 1995). This is necessary because of the scarcity of deep Carboniferous wells in the Central North Sea. The deepest reliable reflector in this region has been taken by analogy with the Northumberland Trough as representing the downward transition from Late Devonian continental red-bed deposits to Early Dinantian Cementstone Group-equivalent strata and labelled as near base Dinantian. Two relatively transparent and stripey reflector packages above this have been interpreted as probably equivalent to the Fell Sandstone Group and Scremerston Coal Group of the Northumberland Trough, respectively, and their boundary picked as a mid-Dinantian event. The areas in which Kyle Limestone and intra-Dinantian reflectors have been picked are not mutually exclusive. Nevertheless, on Figure 4 the isopachs from the base of the Zechstein to near base Dinantian reflector provide a first impression of the potential thickness of Middle Devonian to Lower Permian strata

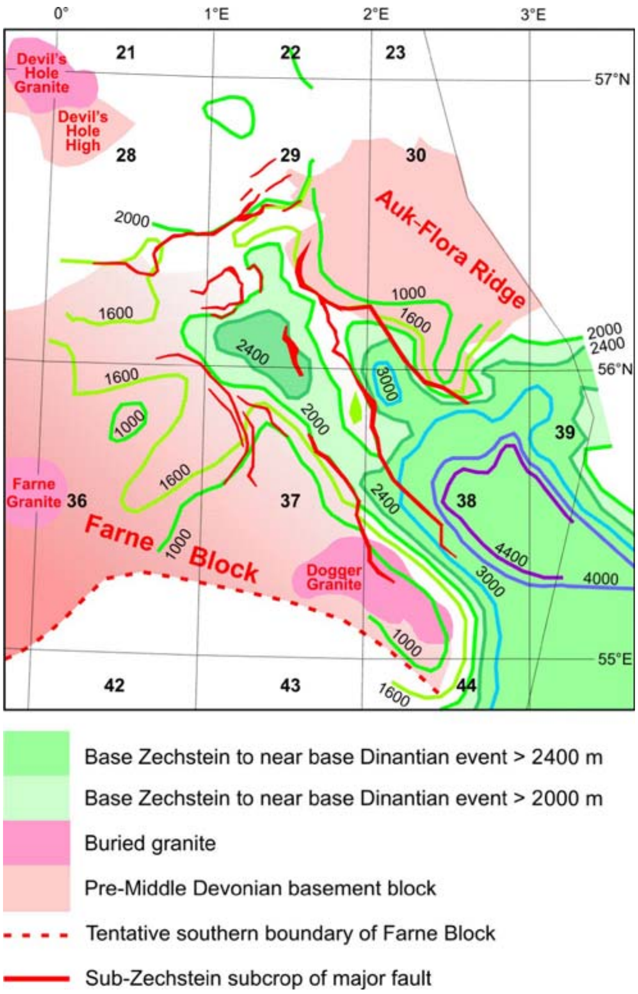

Fig. 4. Approximate thickness of pre-Zechstein Upper Palaeozoic (base Zechstein Group to near base Dinantian); isochrons converted to thickness assuming a standard interval velocity of 4 km s^{-1}.

in the region, as derived from the seismic interpretation. In the following sections we describe key long-offset seismic profiles and link them to known onshore geological analogues.

Sub-Zechstein seismo-stratigraphic relationships in the Auk–Argyll–Flora area

All of the principal sub-Zechstein stratigraphic relationships of the Central North Sea can be observed on seismic profiles from between the Auk and Flora oil fields. On Figure 5, acquired close to the west of the Flora Field, a prominent deep reflector that correlates with the drilled Middle Devonian Kyle Limestone at the Argyll Field is overlain successively by seismic units correlated with continental red-bed facies of the Upper Old Red Sandstone and overlying Cementstone Group and Fell Sandstone Group. Another prominent mid-Dinantian reflector is correlated with the base of the Scremerston Coal Group equivalent coal measures, which were drilled nearby in well 39/7-1. A regional mid-Carboniferous unconformity separates remaining Dinantian to early Namurian strata from an overlying succession that includes the Westphalian A coal measures drilled in well 31/27-1 and the Late Westphalian to Stephanian red-bed and volcanic units proved at the Flora Field. In structural terms, the relatively simple relationships depicted on this profile are broadly comparable with the east Pennine Basin of eastern England, in which thick sections of Upper Carboniferous strata are preserved in broad, open gently synclinal features.

The whole of this sub-Permian section is strongly condensed on a second example seismic profile (Fig. 6), located north of the previous example west-northwestwards towards the Auk Field. The entire Dinantian section is missing, with Upper Devonian continental red-bed facies subcropping the mid-Carboniferous unconformity on this profile. Upper Carboniferous strata are also completely eroded beneath the base Permian unconformity along much of its length. The Middle Devonian Kyle Limestone is at relatively shallow depths beneath the Permian, and it becomes even shallower to come close to subcropping the base of the Permian in nearby Auk Field well 30/16-5 (Trewin *et al.* 2003). Lower Palaeozoic strata of Southern Uplands affinity have been drilled in the same well, indicating that the seismic profile depicts part of an uplifted block of pre-Middle Devonian basement, which we term the Auk–Flora Ridge. Comparable uplifted blocks overlain by deeply eroded Upper Devonian and/or Carboniferous strata are widespread in onshore Britain, and include the Pentland Hills Inlier in the Midland Valley of Scotland and the Southern Uplands Lower Palaeozoic massif. Comparable English uplifted Lower Palaeozoic basement blocks include the Cross Fell Inlier alongside the Alston Block and parts of the East Midlands, where some Carboniferous anticlines are underlain by uplifted Lower Palaeozoic basement blocks.

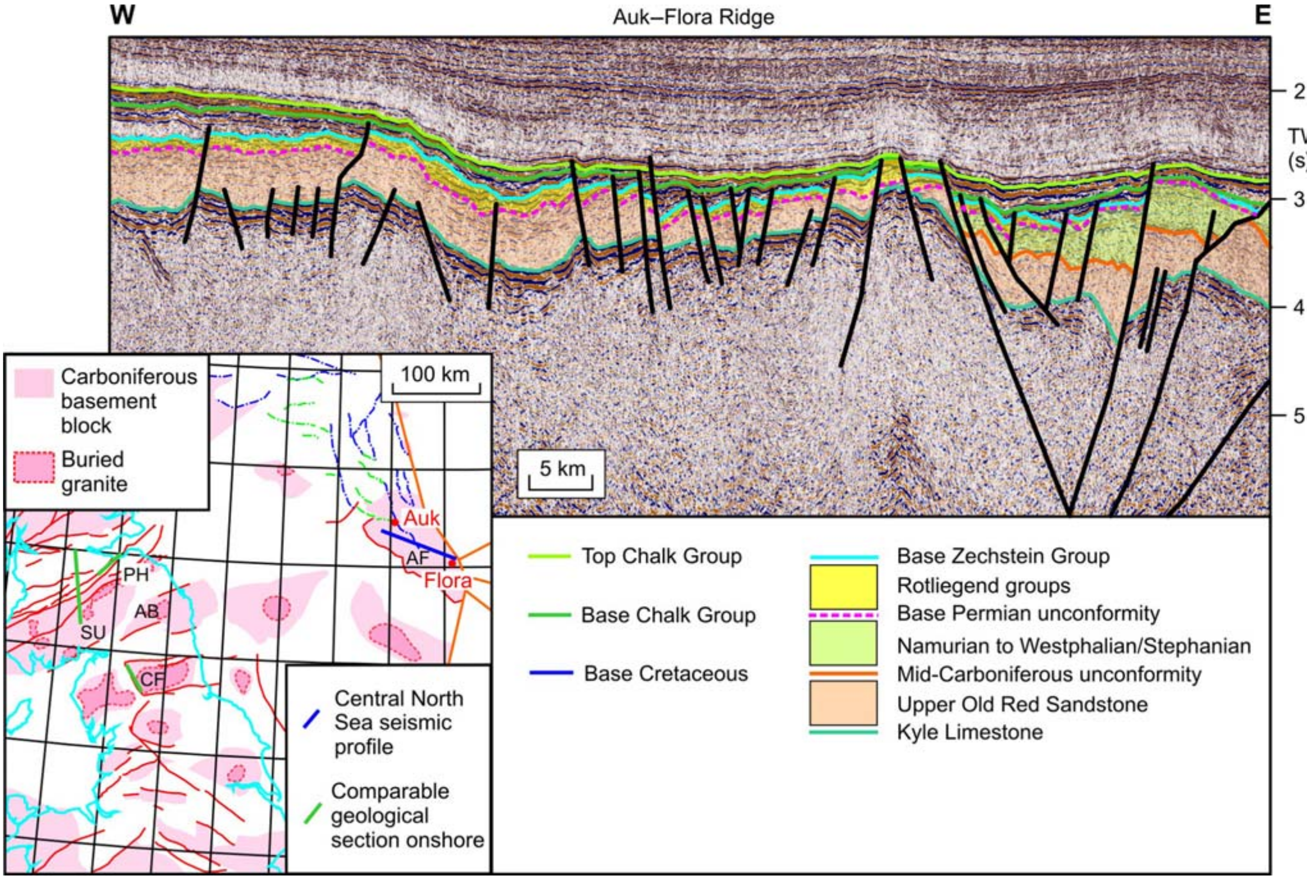

Fig. 6. Interpretation of example seismic profile along the crest of the Auk–Flora Ridge (AF); data courtesy of TGS NOPEC Geophysical Co. (UK) Ltd. PH, Pentland Hills Inlier; SU, Southern Uplands; AB, Alston Block; CF, Cross Fell Inlier.

All of the onshore examples of Lower Palaeozoic basement blocks are bounded by one or more prominent oblique-slip, reverse or normal fault systems (e.g. Askrigg Block, Underhill *et al.* 1988; East Midlands, Smith *et al.* 2005), and there is evidence on the seismic profile shown on Figure 7 that the northern flank of the Auk–Flora Ridge is also delimited by a major reverse fault system. The Auk–Flora Ridge is represented by the seismically transparent sub-Rotliegend feature in the southern third of this profile, and is interpreted to be composed largely or entirely of pre-Middle Devonian basement here. This pre-Middle Devonian basement block is cut in the south by the boundary fault of the Mesozoic West Central Graben, which has a substantially thicker Lower Permian section preserved on its hanging wall. At the intra-grabenal high near the centre of the profile this Lower Permian section can be divided by a prominent reflector into seismic units that most likely correlate with the Upper and Lower Rotliegend units of the Flora area. Our interpretation suggests that this intra-grabenal high lies near the depocentre for the combined Upper and Lower Rotliegend units in the Central North Sea.

The reflective section beneath the intra-grabenal high on the same profile (Fig. 7) appears to extend to the northern boundary fault of the Auk–Flora Ridge, and has been interpreted by analogy with seismic facies in the Southern North Sea and Northumberland Trough to include folded Dinantian strata that are absent over the crest of the Ridge. High-amplitude events deeper in the section are perhaps imaging igneous intrusives such as those modelled in this area by Lyngsie & Thybo (2007). Local reduction in thickness of and unconformable relationships between the Upper Cretaceous Hod and Tor formations directly above the Auk–Flora Ridge boundary fault system (S. J. Stoker, pers. comm.) suggest a component of subsequent reverse reactivation in its movement history.

Sub-Zechstein seismo-stratigraphic relationships in the Mid North Sea high area

On the southern flank of the Auk–Flora Ridge (Figs 4 & 8), there is compelling evidence for the preservation of up to 5.5 km of Upper Devonian to Dinantian strata in an approximately half-graben feature within what is conventionally regarded as the Mid North Sea High. This conclusively demonstrates that the Mid North Sea High is at least in part a post-Carboniferous feature. Notably, the fill of this basin could potentially include a significant thickness of Scremerston Coal Group-equivalent gas-prone source rocks, although thermal modelling (Hay *et al.* 2005) suggests that such may be only marginally mature here. Below these, its fill also includes a unit of high-amplitude reflections similar to that equated by Chadwick *et al.* (1995) with an anhydrite-rich sabkha interval of earliest Dinantian age within the Northumberland Trough in northern England. Notably, the interval above these high-amplitude reflections appears to thicken onto the hanging walls of the half-graben controlling faults, suggesting an element of rifting in this early Carboniferous basin, perhaps of broadly comparable age to active pre-Asbian faulting recorded in the east Pennine area by Fraser & Gawthorpe (1990).

The southern flank of this Upper Devonian to Dinantian basin is constrained by a prominent Lower Palaeozoic basement block that was structurally elevated persistently through Carboniferous times. Our potential field modelling confirms and refines the interpretation by Donato *et al.* (1983) that this Lower Palaeozoic basement block contains a Caledonoid granite core. Comparable granite-cored Lower Palaeozoic basement blocks in England include the Askrigg Block; hence the half-graben on the profile can be regarded as an analogue of the early Carboniferous Stainmore Trough of northern England.

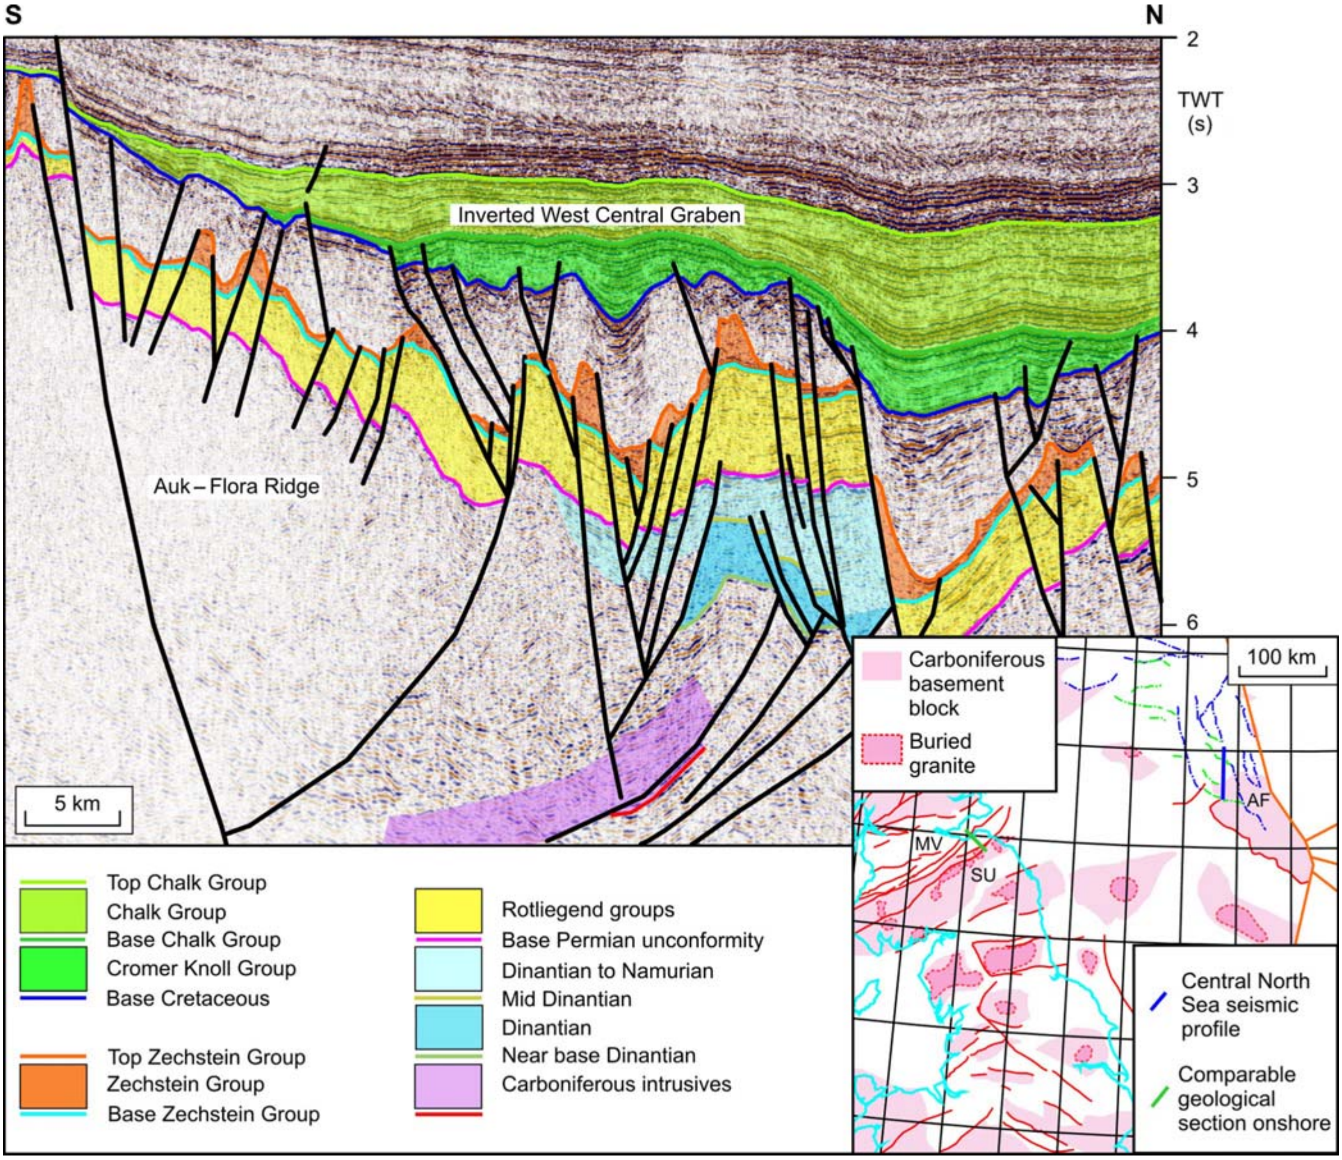

Fig. 7. Interpretation of example seismic profile crossing the northern flank of the Auk–Flora Ridge (AF); data courtesy of CGGVeritas. MV, Midland Valley of Scotland; SU, Southern Uplands.

Sub-Zechstein seismo-stratigraphic relationships in the Jaeren high area

The seismo-stratigraphic relationships established in the drilled Auk–Flora area can be extrapolated to enable interpretation of undrilled sub-Zechstein sections in other parts of the Central North Sea. On the illustrated seismic profile crossing the Jaeren High (Fig. 9), a uniform thickness of Upper Rotliegend strata overlies a northward-thinning unit, which is interpreted to be equivalent to the Lower Rotliegend unit of the Flora area because it rests on a truncation surface that is most likely to be the base Permian unconformity. Imaged only at the northern end of the profile, the faulted, high-amplitude reflector at the base of the underlying steeper-dipping strata is interpreted to be a continuation of the Kyle Limestone event of the Auk–Argyll area. By extrapolation from the Mid North Sea High profile (Fig. 8), these steeper-dipping strata are interpreted to also include Upper Devonian, Lower Carboniferous and Upper Carboniferous seismo-stratigraphic units.

The relative thicknesses of Upper Carboniferous and Lower Carboniferous strata might appear to be anomalous on this profile. However, similar relationships are well known from onshore. For instance, Figure 10 illustrates that, along the southern margin of the Craven Basin, the Upper Carboniferous interval has been completely eroded from the inverted Craven Basin (Evans & Kirby 1999), but is thickly preserved above a condensed Lower Carboniferous shelfal sequence across a Lower Palaeozoic basement block, the Central Lancashire High. The southern part of the Jaeren High Mesozoic footwall block is inferred to overlie a shallow pre-Carboniferous basement block.

Sub-Zechstein seismo-stratigraphic relationships on the West Central Shelf

In an example seismic profile from the West Central Shelf (Fig. 11), the Rotliegend strata are again composed of two discrete seismo-stratigraphic units, although the Upper Rotliegend interval oversteps the Lower Rotliegend beyond the western end of the profile. The most striking feature on this profile is a strongly erosional intra-Carboniferous unconformity that appears to have been dissected into a seismic facies of discontinuous high-amplitude reflectors that may be indicative of coal measures. A lenticular seismic package is imaged directly overlying the deepest notch in the unconformity surface. The lenticular package is interpreted to represent the fill of an erosional channel. In 3D, both the channel

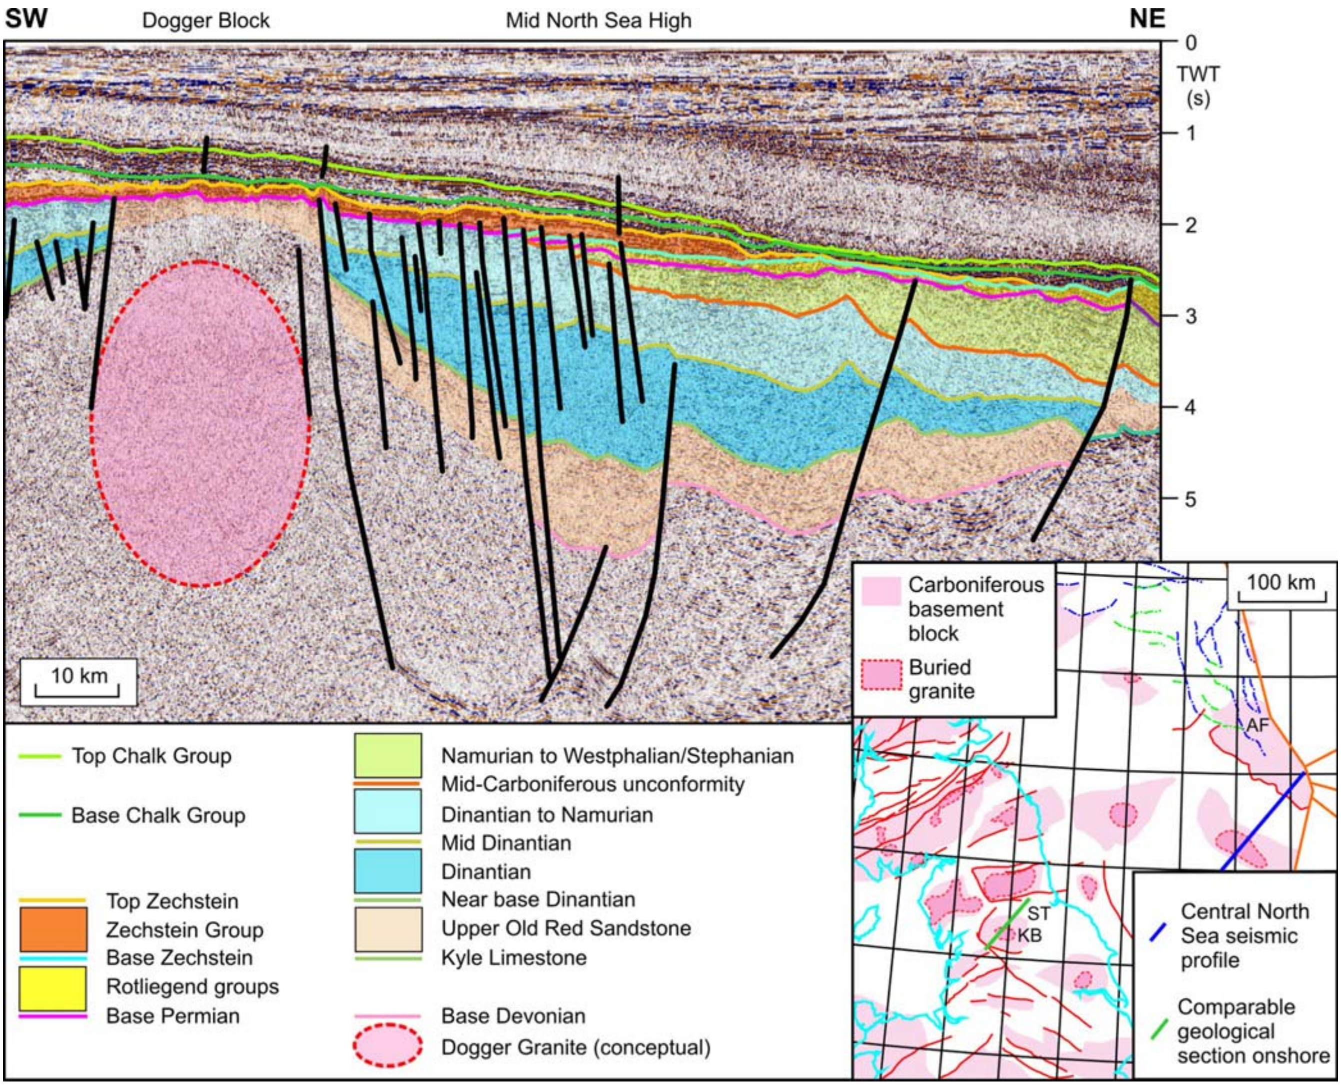

Fig. 8. Interpretation of example seismic profile from the Dogger Granite to the southern flank of the Auk–Flora Ridge (AF); data courtesy of TGS NOPEC Geophysical Co. (UK) Ltd. KB, Askrigg Block; ST, Stainmore Trough. The top of the Dogger Granite cannot be resolved on the seismic data.

and its infill body trend roughly west–east and are up to 2 km wide. Their scale and trend are comparable with mapped mid-Namurian channel features associated with an influx of coarse detritus in the Midland Valley of Scotland (Read 1990).

North of this, another seismic profile (Fig. 12) provides an illustration of a simple pre-Permian syncline, bounded to the west by a westerly-dipping reverse fault, and comparable in style and orientation if not in scale to the Midlothian Syncline in the Midland Valley of Scotland. The latter developed in the Late Carboniferous as syn-sedimentary folding superseded extension in front of a Lower Palaeozoic basement block (Ritchie *et al.* 2003; Underhill *et al.* 2008). These two profiles suggest that large parts of the Carboniferous tectonic style beneath the West Central Shelf have more in common with the Midland Valley of Scotland than with the tectonic style of the Auk–Flora area and the eastern part of the Mid North Sea High.

Potential field modelling

The aim of our potential field modelling has been to separate the gravity response of the crystalline (sub-Lower Palaeozoic) basement from the gravity responses of its overlying Lower Palaeozoic, Devono-Carboniferous, Permian and post-Permian sedimentary basins. It is worth emphasizing that the end result of the 3D modelling is a depth surface to high-density or crystalline basement – this surface defines the base of the accommodation space to be filled by the Lower Palaeozoic and overlying sedimentary basins.

Three-dimensional forward and inverse modelling – modelling technique

A 3D-forward and inversion modelling technique has been used to derive the crystalline basement and other surfaces, combining the methodologies of Parker (1972) and Oldenburg (1974). The user has full control over the spatial wavelengths being inverted, thereby allowing the physical properties of specific horizons to be targeted. The modelling software uses an iterative method to calculate layer depths in such a way that the computed potential field response of the final model provides best fit to the geological data observed from the seismic interpretation.

The 3D inversion involves two principal stages: (i) construction of an input earth model, including 3D inversion for deep crustal surfaces, and (ii) 3D inversion for structure of the crystalline basement to minimize the difference grid, defined by the difference between calculated and observed gravity response. In this study the model was a complex seven-layer model comprising a combination of sedimentary and crystalline basement layers, most with laterally varying densities. The top crystalline basement is usually the

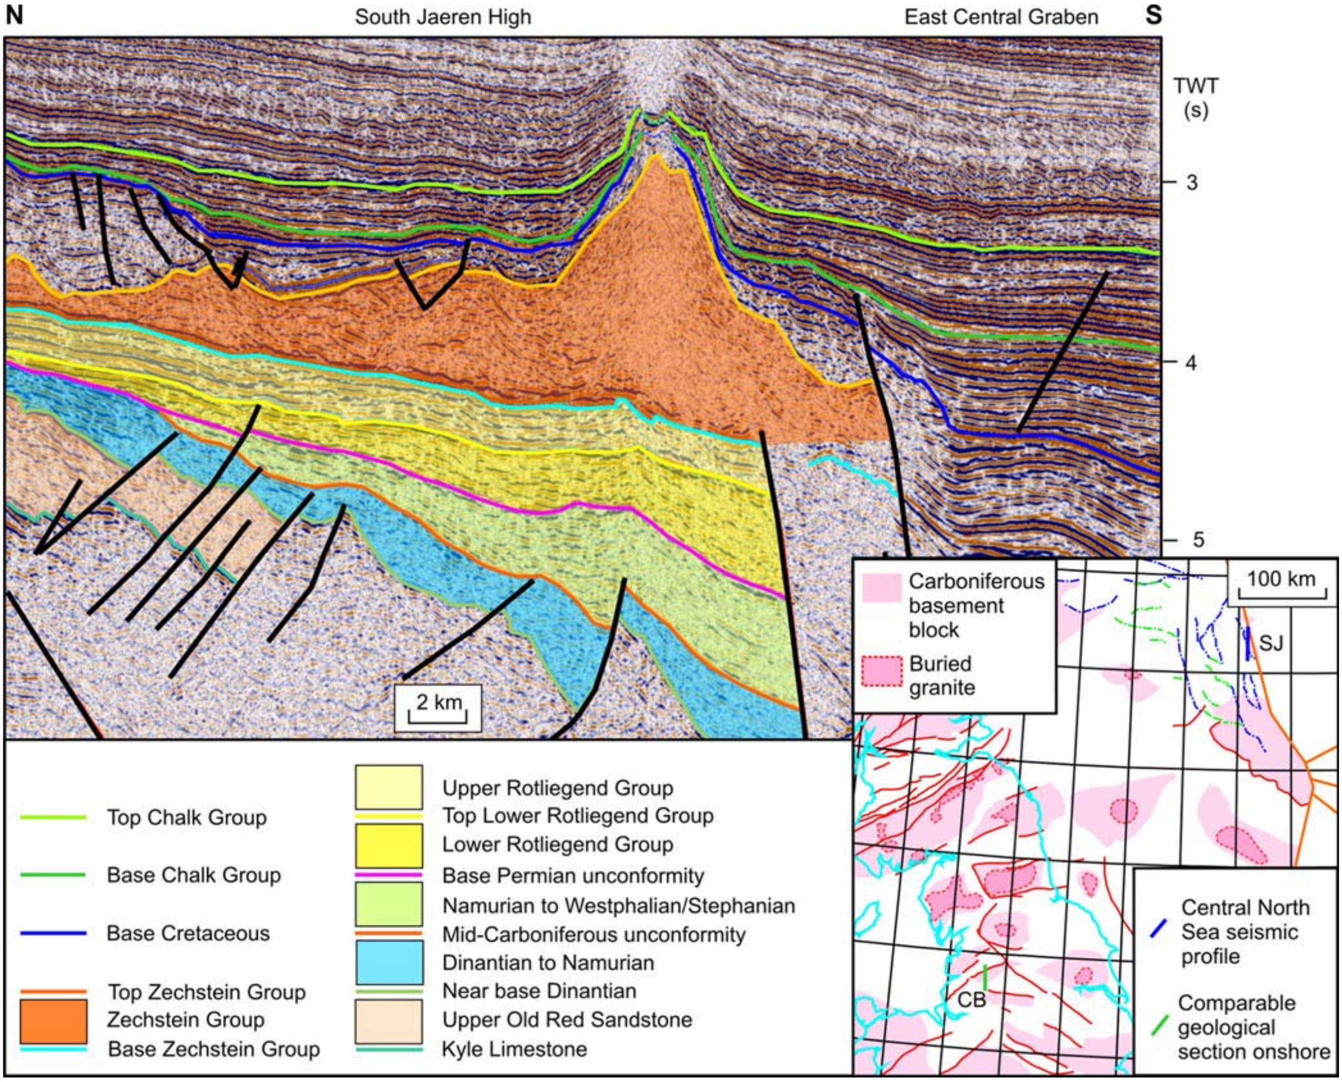

Fig. 9. Interpretation of example seismic profile from the south Jaeren High (SJ); data courtesy of CGGVeritas. CB, Craven Basin.

'seed' horizon which is modified during the inversion. For this project, a filtered version of the base Zechstein surface derived from seismic interpretation was used as the seed crystalline basement horizon.

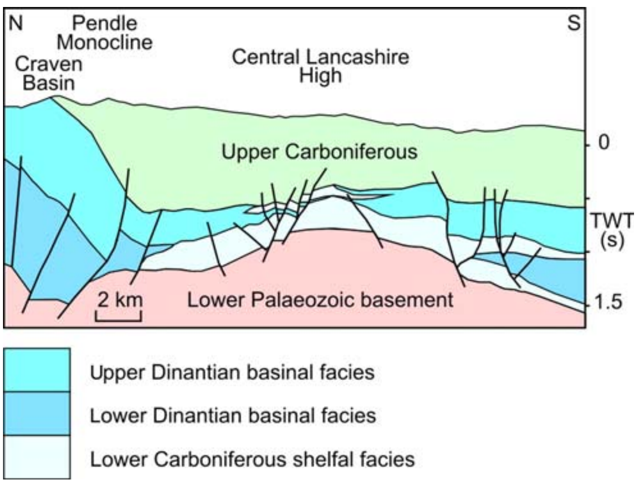

Fig. 10. Analogue from the southern margin of the Craven Basin (interpretation after Evans & Kirby 1999) for the sub-Permian stratigraphic relationships observed beneath the southern Jaeren High.

Construction of the input model: data input considerations

The regional control depth horizons were derived principally from the PGS 'North Sea Digital Atlas' time horizons, providing a more comprehensive data coverage than is currently available from the long-offset seismic data. Depth conversion of the input time surfaces was achieved by trendform gridding of interval velocities obtained from all exploration and appraisal wells in the study area. Initial inversions suggested considerable errors in the thickness of interpreted Permian salt in the Digital Atlas in the Central Graben. The top Permian salt horizon was therefore revised across the Central Graben using modern 3D seismic datasets. Further constraints included the results from preliminary 2D modelling of key seismic lines and selected magnetic crystalline basement depth estimates.

The Moho beneath the area was derived from an inversion of a surface obtained from the results of a refraction seismic study by Kelly *et al.* (2007). The gravity inversion for the Moho surface was constrained to the long-wavelength gravity signal only.

Lateral horizon density variations are difficult to represent adequately in a potential field model. In many studies the model is kept as simple as possible by applying single value densities to individual layers. Initial test inversions indicated that this approach is inappropriate in the Central North Sea, generating significant deviations with the depths derived from the seismic interpretation,

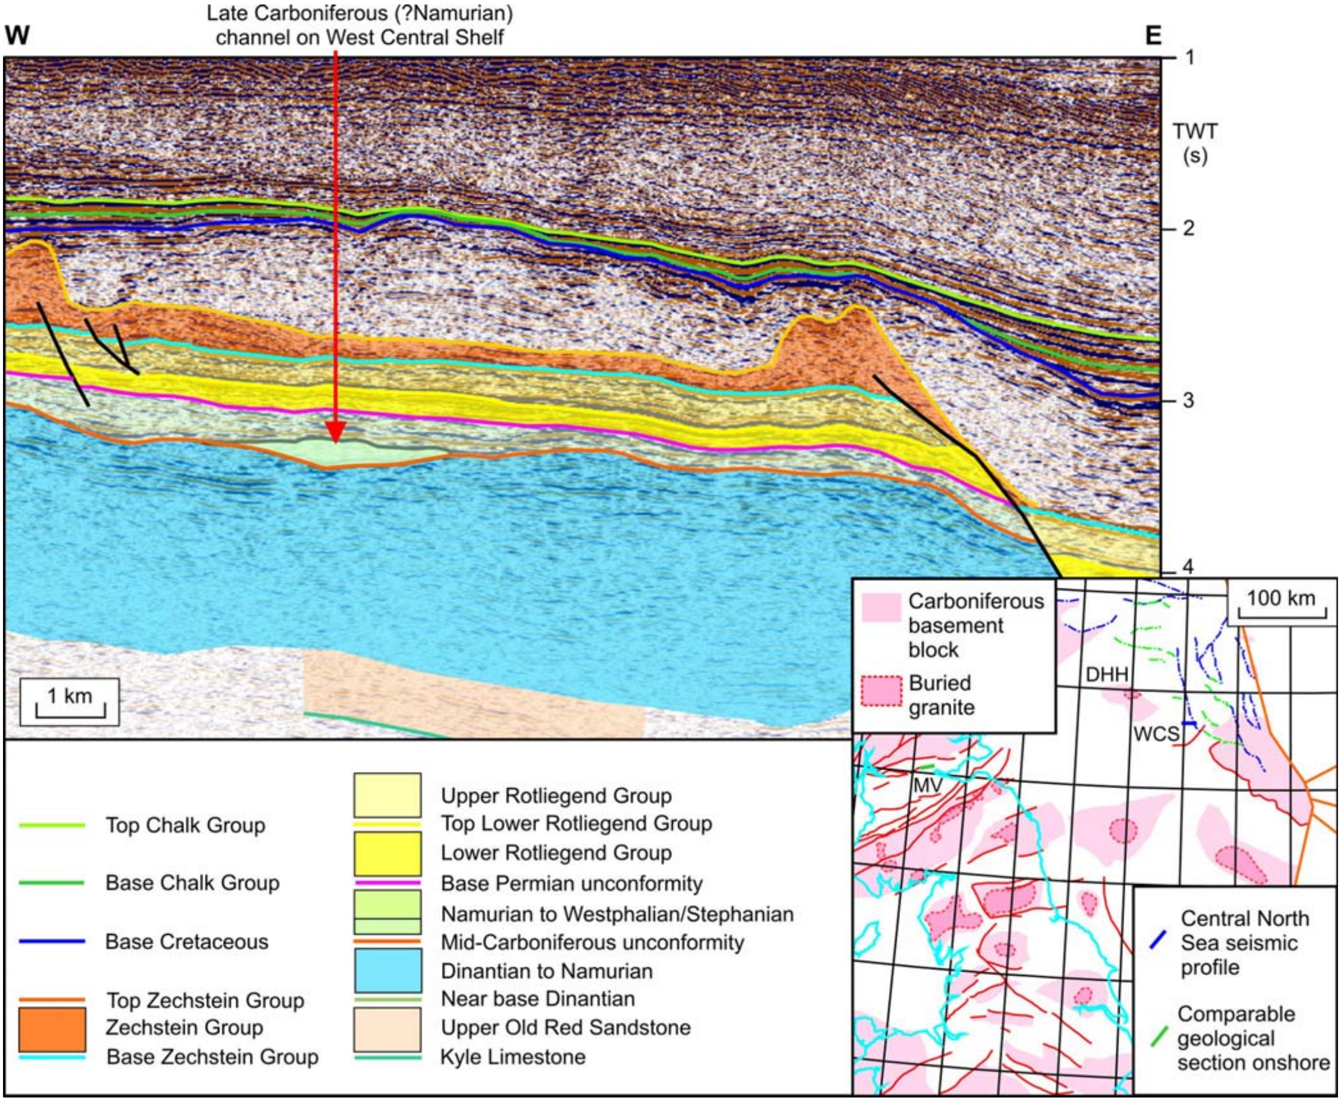

Fig. 11. Interpretation of example seismic profile from the West Central Shelf (WCS); data courtesy of CGGVeritas. DHH, Devil's Hole Horst; MV, Midland Valley of Scotland.

for instance on the western flank of the Central Graben. The solution applied was to derive grids of variable densities for all of the post-Permian layers (Table 1) from the grids of interval velocities that had been used for depth conversion of the seismic data – essentially producing a 'density cube' from the seismically derived 'velocity cube' over the entire project area. The final 3D input model is summarized in Figure 13.

Three-dimensional inversion solution

Top crystalline basement depths were computed by 3D inversion of the free air gravity. Predicted crystalline basement relief was computed by perturbing the top crystalline basement surface until the updated forward response of the model closely matched the observed gravity data. The inversion algorithm was then used to adjust this surface until the observed and computed responses matched within acceptable limits. The wavelengths are controlled during the inversion, allowing the longer wavelengths (deeper structure) to be targeted first, and gradually reducing the wavelengths to target the shallower structure. This is an iterative process, with the results examined at each stage. As most of the long-wavelength anomalies had been accounted for during the construction of the input model and the associated inversion processes to create the Moho/Lower Crustal surface, and since there was a fairly high degree of confidence in the starting surface, the input residual gravity grid did not contain many long-wavelength features. Hence the starting wavelength in the final inversion was 50 km, and this was successively iterated down to 2 km. The initial crystalline basement result, masked back to the limit of the study, is shown in Figure 14.

Three concentric 'lows' modelled within the initial crystalline basement surface were interpreted to be artefacts related to granitic intrusions (Fig. 15). The Farne and the Dogger granites within the Mid North Sea High have been described by Donato *et al.* (1983) and the third, the Devil's Hole Granite within the Devil's Hole High, by Hay *et al.* (2005). The morphology of these granitic bodies was projected downwards from the initial crystalline basement surface to a depth of 10 km. A further iteration of the 3D model (Fig. 16) produced a final crystalline basement surface (Fig. 17). The associated gravity error grid suggests that the crystalline basement depth surface has accounted for the appropriate anomaly wavelengths, and that most of the remaining errors can be attributed to post-crystalline basement geology or small-scale data anomalies.

Observations on sub-Permian basin architecture from the potential field model

In this study we have attempted to image the top of the crystalline basement from the gravity data as a first step towards deriving sub-Zechstein isopachs, which in turn should provide indications for the

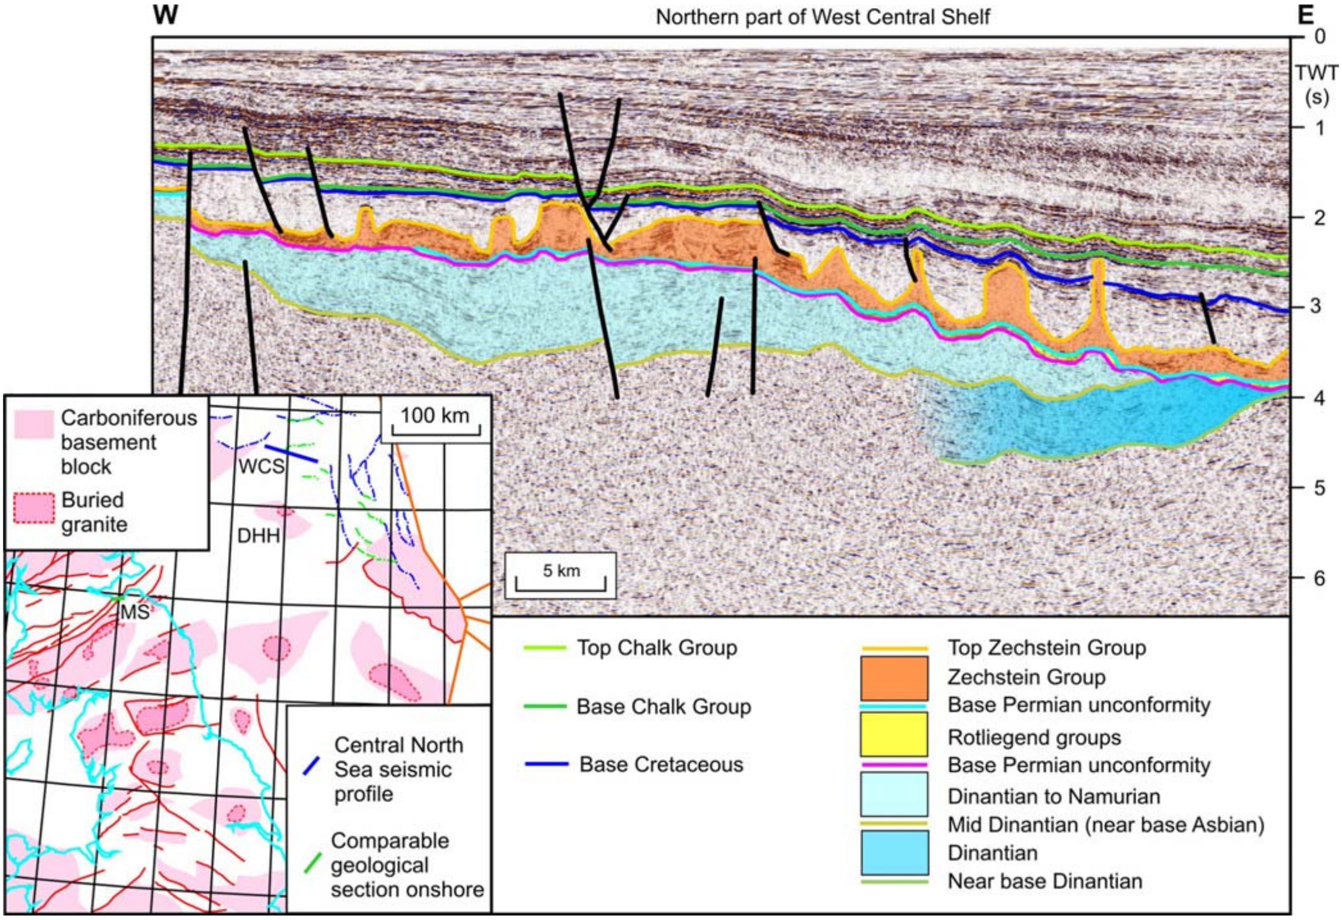

Fig. 12. Interpretation of example seismic profile from the West Central Shelf (WCS); data courtesy of TGS NOPEC Geophysical Co. (UK) Ltd. DHH, Devil's Hole Horst; MS, Midlothian Syncline, Midland Valley of Scotland.

locations of candidate Devono-Carboniferous basins in the subsurface.

Isopachs derived from the gravity modelling for the '*composite layer*' between the base of the Zechstein Group and the top of crystalline basement are shown in Figure 18. This '*composite layer*' includes the Rotliegend Group sediments that have been mapped from seismic interpretation as ranging between 0.1 and 1.8 km thick (Fig. 19). It also includes the underlying Devonian and Carboniferous strata, and at least in the offshore continuation of the Southern Uplands, it may also contain substantial thicknesses of Lower Palaeozoic rocks. This '*composite layer*' is up to 3.8 km thick, but it is modelled as being patchily thin or absent beneath the Mesozoic graben. In these patchily thin or absent areas, the 3D inversion has pushed the crystalline basement surface all the way up to the base of the Zechstein Group in order to match with the observed (survey) gravity. Density variation within the crystalline basement is likely to be small, so a more likely cause is lateral density variation within the composite Lower Palaeozoic to Rotliegend layer. It might be expected, for instance, that the stretched and hence condensed sub-Zechstein sections beneath the Mesozoic graben might have significantly higher density than laterally equivalent sections elsewhere in the region. Similarly, where the layer is dominated by Lower Palaeozoic strata it should have higher density than where it contains significant thicknesses of Rotliegend or Devono-Carboniferous sediments. It is possible to subdivide the composite layer in areas where there may be patchy seismic or well control, but the reliability of that subdivision derived purely from the 3D model would decrease rapidly further from the control points.

The potential errors in the modelled thickness of the composite sub-Zechstein layer, interpreted as resulting from lateral density variations, are calculated to be of the order of 0.3–0.4 km. We also recognize that Lyngsie *et al.* (2006), Lyngsie (2007) and Lyngsie & Thybo (2007) suggest a possible explanation involving a contrast in lower crustal density across the suture between Laurentia and Baltica crystalline basement, which they trace approximately beneath the northern flank of the Auk–Flora Ridge, and continuing northwestward below the western margin of the Central Graben. Bearing these two caveats in mind, the

Table 1. Summary of layer density values input to the 3D inversion model; where a density range is specified this represents lateral variation in density as derived from the velocity cube

Bounding horizon names for layers	Density ($g\ cm^{-3}$)
Sea-level to sea bed	1.03
Seabed to top Chalk Group	1.99–2.16
Top Chalk Group to base Chalk Group	2.20–2.50
Base Chalk Group to base Cretaceous	2.09–2.57
Base Cretaceous to top Permian (top Zechstein Group)	1.99–2.54
Top Permian to top Rotliegend Group (base Zechstein Group)	2.16
Top Rotliegend Group to top crystalline basement	2.55
Top crystalline basement to Moho	2.80
All sub-Moho section	3.20

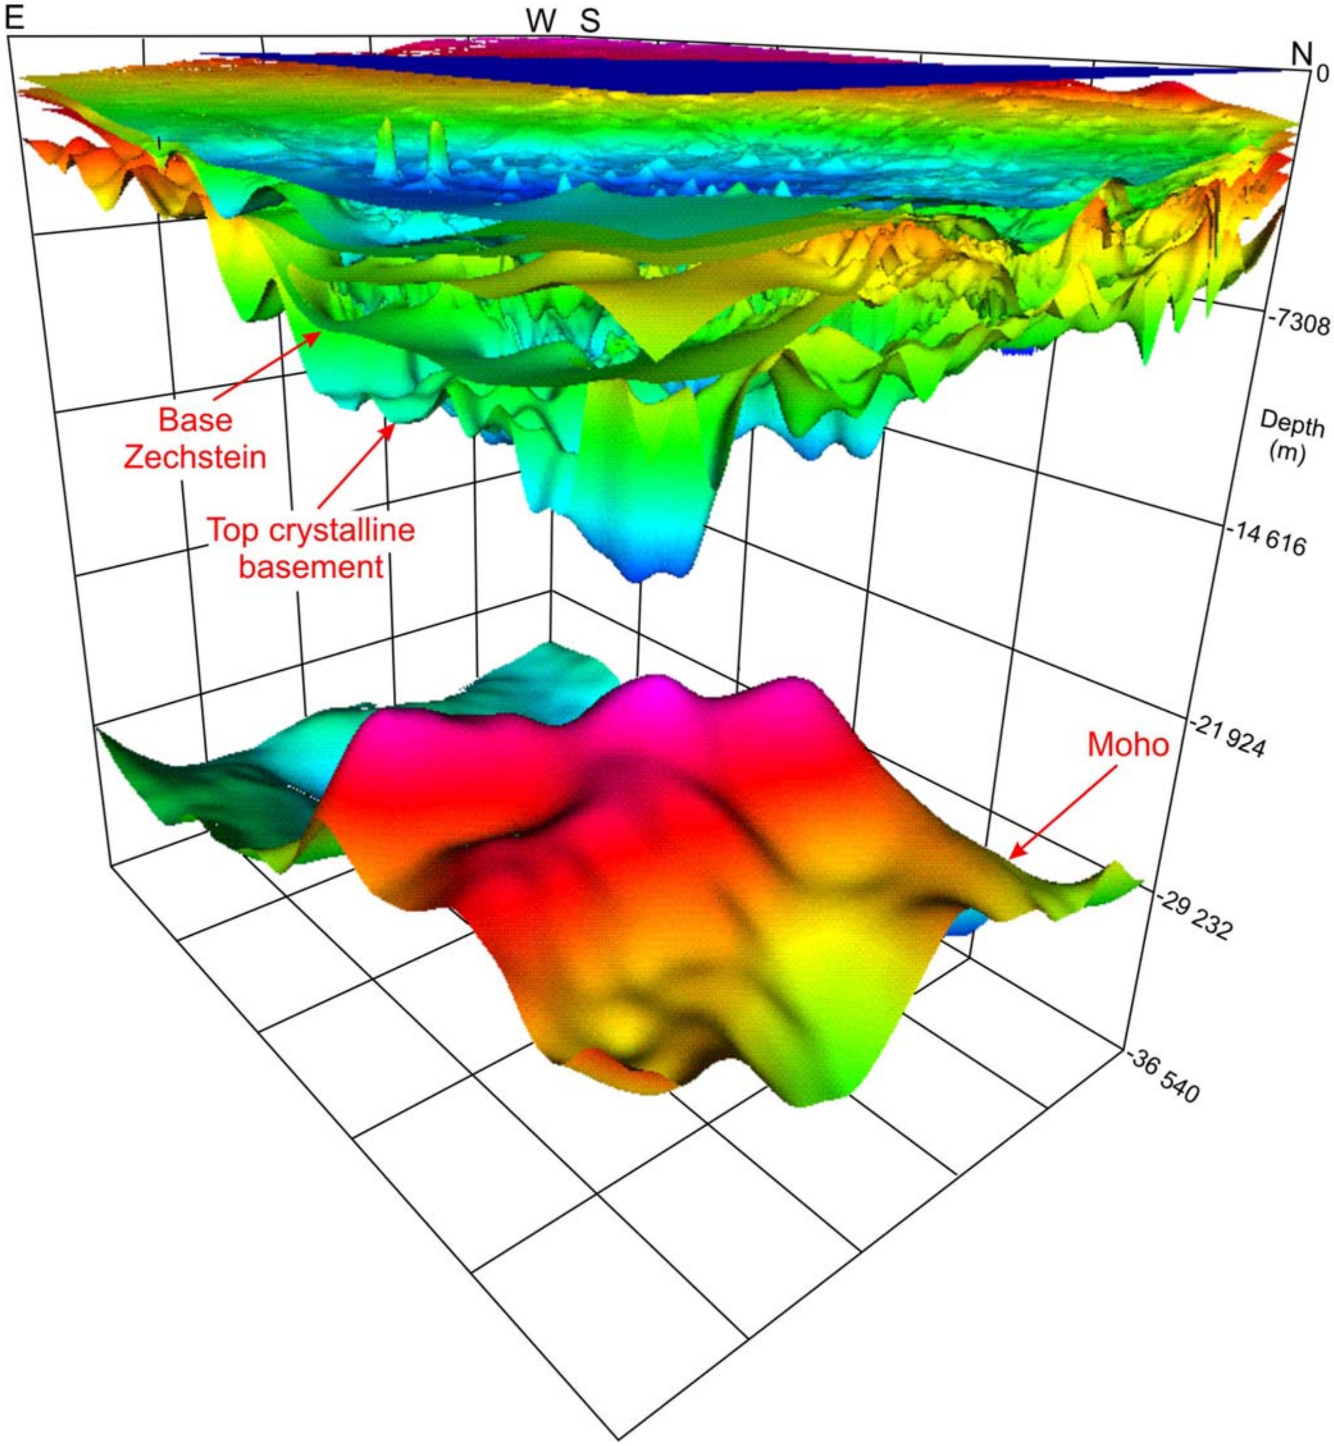

Fig. 13. Starting 3D model with the crystalline basement depth seed surface prior to inversion, viewed from the NE.

sub-Zechstein isopach map (Fig. 19) does provide encouraging indications for the presence of substantial sedimentary basins beneath the Zechstein Group. Also, bearing in mind the thickness of Rotliegend strata derived from the seismic interpretation (Fig. 19), these are the most likely locations for candidate Devono-Carboniferous basins as derived from the gravity data.

The fit of the modelled top of crystalline basement to the long-offset seismic data is demonstrated in Figure 20, which traverses the West Central Shelf, the West Central Graben, the Forties–Montrose High, the East Central Graben, and ends on the Jaeren High with its Devono-Carboniferous core. The sub-Zechstein 'composite layer' is uncoloured on the seismic profile; see Figure 18 for location of the profile.

Synthesis of the geophysical methods

The seismic interpretation has provided indications that many of the basement controls that defined the architecture of the onshore UK Lower Carboniferous basins also operated across the UK Central North Sea. In the SE Central North Sea where the seismic imaging is clearest, it contains elements comparable with the Askrigg Block (Dogger Block) and Stainmore Trough (Mid North Sea High Carboniferous Basin) (Figs 4 & 21–23). The up-thrust Auk–Flora Ridge intra-basinal Lower Palaeozoic basement block resembles the Pentland Hills Inlier within the Midland Valley of Scotland and the Cross Fell Inlier in northern England. We recognize that in one area just south of the Devil's

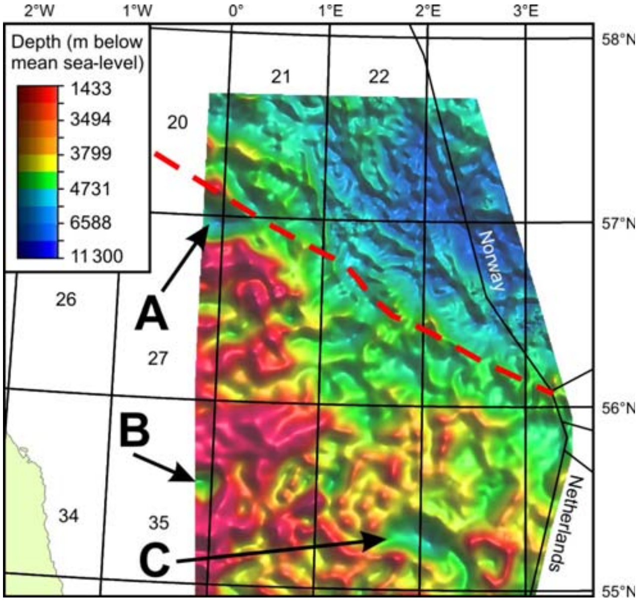

Fig. 14. Initial output of the crystalline basement surface showing the anomalies associated with granites. A, Devil's Hole Granite; B, Farne Granite; C, Dogger Granite.

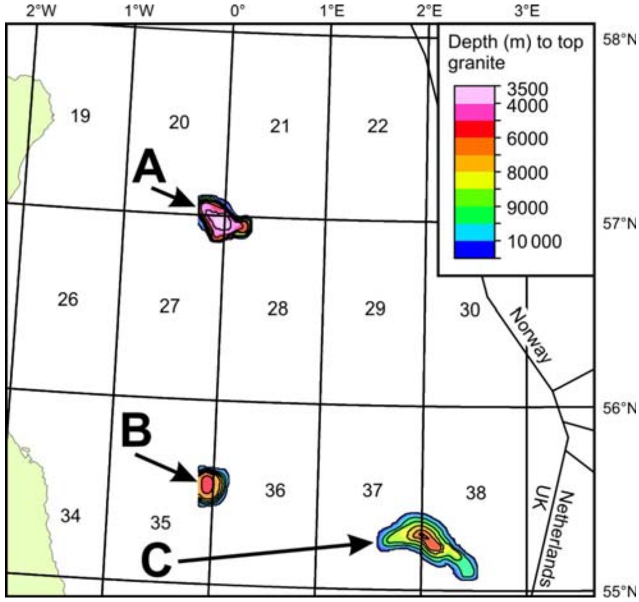

Fig. 15. Depth contours (1000 m interval) at the top of granites A to C. A, Devil's Hole Granite; B, Farne Granite; C, Dogger Granite.

Hole High there is a discrepancy between the gravity & seismic results, which suggest relatively thin and thick sub-Zechstein strata respectively, and this requires further investigation.

On a regional scale, the seismic interpretation has been used to provide a preliminary indication of Lower Carboniferous basin distribution in the east-Central North Sea (Fig. 24). In addition to Lower Carboniferous basins proven by drilling on the eastern Mid North Sea High and in northern Quadrant 21, undrilled Lower Carboniferous basins have also been interpreted in southern Quadrant 29, and to the north and NW of the Auk–Flora Ridge.

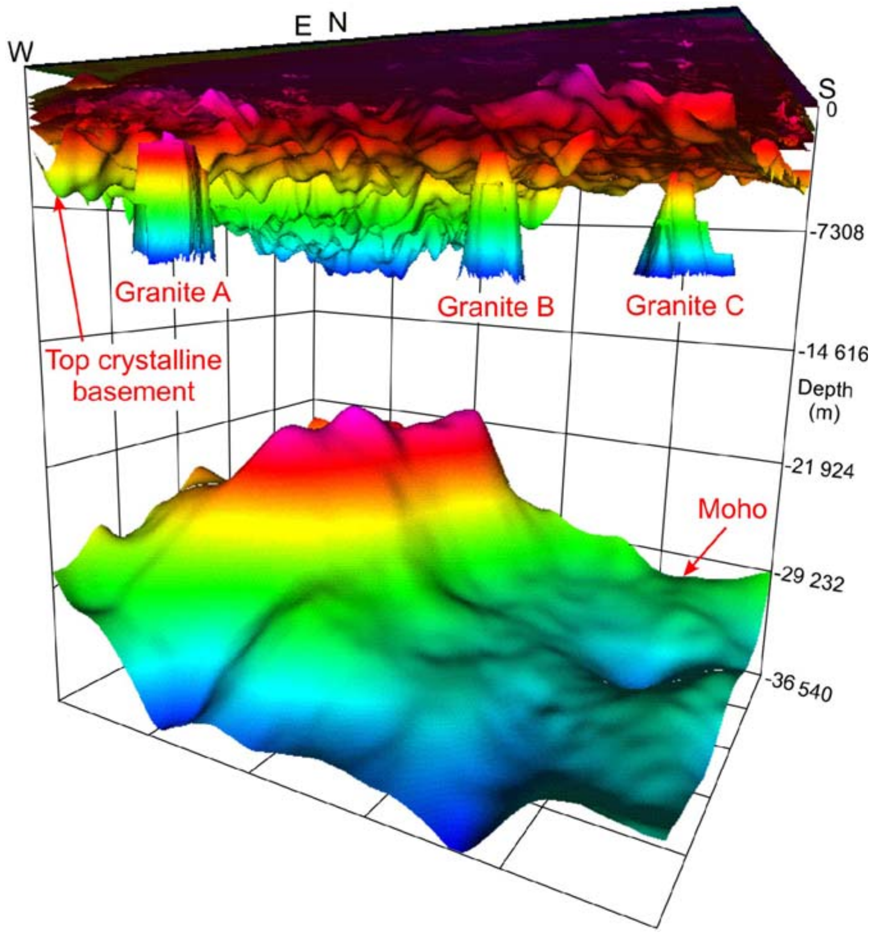

Fig. 16. Modified 3D model showing the detailed morphologies of granites A–C prior to inversion, viewed from SW. A, Devil's Hole Granite; B, Farne Granite; C, Dogger Granite.

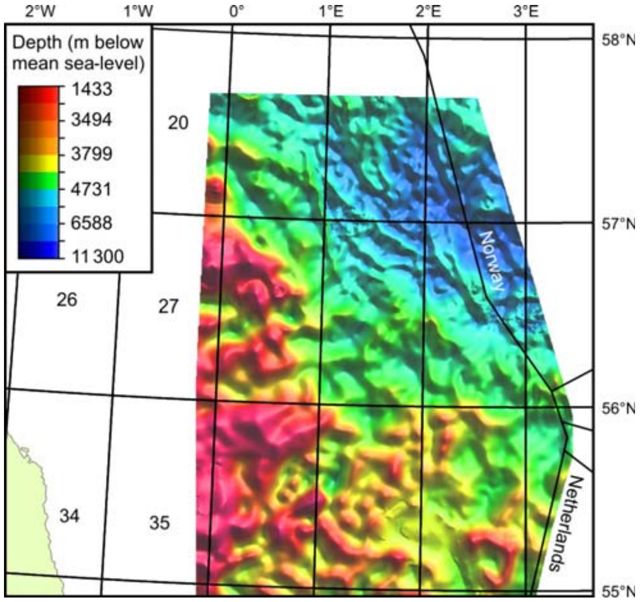

Fig. 17. Final output of the crystalline basement surface.

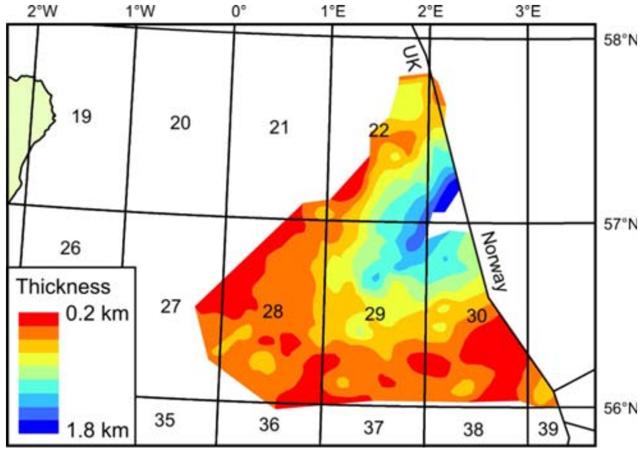

Fig. 19. Approximate thickness of combined Upper and Lower Rotliegend Groups; isochrons converted to thickness assuming a standard interval velocity of 4 km s^{-1}.

Based on the seismic interpretation, these are the regions that are most likely to contain significant volumes of coal-measure source rocks within the sub-Permian section.

The locations of candidate Devono-Carboniferous basins as deduced from gravity modelling do show some features in common with the seismic interpretation (Fig. 25). Encouragingly, both methods provide indications for the undrilled Devono-Carboniferous basin in the south of Quadrant 29, here shown on the contoured crystalline basement surface (Fig. 26) and on a 3D representation of this (Figs 27 & 28). This lends support for a working petroleum system in the south of Quadrant 29, based on the possible presence of significant volumes of mature Carboniferous source rocks. The gravity modelling suggests a NW-trending chain of apparent sub-Zechstein sediment thicks underlying and extending NW of the Auk–Flora Ridge of relatively thin Middle Devonian to Carboniferous strata based on the seismic interpretation. If this observation is derived from a low density unit within the upper crust, then it indicates the Auk–Flora Ridge is possibly underlain by an inverted Lower Devonian basin.

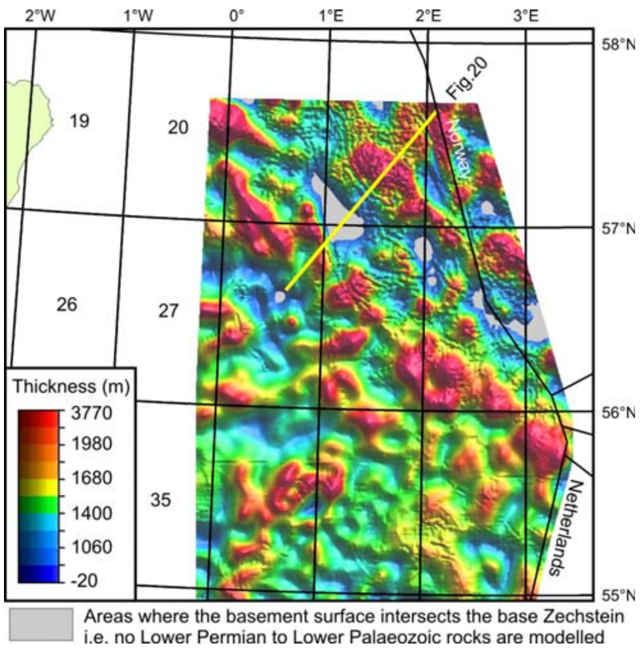

Fig. 18. Isopachs of the sub-Zechstein 'composite layer'.

The Rotliegend strata are divisible into Upper and Lower Rotliegend seismic units in the Flora area, on the Jaeren High and on parts of the West Central Shelf, but are not divisible consistently on a regional scale. Where they can be distinguished, the Upper Rotliegend unit is of relatively uniform thickness, and it oversteps the Lower Rotliegend unit at the basin margins. On some seismic profiles there are indications that thickness variation within the Lower Rotliegend unit is partly a result of penecontemporaneous Early Permian fault activity. This unit is largely composed of volcanic rocks in the Flora area and further east in the North Sea (Heeremans & Faleide 2004), but it may be predominantly composed of continental red-bed facies in the remainder of the UK sector, where it remains relatively undrilled. Isopachs of the combined Upper and Lower Rotliegend units follow a concentric pattern about a NE-trending depocentre that intersects the UK/Norway median line at 57°N (Fig. 19).

Hydrocarbon prospectivity implications

Source rocks

Potential source rocks of the Central North Sea's Carboniferous petroleum system have been poorly sampled by exploration drilling. Only 25 wells have drilled through the base of the Permian into Carboniferous strata in an area of 95 000 km^2 (Fig. 2), with the majority of these wells located around the periphery of the area. Despite this, 11 of the wells have drilled sections of Dinantian and/or Westphalian coal measures. From analyses of these coal measures in well 26/8-1, Hay *et al.* (2005) confirmed their potential for significant hydrocarbon-generating capacity where these are thermally mature. Geochemical analyses indicate that oil within Rotliegend sandstone fluid inclusions in well 29/20-1 has been most likely derived from Carboniferous lacustrine source rocks (PA Resources UK 2010).

Dinantian to Namurian palaeogeography in the onshore UK was dominated by the progressive southwards advance of a major fluvio-deltaic system across the region (Fraser & Gawthorpe 1990; Fraser *et al.* 1990). In the northernmost basins that were overwhelmed earliest by the fluvio-deltaic influx, potential pre-Westphalian source rocks are limited to the mid-Dinantian coal measures of the Scremerston Coal Group or to the thick non-marine oil shales developed within volcanic terrain in the Midland Valley of Scotland. Notably absent from the northern onshore basins are substantial thicknesses of Late Dinantian to Early Namurian

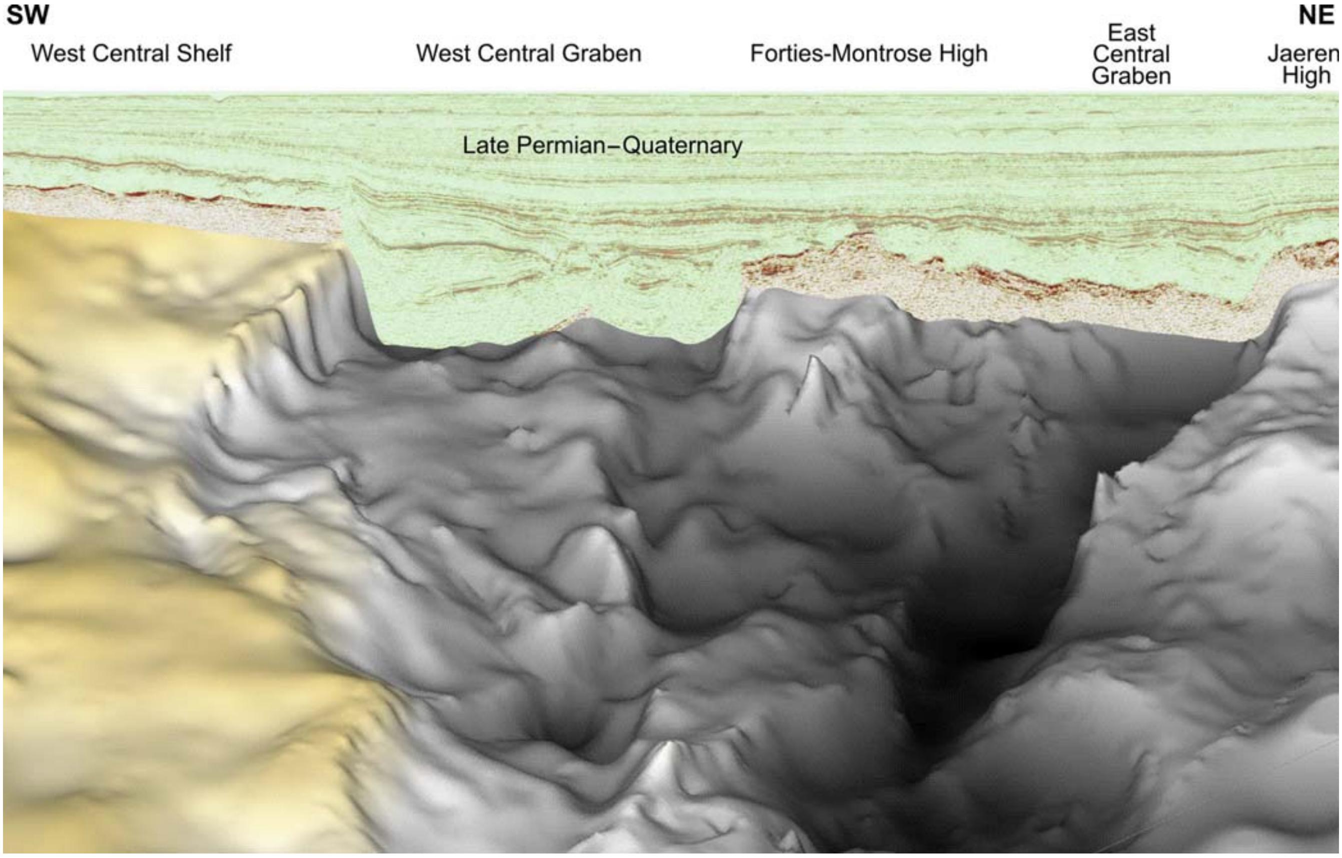

Fig. 20. Three-dimensional view from SE of modelled top crystalline basement surface intersecting a 2D long-offset seismic profile across the northern part of the study area, which traverses the West Central Shelf, the West Central Graben, the Forties–Montrose High, the East Central Graben, and ends on the Jaeren High with its Devono-Carboniferous core. Fig. 21. Schematic profile showing generalized structural and stratigraphic relationships across the Mid North Sea High, from south of the Dogger Block to the Central Graben.

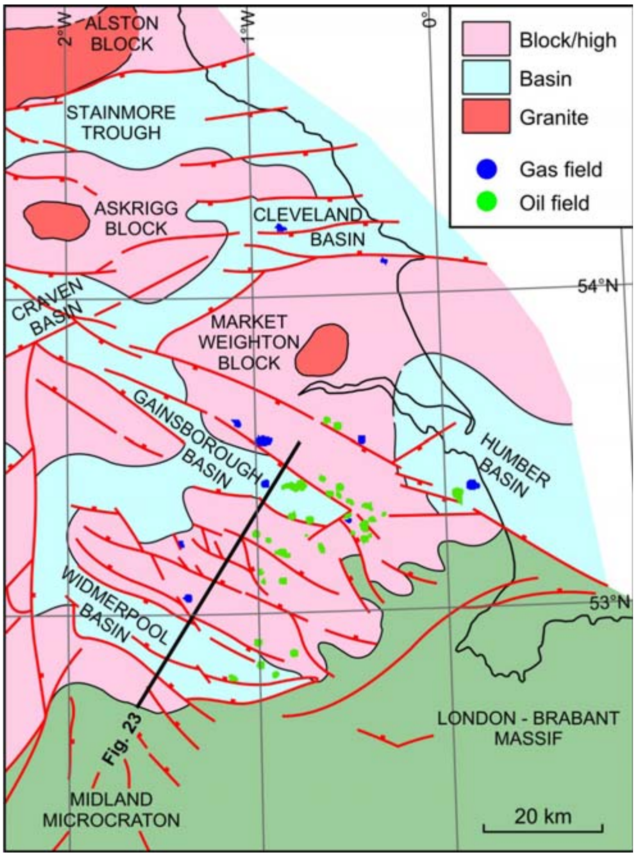

Fig. 22. Map of the Carboniferous block and basin structure of northern England, showing the onshore oil and gas fields and their structural setting; adapted from Fraser *et al.* (1990).

organic-rich marine shales such as those that accumulated in sediment-starved basins beyond the advancing deltas to form the principal source rocks for the oil and gas fields of the East Midlands of England and the East Irish Sea Basin.

For this reason, mid-Dinantian coal measures or oil shales are considered to provide the best opportunity for significant volumes of source rocks in the east-Central North Sea. This is because the seismic mapping indicates that Westphalian coal measures, the principal source rocks in the Southern North Sea, have been largely removed by pre-Permian erosion. The Dinantian sections drilled in wells 38/16-1 and 39/7-1 provide encouragement for potentially significant volumes of source rocks in the southern Devono-Carboniferous basins – the latter well proved coal seams up to 4.5 m thick, constituting 16% of an 87 m-thick coal-measure unit. Bruce & Stemmerik (2003) recorded likely oil shales with TOC values as high as 15–24% within 500 m of Late Dinantian to earliest Namurian strata drilled in well 20/10a-3.

Underhill *et al.* (2008) noted that Carboniferous source rocks at elevated structural locations in the eastern Midland Valley of Scotland and in offshore well 25/26-1 lie close to the oil window. They inferred from burial history modelling that deeper-buried sections became mature for oil generation in the Late Carboniferous, and following end-Carboniferous, Variscan uplift re-entered the oil window during the Mesozoic. Much of the Midland Valley was elevated out of the oil window once more by Palaeogene uplift, but petroleum generation may be continuing in the deepest-buried strata today.

Offshore, Hay *et al.* (2005) concluded from burial history modelling that mid-Dinantian coal-measure source rocks that they interpreted beneath south-central Quadrant 29 are also mature for oil generation, and may even have entered the gas window locally. They estimated that up to 28 billion barrels of oil and 156 tcf of gas could have been expelled from this area alone. Their modelling suggests that most of this hydrocarbon expulsion has been since the Paleocene, hence post-dating all reservoir and trap development in the region. However, Hay *et al.* (2005) predicted that any Dinantian strata preserved in Mid North Sea High Carboniferous basins are only marginally mature for oil generation.

Play types and traps

On a local scale, the ranges of Central North Sea play types that can be invoked from thermally mature Carboniferous source-rock kitchens are largely dependent on the efficiency of the regional Zechstein Group evaporite seal. Where this seal is intact, hydrocarbon charge will be limited to reservoirs and traps within the sub-Zechstein section, in a block and basin setting similar to northern England (Fig. 22). Where this seal has been breached in areas of Zechstein Group salt withdrawal, there are also opportunities for charging reservoirs in the post-Permian section. Hay *et al.* (2005) have used the occurrence of gas chimneys within the Mesozoic section as indicators of relatively widespread Zechstein seal breach in the south of Quadrant 29. Modern long-offset seismic

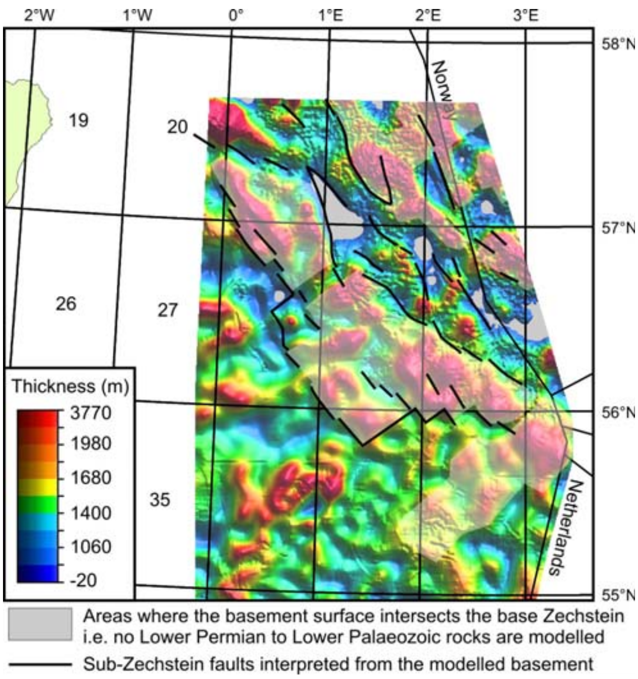

Fig. 25. Isopach map of the sub-Zechstein 'composite layer' and candidate Devono-Carboniferous basin outlines.

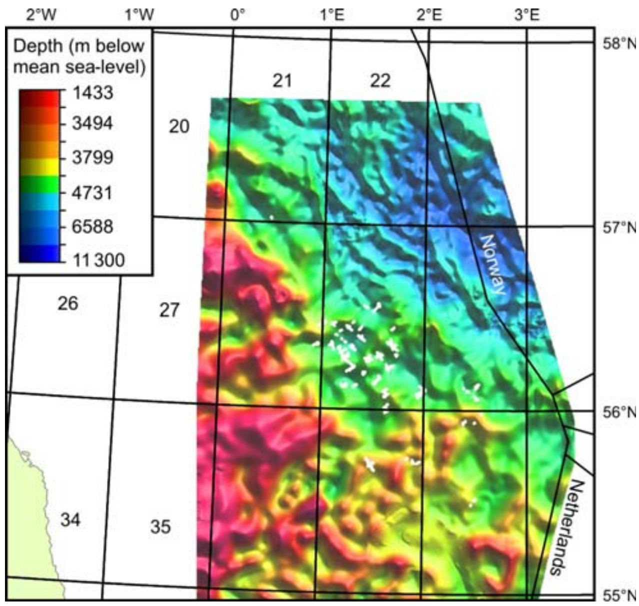

Fig. 26. Shaded relief crystalline basement surface overlain with the gas chimneys (white polygons).

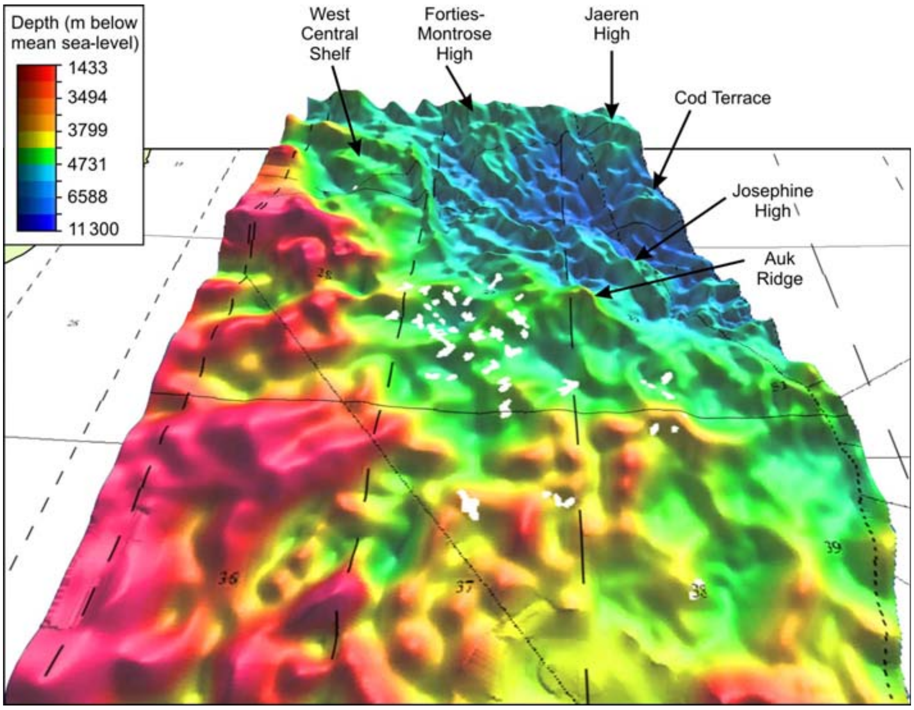

Fig. 27. Three-dimensional display of the crystalline basement surface overlain with the gas chimneys.

coverage is sparse in this area, but is sufficient to verify that some of these gas chimneys are genuine and likely to be thermogenic, whereas others relate to amplitude anomalies confined to the Quaternary section and may be indicators of biogenic gas. Gas chimneys are uncommon above all other candidate Carboniferous source rock basins (Fig. 26), indicating that, if mature, their Zechstein topseal is intact. Where the Zechstein topseal is breached, hydrocarbons could potentially migrate into Triassic to Cenozoic play fairways, which are equally underexplored to the west of the Central Graben's Jurassic source kitchen.

Rotliegend Group desert sandstones have been the primary focus of Central North Sea sub-Zechstein exploration to date, with the Auk, Argyll/Ardmore and Innes fields sourced from the Upper Jurassic kitchen of the Central Graben. Less well appreciated has been the potential for Rotliegend Group targets above thermally mature Carboniferous source-rock basins, either in structurally constrained traps or in updip pinchout traps around the margin of the Rotliegend basin.

Potential sub-Rotliegend targets fall into three categories – Zechstein subcrop traps beyond the limit of the Rotliegend

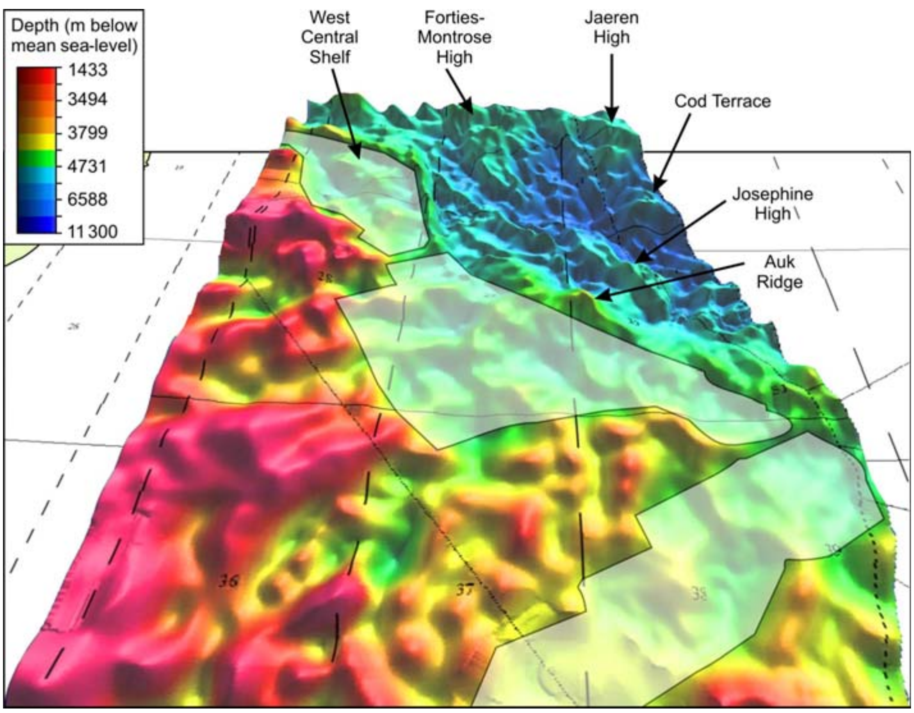

Fig. 28. Three-dimensional display of the crystalline basement surface and candidate Devono-Carboniferous basins, which predominantly underlie the gas chimneys mapped by Hay *et al.* (2005).

fairway, Lower Rotliegend subcrop traps, and intra-Carboniferous traps. Prime examples of the first two categories are the Upper Devonian producing reservoir in the Argyll/Ardmore Field (Robson 1991) and the Upper Carboniferous, Upper Flora Sandstone producing reservoir in the Flora Field (Martin *et al.* 2002). Both of these discoveries were made by serendipity, with Rotliegend reservoirs being their primary targets, but both were sourced from the Jurassic source kitchen.

In summary, our paper reaffirms the likely existence of the overlooked Carboniferous petroleum system proposed by Hay *et al.* (2005). This petroleum system has the potential for extending the geographic distribution of valid exploration targets, in all of the principal play fairways of the Central North Sea, with potential Carboniferous drilling objectives as shallow as 8500 feet.

Conclusion

Our interpretation has revealed a Devono-Carboniferous basin architecture for the Central North Sea, which exhibits many features in common with the contemporary basins of northern England and southern Scotland. By analogy with these basins, their Central North Sea equivalents are likely to contain significant volumes of coal-measure and perhaps also oil-shale source rocks. Where thermally mature, these source-rock intervals are key elements of an underexplored Carboniferous petroleum system, potentially extending far to the west of the Jurassic source kitchen, which has been the focus of almost all Central North Sea exploration to date. The recognition by Hay *et al.* (2005) of gas chimneys above the Zechstein layer stretching from block 21/27 through southern Quadrant 29 to the Mid North Sea High suggests that postulated underlying Carboniferous source rocks may be thermally mature in many of the Devono-Carboniferous basins imaged in this study (Figs 2 & 24–28). We conclude that exploration opportunities associated with this petroleum system occur both in Devonian to Lower Permian plays beneath the regional Zechstein evaporite seal and, where halokinetic thinning has enabled seal breach, in the underexplored Mesozoic and Cenozoic plays above.

Channel structures formed by contour currents and fluid expulsion: significance for Late Neogene development of the central North Sea basin

P. C. KNUTZ

Geological Survey of Denmark and Greenland, Geophysics Department, Øster Voldgade 10, 1350 Copenhagen, Denmark (e-mail: pkn@geus.dk)

Abstract: Channel horizons, delimiting a major Pliocene sedimentary prism in the central North Sea basin, have been investigated in the context of oceanographic, climatic and tectonic controls, using 3D seismic and well data from the UK and Norwegian sector. Aggrading channel structures, forming 700–2500 m wide and 75–150 m deep linear to arcuate troughs, superimpose the truncated distal part of the prism in the northern Central Graben. The origin of the aggradational channel and prism complex is related to differential deposition and erosion by contour currents that intensified as tectonic subsidence formed a deep marine basin (>600 m) with open connections to the Atlantic and Norwegian Sea. The largest channel troughs appear to be filled with consolidated sediments and emerge from areas where the Neogene strata is pierced by salt diapir chimneys. From Early Pleistocene (*c*. 2.5 Ma) the channels were subject to progressive burial by rapid clinoform progradation. Based on the seismic observations, a depositional model is proposed that relates contourite channel development to fluid expulsion from salt diapir structures and fracture zones extending from lower Miocene strata. The sedimentary prism accumulated over a Late Miocene/Early Pliocene Unconformity marked by incised channels that are reminiscent of a northward diverging drainage system. This erosive low-stand development is probably related to late Alpine compression, which promoted uplift in the British Isles and the Channel region. The ensuing subsidence of the central North Sea, associated with concomitant uplift of the Norwegian–Danish Basin, generated the present southwestward dip of 0.5–0.8° of the basal unconformity. The Late Miocene compressional phase followed by rapid basin depending during Pliocene to early Pleistocene suggests that present concepts of North Sea basin development have to be re-evaluated.

Keywords: North Sea, neogene basin, pliocene, 3D seismic, aggradational prism, contour current, salt diapir leakage, tectonic subsidence

The Late Cenozoic succession forms an integral part of the North Sea petroleum system by sustaining overpressure in the deeper stratigraphic sections and preventing prolific hydrocarbon leakage from Cretaceous and Early Cenozoic reservoir accumulations (Cayley 1987; Thrasher *et al.* 1996). The infill history of the 1500 m deep Late Neogene basin (i.e. last 15 Ma) is manifest by a succession of Upper Miocene, Pliocene and Quaternary depositional units, formed in response to tectonically induced subsidence, sediment supply, eustatic sea-level changes and oceanographic currents (Nielsen *et al.* 1986; Kooi *et al.* 1991; Galloway *et al.* 1993; Michelsen *et al.* 1995). 2D and 3D seismic studies of this package have demonstrated the presence of buried geomorphic features, representing channels, pockmarks and sedimentary extrusion, as well as fluid-flow anomalies generated by hydrocarbon leakage from structural reservoirs (Cartwright 1995; Heggland 1998; Fichler *et al.* 2005; Andresen *et al.* 2008). These lateral and vertical heterogeneities in the Late Cenozoic overburden have received modest attention despite the relevance for evaluating remaining hydrocarbon prospects in the mature North Sea province. Moreover, an assessment of velocity anomalies induced by these features is important for identifying drilling hazards and achieving precise depth conversion of deeper target horizons (Armstrong *et al.* 2001). Also, recognition of geomorphic elements associated with palaeo-surfaces may further new understandings of how depositional patterns and processes are related to changes in basin configurations. The objective of this study is to investigate complex channel structures in the Late Neogene section of the Central Graben (UK and Norwegian sector) based on 3D seismic interpretation using the PGS Central North Sea MegaSurvey. The seismic–stratigraphic framework is mainly defined by major unconformities tied to geophysical log parameters from key wells, and correlation to biostratigraphic records in the southern Central Graben. The origins of the channel systems are discussed in context of the depositional and tectonic development of the Neogene North Sea basin.

Regional background

The North Sea Central Graben is an epicontinental basin formed by lithospheric extension during the Permo-Triassic and Late Jurassic–Early Cretaceous (Ziegler 1992). Its present structural configuration of intra-basinal lows and highs is the result of multiple tectonic inversion phases that ceased during Paleocene to Early Eocene (Gatliff *et al.* 1994). From Eocene to Late Pleistocene, a succession of up to 2800 m of mainly undercompacted marine mudstone filled the North Sea basin (Jordt *et al.* 1995; Michelsen *et al.* 1995). A phase of rapid aggradational and progradational infill occurred during the Late Neogene with more than 1000 m of sediments accumulating in the Central Graben depocentre, mainly by transport from NW and west (Michelsen *et al.* 1995; Sorensen *et al.* 1997). The southern North Sea basin was infilled by progressive westward expansion of deltaic sedimentation that was active until Early–Mid Pleistocene (Cameron *et al.* 1993; Overeem *et al.* 2001; Kuhlmann & Wong 2008). In the northern North Sea (south Viking Graben) mounded sand accumulations of the Late Miocene–Early Pliocene Utsira Fm. (Gregersen *et al.* 1997; Eidvin & Rundberg 2007) were probably formed in a deep shelf setting (water depths of 200–300 m) with sediment transport predominated by strong ocean currents (Galloway 2002). In this region Neogene chronology has been established by foraminifer

biostratigraphy from key wells, Sr isotope dating and multiple well log correlation (Head *et al.* 2004; Eidvin & Rundberg 2007). In the southern and eastern North Sea, the age of Neogene units is construed primarily by application of dinocyst biostratigraphy (Kuhlmann *et al.* 2006; Dybkjær & Piasecki 2008), assisted by marine-to-onshore correlations using an extensive 2D seismic and borehole database (Rasmussen *et al.* 2005).

Basin modelling suggests that periods of anomalous subsidence, deviating from predicted post-rift thermal subsidence, are required to explain the Cenozoic sedimentary architecture of the North Sea (Kyrkjebø *et al.* 2000; Faleide *et al.* 2002). The causes of intraplate tectonic movements are not fully understood, but may involve crustal flexuring, associated with changes in the regional stress field produced by Mid-Atlantic Ridge dynamics and the African–Eurasian plate collision (Kooi *et al.* 1991; Dore & Lundin 1996). Long-wave geodynamic movements, associated with the Neogene Alpine collision, exercised a primary control on the palaeogeography in NW Europe and sediment fluxes to the southern North Sea basin (Ziegler 1992; van Vliet-Lanoë *et al.* 2002; Hillis *et al.* 2008). Late Miocene (i.e. Messinian) compression is associated with a major transgressional phase in the southern North Sea region, resulting in by-pass of river systems and peat development in the central parts (Vandenberghe *et al.* 1998; Rasmussen 2004). The complex development of Neogene strata, resulting from interaction between subsidence, erosion and deposition, has attracted opposing views with respect to primary controls on basin development. In the eastern North Sea over the Norwegian–Danish Basin, an exhumed section (500–1000 m) of post-Mid-Miocene sediments has been a principle argument for a Pliocene phase of active tectonic uplift (Japsen *et al.* 2007). Others have disputed this concept, giving preference to Late Cenozoic progressions in climate-induced weathering and sediment isostacy as an explanation for incongruent sedimentation patterns (Huuse 2002; Nielsen *et al.* 2002). From an E&P perspective, an important consequence of Neogene subsidence was the westward tilting of strata along the eastern basin margin, promoting updip movement of Jurassic hydrocarbon fluids via Cenozoic formations into structural traps of the Danish chalk fields (Rasmussen *et al.* 2005; Vejbæk *et al.* 2005).

The Cenozoic package is pierced by salt diapirs that protrude from Triassic salt ridges through deep-seated structural faults (Jackson & Seni 1984; Bishop 1996). In the east Central Graben, salt domes form prominent structural traps by the wedging of Upper Cretaceous and sand-prone Paleocene units against their downturned crests (Davison *et al.* 2000*b*). The majority of these salt structures have been drilled, encountering hydrocarbon columns ranging from 600 to 1300 m within Upper Cretaceous and Paleocene formations. The salt diapirs are commonly associated with gas chimneys, that extend into the younger Cenozoic succession as a product of vertical fluid-flow from deeper stratigraphic horizons (Thrasher *et al.* 1996; Løseth *et al.* 2008). Hydrocarbon leakage is observed above several producing fields in the Central Graben (e.g. Machar, Medan and Tommeliten), by the presence of seabed pockmarks and traces of thermogenic gas (Heggland 1998).

A 2D seismic study of the Late Neogene package by Cartwright (1995) revealed a series of ridge–trough sedimentary structures in the NW part of the Central Graben (UK quadrant 22). In compliance with the restricted resolution and geographical extent of the data, Cartwright suggested the features could have formed as a result of downslope sediment transfer from a deltaic system, or, alternatively, alongslope oceanic currents flowing through the North Sea basin. Over the last decade, the increasing availability of commercial 3D seismic data has endorsed a process-based understanding of spatial depositional and erosional patterns within the strata column (Gregersen 1997; Praeg 1997; Hansen *et al.* 2004; Kuhlmann & Wong 2008; Andresen *et al.* 2009).

Geophysical data and methods

The study area is located within the UK and Norwegian Central Graben and includes UK quads 22, 23 and 29, and Norwegian quads 1, 2 and 7 (Fig. 1). The seismic interpretation, based on PGS Central North Sea MegaSurvey (version 2006), covers approximately 25 000 km^2 with a bin spacing (line and trace) of 12.5 m. The record length is 7000 ms and the sample rate is 4 ms. The dominant frequencies extracted from the seismic data at well positions varied from 15 to 40 Hz. With checkshot velocities of 1.8–2.0 km s^{-1} recorded in the Neogene interval, this yields a vertical resolution ranging from 10 to 33 m. The seismic data was converted to zero phase and is in reverse SEG standard (a positive pulse corresponds to a downward decrease in acoustic impedance). The regional mapping was based on a decimated dataset with a line and trace spacing of 37.5 m.

The MegaSurvey is constructed from many individual 3D survey volumes, allowing a consistent tracing of prominent reflectors over a wide region, with only a few limited areas missing. The seismic data patches still mirror the original sampling and processing parameters, which differ from area to area, visible on time slice maps as significant amplitude changes. In some areas the amplitudes in neighbouring survey patches change phase, suggesting different phase rotations or time shifts between individual surveys. Because of these edge effects, care was required in the mapping of seismic horizons and the use of autopicking utilities. In addition to these data and processing artefacts, the seismic image quality is influenced by velocity anomalies in the overburden caused by infilled Quaternary valleys and shallow gas accumulations.

Following seismic stratigraphic principles based on geometries and terminations of strata (Mitchum *et al.* 1977), six seismic horizons, representing major depositional or erosional boundaries, were identified within the Late Neogene package. Detailed mapping was performed on the northern sections of horizons 4 and 6 to capture sub-kilometre scale channel features. A regional seismic interpretation of all horizon was carried out, in order to relate the channel features to major depositional phases in the central basin, and establish seismic–stratigraphic (e.g. chronological) ties southward into the Danish sector, where the biostratigraphic framework is based on dinocyst zonations (Rasmussen *et al.* 2005; Dybkjær & Piasecki 2008). As part of the regional seismic interpretation, TWT thickness (isochron) maps, based on a 5×5 km grid, were produced for the Late Neogene mega-units. The horizons have been tied to selected wells using log traces of gamma-ray (GR), deep resistivity (ILD), sonic (DT), density (RHOB) and calliper (depending on the availability and quality of borehole data from the Neogene interval).

Results

Seismic-stratigraphy of the Late Neogene succession

The interpreted horizons are demonstrated on three regional seismic sections with ties to selected wells (Figs 2–4). Table 1 summarizes information on horizon reflection character, well log response and stratigraphic correlation. A regional well log correlation and stratigraphic time scale are shown in Figure 5. Late Neogene depositional changes in the Central Graben are illustrated by isochron maps of three major horizon intervals (Fig. 6).

Horizon 1 is equivalent to the Mid Miocene Unconformity (MMU) that forms the base boundary of the Late Neogene basin (Fig. 1) (Clausen & Korstgaard 1993). It is defined by a negative (red) high-amplitude pulse, corresponding to a downward decrease in acoustic impedance from normally compacted sediments to overpressured sediments (Figs 2–4). The horizon is modified by small-scale polygonal faulting related to shale dewatering during

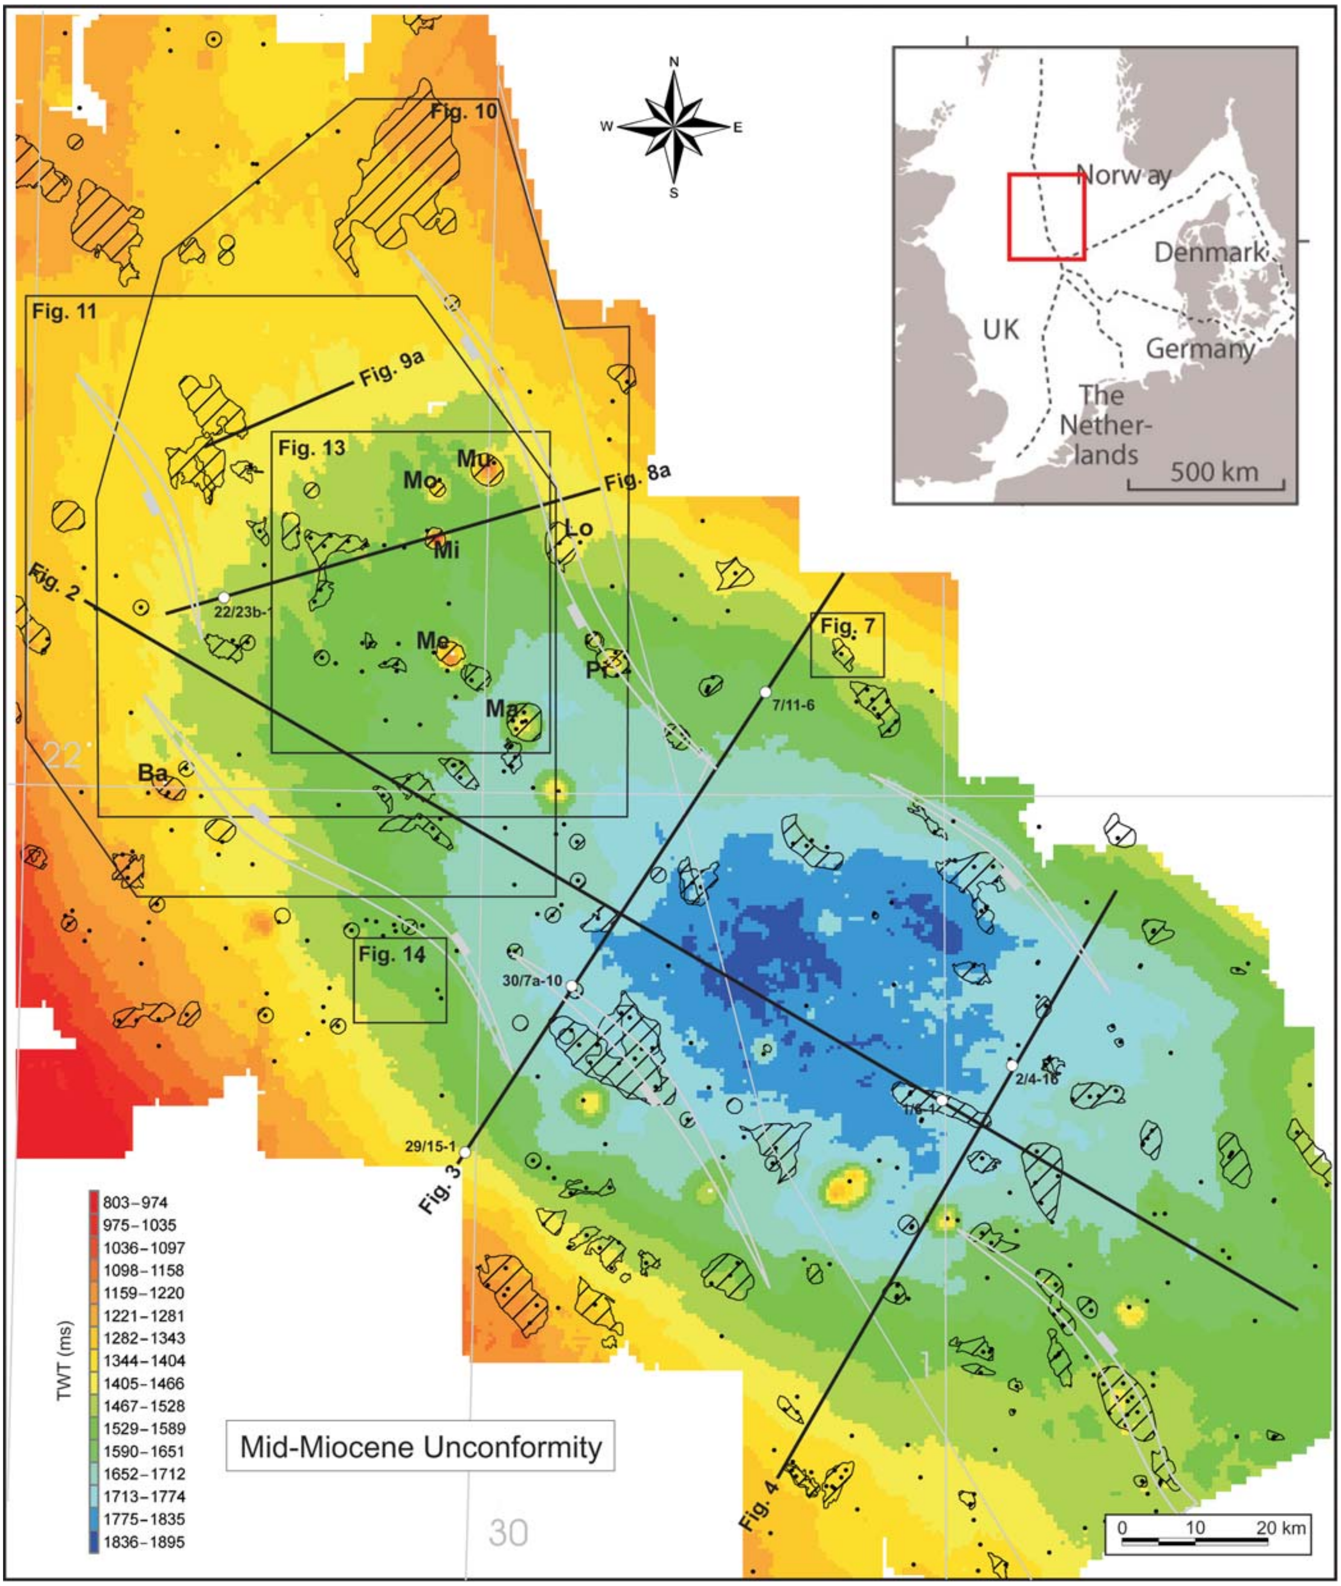

Fig. 1. TWT structure map of the Mid Miocene Unconformity across the UK and Norwegian sector of the Central Graben. Positions of seismic lines, wells and 3D horizon maps in subsequent figures are indicated. Hydrocarbon fields/discoveries are outlined (cross-hatch). Concentric salt diapirs within the detailed mapping area are indicated: Banff (Ba), Lomond (Lo), Machar (Ma), Merganser (Me), Mirren (Mi), Monan (Mo), Mungo (Mu) and Pierce (Pi). Major bounding faults delimit the Central Graben from Jæren High and Sørvestlandet High to the NE, and the West Central Shelf and Mid North Sea High to the SW.

the early burial stage (Cartwright & Dewhurst 1998). These features become more pronounced in the basin centre where the MMU attains a maximum depth of 1800 m. Horizon 2 marks the upper boundary of a parallel stratified unit that drapes across the basin topography, displaying a maximum TWT thickness of *c.* 0.2 s in the central parts and onlap onto the basin margin toward west and SW (Figs 3 & 4). As such, it is conformable to the MMU horizon, except over salt diapir structures where the entire sequence is truncated (Figs 1 & 8). On the SE flank of the basin, Horizon 2 forms a prominent downlap surface for the overlying succession (Fig. 4). A strong and regionally consistent GR log response, often seen as an upper and lower peak, indicates a

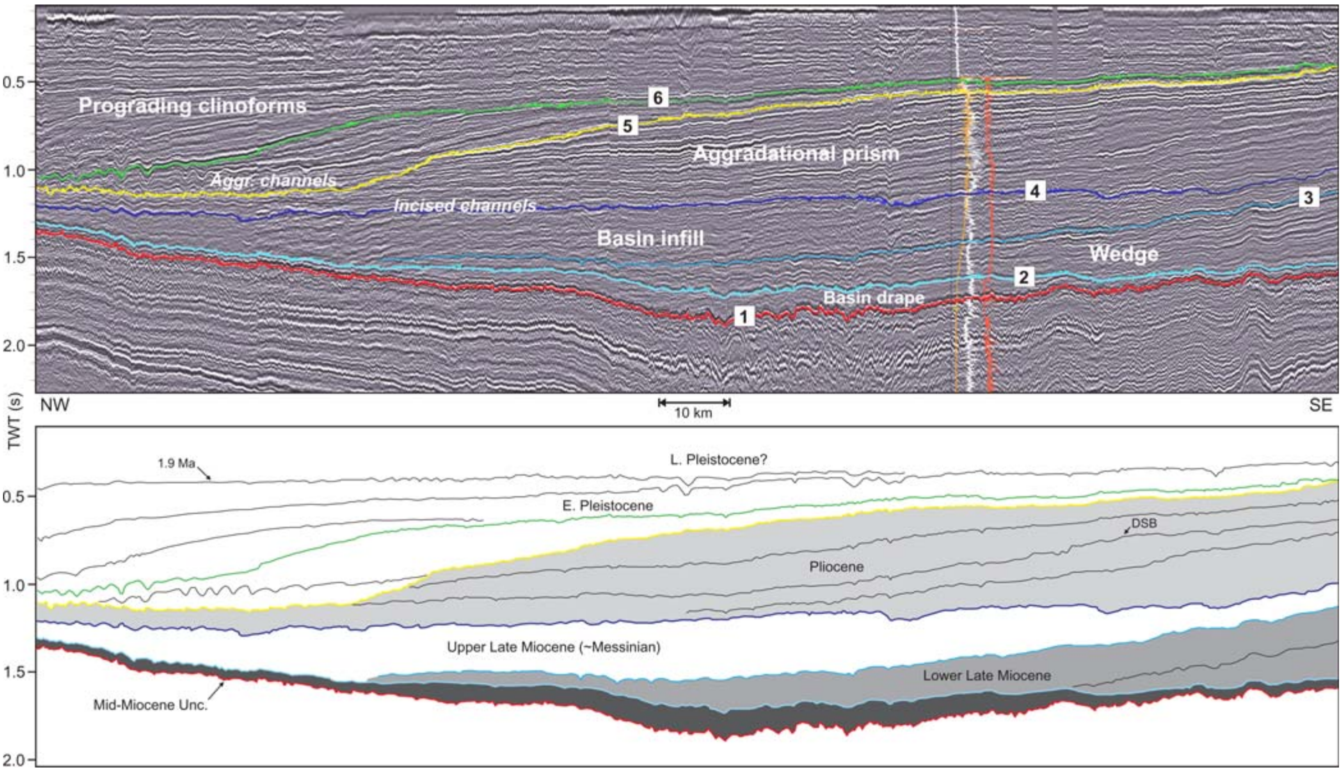

Fig. 2. Regional seismic profile and corresponding interpretation along the NW–SE axis of the Central Graben (line position shown in Fig. 1). Seismic character, well log signature and stratigraphic correlation of horizons are summarized in Table 1. An age of 1.9 Ma at the top marker of the progradational succession is based on chronological results from the southern Central Graben (Kuhlmann & Wong 2008). Position of well 1/6–1 is shown with log traces representing resistivity (orange), GR (white) and sonic (red). Position of a DSB within the Pliocene prism is interpreted from a shift in dip above a series of truncated wedge-shaped units. Total line length: 185 km. Data courtesy of PGS Ltd.

mica-rich shale composition. The unit is interpreted as a hemipelagic transgressive deposit, representing a maximum flooding surface that is time-equivalent with the Hodde Formation in western Denmark (Michelsen *et al.* 1995).

The ensuing Late Miocene succession, delimited by horizons 2 and 4, displays progressive infill of the central basin by two major depositional units. The lower unit (horizons 2–3) forms a wedge package that extends over the southeastern Central Graben and thins over the western margin towards west and SW (Figs 2 & 6a) (Michelsen *et al.* 1995). The upper unit of the Late Miocene succession (horizons 3–4) fills the distal accommodation space of the central basin. Internally, the unit is weakly reflective,

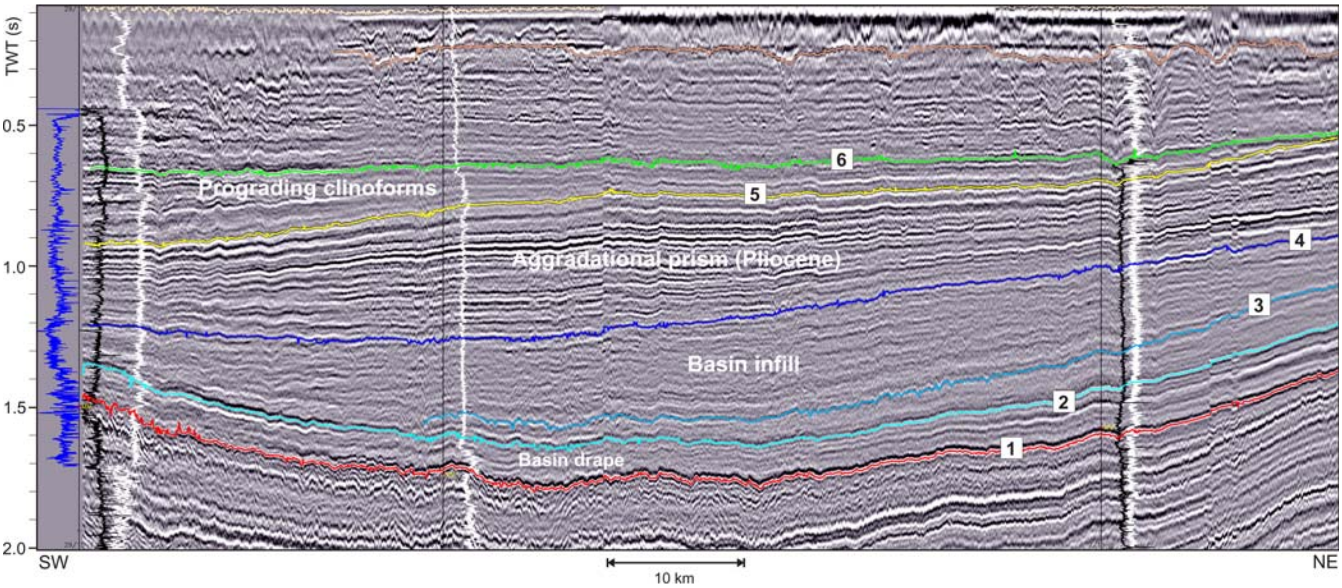

Fig. 3. Regional seismic profile perpendicular to the basin axis (line position shown in Fig. 1). Seismic character, well log signature and stratigraphic correlation of horizons are summarized in Table 1. Position of wells 29/15–1, 30/7a-10 and 7/11–6 are shown with log traces representing calliper (blue), density (black) and GR (white). Note thickening of the Pliocene prism over the central part of the basin. Truncation formed by glacial valley systems is observed in the shallow interval (brown horizon). Total line length: 93 km. Data courtesy of PGS Ltd.

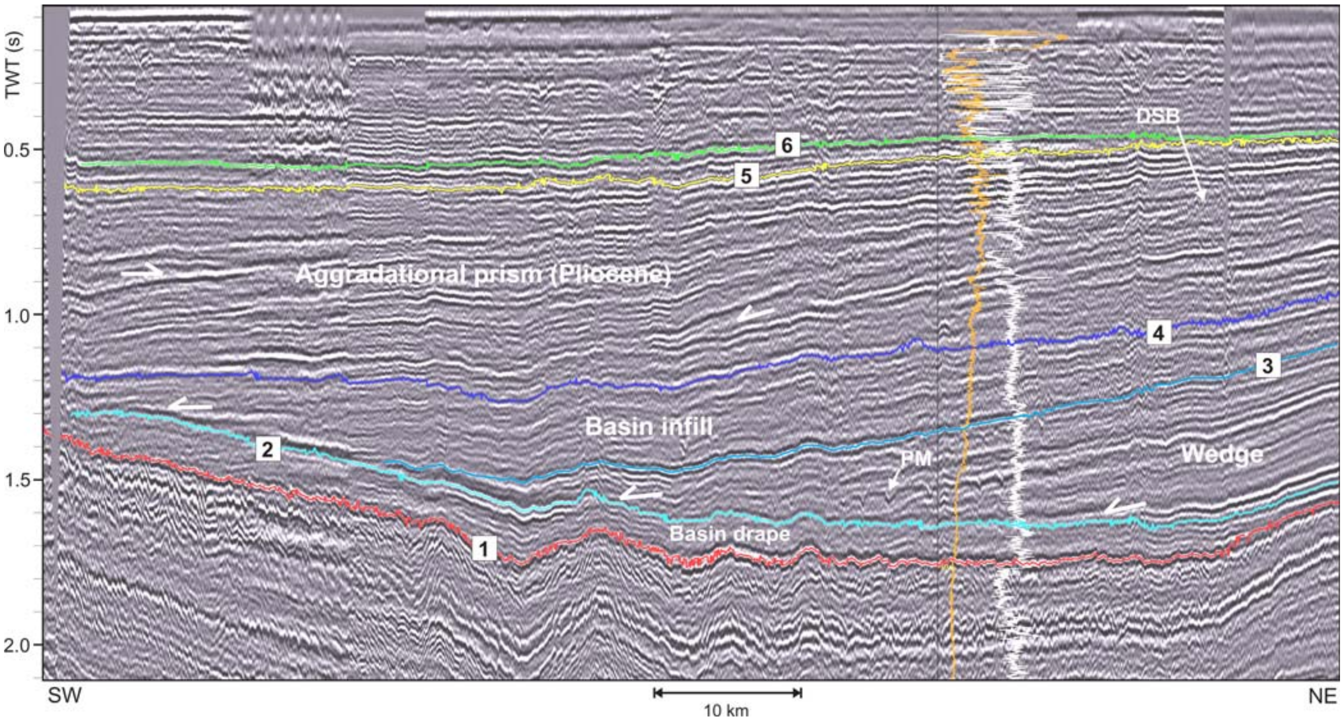

Fig. 4. Regional seismic profile perpendicular to the basin axis (line position shown in Fig. 1). Seismic character, well log signature and stratigraphic correlation of horizons are summarized in Table 1. Position of well 2/4–16 is shown with log traces representing resistivity (orange) and GR (white). Notice the internal strata complexity of the Pliocene succession, manifest by a series of coarsening-upward depositional units that appear to onlap a concave dipping and truncating reflector, interpreted as a DSB. Pockmark (PM) features are observed below Horizon 3. Total line length: 90 km. Data courtesy of PGS Ltd.

displaying a discontinuous and hummocky seismic facies with elements of progradation toward NW (Fig. 2). The erosional character of Horizon 4 is best defined in the northern and western part of the basin, where it is clearly marked by incised channel features (see detailed description detail below). The unconformity can be traced into the southern basin (Feda Graben), but becomes less distinctive as the horizon enters a more conformable package updip eastwards. Along the northeastward basin margin Horizon 4

Table 1. Summary of horizon characteristics and inferred ages

Horizons	Seismic reflection character	Log response	Correlation	Stratigraphic age*
H6	Strong, continuous reflector (N in basin section); part of conformable prograding succession	GR decrease (or sharp transition); DT trough	Intra CSS-9 (1) Condensed interval above Unit 7.4 (2) and Seq. I (3)	Early Pleistocene (2.2–2.5 Ma)
H5	Strong, continuous reflector (P) over sediment prism; truncated and poorly traceable on northward downdip section	GR and DT trough; ILD peak	Top CSS-8 (1) Top Unit 7.4 (2) Top Sequence I (3)	Late Pliocene (*c*. 2.6 Ma)
H4	Moderate to weak response (P) with low lateral continuity; displays incised unconformity with low-angle downlap above	GR minima; ILD culmination after gradual increase; CALIP decrease	Top CSS-7 (1) Top Unit 7.1 (2) Top Sequence F (3)	Miocene/Pliocene transition (5–6 Ma)
H3	Moderate, semi-continuous reflector (N) with onlap termination or distal pinchout toward N and W	Base of GR peak; ILD trough	Intra CSS-7 (1) Intra Unit 7.1 (2) Top sequence E (3)	Upper Late Miocene (7–8 Ma)
H2	Moderate, continuous reflector (N); prominent downlap surface in the Central Graben, distal onlap over the western basin margin	GR and CALIP increase; DT and RHOB decrease	Intra CSS-7 (1) Intra Unit 7.1 (2) Base Sequence E (3)	Upper Mid Miocene (11–12 Ma)
H1	Strong continuous response (N); unconformable horizon marked by polygonal faulting	Base of GR peak; DT and RHOB low; minor ILD decrease	Top CSS-6 (1) Top Unit 6 (2) Top Sequence D (3)	Lower Mid Miocene (15–16 Ma)

*ICS International Stratigraphic Chart, 2009.

Summary of reflection character, well-log response, correlation to previously defined units, and stratigraphic ages of seismic horizons 1–6. P, positive phase ('hard kick'); N, negative phase ('soft kick'). Bracketed numbers in correlation column refer to (1) Jordt *et al.* (1995), (2) Michelsen *et al.* (1995) and (3) Rasmussen *et al.* (2005). Approximate stratigraphic ages are based on Dybkjær & Piasecki (2008), although with the Pliocene/Pleistocene boundary defined at 2.59 Ma, equivalent to Top Piacenzian, following the International Stratigraphic Chart, version 2009 (www.stratigraphy.org/upload/ISChart2009.pdf).

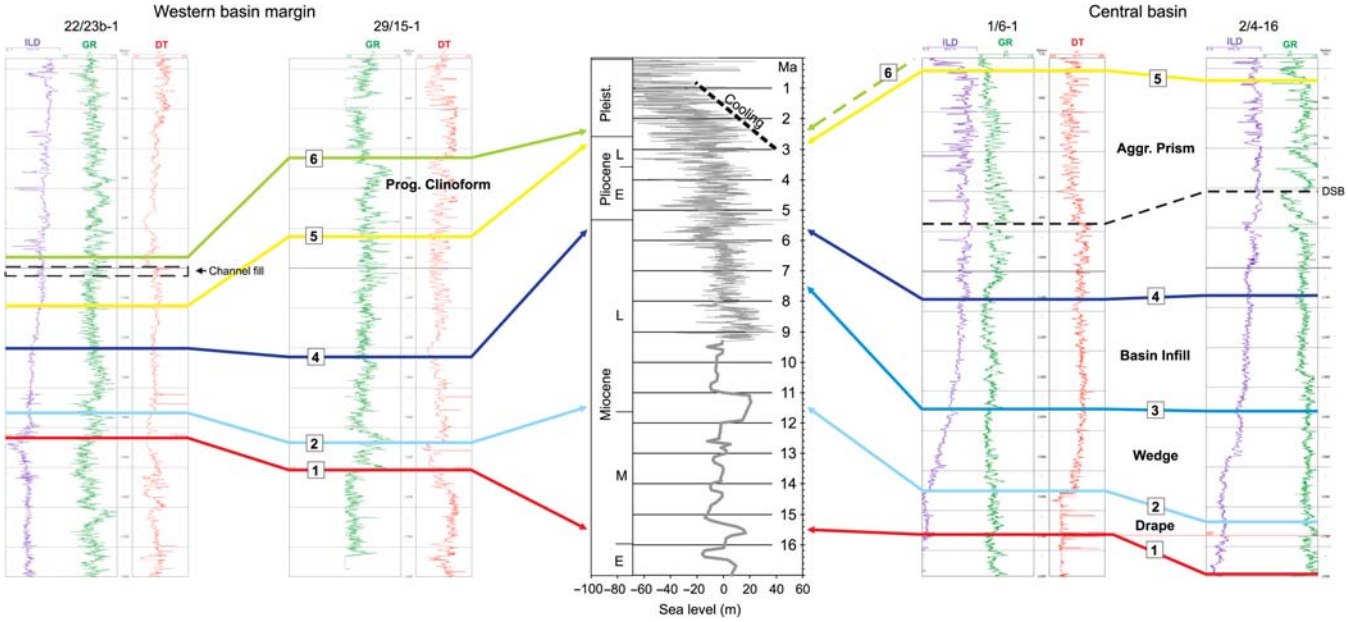

Fig. 5. Correlation of interpreted horizons between four wells forming a SE–NW transect through the Central Graben (see Fig. 1 for well locations). The horizons are projected onto a time-scale of global sea-level fluctuations over the last 17 Ma (Miller *et al.* 2005) using the inferred stratigraphic ages in Table 1. Hatched line between wells 1/6-1 and 2/4-16 demarcates the base of the mounded prism component that correlates updip to a DSB (Figs 2 & 4).

displays a southwesterly dip of 0.5–0.8° (Figs 3 & 4). On log motifs the horizon is characterized by the culmination of a steady increase in resistivity (Fig. 5).

The Pliocene succession, bounded by horizons 4 and 5, forms a wedge-shaped sedimentary prism constructed by progradational and aggradational units that build out towards the NW from a main depocentre over the Feda Graben (Figs 2–4, 6b). The aggradational component of the prism, occupying the central basin, is characterized by convex, high-amplitude reflectors forming individual units that thin toward the margins of the prism body (Fig. 3). In the southwestern sector of the basin the base of the succession thickens into a separate package of westward dipping units. This package is bounded above by a positive phase reflector, displaying a marked change in dip interpreted as a depositional shore-line break (DSB) (Van Wagoner *et al.* 1988) (Figs 2 & 4). On well log motifs, the mounded aggrading component of the prism is characterized by high-frequency GR variations and distinct saw-tooth patterns, indicative of upward-coarsening cycles (Fig. 5) (see also Sorensen *et al.* 1997). Internal strata configurations of the sedimentary prism have been noted, but a detailed analysis of these features has not been completed as part of this study. Toward NW, the gross geometry of the prism is determined by thinning and apparent truncation of strata underneath the dipping section of Horizon 5 (Fig. 2). Along its deep basinward position in the northern basin, Horizon 5 is superimposed by hummocky reflectors representing aggradational channel formations encapsulated by a progradational clinoform unit (see detailed description below). Further north, the horizon becomes a downlap surface for younger progradational units. The relief assumed from the internal depositional break amounts to 400 m, while the maximum relief of the prism, from topset strata to its basinward unconformity, is *c*. 700 m (based on average V_{seis} of 2000 m s^{-1}). Correlating

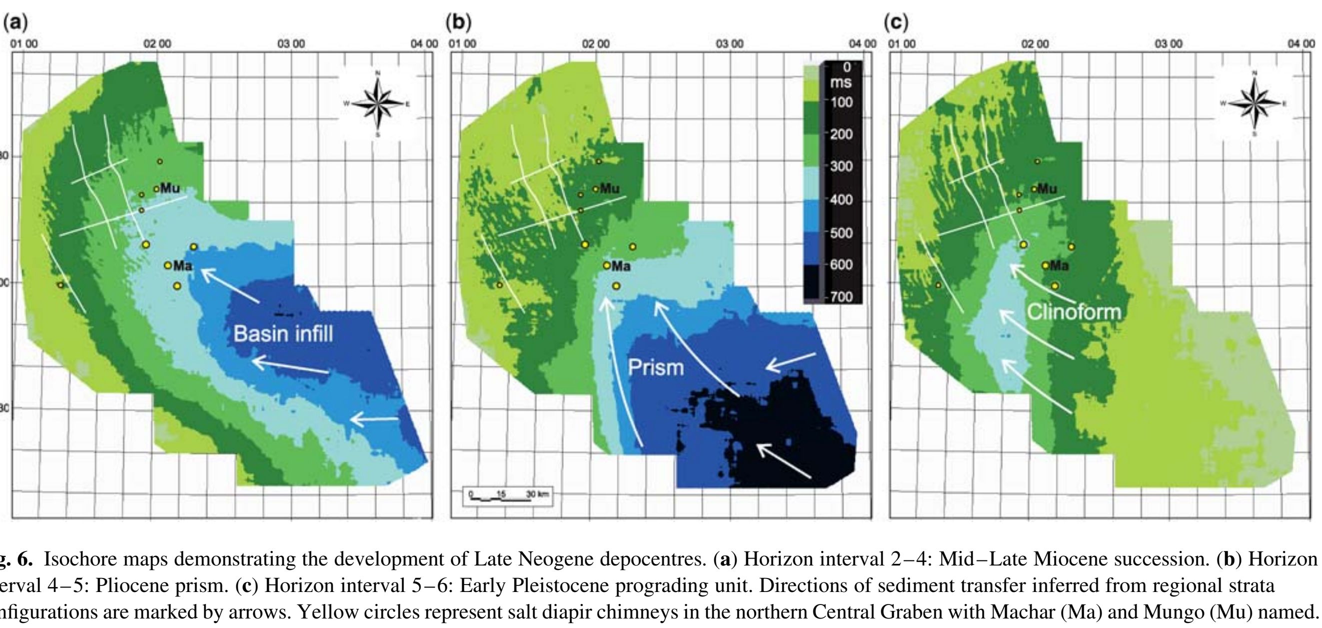

Fig. 6. Isochore maps demonstrating the development of Late Neogene depocentres. (**a**) Horizon interval 2–4: Mid–Late Miocene succession. (**b**) Horizon interval 4–5: Pliocene prism. (**c**) Horizon interval 5–6: Early Pleistocene prograding unit. Directions of sediment transfer inferred from regional strata configurations are marked by arrows. Yellow circles represent salt diapir chimneys in the northern Central Graben with Machar (Ma) and Mungo (Mu) named. Positions of seismic sections in Figures 8, 9 and 12 are shown.

Horizon 5 to the Lone-1 well in the Danish sector suggests a biostratigraphic age of 2.4–2.6 Ma (Piasecki, pers. comm.). Assuming a Pliocene age for the entire sediment prism (2.6–5.3 Ma) yields average sediment rates of 0.1–0.2 m ka^{-1}. However, the northward depocentre progression of the prism, and hence asynchronous development along the graben axis, implies that true sedimentation rates were higher.

Horizon 6 defines the top of a clinoform within a progradational system above the sedimentary prism. The clinoform unit contains the geomorphic elements of an aggrading channel system (see detailed description below) and demarcates a 400 m thick, north–south elongated depocentre across the northern Central Graben (Fig. 6c). Horizon 6 can be traced from a basinward position at the northern end of the survey and southward updip, where it converges to a near-horizontal position above Horizon 5 (Figs 2 & 3). Here, thinning and apparent truncation of topset strata is observed within the condensed interval over the prism succession (Fig. 7). There is no evidence of channel incision or patterns associated with fluvial-deltaic point sources for the progradational complex, but signatures of iceberg scouring in the 40–60 ms interval above H6 suggests that shallow glacial-marine conditions were introduced during deposition of subsequent progradational units (Fig. 7). Iceberg grooves at this level may possibly reflect the onset of major glaciations in the North Sea. A minimum age of 1.9 Ma of the progradational package is suggested by correlation of Horizon 6 southward along the condensed section into the Danish sector.

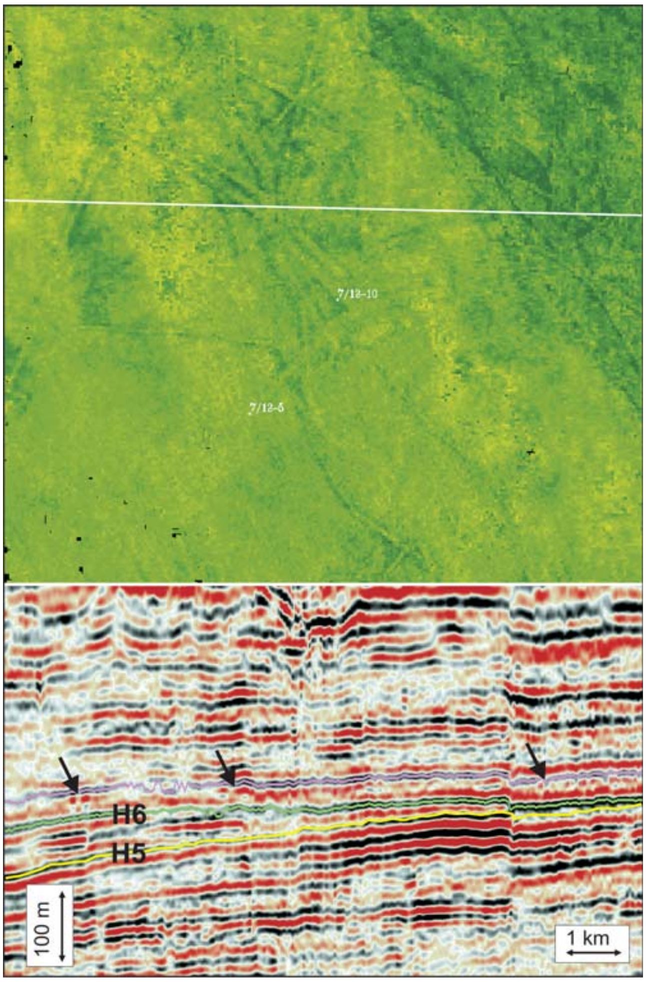

Fig. 7. Randomly interlaced furrows related to iceberg keel erosion along the condensed section of the Early Pleistocene progradational system (location of map shown in Fig. 1). The map was derived from amplitude extraction between Horizon 6 and the reflector located 40–60 ms above. In the seismic profile the iceberg furrows are seen as very subtle features (indicated by arrows) and thus are difficult to indentify without 3D attribute mapping. Vertical discontinuity to the right represents survey boundary.

The sigmoidal clinoform package (Fig. 2) is related to a rapid phase of deltaic progradation, infilling the remaining western part of the North Sea basin in a general direction from east to west. Previous work in the southern North Sea basin (Cameron *et al.* 1993) has established the seismic-stratigraphy with ties to Dutch reference wells (Kuhlmann & Wong 2008). These results date the progradational units to between 2.6 and 1.9 Ma, thus supporting the inferred minimum age. As far as a near-synchronous basin-wide development of the progradational complex can be assumed, the initial clinoform defined by Horizon 6 was probably deposited during the earliest Pleistocene (2.2–2.5 Ma) with very high sedimentation rates in excess of 0.80 m ka^{-1} (Fig. 5). The clinoform may correlate with the 'mudstone drape' capping the Utsira Sand north of the study area (Head *et al.* 2004).

Observations from detailed mapping of channel features

Incised channels on Horizon 4. The erosional character of Horizon 4 is clearly displayed on the seismic sections across the northern Central Graben (Figs 8 & 9). Incisional features form a network of cross-cutting channels, which can be traced from the central parts of the basin and northwards following a main trend along the inclined NE section of Horizon 4 (Fig. 10). The channel network disappears toward south (approximately defined by seismic line in Fig. 3), or becomes untraceable due to scale resolution and processing quality. The TWT structure of Horizon 4 demonstrates a complex morphology, representing two generations of erosional events (Fig. 10). Linear channel-ridge features, manifest by a low relief (<30 ms TWT) along a 330° strike, are superimposed by segments of cross-cutting curvature channels displaying depths of 40–70 ms and widths of 600–1200 m. Infilling of the incised channels occurs predominantly by lateral accretion, on a scale approaching the limit of seismic resolution (Fig. 10, seismic insert). On the eastward basin margin, incised channels are observed to pass alongside concentric zones above major salt diapirs. The channel pathways, however, do not appear to be determined or influenced by these features, suggesting that they commenced prior to salt piercement of the Late Neogene sediment package.

Seismic facies of lateral accretion, covering the incised channels, is indicative of a high-energy setting dominated by bedload transport, representing a fluvial-deltaic or possibly shallow marine (e.g. intertidal) environment (Collinson 1996). The channel pattern is reminiscent of a drainage system, following the central axis of the basin and diverging towards the north. A high proportion of non-cohesive sediments in the Upper Late Miocene interval, below Horizon 4, is suggested by low GR and calliper log values, combined with a gradual and consistent increase in resistivity (e.g. wells 29/15-1 and 1/6-1) (Fig. 5). Formation of the incised channels at base sea-level is supported by the presence of freshwater flora and increased levels of reworked dinocysts in the corresponding Messinian interval in Danish wells Lone-1 and Tove-1 (Piasecki, pers. comm.).

Aggrading channels below Horizon 6. The TWT structure of Horizon 6 (Fig. 11a, b) illustrates the morphology of channels at a stage of progradational infill below the clinoform unit (Fig. 8). Laterally, two different types of channel geometry are recognized: (1) curved and discontinuous (i.e. segmented) channels with a variable spacing of 3–8 km, extending from the NE section of the lower slope; (2) linear, but likewise discontinuous, channels with a more regular spacing of 2–3 km in the NW part of the basin.

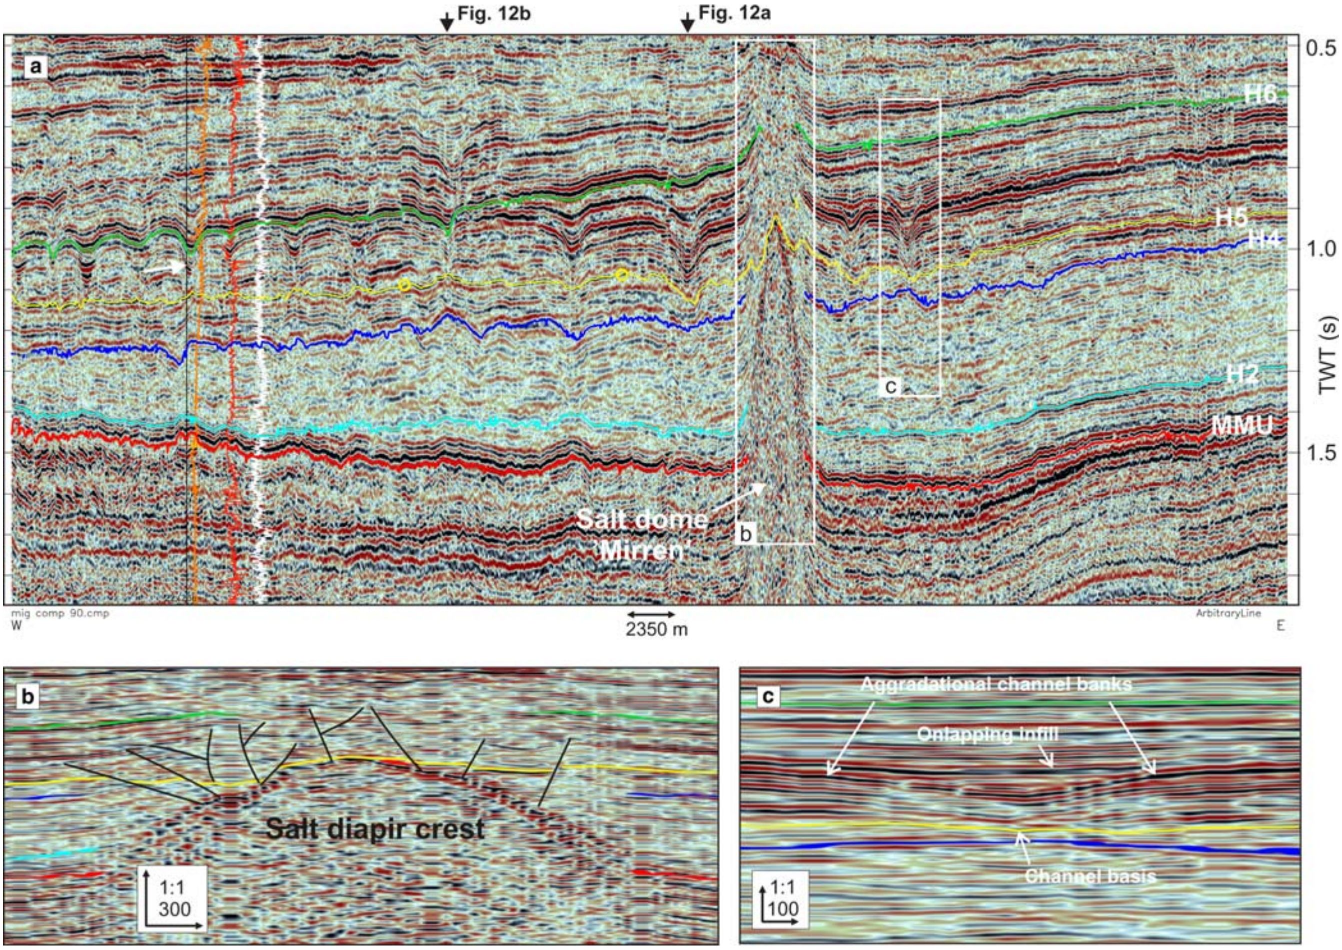

Fig. 8. (**a**) Seismic cross-section of channel features in vicinity of the 'Mirren' salt dome (line position shown in Figs 1, 10 & 11). Horizon 4 (blue) is marked by erosion and incised channelization (compare with Fig. 10). Aggradational channels build up from a stratigraphic level close to Horizon 5 (yellow) and are subject to progressive downdip burial within the clinoform below Horizon 6 (green). Notice the incongruent infill patterns of adjacent channels east of the 'Mirren' dome. Well log traces represent GR (white), sonic (red) and resistivity (orange). Strong reflection at the base of aggradational channel corresponds to sonic velocity peaks (marked by arrow). Abrupt shifts on Horizon 5 reflect survey patches. (**b**, **c**) Detailed zoom-in on specific sections displayed with 1:1 aspect ratios (ms v. m) approaching a true scale. (**b**) Top of the 'Mirren' structure illustrating thinning and extensional faulting of Horizon 5 over the diapir crest. (**c**) Detailed structure of channel profile indicating aggradational channel banks and onlapping infill within a 100 ms deep trough. Data courtesy of PGS Ltd.

The channel widths range from 700 to 2500 m, with type 1 troughs showing the largest cross-sections. The discontinuity of type 1 channels occurs in a manner where troughs die out and re-appear in a slightly offset position, resulting in en-echelon geometries on Horizon 6 (Fig. 11). Type 1 channels are oriented almost due north while type 2 are aligned NNW (330°). It is noteworthy that the channels are orientated at an oblique angle to the general strike of the clinoform slope.

The architecture of the aggrading channel (Figs 8 & 9) demonstrates consecutive stages of development. The base of the channel thalwegs apparently corresponds to Horizon 5, although a precise definition of the deepest stratigraphic level is difficult due to acoustic distortion (e.g. seismic pull-up) below the troughs, intrabed multiples and possible tuning artefacts. Truncation of Horizon 5 is generally observed below the deepest channel troughs, suggesting that the initial channel pathway was generated by erosion (Fig. 9b). Basal truncation occasionally coincides with incision on Horizon 4, below, although a regular superposition of the two channel morphologies is not observed (Figs 8 & 9). The erosive stage is associated with formation of low-relief channel banks. Subsequently, the channel profile deepens by preferential deposition over interchannel regions, forming mounded and generally symmetric structures that tend to be marked by erosion along steep channel flanks (Fig. 9c). Channel depths measured by the height from aggrading flanks to the incised base are in the range of 60–120 ms TWT, while apparent dips across the steep flanks are within 5–15°. The deepest parts of the troughs are characterized by parallel onlap and occasionally lenticular infill facies (Figs 8c & 9b). The channel morphology is gradually reduced and buried as younger clinoforms prograde northwestward (Fig. 8a). The asynchronous development implies that the channel sections furthest to the south, underneath the depocentre of the clinoform, are completely buried at a time when channels further north are still active, in agreement with observations by Cartwright (1995). Channel segments further into the basin experience burial at a later stage during deposition of younger clinoform units above Horizon 6.

Type 1 channels are associated with marked acoustic pull-ups on the MMU below. These seismic anomalies of up to 25–30 ms TWT are clearly visible on the MMU structure map (Fig. 11c), and correspond vertically to the deepest segments of the aggradational channel network (compare with Fig. 11b). A time–depth conversion study by Armstrong *et al.* (2001) indicates that these anomalies are generated by P-wave velocity contrasts between *intra*channel deposits and the juxtaposed *inter*channel aggradational regions. A difference in V_{seis} of 400–600 m s^{-1} is required to explain the pull-up on the MMU level, suggesting that the infill represents consolidated sandstone, presumably formed by early diagenetic calcite precipitation (Hovland *et al.* 1987; Schulz-Rojahn *et al.* 1998).

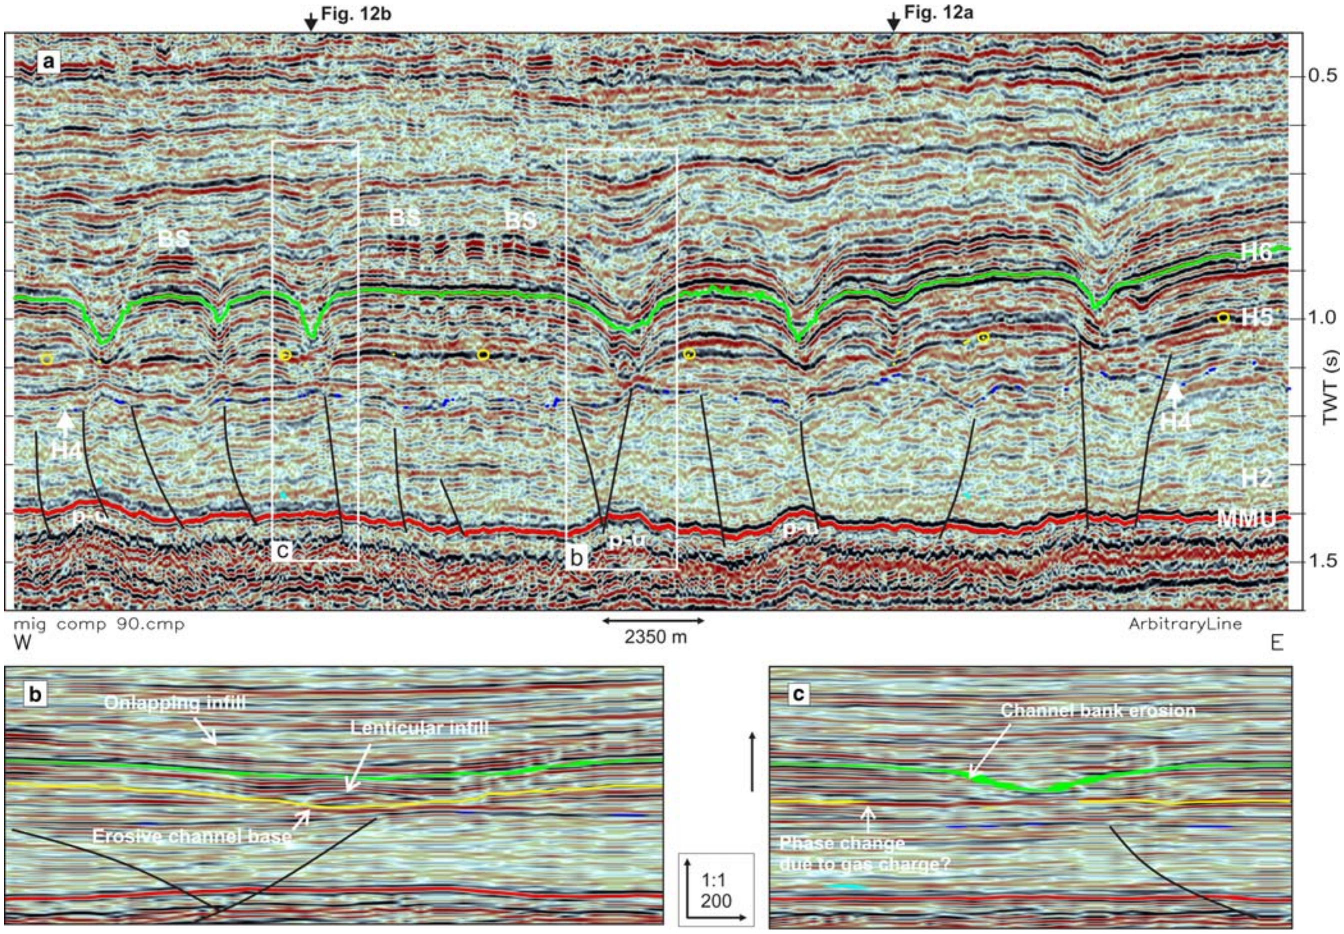

Fig. 9. (**a**) Seismic cross-section of channel formations in the northern part of the basin (line position shown in Figs 1, 10 & 11) with indications of faults extending from the MMU. Horizon 4 (blue) is marked by erosion and incised channelization (compare with Fig. 10). Aggradational channels build up from a stratigraphic level immediately below Horizon 5 (yellow). At this location active channel troughs are time-correspondent with Horizon 6 (compare with Fig. 11). Notice bright spots (BS) over interchannel regions and prominent acoustic pull-up (p-u) of the MMU below channel troughs. (**b**, **c**) Detailed architecture of the aggradational channels is shown in zoom-in sections with 1:1 aspect ratios (ms v. m) approaching a true scale. The channel trough in (**b**) displays a lenticular infill above an erosional base. A local amplitude phase shift along Horizon 5 (**c**) suggests presence of gas charged sediments below the channel trough (notice lack of pull-up). Data courtesy of PGS Ltd.

An average V_{seis} of 2500 m s^{-1} for the infill facies implies that actual trough depths are likely to be in the range 75–150 m. Well verification of inferred channel sands was limited to a single borehole penetrating a type 2 channel trough (Figs 5 & 8a). The base of this channel is marked by a 'hard-kick' that correlates with two sharp but minor peaks on the sonic log. It is noteworthy that some of the channels lack a distinctive pull-up response despite the presence of deeply infilled troughs. This may possibly be explained by a more fine-grained channel infill (e.g. less intense cementation), or the presence of gas charged sediments, as suggested in Figure 9c.

The extent and geometry of the channel segments buried below the clinoform is illustrated by axial seismic profiles (Fig. 12) and channels traces on time-slice sections (Fig. 13). The axial profiles highlight the discontinuous channel pathways and noticeable lack of gradient along thalwegs. Some of the channels terminate at accumulations of hummocky or mounded depositional features which resemble contourites (Nielsen *et al.* 2008). A migrating seismic facies of these deposits suggests a northward sediment transport (Fig. 12c).

Relationship between channels and salt diapir leakage zones

Type 1 channels tend to commence from a position at (or in vicinity of) concentric chimney features related to fluid-escape over the major salt diapirs, henceforth abbreviated SLZ, Salt diapir Leakage Zones (Fig. 13). A prominent example is the channel beginning at 'Merganser' SLZ, which is infilled by a 200 m thick succession of downlapping wedge-formed units that thicken toward the steeply inclined reflectors of the chimney (Fig. 12a). The two channel segments commencing north of the 'Machar' SLZ appear to coalesce as they by-pass three SLZ further to the north (Fig. 13b). The diachronous infill structure of these adjacent channels (Fig. 8a) implies abrupt, localized shifts in sediment flux or hydrodynamic conditions. The youngest channel elements commence north of the clinoform depocentre, apparently time-equivalent with Horizon 6 (Fig. 11). The east Central Graben diapirs protrude into Late Neogene strata (post-MMU), while protrusion into the Pleistocene interval is observed for the 'Pierce' structures, located over the main eastern boundary fault (Fig. 1) (Davison *et al.* 2000*b*). Over the salt crests the unit below Horizon 5 is marked by thinning and extensional faulting (Fig. 8b). Mapping of these features and determination of their stratigraphic relationship is limited by the seismic resolution and sediment deformation caused by subsequent fluid leakage.

Type 2 channels generally commence at the base of the clinoform unit (Horizon 6) and are not associated with concentric leakage zones. In the western basin linear pathways of type 2 channels are seen to pass through the 'Banff' SLZ, suggesting that the channels formed prior to major fluid expulsion at this site

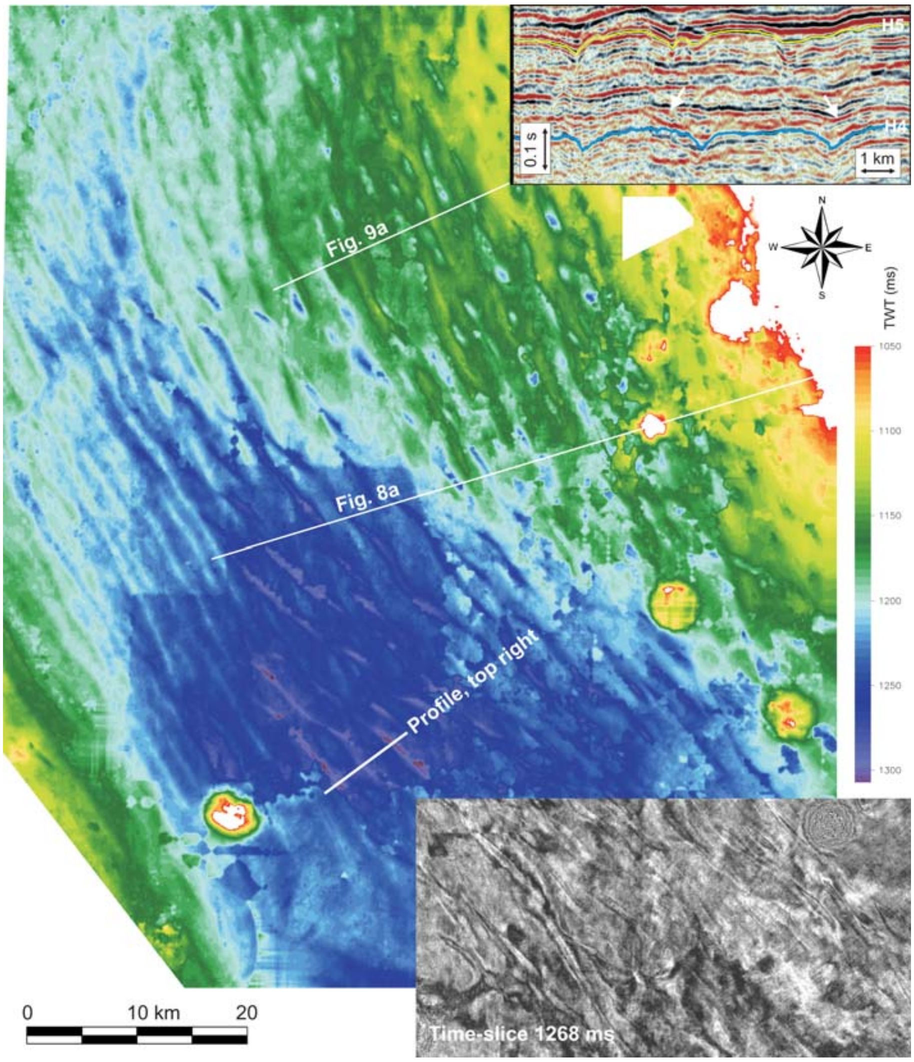

Fig. 10. TWT structure map of Horizon 4, displaying multiple incised channels that appear to cut across a former relief of ridge-trough elements. Insert, lower right, shows a seismic time-slice revealing the channel network in more detail. Channel pathways are apparently unaffected by concentric salt diapirs. The detailed seismic section (insert, top right) demonstrates seismic facies interpreted as lateral accretionary units (arrows) that infill and bury the incised channels. Notice the regional westward dip (*c.* 0.5°) across the eastern basin margin.

(Fig. 11). Potential linkages to minor (i.e. non-diapiric) gas chimneys that punctuate the Cenozoic overburden in numerous places (Fig. 12) have not been explored as part of this study, since it would require seismic attribute analyses based on individual 3D volumes. Nonetheless, it is noticeable that some of the channel elements initiate from positions close to leakage zones, marked by seismic pull-down and bright anomalies (Figs 12 & 14).

Discussion

Evidence for a contour current depositional setting

Cartwright (1995) proposed that the aggrading channels form the downslope component of a deltaic system prograding westward from the eastern North Sea (Skaggerak region). Alternatively, it was suggested that the channel features could be related to oceanic contour currents that inundated the basin at a time when a southern connection to the North Atlantic became established. Observations extracted from the present 3D seismic analyses favour a contour current mechanism, rather than gravity-driven sediment transport, for these features: firstly, the channel banks build up from a basal unconformity, which lacks a regional inclination for gravity-driven transport and updip connection to a major sediment source, for example, a fluvio-deltaic distributary system. Secondly, the channels are not continuous but display linear or arcuate segments, oriented at an oblique angle to the slope of the clinoform unit. Finally, mounded-elongate sedimentary bodies at channel terminations (Fig. 12) display asymmetric geometries and a base-disconcordant relationship that are characteristic of contourites (Faugeres *et al.* 1999; Nielsen *et al.* 2008).

The semi-parallel to arcuate pattern of channel troughs expressed by Horizon 6 (Fig. 11) displays a close resemblance to contourite ridges, channels and furrows, generated by geostrophic bottom currents (i.e. driven by horizontal pressure gradients balanced by the Coriolis effect), as observed in the Faroe–Shetland Channel (Knutz & Cartwright 2004) and Gulf of Cadiz (Hernandez-Molina *et al.* 2006). A noticeable difference is the gross symmetric shape of interchannel regions compared with the typical upslope migrating character of contourite bedforms (Nielsen *et al.* 2008). This may be attributed to the modest slope gradient in the North Sea basin and a high sediment flux focussed along the basin axis. Despite the abundance of contourites described from continental margins, modern analogues formed in semi-enclosed marginal basins are sparsely documented (Rebesco & Camerlenghi 2008). Moreover, a detailed morphological definition of these deep marine deposits rests on the availability of 3D acoustic imaging. Analogue comparisons may be considered from the pre-Neogene depositional record

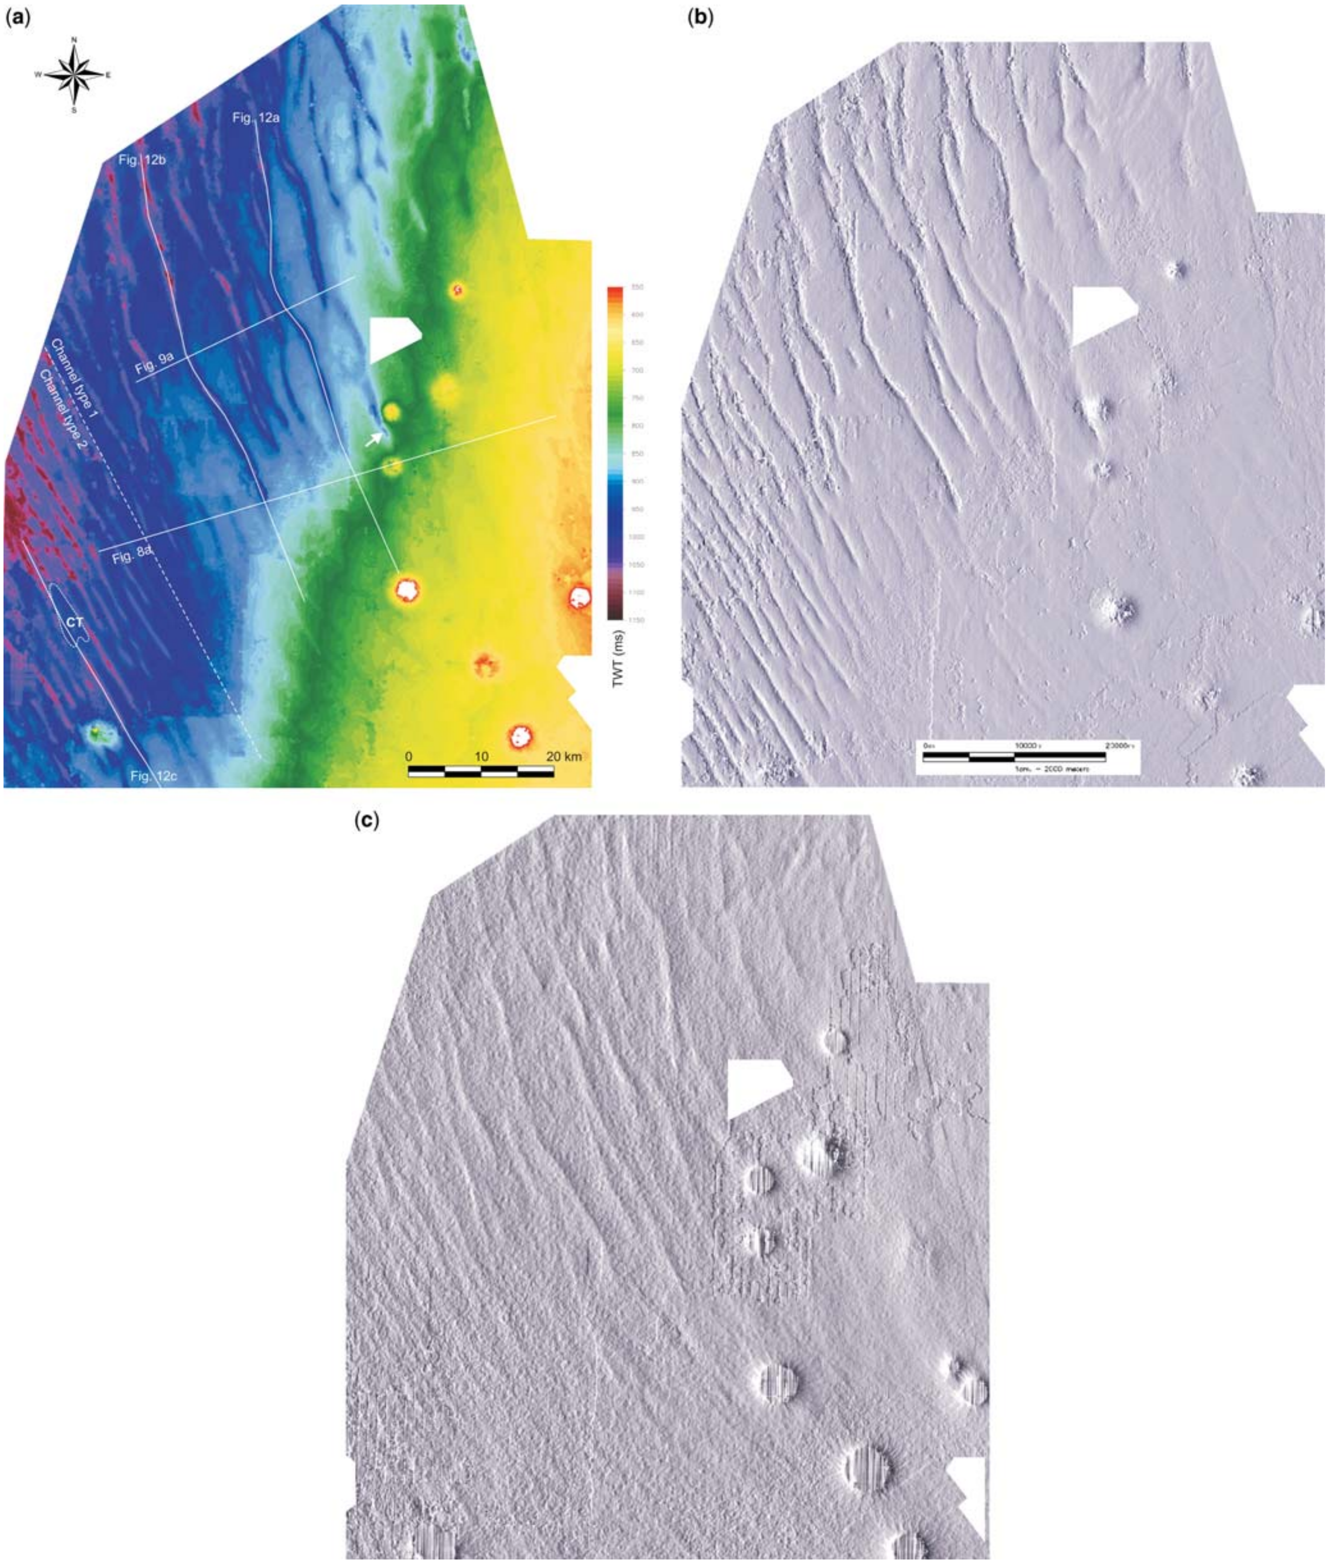

Fig. 11. (**a**) TWT structure map of Horizon 6 (position shown in Fig. 1), displaying aggradational channel elements and concentric leakage zones protruding from salt diapirs. Two types of channel geometries are recognized: curved channels with a variable en-echelon style spacing (type 1), and linear channels with a more regular spacing of 2–3 km (type 2). The channel pathways generally extend updip into the clinoform unit below the horizon, except one channel commencing from the slope break of Horizon 6 (marked by arrow). The slightly bulging character of the slope section towards the south corresponds to the northern fringe of the clinoform depocentre (compare with Fig. 6a). Position of contourite (CT) deposit inferred from the profile in Figure 12c is outlined. Delineations of seismic data patches are visible. (**b**, **c**) 3D differential maps of Horizon 6 (b) and MMU (c), enhancing the detailed topology of the seismic surfaces. The ridge-like features on the MMU horizon (c) are interpreted as artefacts representing seismic pull-up from high-velocity infill of the channel troughs, presumably carbonate cemented sand (compare with seismic cross-sections in Figs 8 & 9).

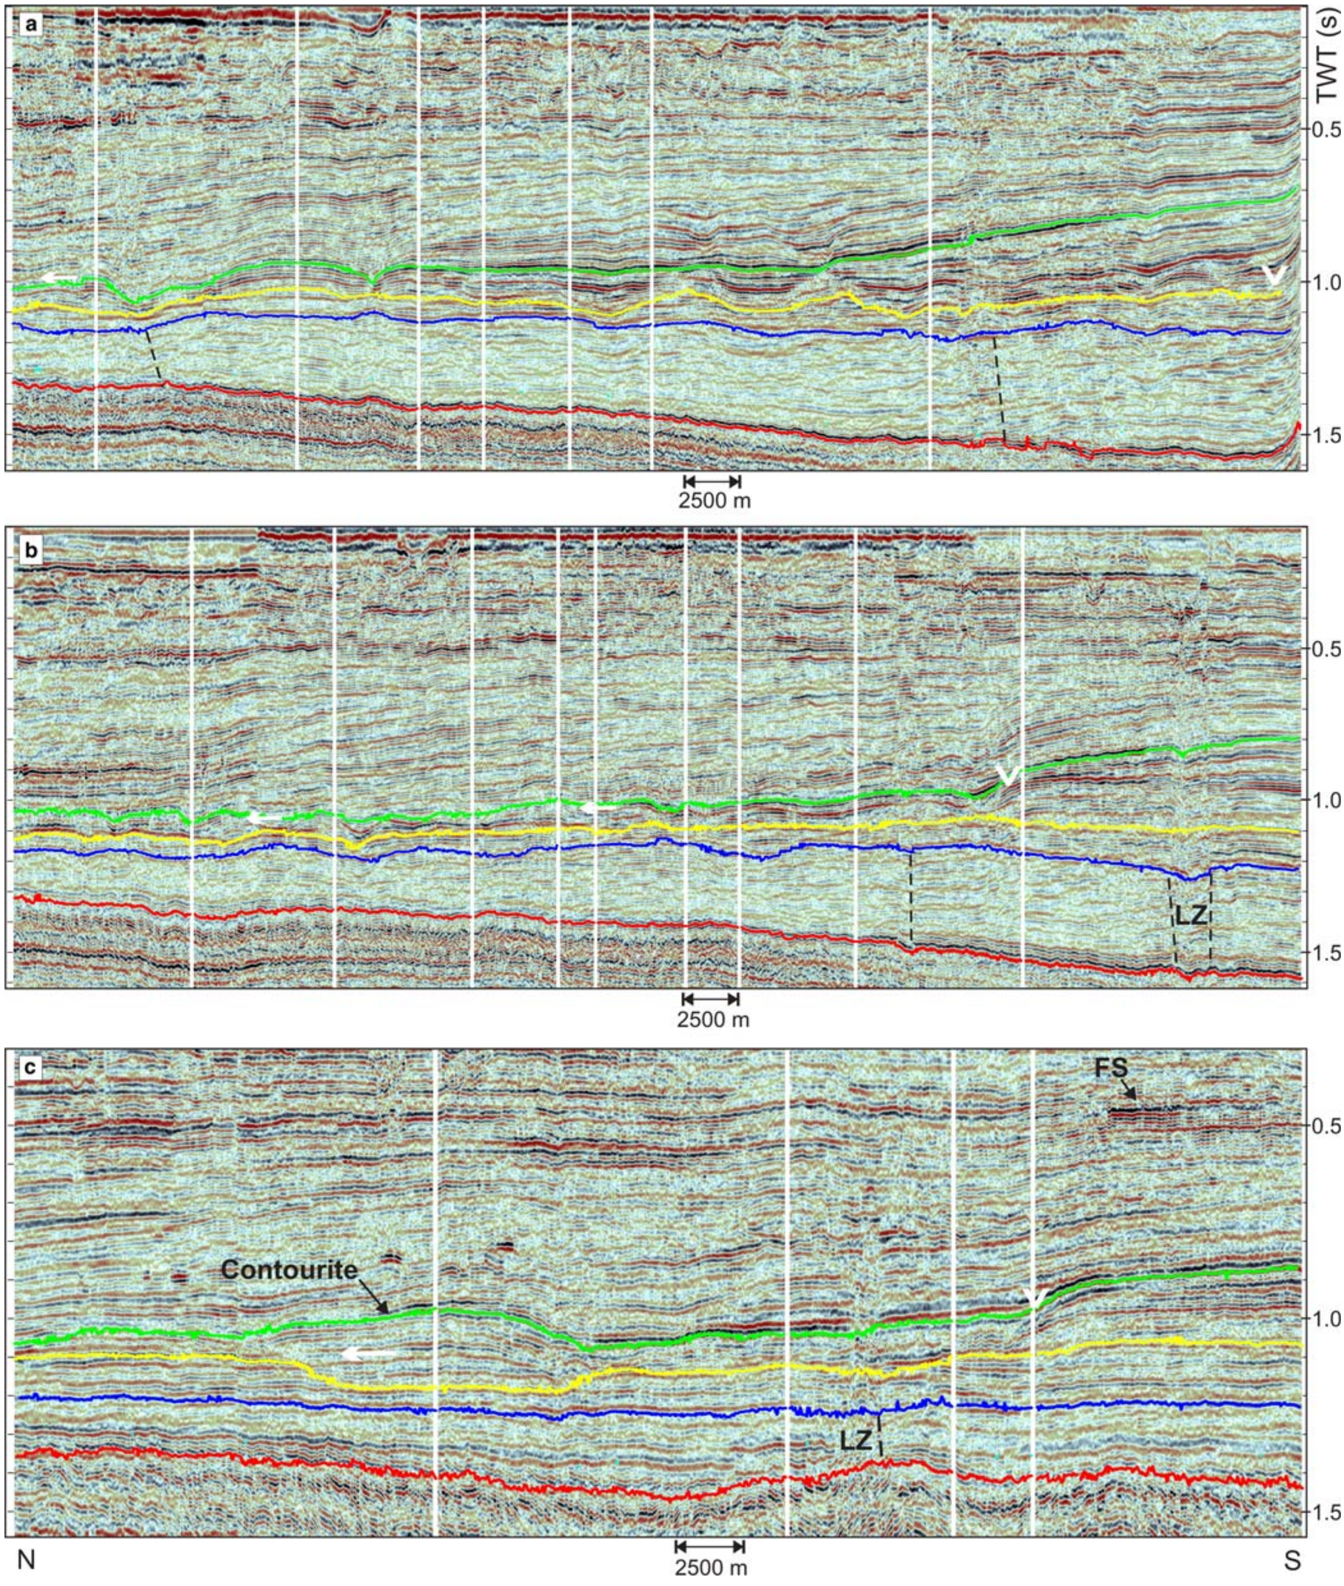

Fig. 12. Multipanel seismic sections (**a**–**c**) tracing the through axis along three channel pathways (line positions shown in Fig. 11). Notation of colour-coded horizons as in Figure 8. V-marks demarcate points of channel commencement below Horizon 6. Notice the initiation point of channel in (a) is located in the clinoform package below downlapping wedge units extending from the 'Merganser' leakage zone. In contrast, channels (b) and (c) commence at the base-of-slope defined by Horizon 6. Channel (b) is located downdip from a diffuse leakage zone (LZ), indicated by amplitude dimming, bright anomalies and seismic pull-down. Channel (c) terminates at a mounded, asymmetric depositional unit interpreted as a contourite deposit. Direction of apparent sediment migration is indicated by arrows. Data courtesy of PGS Ltd.

of the North Sea basin. Interestingly, the initial erosive stage of channelization (Figs 8 & 9) resembles low-relief channel elements recognized in the Upper Cretaceous Hod Formation, conceivably generated by geostrophic bottom-currents traversing the epieric Chalk Sea (Esmerode *et al.* 2008). This may suggest a non-cohesive character of the erosive precursor channels in contrast to the subsequent aggradational build-up, presumably requiring a high flux of clay-rich sediments.

The mounded geometry of the prism and internal high-amplitude reflection character, displaying downflank thinning/erosion

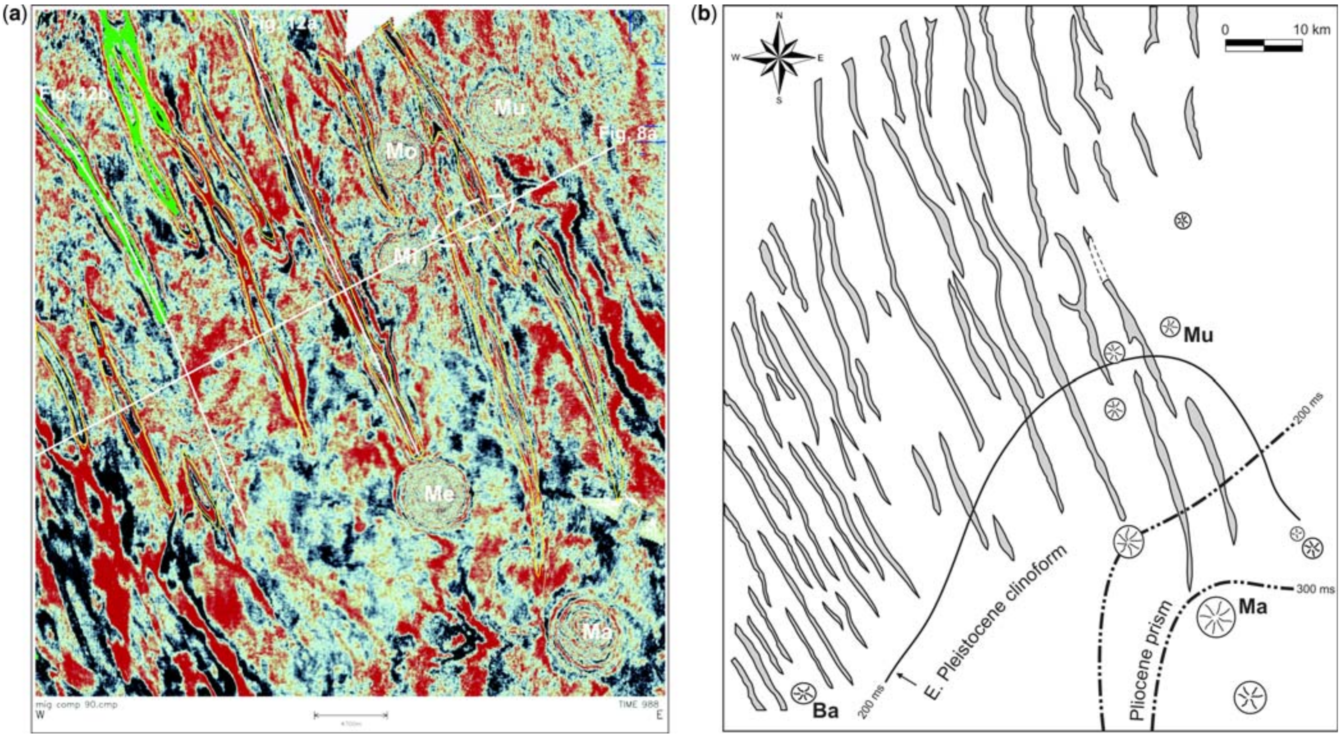

Fig. 13. (**a**) Time-slice map (988 ms TWT), cross-cutting the concentric leakage zones and aggrading channels within the clinoform unit (position is shown in Fig. 1). The leakage zones are named according to underlying salt structure: Ma, Machar; Me, Merganser; Mi, Mirren; Mo, Monan; Mu, Mungo. Position of diachronously infilled channels east of 'Merganser' is highlighted (Fig. 8a). (**b**) Traces of channel troughs based on Horizon 6 (Fig. 11a, b) and time-slice maps. The large aggradational channels (type 1) extend below the clinoform, where they appear to converge toward the concentric leakage zones. Depocentre limits of the Pliocene sediment prism (hatched lines) and Early Pleistocene clinoform (full line) are demarcated by isochrons obtained from Figure 6.

(Figs 2 & 3), represents features common to giant sediment drifts shaped along continental margins by geostrophic boundary currents (McCave & Tucholke 1986; Faugeres *et al.* 1999; Nielsen *et al.* 2008). The configuration of the erosive base of channel features juxtaposed to the aggradational prism implies that oceanographic currents were a controlling factor for sediment dispersal throughout the Pliocene. The situation of the prism, north of the main Late Neogene depocentre (Fig. 6b; see also Michelsen *et al.* 1995), is suggestive of a fan–drift contourite system (Faugeres *et al.* 1999; Knutz 2008) constructed by muddy sediments dispersed from fluvio-deltaic sources and subsequently carried alongslope by northbound oceanic currents. A potential sediment source for the Pliocene prism is the giant Baltic River (or 'Eridanos') system that drained into the German Bight until commencement of major glaciations (Zagwijn 1989; Overeem *et al.* 2001). The progradational complex of the 'southern embayment' outlined by Sorensen *et al.* (1997) appears to form the deltaic component of this drainage system. It is conceivable that sediment transport was enhanced by tidal forces but, even so, the scale and configuration of depositional elements suggests that persistent unidirectional currents were operative, similar to the geostrophic meridional flow of intermediate water masses along the NE Atlantic margin (Kenyon 1986; McCave & Tucholke 1986). For oceanographic currents to winnow and transport silt-size sediments, persistent currents of 0.15–0.20 m s^{-1} would be necessary, while currents in excess of 0.40 cm^{-1} are required for bedload movement of quartz sand (McCave 1995). Thus, construction of the aggradational channels involved steep hydrodynamic gradients, from near-quiescence over interchannel regions to high-competence flow speeds in the deep troughs. The parallel stratified channel-fill is comparable to modern environments of contourite sands, generated by strong bottom-currents in confined moat-channel settings, developed along continental slopes or circumventing sea mounts (Viana *et al.* 1998; Akhmetzhanov *et al.* 2007).

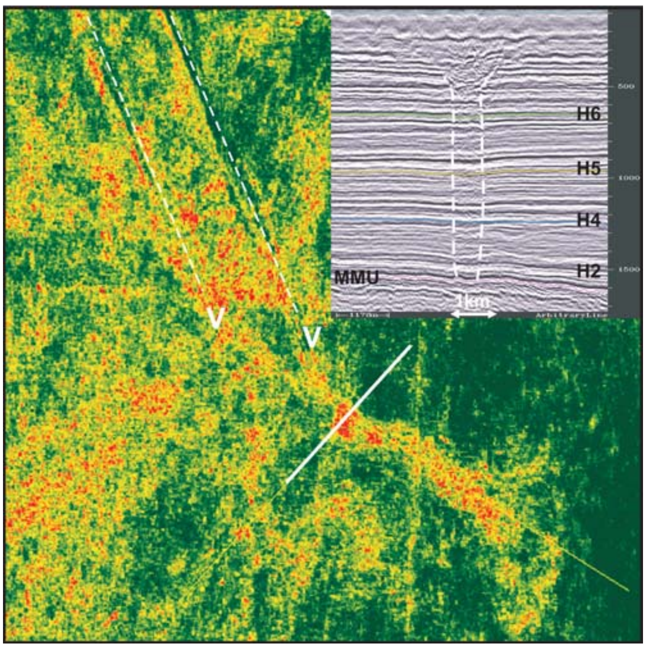

Fig. 14. Coherency map, extracted from a 100 ms interval above Horizon 4, illustrating the southernmost limit of two linear channels (type 2). The channels commence downdip from an area of low coherency (bright colours) and low-velocity pull-down below a glacial tunnel-valley (see seismic insert).

Geological controls on aggrading channels

The convergence between type 1 channels and the SLZ (Fig. 13b) alludes to a mechanistic linkage between focussed fluid-flow and bottom-current sediment transport. Previous studies have associated fluid leakage over the salt diapirs with the main phase of hydrocarbon migration into structurally confined closures along the flanks (Heggland 1998). Accordingly, fluid leakage must have succeeded peak oil maturity of Upper Jurassic source rocks, estimated to Mid–Late Miocene (Kubala *et al.* 2003). Observations by Davison *et al.* (2000*a*) of tensile fracturing, brecciation and abundant calcite cementation in chalk units above salt diapir crests, suggest that the concentric chimneys of the eastern Central Graben were conducive for pressurized fluids from older units. Episodic fluid expulsion, promoted by the buoyancy effects of the large hydrocarbon columns, is also indicated by underfilling of diapir traps (Davison *et al.* 2000*b*). Previous studies have identified Neogene sediment loading as a primary factor for development of a regional SE-to-NW pore-pressure gradient in Upper Cretaceous–Early Cenozoic formations (Japsen 1998; Vejbæk *et al.* 2005). Likewise, it is possible that fluid expulsions from the salt diapir structures may have been triggered by the northward progressing sedimentary prism (Figs 6, 13b & 15).

The structural observations and likely timing of hydrocarbon charge suggest that the formation of aggradational channels was promoted by fluid expulsion from leakage zones, positioned upstream in the bottom-current flow. This scenario is illustrated by the depositional model in Figure 15. Intense fluid escape from the seabed would facilitate mobilization of fine-grained sediments passing through the progradational system, thus making it available for suspension-transport by contour currents. It is plausible that extrusion of sediments from deeper stratigraphic intervals contributed to the channel architecture, by forming a point source for coarse-grained channel infill. Extrusive processes are presently observed over leakage zones in Gulf of Mexico, supplying an allochtonous Miocene foraminifer assemblage to the modern seabed (Kohl & Roberts 1994). Seismic results from the Norwegian–Danish Basin suggest that pressurized fluids from Paleocene formations are capable of injecting sand-prone sediments through 1 km of overburden, resulting in extrusive mounds at Mid-Miocene level (Andresen *et al.* 2009).

The previous discussion has focussed on the aggradational stage of channel formation. An important question remains as to what mechanism promoted the initial erosive trace along the channel base (Fig. 9). It is difficult to explain the segmented pattern of primary incision and bank accretion as driven exclusively by self-organizing ocean current dynamics, without an element of geological control. A more plausible scenario is that current erosion occurred preferentially along corridors of low sediment strength, promoted by fluid-flow from faults and fracture zones (Fig. 15). An early stage of this process may be represented by elongate pockmarks, observed as common phenomena in the Miocene interval of the central basin (Andresen *et al.* 2008, p. 1270) and in the present North Sea (Skaggerak) (Bøe *et al.* 1998). Also, it is pertinent to note a striking resemblance between type 1 channel styles and extensional fault patterns in the Cenozoic section west of the Central Graben (UK quad 20) (Bishop 1996). The similarity includes the arcuate en-echelon geometry scale dimension as well as the NNW–SSE orientation of these features. An inherited structural control on channel pathways is insinuated by small-scale faults that extend from the polygonally faulted lower Miocene interval to positions below the channel troughs (Fig. 9). Complete recognition of insidious faults and fracturing underneath the channels is hampered by prominent seismic pull-ups, acoustic distortion below thalwegs, and abundant seismic data boundaries. These issues stipulate the need for more research based on dedicated seismic processing. Nevertheless, enhanced fluid-flow into the channel troughs, along fracture zones connected to the MMU, would promote carbonate cementation of channel sands (Schulz-Rojahn *et al.* 1998), thus explaining the high-velocity infill (Fig. 15).

Conceivably, the concept of enhanced seabed erosion induced by fluid escape could also apply to the formation of the linear aggrading channels (type 2). However, since their spacing and NNW alignment is very similar to the antecedent incised channels, developed on the Late Miocene/Early Miocene unconformity (Horizon 4), an inherited morphological control cannot be ruled out (Cartwright 1995). Commencement of linear channels in the vicinity of fluid anomalies and velocity pull-down may suggest enhanced sediment mobility generated by hydrocarbon leakage (Fig. 14). These low-velocity zones are commonly associated with buried Pleistocene valleys formed by melt-water drainage, thus affording a potential linkage between subglacial erosion and zones of fluid expulsion (Fichler *et al.* 2005).

Implications for Late Neogene basin development

The morphological expressions of the channel horizons and the regional mapping of major depositional units in the central basin add new constraints on the Late Cenozoic development of the North Sea basin. The seismic geometry of the Late Miocene/Early Pliocene low-stand unconformity (Horizon 4) and the overlying aggradational sediment prism demonstrate rapid basin subsidence, with 600–700 m of accommodation space generated over less than 3 Ma. The development of the basal unconformity also corresponds to a 50 m eustatic sea-level fall during the Messinian, lasting *c.* 0.7 Ma (Miller *et al.* 2005), but clearly the contribution of sea-level dictated by global ice-volume is insignificant compared with the observed changes (Fig. 5). The Late Cenozoic subsidence history of the North Sea basin has been related to changes in intra-plate stress regimes (Kooi *et al.* 1991), invoking a response to the last tectonic cycle of the Eurasian–African plate collision, which culminated during Late Miocene (Ziegler 1992). Palaeo-records from NW Europe indicate a Late Miocene sea-level regression and exposure of the Dover Strait associated with compression along the Variscian deformation front (van Vliet-Lanoë *et al.* 2002). According to Hillis *et al.* (2008), crustal compression during the Miocene was the main cause of uplift in the British Isles and southern North Sea, evident by widespread exhumation of older Cenozoic strata, notably in the Wessex–Weald Basin. A Mid to Late Miocene compressional phase has also been advocated for the British–Norwegian Atlantic margin (Ritchie *et al.* 2003; Løseth & Henriksen 2005), suggesting that tectonic stress-fields developed by a combination of Mid-Atlantic oceanic ridge-push and Late Alpine collision (Dore & Lundin 1996).

As discussed earlier, formation of aggrading channels and the prism complex appears to have evolved under the influence of geostrophic currents, implying an open connection to the Atlantic Ocean via the Channel strait. Such a current system would probably require water depths of more than 300 m (Kenyon 1986; New & Smythe-Wright 2001), unless hydrographic conditions specific to the Pliocene palaeoceanography (Raymo *et al.* 1996) permitted a shallower mode of circulation. Palaeogeographic reconstructions, based on the shelly ‘Crag’ and ‘Red Sand’ formations in NW Europe, indicate that a broad seaway to the Atlantic existed during Late Pliocene, 3.75–2.55 Ma (Zagwijn 1989; Funnell 1996; van Vliet-Lanoë *et al.* 2002). The elevated position, up to 180 m above datum in eastern England, and the marine fauna assemblage of these deposits, suggests that sea-levels were substantially higher than present (Funnell 1996). The palaeobathymetric configuration of the Channel is difficult to ascertain but seismic signatures of bottom-current erosion in the southern North Sea basin, at palaeo water depths of at least 250–300 m, support the presence of a Late Pliocene–Early Pleistocene intermediate water passage (Kuhlmann & Wong 2008). From *c.* 2.4 Ma (pre-Tiglian) the Channel seaway closed as the southern North Sea basin became

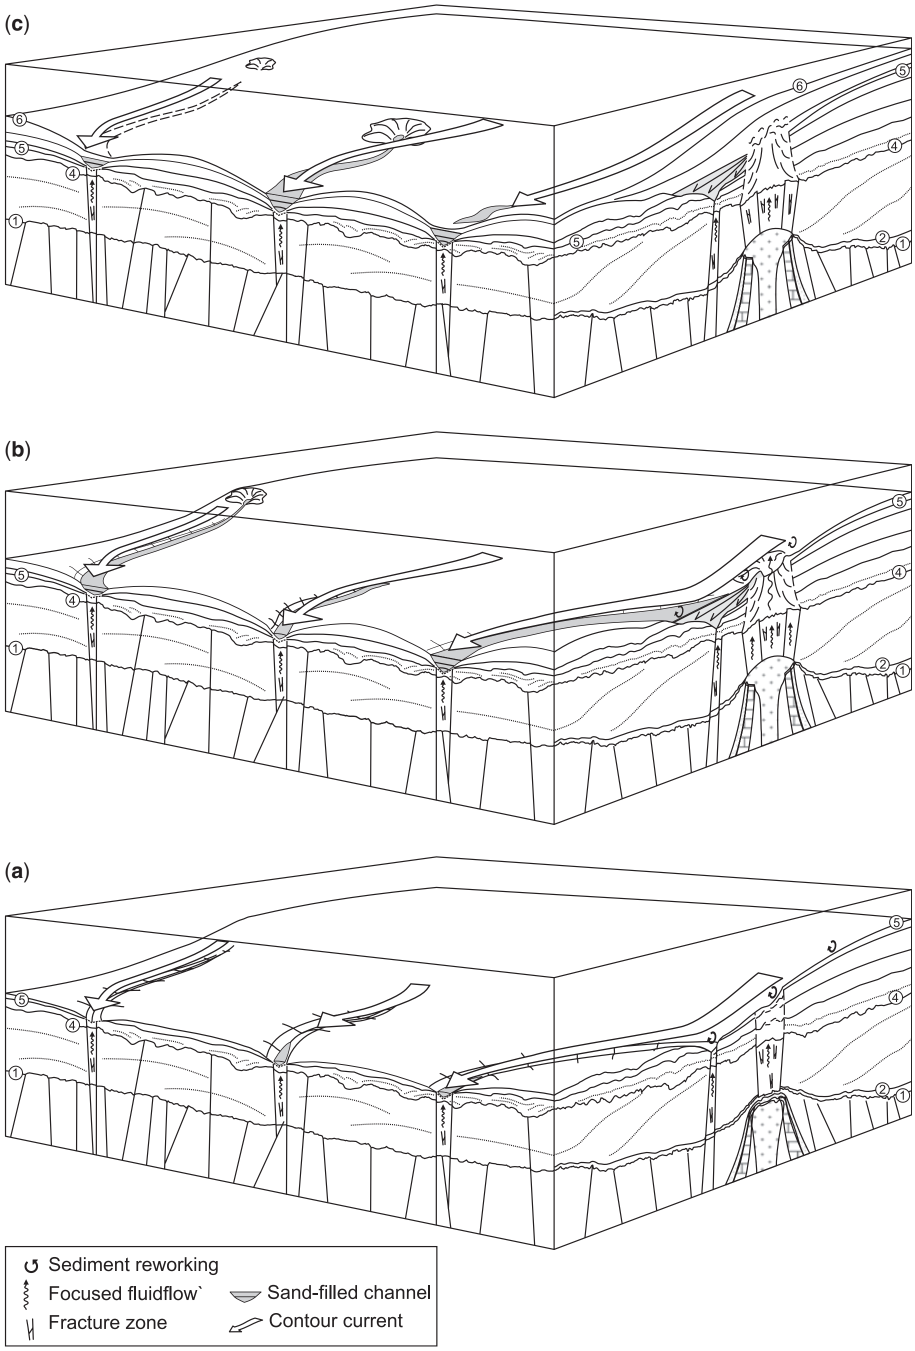

Fig. 15. Depositional model illustrating development stages for the aggradational channels. (**a**) Erosional stage: initial channel trace is formed by strong contour currents, eroding and winnowing the seabed, preferentially along corridors of low sediment strength related to fault/fracture zones. A primordial thalweg is formed by accretion of low-relief banks along the flanks of channel pathways. At this stage, fluid-flow activity over SLZ is low but increasing due to gravitational loading of the sediment prism. (**b**) Aggradational and infilling stage: channels are confined by high fine-clastic accumulation rates over interchannel regions. Hydrographic conditions at the seabed are augmented by the relief of the channel profiles (60–120 m deep, 700–2500 m wide), causing erosion in the deepest troughs. Deepening of the channels is succeeded by infill of non-cohesive silt and sand. A principle source for this material is related to extrusive sediments, derived from intense fluid expulsion over SLZ and subsequently distributed into the channel network by northward bottom-currents. The leakage zones formed pockmarks or mud-volcanoes on the seabed, similar to modern features observed in Gulf of Mexico (Milkov 2006), east Atlantic margins (Berndt 2005; Gay *et al.* 2007) and Mediterranean (Geletti *et al.* 2008). The dynamic linkage to SLZ point sources upstream means that infilling of troughs tends to proceed diachronously (e.g. infill history may differ between adjacent channel). (**c**) Burial stage: rapid burial by progradational units eventually terminates the channel formations and SLZ fluid-flow activity. This occurs progressively so that, when channels and SLZ to the south are completely buried by the clinoform unit (Horizon 6), channel profiles in basinward positions to the clinoform depocentre continue to be maintained by contour currents. Consolidation of channel infill by carbonate cementation commences during early burial stage. Horizons are numbered according to Figure 2 and Table 1. The model is not to scale although a vertical exaggeration of 1:5 may be assumed for the channel profiles.

progressively infilled by the Ur–Frisia delta complex (Cameron *et al.* 1992).

The Late Miocene/Early Pliocene unconformity is a key horizon for understanding the Late Neogene basin development of the Central Graben. The regional tilt expressed by this horizon has previously been associated with the most recent exhumation phase of the Norwegian–Danish Basin, attributed to active uplift of Scandinavia (Overeem *et al.* 2001; Japsen *et al.* 2007). The alignment of incised channels along the graben axis suggests that the SW dip of Horizon 4 (Fig. 10) was introduced subsequent to the erosive formation of these channels. Basin subsidence probably commenced during the Early Pliocene as the prism complex accumulated northward, in response to accommodation space. The oceanographic response to this bathymetric deepening was the development of south-to-north geostrophic currents, intensifying along the eastern margin of the basin. Depositional breaks within the prism package (Figs 1 & 3) suggest that during the first stage of subsidence increase in sea-level was balanced by high sediment fluxes. As subsidence progressed, the depositional system appears to have drowned, resulting in the mounded aggradational geometry of the prism. Post-depositional modification of deltaic units in the Danish sector suggests that the basin continued to tilt into the Early Pleistocene (Gelasian) (Japsen *et al.* 2007), which may explain the shift in geometries from the prism wedge to clinoform development (Fig. 6).

Gravitational loading by the succeeding late Neogene depositional units would sustain subsidence in the central parts of the basin (Fig. 1) by an amount depending on flexural rigidity of the lithosphere and bulk density of overburden (Thorne & Watts 1989). However, a passive subsidence model relying on intensified weathering induced by glaciations (Huuse 2002) is incompatible with the interpretation of the prism and abounding channels as elements of North Atlantic upper-intermediate circulation during the Pliocene climate optimum (Haywood *et al.* 2000). On the other hand, the mechanism(s) for active tectonic uplift of large intra-continental regions and corresponding basin subsidence are enigmatic and remain to be identified (Stoker *et al.* 2005). In the present case, the development of a deep seaway through the central North Sea, subsequent to late Miocene compression, suggests that mechanisms alternative to recent concepts of intraplate tectonics should be explored (Wees & Cloethingh 1996). The detailed basin stratigraphy and depositional patterns presented in this study provide a relevant comparison for future work on basin analysis.

Conclusions

Aggrading channels, 700–2500 m wide and 75–150 m deep, developed over the basinward condensed section of a Pliocene sedimentary prism in the northern Central Graben. The seismic architecture indicates that they evolved in consecutive stages of basal erosion, aggradational build-up, infilling and burial by clinoform progradation during the Early Pleistocene (from *c.* 2.6 Ma). The channels are oriented north to NNW with a geometric style that changes laterally from linear, closely spaced ridge-trough structures *sensu* (Cartwright 1995) to arcuate channel shapes.

The channel formations are related to a contour current depositional regime that commenced subsequent to rapid basin subsidence during the Pliocene. Observations in favour of this interpretation include a lack of a consistent slope gradient along thalwegs and the presence of migrating depositional mounds at channel terminations. A contour current mechanism is also implied by the mounded wedge geometry of the contiguous aggradational prism that extends northward from its main depocentre in the south Central Graben, reminiscent of a fan-drift depositional system (Faugeres *et al.* 1999). The relief of the Pliocene sediment prism suggests that water depths reached 600 m or more in the northern Central Graben, promoting the development of the prism complex by northbound geostrophic currents. The sediment source for the prism is probably related to the large Baltic River system that drained into the German Bight.

A striking character of the aggradational channels is the seismic pull-up they generate on the MMU, suggesting a coarse-grained and carbonate cemented infill. Also, it is noticeable that the largest of the arcuate channel elements commence in the vicinity of concentric chimneys related to leakage zones above salt diapirs. At these locations, troughs tend to deepen with infill displaying downlap away from the leakage zones. A geological control on the initial formation of channel pathways (erosional stage) is suggested by the presence of faults approaching seismic resolution below the troughs. Based on the 3D seismic observations, a depositional model is presented that links channel development stages to fluid expulsion from salt diapir structures and fracture zones extending from the MMU. It is recommended that geological factors for channel development, involving extensional faults and fluid leakage, are investigated in future studies.

The sedimentary prism accumulated over a Late Miocene/Early Pliocene low-stand unconformity, marked by numerous incised channels infilled by accretionary units. The erosive development of this horizon, reminiscent of a drainage system, is associated with Late Alpine compression related to uplift in the British Isles and the Channel region (Hillis *et al.* 2008). The southwestward inclination of the basal unconformity (0.5–0.8°) is related to rapid basin subsidence, facilitating successive stages of aggradational and progradational build-up of the prism complex.

The onset of basin subsidence and modification of the Late Miocene/Early Pliocene unconformity is linked to concomitant uplift of the Norwegian–Danish Basin, thus highlighting a first-order tectonic control on accommodation space and sediment supply. However, the underlying mechanism for active tectonic uplift over large intra-continental regions is presently unknown, and recent basin modelling of intraplate flexure cannot explain the observed late Neogene depositional record of the central North Sea.

PGS Ltd and EON UK are thanked for allowing access to the 3D seismic volume and North Sea well data. The chronology of the seismic stratigraphy has benefitted from helpful comments and information provided by E. S. Rasmussen and S. Piasecki. The manuscript was improved by the helpful comments from two reviewers. This work is supported by GEUS and a stipend from the Inge Lehmann foundation.

Source rock quality and maturity and oil types in the NW Danish Central Graben: implications for petroleum prospectivity evaluation in an Upper Jurassic sandstone play area

H. I. PETERSEN, H. P. NYTOFT, H. VOSGERAU, C. ANDERSEN, J. A. BOJESEN-KOEFOED and A. MATHIESEN

Geological Survey of Denmark and Greenland (GEUS), Øster Voldgade 10, DK-1350 Copenhagen K, Denmark (e-mail: hip@geus.dk)

Abstract: The principal exploration targets in the northwestern part of the Danish Central Graben have been Upper Jurassic sandstone reservoirs. The presence and effectiveness of the oil-generating rocks of the Upper Jurassic–lowermost Cretaceous marine shales of the Farsund Formation has generally not been considered as a significant risk. This study provides an evaluation of the source rock quality, maturity and distribution and of the oils in this area. The kerogen in the Farsund Formation is algal-derived, and kerogen type ranges from Type II to Type III. Generally the source rock quality is fair to excellent, but the petroleum generation potential varies considerably. In most wells the uppermost part of the Farsund Formation (Bo Member) consists of highly oil-prone shales. However, the presence of oil-prone kerogen may be masked by kerogen of poorer source quality. Favourable conditions for oil-prone kerogen preservation were present during the time of deposition of upper parts of the Farsund Formation, but exceptions are not unusual. Similar vitrinite reflectance gradients indicate a uniform thermal regime over the area. The oil window occurs from *c.* 3800–4000 to 4800 m, i.e. spanning approximately 800–1000 m. A general decrease in the generation potential from the top towards the base of the formation is caused by both generation and deterioration of kerogen quality. The Gertrud Graben and Feda Graben constitute the main kitchen areas, and oil compositions indicate sourcing from marine shales. In the shallow parts of the Outer Rough Basin the shales are mostly immature and the sourcing is dependent on kitchen areas outside the area or on Palaeozoic rocks. Mature Zechstein is indicated by a minor oil show probably locally sourced.

Keywords: source rock, maturity, petroleum potential, oil, Upper Jurassic, Danish Central Graben, North Sea

The Danish Central Graben (DCG) is part of the Jurassic North Sea Central Graben rift complex and consists of a system of NW–SE trending halfgraben (Fig. 1). Three main hydrocarbon reservoirs occur in the DCG: Middle and Upper Jurassic sandstones and Upper Cretaceous–Danian chalk. In the study area situated in the northwestern part of the DCG bordering the Norwegian, British and German sectors the exploration targets have mainly been Kimmeridgian back-barrier and shoreface sandstones belonging to the Heno Formation, located on tilted fault blocks (Johannessen 2003). Exploration results have been less successful compared with the chalk fairway further south due to large variations in reservoir quality. A number of discoveries have been made, and two fields have been declared commercial, although not yet in production. These are the Freja Field on the Gert Ridge, and the Hejre Field in the Gertrud Graben (Fig. 1). Both accumulations are deep at about 5000 m and characterized by high temperatures (154–163°C) and overpressure in the order of 7000 psi. On the flanks of the Mid North Sea High the primary target has been Volgian shallow marine sandstones. Similar sands are known from the nearby Fife and Fergus Fields in the UK sector (Fig. 1).

The Upper Jurassic to lowermost Cretaceous marine shales of the Farsund Formation, including the organic-rich Bo Member, are the principal source rocks (Damtoft *et al.* 1992; Ineson *et al.* 2003). They correspond to the Kimmeridge Clay Formation and equivalents elsewhere in the North Sea (Cornford 1998). The presence and effectiveness of the source rocks has not been considered a significant exploration risk. However, a better understanding of source rock distribution and maturity, lateral and vertical variations in kerogen quality, and oil composition may play an important role in the exploration success.

The present study aims to provide a comprehensive evaluation of (i) the variations in source quality, maturity and distribution of the Farsund Formation in the northwestern part of the DCG, and (ii) the composition of oils encountered in the area.

Methods

Source rock data from 966 samples from the Farsund Formation in 21 wells were obtained by pyrolysis using Rock-Eval instruments and more recently using a Humble Source Rock Analyzer. Total organic carbon (TOC) contents were determined by combustion in LECO induction furnaces. Samples with TOC contents of <0.5 wt% and/or S_2 pyrolysis yields of <0.2 mg HC g^{-1} rock were omitted as these give an unreliable hydrogen index (HI). Samples from wells drilled with oil-based mud (OBM) were extracted with dichloromethane–methanol (93:7 v/v) before analysis to avoid contamination and flawed S_2 yields. Vitrinite reflectance (VR) measurements (random) were performed on dispersed organic matter by means of a Leitz MPV-SP system. Oils from the Mona-1, Gert-1, Rita-1, Olaf-1, Wessel-1, Saxo-1 and Tordenskjold-1 wells were analysed together with source rock extracts from the Farsund Formation in the Rita-1 well (11 samples), the Tordenskjold-1 well (three samples) and the Wessel-1 well (four samples). Four of the samples from the Rita-1 well were from the Bo Member. Four Permian (Zechstein Z2) carbonate samples (3134.0–3142.5 m) from the Wessel-1 well were also analysed. The gas chromatography–mass spectrometry (GC–MS and GC–MS–MS) analyses were carried out using an Agilent 6890N gas chromatograph connected to a Waters (Micromass) Quattro Micro GC tandem quadropole

Jurassic and only an oil sample has been analysed from the well. PT: Piggvar Terrace.

mass spectrometer. A Phenomenex ZB-5 capillary column (30 m × 0.25 mm i.d., film thickness 0.10 μm) was used. The injection temperature was 70°C (2 min hold). The temperature program was 30°C/min from 70 to 100°C and 4°C/min from 100 to 308°C followed by 8 min at 308°C. Argon was used as collision gas for MS–MS experiments.

Regional setting

The DCG consists of a system of generally NW–SE trending half-graben bounded by the Coffee Soil Fault to the east, and by the Mid North Sea high in the west (Japsen *et al.* 2003) (Fig. 1). Jurassic rifting commenced during Bajocian in the east. During the Kimmeridgian, the depocentre shifted westward and deposition gradually coved larger areas reaching the flanks of the Mid North Sea High during the Volgian (Johannessen *et al.* 2010). In the overall extensional regime, compressional features also occur, resulting from oblique-slip movements between different graben segments. The structure of the study area is illustrated by depth structure maps of the top and base of the Upper Jurassic section, the Upper Jurassic isochore and a simplified structural profile through the northwestern part of the DCG (Figs 2 & 3). The Piggvar Terrace in the NE is located between the Mandal High and the northeastward tilted Gertrud Graben, which is separated from the southwestward dipping Feda Graben by the Gert Ridge. In both graben segments the thickness of Upper Jurassic strata locally exceeds 1500 m. The Ål Basin and the shallow Outer Rough Basin, which has a thin Upper Jurassic section, are located west of the Inge High, on which Jurassic strata are thin or absent.

The syn-rift sedimentary fill in the northwestern part of the DCG is dominated by the shales of the Kimmeridgian to Ryazanian Farsund Formation (Figs 2 & 3; Table 1). Widespread shallow to marginal marine sandstones of the Heno Formation were deposited over an erosion surface associated with a cessation or slowdown of subsidence during the Late Kimmeridgian (Andsbjerg & Dybkjær 2003). In the west, shallow marine sandstones of Volgian age have been encountered on the flanks of the Mid North Sea High (Johannessen *et al.* 2010).

Source rock maturity and quality

The organic richness and source rock quality of the shales of the Farsund Formation are known to show lateral and stratigraphical variations (Damtoft *et al.* 1992). These variations in TOC and HI suggest that several factors, such as variations in oxygen content in the bottom waters, organic matter production and sediment input, determined composition and preservation of kerogen in the rocks. The shales in the upper levels of the Farsund Formation are generally 'hot' and were previously referred to as the informal 'Hot Unit' because of high levels of radioactivity recorded by the γ-ray logs (Jensen *et al.* 1986; Ineson *et al.* 2003). These shales are referred to as the Bo Member (Volgian–Ryazanian). The member is partly equivalent to the Clay Deep Member and Mandal Formation from the Dutch and Norwegian North Sea sectors, respectively, and it is defined by significantly higher gamma-ray (GR) levels than the underlying and overlying shales (Michelsen *et al.* 2003) (Fig. 4). It is normally assumed that the HI values and TOC content increase and the kerogen becomes more oil-prone through the Farsund Formation, particularly in the Bo Member, which generally is considered to possess the best source potential (Damtoft *et al.* 1992). In the northwestern part of the DCG the Bo Member is present in the Piggvar Terrace, the Gertrud and Feda Grabens and the Ål Basin, whereas it is thin to absent on the Gert Ridge and seems to be absent on the Inge High and in the Outer Rough Basin (Table 1). The member is anomalously thick in a few wells (*c.* 100 m), but in most wells the thickness is between 20 and 50 m.

Thermal maturity and the oil window

VR gradients for the Outer Rough Basin/Ål Basin, Feda Graben/Gert Ridge and Gertrud Graben/Piggvar Terrace areas show largely similar and relatively well defined maturity trends (Fig. 5). The similar maturity gradients indicate a uniform thermal regime for the northwestern part of the DCG. If a VR of 0.6%R_o is used as the start of the oil window, the VR trends suggest a burial depth of approximately 4000 m for the start of the oil window. The occurrence of oils with low-maturity biomarker signatures elsewhere in the DCG may suggest that petroleum generation in some cases may take place at modest levels of thermal maturation (about 0.5%R_o or less). In the Piggvar Terrace, Gertrud Graben, Feda Graben, Ål Basin and partly on the Gert Ridge, the entire or part of the Farsund Formation seems to be buried to 4000 m or deeper, indicating that the source rocks are within the oil window (Fig. 6a, b; Table 1). On the Inge High

[a]Base Farsund Formation not reached.

and in large parts of the Outer Rough Basin, the top of the Farsund Formation is buried to less than about 3600 m, implying immaturity of the source rocks (Fig. 6a, b; Table 1). This renders the Outer Rough Basin dependent on kitchen areas located outside the area, or on Palaeozoic source rocks. However, in the Liva-1 well, which was drilled on an anticlinal structure in the Outer Rough Basin close to the bounding fault of the Inge High, the Farsund Formation is buried below 4000 m depth and a local kitchen with mature source rocks may be present immediately NW of the well (Fig. 6a, b). Thermally mature shales of the Farsund Formation occur mainly in the Feda Graben and Gertrud Graben (Fig. 6a, b). The highest maturities (VR $>1\%R_o$) have been reached in depocentres in these graben. A VR of $1.02\%R_o$ at the base of the Farsund Formation at *c.* 5000 m burial depth in the Hejre-1 well is low, which could be due to retardation of VR caused by the overpressure (Carr 2000) in the well.

A decrease in HI and an increase in the production index ($PI = S_1/S_1 + S_2$) below *c.* 3800–4000 m, supports the top of the oil window as defined by VR ($0.6\%R_o$), and suggests that the decrease in HI is related to generation (Fig. 7a, b). Generally PI increases from approximately 0.1–0.4 from the onset of oil generation and through the oil window (Espitalié *et al.* 1985, 1986). Many of the studied wells were drilled with OBM, and the samples from these wells were solvent-extracted before analysis in order to avoid unreliable geochemical data caused by contamination. However, in nine wells samples were not contaminated by OBM and for these samples the PI was calculated (Fig. 7b). In the majority of the samples PI reached 0.1 at *c.* 3800–4000 m and increased gradually to 0.35–0.4 at about 4700 m. The observed variation in PI may be due to differences in kerogen composition (Hunt 1996), but some of the very high PI values between 3900 and 4000 m may indicate migrated hydrocarbons. Below *c.* 4800 m

the HI values are generally less than 200–300 mg HC/g TOC, indicating that mainly a gas-potential remains. The oil window thus occurs from *c*. 3800–4000 to 4800 m, i.e. spanning approximately 800–1000 m (Fig. 7a). However, HI values also fluctuate through the Farsund Formation, reflecting organic facies variations. This issue is discussed below.

Kerogen composition and source rock quality

The organic matter in the marine shales of the Farsund Formation is dominated by algal-derived fluorescent amorphous organic matter (AOM), and alginite with *Leiosphaerida* and *Tasmanites* morphology (Fig. 8). Immature to early mature samples from four wells show variations in kerogen composition from Type II to Type III (Fig. 9). The kerogen in the Farsund Formation (excluding the Bo Member) is classified as Type III in the Jeppe-1 well, Type II/III in the Gert-1 and Rita-1 wells, and Type II in the Diamant-1 well. The kerogen in Diamant-1 is of better quality than the Type II kerogen in the Bo Member in both Jeppe-1 and Rita-1 (Fig. 9).

The shales of the Farsund Formation show a large range in HI in the different graben and basins, which is partly controlled by maturity, but also by variations in kerogen quality (Figs 7a & 10a, c). The source rock quality can generally be classified as fair to excellent (Fig. 10b, d). In the Jeppe-1, Gwen-2 and Q-1 wells, however, many samples of the Farsund Formation (excluding the Bo Member) are classified as poor source rocks. The range in HI and average HI values indicates petroleum generation potential from non-generative/gas-prone (e.g. Jeppe-1, Gwen-2 and Q-1 wells) to highly oil-prone (Jette-1, Diamant-1, Tordenskjold-1 and Wessel-1 wells) (Table 1). Hence, in the Gertrud Graben and Piggvar Terrace area, the Farsund Formation (excluding the Bo Member) is a less oil-prone source rock. Only the Jette-1 and Hejre-1 wells contain shales with an enhanced oil-generating potential (Table 1). The oil-prone nature in Hejre-1 is present despite the higher thermal maturity of the shales, where VR values from approximately 0.75 to 1.0%R_o indicate depletion of the generation potential. The oil potential of the Farsund Formation is better developed in the Feda Graben and Gert Ridge, where the shales mostly are gas/oil prone (Table 1). The thick Farsund Formation in the Kim-1 well in the Ål Basin is gas-prone (Table 1). In the Outer Rough Basin, the shales of the Farsund Formation are rich oil-prone source rocks in a number of wells, but the formation is generally thin and in all wells the shales are immature (Fig. 6a, b; Table 1).

The Bo Member is traditionally considered to be the most oil-prone part of the Farsund Formation, and in the studied wells the HI values and TOC contents show a significant increase in the member (Fig. 11). In the majority of the wells the Bo Member has average HI values from 316 to 453 mg HC g^{-1} TOC, indicating a potential for oil and gas generation (Fig. 10c; Table 1). In the Mona-1 and Kim-1 wells the shales are gas- or gas/oil-prone. Hence, although the Bo Member has high GR values, it is not necessarily oil-prone (Fig. 4). The source rock quality of the Bo Member seems to be best developed in the deeper parts of the Feda and Gertrud Grabens (Fig. 6c, d). The Norwegian Hod and Valhall oilfields immediately north of the Danish sector occur on trend with the Feda Graben, which makes it likely that the good generation potential in the Feda Graben continues northward into the Norwegian sector. The Danish Freja Field (Gert wells) and

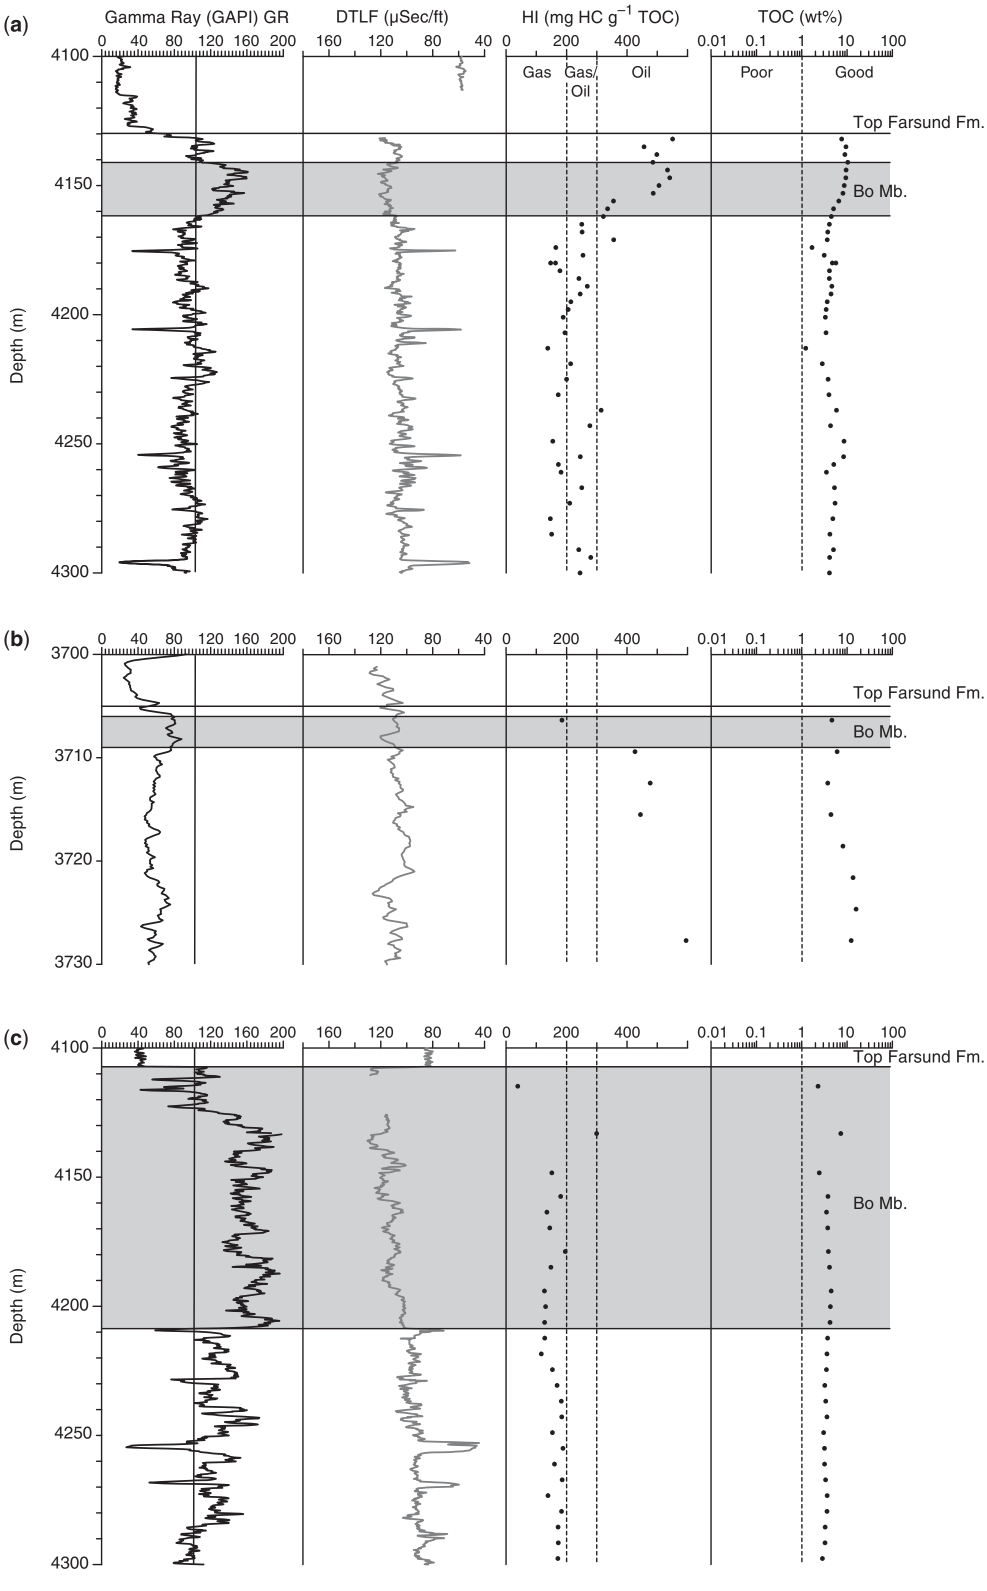

Fig. 4. GR and sonic logs of three wells showing (**a**) high GR, TOC and HI values in the Bo Member in the Eg-1 well, (**b**) low GR values in both the Farsund Formation and the Bo Member but high TOC and HI values in the Farsund Formation in the Diamant-1 well, and (**c**) high GR values but low TOC and HI values in the Bo Member in the Kim-1 well.

the Hejre oil discovery are likewise derived from areas predicted to have good source quality in the Gertrud and Feda Grabens. High HI values seem overall to coincide with high TOC contents. The apparent decline in TOC content closer to structural highs, such as the Inge High, may be caused by dilution from siliciclastics, whereas the decline in generation potential may be caused by a higher input of terrestrial organic matter and/or more oxygenated conditions (e.g. Damtoft *et al.* 1992) (Fig. 6c, d). In areas where the Bo Member is either poorly developed or absent to very thin, the shales of the remaining Farsund Formation may be rich source rocks (encircled wells Jette-1, Diamant-1, Wessel-1 and Tordenskjold-1 in Fig. 6c).

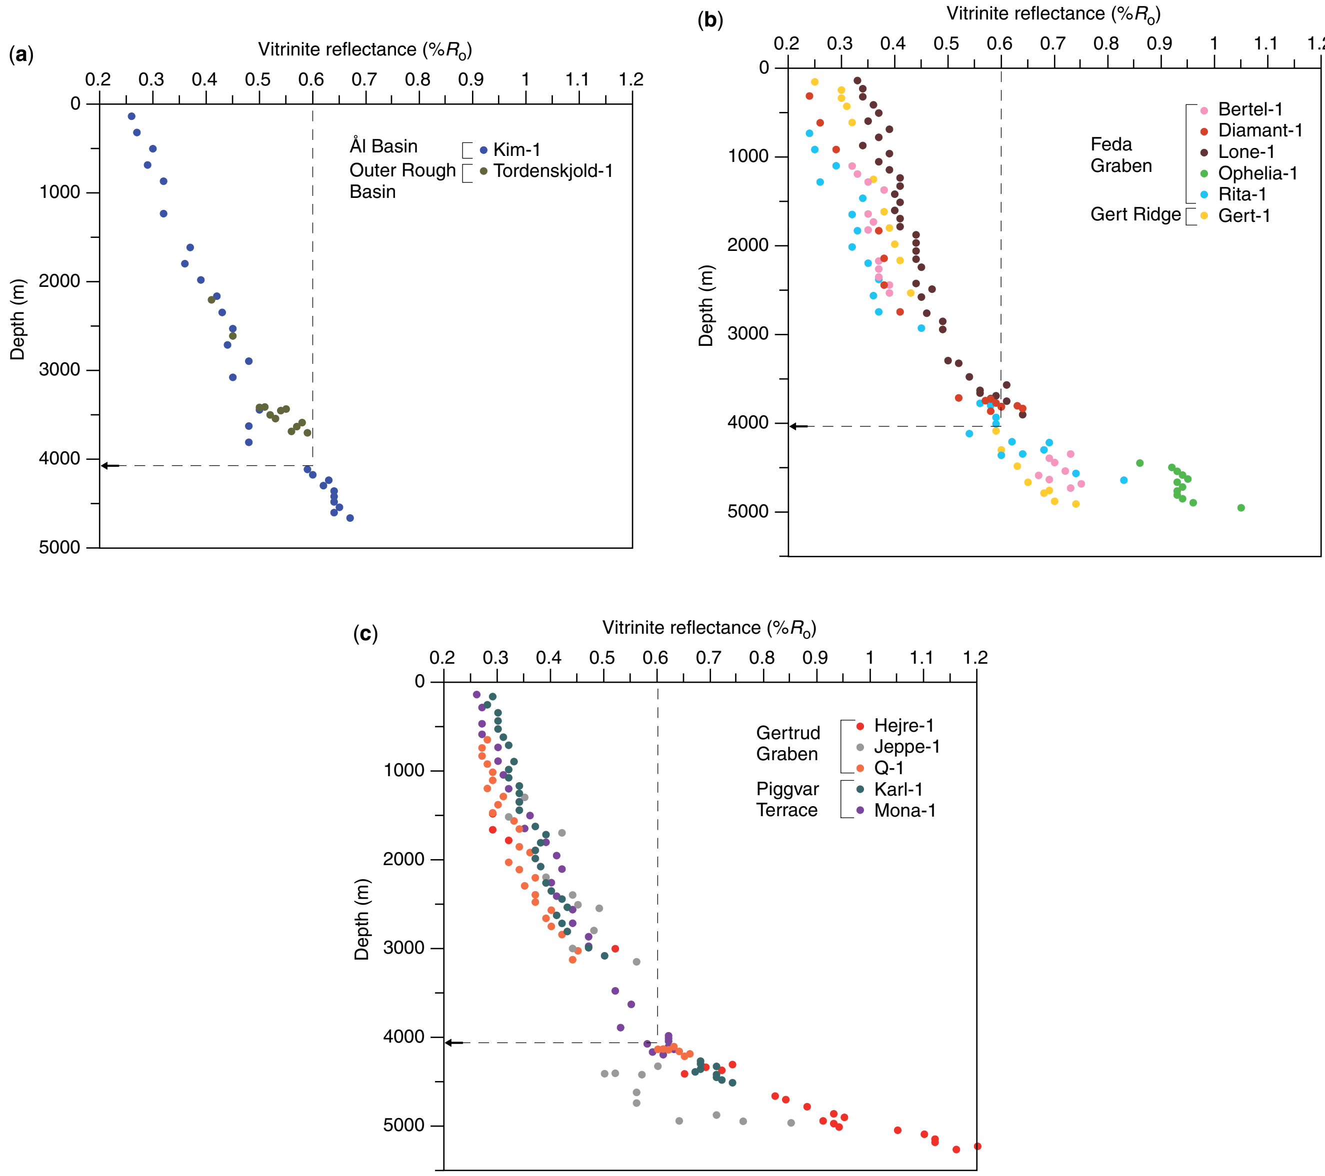

Fig. 5. VR trends of the wells in the (**a**) Outer Rough and Ål Basins, (**b**) Feda Graben and Gert Ridge, and (**c**) Gertrud Graben and Piggvar Terrace. Using a VR of 0.6%R_o the top of the oil window is at about 4000 m depth.

Although HI decreases with burial below 3800 m due to maturation, HI and TOC fluctuate throughout the Farsund Formation, and intervals within the formation may be considerably richer than suggested by the average HI. For example the Gert-2 and Hejre-1 wells contain about 300 and 200 m, respectively, thick oil-prone intervals in the lower–middle part of the Farsund Formation. The Gert-2 and Bertel-1 wells have a pronounced TOC-peak in the lowermost part of the Farsund Formation (Fig. 11). These variations in TOC and HI are consistent with the subtle facies changes observed in a core spanning a minor part of the Farsund Formation and the base of the Bo Member in the Jeppe-1 well (Ineson *et al.* 2003). A gradual decrease in HI with depth in the Farsund Formation of the Ophelia-1 well and the Gert-2 well may thus result from maturation but also deterioration in kerogen quality with depth (Fig. 11). For example, the lower (4632 m; TOC = 5.77 wt%, HI = 200 mg HC g^{-1} TOC) and upper (4344 m; TOC = 8.13 wt%, HI = 321 mg HC g^{-1} TOC) part of the Farsund Formation in the Bertel-1 well show variations in kerogen composition. The upper sample is characterized by fluorescing AOM, alginite, liptodetrinite and abundant pyrite, whereas the lower sample is characterized by less and weaker fluorescing AOM, more vitrinite and inertinite, and non-fluorescing organic matter. The weaker fluorescence intensity could be caused by higher maturity, but the higher vitrinite and inertinite content and lower TOC suggests stronger terrestrial influence and higher oxygen availability. More favourable conditions for preservation of oil-prone kerogen appear to have existed during deposition of the upper parts of the Farsund Formation, including the Bo Member, although exceptions occur. The kerogen quality is, for example, excellent (average HI = 468 mg HC g^{-1} TOC) through the entire Farsund Formation in the Diamant-1 well where the Bo Member is absent or may be very thin (?3 m). In the Upper Jurassic Draupne Formation in the North Viking Graben of Norway, similar lateral and stratigraphical organic facies variations with significant variations in source potential have been identified (Keym *et al.* 2006). Kerogen composition ranges from Type II to Type II/III with more gas- and condensate-prone kerogen containing a higher proportion of terrestrial organic matter occurring in the lower parts of the formation.

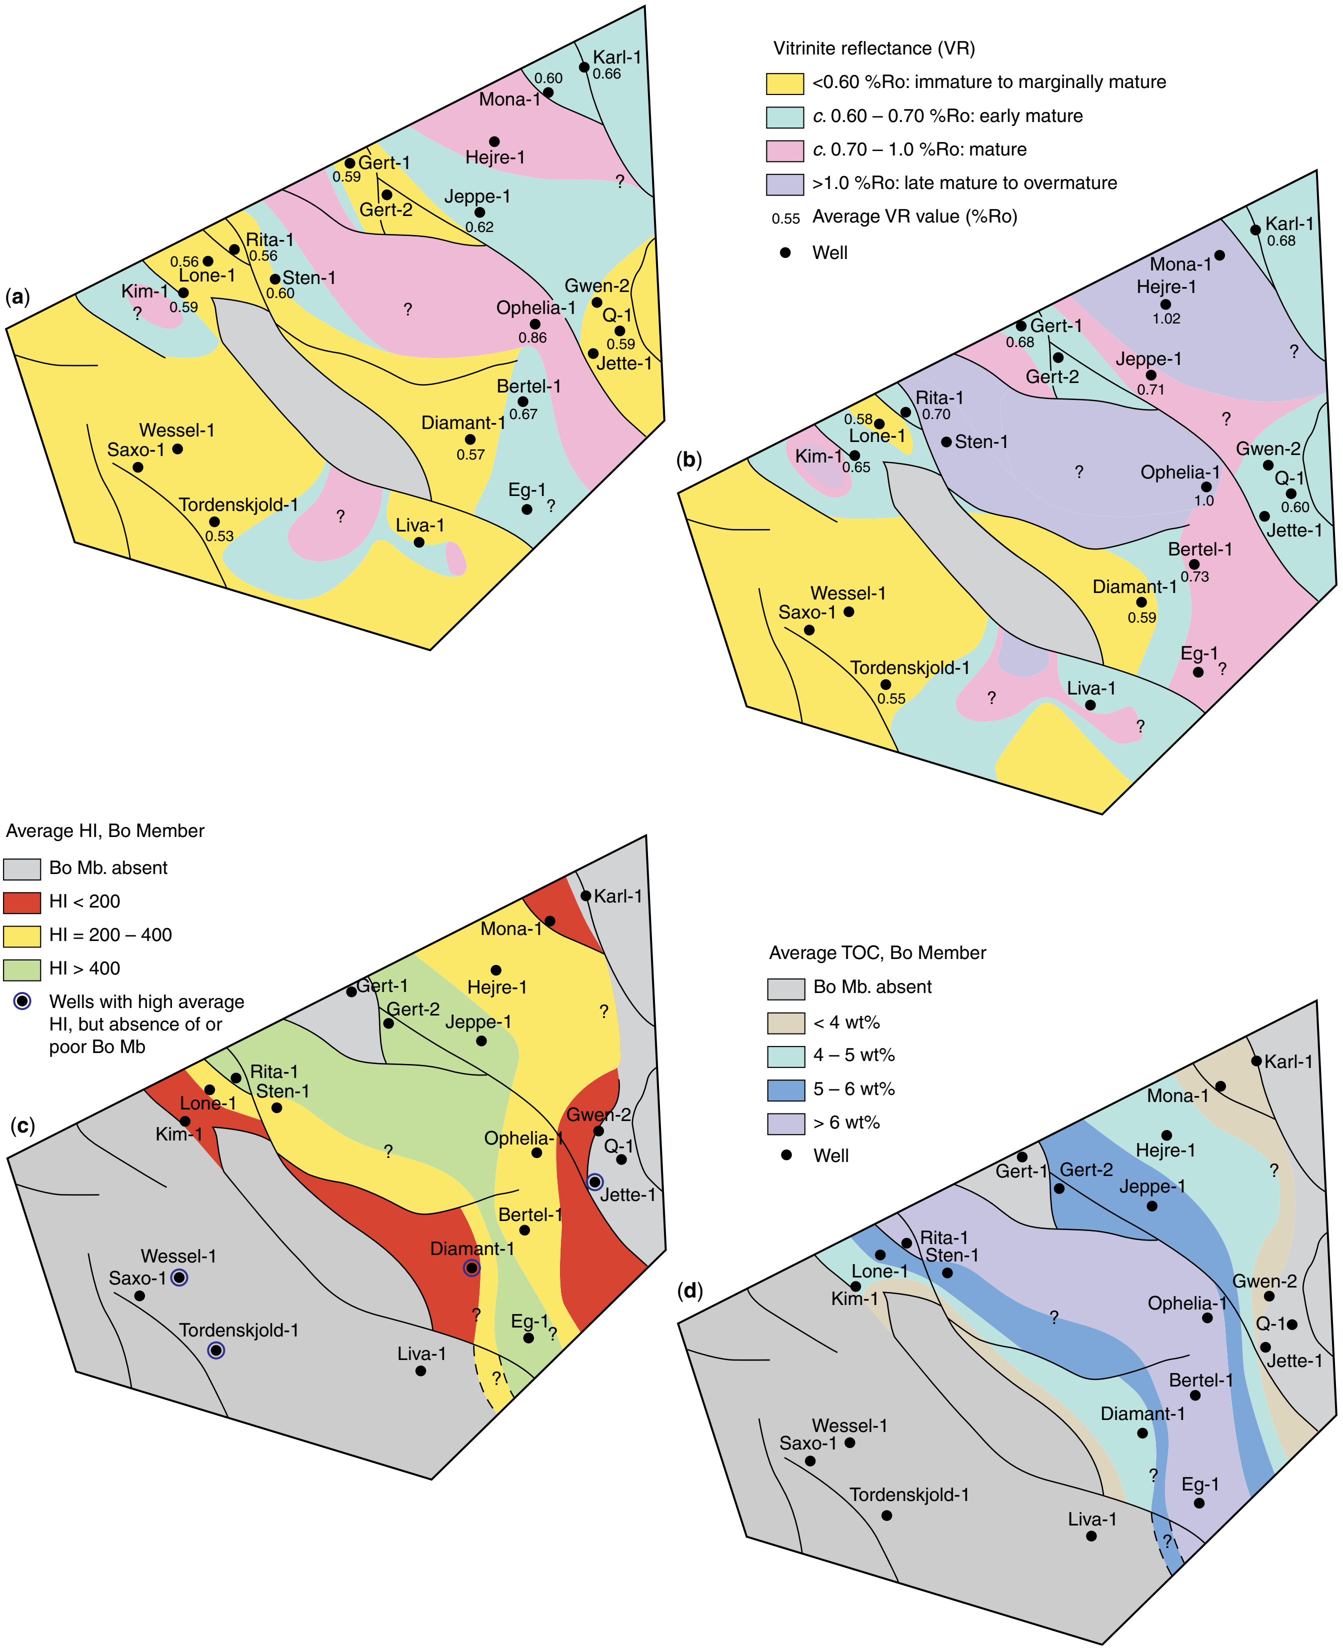

Fig. 6. (**a**) Thermal maturity map of the 'top Farsund Formation', (**b**) thermal maturity map of the 'base Farsund Formation', and (**c**) map showing the average HI of the Bo Member. Wells with high average HI values (>300 mg HC g^{-1} TOC) but with an absent or only very thin Bo Member are encircled. (**d**) Map showing the average TOC content of the Bo Member.

Estimation of HI of the generative kerogen

The measured HI is a measure of the current bulk petroleum generation potential of the kerogen present in the source rock. The kerogen may be a mixture of oil-prone (sapropelic), gas-prone and inert organic material, and the HI value is an average of the source potential. It is, however, possible to estimate the HI for the generative (or 'live') kerogen (HI_{live}). The intercept TOC

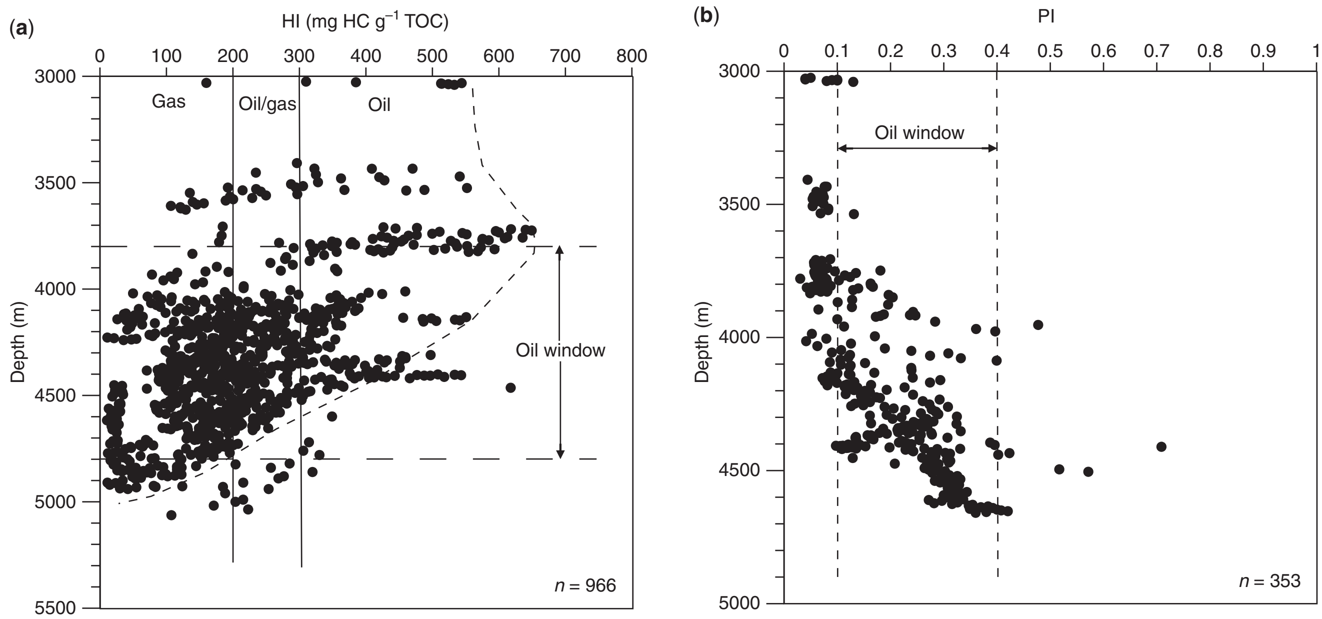

Fig. 7. (**a**) HI v. depth plot for all studied wells. HI shows a gradual decrease through the Farsund Formation at depths greater than *c*. 3800 m, which is caused by generation as the shales pass through the oil window with increasing burial depth. At *c*. 4800 m HI is generally less than 200–300 mg HC/g TOC. (**b**) PI v. depth plot for nine wells not contaminated by oil-based drilling mud. PI is generally 0.1 or higher at about 3800–4000 m and increases to 0.35–0.4 at *c*. 4700 m. The oil window is thus spanning about 800–1000 m.

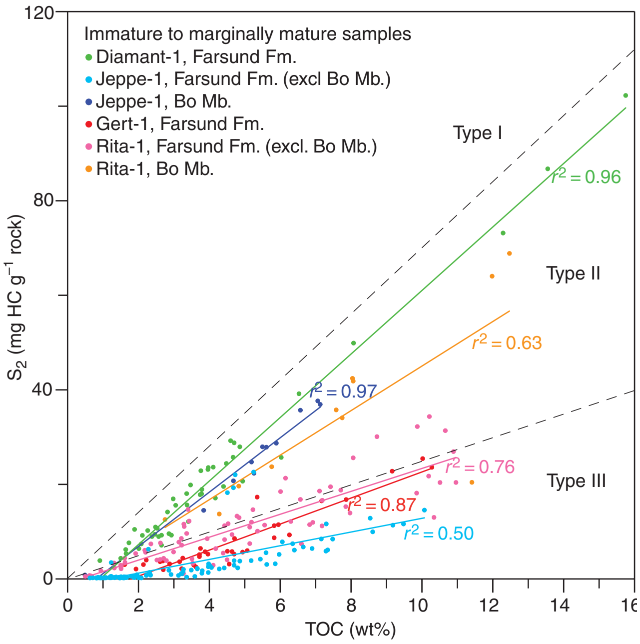

Fig. 9. S_2 v. TOC plot of immature to marginally mature samples from the Farsund Formation and Bo Member in four selected wells. The regression lines show the variation in kerogen type (cf. Langford & Blanc-Valleron 1990) between wells but also between the Farsund Formation and Bo Member in individual wells.

value of the gradient in a S_2 v. TOC cross-plot may be absorptive capacity of the mineral matrix (Langford & Blanc-Valleron 1990), or dead organic carbon, i.e. non-generative kerogen (Cornford *et al.* 1998). Dahl *et al.* (2004) used the equation $HI_{live} = 100 \times S_2/(TOC_{measured} - TOC_{dead\ carbon})$ to estimate the average HI for the generative kerogen. This method has been used to calculate the HI_{live} for immature to early mature samples from the Bo Member and Farsund Formation (excluding the Bo Member) in a number of wells (Fig. 12; Table 2). In the Farsund Formation 39–83% of the measured TOC contents are 'live', whereas 64–82% of the measured TOC contents in the Bo Member are 'live' (Table 2). Using this correction in the Diamant-1 and Jette-1 wells the organic matter in the Farsund Formation is mostly composed of oil-prone kerogen, while in the Eg-1 and Gert-1 wells less oil-prone kerogen is present. Calculation of HI_{live} indicates the presence of substantial proportions of oil-prone kerogen, which is masked by kerogen with a poorer source quality. In the Gert-1 well, the Farsund Formation is rated gas-prone from an average HI of 152 mg HC g^{-1} TOC, but using the correction a HI_{live} of 317 mg HC g^{-1} TOC_{live} is obtained, albeit with a lower richness ($TOC = 4.56$ wt% $\rightarrow$ $TOC_{live} = 2.41$ wt%) (Tables 1 & 2). This suggests that areas considered to be gas-prone based on average HI values may be more oil-prone than previously assumed from Rock-Eval data alone.

Oils: composition and source

Hydrocarbons have been encountered in a number of wells in the northwestern part of the DCG, but only two discoveries have hitherto been declared commercial, the Freja Field and the Hejre discovery (Fig. 1). Biomarker analyses of oils indicate a marine shale source, but there are also indications of a Palaeozoic source in the Outer Rough Basin. Oils from the Mona-1 well (Fig. 13) and Olaf-1 well show the typical biomarker characteristics of the Bo Member of the Farsund Formation as exemplified by the four uppermost Rita-1 well extracts (Table 3). These characteristics include the presence of 28,30-bisnorhopane and higher carbon number 28-norhopanes, a high C_{35} homohopane index, and a high proportion of C_{30} steranes (Table 3). Sterane maturity parameters such as C_{29} 20S/(20S + 20R) and the relative proportions of $\beta\beta$-steranes and diasteranes indicate, however, generation from a more mature Bo Member than in the Rita-1 well (Table 3). Oils from the Gert-1, Lone-1 and Rita-1 wells contain virtually no 28,30-bisnorhopane. The C_{35} homohopane index and the proportion of C_{30} steranes is low, and in that way they are more similar to extracts from the deeper part of the Farsund Formation in the Rita-1 well. The relative proportion of rearranged steranes and hopanes (diasteranes, neohopanes, diahopanes and the early eluting series of rearranged hopanes) is related to both source facies and thermal maturity. An increase with depth in the relative abundances of these compounds can be seen in the Rita-1 well around 3900 m (Table 3). This is partly related to the transition from the Bo Member to the deeper part of the Farsund Formation, which probably was deposited under more oxic conditions. However, the rearranged steranes and hopanes are more stable than regular counterparts. At high maturities the latter are preferentially destroyed giving an increase in all ratios involving the rearranged compounds (Farrimond *et al.* 1998). Also deeper in the well there is a decrease in the hopane:sterane ratio. In the Rita-1 well this happens below 4200 m (Table 3). The hopane:sterane ratio, the diasterane:reg. sterane ratio, and the various rearranged hopane ratios for oils from the Gert-1 and Rita-1 wells are similar to those of the source rock extract from 4474 m in the Rita-1 well, suggesting that the oils were generated from a source of the same thermal maturity.

Oils from the Saxo-1 well and to some extent also the Tordenskjold-1 well, both reservoired in Zechstein intervals, have the same biomarker characteristics as extracts from Permian (Zechstein Z2) samples from the Wessel-1 well. These indicate a carbonate/marly source rock, deposited under conditions of high salinity, which received only minor contributions from higher land plants (Fig. 13; Table 3). These biomarker characteristics include a very high hopane/sterane ratio, abundant 30-norhopanes including 29,30-bisnorhopane, high proportions of $\alpha\beta\beta$-steranes, low proportions of diasteranes and rearranged hopanes, high proportions of homohopanes $>C_{30}$ (e.g. as reflected in the C_{35} homohopane index), and the presence of significant gammacerane, which indicates water-column stratification (by salinity gradient) (Sinninghe Damsté *et al.* 1995). The extracts have lower $C_{30}/(C_{27}–C_{30})$ sterane ratios than samples from oils and source rock extracts from the Farsund Formation (open marine). C_{30} steranes (24-*n*-propylcholestanes) in crude oils are indicators of input of marine organic matter to source rocks (Moldowan *et al.* 1990). One of the two oil samples from the Saxo-1 well (3208 m) has a very high content of β-carotane which, like gammacerane, is associated primarily with anoxic, saline lacustrine or highly restricted marine settings (Hall & Douglas 1983). Oil traces extracted from Upper Jurassic sandstones in the Wessel-1 well show a few of the same characteristics, such as the presence of gammacerane and a high C_{35} homohopane index, whereas most other biomarker ratios including the 24-nordiasterane ratio (NDR, age-related; Fig. 13, Table 3; Holba *et al.* 1998) suggest a Jurassic source.

Discussion

Highly organic-rich and oil-prone shales of the Bo Member are largely restricted to the depocentres of the Feda and Gertrud Grabens (Fig. 6c, d). Outside of these areas the Bo Member constitutes a poor source rock or is absent, but the rest of Farsund

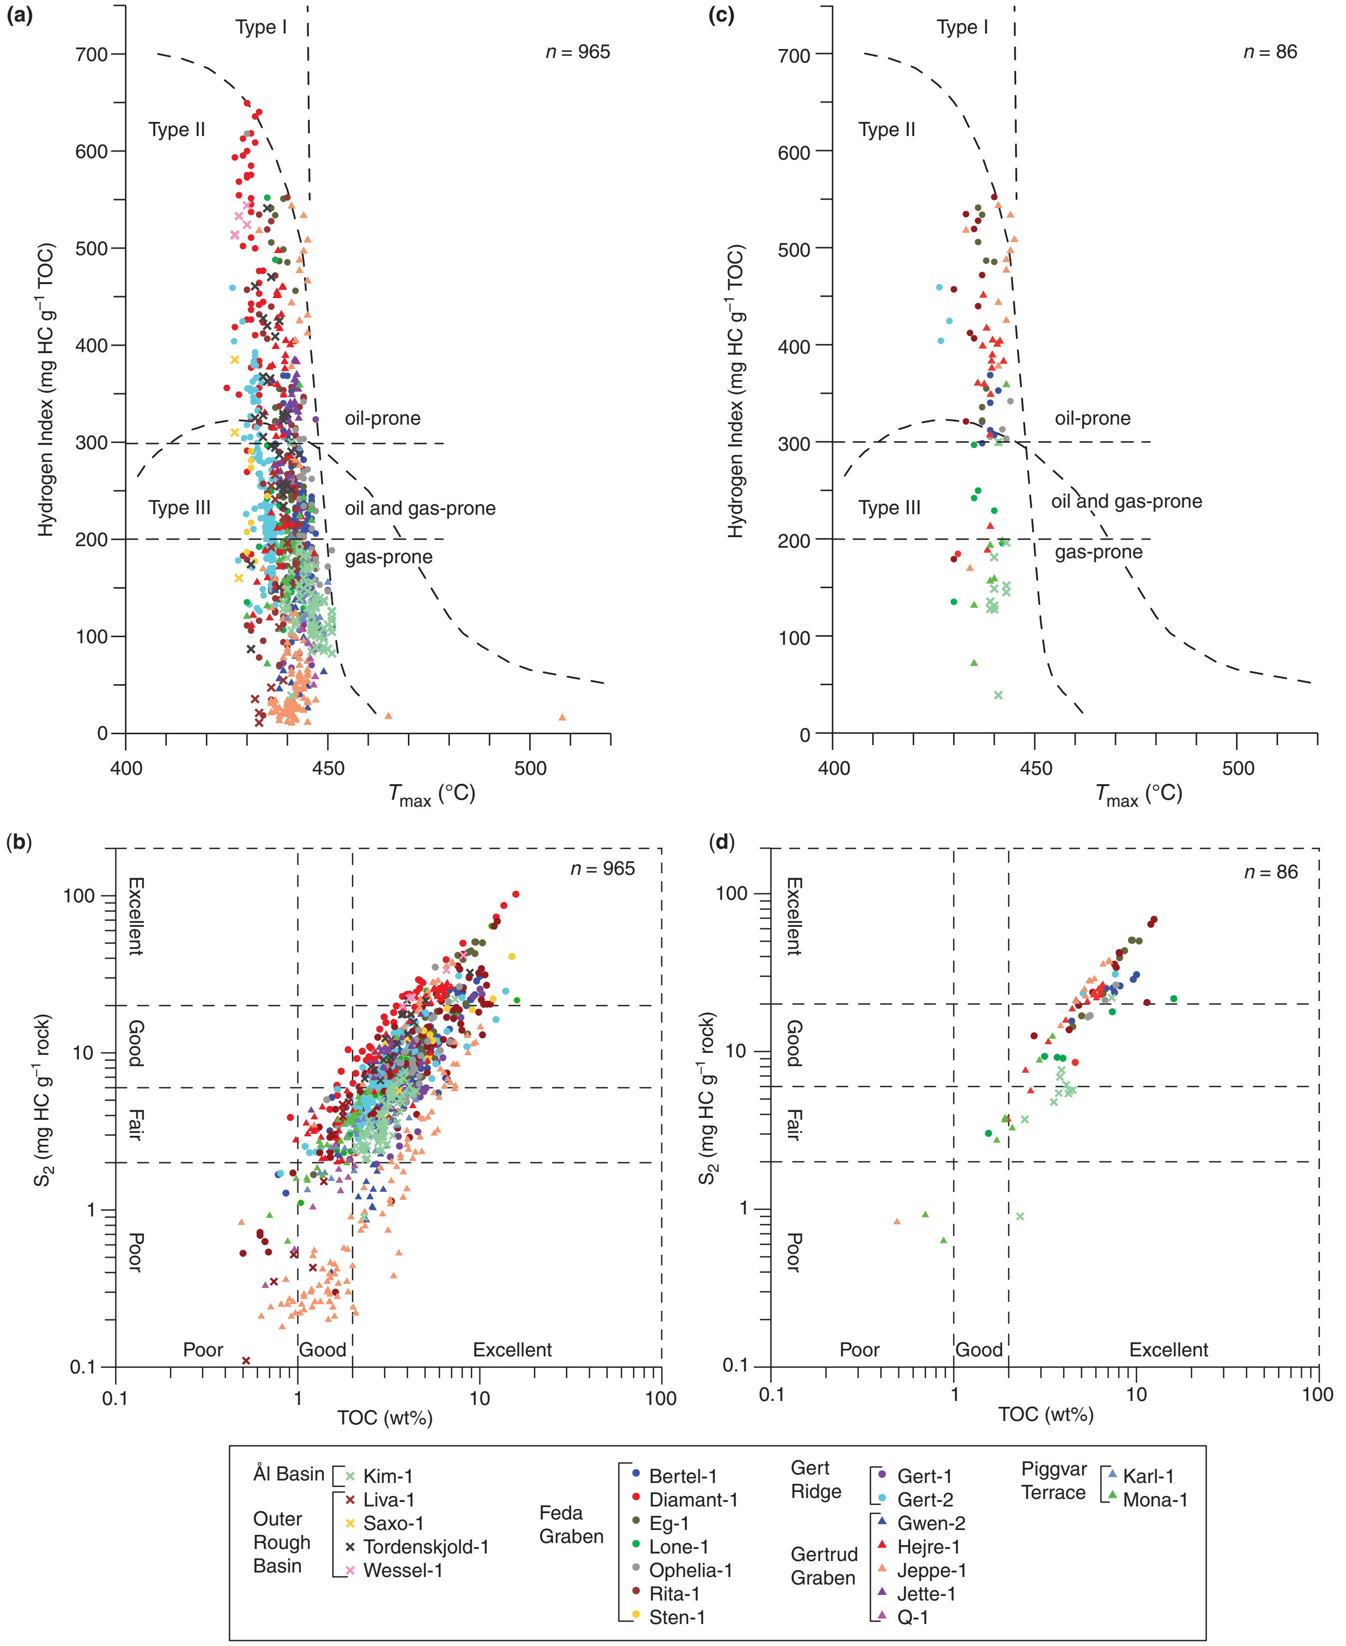

Fig. 10. Source rock potential and quality of the Upper Jurassic–lowermost Cretaceous marine shales in the study area shown by HI v. T_{max} and S_2 v. TOC plots. (**a**) and (**b**) Farsund Formation including the Bo Member, (**c**) and (**d**) only Bo Member.

Formation may be a good source (e.g. Diamant-1, Jette-1, Tordenskjold-1, Wessel-1; Fig. 6c). The HI values of the Farsund Formation are generally highly variable in the wells. Although the average HI value of the Farsund Formation in a well may indicate minor potential, intervals in the formation can be highly oil-prone (Fig. 11). In addition, estimation of HI_{live} values suggests that the shales may contain higher proportions of oil-prone kerogen, which can be 'masked' by the presence of dead carbon (e.g.

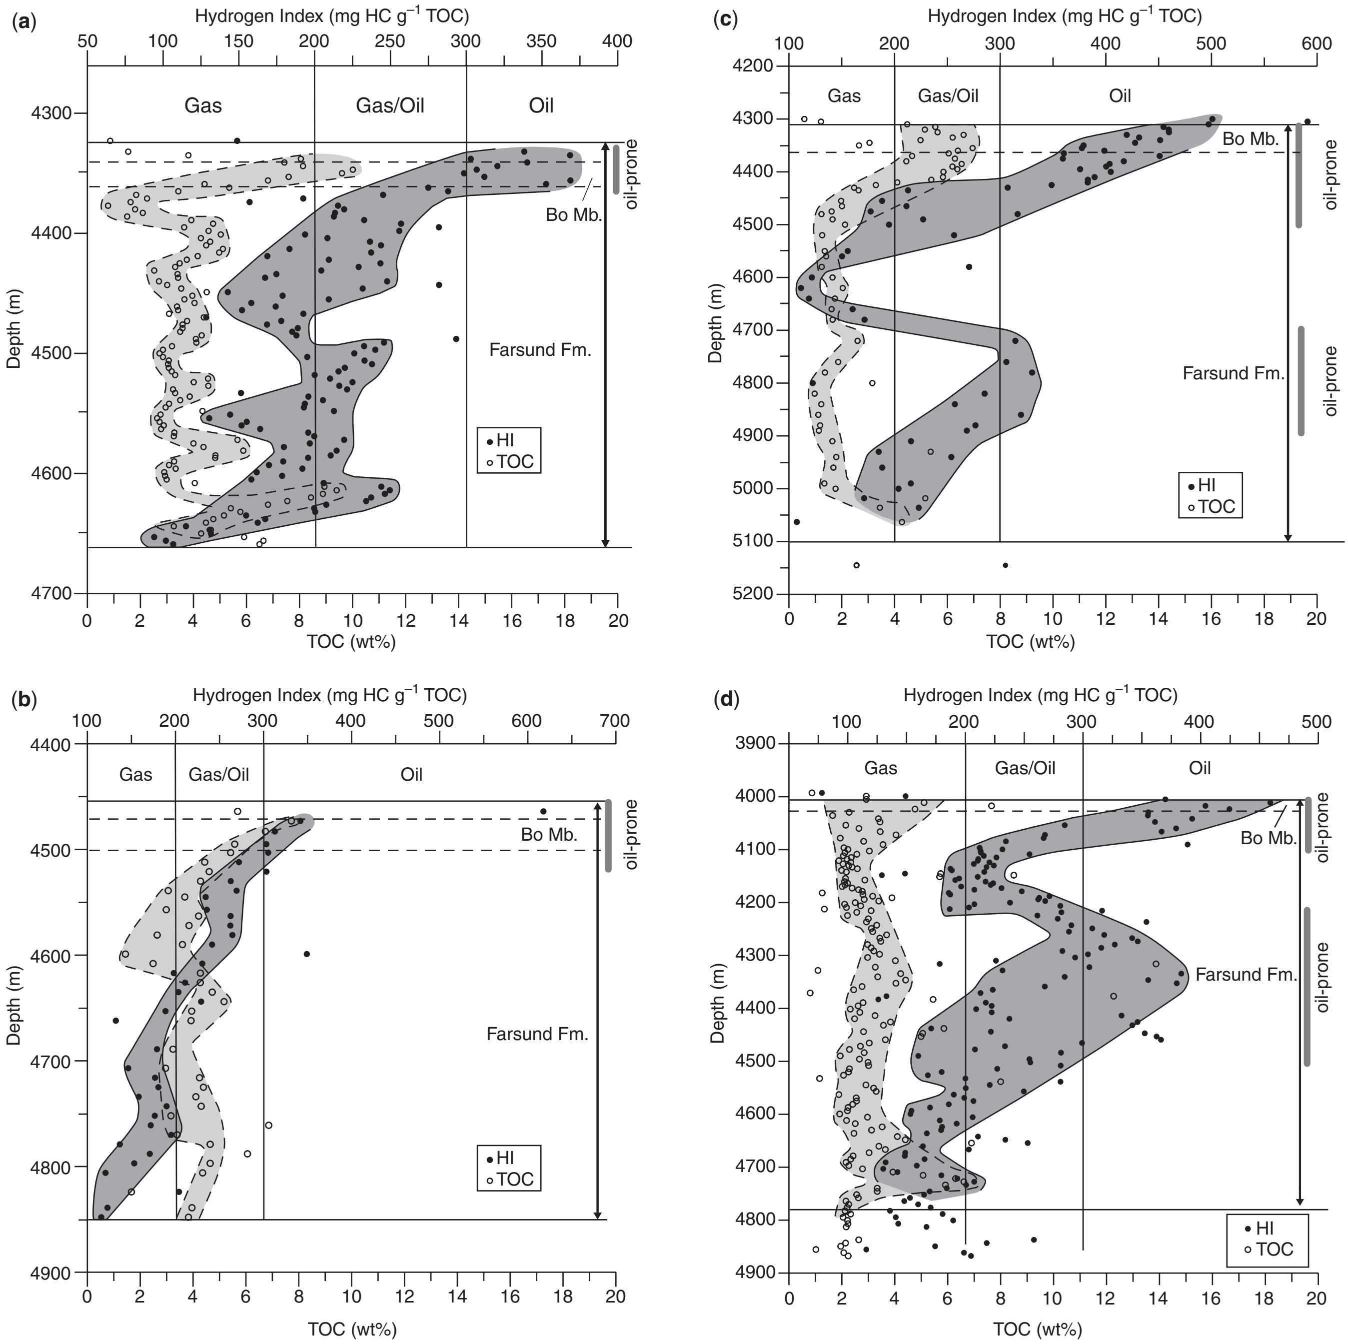

Fig. 11. Variability in TOC content and HI through the Farsund Formation in the (**a**) Bertel-1 well, (**b**) Ophelia-1 well, (**c**) Hejre-1 well and (**d**) Gert-2 well. A general increase in both values is recorded in the upper part towards the Bo Member.

Gert-1 well; Table 2). This indicates that the oil generation potential in some areas may be underestimated by using average HI values. It has generally been assumed that the oil-prone organofacies declines from top to base of the Farsund Formation (Damtoft *et al.* 1992), owing to more oxic depositional conditions. Geochemical data and petrographical observations from this study support this assumption. However, it is obvious that the gradual decrease in HI and associated increase in PI at depth greater than *c*. 3800–4000 m in all wells is caused by increasing maturity as the shales pass through the oil window (Fig. 7a, b). Lower HI values in the lower part of the Farsund Formation are thus mainly a function of higher maturity. The Farsund Formation is mature in the depocentres of the Feda Graben, Gertrud Graben and Ål Basin and possibly in a deep between the Tordenskjold-1 and Liva-1 wells in the Outer Rough Basin (Fig. 6a, b). However, in the deepest parts of the Feda Graben and Gertrud Graben the lower Farsund Formation is probably overmature due to burial depths of 6000 m or more (Fig. 2b). The Farsund Formation is early mature on the Piggvar Terrace, whereas only the lower part of the formation is early mature on the Gert Ridge and in the area around the Gwen-2, Q-1 and Jette-1 wells. By superimposing the areas with oil-prone source rocks (HI >300 mg HC g^{-1} TOC; Bo Member and/or Farsund Formation) with areas where the source rocks are thermally mature, kitchen areas can be delineated (Fig. 14). The Feda and Gertrud Grabens constitute potential kitchen areas. The main kitchen areas probably occur in the Gertrud Graben, including the area around the Hejre discovery, and in the Feda Graben from the area around Ophelia-1 and

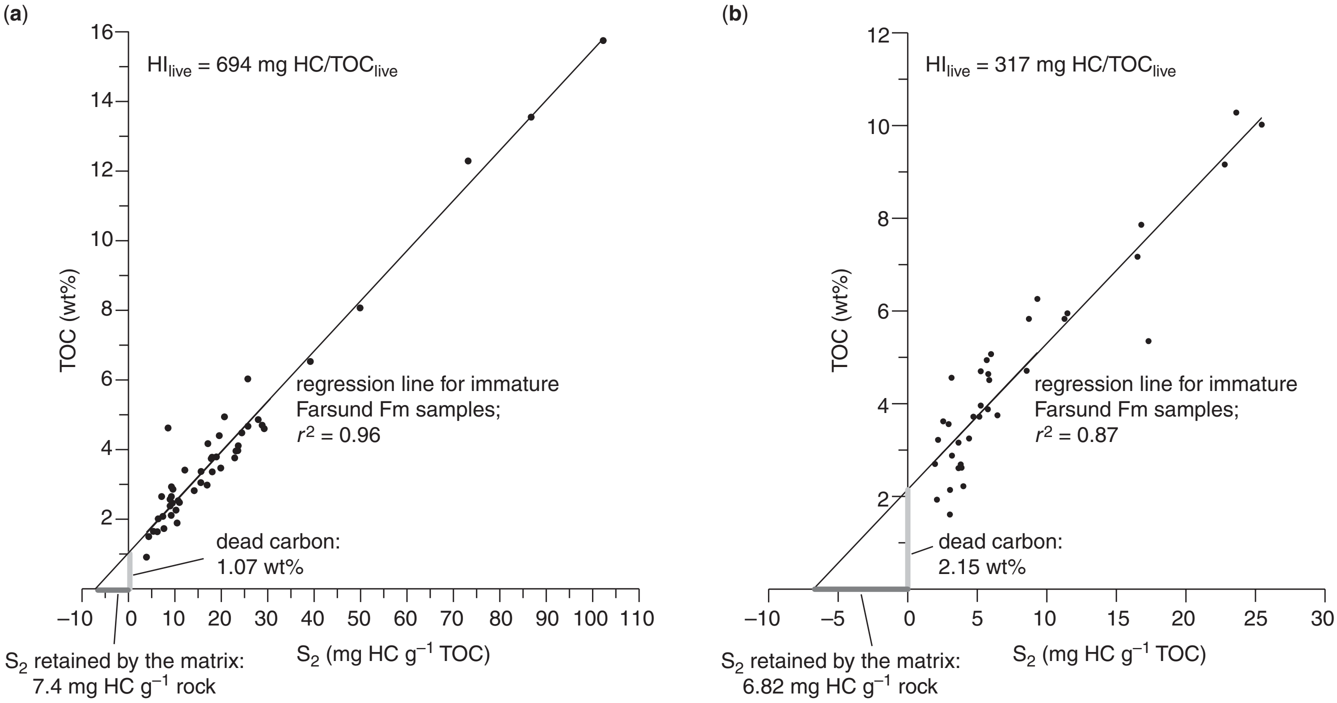

Fig. 12. Estimation of the average proportion of dead carbon and average HI_{live} for the Farsund Formation in the (**a**) Diamant-1 well and (**b**) Gert-1 well.

northwards, continuing into the Norwegian sector (Fig. 14). A small kitchen may be present in the deep close to the Liva-1 well in the Outer Rough Basin, which may source the hydrocarbons encountered in Cretaceous chalk of the Olaf-1 well, located up-dip from the kitchen.

The vast majority of hydrocarbons encountered have geochemical characteristics that are typical for oils sourced from the Upper Jurassic–lowermost Cretaceous marine shales. The distribution of C_{27}–C_{30} steranes was analysed by principal component analysis (Fig. 15). Most extracts from the Farsund Formation shales in the Rita-1 and Tordenskjold-1 wells, and tested crude oils (Lone-1, Mona-1, Olaf-1, Rita-1 and Gert-1 wells), plot on a diagonal line, mainly reflecting a similar source but increasing maturity (from the upper left corner towards lower right corner; Fig. 15). The extracts from the Farsund Formation in Wessel-1 well are atypical, and the biomarker composition does not resemble that of the oil shows in this well. Despite excellent source potentials recorded in the Farsund Formation in the Wessel-1 and Tordenskjold-1 wells, thermal immaturity of the shales indicates that generation from Farsund Formation is highly unlikely in the shallow parts of the Outer Rough Basin. This suggests that the Outer Rough Basin is dependent on migration from outside the area, or on deeper buried Palaeozoic source rocks. Oil show samples from the Saxo-1 well resemble the extracts from the Zechstein section in the Wessel-1 well (Fig. 15), and the geochemical signature indicates that they were sourced from carbonate/marly source rocks, suggesting the presence of mature Zechstein source rocks in Outer Rough Basin.

Conclusions

The Upper Jurassic–lowermost Cretaceous marine shales of the Farsund Formation are present regionally in the northwestern part of the DCG. In the Outer Rough Basin the formation is relatively thin, and on the Inge High it is thin or absent. The generally organic-rich Bo Member ('Hot Unit') in the upper part of the Farsund Formation is present in the Piggvar Terrace, the Gertrud

Ho/St: Sum C_{27-35} hopanes (19)/Sum C_{27-30} diasteranes + C_{27-30} reg. steranes (32).

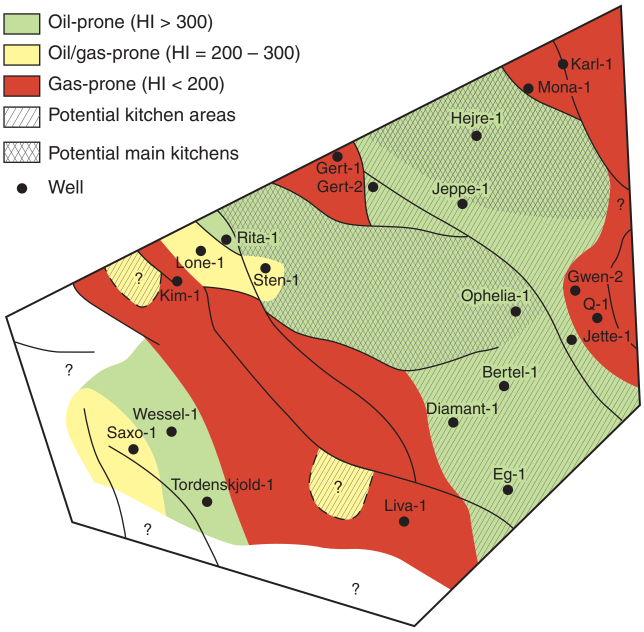

Fig. 14. Potential kitchen areas in the northwestern part of the DCG based on the presence of rich and thermally mature shales of the Bo Member and/or the Farsund Formation. Main kitchens are defined where the shales are rich, thick and mature, which is restricted to the depocentres of the Gertrud and Feda Grabens.

and Feda Grabens and the Ål Basin, but is thin to absent on the Gert Ridge and absent on the Inge High and in the Outer Rough Basin.

The kerogen composition varies from Type II to Type III. The kerogen is principally algal-derived material consisting of fluorescing AOM and alginite with *Leiosphaerida* and *Tasmanites* morphology. Organic richness (TOC) and HI show lateral and stratigraphical variations, with a significant improvement in the Bo Member. The variations indicate shifts in kerogen quality from non-generative through gas-prone to highly oil-prone. The source quality can be classified as fair to excellent, and in most wells the shales of the Bo Member are oil-prone with average HI values ranging from 316 to 453 mg HC g^{-1} TOC. The presence of oil-prone kerogen delineated by HI alone may be masked by kerogen of poorer quality. Hence, areas considered to be gas-prone based on average HI values may be more prolific than initially interpreted. The start of the oil window occurs at *c.* 3800–4000 m depth and the oil window spans 800–1000 m. The decrease in HI and associated increase in PI at depth greater than *c.* 3800–4000 m in all wells is caused by increasing maturity as the shales pass through the oil window. An overall deterioration of kerogen quality with depth in the Farsund Formation probably contributes to the decreasing HI. Potential main kitchen areas with rich, mature and thick source rock units occur in the Gertrud Graben and the Feda Graben.

Oils analysed were generated from the highly oil-prone shales mainly present in the upper part of the Farsund Formation, including the Bo Member, and from the more mature and slightly poorer

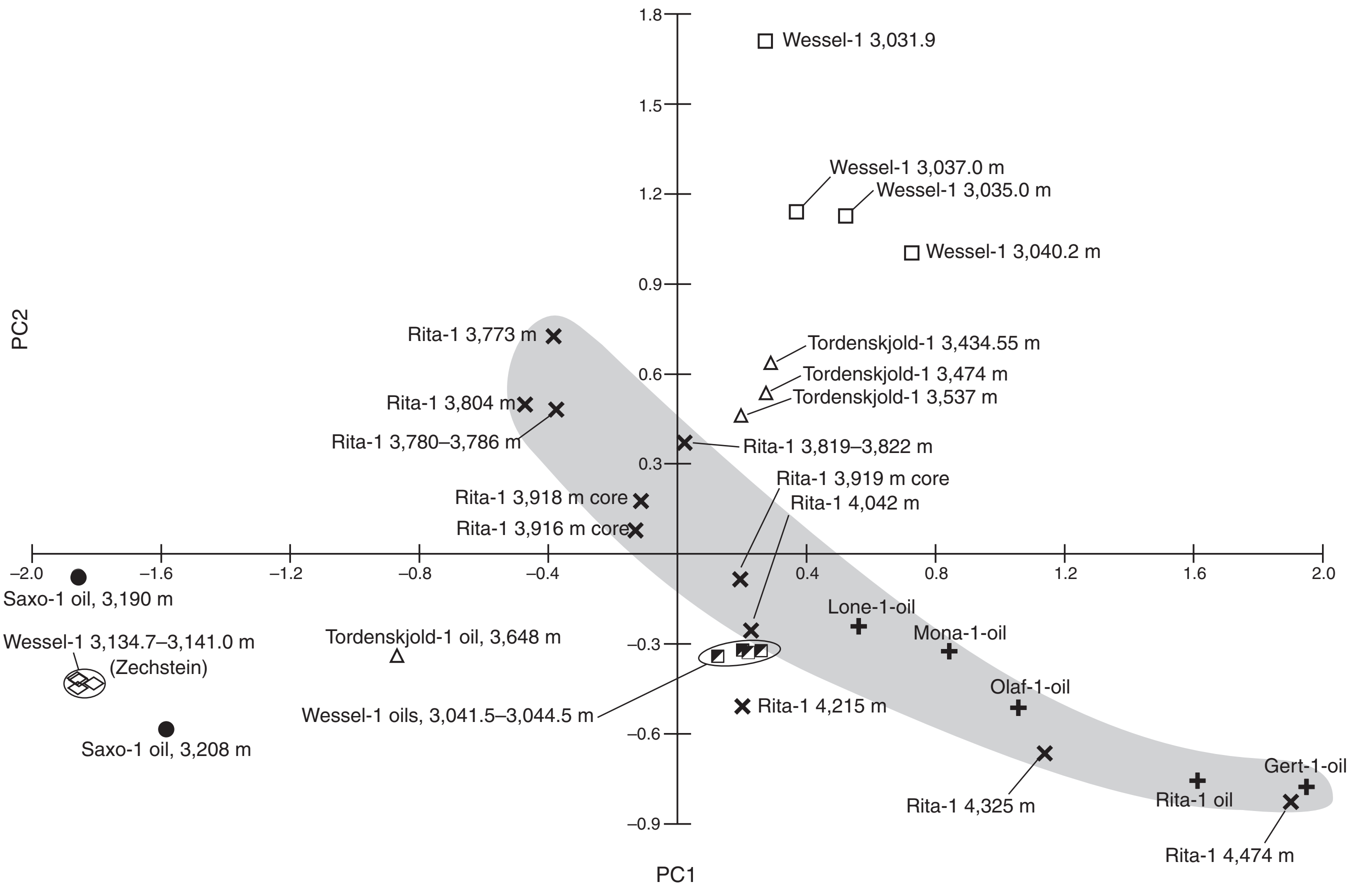

Fig. 15. Principal component analysis of C_{27}–C_{30} steranes in oils and source rocks in the northwestern part of the DCG (see also Table 3). Shaded area shows trend of extracts from the Farsund Formation in the Rita-1 well.

quality lower part of the Farsund Formation. A probable Zechstein-sourced oil-show on the flanks of the Mid North Sea High indicates the presence of mature Palaeozoic source rocks in the Outer Rough Basin.

J. Halskov and S. Sølberg (GEUS) are thanked for drafting the figures. The paper benefited from constructive reviews by J. Miles and A. Law.

From thrust-and-fold belt to foreland: hydrocarbon occurrences in Italy

F. BERTELLO, R. FANTONI, R. FRANCIOSI, V. GATTI, M. GHIELMI and A. PUGLIESE

Eni Exploration & Production Division, via Emilia, 1-20097 San Donato Milanese, Italy (e-mail: francesco.bertello@eni.it)

Abstract: Italy is the most hydrocarbon endowed country of southern Europe, with total discovered reserves (produced + remaining) of 1840 million barrels of oil and 30 trillion ft^3 of gas. The production of oil amounts to 43.2 million barrels per year, about 75% of which comes from the Val d'Agri Field in the southern Apennines. The production of gas is 340 billion ft^3 per year, most of it coming from the northern Adriatic Sea. Hydrocarbon occurrences derive from a variety of petroleum systems which are the result of a complex geological history. At least five important source rocks have been recognized which are distributed in age from Mesozoic through Pleistocene. Three of them were deposited during Mesozoic crustal extension and are mainly oil-prone. Hydrocarbon occurrences associated with these sources are usually found in complex carbonate structures along the Apennines thrust-and-fold belt and in the foreland. Villafortuna–Trecate (Po Plain), Val d'Agri/Tempa Rossa (southern Apennines) and Gela (Sicily) fields represent the largest oil accumulations pertaining to these systems. Two other important sources rocks were deposited in the foredeep terrigenous units of the foreland basins which formed during the Cenozoic orogenesis. The older source is thermogenic gas-prone and is found in the highly tectonized Oligo-Miocene foredeep wedges: gas occurrences associated with this source are mainly concentrated along the northern Apennines margin (e.g. Cortemaggiore Field), in Calabria (e.g. Luna Field) and Sicily (e.g. Gagliano Field). The younger source is biogenic gas-prone and is situated in the outer Plio-Pleistocene foredeeps. The most important gas fields of Italy, located in the eastern Po Plain and northern Adriatic sea (Barbara and other gas fields), have originated from this source. Hydrocarbon exploration in Italy is overall mature, especially for gas, whose residual potential is estimated to be 6.0 trillion ft^3 of reserves. The remaining potential of oil is estimated to be 800 million barrels.

Keywords: Alps, Apennines, Cenozoic compression, foreland, hydrocarbon occurrences, Italy, Mesozoic extension, gas fields, oil fields, thrust-and-fold belt

Geological framework

The Italian landscape is largely dominated by the Southern Alps and Apennines mountain chains. The Alps bound Italy on the north, whilst the Apennines traverse the entire peninsula and form the backbone of the country. These mountains constitute two thrust-and-fold belts which arose during Cenozoic times as a result of the interaction between the European and the Adriatic–African tectonic plates.

The Southern Alps have a southward vergence and constitute the antithetic retrobelt of the Alpine orogen which started to develop from Cretaceous times and went through the main collisional phase from Eocene to Pliocene times. The Apennines have an orogenic polarity towards the East and developed mostly after the Oligocene (Carminati *et al.* 2004). The two chains are bordered in their outer margins by foreland basins (with foredeep and piggyback basins), which are well developed, especially along the Adriatic sectors, and by relatively wide foreland areas (i.e. Po Plain, Adriatic Sea and Hyblean Basin). The Po Plain is unusual in that it represents the common foreland of the Southern Alps and the northern Apennines (Fantoni & Franciosi 2008). The Tyrrhenian Sea and the western sectors of the Apennines are considered a back-arc basin system developed in response to the counterclockwise rotation of the Apennines (Carminati *et al.* 2004).

The formation of the two orogens was preceded by a lengthy crustal stretching and extension episode which lasted for most of the Mesozoic and was generally characterized by carbonate type sedimentation (e.g. Bertotti *et al.* 1993 and references therein, for the Southern Alps). Most of the carbonate structures were later rejuvenated and involved in the Cenozoic orogenesis.

In this geological framework several petroleum systems have developed, some of which are of paramount economic importance and make Italy the most endowed hydrocarbon province in southern Europe.

The simplified geological map of the country and the schematic cross-section in Figure 1 illustrate the general location of oil and gas accumulations in Italy. Hydrocarbons are found in the thrust belt, along the foreland basins and in the foreland. In particular, oil and associated natural gas are present in the stratigraphically deeper – mainly Mesozoic – successions of the foreland regions and in the outermost sectors of the Southern Alps and Apennines belts, while thermogenic gas is found in the Oligo-Miocene tectonized sediments of the Apennines. Biogenic gas is abundant in the Plio-Pleistocene successions of the foreland basins (mostly in the foredeeps). No hydrocarbons have been discovered to date in the back-arc tectonic zone.

Historical perspective

Entrepreneurial exploration for hydrocarbons in Italy is thought to have started in 1860 when in Ozzano, near the city of Parma, the Achille Donzelli company drilled two wells to depths of 32 and 45 m, obtaining 25 kg of oil per day (Magini 1937; Eni S.p.A. 2009). In the following decades until the close of the century, several shallow wells were drilled by small enterprises along the southern margin of the Po Plain and in central Italy (around the cities of Pescara and Frosinone), leading to small volumes of oil production, which were used mainly for public lighting purposes. During the first three decades of the 1900s other small discoveries were made in the same areas and in Sicily. Gas also started to be used for domestic purposes or to fuel lights.

In 1926 AGIP (Azienda Generale Italiana Petroli) was founded by the government as an attempt to break the market for petroleum

VINING, B. A. & PICKERING, S. C. (eds) *Petroleum Geology: From Mature Basins to New Frontiers – Proceedings of the 7th Petroleum Geology Conference*, 113–126. DOI: 10.1144/0070113

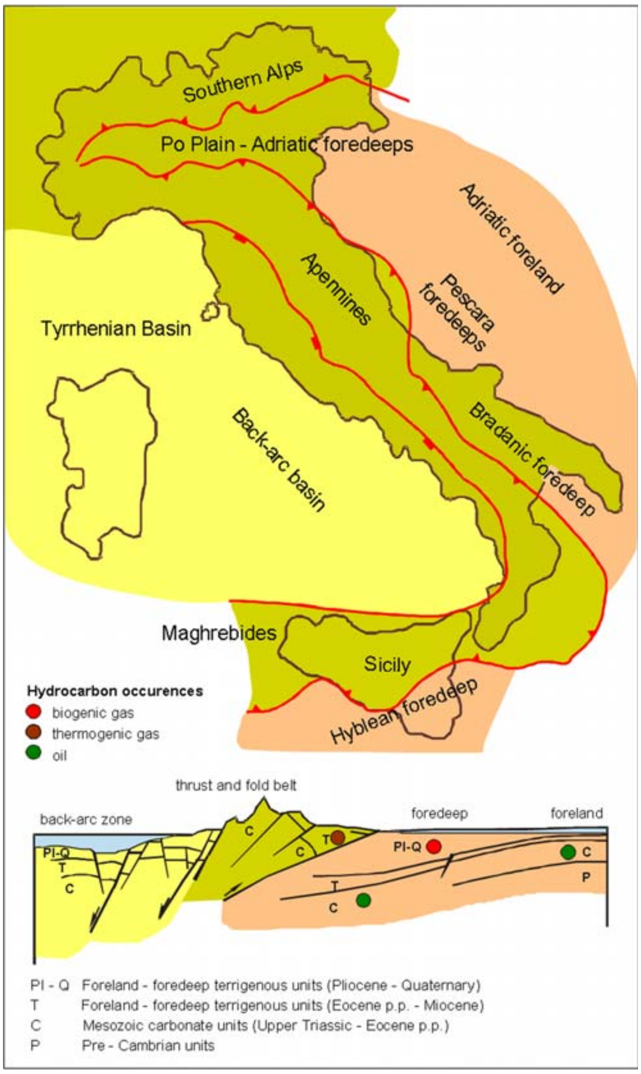

Fig. 1. Geological framework and hydrocarbon occurrences.

products which, in Italy, had fallen under the control of branches of multinational oil companies. AGIP, later incorporated in Eni (Ente Nazionale Idrocarburi), was soon to become the principal player in the oil and gas business of the country.

The search for hydrocarbons rose to an industrial level of activity during the 1940s. The exploration moved from the hills of the northern Apennines to the Po Plain: Caviaga was here discovered in 1944 and turned out to be the largest gas field in western Europe of that time. Gas was to become the backbone of the Italian energy policy. During those years the first natural gas pipeline network was also built to convey gas from the fields of the Po Plain to the cities of Lodi and Milan. In the following decades successful exploration campaigns were also carried out all along the peri-Adriatic foredeeps, in Calabria and Sicily, both onshore and offshore. Besides Eni, other major companies, such as Edison, Enterprise, Elf, Esso, Fina, Gulf, Shell and Total, greatly contributed to these successes. Subsequently, the national gas pipeline network was much increased (up to 30 000 km) and, because of the growing demand, import lines from outside the country were also laid. In the early 1970s international pipelines from the Netherlands and the Soviet Union were opened, and in 1983 the 2500 km-long Transmediterranean pipeline, transporting gas from the Hassi-R-Mel Field in Algeria to the Po Plain, was inaugurated. More recently, in 2004, the Green Stream, a gas pipeline connecting Libya to Sicily, was opened.

During the almost 150 years of exploration and production activity in Italy, the following records were attained:

- 1944 – Caviaga, the largest gas field in the western Europe at the time, is discovered.
- 1959 – Agip's 'Gela Mare 21', the first offshore well in Europe, is drilled offshore Sicily.
- 1976 – the first remote-controlled platform in Italy for crude oil production is put in place at Perla 1, offshore Sicily.
- 1977 – Agip drills to a record depth of 5500 m in the Malossa Field (near Milan) and discovers a new oil pool.
- 1984 – Villafortuna, the largest onshore oil field in Europe, is discovered in northern Italy at a new record depth of 6000 m. Its size will be superseded by the giant Monte Alpi Field (Val d'Agri), discovered in 1988.
- 1990s – Aquila oil field (Otranto Channel) is put into production. The field is in 800 m of water, the deepest in Europe.

Today, the Italian petroleum acreage comprises 86 exploration permits and 195 development leases covering more than 53 000 km^2. The licences are distributed mainly in the Po Plain, in the peri-Adriatic foredeeps, in the southern Apennines and in Sicily (Fig. 2). More than 250 000 km of 2D seismic lines and 35 000 km^2. of 3D seismic surveys have been acquired, and more than 7000 wells have been drilled for hydrocarbon exploration and production (Fig. 3).

In terms of petroleum endowment, Italy is the fourth richest country of western Europe, after Norway, the UK and the Netherlands. According to the Italian Ministry of Economic Development (UNMIG 2009) and the Italian Association of Oil Companies (Unione Petrolifera Italiana 2009), 140 million tonnes (1040 MMbbl) of oil and 700 billion m^3 (24.7 Tcf) of gas have been produced so far in the country. The production of oil is

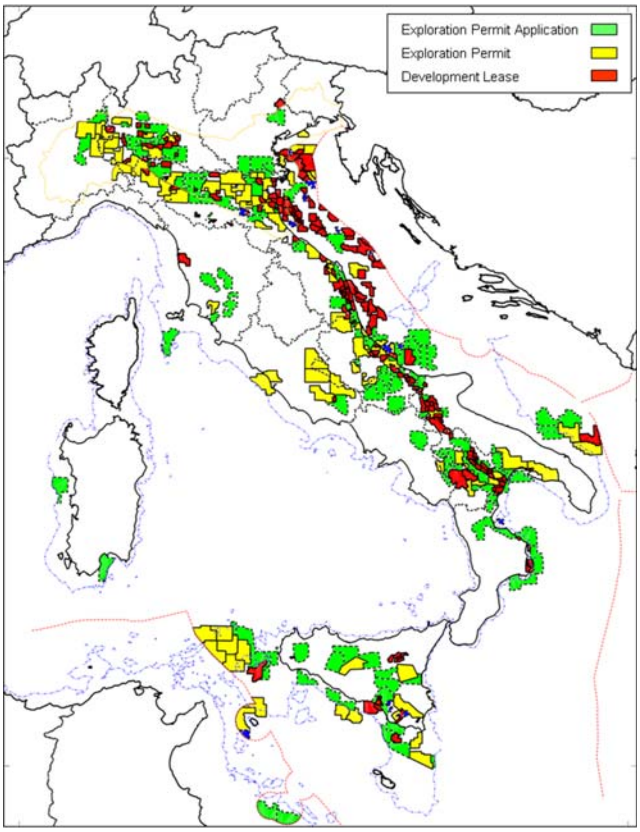

Fig. 2. Petroleum acreage.

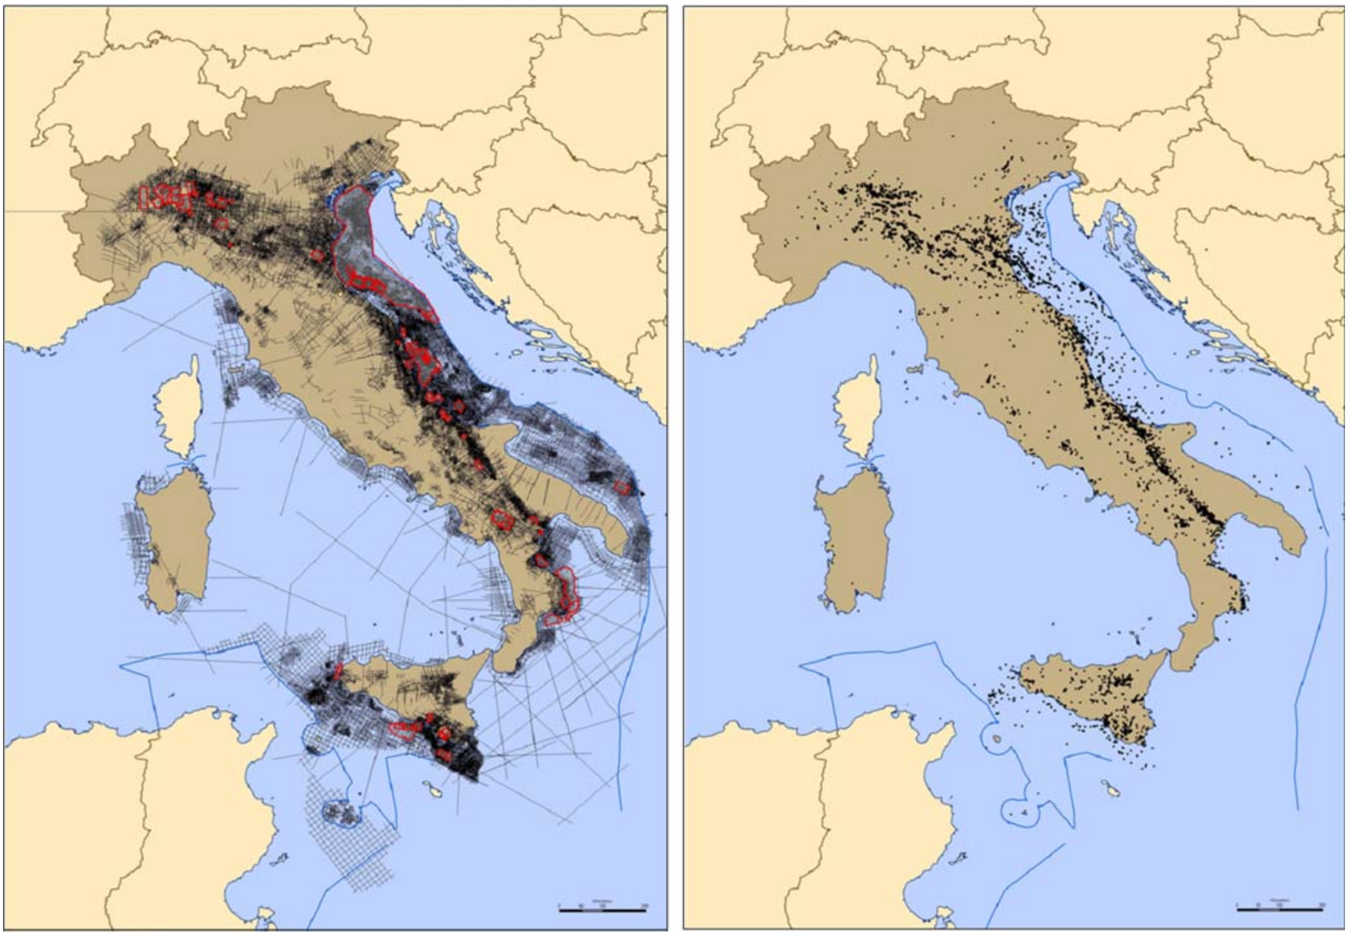

Fig. 3. Two-/three-dimensional (red areas) seismic surveys (left) and wells (right).

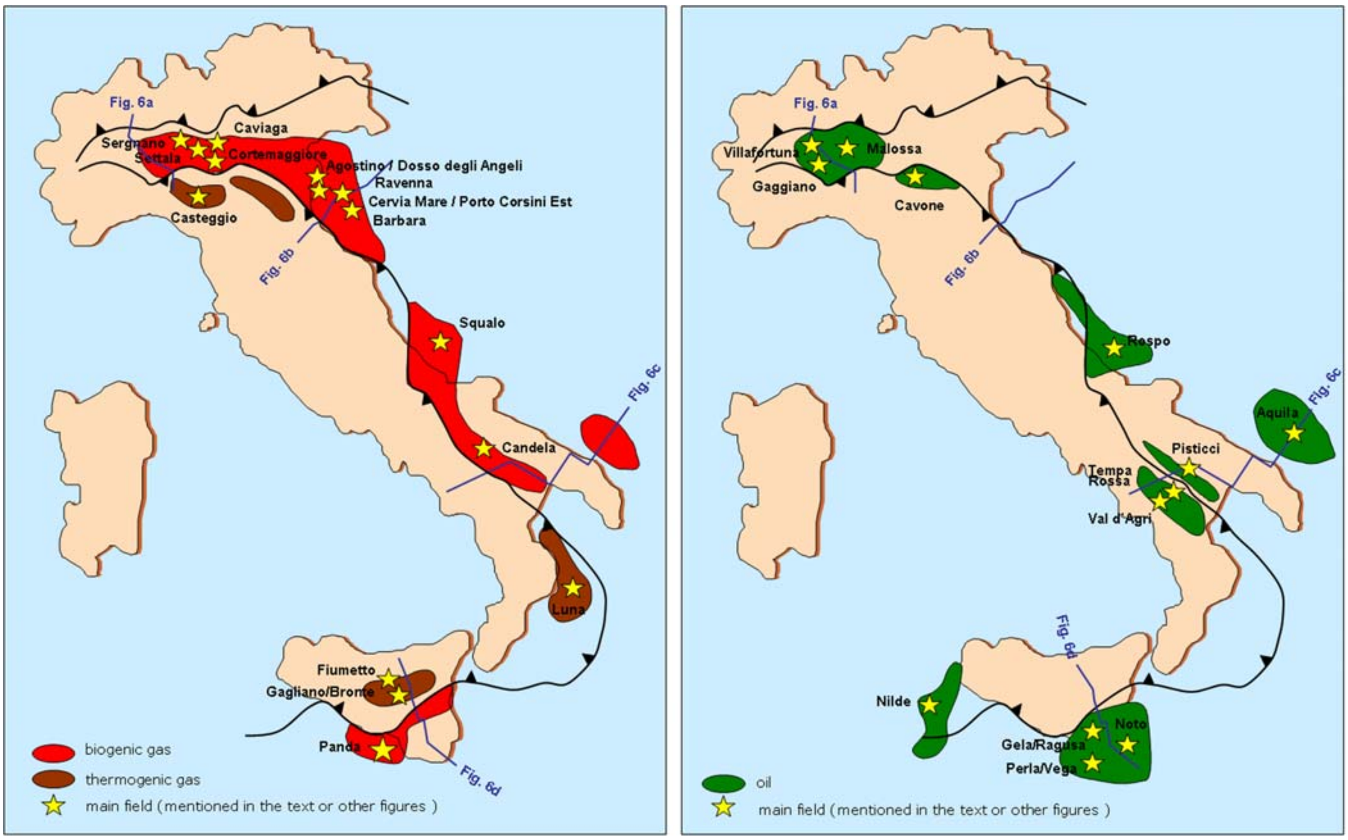

Fig. 4. Gas provinces (left) and oil provinces (right). Location of the geological sections of Figure 6.

5.8 MMtonne per year (43.2 MMbbl/year) (2007), about 75% of which comes from the Val d'Agri Field. The production is expected to increase slightly in the next few years due to new development wells of Val d'Agri coming on stream and the start of production in the nearby Tempa Rossa Field.

The production of gas in 2007 was 9.7 billion m^3 per year (340 Bcf/year), continuing the declining trend from the peak of 20.6 Bcm (730 Bcf/year) attained in 1994. Today's production comes from more than 100 fields, the largest ones being located in the Adriatic Sea.

Overall, Italian hydrocarbon production accounts for less than 10% of the energy demand, and the country therefore has to rely on large oil and gas imports. At the end of 2006 remaining hydrocarbon reserves (proven + 50% of the probable + 20% of the possible reserves) amounted to 110 MMtonne (800 Mbbl) of oil and 150 Bcm (5.3 Tcf) of gas, with an expected residual life of 20 and 14 years respectively. According to UNMIG (2009), the yet-to-be-discovered reserves are estimated to be 110 MMtonne (800 MMbbl) of oil and 170 Bcm (6.0 Tcf) of gas.

Hydrocarbon occurrences

The hydrocarbon occurrences of Italy tend to concentrate in oil and gas provinces as illustrated in Figure 4, where the names of the major fields are also indicated. Oil is found principally in the western Po Plain, in the southern Apennines and in Sicily, while gas accumulations are mainly concentrated in the Po Plain and northern Adriatic Sea (Anelli *et al.* 1996; Casero 2004). Three groups of hydrocarbon occurrences have been identified (Bertello *et al.* 2008*a*, *b*):

- oil and thermogenic gas in the carbonate Mesozoic substratum;
- thermogenic gas in the thrusted terrigenous Oligo-Miocene foredeep sedimentary wedges; and
- biogenic gas in the terrigenous Plio-Pleistocene foredeep wedges.

At the origin of these different hydrocarbon types is a variety of petroleum systems (Fig. 5). The Mesozoic carbonate units mostly contain oil and thermogenic gas in different geological scenarios due also to the fact that, as will be illustrated later, three main Mesozoic source rocks exist and were effective in generating hydrocarbons. The Oligo-Miocene tectonized terrigenous foredeeps host only thermogenic gas with subordinated quantities of condensate, derived from widespread but poorly effective type III source rocks. The terrigenous units of the Plio-Pleistocene foredeeps accommodate large quantities of biogenic gas which are at the origin of the largest and most productive fields, notably in the eastern Po Plain and northern Adriatic sea.

The stratigraphic position and structural domain of the Italian hydrocarbon occurrences is also illustrated in the geological sections of Figure 6, where the locations of some important fields are indicated as well.

Oil and thermogenic gas in the Mesozoic carbonate substratum

In the Mesozoic carbonate successions three different petroleum systems are present, of Middle Triassic, Late Triassic/Early Jurassic and Cretaceous age (Zappaterra 1994; Fantoni *et al.* 2008).

Middle Triassic petroleum system (Villafortuna–Trecate Field). The Middle Triassic petroleum system is linked to the earliest stage of the Tethyan fragmentation. Because of its depth it can

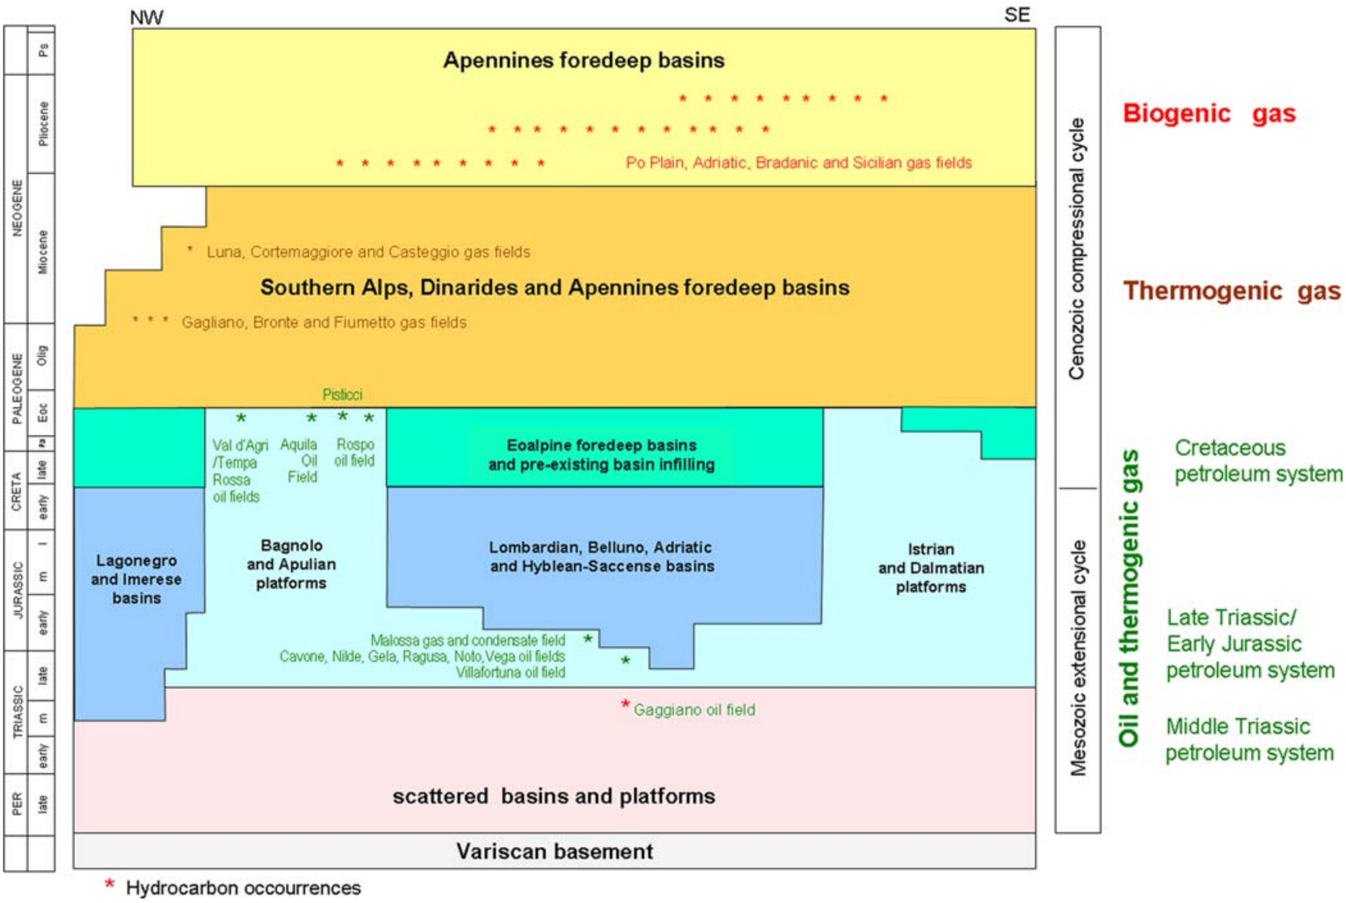

Fig. 5. Tectono-stratigraphic cycles and hydrocarbon occurrences.

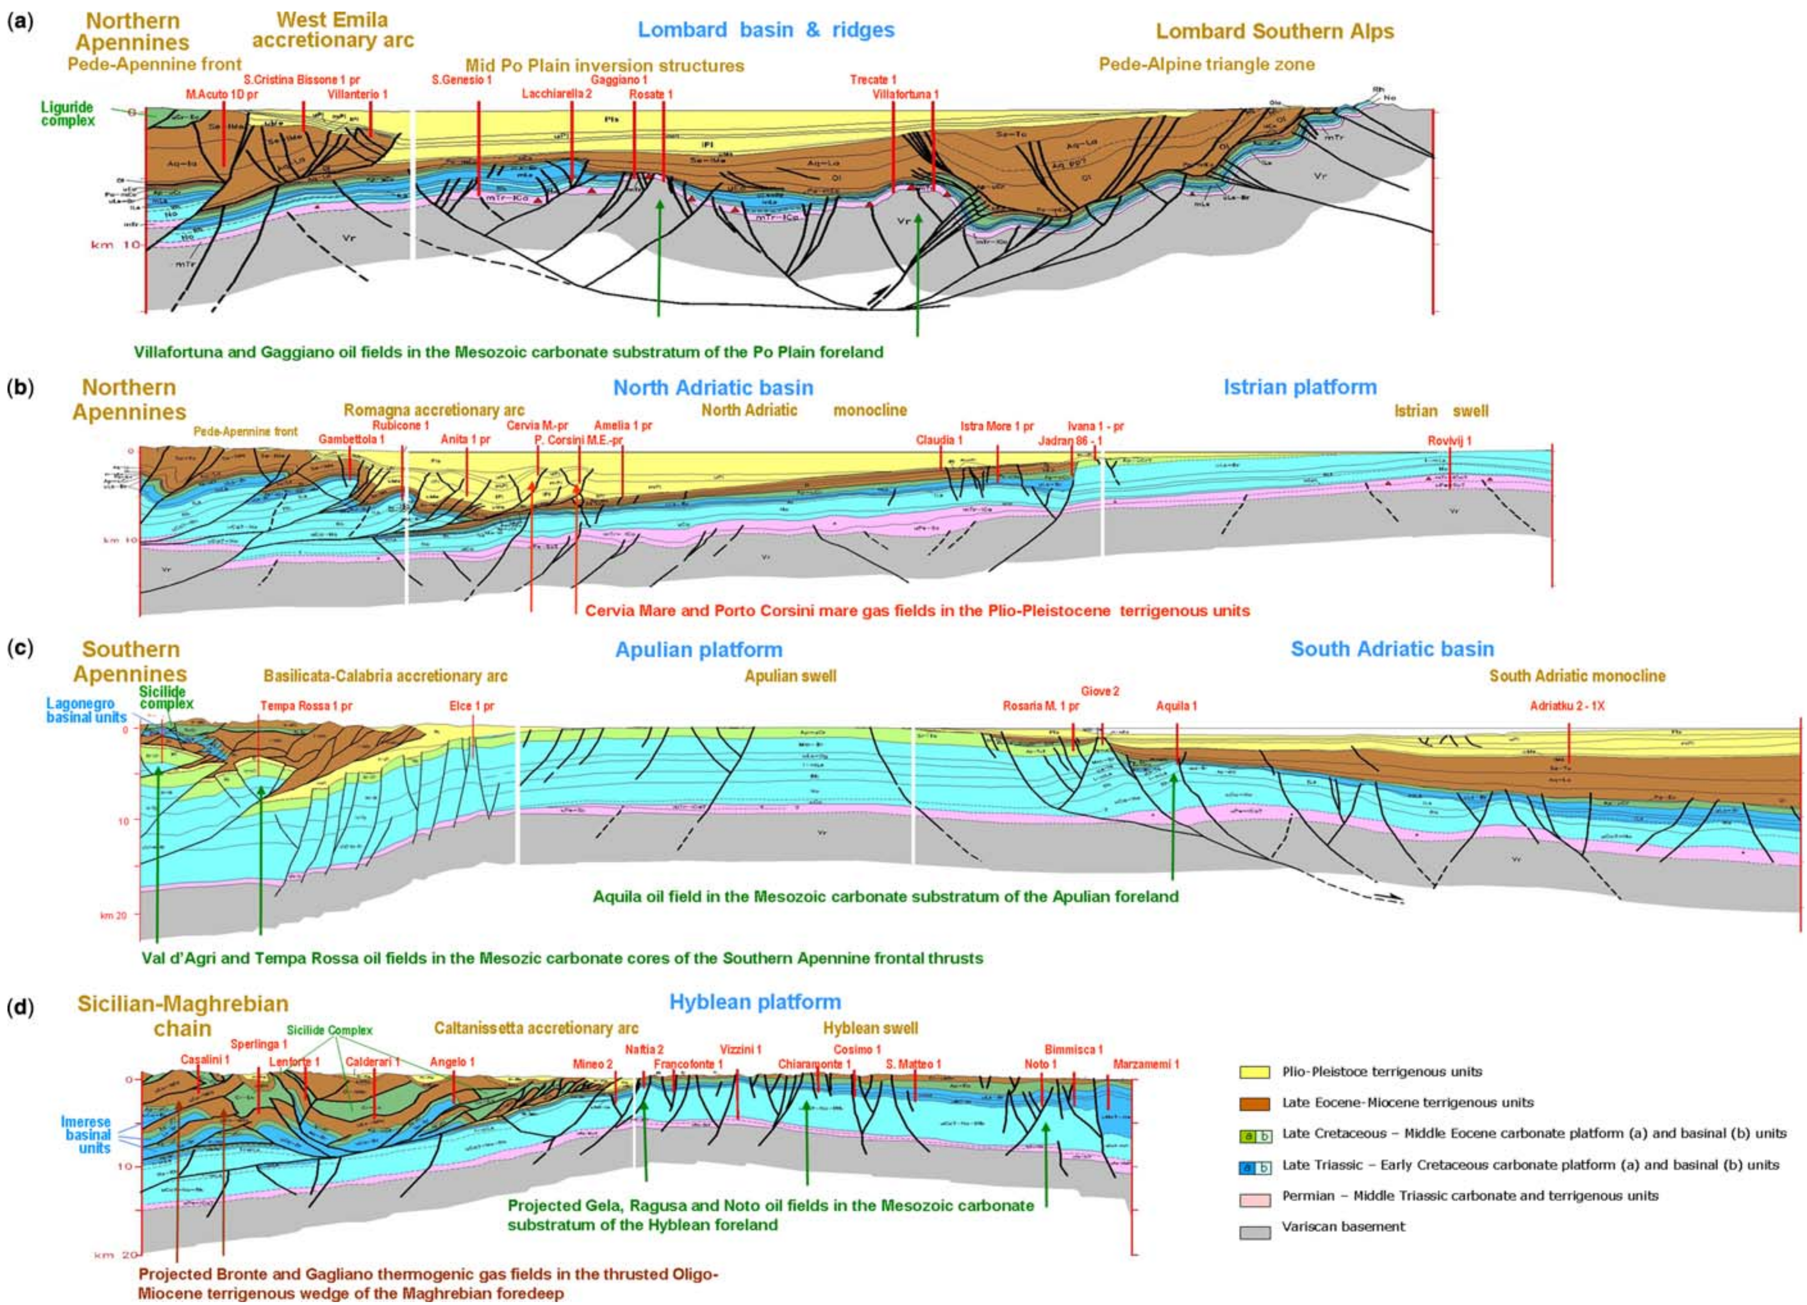

Fig. 6. Geological sections and major hydrocarbon occurrences (vertical exaggeration 2:1). Location in Figure 4.

be pursued only in the outer sector of the foredeeps and in foreland regions, whereas along the thrust belt it is generally too deep and overcooked. It involves dolomitized platform units of Late Triassic–Early Jurassic which were charged by Middle Triassic carbonate source rocks deposited in the confined basins created by the rifting. Traps are mostly provided by Mesozoic structures locally inverted by the Cenozoic compression (Fig. 6a).

The Villafortuna Field, discovered in 1984 in northern Italy, and its Trecate extension constitute the largest oil accumulation pertaining to this play (Fantoni *et al.* 2001; Bello & Fantoni 2001; Fig. 7). The trap consists of a buried alpine fold involving a pre-existing Mesozoic extensional relief. The structural high of the Mesozoic carbonate succession has a vertical relief of about 3000 m relative to the adjacent northern zone, and is bordered by an alpine southerly dipping backthrust forming a triangle zone. Mesozoic extensional features are also present which consist of blocks of a smaller hierarchical order, rotated and bordered by NNW trending faults.

The petroleum system is wholly developed inside the Triassic succession, and consists of two main reservoirs, made from dolomitized carbonate platform rocks, and a set of source rocks deposited in the adjacent anoxic intra-platform basins. All these rocks have important outcrop analogues in the western sector of the Southern Alps which have allowed a detailed study of their characteristics. The lower reservoir is represented by the Anisian (Middle Triassic) Monte San Giorgio Dolomite, which was deposited in a peritidal to subtidal environment and is today entirely dolomitized. The porous system is represented by a few small vugs, moulds and rarely by intercrystalline porosity. The porosity and permeability values are generally low, the reservoir producing from a fracture network that provides a certain degree of permeability and improved porosity. Fractures are locally enlarged by dissolution. The overlying shaly and tuffaceous Besano Shales (Anisian/Ladinian, Middle Triassic) provide the seal and are at the same time a source rock. The upper reservoir consists of three carbonate platform units of Norian (Late Triassic) to Hettangian (Early Jurassic) age: the Dolomia Principale, the Campo dei Fiori Limestone and the Conchodon Dolomite. They are characterized by different petrophysical properties due to their different original textures and subsequent diagenesis. The Dolomia Principale and Campo dei Fiori Limestone formations exhibit similar petrophysical properties, with low porosity and permeability values, locally increased by the presence of a network of fractures. A red palaeosoil, originating from a temporary subaerial exposure, separates the Campo dei Fiori Dolomite from the Conchodon Dolomite. The latter formation shows great variations in the porous system, as a result of an intense diagenesis, including deep burial dolomitization and various steps of recrystallization and dissolution. The petrophysical characteristics of the Conchodon Dolomite make it the most productive reservoir interval of this play. The overlying shaly limestone of the Medolo Group (Lower Liassic) constitutes the regional seal for these three reservoirs.

The hydrocarbons were generated from Middle Triassic source rock formations, namely the previously mentioned Besano Shales (Anisian/Ladinian) and the Meride Limestone (Ladinian). In the Villafortuna–Trecate area the maturity of the kerogen in these rocks is high and only the residual naphthogenic properties can be measured; therefore the original properties have been estimated by considering the geochemical data of immature outcrop samples. The two source rocks are characterized by type II kerogen content. The Besano Shales comprise dark laminated dolostones and black shales with very high TOC. The Meride Limestone has lower TOC values, but the formation has a very significant thickness (up to 500 m). The main hydrocarbon expulsion phase in the drainage area of Villafortuna–Trecate occurred very recently, during the Plio-Pleistocene strong burial (Fantoni & Scotti 2009), and after the last structuring age (Oligocene to Messinian) (Fantoni *et al.* 2004 and references therein).

Late Triassic–Early Jurassic petroleum system (Gela Field). The Late Triassic–Early Jurassic petroleum system is linked to the main phase of the Tethyan rifting and is the most explored of the three systems, both in the foreland and in the thrust belt, and from Lombardy to Sicily. The source rocks are terrigenous or mixed carbonate/terrigenous, and were deposited during the anoxic stage that preceded the extension of the Jurassic basins. Because of the discontinuity of the regional and local seals, the reservoirs are located in a wide chronostratigraphic range, from the coeval platform units up to the topmost carbonate units, and even in the overlying terrigenous sequences (Nilde Field, Miocene, Sicily). The related hydrocarbon accumulations mainly occur in the reactivated structures of the foreland margin: Malossa and other Po Plain gas and condensate fields (Mattavelli & Margarucci 1992); northern Appennines (Cavone Field); all Apulian (Pisticci) and mid and south Adriatic oil fields (e.g. Aquila Field: Fig. 6c); Gela and all the other Sicilian oil fields (Fig. 6d).

The Gela heavy oil field, discovered in 1956, is a remarkable example of the Late Triassic–Early Jurassic system, its geological framework being illustrated in Figure 8. The field is located in the Ragusa Basin, in the southern part of Sicily, and extends both onshore and offshore. It is the largest oil accumulation of this petroleum system. The trap is a gentle NE–SW trending asymmetric faulted anticline. The structure formed during the Mesozoic as an extensional feature and was subsequently inverted and folded during the Miocene–Pliocene compressive/transpressive phase.

The reservoirs are located in the Upper Triassic to Early Jurassic succession. The main reservoir is the Upper Triassic Sciacca Formation, consisting of dolomitized carbonate platform rocks. This formation is overlain by the Upper Rhaetian Noto Formation, which is made from alternating laminated carbonates and euxinic shales, the carbonate layers having poor to moderate reservoir characteristics. On top of the Noto Formation lies the shale and shaly limestone Hettangian Streppenosa Formation, which constitutes a regional seal and has moderate source rock characteristics as well (Frixa *et al.* 2000).

The origin and distribution of porosity in the Sciacca Formation are controlled by a complex diagenetic history. The original sediment was partly cemented in peritidal environments. This early diagenetic phase produced extensive meteoric dissolution, followed by pervasive cementation. Carbonate cements subsequently filled primary fenestral, sheet-crack and mouldic porosities. Dolomite cements and internal sediments occur in fenestral cavities, reflecting early phases of diagenesis. Coarse dolomite fabrics are very common in the reservoir and could be considered to be the result of a successive diagenetic phase controlled by fractures.

The porosity and permeability values are usually low, but are locally improved by fracture networks that connect vugs and porous layers and support the production of the field.

The heavy oil of the Gela Field was generated by the anoxic marls and marly limestones of the Noto Formation and by the overlying black shales of the Streppenosa Formation (Brosse *et al.* 1988). These source rocks have a type II kerogen and are of predominantly marine origin. The heavy oil gravity (less than 20° API) is thought to be related to the carbonate origin, notably of the Noto Formation, and to the low degree of maturation reached by the sources. The Noto Formation has the highest TOC, while the Streppenosa Formation has somewhat poorer geochemical characteristics which are nevertheless compensated for, in terms of hydrocarbon generation effectiveness, by the greater formation thickness (>3000 m in the depocentre of the Ragusa Basin). The source rock's maturation was probably reached during the

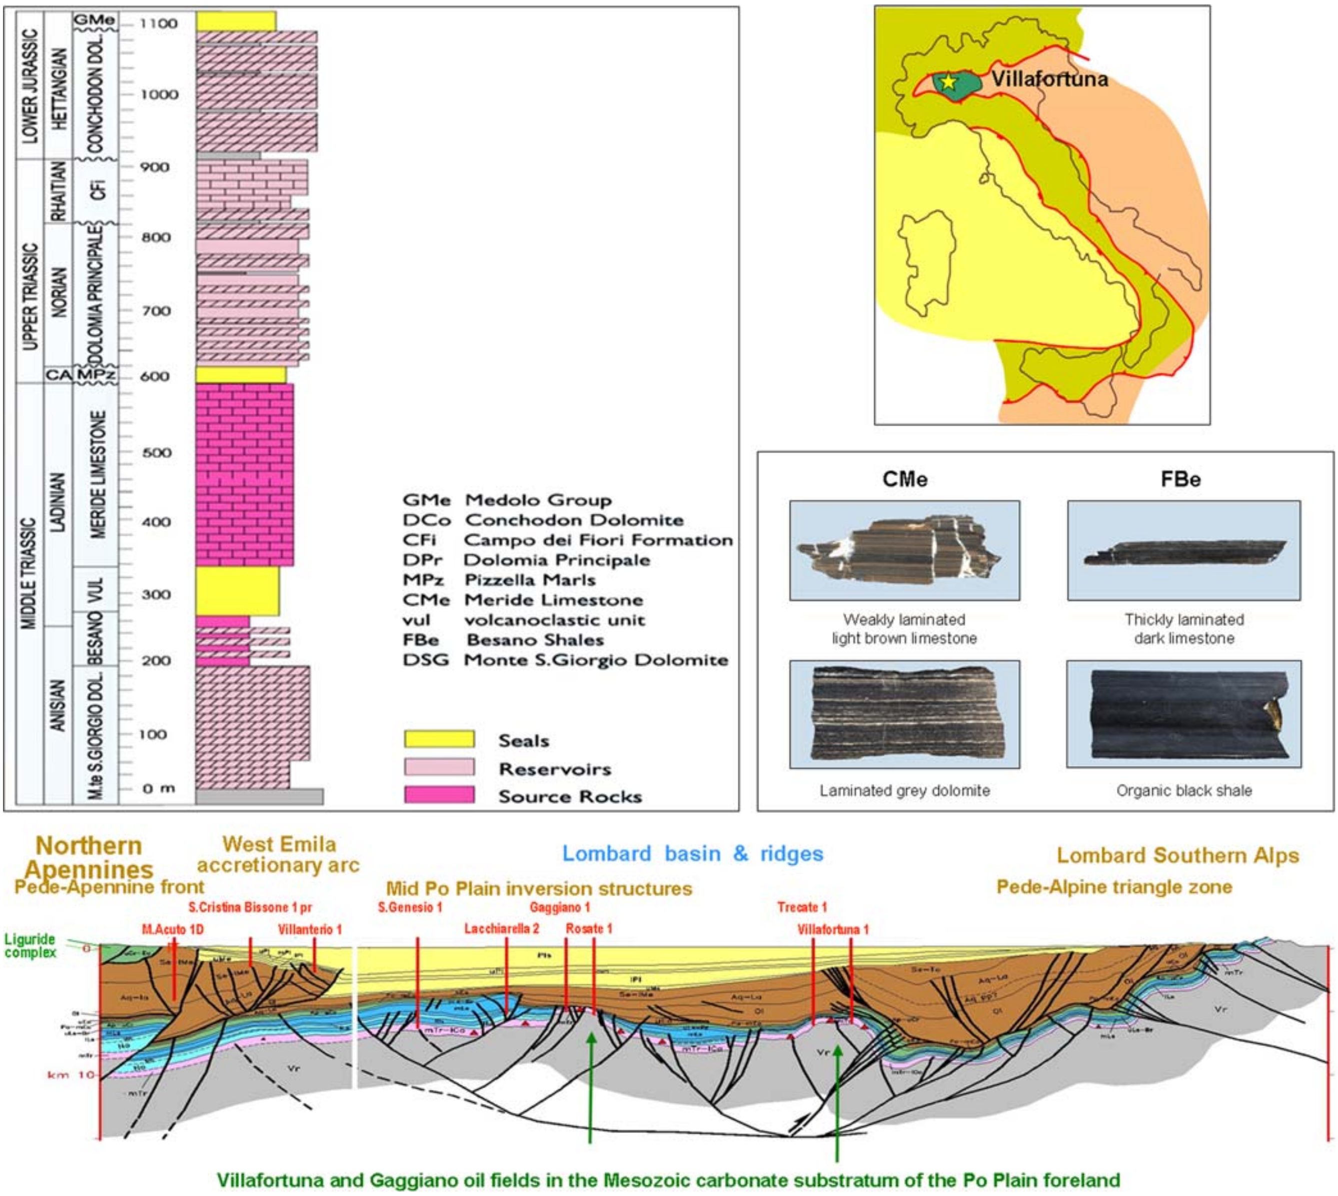

Fig. 7. Villafortuna–Trecate oil field.

Plio-Pleistocene, that is, when the allochtonous Gela Nappe was emplaced in the area.

Cretaceous petroleum system (Val d'Agri Field). This system lies in the Mesozoic carbonate substratum of the foredeep/foreland area and of the external thrust belt of the southern Apennines, and bears the largest oil and gas accumulations of Italy, namely the oil fields of Val d'Agri (composed by the Monte Alpi, Monte Enoc and Cerro Falcone culminations) and Tempa Rossa.

Long-lasting carbonate platforms were deposited, the largest ones being the Apulian (southern Apennines) (Mostardini & Merlini 1986), the Bagnolo (northern Apennines) and the Dalmatian (Croatia, Montenegro and Albania) platforms. Within these platforms, extension created new accommodation space in which thick shallow-water carbonate successions accumulated and a major anoxic event occurred during Albian–Cenomanian times, leading to the formation of the main source rock. During the Miocene and Pliocene, the Apulian Platform, sitting on the Ionian–Adriatic lithosphere, was strongly involved in several thrusts and backthrusts. It was also overlain by earlier allochthonous ENE-ward verging tectonic units (Allochthonous Complex) composed of Mesozoic–Cenozoic mostly deepwater marine sediments deposited along the Adriatic passive margin, and by Lower–Middle Miocene turbidite successions. The accretionary prism was eventually cross-cut by normal faults, formed during the extensional phase, active to the present.

Because of the low permeability of its reservoirs, the Cretaceous play is most successfully explored in the highly fractured frontal structures of the thrust belt (e.g. Val d'Agri and Tempa Rossa oil fields: Fig. 6c). The Val d'Agri giant oil field, discovered in 1988, is the largest oil accumulation of the Cretaceous petroleum system and is briefly described in Figure 9. The reservoir is represented by the Cretaceous to Miocene limestone and dolostone of the Apulian Platform. The sedimentary evolution of this succession is complex and can be summarized, from the bottom to the top, as follows. The Early Cretaceous (Neocomian and Aptian) is characterized by a thick succession of shallow-water dolomitic limestones deposited in a restricted platform environment. The deposition of a less restricted Albian platform facies precedes the formation of intra-platform basins that developed during the Cenomanian within the Apulian Platform as a result of an important phase of extensional/trans-tensional tectonics (Carannante *et al.*

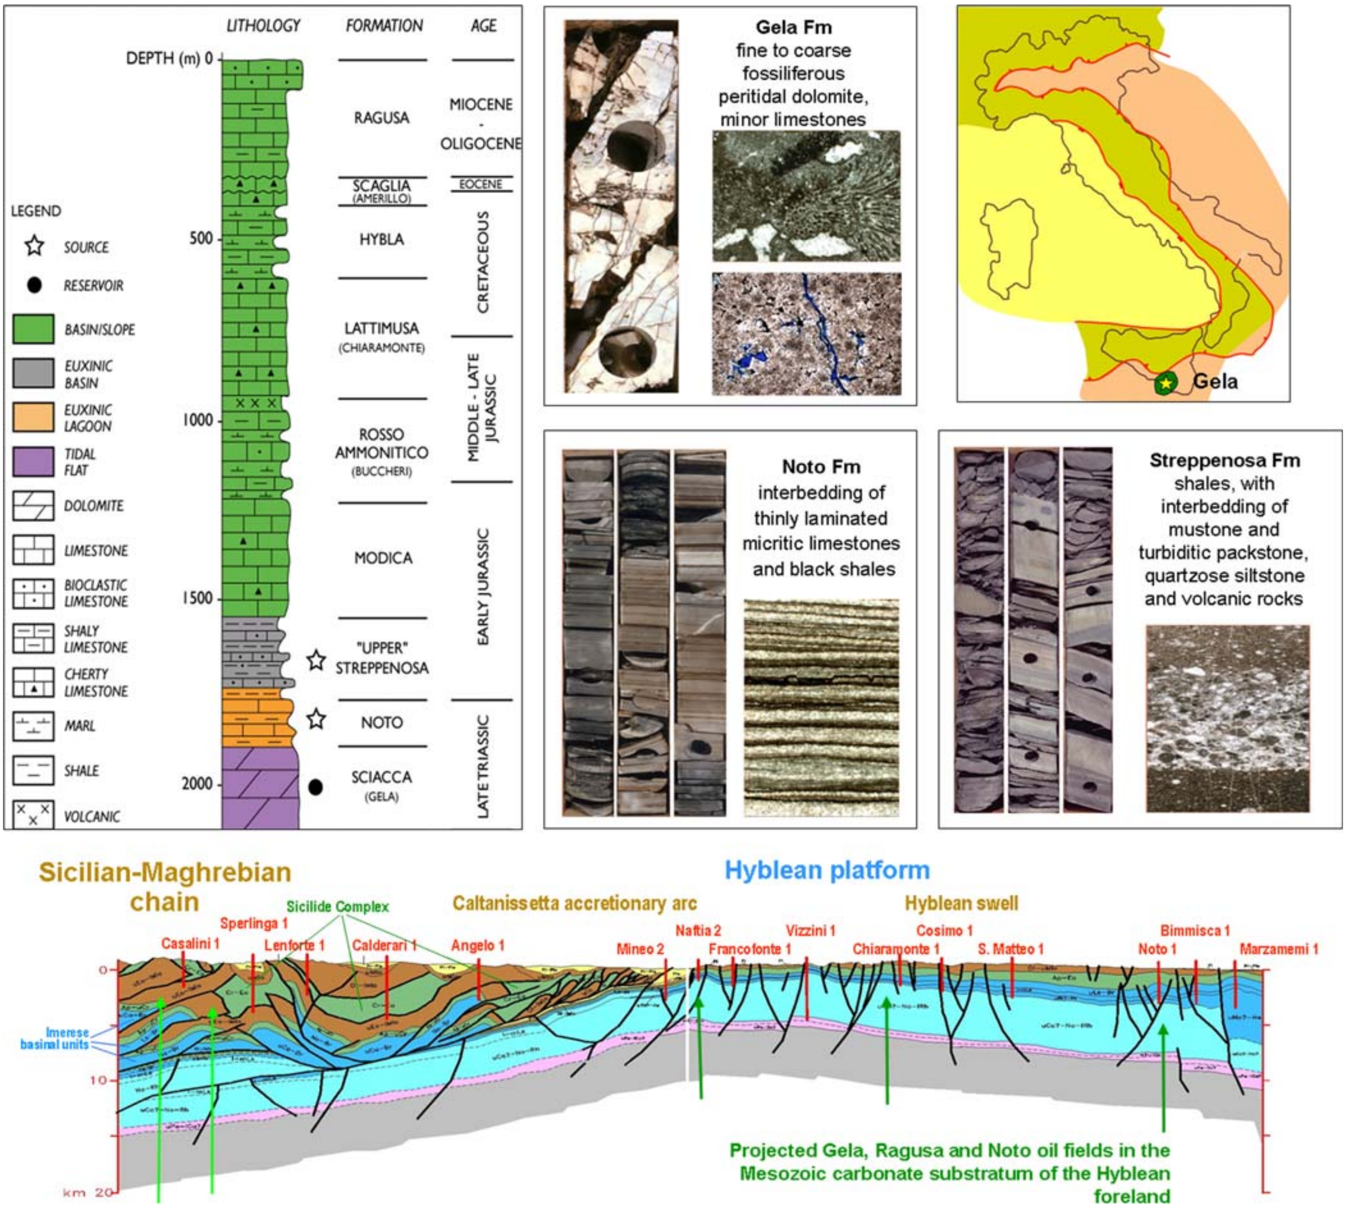

Fig. 8. Gela oil field.

2009). These basins were probably NW–SE oriented and hosted the deposition of organic-rich laminites that constitute the source rock of this petroleum system. The Early Senonian is characterized by a shallow-water limestone succession related to a carbonate ramp pervasively populated by rudists. An outer ramp facies with planktonic organisms rests on top of the rudist limestone and testifies to the first platform drowning episode. During the Late Senonian, the deposition of pelagic limestone (Scaglia Formation) defines the final platform drowning.

The petrophysical characteristics of the Val d'Agri reservoir are strongly dependent on the type of depositional facies. The Albian–Cenomanian sequence is generally characterized by low intercrystalline porosity, but reservoir quality can improve where karst-fractures (fractures enlarged by dissolution) are present. The Senonian shallow-water limestone generally exhibits low porosity, of intragranular and mouldic type. In contrast, the layers containing rudist fossils have relatively good properties due to intrafossil porosity.

The Lower Pliocene shales and marls overlying the Apulian Platform constitute the main seal of the Cretaceous play. Top and lateral seals of the Val d'Agri Field are locally made also by the thick Miocene shaly and marly sequence of the Allochthonous Complex.

The hydrocarbons of the Val d'Agri Field originated from an Albian–Cenomanian marine source-rock. This sequence is characterized by laminated dolomitic limestone (500–600 m of thickness) deposited on a shallow-water carbonate ramp during episodes of restricted water circulation and anoxic conditions. It is a fair to good quality source rock. The kerogen is a sulphur-rich type II. The source-rock entered the oil window during the Pliocene, when the Apennines accretionary prism involved the field area and the Allochthonous Complex built up.

The trap of the field is represented by a large-scale pop-up bounded by NW–SE high-angle reverse faults. The structure is a result of the intense Apennines transpressive deformation that affected the area during the Middle–Late Pliocene and Early Pleistocene (van Dijk *et al.* 2000; Shiner *et al.* 2004). The vertical throw exceeds 1000 m.

The Cretaceous Apulian Platform succession of the Val d'Agri Field is considered a single-layer reservoir. The main hydrocarbon phase is light oil with associated gas. Gas and condensate (gas-cap) and heavy oil are also represented.

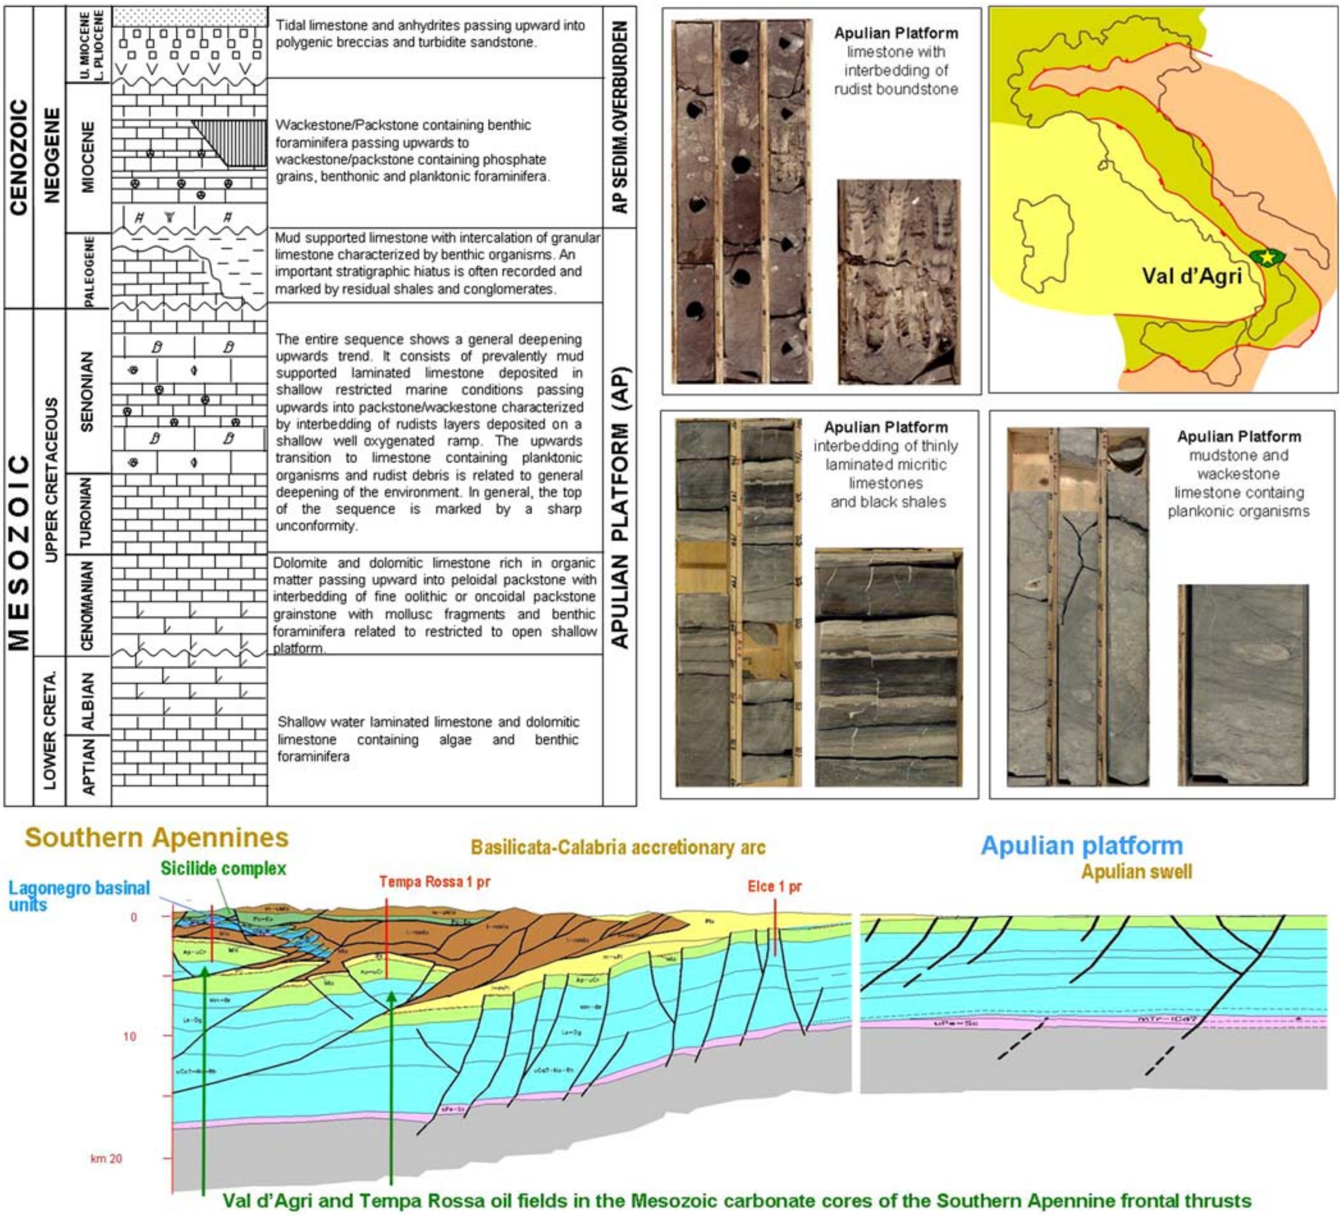

Fig. 9. Val d'Agri oil field.

Thermogenic gas in the thrusted terrigenous Oligo-Miocene foredeep sedimentary wedges

This system includes the Oligo-Miocene turbidite foredeep sedimentary wedges of the Southern Alps and of the Apennines, whose successions have been tectonically involved in the thrust belts of the two chains (Fig. 5). The turbidite reservoirs are mostly represented by type I thick-bedded sandstone lobes and thin-bedded, fine-grained basin plain/lobe fringe deposits (Ricci Lucchi 1986; Dalla *et al.* 1992). The deep burial of these sediments allowed an early thermogenic generation from the shales interbedded in the successions. The organic matter is of terrestrial origin (gas-prone kerogen type III) with very low average TOC. The main hydrocarbon phase is thermogenic gas with minor amounts of condensate and light oil.

The traps are usually structural. Gas occurrences related to this petroleum system have been found in the Southern Alps and the northern Apennines (e.g. Cortemaggiore and Casteggio fields), but the most important discoveries were made in the southern Apennines, namely in Calabria (Luna Field) and in Sicily (Gagliano, Bronte and Fiumetto fields: Fig. 6d). The exploration of this play is made difficult by generally poor seismic imaging, a result of the structural complexity of the related geological framework. Exploration can also be of little reward in terms of amount of gas in place (small traps) and reservoir quality (low porosity and permeability due to diagenesis).

Biogenic gas in the terrigenous Plio-Pleistocene foredeep wedges

Several biogenic gas fields have been discovered in the Plio-Pleistocene successions of the late Apennine foredeep depocentres and in the outer fronts of the Apennine thrust belt, namely in the Po Plain, in the northern and central Adriatic Sea, in southern Italy and in Sicily (Fig. 5). These successions mainly consist of some thousands of metres of sand-rich turbidites. As in the older Oligo-Miocene foredeeps, the high-efficiency type I turbidite systems with longitudinal palaeocurrents are largely predominant (Minervini *et al.* 2008; Ghielmi *et al.* 2008*b*). Thick-bedded sand lobes and thin-bedded, fine-grained basin plain/lobe fringe deposits are the main facies associations of the turbidite reservoirs. The

Plio-Pleistocene clays interbedded in the turbidite successions are both the source-rock and the effective vertical seal. Also in this case, the organic matter is of terrestrial origin (kerogen type III) and the average TOC is usually very low. The derived hydrocarbon phase is biogenic gas. The gas generation and expulsion started immediately after deposition. Exceptionally, the reservoirs may consist either of Messinian conglomerates and sandstones sealed by Lower Pliocene clay (e.g. Sergnano Field, Po Plain area) or of Cretaceous Apulian Platform carbonates (e.g. Cupello and Ferrandina fields, Bradanic Foredeep). In these reservoirs the biogenic gas is mixed with minor amounts of thermogenic gas generated by older and deeper source-rocks.

Traps are most commonly structural and range from thrust propagation folds of the inner foredeep margins (e.g. Cervia Mare and Porto Corsini East: Fig. 6b) to gentle folds draping the underlying morphology of the pre-Pliocene substratum in the outer foredeep margins, the substratum being represented by Miocene or older terrigenous sediments or by the Mesozoic–Cenozoic carbonate platforms (e.g. Barbara Field). Stratigraphic traps also occur and are mainly related to turbidite reservoir onlaps on the flanks of the thrust propagation folds or on the foreland ramp.

The exploration of the biogenic play started during the late 1940s in the central Po Plain and progressively moved southeastward and offshore. From the early 1980s, the seismic DHI technologies became the key support for any successful exploration in this play. The most important discoveries occurred in the Adriatic Sea, where hundreds of seismic bright spots were successfully tested and put into production. Among them the Barbara gas field stands out for its giant size.

Today the exploration of the biogenic play is very mature and limited to the search of small accumulations near the existing fields. Some potential is also left in thin-bedded reservoirs below the seismic resolution.

Two examples of biogenic gas accumulations, the Porto Corsini East and the Settala fields, are illustrated.

The Porto Corsini East Field is one of the largest biogenic gas fields of the northern Adriatic Sea (Fig. 10). The trap is structural: a clear four-way closure in a NE-verging fault-propagation fold (Ghielmi *et al.* 2008*a*). The fold shows a regular and elongated shape and is affected by a system of frontal thrust planes and by one major NW–SE trending back-thrust. The trap was generated during the Late Pliocene and the Early Pleistocene as a response

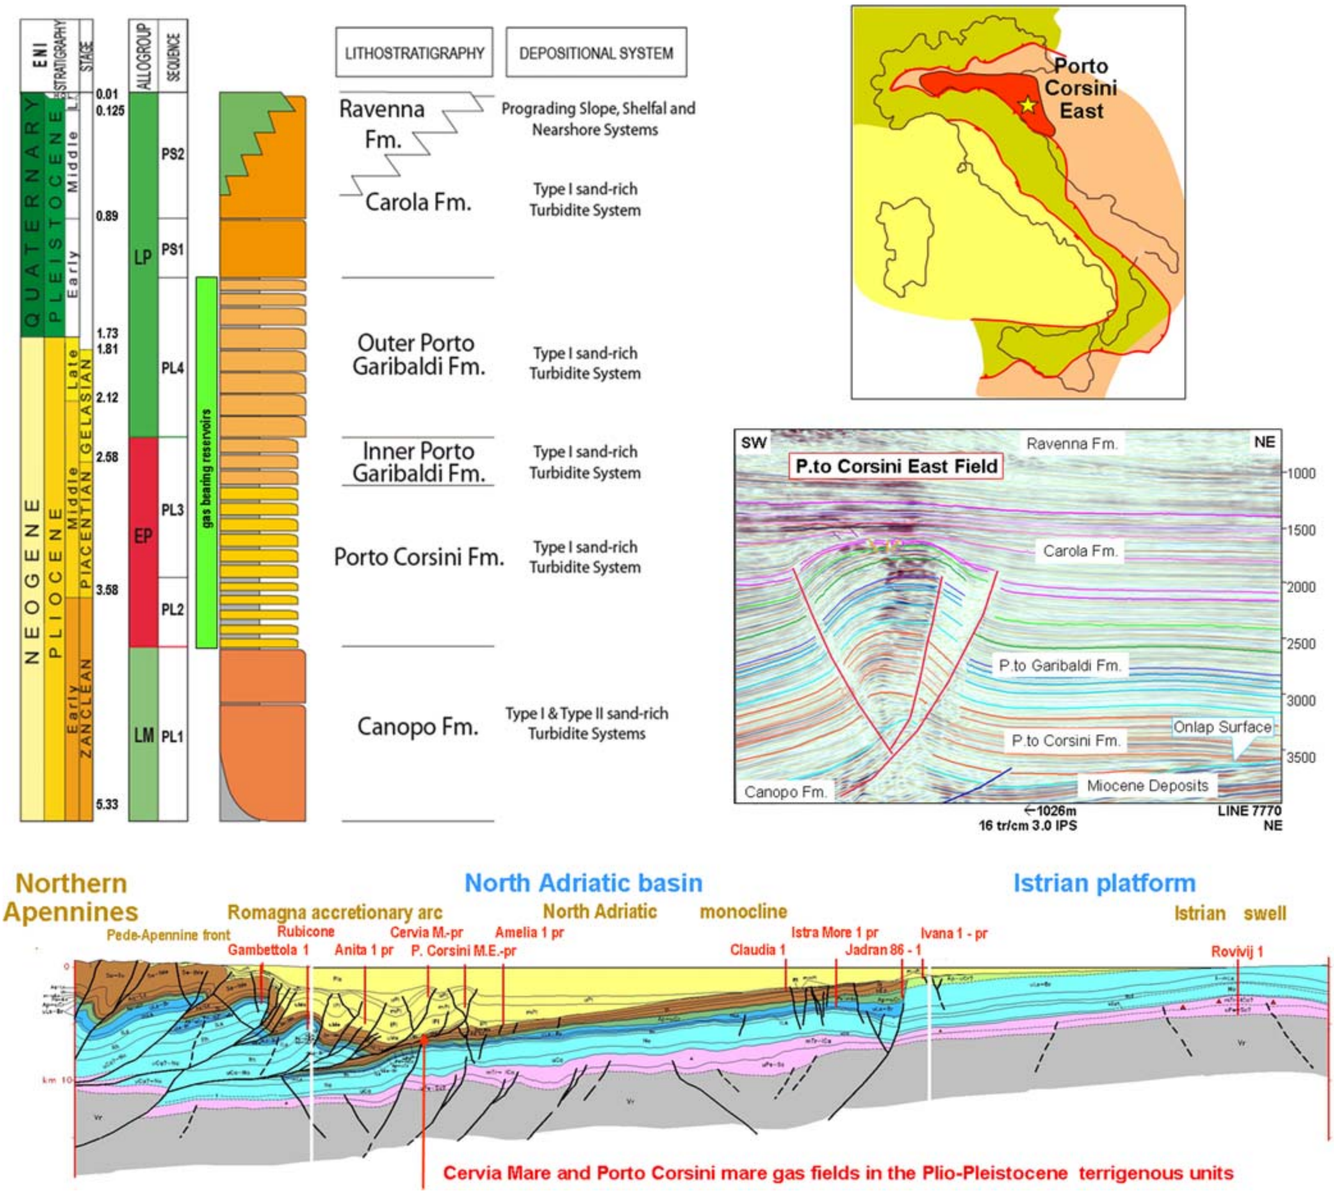

Fig. 10. Porto Corsini East gas field.

to the Apennine compressive deformation. The vertical displacement can reach 800–1000 m for some layers.

The gas field consists of several independent superimposed pools (single layer or multilayer). The target is represented by a thick sequence of Lower Pliocene to Lower Pleistocene foredeep turbidites of the Porto Corsini, Porto Garibaldi and Carola Formations. Thick-bedded turbidite proximal and distal sand lobes are the prevailing facies associations (Bettazzoli & Visentin 1998; Ghielmi *et al.* 2008*b*). Thin-bedded fine-grained turbidite basin plain deposits are also present but are subordinate. The turbidite sequence was deposited by high-efficiency large-scale type I turbidite systems (*sensu* Mutti *et al.* 1999) in the Po Plain–Adriatic Foredeep (Ghielmi *et al.* 2008*b*). The palaeocurrents are from the NW and are parallel to the foredeep main axis. The pelitic layers interbedded with the sandy reservoirs provide the multiple vertical seals. The source-rock for the biogenic gas is mainly represented by the interbedded Plio-Pleistocene clays. The presence of biogenic gas is associated with clear DHIs: superimposed bright spots, flat spots reflecting the gas–water contact and pull-down (Fig. 10).

The Settala Field is a remarkable example of a mixed structural–stratigraphic trap (Fig. 11). It was discovered in 1977 in the central Po Plain close to Milan. The target is represented by the Middle–Upper Pliocene turbidite sands of the Asti Formation deposited in the central part of the west–east oriented western Po Plain Foredeep (Minervini *et al.* 2008). The reservoir mostly consists of amalgamated thick-bedded medium-grained sand, which is referred to distal sand lobes deposited by a high-efficiency type I turbidite system. The palaeocurrents, parallel to the foredeep main axis, were from west. The mixed trap is represented by a stratigraphic closure (onlap) of the turbidite reservoirs towards the northeast onto a quite steep foreland ramp. A clear angular unconformity is due to the basinward tilting of the former foreland area during Messinian and Pliocene. The lateral closures (towards NW and SE) are provided by the draping of an erosional Messinian high, while the closure towards the foredeep depocentre is due to dip. The vertical and lateral seals are made by the interbedded turbidite clay of Asti Formation and by the foreland and foreland ramp Lower Pliocene clay of the Santerno Formation respectively. Also in this case, the biogenic gas accumulation is associated with recognizable seismic DHI: amplitude anomaly with a clear flat spot at the base (Fig. 11). Because of the amalgamation of the sand beds, no intermediate clay seals are present and the field consists of a 100 m-thick single layer reservoir.

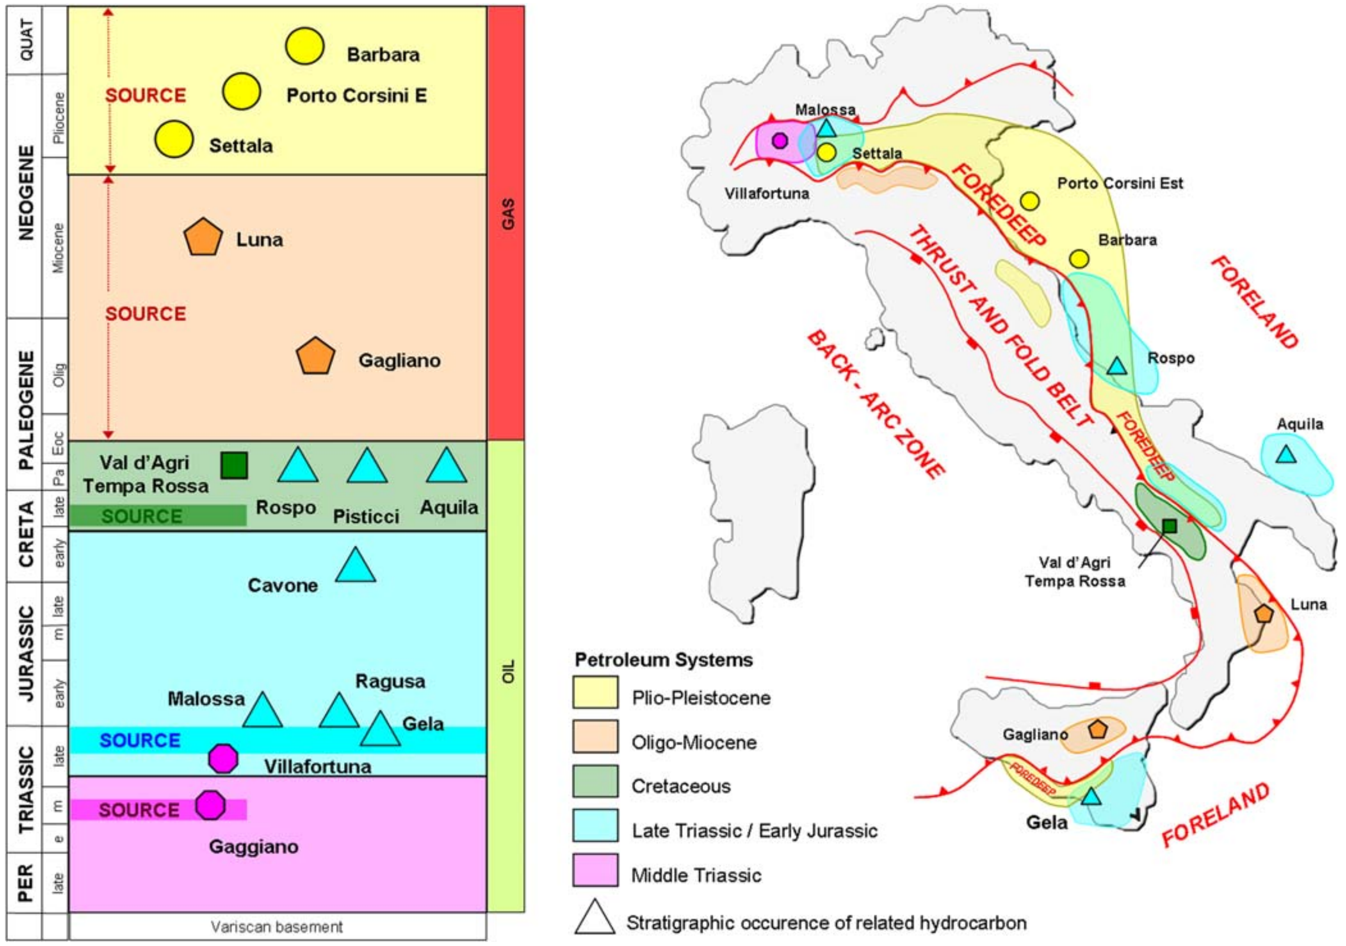

Fig. 12. Stratigraphic and geographic location of the Italian petroleum systems.

Conclusions

A variety of petroleum systems are present in Italy as a result of a complex geological history. At least five important hydrocarbon source rocks have been recognized which are distributed from Mesozoic through Pleistocene.

Three of these (Besano Shales – Meride Limestone, Streppenosa and Noto Formations and Albian–Cenomanian units) were deposited during Mesozoic crustal stretching and extension and are mainly oil-prone. Hydrocarbon occurrences associated with these sources are found in complex geological scenarios along the Apennines belt, both in sub-thrust and thrusted units and in the foreland. Villafortuna–Trecate (Po Plain), Val d'Agri/Tempa Rossa (southern Apennines) and Gela (Sicily) fields represent the largest oil accumulations pertaining to these systems and rank among the largest onshore fields of western Europe.

Two other important source rocks (Oligo-Miocene terrigenous units and Plio-Pleistocene terrigenous units) were deposited in the foredeep basins which formed during the Alpine and Apennine orogenesis. The first source rock is thermogenic gas-prone and occurs in the Oligo-Miocene foredeep basins, which were later involved in the tectonic compression. Gas occurrences associated with this source are mainly concentrated along the northern Apennine margin (e.g. Cortemaggiore Field), in Calabria (e.g. Luna Field) and Sicily (e.g. Gagliano Field). The second source is biogenic gas-prone and is found in the recent undeformed (or slightly deformed) Plio-Pleistocene foredeeps. The most important gas fields of Italy, located in the eastern Po Plain and northern Adriatic (Barbara et alia), have originated from this source.

Figure 12 summarizes the stratigraphic and structural location of the Italian petroleum systems. It clearly shows the geographic limitation of the oil prolific Villafortuna–Trecate Middle Triassic and Val d'Agri/Tempa Rossa Cretaceous systems, as opposed to the wide distribution of the oil-prone Late Triassic–Early Jurassic and of the biogenic gas-prone Plio-Pleistocene systems. The Late Triassic–Early Jurassic system is also peculiar in that, due to a general lack of regional seals in the section overlying the source rock, oil accumulations can be found in a variety of stratigraphic intervals of the Mesozoic and Early Cenozoic carbonate succession.

The results of the exploration history of Italy can be summarized in the creaming curves. The curve (Fig. 13) for the gas has a moderate slope until the late 1950s, when exploration and discoveries were limited to the northern Apennines and the Po Plain (Caviaga, Cortemaggiore). Then the curve becomes very steep, reflecting a series of successes in the Adriatic Sea (Agostino and Dosso degli Angeli, Barbara), in the Pescara and Bradanica foredeeps (Squalo and Candela respectively), in Calabria (Luna) and Sicily (Gagliano). From the early 1980s onward the curve becomes much less steep, indicating that the gas exploration in Italy is mature and activities are mainly conducted near the existing fields.

The creaming curve for the oil discoveries (Fig. 13) is remarkably different. After an initial boost with the discoveries in Sicily in the late 1950s (Ragusa, Gela), no significant successes were attained until the early 1970s, when discoveries were made in the deepest carbonate succession of the Po Plain (Malossa) and in the Pescara offshore (Rospo). Two other significant boosts occurred in the 1980s (Villafortuna–Trecate, Aquila, Vega) and in the late

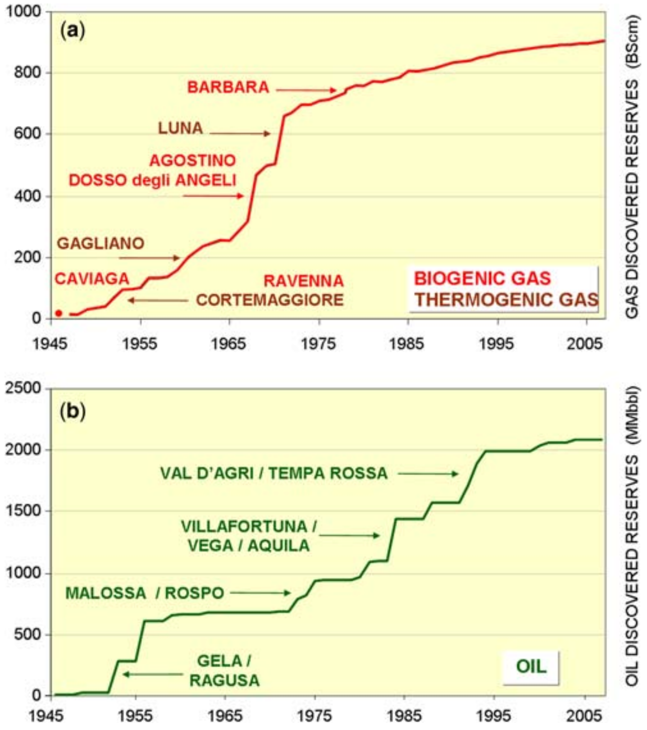

Fig. 13. Cumulative discovered reserves: (**a**) gas in the terrigenous foredeep wedges; (**b**) oil and thermogenic gas occurrence in the carbonate Mesozoic substratum).

1980s/early 1990s (Val d'Agri, Tempa Rossa). The curve seems to indicate that oil exploration in Italy has probably not reached as mature a stage as gas. Some further potential is believed to be left in more complex and deep structural scenarios along the Apennine thrust belt.

In terms of petroleum endowment, Italy is the fourth richest country of western Europe, after Norway, the UK and the Netherlands. About 1040 MMbbl of oil and 24.7 Tcf of gas have been produced so far in the country. Nowadays the production of oil is 43.2 MMbbl per year (2007), about 75% of which comes from the Val d'Agri Field. The production of gas is 340 Bcf/year, continuing the declining trend from the peak of 730 Bcf/year attained in 1994, the largest producing fields being located in the Adriatic Sea. The yet-to-be-discovered reserves are estimated to be rather limited (800 MMbbl of oil, 6.0 Tcf of gas) and in the next decades the country will become more and more dependent on oil and gas imports.

The authors would like to thank C. Doglioni for his kind review of this manuscript. Comments and suggestions by Mike Thomas and Enzo Zappaterra also helped improve the clarity of the text. The authors are grateful to all Eni colleagues who contributed with data, ideas and useful discussions to the preparation of these notes. They acknowledge Shell Italia E&P S.p.A. for the permission to publish an outline of the Val d'Agri Field and a regional geological section where the location of the Val d'Agri and Tempa Rossa fields is shown. They also acknowledge Stogit S.p.A. for the permission to publish an outline of the Settala Field.

Geological Survey of Denmark and Greenland (GEUS), Øster Voldgade 10, DK-1350 Copenhagen K, Denmark (e-mail: pjo@geus.dk)

Abstract: Recently available well data from the northern part of the Danish Central Graben have been analysed to further understand the basin development, biostratigraphy, depositional models and palaeogeography of Upper Jurassic reservoir sandstones, which are the primary exploration targets in this basin. Notably, the discovery of the Hejre accumulation in 2001, where oil has been encountered in Upper Jurassic good reservoir quality sandstones at a depth of more than 5000 m, triggered renewed interest in the Upper Jurassic High Temperature–High Pressure sandstone play in the area.

Overall the Danish Central Graben was transgressed from east to west during the Late Jurassic. During the Late Kimmeridgian, marginal and shallow marine sandstones assigned to the Heno Formation were deposited at the margin of the Feda Graben, and on the Gertrud and Heno Plateaus and constitute the reservoirs in the Freja and Hejre discoveries. The sandstones are analogues to the UK Fulmar and Norwegian Ula Formations encountered in several hydrocarbon fields.

During the Early Volgian, the transgression continued westwards across the Outer Rough Basin along the margin of the Mid North Sea High, where shoreface sandstones with excellent porosities and permeabilities were deposited close to similar sandstones of the Fulmar Formation in the British Fergus, Fife and Angus fields.

During this overall westward transgression, the eastern and central parts of the Danish Central Graben continued to subside and offshore mudstones accumulated, locally intercalated with gravity-flow sandstones. In the easternmost Danish Central Graben, in the Tail End Graben, Upper Kimmeridgian gravity-flow sandstones of the Svane-1 well have proved the presence of gas at *c.* 6 km depth.

Hydrocarbon-bearing Upper Jurassic sandstone reservoirs at significant depths (deeper than 5 km) may form the future exploration targets in the northern part of the Danish Central Graben.

Keywords: reservoir sandstones, sedimentology, biostratigraphy, basin development, palaeogeography, Upper Jurassic, Danish Central Graben, North Sea

Compared with neighbouring areas in Norwegian and UK waters, where production takes place from shallow marine Ula and Fulmar Formations (Fraser *et al.* 2003), the Upper Jurassic sandstone play in the Danish sector has historically been less successful, due mainly to large variations in reservoir quality. A number of technical discoveries have been made and two accumulations have been declared commercial although not yet in production. These are the Freja Field on the Gert Ridge, located near the Norwegian border with reservoirs in Upper Kimmeridgian back-barrier and shoreface sandstones of the Heno Formation, and the Elly Gas Field located in the south close to the German sector hosted in Upper Kimmeridgian shoreface sandstones of the Heno Formation (Figs 1 & 2) (Hemmet 2005).

In 2001, oil was encountered in sandstones of the Heno Formation in the Hejre-1 well located on a tilted fault block in the Gertrud Graben area at a depth below 5000 m. The discovery was appraised down-flank by the Hejre-2 well in 2005, where good production rates of oil and associated gas were recorded (Danish Energy Agency 2005). The Svane-1 well located in a High Temperature–High Pressure (HTHP) environment in the northern part of the Tail End Graben was drilled in 2002 to a total depth of 5865 m. Four sandstone-bearing successions of presumed gravity-flow origin of Upper Kimmeridgian to Lower Volgian age were found below 5300 m with high gas saturations. The net sand thickness is about 150 m but individual sandstones are thin (up to 15 m). The recent deep-seated Hejre and Svane discoveries have triggered renewed interest in the Upper Jurassic HTHP sandstone plays in the area.

The aim of this paper is to present an updated overview of the stratigraphy, sand distribution, depositional environments and reservoir characteristics of the Upper Jurassic potential reservoir sandstones in the northern part of the Danish Central Graben. A series of palaeogeographic maps illustrates the basin evolution during the Late Kimmeridgian to Ryazanian.

Structural setting

The northern Danish Central Graben study area forms part of the Jurassic North Sea rift complex (Fig. 1). The basin consists of a system of NNW–SSE trending half-grabens bounded by the Coffee Soil Fault to the east (western margin of the Ringkøbing–Fyn High), and by the Mid North Sea High to the west (e.g. Japsen *et al.* 2003; Møller & Rasmussen 2003). Rifting took place from Middle Jurassic times and persisted into the Early Cretaceous. The syn-rift sedimentary fill is mudstone-dominated, rich in organic matter at certain intervals and with subordinate amounts of sandstones (Petersen *et al.* 2010). The early development was characterized by fault-controlled subsidence and deposition in the eastern part, especially along north–south segments of the Coffee Soil Fault (Korstgaard *et al.* 1993; Bruhn & Vagle 2005). During the Kimmeridgian, the tectonic trend shifted to a dominant NW–SE trend; the depocentres shifted westwards and deposition

Position of the geotraverse in Figure 4 is shown in yellow, while the positions of the seismic lines shown in Figures 14 and 15 are shown in red-brown and pink, respectively. The positions of the log-panels shown in Figures 6–8 are shown in red, blue and green, respectively. Inserted map shows the Central Graben, Viking Graben and Moray Firth Basin.

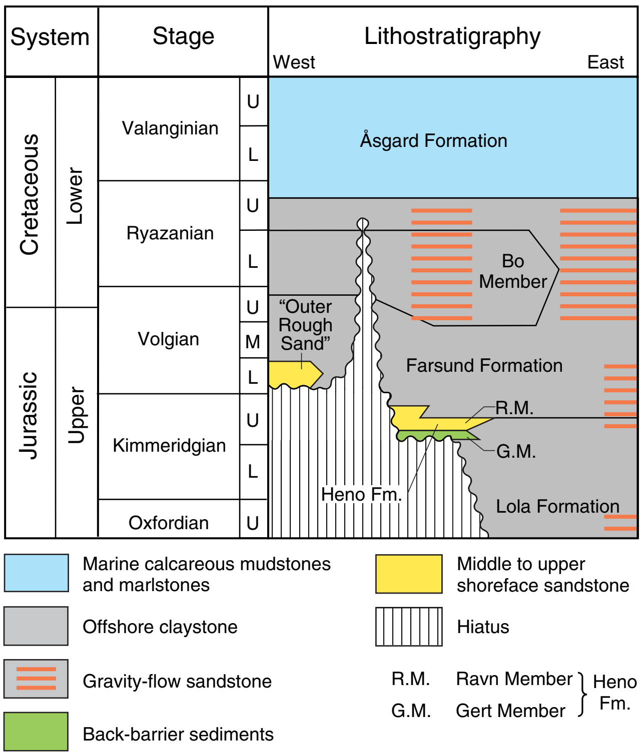

Fig. 2. Time stratigraphic chart covering the Upper Jurassic and Lower Cretaceous succession in the Danish Central Graben.

gradually covered larger areas, reaching the flanks of the Mid North Sea High during the Early Volgian. Despite the overall extensional tectonic regime, compressional features occur, caused by oblique-slip movements along different graben segments.

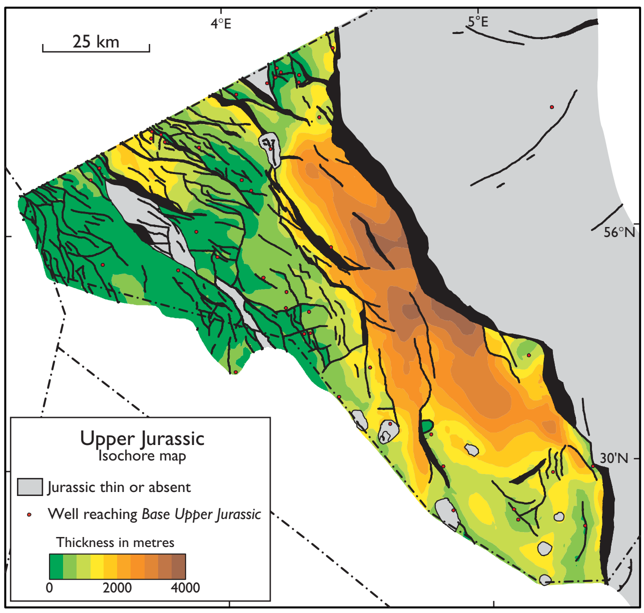

Fig. 3. Upper Jurassic isochore map of the Danish Central Graben (Britze *et al.* 1995).

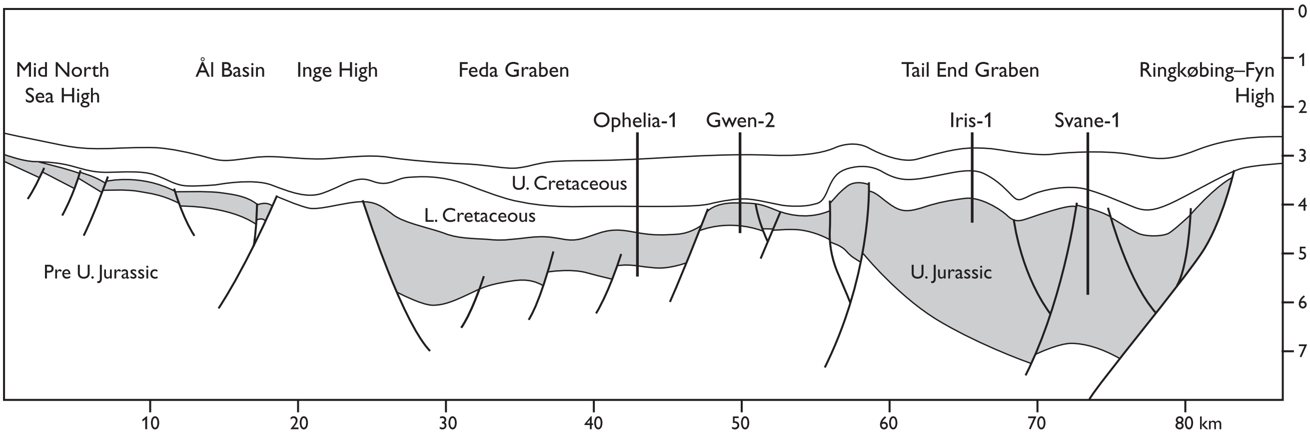

Fig. 4. Simplified structural profile across the northern part of the Danish Central Graben. For location see Figure 1.

The structural control on deposition is illustrated by the Upper Jurassic isochore map in Figure 3 (Britze *et al.* 1995) and by the simplified structural profile across the northern part of the study area (Fig. 4). The dominant Jurassic structural element is the Tail End Graben in the east containing up to 3600 m of Upper Jurassic sediments dominated by claystones. It grades into the Søgne Basin in the north with reduced sediment thicknesses. Towards the west, the Tail End Graben is separated from the Heno Plateau with westward thinning Jurassic cover by the Arne–Elin Graben (Fig. 1). The Heno Plateau passes northwards into the Gertrud Plateau/Graben, which is separated from the southwestward dipping Feda Graben by the Gert Ridge. In both graben segments, the thickness of Upper Jurassic strata locally exceeds 1500 m. The Early Cretaceous Ål Basin and the shallow Outer Rough Basin are located west of the Inge High in which Jurassic strata are thin or absent (Figs 1, 3 & 4) (Britze *et al.* 1995).

Methods

The chronostratigraphic framework for the studied succession is primarily based on first and last occurrences of dinoflagellate cyst (dinocyst) species (Fig. 5). Each bioevent has been given a number in order to be able to show the location of that specific bioevent in the wells included in the log panels (Figs 6–8). The biostratigraphic data have been compiled from published papers (Johannessen *et al.* 1996; Dybkjær 1998; Andsbjerg & Dybkjær 2003; Ineson *et al.* 2003), unpublished data and service company reports. Spores and pollen were included in the Rita-1 and Gwen-2 wells to support the stratigraphic interpretations. In addition, new biostratigraphic and palynofacies investigations have been carried out on cuttings and core samples for the present study. In the present study we have not correlated the studied succession with the 'genetic stratigraphic sequences' defined by Partington *et al.* (1993*a*, *b*), although this subdivision is used by several companies operating in the Danish Central Graben. The biostratigraphic events used for dating the sequences (and especially the maximum flooding surfaces) by Partington *et al.* (1993*b*) was mainly based on data from the Outer Moray Firth (pers. comm. M. Partington 1995). In many cases the biostratigraphic events used by Partington *et al.* (1993*b*) are acmes of specific species and these acmes do not occur in the same stratigraphic levels and the same order in the Danish Central Graben. Furthermore, the last occurrences ('species top' by Partington *et al.* 1993*b*) in some occasions occur in a different order in the Danish Central Graben than are indicated by Partington *et al.* (1993*b*).

The sedimentology of the cores has been studied in detail, focussing particularly on trace fossil assemblages, because most primary sedimentary structures are not preserved due to intensive bioturbation. The interpreted depositional environments from the core studies have been extrapolated via petrophysical well logs above and below the cored sections. Utilizing the new sedimentological and biostratigraphical data, an updated time stratigraphic chart has been constructed to show the overall depositional history of the northern Danish Central Graben (Fig. 2).

Log-correlation panels have been constructed to show the interrelations and distribution of depositional environments within the basin (Figs 6–8) and schematic palaeogeographical summary maps are created (Fig. 9). Note that the term 'shoreface' is used in this paper in a broad sense to cover various wave-influenced and wave-dominated shallow marine environments. Porosity–permeability plots are presented from cores and compared with poroperm data from the nearby Fergus and Fife fields of the UK sector.

Upper Jurassic reservoir sandstones

Initial subsidence along the Coffee Soil Fault, the eastern boundary of the Danish Central Graben, during the Middle Jurassic resulted in deposition of paralic to shallow marine sandstones in the Søgne Basin and in the Tail End Graben (Andsbjerg 2003; Andsbjerg & Dybkjær 2003). Westward propagation of active NW–SE trending normal faults occurred during the Late Jurassic. This was coeval with a eustatic sea-level rise and resulted in an overall stepwise transgression towards the west (Fig. 9a–g) (Andsbjerg & Dybkjær 2003; Johannessen 2003).

The overall depositional environments, the distribution and the reservoir characteristics of the different Upper Jurassic sandstones in the Danish Central Graben will be presented chronologically in the following sections, based on published literature and unpublished data from new wells.

Upper Kimmeridgian paralic and shoreface sandstones

Distribution and stratigraphy. The sandstones referred to as the Gert Member of the Heno Formation (Fig. 2) (Michelsen *et al.* 2003) were deposited in the marginal areas of the Feda Graben and on the Gertrud and Heno Plateaus during the Late Kimmeridgian (Fig. 9a, b) (Johannessen *et al.* 1996; Andsbjerg & Dybkjær 2003; Johannessen 2003). The succession is represented by cores in the Gert-1, Rita-1 and 2/12-1 wells in this paper (Fig. 6).

Depositional environments. The cored succession in the Gert-1 well, situated at the margin of the Feda Graben up against the Gertrud Plateau (Fig. 1), is composed of sandstones interbedded with thin claystone and coal beds often underlain by rootlets.

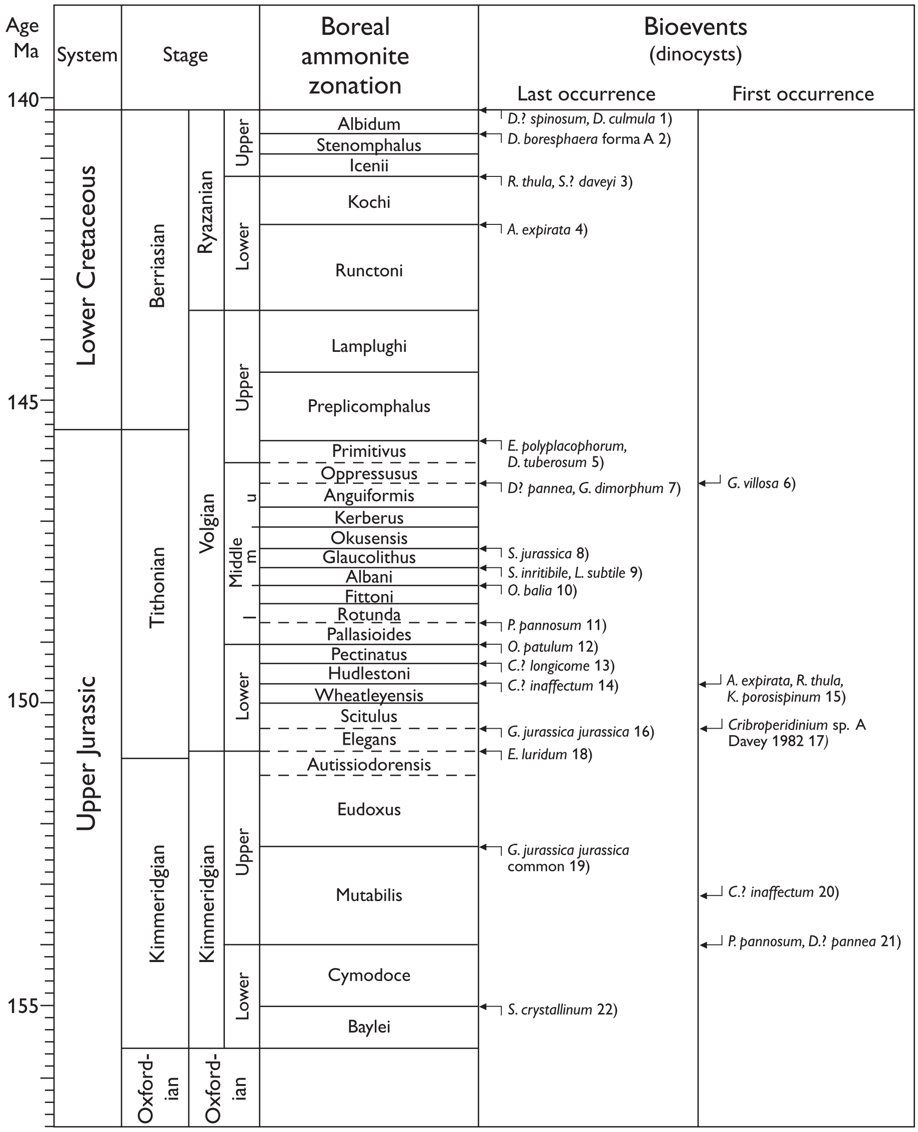

Fig. 5. Chronostratigraphic scheme showing the correlation between the bioevents (first and last occurrences of dinocyst species) recorded in the studied wells, the boreal ammonite zonation and the chronostratigraphy. Ages after Gradstein *et al.* (2004). The correlation is based on Davey (1979, 1982), Cox *et al.* (1987), Heilmann-Clausen (1987), Riding (1987), Poulsen (1991), Poulsen & Riding (1992), Riding & Thomas (1992) and Costa & Davey (1992). Note that each bioevent has been given a number in order to be able to show the location of that specific bioevent in the wells included in the log panels (Figs 6–8).

Spores and pollen are abundant, and numerous burrows of *Ophiomorpha* are observed but dinoflagellate cysts are scarce; together these features suggest deposition in a back-barrier setting (Johannessen *et al.* 1996; Johannessen 2003). Cross-bedded sandstones that overlie claystones and are capped by claystones or coal beds (sometimes with rootlets) were probably deposited by washover fans (Fig. 10a) (Schwartz 1982). The gamma-ray (GR) and sonic log motif is highly serrated (Fig. 11). Above the cored section, the log motif is non-serrated, suggesting that a cleaner sandstone unit abruptly overlies the back-barrier sediments, indicating deposition during high energy levels on the shoreface. The uppermost part of the sandy section shows a fining-upward, backstepping shoreface sandstone succession which fines upwards to offshore claystones of the Lola Formation, indicating an overall transgressive succession (Fig. 6) (Johannessen 2003).

It is very unusual to develop and preserve such *c.* 60 m thick back-barrier sediments as seen in the Gert-1 well. This thick accumulation resulted firstly because there was a sand surplus and secondly because they were accumulated at the steep margins of the Feda Graben towards the plateau areas during a transgression, forcing the back-barrier sediments and the shoreface sandstones to stack vertically (Johannessen *et al.* 2008, 2010). The sandstones of the Gert Member were probably derived from local sediment sources during the transgression, such as the exposed Carboniferous sediments in the Gert Ridge area and sediments on the Heno and Gertrud Plateaus (Johannessen *et al.* 1996).

The Norwegian 2/12-1 well, situated 2.5 km NW of the Gert-1 well, farther out in the Feda Graben, comprises an equally thick Gert Member sandstone succession but one that is dominated by shoreface sandstones (Fig. 6). Only the lowermost part was deposited in a back-barrier environment (Bergan *et al.* 1989; Söderström *et al*. 1991; Johannessen 2003).

In the Rita-1 well, situated at the western margin of the Feda Graben (Fig. 1), the cored interval of the Gert Member consists of alternating mudstones, mud-draped sandstones and conglomeratic intervals. Recurring sedimentary successions consist of 1–3 m thick units of diminutive, (pyritized) *Chondrites*-bearing massive organic-rich mudstones that grade upward into mud-crack-bearing heterolithic bedding, which is interpreted to reflect a gradation from an oxygen-deficient lagoonal environment to an intertidal setting.

Locally, these successions are further overlain by root-bearing mudstone intervals, or are truncated by 1–2 m thick rhythmically cross-stratified heterolithic sandstone successions interpreted as tidal channel and bar deposits. The base of the channel units typically contains interbedded or mixed conglomerates and highly deformed, carbonaceous mudstone beds pointing to high-energy conditions and formation of abundant fluid mud in the depositional system. The channel units are mainly unburrowed, but toward the top of the cored interval, local occurrences of *Asterosoma, Cylindrichnus* and *Ophiomorpha* were observed, suggesting increasing marine influence, and thus transgressive setting for the upper-most part of the core. In concert, the observed lagoonal, tidal and marsh sub-environments are consistent with the overall interpretation of a back-barrier and paralic setting for the Gert Member (Fig. 6).

Reservoir characteristics. Despite reservoir depths of *c.* 5 km, the sandstone reservoir of the Gert Member contains producible volumes of oil in the Freja Field, herein represented by the Gert-1 and 2/12-1 wells (Fig. 11) (Hemmet 2005; Danish Energy Agency 2008). The Gert Member consists of clean sandstones with good reservoir quality and reaches a thickness up to *c.* 90 m in both the Gert-1 and the 2/12-1 wells. Sandstone thickness

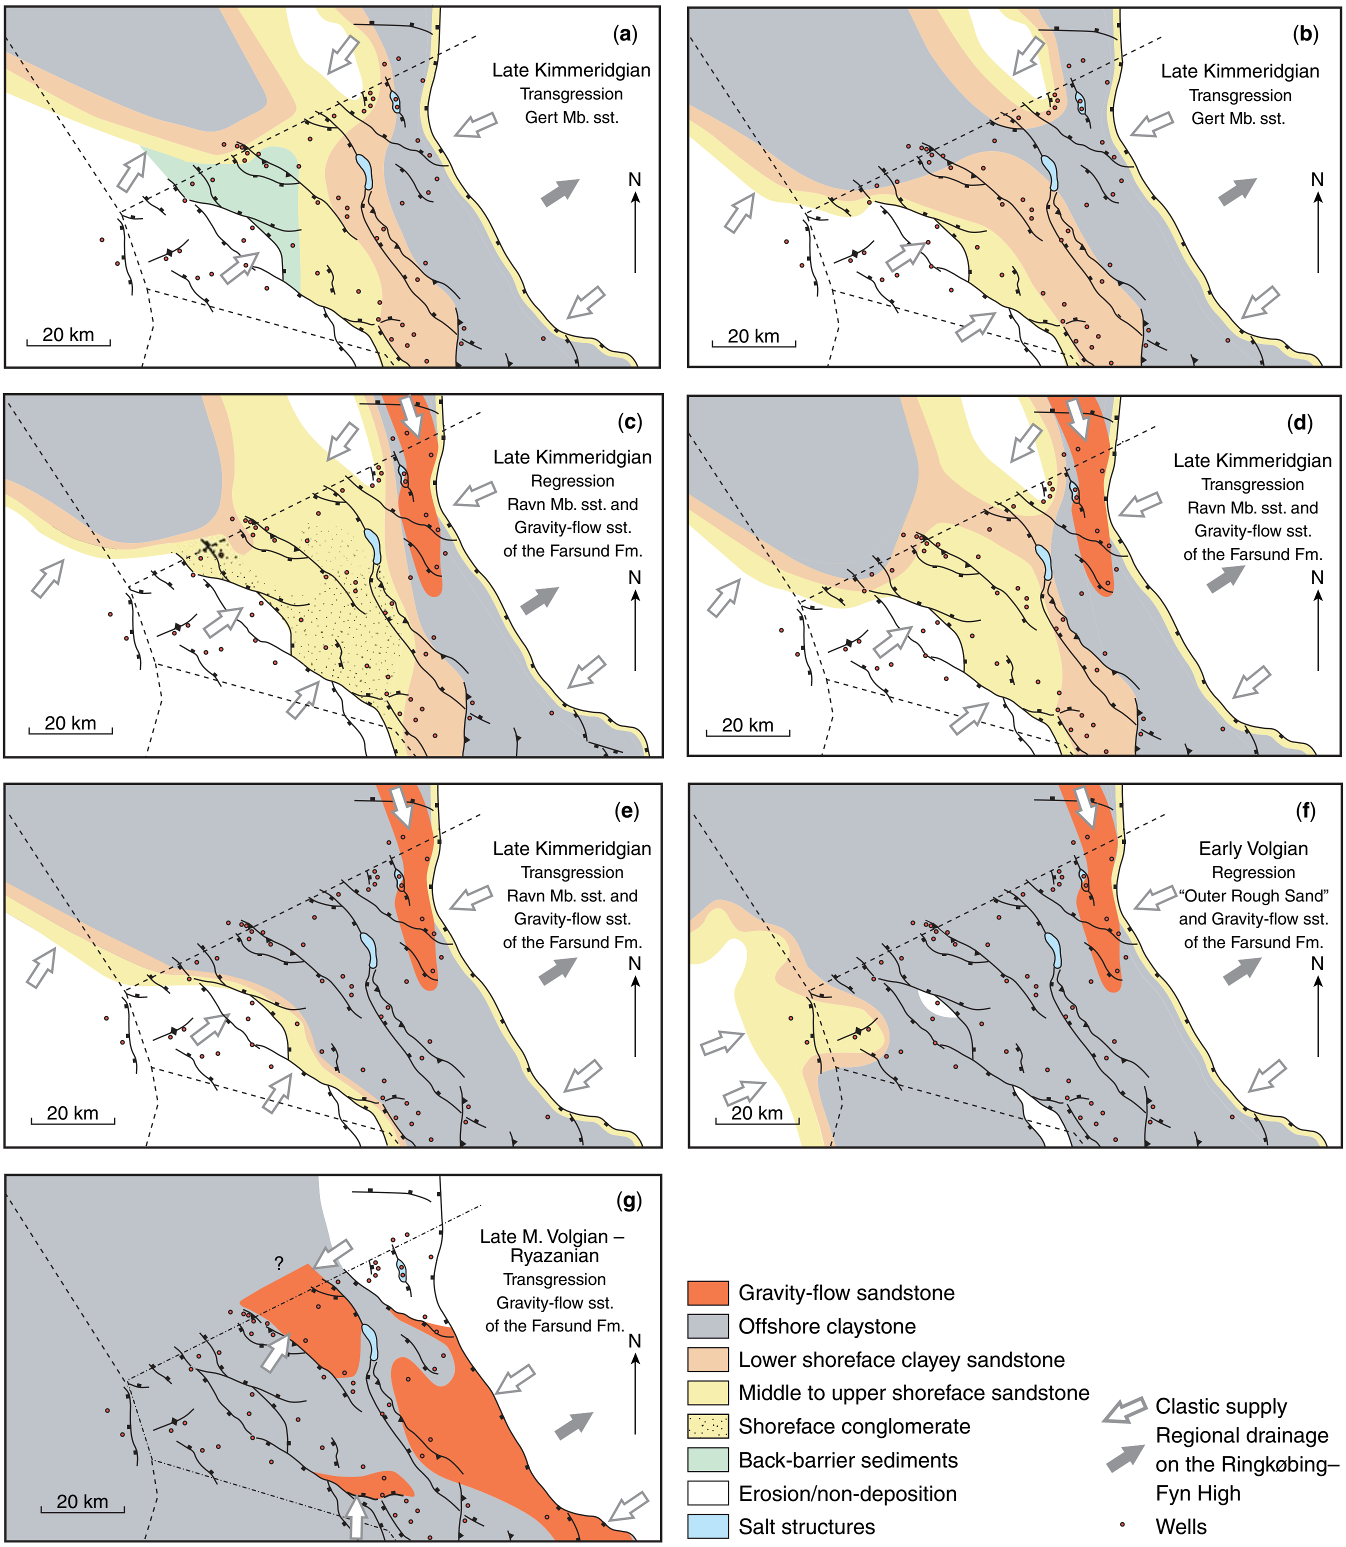

Fig. 9. Series of palaeogeographic maps illustrating facies distributions and basin evolution during the Late Kimmeridgian to Ryazanian.

decreases in a southerly and easterly direction, and in the Hejre-1 well, for example, the net sand thickness is less than 25 m (Fig. 6). Porosities are generally in the range 15–20%. The presence of high porosity sandstones of the Hejre-2 is caused by dissolution and illite replacement of detrital feldspars and early authigenic K-feldspar cement, thus creating secondary porosity (Weibel & Keulen 2008). Oil saturations up to 80% are recorded in the Gert-1, 2/12-1 and Hejre-1 wells (Fig. 11). In spite of overall good reservoir quality, core data from the Gert-1 well do not show a well defined relationship between porosity and permeability. The permeability varies considerably at a given porosity value. Generally the sandstone permeability is less than 100 mD in Gert-1, but occasionally the permeability may exceed 100 mD provided that the porosity is fairly high (Fig. 12). In the Rita-1, Ophelia-1 and Jeppe-1 wells, the reservoir sandstones are characterized by poorer reservoir quality than seen in Gert-1, Hejre-1 and 2/12-1. The reservoir quality sandstones of the Hejre-1 and Gert-1 wells are situated in a HTHP environment with overpressures of 7020 and 6800 psi, respectively (Table 1).

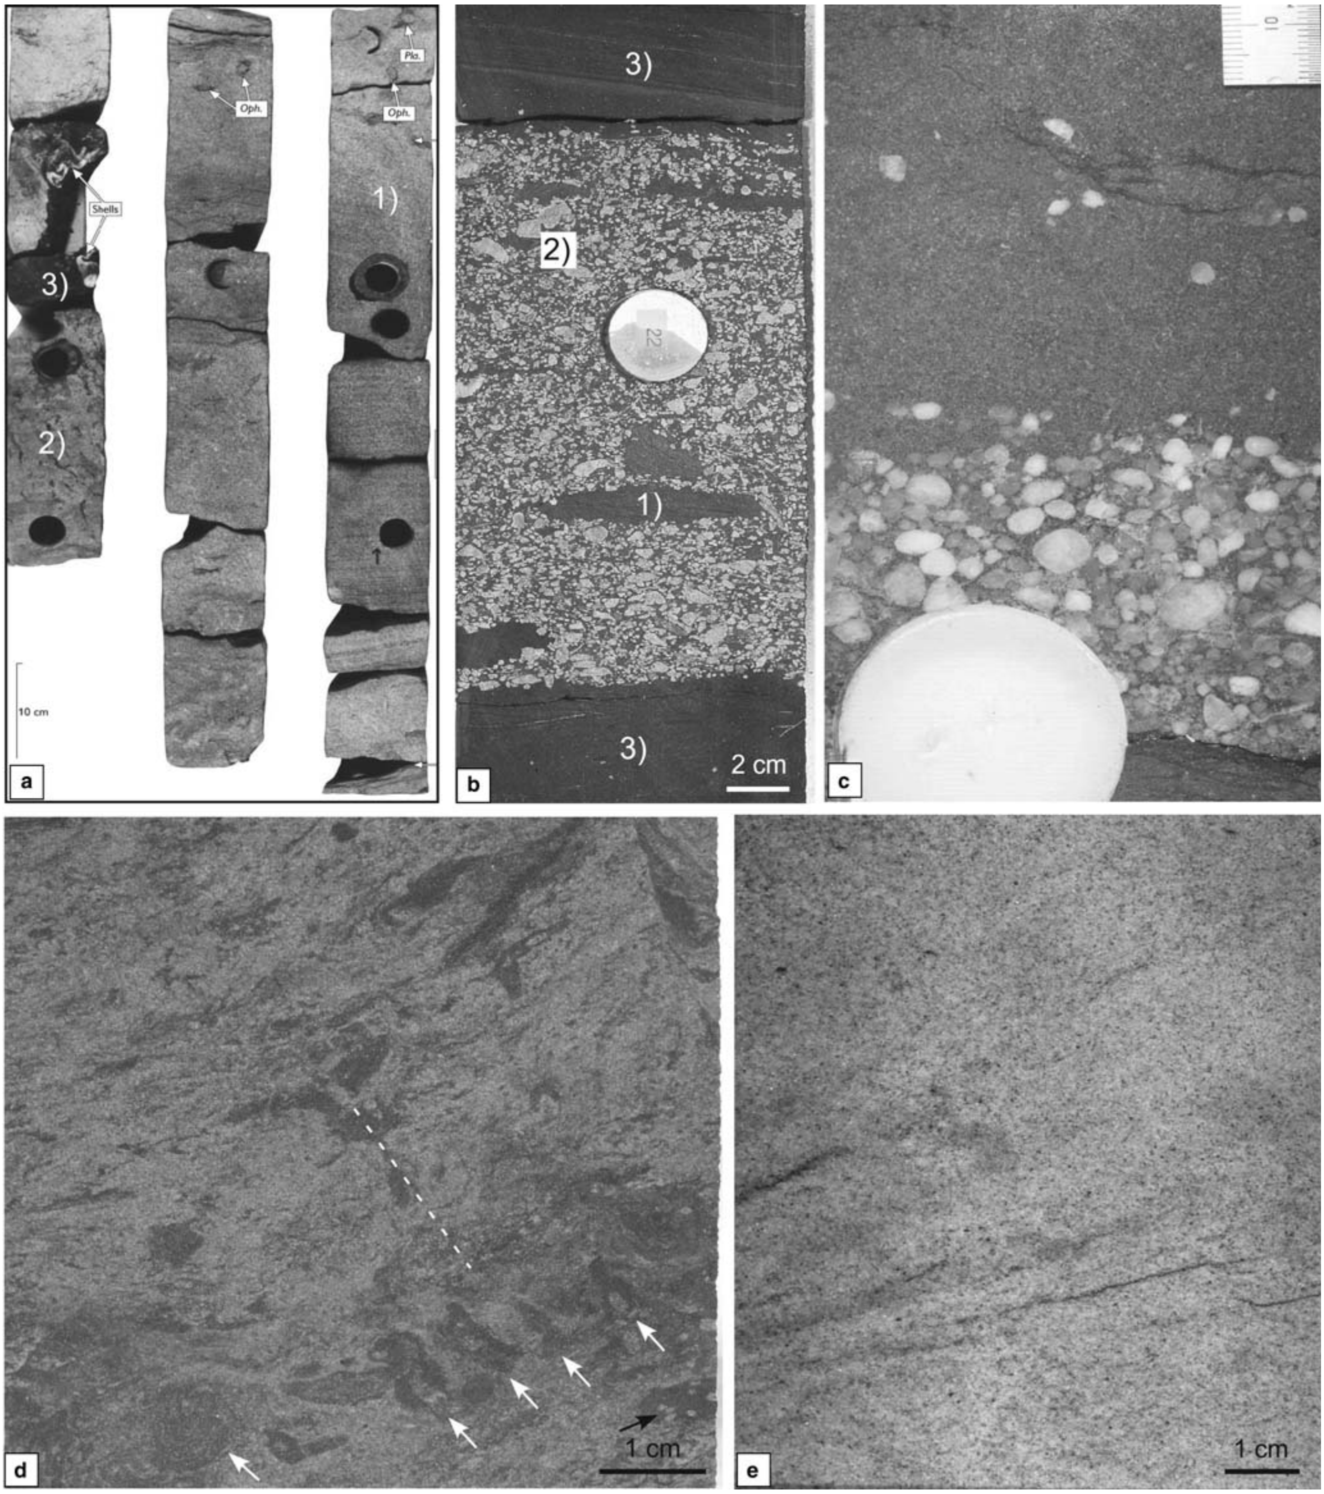

Fig. 10. Core photos of selected facies. (**a**) A sediment succession consisting of cross-stratified sand (1) grading upward into root-bearing sand (2) and further into a coal-layer (3). This succession overlies organic rich mudstones and is interpreted to represent a washover fan in a back-barrier setting. Gert Member, Gert-1 well. (**b**) Intra- and extraformational clast (1 and 2, respectively) bearing conglomeratic bed interbedded with laminated claystones (3). Farsund Formation, Tabita-1 well. (**d**) Bioturbated muddy sandstone. Characteristic trace fossils include abundant *Asterosoma* (white arrows), which is re-burrowed with *Chondrites* (black arrow). Dashed white line indicates the location of a central vertical tube. Ravn Member, Rita-1 well. (**e**) Tangentially cross-stratified sandstone. 'Outer Rough Sand', Saxo-1 well.

Palaeogeography. The Heno and Gertrud Plateaus formed a positive north–south trending area between the Mandal High to the NE and the Mid North Sea High to the SW (Fig. 9a–d). The back-barrier and shoreface sandstones of the Gert Member were deposited during the Late Kimmeridgian, when the transgression started in the deep part of the Feda Graben and moved towards the Heno and Gertrud Plateau margins and ultimately drowned the plateau areas (Fig. 9a, b). As the regional gradient on the plateau areas was low, the transgression was rapid, leaving only a thin section of back-barrier sediments overlain by thin shoreface sands and topped by offshore claystones (Fig. 6, Jeppe-1) (Johannessen *et al.* 1996; Johannessen 2003).

The upper parts of the shoreface sandstones are back-stepping and are overlain by offshore claystones of the Lola Formation in the

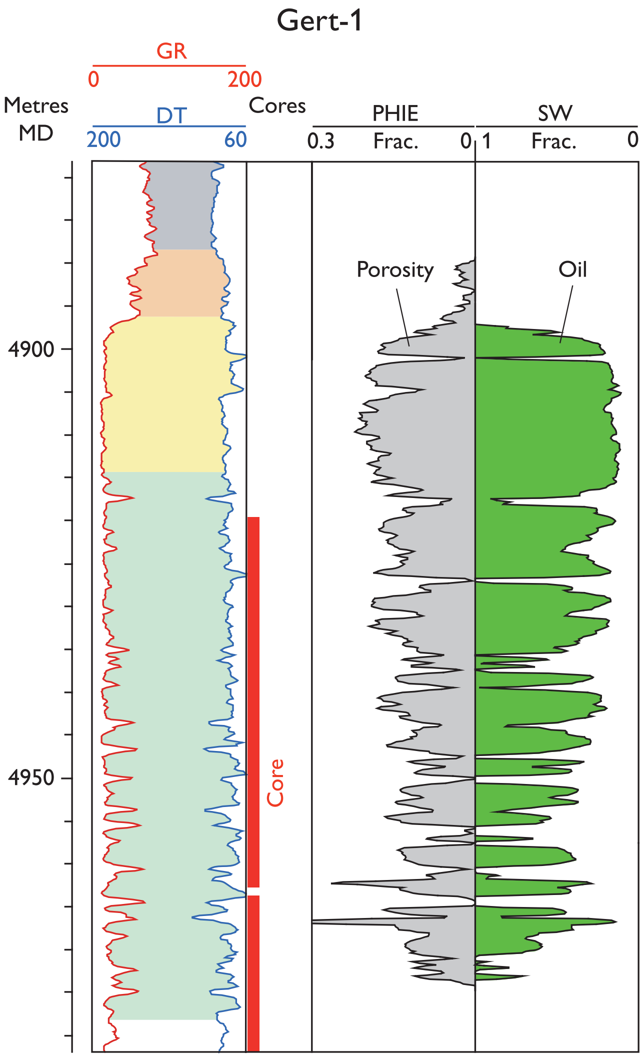

Fig. 11. Porosity and oil saturation plot for back-barrier and shoreface sandstones of the Gert Member in the Gert-1 well. PHIE is the effective porosity (highlighted by grey colour fill) as interpreted from the well log data. SW is the water saturation estimated on the basis of the porosity evaluation, resistivity log data and a set of petrophysical parameters representing the sandstone layers. The oil saturation (green colour fill) is calculated as 1-SW. For legend see Figure 7.

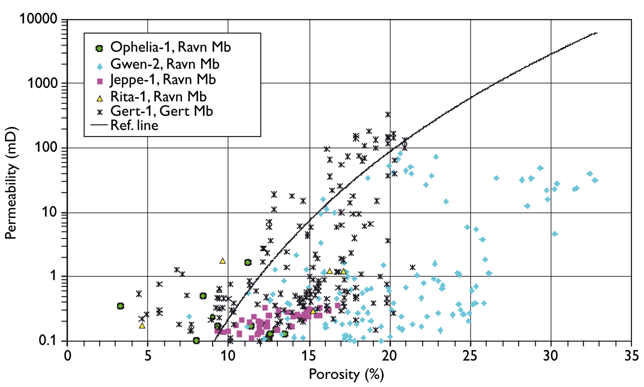

Fig. 12. Porosity–permeability relationship: shoreface to paralic sandstones of the Heno Formation (Gert and Ravn Members), cored in selected wells. The plot is based on conventional core analysis data from the wells Gert-1 (Gert Mb); Ophelia-1, Gwen-2, Jeppe-1 and Rita-1 (Ravn Mb). The trend line is from Figure 17 and plotted for reference.

Table 1. Formation pressures of the Svane-1, Hejre-1 and Gert-1 well

Well	Approximate depth (m)	Formation pressure (psi)	Hydrostatic pressure (psi)	Overpressure (psi)	Temperature (°C)
Svane-1	5350	16 530	7900	8630	180
Hejre-1	5100	16 740	7530	7020	165
Gert-1	4900	14 000	7200	6800	155

basin areas (Figs 6 & 7). On the higher plateaus, the water depth was too shallow and energy levels too high for deposition of clay and thus sandstones were deposited here, for example, Jeppe-1 (Fig. 6).

Upper Kimmeridgian shallow marine sandstones

Distribution and stratigraphy. The sandstones referred to the Ravn Member (Fig. 2) (Michelsen *et al.* 2003) were deposited in the same areas as the Gert Member, later during the Late Kimmeridgian (Fig. 9c–e) (Johannessen *et al.* 1996; Andsbjerg & Dybkjær 2003; Johannessen 2003). The succession is represented by cores in the Rita-1, Ophelia-1, Jeppe-1 and Gwen-2 wells in this paper (Figs 6 & 7).

Depositional environment. Deposition of the regressive shoreface and deltaic sandstones of the Ravn Member followed the transgression during which the paralic and shoreface sandstones of the Gert Member were deposited (Fig. 9c–e). In general, they consist of intensely bioturbated shallow marine sandstones. The lowest part is prograding whereas the uppermost part is retrograding (Johannessen *et al.* 1996; Johannessen 2003). This vertical trend is also seen in the Norwegian and UK sectors in the time equivalent Ula and Fulmar Formations, respectively (Bergan *et al.* 1989; Howell *et al.* 1996; Mackertich 1996). A conglomerate bed, 0.2–2 m thick, marks the maximum regression which can be mapped over a large area (Fig. 9c). The shoreface sandstones are often thick and very widespread. The best reservoir sands are developed on the Heno and Gertrud Plateaus and shale out towards the Feda and Tail End Grabens.

The 50 m long core in the Rita-1 well, situated at the SW margin of the Feda Graben, covers much of the Ravn Member interval (Figs 6 & 13). At the base it consists of a 25 m thick coarsening upward claystone to clayey sandstone succession, which represents a distal offshore to offshore-shoreface transition from the Lola Formation to the Ravn Member. This succession is truncated by a prominent erosion surface in the middle of the core, above which the deposits grade into a succession of stacked, variably developed, coarsening upward, 1–4 m thick parasequences. Figure 13 illustrates a section of the core, which contains many of the characteristic features for these sediments: the base of a parasequence typically consists of sporadically bioturbated interlaminated mud and sand, which grades upward into bioturbated heterolithic bedding and further into clayey and pebbly sand at the top of the parasequences (Figs 10d & 13). The dominance of elements of distal and archetypal *Cruziana* ichnofacies (Fig. 10d) (MacEachern *et al.* 2008) coupled with high clay content even in high-energy facies in these successions is interpreted to reflect a downdrift offshore–lower shoreface setting.

Ophelia-1, located on the Heno Plateau, has a 27 m thick core consisting typically of variably developed 1–6 m thick parasequences (Fig. 13). Some typical recurring features of these sediments are shown in Figure 13, and include the following elements: the lower part of a sequence may contain interlaminated clay and sand or heterolithic climbing combined-flow ripple cross-stratification. The heterolithic intervals display occasional double

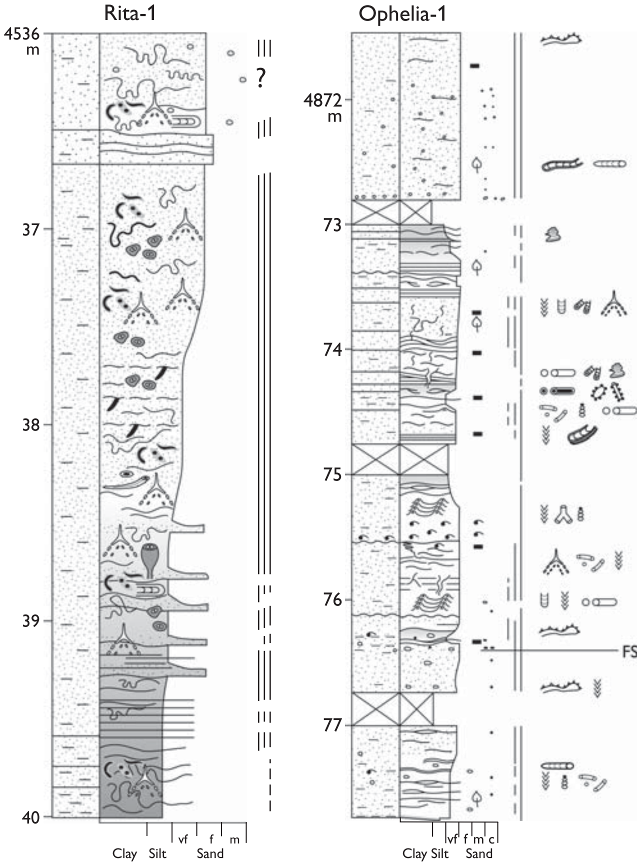

Fig. 13. Detailed sedimentological core logs of Ravn Member intervals in Rita-1 and Ophelia-1 wells. The Rita-1 interval demonstrates an intensively bioturbated coarsening upward parasequence. The sediments are characterized by abundant soft sedimentary deformation structures, relict sand–clay couplets, and pervasive deposit feeding trace fossils such as *Asterosoma* and *Chondrites*. The succession is interpreted to reflect a downdrift offshore–lower shoreface setting. The illustrated Ophelia-1 interval is interpreted to show, for example, common tempestite intervals interbedded with tidal and wave-influenced, heterolithic fair weather facies. The interval is interpreted as mixed-influenced delta front. See Figure 16 for symbols.

mud-drapes and subdued trace fossil diversity, which is interpreted to indicate tidal and possibly local brackish water influence. Upwards, these deposits begin to alternate with erosionally based, planar-laminated and low-angle cross-stratified, decimetre-scale sandstone intervals, which are interpreted as tempestites. On the top of the parasequence, the sediments further grade or are abruptly overlain by a 1–3 m thick succession of sporadically bioturbated, massive, graded and parallel-laminated sandstone beds, which contain locally thick mud-drapes and dispersed conglomerates. In general, Ophelia-1 sediments are interpreted to represent various storm-, wave- and tide-influenced deltaic and proximal offshore environments (Figs 10c & 13).

Reservoir characteristics. Porosities exceeding 15% are interpreted from log data acquired in the Jette-1 and Gwen-2 wells, located on the Gertrud Plateau (Fig. 1). Highly porous sandstone beds, having porosities in the range 20–30%, are interpreted in the upper part of the Ravn Member in Jette-1. The net sand thickness is *c.* 40 m, but despite good reservoir quality it is not hydrocarbon bearing. Similarly in Gwen-2, the presence of *c.* 20 m net sand with porosities exceeding 20% is verified by log and core data, and it is noteworthy that the permeability range is large (0.1–100 mD) (Fig. 12). This range is presumably related to varying clay content and the presence of cement in the sandstone matrix.

In a large number of wells situated on the Gertrud Plateau and in the Feda Graben, the Ravn Member is characterized by rather poor reservoir properties, as the sandstones may be cemented by calcite and, moreover, the pores are to some extent filled with diagenetic clay (illite). In such tight Ravn Member reservoirs, the porosity is generally below 15% and the permeability is in the range 0.1–1 mD, as observed in the cores from Ophelia-1, Jeppe-1 and Rita-1 (Fig. 12). A low-porosity Ravn Member has also been encountered in the 2/12-1, Gert-1 and Hejre-1 wells. Despite such low porosities in the Ravn Member reservoir, oil has been encountered in both the Ophelia-1 and Rita-1 wells. It appears that the back-barrier and shoreface sandstones of the Gert Member in general have a better reservoir potential than the shoreface sandstones of the Ravn Member.

Palaeogeography. Regressive to transgressive shoreface sandstones of the Ravn Member were deposited during the Late Kimmeridgian on the Gertrud and Heno Plateaus and cover a large area of the northern Central Graben (Fig. 9c–e). The plateaus were flanked by two deep, broad graben areas: the Feda Graben to the NW and the Tail End Graben to the SE. The basal regressive shoreface sandstones were probably formed due to a pause in fault activity and subsidence (Andsbjerg & Dybkjær 2003). Subsequently, the shoreface sandstones back-stepped during renewed subsidence (Fig. 9d). The shoreface sandstones of the Ravn Member are comparable to Upper Jurassic sandstones of the UK Fulmar and Norwegian Ula Formations (Fraser *et al.* 2003). At this time, the Mid North Sea High reached as far east as the Inge and Mads Highs and contributed much of the sand to the Heno and Gertrud Plateaus, although sand was probably also derived from the Mandal High, NE of the Gertrud Plateau (Fig. 9c–e). Farther out in the basins, claystones of the Farsund Formation were deposited.

In the latest Kimmeridgian, the previously positive Heno and Gertrud Plateaus were transgressed both from the NW from the Feda Graben and from the SE from the Tail End Graben. Later the Gertrud Plateau began to subside and was thus transformed into a graben (henceforth the Gertrud Graben) (Japsen *et al.* 2003; Møller & Rasmussen 2003).

Upper Kimmeridgian to Lower Volgian gravity-flow sandstones

Distribution and stratigraphy. Thin sandstone units, 0.1–5 m thick, are interbedded with the offshore claystones of the Farsund Formation in the Tail End Graben (Svane-1 and Amalie-1) and the Søgne Basin (Lulu-2, Cleo-1 and 3/7-6) (Figs 6–8 & 9c–f). The sandstones are probably of Late Kimmeridgian to Early Volgian age, but are poorly dated.

Depositional environment. In the Lulu-2 well, two sandstone beds (2 and 5 m thick respectively) are encountered. A 36 m long core shows that the sandstones are fine-grained and interbedded with parallel laminated, mostly non-bioturbated claystones. The two sandstones are mostly structureless, but cross-lamination has been observed locally. Thin siltstone and very fine-grained sandstone laminae are often slumped. Partial Bouma sequences occur. The siltstones and fine-grained sandstones were probably deposited from turbidity currents while anoxic conditions prevailed at the sea-bottom. The sediments have also undergone slump processes (Johannessen 1997).

In the Svane-1 well in the Tail End Graben, the GR and sonic logs show four sandy units, *c.* 40–125 m thick. The log patterns are very serrated and blocky and are similar to those in the

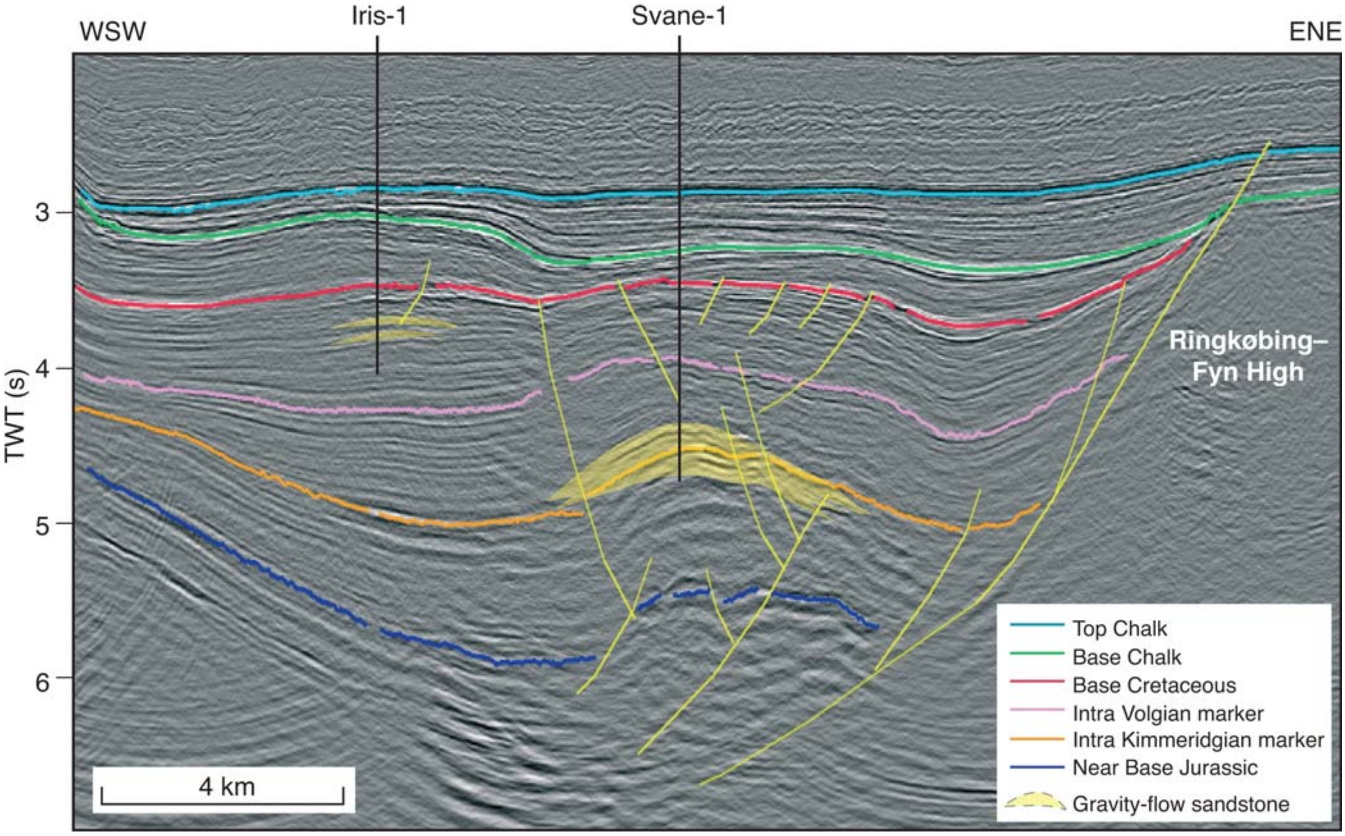

Fig. 14. Seismic section across the Tail End Graben through the Iris-1 and Svane-1 locations highlighting the location of the gravity-flow sandstones. For location see Figure 1.

Norwegian 3/7-6 well in the Søgne Basin (Fig. 8). A 10.5 m long core from the 3/7-6 well shows thin centimetre-scale sandstone beds within offshore claystones of the Farsund Formation (Oljedirektoratet 2009). The clay and sandstones are non-bioturbated and were probably deposited from turbidity currents. Thus it is assumed that the sandstones in the Svane-1 also were deposited from turbidity currents. The Svane-1 well is almost 6000 m deep and located on a four-way dip closed structure with seismic amplitude anomalies encountering the sandstone-bearing successions below 5300 m (Fig. 14).

In the Amalie-1 and Cleo-1 wells, lying between the Svane-1 and 3/7-6 locations, thin sandstone beds of inferred turbidite origin occur interbedded within claystones of the Farsund Formation (Fig. 8). This could imply that the turbidite sandstones of the Svane-1 may well have been derived from the north, from the Søgne Basin (Fig. 9c–f). The sandstones could alternatively have been derived from the east, from the Ringkøbing–Fyn High.

The lowermost part of the Upper Jurassic section in the Amalie-1 well encounters three gas-bearing massive sandstone beds, 5–8 m thick, with no upward coarsening or fining grain-size trends, probably deposited by gravity-flow processes (Figs 2 & 8). They are Oxfordian in age (Andsbjerg & Dybkjær 2003).

Reservoir characteristics. The Svane-1 well has proved the presence of gas in sandstones at *c*. 6 km depth. The net sand thickness is greater than 150 m in the Svane-1 and the 3/7-6 wells. No core data are available from the Svane-1 well, but locally relatively high porosities up to 15–20% at a depth of almost 6000 m have been interpreted from log data in certain intervals. The reservoir sandstones are gas-charged and a DST conducted in the lower part of the well flowed 2.3 MMscf of gas per day; the DST tested a net sand interval of *c*. 100 m. The reservoir quality sandstones of the Svane-1 well are situated in a HTHP environment with overpressures of 8600 psi (Table 1). The substantial overpressures at a depth of 5350 m signify that the pore pressure is close to the fracture pressure.

The thin gas-bearing cored sandstone interval in Lulu-2, located at a depth of 3500 m, shows porosities up to 23% and permeabilities up to 100 mD, but these data may not be representative of the turbidite sandstones in general in this area.

Palaeogeography. During the Late Kimmeridgian to Early Volgian the Tail End Graben and Søgne basin subsided and thick offshore mudstones of the Farsund Formation were locally intercalated with gravity-flow sandstones (Fig. 9c–f). Sand may have been derived from the Ringkøbing Fyn High to the east, forming marginal fans, and from the north, from the Søgne Basin and Mandal High, producing basin-axial gravity-flow systems.

Lower Volgian shoreface sandstones

Distribution and stratigraphy. Shoreface sandstones, informally termed the 'Outer Rough Sand', were deposited in the Early Volgian on the eastern part of the Mid North Sea High, where the Outer Rough Basin began to subside. The 'Outer Rough Sand' is documented by the Saxo-1 and Wessel-1 wells in the Danish sector (Figs 2 & 9f). The wells are located on separate tilted fault blocks on the flanks of the Mid North Sea High about 3 km apart (Fig. 15). The shoreface sandstones of the Saxo-1 and Wessel-1 wells have now been very precisely dated to Early Volgian (Scitulus to Pectinatus Zones), deposited within a period no longer than 1.4 million years (Fig. 5). At this time the sand source area of the Mid North Sea High was situated in the easternmost part of the UK sector (Fig. 9f).

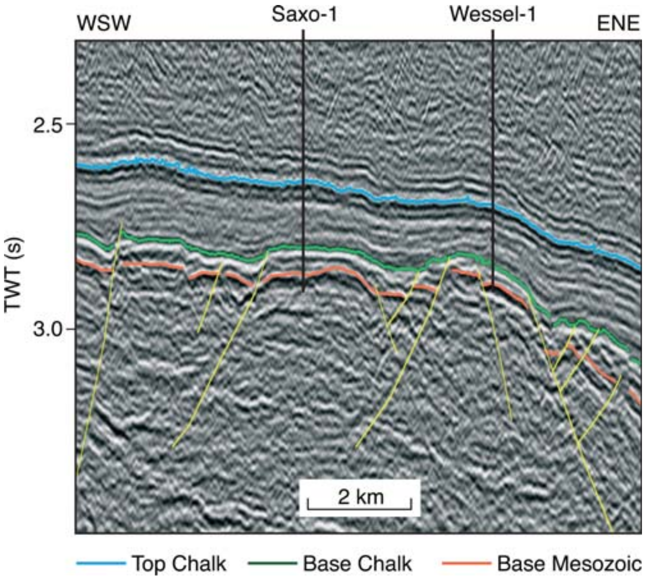

Fig. 15. Seismic section through the Saxo-1 and Wessel-1 locations on the flank of the Mid North Sea High. The Volgian sandstone intervals are close to seismic resolution. For location see Figure 1.

Depositional environment. The Saxo-1 core records a 65 m thick succession of moderately to well sorted, fine- to medium-grained sandstones (Fig. 16). The sandstones are organized into variably developed, 2–12 m thick, coarsening upward or aggrading parasequences that are generally interpreted to represent shoreface complexes. This interpretation is supported by abundant elements of the *Skolithos* ichnofacies, occurrences of *Macaronichnus* in the top parts of the parasequences, well-sorted sandstones and local tangentially cross-stratified intervals, which in concert are consistent with a high-energy, wave-dominated shoreface setting (Figs 10e & 16).

The Wessel-1 core records a 8 m thick succession of fully bioturbated, fine- to medium-grained sandstones, which are locally intercalated with few centimetre- to decimetre-thick (extraformational) pebble rich intervals. These deposits are organized into sharp-based *c.* 1 m thick aggrading parasequences, which are typically burrowed with abundant *Macaronichnus* burrows. Elements of *Skolithos* ichnofacies (e.g. *Diplocraterion*, *Palaeophycus*, vertical shafts) are also present in several parasequences, but their occurrence is limited to certain intervals (brief colonization windows for suspension feeders). At the top, the parasequences are capped by prominent erosive hiatal surfaces. The hiatal surfaces are typically burrowed with spreite-bearing trace fossils and locally of passively filled vertical burrows forming *Glossifungites* ichnofacies demarcated surfaces. The deposits are interpreted to represent low-accommodation space shoreface successions in a tectonically complex setting.

The reservoir thickness decreases rapidly from 65 m in the Saxo-1 well to less than 10 m in Wessel-1, 3 km towards the NE (Fig. 7). Towards the west (11 km) to the UK well 39/2-2 of the Fergus Field and towards the NW (15 km) to the UK Fife Field, the shoreface sandstones increase in thickness (*c.* 125 m thick) and are dated to be of Late Kimmeridgian to Middle Volgian age (Figs 1 & 7) (Fraser *et al.* 2003). This indicates that the regional sand source area and most of the accommodation space was located to the west on the Mid North Sea High and that shoreface sands prograded towards the east into the Outer Rough Basin (Fig. 9f). Detailed studies of shoreface sandstones in the British Fife Field area shows that they prograded four times: twice towards the SW and twice towards the SE (Currie *et al.* 1999).

No sandstone was encountered in the remaining wells in the Danish part of the Outer Rough Basin. The offshore claystones of the Farsund Formation in the Liva-1, Tordenskjold-1 and Lilje-1 wells were deposited at the same time as the prograding shoreface sandstones in the Saxo-1 and Wessel-1 wells (Fig. 9f).

In the Ål Basin area and the area north of the Inge High and the SW margin of Feda Graben, the Kim-1, Lone-1 and Rita-1 wells show an upward coarsening succession overlain by an upward fining succession in the Lower Volgian claystones of the Farsund Formation (Fig. 6). This regressive–transgressive trend in the claystone successions may reflect the distal signal of a shoreface sand progradation and retrogradation from west, but not reaching these wells.

Parts of the Inge High must have been submerged, as Lower Volgian claystones of the Farsund Formation are recorded in the Isak-1 well (Figs 7 & 9f). As Permian Rotliegend strata are unconformably overlain by Upper Cretaceous sediments in the P-1 well, Jurassic sediments were either not deposited or later eroded in this part of the high.

Reservoir characteristics. The 'Outer Rough Sand' is generally characterized by good to excellent reservoir properties. The porosity range is 19–31% in the two UK oil fields, but they differ with respect to permeability; in the Fergus Field the average permeability of the sandstones is about 500 mD whereas in the Fife Field it is less than 100 mD (Fig. 17) (Shepherd *et al.* 2003). The sandstones of the Saxo-1 well display porosities as high as 22–33% and the average permeability is about 1000 mD (range 500–2500 mD) but it is not oil-bearing (Fig. 17). The average permeability of the reservoir sandstone in Saxo-1 is thus higher than observed in the Fergus Field. The reservoir properties of the 'Outer Rough Sand' deteriorate in an easterly direction.

Palaeogeography. During the Early Volgian, the Outer Rough Basin (eastern margin of the Mid North Sea High) probably began to subside and shoreface sandstones ('Outer Rough Sand') were deposited while the rest of the Danish Central Graben was subsiding and offshore claystones were deposited except the Inge and Mads Highs, which probably formed sub-aerial intra-basinal highs (Fig. 9f). The sand was derived from the Mid North Sea High and the shoreline was located farther west in the eastern part of the UK sector. The 'Outer Rough Sand' was probably in connection with the shoreface sandstones of the Fulmar Formation in the UK sector (Fig. 9f).

Upper Middle Volgian to Ryazanian gravity-flow sandstones

Distribution and stratigraphy. After deposition and drowning of Lower Volgian shoreface sandstones on the eastern margin of the Mid North Sea High offshore, claystones of the Farsund Formation, locally intercalated with gravity-flow sandstones, were deposited in the Danish Central Graben (Fig. 9g). Gravity-flow sandstones have been recorded in the Tail End Graben, Arne-Elin Graben, Poul Plateau, Gertrud Graben, and the southern part of the Heno Plateau NE of the Mads High (Figs 1 & 9g) (Damtoft *et al.* 1992; Johannessen 1997; Andsbjerg & Dybkjær 2003; Michelsen *et al.* 2003). No shallow marine sandstones were deposited.

Depositional environment. Cores from the Tabita-1 well in the Tail End Graben include a 20 cm thick quartz clast-supported conglomerate bed with clast sizes up to *c.* 1 cm and also contain several claystone clasts up to 4 cm in length (Fig. 10b). The conglomerate has a sharp boundary at the base and top to the non-bioturbated claystones of the Farsund Formation. Abundant outsized quartz

Fig. 16. Sedimentological core log of 'Outer Rough Sands' in the Saxo-1 well. The deposits are interpreted to represent stacked shoreface complexes. Note the common occurrence of elements of the *Skolithos* ichnofacies (e.g. *Ophiomorpha, Diplocraterion* and *Skolithos*) and *Macaronichnus*, which are all consistent with high-energy wave-dominated settings.

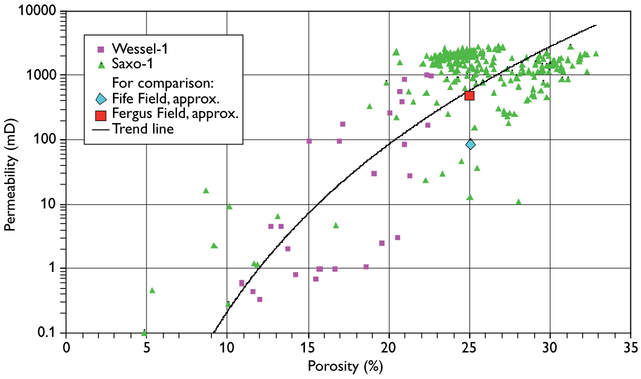

Fig. 17. Porosity–permeability relationship for shoreface sandstones of the 'Outer Rough Sand' on the eastern flank of the Mid North Sea High. The plot is based on conventional core analysis data from the Wessel-1 and Saxo-1 wells supplemented with average values applying to the Fife and Fergus Fields in the UK sector (Shephard *et al.* 2003). The solid trend line represents the assumed porosity–permeability relation.

clasts, up to 1.5 cm, are often seen in the claystones in different concentrations, sometimes clast-supported and sometimes matrix-supported. The relatively large amount of outsized quartz clasts indicates that coarse-grained sediments were available in or at the margins of the basin, thus it may be possible to find thick coarse-grained reservoir sandstones in the basin. The clay clast conglomerates in cores show at least four types of claystone lithologies which may have been derived from different areas and may represent different ages. The conglomerates were deposited by a range of gravity-flow processes. Amalie-1, situated *c.* 3 km north of the Tabita-1 well, contains thin sandstone beds probably also of gravity-flow origin and of similar age (Figs 8 & 9g).

Sandstones and siltstones deposited by gravity-flows are also represented in cores in the upper part of the Farsund Formation in the Iris-1 well located in the axis of the Tail End Graben (Figs 7, 9g & 14) (Damtoft *et al.* 1992; Johannessen 1997). Quartz conglomerate beds, 5 cm thick, with clast size of up to 2 cm, occur within the claystones of the Farsund Formation. In addition, large claystone clasts up to 6 cm have been observed.

The sandy succession within the organic-rich claystones of the Bo Member in the Jeppe-1 well is cored and is dominated by packets of thin non-bioturbated sandstone–mudstone turbidites interbedded with hemi-pelagic laminae and beds (Figs 6 & 9g) (Ineson *et al.* 2003). Medium-grained sandstone turbidites and debris flows 5–20 cm thick, and sandstone-mudstone slump sheets 10–15 cm thick are also seen. Small-scale, 1–10 cm, sand injections is the main post depositional modification of the sandstones (Ineson *et al.* 2003). The slump sheets and debris flow sandstones and mudstones were deposited on intra-basinal slopes in the vicinity of Jeppe-1 and were probably derived from the Gert Ridge, 2 km west of Jeppe-1. Here locally exposed, uplifted fault slices of shoreface sandstones of the Heno Formation may have been eroded and transported into the basin (Ineson *et al.* 2003). Sandstones, *c.* 10 m thick, are recorded above the claystones of the Farsund Formation and the organic-rich shales of the Bo Member in the Gwen-2 well (Figs 7 & 9g). They were probably deposited by gravity-flows (Johannessen *et al.* 1996).

High-amplitude seismic horizons with high acoustic impedance values have been interpreted to represent sand-rich turbidites preserved in hanging-wall blocks in the depocentres of the Gertrud Graben and are correlated to the turbidites in Jeppe-1 (Fig. 9g) (Rasmussen *et al.* 1999; Gregersen & Rasmussen 2000). Thus these turbidite sandstones may have derived from the Gert Ridge as the turbidite sandstones of the Jeppe-1 well.

Reservoir characteristics. In both in the Jeppe-1 and Tabita-1 cores, oil shows have been encountered in the gravity-flow sandstones.

Palaeogeography. Deposition of offshore claystones of the Farsund Formation completely dominated the Danish Central Graben in Late Middle Volgian to Ryazanian times (Fig. 9g) (Ineson *et al.* 2003). The wells in the Danish part of the Søgne Basin do not encounter Middle to Upper Volgian and Ryazanian sediments (Andsbjerg & Dybkjær 2003; Møller & Rasmussen 2003). This may indicate a Middle to Late Volgian inversion and erosion of the Søgne Basin and Mandal High areas, which may have given rise to gravity-flow sandstones towards south in the Tail End Graben and SW in the eastern side of the Gertrud Graben. Sand may also have been shed from the Ringkøbing–Fyn High from the east forming marginal fans. Organic-rich claystones of the Ryazanian Bo Member of the Farsund Formation were deposited over most of the Danish Central Graben with the exception of the easternmost part along the Ringkøbing Fyn High, probably because of large sediment input diluting the organic matter (Figs 2 & 9g) (Dybkjær 1998; Ineson *et al.* 2003).

Conclusions

New released wells and detailed sedimentological studies of new cores, together with new biostratigraphic datings, have added to our understanding of the depositional history of the Upper Jurassic succession in the northern part of the Danish Central Graben. The depositional model has been re-evaluated and summarized as a series of palaeogeographic maps covering the Late Kimmeridgian to Ryazanian interval. New wells drilled on the Heno and Gertrud Plateaus during the last 5–8 years overall confirm the earlier published interpretations of the depositional environments and distribution of paralic to shallow marine sandstones of the Upper Kimmeridgian Heno Formation (Gert and Ravn Member) and thus prove the general applicability of the depositional model. However, new core data has revealed that the shoreface sandstones of the Heno Formation are more heterogeneous than previously considered, displaying substantial variability in claystone content. This variability is interpreted to be caused by the interplay between shoreface sandstones, location of deltas and long-shore current directions. The down-drift shoreface sandstones may show particularly diminished vertical permeability comparing to their up-drift counterparts due to abundant clay-drapes characteristic for these deposits. Moreover, as much of the mudstones are derived from a continental setting in the down-drift examples, the quantity of TOC may be variable in these strata. Further work in the area should include mapping of the river mouth locations so that these reservoir quality controlling factors could be predicted. The discovery of the Freja and Hejre Fields proves that Upper Jurassic reservoir quality sandstones of the Gert Member exist at great depths (5000 m or even deeper). In particular, the discovery of the Hejre accumulation triggered renewed interest in Upper Jurassic HTHP sandstone plays in the area.

Thick, porous shoreface sandstones of the Lower Volgian 'Outer Rough Sand' in the Danish Outer Rough Basin at the margin of the Mid North Sea High are documented east of the equivalent sandstones of the UK Fulmar Formation. The palaeogeographic understanding of this westernmost Danish area may help to a more focused exploration of the reservoir potential in the Outer Rough Basin.

Gravity-flow sandstones intercalated in offshore claystones were mainly deposited during two periods: (1) Late Kimmeridgian to Early Volgian in the Tail End Graben and the Søgne Basin; and (2) Late Middle Volgian to Ryazanian in the central part of the Tail End Graben and along the Ringkøbing–Fyn High, in the

Gertrud Graben and in the southern part of the Heno Plateau NE of the Mads High. In some cases these gravity-flow sandstones are situated within or near the organic-rich offshore shales of the upper Middle Volgian–Ryazanian Bo Member, which is an excellent source rock. Surprisingly good reservoir quality of the gravity-flow sandstones at almost 6000 m of depth has been encountered in the Svane-1 well.

The frequent occurrence of gravel- to pebble-sized quartz clasts throughout the Upper Jurassic in shoreface sandstones, gravity-flow sandstones and in the offshore mudstones all over the Danish Central Graben shows that there were coarse clastic sediment source areas nearby. The challenge is to predict where these coarse-grained sediments have been deposited in thick successions where they probably will constitute good reservoirs.

Jon R. Ineson is thanked for stimulating discussions, critical reading of an early version of the text and major improvements to the English. We also thank Lars Hamberg and two anonymous reviewers for their constructive comments.

Abstract: An unusually thick (*c.* 88 m), transgressive barrier island and shoreface sandstone succession characterizes the Upper Jurassic Heno Formation reservoir of the Freja oil field situated on the boundary of Denmark and Norway. The development and preservation of such thick transgressive barrier island sands is puzzling since a barrier island typically migrates landwards during transgression and only a thin succession of back-barrier and shoreface sands is preserved. Investigation of the development and geometry of the Freja reservoir sandstones is problematic since the reservoir is buried *c.* 5 km and seismic resolution is inadequate for architectural analysis. Description of the reservoir sandstone bodies is thus based on sedimentological interpretation and correlation of seven wells, of which five were cored. Palaeotopography played a major role in the position and preservation of the thick reservoir sandstones. Using the nearest maximum flooding surface above the reservoir as a datum for well-log correlations, the base of the barrier island succession in the wells is reconstructed as a surface with steep, seaward-dipping palaeotopography. The relief is *c.* 270 m over a distance of *c.* 8 km and dips WNW.

As a complementary approach to investigation of the reservoir architecture, a Holocene–Recent barrier island system in the Danish part of the NW European Wadden Sea has been studied and used as an analogue. The barrier island of Rømø developed during a relative sea-level rise of *c.* 15 m during the last *c.* 8000 years and is up to 20 m thick. To unravel the internal 3D facies architecture of the island, an extensive ground penetrating radar (GPR) survey of 35 km line length and seven cores, *c.* 25 m long, was obtained. Although the barrier island experienced a rapid relative sea-level rise, sedimentation kept pace such that the island aggraded and even prograded seawards and became wider and longer due to the large surplus of sand.

Keywords: barrier island sandstones, Central Graben, Upper Jurassic palaeotopography, Freja–Mjølner Field, modern analogue

Back-barrier and shoreface sandstones (88 m thick in the Gert-1 well) constitute the reservoir in the Freja commercial oil field, which lies on the border between Denmark and Norway in the northern part of the Danish Central Graben (Fig. 1) (Johannessen 2003; Johannessen *et al.* 2010). The Freja discovery is expected to contain oil reserves of about 1 000 000 m^3 (Danish Energy Agency 2008). Oil saturations are up to 80% in the Gert-1 well where the sandstone permeability is generally less than 100 mD and the porosity is 10–20% (Figs 2 & 3). Feldspar dissolution has increased the porosity. The depth of the reservoir is *c.* 4900 m. Formation pressure is *c.* 14 000 psi; hydrostatic pressure is 7200 psi and overpressure is 6800 psi. Reservoir temperature is 155°C.

The Norwegian part of the discovery is called the Mjølner Field. The Norwegian 2/12-1 well encounters a 71 m thick primarily shoreface sandstone succession at a depth of 4600 m containing oil (Söderström *et al.* 1991). The porosity is higher than normal at such depths, probably because of the high pressure in the reservoir (Söderström *et al.* 1991).

Well-constrained reservoir models are mandatory for effective drainage of trapped hydrocarbons. As the sandstone reservoir of the Freja discovery is situated in a structurally complex area at great depths, the seismic resolution is low, *c.* 50 m (Rasmussen 1995). Consequently, it is necessary to make a sedimentological and stratigraphical interpretation based on cores and well logs to make a model of the sand distribution in the Freja discovery.

Unusually thick back-barrier sediments, 70 m thick, are encountered in the Gert-1 well. Normally barrier island systems are considered to migrate landwards during transgressions, mainly by washover events breaching the subaerial barrier during storm episodes and depositing washover fans in the back-barrier lagoon (Elliott 1986). Storm-induced erosion also transports barrier island sand seaward where the sand is deposited as storm sand beds. With continued sea-level rise, the barrier–lagoonal system moves in a landward direction leaving only a relatively thin sand succession behind, owing to transgressive erosion.

How then were such thick transgressive back-barrier sandstones developed and preserved in the Freja discovery? To answer this question two studies have been carried out, an analogue study of the Holocene–Recent barrier island of Rømø and an analysis of the palaeotopography of the Freja discovery area.

Ongoing well documented studies of the Rømø barrier island show that it has aggraded during a relative sea-level rise of *c.* 15 m during the last *c.* 8000 years and consists of 10–15 m thick barrier island and back-barrier sediments (Johannessen *et al.* 2008). The present-day physiographic setting and depositional processes are well known (Lumborg & Pejrup 2005; Madsen *et al.* 2007; Johannessen *et al.* 2008). Rømø is thus an ideal place for direct analogue studies which can be used in the Freja discovery area.

Although the barrier island experienced a rapid relative sea-level rise, sedimentation kept pace and the island aggraded and even prograded seawards and also became wider and longer due to the large surplus of sand. The internal architecture has been characterized using cores from seven wells and 35 km of GPR lines (Nielsen *et al.* 2009).

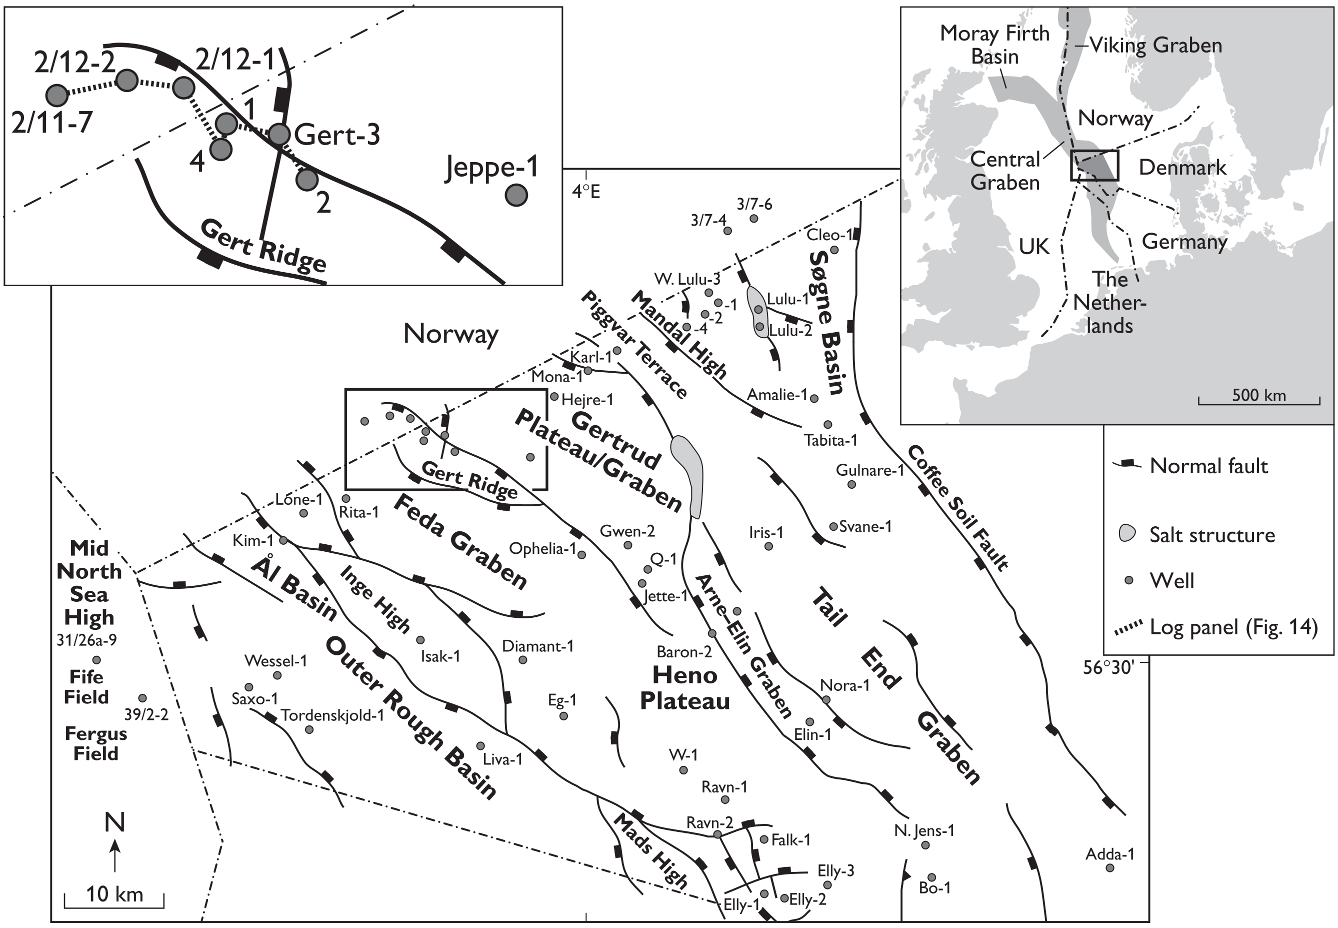

Fig. 1. Map of the Danish Central Graben showing structural elements and location of wells in the Freja–Mølner Field. Major Upper Jurassic to Lower Cretaceous faults are shown.

To explain the thick barrier island sandstones in the Freja discovery, it is also necessary to consider the palaeotopography which was inundated during the Late Jurassic transgression. A steep topography would have forced the stacking of thick barrier island and shoreface sandstones and lagoonal sediments if large amounts of sediment were available. Using the nearest maximum flooding surface above the reservoir as a datum line for well-log correlations, the base of the barrier island succession in the wells outlines a surface with steep, seaward-dipping palaeotopography.

The Holocene–Recent Rømø barrier island system

The Holocene–Recent Rømø barrier island situated in the Danish part of the Wadden Sea in the SE part of the North Sea developed on a gently westward dipping Weichselian outwash plain of fluvial sand that was transgressed by the sea due to the rapid Holocene sea-level rise (Fig. 4). A hiatus (*c.* 13 000–8000 BP) separates the Holocene marine sediments from the underlying fluvial sand.

Morphology and depositional environments

The advantage of using the micro-tidal Rømø barrier island as a reservoir analogue is that modern sedimentary processes and environments, geomorphology and historical development are very well known (Fig. 5) (e.g. Bartholdy & Pejrup 1994; Lumborg & Pejrup 2005). The island is *c.* 14 km long, *c.* 4 km wide and up to 20 m thick and separated from the mainland by a *c.* 8 km wide lagoon (Fig. 5). Tidal inlets, *c.* 1 km across and up to 30 m deep, occur at the northern and southern tips of the island. The inlets continue as tidal channels into the lagoon where shallow creeks cut sand flats and mixed flats. Subtidal ebb-deltas are located where the tidal inlets terminate in the North Sea (Fig. 5). The NE and SE part of the Rømø lagoonal coast consists of salt marsh up to 2 km wide. The NW and SW parts of the island are characterized by sandflats, up to 2.7 km wide, with four broad (0.8–1.6 km) swash bars separated by three tidal troughs (up to *c.* 50 m wide) migrating towards the island (Fig. 6). Aeolian dunes are found on large parts of the island. The spring tidal range is 2 m. Westerly winds with a fetch of *c.* 800 km dominate and, during strong wind setup, the water level increases considerably, up to 5 m above mean sea-level. Storm surges break through beach ridges and aeolian dunes and, in the initial stages of island development, when the island was narrow, numerous washover fans were deposited in the back-barrier lagoon. During the last 3000–5000 years, the island has been too wide to be fully breached and thus washover deposits accumulated between old beach ridges.

Methods

To investigate the internal 3D facies architecture of the *c.* 8000-year-old Rømø barrier island, seven cores, each up to *c.* 25 m long, were taken (Figs 6 & 7). Sedimentary units were defined and interpreted on the basis of sediment texture and structures, bedding, organic content, macrofauna and palynomorphs. To facilitate correlations between the cored wells, a survey of 35 km of GPR profiles was carried out (Fig. 6) (Johannessen *et al.* 2008; Møller *et al.* 2008; Nielsen *et al.* 2009). Maximum signal penetration is *c.* 15 m with a resolution of 0.2–0.3 m. The interpreted sedimentary environments based on the entire dataset are compared with the recent environments of the barrier island. This full-scale ‘natural laboratory’ gives a unique dataset which may be used as an analogue for deeply buried hydrocarbon reservoirs where data are limited.

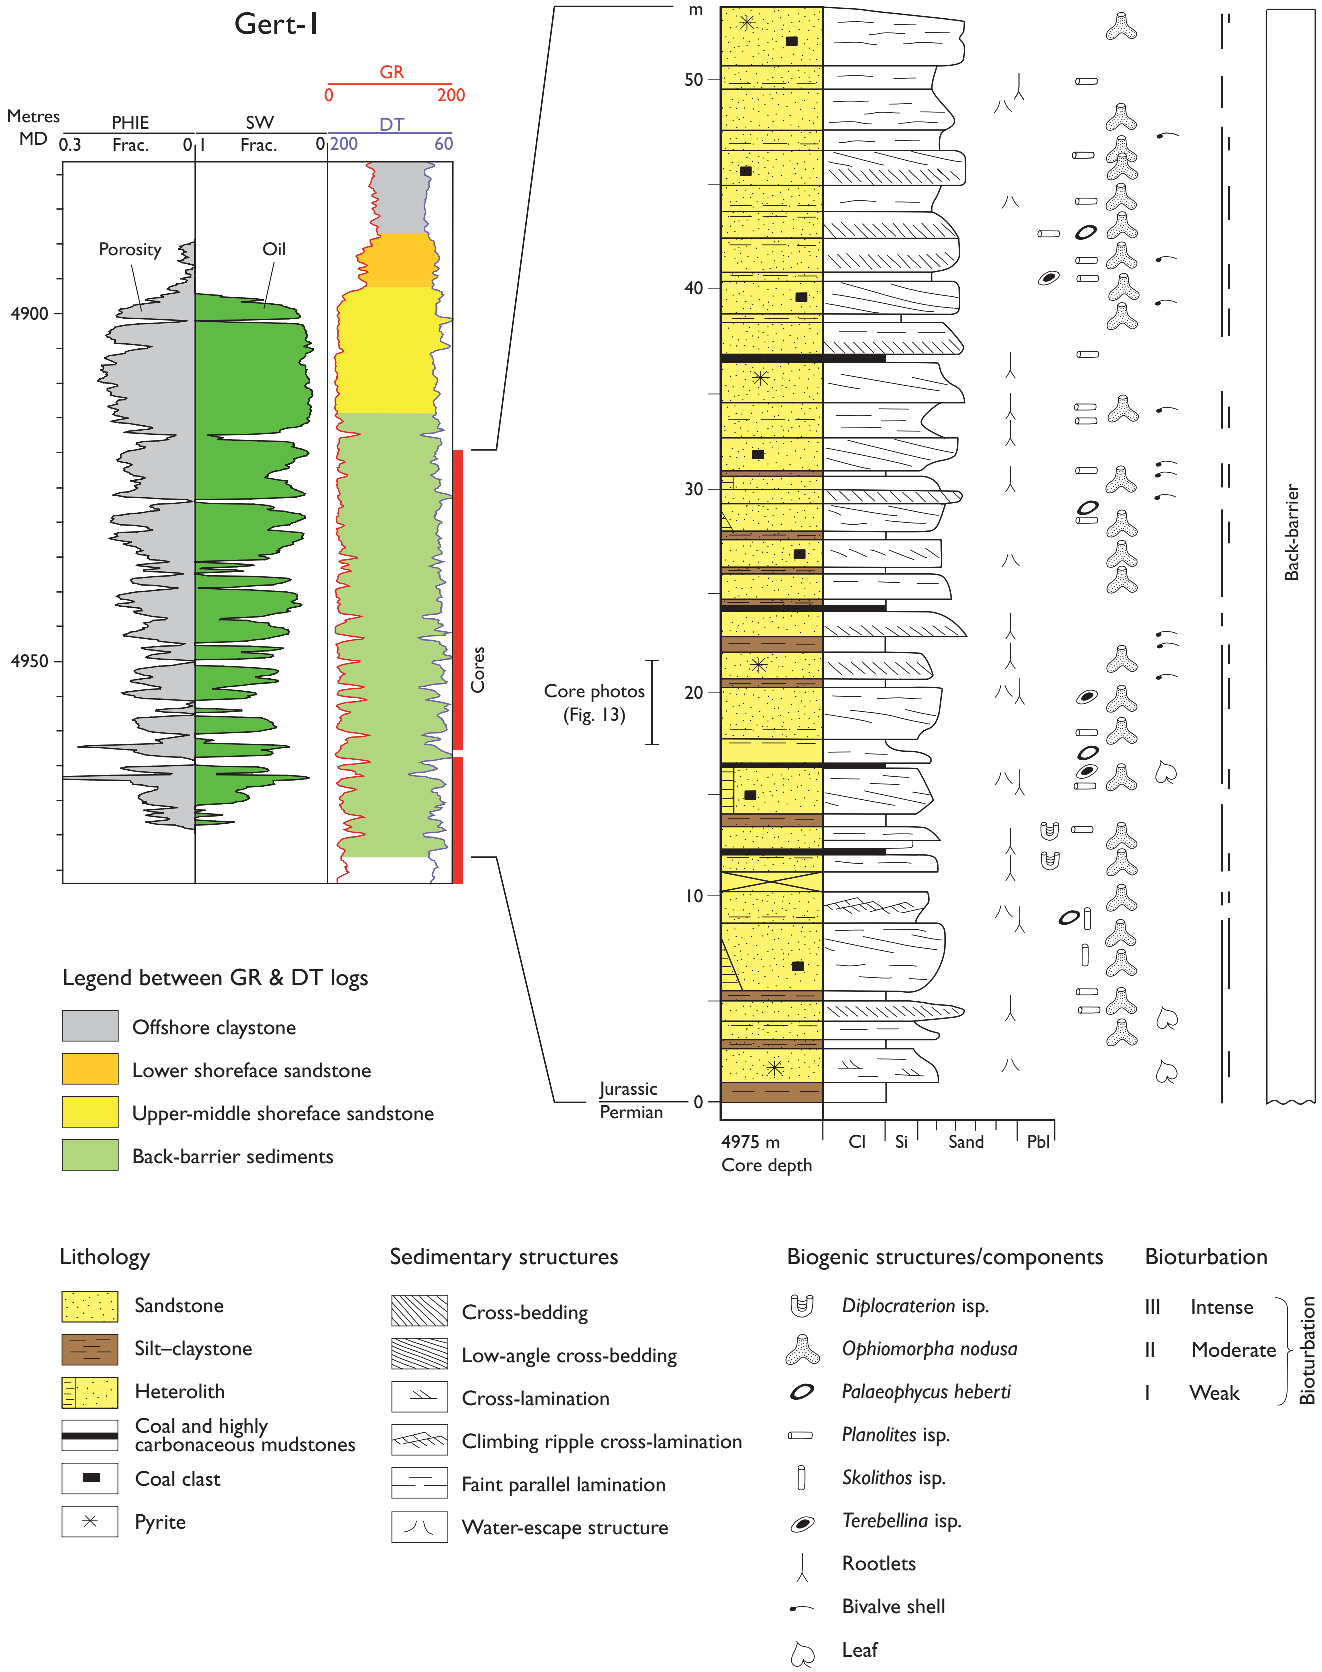

Fig. 2. Sedimentological core log and porosity–oil saturation plot in the Gert-1 well (Fig. 1). The cored sediments were deposited in a back-barrier environment. Many of the cross-bedded sandstones were probably deposited by washover fans.

Vertical section through the Rømø barrier island

The barrier island sediments are up to 20 m thick, including the aeolian dune sands. The island originated on a local palaeohigh on the Pleistocene outwash plain while lagoonal sedimentation was initiated in a palaeolow directly landward of the barrier (Fig. 7). The Holocene succession of the easternmost cores, Rømø-1 and Rømø-2, drilled in the present lagoon, consists entirely of lagoonal sand and mud flat deposits (Fig. 7). The Holocene succession of the easternmost core on the barrier island of Rømø

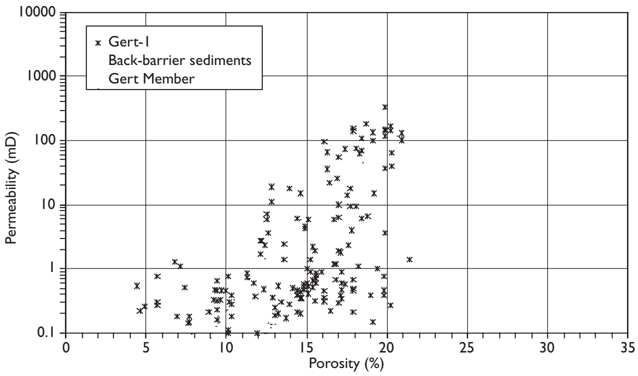

Fig. 3. Porosity–permeability plot of the back barrier sediments of the Gert Member in the Gert-1 well (Fig. 2).

(Rømø-3) is composed mostly of washover fan sand, minor salt marsh and lagoonal sediments topped by aeolian sand (Fig. 7). Lagoonal sediments are not found in the central and western parts of the Rømø barrier island, where the Holocene is composed of prograding shoreface sands.

A series of beach ridges up to 2.5 m high, often with fine-grained swales in between, are observed on GPR sections from the central part of the island beneath the modern aeolian dune sands (Fig. 8) (Møller *et al.* 2008; Nielsen *et al.* 2009). The beach ridges are often characterized by steep erosional seaward flanks and more gently dipping landward flanks. Cross-bedded sets, up to 2.5 m thick, with eastward dipping foresets are shown by the GPR sections immediately east of the beach ridges and can be followed for up to 1 km eastwards (Fig. 8). These cross-bed sets typically rest on weakly eastward (lagoon-ward) dipping surfaces and are interpreted as washover fans. As washover fans constitute a major part of the barrier island sand, a modern example of a washover fan is shown from the Skallingen peninsula, situated in the northernmost part of the Danish Wadden Sea (Fig. 9). During a storm in 1990, storm surges broke through beach ridges and aeolian dunes at peak sea-level 4.12 m above m.s.l. and a washover fan, 250 m long and wide, was deposited in the lagoon within a few hours; this fan displayed a steep slipface, indicating that internally it comprised a steep cross-bedded set *c.* 0.5 m thick (Fig. 9) (Nielsen & Nielsen 2006).

Fig. 4. The Wadden Sea situated in the SE part of the North Sea. The study area is located in the Danish part of the Wadden Sea.

Within the Rømø barrier island complex gently westward dipping sandy shoreface clinoforms can be followed upward and eastward to beach ridges (Fig. 8). Cross-bed sets, up to 125 m long, with eastward dipping foresets are occasionally seen on the westward-dipping shoreface clinoforms close to the beach ridges and are interpreted as swash bars that migrated towards the beach (Fig. 8). Channel fills, *c.* 2 m deep and 20 m wide, cutting into the upper part of the shoreface sands and located landward of the swash bars are interpreted as filled troughs (Fig. 8). As sand from the landward moving swash bars filled the troughs, the troughs moved towards the east (Fig. 8). Today such swash bar–trough systems are seen on the NW and SW coast of Rømø.

The number of beach ridges decreases towards the north and south. In the northern and southern parts of the island, the GPR sections are dominated by co-sets with westerly and easterly dipping foresets with reactivation surfaces, indicating bipolar current directions (Fig. 10) (Møller *et al.* 2008). These sediments were probably deposited in deep, broad tidal inlets at both ends of the barrier island, similar to those observed today. The Rømø cross-section clearly shows that all of the various facies packages have both aggraded and prograded (Fig. 7).

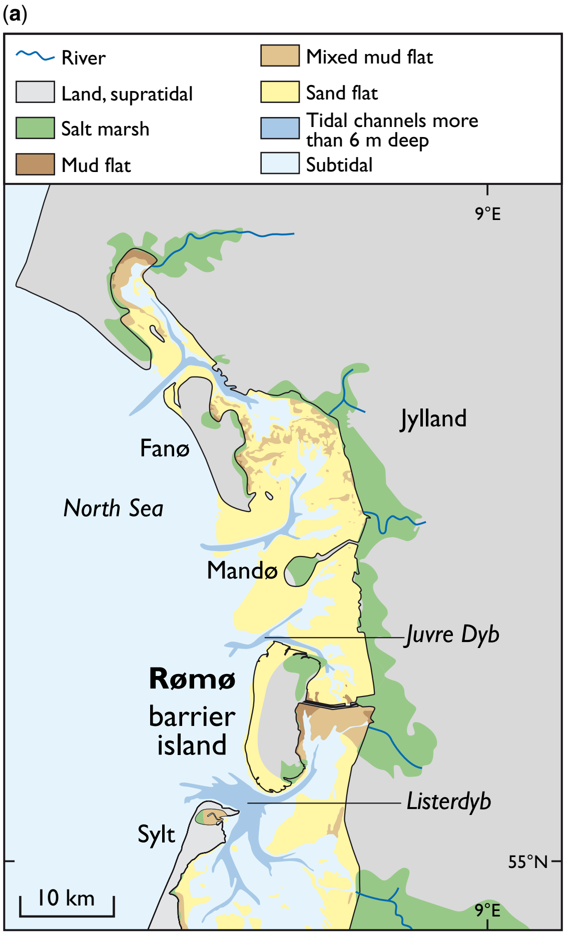
Palaeogeographic reconstruction of the Rømø barrier island from 8000 years BP–Recent

The core and GPR data in combination with the Recent morphology allow a detailed palaeogeographic interpretation of the barrier island through time. The oldest part of the barrier island formed *c.* 8000 years BP and since then the island has aggraded and prograded towards the west, north and south during a sea-level rise of *c.* 15 m (Fig. 7). During the last 3500 years, progradation has accelerated due to decreased rates of relative sea-level rise. Only very minor back-stepping into the lagoon is seen, despite the sea-level rise, demonstrating that there has been a large surplus of sand compared with the accommodation space, which allowed the barrier island to aggrade and prograde seaward. The dominance of sand is also evident from the sandy back-barrier environment. The sand was supplied by longshore drift and onshore transport.

The Rømø barrier island thus shows that barrier islands do not necessarily back-step, preserving only a thin transgressive sand unit. On the contrary, the Rømø case shows that, if there is a surplus of sand, a barrier island can aggrade and prograde during a sea-level rise, creating thick barrier island, shoreface and lagoonal successions.

The Upper Jurassic barrier island system of the Freja discovery

The Upper Jurassic (Upper Kimmeridgian) barrier island and shoreface sandstones of the Freja discovery are situated in the northernmost part of the Danish Central Graben in the North Sea, straddling the boundary between Denmark and Norway (Fig. 1) (Johannessen 2003; Johannessen *et al.* 2010). Barrier island and shoreface sandstones were deposited at the head of a NW–SE trending, *c.* 375 km long and 65 km broad marine basin extending from the northern Central Graben northwards to the Outer Moray Firth (Fig. 11) (Fraser *et al.* 2002). The southern part of this basin coincided with the Feda Graben and narrowed in a SE direction, terminating at the Heno and Gertrud Plateaus in the Freja area (Fig. 11) (Johannessen 2003). During the Late Kimmeridgian, the northernmost part of the Danish Central Graben and the southernmost part of the Norwegian Central Graben were characterized by two prominent highs: the Mandal High NE of the Freja structure and the Mid North Sea High SW of the Freja structure (Fig. 11). Large amounts of sand were probably transported to this area by



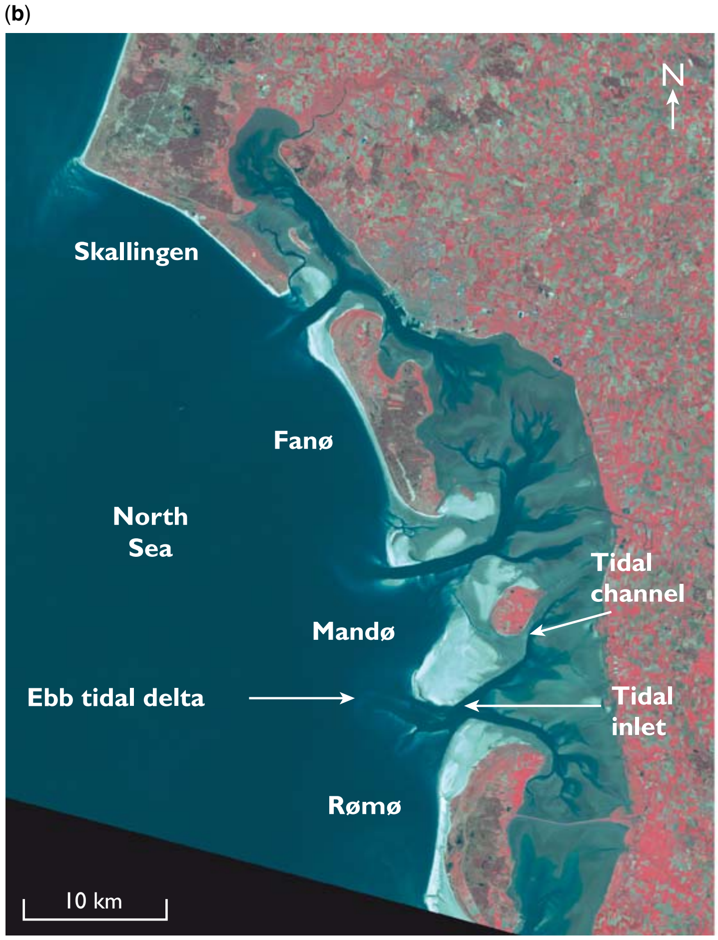


Fig. 5. The Danish Wadden Sea. (**a**) The distributions of sediment types and subtidal channels are shown. The mainland of Jylland east of the lagoon consists mainly of sandy glacial deposits. Modified from Pejrup (2006) and Sørensen *et al.* (2006). (**b**) Landsat photo (+ETM 9 May 2001) of the Danish tidal area with distinct tidal sand flats and subtidal channels. Note the subtidal ebb-deltas where the main channels terminate in the North Sea.

rivers from the plateau areas in the north, south and east with subsequent longshore transport and reworking by waves. The large thickness of reservoir sandstones in the Freja area (88 m in Gert-1 and 71 m in 2/12-1) indicates it was a sand-rich system.

Stratigraphy

The westernmost part of the Heno Formation overlies the Base Upper Jurassic unconformity (Andsbjerg & Dybkjær 2003; Johannessen 2003; Michelsen *et al.* 2003; Johannessen *et al.* 2010). The formation consists of back-barrier and shoreface sandstones of the Gert Member succeeded by shoreface sandstones of the Ravn Member (Fig. 12). In the Freja discovery area, offshore claystones of the Lola Formation separate the reservoir sandstones of the Gert and Ravn Members, but claystones are absent on the plateau areas where the Gert Member is directly overlain by the Ravn Member (Fig. 12). The present study focuses on the reservoir sandstones of the Gert Member.

Depositional environments

As the vertical seismic resolution at the reservoir depth of *c.* 5 km is only *c.* 50 m and the post-depositional structural development is very complex, the construction of a reservoir model relies on sedimentological and stratigraphical interpretations based on cores and well logs.

Back-barrier sediments. Interpretation of depositional environments is based on all cores and well logs from the Freja discovery (Damtoft *et al.* 1992; Johannessen *et al.* 1996; Johannessen 1997, 2003). In the cores from the Gert-1 well, the back-barrier sediments are characterized by interbedded, fine-grained sandstones and claystones with coal beds up to 15 cm thick (Fig. 2). Rootlets are abundant and often associated with coal or claystone beds. The organic matter is dominated by continentally derived particles such as black wood, spores and pollen. There are also remnants of leaves. Only a few marine dinoflagellate cysts are present and the dominance amongst these of a single genus (*Sentusidinium*) indicates a low salinity, highly-stressed environment (e.g. Noe-Nygaard *et al.* 1987; Smelror & Leereveld 1989). Numerous burrows of *Ophiomorpha*, *Planolites*, *Skolithos*, *Diplocraterion*, *Phycosiphon* and *Terebellina* are recognized. Cross-bedded sandstones, up to 2 m thick, overlying claystones and topped by claystones or coal beds with underlying rootlets are interpreted as washover fan sandstones deposited in the lagoon (Fig. 13). The association of the identified sedimentary structures, ichnofacies and fossils indicates that the sediments were deposited within a back-barrier setting (Johannessen 2003). The back-barrier section of the Gert-1 well is characterized by a serrated gamma-ray (GR) log pattern (Fig. 2). It is overlain abruptly by an 18 m thick section characterized by consistently low and uniform GR readings, which suggests cleaner and probably coarser sandstones than in the lagoonal deposits below, and that probably were deposited in the upper-to-middle shoreface above a ravinement surface (Fig. 2) (Johannessen 2003). A 6 m thick succession of very fine-grained sandstones overlies the upper-to-middle shoreface sandstones and is in turn overlain by offshore claystones; these deposits represent back-stepping lower shoreface sandstones (Fig. 2). The whole vertical section from back-barrier sediments at the base through

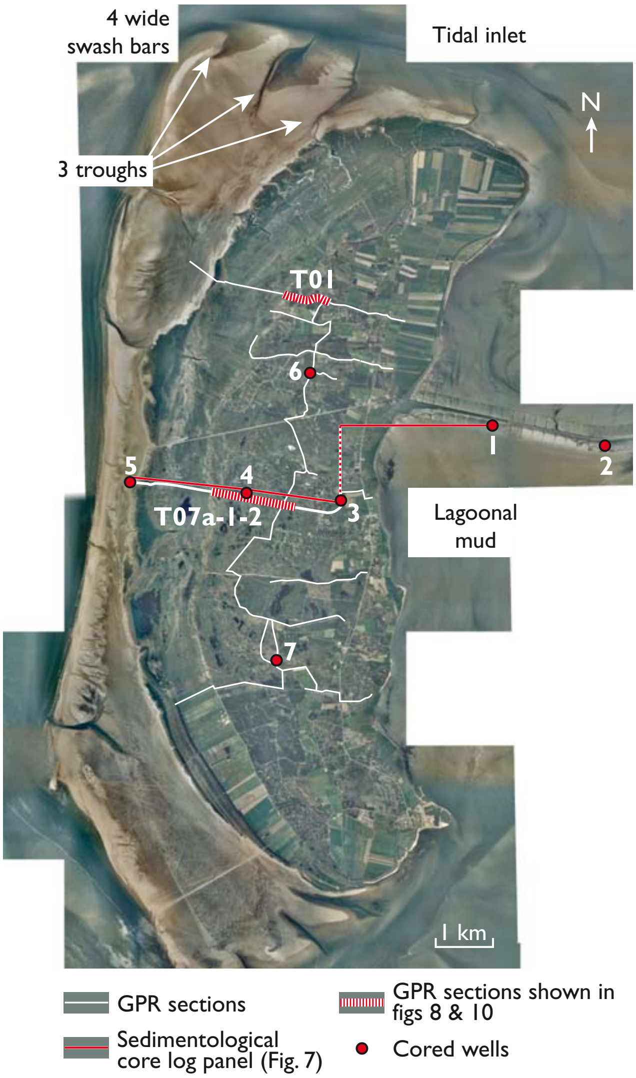

Fig. 6. Ortho photo of the Rømø barrier island showing the distribution of GPR reflection profiles and position of the seven cored wells. Very wide tidal flat sands characterize the NW and SW end of Rømø. The island is dominated by aeolian dune sand. Copyright Scankort.

back-stepping shoreface sandstones, to offshore claystones indicates that this succession was deposited during a transgression. All wells in the area show the same overall facies trend as the Gert-1 well, indicating an overall transgression which came from the NW and spread to the SE from the Feda Graben to the Gertrud Plateau (Fig. 14). Aeolian sandstones are lacking between the back-barrier sandstones and the shoreface sandstones, probably due to erosion during the transgression.

Shoreface sandstones. The Upper Jurassic very fine- to medium-grained sandstone reservoir in the Norwegian well 2/12-1 farther palaeoseaward in the Feda Graben consists of a thin (2 m) basal back-barrier mudstone unit overlain by a very thick (69 m) section of shoreface sandstones (Fig. 14) (Söderström *et al.* 1991); the lower half of this reservoir sandstone section is cored. The lowermost 20 m of the shoreface sandstone section is organized into thin (1–6 m) stacked cycles. Each cycle is characterized by an erosional base that is often overlain by a transgressive lag. The overlying sandstones in a cycle are either massive or cross-bedded; some mud-drapes are present. The degree of bioturbation is most often high to moderate and burrows of *Skolithos*, *Teichichnus*, *Terebellina* and *Asterosoma* are identified. The upper 10–40 cm of individual cycles are often penetrated by rootlets (Söderström *et al.* 1991).

Thick stacked Upper Jurassic barrier island sandstones

In order to reconstruct the palaeotopography over which the Late Jurassic barrier island system retreated, the first maximum flooding surface above the reservoir is chosen as a datum that is assumed to approximate to a horizontal surface at the time of the deposition (Fig. 14). This is of course a misrepresentation, as the seabed probably was dipping weakly seaward. As the claystone succession becomes thinner and sandier from the Feda Graben towards the Gertrud Plateau, the claystones are decompacted by a factor of 1.3 in order to obtain a more correct sediment thickness for the reconstruction of the palaeotopography. It is clear that the 2/11-1, 2/12-2, 2/12-1, Gert-4 and Gert-1 wells are located at the margin of the Feda Graben, whereas the Gert-3, Gert-2 and Jeppe-1 wells are located on the margin of the Gertrud Plateau (Fig. 14). The overall sandstone architecture is reconstructed by applying the simple principle that back-barrier sediments, shoreface sandstones and offshore claystones were deposited at the

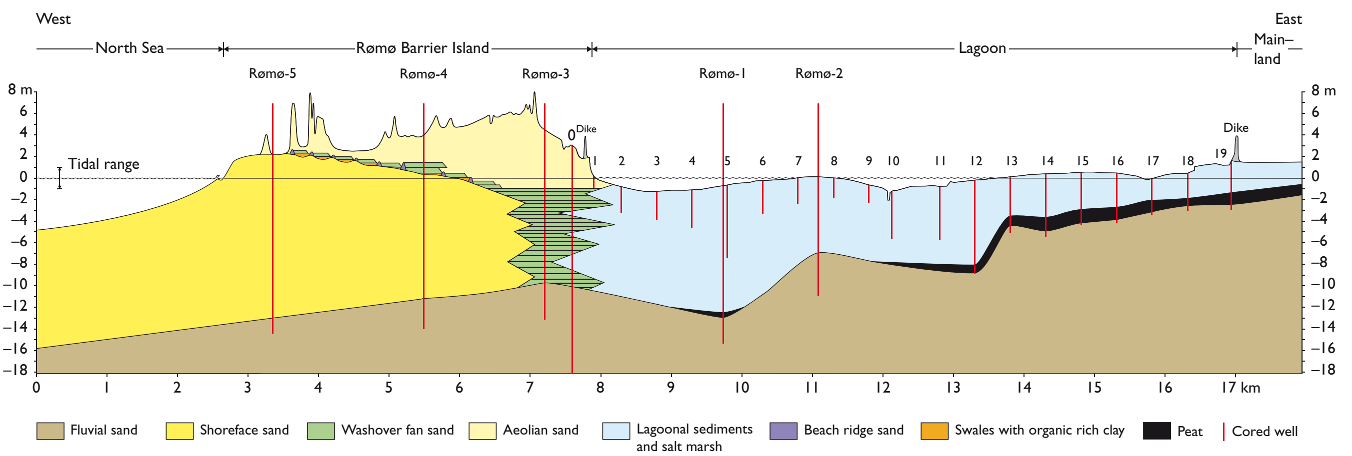

Fig. 7. West–east cross-section across the Rømø barrier island system from the North Sea to the west coast of Jylland, based on the Rømø-5 to Rømø-1 cores. Shoreface sands dominate the western part of the island and washover fans and salt marsh sediments dominate the easternmost part of the island. Lagoonal sediments are only seen in the absolute easternmost part of the island and further to the east in the lagoonal area. Aeolian dune sands dominate the topmost part of Rømø barrier island. Information from the 19 wells in the lagoon is taken from Betænkning angaaende Dæmning mellem Rømø og Fastlandet og Landvindingsarbejder i Vadehavet indenfor Rømø (1938).

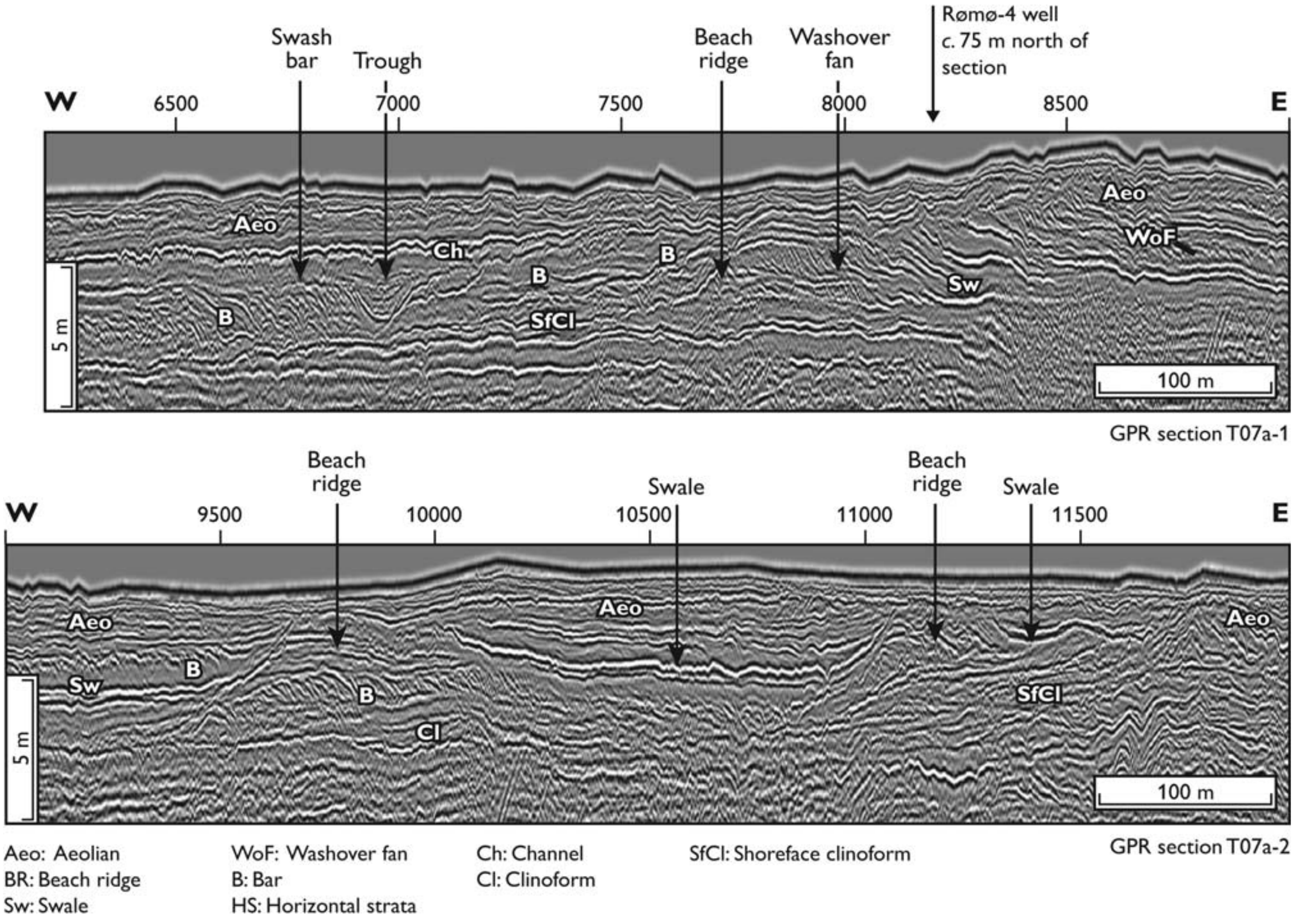

Fig. 8. GPR profile on Rømø barrier island oriented west–east. Sections T07a-1 (upper) and T07a-2 (lower) form a continuous line across the centre of the island (Fig. 6). The succession of beach ridges show shoreface progradation towards the west. The upper part of the section consists of aeolian sand. For location see Figure 6.

same time in laterally extensive, virtually horizontal packages bounded by minor flooding surfaces. Thus, based on core and log data, the sediments are grouped into a series of thin (4–7 m) parasequences that form the fundamental building blocks in the reconstruction (Fig. 14). Furthermore the depositional facies interpreted from cores and petrophysical logs are honoured, and it is assumed that these parasequences onlap the palaeotopography towards the SE.

Although the aggradational sandy successions are nearly similar in thickness, the entire back-barrier succession is much thicker in

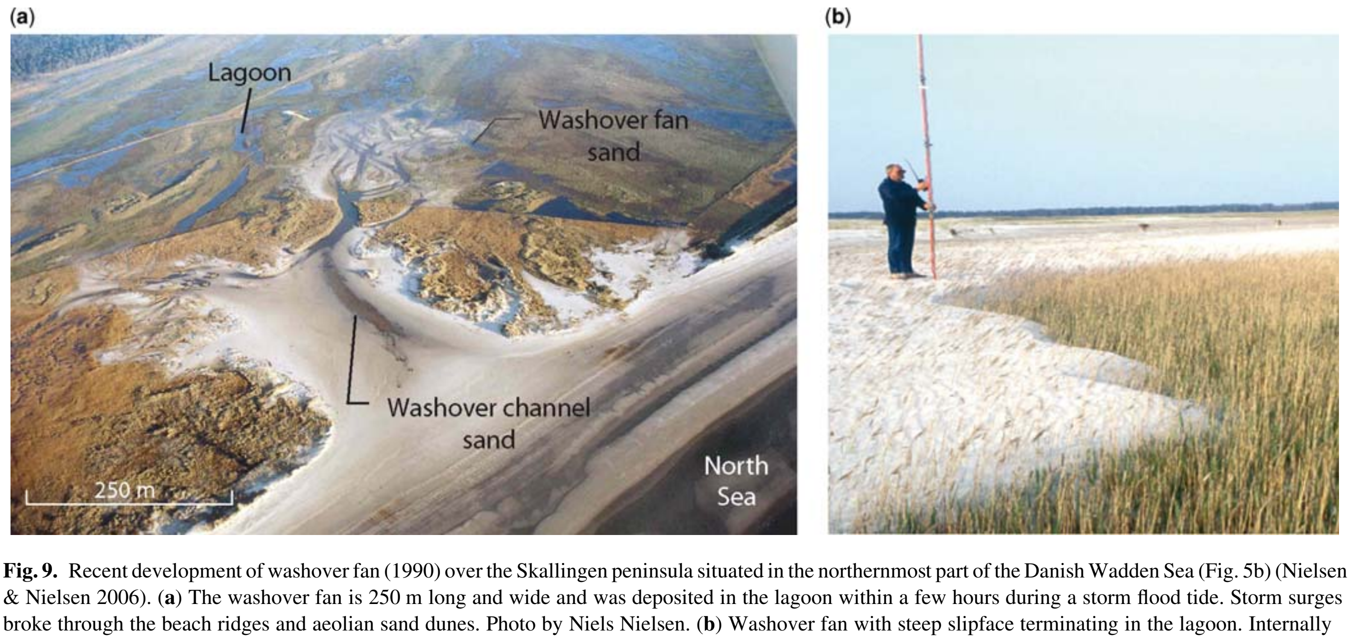

Fig. 9. Recent development of washover fan (1990) over the Skallingen peninsula situated in the northernmost part of the Danish Wadden Sea (Fig. 5b) (Nielsen & Nielsen 2006). (**a**) The washover fan is 250 m long and wide and was deposited in the lagoon within a few hours during a storm flood tide. Storm surges broke through the beach ridges and aeolian sand dunes. Gert-1 than in 2/12-1, indicating that the sandy successions were accumulating vertically and that Gert-1 is situated palaeolandward of 2/12-1 (Fig. 14). The Gert-1 well may thus have been situated in a position similar to the Rømø-3 core close to the back-barrier

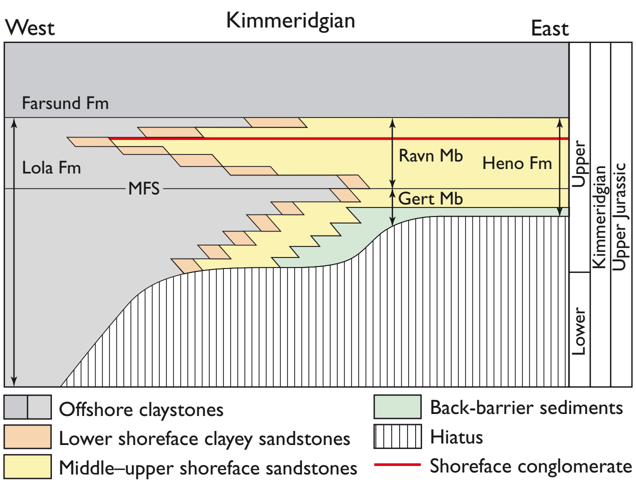

Fig. 12. Late Kimmeridgian time stratigraphic scheme.

area, whereas the 2/12-1 well was probably situated in a position similar to the Rømø-4 or Rømø-5 cores on the seaward shoreface (Fig. 7).

By applying these relatively simple principles in combination with the detailed sedimentary facies analyses, a model of the deeply buried Upper Jurassic Freja discovery is established. The model acknowledges realistic sedimentary processes and the response of a barrier island–lagoonal system to a significant relative sea-level rise. This fairly simple geological model of rising sea-level meeting a high relief palaeotopography that halted the overall transgression and leads to a vertical stacking of thick reservoir sandstones adequately explains the distribution of the reservoir sandstone facies in the Freja Field area as presented here.

This model facilitates estimates of high, mean and low case reservoir volumes, by shifting the position of the seaward and landward termination of the shoreface sandstones within each parasequence between the wells, while honouring the information at each well (Fig. 14). These sandstones are probably the most porous part of the reservoir.

The modern analogue of the Rømø barrier island in the Danish part of the Wadden Sea shows clearly that barrier islands can aggrade and even prograde during a rise in relative sea-level, as Rømø has experienced over the last 8000 years as sea-level has

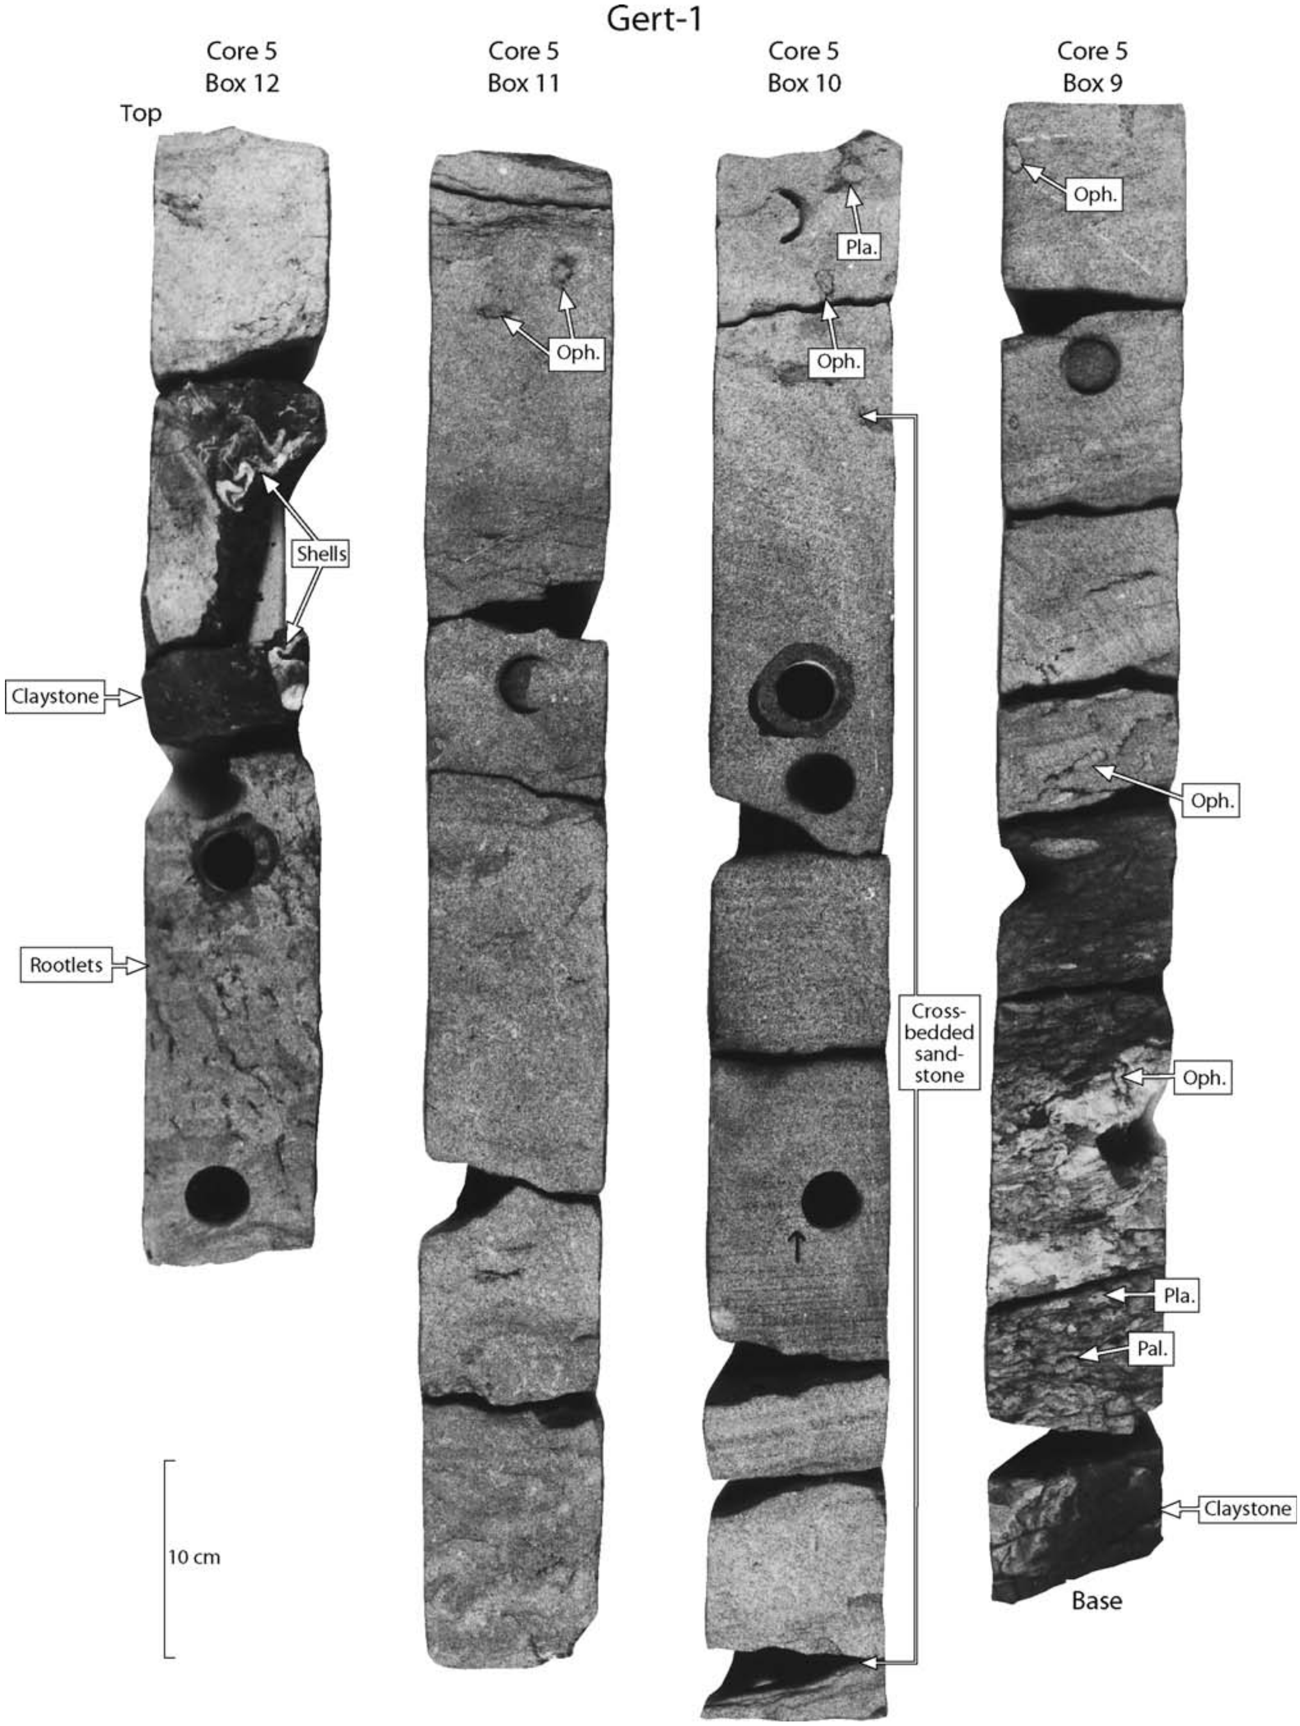

Fig. 13. Core photographs of an interpreted washover fan in the Gert-1 well. For position of core photographs see Figure 2 on sedimentary core log.

risen 15 m. In sand-rich systems, sedimentation can easily keep pace with sea-level rise.

As the top and bottom defining the thickness of the Gert Member is very difficult to define on seismic sections at these depths, it is impossible to show growth strata in the hanging walls indicating syn-depositional normal fault activity. Thus normal faults in Figure 14 may have been syn-depositional, but are not needed to explain these unusual thick back-barrier sediments.

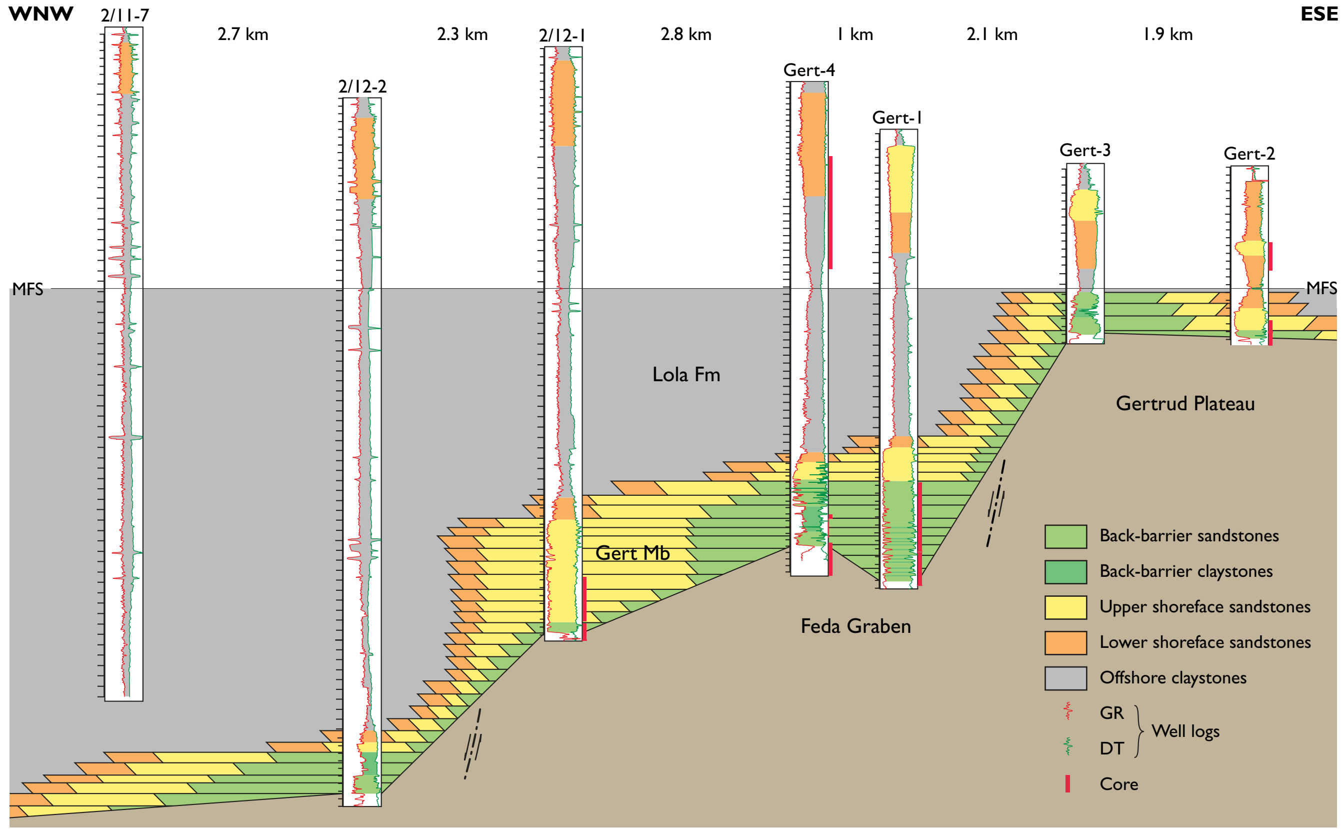

Fig. 14. Well log panel through the wells of the Freja oil field, showing distribution of reservoir facies within the basic stratigraphic building blocks (parasequences) which define the reservoir geometry. Discrimination between back-barrier sandstones and claystones is only indicated between the log curves for each well. Pre-Jurassic to Kimmeridgian faults are shown. They may have been active when the reservoir sandstones were deposited.

Conclusions

The thick back-barrier and shoreface sandstones of the Freja commercial oil field can be explained on the basis of simple sedimentological principles using depositional mechanisms, palaeotopography and rising sea-level. The Rømø barrier island analogue shows that, if there is a large surplus of sand, a barrier island may aggrade and even prograde during a sea-level rise. The reconstruction of the palaeotopography in the Upper Jurassic Freja discovery area shows that barrier island sandstones may have aggraded during a sea-level rise if the underlying, seaward-dipping palaeotopography was sufficiently steep to retard the transgression. Both mechanisms have probably contributed to the accumulation of the thick barrier island sandstone successions in the Freja discovery. Syn-sedimentary normal fault activity is not needed to explain these thick back-barrier sediments.

The resulting depositional model, built on detailed facies analysis of cores and well logs from the reservoir combined with modern analogue data, allow the construction of a reliable reservoir model that can be used for volumetric calculations and field development plans.

Jon R. Ineson is thanked for critical reading of the text and major improvement of the English. Finn Jakobsen is thanked for very helpful discussions. The Danish Natural Science Research Council (grant no. 272-05-0278) and Geocenter Copenhagen Foundation (grant no. 603-00003) are thanked for financial support. We also thank Gary Hampson and two anonymous reviewers for their very constructive comments.

Abstract: The Middle Jurassic Hugin Formation has been the target of exploration within Quadrant 15 of the Norwegian South Viking Graben since the 1960s. The Hugin formation comprises shallow-marine and marginal-marine sediments deposited during the overall transgression and southward retreat of the 'Brent Delta' systems. Sedimentological analysis of cores across the quadrant has identified six facies associations: bay-fill, shoreface, mouth bar, fluvio-tidal channel-fill, coastal plain and offshore open marine. These facies associations are arranged in a series of parasequences bounded by flooding surfaces, several of which are correlated regionally using biostratigraphic data. Within this stratigraphic framework, facies association distributions and stratigraphic architectures are complicated, reflecting the spatial and temporal interaction of various physical processes (e.g. waves and tides) with an evolving structural template produced by rift initiation and salt movement. The overall transgression was highly diachronous, becoming younger from north to south. The northern part of the study area (Sigrun–Gudrun area) is characterized by a series of backstepping, linear, north–south-trending barrier shorelines and sheltered bays. The central part of the study area (Dagny area) contains stacked, backstepping strandplain shorelines that fringed syn-depositional topographic highs. Local angular unconformities are developed around these highs, implying that they formed above fault-block crests and salt-cored structures. The southern part of the study area (Sleipner area) contains stacked deltaic shorelines that were modified by both waves and tides. Sandbody geometry is closely related to depositional regime and syn-depositional tectonic setting within the basin; a robust understanding of both is critical to successful exploration of Hugin Formation reservoirs.

Keywords: Hugin Formation, South Viking Graben, shallow marine, transgression, Jurassic

The Middle Jurassic Hugin Formation has been the subject of exploration efforts in the South Viking Graben, northern North Sea, since the 1960s. The Hugin formation forms part of the Vestland Group, and comprises shallow-marine and marginal-marine deposits that interfinger with the continental deposits of the underlying Sleipner Formation and the offshore marine shales of the overlying Heather Formation (Vollset & Dore 1984; Partington *et al.* 1993). Despite the discovery of the Sleipner Vest and Øst Fields in 1974 and 1981, respectively (Milner & Olsen 1998; Isaksen *et al.* 2002), exploration has been hampered by the absence of a regional sequence stratigraphic framework supported by depositional models that allow prediction of reservoir distribution and quality within specific stratigraphic intervals. The development of an integrated sedimentological and stratigraphic understanding of the formation is complicated by two factors. Firstly, shallow-marine and marginal-marine deposits in the formation exhibit a mixed regime of physical processes (i.e. waves, tides and riverine) that varies laterally within the South Viking Graben (e.g. Richards 1991; Folkestad & Satur 2008), suggesting that a single depositional model is inappropriate for the area as a whole. Secondly, the construction of a stratigraphic framework is complicated by syn-depositional rift-related faulting and halokinesis (Kessler *et al.* 1995; Sneider *et al.* 1995; Milner & Olsen 1998). The resulting syn-depositional structural template was complex and dynamic. In similar rift- or salt-basin settings, an evolving structural template controls the local development of accommodation, topography and sediment routing, which in turn influence facies distributions, architectures and character (e.g. Gawthorpe & Leeder 2000; Shelley & Lawton 2005). The aims of this paper are to present an updated regional depositional model and sequence stratigraphic framework for the Hugin Formation within Quadrant 15 (Fig. 1). Additional wells and new biostratigraphical analyses have been used to update previous studies (e.g. Varadi *et al.* 1998). This study is aiding current exploration within the region, as well as providing generic insights into the relationship between sedimentology, sequence stratigraphy and structural development that may be applicable to other rift basins and areas of halokinesis.

Previous studies

The Hugin Formation is an overall transgressive unit that was deposited during rift-related subsidence and subsequent flooding of the South Viking Graben during north-to-south retreat of the 'Brent Delta' megasequence (e.g. Rattey & Hayward 1993; Husmo *et al.* 2003). The Hugin Formation is Late Bajocian to Oxfordian in age, but transgression of the graben was diachronous and the formation becomes younger from north to south (Fig. 2; Mitchener *et al.* 1992; Partington *et al.* 1993; Rattey & Hayward 1993; Richards *et al.* 1993). Several other names have been used to describe the same lithostratigraphic interval, including the Beryl Formation and 'Bruce Group sands' in the Bruce–Beryl embayment of the UK sector (Mitchener *et al.* 1992; Richards *et al.* 1993; Husmo *et al.* 2003). Time-equivalent deep-marine turbidites in the basin axis have been referred to as the Ling Sandstone Member of the Heather Formation (Cockings *et al.* 1992; Husmo *et al.* 2003) or as part of the Bruce or Heather Sandstones

VINING, B. A. & PICKERING, S. C. (eds) *Petroleum Geology: From Mature Basins to New Frontiers – Proceedings of the 7th Petroleum Geology Conference*, 157–176. DOI: 10.1144/0070157

(Richards *et al.* 1993; Spence & Kreutz 2003). Rift-related faulting and associated localized tectonic subsidence within the South Viking Graben have influenced sediment routing, gross thickness, facies distributions and facies belt orientations within the Hugin Formation (Sneider *et al.* 1995; Milner & Olsen 1998; Varadi *et al.* 1998).

The Hugin Formation was first described from the Sleipner Vest Field to the south of the study area (well 15/9-2; Vollset & Dore 1984) to comprise a stacked succession of nearshore-to-shallow-marine sandstones and coals with some fluvio-deltaic influence. A wave-dominated barrier shoreline was interpreted from well data distributed more regionally in the South Viking Graben (Harris & Fowler 1987). Sequence stratigraphic analysis (Varadi *et al.* 1998) resulted in recognition of regional flooding surfaces and sequence boundaries that divide the succession into a series of cycles, each recording shoreline progradation and subsequent retrogradation. More detailed studies on the Sleipner Vest and Øst fields have defined several facies associations within such cycles: alluvial plain, coastal swamp, barrier-shoreline complex (including shoreface, mouth bar, tidal channel, tidal dune and tidal flat deposits), lagoon and/or bay, and offshore deposits, with the last corresponding to the shelfal Heather Formation (Milner & Olsen 1998; Folkestad & Satur 2008). The best quality reservoir units occur within shoreface deposits whilst the worst occur within lagoon and/or bay deposits (Harris & Fowler 1987; Milner & Olsen 1998). The strong tidal signatures recognized

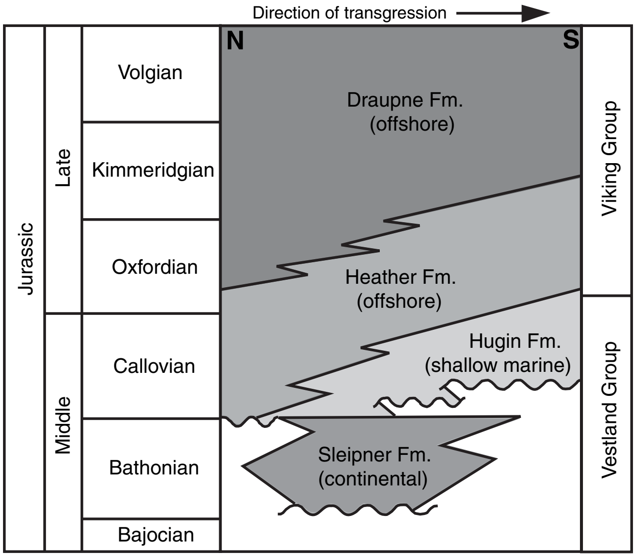

Fig. 2. Jurassic lithostratigraphy of the study area.

throughout the Hugin Formation are interpreted to be the result of wave suppression within the narrow (*c*. 30 km), elongate (*c*. 100–120 km) graben during deposition (Richards 1991; Folkestad & Satur 2008).

Tectonic setting

Since the Cambrian, four major tectonic events have influenced the area now defined as the South Viking Graben: (1) Late Ordovician–Early Silurian collision of the Caledonian Orogeny; (2) Carboniferous to Permian rifting and basin formation; (3) Mesozoic rifting and graben formation; and (4) Late Cretaceous to Early Cenozoic inversion (Ziegler 1990; Lyngsie *et al.* 2006). The South Viking Graben is a NNE–SSW trending half-graben, bounded to the west by a series of ESE-dipping faults and the Palaeozoic high of the Fladen Ground Spur (Thomas & Coward 1996; Husmo *et al.* 2003). To the east, the graben shallows onto the Utsira High, a structurally complex area of localized faulting, tilting and erosion (Thomas & Coward 1996; Husmo *et al.* 2003). This study focuses on Norwegian Quadrant 15, which is located on the hanging-wall dipslope of the South Viking Graben (Fig. 1).

The study area is dissected by a series of intra-graben, NNE–SSW-trending normal faults that predominantly detach on the Upper Permian Zechstein Supergroup salt layer (Thomas & Coward 1996; Jackson & Larsen 2008). These faults are antithetic to the main graben-bounding fault array that lies to the west of the study area. In the north of the study area, these faults developed in response to gravity-driven sliding of units above the mobile Zechstein Supergroup salt (Thomas & Coward 1996; Jackson & Larsen 2008). Towards the south, salt-related structures become more prominent, with the occurrence of salt-cored anticlines, diapirs and salt-withdrawal basins. Differential subsidence across these faults and salt-cored features was superimposed on the overall westward-rotation of the hanging-wall dipslope, leading to complex interaction between these local and regional tectonics, eustasy and drainage patterns. Locally, compressional anticlines and growth folds are associated with reverse reactivation of older extensional faults (e.g. Thomas & Coward 1996; Knott 2001; Jackson & Larsen 2008). These structures are interpreted to have developed during the Late Jurassic (Thomas & Coward 1996; Jackson & Larsen 2008) and they therefore post-date Hugin Formation deposition.

Dataset and methodology

Almost 600 m of Hugin Formation core from 16 regional wells (Fig. 3) has been logged for this study. Wireline-logs were available for all of the cored wells and new, high-resolution biostratigraphic analyses were available for 13 of the wells. Sedimentological analysis involved recording grain size, sorting and sphericity of matrix and clasts, colour variations, sedimentary structures, bed thickness, the nature of bounding contacts and macro-fauna type and preservation state. The degree of bioturbation is recorded using the bioturbation index (BI) scheme of Taylor & Goldring (1993), which is based on a visual assessment of the amount of 'bioturbated' v. 'unbioturbated' texture and ranges from 0 (no bioturbation) to 6 (complete bioturbation). Wireline-log character and cross-plot analyses (sonic (DT) v. gamma ray (GR); density (RHOB) v. neutron porosity (NPHI)) have been used to identify distinctive wireline-log responses for each facies identified in core. The characteristic wireline-log responses were then used to qualitatively interpret uncored intervals within the studied wells.

Sedimentology of the Hugin Formation

Fifteen facies have been recognized within the Hugin Formation (Table 1). These facies have been grouped into six facies associations, which are discussed below and summarized in Figures 4–6.

Bay-fill facies association: A

Complete, well-developed successions of the bay-fill facies association occur in the northern part of the study area (wells G–L; Fig. 3). Incomplete successions of the association, comprising individual facies, are also recognized interbedded with fluvio-tidal channel and shoreface facies associations (described below) in the south of the study area (well A; Fig. 3).

Description. Units of this facies association are typically composed of a coarsening-upwards succession that comprises, from base to top, facies A1, A2, A3 and A4 (Figs 4a & 5a). Parallel-laminated mudstones and siltstones at the base of the succession (facies A1) locally contain beds of densely packed, disarticulated bivalve shells. This facies passes gradationally upward into interbedded heteroliths (facies A2). Very fine-grained sandstones in these heteroliths occur as non-parallel or wavy laminae and lenticular, trough and low-angle (hummocky?) cross-stratified beds. Sandstone beds thicken and coarsen upwards in the succession, until mudstones occur only as thin laminae and drapes (facies A3). Bioturbation is variable in intensity, although *Diplocraterion* is occasionally identified in the lower, finer-grained parts of the facies association. Wavy bedding, high-angle cross-bedding and occasional wave ripples are preserved where bioturbation intensity is low. Locally this facies is truncated by sharp-based successions of coarse-grained sandstones with rare wispy lamination, ripples and sparse bioturbation (facies A4). Although shells and shell fragments are common throughout these sharp-based successions, they are typically concentrated towards the base. Successions of this facies association are commonly capped by thin deposits of the coastal plain facies association (described below).

Interpretation. The coarsening-upwards successions that typify this facies association imply a shallowing-upward or progradational trend, with increasing proximity to the source of sand towards the top of the succession. Parallel-laminated mudstones record deposition from suspension, while sandstone laminae and beds contain structures that record episodic deposition from suspension or tractional currents. Quasi-rhythmical interbedding of mudstone and sandstone (facies A2 and A3) suggest regular and

Table 1. Summary of facies in the Hugin Formation. Thickness and lateral extent reflect the observed thickness from core and the interpreted lateral extent based on well correlations. Bioturbation fabric is described using the Bioturbation Index (BI) scheme of Taylor & Goldring (1993)

Facies	Description	Thickness (t) and (l) lateral extent	Bioturbation	Wireline-log character	Interpretation
A1	Parallel-laminated mudstone with rare siltstone laminae, locally sideritic. Monospecific assemblage of disarticulated bivalves oriented parallel to bedding and concentrated into thick (60–205 cm) bioclastic-rich beds. Rare gastropods	t = 30–425 cm l = <6 to >29 km	BI = 0–2 (Pl)	GR 41–308 API DT 225–355 μs m^{-1} NPHI 0.167–0.464 v/v RHOB 2280–2820 g cm^{-3}	Restricted marine shale
A2	Interbedded claystone and very fine-grained sandstone. Non-parallel and wavy lamination, trough cross-stratification and hummocky cross-stratification in sandstone beds. Rare disarticulated bivalve shells oriented parallel to bedding	t = 10–725 cm l = <8 km to >13 km	BI = 2–3 (Te, Sk, Pl, Ar, Pa, Op)	GR 17–65 API DT 189–268 μs m^{-1} NPHI? RHOB 2280–2820 g cm^{-3}	Muddy shallow bay-fill
A3	Fine- to medium-grained sandstone. Moderately to well sorted. Wavy bedding, high-angle cross-bedding and occasional wave ripples. Calcite cement and soft sediment deformation locally observed. Disarticulated bivalves throughout, sometimes concentrated in thin beds (<10 cm)	t = 60–370 cm l = <8 km to >8 km	BI = 0–4 (Pa, Dip, Ro/Cy?, Pl, Op)	GR 18–46 API DT 199–314 μs m^{-1} NPHI 0.077–0.518 v/v RHOB 1690–2745 g cm^{-3}	Sandy shallow bay-fill
A4	Coarse- to fine-grained sandstone with fining- and coarsening-upward motifs. Moderately to well sorted with sub-rounded grains. Sparse sedimentary structures include ripples and mudstone drapes. Disarticulated bivalves and shell fragments common, concentrated into thin beds (<40 cm). Locally contains calcite-cemented nodules. Sharp, possibly erosive contacts at individual bed bases	t = 250–500 cm l = <1.8 km to >4.2 km	BI = 1–3 (Op, ET)	GR 7–35 API DT 175–230 μs m^{-1} NPHI 0.038–0.146 v/v RHOB 2280–2820 g cm^{-3}	Marine channel-fill sandstone
B1	Upward-coarsening, siltstone to very fine-grained, moderately sorted sandstone. Shell debris, quartz granules and angular carbonaceous fragments throughout. Primary sedimentary structures are poorly preserved, but contains rare thin (30–75 cm), sharp-based, very fine- to fine-grained cross-laminated sandstone beds	t = 30–480 cm l = <2 km	BI = 4–5 (Pa, Ch, Op, Pl, Ter, As?)	GR 18–80 API DT 168–291 μs m^{-1} NPHI 0.038–0.191 v/v RHOB 2322–2723 g cm^{-3}	Distal lower shoreface
B2	Very fine- to fine-grained, moderately to well sorted sandstone. Fine-grained, carbonaceous laminae throughout. Dominantly low-angle cross-bedding, with subordinate parallel lamination. Carbonate-cemented nodules	t = 130–440 cm l = 1.7 km (min) to 12 km (max)	BI = 3–4 (Op)	GR 20–56 API DT 179–277 μs m^{-1} NPHI 0.048–0.168 v/v RHOB 2314–2696 g cm^{-3}	Proximal lower shoreface
B3	Fine- to medium-grained, well sorted, coarsening-upwards, cross-laminated sandstone. Discrete laminae of coarser sediment, carbonaceous fragments and shell fragments occur throughout	t = 425–800 cm l = <1.7 km (min) to 8 km (max)	BI = 0* (crypto/Mac?)	GR 15–25 API DT 250–275 μs m^{-1} NPHI 0.094–0.113 v/v RHOB 2271–2342 g cm^{-3}	Upper shoreface
C1	Highly bioturbated siltstone to very fine-grained sandstone with stringers and thin (5–20 cm) beds of rounded granules	t = 175–1010 cm l = <7.2 km (min) to <19.6 km (max)	BI = 4–5 (Pa, Ch, Op, P)	GR 20–80 API DT 230–260 μs m^{-1} NPHI 0.084–0.169 v/v RHOB 2327–2521 g cm^{-3}	Distal mouth bar
C2	Very fine- to fine-grained sandstone with low-angle cross-bedding. Stringers and thin (5–15 cm) beds of rounded granules occur throughout. Monospecific trace fossil assemblage (*Ophiomorpha*)	t = 290–775 cm l = <5 km	BI = 0–2 (Op)	GR 12–58 API DT 167–397 μs m^{-1} NPHI 0.051–0.595 v/v RHOB 1612–2705 g cm^{-3}	Proximal mouth bar
D1	Fining-upward very coarse- to fine-grained sandstone with possible bidirectional cross-sets and swaley cross-stratification. Stacked fining-upward beds with sparse coarse-grained stringers. Sharp, possibly erosive contacts at individual bed bases	t = 740–820 cm l = <2 km	BI = 0–1 (Sk, ET)	GR 8–134 API DT 235–335 μs m^{-1} NPHI 0.140–0.469 v/v RHOB 2284–2570 g cm^{-3}	Tidally influenced fluvial channel-fill sandstone

Table 1. *Continued*

Facies	Description	Thickness (t) and (l) lateral extent	Bioturbation	Wireline-log character	Interpretation
D2	Fining-upward coarse- to medium-grained sandstone with unidirectional cross-bedding, carbonaceous laminae and fragments throughout. Sharp, possibly erosive contacts at individual bed bases	t = 580 cm l = <2 km to >2 km	BI = 0–1 (ET)	GR 9–34 API DT 241–297 μs m^{-1} NPHI 0.140–0.289 v/v RHOB 2168–2447 g cm^{-3}	Fluvial channel-fill sandstone
E1	Coal and carbonaceous shale. Basal contact typically parallel although may be undulose. Diagenetic pyrite nodules are recognized	t = 30–520 cm l = <6 km to >19.6 km	BI = 0	GR 8–56 API DT 313–427 μs m^{-1} NPHI 0.2405–0.529 v/v RHOB 1930–2225 g cm^{-3}	Coal
E2	Interbedded dark grey mud/claystone and siltstone to very fine-grained sandstone. Wavy to non-parallel lamination penetrated and disrupted by roots	t = 60 cm l = <2 km to >2 km	BI = 3–4 (roots)	GR 32–60 API DT 358–415 μs m^{-1} NPHI 0.4225–0.4993 v/v RHOB 1994–2148 g cm^{-3}	Coastal plain fines
F	Mudstone with rare siltstone beds. Parallel lamination, soft sediment deformation developed locally at bed tops. Rare thin (<100 cm), finely laminated, unbioturbated beds of very fine-grained sandstone	t = complete section not penetrated l = <1.7 km to >37.6 km	BI = 3–5, occ. 0 (Pl, Op, Ch, Zo, Tae, As. Te)	GR 4–134 API DT 187–450 μs m^{-1} NPHI 0.114–0.618 v/v RHOB 1730–2925 g cm^{-3}	Open marine shale

*Note that the bioturbation scheme cannot be used to describe cryptobioturbation, where sediment is pervasively bioturbated with little to no distortion of primary structures (e.g. facies B3). Individual trace fossils, listed in brackets, are abbreviated as follows: Te, *Teichichnus*; Sk, *Skolithos*; Ar, *Arenicolites*; Pa, *Palaeophycus*; Op, *Ophiomorpha*; Dip, *Diplocraterion*; Ros, *Rosselia*; Cy, *Cylindrichnus*; Pl, *Planolites*; Ch, *Chondrites*; Ter, *Terebellin*a (*Schaubcylindrichnus Fria*); As, *Asterosoma*; Mac, *Macaronichnus*; ET, escape traces; crypto, cryptobioturbation.

repeated fluctuations in energy regime, which implies tidal action (e.g. Nio & Yang 1991). Wave and storm influence is also present, indicated by rare wave ripples and low-angle cross-stratification, interpreted as hummocky cross-stratification on the basis of its occurrence only in very fine- to fine-grained sandstone (e.g. Dott & Bourgeois 1982; Duke *et al.* 1991). Sharp-based sandstones that occur locally in the upper part of the successions are interpreted as channel fills (facies A4). The occurrence of shell fragments in lags and dispersed through these sandstones, together with rare mudstone drapes, has been recorded as a common feature in tidal inlet channel-fill deposits (e.g. Moslow & Tye 1985; Israel *et al.* 1987; Simms *et al.* 2006). The occurrence of a monospecific shell assemblage and low-to-moderate intensity bioturbation by a restricted trace fossil assemblage indicates deposition in a restricted marine environment (Pemberton *et al.* 1992; MacEachern & Bann 2008). This interpretation is supported by the common occurrence of low-diversity dinocyst assemblages. Successions of this facies association are therefore interpreted to record periodic infilling of restricted marine embayments and/or lagoons that were locally contiguous with tidal inlet channels. The restricted marine character of these successions may be explained by deposition in sheltered lagoons and/or embayments that either lay behind coeval barriers and spits fronted by wave-dominated shorefaces (Harris & Fowler 1987; Hampson *et al.* 2009) or were protected by rift-generated islands and shoals. The pervasive tidal signature in this facies association may simply reflect the absence of wave reworking in the sheltered lagoons and/or embayments, although the narrow, elongate shape of the South Viking Graben may have locally amplified tidal currents and further suppressed wave activity (Husmo *et al.* 2003; Folkestad & Satur 2008).

Sequence stratigraphy. At the base of successions of this facies association, lagoonal and/or bay-fill mudstones (facies A1) representing relatively deep water (4–45 m based on thickness of associated parasequences; see below) are typically juxtaposed directly above coastal plain coals. The bases of these successions are therefore interpreted as flooding surfaces (*sensu* Van Wagoner *et al.* 1988), although they may have formed in response to allogenic or autogenic changes in relative sea-level and sediment supply. An increase in bioturbation intensity is typically observed at these flooding surfaces, combined with the occurrence of *Diplocraterion*, an indicator of more marine conditions (Taylor & Goldring 1993). Some flooding surfaces are also associated with a lag deposit of fine- to medium-grained sandstone. Where flooding surfaces are underlain by tidal inlet channel-fill deposits (facies A4), the basal erosion surfaces of the channels may record tidal erosion during transgression (i.e. tidal ravinement surfaces, *sensu* Swift 1968). This interpretation is supported by the occurrence of winnowed, coarse-grained and/or bioclastic lags at the bases of some channels. In one instance, a lagoonal and/or bay-fill succession is erosively overlain by upper shoreface sandstones (facies B3, described below); the base of this sandstone is interpreted to record wave erosion during transgression (i.e. a wave ravinement surface, *sensu* Swift 1968). Each of the upward-shallowing, flooding surface-bound successions is termed a parasequence (*sensu* Van Wagoner *et al.* 1990). Individual parasequence thickness varies from 4 to 45 m, and the duration of each parasequence is approximately 500–600 ka, based on high-resolution biostratigraphy (Hampson *et al.* 2009). The thickest parasequences occur in the western part of the study area, where subsidence and accommodation space are greatest due to activity on the basin-bounding fault zone.

Wireline-log character. Gamma ray (GR) logs through successions of this facies association show an upward-decreasing trend as they become more sandstone-rich towards their tops (Fig. 4a). Facies A1 and A2 exhibit high GR values and a serrate pattern, reflecting their heterolithic character, whereas sandstone-dominated facies A3 has a smoother, funnel-shaped GR profile. Facies A4 has the lowest GR values and a sharp-based blocky log character, consistent with its association with channel-fill sandstones. The four constituent facies also have distinctive

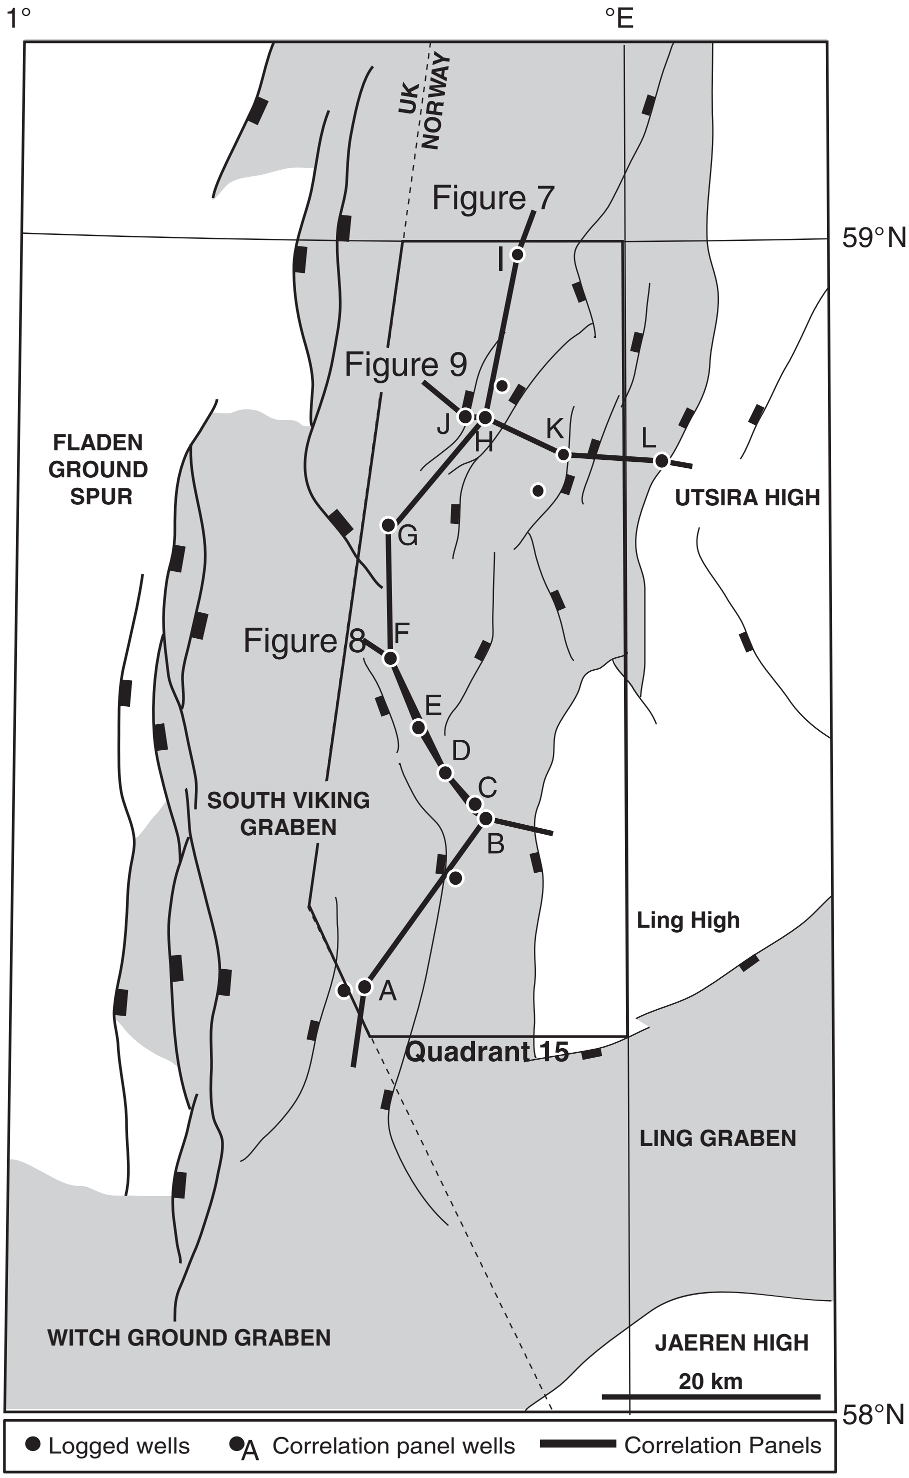

Fig. 3. Map showing the distribution of cored wells, correlation panels and seismic lines used in this study (Figs 4 & 7–9).

signatures when wireline-log cross-plots are generated (Fig. 6a); their wireline-log characteristics are summarized in Table 1.

Shoreface facies association: B

Complete, well-developed successions of the shoreface facies association are developed in the central and southern parts of the study area (wells A–E, Fig. 3). Several stacked shoreface successions are recognized within the central portion of the study area (e.g. wells C & E, Fig. 3), whilst to the south they interfinger in vertical successions with facies of the bay-fill, coastal plain, mouth bar and fluvio-tidal channel associations (e.g. well A, Fig. 3).

Description. Units of this facies association are typically composed of upward-coarsening and cleaning successions. Complete successions comprise, from base to top, facies B1, B2 and B3; incomplete successions of B1 to B2 facies and B2 to B3 facies are more typical of the central part of the study area (Figs 4b & 5b). Highly bioturbated siltstone to very fine-grained sandstone at the base of a succession (facies B1) passes gradationally upwards into moderately to well-sorted, very fine- to fine-grained sandstones (facies B2) and then well-sorted, fine- to medium-grained sandstones (facies B3). Sharp-based beds of very fine- to fine-grained, unbioturbated, low-angle cross-laminated sandstone (30–75 cm thick) occur within facies B1 and B2, and cross-lamination is

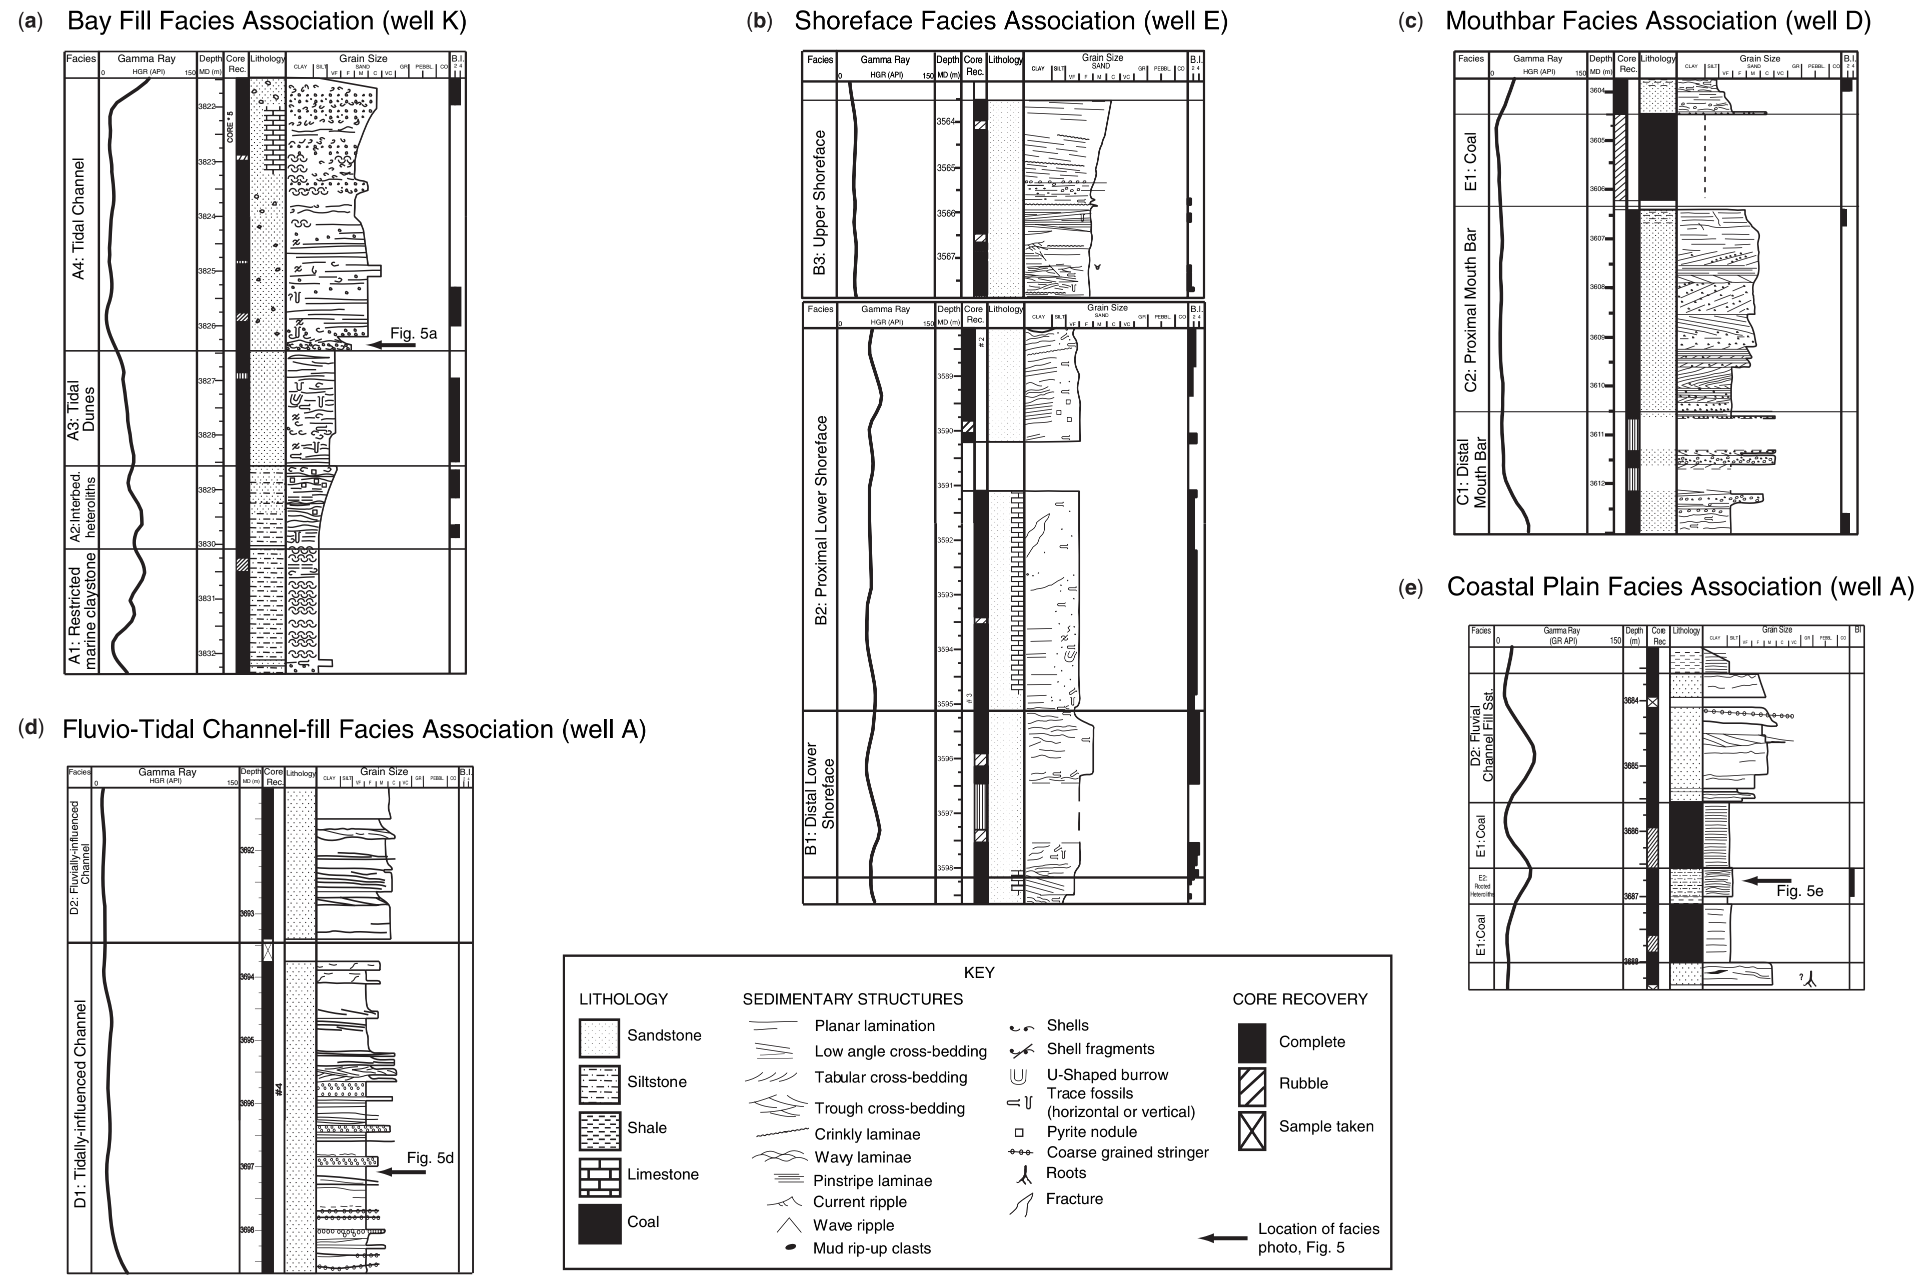

Fig. 4. Core descriptions and GR log characteristics of successions illustrating the principal facies associations in the Hugin Formation: (**a**) bay-fill; (**b**) shoreface; (**c**) mouth bar; (**d**) fluvio-tidal channel-fill; and (**e**) coastal plain.

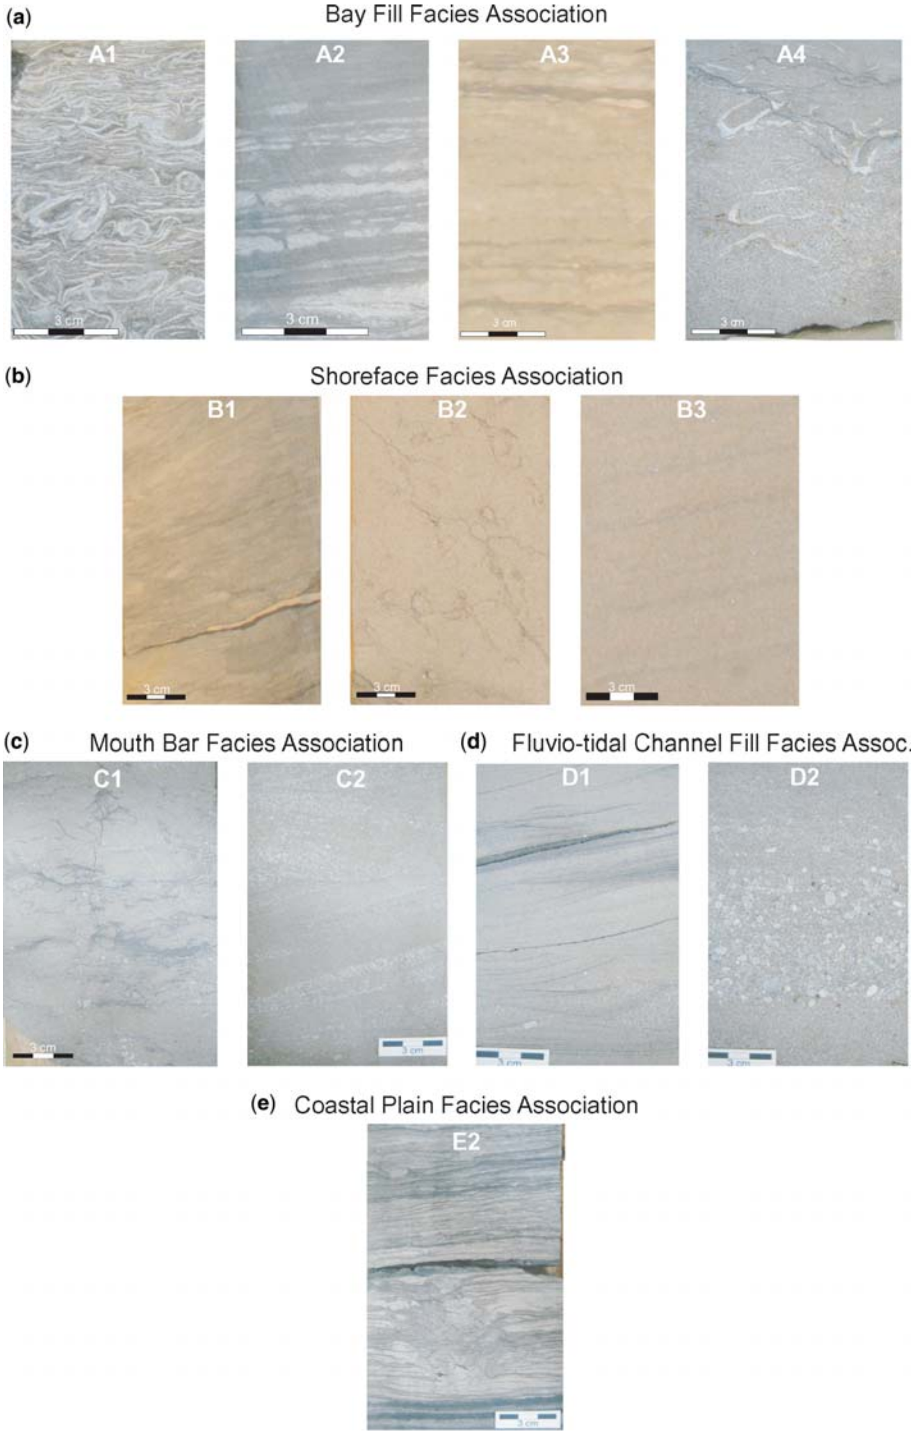

Fig. 5. Core photographs illustrating the selected facies in the principal facies associations of the Hugin Formation: (**a**) bay-fill; (**b**) shoreface; (**c**) mouth bar; (**d**) fluvio-tidal channel-fill; and (**e**) coastal plain. Photographs are located in the successions illustrated in Figure 4 where possible. Photos from: (a) A1, well K, 3838.70 cm; A2, well K, 3836.80 m; A3, well K, 3836.00 m; A4, well K, 3826.35 m; (b) B1, well D, 3599.70 m; B2, well D, 3584.25 m; B3, well D, 3581.10 m; (c) C1, well K, 3615.30 m; C2, 3608.30 m; (d) D1, well A, 3698.6 m; D2, well A, 3661.25 m; (e) E2, well A, 3687 m. Depths given are core depths and have not been shifted to wireline-log depths.

pervasive in facies B3. Bioturbation decreases in intensity and diversity from the base to top of the successions, allowing increasing preservation of cross-lamination. A monospecific assemblage of *Ophiomorpha* characterizes facies B2, whereas the ‘fuzzy’ appearance of some laminae in facies B3 may indicate cryptobioturbation or *Macaronichnus*.

Interpretation. The coarsening-upward trend in grain size and upward decrease in bioturbation intensity within the successions implies an upward increase in energy due to shallowing. The high intensity and diversity of bioturbation within fine-grained sediments is typical of the *Cruziana* ichnofacies indicating a low-energy and low-stress fully marine environment of deposition (MacEachern & Pemberton 1992; MacEachern & Bann 2008), whilst monospecific bioturbation by resilient *Ophiomorpha* burrows is typical of the *Skolithos* ichnofacies and is indicative of a loose substrate or higher energy setting such as middle or upper shoreface (MacEachern & Pemberton 1992; Martin 1993). Sharp-based, sparsely bioturbated sandstone beds within facies B1 and B2 are interpreted to record storm events (e.g. Pemberton

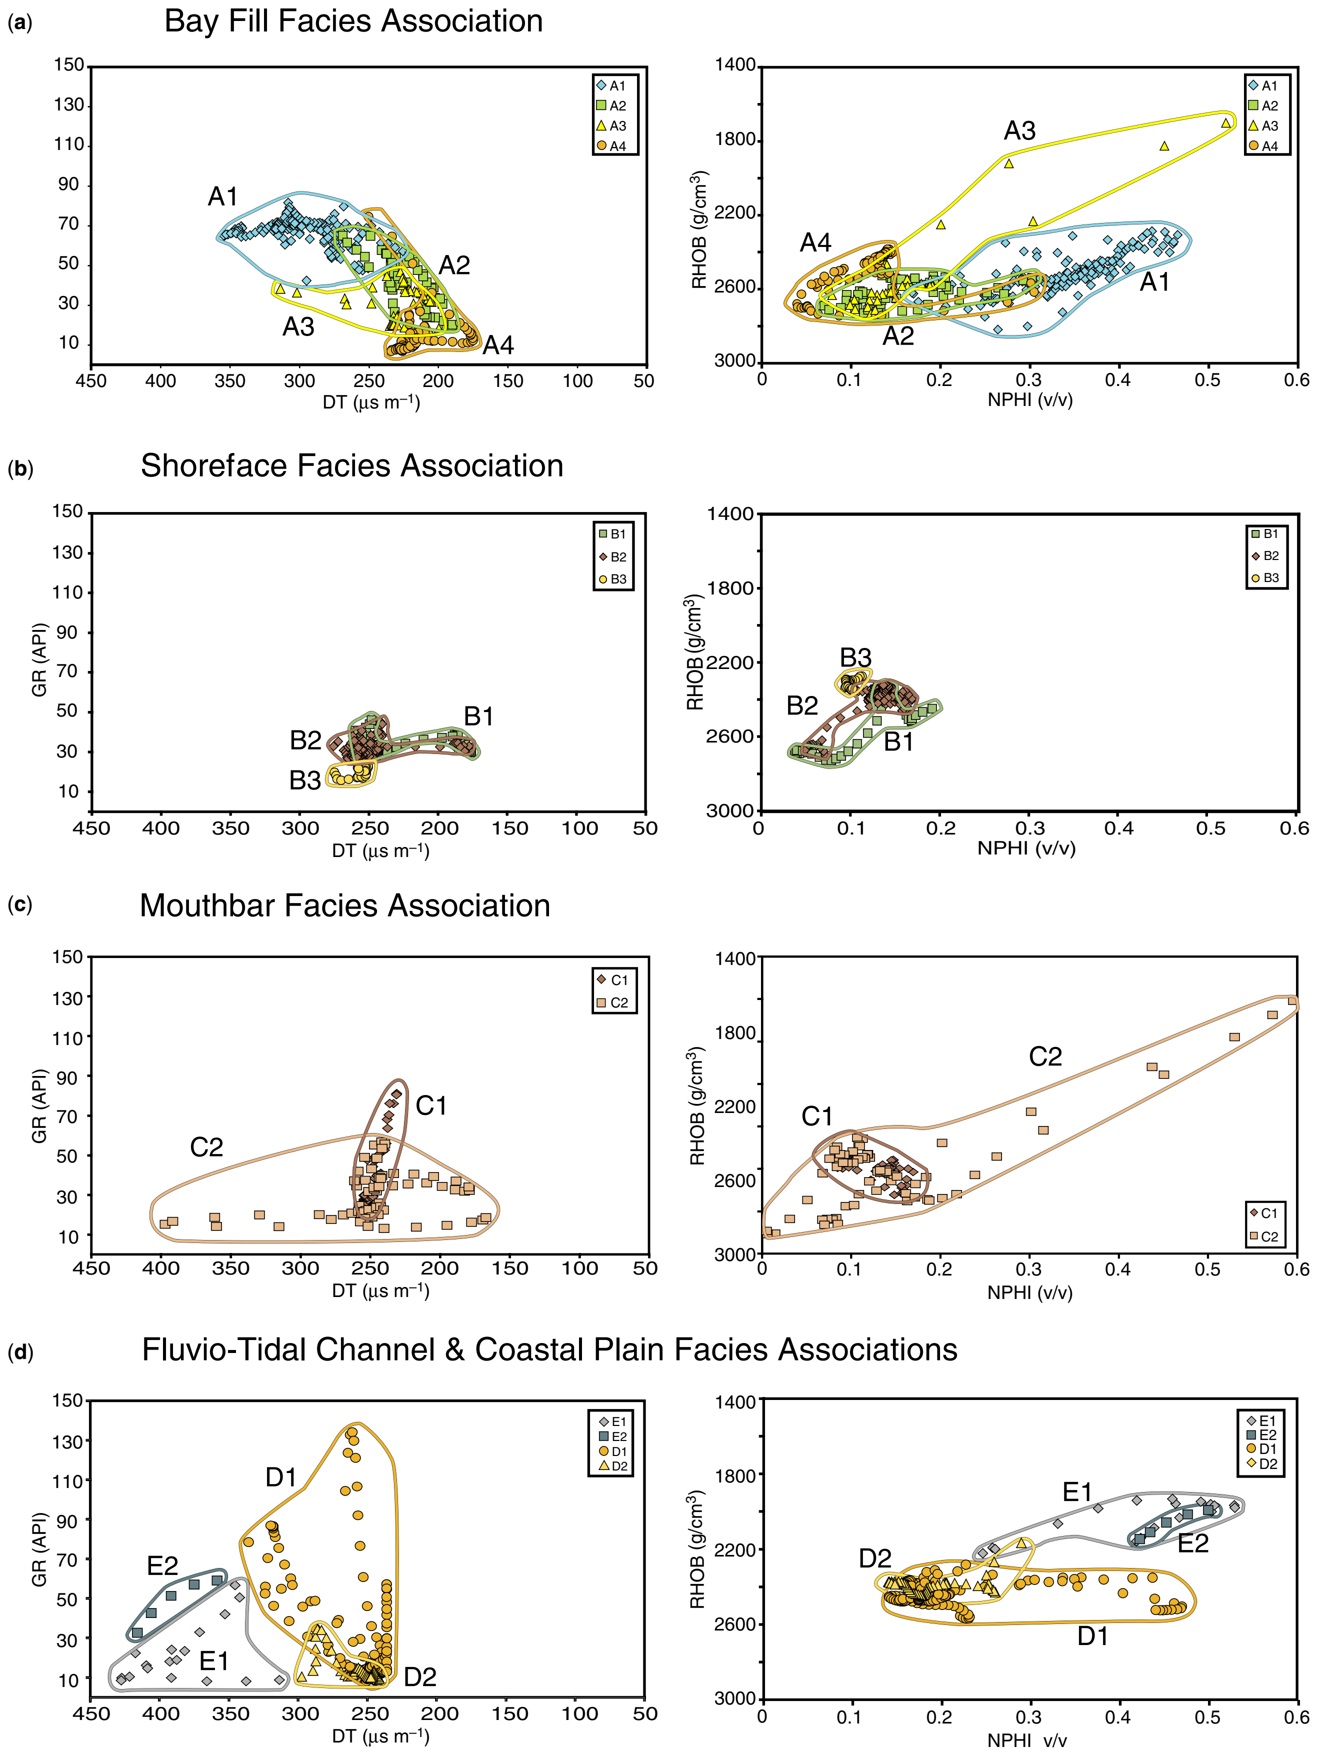

Fig. 6. Wireline-log cross-plots of, in the left-hand column, GR v. DT data and, in right-hand column, RHOB v. NPHI data. These cross-plots illustrate the quantitative log character of the principal facies associations of the Hugin Formation: (**a**) bay-fill (well H); (**b**) shoreface (well E); (**c**) mouth bar (well D); and (**d**) fluvio-tidal channel-fill and coastal plain (well A). The cross-plots are compiled with data from logged core intervals within the named wells.

et al. 1992). Well-sorted cross-laminated sandstones with low levels of bioturbation or cryptobioturbation (facies B3) are typical of upper shoreface-to-foreshore settings (Pemberton *et al.* 2008). This facies association is interpreted to have been deposited within a prograding shoreface with variable storm influence, as part of a strandplain, barrier-island or spit shoreline.

Sequence stratigraphy. At the base of successions of this facies association, distal or proximal lower shoreface deposits (facies B1 and B2) representing relatively deep-water marine deposition below the fair-weather wave base are juxtaposed directly above coastal plain coals or, less typically, fluvio-tidal channel-fill sandstones. The bases of these successions are therefore interpreted as flooding surfaces (*sensu* Van Wagoner *et al.* 1988). Some such flooding surfaces occur coincident with coarse-grained, locally carbonaceous or bioclastic lag deposits 5–15 cm thick. The stratigraphic context of these lags records transgression, and they are thus interpreted as wave ravinement surfaces (*sensu* Swift 1968), which suggests erosion of the uppermost part of the underlying succession during shoreface retreat. A few of these flooding surfaces are also associated with a calcite-cemented interval that may represent re-precipitation of bioclastic material (e.g. within a transgressive lag). In the central part of the study area, shoreface parasequences are rarely complete, comprising successions of facies B1–B2 only. The shoreline may not have prograded far enough into the basin to deposit upper shoreface deposits (facies B3) in this location, or they may have been deposited and subsequently removed by transgressive erosion during shoreline retreat. Alternatively, the deep *Ophiomorpha* that are characteristic of facies B2 may have intensely bioturbated remnant upper shoreface sandstones after flooding, giving the appearance of facies B2. Parasequence thickness varies from 10 to 23 m, and the duration of each parasequence is approximately 500 ka to over 1 Ma based on high-resolution biostratigraphy. To the south of the study area, shoreface parasequences comprise complete facies successions (B1–B3) that pass upwards into coal and coastal plain deposits, recording continued progradation of the shoreline without a sequence stratigraphic discontinuity.

Wireline-log character. The GR log character of successions of this facies association shows an upward-decreasing trend as they become more sandstone-rich towards their tops (Fig. 4b). The gradational contacts between facies can make recognition of distinct facies boundaries in wireline-log data difficult, although typically facies B1 is represented by a serrate, sometimes funnel-shaped GR curve, whilst facies B2 and B3 have lower GR values and are more blocky in character. Cross-plotting GR against DT and NPHI against RHOB (Fig. 6b) shows extensive overlap between facies B1 and B2, which makes distinguishing these facies difficult away from core control, whilst facies B3 plots as a distinctly separate group on both graphs.

Mouth bar facies association: C

This facies association is developed in the central part of the study area, where it interfingers with shoreface deposits. Deposits of this association are similar to the mouth bar facies association described in the Sleipner Vest Field by Folkestad & Satur (2008).

Description. Units of this facies association comprise either a complete upward-coarsening succession of C1 and overlying C2 facies, or individual beds of C1 and/or C2 facies that interfinger with shoreface deposits (Figs 4c & 5c). The lower part of complete successions consists of moderately to highly bioturbated siltstones and very fine-grained sandstones that coarsen upward to medium- through very coarse-grained sandstones (facies C1). Cross-bedding, including coarse-grained stringers, and mudstone laminae are preserved at bed tops and as drapes along cross-bed foresets where bioturbation intensity is lowest. Complete successions are more sand-rich in their upper parts, which corresponds with a decrease in bioturbation intensity and the loss of very coarse-grained sandstone stringers (facies C2). Successions of this facies association are commonly capped by a coal, although some are truncated by overlying shoreface deposits.

Interpretation. The upward-coarsening grain-size trend of successions of this facies association implies a progradational trend, with increasing proximity to the source of coarse sand and granules towards the top. The intensity and diversity of bioturbation suggests a marine depositional setting, whilst poorly sorted, coarse-grained sandstones and stringers are indicative of fluvial input (e.g. Fielding *et al.* 2005) and mudstone drapes and laminae may imply tidal action (e.g. Nio & Yang 1991). Preservation of indicators of fluvial sediment influx suggests deposition in mouth bars and signifies low wave reworking of fluvially supplied sediment, which may support wave suppression within the narrow graben (Folkestad & Satur 2008).

Sequence stratigraphy. Distal mouth bar deposits (facies C1) at the base of the succession are seen juxtaposed directly above both coastal plain coals and upper shoreface sandstones, implying a flooding surface (*sensu* Van Wagoner *et al.* 1988) at their base. A sharp increase in bioturbation, locally coupled with coarse-grained sandstone, carbonaceous and bioclastic beds, marks this surface. Where this facies association occurs interfingered with units of the shoreface facies association, autogenic lateral migration of the fluvial system is inferred to drive this stratigraphic relationship rather than a relative sea-level change.

Wireline-log character. The GR log character of this facies association is variable with upward-decreasing profiles and, less commonly, upward-increasing, blocky and funnel-shaped profiles recognized. Wireline-log cross-plots (Fig. 6c) show significant overlap between facies C1 and C2, although facies C2 exhibits a broader range of values. The wireline-log character of the mouth bar facies association (particularly facies C1) is very similar to that of the shoreface facies association, making it difficult to differentiate between the two facies associations away from core control.

Fluvio-tidal channel-fill facies association: D

Identified in the southern part of the study area, this facies association occurs closely associated with mouth bar and coastal plain deposits. Facies D1 is broadly equivalent to the tidal channel facies association previously described from the Sleipner Vest Field (Folkestad & Satur 2008).

Description. Facies D1 and D2 both comprise sharp-based, upward-fining successions of coarse- to medium-grained, cross-bedded sandstones (Figs 4d & 5d). In facies D1, the sandstones contain bi-directional cross-bed sets and/or swaley cross-stratification, and asymmetrical ripple forms preserved by mudstone drapes. Bioturbation intensity is low to zero, with rare escape traces present within finer-grained intervals. The sandstones in facies D2 contain unidirectional cross-bed sets which lack bioturbation and mud drapes, although carbonaceous fragments and laminae are common. Some successions of facies D2 exhibit a weak upward-coarsening trend in grain size in their lower parts. Units of facies D1 pass vertically and laterally into units of facies D2, but are also overlain by bay-fill, shoreface, mouth bar and offshore deposits. Units of facies D2 are commonly overlain by coals and coastal plain deposits.

Interpretation. The sharp, possibly erosive, bases and upward-fining character of successions of this facies association indicate deposition within channels under conditions of gradually decreasing energy, which may record channel migration or abandonment. Bi-directional cross-bed sets and mud drapes in facies D1 are indicative of tidal influence (e.g. Nio & Yang 1991), whilst the absence of such features in facies D2 suggests less tidal and marine influence. These interpretations imply that facies D2 is the updip equivalent of facies D1. Alternatively, the lack of tidal influence within facies D2 could represent deposition in rivers that lacked tidal amplification near their mouths and were associated with linear-to-lobate, deltaic shorelines; facies D1 would then represent deposition within funnel-shaped estuaries that locally amplified tidal currents. The overall depositional setting of this facies association is interpreted to be variably marine-influenced fluvial channel fills.

Sequence stratigraphy. The basal surfaces of successions of this facies association may not necessarily have sequence stratigraphic importance, but instead record autogenic channel migration and avulsion. However, where a unit of marine-influenced facies D1 directly overlies coastal plain deposits, a tidal ravinement surface is interpreted at its base, as the precursor or updip correlative to a flooding surface. Where such units overlie bay-fill deposits, they are difficult to distinguish from tidal inlets that formed as part of a barrier island and associated shoreface (facies A4, Table 1); inlet channel-fills pinch out landward into bay-fill deposits, whereas fluvio-tidal channel-fills extend up depositional dip into fluvial channels in the coastal plain. Sequence stratigraphic interpretation and correlation of channel-fill sandstones that overlie bay-fill deposits are therefore uncertain, particularly in the absence of core.

Wireline-log character. This facies association is generally represented by low GR values and a blocky GR profile (Fig. 4d), although rare upward-decreasing and upward-increasing GR profiles are also noted. Wireline cross-plots (Fig. 6d) highlight variation in the GR, RHOB and NPHI response of the facies (Table 1).

Coastal plain facies association: E

Thin accumulations of this facies association occur throughout the study area, although the thickest and best developed examples are closely associated with fluvio-tidal channel-fill deposits in the southern part of the study area.

Description. This facies association predominantly comprises coal (facies E1) with associated heterolithic deposits of interbedded mudstone, siltstone and very fine-grained sandstone (facies E2) (Figs 4e & 5e). Preserved root traces are common throughout the heteroliths, disrupting lamination below coal beds. Wood fragments occur within coal beds, and angular carbonaceous fragments from the coal beds are reworked into overlying sediments. Units of this facies association are locally eroded by fluvio-tidal channel-fill deposits and pass laterally into bay-fill and shoreface deposits. The units are abruptly overlain by offshore, shoreface, mouth bar and bay-fill deposits. Coal beds and thin successions of facies E2 cap upward-coarsening shoreface, mouth bar and bay-fill successions.

Interpretation. Coal deposition can occur in a wide range of depositional environments; however, the context of coals (facies E1) in the Hugin Formation suggests a coastal plain environment. Roots beneath the coal beds indicate that they developed *in situ*. The interbedding of sandstones and siltstones with mudstones in facies E2 suggests a regularly fluctuating energy regime, most likely related to variations in discharge and sediment load in adjacent fluvio-tidal channels. The association of facies E2 with coals (facies E1), bay-fill, shoreface, mouth-bar and fluvio-tidal channel-fill deposits supports a coastal plain environment of deposition.

Sequence stratigraphy. Thin intervals of the coastal plain facies association that cap upward-coarsening shoreface, mouth bar and bay-fill successions are interpreted to record subaerial deposition in response to shoreline progradation, and they thus form the upper part of shallow-marine and marginal-marine parasequences. Where these coastal plain intervals are abruptly overlain by offshore, shoreface, mouth bar and bay-fill deposits, their upper bounding surfaces are interpreted as flooding surfaces that record increases in water depth. Coal fragments reworked from the coastal plain intervals into overlying deposits imply erosion during transgression.

Wireline-log character. This facies association is typically represented by a low GR, blocky to serrate log curve (Fig. 4e), although funnel shaped patterns are also observed. This facies association is characterized by high DT values combined with low GR values (Fig. 6d). Coal units (facies E1) are distinctive throughout the study area with low GR, very slow sonic and low density values, allowing them to be easily identified away from core control.

Offshore open-marine facies association: F

This facies association is equivalent to the shales of the Heather Formation, and interfingers with shoreface, mouth bar and bay-fill deposits in the southern part of the study area.

Description. This facies association comprises highly bioturbated mudstones and siltstones that constitutes a single facies (F). Bioturbation ranges from moderate to high in intensity, and is highly diverse. Trace fossil assemblages are similar to the archetypal *Cruziana* ichnofacies (cf. MacEachern & Bann 2008). Unbioturbated, coarse-grained siltstone to very fine-grained sandstone beds occur locally, and contain parallel lamination and soft sediment deformation. Units of facies F are gradationally overlain by upward-coarsening shoreface and mouth bar deposits, and they pass laterally into bay-fill, shoreface and mouth bar deposits. These units abruptly overlie shoreface, bay-fill, fluvio-tidal channel-fill and coastal plain deposits.

Interpretation. The fine-grained character of these deposits, combined with their parallel laminated character where not bioturbated, suggests deposition by fall-out from suspension. The high degree of bioturbation by a fully marine trace fossil suite of the *Cruziana* ichnofacies implies deposition in an open-marine setting, below fair weather wave base. Sharp-based, coarser-grained beds that lack bioturbation are interpreted to have been deposited during major storm events. Soft-sediment deformation within and below these beds is attributed to loading and water escape.

Sequence stratigraphy. This facies association represents the deepest fully marine setting observed within the studied interval. Where units of the facies association are juxtaposed directly above shoreface, bay-fill, fluvio-tidal channel-fill or coastal plain deposits, their bases represent abrupt deepening across a flooding surface (*sensu* Van Wagoner *et al.* 1990). The gradational upper contacts of the units represent gradual shallowing into shoreface and mouth bar deposits.

Wireline-log character. Units of this facies association have consistently high GR values, with bed-scale variations in grain size represented by a slightly serrate GR-log character.

Sequence stratigraphic framework

The facies associations described above and their bounding sequence stratigraphic surfaces have been correlated to construct a regional sequence stratigraphic framework for the Hugin Formation within the study area. Correlation between the wells has been constrained by a newly revised, high-resolution biostratigraphic and chronostratigraphic scheme that is based on the Statoil ASA biostratigraphic framework for Jurassic strata in the North Sea. Although fine biostratigraphic resolution (*c.* 500 ka) was achieved within the marine Hugin and Heather formations, the long-ranging character of pollen and spores within the Sleipner Formation precludes a similarly detailed zonation of this unit. As a result, correlation of sequence stratigraphic surfaces between the Hugin and Sleipner formations is difficult. Regionally extensive flooding surfaces have been identified where marine microfossil assemblages with high diversity and abundance occur associated with distinctive GR profiles. Where possible, these regional extensive flooding surfaces have been tied into the widely used nomenclature of Partington *et al.* (1993) and are, therefore, referred to as maximum flooding surfaces. One additional regional maximum flooding surface has been identified, referred to below as MFS A; this surface is slightly older than MFS J42 (Partington *et al.* 1993). Higher-order flooding surfaces of sub-regional and local extent have been identified by facies interpretation of core and wireline-log data, and their correlation constrained by distinct palynological events and zones. The sequence stratigraphic framework and associated facies distributions are illustrated below using three correlations through the study area (Figs 3 & 7–9) and two gross palaeogeographic reconstructions that represent early Hugin deposition (MFS A) and mid to late Hugin deposition (MFS J44) (Fig. 10). The presented maps reflect snapshots in time recording final shallow-marine deposition within the parasequence that precedes the transgression associated with the named MFS.

The highly variable nature of interpreted subsidence rates and sediment supply across the study area, which is typical of both rift basins and salt-influenced provinces, makes it both scientifically unsound and impractical to apply systems-tract terminology. Stratigraphic architectures are demonstrably different in the northern, central and southern parts of the study area (Figs 7–9), and they are also likely to have varied around actively growing structures such as rift-related fault blocks (e.g. Gawthorpe *et al.* 1994; Gawthorpe & Leeder 2000) and salt diapirs and walls (e.g. Giles & Lawton 2002; Aschoff & Giles 2005). Although alternating highstand and transgressive systems tracts have been interpreted in the rapidly, but laterally uniformly subsiding Sleipner Vest Field (Folkestad & Satur 2008), it is more appropriate over much of the study area to apply descriptive sequence stratigraphic schemes that do not assume cyclical relative sea-level changes of at least sub-regional extent. Such descriptive schemes include the terminology of parasequence stacking patterns (Van Wagoner *et al.* 1988) and shoreline trajectory analysis (Helland-Hansen & Martinsen 1996; Helland-Hansen & Hampson 2009). We refer to sequence stratigraphic surfaces of various types and lateral extents below, without forcing the intervening stratigraphic packages into an inappropriate systems-tract template.

Regional correlation along basin axis

The studied strata are subdivided into five intervals bounded by regional maximum flooding surfaces that can be correlated along the axis of the South Viking Graben (Figs 3 & 7). Within the first, lowermost interval (below MFS J36), shallow marine deposition (Hugin Formation) was confined to the northern part of the study area within restricted marine bays and/or lagoons which pass to the south into coastal plain deposits (Sleipner Formation). In the second interval (between MFS J36 and MFS A), bay-fill deposition persisted in the north and passed towards the central part of the study area into coastal plain deposits (Sleipner Formation) overlain locally by shoreface deposits (Hugin Formation) and offshore mudstones (Heather Formation). These offshore mudstones are penetrated within the most basinward (i.e. westwards) well (well F, Figs 3 & 7) and imply that locally irregular shoreline trends were developed as a result of early flooding of the graben. Further south, shoreface deposits pass updip into coastal plain (Sleipner Formation) deposits. In the third interval (between an MFS A and MFS J44), offshore mudstone (Heather Formation) deposition dominated the study area with shoreface deposition (Hugin Formation) locally restricted to the central and northernmost parts of the study area. Interpretation of the age and depositional setting of sandstones in the northernmost well (well I, Fig. 7) is, however, poorly constrained by biostratigraphic and core data. Similarly, the fourth interval (between MFS J44 and MFS J46) is dominated by offshore mudstone (Heather Formation) deposition across the study area, with two exceptions. Firstly, shoreface sandstones persist in the central part of the study area (well E, Fig. 7). Secondly, a series of parasequences comprising fluvio-tidal channel-fill, bay-fill, mouth bar and coastal plain deposits build out from the south (well A, Fig. 7), as part of a major delta system present in the vicinity of the Sleipner Vest Field (Vollset & Dore 1984; Milner & Olsen 1998; Folkestad & Satur 2008). This depositional pattern persists into the fifth, uppermost interval (between MFS J46 and MFS J52), with both shoreface and fluvio-deltaic deposits being capped by offshore mudstones (Heather Formation) in the upper part of this interval.

The intervals defined by regional maximum flooding surfaces can be further subdivided by flooding surfaces of sub-regional and local extent. The limited extent of these flooding surfaces most likely reflects variations in sediment supply and accommodation creation that were caused by rift-fault initiation and linkage and/or by the growth of salt-cored highs (e.g. Figs 7b & 9b). Candidate sequence boundaries of local extent are interpreted in the southernmost part of the study area (well A, Fig. 7), based on vertical facies juxtapositions that suggest abrupt basinward facies dislocations. These sequence boundaries can be traced into and through the Sleipner Vest Field (corresponding to the surfaces of maximum regression of Folkestad & Satur 2008), but cannot be correlated more widely. Their limited extent is typical of net-transgressive strata, within which sequence boundary expression is suppressed (e.g. Nummedal & Swift 1987; Sneider *et al.* 1995), and also of rift basins, where sequence boundary development is enhanced by uplift in marginal areas and suppressed by increased subsidence in axial depocentres (e.g. Mitchener *et al.* 1992; Gawthorpe *et al.* 1994).

Axis-perpendicular sub-regional correlation, Sigrun–Gudrun area

In the northern part of the study area, near the Sigrun and Gudrun fields, thick (up to 200 m) successions of up to 12 stacked bay-fill and shoreface parasequences are defined by localized flooding surfaces (Fig. 8). Most of this succession occurs within the second regionally mapped interval (between MFS J36 and MFS A). The underlying regionally mapped interval (below MFS J36) lies below the interval penetrated in the westward-lying wells (well J, Fig. 8) and is represented by coastal plain (Sleipner Formation) deposits or an unconformity in the eastern part of the Sigrun–Gudrun area. The bay-fill parasequences thicken markedly

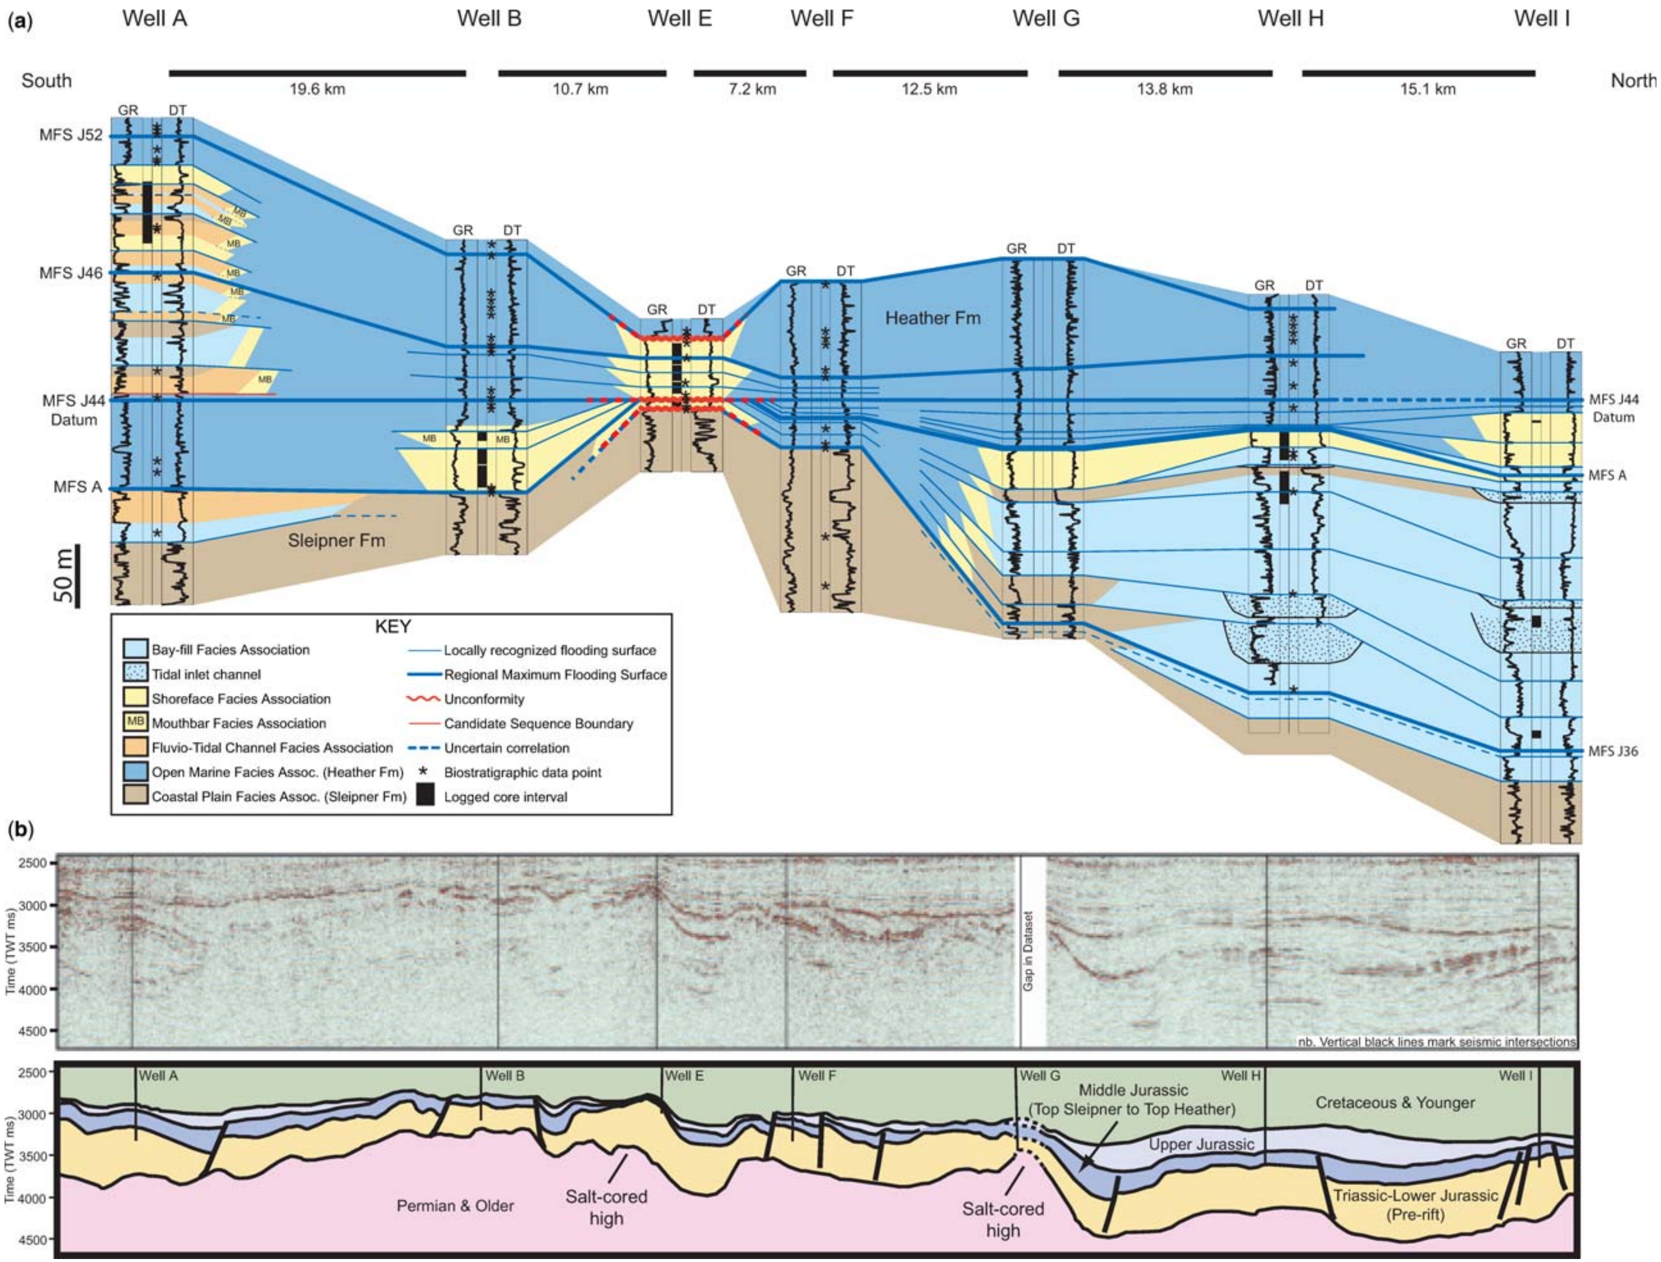

Fig. 7. (**a**) Regional north–south-oriented well-log correlation panel and (**b**) corresponding seismic section along the axis of the South Viking Graben (see Fig. 3 for location). In general, the Hugin Formation becomes younger towards the south. Well-log correlation is constrained by a combination of seismically mapped thicknesses and biostratigraphic data in wells A, B, E, F and H (biostratigraphic sample points are marked by asterisks).

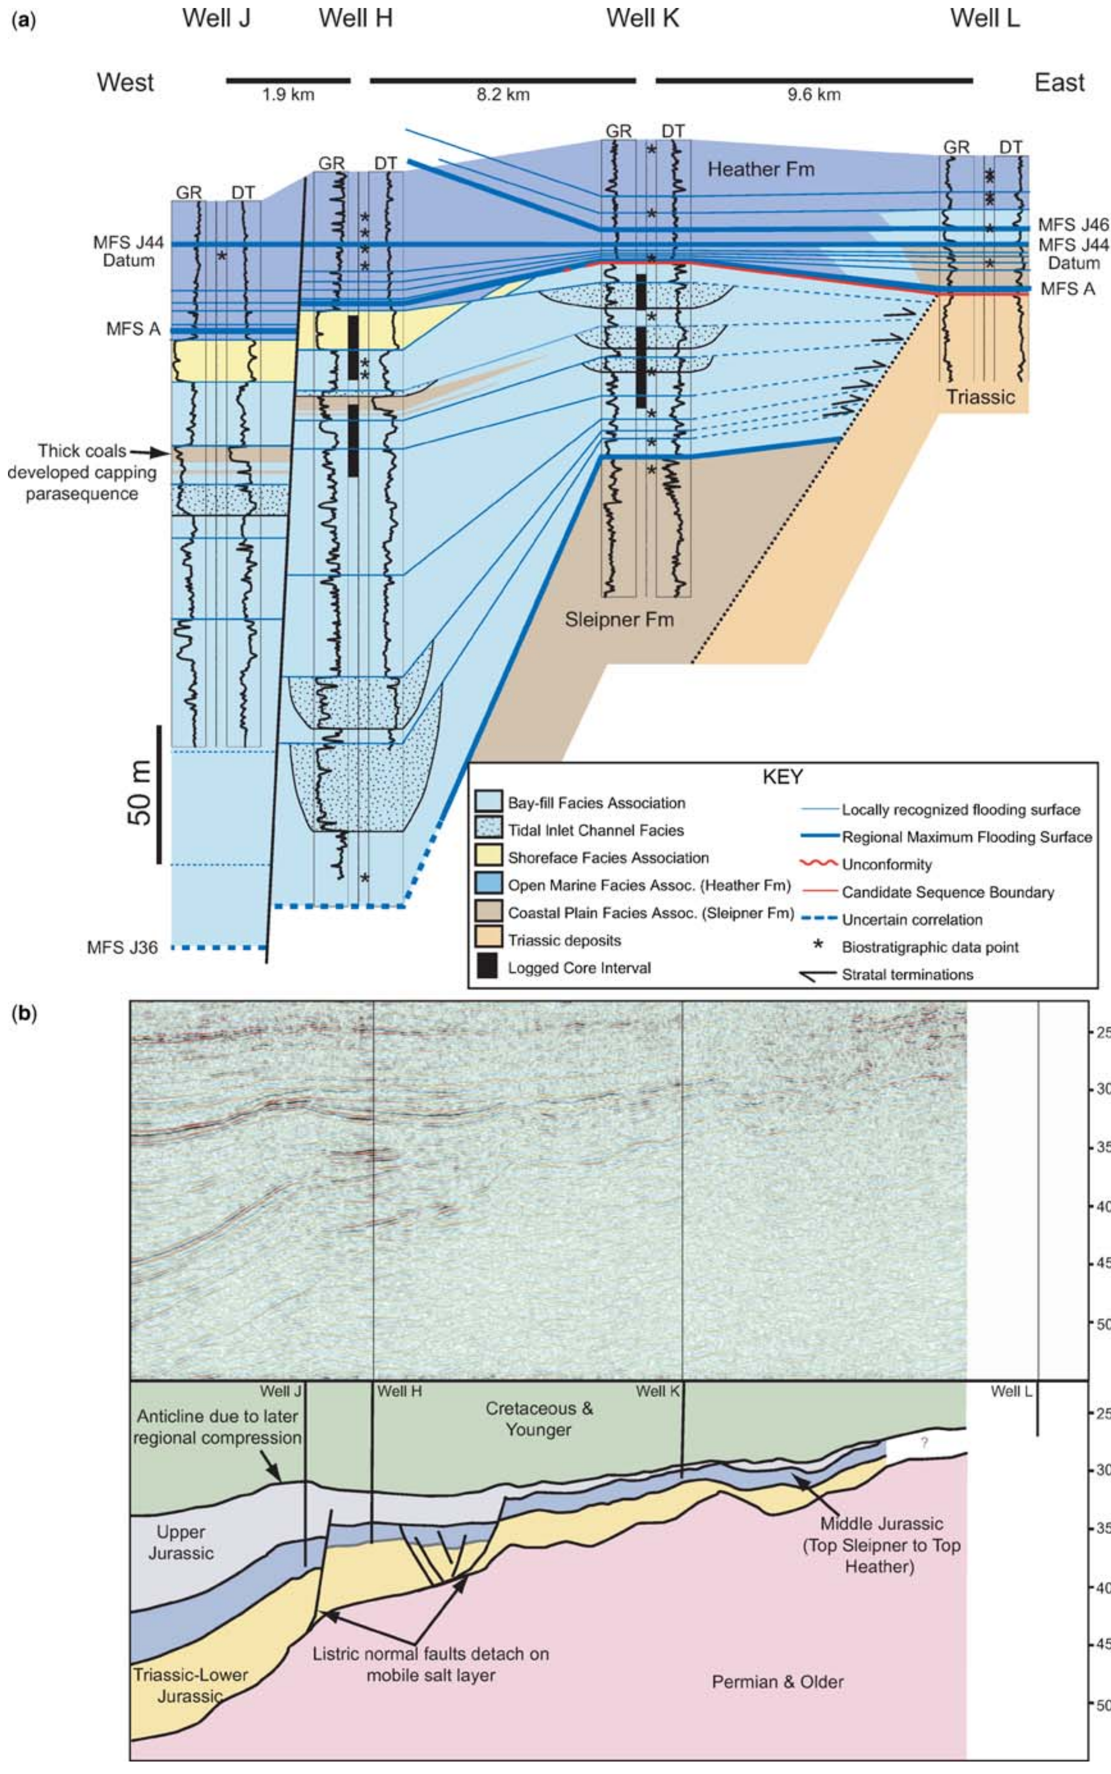

Fig. 8. (**a**) Regional west–east-oriented well-log correlation panel and (**b**) corresponding seismic section perpendicular to the axis of the South Viking Graben in the Sigrun–Gudrun area (see Fig. 3 for location). The Hugin Formation becomes younger towards the east. Well-log correlation is constrained by a combination of seismically mapped thicknesses, which indicate that the fault between wells H and J was active during Hugin Formation deposition, and biostratigraphic data in wells H, J, K and L (biostratigraphic sample points are marked by asterisks). The key is the same as for Figure 7.

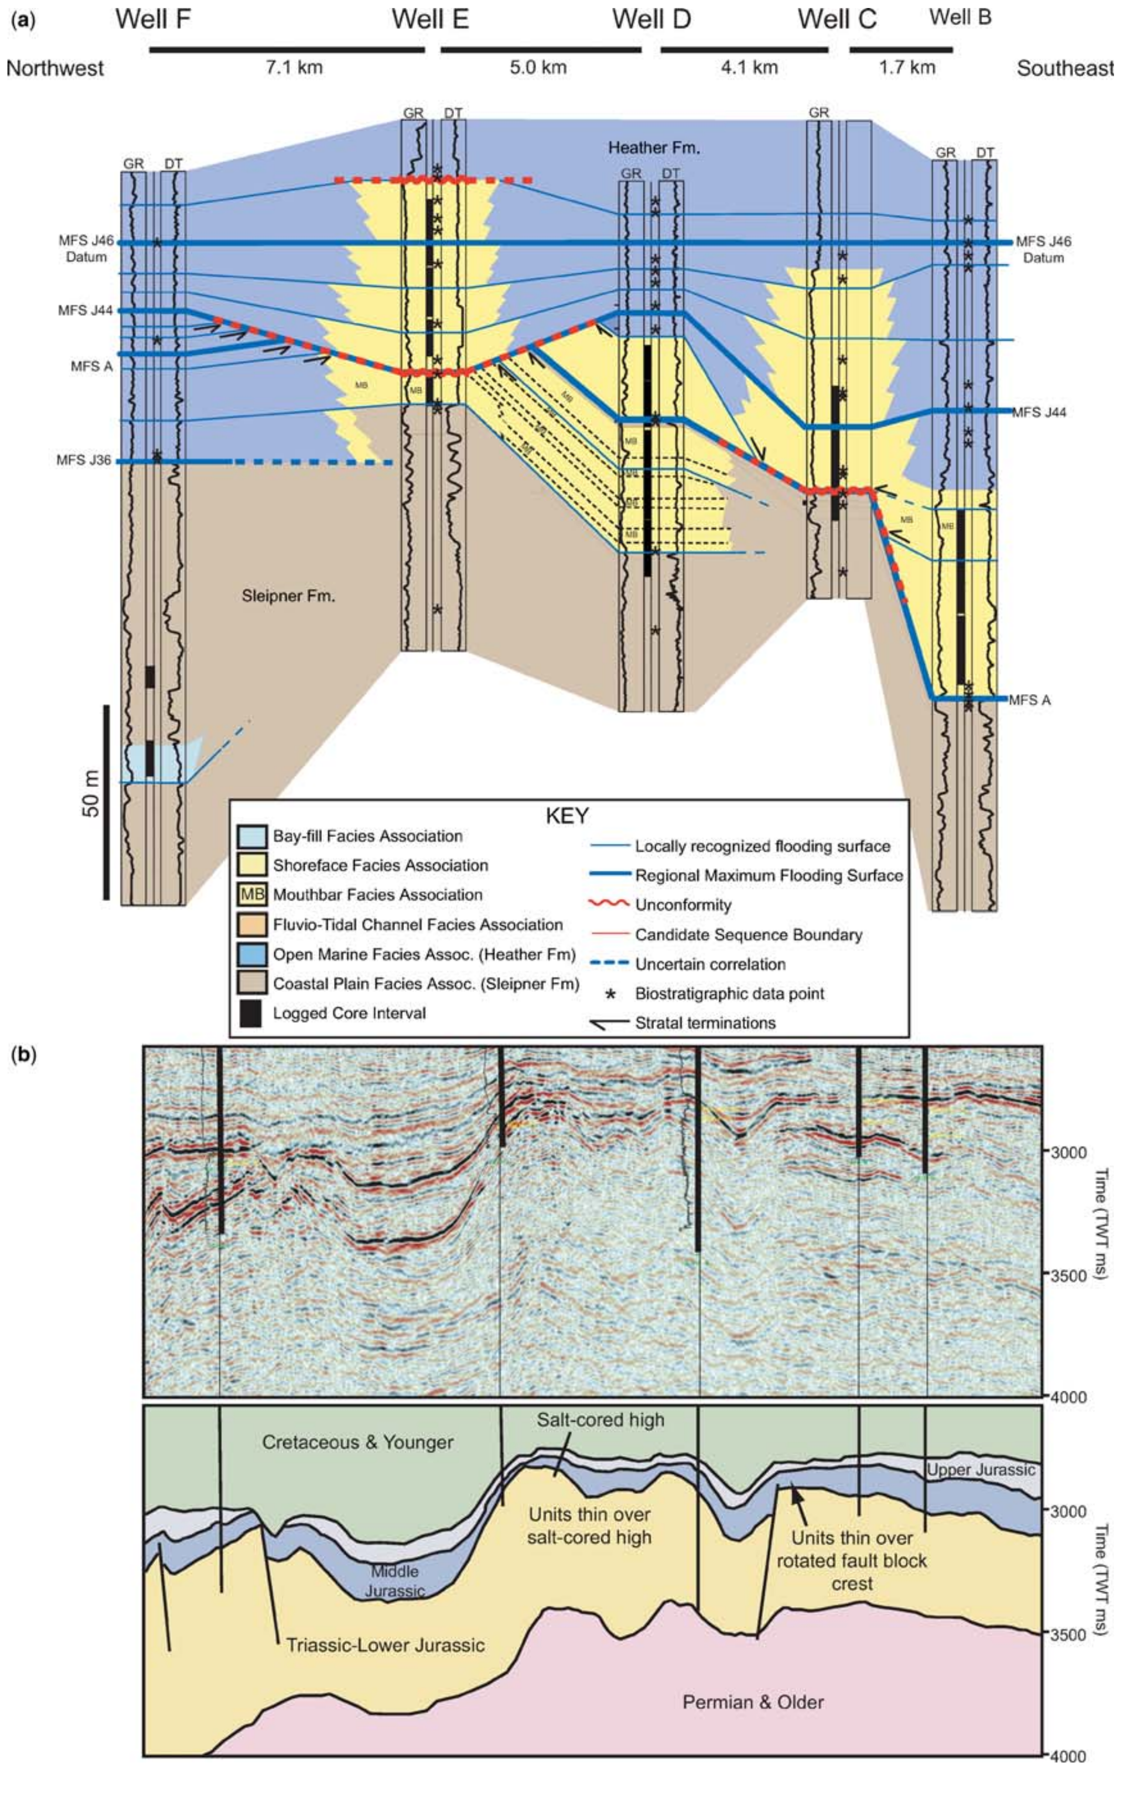

Fig. 9. (**a**) Regional NW–SE-oriented well-log correlation panel and (**b**) corresponding seismic section oblique to the axis of the South Viking Graben in the Dagny area (see Fig. 3 for location). The Hugin Formation is highly diachronous and exhibits large local thickness variations, including across syn-depositional faults. Well-log correlation is constrained by a combination of seismically mapped thicknesses and biostratigraphic data in wells B, C, D, E and F (biostratigraphic sample points are marked by asterisks). The key is the same as for Figure 7.

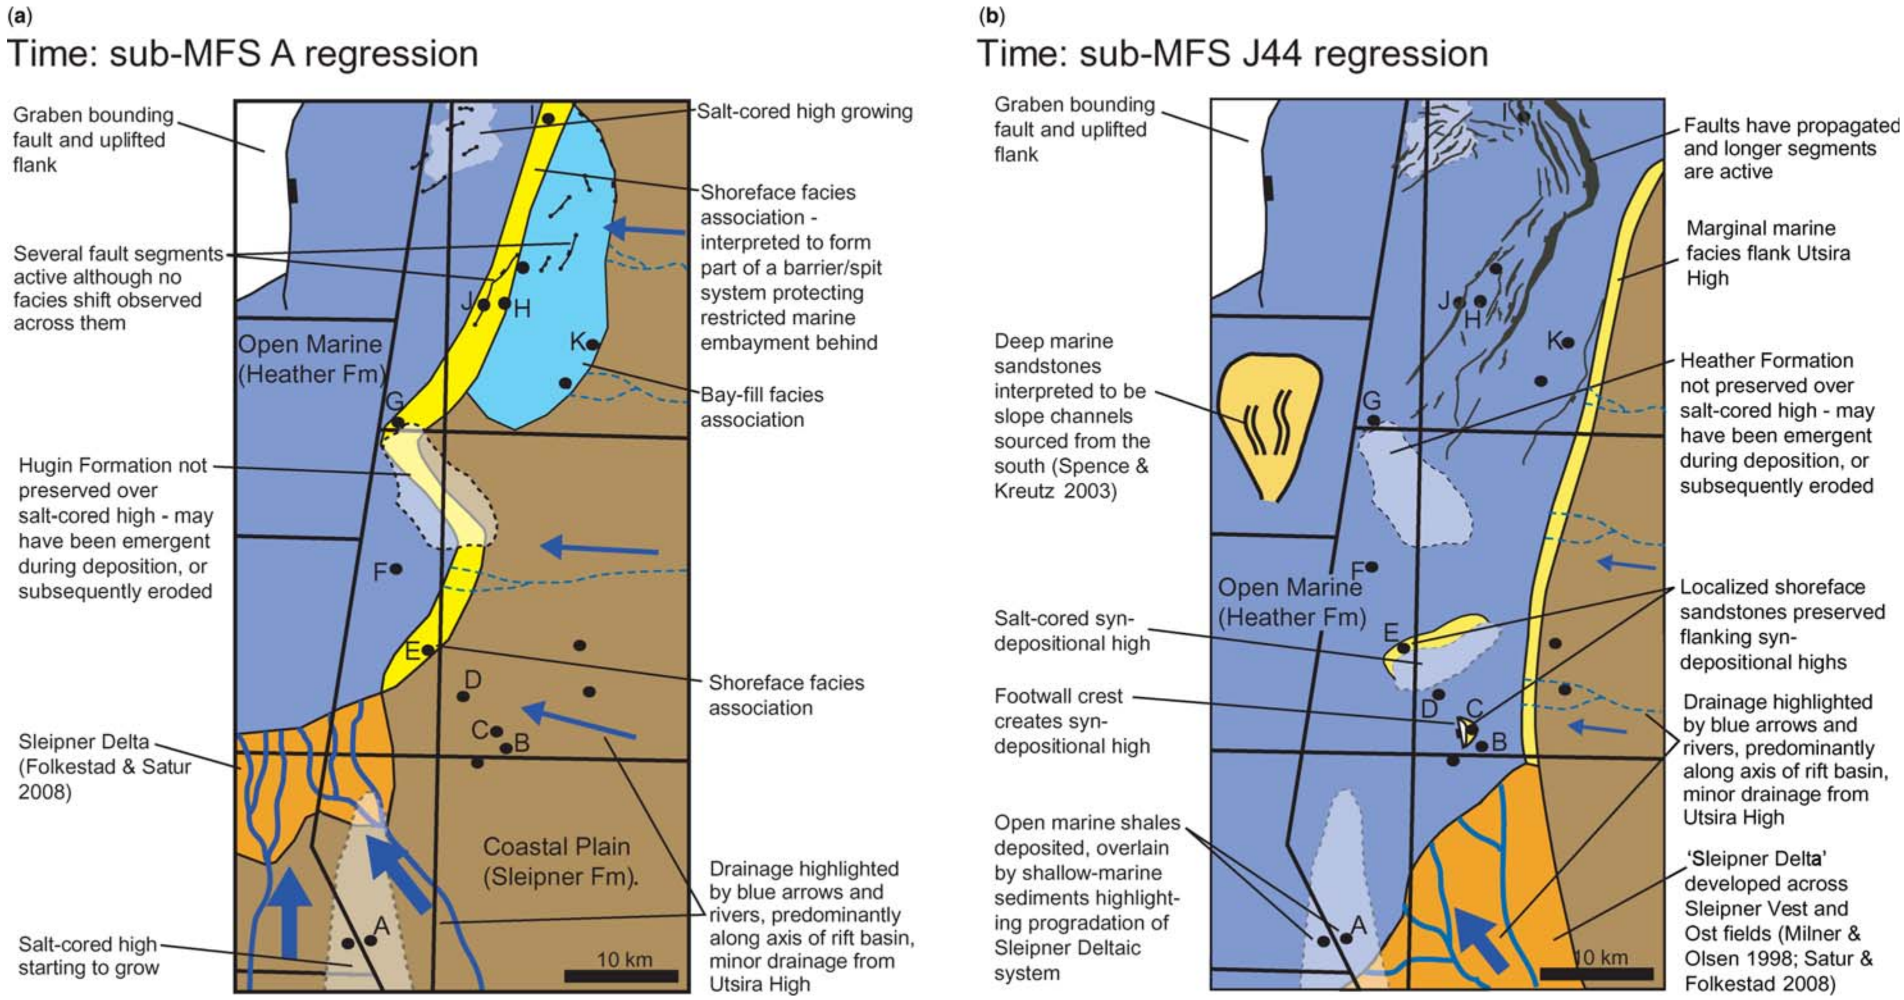

Fig. 10. Palaeogeographic reconstructions of deposition in the study area during (**a**) Early Callovian (MFS A) and (**b**) Middle Callovian (MFS J44) times.

towards the west and thin to the east, where they are interpreted to onlap Triassic strata. Westward thickening also occurs in the hanging wall of a normal fault in the western part of the Sigrun–Gudrun area, but this thickening is not accompanied by a noticeable facies shift. Several of the bay-fill parasequences are truncated by thick (up to 45 m) channel-fill sandstones that are not cored. These sandstones are interpreted as tidal inlet channel-fill deposits (facies A4), based on their clean, low GR character, which is consistent with marine reworking, and the occurrence of shoreface sandstones in overlying strata. Alternatively, these sandstones may alternatively represent fluvio-tidal channel-fill deposits (facies D1, D2). Shoreface sandstones occur in the uppermost Hugin Formation, above the stacked bay-fill parasequences, in the western part of the Sigrun–Gudrun area. These shoreface deposits pass eastward into bay-fill deposits. Prior to formation of regional flooding surface MFS A, most of the Sigrun–Gudrun area had been covered by offshore mudstones (Heather Formation). Above this surface, in the third and fourth regionally mapped intervals (between MFS A and MFS J46), coastal plain deposits (Sleipner Formation) unconformably overlie Triassic strata and pass westward into bay-fill deposits and offshore mudstones (Heather Formation). The entire Sigrun–Gudrun area was flooded during the fifth regionally mapped interval (between MFS J46 and MFS J52).

Flooding of the Sigrun–Gudrun area was diachronous, becoming younger from west to east. The relatively low-energy, restricted-marine character of the bay-fill parasequences implies the presence further west of coeval barriers and spits fronted by wave-dominated shorefaces (Harris & Fowler 1987; Hampson *et al.* 2009) or rift-generated islands and shoals. The local occurrence of wave-dominated shoreface deposits above the bay-fill parasequences supports the former interpretation, although the latter cannot be discounted. In any case, aggradational stacking of the bay-fill parasequences indicates that sediment supply and accommodation generated by tectonic subsidence were roughly in balance during deposition of the second regionally mapped interval (between MFS J36 and MFS A).

Axis-perpendicular sub-regional correlation, Dagny area

In the centre of the study area, around the Dagny Field, localized flooding surfaces subdivide the five regionally mapped intervals into 11 parasequences (Figs 3 & 9), which cannot be correlated to those in the Sigrun–Gudrun area (Fig. 8). Coastal plain (Sleipner Formation) deposition occurred across the Dagny area in the lowermost regionally mapped interval (below MFS J36). Marine flooding of the Dagny area commenced during deposition of the second regionally mapped interval (between MFS J36 and MFS A). Within this interval, offshore mudstones (Heather Formation) in the NW pass to the south through mouth bar and shoreface deposits (Hugin Formation) into coastal plain deposits (Sleipner Formation). Within the overlying regionally mapped interval (between MFS A and MFS J44), marine flooding occurred over the whole of the Dagny area, with shoreface sandstones and offshore mudstones being deposited. The base and top of this interval are marked by local unconformities, interpreted due to missing or significantly thinned biostratigraphic zones. Observation of seismic reflection event geometries suggests these surfaces are angular unconformities developed towards the crest of salt-cored structural highs or rotated fault blocks. The lower unconformity correlates to a thick shoreface succession (well B, Fig. 9), which is interpreted to onlap or downlap the underlying shoreface parasequences (well C, Fig. 9). Biostratigraphic data indicate that the upper unconformity is marked by significant missing sections, implying deep erosional truncation of underlying shoreface parasequences that may have been deposited coevally with those observed to the SE (well D, Fig. 9), while correlative offshore mudstones occur towards the NW (in well E, Fig. 9). The fourth regionally mapped interval (between MFS J44 and MFS J46) is present across the Dagny area and contains laterally discontinuous shoreface sandstones (in wells C and E, Fig. 9) that pinch out to the NW and SE into offshore shales (Heather Formation). The entire Dagny area was flooded prior to deposition of regional maximum flooding surface MFS J46, with the exception of well E (Fig. 9), in which shoreface sandstones were deposited. Biostratigraphic data indicate that these sandstones are capped by another locally developed Early to Middle Oxfordian unconformity, which lies within the fifth regionally mapped interval (between MFS J46 and MFS J52) and is overlain by offshore mudstones (Heather Formation).

The mouth bar deposits interpreted within the second and third regionally mapped intervals (between MFS J36 and MFS J44) in the northwestern part of the Dagny area pass updip into coastal plain deposits (Sleipner Formation) (Fig. 9), suggesting that they are linked to either the delta system in the Sleipner Vest area to the south or to small rivers draining the eastern graben margin. This subtle fluvial signature is absent in younger units, corresponding to the fourth and fifth regionally mapped intervals (between MFS J44 and MFS J52). In these younger intervals, the complex and highly localized distribution of shoreface deposits suggest that they were geographically detached from the Sleipner Vest delta system to the south and potentially from the shoreline along the eastern graben margin. The resulting shoreface sandstone distribution is interpreted to have been controlled by syn-depositional development of salt-cored highs and rotated fault-block crests that formed islands and shoals whilst deeper water depositional conditions prevailed elsewhere in the Dagny area. These 'isolated' shoreface sandstones may have been deposited by in-place reworking of older sandstones that were eroded at angular unconformities, or they may have been fed by southward-directed longshore currents that nourished spit systems connected to the Utsira High, on the eastern graben margin (Figs 1 & 10b). The rapid facies transitions from syn-depositional topographic highs, marked by angular unconformities, into adjacent areas of expanded stratigraphy indicate that sediment supply was not sufficient to keep pace with accommodation generated by rift-fault development and salt movement.

Palaeogeographic reconstruction, sub-MFS A regression

The well correlations described above highlight the diachroneity and complex spatial distribution of flooding within the South Viking Graben during the Middle Jurassic. These patterns become clearer in palaeogeographic reconstructions described below.

Prior to transgression and development of regional maximum flooding surface MFS A (Figs 7–9), coastal plain deposition (Sleipner Formation) was prevalent throughout much of the study area, with shallow-marine sedimentation limited to the NW, in the Sigrun–Gudrun area (Fig. 10a). Barrier islands fronted by wave-dominated shorefaces are interpreted to have been the predominant shoreline type in the northern part of the study area. These barrier islands sheltered a restricted marine embayment to the east, on the western flank of the Utsira High. The barrier islands are inferred to have developed initially during parasequence-bounding transgressions, but may have been maintained during subsequent regressions by southward-directed sand transport via longshore currents, as occurs in approximately one-third of modern barrier island systems (Stutz & Pilkey 2001). Minor river systems are interpreted to have drained from the Utsira High down the hanging-wall dipslope towards the main graben-bounding fault and into this embayment. The barrier island system may have been supplied with sediment by southward-directed longshore drift generated by oblique wave approach from the north or NW, or by transgressive reworking of underlying bay-fill deposits during barrier retreat. The former mechanism appears more likely, because the shoreface sandstones are significantly coarser grained than the bay-fill deposits. The ultimate source of such coarse sand was most likely the Utsira High (Fig. 1), where Cretaceous and Cenozoic sediments directly overlie eroded granitic basement (e.g. Zanella & Coward 2003), although potential drainage systems that supplied this sediment to the shoreline are not resolved in seismic and well data.

A salt-cored high is mapped in seismic data to the south of the restricted marine embayment, in an area lacking well control in between the Sigrun–Gudrun and Dagny areas; Middle Jurassic strata are absent over this structure. This absence implies either non-deposition or subsequent erosion of the Middle Jurassic section; the former interpretation would indicate that the structure formed a syn-depositional topographic high that may have defined the southern limit of the restricted marine embayment.

To the south of this salt-cored high, in the Dagny area, shoreface sandstones abut directly against coastal plain deposits, implying a wave-dominated strandplain shoreline. Further south, in the area around the Sleipner Vest Field, fluvial–deltaic deposition occurred. The deposits of the 'Sleipner Delta' were influenced by both waves and tides (Folkestad & Satur 2008). Although the limited wave energy in these deposits appears to contradict the interpretation of strong wave-generated longshore currents in the Sigrun–Gudrun area, the discrepancy can be explained by the more enclosed and sheltered location of the Sleipner Vest area at the southern limit of the embryonic South Viking Graben. Folkestad & Satur (2008) argue that the narrow geometry of the graben in this area would have suppressed wave action and amplified tidal currents. Dominant fluvial drainage into the South Viking Graben is interpreted to have been from the south, along the basin axis, and the 'Sleipner Delta' deposits form a small component of the regional back-stepping Middle-to-Upper Jurassic 'Brent Delta' systems (Rattey & Hayward 1993; Milner & Olsen 1998; Husmo *et al.* 2003).

Palaeogeographic reconstruction, sub-MFS J44 regression

Prior to transgression and development of regional maximum flooding surface MFS J44 (Figs 7–9), the majority of the study area was flooded and offshore mudstone deposition (Heather Formation) was prevalent (Fig. 10b), with deepwater fan sandstones (Ling Member, Heather Formation) deposited in the basin axis within the UK sector (e.g. in well 16/8A-4; Cockings *et al.* 1992). The distribution of these deepwater fan sandstones is poorly defined, but they are interpreted to have been axially sourced from the south (Spence & Kreutz 2003). Coastal plain deposits (Sleipner Formation) lay in the SE of the study area and are interpreted to have been fringed by shoreline deposits that are not penetrated by wells. These deposits are inferred to be shoreface sandstones rather than bay-fill heteroliths due to the wider, more open geometry of the basin at this time. 'Isolated' shoreface sandstones are locally developed within the Dagny area, most likely fringing syn-depositional topographic highs formed by fault-block crests and salt-cored structures. Fluvial–deltaic deposits are not present in the study area at this time but occur further south in the area of the Sleipner Vest and Ost fields (Folkestad & Satur 2008). The 'Sleipner Delta' system later prograded to the north and west, to deposit younger fluvio-deltaic units within the study area (between MFS J44 and MFS J52 in well A, Fig. 7).

Summary and implications for exploration

The Hugin Formation was deposited during a tectonically driven transgression that flooded the South Viking Graben. Biostratigraphic data permit robust correlation of regional maximum flooding surfaces over distances of several tens of kilometres, and these correlations indicate overall younging of the unit up the hanging wall to the east, and along the main basin axis to the south. Relatively early flooding (Middle Callovian, MFS A) of the southernmost wells, however, implies that open marine conditions may have existed within the basin axis at this time. Biostratigraphically driven correlations also indicate that each of the main facies associations was developed within a different structural location and therefore had local stratigraphic development controlled by markedly different tectonic styles. In addition, distance from the main fluvial sediment supply system into the basin axis from the south was also a key control on facies development and distribution. Parasequence-bounding flooding surfaces and candidate sequence boundaries are also recognized and correlated locally; they cannot, however, be confidently correlated throughout the area. This is interpreted to be a function of the overall transgressive nature of the succession and, more importantly, significant spatial variations in fault- and halokinesis-controlled subsidence across the basin. Differential subsidence restricted sequence boundary development to the basin flanks and these surfaces are interpreted to pass into correlative conformities or flooding surfaces in more basinal settings.

The complex spatial variations in facies within the Hugin Formation have significant implications for regional exploration within the South Viking Graben. The more prospective reservoir intervals are likely to be in the upper part of the unit where shallow-marine rather than restricted-marine deposits are best developed. Potential reservoir sandstones occur in four locations:

(1) North–south-trending belts of shoreface sandstone occur in northern parts of the study area, together with more laterally restricted, tidal inlet channel-fill sandstones that erode into bay-fill deposits of marginal reservoir quality. These potential reservoir sandstones, although deposited during active growth faulting, do not appear to have had their location or areal extent determined by syn-depositional tectonic features. Therefore, predicting their occurrence based on structural location is problematic.
(2) Shoreface sandstones with complex plan-view geometries and rapid lateral pinchouts occur in central parts of the study area. These sandstones fringe or overlie growing halokinesis-related structures and other palaeo-topographic highs.
(3) North–south-trending, channelized and lobate mouth-bar sandstones of the 'Sleipner Delta' remained relatively fixed in their overall location within southern parts of the study area. The gross distribution of these sandstones is caused by high fluvial sediment supply from the south, focussed along the main axial drainage pathway.
(4) Axially fed deepwater fan deposits of the Ling Sandstone Member (Heather Formation) occur in the basin centre. These deepwater sandstones may have been genetically linked to the broadly coeval shallow-marine and coastal-plain deposits of the 'Sleipner Delta', although the details of this linkage are unclear in the absence of more data to further constrain their age and palaeogeographic distribution.

The stratigraphic and palaeogeographic reconstructions presented here indicate that the geometry and distribution of these various potential reservoir sandstones is closely related to both depositional regime (i.e. shoreface, river-dominated delta, barred lagoons) and structural location. Therefore, a robust understanding of temporal and spatial variation in depositional system type and tectonically driven, syn-depositional basin geometry is critical to successful exploration of reservoirs in the Hugin Formation and coeval strata.

Statoil ASA are thanked for funding this research project, and together with their partners within licence PL303 are thanked for permission to publish this work. We also thank A. Tjemsland for biostratigraphic analysis and related discussions, and K. Kane for help with seismic interpretation and drafting of some figures. Landmark Graphics are gratefully acknowledged for provision of OpenWorks software through the Academic Licence Agreement with Imperial College.

Reappraisal of the sequence stratigraphy of the Humber Group of the UK Central Graben

P. J. SANSOM

BG Group, Thames Valley Park, Reading, Berkshire RG6 1PT, UK (e-mail: pamela.sansom@bg-group.com)

Abstract: Deposition of the Callovian–Ryazanian Humber Group of the UK Central Graben occurred during rifting and long-term relative sea-level rise, which acted to suppress the formation of eustatically forced Exxon-type sequence boundaries. The superposition of highly variable halokinetically controlled subsidence means that classic, passive-margin derived sequence stratigraphic models are not appropriate to describe stratigraphic evolution in this rift setting. The sequence stratigraphy of the Humber Group has been re-evaluated using a transgressive–regressive sequence model, where maximum regressive surfaces are employed as sequence bounding surfaces. The Humber Group comprises two megasequences which reveal distinct phases of evolution of the basin. The latest Callovian–Kimmeridgian megasequence comprises a conformable sequence stack which lacks significant internal unconformities and records progressive marine flooding and overall backstepping onto the basin flanks during a phase of active rifting. The Volgian–Ryazanian megasequence is condensed and highly fragmentary due to punctuation by a number of unconformities which are consistently recognizable throughout the basin. The onset of this change in architectural style corresponds to the oldest unconformity at the base of the Volgian–Ryazanian succession, termed the Base Volgian–Ryazanian Unconformity, of latest Kimmeridgian to earliest Volgian age. The patterns of erosion of the Callovian–Kimmeridgian megasequence and the intra Volgian–Ryazanian unconformities record the effects of dramatic redistribution of underlying salt accompanied by probable uplift of the Forties–Montrose High and J Ridge, resulting in major modification of the basin morphology and the severing of possible earlier links with the Fisher Bank Basin. The kinematics of this event are equivocal, but it is possible that restricted Volgian–Ryazanian depocentres resulted from localized salt collapse rather than basement extension. Widespread erosion of Callovian–Kimmeridgian Humber Group sediments may have occurred in some areas where Volgian–Ryazanian Kimmeridge Clay deposits now overlie pre-Jurassic strata, and exploration models must incorporate the effects of Volgian reconfiguration in order to accurately predict reservoir distribution.

Keywords: Central Graben, Fulmar Sandstone, Humber Group, sequence stratigraphy, tectonic reconfiguration, Upper Jurassic

The Upper Jurassic succession of the UK Central Graben is a well studied interval which is considered relatively mature from an exploration perspective (see Erratt *et al.* 2005 for a review of exploration history). The shallow-marine Fulmar Sandstone and its equivalents comprise the primary reservoir, and significant fields include Fulmar and the high-pressure high-temperature (HPHT) Elgin, Franklin, Shearwater and Erskine trend (Fig. 1). The presence of Permian Zechstein salt below the Triassic and Jurassic sequences has resulted in major halokinesis, which has given rise to a complex structural and depositional history throughout much of the basin. Despite the long history of exploration, significant uncertainties remain, especially around the prediction of both the original depositional extent and the subsequent post-depositional preservation of reservoirs. This complexity and inherent uncertainty mean that further potential remains within the Upper Jurassic and drilling continues to deliver some surprising results.

Background

Understanding and predicting the stratigraphic architecture of the Upper Jurassic interval in the Central Graben relies upon the integration of three main areas of geological study: the sequence stratigraphic framework within the evolving rift system, the depositional model for the paralic, shallow marine and offshore deposits and the structural model linking extension, halokinetic movements of the underlying salt and deposition of the intervening Triassic–Jurassic sequences (see Fraser *et al.* 2002 for a summary of the petroleum geology of the Upper Jurassic of the North Sea). The 1990s marked a significant advance in the understanding of these elements with the publication of key work, including: biostratigraphically-calibrated sequence stratigraphic schemes (Partington *et al.* 1993*a*, *b*; Price *et al.* 1993; Duxbury *et al.* 1999; Jeremiah & Nicholson 1999); the shoreface depositional model and the use of detailed ichnofabric analysis to construct sedimentological and sequence stratigraphic models (Taylor & Gawthorpe 1993; Gowland 1996; Martin & Pollard 1996); models describing the influence of salt movements on Triassic and Jurassic deposition (Hodgson *et al.* 1992; Erratt 1993; Wakefield *et al.* 1993; Penge *et al.* 1999; Stewart & Clark 1999); and basin-scale structural evolution models (Underhill & Partington 1993; Erratt *et al.* 1999).

Much of the uncertainty in Upper Jurassic interpretation stems from the difficulty of acquiring good data on which to base predictive models (e.g. summary in Price *et al.* 1993). Probably the most significant of these is the thermal maturity of deeply buried (>10 000 ft) sediments, causing degradation of the palynomorphs (dinocysts) on which the biostratigraphic dating schemes are largely based. Dating of reservoir intervals is further compromised by poor recovery from sandstones, and reservoir correlation is further complicated by the similarity of shallow marine facies across wide areas and through time. The regional seismic interpretation was enhanced by the release in 2001 of the PGS 3D Mega-Survey seismic dataset covering the whole basin, but resolution is generally poor below the Base Cretaceous Unconformity (BCU) and may be affected by BCU multiples in the critical Upper Jurassic interval, although quality is improving with the latest long-offset

surveys. However, a lack of impedance contrast between shallow marine Fulmar sandstones or turbidite sandstones and the associated Heather and Kimmeridge Clay shales means that reservoir intervals and intra-Jurassic unconformities can often not be mapped directly. There is limited potential for seismic sequence stratigraphy as the Upper Jurassic sequences are mostly below seismic resolution. Furthermore much of the study area lies within the HPHT province of the Central Graben, and drilling problems, often related to high overpressure and high temperature, have resulted in failed logs (e.g. 21/25-11, 22/21-2, 22/25-1, 22/27a-1) or failure to reach target reservoirs (e.g. 21/20b-4y, 29/2a-4), reducing the data value of some wells in key locations. The key outstanding uncertainties are summarized below:

- Inconsistency exists between the various sequence stratigraphic models and the interpretations based on them.
- The relative importance of eustatic, tectonic and sediment supply controls on sequence architecture and facies distribution is equivocal.
- The dating of rift events is complicated by the difficulty of distinguishing between halokinetically induced and basement extension-related subsidence and their respective influences on accommodation space.
- The age and origin of erosional unconformities within the Kimmeridge Clay Formation (KCF) and their impact on the prediction of reservoir distribution and preservation have not been studied in detail.
- The presence of a significant unconformity within the Pentland Formation is equivocal due to poor biostratigraphic control, and the extent to which shallow marine Fulmar and Heather deposition was coeval and/or conformable with deposition of the Pentland Formation can be ambiguous.
- The shallow marine bioturbated shoreface model is well established for the Fulmar Sandstone, but does not account for the deposition of mass flow sands which occur both intercalated with and laterally equivalent to shoreface deposits.

Alternative stratigraphic models can be constructed which are valid within the relatively loose biostratigraphic and seismic control, and this is manifested by the variation seen between Central North Sea (CNS) Upper Jurassic palaeogeographic maps and correlation models from published work (Price *et al.* 1993; Rattey & Hayward 1993; Jeremiah & Nicholson 1999; Fraser *et al.* 2002), non-proprietary consultant reports and in-house company studies. The first part of this paper attempts to address these issues through the revision of the sequence stratigraphic framework and development of an updated basin-wide correlation model. In the second part of this study, the model is employed to investigate the timing, effects and implications of tectonic reconfiguration of the graben system.

Study methodology

This study involved stratigraphic analysis of the Humber Group interval in over 300 wells in the Central Graben, in an area comprising parts of Quads 21, 22, 23, 29 and 30 (Fig. 2). The study interval is loosely referred to as the Upper Jurassic, but in fact comprises the latest Middle Jurassic (Callovian) to earliest Cretaceous (Ryazanian) succession. A database was compiled from released and proprietary well logs, biostratigraphic reports and core descriptions together with published studies. However, no new analyses were

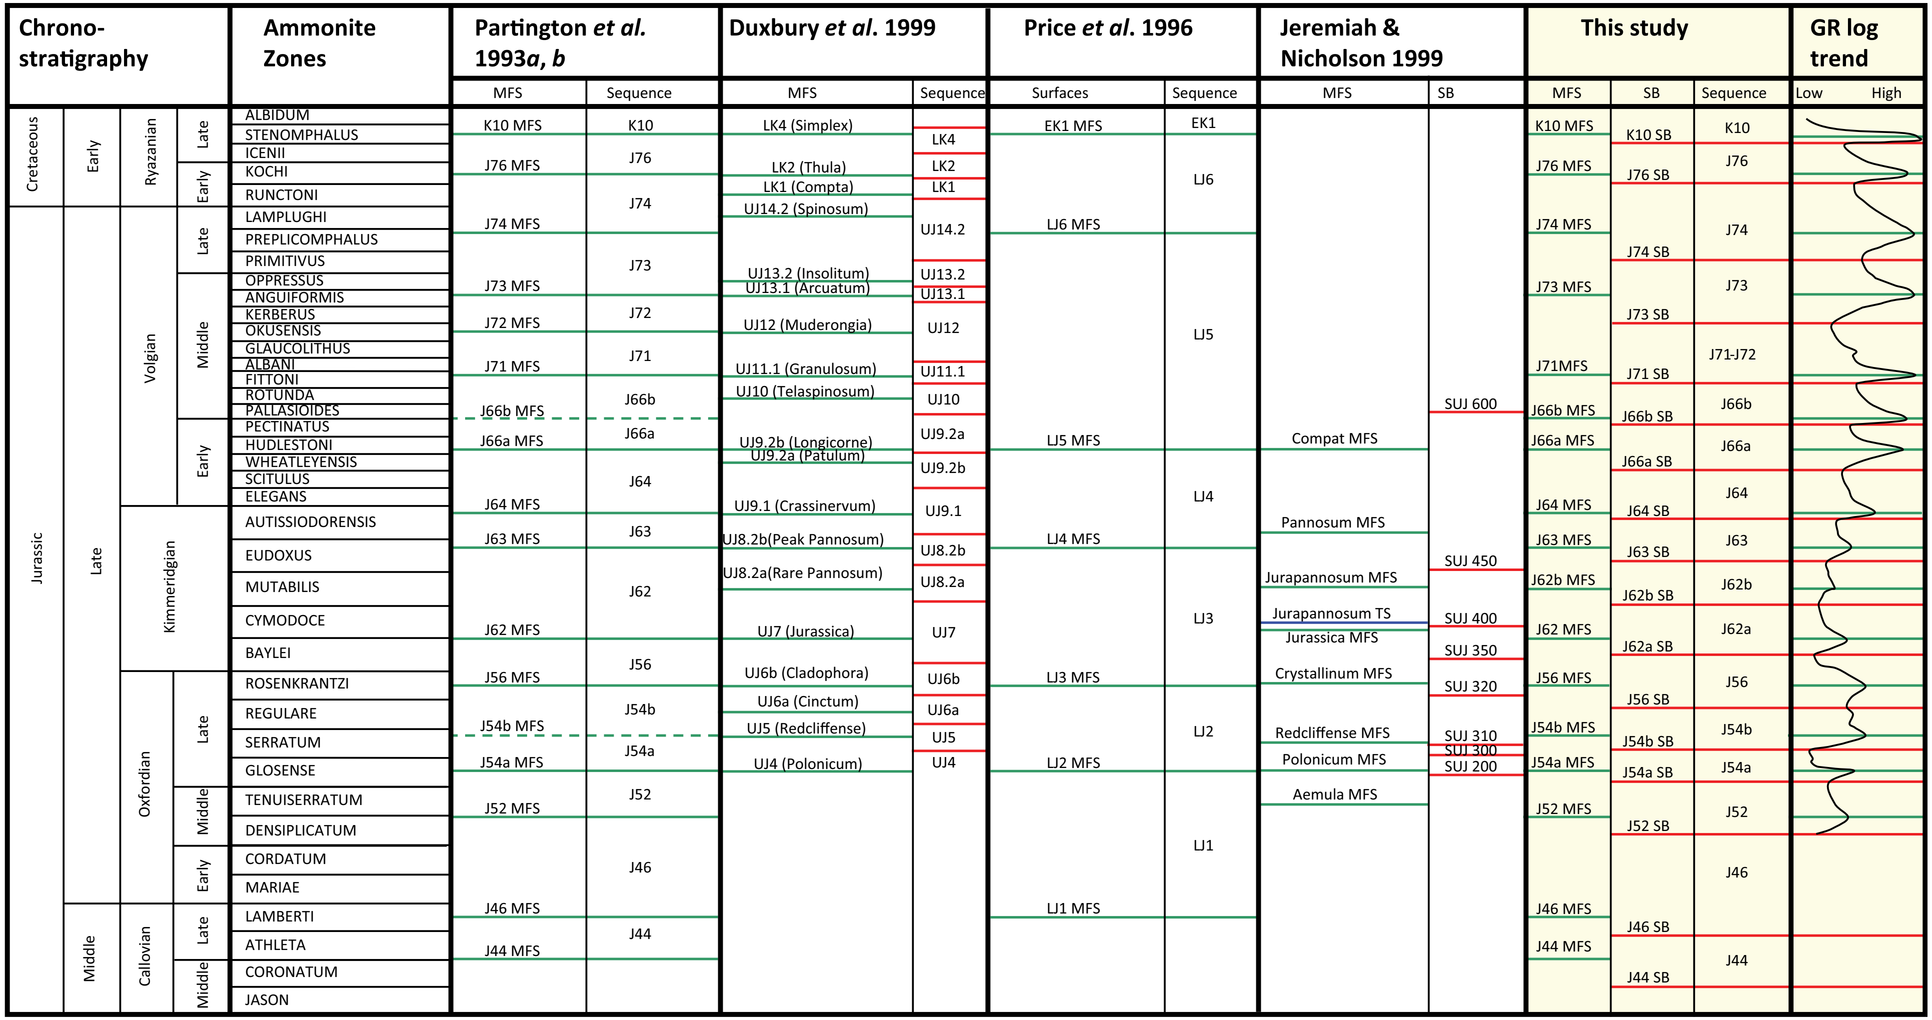

Fig. 2. Comparison of published sequence stratigraphic schemes for the Callovian–Ryazanian interval of the Central Graben with the scheme used in this study.

carried out and the age and quality of the biostratigraphic data in particular is highly variable. A sequence stratigraphic interpretation was made for each well containing an Upper Jurassic succession. Maximum flooding surfaces (MFSs), maximum regressive surfaces (MRSs) and unconformities were identified from log character and core descriptions and dated using the available biostratigraphic data. Where the biostratigraphic data was poor or absent, interpretations were made based on log character motifs and comparison with adjacent better-dated wells. MFSs and sequence boundaries (SBs) (MRSs and unconformities) were identified and correlated to produce a stratigraphic framework, which describes the thickness and facies variations of the Upper Jurassic interval. This was integrated with seismic data to provide an understanding of the relationship between structural history and stratigraphic architecture. Because of the limited biostratigraphic control, particularly in the Late Oxfordian to Early Kimmeridgian section, the correlation is necessarily model-driven and it is accepted that alternative models may be valid within the data constraints.

Geological setting

Structurally, the West Central Graben (WCG), East Central Graben (ECG) and 30/6 Graben form part of a series of en-echelon rift basins (Erratt *et al.* 1999) which are well defined at the Top Rotliegend structural level (Fig. 1). The platform areas (Western Platform, Jaeren High) and intrabasinal highs (Forties–Montrose High, J Ridge) are defined by major north–south to NNW–SSE trending faults at Top Rotliegend level, which pass into terrace areas in the transfer zones between the major graben (e.g. Puffin Terrace, Fulmar–Clyde Terrace). The Permian Rotliegend 'basement' is overlain by variable thicknesses of mobile Upper Permian Zechstein salt, which is believed to have been initially thicker in the basinal areas and thinner over the platforms and highs (Smith *et al.* 1993, fig. 4). Early Triassic rifting initiated salt movements and deposition of the succeeding fluvio-lacustrine deposits of the Smith Bank Formation shales and fluvial deposits of the Skagerrak Formation sandstones led to the differentiation of sediment mini-basins, or 'pods', and intervening salt highs (Hodgson *et al.* 1992).

The region experienced uplift and erosion during the Early Jurassic as a result of thermal doming centred on the North Sea triple junction to the north (Underhill & Partington 1993) so that latest Triassic and Early Jurassic sediments are only rarely preserved in isolated salt-withdrawal depocentres. Collapse of the thermal dome led to the establishment of fluvial and then fluvio-deltaic conditions and the deposition of the Pentland Formation sediments during the Middle Jurassic. Coincident localized volcanic activity led to the accumulation of lavas and tuffaceous sediments of the Rattray Formation in the north (Forties Volcanic Province) and south (Puffin Centre) of the study area (Smith & Ritchie 1993).

Callovian to Early Oxfordian subsidence and/or relative sea-level rise led to marine flooding of the Pentland depocentres in the grabens and the transition from coastal plain to shallow marine shoreface deposits of the Fulmar Formation sandstones and shelf shales of the Heather Formation. During the Kimmeridgian to Ryazanian these shallow marine systems backstepped onto exposed Triassic sediments on the platforms and highs as anoxic marine shales of the Kimmeridge Clay Formation were deposited in the graben centres. Isolated turbidite sandstones, such as the informally named Freshney, Erskine and Selkirk members, were deposited within the Heather and Kimmeridge Clay shales. Anoxic conditions were terminated in the Late Ryazanian as the North Sea rift was abandoned and extension switched to the Atlantic Margin (Rattey & Hayward 1993). Within the Central Graben, the Triassic and Jurassic sequences are affected by complex structural and sedimentary architectures resulting from the superposition of rift events onto an area with varying thicknesses of Zechstein halite, both within the grabens and on the marginal platforms and highs. It is important to understand the effects of halokinesis on the Jurassic section because it affects both the initial distribution of the Fulmar sandstones and their subsequent preservation. Models for the development of complex salt structures and their impact on Fulmar sand distribution during the Upper Jurassic are summarized in Fraser *et al.* (2002).

The relationship between the salt and basin architecture provides a fundamental and relatively predictable control on the location of Humber Group depocentres. On platform areas such as the Western Platform, Forties–Montrose High (FMH) and Jaeren High, the salt layer was relatively thin, short-wavelength Smith Bank pods had grounded and deformation of the supra-salt cover and the subsalt 'basement' became coupled from Triassic time onwards. Dissolution or extensional collapse of salt wall areas provided accommodation space for Triassic Skagerrak and Jurassic Fulmar sandstones, so that salt highs and Humber Group depocentres were mostly co-located throughout the Upper Jurassic. In contrast, deformation remained largely decoupled in the basinal areas containing thick salt, at least until the late Kimmeridgian. Late Callovian–Kimmeridgian depocentres were located in the axes of larger wavelength basins which had been subsiding between the salt highs throughout the Triassic and Middle Jurassic. The salt walls, whilst covered, were areas of low accommodation space. Pod grounding, coupled with possible changes in stress regime in the Volgian (Erratt *et al.* 1999), led to widespread collapse of the basinal salt walls so that depocentres shifted into new, often highly asymmetrical salt withdrawal synclines between the pods. Hence the location of Callovian–Kimmeridgian sediment thicks and Volgian–Ryazanian thicks is commonly mutually exclusive in the graben centres.

The involvement of salt modifies the basin geometries and loci of accommodation space development which controlled Fulmar sand distribution compared with a salt-free rift model. In salt-free rift models, surface faulting is hard-linked to basement displacement (e.g. at the graben bounding fault). The creation of maximum accommodation space is localized in the immediate hanging wall of the active fault and the syn-depositional sequence thickens into the active fault (fig. 10b of Howell *et al.* 1996). Where salt is involved and basement faulting is decoupled from surface deformation, the displacement is spread over a wider area and extends into the footwall of the active fault (Dooley *et al.* 2003, fig. 3). This produces a ramp margin without the obvious thickening of syn-rift packages into the hanging wall. The syn-rift deposits extend onto the footwall and may be thickest some distance outboard of the fault in the centre of an actively subsiding mini-basin. During the Oxfordian to Kimmeridgian it is considered more likely that salt acted to produce a complex pattern of differential accommodation space, with basin margins comprising gentle ramps and intrabasinal highs forming low-relief emergent areas, rather than active faults extending to the surface to produce areas of high differential relief (as is suggested in fig. 11.34, Diagram H of Fraser *et al.* 2002; Howell *et al.* 1996).

Previous sequence stratigraphic studies

The 4th Petroleum Geology Conference (1993) saw the publication of several regional sequence stratigraphic syntheses of the Upper Jurassic of the North Sea (Donovan *et al.* 1993; Partington *et al.* 1993*a*, *b*; Price *et al.* 1993; Rattey & Hayward 1993, 'BP Scheme'), which represented a major advance over the previously lithostratigraphically-dominated approach. These were followed by others during the late 1990s (Shell scheme of Jeremiah & Nicholson 1999 for the Greater Shearwater area; Duxbury *et al.* 1999 for the Outer Moray Firth), together with a number of field specific

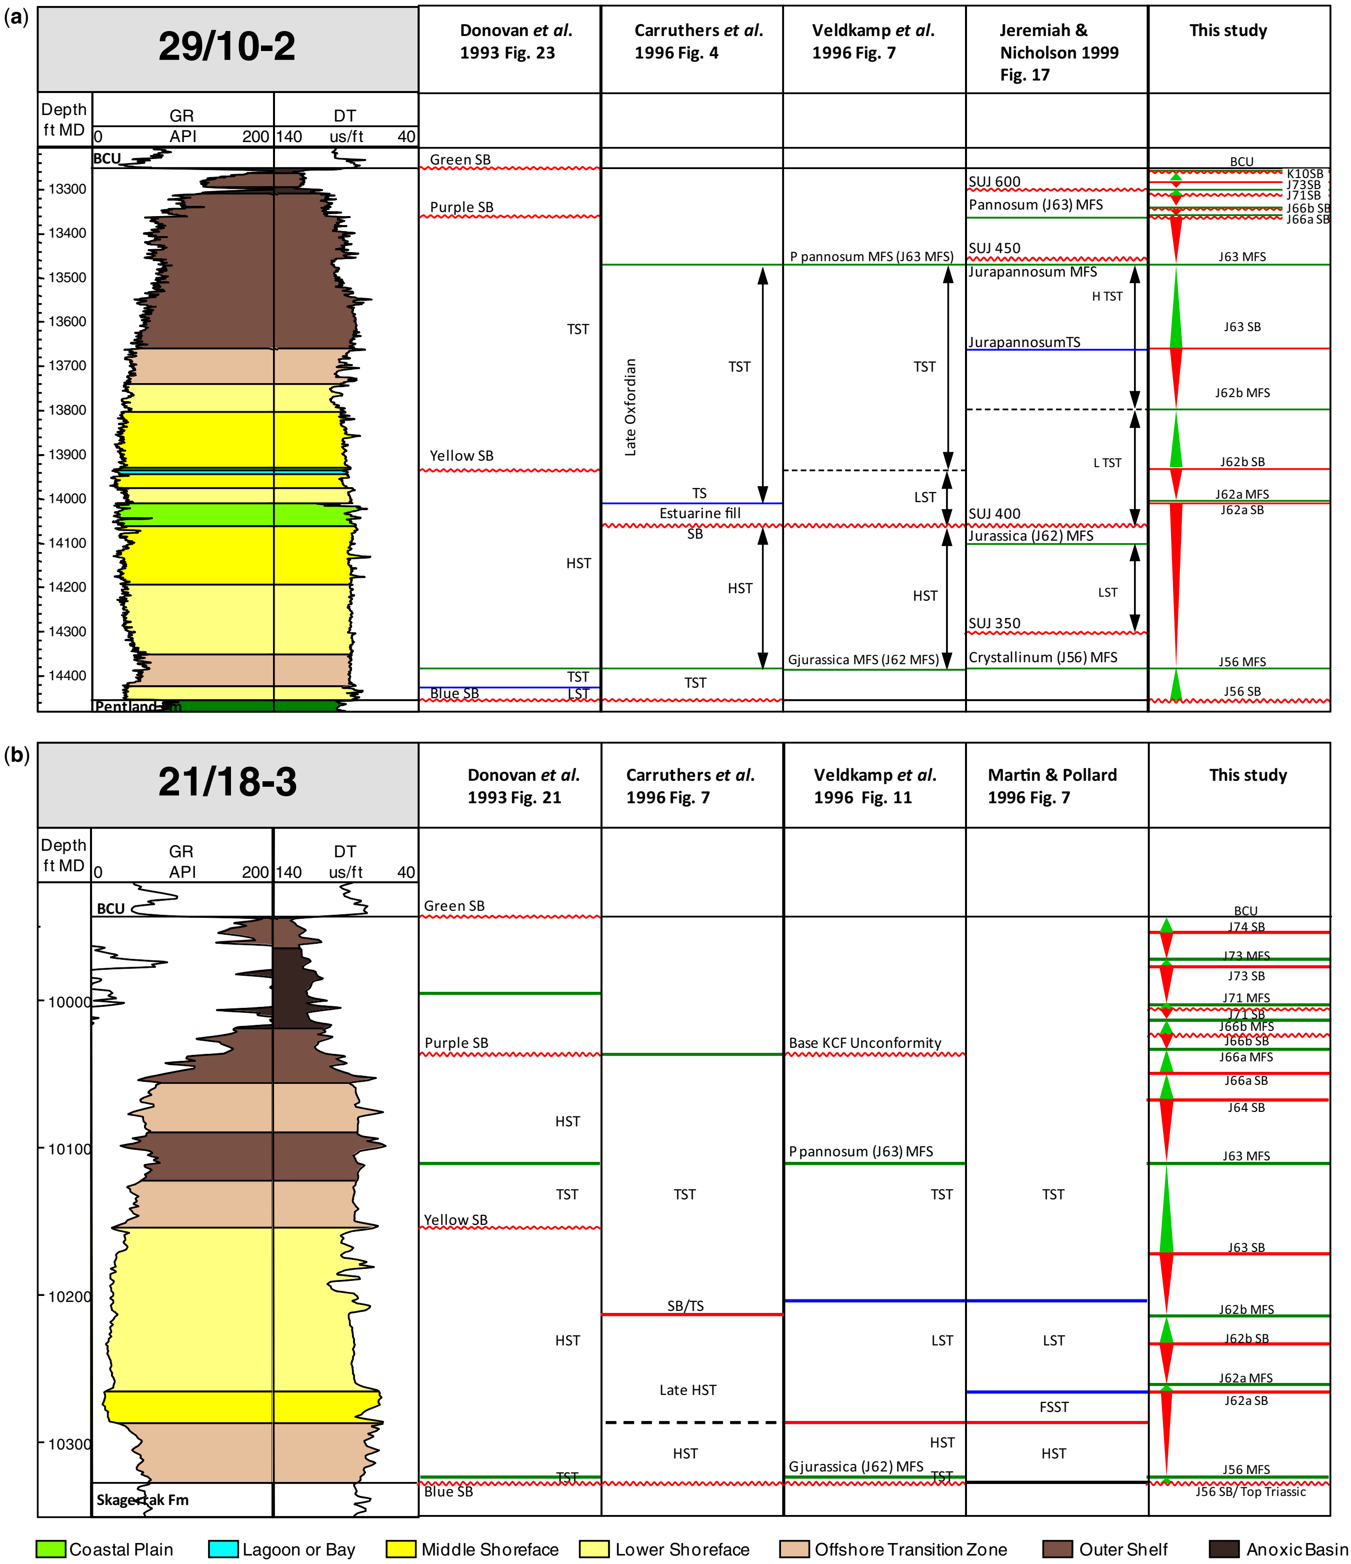

Fig. 3. Comparison of published sequence stratigraphic interpretations of (**a**) well 29/10-2 and (**b**) well 21/18-3 with the interpretation of this study.

reservoir layering schemes (Kittiwake, Martin & Pollard 1996; Elgin–Franklin, Lasocki *et al.* 1999; Erskine, Coward 2003; Fulmar, Kuhn *et al.* 2003; Clyde, Turner 1993). As a result, a variety of published (Fig. 2) and unpublished stratigraphic schemes is currently in use in the North Sea industry at the exploration and reservoir scales, but there is disagreement on the calibration of some key bioevents between schemes, as demonstrated by Hesketh and Underhill (2002, fig. 16). The lack of a consistent scheme and terminology is problematical for industry users looking to compare interpretations and reflects both the inherent uncertainties and data deficiencies highlighted above but also variations in the use of the sequence stratigraphic method, specifically the definition of sequence boundaries.

Genetic stratigraphic schemes have been the most widely used, because of the relative ease of picking and correlating MFSs using wireline log data. Sequence stratigraphic schemes based on the definition of unconformity-bounded units (Donovan *et al.* 1993; Rattey & Hayward 1993) have not been adopted due to the lack of well developed Exxon-type SBs in the Upper Jurassic succession and the difficulty of picking the equivalent surfaces in the basin. Rattey & Hayward (1993) outlined the Middle Jurassic to Early Cretaceous evolution of the North Sea by describing a series of regional, seismically mappable tectonostratigraphic sequences (J20–J70), where SBs were defined as regional unconformities or hiatuses. However, the basal 'sequence boundaries' of sequences J50, J60 and J70 described in the Central Graben area are flooding events causing deepening in basinal areas and/or onlap onto older unconformities at the basin margins, rather than widespread erosive events.

The BP J sequence scheme of Partington *et al.* (1993*a*, *b*) has become the most widely adopted framework due to the detailed publication of the biostratigraphic calibration of the MFSs that bound the sequences, although it was proposed as a 'preliminary subdivision' and updates have not been published. There is general agreement between most of the MFSs in this scheme and similar biostratigraphically-calibrated schemes of Price *et al.* (1993), Jeremiah & Nicholson (1999) and Duxbury *et al.* (1999) (Fig. 2). Palynological (dinocyst) zonation provides the primary means of dating the Upper Jurassic marine sequences, but recovery can be poor due to high thermal maturity. The preservation of radiolaria and foraminifera is unaffected and micropalaeontological zonation, although of lower resolution, can provide control where palynology is lacking (Partington *et al.* 1993*b*; Price *et al.* 1993). However, the use of agglutinating forams in particular was challenged by Veldkamp *et al.* (1996) due to facies dependency.

The term 'sequence boundaries' has been used variably in previous studies. Partington *et al.* (1993*a*), Price *et al.* (1993) and Carruthers *et al.* (1996) use the term to refer to subaerial unconformities and their correlative (start of base level fall) conformities, rather than to mean the surfaces that bound their sequences, which are MFSs in their genetic schemes. This has led to variation in the nomenclature between schemes where the 'sequence boundary' is younger than the MFS with the same name (e.g. Partington *et al.* 1993*a*) and others where it is older than the MFS with the same name (e.g. Duxbury *et al.* 1999). Jeremiah & Nicholson (1999) avoided this by presenting a 'hybrid' scheme with MFSs following a dinocyst naming convention and 'Exxon-type' (start of base level fall) SBs following a numerical scheme.

Most of the published studies place candidate Exxon-type SBs at the base of submarine fan deposits and at the base of shoreface sandstones. Partington *et al.* (1993*a*) proposed candidate SBs at the base of turbidite deposits laid down following their 'tectonically enhanced maximum flooding surfaces' J63, J71 and J73. Carruthers *et al.* (1996) and Jeremiah & Nicholson (1999) placed SBs at the base of intra-Heather Formation turbidite deposits also at the base of some shoreface packages marked by an abrupt reduction in GR response, interpreted as representing a basinward shift in facies. Embry *et al.* (2007) criticized this method of defining the SB since the start of mass flow deposition may not coincide with the onset of base level fall, and the base of a shoreface sandstone is a diachronous surface, constituting either a 'within-trend facies change' or a regressive surface of marine erosion. Veldkamp *et al.* (1996) discussed the different options for picking the SB in Kimmeridgian shoreface successions in the Central Graben and noted that in core from well 21/18-2Az the sharp GR reduction correlated to a gradational facies change rather than an abrupt surface.

Turner (1993) subdivided the Fulmar Sandstone of the Clyde Field into progradational and retrogradational units using MFSs and MRSs. Kuhn *et al.* (2003) placed the Fulmar field reservoir within the sequence stratigraphic scheme of Duxbury *et al.* (1999). The SBs in this example correspond to MRSs at the top of prograding shoreface packages. The intervening MFSs divide each sequence into a transgressive and a regressive portion. Kuhn *et al.* (2003) referred to the regressive portion as the highstand systems tract (HST). Folkestad & Satur (2008) is the only example of the application of a true transgressive–regressive model to a comparable succession in the North Sea. They defined eight depositional sequences bounded by MRSs, each comprising a transgressive systems tract (TST) and a regressive systems tract (RST), in the Callovian–Oxfordian Hugin Formation of the Sleipner area of the South Viking Graben and highlighted the difference between stratigraphic architecture in rapidly subsiding basins and sequence stratigraphic models developed for passive margins.

Most of the previous work has attempted to pick an unconformity or correlative conformity corresponding to the start of base level fall as the SB (Exxon-type SB) and differentiate the regressive deposits into HST and lowstand systems tract (LST). Whilst there is general agreement on the placement and correlation of MFSs, there is much less agreement on the location of SBs. The difficulty of picking a start of base level fall SB within the conformable regressive packages of the Upper Jurassic succession has resulted in a wide variety of sequence stratigraphic models based on the same dataset for some wells (Fig. 3). There is some evidence for forced regression in the current well (wireline log and core) dataset of the Central Graben (e.g. well 21/18-3, Martin & Pollard 1996), but its expression appears to be very sensitive to the local balance of subsidence and sediment supply and it is not generally possible to differentiate between a prograding succession deposited during rising relative sea-level rise (HST) and one deposited after the onset of base level fall (forced regressive systems tract) or shortly after the end of base level fall (LST). It is argued therefore that the use of the Exxon-type passive margin sequence stratigraphic model is inappropriate for the Upper Jurassic of the Central Graben and it is much more practical to pick the MRS (start of base level rise) as the SB in this setting.

Revised sequence stratigraphic model

In this study, a transgressive–regressive (T–R) sequence stratigraphic scheme (Fig. 2) was derived from the BP genetic sequence scheme of Partington *et al.* (1993*a*, *b*) by recognizing SBs at MRSs and/or unconformities between the MFSs. A regional correlation of wells with the most complete Oxfordian–Kimmeridgian succession using this scheme is shown in Figure 4, and a correlation demonstrating the most complete Volgian–Ryazanian successions is shown in Figure 5. The Partington *et al.* (1993*a*, *b*) scheme gives MFSs both a number and an ammonite zone name (e.g. J62 MFS/baylei MFS). There has been subsequent argument against the use of onshore-derived ammonite zones for naming MFSs because of the uncertainty in the calibration of the ammonite and microfossil data sets, with dinocyst names used in preference (Duxbury *et al.* 1999; Jeremiah & Nicholson 1999). In this study the use of a numerical scheme for MFSs and SBs is preferred because the relative age of the sequences is inherent in the nomenclature. Also, picks for these surfaces are made on log character alone where biostratigraphic data are lacking, and the use of a numerical scheme avoids the implication that diagnostic taxa were identified. An additional MFS has been designated to aid subdivision of the thick Kimmeridgian sequences of the Central Graben, and is named J62b MFS in this study. It equates to the Jurapannosum MFS of Jeremiah & Nicholson (1999) and the UJ8.2a (Rare Pannosum) MFS of Duxbury *et al.* (1999), although biostratigraphic calibration differs between these two schemes, with the Jurapannosum MFS defined as lying below the last down-hole occurrence of *Perisseiasphaeridium pannosum* and the LJ8.2a MFS defined as lying above the deepest (rare) occurrence of *P. pannosum*. This degree of sequence resolution is believed to be necessary to capture both the main stages of expansion of the Callovian–Kimmeridgian

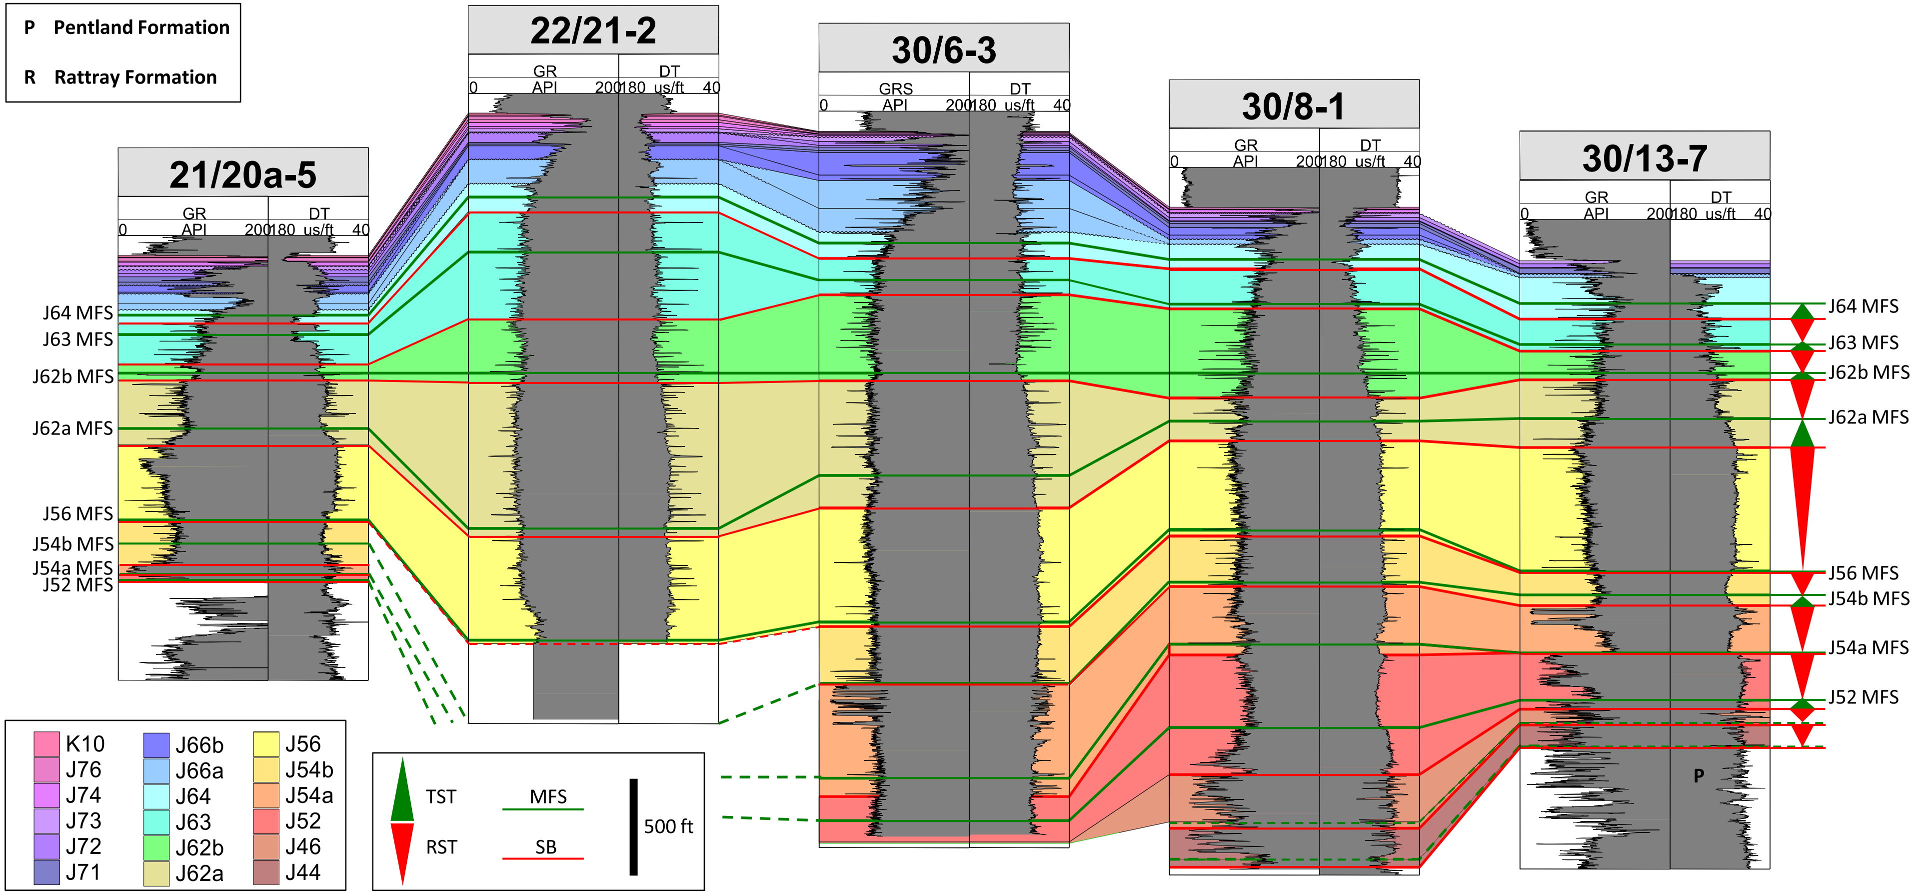

Fig. 4. Regional sequence stratigraphic correlation of wells with the most complete Callovian–Kimmeridgian megasequence succession. Note the relatively consistent log trends, particularly the thick, progradational sequence that defines the J56 RST, and the change from more strongly progradational (RST dominated) sequences J52–J62a to dominantly aggradation in J62b and J63 and overall regression at the J64 SB, which defines the top of the Callovian–Kimmeridgian megasequence. Note also the high degree of condensation of sequences J64–K10 compared with the older succession. See Figure 1 for location.

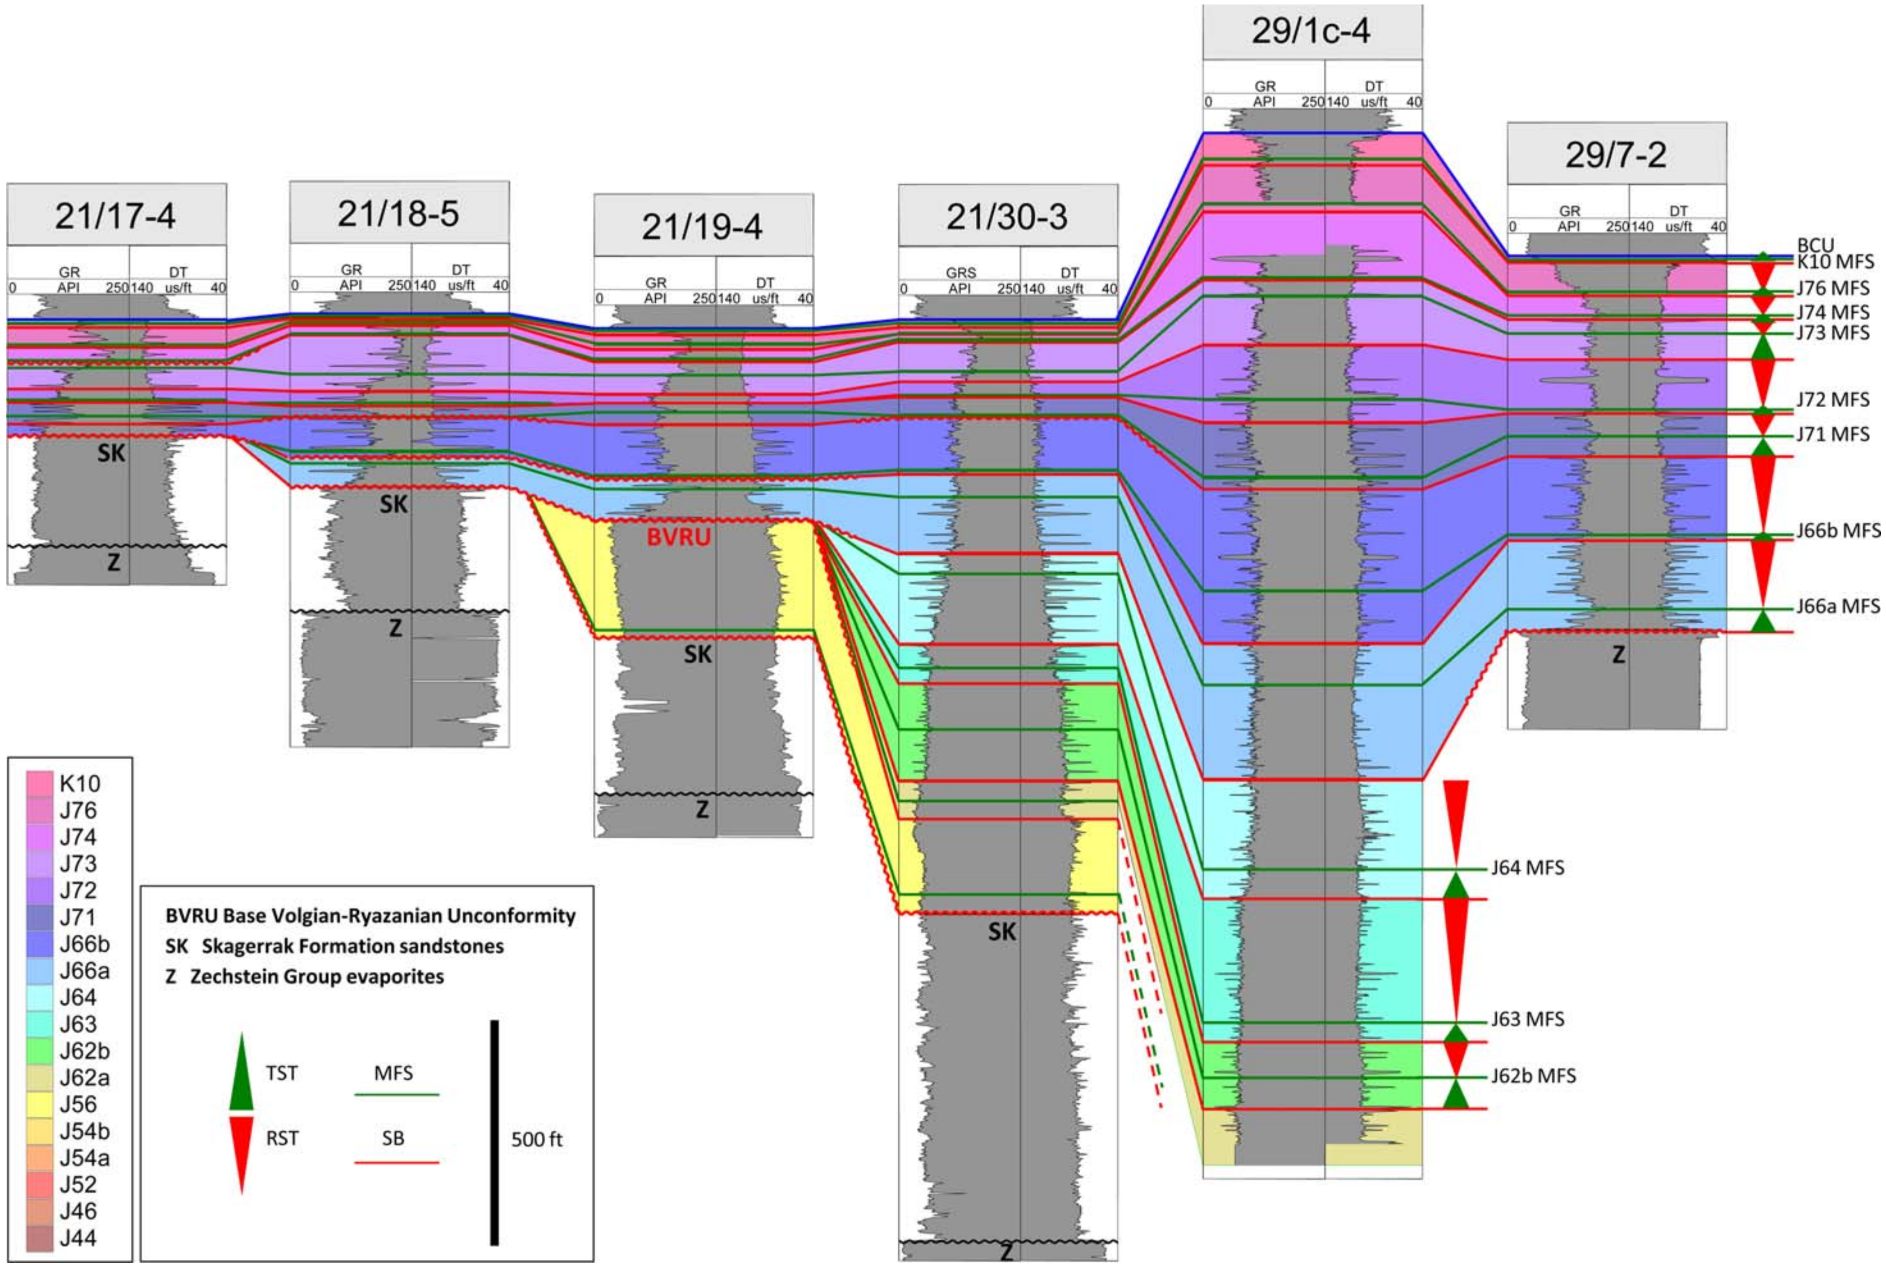

Fig. 5. Regional sequence stratigraphic correlation of wells with a more complete Volgian–Ryazanian megasequence succession. Note the thick, well-defined TSTs of sequences J64 and J66a and the characteristic GR-SONIC bow between the J71 MFS and the J73 MFS. Most of these wells are located over relatively shallow salt, and late salt withdrawal is interpreted to have created accommodation space for more complete preservation of the Volgian–Ryazanian megasequence, although the Late Volgian–Ryazanian sequences remain relatively thin and condensed.

megasequence and the significant unconformities in the Volgian–Ryazanian megasequence.

Sequence stratigraphic surfaces are more difficult to define in coastal plain settings lacking marine flooding events and in transitional marine environments where a complex embayed deltaic coastline characterized by rapid lateral facies changes is envisaged. In this study, MFSs have been correlated to widespread lacustrine shales or coal horizons within the upper Pentland Formation and candidate SBs are placed at the top of sandy units underlying coals, which is taken to represent the MRS of the fluvial system prior to base level rise and swamp development. Where a coal lies at the interface of coastal plain and marine deposits, it is placed at the base of the TST. However, it is recognized that, without biostratigraphic control, the picking of these surfaces is much more subjective than their marine equivalents. In the absence of core it is difficult to differentiate between lagoonal or restricted bay mudstones and shelf shales. Even where clear coal-bearing coastal plain deposits occur between shoreface sandstones (e.g. 29/10-2, Fig. 3a), it is not always easy to determine if these lie beneath the MRS at the top of a regressive sequence capped by a normal marine ravinement surface, or overlie the subaerial unconformity at the base of a transgressive systems tract, although there are obvious implications for the amount of erosion and potential for downdip reservoirs between the two interpretations.

The decision on whether to propose a T–R sequence scheme, or the inverse genetic or R–T (regressive–transgressive) scheme with sequences bounded by the MFSs is not trivial. The appeal of a T–R sequence scheme is that the higher-order sequences are components of, and share boundaries with, the major lower-order tectonostratigraphic units that define the large-scale basin history such as the Aalenian unconformity and the BCU. Furthermore, the Upper Jurassic succession records progressive marine flooding and expansion of the basin and it seems appropriate to think of each sequence beginning with transgression rather than regression following the MFS. The disadvantages of choosing a depositional sequence scheme here are that subaerial unconformities are not well developed within the Upper Jurassic succession, so that most SBs would be defined by MRSs. The disadvantage of MRSs is that they may have a strong local sediment supply control, so that the MRS of a low-order sequence may occur within different higher-order component sequences in different areas of the basin if, for example, delta lobe or fan lobe switching occurs. MRSs are also difficult to identify in deepwater mass flow deposits and Embry *et al.* (2007) suggest picking the MRS at the interface between thickening-up and thinning-up deposits. The MRS can also be difficult to define consistently in thick aggradational packages. Furthermore, the MRSs are not biostratigraphically calibrated in the published schemes so that their position in relation to key bioevents is uncertain.

Unconformities in the Central Graben

Significant unconformities of varying areal and temporal extent have been recognized both bounding and within the Callovian–Ryazanian interval in the North Sea. Over much of the CNS, the Pentland and Rattray Formations are absent and the base of the study interval is clearly defined where it unconformably overlies Triassic sediments. This has been termed the Mid-Cimmerian or Aalenian Unconformity and records thermal doming centred on the North Sea triple-junction during the Early Jurassic (Underhill & Partington 1993; Davies *et al.* 1999). This resulted in the non-deposition or erosion of virtually all Lower Jurassic deposits, except for rare isolated occurrences preserved in salt-withdrawal accommodation space, so that Middle Jurassic and younger deposits rest unconformably on the Triassic. Deposition of the Middle Jurassic Pentland Formation deposits and Upper Jurassic marine deposits resulted in the gradual onlap and burial of this unconformity, so that at any one location it is a compound subaerial unconformity forming the SB at the base of the overlying sequence, although the bulk of the erosion occurred during the Early Jurassic.

Where the Pentland Formation is present, it is not clear whether a significant pre-Callovian intra-Pentland unconformity exists. The Middle Jurassic fluvial deposits of the Pentland Formation have not been investigated in detail for this study and their dating and correlation is difficult due to poor recovery of diagnostic palynomorphs, rapid lateral facies variation of the fluvial channel and lacustrine deposits and lack of marine incursions throughout most of the succession. Several workers have interpreted a significant unconformity between Pentland deposits and the Upper Jurassic marine succession, such as the Lavender SB of Donovan *et al.* (1993). Rattey & Hayward (1993) state that 'much of the CNS that was covered by coastal plain in J30 [latest Bajocian–Middle Callovian] has no recognized J40 [Middle Callovian–Middle Oxfordian] cover' although their figures 14 and 15 imply continued deposition in the East and West Central Graben axes. Davies *et al.* (1999) interpreted an intra-Callovian unconformity separating Bathonian–Bajocian aged Pentland deposits from younger Fulmar and Heather deposits in West Central Graben blocks 21/15, 21/20, 22/16 and 22/22. However, no firm dating of the Pentland Formation in this area was available for this study. The similar thickness and facies consistency of the coastal plain deposits in block 21/15 suggests that the Pentland facies may be genetically related to the overlying Fulmar shallow marine sandstones, representing base level rise and onlap during the early stages of flooding of the West Central Graben during the Middle Oxfordian, with an unconformity existing between the Rattray Formation and the base of the Pentland Formation here. In this study, some released well reports in the 22/13 area provide evidence for a Bathonian age for the upper Pentland Formation deposits (presence of *Quadraeculina anellaeformis*) and indicate an unconformity between the Bathonian and the Upper Callovian. It is therefore likely that an unconformity spanning at least the Middle and Early Callovian exists in the area, although it cannot be picked reliably from log data within Pentland successions. In the Danish sector, Andsbjerg (2003) documents a regional erosional unconformity of Late Bathonian to Early Callovian age that separates floodplain deposits of the Lower Bryne Formation (Pentland Formation equivalent) from estuarine deposits of the Upper Bryne Formation.

Throughout much of the WCG and ECG a high-amplitude reflector corresponds to low-density/slow-sonic shale units associated with coals near the top of the Pentland Formation, and the consistency of this 'near Top Pentland' marker suggests that no significant erosion of the upper Pentland has occurred and that the upper Pentland and Fulmar/Heather formations are conformable here (Price *et al.* 1993; Erratt *et al.* 1999; Jeremiah & Nicholson 1999). Jeremiah & Nicholson (1999) reported increased marine affinities in the micropalaeontological association in the upper parts of the Pentland Formation in the Shearwater area. Coward (2003) reported marine palynomorphs from the uppermost Pentland Formation in the Erskine field and suggested that it was deposited in a marginal marine setting and is conformable with the overlying Heather Formation shales. This study supports the conclusion that the Pentland Formation, at least in the deeper parts of the basin characterized by the near Top Pentland seismic marker and where marine incursion occurred by sequence J52 or earlier, is conformable with the basal Fulmar or Heather Formation deposits. The increased presence of coals in the uppermost part of the Pentland Formation and the common occurrence of coal at the contact between the Pentland and Fulmar/Heather deposits suggest a gradual rise in base level and widespread development of swampy delta plain conditions characterized by mouthbars, tidally influenced lagoons and lakes in response to marine incursion in other parts of the basin. Isolated and locally thick occurrences of Pentland facies occur on some terrace areas, such as the Puffin Terrace, and Veldkamp *et al.* (1996) report Kimmeridgian-age Pentland deposits from the Western Platform (well 21/18-6). It is therefore envisaged that coastal plain deposition occurred in restricted lows on platform and intrabasinal high areas related to Oxfordian–Kimmeridgian shoreface deposition in the basin. In general, however, there is only limited evidence for Fulmar age-equivalent coastal plain deposits, which is surprising considering the thick aggradational packages of Fulmar sandstone seen in some areas. This may be because the combination of the rift setting and the controlling influence of the salt walls on accommodation space resulted in relatively narrow coastal plain margins in comparison to passive margin settings.

The upper boundary to the Callovian–Late Ryazanian tectonostratigraphic succession is the so-called ‘Base Cretaceous Unconformity’, although this comprises a conformable facies change from anoxic claystones of the Kimmeridge Clay Formation to oxic marls and claystones of the Cromer Knoll Group in some areas where the latest Upper Jurassic depocentres continued into the Lower Cretaceous (Rattey & Hayward 1993). Elsewhere Cretaceous deposits onlap remnant topography so that a significant angular unconformity is developed, with Lower or Upper Cretaceous deposits commonly overlying Triassic sediments.

Significant unconformities are also apparent within the Upper Jurassic interval (Rawson & Riley 1982, Base Kimmeridge Clay unconformity of Veldkamp *et al.* 1996, figs 8 & 12 and the Intra Kimmeridgian unconformity of Kuhn *et al.* 2003, fig. 5). These are manifested by sharp truncation of Fulmar or Heather successions which are unconformably overlain by high gamma ray (GR) claystones of the Kimmeridge Clay Formation. Rawson & Riley (1982) describe a number of intra-Volgian unconformities from the onshore Upper Jurassic of the UK and the offshore North Sea, which they attribute to a major phase of uplift and erosion across Europe during Volgian to Ryazanian time. These may equate to unconformities seen at the J66a, J66b, J71, J73 or J74 SBs in this study. Davies *et al.* (1999, fig. 8) showed a localized unconformity of latest Kimmeridgian to earliest Volgian age in the Puffin and Shearwater–Erskine area, but it was not discussed further. In general, however, the focus has been on describing reservoir intervals, and detailed studies of the age and extent of intra-Humber Group unconformities in the UK Central Graben area have not been published.

Callovian–Kimmeridgian megasequence (J44–J63)

The Callovian–Kimmeridgian megasequence comprises sequences J44–J63 in the study area and is interpreted as a conformable stack of composite transgressive and regressive packages that lacks significant internal unconformities. Proximal–distal trends are maintained from sequence to sequence, and there is a clear consistency to the sequence trends, manifested by characteristic basin-wide GR motifs (Fig. 4). This aids correlation where biostratigraphic data is lacking and indicates a regional tectonic and/or eustatic control on accommodation space, which is modified by local halokinesis and sediment supply variations.

Sequences J44 (Callovian)

Sequence J44 is believed to be entirely represented by coastal plain deposits of the Pentland Formation within both the WCG and ECG. The nearest marine sediments at this time comprise marginal marine barrier and lagoon deposits at the southern end of the Fisher Bank Basin (FBB) in blocks 22/12 and 22/13, and support subsequent northerly marine flooding of the West Central Graben, as suggested by Jeremiah & Nicholson (1999). The boundaries of sequence J44 cannot be defined with any certainty within the fully continental succession. However, it is believed to be present at least in areas of the basin which saw the onset of marine conditions in sequences J46 and J52 (axis of the WCG, Elgin–Franklin–Shearwater–Erskine trend, axis of the ECG). In other areas of the basin, older Middle Jurassic Rattray deposits were exposed (northern block 21/15), whilst older Pentland Formation deposits were possibly exposed on flanks of the basin bounding platforms and intrabasinal highs. Triassic sediments remained exposed on the Western Platform, Puffin Terrace, the J Ridge and the Clyde–Fulmar Terrace. The FMH is believed to have been mostly exposed at this time, although Pentland facies may have traversed the high in the 22/11–22/12 area as a precursor to later northerly marine incursion into the WCG.

Sequence J46 (Late Callovian–Early Oxfordian)

The presence of sequence J46 deposits in the WCG records the establishment of fully marine conditions south of the FBB (Fig. 6). This sequence comprises outer shelf shales (wells 22/21-4, 22/21-7 and 22/22b-2y, Fig. 7) with possible tidal flat deposits recorded from a short core in well 22/27a-2. Coastal plain environments are interpreted to either have continued conformably from sequence J44 or to have been established for the first time in the south of the graben in the 29/2 and 29/7 areas. The J46 SB is picked as an MRS at the interface of non-marine shales and a transgressive marine shale package. Where a coal is present at this interface it is placed at the base of the J46 TST. This sequence records rapid flooding of a low-relief swampy coastal plain in a narrow zone possibly restricted to the eastern side of the WCG. Probable bar-barrier sandstones were deposited at the southern end of the FBB and may extend into the northern part of the WCG (wells 21/15a-6 and 22/11-4), although there is no supporting age data. In the ECG swampy delta plain conditions are interpreted to have developed throughout the Elgin–Franklin–Shearwater–Erskine trend and down into the 30/8 and 30/13 areas, with possible tidal influence suggesting a link to marine conditions in the WCG, and also possibly to the southern FBB via the northern end of the ECG. Here, the J46 SB is interpreted to lie at the base of the near-Top Pentland shale marker with the MFS lying within the shale.

Sequence J52 (Middle Oxfordian)

Sequence J52 records the onset of marine flooding of a large part of the ECG (Jeremiah & Nicholson 1999), although it is unclear whether this occurred from the FBB to the north or WCG to the west, or even via the Feda Graben to the east. In the WCG, marine conditions remained restricted to the east side of the graben (Fig. 8), but Pentland deposits in the 21/15 and 21/20 areas are interpreted as recording onlap of coastal plain sediments onto the exposed Triassic land surface. Probable mouthbar deposits accumulated in the Curlew embayment at the southern end of the WCG, suggesting establishment of deltaic conditions and proximity to a significant fluvial input point. Again shoreface sandstones are not widely developed, suggesting widespread drowning of low-gradient sediment source areas. The exceptions to this are areas surrounding the Puffin High where J52 sandstones of shoreface or equivocal marginal marine facies are seen in wells 29/2a-2, 29/2b-5, 22/27a-2 and the Elgin and Franklin fields (e.g. 22/30c-10, 29/5b-6z), suggesting a significant sediment source in this area. A 125 ft-thick sandstone package of possible turbidite origin may lie in sequence J52 in well 22/21-7. Elsewhere sequence J52 comprises shelf shales. In the Erskine area, Jeremiah & Nicholson (1999) interpreted the Fulmar Sandstone to be a composite body comprising the equivalent of J52 and J54 sequences, with the

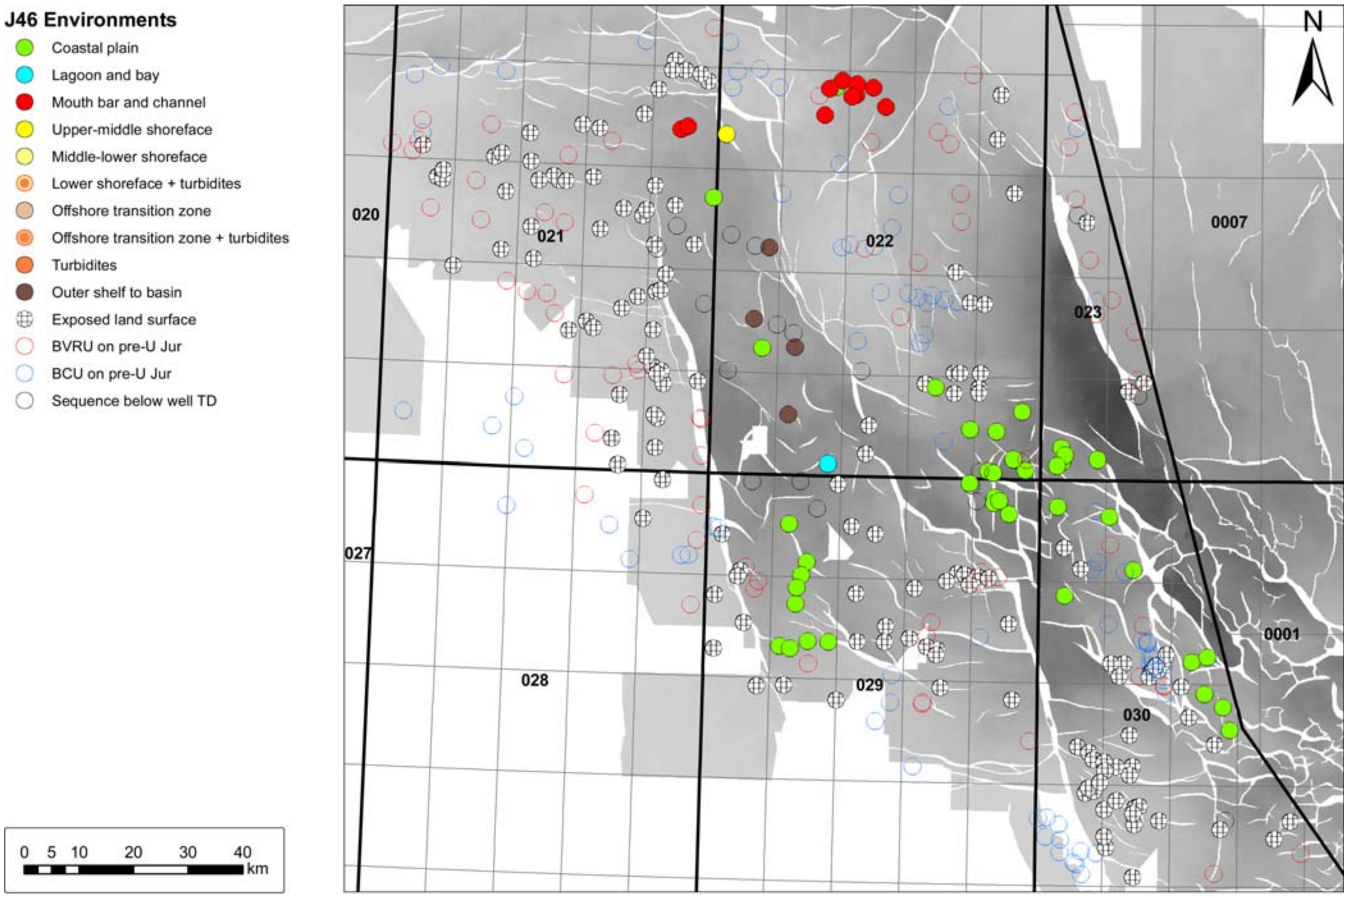

Fig. 6. Sequence J46 depositional environments. Marine conditions were established in the WCG, possibly linking to barrier and lagoon deposits at the southern end of the FBB. Swampy coastal plain conditions are interpreted to have developed in the axis of the East Central Graben as a precursor to marine transgression in sequence J52.

equivalent of the J54a MFS (Polonicum MFS of Jeremiah & Nicholson 1999) cut out by the SJU300 SB. This study interprets J52 sandstones as present here, but there is insufficient biostratigraphic control to confirm the interpretation. In the Shearwater area, Jeremiah & Nicholson (1999) also interpreted the coal-rich deposits at the top of the Pentland to represent 'the initial part of the Middle Oxfordian transgression'. These deposits are here interpreted to comprise the J52 TST which culminates in the J52 MFS at or near the base of the overlying Heather Formation marine shales.

Sequence J54a (Late Oxfordian)

Despite the importance of sandstones of sequence J54a as productive reservoirs in the Elgin–Franklin–Shearwater–Erskine trend (Fig. 9), this sequence is poorly biostratigraphically constrained. Within the available biostratigraphic dataset, it is not possible to differentiate with certainty between sequences J54a, J54b and J56 because of the lack of palynological distinction between these units coupled with commonly poor microfossil and palynomorph recovery. Thus the definition and correlation of these sequences, especially in marginal marine facies, is often subjective and alternative interpretations are possible. The correlations proposed here are constrained largely by working upwards from good J52 sequence dating and downwards from good J62 sequence control.

The J54a SB conforms to a MRS at the top of the J52 RST over most of the basin, although this may only be weakly developed where sequence J52 comprises Heather Formation shales with a dominantly aggradational trend. Where the J54a sequence oversteps J52 coastal plain deposits the SB is picked as a MRS at the base of coals immediately underlying the first marine deposits (e.g. 21/20-1, 21/20a-5). The J54a TST records continued flooding of the basin and limited overstepping of the Pentland basin for the first time onto Triassic deposits (e.g. 30/7a-P12), where the SB comprises an unconformable shoreline ravinement surface. The flooding culminates in the J54a MFS.

The J54a RST records a major progradation of sandy shoreface deposits into the basin coupled with the deposition of locally thick mass-flow sandstones as a result of the re-establishment of major sand supply systems to the basin following the J46–J52 (Late Callovian to Middle Oxfordian) transgressions. In the Curlew (29/7) area, deltaic conditions prevailed, characterized by mouthbar, barrier, lagoon and coal swamp deposition. The interpretation favoured here places the shoreface sandstones of both wells 21/20-1 and 22/16a-2z in the J54a RST. This differs from the more complex interpretation of Donovan *et al.* (1993), which interprets the shoreface package of well 22/16a-2z as a HST and the shoreface package of 21/20-2 as the following LST, despite the fact that 22/16a-2z appears to lie in a more basinal location.

The regressive shoreface sandstones of sequence J54a show a considerable variation in thickness from around 200 ft in WCG wells 21/20-1, 21/20a-5 and 22/16a-2z to over 600 ft thick in the Elgin depocentre (e.g. 22/30c-13), attributed to differential halokinetic control of accommodation space. The presence of salt highs and withdrawal basins disrupts the assumption of the basic sequence stratigraphic model that accommodation space and water depth increase with increasing distance from shore. Jeremiah & Nicholson (1999) attribute the lack of Fulmar

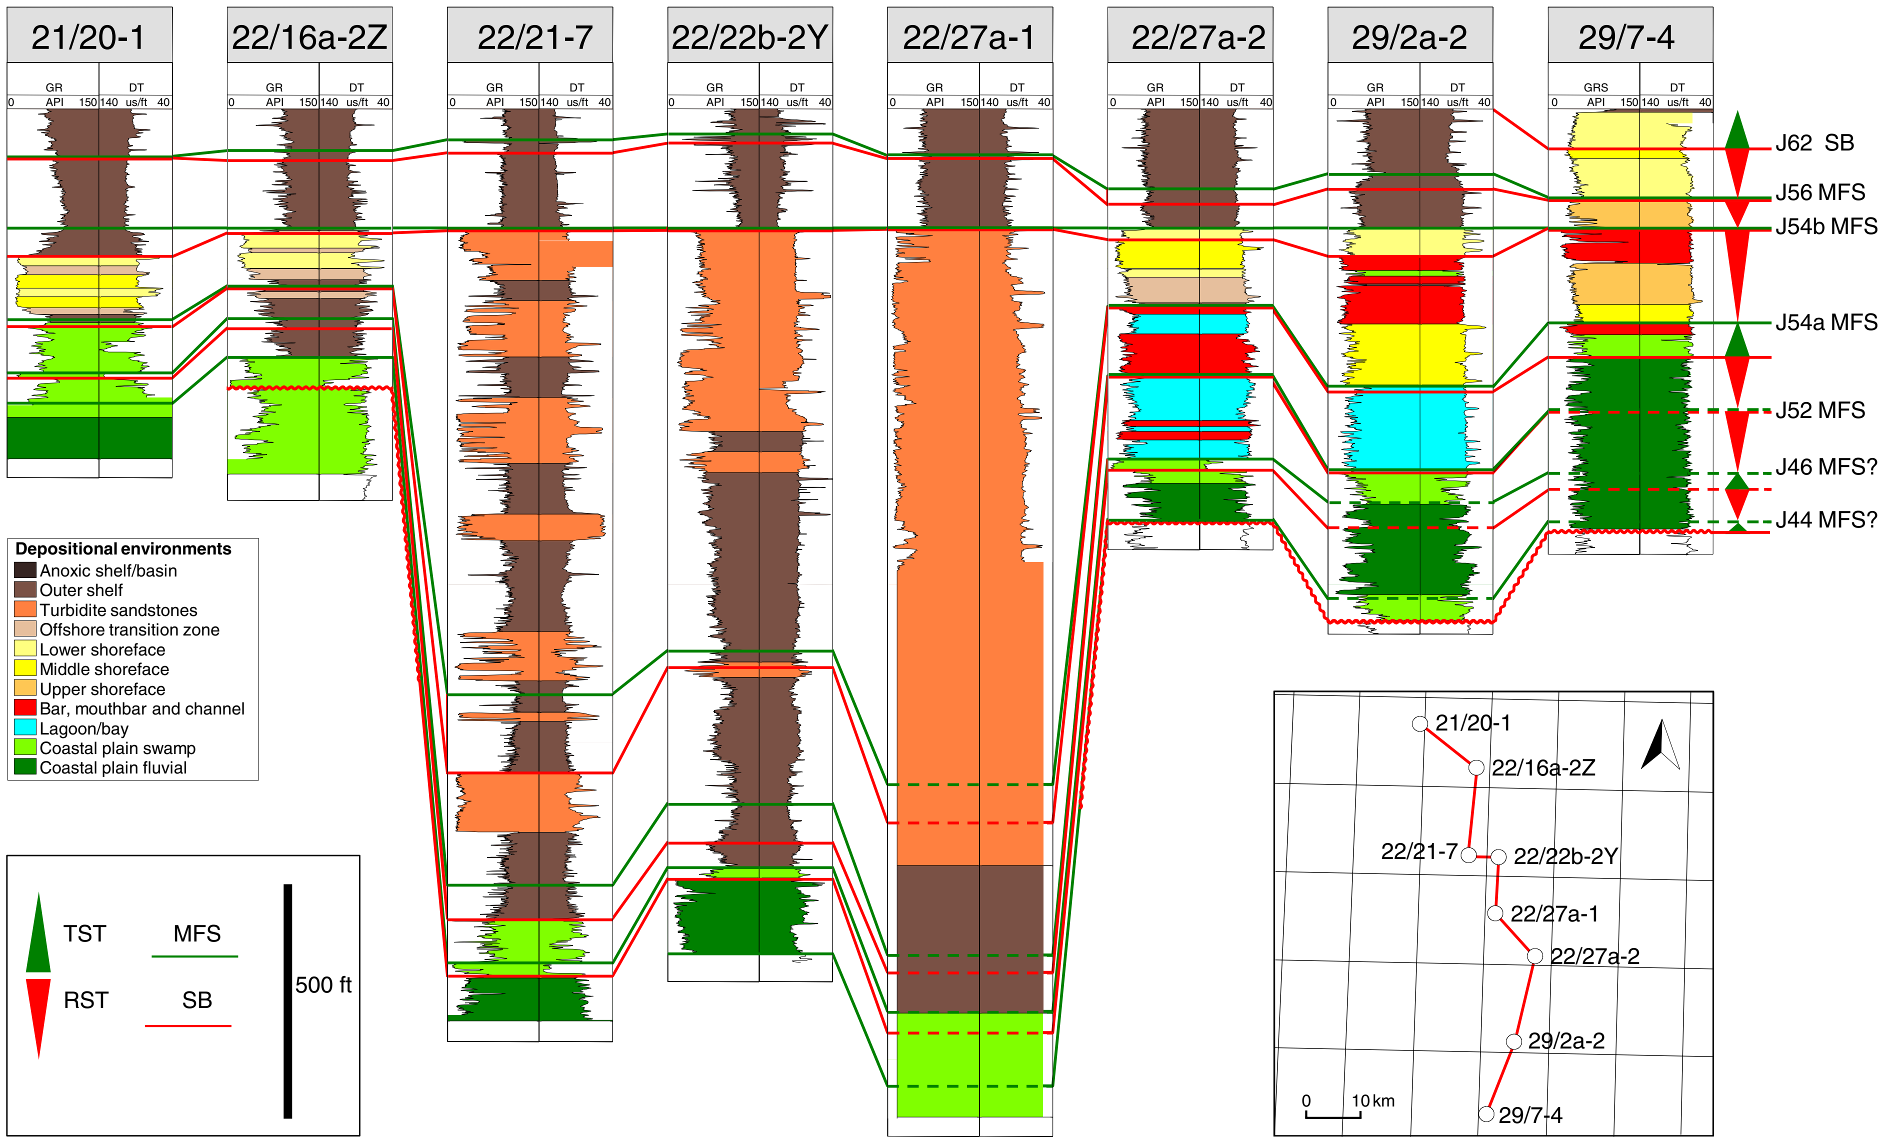

Fig. 7. Well correlation of sequences J46–J54b along the axis of the West Central Graben. The thick turbidite sandstones of sequence J54a indicate both high accommodation space and high sediment supply and are interpreted to indicate an area of enhanced salt withdrawal. The turbidite deposits are interpreted as being coeval with shoreface deposits in the north of the basin and shoreface and deltaic (mouthbar and/or tidal deposits) in the south of the graben.

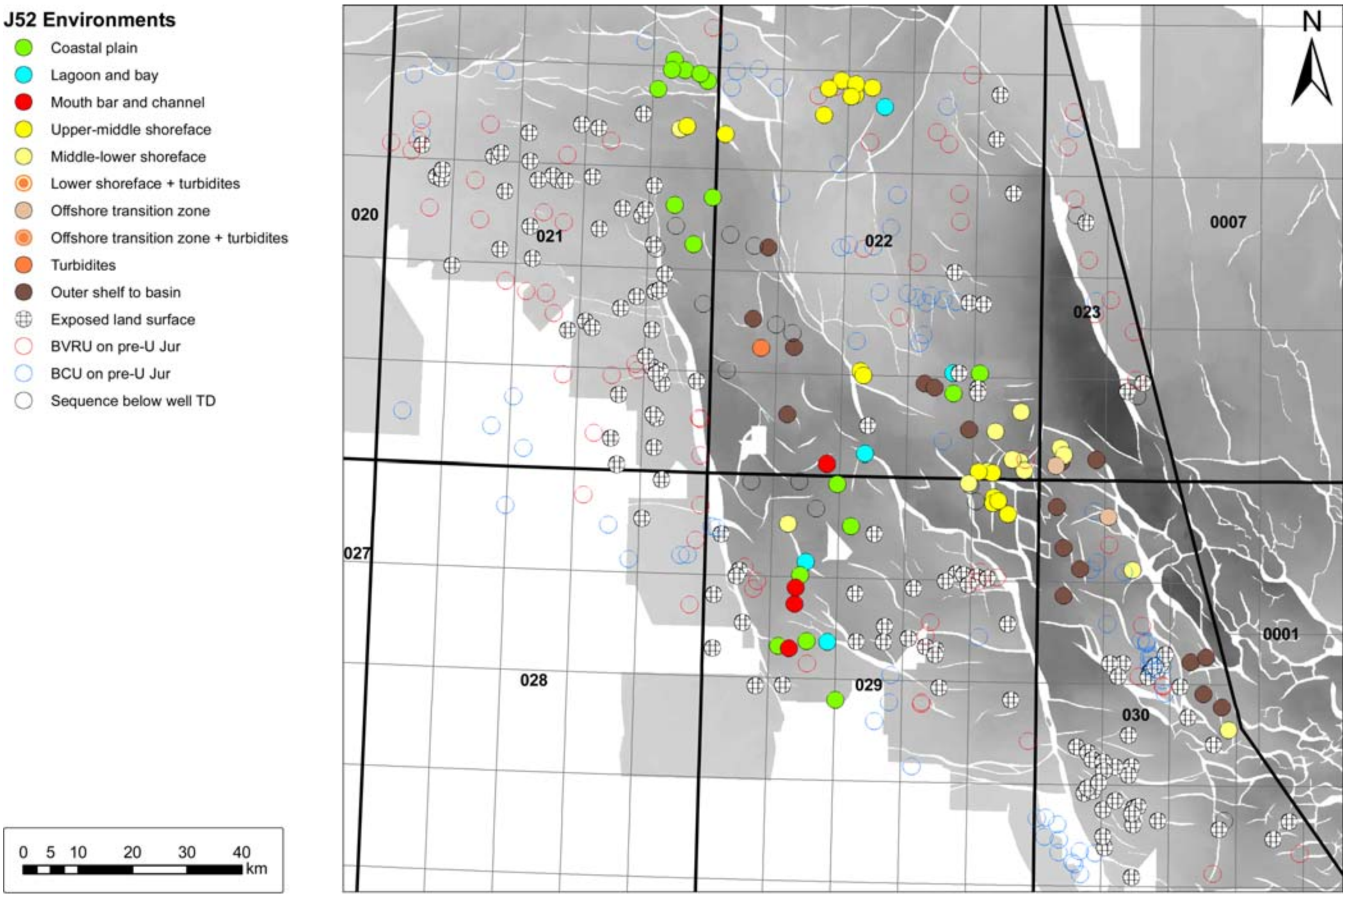

Fig. 8. Sequence J52 depositional environments. Marine conditions were established in the East Central Graben together with shoreface deposition in the Elgin–Franklin area (ECG) and the Howe area (southern end of the FBB). A marine link is believed to have been established between the West and East Central Graben.

sandstones on the Kessog high (well 30/1c-3) to a forced regression above their SJU200 SB, which translated the shoreline into the basin in the Shearwater (22/30) area (their fig. 9). This would imply the formation of a subaerial unconformity in the 30/1c-3 area. However, the succession in 30/1c-3 can be interpreted as complete, although condensed and shale-prone.

Sequence J54a contains the best-developed Humber Group turbidite deposits in the study area. The thickest J54a mass-flow sandstones are found in the centre of the WCG in wells 22/21-7, 22/22b-2z and 22/27a-2 (Fig. 7), with thinner successions also present in the 30/6 graben and 30/13 area of the southern ECG (Fig. 9). Gravity flow deposits are seen in core in the topmost part of the sequence in well 22/27a-2 where they correspond to a characteristic blocky log character and are interpreted on the basis of this log character in uncored wells. The detailed relationship of the turbidite deposits to the shoreface sandstones is unclear, although they occur both interbedded with offshore transition zone sediments (e.g. well 22/30-1) and more basinal shales (e.g. 30/13-4). Jeremiah & Nicholson (1999) attribute turbidite deposits overlying shoreface sandstones at the top of the Fulmar Sandstone in well 22/30b-11 to a distinct tectonic pulse resulting in the emplacement of mass flow sands within the lower shoreface to offshore environment above their SJU310 SB. However, the thick succession of turbidites in the WCG (Fig. 7) is interpreted as demonstrating that mass flow sandstones were being deposited throughout the duration of sequence J54a and are coeval with the shoreface deposits, rather than comprising separate lowstand deposits. The correlations of Jeremiah & Nicholson (1999, their figs 12 & 17) imply that turbidite deposition is mutually exclusive with shoreface deposition and occurs as a result of erosion and bypass of the shoreface during forced regression. This study proposes that turbidite deposition occurred synchronously with shoreface progradation and also potentially during transgression as a result of erosive ravinement of the shoreface. It is possible that the turbidite sandstones are sourced by bypass of sediment through the low-accommodation space areas of condensed shoreface deposition (e.g. 21/20, 22/28) or they may have been sourced more directly from marginal platforms and intrabasinal highs, so that they are laterally interfingering with distal shoreface sediments. The mechanism for putting sufficient sediment into suspension to generate the turbidity currents in this setting remains unclear. Pattison & Hoffman (2008) describe shelf turbidite deposits from the Campanian Blackhawk Formation of the Book Cliffs, Utah, which are detached from their coeval shorefaces and deposited below fair-weather wavebase. They proposed that turbidity currents, generated by storm waves, river flood events (hyperpycnal flows), high rates of sedimentation or earthquakes, cut channels across the shelf that allowed sediments to bypass the shoreface and be deposited on the outer shelf. In this outcrop analogue, mass-flow sandstones were deposited in both shelf channel and lobe settings. The location of the best-developed turbidite deposits in wells 22/21-7, 22/22b-2 and 22/27-1 (although lower section is not logged) may suggest proximity to a major fluvial input, to the west (Western Platform), south (Curlew embayment) or east (FMH). Seismic data indicates that wells 21/25-11 and 22/21-2 both terminate above the base of the Upper Jurassic and just penetrate possible J54a sandstones, although their depositional environment is unknown and logs failed in the basal sections of both wells. It is therefore possible that well developed J54a shoreface or turbidite deposits are

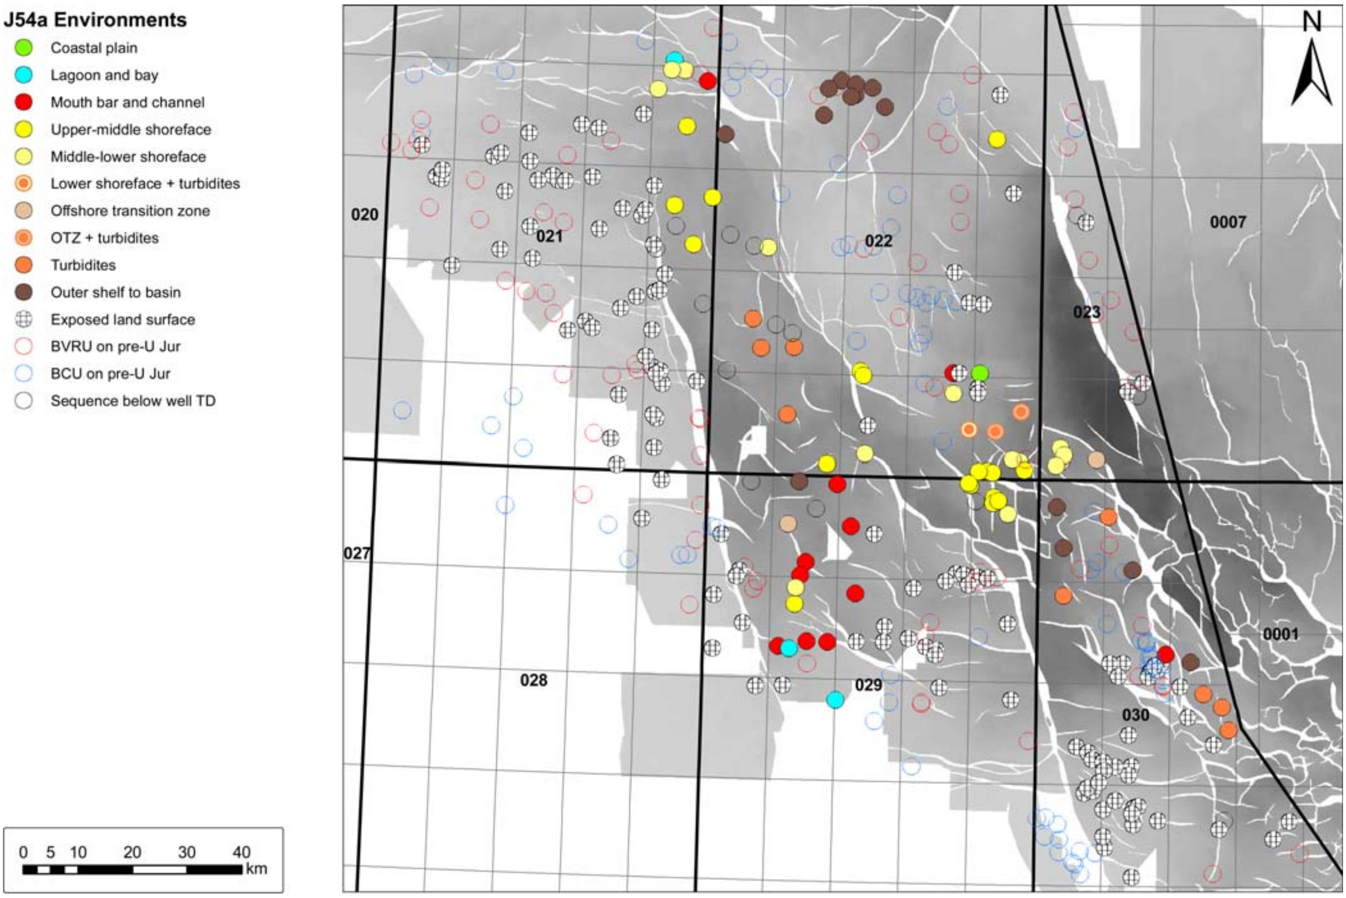

Fig. 9. Sequence J54a depositional environments. Widespread shoreface deposition was established in both the WCG and ECG, together with the deposition of turbidite sandstones in the graben axes, during a period of high sand supply. Deltaic conditions were established in the Curlew Embayment at the southern end of the WCG.

present on the western side of the WCG, sourced from erosion of Skagerrak sandstones on the Western Platform.

Sequence J54b (Late Oxfordian)

The J54b SB is picked at the uppermost MRS of sequence J54a (equivalent to the Redcliffense TS of Jeremiah & Nicholson 1999, fig. 7). The onset of transgression at the base of the J54b TST is an important event that terminated shoreface deposition across the Shearwater and Erskine fields (Jeremiah & Nicholson 1999) and across most of the West and East Central Grabens. This transgressive event significantly overstepped the Pentland Basin (as defined by the extent of the near-top Pentland seismic marker) and initiated flooding of exposed Triassic sediments on the margin of platform areas such as the Teal embayment (21/25, Fig. 10). In many wells, the TST is very thin or virtually absent, suggesting that transgression was rapid and possibly erosive. Thin turbidite deposits are seen at this flooding event in well 22/23b-6 and transgression may have initiated the turbidite deposition described by Jeremiah & Nicholson (1999) in well 22/30b-11. In basinal areas, sequence J54b is characterized by shales with an aggradational GR log signature. J54b shoreface sandstones are limited, but where present in the Elgin and Franklin fields, Turnstone discovery (22/23b-5 and -6) and Teal embayment wells, they exhibit a characteristic log profile commonly showing two or more prograding packages. In the Curlew (29/7) area deltaic and marginal marine environments of sequence J54a were succeeded by fully marine shoreface conditions. In these locations, higher rates of sediment supply were able to compete with the pulses of relative sea-level rise and re-establish shorefaces, and this may indicate the location of major sediment input points into the basin.

J56 (Late Oxfordian–earliest Kimmeridgian)

The J56 SB is very weakly defined within the aggradational J54b shales. The J56 MFS is again poorly controlled by the available biostratigraphic dataset, but is clear on logs at the base of a characteristic, thick, upward-decreasing (prograding) GR profile which characterizes the J56 RST (Fig. 4). This culminates in a clear MRS which constitutes the J62a SB. The J56 MFS is equivalent to the Crystallinum MFS of Jeremiah & Nicholson (1999), which records the widespread flooding of Triassic platform areas such as the Puffin Terrace, eastern part of the Western Platform, J Block/J Ridge and Fulmar–Clyde Terrace (Fig. 11). Prior to this, J Block and the J Ridge were exposed and acted to separate the 30/6 graben and southern ECG. Widespread flooding of the FMH is also envisaged to have occurred at this time, although the evidence has been subsequently eroded. Across most of the graben areas, the J56 sequence is shale prone and the TST is usually thin. Where it transgresses Triassic sediments, the basal SB corresponds to an unconformable shoreline ravinement surface and a glauconitic transgressive sandstone is commonly developed. On J Block and the J Ridge, transgression appears to have cut off the sand supply so that shelf shales were deposited above the initial transgressive sandstone. However, sandy shoreface deposition became established on the Western Platform, Puffin Terrace, Fulmar–Clyde Terrace and Curlew Embayment.

An important observation of the J56 MRS in basinal areas is that it marks the most proximal (lowest GR) shales seen following the

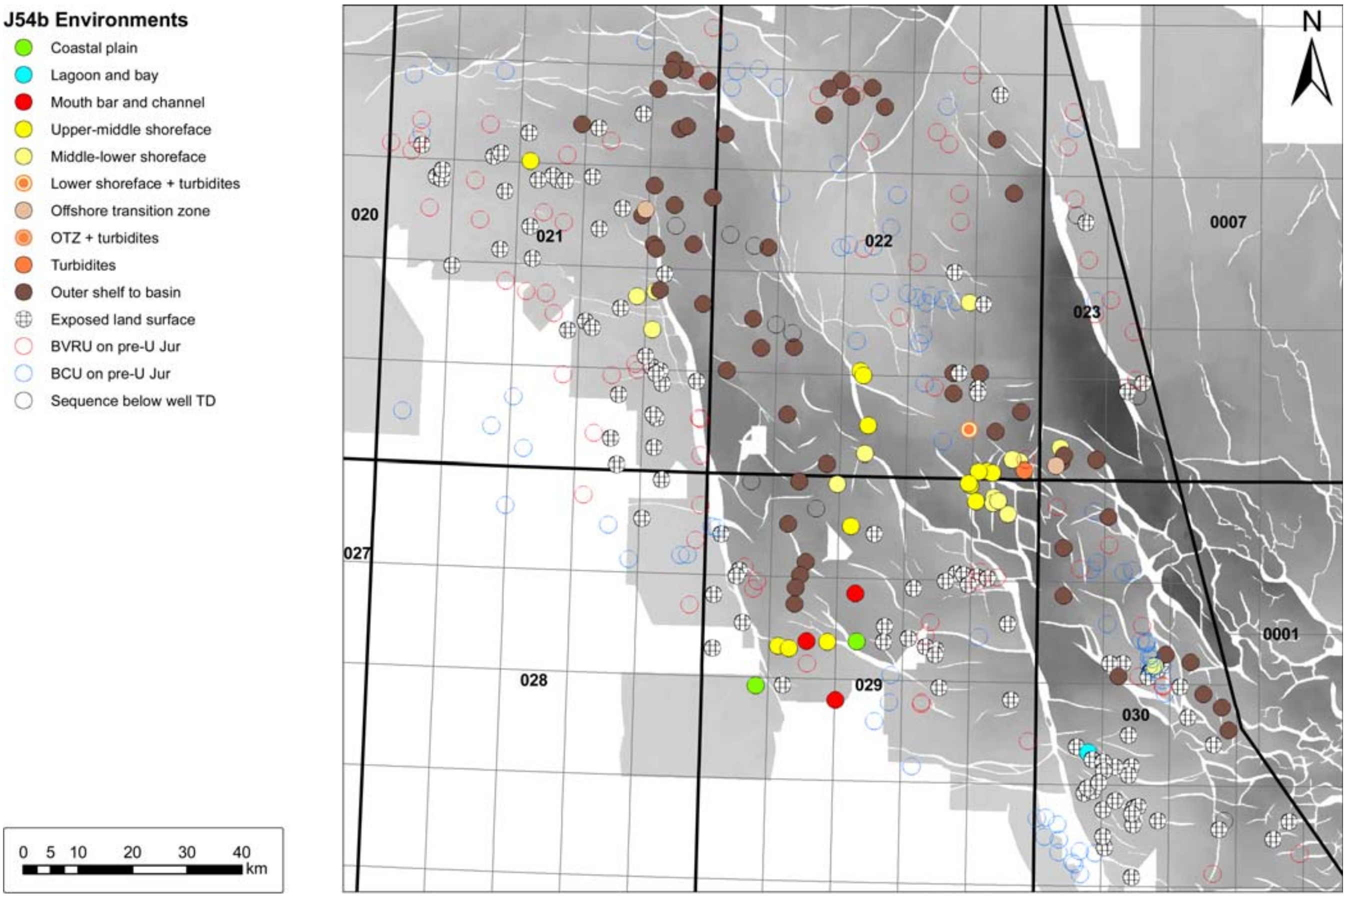

Fig. 10. Sequence J54b depositional environments. Shallow marine environments stepped outside the Pentland basin onto exposed Triassic strata on the Western Platform (Teal embayment) and J Block. Shoreface deposition was established in the Curlew Embayment, but shoreface sandstones are reduced compared with sequence J54a, possibly reflecting the drowning of sediment source areas.

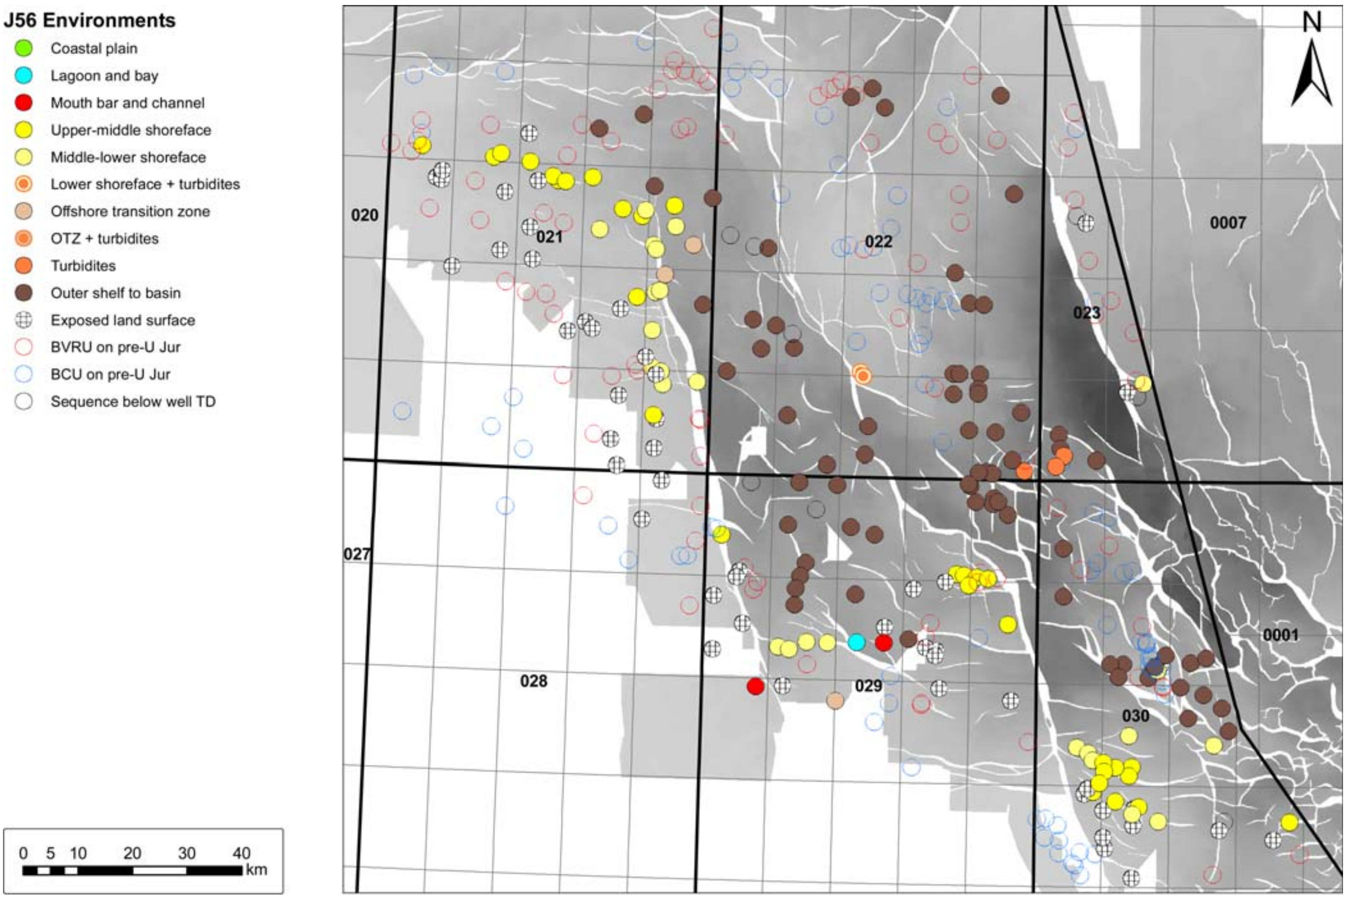

Fig. 11. Sequence J56 depositional environments. Widespread flooding of the marginal platforms and highs occurred, together with limited turbidite deposition in the Shearwater and Erskine areas. Shoreface environments were established on the Western Platform, Puffin Terrace and Fulmar–Clyde Terrace.

J54b MFS, and marks the change from overall progradation of the Humber Group system to aggradation and retrogradation. The RST culminates in the deposition of shoreface sands in the western parts of the WCG (wells 21/20b-4, 21/20a-5, 21/20b-6z), and suggests both the presence of an increased sand supply to the west or NW of the WCG and possibly also the occurrence of a forced regression towards the end of sequence J56. Mass-flow sandstones seen in Shearwater (22/30b-11) and Erskine (23/26b-15) are interpreted to lie within sequence J56, rather than J62 as proposed by Jeremiah & Nicholson (1999, above their Jurassica MFS and SJU400 SB), because they lie within a clearly progradational shale trend characteristic of the J56 RST elsewhere. These turbidite deposits could have been derived from sequence J56 shorefaces on the Puffin Terrace to the SE, southern end of the FMH to the north or the edge of the Jaeren High to the east.

The observation that the J56 RST contains the most proximal post-J54b MFS sediments in the graben is followed through to the analysis of shoreface sandstones on the platform and terrace areas and leads to a different interpretation of sequences J56 and J62 in these areas from that of previous authors (Fig. 3a). Well 29/10-2 on the Puffin Terrace lies in an area of enhanced accommodation space where a thick Pentland-facies coastal plain sequence, which may be partially equivalent to the thick J54a–J54b shoreface sandstones in the Elgin and Franklin fields, is overlain by the J56 TST (Fig. 12). This is succeeded by a thick J56 progradational shoreface sequence (J56 RST), which is cored and capped by coal-bearing coastal plain deposits. Markedly different sequence stratigraphic interpretations of this well have been made by several authors (Fig. 3a; Donovan *et al.* 1993; Carruthers *et al.* 1996; Veldkamp *et al.* 1996; Jeremiah & Nicholson 1999), with most suggesting that the coastal plain deposits overlie a subaerial unconformity constituting a SB that post-dates and may cut out the J62 MFS (Jurassica MFS of Jeremiah & Nicholson 1999). The coastal plain deposits seen in 29/10-2 are the most proximal facies seen in the well post the J56 MFS, and an alternative interpretation suggested here is that this deposit represents the maximum progradation of the J56 RST, so that the J62 SB lies at the top of the coastal plain package, where it is either a MRS or an unconformable shoreline ravinement surface. Alternatively the coastal plain package could form the J62 TST so that the J62 SB is a subaerial unconformity at the base package. In both cases, the J62 MFS is interpreted as lying in a higher GR shoreface unit just above the coastal plain deposits. The J62 RST is then interpreted as comprising a relatively thin unit of proximal shoreface deposits capped by a further thin coal.

Well 21/18-3 has also been subject to a range of different interpretations (Fig. 3b), but this succession can be interpreted in a very similar way to 29/10-2. The J56 TST is limited to a thin transgressive lag (Veldkamp *et al.* 1996) overlying the top Triassic surface. The J56 RST is a shallowing-upwards succession which commences with offshore transition zone deposits and culminates in a strongly prograding middle to upper shoreface package which may represent a forced regression (Martin & Pollard 1996). The MRS at the top of this package corresponds to the J62a SB, which is closely followed by the J62a MFS. This relationship becomes clearer towards the basin in wells 21/20a-2 and 21/20a-5, where increased accommodation space has resulted in a clearer separation of the systems tracts (Fig. 13).

Sequences J62a and J62b (Kimmeridgian)

Sequences J62a and J62b contain the bulk of the productive reservoirs in a number of fields including Fulmar, Clyde, Kittiwake and Cook (Fig. 1). Sequences J62a and J62b have been defined based on the recognition of the Jurapannosum MFS of Jeremiah & Nicholson (1999), which is termed the J62b MFS in this study. The J62a SB conforms to the clear MRS at the top of sequence J56 and the J62a TST is moderately to well developed above this. The J62a and J62b MFSs record further backstepping of the shallow marine system onto the surrounding platform areas (Figs 14 & 15), although they are not as marked as the J56 transgression, except on the western part of the Puffin Terrace (29/8 area) where the Fulmar shorefaces bypassed the 29/8 area as a result of rapid transgression of a low-relief area (Jeremiah & Nicholson 1999). Sequences J62a and J62b commonly exhibit an overall aggradational trend, with only weakly developed progradational and retrogradational profiles, indicating equilibrium between sediment supply and accommodation space. The accumulation of thick aggradational shoreface deposits in the Fulmar and Clyde areas has been suggested to indicate a link between sediment supply and accommodation space controlled by salt withdrawal (Kuhn *et al.* 2003; Turner 1993). The J62b MFS is interpreted as corresponding to the UJ8.2a MFS in the Fulmar Field (Kuhn *et al.* 2003) and the MFA1 MFS in the Clyde Field (Turner 1993). SBs are difficult to define consistently in these sequences where only a small change in the sediment supply/accommodation space relationship can change the position of the MRS defining the J62b SB between the two MFSs, and the proportion of each sequence represented by TST and RST appears variable. In some cases sequence J62a appears thin where the MRS lies only a short distance above the J62a MFS (e.g. wells 21/18-3 and 29/10-2), whilst in others it is much thicker where the MRS occurs much closer to the J62b MFS (e.g. 21/20b-4y, 21/20a-5 and 21/20b-6z). This suggests that the J62b SB as picked in this study is likely to be time transgressive in some areas. In most areas, however, the J62b RST is thin, recording the overall reduction in sediment supply relative to accommodation space.

In this study, significant sequence J62a turbidite sandstones have only been recognized in well 21/20b-4y, with possible stringers extending into well 21/20a-5, despite the extensive development of J62 shorefaces. This contrasts markedly with the widespread turbidite deposition in sequence J54a, and may reflect the overall aggradation rather than progradation of the J62a shorefaces.

Sequence J63 (late Kimmeridgian)

Sequence J63 is mostly represented by anoxic shales and is dominated by a well developed TST, again reflecting the long-term relative sea-level rise. The J63 SB comprises a coincident MRS and transgressive surface. The overlying TST terminates Fulmar shoreface deposition on the eastern side of the Western Platform (e.g. Kittiwake) and across the Puffin Terrace (e.g. 29/10-2), and as the shoreline stepped back to the west and south, shoreface environments were developed for the first time further west on the Western Platform (e.g. 21/17-3) and on the southern margin of the Puffin Terrace (e.g. 29/2b-2, 29/9b-9, 29/14b-1A). In the Fulmar Field, the Auk Terrace continued as a sediment source but also limited the extent of transgression so that J62b shoreface deposition (Mersey Sands) continued into sequence J63. The J63 SB is interpreted at the change from an aggradational to a retrogradational trend in the lower part of reservoir unit U3.2 of Kuhn *et al.* (2003, fig. 8). The thick TST culminated in the J63 MFS, which was followed by the rapid, but short-lived progradation that characterizes the thin J63 RST, which was rapidly overwhelmed by the ongoing relative sea-level rise.

Volgian–Ryazanian megasequence (J64–K10)

The Volgian–Ryazanian megasequence comprises sequences J64–K10 and is mostly represented by warm to hot shales of the Kimmeridge Clay Formation, with subordinate turbidite and shoreface deposits (Fig. 16). Where the megasequence unconformably

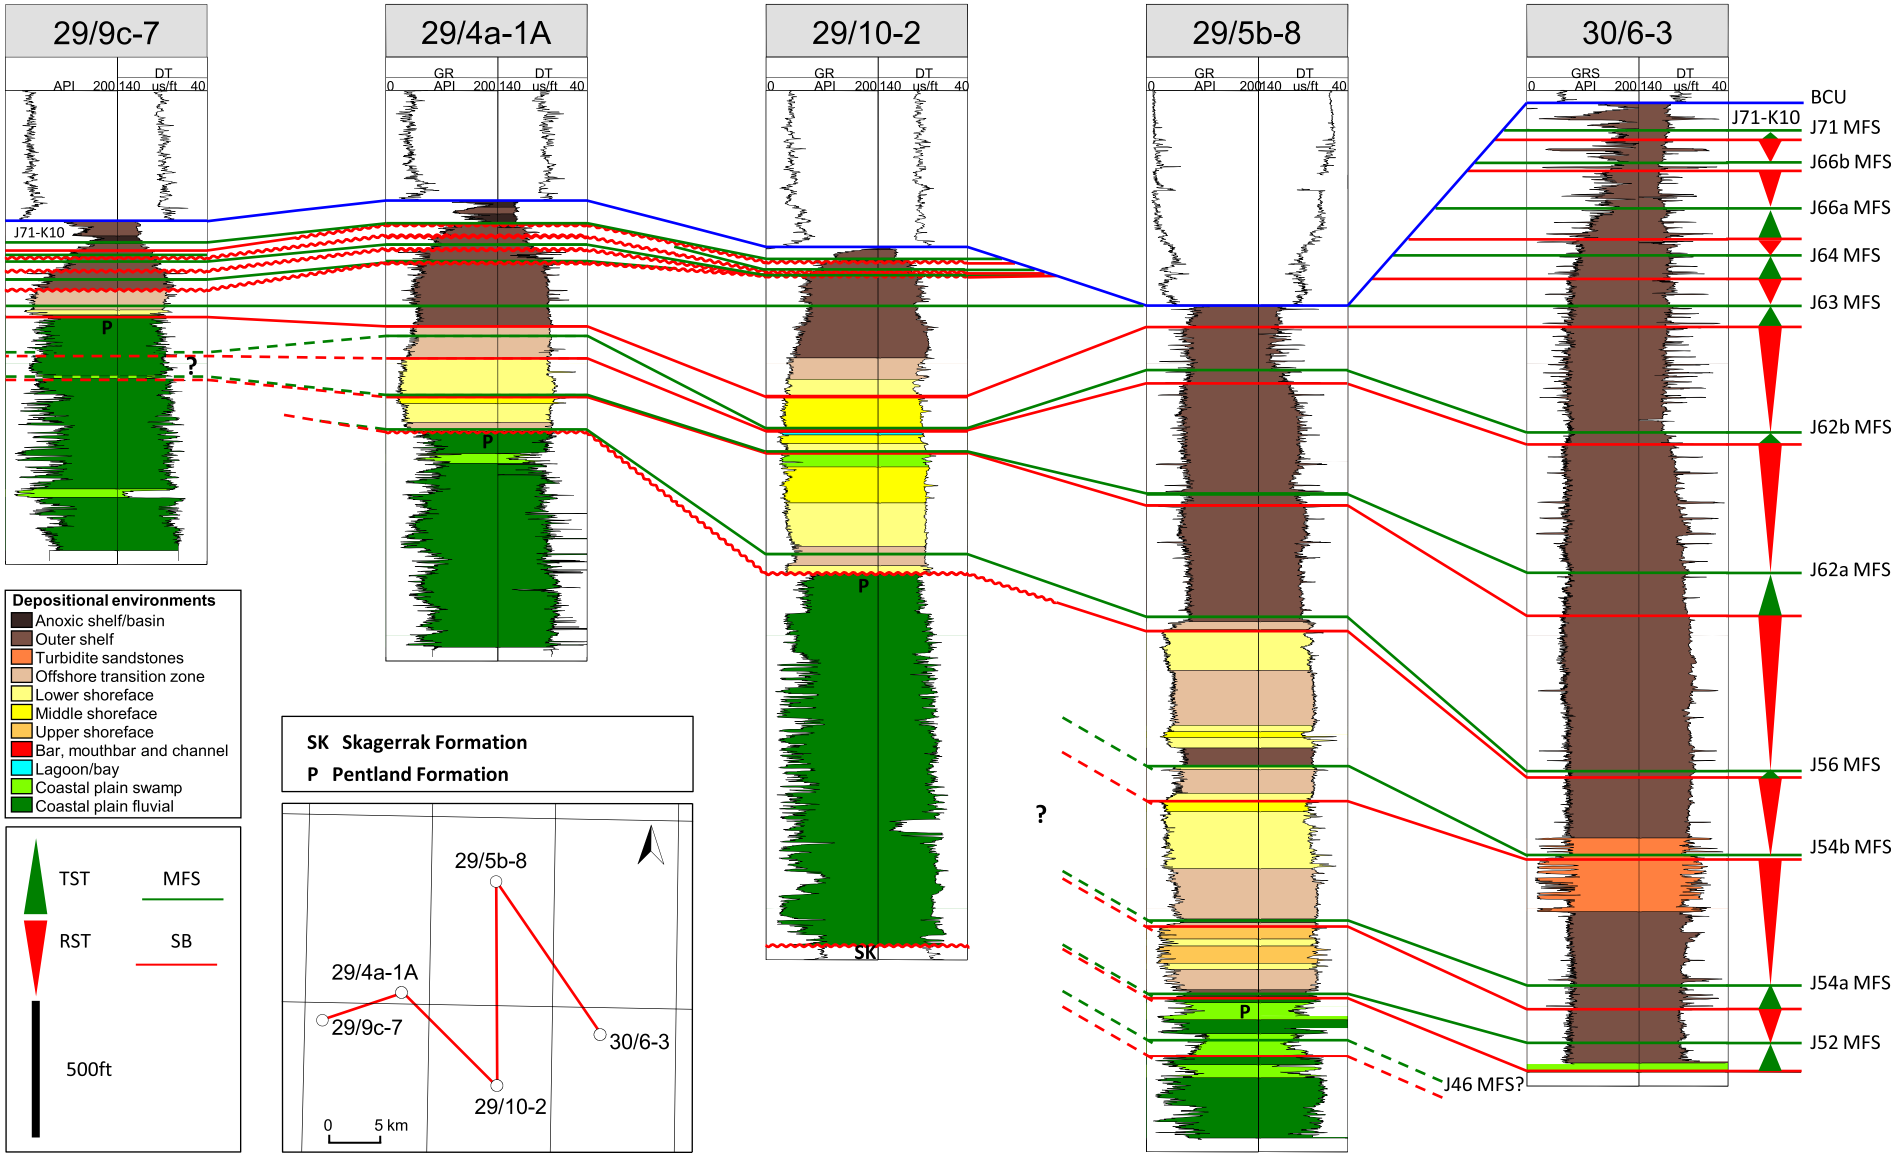

Fig. 12. Well correlation showing back-stepping of the shallow marine system from the 30/6 graben onto the Puffin Terrace in sequence J56. Biostratigraphic data are lacking to confirm whether the upper part of the Pentland succession represents the landward equivalent of the thick aggradational Fulmar Sandstone deposits seen in sequences J52–J54b in the Elgin and Franklin fields.

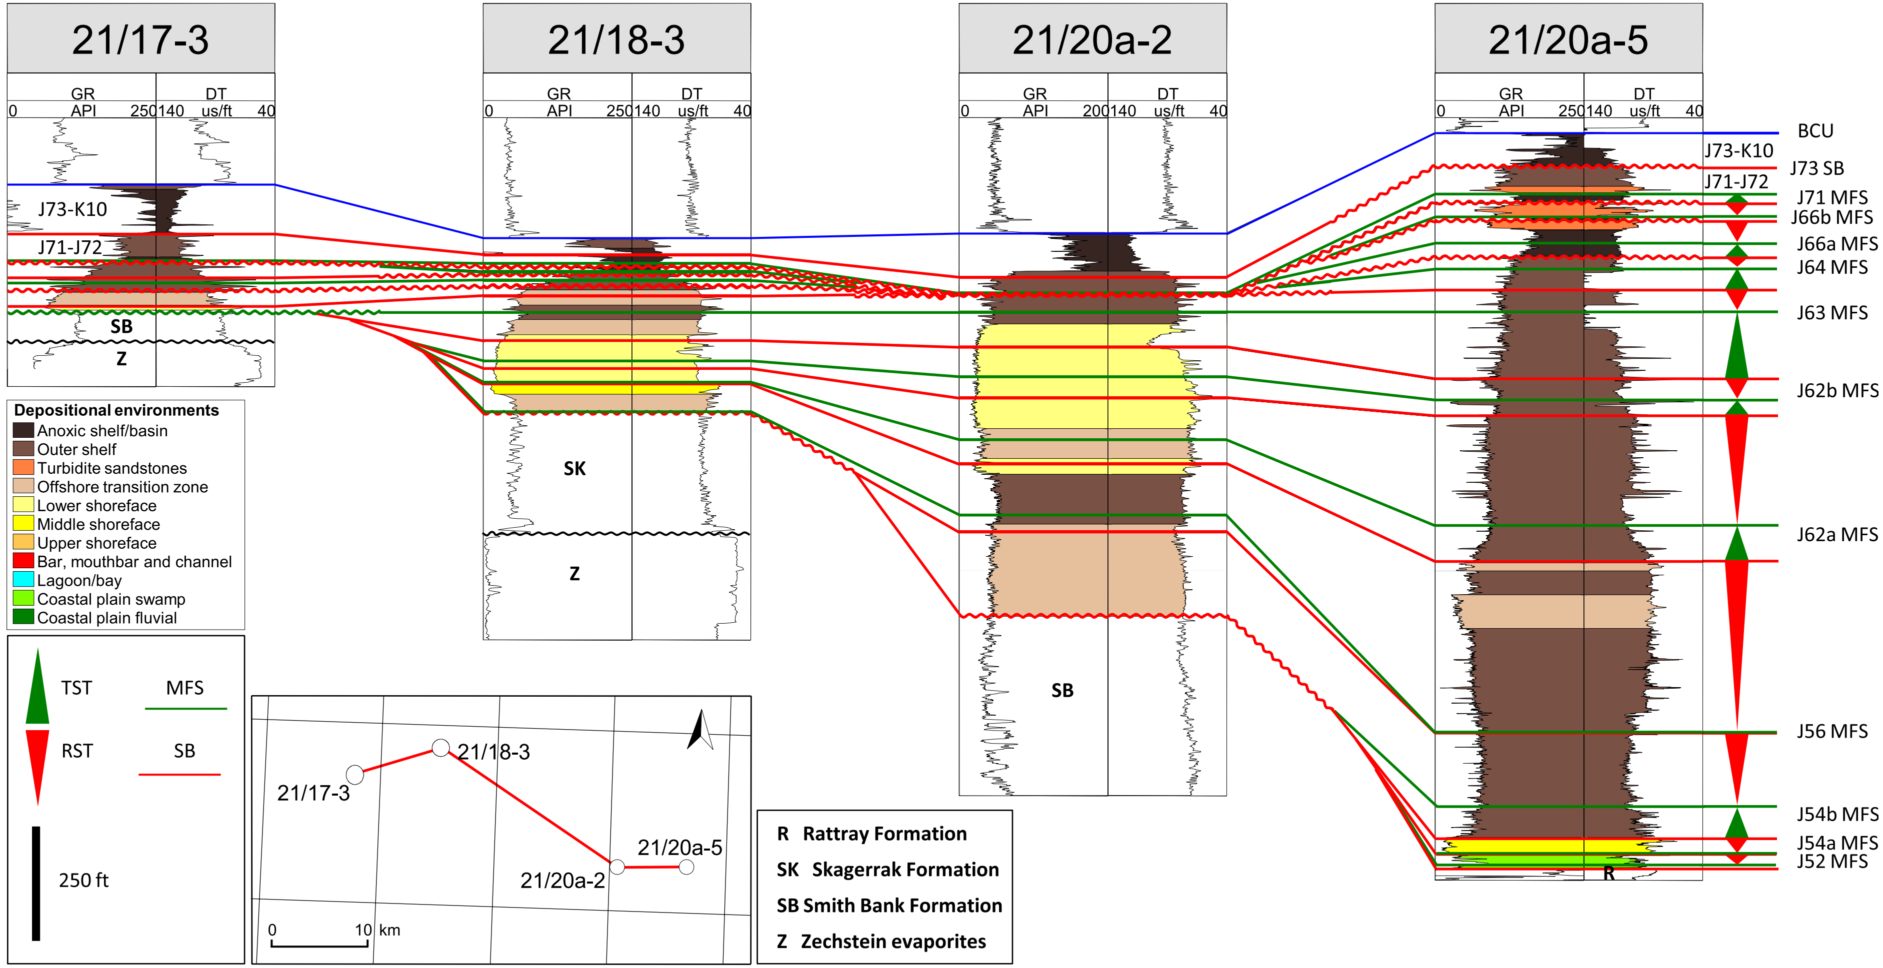

Fig. 13. Well correlation illustrating the back-stepping of the shallow marine system from the WCG onto the Western Platform in sequences J54b and J56 and illustrating the relationship between sequence J56 deposits on the platform area and the graben. A marked increase in progradation is seen at the top of sequence J56 in wells 21/20a-5, 21/20a-2 and 21/18-3. This trend is seen across the basin and may record a forced regression.

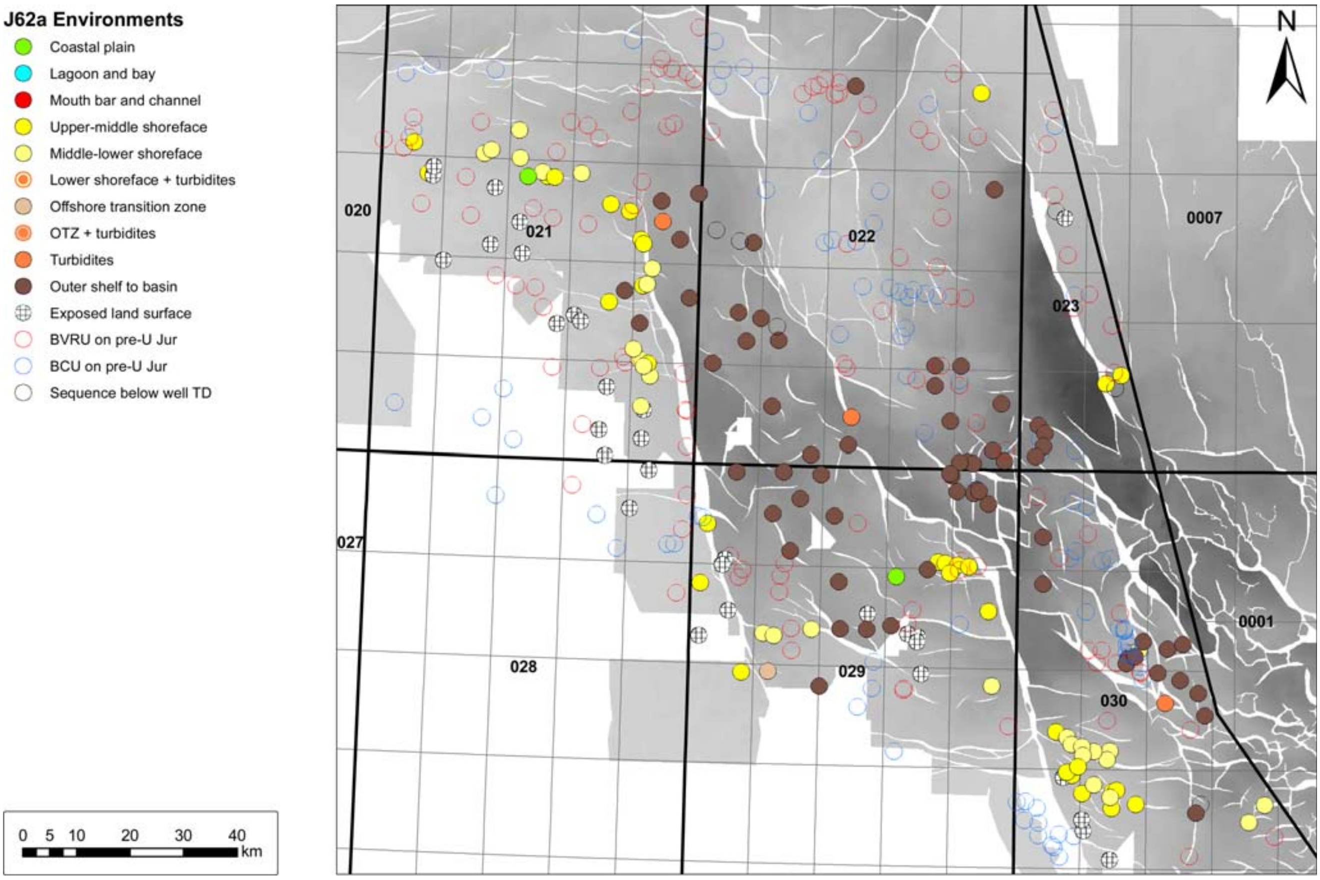

Fig. 14. Sequence J62a depositional environments. Deposition of thick, aggradational shoreface successions occurred on the Western Platform, Puffin Terrace and Fulmar–Clyde Terrace, accompanied by limited turbidite deposition in the basinal areas.

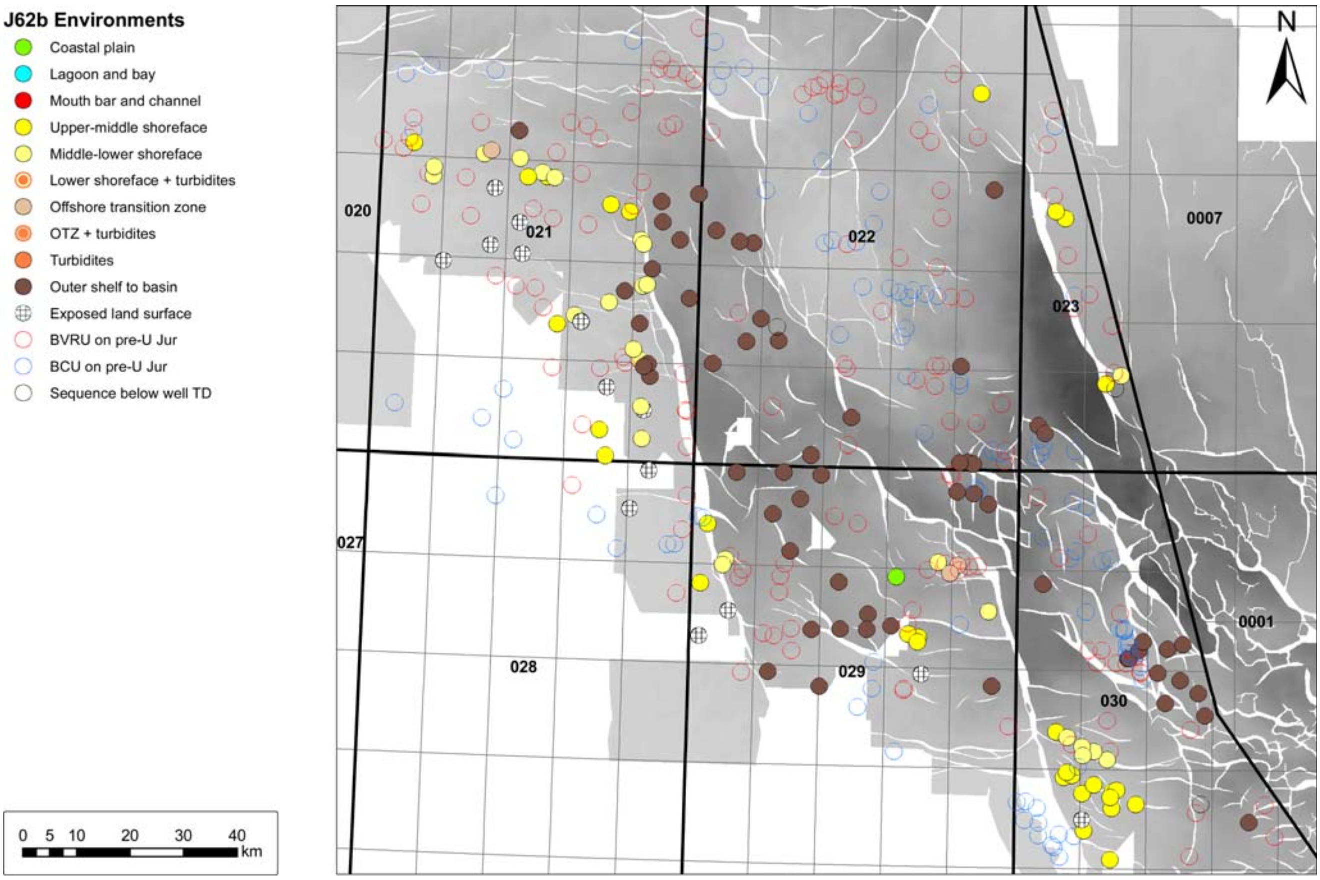

Fig. 15. Sequence J62b depositional environments. Aggradational to retrogradational shoreface deposition continued on the terrace areas with limited expansion of the marine basin.

overlies deposits of the Callovian–Kimmeridgian megasequence, a basal Volgian–Ryazanian megasequence unconformity (BVRU) can be defined. Most of the SBs within the megasequence are also commonly unconformities and the succession is usually highly incomplete in the majority of wells, owing to a combination of internal time-gaps and missing section at the BCU. The BVRU is commonly a composite unconformity, representing erosion and/or non-deposition at two or more of the J64–K10 SBs. The dominance of incomplete successions is due to the preferential location of wells on the structural highs. The unconformities are interpreted as being of dominantly tectonic origin, formed by block rotation and break-up during Volgian–Ryazanian salt collapse. The Volgian salt-withdrawal depocentres are rarely penetrated as they represent present-day lows, but are likely to contain a more complete succession. An element of eustatic control is, however, suggested by consistent log profiles within the more complete successions (Fig. 5), which aids the recognition of incomplete sequences. In the incomplete successions, retrogradational packages dominate over progradational packages and abrupt GR increases occur within composite retrogradational packages which are interpreted as representing stacked TSTs with the RSTs missing at the unconformities.

Where the BVRU is present, determination of the exact timing of the erosional event is complicated by poor biostratigraphic control, and once the unconformity is recognized, the potential for reworking and further blurring of the biostratigraphic resolution becomes apparent. If an unconformity is not recognized and reworking is not correctly identified, then deposits overlying the unconformity may be mis-dated as older than their true age. This is a particular problem where biostratigraphic analyses are based on cuttings, or the original core and sidewall core derived datasets are not available, so that it is difficult to distinguish reworking of older forms from caving of younger forms. Jeremiah & Nicholson (1999) attributed the formation of their SJU600 SB to the tectonic reconfiguration event of Erratt *et al.* (1999), which they dated as latest Early Volgian to basal Middle Volgian based on the occurrence of the marker dinocysts *Muderongia* sp. A Davey 1979 (*Muderongia c.f. simplex* of Duxbury *et al.* 1999) in conjunction with rare *Oligosphaeridium patulum* in sediments immediately overlying older, truncated sequences in the Greater Shearwater area. However, this study has identified wells with a significant interval of older KCF sediments between the BVRU and the characteristic cool KCF facies interval containing the above palynomorphs, suggesting an older age for the onset of reconfiguration. Within the dataset available for this study, the oldest unconformity at the base of the Volgian–Ryazanian megasequence is interpreted as corresponding to the J64 SB, dating the onset of the structural reconfiguration event as latest Kimmeridgian to earliest Early Volgian. This can be demonstrated by tracing the progressive truncation of sequences from wells with a complete succession into wells with a truncated profile. On the western side of the WCG, a complete, although condensed, succession is interpreted in well 21/20a-5, and the basal Volgian–Ryazanian unconformity can be seen progressively down-cutting towards the north, resulting in the complete removal of sequences down to J54b in well 21/15a-6 (Fig. 17). In the Curlew area at the southern end of the WCG, the BCU lies shallower at around 7900–12 300 ft TVDss and biostratigraphic control is relatively good (Fig. 18). Complete condensed, or possibly slightly truncated, successions are

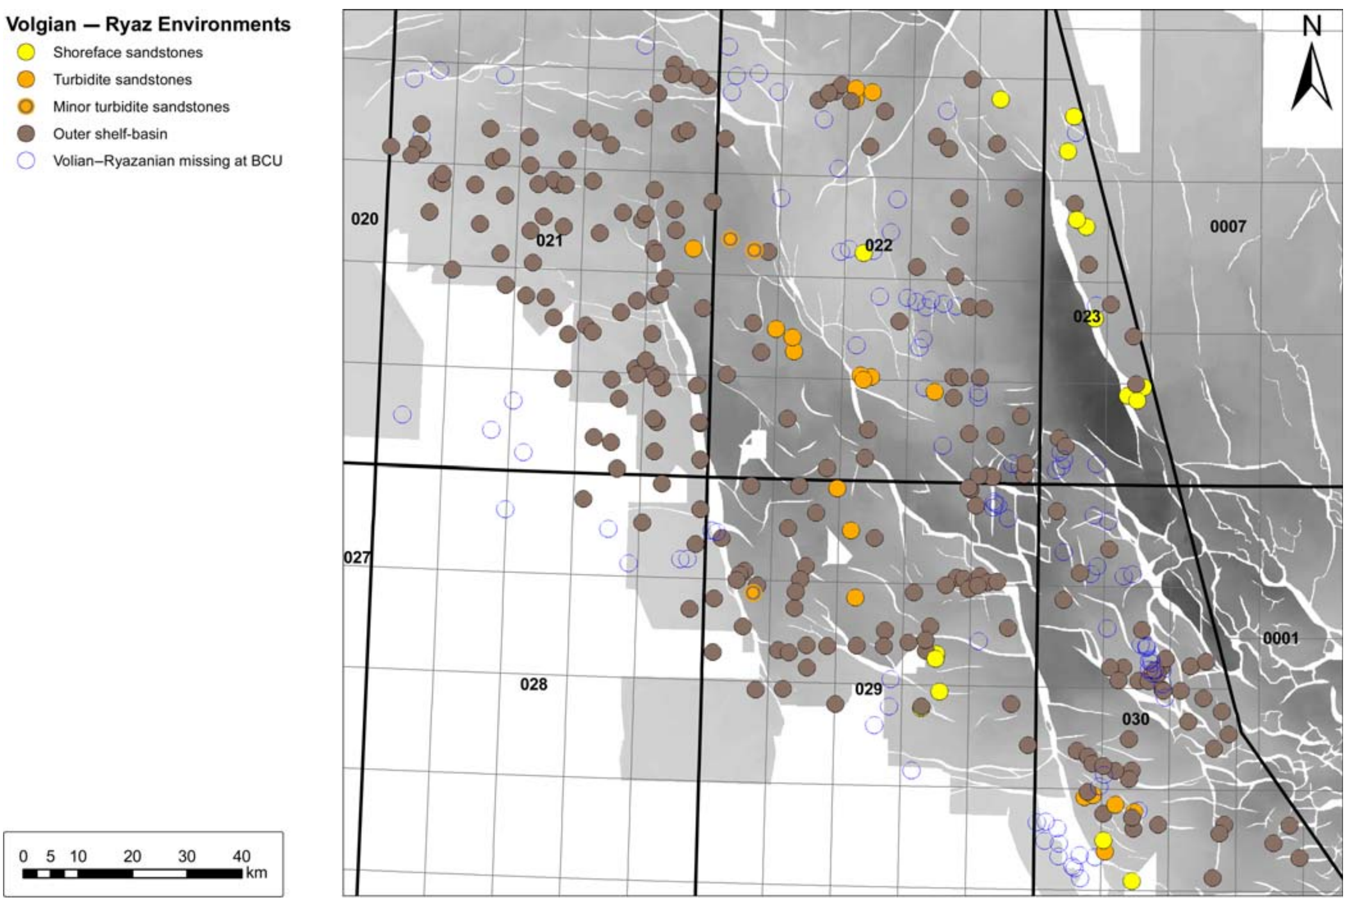

Fig. 16. Summary of environments in the Volgian–Ryazanian megasequence. Shoreface and turbidite sandstones are mostly restricted to sequences J64 and J66a. The shoreface sandstones represent back-stepping onto the remnant topography of the Auk Terrace in the south of the area and Jaeren High in the east, whilst turbidite deposition is interpreted to represent increased sediment supply resulting from block rotation, uplift and erosion.

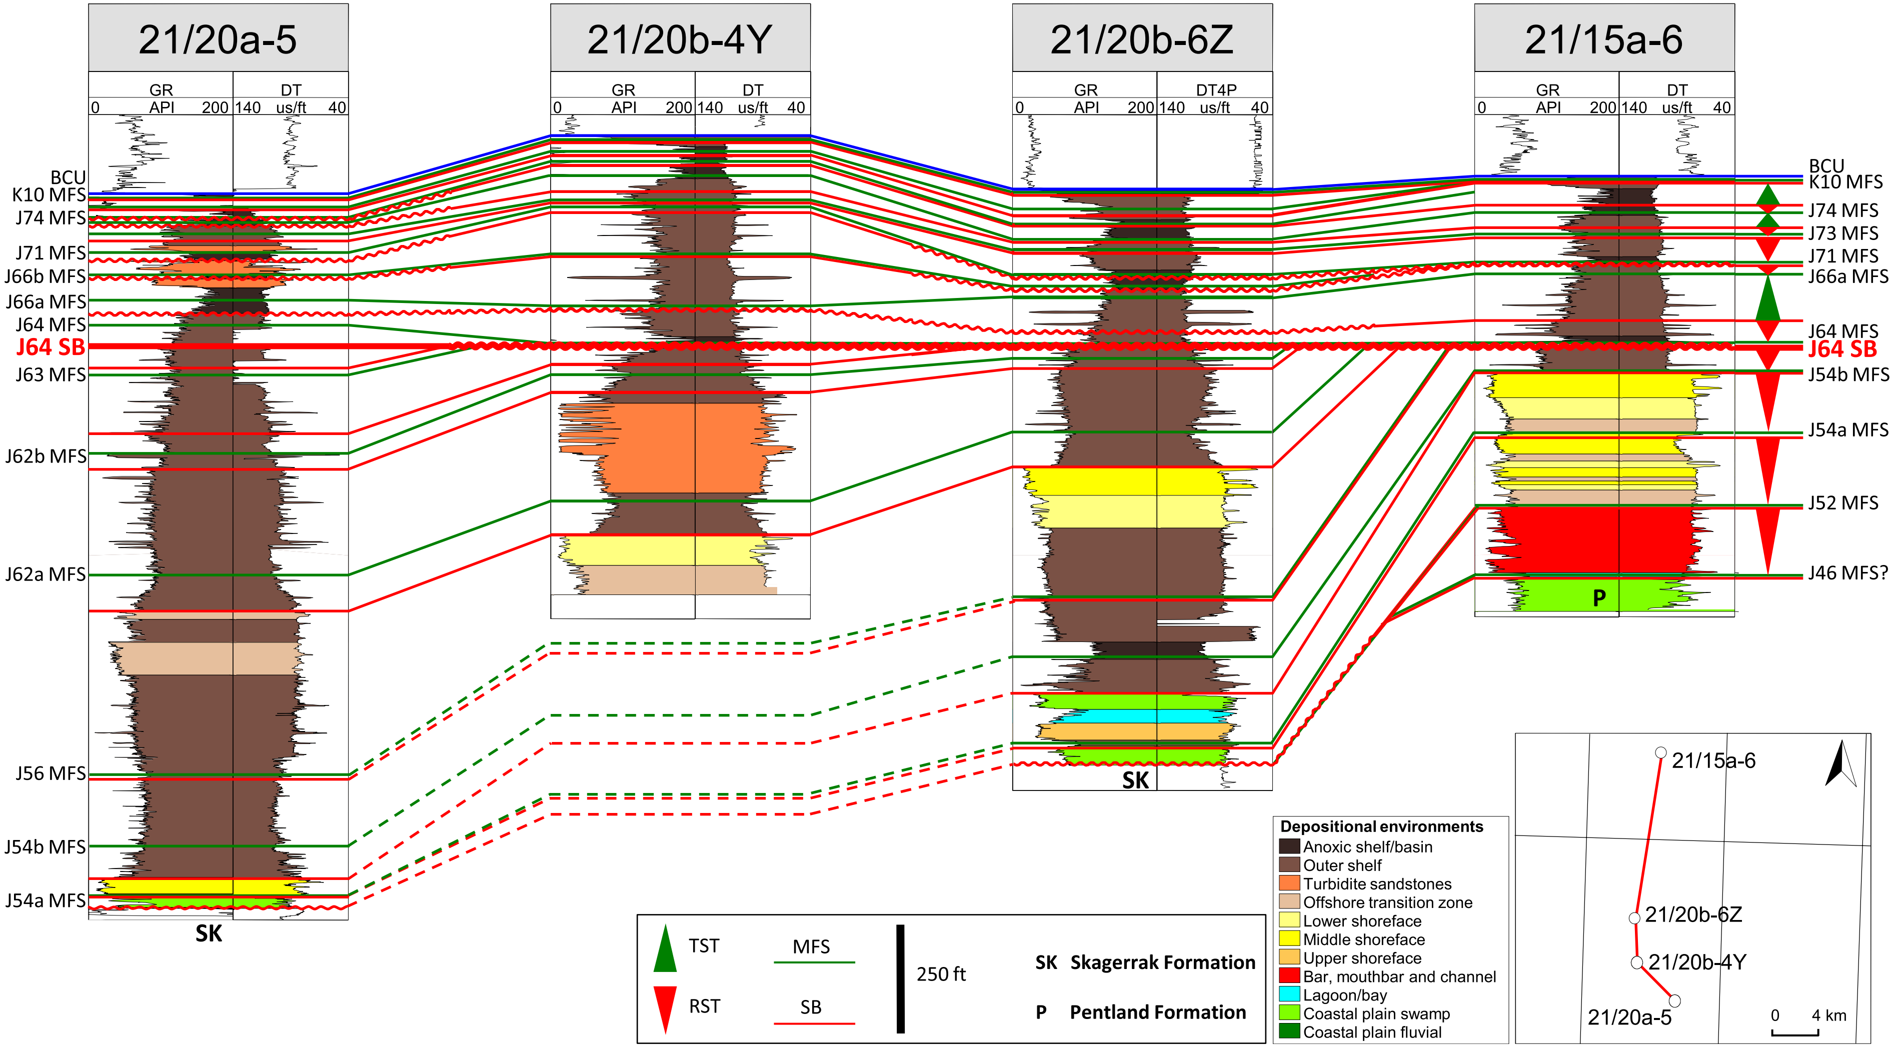

Fig. 17. Well correlation from the WCG showing progressive truncation below the BVRU, which correlates to the J64 SB in the more complete succession in well 21/20a-5. The BVRU is interpreted as cutting down into sequence J63 in 21/20b-4, sequence J62b in 21/20b-6 and sequence J54b in 21/15a-6.

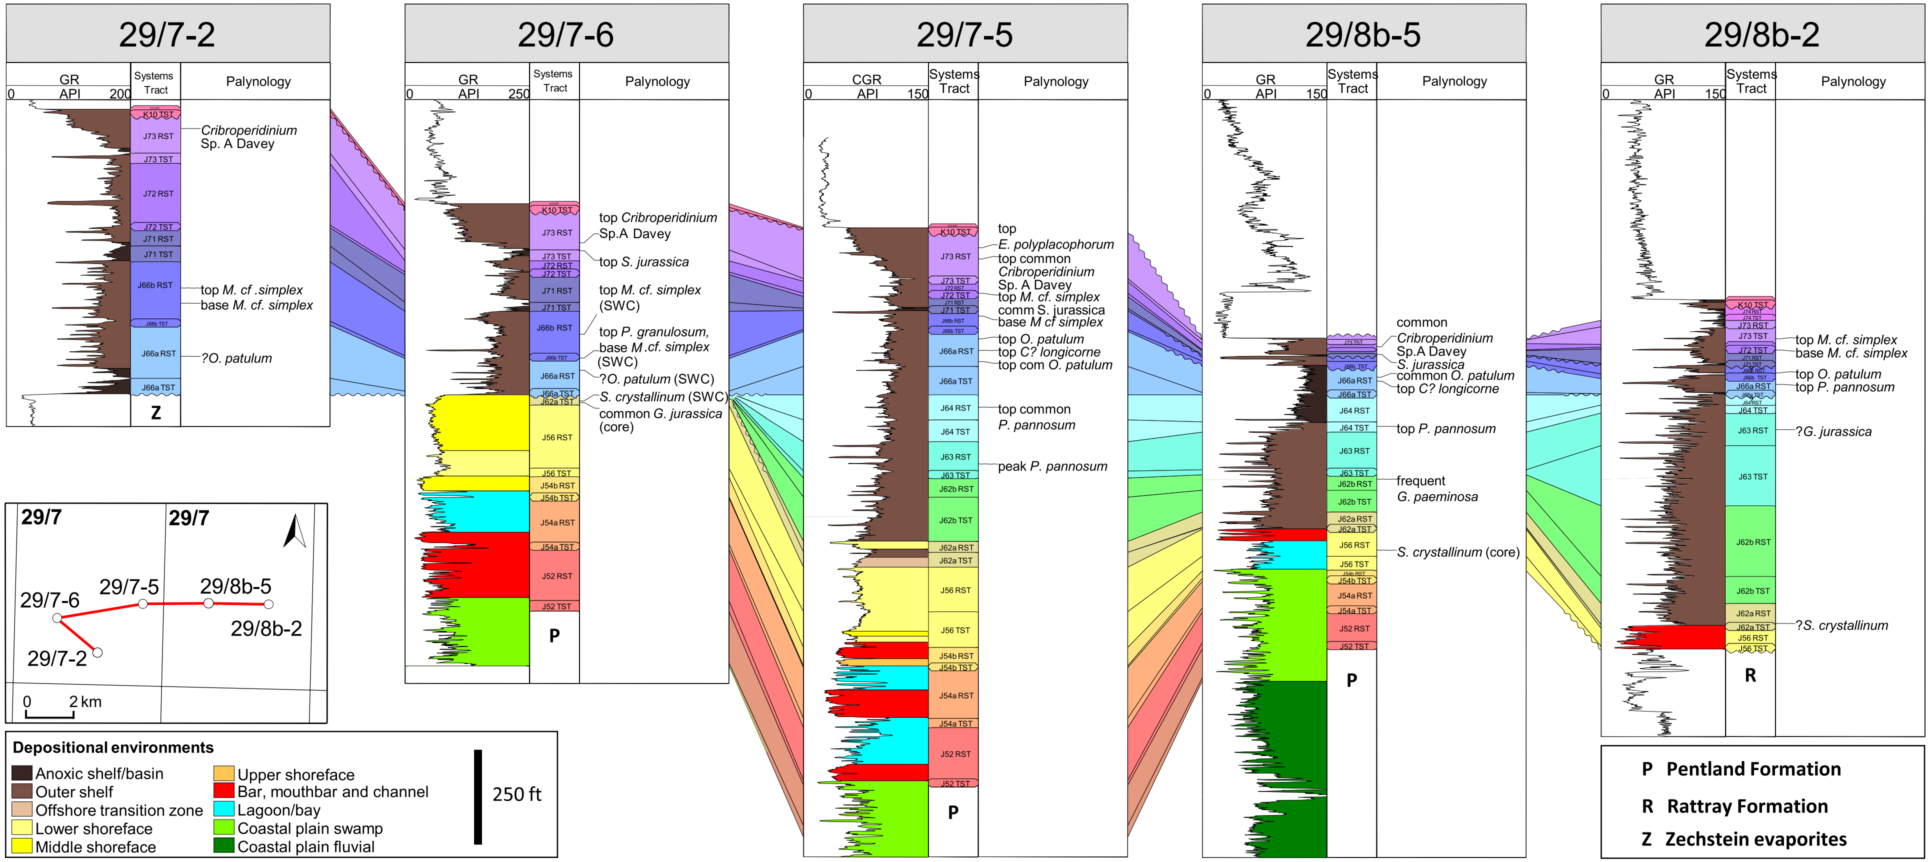

Fig. 18. Well correlation showing biostratigraphic calibration of the sequences and the BVRU in the Curlew area. Complete condensed, or possibly slightly truncated, successions are interpreted in wells 29/7-5 and 29/8b-2, whilst the J66a SB is interpreted as having cut down to sequence J62a TST in 29/7-6. The base occurrence of *M.c.f. simplex* is taken to calibrate sequence J66b, although the top occurrence is interpreted to be depressed in 29/7-2 and 29/7-6 by comparison to adjacent wells.

interpreted in wells 29/7-5 and 29/8b-2, whilst the J66a TST is interpreted as overlying the basal unconformity in 29/7-6, where erosion has cut down to the J62a TST, dating the unconformity as late Kimmeridgian to Early Volgian. The complex Heather and Kimmeridge Clay relationships seen across the Curlew field are attributed to differential erosion and onlap on to the BVRU rather than the rapid lateral facies changes envisaged by Eneyok *et al.* (2003).

The expression of the BVRU and overlying Volgian–Ryazanian megasequence can be grouped into three broad log character motifs. 'Expanded' successions are relatively complete and conformable with the underlying sequence J63. They usually comprise thick sequences of Kimmeridge Clay, which show weak to rarely strong development of the J64 RST. 'Condensed' successions show a marked convex shoulder on GR logs, where the GR increases sharply and sequences J64 and J66 appear either complete and condensed relative to the older sequences in the well and the expanded wells, or the J64 and J66a RSTs are absent, resulting in stacking of the J64 and J66a TSTs, culminating in the J66a MFS. In these wells where sequence J64 overlies sequence J63, the J64 SB corresponds to a MRS at the top of a thin J63 RST, and in some cases the shift to high GR KCF facies above the MRS may be very abrupt so that it is difficult to ascertain whether this represents simply a very sudden tectonically forced deepening (a tectonically enhanced MFS in the sense of Partington *et al.* 1993*a*) or whether some erosion is involved. In 'truncated' successions, the BVRU is clearly an erosional unconformity representing a significant time gap and high-GR sequence J64 or younger Kimmeridge Clay deposits unconformably overlie J63 or older deposits. An extreme end member of this type of succession occurs where sequences J64–K10 overlie pre-Upper Jurassic (typically Triassic) deposits. Whilst this may simply record the final stages of onlap of the Humber Group onto pre-existing topography, there is also the potential that older Humber Group sediments have been eroded at these locations.

Sequence J64 (Early Volgian)

Sequence J64 is commonly missing at the BVRU, with J66a or younger sequences overlying pre-J64 deposits. Where present, the J64 TST is characterized by a marked upward increase in GR values above the J63 RST, indicating rapid deepening culminating in the J64 MFS. The J64 RST is commonly truncated by the J66a SB. However, in some expanded intervals, the J64 RST is well developed and contains sandy turbidite deposits, as seen in the Selkirk discovery (22/22b-2 and -4). Rarely, well developed progradational shoreface deposits are present, as in the Wood field (22/18-6) on the FMH, at the southern edge of the Puffin Terrace (29/9 and 29/14 area) and on the western margin of the Jaeren High, which are equivalent to the thick J64 shoreface sandstones of the Norwegian Gyda field (Partington *et al.* 1993*a*, fig. 13). Both the deposition of the turbidites and the renewed shoreface progradation may be indicative of structural uplift and rejuvenation of sediment source areas.

Sequence J66a (Early Volgian)

Sequence J66a is characterized by a thick transgressive shale package with an upwardly increasing GR profile which commonly overlies Kimmeridgian or older sequences on the BVRU. The J66a MFS is commonly characterized by higher GR values than the older J64 MFS. The J66a RST is variably truncated by the J66b SB unconformity, but where present, it is represented by lower GR shales with occasional sandy turbidite deposits, and rarely shoreface sandstones (22/18-6).

Sequence J66b (latest Early–earliest Middle Volgian)

Sequence J66b is also commonly highly truncated or missing below the J71 SB. It comprises Kimmeridge Clay Formation shales and is similar in log character to sequence J66a so that the two can be difficult to distinguish in the absence of biostratigraphic control. The differentiation of the J66b sequence is necessary, however, to differentiate the Early Volgian erosional events.

Sequence J71–J72 (Middle Volgian)

Sequences J71 and J72 are characterized throughout the study area by a well-developed and diagnostic GR-SONIC bow between the J71 and J73 MFSs, and recording a major influx of cooler Kimmeridge Clay facies into the basin (Fig. 5). The sequences themselves can be difficult to distinguish due to only weak development of the J72 MFS. The J71 MFS is readily identified throughout the study area as a well defined GR peak that marks the culmination of the overall transgressive trend seen throughout sequences J63–J66b and the development of anoxic conditions throughout the basin. The J71 TST is usually thin and the base is commonly marked by an abrupt GR log break at the top of sequence J66b, which suggests that the J71 SB is an unconformity. The J71 MFS is widely recognized even in highly incomplete Volgian–Ryazanian successions, suggesting it represents widespread flooding of topography and fault blocks created during the Early Volgian tectonic reconfiguration. This may suggest that it represents a regional eustatically-controlled sea-level rise.

The J71 and J72 RSTs comprise the lower part of the GR-SONIC bow, with the lowest GR values probably occurring at the top of sequence J72 and defining the J72 MRS/J73 SB. This records a significant pulse of progradation, but sands are limited to rare, thin turbidite stringers, probably reflecting the regional drowning of source areas by the J71 MFS. The first downhole and top common occurrences of *M. simplex* (*Muderongia* sp. A Davey) occur between the J73 and J71 MFSs, providing good dating constraint.

Sequences J73–J76 (latest Middle Volgian–Early Ryazanian)

The J73 TST is commonly thick and comprises the upper part of the well-defined Middle Volgian GR-SONIC bow, representing renewed relative sea-level rise culminating in the J73 MFS. In highly incomplete Volgian–Ryazanian intervals, the lower part of the GR-SONIC bow may be absent above the J71 MFS, representing a significant missing section at the J73 SB. The J73 RST is commonly either very thin or missing at the J74 SB, so that the J73 and J74 TSTs are commonly stacked into a composite transgressive sequence culminating in very high GR anoxic shales that characterize the J74 MFS. Sequences J74 and J76 are poorly defined in the study area, owing to a combination of condensation, onlap and erosion at either the K10 SB or the BCU. Where identified, they are characterized by thin, abrupt TSTs. The K10 SB is commonly underlain by a thin but well-defined cool shale package that may represent the J76 RST. The lack of accommodation space and sediment supply during the Late Volgian and Early Ryazanian contrasts with the Moray Firth Basin, which was a site of significant turbidite deposition at this time (Fraser *et al.* 2002, fig. 11.17).

Sequence K10 (Late Ryazanian)

Although it is thin (typically 10 ft), sequence K10 is usually easily recognized by a characteristic GR log couplet just below the 'BCU' (base of the Cromer Knoll Group). Lower GR values at the base of the sequence define the SB, which is overlain by highly condensed Kimmeridge Clay deposits that are characterized by very high GR values. Sequence K10 is also easily recognized in the available micropalaeontological datasets by the presence of *Tricolocapsa* species 1. The K10 SB is an unconformity which commonly cuts out Early Ryazanian and Late Volgian (J74–J76) deposits. However, the sequence may be conformable with the basal deposits of the Cromer Knoll Group. The very high GR values suggest that relative sea-level rise contributed to further restriction of water circulation and stagnation in conditions of very low sediment supply.

Evidence for and implications of tectonic reconfiguration of the Central Graben

Salt redistribution and block rotation

The formation of the basal Volgian and intra Volgian–Ryazanian unconformities and relationship between wells showing expanded, condensed and truncated log profiles can be attributed to the wells being located on different parts of a fault block that was undergoing rotation from sequence J64 times onwards (Fig. 19). Erosion and deep truncation takes place on the crest of the block updip of the pivot point as illustrated by Davies *et al.* (1999, fig. 11). Truncation becomes progressively less downdip, passing into a zone of omission then condensation around the pivot point, before expanding further downdip into a syn-rotational growth sequence in the hanging wall to the active fault. Within the Central Graben, this situation arose during redistribution of the underlying salt in response to the change of kinematic regime proposed by Erratt *et al.* (1999). This had a dramatic and sudden effect, inducing lateral movements of the salt along the salt walls, causing some areas to rise and others to collapse, with new Volgian faults forming at the interface. This broke up the Triassic–Jurassic mini-basins and the new fault blocks rotated into the evolving Volgian depocentres located over falling salt structures. The CNS diapirs are envisaged to have been initiated at this time by these movements.

The seismic line in Figure 20 from the West Central Graben illustrates this process. The Upper Jurassic section is shown thickening westward into a basin-margin salt-withdrawal depocentre which persisted into the Lower Cretaceous. Grounding of the Triassic pod onto a Rotliegend horst in the centre of the basin and collapse of the marginal salt highs caused dissection of the depocentre into two smaller Volgian basins and collapse of the basin margins. On the western margin, a Triassic Smith Bank pod is interpreted to have rotated into the basin due to deflation of the basin margin salt wall. On the eastern side, the turbidite deposits which form the Selkirk reservoir (wells 22/22b-2 and -4) are placed within the J64 RST (Fig. 21). These sandstones are interpreted as providing further evidence of the timing of uplift, erosion and reworking of Fulmar and/or Skagerrak sandstones on the FMH as a result of the tectonic reconfiguration of the basin.

Evidence for basement uplift

Whilst the pattern of erosion associated with the formation of the BVRU is obviously biased by the location of most wells on the structural highs and not in the Volgian depocentres, consideration of this pattern suggests that pod grounding and fault block rotation due to salt redistribution alone may not be sufficient to account for the degree of erosion seen in some areas. Figure 22 shows the sequence age of the subcrop to the BVRU (J64 SB or younger SBs). This shows a pattern of deep truncation of the pre-Volgian succession down to sequences J52–J56 on the flanks of the FMH and along the SE-trending axis between the West and East Central Graben which terminates in J Block and the J Ridge. Deep truncation of the succession down to sequences J56–J62a is also seen at the northern end of the Western Platform (border of blocks 21/19 and 21/20) and in the south of the WCG in the Curlew (29/7) area. This correlates with the areas of uplift and subsidence observed by Erratt *et al.* (1999), who documented uplift of the Auk Terrace and J Ridge together with collapse of the Puffin Terrace and dissection of the Jacqui (30/8) graben. Along the crest of the Forties–Montrose, Kessog and J-Block highs, Upper Jurassic sediments are either completely absent, so that Cretaceous strata overlie predominantly Triassic (less commonly Middle

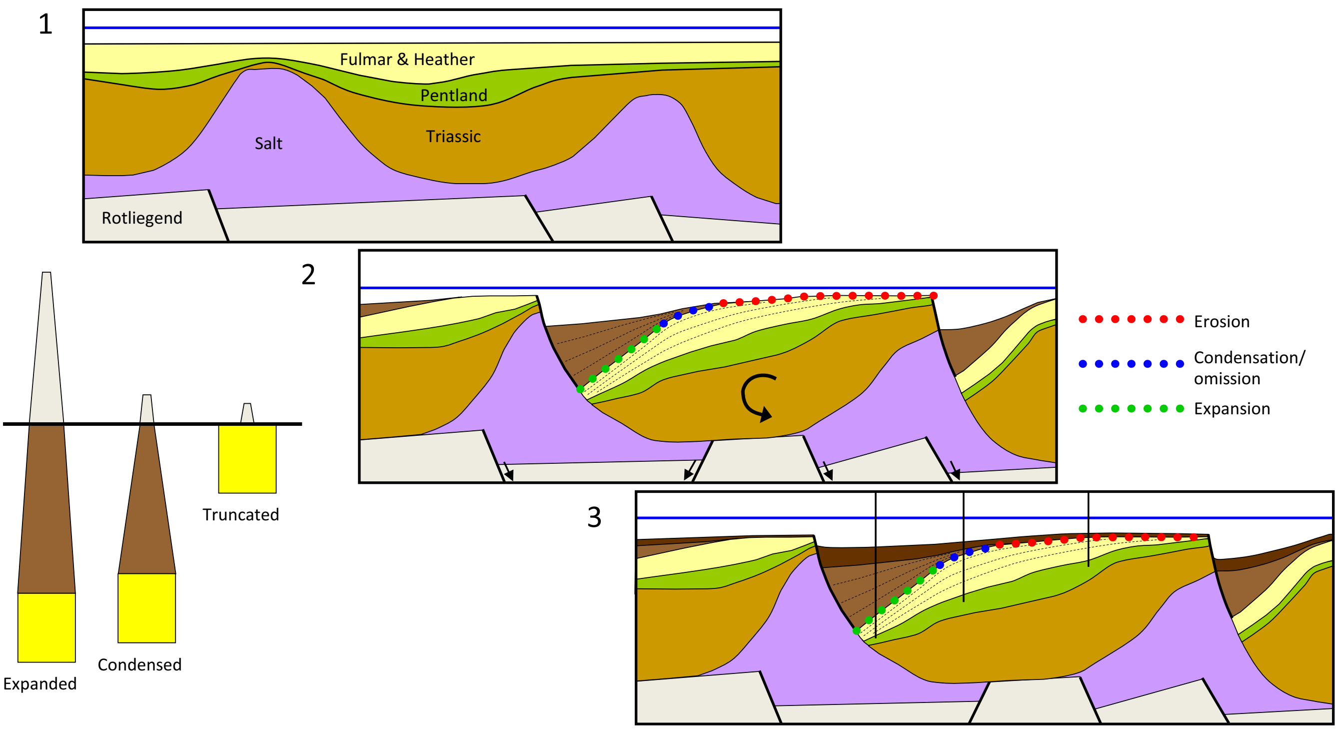

Fig. 19. Conceptual model illustrating the process of formation of truncated, condensed and expanded Volgian–Ryazanian (J64–K10) successions during pod breakup and rotation resulting from partial collapse of the adjacent salt walls.

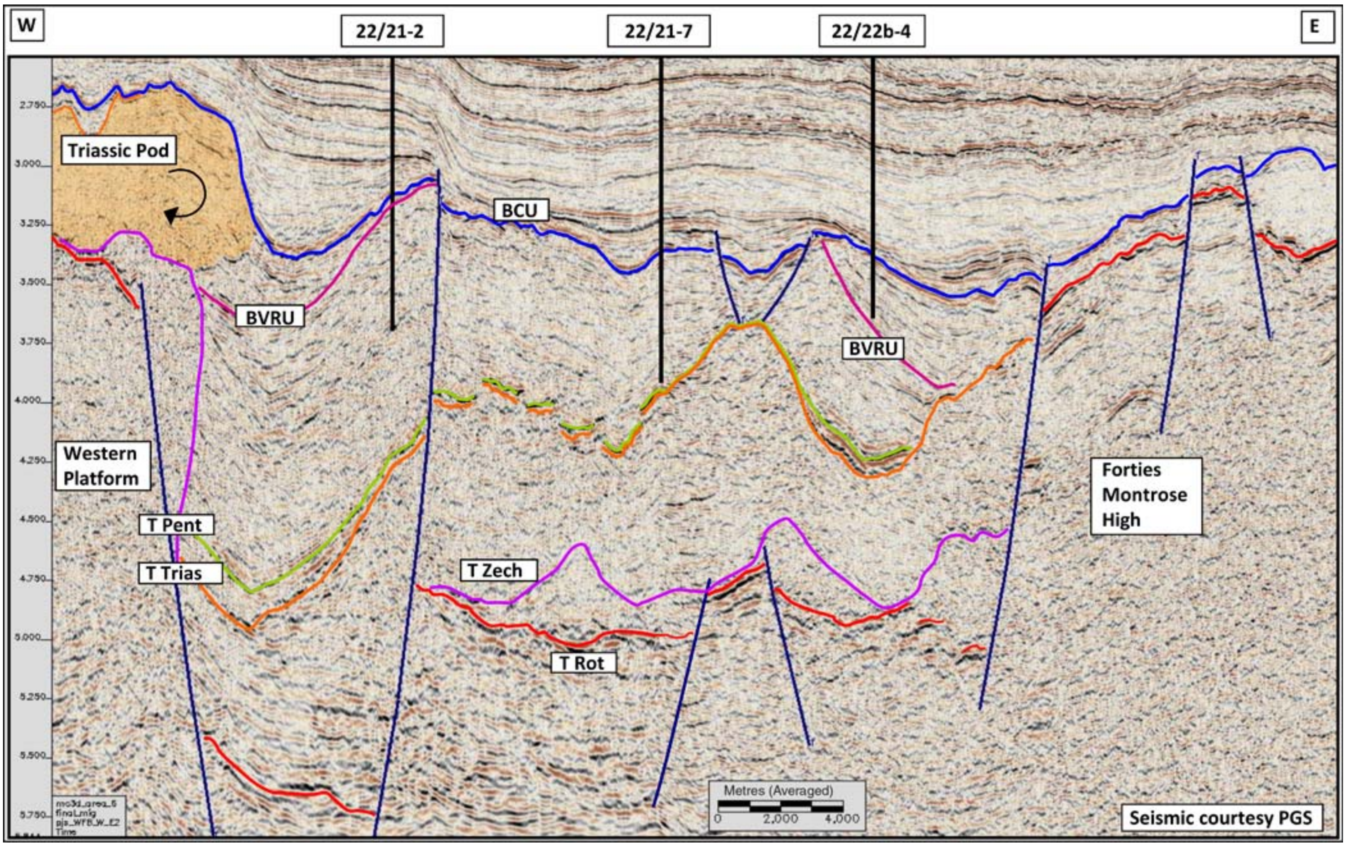

Fig. 20. Seismic line across the WCG showing a large, grounded Triassic pod in the centre of the basin and the development of Volgian depocentres at the basin flanks due to deflation of salt walls at the basin margin. The removal of salt has caused a Triassic pod to rotate into the graben from the Western Platform.

Jurassic or Permian) sediments, or are represented by sequence J64–K10 (Volgian–Ryazanian) KCF only. At first glance, the pattern of wells containing only a Volgian to Ryazanian Upper Jurassic succession, or where the Upper Jurassic is absent, could be explained by the simple onlap of the Upper Jurassic sequences onto the intrabasinal highs as rifting progressed, with the Volgian shoreface deposits representing the final stages of backstepping of the Fulmar system. However, the recognition of the BVRU allows the possibility that some, if not all, of these areas were drowned prior to tectonic reconfiguration, and that widespread uplift and erosion of the highs has occurred.

Figure 23 shows a north–south seismic line along the northern axis of the West Central Graben. This demonstrates northward thinning of the Upper Jurassic succession, as might be expected due to onlap onto the FMH. However, a well correlation along this line (Fig. 24) indicates that this thinning is in large part due to truncation within the Upper Jurassic interval by the J64 SB and/or younger SBs and onlap of this surface by successively younger Kimmeridge Clay sequences to the north. This implies that uplift of the FMH and tilting of the West Forties basin occurred as a result of the tectonic reconfiguration.

Timing and style of tectonic events

There is considerable variation in the interpreted ages and kinematics of the Late Jurassic rift events in the Central Graben. Price *et al.* (1993) suggested that rifting was largely confined to the Late Oxfordian to Early Kimmeridgian, since this was when the major sand influxes occurred. Rattey & Hayward (1993) and Partington *et al.* (1993*a*) favoured a younger late Kimmeridgian to Early Volgian (J63–J66) age for the onset of the main rift phase in the Central Graben. Rattey & Hayward (1993) concluded that the change from rifting to thermal subsidence occurred at the base of sequence J70, owing to an apparent absence of J70 and younger unconformities. Davies *et al.* (1999) distinguished an intra-Callovian unconformity and a Middle Oxfordian unconformity, both generated by extension-related uplift, from the older intra-Aalenian (Mid Cimmerian) unconformity generated above the North Sea thermal dome. Significantly they noted changes in the geometry of the rift system at these events and attributed the switch to a NW–SE orientated depocentre in Kimmeridgian–Volgian times in the Witch Ground Graben to a third phase of re-orientated rifting.

Erratt *et al.* (1999) attributed the overprinting of the Oxfordian–Kimmeridgian basin fabric to a change in the extension direction from west–east to SW–NE, resulting from rotation of the kinematic axes of the Central Graben in the Middle to Late Volgian, although Jeremiah & Nicholson (1999) interpreted a latest Early Volgian to basal Middle Volgian age for this event. Erratt *et al.* (1999) attributed the reactivation of the Auk margin and J Ridge to footwall uplift associated with a pulse of basement extension and suggested that some structures of apparent strike-slip origin could be attributed to the superposition of rift events with differing orientations. Conversely, Jones *et al.* (1999) argued that the apparently conflicting extension directions presented in earlier work could be explained by a phase of relatively weak Callovian to early Kimmeridgian NW–SE extension, succeeded by a phase of sinistral shear between the Tornquist Zone and the Trans-European Fault Zone in the Kimmeridgian to Ryazanian, during which the Central Graben experienced transpression along NW–SE faults and extension across west–east faults. They argued that no change in the regional extension vector was necessary to explain the observed structures. Alternatively, Stewart & Clark (1999)

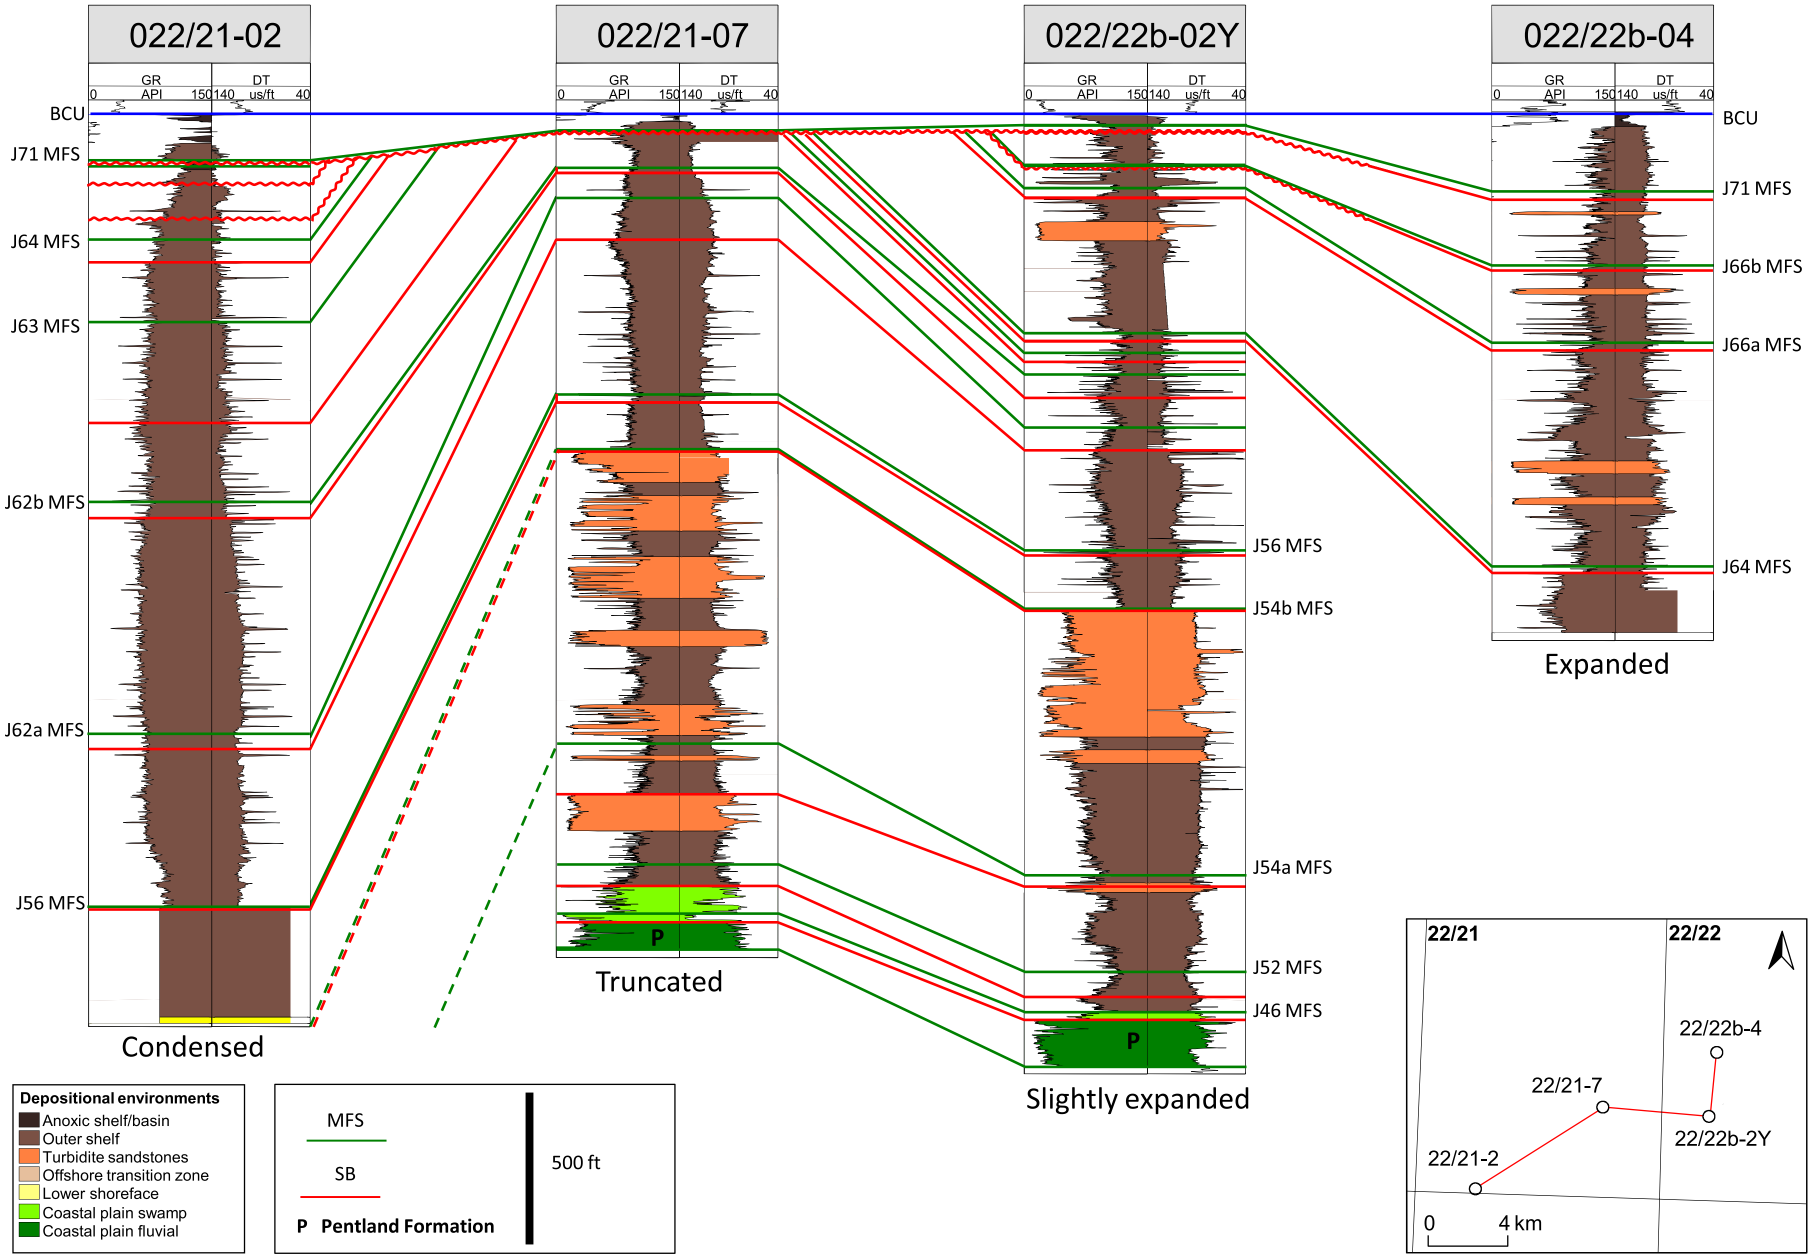

Fig. 21. Well correlation showing marked truncation below the BVRU in the centre of the WCG and expansion of the Volgian section (sequences J64–J66b) into the marginal depocentre, where the Selkirk turbidites were deposited during sequences J64 and J66a in wells 22/22b-2Y and 22/22b-4. Note, however, that Late Volgian–Ryazanian sequences are missing in these wells despite their increased accommodation space during the Volgian, possibly recording progressive grounding of the underlying pod flank.

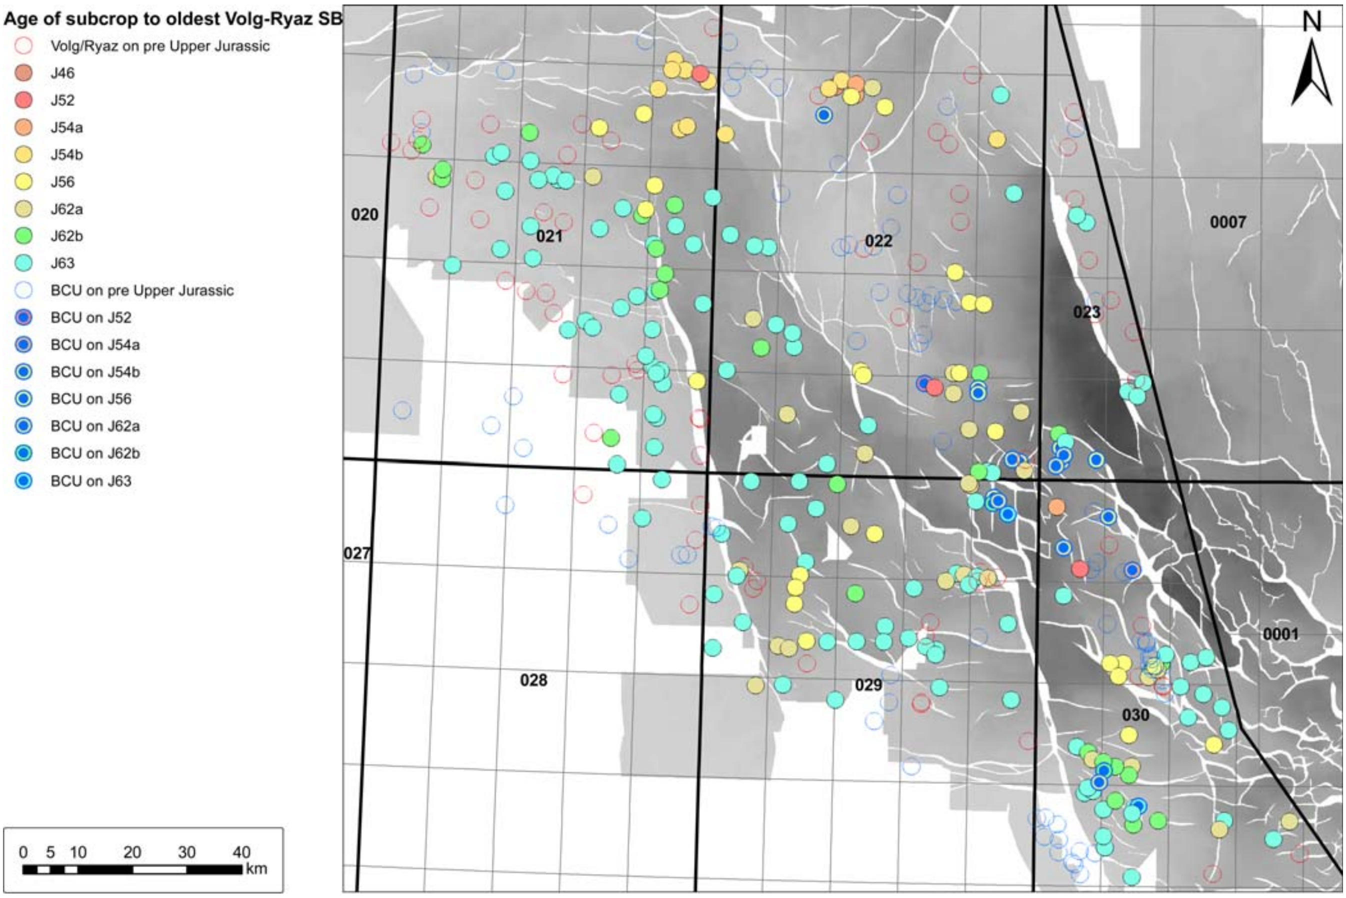

Fig. 22. Subcrop to the oldest Volgian–Ryazanian SB by sequence age. Note the deep truncation down to sequences J52–J56 on the flanks of the FMH and J Ridge. Areas where the Callovian–Kimmeridgian megasequence (e.g. Shearwater–Erskine area) or pre-Upper Jurassic deposits now subcrop the BCU may also have been deeply truncated at this time, but the evidence has been removed by subsequent erosion.

proposed that the late Upper Jurassic and Lower Cretaceous isopachs were a function of salt redistribution controlled by thin-skinned, gravity-driven tectonics rather than basement extension. Stewart (1993) proposed that the geometry of the Ula Trend in the Norwegian Central Graben resulted from a combination of dip-slip and sinistral oblique-slip on deeper Early Permian faults, and that halokinesis played only a minor role in controlling deposition of the Upper Jurassic succession.

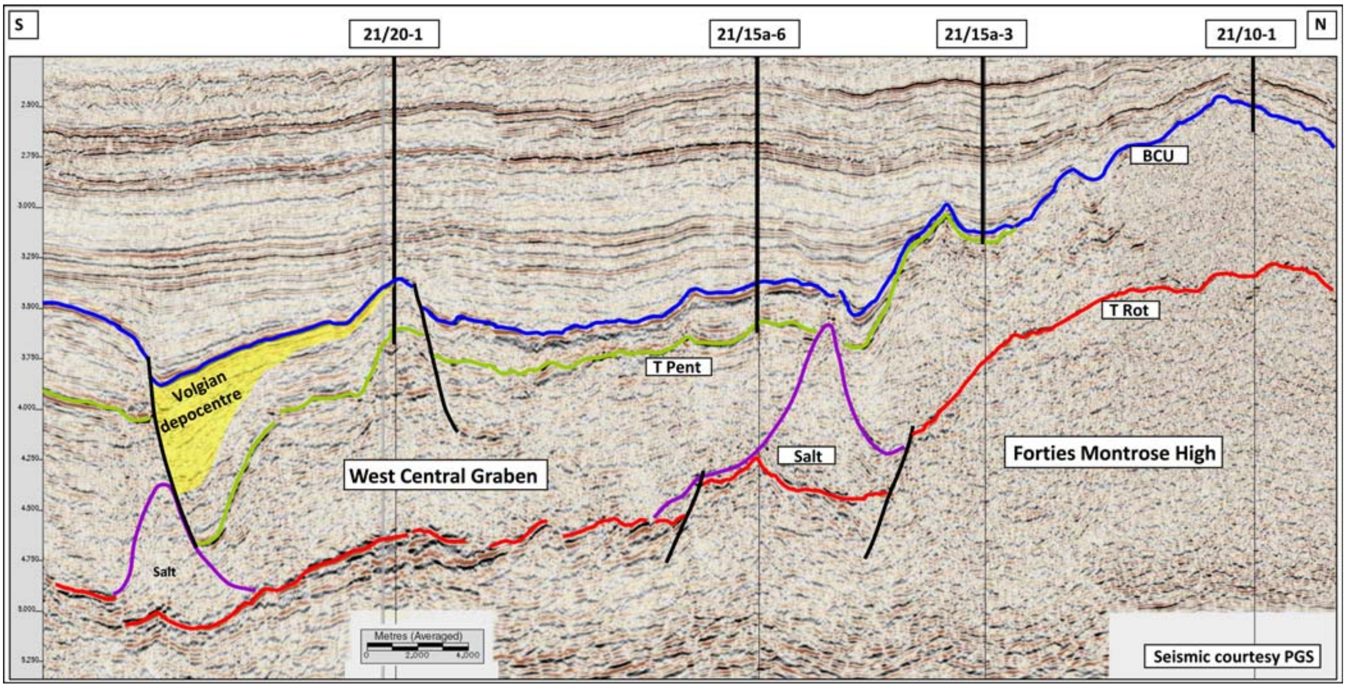

Fig. 23. Seismic line from the northern axis of the WCG showing northward thinning of the Humber Group succession on to the FMH and the location of a Volgian depocentre downdip from well 21/20a-1.

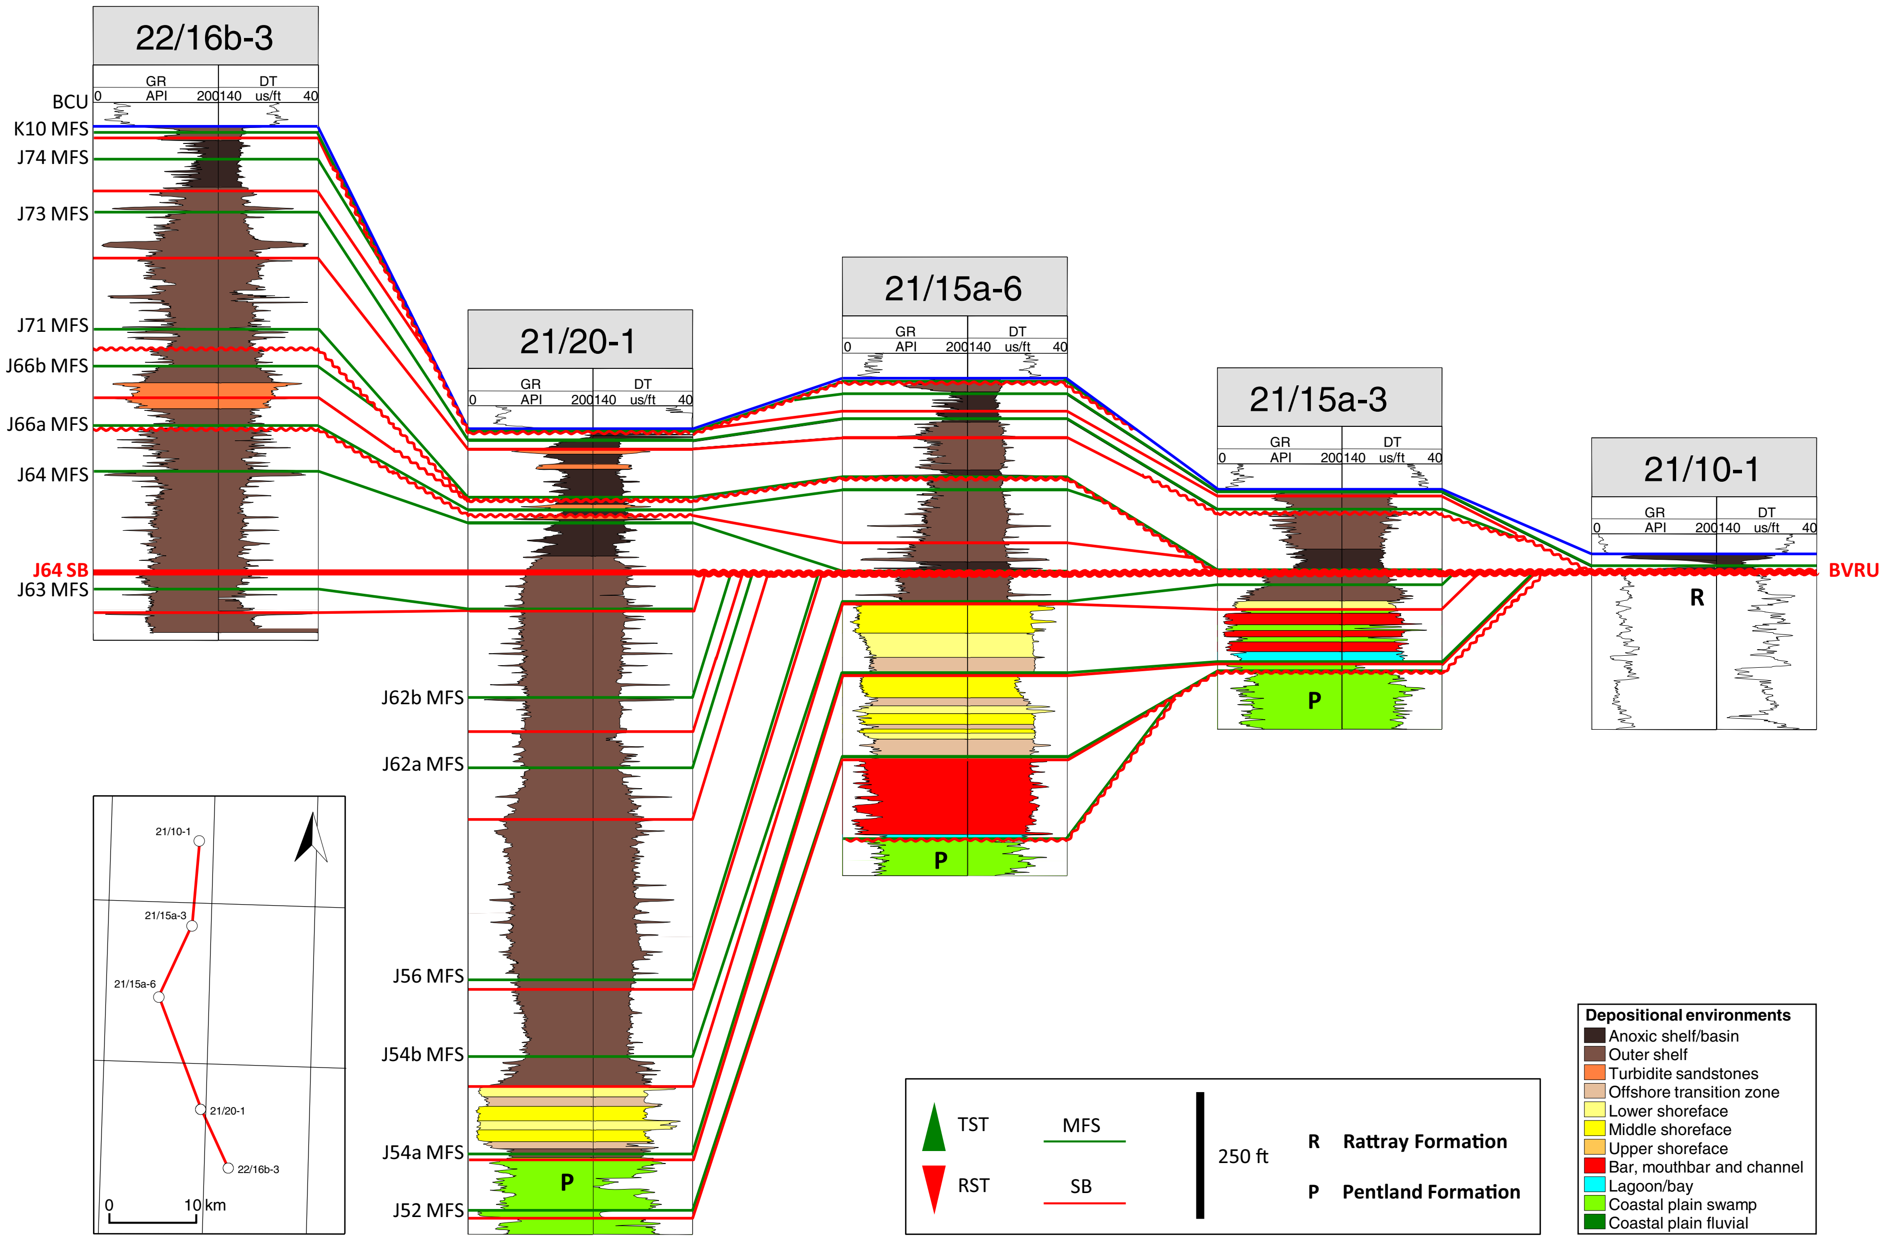

Fig. 24. Well correlation showing the progressive truncation of the Callovian–Kimmeridgian megasequence beneath the BVRU, which is interpreted as recording reactivation of the FMH during the latest Kimmeridgian to earliest Volgian. Section is missing both as a result of truncation below and onlap onto the BVRU.

The sequence stratigraphic interpretation presented here clearly records a major change in the factors controlling sequence architecture during the deposition of the Humber Group and favours a latest Kimmeridgian to earliest Early Volgian age for the onset of this event. Prior to this, the regionally consistent nature of log motifs and sequence stacking patterns and lack of obvious unconformities seen within the component sequences of the Callovian–Kimmeridgian megasequence indicates basin-wide controls on relative sea-level, which could be eustatic or tectonic, but were most likely a combination of both. Jeremiah & Nicholson (1999) favoured rifting-induced tectonic events as the main control on sequence geometry and flooding events. Alternatively, rifting could have been relatively weak, as suggested by Jones *et al.* (1999) so that salt acted very effectively to decouple basement extension from surface displacement and the effects of basement extension were distributed more widely across the basin, masking the movement on individual faults and giving the appearance of more areally uniform subsidence.

It is unclear to what extent the redistribution of salt and the breakup of the Callovian–Kimmeridgian basin required, or was indicative of, a major rift pulse, and whether the rejuvenation of the FMH and other elements was simply due to footwall uplift, or reflects a more regional uplift event. It is possible that the development of Volgian–Ryazanian depocentres can be attributed to the redistribution of salt, as suggested by Stewart & Clark (1999), triggered by relatively minor basement extension. Whilst the Volgian was a time of rapid creation of accommodation space and turbidite deposition in the Moray Firth Witch Ground Graben (Davies *et al.* 1999; Erratt *et al.* 1999), it largely resulted in a reduction of accommodation space and erosion in the WCG and ECG, except in the relatively localized areas undergoing salt collapse. It is suggested that the BVRU may effectively record the end of major basement extension in this part of the Central Graben, with the rifting largely transferring to other areas, and the overprinting of the earlier basin fabric, due to a combination of basement uplift and halokinesis resulting from a changing stress regime.

Implications of Early Volgian reconfiguration for exploration models

From a petroleum exploration perspective, the most important implication arising from recognition of the BVRU and younger unconformities is that the present-day structure of the Central Graben does not reflect the architecture of the basins in which the bulk of the Fulmar Sandstone and subordinate Oxfordian–Kimmeridgian turbidite sandstone reservoirs were deposited. It is therefore necessary to remove the effects of the Volgian reconfiguration and reconstruct the Callovian–Kimmeridgian basin morphology to predict the original extent and likely depositional facies and produce effective predictive models. No structural restorations of the Central Graben using the ability of modern software to effectively model salt movements and incorporating the latest Kimeridgian–earliest Volgian reconfiguration have been published, and the older published models tend to treat the Upper Jurassic interval as a single time-step, showing the Upper Jurassic thickening as a simple wedge into the basin bounding faults (e.g. Price *et al.* 1993; Rattey & Hayward 1993).

Basin-scale palaeogeographic reconfiguration

At the basin scale, Early Volgian reactivation of the FMH and J Ridge trend is believed to have been responsible for major reconfiguration of the connections between the ECG and WCG and between both these areas and the FBB (Erratt *et al.* 1999; Jeremiah & Nicholson 1999). The presence of older Callovian to Early Oxfordian (J44–J46) barrier, lagoon and shoreface deposits in the Howe area (22/12 and 22/13) at the transition between the FMH and the FBB suggests that marine incursion of the West Central Graben could have occurred from the north, across the present-day FMH through blocks 22/12 and 22/11. This implies that a structural low connecting the WCG and FBB in the Early Oxfordian was inverted to become a structural high by the end of the Upper Jurassic, resulting in complete erosion of Jurassic sediments so that Lower Cretaceous successions now rest on Triassic strata. If this interpretation is correct, it indicates the potentially large amounts of uplift and erosion that accompanied the formation of the BVRU.

Similarly, Early Volgian uplift is interpreted to have formed the structural arch between the FMH and the Jaeren High, along the trend of the Montrose–Jaeren transfer fault of Penge *et al.* (1999). Volgian Kimmeridge Clay, interpreted as representing onlap onto the BVRU, now overlies Triassic strata in this area (southern part of block 22/14 and northern part of block 22/19). This uplift may have severed an earlier connection between the FBB and the northern end of the East Central Graben, and it is possible that Early Oxfordian shallow marine deposition occurred in the deep parts of the ECG in the hanging wall of the Jaeren High bounding fault, where the Upper Jurassic has not been penetrated (SW block 23/16, N blocks 23/26 and 23/27). Early Volgian uplift in the 22/29 area between the southern end of the FMH and the Puffin Terrace is also interpreted to have removed the connection between the WCG and ECG, which had probably existed since Middle or Late Oxfordian times.

In published palaeogeographic maps, the FMH is shown as a subaerially exposed ridge and therefore a potential sediment source, throughout most of the Upper Jurassic (Rattey & Hayward 1993, figs 16 & 17; Erratt *et al.* 1999; Fraser *et al.* 2002, fig. 11.18), although Rattey and Hayward (1993) interpret drowning by the Ryazanian (their fig. 19). Recognition of the potentially large degree of uplift of the FMH suggests that the high could have been drowned much earlier. Sequence J56 shoreface sandstones are interpreted on the margins of the FMH, indicating that it was exposed at this time (wells 22/23-5 and -6). Younger pre-Volgian shoreface sandstones (sequences J62a–J63) have not been found here to date. The FMH could possibly have been mostly drowned as early as the early Kimmeridgian J62a MFS, so that it did not act as a significant sediment source again until re-exposure and rejuvenation in the Early Volgian. It is suggested here that the Volgian (J64 and J66) shoreface sandstones of the Wood discovery (22/18-6) could have been deposited as a result of this rejuvenation and erosion of Skagerrak and possibly older Fulmar source areas, rather than simply representing the final stages of backstepping of the Fulmar system onto a quiescent high. It remains possible that further J54a and possibly J54b–J62 Fulmar shoreface sandstones exist in undrilled interpod areas on the FMH, preserved in salt-withdrawal depocentres that subsided below the level of Volgian–Ryazanian erosion.

Modification of the palaeovalley model

Taking this interpretation a stage further, a modification is suggested to the model of Wakefield *et al.* (1993) which ascribes the distribution of Kimmeridgian Fulmar sandstones on the Western Platform to deposition in salt-cored palaeovalleys between exposed Smith Bank pods. In this area, Fulmar Sandstones of sequences J56–J62b are preserved in the interpod areas between grounded Smith Bank pods, whilst only Volgian Kimmeridge Clay units are typically found on the pods themselves. Sequences J56–J62b show a very similar architecture across the area from Kittiwake (e.g. 21/18-3) in the north to Guillemot (e.g. 21/30-3) in the south (Wakefield *et al.* 1993; Veldkamp *et al.* 1996) and this pattern continues on the Puffin Terrace (e.g. 29/9a-5 and 29/10-2).

Transgressive sandstones associated with the J56 basal flooding event are commonly characterized by the presence of glauconite, suggesting fully open marine conditions and widespread winnowing during transgression. On the Western Platform, precursor Oxfordian marginal marine facies are absent, and Fulmar marine deposits directly overlie the Top Triassic unconformity with no lateral variation in the environment of the basal units (Wakefield *et al.* 1993). Well 21/18-6, however, contains a basal succession of Kimmeridgian-aged Pentland facies (Veldkamp *et al.* 1996). Wakefield *et al.* (1993) attribute the lack of preserved coastal plain facies to erosional ravinement during the J56 transgression. However, it seems unlikely that so little facies variation and the widespread evidence of relatively high-energy winnowing would be seen if the Fulmar sandstones had been deposited in narrow palaeovalleys with the complex and sinuous plan-form morphology of the salt-cored interpods. Much more evidence of coeval marginal marine facies, such as that seen in 21/18-6, might be expected in embayments and terminations of the palaeovalley system, and it is unlikely that transgressive ravinement would have been efficient enough to remove all evidence of precursor coastal plain sediments across such a complex topography.

Thickness variations in sequences J56–J62b and onlap onto Smith Bank pods (Veldkamp *et al.* 1996; Stewart *et al.* 1999) support the existence of variations in accommodation space and palaeotopography on the Triassic exposure surface. However, it is suggested that palaeotopography might not have been great and that the Fulmar sand deposition could have originally been more widespread, extending further over the Smith Bank pods. Differential syn- and post-depositional subsidence of the salt-cored interpod areas during the Kimmeridgian, driven by extension or gravity sliding, created additional accommodation space so that Fulmar sands were preserved there and eroded from the crests of the grounded Smith Bank highs by the BVRU. Deep truncation seen at the base Volgian unconformity in wells such as 21/19-4 and 21/25-9 indicates that a significant amount of Fulmar Sandstone may have been eroded in some areas. Deposition of the Kimmeridge Clay resumed with rising sea-levels across both the interpods containing Fulmar deposits and the exposed Smith Bank highs.

Volgian turbidites

Volgian (dominantly sequence J64 and J66a) turbidite sandstones, attributed to erosion on the BVRU, occur scattered throughout the Central Graben (Fig. 16), but are generally thin and of limited areal extent. Early Volgian uplift of the FMH and J Block, together with fault block rotation and crestal erosion, resulted in the rejuvenation or creation of new sand source areas in the basin. The subcrop to the base Volgian–Ryazanian megasequence (J64 or younger SBs) is shown by formation, as a proxy for lithology, in Figure 25. Mostly the BVRU erodes into Kimmeridge Clay or Heather shales in the graben areas, but it can be seen cutting into Fulmar sandstone in several areas such as Curlew (block 29/7) and the updip (eastern) portions of Fulmar and Clyde (blocks 30/16 & 17). Along the crest of the FMH and on J Block, Volgian Kimmeridge Clay overlies Triassic sediments and the BVRU is interpreted to have eroded most pre-Volgian Upper Jurassic sediments, including potentially large areas of Fulmar sandstone, re-exposing Skagerrak Sandstone source areas. Locations where Cretaceous deposits directly overlie pre-Upper Jurassic successions were either never onlapped, or any evidence of Jurassic sediments and Volgian–Ryazanian erosion has been removed by younger unconformities.

In a modification of the Fulmar Field evolution model of Kuhn *et al.* (2003), the Ribble turbidite deposits that constitute the shallowest reservoir in the Fulmar Field are here assigned to the J64 RST and interpreted as representing the best developed of the J64 turbidite deposits discovered to date in the Central Graben. The Fulmar Field stratigraphy records the westward migration of the Fulmar sandstone onlap onto the Auk Terrace. The Fulmar Sandstone thickens dramatically across a NW–SE orientated hinge line, which Kuhn *et al.* (2003) interpret as recording the enhancement of accommodation space due to withdrawal of the underlying salt resulting in thick, aggradational deposition of sequence UJ8.2a (sequence J62b of this study) in the central and western parts of the field. Kuhn *et al.* (2003) state that biostratigraphic evidence clearly calibrates the UJ8.2b (J63) MFS within the Avon shale, between the top of the Fulmar Sandstone and the Ribble turbidite sandstones, although the supporting data are not presented. The current study proposes an alternative correlation model (Fig. 26) to that of Kuhn *et al.* (2003, fig. 8), where the J63 MFS is placed just below the top of the Fulmar sandstone, at the top of a gradually retrograding package that corresponds to layer U3.2 (interpreted as the J63 TST in this study). The J64 SB and virtually coincident J64 MFS are placed at the interface of the Fulmar sandstone and Avon shale (Fig. 26). The J64 SB may be conformable to only slightly erosive in the west of the field, but in contrast to the model of Kuhn *et al.* (2003), it is interpreted as cutting down deeply into sequence UJ8.2a (J62b) sandstones to the east of the hinge line, so that the eastward thinning of the Fulmar reservoir is due to erosional truncation in addition to westward expansion into a salt withdrawal depocentre. Whilst some syn-depositional thickening of the Fulmar sandstone due to depositional loading of the salt may have occurred, the main salt withdrawal event is envisaged to have been triggered by the tectonic reconfiguration, and to have terminated Fulmar Sandstone deposition through rapid deepening. Breakup and rotation of the underlying Triassic pod caused uplift of the eastern part of the field, resulting in erosion of considerable thicknesses of Fulmar sandstone to the east of the hinge line, which was potentially reworked into the Ribble turbidites. The biostratigraphic data is not available to test this alternative interpretation, but the apparent discrepancy in age interpretation between this study and Kuhn *et al.* (2003) may be accounted for by their *sensu lato* use of sequence UJ8.2b, as Kuhn *et al.* state that the Shell sequence stratigraphic scheme does not recognize the UJ9.1 (J64) MFS, and/or may reflect reworking of Kimmeridgian biostratigraphic markers into the Early Volgian. The Ribble Turbidites are shown as occurring in sequences UJ9.1 and UJ9.2a in Fraser *et al* (2002, fig. 11.17), mostly above the J64 MFS.

Despite the evidence for Early Volgian to Ryazanian erosional events, contemporaneous turbidite deposits are limited compared with the well developed reservoirs of the Moray Firth. This is probably due to the combination of the poor development of contemporaneous shorefaces to concentrate and winnow the sand and the highly dissected nature of the salt-collapse depocentres, so that relatively small volumes of sand were redeposited locally rather than being delivered to a single depocentre. The distribution of the turbidite deposits does not conform to any relationship with the overall thickness of the Volgian succession, or location of the depocentres, and they are often not visible on seismic, making them a challenging exploration target. In some cases, turbidites are seen directly overlying the BVRU on deeply truncated Oxfordian successions, which may represent penetration of slope channel systems (e.g. 22/13a-1z and -2).

Prospect-scale models

Recognition of erosion at the BVRU has a large impact on the prediction of reservoir presence in undrilled prospects. If the unconformity is not recognized and the Fulmar–Kimmeridge Clay relationship is interpreted as depositional facies change,

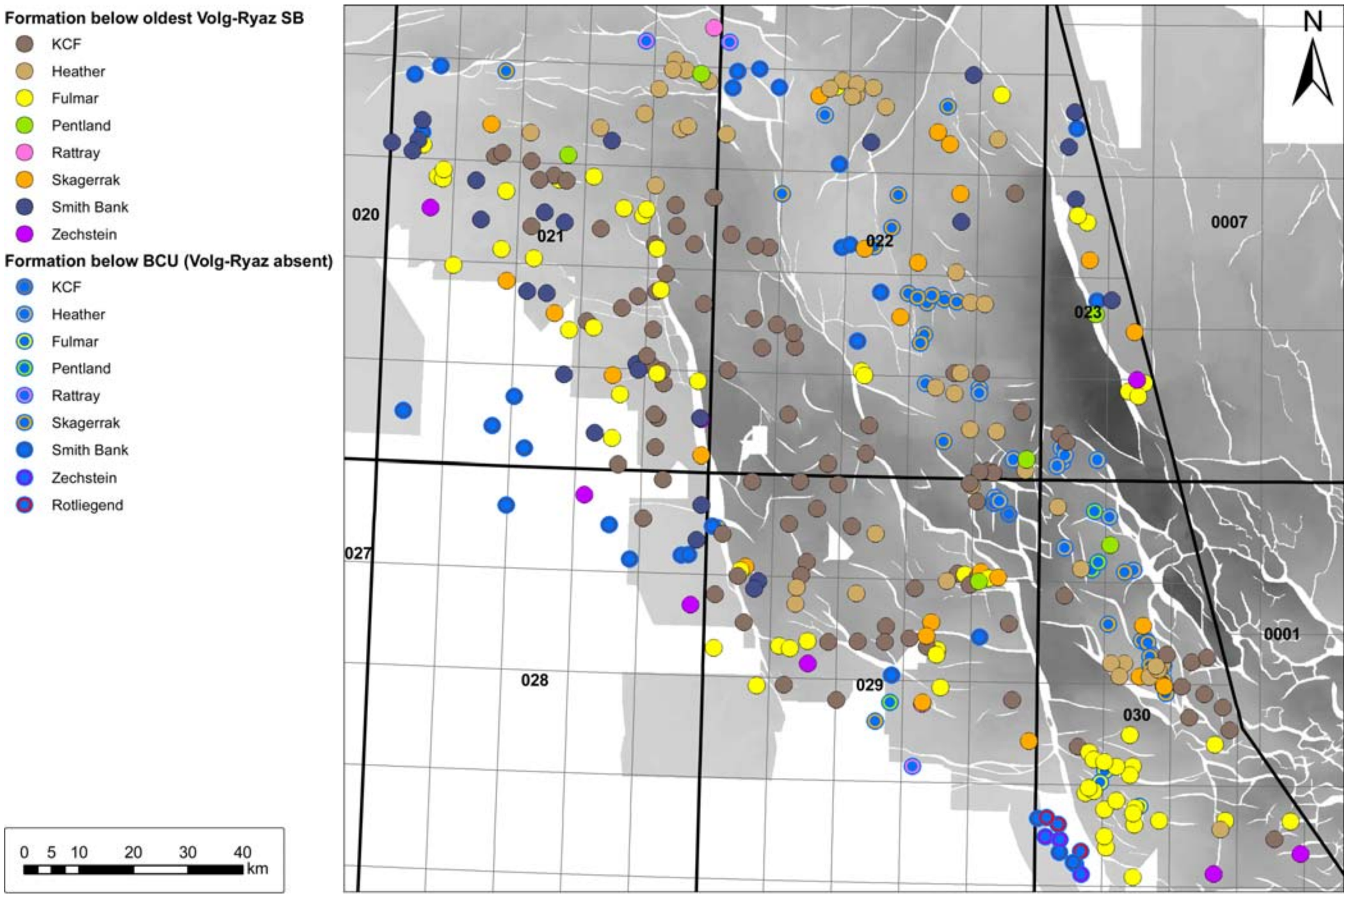

Fig. 25. Subcrop to the J64 SB or younger SBs by formation (lithology). Note areas where the Fulmar and Skagerrak sandstones are eroded, providing a possible sediment source for Volgian turbidites.

then the potential for downdip prospectivity may be limited (Fig. 27a), compared with a model where the unconformity is interpreted and the potential for increased preservation of the reservoir downdip is seen (Fig. 27b). Some exploration models have used a simple formula to predict the thickness of the Fulmar Sandstone as a percentage of the total Humber Group thickness. Although this appears to work locally (e.g. Hollywood 2009, Huntingdon discovery), consideration of the effects of late Kimmeridgian–Early Volgian reconfiguration and salt remobilization implies that this should only hold true where the BVRU forms the top of the Fulmar sandstone across the fault block, as the degree of truncation of the pre-Volgian interval would increase towards the block crest (Fig. 27c). However, this relationship will not work where the Fulmar sandstone does not fill the entire space under the base Volgian unconformity and some of the Heather Formation is preserved. In this case, the Fulmar may be thickest near the crest of the fault block, especially if the Volgian fault has broken through the centre of a pod where accommodation space was greatest during Fulmar deposition (Fig. 27d).

Pre-drill seismic interpretation of Fulmar fault block crest or pinch-out prospects is always challenging due to the difficulty of distinguishing thinning and onlap of sequences that are below seismic resolution, particularly when affected by BCU multiples. In the case of three-way dip and stratigraphic traps, the BVRU can further complicate the interpretation of the reservoir pinchout. For example, well and seismic data can show the pinchout of the Upper Jurassic below the BCU, but erosion on the unconformity may mean that the Fulmar pinchout is further downdip than expected (Fig. 27e). On the positive side, the Upper Jurassic succession may not pinch out, but the BVRU may provide an element of trapping that either produces a stratigraphic trap (Fig. 26f) or enhances the closure of a primarily structural trap.

Conclusions

- Subdivision and correlation of the Humber Group sediments of the Central Graben are poorly constrained biostratigraphically, due to poor palynomorph recovery and, seismically, due to the sub-seismic nature of the sequences. Correlation is therefore largely based on well log data and there is considerable scope for variations in interpretation.
- The widely differing sequence stratigraphic interpretations of some wells demonstrate the difficulty of applying an 'Exxon-type' model for SB and system tract definition in this setting. A T–R model, where transgressive and regressive systems tracts are defined on the basis of MFSs and SBs which comprise unconformities and MRSs, is a more effective means of subdividing and correlating the Humber Group. A T–R model has been derived from the J sequence scheme of Partington *et al.* (1993*a*) and results in a more robust and objective sequence stratigraphic framework for the Humber Group. Whilst it is recognized that there are some difficulties with defining consistent MRSs, the uncertainty associated with this approach is considered to be much less than that involved in picking SBs that are correlative conformities relating to the start of base level fall and using these to assign lowstand and highstand tracts.
- The Humber Group comprises two megasequences which record distinct phases of evolution of the Central Graben Upper Jurassic rift. The Late Callovian–Kimmeridgian

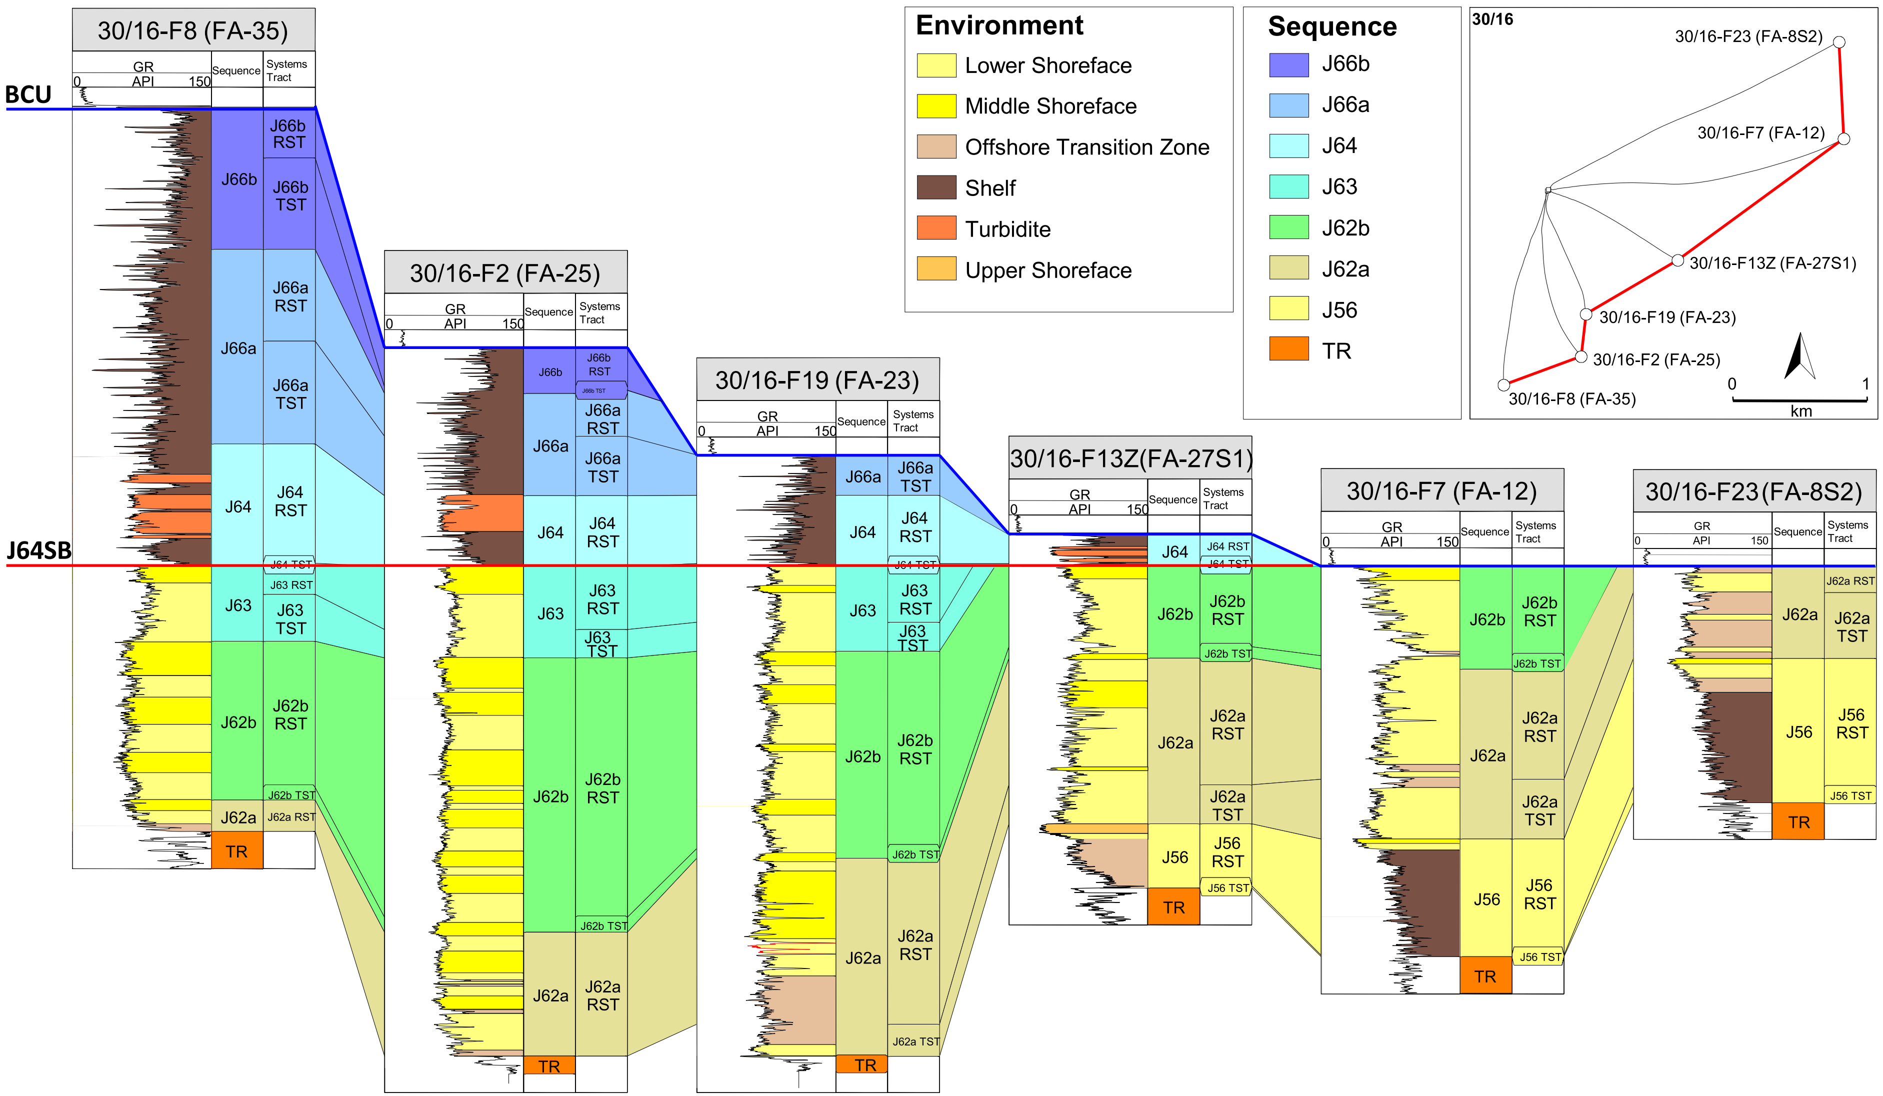

Fig. 26. Alternative correlation model for the Fulmar Field, attributing eastward thinning of the succession to erosion beneath the J64 SB/BVRU. The Ribble Turbidites are assigned to sequence J64 RST.

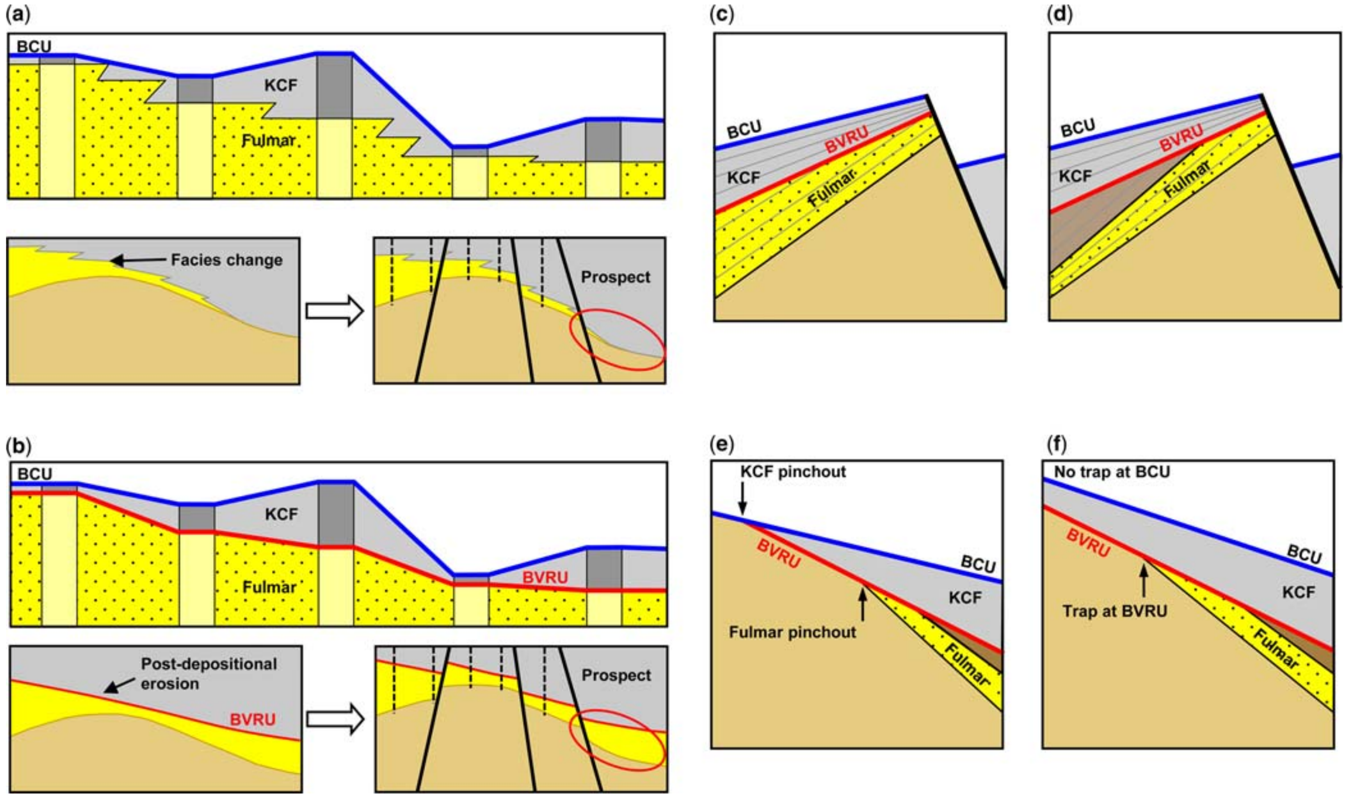

Fig. 27. Implications of the BVRU and tectonic reconfiguration event for prospect models.

megasequence (J44–J63) records the progressive back-stepping of the shallow marine system onto the basin margin platforms and intrabasinal highs. Erosional unconformities are not significant and individual sequences show a consistent architecture throughout the study area, reflecting regional tectonic or eustatic control, but vary significantly in thickness, reflecting local variations in halokinetically controlled accommodation space and sediment supply. Some sequences can be recognized by their characteristic log profiles where biostratigraphic dating evidence is lacking. The Volgian–Ryazanian megasequence is fragmentary and punctuated by unconformities which record erosion on rotating fault block crest and probable basement uplift. However, sequences again show a consistent log character reflecting regional controls on relative sea-level.

- The onset of tectonic reconfiguration is marked by an unconformity at the base of the Volgian–Ryazanian megasequence, termed the Base Volgian–Ryazanian Unconformity, on fault block crests and the influx of cool shales with subordinate turbidite sandstones into the evolving salt-collapse depocentres. The apparent age of this unconformity varies depending on degree of truncation below and onlap above the surface. However, the oldest unconformity is consistently underlain by J63 or older deposits and overlain by J64 or younger deposits. This event is therefore considered to correspond to the J64 SB in more complete successions and is dated as latest Kimmeridgian to Early Volgian.
- Shelf turbidite deposits are recognized as being an integral part of the Upper Jurassic shoreface system. They are believed to have been initiated during 'normal' progradation by storm and/or river flood events and do not necessarily require or indicate a base-level fall. Turbidite deposits are abundant in sequence J54a and are also present in sequence J56 and rarely in sequence J62a.
- Three characteristic log profiles, termed expanded, condensed and truncated, can be recognized within the Volgian–Ryazanian megasequence and reflect the position of wells on the fault blocks created during the latest Kimmeridgian–earliest Volgian reconfiguration. The pattern of truncation and erosion of pre-Volgian sequences reflects both fault block formation and rotation due to salt distribution and basement uplift of areas such as the FMH and J Ridge.
- Basement uplift resulted in significant dissection and modification of the basin architecture and potentially widespread erosion of Callovian–Kimmeridgian (sequences J46–J63) Humber Group sediments in areas where Volgian Kimmeridge Clay deposits now overlie Triassic strata. This erosion resulted in the localized deposition of turbidite sandstones.
- The effects of basement extension and eustasy cannot be clearly distinguished in the Callovian–Kimmeridgian megasequence and regional consistency of component sequences points to basin-wide controls on relative sea-level. The tectonic reconfiguration event may record salt distribution and basement uplift although the kinematics of this event are uncertain.
- Exploration models must take account of the effects of tectonic reconfiguration and erosion on the BVRU in order to accurately predict the original depositional extent of Fulmar Sandstone and associated turbidite reservoirs and the likelihood of their preservation.
- Further work is required across the entire Upper Jurassic rift system to help distinguish between the relative importance of basement extension, halokinesis and eustasy in controlling accommodation space. However, whilst prediction of the age and likely component sequences of the Upper Jurassic succession can be made based on the structural position in the basin, the limited understanding of factors controlling sediment supply remains the biggest unknown for the prediction of reservoir presence, particularly for the turbidite sandstone

play. More detailed regional mapping of unconformities is required to differentiate areas with differing structural history and to better inform the discussion on the timing, magnitude, effects and kinematics of tectonic events.

The Huntington discoveries: efficient exploration in the UK Central North Sea

J. M. HOLLYWOOD and R. C. OLSON

Carrizo Oil & Gas Inc., 1000 Louisiana Street, Suite 1500, Houston, Texas, USA (e-mail: jim.hollywood@crzo.net)

Abstract: The Huntington discoveries are an unusual exploration success in that two oil accumulations were tested in separate syn- and post-rift reservoirs with a single well. The discoveries are located 205 km east of Aberdeen in the East Central Graben some 35 km east of Forties Field in 300 ft of water. The 22/14-5 discovery well, drilled in May 2007, encountered a 122 ft oil column in the Paleocene Forties Sandstone and also a 136 ft oil column in the Upper Jurassic Fulmar Sandstone. Both the Forties and the Fulmar contain high-quality oil, 41 and 39° api gravity, respectively. Aggregate flow rates from the two zones exceeded 11 000 boepd on test. Appraisal drilling of the Forties was completed in late 2007 with first oil targeted for 2011. The Fulmar appraisal programme is currently in progress. The Forties reservoir is a high net to gross sandstone containing stacked channel sequences deposited in a submarine fan system. The Fulmar reservoir also contains a thick sand package deposited in a shallow marine shelf setting. Pre-drill mapping based on reprocessed 3D seismic indicated a structural closure on both horizons at the location tested by the well. At both the Forties and Fulmar targets, however, the oil column height exceeded the pre-drill prognosis. This overview will focus on pre-drill perceptions of the prospect relative to actual drilling results.

Keywords: Huntington, North Sea, Paleocene, Jurassic, exploration

The Huntington discoveries lie in the northern part of the East Central Graben in block 22/14b (Fig. 1). Carrizo Oil & Gas Inc. acquired Traditional Licence P. 1114 (blocks 22/14b and 22/19b) in the UK 21st Round of licensing in 2003. The area was selected for application by Carrizo as it contained the 22/14b-3 and 22/14b-4 discoveries made in Triassic Skagerrak Sandstones in 1988 and 1992, respectively. Although only the 22/14b-3 well was tested with subcommercial flow rates of 113 barrels of oil per day (bopd), the wells demonstrated the presence of a large, oil-bearing trap. Reservoir potential was also seen in the Paleocene Forties, Andrew and Maureen Sandstones and the Upper Jurassic Fulmar Sandstone (Fig. 2).

Following award of the licence, Carrizo conducted a technical evaluation of well and 3D seismic data to identify prospects, assess technical risk and estimate potential resources in the event of a discovery. This work highlighted the Huntington prospects (Paleocene and Fulmar) as the best opportunity on the acreage, given reservoir and trap potential at two separate horizons. Throughout this period, Carrizo was also attempting to farmout the licence to reduce project risk during the drilling phase. Notwithstanding the multi-zone reservoir potential at Huntington, the farmout required three years to complete with the prospects being shown to more than 40 companies. Ultimately, Carrizo was joined in blocks 22/14b, 19b and the Huntington prospects by Oilexco (40% and operator), E.ON Ruhrgas UK Ltd (25%) and Denerco (20%), with the latter interest subsequently being acquired in corporate acquisitions by first Altinex and finally Noreco. The Huntington 22/14-5 well spudded in April 2007 after the partner group was finalized.

This paper will focus on the technical work and pre-drill predictions underpinning the farmout effort, some of the perceptions of the farmout companies and finally, the well results. We believe this comparison of project perception and outcome is interesting and provides encouragement for further exploration of the UKCS.

Pre-discovery exploration

Exploration of the Paleocene Forties Sandstone in this area kicked off in the late 1960s with the discovery of Arbroath Field (1969) in block 22/18 (Fig. 1). One year later the supergiant Forties Field (1970) was discovered which further increased interest in the area. These early discoveries were followed by a series of Paleocene discoveries in the area at: Montrose (1971), Fleming (1982), Everest (1985), Nelson (1987) Mungo (1989) and Arkwright (1990). By 1990, all significant Forties structural closures had been tested and from 1990 to 2007 only five exploration wells were drilled for the Paleocene in this area.

Following the early successes in the Paleocene Forties Sandstone, considerable effort was focused on evaluating the Upper Jurassic Fulmar Sandstone in the middle to late 1980s. Fulmar discoveries at Howe (1987) and Bardolino (1988) which tested 1781 bopd and an aggregate 16 721 bopd from Upper Jurassic reservoirs, respectively, triggered a wave of exploration and appraisal drilling in the area. Unfortunately, the Fulmar is not as uniformly distributed as the Forties and about 50% of the wells targeting the Fulmar did not encounter the reservoir. The disappointing drilling outcomes discouraged further exploration in the area and no wells targeting the Fulmar were completed from 1997 until Huntington was tested in 2007.

The Triassic Skagerrak Sandstone also represented a reservoir objective in the 22/14-3 well. This well encountered a 139 ft gross oil column in the Skagerrak and tested 33° api oil at a rate of 113 bopd. An appraisal well drilled four years later targeting both Fulmar and Skagerrak reservoirs established a 389 ft gross oil column in the Skagerrak but was not tested. No Fulmar section was present in the well. Notably, both of these oil-bearing zones occur within the Base Cretaceous Unconformity (BCU) closure that the 22/14-5 Huntington discovery was drilled in.

Previous drilling results significantly shaped the perceived technical risks in the area. Historically, Forties discoveries were made

VINING, B. A. & PICKERING, S. C. (eds) *Petroleum Geology: From Mature Basins to New Frontiers – Proceedings of the 7th Petroleum Geology Conference*, 213–223. DOI: 10.1144/0070213

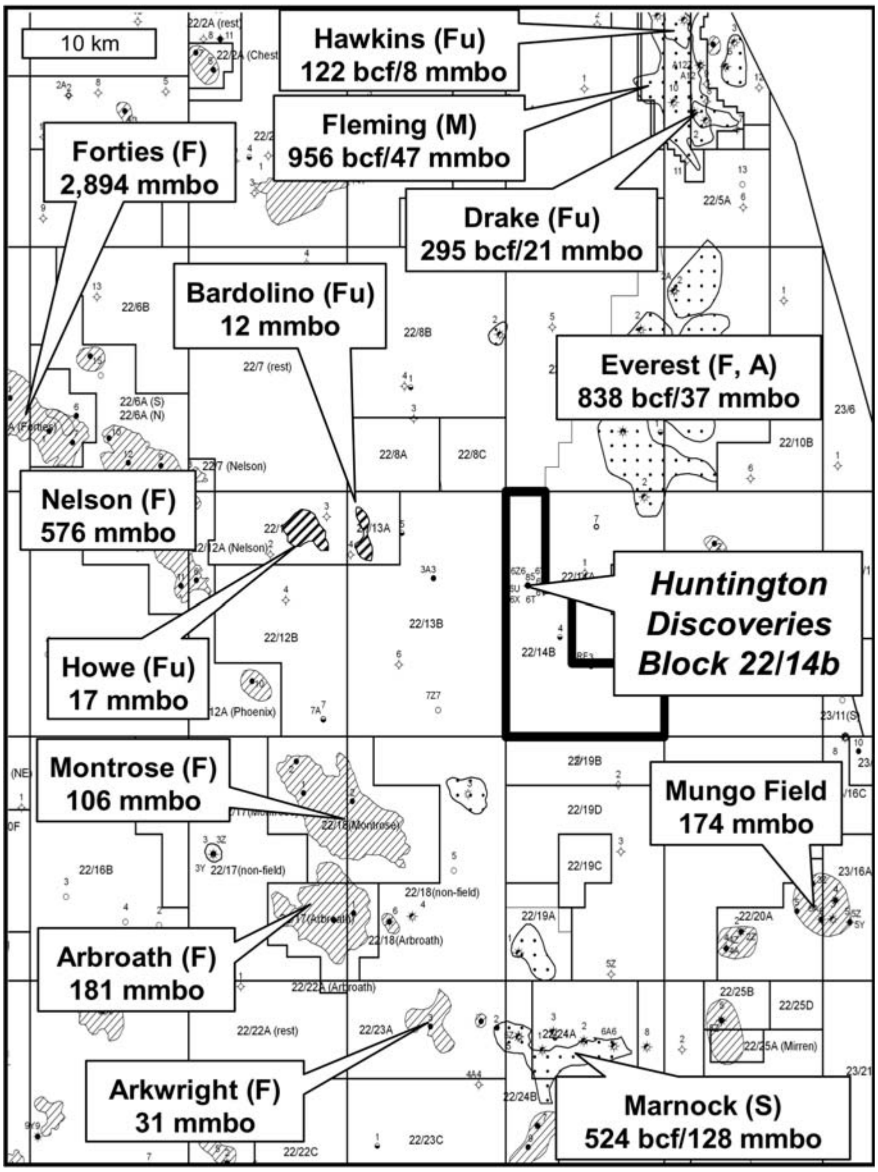

Fig. 1. Location map. Oil and gas fields indicated with cross-hatch and stipple patterns, respectively. Fields are labelled with reserves and productive reservoir. Reservoirs are abbreviated as follows: Paleocene Forties (F); Andrew (A); Maureen (M); Jurassic Fulmar (Fu); and Triassic Skagerrak (S). The primary producing reservoirs in the Huntington area are Paleocene sandstones but there is also production from the Jurassic and Triassic nearby.

largely on structural closures, although stratigraphic elements often alter reservoir distribution and connectivity within any given feature. Stratigraphic trapping potential with possible reserves upside, however, was not seen to add incremental volume to Forties structural closures. The mixed results in pursuing the Fulmar and the poor seismic resolution of the Fulmar reservoir led many to regard it as too risky for further drilling. Also, the poor flow rates obtained from the Skagerrak in the 22/14-3 well discouraged others from pursuing Triassic reservoirs in the area.

Technical evaluation

Block 22/14b is located on the SE flank of the Jurassic Fisher Bank basin (Fig. 3). The SW, downthrown extension of the Jaeren High transects the block, separating the Fisher Bank basin in the north from the East Central Graben basin, another major Jurassic depocentre, to the SE. These basins were filled with thick Upper Jurassic sandstone and claystone deposited in response to rifting and coeval with an overall rise in eustatic sea-level (Erratt *et al.* 1999). During post-rift thermal subsidence, significant thicknesses of Cretaceous, Paleocene and Eocene sediments in-filled the area.

The Upper Jurassic Kimmeridge Clay Formation (KCF) is the primary source rock for oil and gas in the area. The KCF is thermally mature to generate oil over most of block 22/14b and several adjacent blocks to the west, south and SE (Kubala *et al.* 2003). To the north in the Fisher Bank basin and to the south in the East Central Graben, it lies within the gas window. Triassic and Jurassic reservoirs within the BCU closure at Huntington lie in an ideal location to receive migrating hydrocarbons generated from downdip kitchens surrounding the structure on all sides but the NE. Reconstructions show this area has been high since the Triassic. Indeed, the presence of substantial oil columns in the Triassic Skagerrak Formation in the 22/14-3 and 22/14-4 wells on the Huntington structure confirms the charge model for the Jurassic and older sections. At the 22/14-3 well, the oil also contains a significant contribution from woody–coaly source rocks in the Middle Jurassic Pentland Formation (Isaksen 2004).

Oil migration from Jurassic source rocks to Paleocene reservoirs requires buoyant movement through several thousand feet of low

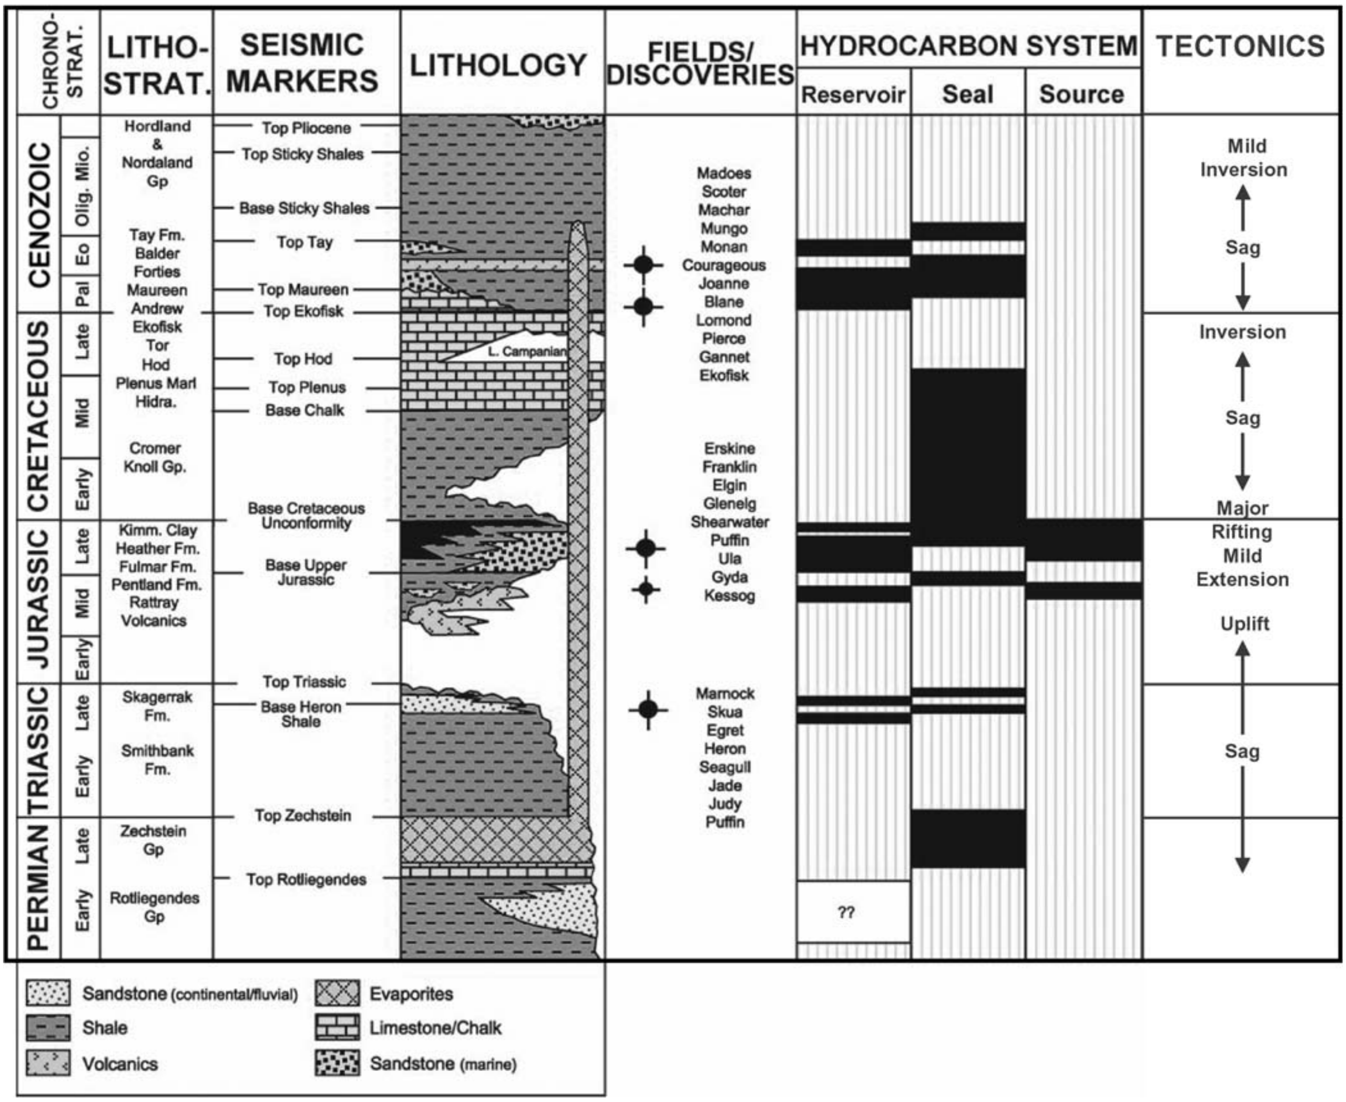

Fig. 2. Stratigraphic framework, modified from Winefield *et al.* (2005). Reservoir potential at Huntington was seen in the Paleocene Forties and Upper Jurassic Fulmar with source potential in the Upper Jurassic Kimmeridge Clay. The main tectonic phases are shown at the right, with the Fulmar being deposited during active rifting and the Forties being deposited during a later sag phase. Modified after Winefield *et al*. (2005).

permeability sediments. Biomarker analysis shows this is possible in the region as oil samples from the Forties and Montrose Fields have been correlated to Kimmeridge source beds. It is not clear, however, where vertical migration is occurring in the immediate vicinity of Huntington. The presence of oil and gas in the Forties in numerous closures on all sides of the Huntington prospect suggests that hydrocarbon charge is working in this area.

Two primary reservoir intervals were studied for the Huntington prospect: the Paleocene Forties Sandstone Member and the Upper Jurassic Fulmar Sandstone. The Forties Sandstone is the primary producing interval at nearly all the nearby fields, that is, Forties, Nelson, Montrose, Arbroath, Arkwright, Everest, Monan and Mungo. The Forties is a sand-rich turbidite system deposited by SE trending currents. In this portion of the turbidite fan, the Forties reservoir is dominated by channel sandstones and associated channel margin and levee facies (Hempton *et al.* 2005). The Forties Sandstone isopach illustrates the channelized nature of the major sand bodies in the area (Fig. 4). Within the channel fairways, net to gross ratios can be as high as 85% while inter-channel facies may have net to gross ratios as low as 25%. Under certain conditions, these inter-channel facies may provide permeability baffles or barriers between channels as seen at several nearby fields such as Everest, Nelson and Montrose and Arbroath.

The average porosity range of the Forties Sandstone in fields near blocks 22/14b is 20–26% with average permeability in the range of 30–300 mD. Recoveries from this reservoir can be excellent. As an example, the first 16 wells on the Forties Field collectively produced 10^6 barrels of oil (Leonard *et al.* 2000) and it is estimated the field may ultimately produce 70% of original oil in place (Hempton *et al.* 2005).

A second reservoir objective at Huntington was the Upper Jurassic Fulmar Sandstone on the western flank of the Huntington BCU structure. Although the 22/14-3 and 22/14-4 wells confirmed the presence of an oil-bearing Triassic Skagerrak reservoir, the challenge was to find a reservoir that could produce at commercial flow rates within the BCU structural closure. The Fulmar is well developed on the west side of the Fisher Bank basin and immediately west of Huntington at the 22/13-1, 2, 3 and 5 wells. On the east side of the basin, the Fulmar reservoir is commonly absent where it has been eroded from the crest of structures during Late Jurassic faulting and block rotation. The schematically restored Fulmar isopach map (Fig. 5) is an attempt to illustrate the thickness of the Fulmar in the Huntington area at the time of deposition. Fulmar thickness is highly variable across the region, attaining a maximum value of 898 ft at the 22/5-2 well to the north while being

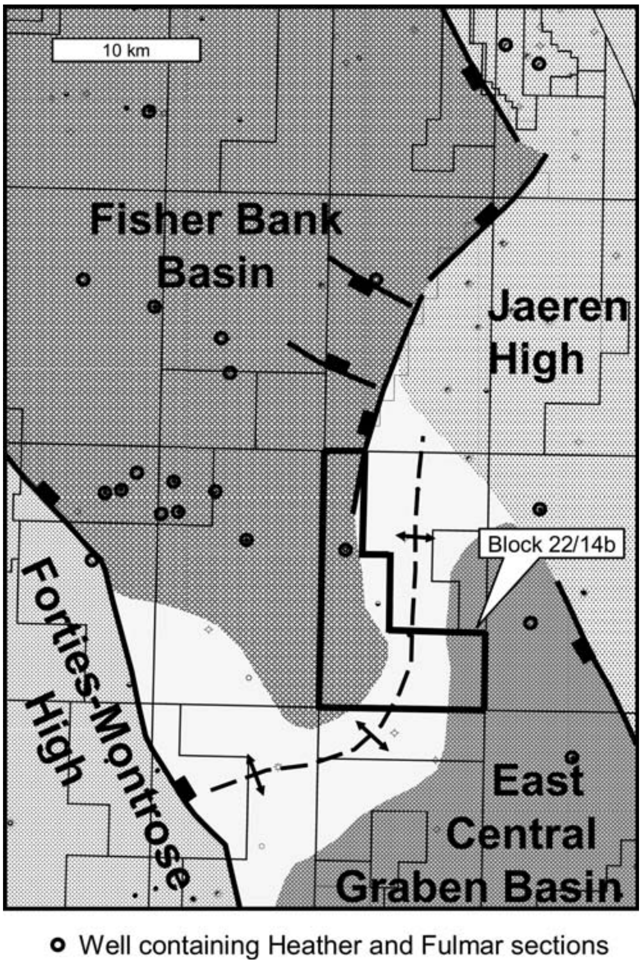

Fig. 3. Structural elements. Jurassic basins are indicated with grey shading while high blocks with little or no Jurassic sedimentation are shown with a stipple pattern. Wells containing both Upper Jurassic Heather and Fulmar sections lie primarily within two Jurassic basins: the Fisher Bank basin to the north and East Central Graben basin to the south.

absent in many locations to the west and east. As a result, isopach contours are simplified and honour the thickest values only to provide an indication of the primary Fulmar depocentre. The restored palaeo-isopach map suggests the Fulmar once covered much of the area except prominent basement features such as the Jaeren and Forties–Montrose Highs with thickening into the basin.

The Fulmar reservoir is highly productive at Fulmar, Kittiwake, Shearwater, Elgin, Franklin and Ula Fields to the south and east of block 22/14b. It also produces at Drake, Hawkins and Howe Fields to the west and north of Huntington. At Howe Field in block 22/12, the initial production from a single well is reported to have exceeded 12 000 bopd. The Fulmar is fine-grained, bioturbated sandstone deposited in a shallow marine setting in the Fisher Bank basin. Typically the interval thickens down-structure within individual fault blocks and within the basin in general. A plot of the gross Upper Jurassic thickness v. gross Fulmar Sandstone thickness for individual wells is illustrated in Figure 6. The best-fit linear relationship from this dataset can be used in conjunction with the Upper Jurassic gross isopach determined from 3D seismic mapping to predict the thickness of Fulmar Sandstone in this area. A Fulmar thickness of 100 ft was predicted for the Huntington 22/14-5 location using this approach. Reservoir quality is variable depending mainly on depositional facies. Surrounding fields have an average porosity range of 17–23% and permeabilities of 5–700 mD.

The initial seismic interpretation was based on the PGS Mega Survey using 3D data acquired with a relatively short cable: 3000–3500 m. The data quality allowed a detailed interpretation of the key horizons within the Cenozoic and Cretaceous sections. The Balder, Sele, Forties, Ekofisk and BCU structure interpretations (time and depth) provided the initial key horizons for evaluation of the Forties, Fulmar and Skagerrak exploration potential. The pre-Cretaceous section interpretation was less reliable due to poorer data quality, but it was possible to create Base Upper Jurassic, Upper Permian Zechstein (top salt) and Lower Permian Rotliegend structure maps in certain areas. A near-top Fulmar was later interpreted and subsequently used to evaluate the Fulmar structure/stratigraphic trap potential at the Huntington prospect. Numerous time to depth sensitivities were calculated primarily to see if there were any significant changes to the low-relief Forties depth structural closure. In the end, a layer cake time to depth conversion using constant interval velocities was used for the Forties, BCU and Jurassic depth structures and this approach provided the best fit to the well control. Essentially the time and depth structures and closures are similar for each of the Fulmar, BCU and Forties interpretations.

While data quality was good to acceptable from the licensed PGS Mega survey data, it was recognized that reprocessing would be essential to acquire an improved image of the subsurface. Carrizo therefore reprocessed the entire 3D dataset surrounding block 22/14b in 2004 and 2005 to produce a modern Pre-Stack Time Migration (PreSTM) image of the subsurface. The reprocessed seismic provided: (1) a seamless, zero-phased (North Sea convention-impedance increase is represented as a trough) 3D dataset between four different seismic surveys; (2) improved data quality in the Paleocene and pre-Cretaceous sections; and (3) AVO products including near (0–20°), mid (20–30°) and far (30–40°) angle volumes for the assessment of reservoir properties and fluid content in the Cenozoic section.

The BCU depth structural closure covers approximately 6000 acres and encompasses the 22/14-3 and 4 discoveries and the Huntington 22/14-5 location within independent four-way dip closure (Fig. 7). The closure lies on the west side of a large north-trending Zechstein salt wall which could act as a stratigraphic seal and provide greater downdip closure. The Fulmar reservoir was interpreted to be preserved along the western flank of the BCU structure with dip closure to the north, west and south and truncation to the east beneath the BCU/Kimmeridge shale with potential lateral and bottom seal with the Triassic Smith Bank shale and Zechstein salt. Both the 22/14-3 and 4 wells proved oil in the Triassic Skagerrak with oil-down-tos (ODT) of 11 980 and 12 517 ft subsea, respectively. Both wells penetrated a thin Upper Jurassic section lying directly on the Skagerrak. The 22/14-5 well targeted the Fulmar downdip of these wells, but above the Skagerrak ODT seen in 22/14-4 (Fig. 8).

The Forties time and depth structural closure based on the PreSTM 3D was the same as that interpreted from the original PGS Mega Survey 3D. The Forties prospect remained a small structural closure with approximately 35 ft maximum relief and 1000 acres of closure (Fig. 9). If the charge to the structure exceeded trap volume, it was expected to spill towards the 22/14-1 dry hole to the NW. The low-relief structural closure limited possible reserves volumes at Huntington unless a stratigraphic barrier could be identified to separate the prospect from the 22/14-1 well.

The PreSTM 3D AVO products proved valuable in the interpretation and prediction of fluid content in the Forties. These AVO products were used to calibrate the offset response of a Forties oil well, gas well and dry hole (Fig. 10). The 22/18-2 oil well on Montrose Field exhibits a trough at Top Forties on the near offset changing to a peak with increasing amplitude on the far offsets using North Sea polarity convention. Thus, an

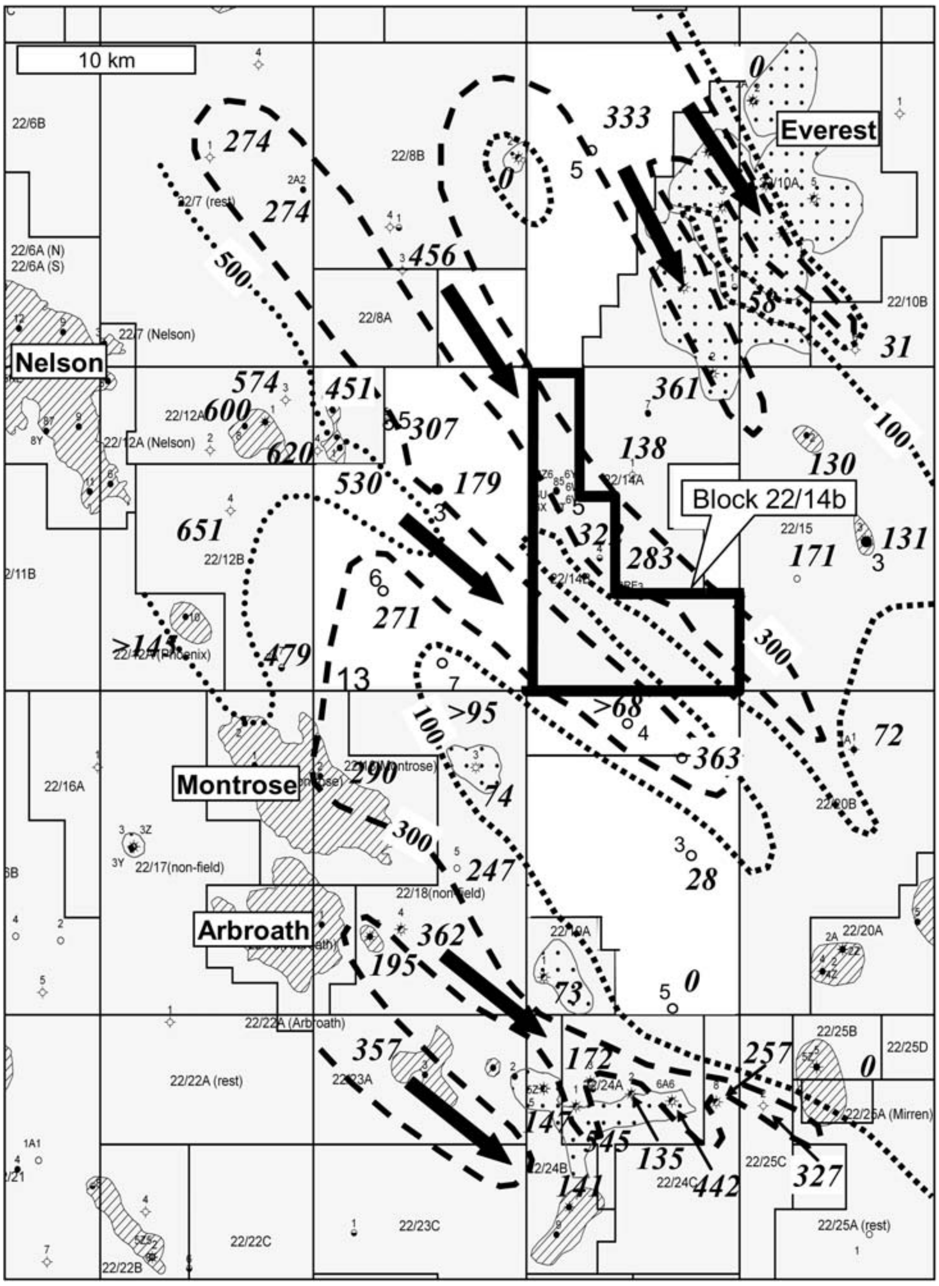

Fig. 4. Paleocene Forties Sandstone isopach map. This isopach has been constructed using only well data. Thickness is in feet as determined using a 45° api gamma ray (GR) cutoff. The contour interval is 200 ft. Areas of thick sandstone are indicated with a black arrow and are believed to correspond to channel complexes which exhibit a SE trend. The Huntington location appears to be in a favourable position for channel axis development.

oil-bearing Forties section yields a Class IIp response on the gathers as a result of the phase change with increasing offset. The gas case was calibrated using the 22/14-2 well from Everest Field. Here the top Forties event is a peak on the near offset going to a stronger peak on the far offsets, resulting in a Class II AVO response. The 22/14-4 well provided the wet reservoir calibration which exhibits a trough on the near and far offsets with little change in amplitude. At the Huntington prospect location, the top Forties event is a trough on the near offset data going to a peak on the far offset data. Huntington was interpreted to be most similar in offset response to the Montrose example and therefore expected to be an oil prospect.

The AVO products from the PreSTM 3D were also used to predict the Forties channel fairway and the likelihood of a stratigraphic component separating Huntington from the 22/14-1 well dry hole. Using the far-angle stack, two reflectors, the 'A' event at the top Forties and 'B' event within the Forties interval were picked and displayed as amplitude intensity. The highest A-amplitude values appeared to correlate to the Forties structural closure with a noticeable shift to the NW of the closure (Fig. 11). This shift of the amplitude anomaly beyond structural closure implied a possible stratigraphic trapping element to the prospect. The B-amplitude did not correspond to structure but instead showed lateral terminations of seismic reflectors along a curvilinear trend extending from the 22/8-3 well south through the Huntington location continuing south to the 22/14-4 well (Fig. 12). It was proposed that this feature might be an erosional scour at the base of a multi-channel complex since the 22/8-3 and 22/14-4 wells both have a thick Forties channel sequence. This feature extended across the Huntington Forties structural closure and it was concluded that a Forties channel sequence would be present at the 22/14-5 well location.

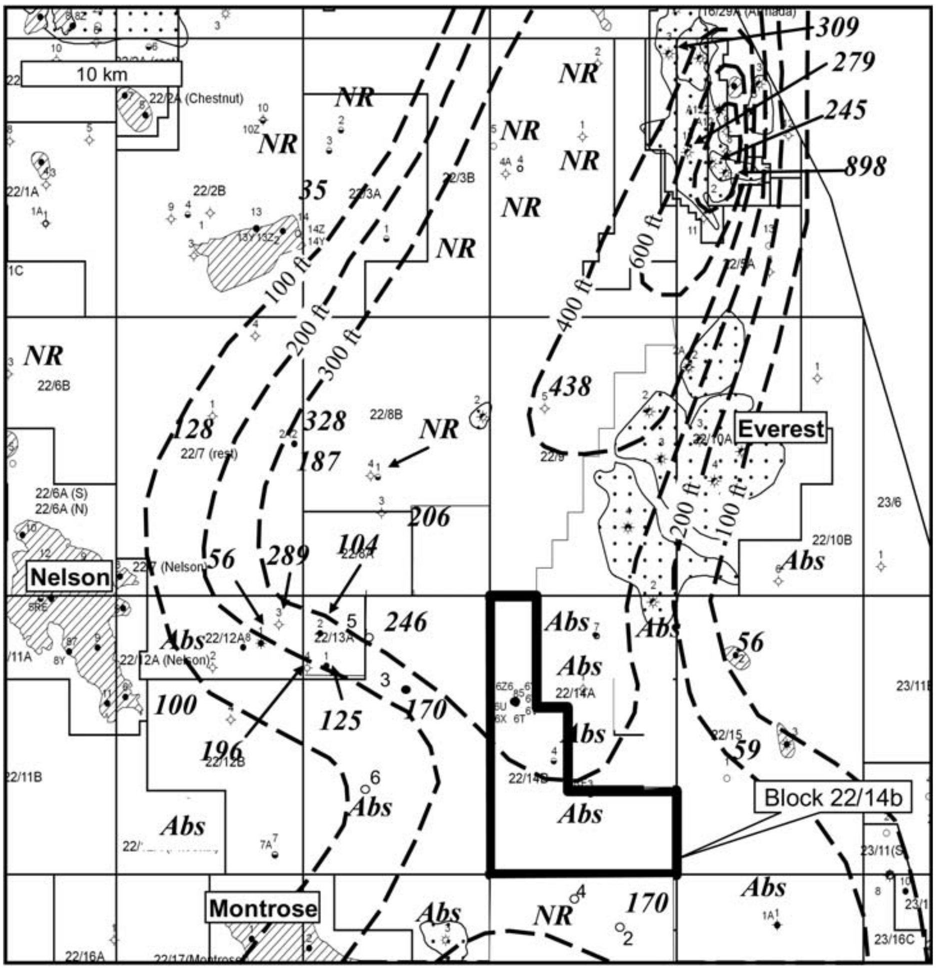

Fig. 5. Upper Jurassic Fulmar Sandstone schematically restored isopach map. This restored isopach has been constructed using only well data. Thickness is in feet as determined using a 50° api GR cutoff. The contour interval is 100 ft. Wells that did not reach the Fulmar are marked 'NR' and those marked 'Abs' are where the Fulmar was absent. The map is a restored isopach in the sense that it contours only the thickest values while ignoring the thinner values.

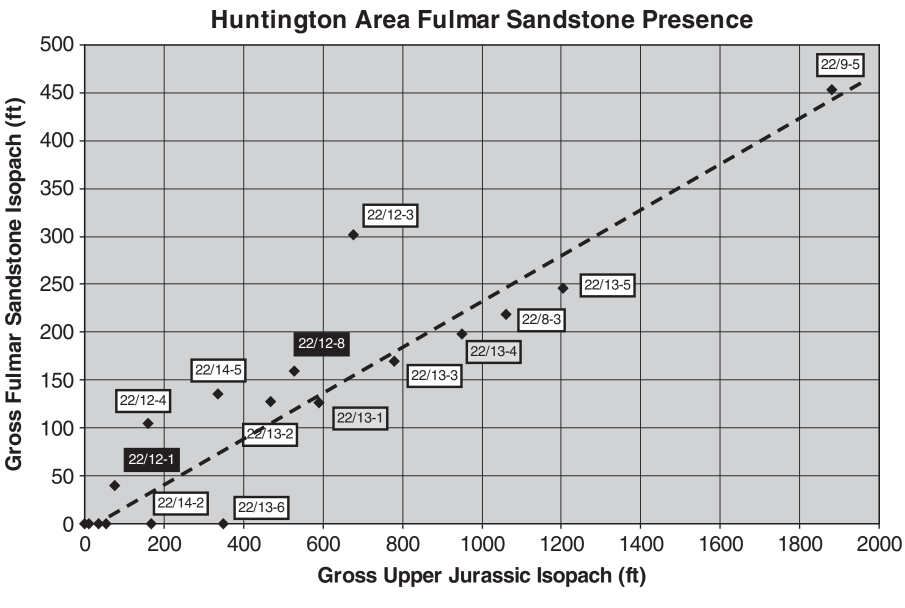

Fig. 6. Plot of the gross Upper Jurassic isopach v. the gross Fulmar Sandstone isopach for wells in the Fisher Bank basin. Wells drilled in the same fault block such as 22/13-1 and 22/13-4 or 22/12-1 and 22/12-8 are highlighted in similar font. Gross Fulmar thickness appears to vary directly with gross Upper Jurassic thickness in a linear manner in this area.

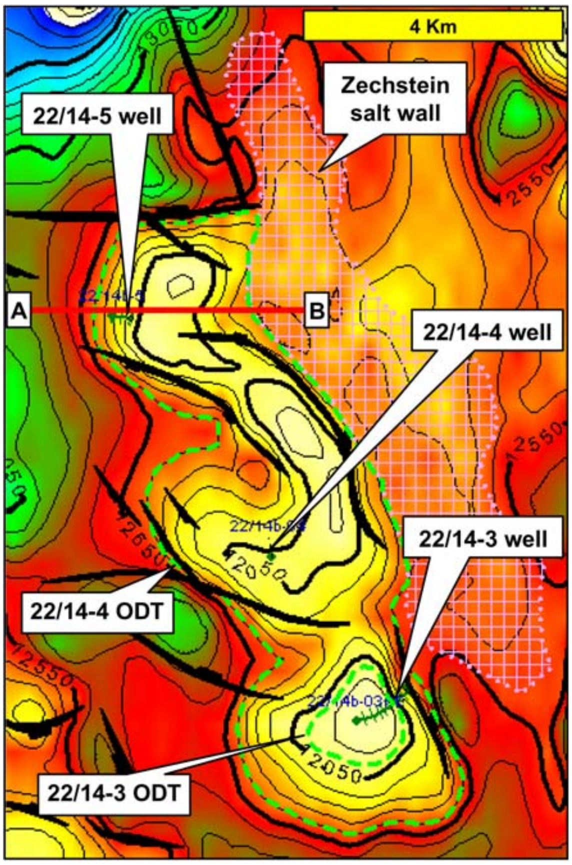

Fig. 7. BCU depth structure map. Huntington 22/14-5 well is located on the west flank of the northern culmination within the closure tested by the 22/14-3 and 4 Skagerrak oil discoveries. Well 22/14-5 was located to evaluate the Fulmar reservoir above the ODT seen in the 22/14-4 well. The BCU closure is flanked by a Zechstein salt wall to the east. Contour interval is 50 ft. The location of the seismic line in Figure 8 is shown here by the line 'AB'.

Pre-drill predictions

Prior to drilling and based on the technical evaluation and observations, Carrizo made the following predictions for the Forties reservoir: (1) it would be oil-bearing, from AVO analysis; (2) it would have a high net-to-gross reservoir section, also from AVO analysis; and (3) the AVO amplitude anomaly suggested that there might be a stratigraphic element to the trap since the anomaly extended beyond structural closure, particularly to the NW.

The key predictions for the Fulmar were: (1) the reservoir was expected to be about 100 ft thick at the well location; (2) it was likely to be oil-bearing based on the charge analysis; and (3) given there is no Fulmar in the 3 and 4 wells a stratigraphic trapping element might exist against the Smith Bank and possibly the Zechstein salt wall flanking the structure to the east. This stratigraphic component was supported both from seismic interpretation and pressure data, which indicated the 22/14-3 and 4 wells both required much higher mud weights to drill the Triassic section than the 22/14-1 well located on the updip side of the salt wall.

Market perceptions

As mentioned earlier, Carrizo conducted an extensive farmout effort in order to spread the risk during the exploration drilling phase. During this process, many companies commented on various aspects of the technical evaluation of the prospects, particularly the technical risks. It is instructive to reflect on these technical concerns in the context of the outcome of the well.

Initially, most companies thought reprocessing the short-cable 3D seismic would not provide the offsets needed to improve data quality in the pre-Cretaceous section or give the angles needed for AVO products to evaluate the Forties interval. Many companies regarded the Paleocene Forties prospect as having a high probability of success but very small reserves potential with limited economic value. Few companies seemed to believe there was upside potential for a stratigraphic trap. Many evaluated the

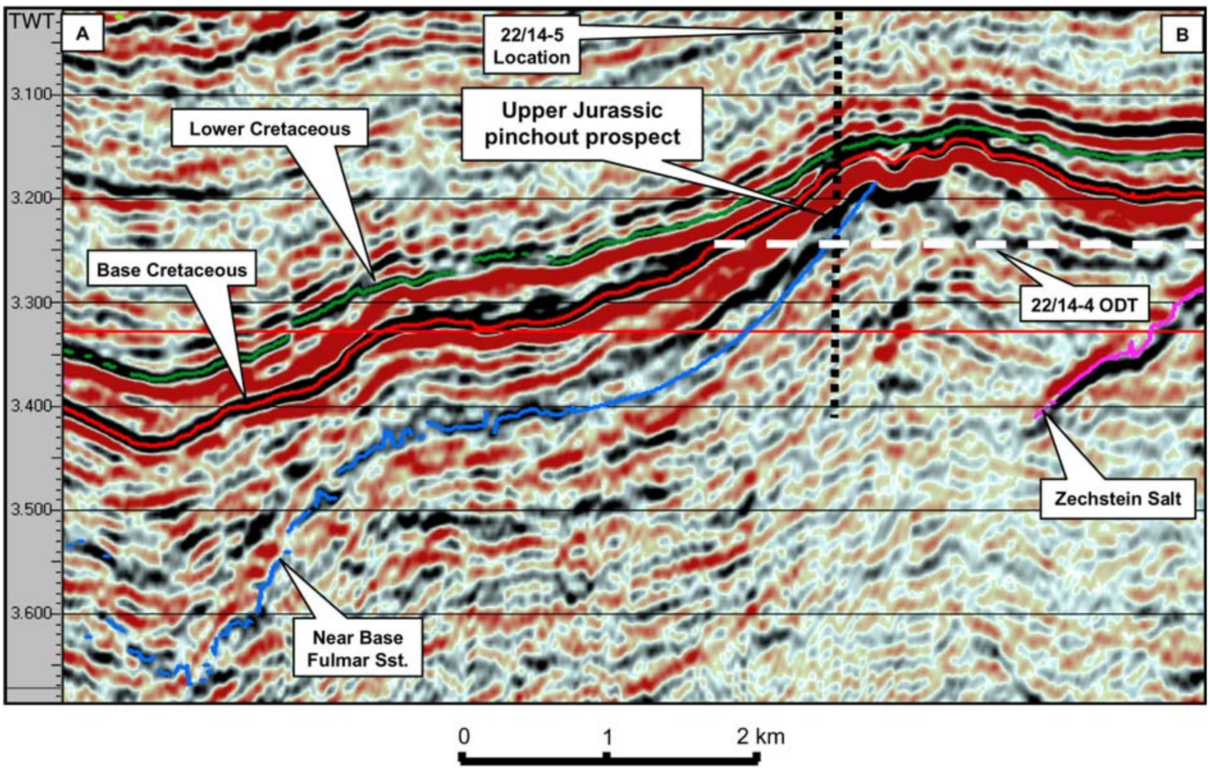

Fig. 8. West to east 3D seismic line (PreSTM) through Huntington Fulmar well location 22/14-5. The Fulmar reservoir is poorly imaged on 3D seismic data in this area. Courtesy of PGS.

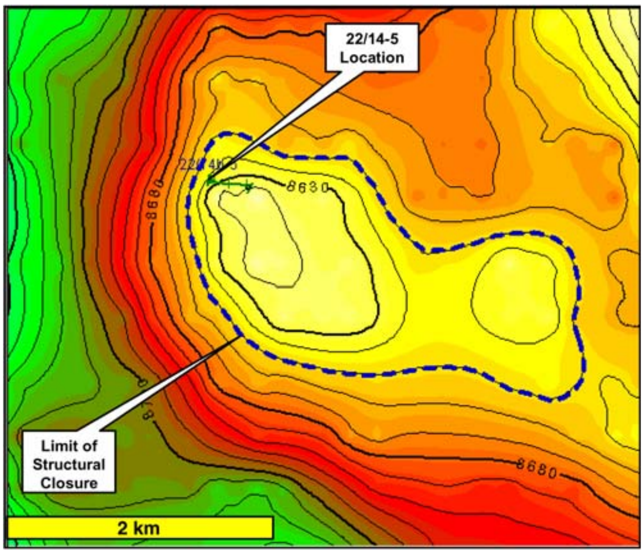

Fig. 9. Huntington Forties depth structure map. Blue dashed contour represents independent four-way dip closure separate from the 22/14-1 dry hole to the NE. Contour interval is 10 ft.

prospect as a gas opportunity rather than an oil prospect due to its proximity to Everest Field. Ultimately, these issues are related to the AVO analysis. Companies could see that the Huntington amplitude response did not look like the nearest offset well at Everest Field. Many companies did not seem to accept the more subtle amplitude response as indicative of oil in the Forties. As a result, they attributed the amplitude response to factors other than fluid and were unable to attribute additional reserves potential associated with a stratigraphic trap to the prospect.

The reaction to the Fulmar prospect was quite different as most companies seemed to believe that it should be possible to image a top Fulmar seismic reflector in this area and that the inability to do so meant the Fulmar may not be present. Others were concerned that if the Fulmar could not be seismically resolved, then its distribution in the area was unknown. Also, some companies rigorously applied the pod concept and thought the well should be drilled on top of the salt wall in order to find the Fulmar Sandstone.

Similar perceptions are likely when evaluating prospects in any mature basin. First, existing well control limits our ability to add ‘romance’ or large upside reserves potential to prospects. In the case of Huntington, there were two deep wells, which proved

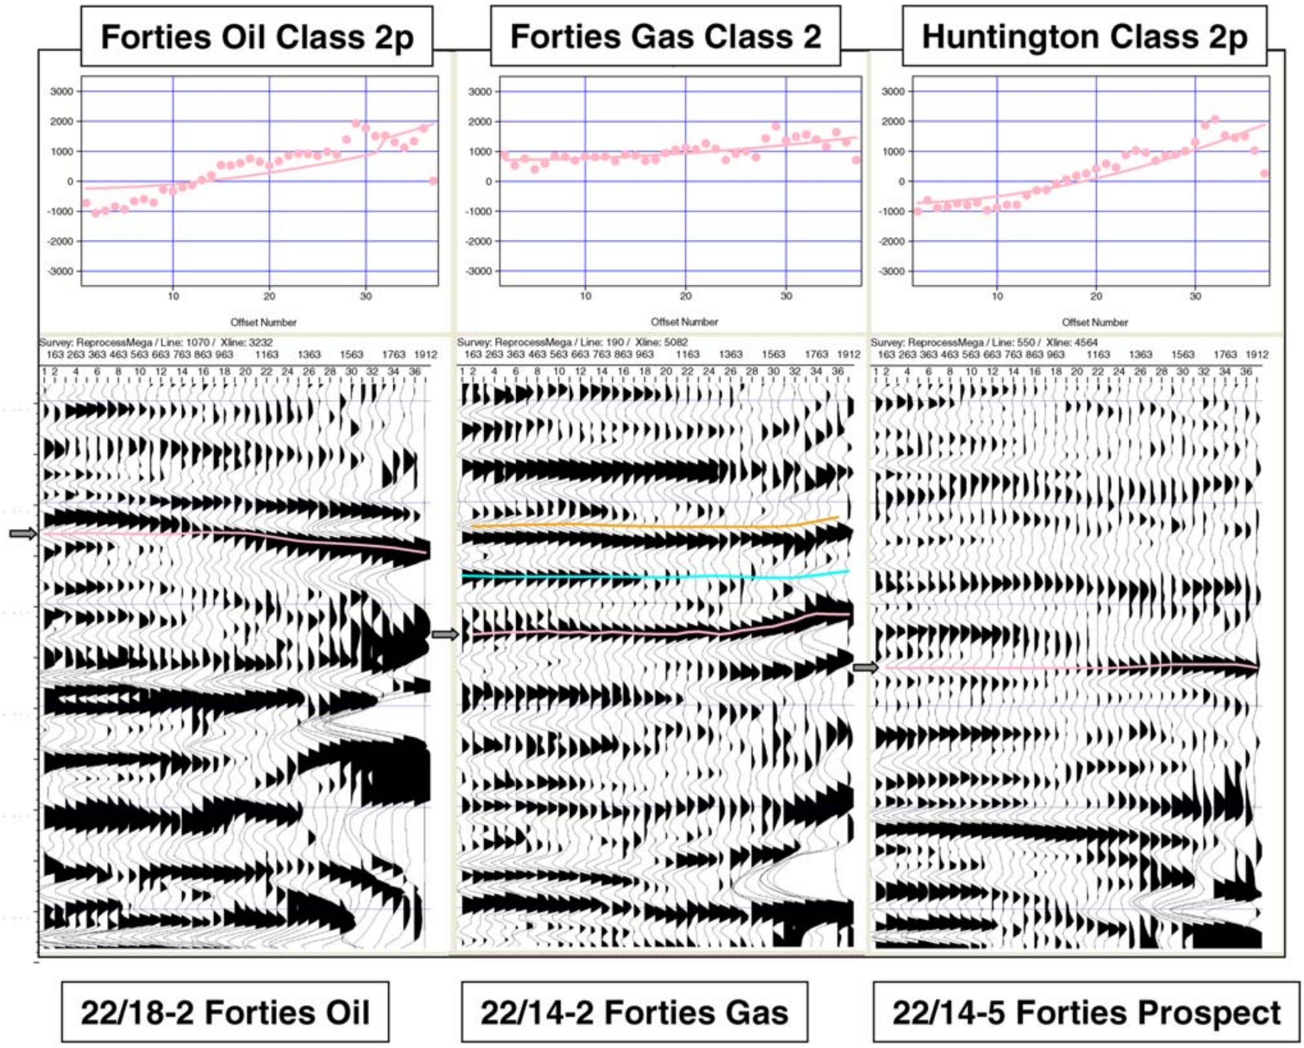

Fig. 10. Forties AVO response, gas v. oil. Three gathers with amplitude v. offset response for wells 22/18-2 Montrose oil (Class IIp AVO), 22/14-2 Everest gas (Class II AVO) and 22/14-5 Huntington (Class IIp AVO). The Top Forties Sandstone event is highlighted with a small grey arrow at the left edge of each panel of gathers. A plot of amplitude strength v. offset is shown at the top of each gather panel for the Top Forties Sandstone event.

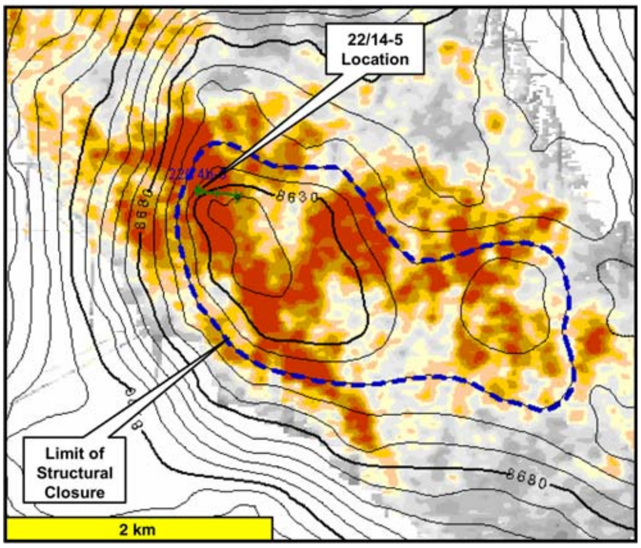

Fig. 11. Forties depth structure with far-offset (30–40°) A-amplitude anomaly. Amplitude extends beyond independent structural closure shown by blue dashed contour. Contour interval is 10 ft.

oil within the BCU closure, and one well, which proved water within the Forties closure, previously drilled. Second, the seismic amplitude response at Huntington did not neatly fit into pre-existing categories and is in fact a fairly subtle response. If the 3D seismic had exhibited an obvious amplitude response at Huntington, the prospect would have been drilled long ago. In general, prospects in mature areas are likely to be fairly subtle with ambiguous responses. Finally, there seems to be reluctance to invest in prospects left behind by other companies unless there is a convincing case for large reserves potential.

Drilling results

The 22/14-5 well penetrated a sand-rich Forties reservoir section containing a gross 122-ft oil column (Fig. 13). Net pay was 82.5 ft, implying a net to gross ratio of 67% with average porosity of 19.7% and average water saturation of 46.5%. A drill stem test over the upper 50 ft of the reservoir yielded maximum flow rates of 5577 bopd. Oil gravity was 41° api and there is no evidence for a free gas cap. The actual gross oil column height is about four to five times the structural relief at the drilling location. This discrepancy implies there is a stratigraphic element to the trap. It is believed that the channel sandstone complex drilled at Huntington shales out to the NE to provide stratigraphic separation from the 22/14-1 dry hole. The small structural closure at Huntington may result from differential compaction of the Huntington channel complex relative to the more shale-rich section in the saddle to the NE.

The Huntington well also drilled a 136 ft gross oil column in the Fulmar Sandstone (Fig. 14). This interval has net pay of 72 ft, indicating a net to gross ratio of 53% with average porosity of 16.1% and average water saturation of 47%. This interval was also tested, yielding a flow rate of 4624 bopd from a 120 ft perforated interval. Oil gravity was 39° api. The ODT in the Fulmar is 56 ft deeper than the ODT in the Skagerrak at the 22/14-4 well. The column height also exceeds closure at the BCU, suggesting a stratigraphic component to this trap. It is believed that the Smith Bank and the Zechstein salt wall to the NE of the Huntington structure provide bottom and lateral sealing components to the Fulmar discovery.

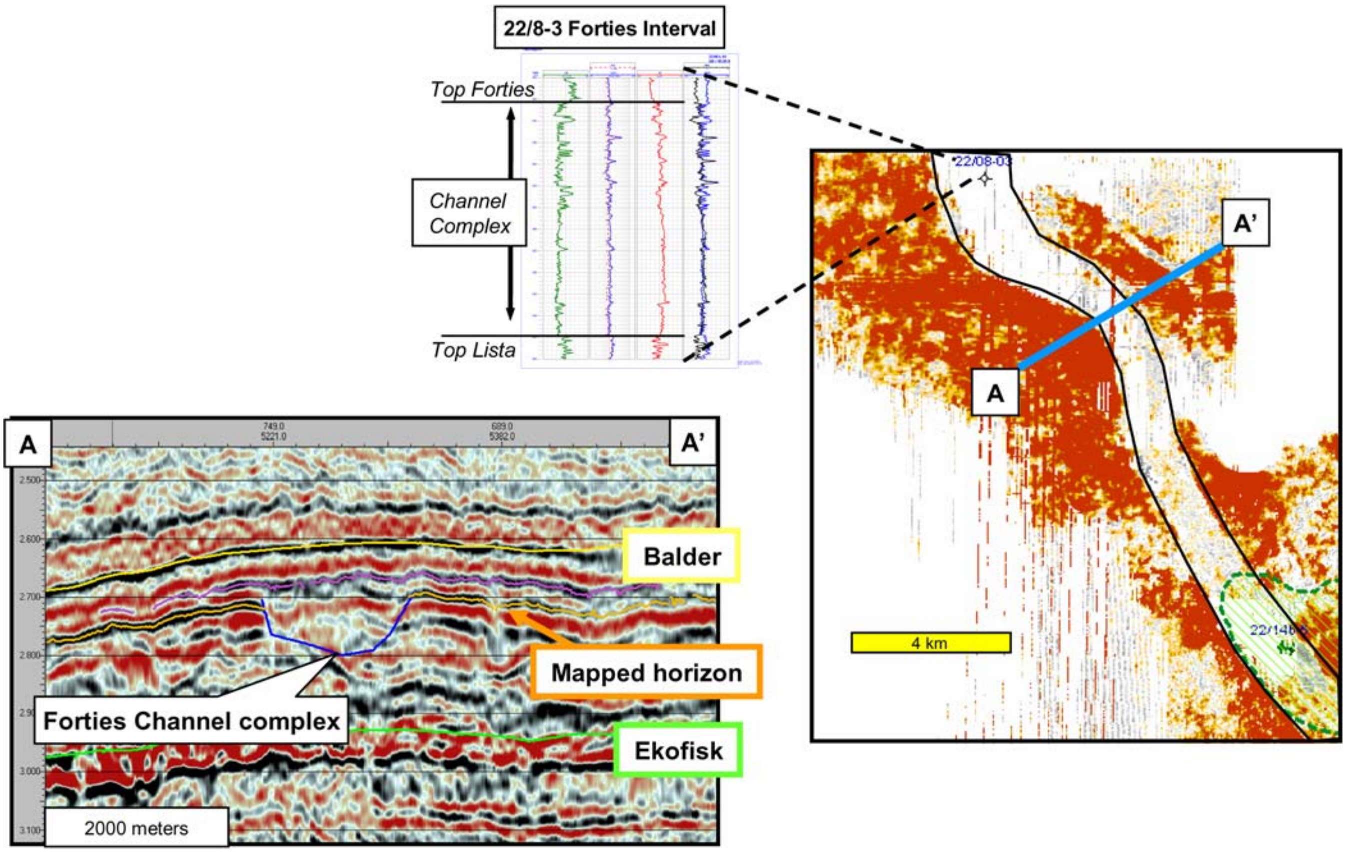

Fig. 12. Forties sandstone reservoir prediction. The far-offset (30–40°) seismic line illustrates a possible channel complex where the mapped horizon is absent. The map on the right displays amplitude on the mapped horizon (B-amplitude). The dim amplitude trending SE from the 22/8-3 is interpreted to represent a channel sandstone. A channel complex was therefore predicted for the 22/14-5 Huntington location. Courtesy of PGS.

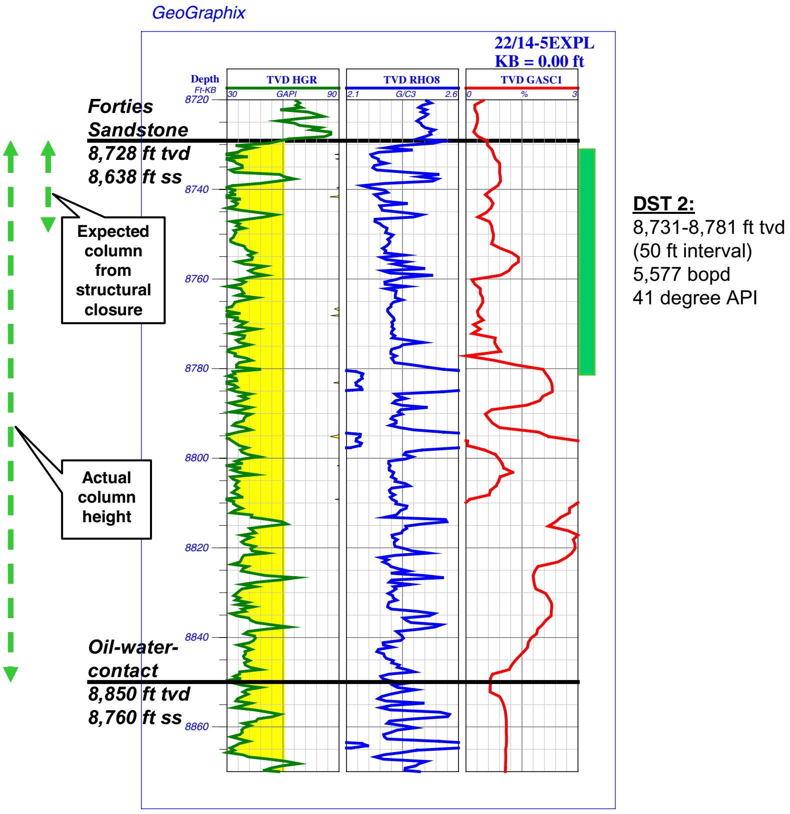

Fig. 13. 22/14-5 Forties well log section. The log display includes GR, density and mud log total gas curves from left to right. The gross column height was 122 ft with 83 ft of net pay. Average porosity was 19.7% and average water saturation 46.5%. The perforated interval is indicated by the green bar at the right edge of the log plot. The expected column height on the left side above was much smaller than the actual column height.

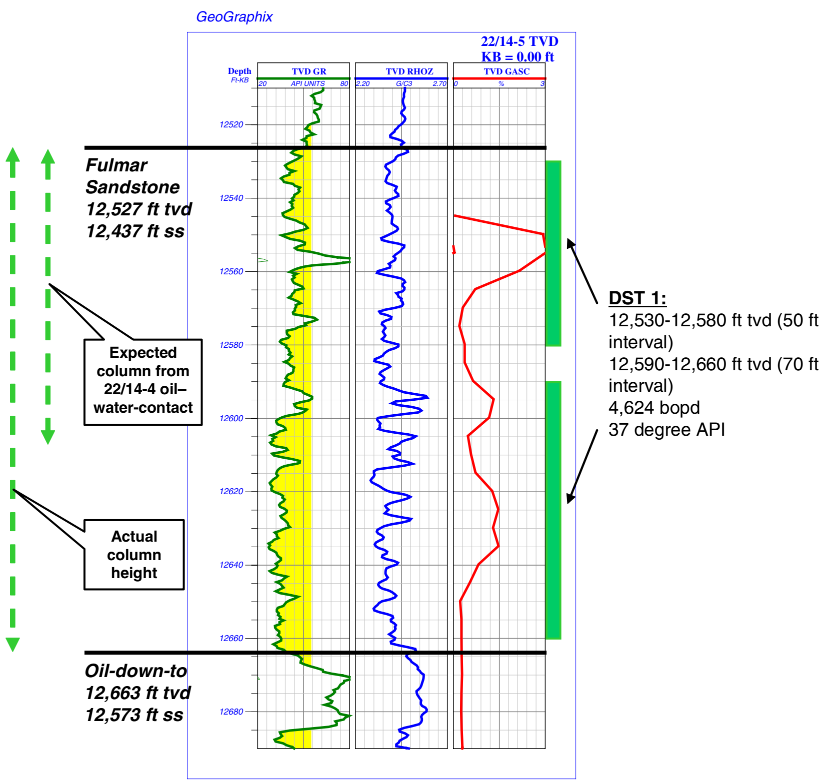

Fig. 14. 22/14-5 Fulmar well log section. The log display includes GR, density and mud log total gas curves from left to right. The gross column height was 136 ft with 72 ft of net pay. Average porosity was 16.1% and average water saturation 47%. The perforated interval is indicated by the green bar at the right edge of the log plot. The expected column height on the left side above was smaller than the actual column height.

Table 1. Comparison of prognosed and actual results for the 22/14-5 Huntington discoveries

	Prognosed	Actual
Forties sandstone		
Depth to top	8640 ft ss	8638 ft ss
Hydrocarbon phase	Oil	Oil
Reservoir pressure	3950 psi	3900 psi
Column height	20 ft	122 ft
Fulmar sandstone		
Depth to top	12 335 ft ss	12 437 ft ss
Hydrocarbon phase	Oil	Oil
Reservoir thickness	100 ft	136 ft
Oil-down-to	12 517 ft ss	12 573 ft ss

The pre-drill predictions were quite accurate except for the oil column heights (Table 1). In an unusually favourable coincidence, the column heights exceeded expectations in both the Forties and Fulmar reservoirs. It is believed that stratigraphic components to the trap increased the height, areal extent and reserves potential for each discovery. While this potential had been foreseen prior to drilling, it was not regarded as the most likely outcome.

The authors wish to thank Carrizo Oil & Gas, Inc. and in particular S. P. Johnson IV, J. Greene, G. Uhland, G. Evans, B. Fisher, J. Lund and J. Thompson for their continued support of this project. We are also grateful to the P1114 co-venturers, E.ON Ruhrgas UK Exploration and Production Ltd, Norwegian Energy Company UK Ltd and Oilexco North Sea Ltd for permission to present and publish this paper. However, the views expressed here are those of the authors and do not necessarily reflect those of the P1114 co-venture group. PGS is thanked for allowing reproduction of several seismic lines. We also acknowledge the technical contributions of R. Gassett for his work in AVO analysis and fluid substitution and E. Pasternack for petrophysical analysis. Finally, we are particularly grateful for the support of M. Stockwell, C. Møller and R. Christensen, who enabled this prospect to be drilled.

Abstract: The Jasmine Field is located in blocks 30/06 and 30/07a on the J Ridge, the southeastern extension of the Forties–Montrose High, which separates the eastern and western basins of the UK Central North Sea. The field was discovered in 2006 and is close to two ConocoPhillips producing fields, Jade and Judy, which serve as useful local analogues. The main *West Limb* structure is a turtle-back faulted anticline NW of the Joanne salt pillow. The primary reservoir is Triassic in age and consists of stacked fluvial sandstones of the Joanne Member of the Skagerrak Formation. The HPHT exploration wells 30/06-6 and geological sidetrack 30/06-6Z discovered a rich gas condensate column of 2300 ft, some 1100 ft deeper than the mapped independent structural closure of the prospect, and achieved good flow rates on test. To appraise the discovery and assess the potential for significant additional volumes in an adjacent downfaulted terrace, a programme comprising a main well and two sidetrack wells was initiated in 2007. Appraisal well 30/06-7 discovered a 550 ft hydrocarbon column in the *Northern Terrace* with a hydrocarbon–water contact shallower than that observed in the West Limb, thereby proving structural compartmentalization between the two fault blocks. Good flow rates were achieved from a drill stem test in mechanical sidetrack well 30/06-7Z. Sidetracks 30/06-7Y and 30/06-7X were drilled to confirm the northwestern extension of the West Limb discovery and to test the northern extent of the Northern Terrace accumulation, respectively. This programme has reduced volumetric uncertainty but the trapping mechanism and the ultimate extent of the Jasmine accumulation remain unknown. Comprehensive data acquisition throughout the exploration and appraisal phases, including drill stem testing, core recovery and seismic data reprocessing, has facilitated a detailed reservoir characterization programme. Jasmine represents a significant new high pressure/high temperature resource in the mature Central North Sea and is currently undergoing development planning.

Keywords: Jasmine Field, Central North Sea, high pressure/high temperature (HPHT), Skagerrak, Triassic, condensate

Location and aims

The Jasmine Field was discovered in 2006 by exploration well 30/6-6. The field straddles blocks 30/06 and 30/07 of the UK sector of the Central North Sea, 270 km east of Aberdeen and is located 9 km west of the Judy Field and 16 km south of the Jade Field (Fig. 1). The aim of this paper is to document the discovery and appraisal history of the Jasmine accumulation and outline the ongoing reservoir characterization programme. The Jasmine Field represents one of the most significant discoveries made in the North Sea in recent years.

Licence and exploitation history

The ConocoPhillips-operated Judy, Joanne and Jasmine fields are located primarily in Block 30/07a with southern and western flanks extending into adjacent blocks 30/12a, and 30/06. Phillips Petroleum UK Ltd acquired operatorship of Licence P.032, which includes blocks 30/07a and 30/12a, from Gulf Oil in 1972, and part of P.011 (30/06) from Shell in 1993.

The *J Block* area is a prolific hydrocarbon-rich region which straddles the J Ridge, a large intra-basinal horst within the Central Graben. The J Block assets comprise a number of hydrocarbon fields with reservoirs in the Triassic Skagerrak Fm., the Upper Jurassic Fulmar Fm., the Upper Cretaceous chalk and Paleocene Andrew sandstone. The Joanne Field was discovered in 1981 by well 30/07a-1, which encountered hydrocarbons in both the Paleocene Andrew ('A1') sands and the Cretaceous chalk Tor Formation. It was appraised by a further four wells including 30/07a-5 (1985), which targeted the western flank of the field terminating in the Lower Cretaceous Cromer Knoll Group *c.* 500 ft above a structure now known to be the Jasmine Field. An opportunity to deepen the well was not taken on account of predicted poor reservoir quality based on the earlier 30/07a-3 well results, and the poor quality of the seismic image of the underlying section.

The Judy Field was discovered in 1985 by well 30/07a-4A, which encountered hydrocarbons in both Upper Jurassic and Triassic sections (Keller *et al.* 2005). It was appraised by five further wells and project sanction was achieved in 1992. The Judy platform and the connected Joanne (Chalk) subsea manifold were installed in 1993, with first production in 1995. Total cumulative production to end 2008 is 160 MMBOE with peak production of 79 MBOE per day being achieved in Q3 2006. Average production rates in 2008 were 41 MBOE per day.

The Jade Field was discovered in 1996 by well 30/02c-3 and appraised by well 30/02c-4 (Jones *et al.* 2005). The field is tied back to the Judy platform and has been on production since 2001 with cumulative production to end 2008 of 107 MMBOE. Peak rates of 58 MBOE per day were achieved during the period 2002–2005 while average rates in 2008 were 31 MBOE per day.

The Jasmine Field was discovered in 2006 on the western flank of the J Ridge (Fig. 2) by a coventurer group comprising three companies: ConocoPhillips (Operator, 36.5%), Eni UK (33.0%) and BG Group (30.5%). The geology of the Jasmine Field is in many ways analogous to that of the other local Skagerrak accumulations and has benefited from both the static and dynamic knowledge

VINING, B. A. & PICKERING, S. C. (eds) *Petroleum Geology: From Mature Basins to New Frontiers – Proceedings of the 7th Petroleum Geology Conference*, 225–243. DOI: 10.1144/0070225

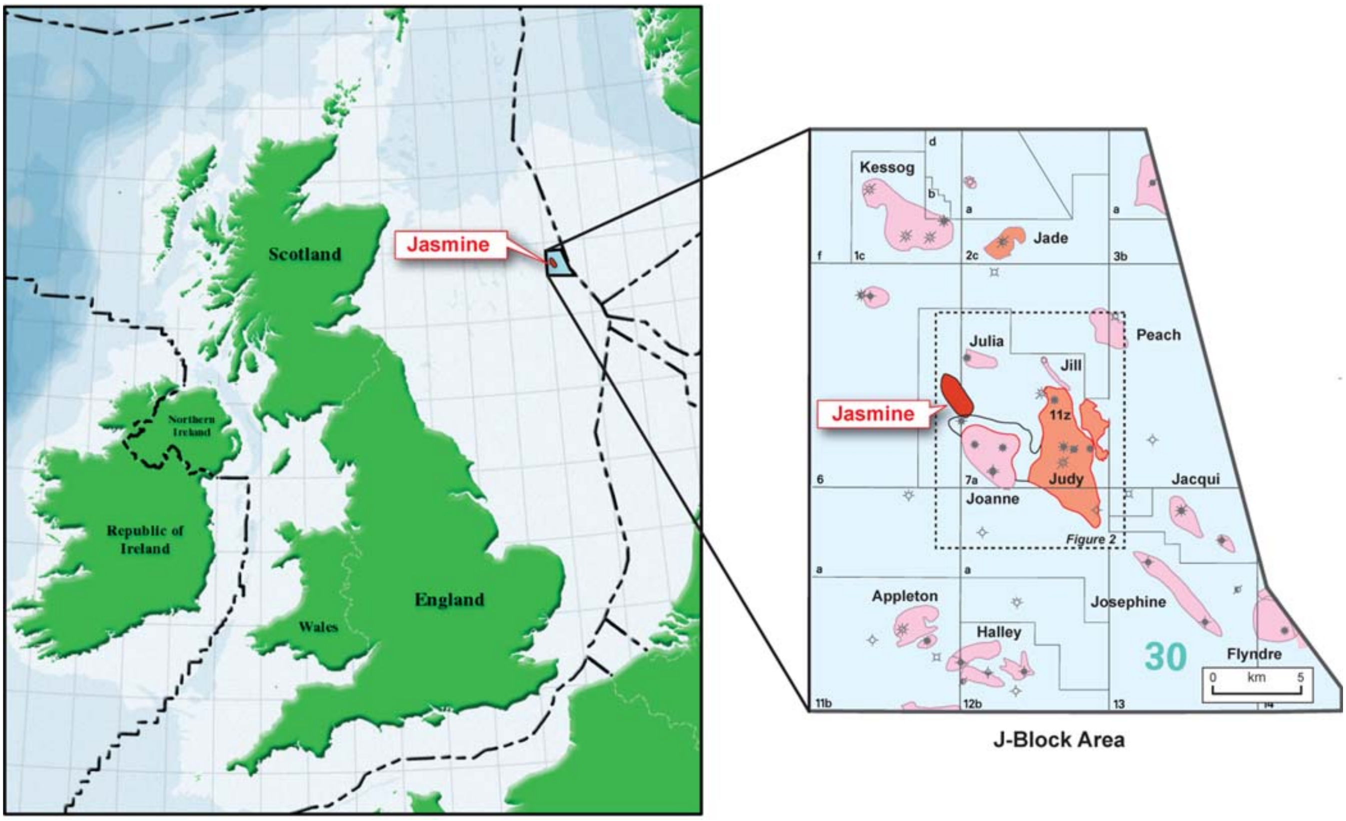

Fig. 1. Jasmine Field location. Figure 2 area shown as dotted outline.

compiled on these reservoirs since their discovery. The Jasmine Field lies at a current burial depth which is intermediate between the shallower Judy and the deeper Jade fields (Fig. 3). These two assets therefore provide useful local analogues as to Jasmine's likely dynamic behaviour, particularly in terms of bracketing pressure, temperature, fluid type and well performance parameters.

Stratigraphic and structural setting

A stratigraphic nomenclature for the Triassic of the Central Graben was proposed by Goldsmith *et al.* (1995). It was based on biostratigraphic and lithostratigraphic methods, including wireline log correlations, and established a stratigraphic framework which introduced the J Member terminology within the Skagerrak Formation, whereby female names represent reservoir sandstone intervals and male names represent thick intervening sealing mudstones (Fig. 4).

The Skagerrak Formation is a sequence of continental sediments, deposited on a wide alluvial plain which extends throughout much of the Central North Sea. The primary reservoir in the Jasmine Field consists of a succession of stacked moderate net to gross fluvial deposits which comprise the Joanne Sandstone Member of the Skagerrak Formation. The average reservoir thickness for Judy and Joanne Sandstone members is *c.* 1000 ft each in the Jasmine area. The fluvial sandstone reservoir facies include both confined, channelized and unconfined, sheet flood and crevasse splay components. Mudstones constitute non-reservoir floodplain, playa and lacustrine facies, although the degree and style of fluvio-lacustrine interaction is still much debated.

The top seal to the Joanne reservoir is provided by the Jonathan Mudstone Member and the base seal by the Julius Mudstone Member (Fig. 4). The Julius mudstone varies between 200 and 300 ft in thickness and the Jonathan mudstone can achieve up to 900 ft thickness where fully preserved. These exceptionally thick mudstone intervals, in addition to the Lower Triassic Smith Bank Formation, are a characteristic yet enigmatic feature of the Skagerrak.

The Skagerrak succession most probably accumulated in a semi-arid terminal basin without direct oceanic connection. The sands were probably shed from hinterlands to the NW and NE, that is, the Scottish and Scandinavian Caledonian Highlands. The Skagerrak reservoirs accumulated in a series of salt-withdrawal mini basins (e.g. Hodgson *et al.* 1992; Smith *et al.* 1993; Barde *et al.* 2002; Matthews *et al.* 2007). The rate of generation of halokinetic accommodation space is thought to play a major role in controlling reservoir architecture and stacking patterns by governing channel location and degree of channel amalgamation (lateral and vertical net to gross).

Structurally, the Jasmine Field sits on the western edge of the J Ridge, a Jurassic age intra-basinal horst block, situated medially within the Central Graben. The horst plunges to the NNW and is bound by deep Late Jurassic aged graben, the Harrier sub-basin to the west and the Eastern Central Graben to the east.

The J Ridge has had a protracted structural evolution. Evidence exists for early Triassic-age fault movements which contributed to the creation of variable accommodation space for deposition of the Smith Bank Formation. This early Mesozoic extension episode combined with sediment loading contributed to early mobilization of the Zechstein salt. The deposition of the Smith Bank Formation was confined to mini-basins flanked by resultant salt walls and larger salt stocks (Goldsmith *et al.* 2003). The Jasmine field occupies one such mini-basin and is a distinct Triassic depocentre from that associated with the Jade and Judy Fields on the eastern side of the J Ridge. Growth of the salt walls and pillows during Triassic deposition led to the broadening of the early mini-basins such that the maximum mini-basin extent occurred during deposition of the Joanne Sandstone Member of the Skagerrak Formation. The eventual grounding of the salt may have led to the

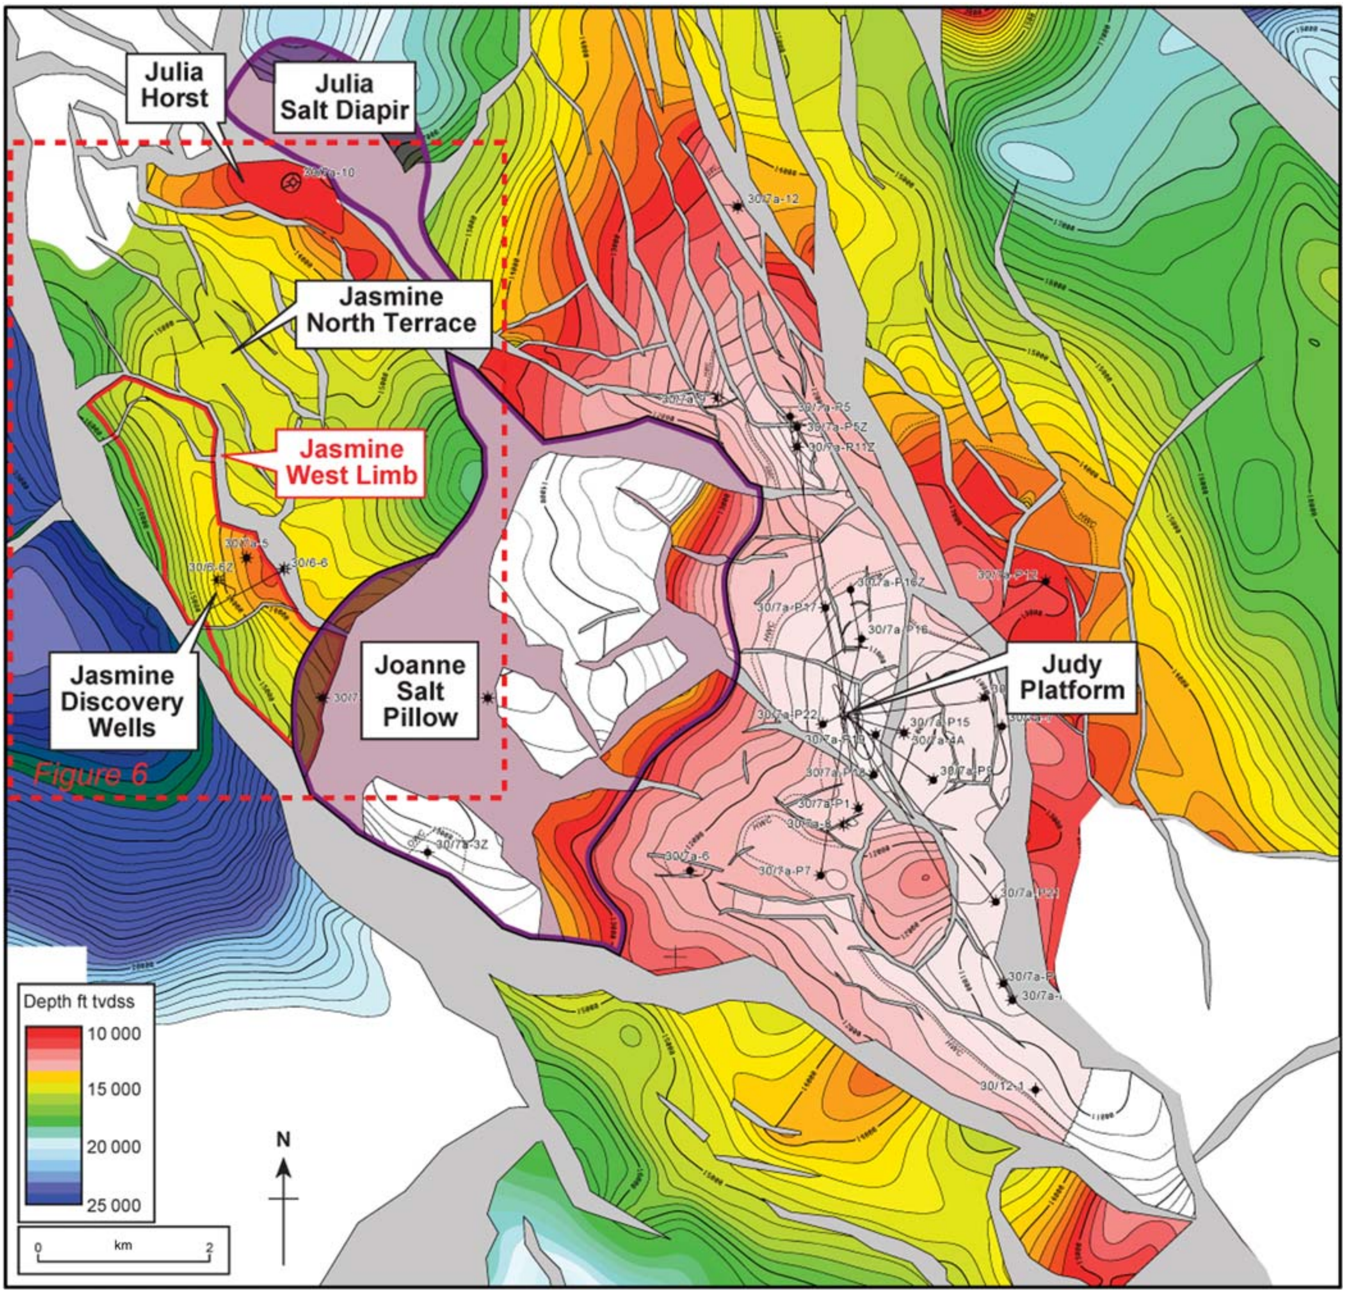

Fig. 2. J Ridge Top Triassic Unconformity structure map.

formation of intra-basinal highs and the development of multiple unconformities. An episode of Late Triassic (Late Joanne/Early Jonathan) faulting is evident, although not easily discernible, within the Northern Terrace area of the Jasmine Field (Fig. 5).

Middle Jurassic uplift and erosion led to the creation of the Mid-Cimmerian unconformity. During Late Jurassic rifting the J Ridge formed as a large intra-basinal horst block. The residual salt bodies suffered extension and collapse during this extensional event, creating localized depocentres both on the flanks and on top of the ridge. Salt collapse and continued extension also resulted in the dismemberment of the Triassic mini-basin fills into a series of faulted, turtle-back anticlines. These form the main trapping structures for the Jade and Judy Fields.

The Jasmine West Limb faulted anticline also owes its formation to this Late Jurassic rifting episode and salt withdrawal. The structure is perched above the western J Ridge boundary fault and is a steeply rotated fault block which evolved from a turtle-back anticline into a forced fold as displacement accumulated on the boundary fault during Late Jurassic rifting.

The Jasmine Northern Terrace area forms a foundered saddle region between the main Jasmine West Limb discovery to the SW and the water-saturated Julia horst block (30/7a-10) to the NE (Figs 2 & 5). The Northern Terrace is characterized by a set of northeasterly dipping domino-style fault blocks where the faulting appears multi-phase with Triassic and Upper Jurassic age structures dominating in different areas. The Northern Terrace saddle area relies heavily on fault seal to be an effective trap. There may also be a stratigraphic seal element provided by the Middle Joanne shale-prone interval, suggesting the possibility of a complex sealing mechanism involving both structural and stratigraphic seal components.

Exploration phase

Pre-drill prospect evaluation

The original Jasmine prospect was perceived to require a lateral side-seal to the SE against the Joanne salt pillow, which was a

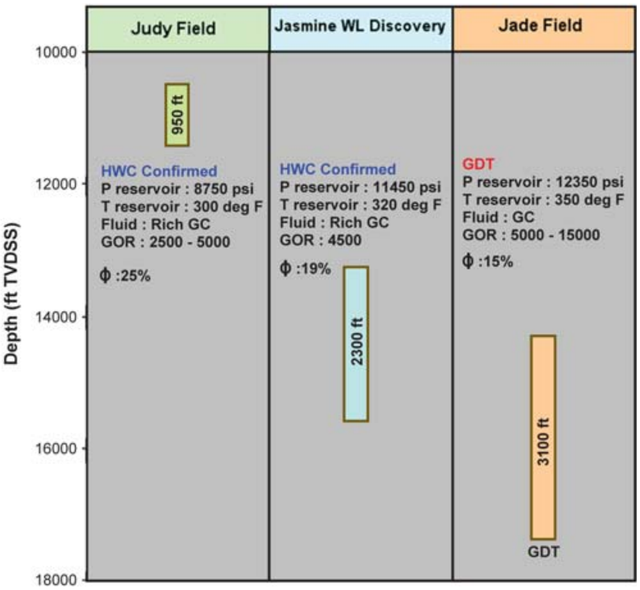

Fig. 3. Jasmine and local producing field analogues.

concept not previously proven in the immediate area. The northern end of the structure was assumed to be a simple spill point toward the NW at a depth of *c.* −14 600 ft tvdss which gave a three-way structural closure of *c.* 1200 ft elevation.

Semi-regional seismic mapping integrated with knowledge of the local analogue fields led to the prognosis that the reservoir comprised Joanne and Judy Member fluvial sandstones of the Triassic Skagerrak Formation. The prognosed fluid type was gas condensate with hydrocarbon charge modelled as being sourced from a kitchen to the SW involving fluid migration across the major Upper Jurassic J Ridge western boundary fault. Although source quantity is abundant in this part of the Central Graben due to the thickness and richness of the Upper Jurassic Kimmeridge Clay Fm. and Heather Fm. shales, the effectiveness of the charge in migrating across the poorly imaged boundary fault was considered a major pre-drill uncertainty.

Discovery well results

30/06-6. Exploration well 30/06-6 was drilled into the crest of the west limb footwall to test the independent structural closure which abutted the Joanne salt pillow (Fig. 6a). The well was successful in discovering a significant, *c.* 1000 ft thick, column of rich gas condensate within the Joanne Sandstone Member of the Skagerrak Formation. The column extended down to the Julius Mudstone and the well terminated in the underlying Judy Sandstone which was water-saturated, confirming hydrocarbons-down-to (HDT) the base of the Joanne Sandstone. Figure 6b shows the mapped extent of the accumulation consistent with the HDT proven by the well.

A comprehensive suite of wireline logs was run which confirmed the Joanne Sandstone interval to have good porosity (average 17%) and a moderate net to gross (average 60%) (Fig. 7). A drill stem test (DST) was conducted and encouraging flow rates of gas and associated condensate were achieved with an estimated production potential consistent with the adjacent producing assets had the well been completed as a typical J Block production well.

Even more encouraging were the pressure data results (see Fig. 12). Modular dynamics tester (MDT) data points from the water-saturated Judy Sandstone interval lay on the same trend as those from the water-saturated Julia horst well (30/07a-10), implying a common regional aquifer. Pressure data acquired in the hydrocarbon leg gave a trend whose projection suggested a FWL of *c.* −15 800 ft tvdss, 1300 ft deeper than the proven HDT and some 1200 ft deeper than the lowest closing contour (LCC) of the Jasmine West Limb structure (Fig. 6c).

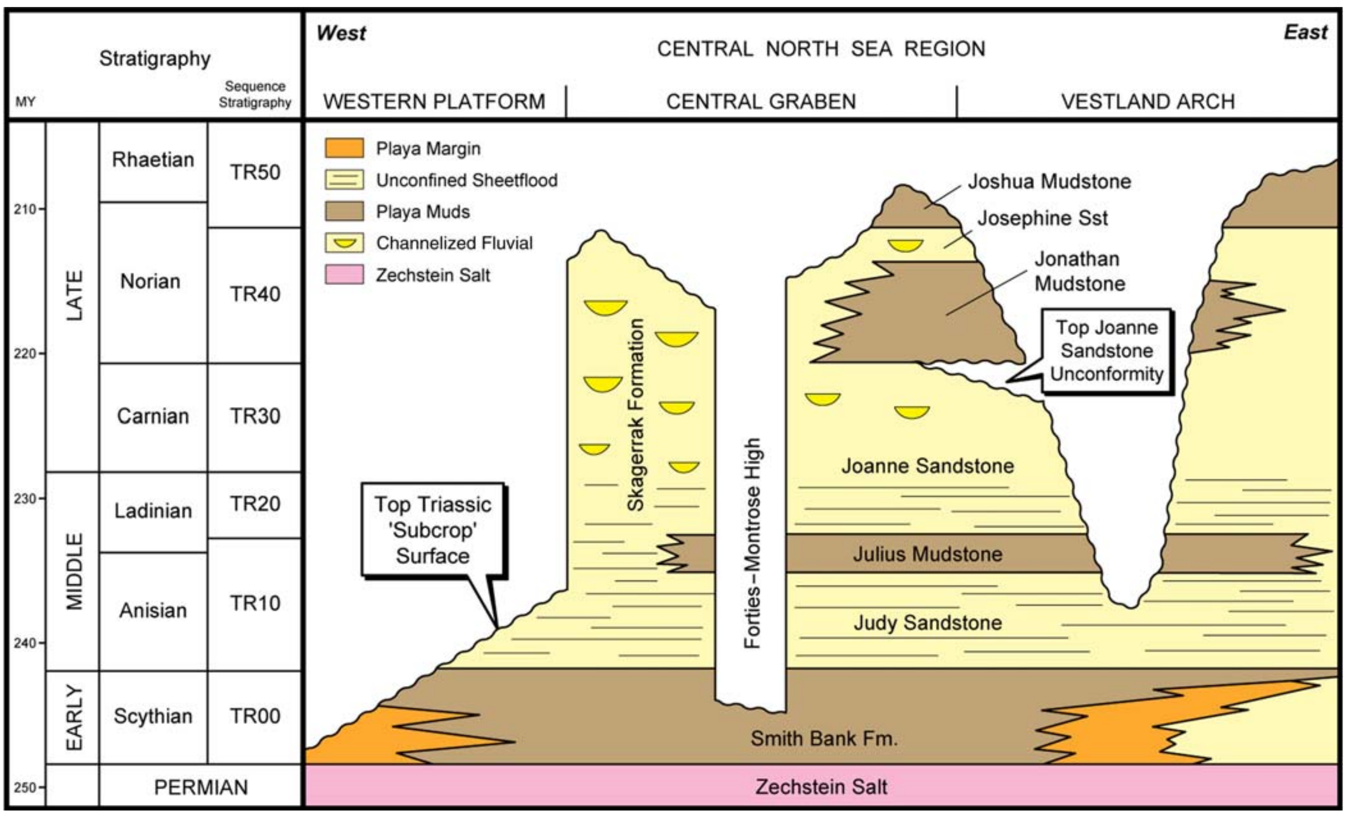

Fig. 4. Triassic stratigraphic framework (modified after Goldsmith *et al.* 1995).

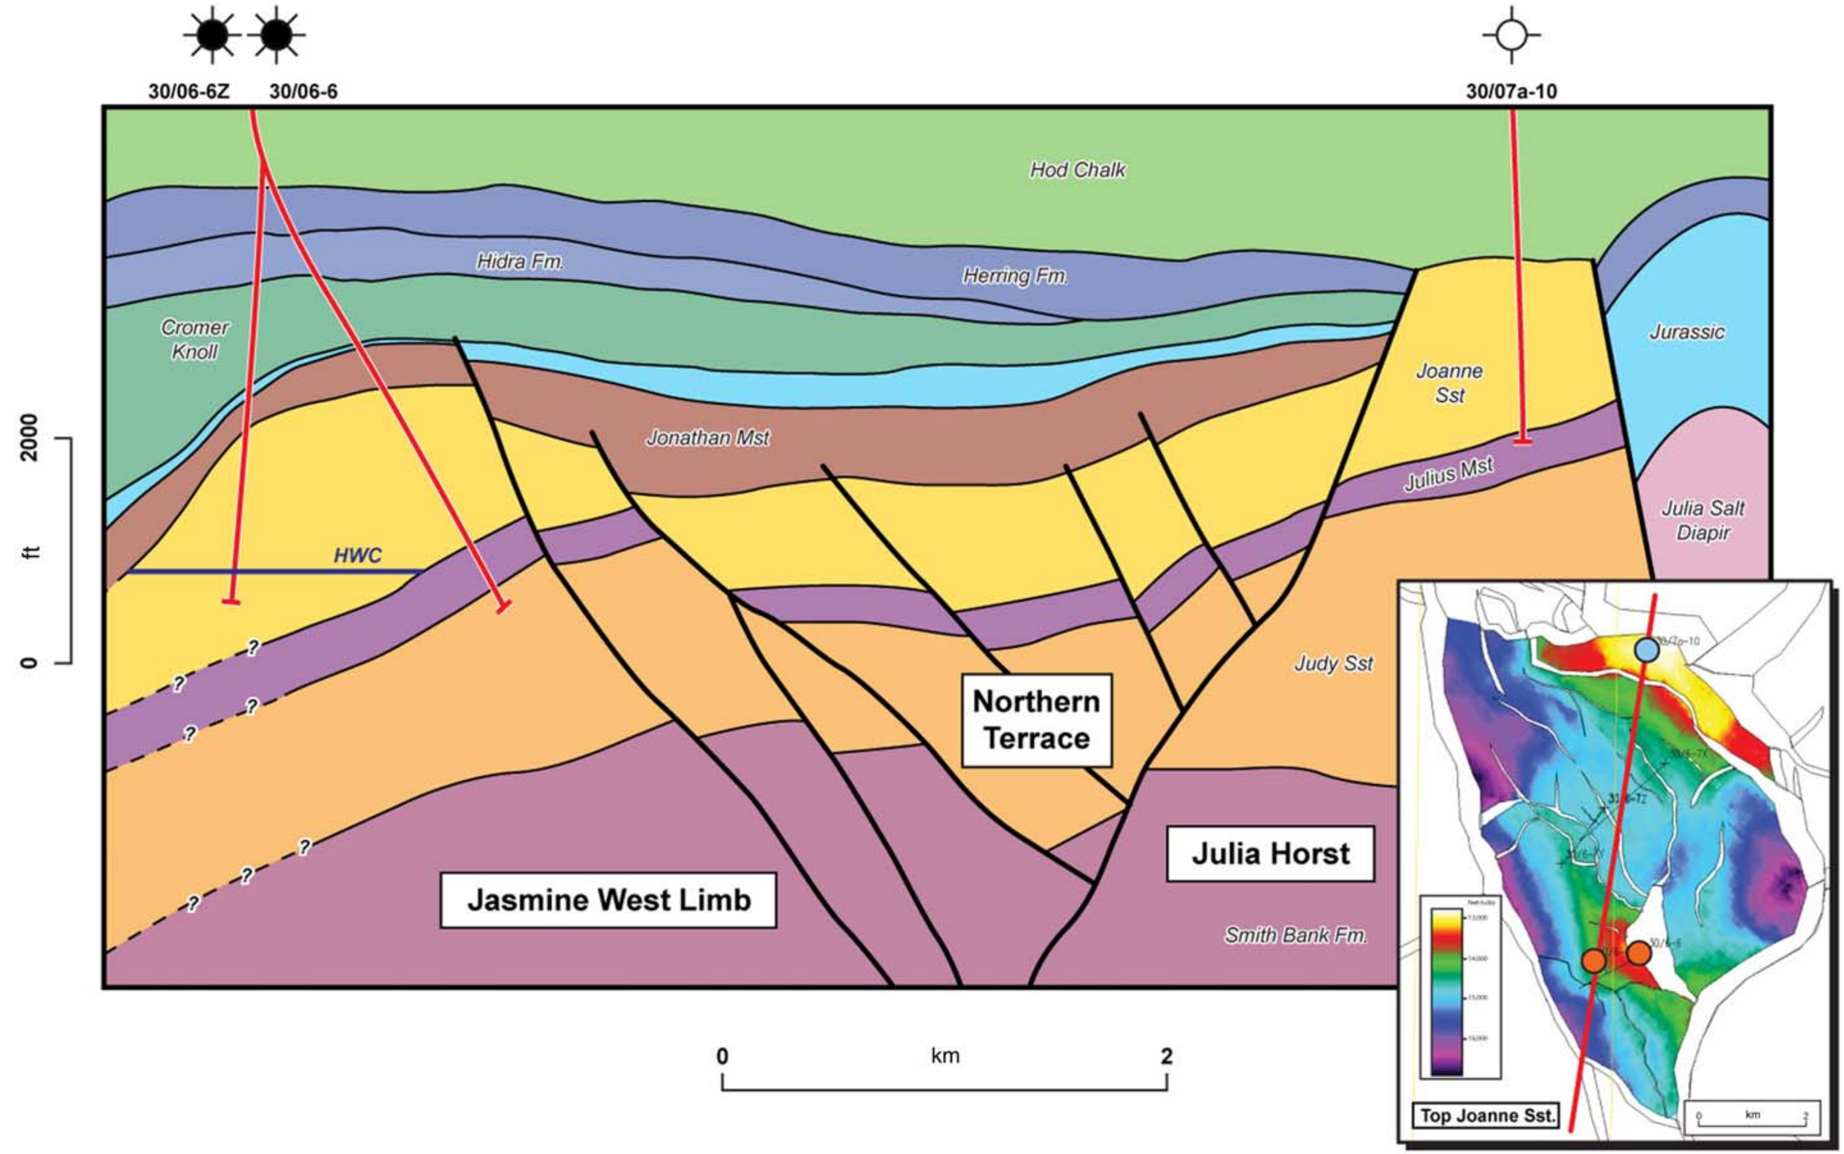

Fig. 5. Jasmine–Julia structural cross section.

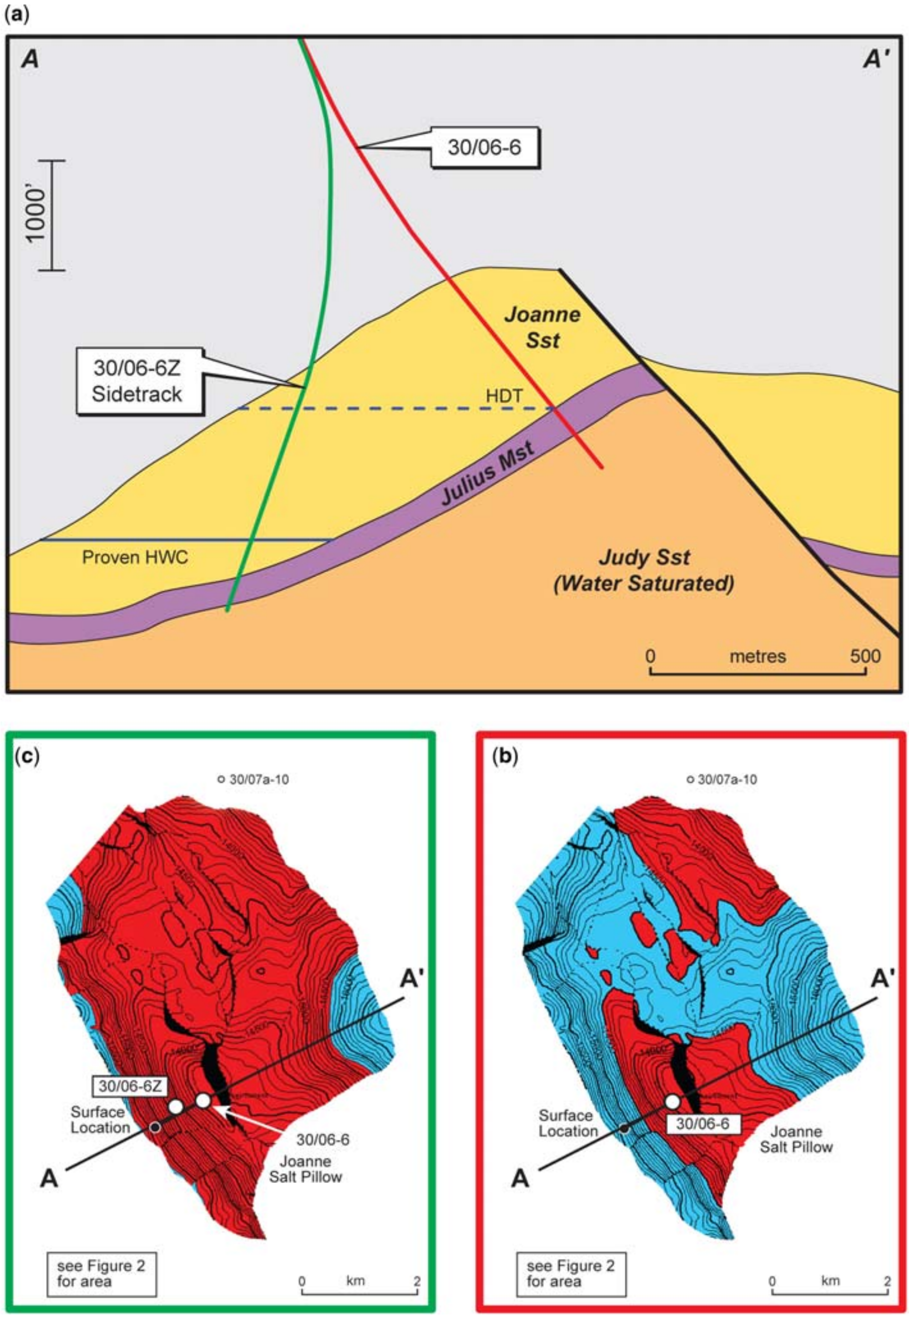

Fig. 6. Exploration drilling phase summary. (**a**) Cross-section through West Limb showing 30/06-6 and -6Z wells. (**b**) Accumulation extent consistent with HDT in 30/06-6 discovery well. (**c**) Accumulation extent consistent with HWC in 30/06-6Z sidetrack well.

30/06-6Z. A geological sidetrack was drilled in order to test the predicted deeper contact suggested by the pressure gradients and potentially prove up a very sizeable accumulation indeed. Geological sidetrack 30/6-6Z was planned to intersect the prognosed hydrocarbon–water contact (HWC) by targeting a downdip location such that the contact would be observed within the Joanne Sandstone reservoir. In order to avoid any ambiguity in contact definition, and to allow for depth uncertainty at Top Julius Mudstone, a deviated well path back towards the WSW was necessary (Fig. 6a).

The sidetrack successfully proved a HWC within the Joanne reservoir at the predicted level of *c.* −15 600 ft tvdss. The hydrocarbon-bearing interval in the 30/06-06Z sidetrack was *c.* 1600 ft TVD in gross thickness and the two wellbores therefore confirmed a hydrocarbon column of *c.* 2300 ft, with a HWC some 1000 ft deeper than the LCC. They conclusively proved the effectiveness of the Julius Mudstone as the bottom seal to the accumulation.

The fact that the HWC was encountered deeper than the spill point and that there was a lack of obvious closure or sealing mechanism at the northwestern extent of the West Limb (Fig. 6c) pointed to the very real possibility that the accumulation may extend into the adjacent Northern Terrace area. The uncertainty in the trapping mechanism was referred to as the ‘Jasmine discovery sealing conundrum’ and the issue is summarized in Figure 8.

Appraisal phase

Appraisal programme

In 2007, an appraisal programme was planned to achieve two main goals: test for volumetric upside in the Northern Terrace and

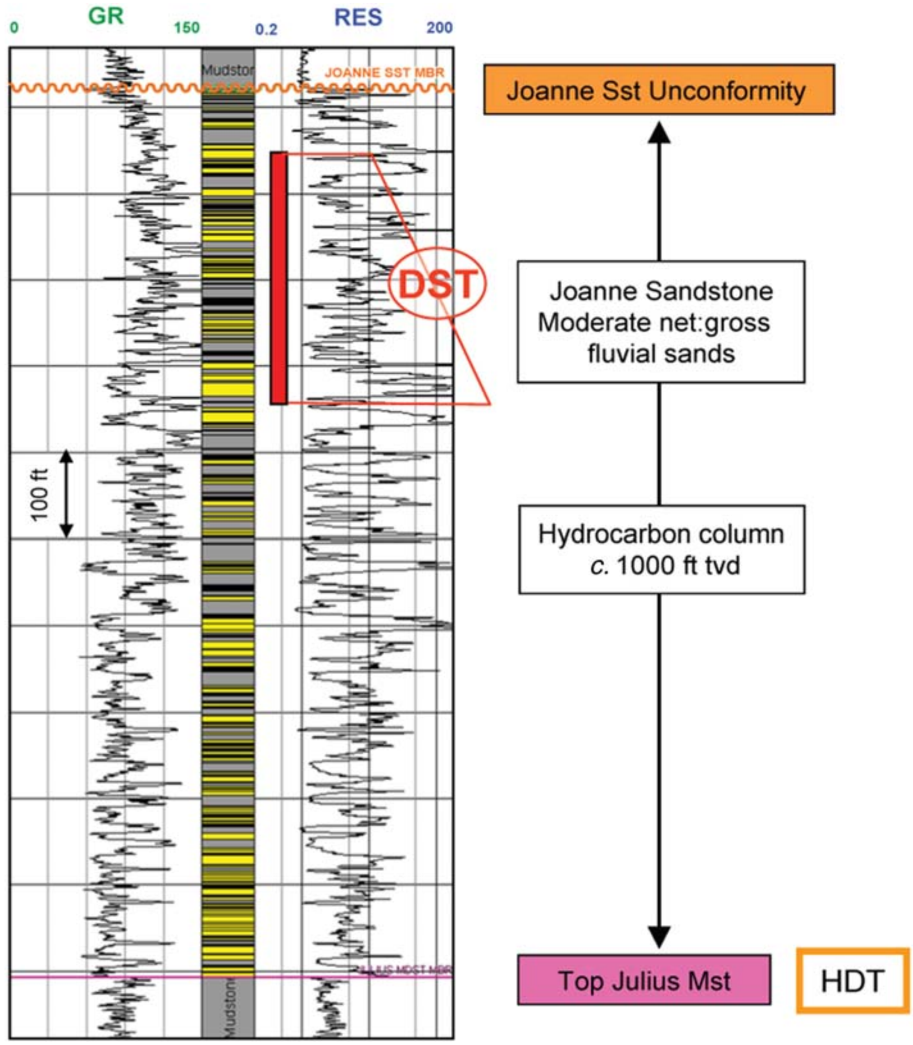

Fig. 7. 30/06-6 wireline log data.

undertake an additional penetration of the Jasmine West Limb to prove lateral continuity of the accumulation along-strike to the NW of the discovery well. A range of well designs and potential locations were considered before deciding on a three-well appraisal programme. The appraisal wellbores were to be drilled from a single top hole location positioned above the NE segment of the West Limb (Figs 9 & 10).

The main bore (30/06-7) was planned to test for the presence of hydrocarbons in the adjacent compartment of the Northern Terrace and, if present, to establish any continuity with the West Limb. A deep sidetrack was planned to drop back to the northern end of the West Limb to further appraise the main structure. A second shallow sidetrack was planned as a longer stepout well, targeting the ultimate northeasterly extent of any accumulation but contingent on success in the main bore (30/06-7).

The Northern Terrace is a poorly imaged, complexly faulted, foundered saddle area which separates the Jasmine West Limb accumulation from the water-saturated Julia horst, 6 km to the NE (see Fig. 2). This area's structural complexity is accentuated by a switch in fault polarity which occurs towards the NW, where two fault arrays with opposing-dip tip out in a transfer–wrench system. The faults can be interpreted on seismic data to terminate along-strike, resulting in a series of relay ramps. In the event that they are non-sealing then the area could conceivably represent a single, large contiguous trap (see Fig. 6c). Even in a sealing fault scenario hydrocarbons could potentially follow migration routes around fault tips, depending on the column heights involved (see Fig. 2).

The quality of the seismic image from the existing seismic datasets was considered inadequate for detailed well planning and control whilst drilling. Hence, early in 2007, a fast-track reprocessing programme was undertaken in order to provide data of sufficient quality. This work comprised several phases designed to deliver early results in a timeframe to support the drilling programme whilst permitting later stage refinements to produce an optimized dataset for reservoir characterization purposes. The reprocessing programme is discussed in detail under 'Reservoir characterization programme'.

The wellpaths were planned using the early products from the reprocessing programme. Key objectives were to target panels of coherent seismic data avoiding the seismically resolvable faulting whilst achieving well trajectories which could be logged using wireline tools (Fig. 10).

Appraisal drilling results

30/06-07 and -07Z. The main bore well targeted the nearest fault block of the Northern Terrace and spudded in October 2007. The well encountered hydrocarbons in both the primary Triassic Joanne Sandstone Member and in an overlying secondary Middle Jurassic Pentland Formation reservoir.

Within the Joanne interval, the well found hydrocarbons down to the top of a distinctive red-coloured shale-prone section (informally termed the Middle Joanne sub-member) at −15 300 ft tvdss, which is 300 ft shallower than the HWC discovered in the West Limb.

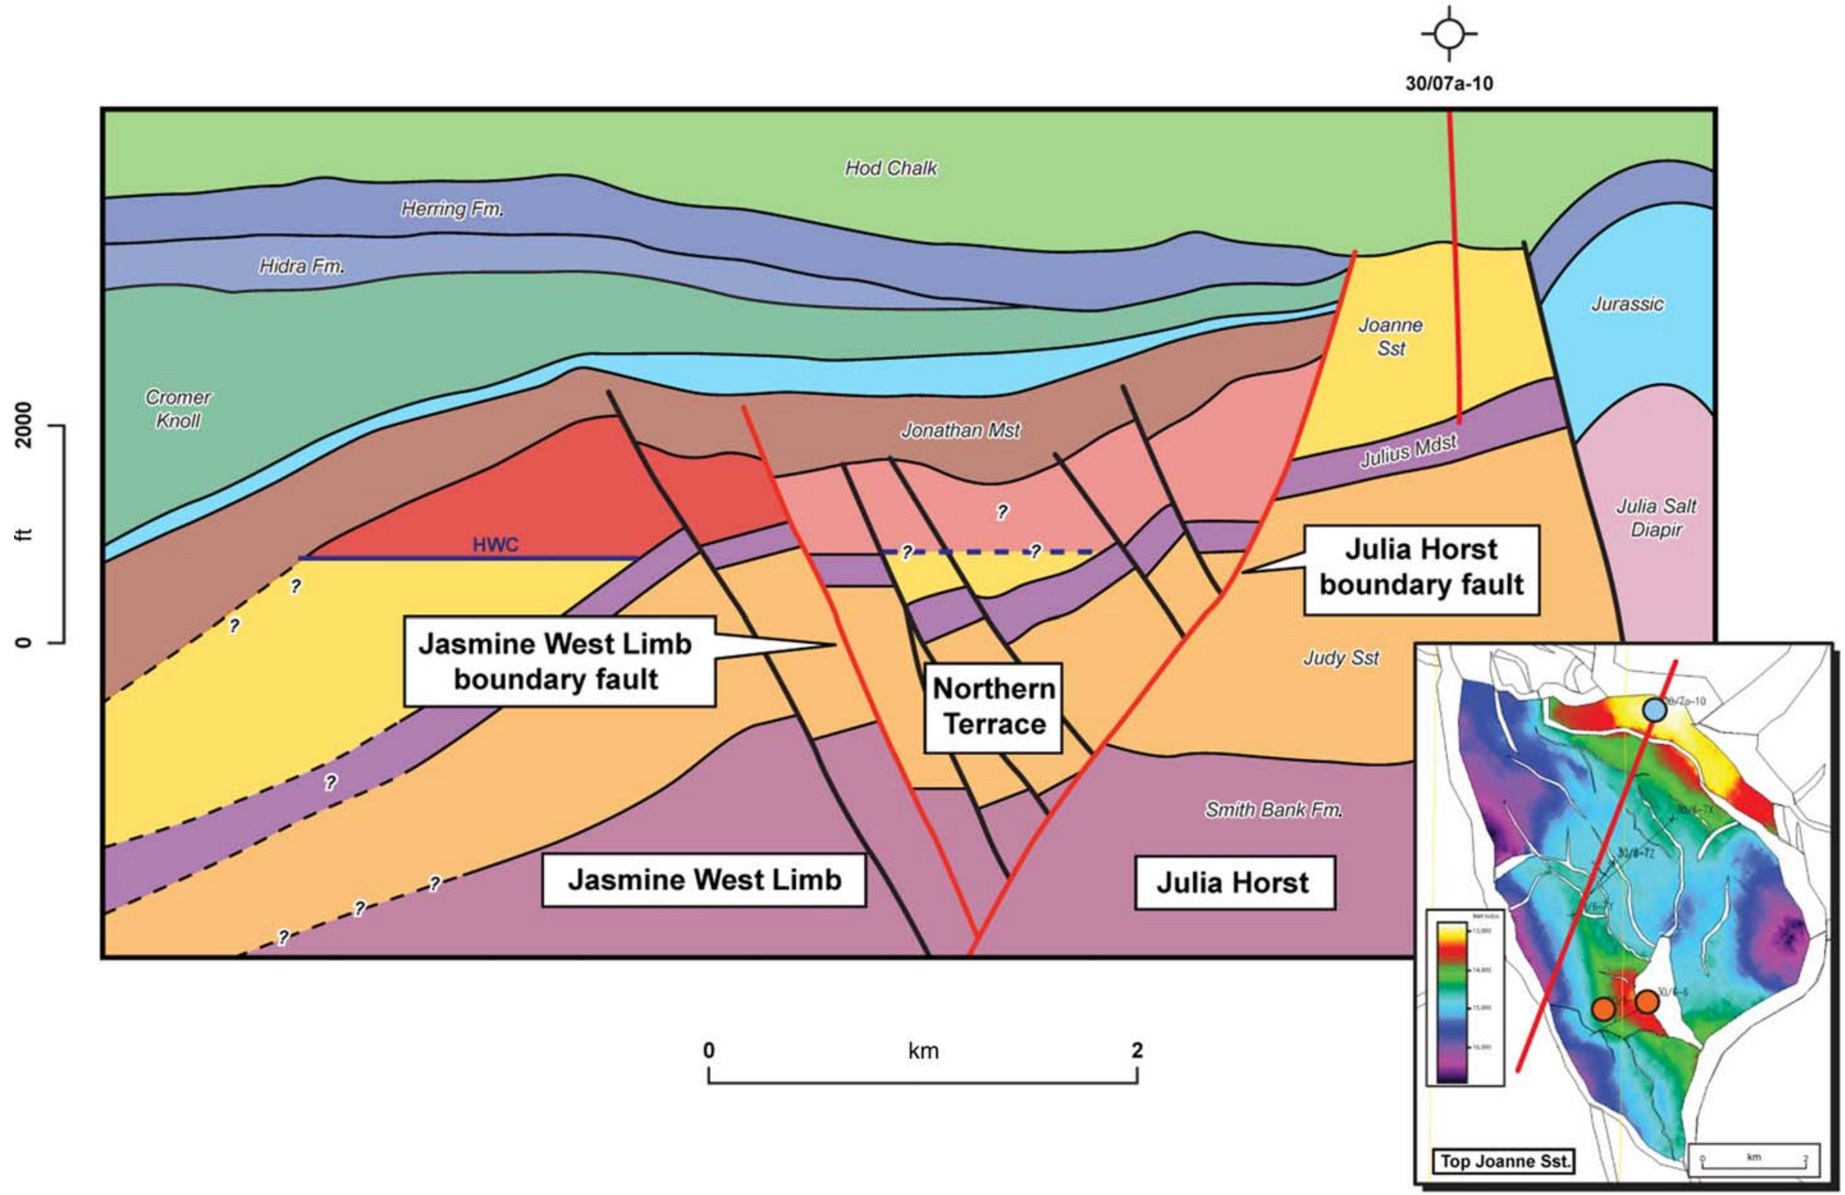

Fig. 8. Jasmine discovery sealing conundrum. What is the sealing mechanism which allows Jasmine West Limb to have an accumulation significantly deeper than the structural spill point and downdip from the water-wet Julia horst? Three candidate options for the sealing mechanism are: (i) West Limb Boundary Fault; (ii) Julia Horst boundary fault; and (iii) intermediate fault or other mechanism?

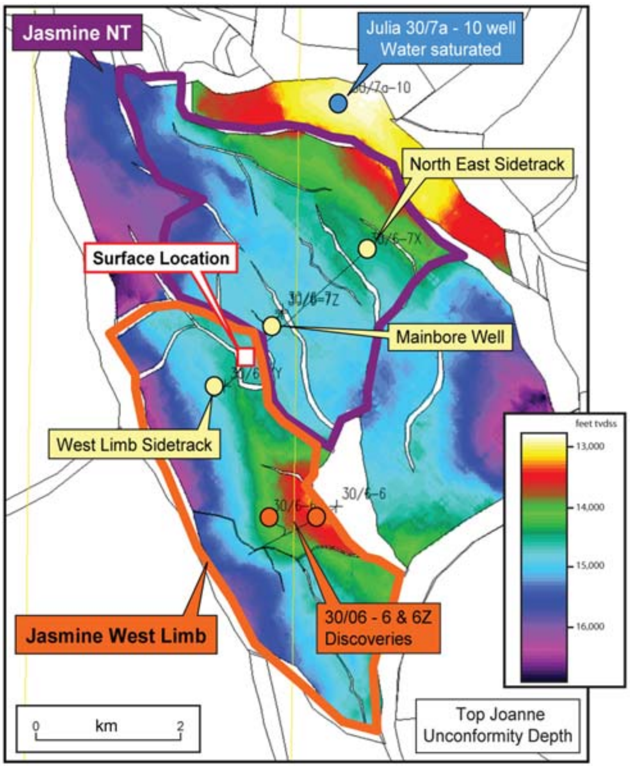

Fig. 9. Appraisal drilling locations.

The underlying Middle Joanne sandstones were water-saturated and the well was terminated within the Lower Joanne. The pressure data and the position of the HWC indicated that the Jasmine Northern Terrace is not in communication with the Jasmine West Limb core area.

In order to better characterize the Jasmine reservoir, a conventional core was taken in this first appraisal well. No core had been obtained in the 30/06-6 or -6Z exploration wells and it was recognized that on account of its down-faulted, deeper structural position, reservoir quality in the Northern Terrace was a significant uncertainty. A 128 ft core was recovered in two coring runs from the Upper Joanne Sandstone section.

A comprehensive logging programme was undertaken and petrophysical analysis revealed the hydrocarbon-bearing Joanne Sandstone to be *c.* 600 ft MD in gross thickness. Porosities of *c.* 16% were better than prognosed given the greater depth compared with the West Limb whilst net to gross was slightly poorer at *c.* 50%. A necessary mechanical sidetrack 30/06-7Z was drilled close to the original borehole to enable a DST to be performed. The DST confirmed that the reservoir could flow at commercial rates.

The fluid type proved to be a volatile oil and hence slightly heavier than the rich gas condensate discovered previously in the West Limb core area at the same depth. The most likely interpretation for the difference in composition is that the same source rock provided both charges at different maturity states with slightly later charge timing to the West Limb compared with the Northern Terrace. The well data has conclusively proven that the master fault separating the Jasmine West Limb from the Northern Terrace acts as a sealing fault over geological time scales.

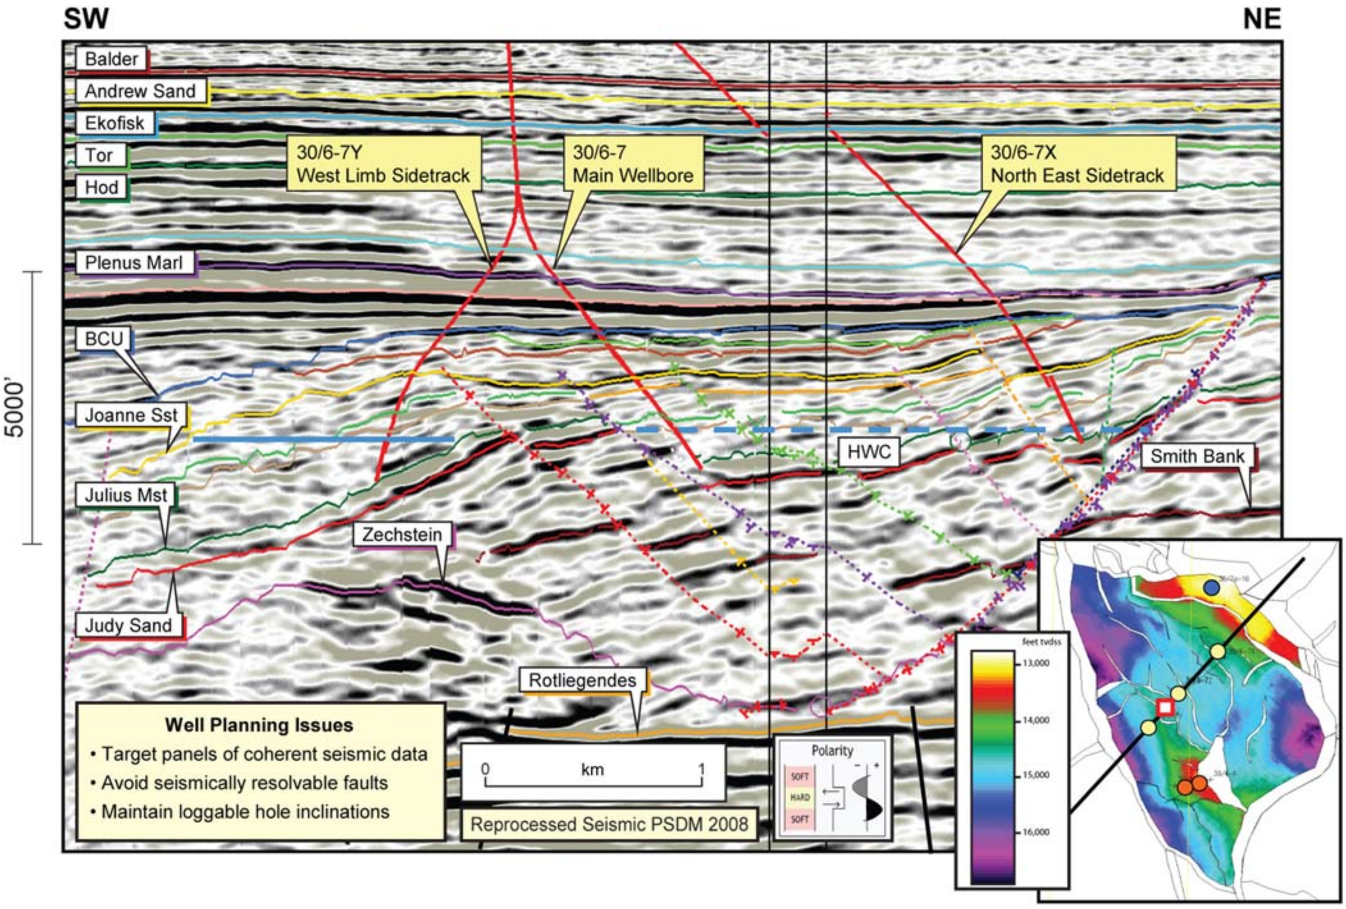

Fig. 10. Appraisal wells on seismic depth section.

Secondary reservoirs had been anticipated in the interval between Base Cretaceous Unconformity (BCU) and Top Joanne Sandstone. Well 30/06-7 encountered hydrocarbon-bearing Middle Jurassic Pentland Formation sandstones (90 ft thick) and thin (15 ft thick) Triassic intra-Jonathan Member sandstones. The Pentland sandstone is in a higher pressure regime than the underlying Joanne Sandstone interval. Therefore the thick Jonathan Mudstone Member acts as an effective top seal to the Joanne accumulation.

30/06-7Y. The 30/06-7Y well was sidetracked from within the Hod Formation SW into the northern area of the West Limb with the aim of reducing uncertainty in the resource volume in Jasmine's core area. Lateral variations in reservoir quantity or quality and the potential for along-strike compartmentalization were the key pre-drill uncertainties (Figs 9 & 10).

The well encountered hydrocarbons in the Triassic Joanne Sandstone Member and also in a secondary Triassic reservoir, the younger Josephine Sandstone Member. The well terminated in the Lower Joanne Sandstone Member immediately above the Julius Mudstone Member. The Joanne Sandstone penetrated by the 30/06-7Y well is *c.* 1500 ft MD in gross thickness with reservoir properties on trend with those from the 30/06-6 and 30/06-6Z discovery wells. The Josephine Sandstone Member in the 30/06-7Y well is *c.* 250 ft MD in gross thickness. Pressure data confirmed that the entire West Limb is within the same pressure regime. No DST was performed in this well.

30/06-7 and -07Y VSP programme. The geometric configuration of the 30/6-07 and the 30/6-07Y sidetrack wells in the same azimuthal plane afforded the opportunity to acquire high-resolution vertical seismic profiling (VSP) control either side of the boundary fault zone separating the West Limb from the Northern Terrace. Data were acquired via a rig-source survey in 30/6-07 and a walkabove survey in 30/6-07Y. The datasets were processed both individually and later migrated together to produce a contiguous high-resolution image across the complex boundary zone (Fig. 11).

The VSP products were compared with the reprocessed seismic volume and the most significant improvement in image quality was noted to occur in the Upper Triassic section. This gave rise to a change in the Top Joanne Sandstone seismic interpretation in 30/06-7 which was now interpreted on a deeper event with the original pick correlated as the top of the Lower Jonathan mudstone. This revision was incorporated into the geological model and into the planning for the long step-out appraisal sidetrack to the NE (30/06-7X).

30/06-7X. The encouraging results from the 30/06-7 and -7Z wells led to the step-out geological sidetrack to the most north-easterly fault block in the Northern terrace to test the extent of the accumulation (see Figs 9 & 10). A shallow kick-off (Mid-Miocene) sidetrack well from the 30/06-7 main bore commenced in April 2008. The well encountered reservoir-quality sandstones in the Middle Jurassic Pentland Formation, the Triassic Josephine Sandstone Member and the Triassic Joanne Sandstone Member, but none showed any indications of the presence of hydrocarbons. The well, combined with the water leg data from the other 30/06 and 30/07 wells, confirmed the presence of a common aquifer within the greater Jasmine area (Fig. 12).

The ultimate trapping mechanism for the Northern Terrace discovery is still not fully understood. Intriguingly the HDT discovered in the 30/06-7 and -7Z wells is coincident with a 60 ft thick red shale unit which may be acting as a stratigraphic bottom seal. Pressure data supports the interpretation that the HWC resides within the depth interval of the shale unit. The mid Northern Terrace area remains untested and the remaining uncertainty in the northern extent of the accumulation will be carried into the development phase of the project. The relative roles and potential interaction between fault seal and thick shales that may act as stratigraphic seals will be an important topic for future investigation. Hence the 'Jasmine sealing conundrum' postulated pre-appraisal drilling has been reduced but not entirely solved (Fig. 13).

Secondary reservoirs summary

Each of the appraisal wells encountered at least one 'secondary' reservoir in the overlying Base Cretaceous to Top Joanne Sandstone interval and these are summarized below.

- 30/06-7 and 30/06-7Z encountered hydrocarbon-bearing Middle Jurassic, Pentland Formation sands;
- 30/06-7Y encountered hydrocarbon-bearing Upper Triassic, Skagerrak Fm., Josephine Member sands;
- 30/06-7X encountered Pentland Fm. and Josephine Member sands which were both water-saturated.

These stratigraphic intervals are not easily resolved seismically and therefore biostratigraphy, chemostratigraphy, cuttings descriptions and the correlation of wireline log signatures have been instrumental in their correlation and dating. No secondary reservoirs were encountered during the drilling of the exploration wells (30/06-6 and 30/06-6Z) due to their crestal position on the West Limb.

Any tectono-stratigraphic model which attempts to explain the distribution of the Pentland Formation has to account for both local and regional erosive events. Local processes have been superimposed on the regional scale effects of the mid-Cimmerian unconformity which cuts out Late Triassic and Early Jurassic strata in all wells. The actual amount of missing section varies considerably from well to well due to variable degrees of erosion/incision and the age of the overlying Jurassic supra-crop. The degree of Late Jurassic incision into the Pentland Formation is difficult to assess, but exerts an additional local control on preserved Pentland thickness. The resource potential presented by these secondary reservoirs will be addressed during field development.

Reservoir characterization programme

An active reservoir characterization programme followed the discovery of the Jasmine accumulation and has progressed significantly with the appraisal drilling and associated data acquisition. Activities have included seismic reprocessing and interpretation, LWD (logging while drilling) and wireline logging (including the acquisition of image logs), core analysis, geomodelling and numerous in-house and contractor/university studies. The key lessons from this integrated reservoir characterization phase are discussed below.

Seismic reprocessing

The existing datasets used in earlier interpretations of the Jasmine area comprised two surveys:

- proprietary Phillips 'JBlock99' survey (1999) acquired in dip (NE–SW) orientation centred on the Judy and Joanne fields and processed as a pre-stack time migration (PSTM);
- non-proprietary regional 'CNS Cornerstone' survey (2003) acquired north–south and reprocessed as a pre-stack depth migration (PSDM) in 2006.

Both surveys suffered from several limitations including poor top reservoir imaging, indistinct fault plane and salt flank definition

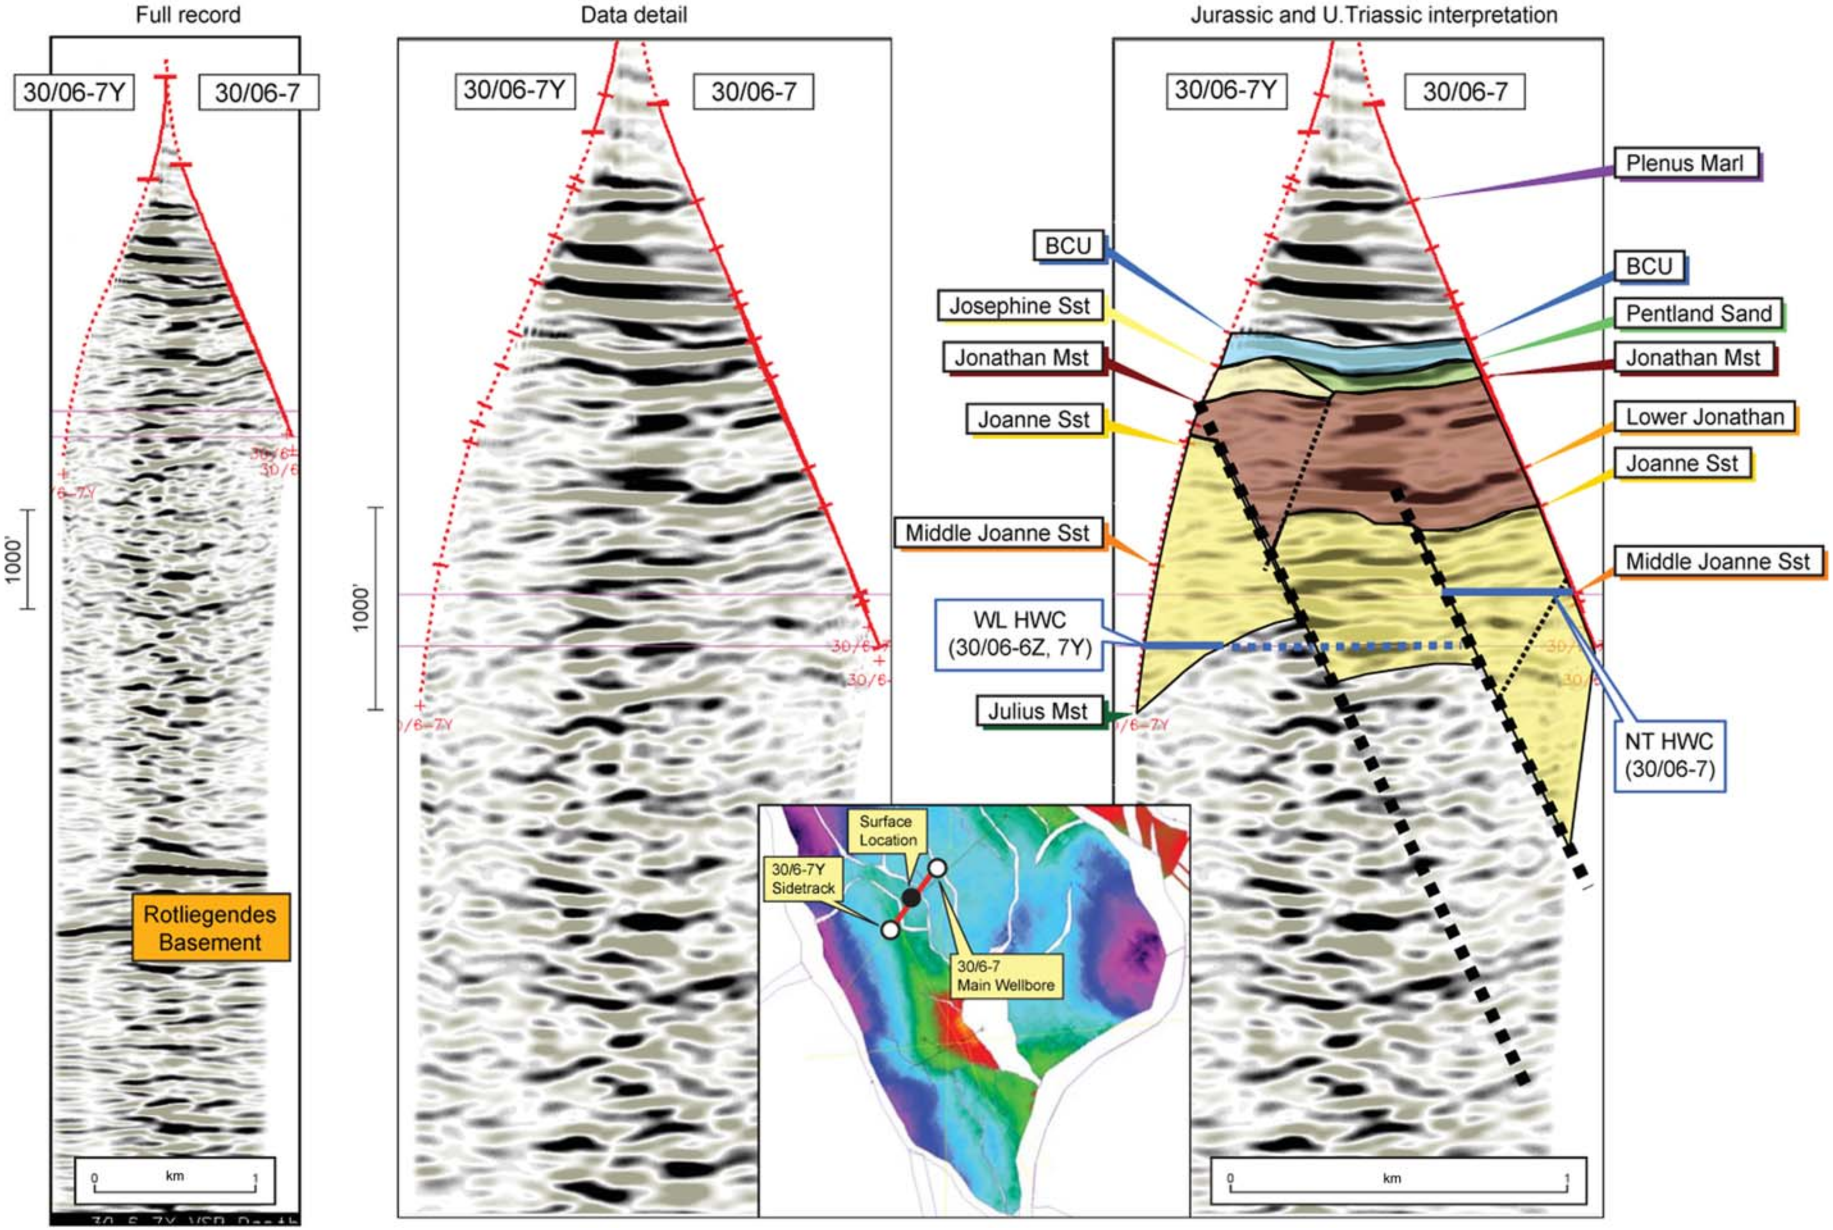

Fig. 11. 30/06-7–30/06-7Y migrated VSP image.

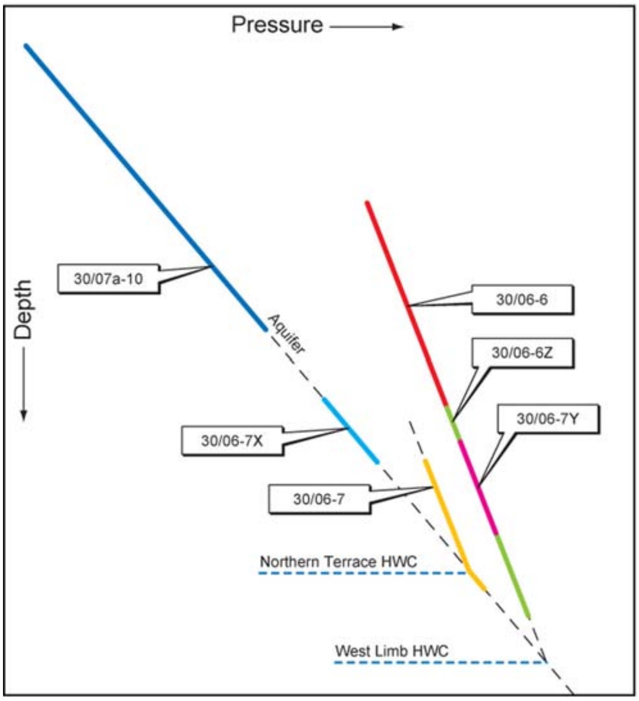

Fig. 12. Jasmine and Julia wells pressure data.

and persistent multiple overprinting, which particularly obscured the internal character of the reservoir interval (see Fig. 15a, c). These factors hindered confident seismic interpretation and the ability to support the planned programmes for the appraisal and development of the Jasmine Field. Hence the need was recognized for a significant improvement in quality of the seismic image across the area.

It was decided that both the above surveys should be processed with a common velocity model in order to utilize their respective advantages in coverage and orientation and then combined post-stack in order to benefit from the dual azimuth illumination (Fig. 14a–c).

The main areas of focus of the reprocessing effort were as follows:

- Noise removal – improvement of signal-to-noise ratio throughout the data using 3D attenuation tools.
- Multiple attenuation – identification of multiple generators through forward modelling and VSP analysis. Attenuation using state-of-the-art demultiple algorithms including surface-related multiple elimination (SRME).
- Model building – dedicated velocity model building project which made major improvements to the existing model, particularly in the high-velocity chalk intervals.
- Imaging – Kirchoff and wave equation anisotropic imaging algorithms.

A theme of the reprocessing project was to take an image-based approach to making key decisions and parameter optimization. This necessitated the output of a series of intermediate PSDM data volumes at key stages during the processing workflow. These products provided the additional benefit of enabling the geological interpretation to be improved and thereby to better support the well planning process. A total of eight iterations of PSDM volumes were output during the processing workflow. Throughout the sequence, verification was maintained on the position of the seismic events in PSDM depth relative to the well control. This was achieved using a combination of well VSPs, synthetic seismograms and a cross-check by converting time domain PSDM (time) and PSTM datasets to depth using a well-based layered velocity model. This enabled the PSDM products to be used in the depth domain, greatly facilitating both operational and geological model building tasks. Significant uplift in image quality was achieved and specific areas of improvement are highlighted in Figure 15b, d.

Structural model

The structural history of the Jasmine area is discussed under ‘Stratigraphic and structural setting’. A more detailed model is currently being reconstructed at both semi-regional and field scales in order to provide a quantitative analysis of fault seal and compartmentalization factors for inclusion in the Jasmine static and dynamic geomodels.

Depositional model

The Central Graben probably constituted an internally draining basin during the Triassic and in the absence of eustatic control, tectonics and climate were the key allogenic controls on sedimentation. Although broadly semi-arid in character, the Triassic climate is thought to have been variable at a number of temporal and geographic scales (McKie & Williams 2009). Long-timescale fluctuations in hinterland climate are thought to be the controlling factor in the generation of the sandstone and mudstone cyclicity observed at the member scale within the Skagerrak Formation (Goldsmith *et al.* 1995, 2003).

A previously published curve of climatic cyclicity (Goldsmith *et al.* 2003) suggests that the thick mudstone members of the Skagerrak Formation represent relatively wet, lacustrine or swamp depositional environments and that the intervening sandstone members represent a fluvial system that progrades and extends basinward during relatively drier climatic phases.

Goldsmith *et al.*’s (2003) interpretation would require that, during lacustrine (humid) phases when mudstones were developing in the basin centre, the fluvial system would retrograde back to the lake margins due to lake expansion, resulting in large-scale Jonathan or Julius age lake margin deltas and lacustrine shoreface facies being supplied by these high discharge (humid climate) streams. These facies types have not been observed. In summary, the logical sequence stratigraphic extension of the Goldsmith *et al.* (2003) interpretation cannot be matched with current observations and knowledge of facies types and their distributions.

The preferred interpretation outlined here advocates a reversal of the Goldsmith *et al.* (2003) climatic curve in order to better match the facies observations from core, cuttings and wireline log data as evidenced by the following:

(1) Core from the Jonathan Mudstone Member in Jade well 30/02c-J07 contains mudstone interbedded with evaporites and there is no evidence for the development of lacustrine laminites.
(2) Cuttings from the Joshua Mudstone Member in Jasmine well 30/06-07Y and from the Julius Mudstone Member on Jade both contain anhydrite.

The commonly observed symmetrical nature of the Julius Mudstone wireline log character, where the central portion is more resistive, denser and sonically faster, is highly suggestive of a more evaporite-rich, drier phase during Middle Julius times than during the transitional periods with Judy and Joanne Sandstone times.

This climatic re-interpretation invokes a semi-arid playa lake environmental interpretation for the Julius and Jonathan Mudstones, during which times the fluvial system retrogrades and is

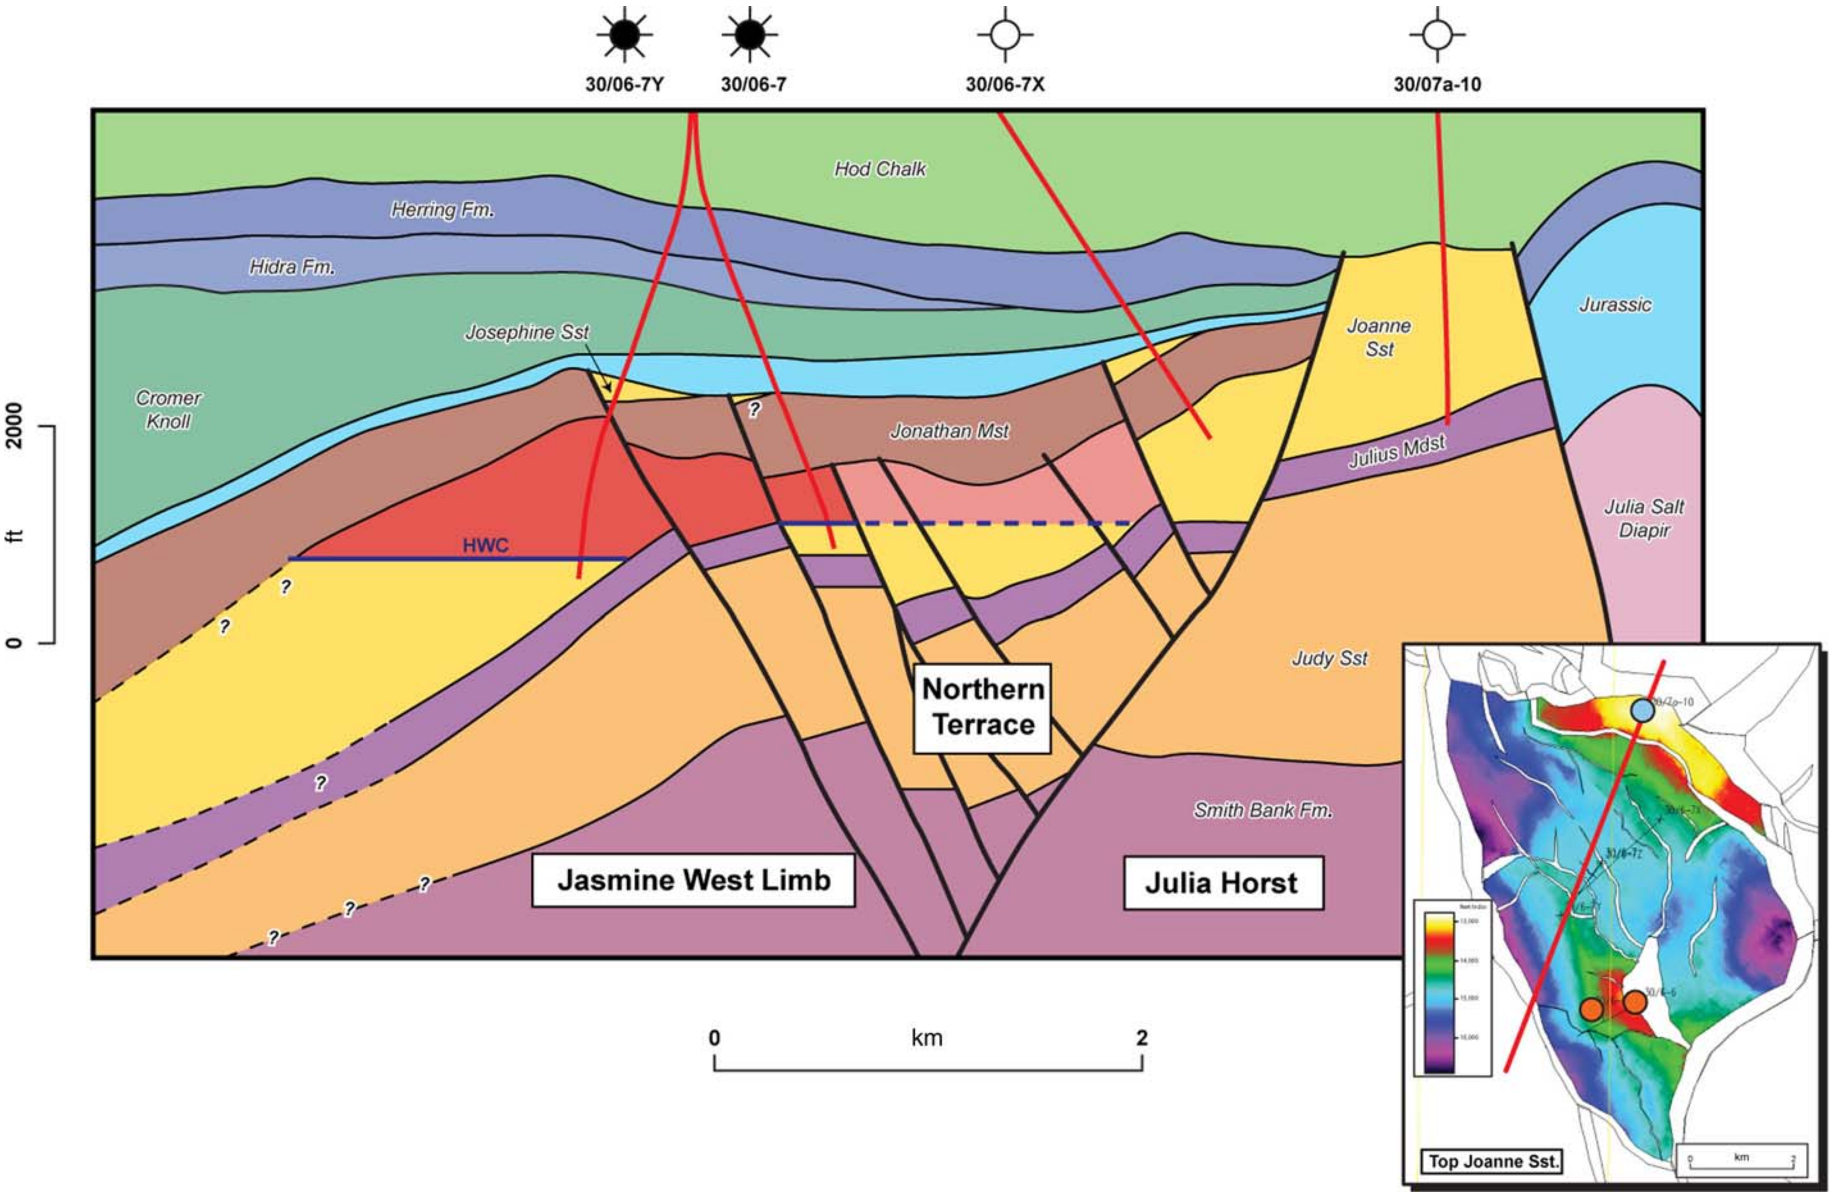

Fig. 13. Jasmine appraisal sealing conundrum.

relatively inactive and incapable of long distance sand transport. In contrast to this semi-arid climatic interpretation for the deposition of thick mudstone members, a wetter sub-humid climate for the Judy, Joanne and Josephine Sandstone Members is envisaged, where higher discharges activate and sustain a competent fluvial system during pluvial climatic phases (Fig. 16). This climatic re-interpretation introduces the possibility that the major switch on of sand supply at the base of the Skagerrak Formation (base Judy Sandstone Member) was, in part, controlled by climatic change to wetter conditions rather than being solely a progradational response to the cessation of active faulting. This major, progradation-driven, basinward shift in fluvial facies strongly suggests that the basal Judy and basal Joanne surfaces represent climatically controlled sequence boundaries.

Intra-reservoir correlation

As standard practice, both biostratigraphic and chemostratigraphic analyses have been performed. There is good agreement between the correlations made independently by the two techniques and this has given increased confidence to the presence and correlatability of the Joanne reservoir in general and, in particular, the 'Middle Joanne' shalier interval shown on the stratigraphic correlation panel (Fig. 17). The Middle Joanne unit is an informal zone that has the stratigraphic status of sub-member. The biostratigraphic pick intimately associated with the middle of the mudstone interval was made in wells 30/06-6 and -6Z. It represents the Carnian–Carnian/Norian boundary and is associated with the *Triadispora* spp. palynological occurrence.

The Middle Joanne shalier interval is only recognized within the Jasmine Field and cannot be readily correlated in a lithostratigraphic sense to either the Jade or Judy Fields. This lack of correlation between the Jasmine and Jade/Judy mini-basins is believed to have significance, and the local nature of this low net/gross interval guides the interpretation of its cause. Rather than appealing to regional scale climate or tectonics, its origin is most likely due to a local change in halokinetic accommodation space (increased rate of salt withdrawal) within the Jasmine pod. The likely controls on sedimentation within the Jasmine reservoir are summarized in Figure 16.

Reservoir zonation scheme

The Jasmine reservoir zonation scheme subdivides the Joanne Sandstone Member into three sub-members, Upper, Middle and Lower, in order to distinguish the Middle Joanne shalier interval from the higher net to gross Upper and Lower Joanne. These informal reservoir sub-divisions are shown in Figure 17.

Top Joanne. The top reservoir surface is a late Joanne age unconformity and the erosion surface is one of the key seismically observable surfaces within the Jasmine mini-basin. Reflector

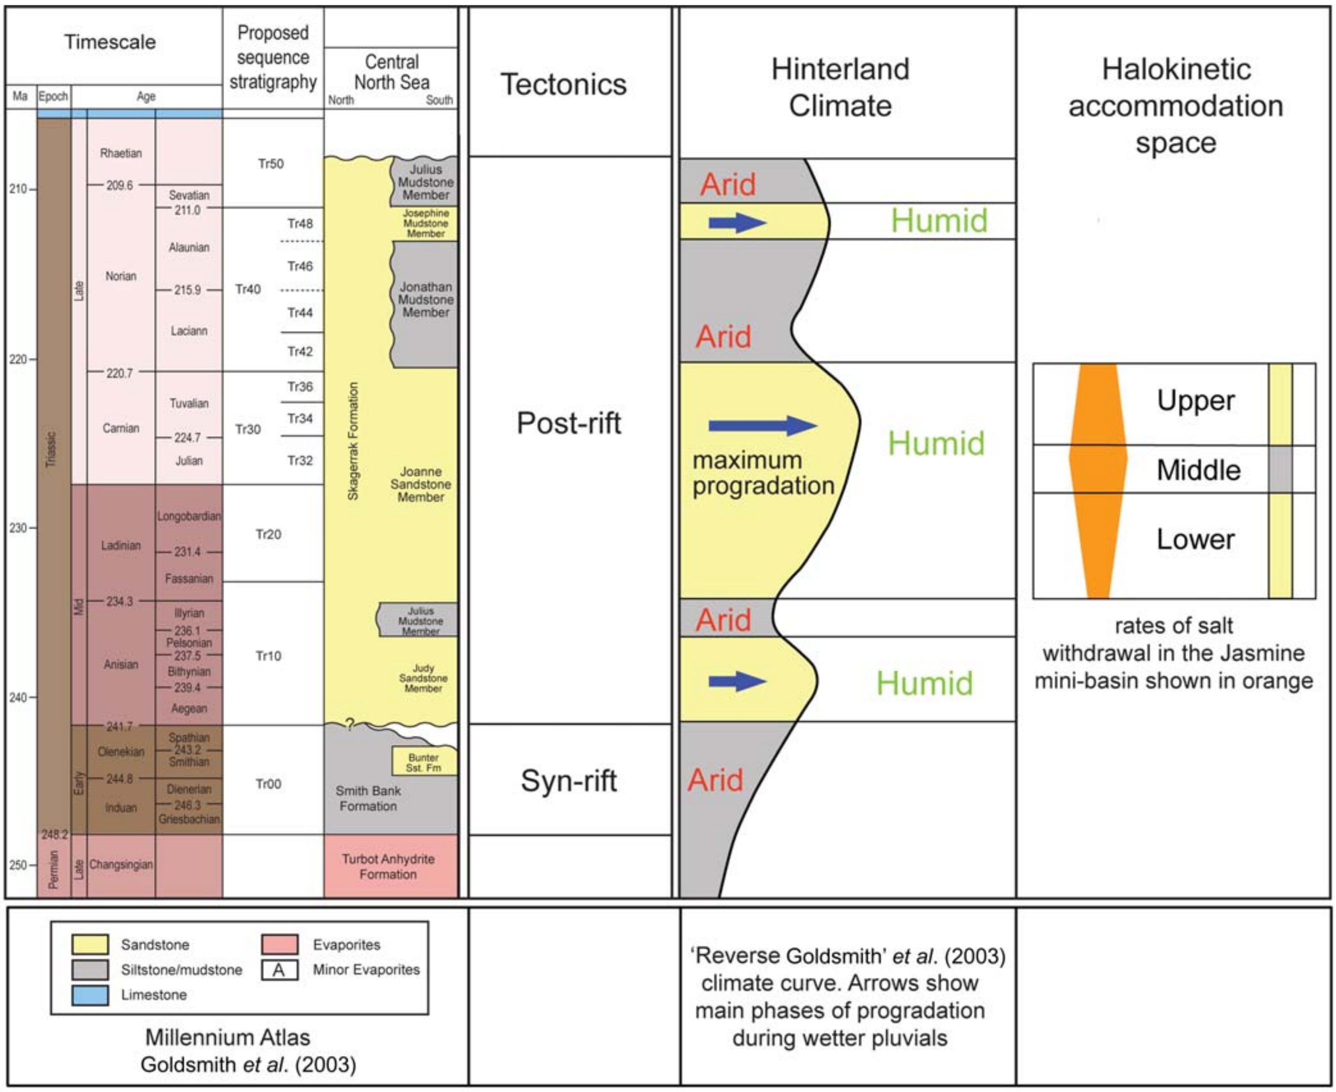

Fig. 16. Summary of controls on Skagerrak sedimentation.

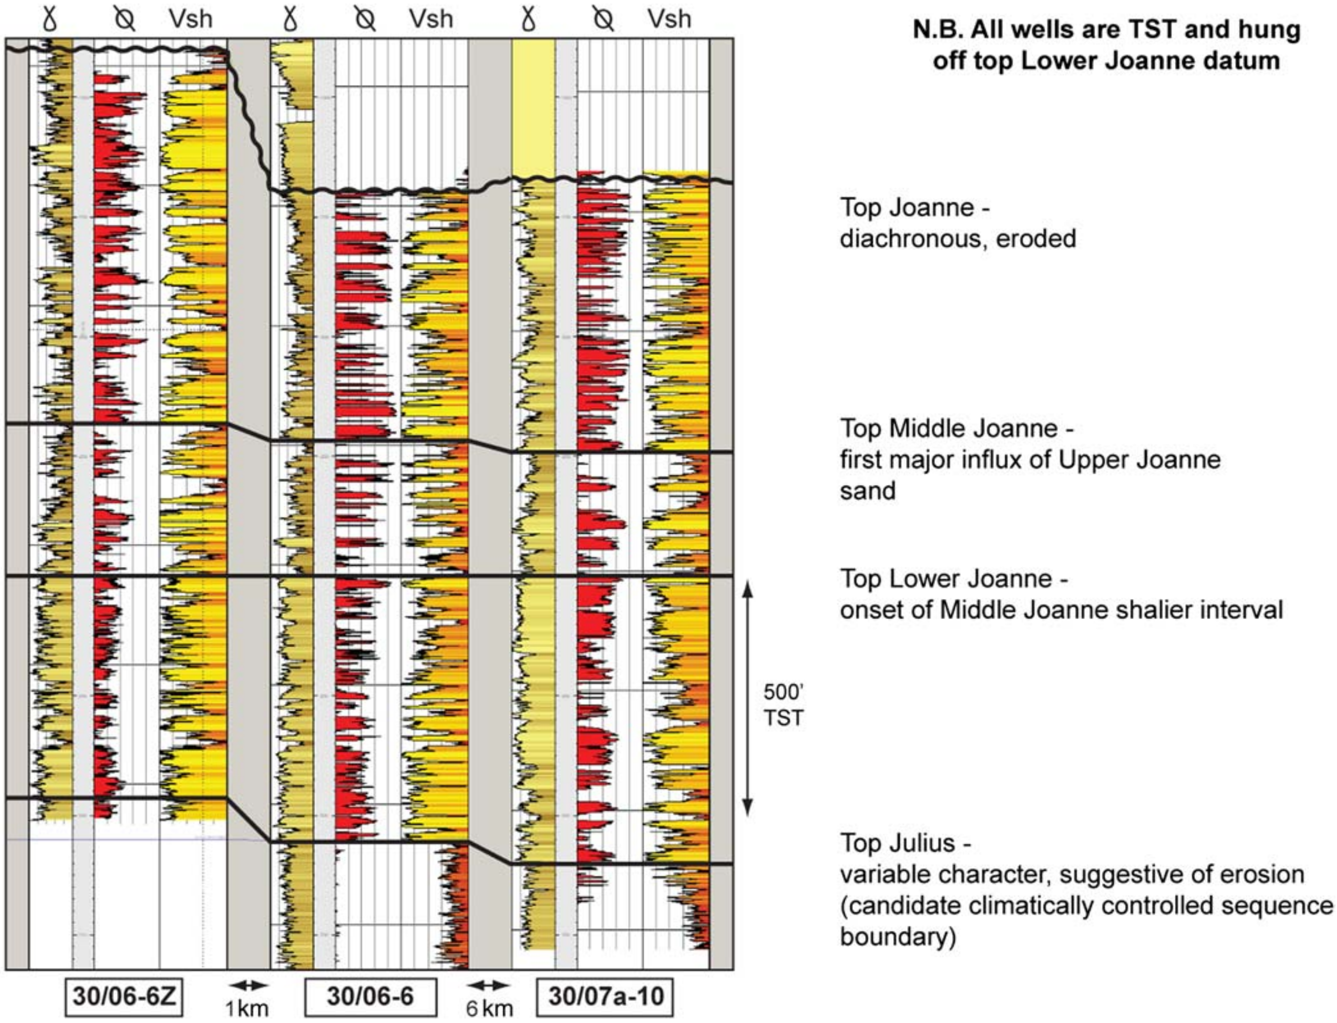

Fig. 17. 30/06-6, 30/06-6Z, 30/07a-10 well correlation panel.

truncation and the angularity of the unconformity are now imaged with increased clarity on the reprocessed seismic data. The causal mechanism behind this erosive pulse is currently not well understood, but one possible interpretation is that erosion was initiated by the grounding of the Jasmine pod. Zechstein salt, thought to have been *c.* 1500 ft thick (Goldsmith *et al.* 2003), may have evacuated sufficiently to ground the Smith Bank Formation on to the Rotliegendes. The initial weld point may have occurred locally in the area of the West Limb crest, allowing the Northern Terrace to continue subsiding, reducing the amount of missing time and ultimately allowing the development of a thicker Jonathan Mudstone.

This interpretation opens up the possibility that the initial grounding point of the pod is coincident spatially with the central, thickest part of the mini-basin, which may have the highest concentration of fluvial channels. This would lead to a predominance of high-quality channel facies within the crestal part of the field, following grounding in the Late Triassic and the Late Jurassic extension and rotation of the turtle back anticline.

In addition to the seismically observed unconformity, chemostratigraphy demonstrates that erosion has truncated the top Joanne, and that this is particularly pronounced at the crest of the West Limb core area. Erosion is less pronounced in the down-flank positions of 30/06-6Z and 30/06-7Y.

The least erosion, and therefore the most conformable relationship, between the Joanne Sandstone and the Jonathan Mudstone, is thought to exist at the 30/06-7 well. The location of this well suggests that the Northern Terrace, in contrast to the grounded West Limb, had already foundered as a relative topographic low at end Joanne times and therefore was not as prone to the end Joanne erosional pulse. The preservation of a ratty, low-porosity, Joanne/Jonathan facies transition zone at the 30/06-7 well location substantiates this model.

Top Middle Joanne. The top Middle Joanne seismic marker has been utilized in the reservoir zonation scheme and the building of the geomodel. In sequence stratigraphic terms, the top Middle Joanne surface is interpreted to be a sequence boundary. This key stratigraphic surface is characterized in wells by a sharp based fluvial channel or amalgamated channel complex, associated with cleaner, high-porosity facies and hails a return to higher net to gross. It is likely that there has been minor erosion across this surface due to a relative decrease in accommodation space. The reworking and migration of the fluvial system into and across itself has apparently increased its reservoir potential.

Top Lower Joanne. The top Lower Joanne stratigraphic surface represents the onset of Middle Joanne sand and shale deposition. The Lower Joanne interval appears to have a log character which is unique within the area. Sand bodies are blockier exhibiting box-car gamma ray (GR) motifs, slightly lower absolute GR API values and higher net to gross in general, possibly due to a greater degree of amalgamation.

Top Julius Mudstone. The Julius Mudstone generates a strong seismic response which has been interpreted with a high degree of confidence and is a key horizon in defining the Jasmine structure (see Fig. 10). The top of the mudstone defines the base of the Joanne reservoir and has been used in the Jasmine geomodel. Figure 17 shows the position of the key stratigraphic surfaces and notes the differences in wireline log character between the Upper, Middle and Lower Joanne.

Reservoir quality

The Jasmine porosity and permeability (poroperm) data broadly overlie the Jade core data from well 30/02c-4. Although not quite matching the highest porosities and permeabilities in Jade (even though Jasmine core was cut roughly 150 ft shallower than the Jade core), permeabilities of up to *c.* 800 mD are observed in the Jasmine core data. The Joanne reservoir sands encountered in the 30/06-7 core are of better quality than the reservoir sands at the same depth in 30/06-6 and 30/06-6Z discovery wells in the West Limb, as determined from wireline log data.

Reservoir quality is known to deteriorate with depth at two scales of observation. A regional trend of degradation in average porosity with depth is observed throughout the analogous fields. Additionally, there is a deterioration with depth down through the hydrocarbon column. A porosity loss gradient of *c.* 5 pu per 1000 ft occurs in sandstones in West Limb wells 30/06-6, 30/06-6Z and 30/06-7Y. This is thought to reflect increased compaction as a function of greater effective stress combined with the diagenetic effects of increasing temperature with depth.

Compartmentalization

Structural compartmentalization plays a significant role in the Jasmine Field as demonstrated by the HWC and pressure differences between the West Limb and the Northern Terrace. There is also a sealing compartment boundary between the 30/06-7 well and the 30/06-7X dry hole but it is not yet known whether this is due to structural or stratigraphic compartmentalization and trapping (the ‘Jasmine sealing conundrum’). Studies are currently ongoing to develop a predictive fault seal model.

The ‘Middle Joanne’ shalier interval may represent an important intrareservoir baffle or barrier due to a subtle increase in the volume of shale. From a reservoir performance standpoint, recognition of this lower net to gross interval is an important element to retain in the static and dynamic reservoir models used to plan the field development. Historical information regarding the lack of vertical communication within Skagerrak reservoirs of the Heron cluster was documented by McKie & Audretsch (2005) and demonstrates from the completion strategy employed that the shales were barriers to vertical flow.

The MDT pressure gradients from the hydrocarbon leg above and below the Middle Joanne in the West Limb are aligned, proving that over geological timescales the interval did not seal two separate fluid compartments. However, it is highly likely that stratigraphic compartmentalization due to the presence of the Middle Joanne shalier interval will be of importance over production timescales. This is a key issue being addressed in development well planning.

Drill stem tests

DSTs were conducted on wells 30/06-6 and 30/06-7Z. In order to reduce the risk of formation damage, both wells were perforated underbalanced.

30/06-6. The planned test programme comprised three main flow periods. A very brief post-perforation cleanup flow and initial shut-in period confirmed the reservoir pressure. This was then followed by a 12 h cleanup flow, an 18 h shut-in period, and finally a 24 h main flow followed by a 36 h shut-in period. Surface and bottom-hole fluid samples were successfully collected during cleanup and main flow periods. No water was produced during any of the production tests.

The analytical results of these data have been used to calibrate the reservoir simulation model. The pressure buildup behaviour in 30/06-6 is similar to that from other J Block wells.

Summary

The Jasmine West Limb discovery (30/06-6 and -6Z) is a major find in a mature area of the Central North Sea adjacent to existing infrastructure. Appraisal drilling (30/06-7Y) on the West Limb has reduced uncertainty of the resource estimate in the core area.

A successful appraisal test (30/06-7 and -7Z) has proven hydrocarbon presence in the adjacent Northern Terrace area. A dry hole penetration (30/06-7X) to the NE has confirmed a single drill centre development concept.

Comprehensive data acquisition has facilitated a detailed reservoir characterization programme, including seismic reprocessing, VSP acquisition, core analysis, biostratigraphy, chemostratigraphy, geomodelling, DST and MDT analyses.

Jasmine is a large and exciting discovery and is one of the most significant discoveries made on the UKCS in recent years. It represents an important resource addition for the Jasmine coventurers and the UK.

Prospectivity of the T38 sequence in the Northern Judd Basin

J. M. RODRIGUEZ,[1] G. PICKERING[1] and W. J. KIRK[2]

Abstract: A seismic amplitude anomaly has been identified at the Upper Paleocene T38 level in the northern Judd Basin and will be tested by the drillbit in 2009. Prospectivity at shallower levels has been largely ignored due to the fact that the main regional seal in the area was recognized to be the T35/T36 mudstones below the Kettla Tuff. Seismo-stratigraphic analysis of the T38 sequence directly above the tuff marker has identified the potential for a new play type, especially adjacent to fault zones where these mudstones are breached, allowing hydrocarbons to migrate from the Upper Jurassic source kitchen into any traps identified above the seal. In this area, the T38 is represented by a series of northerly prograding low-angle clinoforms representing the final marine infill of sediments into the basin from the south. Erosion of top sets in a more marginal setting is observed, along with deposition of basin floor fans at the toe of the prograding clinoforms. The overlying seals are basinal sediments as well as mudstones and siltstones of subsequent progradational sequences. Mild structural modification of potential stratigraphic traps in the Judd Basin occurred during the Oligo-Miocene inversion associated with continued opening of the North Atlantic. Drilling seismic amplitude anomalies in the West of Shetlands area has often been unsuccessful. Therefore, a fully integrated geophysical and geological evaluation was carried out on the T38 anomaly comprising rock physics, amplitude variation with offset analysis, fault seal analysis and the acquisition of a CSEM survey which, supported by a valid geologic model, have reduced the risk from high to moderate. The results indicate that the anomaly has the potential to be sand-bearing and contain oil and gas. It is proposed that an integrated evaluation can reduce the level of uncertainty associated with an anomaly much more effectively and so improve the chance of exploration success.

Keywords: Paleocene, Judd Basin, T38 prospectivity, seismic amplitude anomaly, rock physics, CSEM

The Judd Basin is situated to the west of the Shetland Isles and lies in the southernmost part of the Faroe–Shetland Basin. It is delineated by the Westray Fault to the north, the southern extent of the Rona Ridge to the east and the Judd High to the south. Its western limits lie close to the UK–Faroese border (Fig. 1). Water depths range from 300 to 1000 m and drilling to date has concentrated predominantly in the shallower southern and eastern areas of the basin (Smallwood & Kirk 2005).

Prospectivity in the Judd Basin has mainly focussed on sands within the Paleocene Vaila Formation, specifically the T31 through to T35 (Ebdon *et al.* 1995; Fig. 2), which are the main producing reservoirs in the area (Lamers & Carmichael 1999). These sands produce oil from the Foinaven, Loyal and Schiehallion Fields (Cooper *et al.* 1999; Leach *et al.* 1999) and are the reservoir in the Suilven discovery (Fig. 3). Both Foinaven and Schiehallion fields have stratigraphic and structural elements and are associated with strong amplitude anomalies, which have an amplitude variation with offset (AVO) response. To date, production in the basin has been from below the main sealing mudstones of the upper Vaila and lower Lamba Formations (T35 and T36), the top of which is well represented by the Kettla Tuff marker on 3D seismic data. A new potential play has been identified by the OMV-led partnership above the Kettla Tuff within the T38 clinoforms of the upper Lamba Formation and is defined by a strong seismic anomaly believed to be associated with a toe of slope fan that is hydrocarbon filled.

Many amplitude anomalies previously drilled in the area have been unsuccessful (Smallwood & Kirk 2005; Loizou *et al.* 2008). The object of this paper is to discuss the T38 play identified in the northern Judd Basin and the various studies which were undertaken in order to reduce the risk on prospectivity.

Stratigraphy

The stratigraphy of the Judd Basin is shown in Figure 2 (Ebdon *et al.* 1995). Many of the wells drilled in the area only penetrated Cenozoic sediments. A few wells which have drilled deeper into the Jurassic and basement were located on structural highs. Well 204/15-2 drilled into Basement on the southern part of the Nave High and identified 234 m of Upper Jurassic shales, silts and sands with shows indicating the presence of an Upper Jurassic source rock in the eastern part of the area. Well 204/19-1 drilled into the Westray Ridge and encountered basement and thick Jurassic sands with oil shows. In the south of the basin, to the west of Foinaven, there are two wells (204/23-1 and 204/22-1), which encountered basement with oil and gas shows as well as Upper Jurassic shales (Fig. 3).

During the Cretaceous, extension and deposition appear to have been directed NE, away from the Judd area, towards the main part of the Faroe–Shetland Basin. As a result the Cretaceous is relatively thin. However, by the Cenozoic, extension and sedimentation had also migrated westward. Strongly influenced by the underlying Cretaceous topography, the basin had become a focus for thick aggradational sequences from the Scottish-Shetland mainland, which was undergoing uplift due to extensive volcanism. The geometry of the Judd Basin was asymmetric with the main depocentre located in the west, affected by significant syn-sedimentary growth on the hanging wall of the Westray Fault within the Faroese sector. Early deposition was focussed in this area with deep water marine sediments (T10–T30s) sourced from the Judd High to the south as well as from the Rona Ridge further to the east. This is reflected in the distribution of coarser clastic deposits in the western part of the basin with predominantly

VINING, B. A. & PICKERING, S. C. (eds) *Petroleum Geology: From Mature Basins to New Frontiers – Proceedings of the 7th Petroleum Geology Conference*, 245–259. DOI: 10.1144/0070245

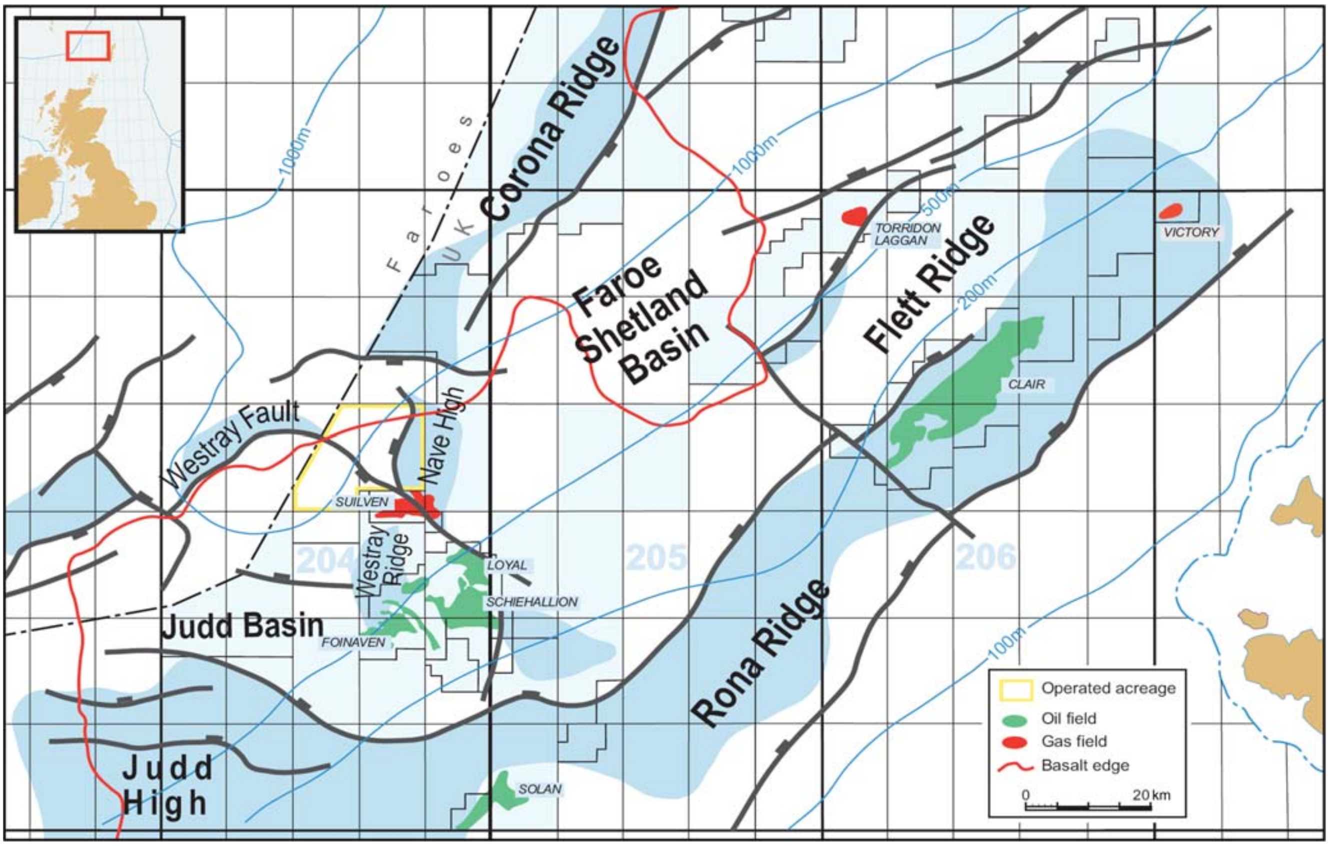

Fig. 1. West of Shetlands area structural elements.

finer-grained sediments laid down further east in a more slope setting.

By the T35, thick mudstones were deposited in the eastern part of the basin, providing the main top seal for the Foinaven and Schiehallion oil producing fields. During the T36 interval, several thick sandy fans, sourced from the south, were deposited into the basin in response to renewed uplift. In the area of interest (North Judd Basin) the Kintail fan is observed thickening towards the NW and pinching out eastwards towards the Westray Ridge. Above the Kintail fan lies the key seismic marker of the Kettla Tuff (T36 Andrew Tuff equivalent). This marks a major change from aggradational infilling to the onset of progradation as additional sediment continues to be shed from the Scottish mainland to the east. In this part of the Judd Basin, progradation is from the south/SE and the T38 interval is represented by a series of predominantly mud-prone, low-angled clinoforms. Several local rises and falls of relative sea-level are recorded during this time as topsets, where preserved, appear to lie at slightly varying heights. The height of the clinoforms indicates that the palaeowater depth was a minimum of 200 m. Toe of slope sands are also observed within the progradational sequences in response to the various relative sea-level falls, for example, 204/18-1, probably as a result of local pulses in sediment input and minor activity along the Westray Fault.

In the northern Judd Basin, erosion of the T38 top sets (204/18-1, Fig. 4) heralds the onset of a more deltaic/paralic environment of deposition represented by sand, mudstone and lignite sediments of the T45-50 sequence (Fig. 2), as the basin progressively fills from the south/SE. Further west, sedimentation interfingers with volcanic lava flows, which take advantage of any topographic lows. After the T50 interval, the basin becomes once again inundated with marine sediments as the basin subsided following ongoing extension further to the NW in response to continued opening of the North Atlantic.

Structure

The main structural trend in the Faroe–Shetland Basin is dominantly NE/SW, derived from an earlier Late Cretaceous rifting phase (Dean *et al.* 1999; Fig. 1). Aeromagnetic data show clearly the main basins and highs within the Faroe Shetland area and the main NE/SW trend of these structures, such as the Corona Ridge and the Rona Ridge (Fig. 5).

In the Judd Basin, the structural grain becomes increasingly east–west, where the NE/SW trend is offset dextrally by the Judd High and Westray Ridge during the Paleocene (Dean *et al.* 1999). These east–west faults not only impact sediment direction into the basin but are also fundamental to trap formation of the Foinaven and Schiehallion fields (Smallwood & Kirk 2005). The NE/SW trend in the northern part of the Judd Basin is also broken up orthogonally by NW/SE lineaments, such as the eastern extent of the Westray Fault. Here it offsets the Westray Ridge to the south from the Nave High to the north (Fig. 1). Close to the Faroes border the fault system becomes increasingly broken up and subsequently alters direction to become SW/NE trending in its western part within the Faroes area. These faults were reactivated transtensionally throughout the Paleocene (Doré *et al.* 1999) and overprint the pre-existing tectonic fabric by modifying and offsetting earlier faulting.

Paleocene lava flows and accompanying sills and dykes are found in the westernmost part of the Judd Basin within the Flett Formation (T40-45) and were emplaced in response to the extensional breakup of the North Atlantic. Finally, inversion of the basin occurred during the Oligo-Miocene along the Westray and Judd Faults in response to extension switching further westwards and to a lesser extent the buttressing effect caused by the impact, on a larger scale, of Alpine compression in western Europe (Doré *et al.* 1999). Plio-Pleistocene effects can also be observed in the

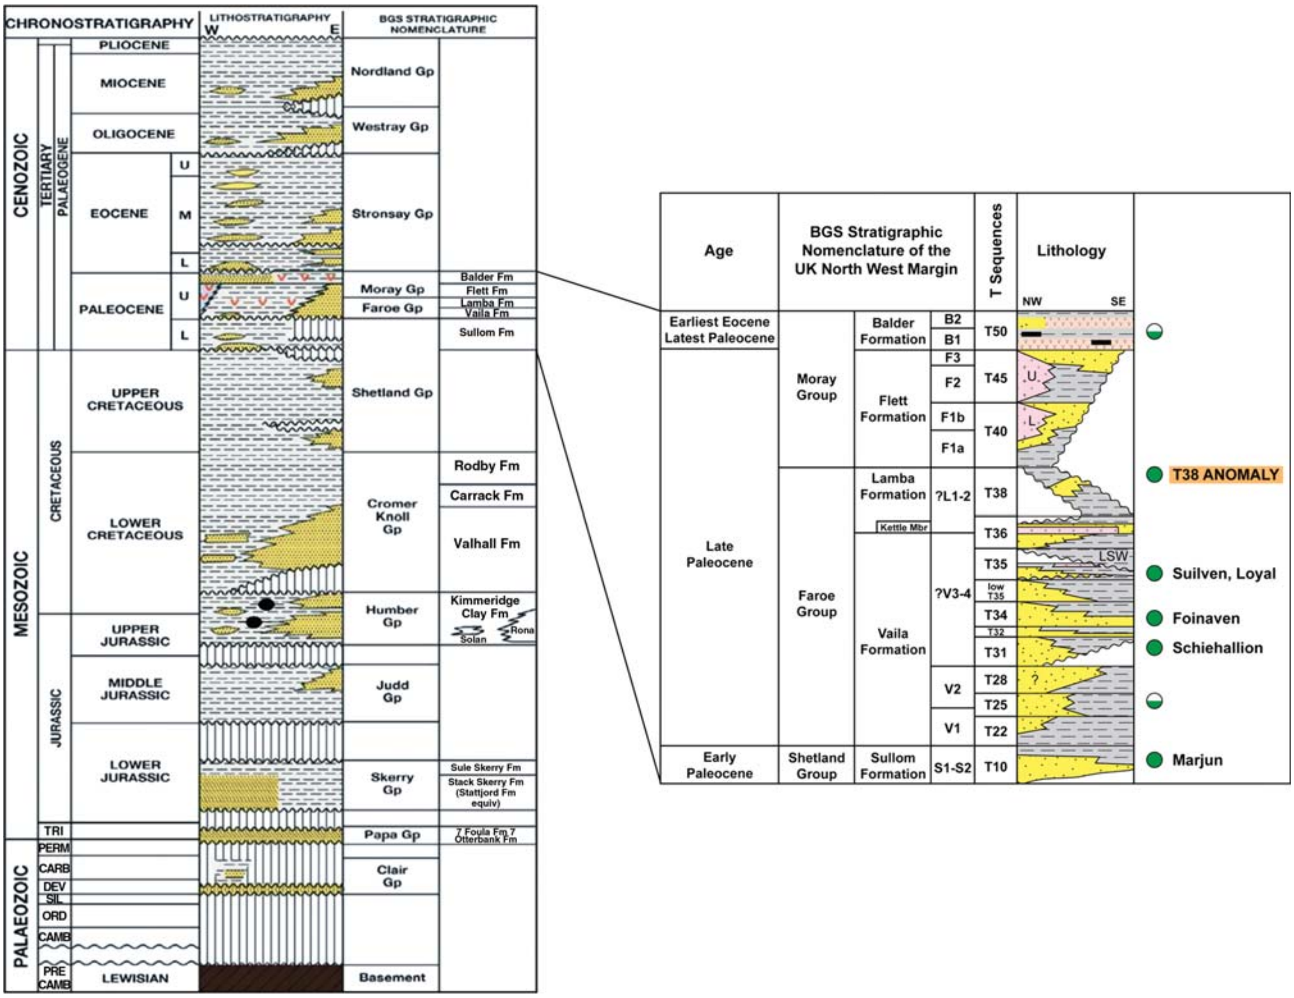

Fig. 2. Stratigraphic column of the Judd Basin. After Smallwood & Kirk (2005).

area at the sea bed attributed to glacial erosion and isostatic adjustment (Fig. 6).

Main prospectivity in the Judd Basin

The main prospectivity in the Judd Basin to date has been within the aggradational sequences of the T31 to T35 (Foinaven, Schiehallion). Lying at depths of approximately 2000–2200 m below the seabed and capped by the main seal in the area (the T35/T36 mudstones), prospectivity has predominantly targeted the pre-Kettla Tuff (T36) sediments. Most wells in the basin contain sand with shows only below this level, with the exception of 204/25a-2, a south Schiehallion exploration well, which has recorded oil from the T50/T45 (Fig. 3) and, more significantly,

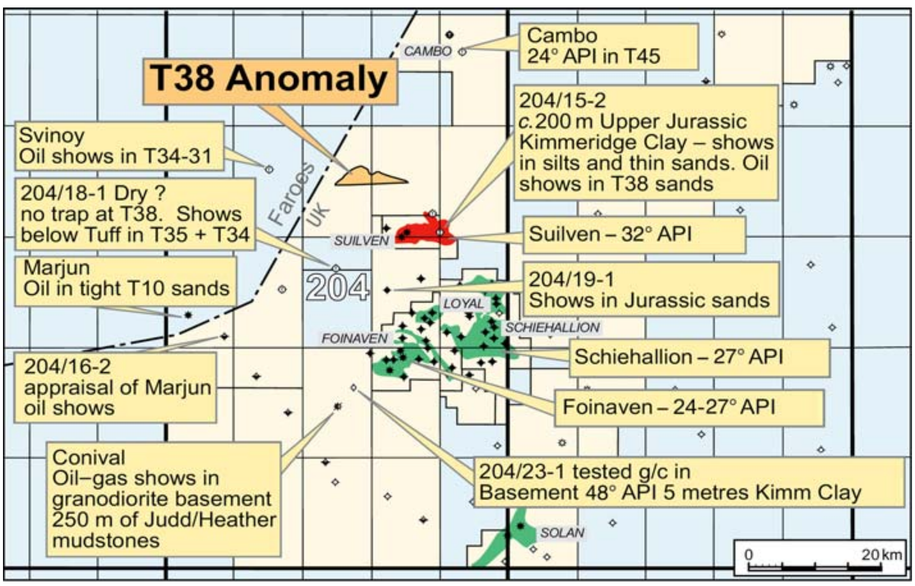

Fig. 3. Hydrocarbon occurrences in the Judd Basin.

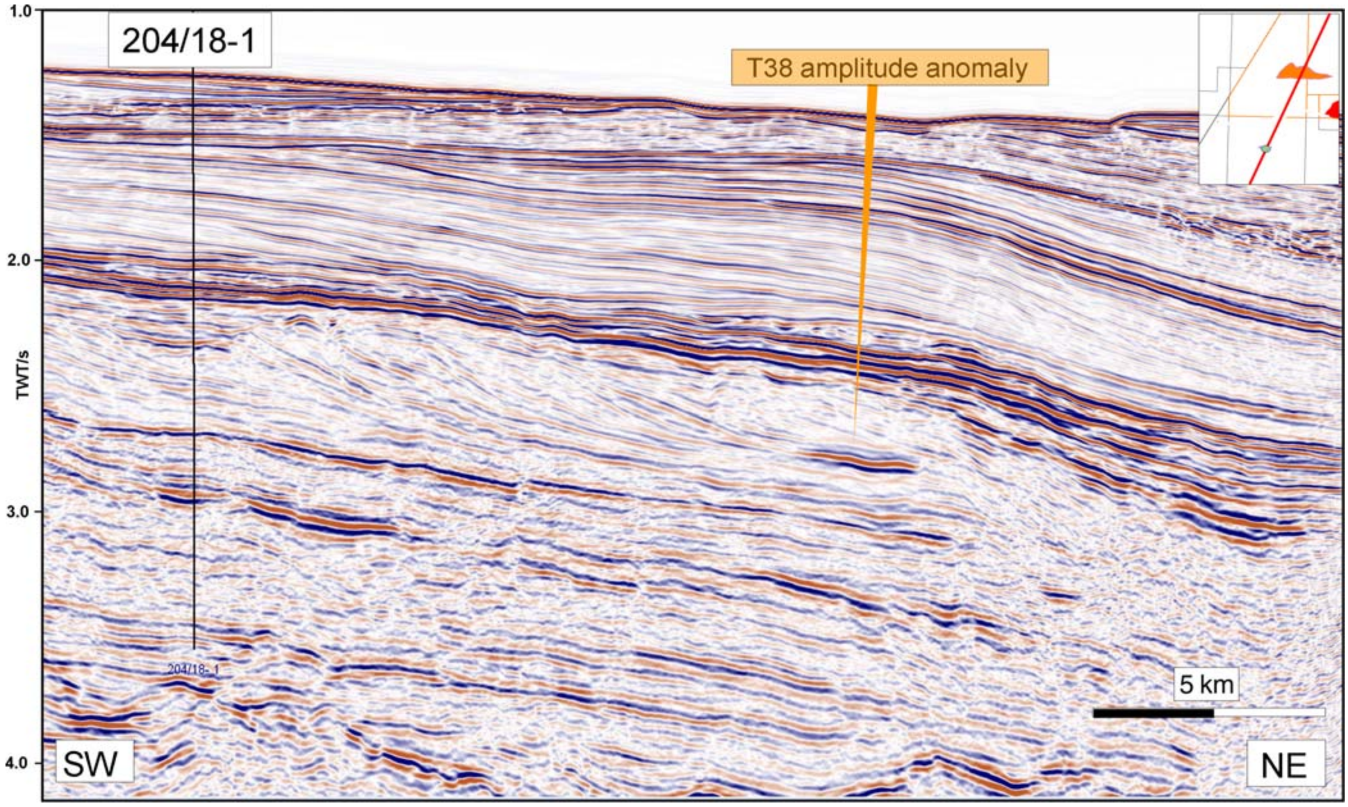

Fig. 4. SW/NE seismic 2D line through the T38 anomaly and well 204/18-1. Red, negative; black, positive.

204/15-2, which has oil shows in thin T38 sands. Both Foinaven and Schiehallion fields are combined structural/stratigraphic traps. Trapping is aided by a general easterly pinchout of the Paleocene sands and by the fact that, during the T25–T35 interval, sands were being deposited in a slope environment, sometimes within confined channels. These fields are represented by amplitudes on seismic which demonstrate a Class 3 AVO effect (i.e. a brightening with offset) in response to the fluid content (and more commonly related to a gas effect) within the reservoir sands. The eastern flank of Schiehallion is defined by the amplitude shutoff and represents the sand pinchout edge. An amplitude shutoff is also clearly observed in parts of the western limit of the field where

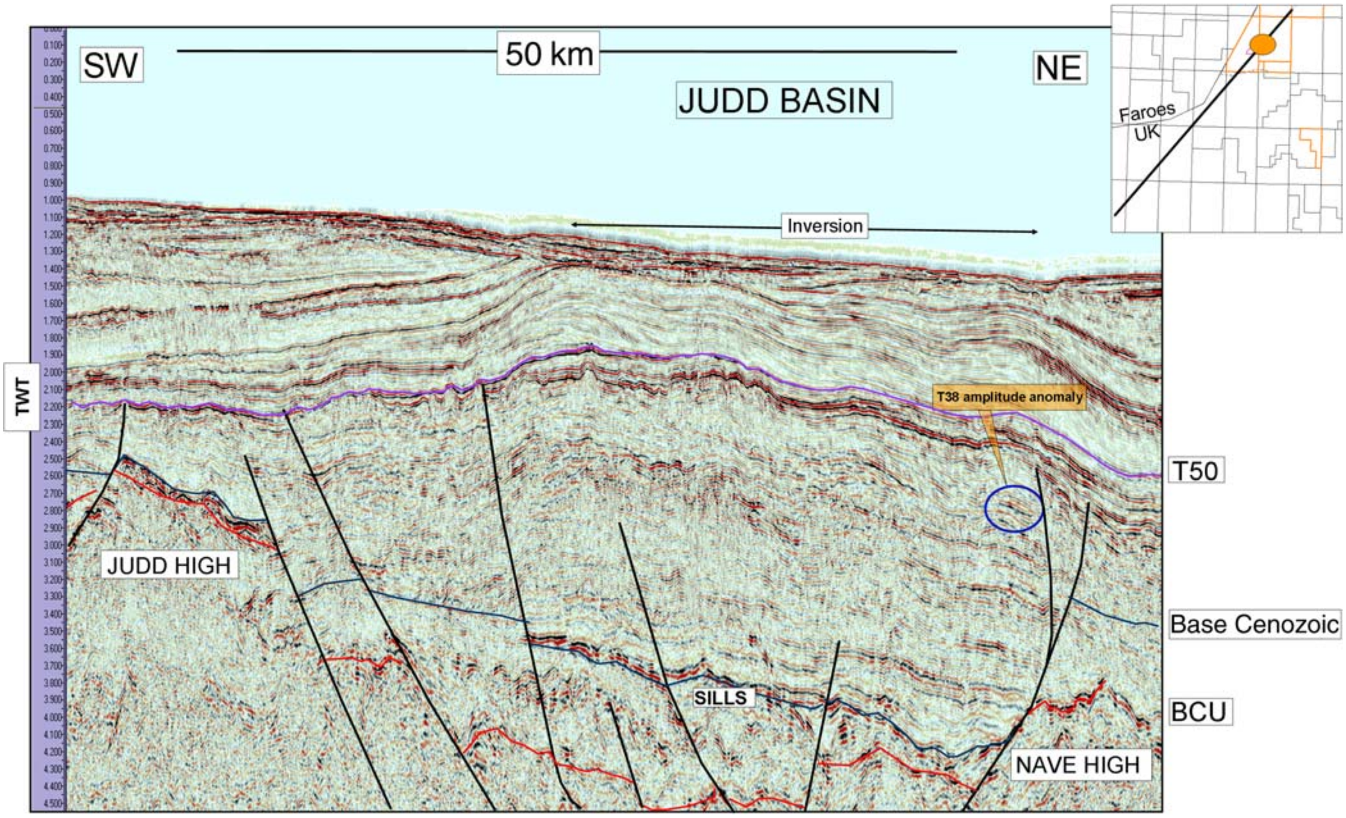

Fig. 6. SW/NE regional seismic line over the Judd Basin showing the basin inversion and the T38 seismic anomaly. Red, negative; black, positive. Courtesy of CGGVeritas.

the T31 sands pass below the oil water contact, confirming the transition from oil to water (Fig. 7).

These oil-producing fields lie in the SE part of the Judd Basin with Foinaven located above the Westray Ridge and Schiehallion further to the east. Understanding the structure as well as the depositional history is key to understanding the prospectivity of the area, especially the sealing, trapping and migration potential within the Judd Basin.

T38 prospectivity within the Lamba formation and reducing the level of uncertainty

Within the T38 sequence of the northern Judd Basin, a significant seismic amplitude anomaly has been identified which has been studied and observed for a number of years by previous operators in the area. Straddling two licences and previously lying mostly within the former ‘White Zone’ (Faroe/UK disputed area) in water depths of over 1000 m, it is only within the last couple of years that this anomaly has been fully licensed to the OMV-led partnership.

Seismic coverage over the area is good, with a 3D seismic survey shot by CGGVeritas in 1998, which has since been reprocessed several times, most recently in 2008. In addition a proprietary 2D 6 km cable seismic survey was shot in 2005 by OMV, which was aimed specifically at the anomaly and tied directly into wells, which lay upslope to the south (204/18-1), and SE (204/14-2).

In the West of Shetlands area, several wells have drilled seismic amplitude anomalies but failed to find hydrocarbons. These were found to be due to a variety of reasons such as the presence of seismic artefacts (such as multiples and tuning effects), tight sands, high-porosity water-wet sands, shale velocity anisotropy and igneous rocks (Smallwood & Kirk 2005; Loizou *et al.* 2008). As a result, several studies have been undertaken to better understand the amplitude anomaly in an attempt to reduce the risk before going ahead to drill in an area of deep water and harsh environmental conditions. It is considered that a more integrated approach to the evaluation of such an amplitude anomaly should reduce the chance of encountering some of these pitfalls.

This paper does not attempt to discuss the techniques but will concentrate on the value the results have had in reducing the level of uncertainty associated with the T38 seismic amplitude anomaly. The following summarizes the results and inferences based on the studies carried out.

Reservoir

As a new play, understanding the environment of deposition is a major key to identifying reservoir presence. The paucity of wells within the northern Judd Basin and the distances away of the few wells from the anomaly imply that the stratigraphy is not fully defined and the possibility of encountering tuffs and intrusives within the target zone is still a concern. However, an attempt has been made to place the anomaly within a recognizable stratigraphic framework.

The analogue well for the prospect is 204/18-1, which lies approximately 12 km to the south of the amplitude anomaly in a marginally more updip location. At the well, there is a 118 m (gross) T38 sand interval, which has an average porosity of 26% and a net to gross (N/G) of 0.8 (Fig. 8), that is interpreted as a base of slope fan at the toe of a series of prograding clinoforms (G. Bertram, pers. comm. 2006). Figure 4 shows a 2D line passing through well 204/18-1 and the T38 anomaly, and demonstrates clearly the similarity in its depositional setting, although the anomaly is slightly younger. The seismic line also demonstrates that the water-wet sands in the well are barely visible on the reflection data.

Regional mapping suggests that the sand is sourced from the south and west from channels which cut down into the top sets of

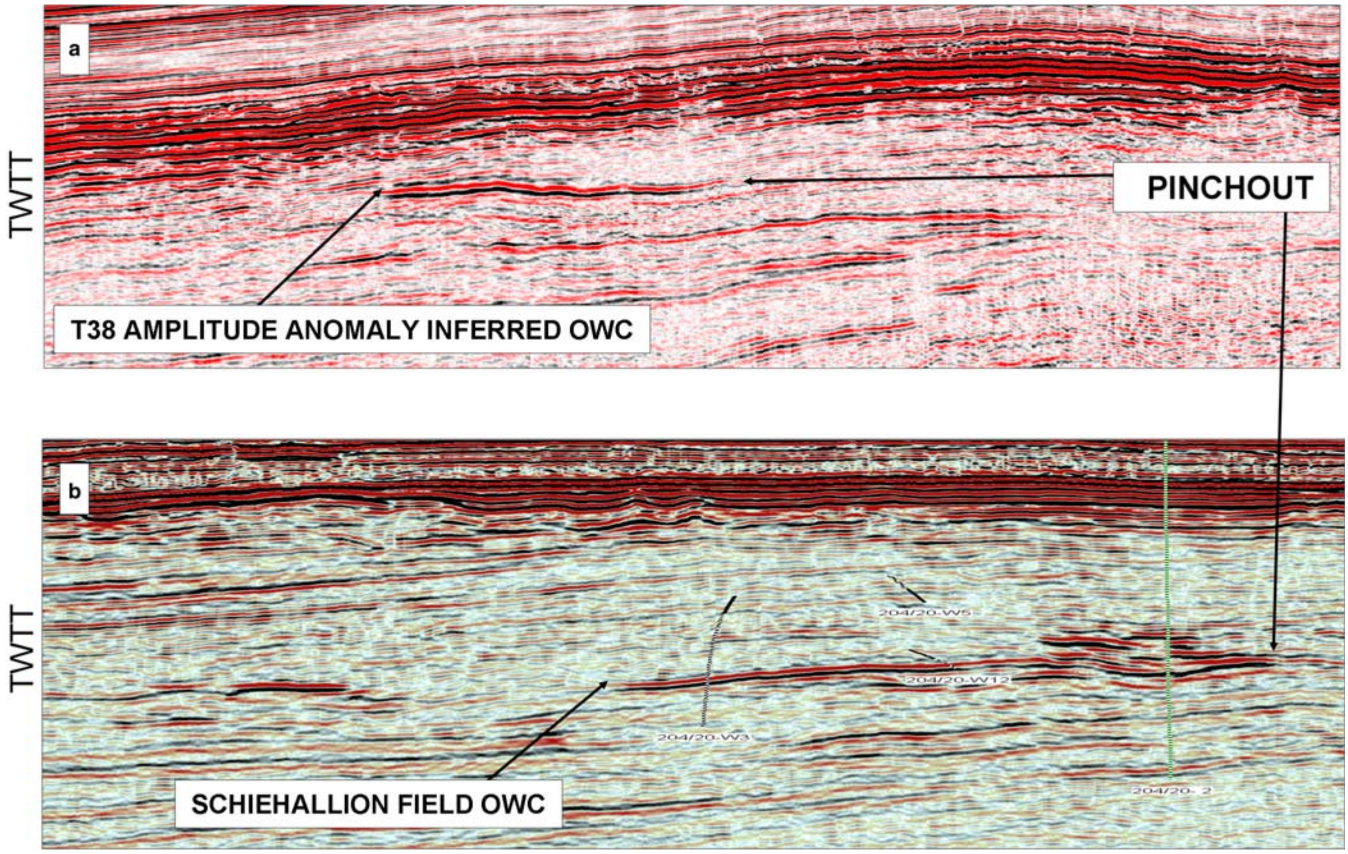

Fig. 7. 3D seismic lines showing the amplitude shutoff at the OWC and pinchout edge. Comparison of (**a**) the T38 anomaly with (**b**) the Schiehallion Field. Red/brown, negative; black, positive. Depths are comparable at approx 2500 m tvdss.

the progrades (such as the one observed in 204/18-1, illustrated in Fig. 4). The interpretation indicates the presence of a sand channel trending NW–SE from the shelf, cutting down into the top sets of the clinoforms. These sands flow into an embayment where its eastern limits are defined by the structural expression of the Nave High and are reworked from the west at the toe of slope (Fig. 9) by basin floor currents. Similar aged sands within a comparable depositional setting have also been observed at the Svinoy well

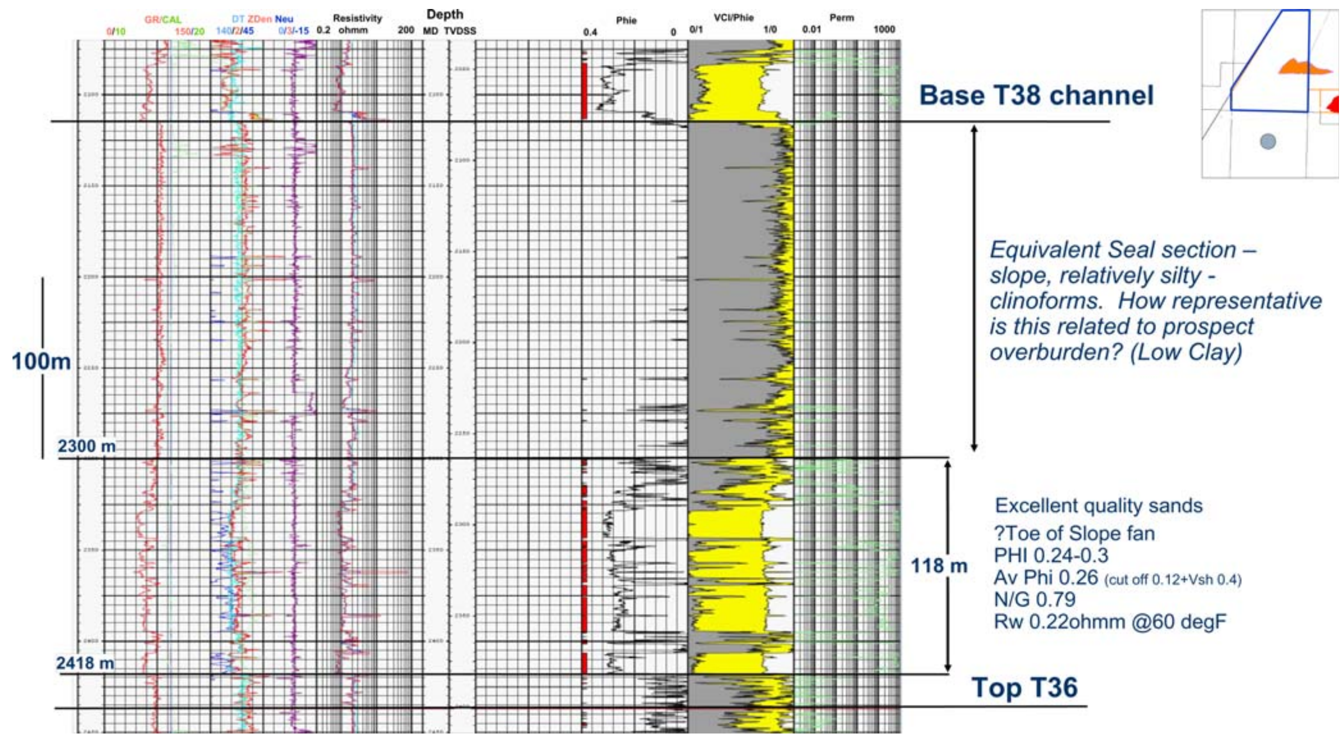

Fig. 8. Well 204/18-1 (reservoir analogue for the T38 anomaly).

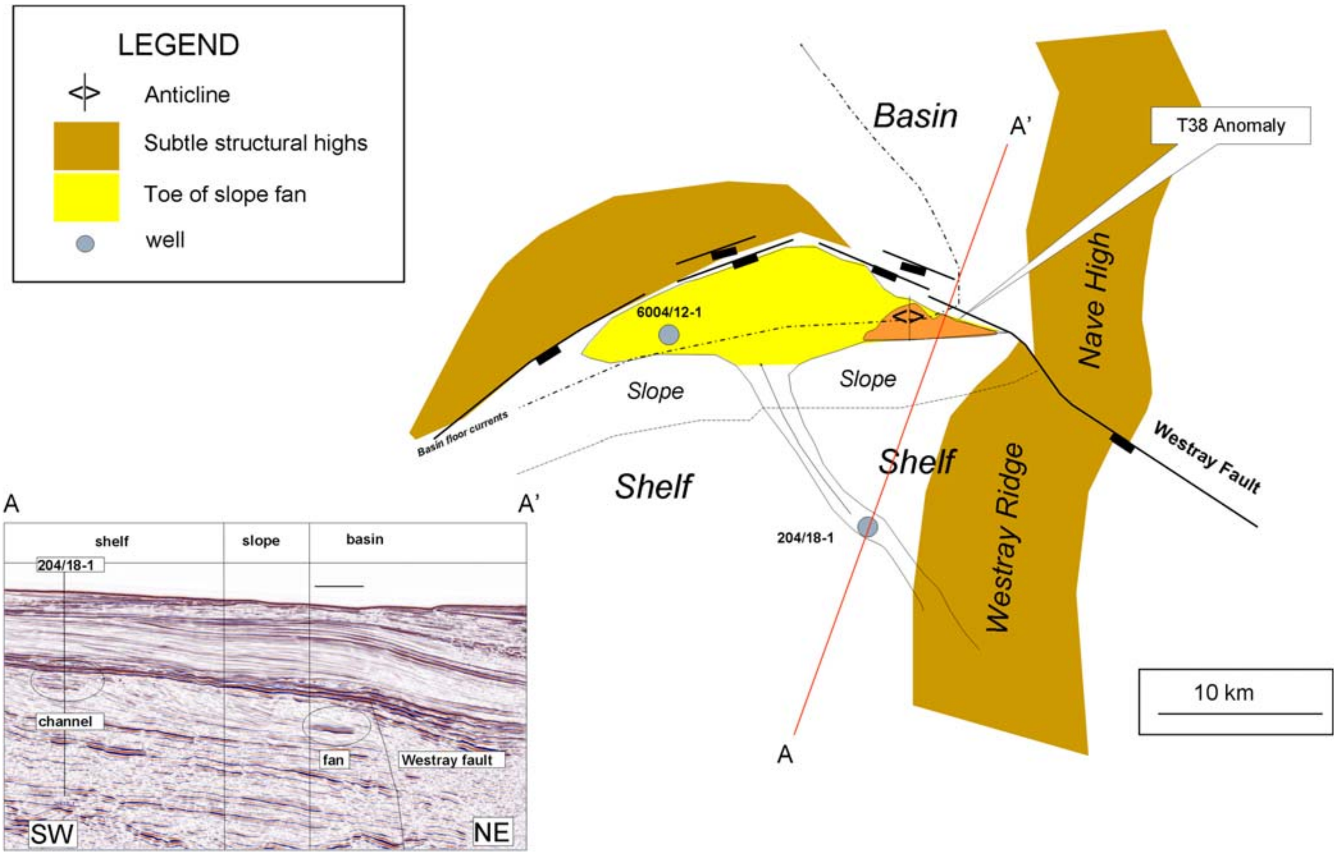

Fig. 9. Depositional concept.

(6004/12-1) further to the west in the Faroes sector. Both the sand in the 204/18-1 well and the amplitude anomaly (or prospect) lie at comparable depths and, therefore, it is considered that the quality of the reservoir will be similar.

The risk that the prospect could be predominantly shale-prone still remains (Johannessen & Steel 2005). However, the Judd Basin is observed to be predominantly sandy away from the slope. The presence of the T38 sand in the 204/18-1 well, in a similar depositional setting, and at Svinoy, as well as the observation of significant later T38 channels downcutting into the top sets, supports the presence of sand input at this time. The top sets also appear to be relatively flat, suggesting that the shelf would not have acted as a barrier to these sands being deposited into the basin.

Trap

The prospect can be mapped as a seismic event which has a soft kick, as demonstrated by detailed wavelet extraction and well-to-seismic ties from nearby wells. Identified as a combination trap, the prospect has a three-way dip closure with a stratigraphic pinchout to the south.

The seismic amplitude anomaly is strongly conformable with structure to the west, where the sand is interpreted to be thicker. This is consistent with a model of sands originating from a westerly direction (Fig. 10). The anomaly conformance with structure is not as evident to the north and east. There are several explanations for this. Surface channels over the anomaly may cause the amplitude event to break up to some degree. However, it is believed that the main cause is due to the sands pinching out in response to the presence of the Nave High – the northerly extension of the Westray Ridge. Comparisons with Schiehallion, approximately 30 km to the SE, can be made with respect to the pinchout of the sands and the resulting amplitude switchoff (Fig. 7), as well as a clear amplitude with depth shutoff observed in the NW segment of the field, where sheet/amalgamated channel sands pass below the oil–water contact (Leach *et al.* 1999).

Seismic amplitudes hint at the presence of the possible sand below the oil–water contact towards the west of the anomaly. This is consistent with the assumption that the source for the sands is controlled from a channel further to the west of the anomaly.

The southerly limit is abrupt. Although it may be possible to invoke a minor southern fault over part of the anomaly, the amplitude shutoff against the toe of the clinoforms is predominantly stratigraphic. The low-angle progrades imply the presence of fine-grained sediments, which act as side and base seals to the inferred sand body.

Hydrocarbon sourcing

Although there are some minor hydrocarbon shows identified below the regional T35/T36 seal, the T38 analogue sands in the 204/18-1 well were found to be dry. Figure 3 shows hydrocarbon occurrences of released wells in the Judd Basin. From the distribution of hydrocarbon shows, it can be demonstrated clearly that there is an extensive petroleum system working within the whole of the Judd Basin. As discussed, the majority of the hydrocarbon occurrences are reservoired within sandstones below the regional seal (the T35/T36 mudstones). However, as mentioned earlier, there are a few wells where hydrocarbons have migrated up into shallower reservoirs, such as in the 204/25a-2 exploration well, which was drilled in the southern part of the Schiehallion field. Most importantly, well 204/15-2, which drilled through the Westray Fault, encountered a thin 5 m T38 sand with significant oil shows and supports the model of charging proposed in this paper.

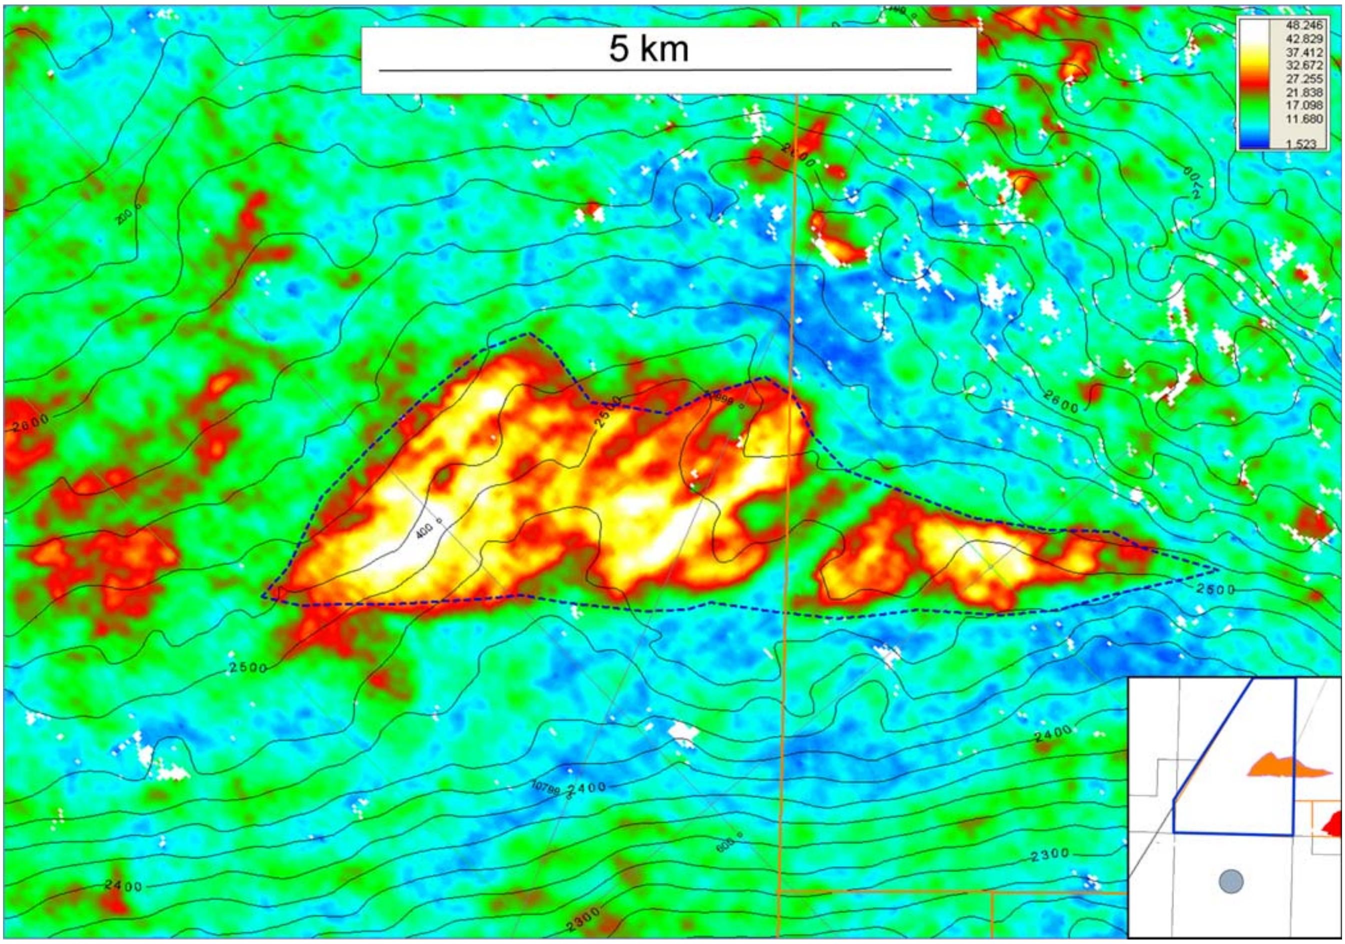

Fig. 10. T38 seismic anomaly: map showing amplitude variation and depth. Contour interval: 20 m. Courtesy of CGGVeritas.

A study undertaken in order to understand the potential sourcing of hydrocarbons into the anomaly focused specifically on how the Westray Fault system could impact migration. The main Westray Fault lies directly to the north and east of the prospect. An important difference between the T38 prospect and the T38 sand body at the 204/18-1 well is that the latter does not appear to be plumbed in to a fault system, which has broken through the regional seal. Additionally, minor antithetic faults associated with the Westray Fault can be observed clearly on seismic to penetrate the prospect without apparently breaching up into the overlying T45 sediments (Fig. 11). It is inferred from observation that the equivalent sands within the 204/18-1 well are either not plumbed in to a migration system and the regional seal is effective, or the sands have no updip seal. However, without further investigation, it is uncertain why these sands failed to trap hydrocarbons.

The Judd Basin is a predominantly oil-prone basin, unlike the Flett Basin further to the NE, which is gas-prone due to the greater depth of burial of the Upper Jurassic Kimmeridge Clay source rock. However, there have been various studies that have tried to accommodate the overwhelming presence of oil discoveries and the occasional presence of gas chimneys in the Judd Basin to one which has been modelled to be predominantly generating gas. The *motel* (Lamers & Carmichael 1999) and the *whoopee-cushion* (Iliffe *et al.* 1999) models are two which have tried to resolve this conundrum. Other models (Carr & Scotchman 2003; Carr *et al.* 2009) have tried varying the amount of overpressure as well as the temperature in response to basin history and the effects of extension, volcanism and inversion. A modelled pseudo-well just to the south of the T38 anomaly in block 204/13 predicts the Kimmeridge Clay source rock to be late mature for oil generation (Carr & Scotchman 2003) based on extensive retardation caused by highly overpressured source rocks.

Suilven, an oil and gas discovery in the T35 interval, also lies directly south of the Westray Fault but unlike the T38 anomaly is situated close to the eastern part of the Nave High. Normally, hydrocarbons require sand-to-sand juxtaposition against the fault in order to migrate into the highest sand below the regional seal (Clarke *et al.* 2005). It was modelled that hydrocarbons could readily migrate into the T35 reservoir by this process, as the Paleocene sediments below are predominantly sandy.

Conversely, it was found that, although the fault system penetrated the base of the T38 amplitude anomaly, it appeared that the regional seal was not breached. There was insufficient throw to provide potential sand-to-sand juxtaposition for hydrocarbon migration based on this model. However, by modelling parallel flow, that is, an open Westray Fault system which acts as a conduit to flow, the T38 anomaly could be charged. The history of this fault system is complex, but it is not inconceivable that part of the network could become capable of allowing parallel flow during the transtensional–transcompressional phases associated with the Oligo-Miocene inversion of the basin. The presence of oil in thin T38 sands in well 204/15-2 (Fig. 3) supports this model.

Interestingly, it was also observed that Suilven located just to the SW of the Faroe–Shetland Basin was in a favourable position to be additionally sourced from the NE. This could explain why the discovery is one of the few accumulations in the area that is predominantly gas with oil, where hydrocarbons are sourced not only from the gas-prone Flett area but also from the oil-prone Judd Basin.

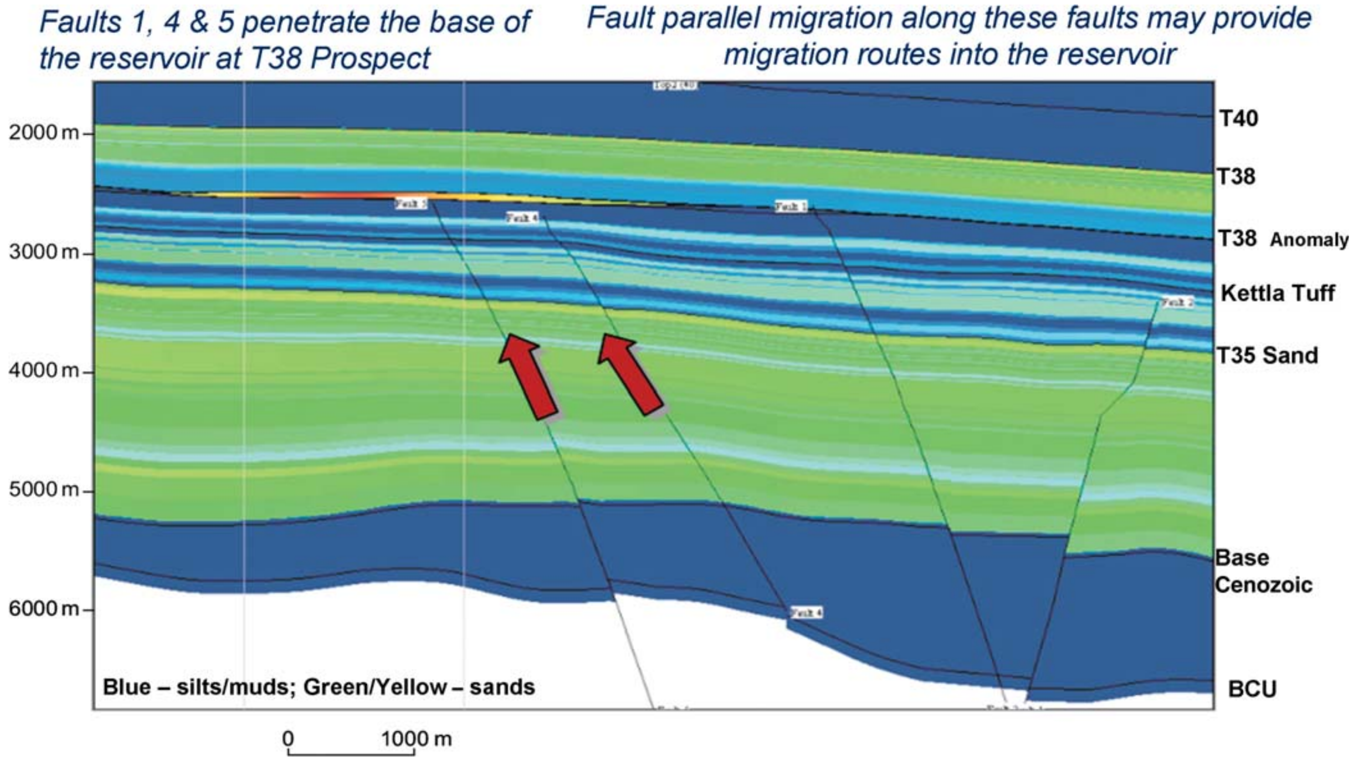

Fig. 11. Oil Migration model: fault parallel migration into the T38 anomaly along the Westray Fault system.

One observation from the study was that, if the fault system became open, then the anomaly could easily be charged by the faults that penetrated its base. It is also possible that the regional seal may be breached to the north of the prospect, for example, downdip from the anomaly in an area not covered by the study. One point that appears to tie in with the rock physics work was that, if the anomaly was no longer plumbed in to the migration system, then the likelihood of the fluid phase being oil was greater.

Seal

The sealing capacity of the overburden comprising the clinoforms and the integrity of the pinchout edge were considered major risks to the success of the prospect. A further study was undertaken on the overburden based on cuttings and sidewall cores from three local wells, 204/18-1, 204/14b-1 and 204/14b-2. In addition, a core from comparable mudstones was used to calibrate the rock strength as some of the sidewall cores had degenerated and cuttings were not suitable. The lithology of the clinoforms from cuttings and sidewall cores was a mixture of siltstone with minor mudstone. Very few silty sands were observed, which supported the assumption made from the seismic that the clinoforms were predominantly composed of finer grained sediment (G. Bertram, pers. comm. 2006).

The results of the study were encouraging. Two clay types were modelled: low clay (predominantly siltstone) and high clay (predominantly mudstone). In the case of the cap rock comprising predominantly silt or low clay, the model indicated that a 150 m column of relatively heavy oil (*c.* 25° API) or a 40 m column of gas could be trapped at the T38 anomaly. In a mudstone or high clay case, the column height increased to a 1000 m column of heavy oil or 270 m column of gas. This latter case is unlikely as the column mapped from the crest to the interpreted shutoff is in the order of 90 m and the crude is anticipated to be relatively heavy, of the order of around 25° API, similar to the Foinaven and Schiehallion fields, which lie at comparable depths below the seafloor. Therefore, the results of the analysis indicate that the top seal could provide sufficient sealing potential for the T38 anomaly and these results can be supported by the column represented by the anomaly observed on the seismic. Furthermore, it was also observed that none of the samples analysed reached the critical brittle index of 2, indicating that the cap rock is unlikely to be subject to brittle fracture and thus be less likely to continually leak hydrocarbons through fractures.

Rock physics analysis

As the interest in this prospect was initially driven by the existence of the seismic amplitude anomaly, it is critical to understand the nature of the seismic response and to try and match it with possible lithological and fluid scenarios. The methods used for this can be characterized as either inversion – using the seismic reflectivity data to create attribute volumes, which can then be related to likely geological cases – or forward modelling – taking a geological case and modelling seismic data and comparing the results to the real seismic. The two approaches have been used for the area, on both re-processed 3D seismic and the longer offset 2D data acquired by OMV. It is beyond the scope of this paper to discuss all the work in detail; however the key results can be summarized:

(1) the seismic amplitude anomaly is present on both the 3D and 2D data and is maintained in the re-processing, so the risk that it is an artefact of either acquisition or processing is very low;
(2) the AVO behaviour of the seismic anomaly is similar on all the datasets; this is an anomaly that has weak near-stack response and strong far-stack response, with any downdip extension of the 'body' having a weak seismic response on both stacks;
(3) the polarity of the anomaly is best modelled by a decrease in impedance with a low Poisson ratio, thus reducing the risk that the cause is either volcanic (high impedance) or a coal (high Poisson ratio).

With these properties in mind, a sand body, probably hydrocarbon-filled, seems a reasonable explanation. A key aspect is whether the anomaly represents the entirety of the sand body, or whether it extends downdip as an aquifer, which appears to be more likely from both the seismic evidence and geological context. If the anomaly represents the entire body then the nature of the fluid is more difficult to determine. If the body extends downdip then the body must give rise to low amplitude when water-filled, with a high far-stack response only when hydrocarbon-filled. This makes conventional gas saturation less likely, as this would have a high (soft kick) near-stack response if the water response is weak in the same sand, but does not preclude a low saturation (*c*. 10–15%) gas. However, a low saturation gas accumulation would not give rise to any resistivity anomaly on the controlled-source electromagnetic (CSEM) survey (see next section). The proposed model of an oil-filled sand body would produce a CSEM anomaly and fits with the seismic observations.

More detailed modelling of such an oil-filled sand body was carried out to try to match the more detailed amplitude variations. These suggested that there were some tuning effects, due to both thinning sands updip and with the contact proposed as the cause of the amplitude 'shut-off' downdip. They are shown in Figure 12, with the background properties extrapolated from the 204/14-2 well and the prospect geobody based on the previous inversion outputs adjusted to optimize the match with the seismic response. A contact was created in the geobody to provide an oil and water leg using standard fluid substitution techniques. The principal seismic used was the OMV 2-D data, which both tied the 204/14-2 well and provided better offset data due to the longer cable used in the acquisition. The modelled and real data from near- and far-angle stacks are shown in Figures 13–17. This shows that the model correctly predicts the low near-stack response in both the oil and water legs of the geobody, with an increase in the far-stack response for the oil leg. The more detailed amplitude match was improved by varying the thickness of the geobody within the oil leg to create a larger degree of tuning. This gave the increased far-stack amplitude approaching the crest of the geobody, and also the secondary increase near the contact where tuning with the OWC occurs. It was also confirmation that a variable sand thickness was present over the structure and that resource estimates needed to take this into account.

CSEM survey

A two-line CSEM survey was acquired over the T38 anomaly with one of the lines passing through the Suilven discovery. To optimize the results, these lines were positioned over the widest part of the anomaly to get the best coverage of data. The method used to analyse the results required that a background model be first built based on the lithology and general structure along the lines chosen. Resistivity values for the expected lithologies were input into the model and, therefore, some assumptions had to be made, especially in the shallower sections where no well data were available. The structure is also quite complex and the model had to deal with shallow seafloor wedging as well as the anticline in the northern part of the Judd inversion. Any resistive anomalies obtained from the CSEM-acquired data which were not part of the background model were highlighted and investigated.

Results from the CSEM line, which also passes through the Suilven discovery, are shown in Figure 18. The results indicate an anomaly at the T38 prospect and to a lesser extent over Suilven. It is possible to observe an effect from Suilven, but this is quite weak due to the fact that the analysis was focussed on the T38 seismic anomaly, which lies approximately 600 m shallower. In addition, the T35 oil- and gas-bearing sands at Suilven have relatively low resistivity readings, not getting much above 20 Ω m and reflect poorer quality reservoirs with correspondingly higher water saturations.

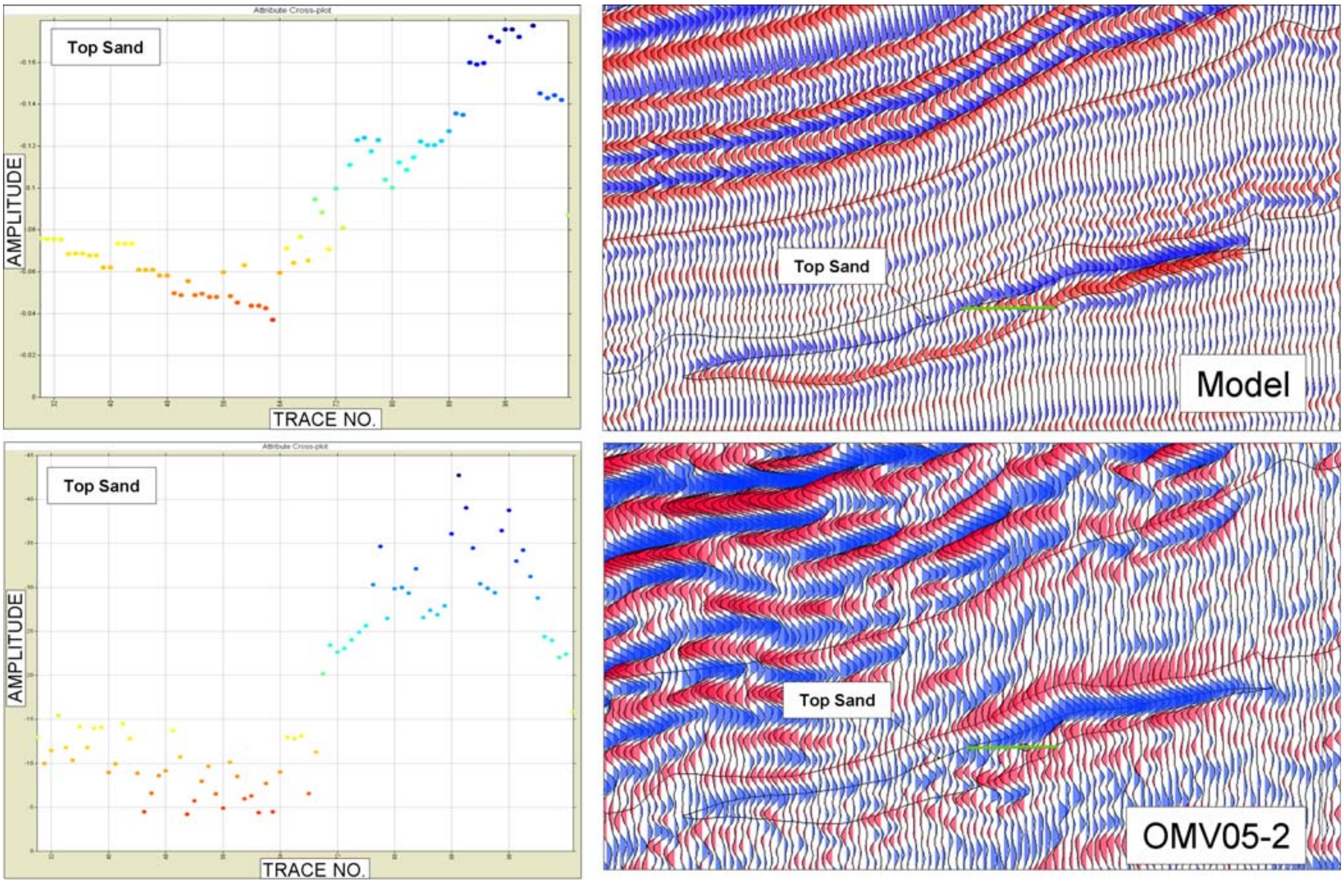

Fig. 17. Top sand amplitude – far stack; optimized thickness model.

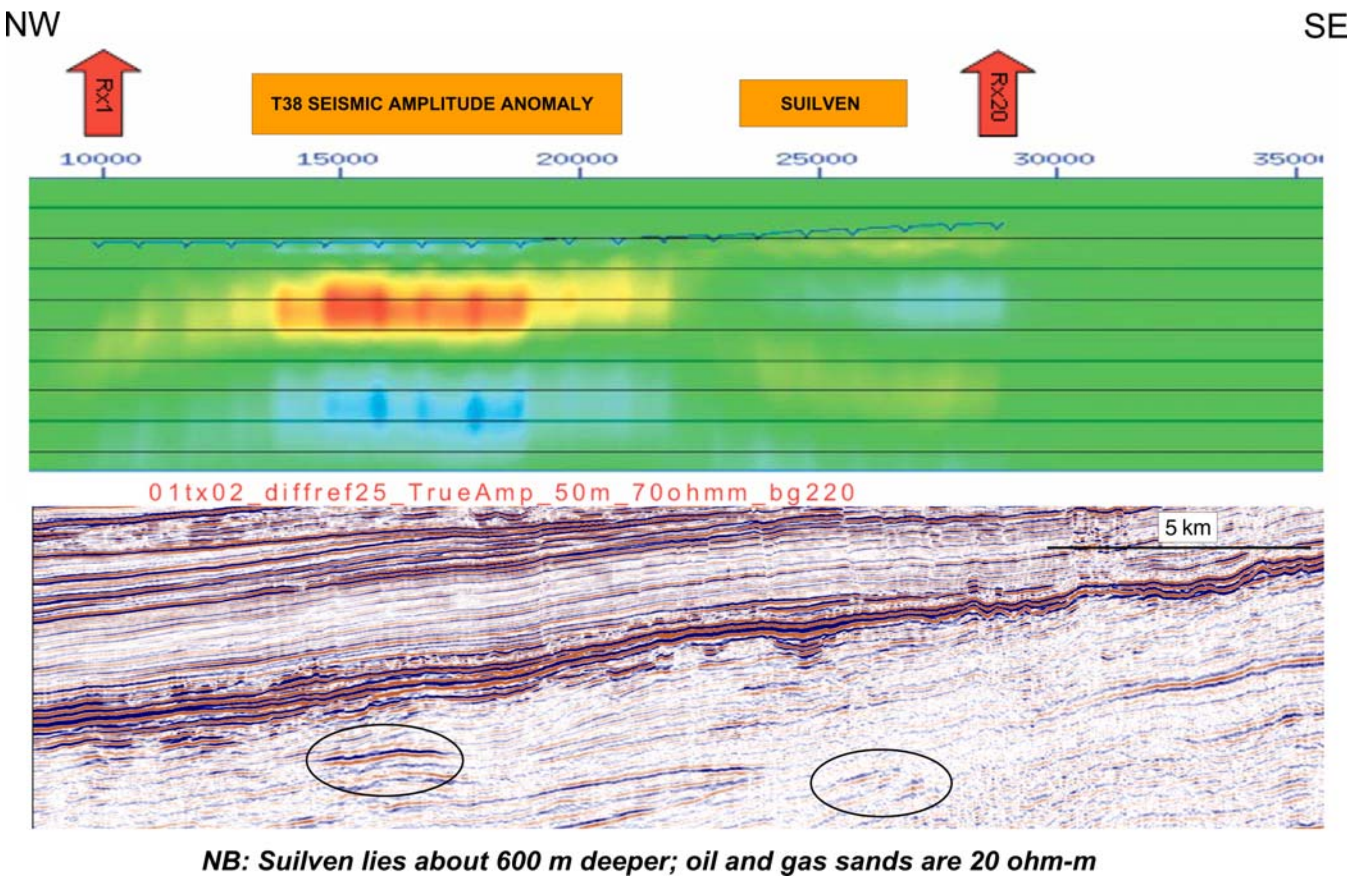

Fig. 18. NW/SE CSEM line over T38 anomaly also showing Suilven. Courtesy of CGGVeritas.

The results from the CSEM analysis are encouraging and may indicate the presence of a highly resistive, hydrocarbon-bearing sandstone with a thickness of 50 m and a resistivity in the order of 70 Ω m. A thicker hydrocarbon-bearing sand with a lower resistivity would also be a valid result from this analysis.

Discussion

The various studies discussed in this paper each appear to support the possibility that there are hydrocarbons present within a T38 sand body and that the hydrocarbon phase is most likely to be oil with the potential for a gas cap. Interestingly, none of these studies has yielded an absolute negative result.

If the phase is not oil, as expressed in the rock physics evaluation as the alternative model, then there is the possibility that the anomaly could be low-saturation gas-bearing sands. Although the Judd Basin is known to be a predominantly oil-bearing province, gas in the Suilven discovery may be sourced today from the gas-prone Faroe–Shetland Basin to the NE via the Westray Fault. In addition, the results from the CSEM survey indicate that the anomaly is associated with a 70 Ω m resistive body, which may be 50 m thick and therefore unlikely to be low-saturation gas, which generally loads to significantly lower resistivity.

The Westray Fault is instrumental in providing the conduit for sourcing the prospect and, although the anomaly lies above the main T35/T36 shales (the regional seal), it can be seen that smaller faults associated with the main Westray Fault system are cutting up through to the base of the anomaly. This fault has been instrumental in the inversion of the Judd Basin throughout the Oligo-Miocene and defines its northernmost extent. It is possible that fault parallel migration into the prospect and into the T38 sands in well 204/15-2 occurred at this time.

There are examples where base of slope fans have been prognosed as sand only to find that the sediment proven by the drill was predominantly mudstone (Johannessen & Steel 2005). However, in this instance, there is an analogue sandstone identified in a very similar depositional setting relatively close by. Additionally, channels can be observed on the 3D seismic data cutting down into the topsets of the clinoforms at well 204/18-1. It is possible that these could be age equivalent to the T38 anomaly.

The top seal for the prospect consists of slope sediments from the overlying clinoforms and the side seal is defined by the change in lithology from a sandy toe of slope fan to the distal mudstones of the toe itself. The toe appears on seismic to be near-horizontal, suggesting the presence of mudstone (coarser clastics would produce a steeper gradient). However, the slope may contain thief sands, which could release hydrocarbons upslope and away from the prospect. While there were silts identified within the cuttings of the adjacent wells, these appear to be capable of retaining a column of relatively heavy oil comparable to the column invoked from the seismic.

The trap lies at the base of the slope and is believed to be unique within the Judd Basin. However, both major fields in the area are known to be partly stratigraphic and, therefore, it is shown that combination traps in this area are successful.

The T38 seismic amplitude anomaly is a new and probably unique play in the Judd Basin – lying above the regional seal and also lying at the base of a set of clinoforms. Although the play was unsuccessful in well 204/18-1, this is thought to be due to the lack of trap at the location and the fact that the sands were not plumbed in to a migration route.

Conclusions

The history of previous seismic anomalies which have been drilled and proved to be unsuccessful in the quest for hydrocarbons has led the OMV group to carry out a series of investigations on the T38 amplitude anomaly. A fully integrated geophysical and geological evaluation comprising rock physics, AVO analysis, fault seal analysis and the acquisition of a CSEM survey supported by a valid geologic model have, together, led to a reduction in the risk from high to moderate. The results of the analyses indicate that the seismic amplitude anomaly has the potential to be sand-bearing and to contain oil. The well will be drilled later this year and the results will be eagerly awaited.

The authors would like to thank the management of OMV (UK) Limited and partners, Dana Petroleum Plc, Faroe Petroleum plc and Idemitsu E&P UK Ltd, for permission to publish this paper, CGGVeritas for allowing us to publish their 3D and 2D seismic data, the Schiehallion group for allowing us to publish a 3D seismic line over the field, RDR, BGS (S. Clarke), EMGS and G. Bertram for their studies and support together with present and past workers, B. Richardson, R. Koehazy from OMV Vienna and R. Robertson now at Fairfield Energy Limited. Further thanks are given to P. Krois, S. Hannke, M. Scherer, J. Parry and J. Austin as well as the conference reviewers for their helpful comments and improvements to the manuscript.

Can stratigraphic plays change the petroleum exploration outlook of the Netherlands?

F. F. N. VAN HULTEN

Energie Beheer Nederland B.V., PO Box 6500, 6401JH, Heerlen, The Netherlands (e-mail: Fran_Hulten@compuserve.com)

Abstract: Fifty years after the discovery of the giant Groningen gas field, good insight into the remaining hydrocarbon exploration potential of the Netherlands is of great interest due to the aging infrastructure. In a review of prospective areas, the stratigraphic element of Dutch play areas has been summarized for conventional and unconventional formations. This is to answer the question of whether stratigraphic traps can contribute to future exploration. Complex faulting, very common in the Dutch subsurface, makes structural definition generally the highest prospect risk. With increase in 3D coverage over the country, many structures have now been drilled successfully. The success of structural traps has left the stratigraphic plays and prospects under-explored. Most hydrocarbon reserves in the Netherlands have been discovered in Permian Rotliegend and Triassic Bunter sandstone reservoirs, which are not prone to much stratigraphic trapping as a consequence of very gradual facies changes. Other prospective horizons and hydrocarbon reservoirs in the country range in age from Carboniferous to Cenozoic and can be found in clastic and carbonate rocks. They share an overall comparable basin setting but the varying interplay at basin margins creates varying stratigraphic elements. Rifting creates new facies variation during the Mesozoic. Salt movement is another factor that creates stratigraphic components in trapping. The various erosional events create other possibilities for stratigraphic trapping. This, combined with varying relative sea-levels through time, creates very distinct stratigraphic intervals often correlatable over large distances. The very limited contribution of stratigraphic traps to present-day gas finds may change in the future because of improved seismic. Risking of prospects needs better understanding of stratigraphic elements in various plays. This includes the stratigraphic aspects of reservoir sealing in dominantly structural traps and the nature of source horizons.

Keywords: the Netherlands, stratigraphic traps

The Netherlands (Fig. 1) is an important hydrocarbon-producing province in NW Europe. Exploration drilling and good seismic coverage have contributed to good knowledge of the deeper geology of the country and the surrounding area (for a comprehensive overview, see Glennie 1998; Wong 2007; Doornenbal & Stevenson 2010). The giant Groningen gas field and Schoonebeek, the largest onshore oil field in Western Europe, were found underneath the Dutch territory. Fifty years after the landmark giant Permian Rotliegend Groningen gas field discovery, about 350 gas and oil fields have been found and petroleum exploration remains successful. Energie Beheer Nederland B.V. (EBN) was founded to represent the national interest in the management of petroleum reserves after the Groningen discovery and today participates in more than 300, mainly gas, fields for the Dutch state. EBN is actively studying the remaining exploration potential because activity is declining and aging infrastructure, in particular offshore, will make exploration less attractive in the foreseeable future. Timing is essential, as relatively small prospects will be increasingly less feasible. The depth of most fields and prospects generally exceeds 3500 m (ranging between 2000 and over 4000 m). This, combined with often heterogeneous shallower layers, makes good seismic coverage a necessity for prospect evaluation. Part of the exploration success of the last 30 years is due to extensive 3D coverage. The ‘sub salt’ Rotliegend exploration target, the most prolific gas-producing horizon, makes it necessary to solve very complicated structural problems. Complex faulting at the prospect level, added to the often complex overburden geology, as a result of salt movements and rifting with associated inversion, makes structural definition generally the highest prospect risk. Within classic play areas increased 3D coverage means that most larger structures have been drilled.

The emphasis of a typical prospect evaluation has remained on structural aspects of the seismic interpretation. Stratigraphic elements are often less researched. Pure stratigraphic plays also gained by 3D seismic, but were at a disadvantage due to higher risk. With improved seismic acquisition and processing power, during the last 15 years amplitude information (Hoetz & Watters 1992) has increasingly become a tool for better field and prospect evaluation. Amplitude information can now in many cases be used for sub salt Rotliegend reservoir assessment, yet it has not delivered the successes the 3D delivered for the structural trap. Stratigraphic plays were also less popular as log and other well information was often not available. A change in mining legislation has changed this. Log data is publicly available now via the TNO/NLOG website (Geological Survey of the Netherlands). This opens up new possibilities for stratigraphic research. A new look at subtle stratigraphic variations in prospective formations can reduce risk and improve prospectivity. In-house EBN data supplemented with the additional log resources have been used in this study. Owing to EBN’s participation in so many hydrocarbon fields, sedimentological settings of reservoirs could be studied across licence boundaries and the trapping of over 300 fields investigated. With the new information, play maps of the various prospective formations could be adjusted.

Structural v. stratigraphic traps

A stratigraphic trap is defined by Levorson (1936) as: A trap in which a variation in the stratigraphy is the chief confining element in the reservoir which traps the hydrocarbons. Examples include wedging out, lateral facies change or truncation of the

VINING, B. A. & PICKERING, S. C. (eds) *Petroleum Geology: From Mature Basins to New Frontiers – Proceedings of the 7th Petroleum Geology Conference*, 261–275. DOI: 10.1144/0070261 © Petroleum Geology Conferences Ltd. Published by the Geological Society, London.

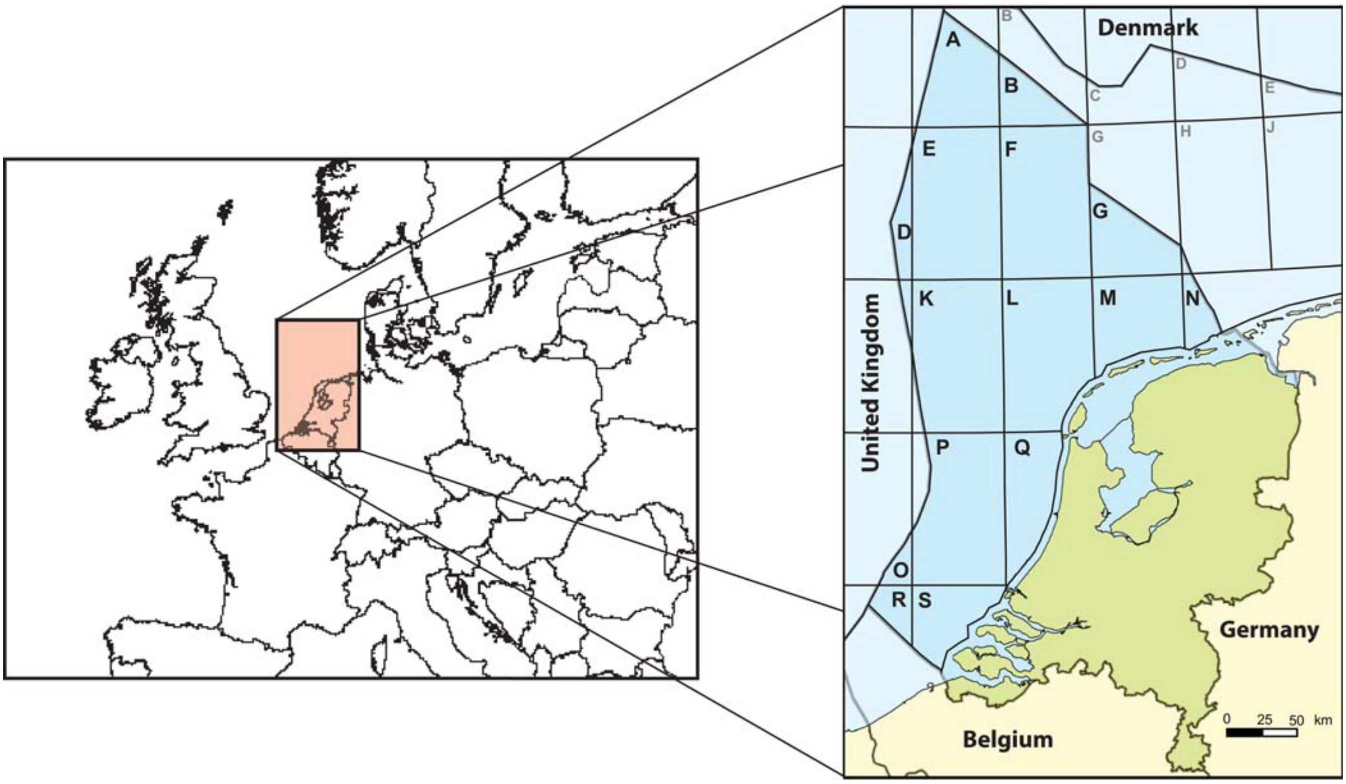

Fig. 1. Index map of the Netherlands. When the Netherlands are discussed it concerns the on- and offshore.

reservoir. When looking for stratigraphic elements that play a major role in the trapping of hydrocarbon accumulations in the Netherlands the following features are important:

- truncation at unconformities;
- other traps related to erosion at unconformities;
- facies change traps;
- facies changes related to salt movement;
- diagenetic traps.

Unconformities are an important element in several traps in combination with faults. A stratigraphical log (Fig. 2) of the Netherlands displays two major unconformities and several minor ones (Van Adrichem Boogaert & Kouwe 1997; Wong *et al.* 2007). Traps associated with unconformities are found in several fields. The truncation is never the main trapping element – there is always faulting as well. Salt movement also causes facies changes and salt dissolution creates accommodation that is filled with good reservoir sands for a number of fields.

There is no good example of a field that displays diagenetic trapping; however, there are (Lower Germanic) Triassic Bunter fields that are partly salt filled, which seems to contribute to trapping of the gas accumulation (Fontaine *et al.* 1993). Salt-plugging can be present in the reservoir several hundred metres from salt-domes (Dronkert & Remmelts 1996).

The survey of over 300 Dutch fields demonstrates that most known producing hydrocarbon accumulations are structurally trapped. The dominance of the Permian Upper Rotliegendes Group reservoirs is the reason why the stratigraphic trap has not been very critical for the Netherlands. Trapping in the Rotliegend Slochteren Formation, being relatively uniform in thickness and reservoir quality, rarely requires a stratigraphic explanation. Fault definition in that formation is often the essential prospect risk. Most Rotliegend as well as Bunter fields can be described as a dip-closure with three or more faults.

A small number of fields have significant stratigraphic elements in their trapping. Quantification is not very meaningful because of large uncertainties. For example, in a number of cases the current interpretation of a fault may turn out to be a facies change after more study.

Some stratigraphy plays a role in all traps, even in structural traps. In almost all cases the stratigraphy creates some kind of permeability barrier (no connections between the pores) needed for the trap:

- Most fields have at least one stratigraphic element due to the top seal. Little has been published on seal quality or regional seals. An exception is the study of late Triassic seals (Spain & Conrad 1997).
- Most Permian and Triassic traps are faulted dip closures. The stratigraphy of down-thrown or up-thrown block determines the sealing.
- Shallower formations are less brittle compared to Palaeozoic Rotliegend and Zechstein and have a lower fault frequency. Facies changes have a higher chance of sealing the reservoir.
- Unconformity traps at the Saalian unconformity are very common in Carboniferous-age reservoirs. At the other unconformities also stratigraphic trapping has been observed. Triassic reservoirs close to saltdomes often show such traps.
- Clastics are the dominant reservoir rock of the Netherlands. In carbonate accumulation a strong stratigraphic element is present. There is no lack of carbonates in the Dutch subsurface. Carbonate gas field reservoirs are mainly found in the Permian Zechstein. Seismic suggests that there are significant buildups of Mississippian age, but they are still exploration leads. Thin Late Triassic Muschelkalk carbonate reservoirs are very marginal and the Chalk is largely disappointing as an exploration target in the Netherlands, with only 1–3 finds.
- Well spacing can obscure stratigraphic trapping. Since most wells are drilled for gas, spacing is rather wide. Therefore it is easy to overlook stratigraphic elements of a trap.

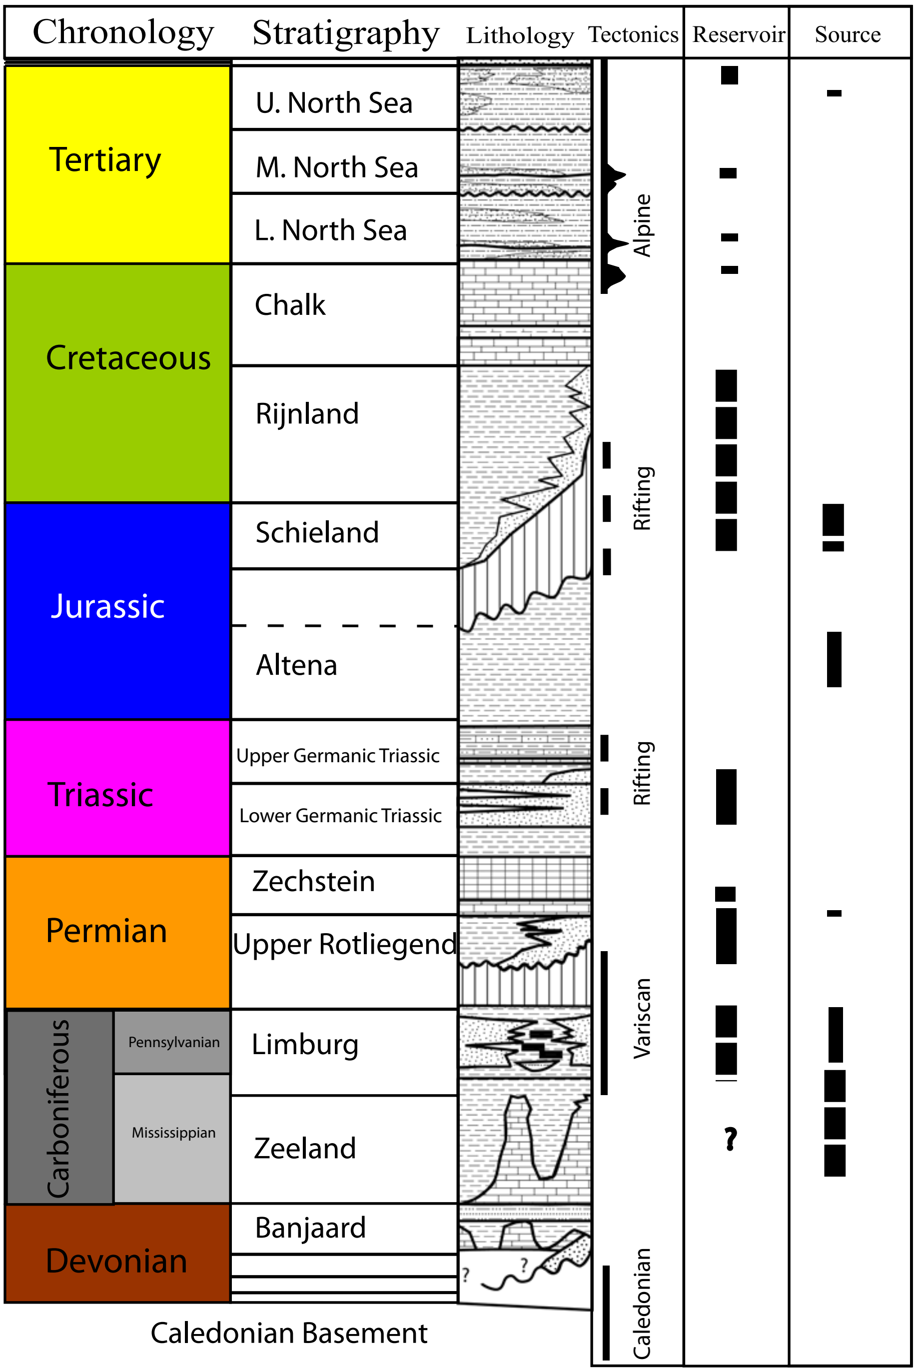

Fig. 2. Stratigraphic column.

Plays in the Netherlands

To understand stratigraphic plays in the Netherlands it is important to give a summary of the major plays. In all plays some stratigraphic element plays a role. In the following a quick review is given of the main source rocks and the structural setting.

Based on source rock a number of play groups can be distinguished (Spencer & Leckie 1996). The most important groups of source rocks are listed below.

Late Carboniferous gas

The main family of plays is associated to charge from coals of Late Carboniferous age. Most gas reservoirs in the Netherlands have been found in the Permian Rotliegend, with 80% of reserves of the country contained in these Permian sandstones. Triassic Bunter sandstone reservoirs hold significant amounts of gas as well and gas is found in other reservoirs of Pennsylvanian, Permian and Cretaceous age. It is generally assumed that most of these gas accumulations are charged by the gas-prone Type III source rocks of the Pennsylvanian age coal measures of the Limburg Group, which underlie almost the entire Netherlands (Wong *et al.* 2007). About 3% of the more than 1000 m section contains coals and organic-rich shales. The cumulative thickness, of several tens of metres, could have charged the basin many times over.

Early Jurassic Posidonia shale

Sixty years ago, oil fields in Cretaceous-age sands were discovered in the vicinity of The Hague and Rotterdam. They belong to a family of play types related to the presence of Early Jurassic Type II source rocks. These marine Late Triassic and Early Jurassic shales contain a few kerogen-rich intervals. The richest bituminous interval is the 15–30 m thick Posidonia with an average TOC of 5%. The Mesozoic oil-generating shale is geographically restricted to basin areas. In the southern part of the Drenthe province, Schoonebeek, the largest onshore oilfield (lbbl bls) of Western Europe, was discovered in an Early Cretaceous reservoir (see Fig. 2). It has been charged by a local lagoonal or lacustrine Ryazanian source rock (Wong *et al.* 2007) and has no significance for a regional play study.

Geverik shale

Gerling *et al.* (1999) noted, based on isotope data, that gas from many Rotliegend and Late Carboniferous gas fields in the Southern Permian Basin area originates from marine source rock. As most Late Carboniferous coal is of terrestrial origin, the marine Mississippian Geverik Type II hot shale, with a TOC of about 8%, is a likely candidate as source (Van Adrichem Boogaert & Kouwe 1997). Few wells have drilled this Geverik black shale. The black shale was deposited during or at the end of the Mississippian, under anoxic conditions which restricted circulation. It is assumed that the basin areas are at least 200 m deeper than the surrounding areas. Based on the overall palaeogeographical setting during the Mississippian (Van Hulten & Poty 2008) it is assumed that the hot shale is present in all deep Mississippian basin areas and has a wide geographical extent with considerable charge potential.

Biogenic gas

Last year production started from offshore Cenozoic-age reservoirs. These and many other shallow gas accumulations are filled with biogenic gas. It is composed exclusively of methane and isotope data indicate a bacterial origin. Schroot & Schüttenhelm (2003) note that methane concentrations near the sediment surface are very low but increase below the sulphate–methane transition zone. At the sulphate-containing zone there is a rapid increase in methane concentration. These authors note that locally thermogenic gas can leak into the shallow formations.

The first three source rock intervals and other less important source rocks like the Permian Kupfershiefer (Wong *et al.* 2007) and the Late Jurassic Kimmeridgian (Clay Deep Formation, Van Adrichem Boogaert & Kouwe 1997) were all deposited during relative sea-level high stands. It is interesting to note that the sediments deposited during the major Late Cretaceous high stand are devoid of source potential (Glennie 1998).

These relatively high stands also have another effect on viable prospects. They provide the regional seals key to prospect risking. The interplay of these major sealing and source horizons in the Netherlands is an important element in play analysis.

Basin evolution: the structural framework

The initial structural setting is comparable to adjacent parts of the Southern North Sea area in the UK. With the Netherlands it shares a general setting along a NW–SE strike. To understand the overall basin setting, two bounding highs have to be considered, the London Brabant Massif in the south and the Mid North Sea High in the north (Fig. 3), that share a Caledonian (Late Silurian) origin. Both highs were hardly a source of sediment but they provide a logical basin termination because erosion and non-deposition show on most maps. They also acted as some kind of

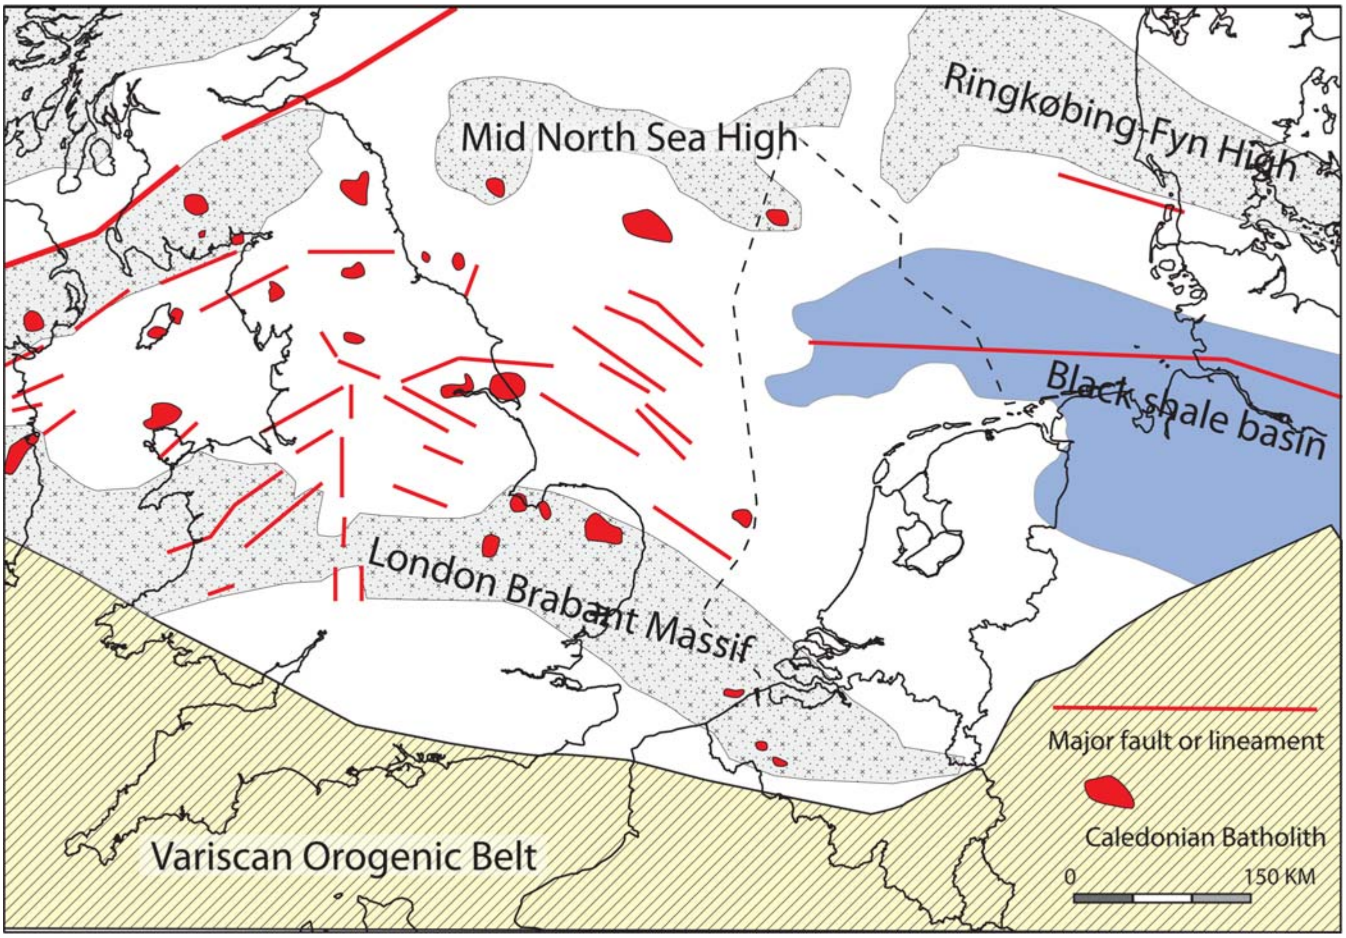

Fig. 3. Structural elements, Palaeozoic.

threshold for the area from sedimentation originating from the Caledonian in the north and later the Variscan southern highlands as well. The northern offshore half of the Netherlands displays a low topography trough time. The southern half with the onshore Texel-IJsselmeer High and the surrounding areas are generally much shallower. This results in asymmetric basin geometry over the Netherlands, which is essential for understanding facies trends in various time intervals.

This geometry is the result of continental scale collision during the Caledonian orogeny. The Netherlands are part of the micro continent Avalonia that amalgamates with Baltica in the Early Silurian when the Tornquist Ocean was closed. Deep seismic shows a shallow Moho in the northern part of the Dutch offshore. This can be explained by the presence of a slice of non-subducted oceanic crust (Abramovitz *et al.* 1998). Sinking ocean crust is also an explanation of why the northern Dutch offshore is a major depocentre. This Silurian–Devonian basin is the predecessor of the Post Variscan Southern Permian Basin. It differs significantly from the latter as it is bordered by a major ocean in the SE.

The Iapetus closure during the Late Silurian occurred outside the Netherlands, but the collision is central to the forming of the London Brabant Massif (Wong *et al.* 2007) and many granite plutons, for example on the Mid North Sea High. In the Devonian and Mississippian, half-grabens formed in the southern part of the Netherlands in an extensional tectonic regime thereafter. The structural grain is more or less NW–SW. The NE strike is parallel to the Thor suture, the boundary between the continents Baltica and Avalonia. The Dutch on- and offshore was largely peripheral to the Variscan orogeny until its latest phases. It resulted in an unconformity between the Carboniferous strata and the overlying Permian Rotliegend and is often clearly visible on newer vintage seismic. Erosion may in places remove more than 1000 m of Carboniferous (Wong *et al.* 2007). A period with relative minor tectonic movements followed and lasted until the mid Triassic.

During the Mesozoic a number of rifting events (Fig. 4) occurred related to the break-up of Pangaea (Glennie 1998). They were of great importance for forming hydrocarbon traps. Also salt tectonics had a severe effect on structuration of shallower layers and generated many traps.

Late Triassic rifting is active in the Dutch Central Graben area. It is also known as the Early Kimmerian tectonic phase (see Van Adrichem Boogaert & Kouwe 1997; Wong *et al.* 2007). Regional uplift and erosion over most of the Netherlands occurred during the Late Jurassic, lasting in some areas until the Early Cretaceous. The major Dutch tectonic elements formed during the Mid and Late Kimmerian tectonic phase, in the later part of the Jurassic. It affects almost the whole country.

The Alpine collision adds a compressional element to rifting tectonics. The soft sediments in newly formed grabens are inverted in at least three major inversion periods. The Sub Hercynian (Late Cretaceous), the Laramide (Early Paleocene) and Pyrenean (Eocene–Oligocene) inversions are recognized widely and have a profound but not always understood effect on traps, hydrocarbon generation and migration. It is not clear if the Mid Miocene unconformity is caused by a tectonic event (Savian phase) or a dramatic sea-level drop or both.

Plays based on basin evolution and depositional model

Beside the structural framework, the source rock mapping and the regional seals, the depositional model of the reservoir rock constrains the play mapping. The general facies development of prospective horizons has been well described (for a more detailed description refer to Glennie 1998; Wong *et al.* 2007). There are a few key periods which most affected the development of the bulk of the petroleum finds and have received most study (Wong *et al.* 2007). Deposits from the different time periods share comparable characteristics since the overall basin setting has been similar over long periods. In the country, plays with a stratigraphic component are frequently associated with basin margins. Insight in facies development at basin fringes yielded some very good gas and oil fields (e.g. Van de Sande *et al.* 1996 for Zechstein; Geluk 2005 for Triassic).

During the Mesozoic rifting new facies variation was created in rift areas. Perhaps more important for trapping of hydrocarbons is

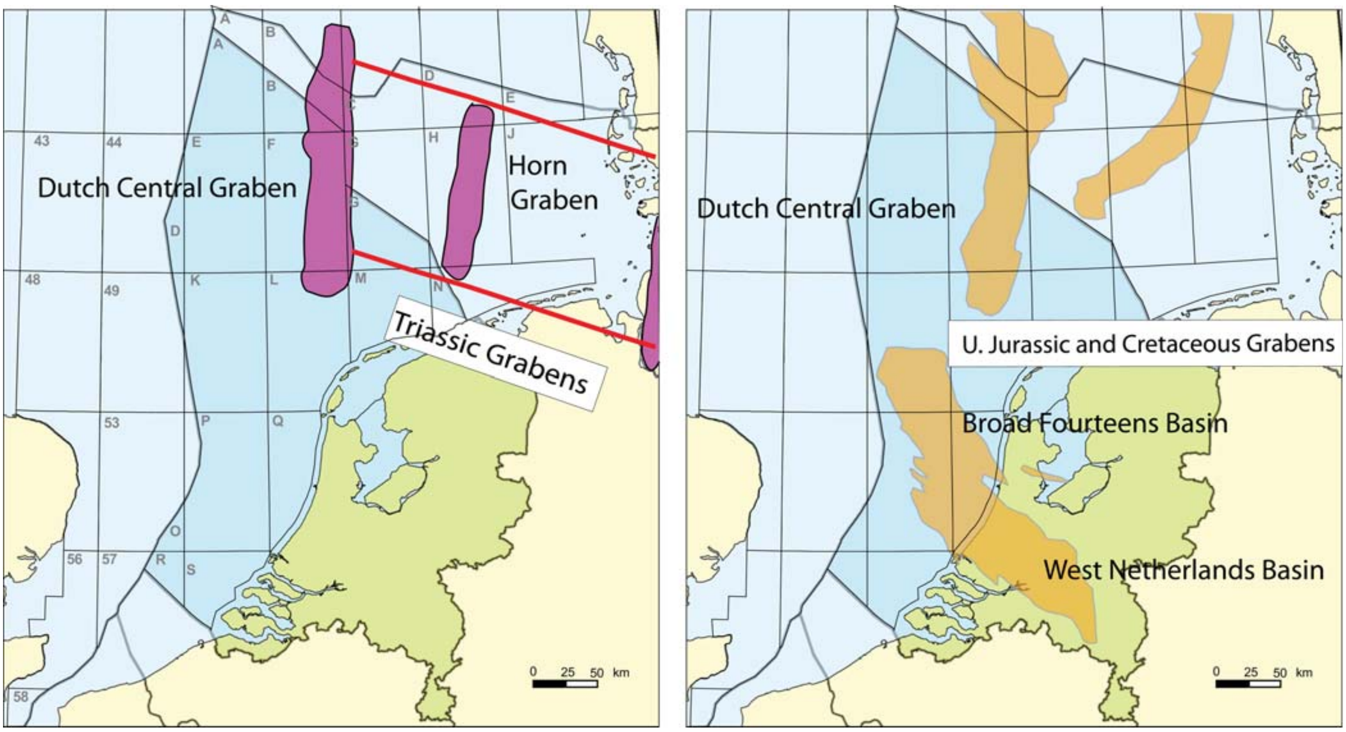

Fig. 4. Structural elements, Mesozoic and Cenozoic.

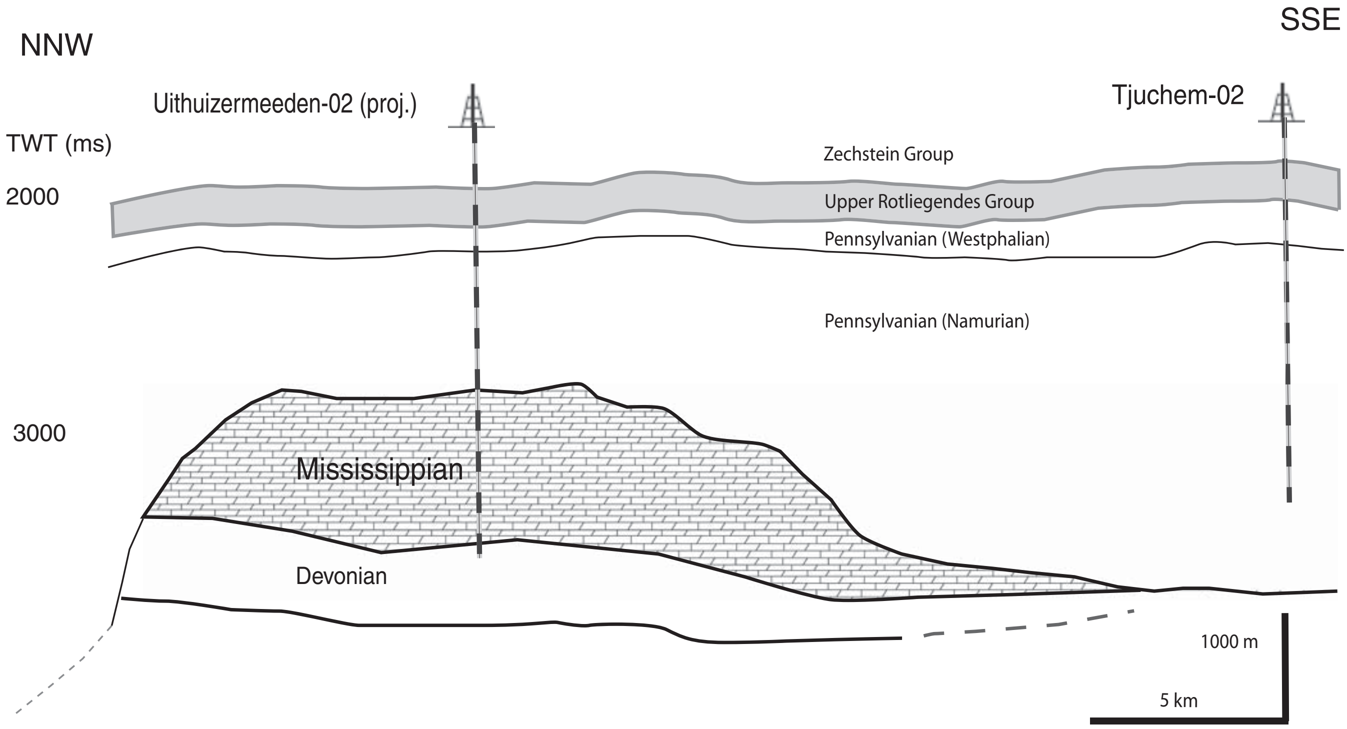

Fig. 5. Sedimentological model of Mississippian reefs. Modified after Kombrink (2008).

the widespread salt movement over large parts of the country after the Mid Triassic.

In the following, a brief summary of play areas based on stratigraphy is given.

Devonian and Mississippian

Recently new information has become available in basin areas on carbonate buildups of Mississippian age (Kombrink 2008; Van Hulten & Poty 2008). These Mississippian reef leads, with no hydrocarbon shows in the Netherlands so far, have a very strong stratigraphic component because their morphology suggests that mounded closures can be expected. In this stage of exploration it is uncertain if reservoir rock is present at the depth of 3000–6000 m where these reefs have been detected. Very few wells in the country go deeper than the Upper Carboniferous, with the exception of some wells close to the London Brabant Massif and a few wells on the Mid North Sea High. Seismic interpretation has shown that large carbonate platforms (Fig. 5) may exist and may form a perfect stratigraphic trap as they are encased in very thick Carboniferous shale. The tallest reefs are in the Groningen Friesland area (Kombrink 2008). Reefs are also seen in the southwestern Dutch Offshore (Van Hulten & Poty 2008). Subcrop information at the Saalian unconformity indicates that a shallow platform area (Fig. 6) is present to the south and a deep basin in the north comparable to Northern Germany (Van Hulten & Poty 2008).

The major reefs as seen on the recently published seismic are most likely of Mississippian age and it is unclear to what extent Devonian carbonates may form traps. Information on the Middle Devonian or older rocks is rarely present in the Netherlands. Devonian of Givetian or Frasnian age in parts of the Netherlands may be developed in carbonate facies. Based on palaeo-wind considerations with trade winds not coming from the (present day) east as in the Mississippian (Van Hulten & Poty 2008), but from the south, reefal buildups may be present in the southern part of the country and in particular on the Mid North High. The assumption is based on a tropical palaeo-position of the area during the Mid Devonian below the equator.

Pennsylvanian

The very thick almost uniform repetition of sand and shale with coals of Late Carboniferous (Pennsylvanian) age are well known in NW Europe in the UK, Belgium and Germany (Glennie 1998; Wong *et al.* 2007). In the Netherlands the more than 1000 m-thick clastic section is called the Limburg Group. Considering its nature, with sands interbedded in shale beds, it is surprising that almost no stratigraphic traps have been found. Major intra-Carboniferous shale intervals like the Maurits coal Formation or even the marine bands may form intra-Carboniferous seals. At this moment it does not form a widely accepted play idea. The facies analysis suggests that the relief is very low due to high sedimentation rate (Wong *et al.* 2007). The Saalian subcrop map, which shows the erosion at the Late Carboniferous to Early Permian Carboniferous unconformity (Van Hulten & Poty 2008), suggests that the deepest part of the basin is situated to the north, in the offshore area off the Frisian Islands. This is supported by observations that suggest prograding sedimentation toward the north in the southern part of the basin and toward the south or SW direction in the northern part of the basin (Wong *et al.* 2007). Almost all known fields (Fig. 7) are traps against the important Saalian unconformity. The Limburg Group displays mostly an angular unconformity with overlying Permian age formations. Channel fills are common reservoir facies type but facies changes are not commonly the main trapping element. Fields are bounded by faults not unlike fields of the Rotliegend Group. In literature the possibility of intra-Pennsylvanian stratigraphic traps is mentioned owing to the presence of incised channels (Hampson *et al.* 1999; Kosters & Donselaar 2003). No gas accumulations have been found that have such trapping configuration.

Rotliegend

The Rotliegend Slochteren sand is the most prospective reservoir unit in the Netherlands (Wong *et al.* 2007). Its geology and depositional setting have been well described (George & Berry 1993,

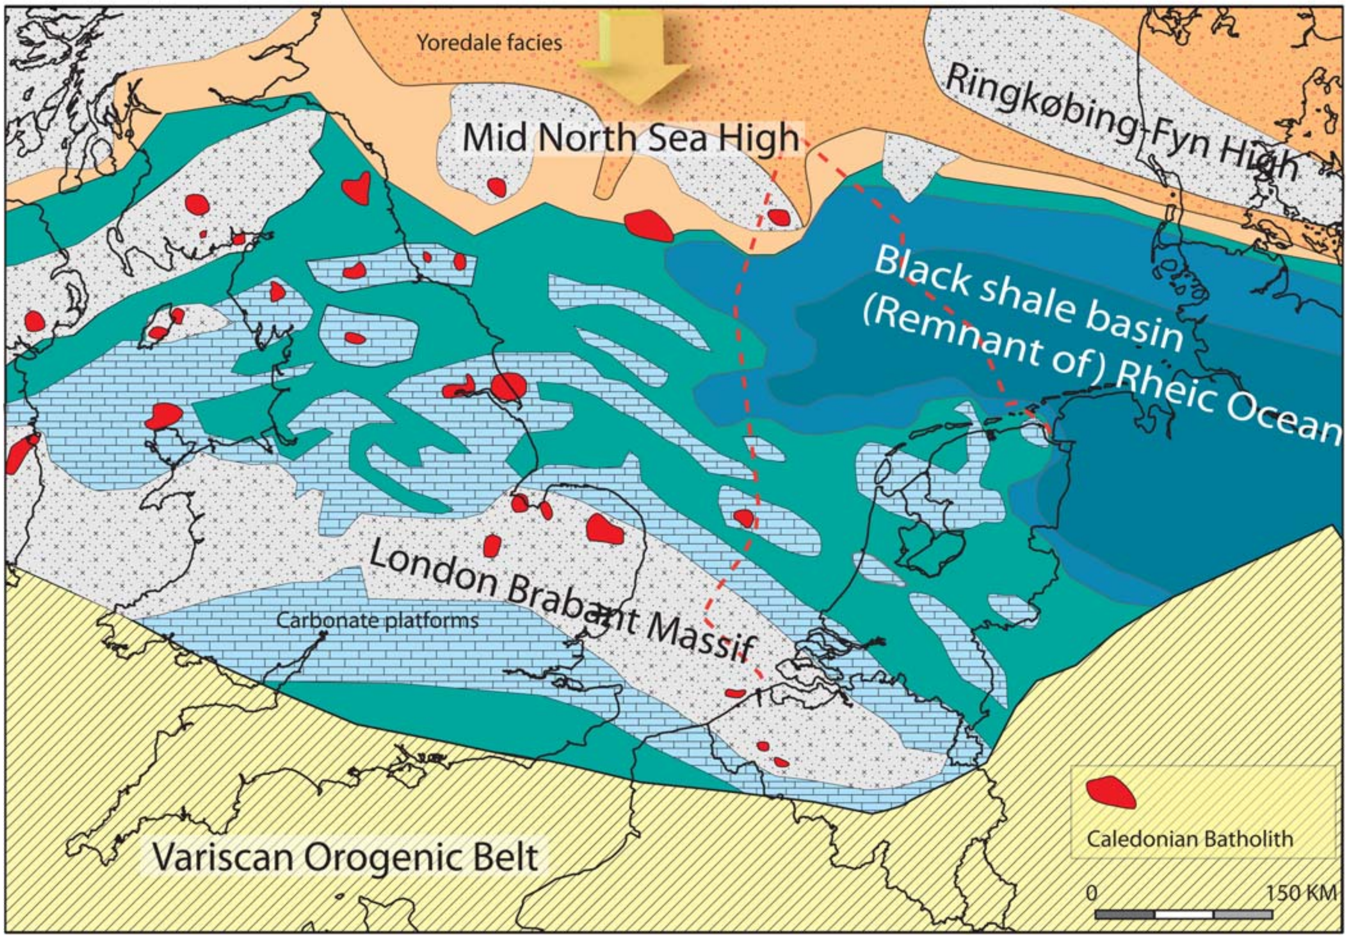

Fig. 6. Facies map, Mississippian.

1994; Verdier 1996; Glennie 1998; Geluk 2005). The deepest part of the basin is found again in the Dutch offshore area and most reservoirs are found at the southern basin margin. The reservoir that is dominated by desert fluviatile and aeolian facies can be subdivided in an Upper and Lower Slochteren stratigraphic unit. Facies changes in reservoir sands are very gradual and large scale compared to the frequency of faulting (Wong *et al.* 2007). This causes most, if not all, Rotliegend gas fields (Fig. 8) to be structural traps. Despite the structural nature of their trapping, studying stratigraphic elements may contribute to reducing exploration risk. There are two stratigraphic elements that are important for exploration. The northern sand limit is a target for exploration. Here it is important to distinguish between Upper and Lower Slochteren Units. They have a different sedimentation history. The other element is the interaction of sedimentation with palaeo-topography. This is key to understanding thickness variations in the Lower Slochteren sands. Sands can be thicker in depressions or be missing on highs. New emphasis on the interaction of palaeo-topography and depositional models (Maynard & Gibson 2001) shows that these models can help understand the trapping and reservoir distribution.

Zechstein

The Zechstein sediments are dominantly evaporitic and are not only known as reservoirs but also have cap rock qualities. Seven evaporitic cycles can be distinguished, of which five are recognized in the Netherlands. The various salt members of the last Zechstein cycles are seals for most Permian and Pennsylvanian traps. The mobile salt often forms structures of the shallower hydrocarbon traps. The first petroleum plays in Western Europe were related to traps associated with salt domes in the Hannover area. Also in the Netherlands, many traps above the salt are related to salt movement.

The basin configuration, essential for facies distribution, is comparable to the earlier formations. The deepest part is again the northern offshore and for play studies the various Zechstein coast lines have to be mapped. For reservoirs in the Zechstein Group the facies distribution plays an important role. Despite the importance of the stratigraphy for the reservoir, all fields (Fig. 9) seem to be structurally trapped. The reservoir rocks are peri-marine carbonates. The early reservoir cycles (Ze2, Ze3) form significant reservoirs. The later cycles have reservoirs in a few exceptional cases. To determine the prospectivity of the Zechstein carbonates, the stratigraphic element is a key element. For example, the main productive Zechstein horizon, the Zechstein Ze2, is prospective over a narrow east–west geographical zone. A time map can be very helpful to map the reef edge (Van de Sande *et al.* 1996).

Most fields were found more than 10 years ago, but near-field exploration or play extension outside known areas may revive the play. The lateral changes of other Zechstein horizons is also less researched.

Triassic

The Triassic Main Buntsandstein Formation is the second important hydrocarbon-producing formation for the Netherlands. The facies development in a desert environment is comparable to the Rotliegend. The fringe facies are now close to the London Brabant Massif in the south. Due to its sedimentological setting

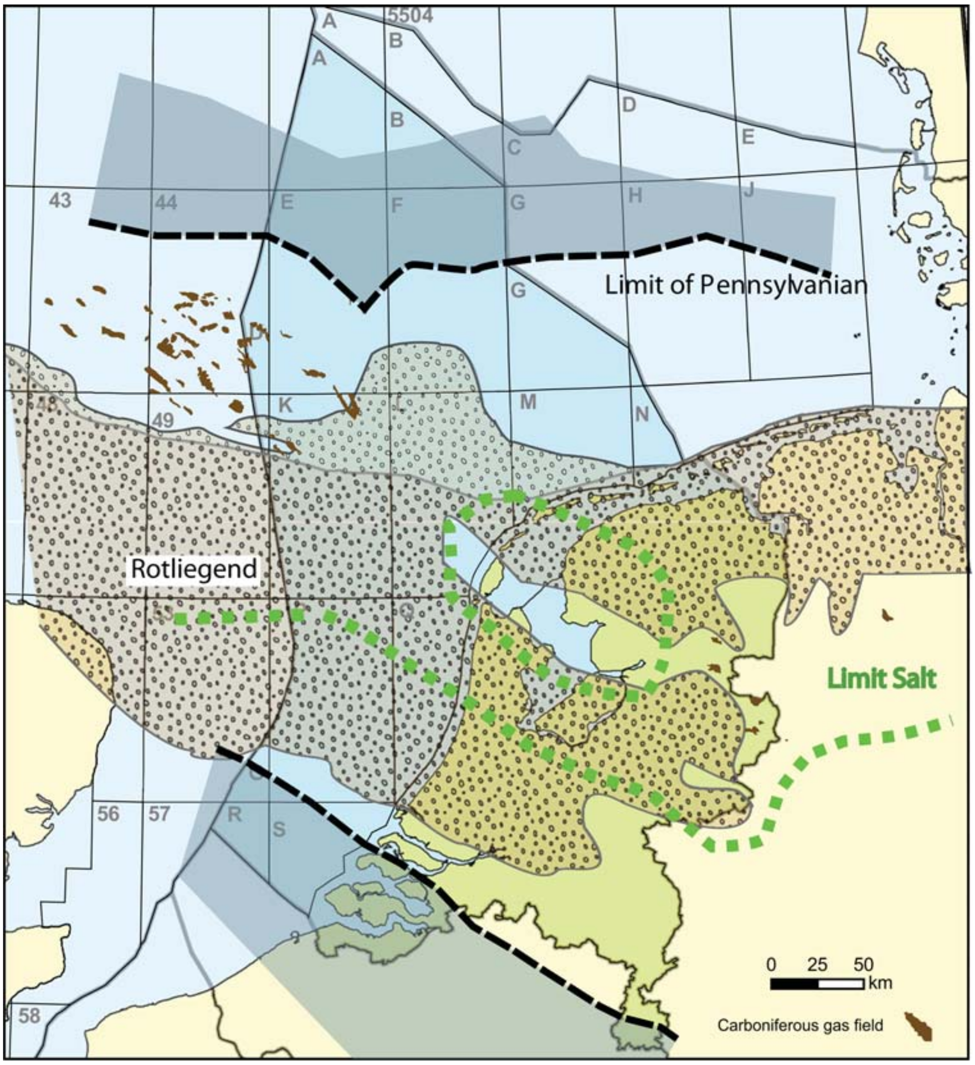

Fig. 7. Play map, Pennsylvanian.

in a desert lake environment (Fontaine *et al.* 1993; Ames & Farfan 1996; Geluk 2005), the formation is remarkably constant over large distances. The basin configuration with erosional highs in the southern half of the country can be seen during minor erosional episodes (Fig. 10). Subtle erosion during the so-called Detfurth and Solling unconformity created some thickness differences and pinchouts (Geluk 2005).

Initial rifting commenced during the Triassic. The combination of the rifting with the first salt movement changes the sedimentation pattern dramatically. Marine conditions were again established in the basin, but it did little to create good reservoir conditions. The only exception is the Solling 'Fatsands' (De Jager & Barrio 2003) deposited in salt dissolution depressions.

The other formations of late Triassic age rarely display good reservoirs. The Muschelkalk displays significant facies changes (Borkhtaria *et al.* 2005; Pöppelreiter *et al.* 2005) and may be a target for stratigraphical trapping, for example the Triassic Muschelkalk age back shoal facies in the Coevorden field. The best reservoir facies are believed to exist towards the east in Germany.

From the Late Triassic section potential reservoirs have been described in Germany, but are not known to trap hydrocarbons like the Shilf sandstone of the Keuper (Geluk 2005). Due to later erosion, the upper Triassic sediments are mainly found in basin areas. This is also the case for deposits of Early Jurassic age.

Early Jurassic

The Early Jurassic section contains mainly shale and is more important as source rock than as reservoir. The shale of this period contains the important Posidonia unit, the most productive oil source rock of the Netherlands (Fig. 11). The Posidonia is only found in basin areas, so the original lateral extent is uncertain. At the top part of the Early Jurassic section, sandstones (Van Adrichem Boogaert & Kouwe 1997) can be found, close to the Mid or Late Kimmerian unconformity, and can create an unconformity trap.

Late Jurassic and Early Cretaceous

After the subsiding of the Mid Jurassic rift dome in the Northern North Sea and coupled to relative rapid rise in sea-level, the erosion stopped and full marine conditions returned to large parts of the Netherlands (Glennie 1998). Late Jurassic geological history is complicated because of erosion, in Cretaceous and Cenozoic times. Its lateral extent is uncertain. Even more than Triassic sediments, most Jurassic sediment has been found in basin areas only (Fig. 12). Outside these rift basins, Late Jurassic sediments are rare and are associated with salt withdrawal or faulting (Van Adrichem Boogaert & Kouwe 1997). The rupturing of the Central Graben rift started in the north and progressed towards the Broad Fourteens Basin. A step-by-step north to south marine

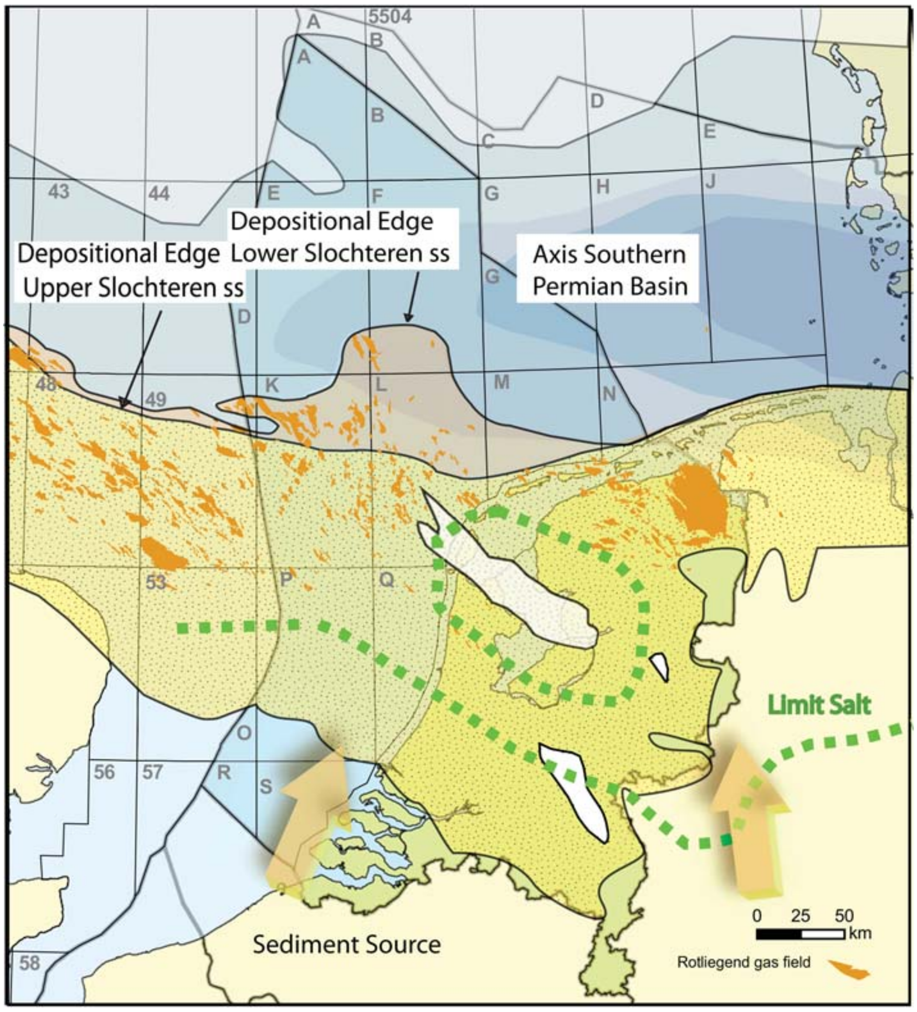

Fig. 8. Play map, Permian Upper Rotliegend.

transgression started during the Callovian and continued into the Lower Cretaceous. A stacked prograding coastal-barrier complex of Callovian age forms, for example, the F3-FB field (Van Adrichem Boogaert & Kouwe 1997). Periods of transgression alternate with periods of terrestrial progradation. This very complex clastic basin fill is the perfect setting for stratigraphic traps; however, the various inversion events turned many potential stratigraphic traps into structural traps.

Halokinetic activity of Zechstein salts complicates trapping in some areas. The reservoir sands are mostly fine-grained. The Jurassic and Cretaceous basin shales are good seals (e.g. the Vlieland shale).

An example of possible stratigraphic traps is given by Abbink *et al.* (2006) for the Dutch Central Graben. A Late Jurassic play in deltaic facies is comparable to the model for the Delfland (Late Jurassic–Early Cretaceous) in the SW part of the Dutch onshore (Den Hartog Jager 1996). Delfland oil reservoirs are stratigraphically trapped and generally very small.

Another example of a play with a stratigraphic component is the spiculite reef play in sands of Late Jurassic age (Abbink *et al.* 2006). Dissolved sponge spicules are creating pore space and its silica enhances reservoir properties. Two fields produce from this reservoir and the thickness trends in buildups suggest a sponge bioherm.

The sands of the Lower Cretaceous Vlieland Formation are one of the prime candidates for stratigraphic traps. For example, the Vlieland Leeuwarden Field and its satellite fields Rauwerd and Grouw (Figs 13 & 14) are some of the few, if not the only, fields described in the literature (Cottençon *et al.* 1975), which have dominant stratigraphic trapping. Zechstein salt dissolution in the subsurface creates accommodation space at the unconformity. The Vlieland reservoir sands pinch out against 'bald zones' with no sand.

The Rijswijk oil province and reservoirs in the Broad Fourteens Basin (Bodenhausen & Ott 1981; Roelofsen & De Boer 1991; Racero-Baena & Drake 1996; Den Hartog Jager 1996) show synsedimentary facies change at faults. Later inversion creates largely structural traps.

Late Cretaceous Chalk

The uniform cover of the cream-colored micritic limestone of the marine Late Cretaceous Chalk Group is present underneath large parts of the country (see Van der Molen 2004; Wong *et al.* 2007). The lithology is dominantly a pelagic bioclastic friable limestone, the autochthonous chalk, with green sands present at the southern fringes of the West Netherlands Basin. With the exception of a few inverted areas near the Dutch Central Graben and the central Netherlands, a 500 m-thick Chalk section is very common. Highs like the London Brabant Massif almost never flooded in geological history. During the Upper Cretaceous they are submerged due to high global sea-level. Average water depth is estimated at a few hundred metres. Near highs the depth is much shallower and locally much deeper. In some areas over 1500 m of Chalk has been deposited (Wong *et al.* 2007). Wireline correlations indicate several intra-formational unconformities. Redeposition of

autochthonous Chalk can be seen on the seismic (Van der Molen 2004). The Chalk Group is an important hydrocarbon producing formation in countries outside the Netherlands like Norway, the UK and Denmark. Thousands of wells have been at least drilled to the Chalk group in the Netherlands. Compared with Denmark (Vejbæk *et al.* 2005) which has Chalk fields on the east side of the Central Graben not too far from the Dutch offshore, the results are very disappointing. One oil field on the west side of the Central Graben and one gas field onshore have been discovered. The poor results may be due to lack of charge. The important Kimmeridge Clay source rock, imperative to charge in many North Sea Chalk fields (Glennie 1998) is not well developed further south. It is not a lack of traps. Salt movements may provide structural traps and the unconformities can create stratigraphic traps.

Cenozoic

The Cenozoic age sediments are called the North Sea Group which is almost present below the whole country. Over large areas the thickness of the dominantly siliciclastic sediments reaches over 1000 m. In the northern offshore area the thickness reaches 2000 m. The North Sea sediments are dominated by marine or near-shore facies (Van Adrichem Boogaert & Kouwe 1997; De Lugt *et al.* 2003; Kuhlmann *et al.* 2006). A number of breaks are created by tectonic events and sea-level low stands. The tectonic inversion caused widespread erosion. The Mid North Sea Group base is defined on a major break at the Late Eocene. The Base of the Upper North Sea Group is the Mid Miocene unconformity. A lowstand as well as a tectonic event have been proposed for the explanation of severe erosion (Wong *et al.* 2007). Shale is dominant, but the section contains various sands linked to the tectonic events and sedimentation breaks (De Lugt *et al.* 2003; Wong *et al.* 2007) that can contain gas. Often the gas is clearly visible on the seismic owing to a bright amplitude effect. The shallow gas in various sands in the North Sea is generally not seen as a prospect and is considered a drilling hazard. Gas production started last year from North Sea accumulations in the northern A and B blocks (Fig. 15). Coastal sands from the late Pliocene Eridanos delta trapped gas in low relief structures created by salt doming. The sediments build out from the east (Sørensen *et al.* 1997; Kuhlmann *et al.* 2006). As a result of rapid facies changes in the delta, there is also a stratigraphic component in trapping. The presence of active salt domes causes most North Sea gas sands to have a strong structural component in their trapping. Facies change in sands also can provide stratigraphic traps.

Conclusions

The success of structural traps for Dutch hydrocarbon exploration prospectivity left the stratigraphic plays and prospects with less attention. Stratigraphic trapping is rarely confirmed and is limited to a few horizons. Stratigraphic aspects of plays are significant to more than the top seal only. Good sedimentological models make it possible to differentiate play areas. In the structural setting of the Netherlands, the stratigraphical trap will be rare in the Rotliegend since facies changes are relatively gradual compared with the high frequency of faulting. The shallow marine Late Jurassic and Early Cretaceous play areas have a number of proven accumulations with strong stratigraphic aspects. Trapping in carbonates has a strong stratigraphic element due to rapid facies changes in most carbonates found in the Dutch subsurface. Mississippian carbonate leads deserve more attention because they may give a new stimulus to exploration, hopefully even more than many high-ranking prospects based on structural trapping. With the improvement of the seismic, acquisition and processing, the search for stratigraphic traps should get a higher priority.

Abstract: Laggan, located in the west of Shetland, was discovered in 1986. There is now an improved understanding of Laggan, thanks to innovative and fully integrated geoscience studies and a successful appraisal campaign. Development studies are well advanced, with the discovery of Tormore in 2007 providing the potential for a combined development project. Laggan and Tormore are Paleocene gas condensate discoveries in approximately 600 m water depth. The traps are both mixed, stratigraphic with updip closure against bounding faults. The reservoir comprises sand-rich turbidite channelized lobes and lobes. Reservoir properties are good (permeability range 30–300 mD) due to the presence of chlorite and pre-sorting on the shelf. The geoscience evaluation of Laggan has matured over the last four years with the help of fully integrated studies using 3D seismic and well data. The depositional model has been defined on the basis of an evaluation of cores and seismic and supported by analogue studies. Seismic inversion studies have also helped constrain the reservoir architecture. Of particular value has been the application of AVO to quantify net gas sand, recognized as the principal static uncertainty. The main dynamic uncertainty is the risk of compartmentalization. This risk has been reduced through an improved definition of the fault configuration by re-processing the seismic and detailed seismic attribute analysis. The potential of Tormore was recognized by applying the geoscience understanding of Laggan to help de-risk the prospect. In particular, it was recognized that Laggan could be used as an analogue for the Tormore trapping configuration and reservoir potential and that AVO could be used to help define the Gas–Water Contact. The exploration well, drilled in 2007, was successful in finding a similar reservoir to that encountered in Laggan. The fluid encountered was a gas condensate, approximately three times richer than Laggan.

Keywords: undeveloped gas condensate discovery, turbidites, chlorite, AVO, uncertainty analysis

Laggan and Tormore are Paleocene gas condensate discoveries in approximately 600 m water depth, in blocks 206/1a and 205/5a respectively in the Flett Sub-Basin of the UKCS Faroe–Shetland Basin (Figs 1 & 2). Laggan and Tormore are situated approximately 35 km to the NW of the Clair Field and 120 km to the NW of the Shetland Islands (Fig. 1).

The traps are both mixed, stratigraphic with updip closure against bounding faults. The reservoir comprises sand-rich turbidite channelized lobes and lobes. Reservoir properties are good (permeability range is 30–300 mD) due to the presence of chlorite and pre-sorting on the shelf.

There are four exploration and appraisal wells in Laggan (Fig. 3). Laggan was discovered in 1986 by the 206/1–2 well which contained lean gas condensate. In 1996, the second well 206/1–3 targeted an amplitude shut-off downdip. The well encountered the gas–water contact (GWC) and confirmed that there was no oil rim. Well 206/1a–4a was drilled in 2004 to appraise the crest of the structure and then side-tracked downdip (as well 206/1a–4z). The 2004 appraisal well programme confirmed the updip potential of Laggan and in particular, the hypothesis that the gas saturations updip were significantly improved relative to the downdip wells, thanks to a long transition zone related to the presence of chlorite.

The Tormore exploration well, located 12 km to the SW of Laggan (Fig. 4) was drilled in 2007 and was successful in finding a similar reservoir to that encountered in Laggan. The fluid encountered was a gas condensate, approximately three times richer than that of Laggan.

Depositional model

The depositional model has been defined on the basis of an integrated study of cores, seismic and analogue studies. Seismic inversion studies have also helped to constrain the reservoir architecture.

The Laggan sands were deposited in a deep water environment. They are very well sorted, with a notable absence of very coarse grained sandstones, pebbly sandstones or conglomerates (Fig. 5). This supports a model of a sand supply that has been sorted on a shelf, prior to being transported and re-deposited in the basin as amalgamated turbidites.

A 'Low Reflectivity Seismic Package', developed in the SW of Laggan with chaotic seismic facies, pre-dates the Laggan sands (location, Fig. 6). This interval was cored in the 206/1–3 well and comprises debris flows and thin-bedded turbidites with poor reservoir potential (maximum permeability 0.17 mD). The conclusion that the interval has poor potential is supported by the absence of an amplitude variation with offset (AVO) response, in contrast to the Laggan sands. The onlap of the Laggan sands to the SW onto the depositional relief associated with the Low Reflectivity Package is evident from seismic data.

The more channelized/confined form of the Laggan sands on the flank of the Low Reflectivity Package is recognized in particular along the trend of the bounding fault, which may have been active prior to the Laggan sands to create a topographic low. The Laggan sands are interpreted to be absent or very thin (less than 10 m) on the depositional relief created by the low reflectivity

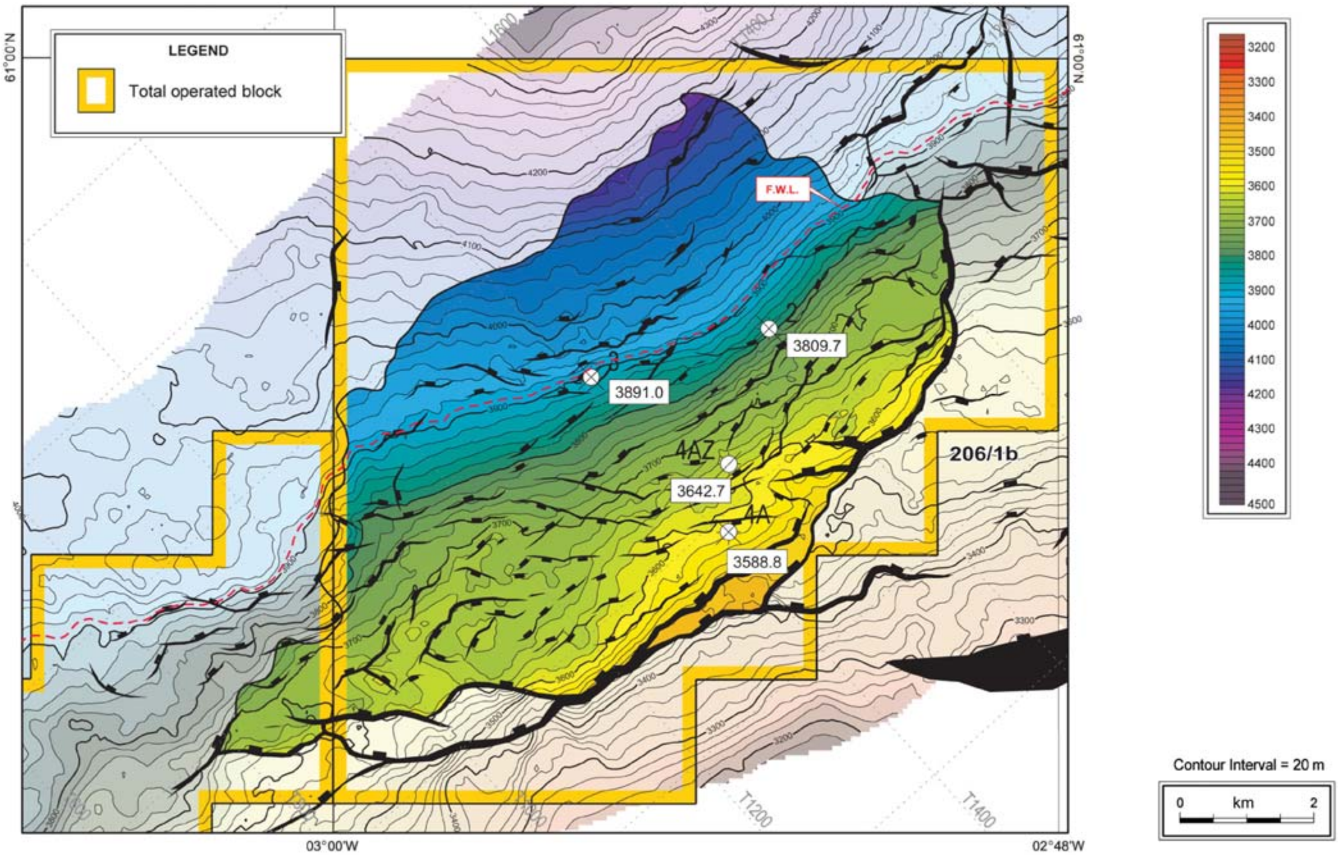

Fig. 3. Laggan, Top Reservoir depth structure map showing the outline of the field and the location of the four exploration and appraisal wells. The Laggan trap is mixed, stratigraphic with updip closure against bounding faults.

mound. The Laggan sands are interpreted to be more lobate/less confined in the main depocentre of Laggan (Fig. 6). This hypothesis is supported by the subtle but recurring coarsening upward pattern noted in the Laggan cores.

The Laggan reservoir is subdivided into three units (A, B and C). The depositional model for the Laggan C sand (lowermost reservoir unit) is also constrained by the seismic interpretation of a near-top C sand seismic event. The C sands were deposited in the initial topographic lows that were related to faulting (Fig. 7). It is noted that the C sand has a greater thickness in the depocentre to the NW of 206/1a–4z than tested by any of the four wells.

The BC shales represent a phase when the sand sedimentation supply was shut off and hemi-pelagites and mud and silt turbidites draped the C sand. Thickening of the BC shales is interpreted basinward towards the NNW and is supported by the trends in the well data (Figs 7 & 8).

The seismic impedance (IP) data shows clearly the mechanism of compensation in response to depositional relief and differential compaction; the B sand depocentres are located on the flank of the C sand depocentre (Fig. 7). Progressive onlap of the margins by the B sand is proposed, noting that the C sand extension is more limited than the B sand.

The AB shales represent another phase of hemi-pelagite mud fall-out or mud to silt turbidites and drape the B sands. Thickening of the AB shales is interpreted basinward towards the NNW and is supported by trends in the well data.

Although the resolution of the seismic data is insufficient to delineate the A and B sands individually, the well data suggests that compensation plays a role in the A sand architecture, similar to the B sand, with the A sand for example being notably thicker in the 206/1a–4a well (with a thin B sand) in comparison to the 206/1a–4z well (with a thick B sand). Thin A sands are therefore expected over the B/C sand depocentres in response to compensation (Fig. 7). The A sand distribution is more widespread than the B sand, in line with a model of progressive onlap onto the basin margins. The A sand deposition was terminated, prior to a high stand period, with no significant sand supply in the Laggan area.

The main implications of the depositional model are as follows:

- In terms of reservoir quality and heterogeneity, the reservoir comprises mature, very well sorted sands and no significant heterogeneity is expected (thin inter-bedded turbidites are likely to be rare).
- In terms of connectivity, there is an inferred low erosion potential associated with these mature, fine sand turbidite flows. The Laggan A, B and C sands are disconnected on a pure stratigraphic basis and therefore for intra-reservoir juxtaposition faults are required.

Laggan sands sediment supply and palaeo-transport direction

On the basis of the analysis of seismically derived isopach maps, amplitude extractions, well correlations, biostratigraphy and heavy mineral analysis, the following depositional scheme is proposed. The Laggan feeder system is not preserved, but is interpreted to be dip-orientated, controlled by bathymetry lows on the slope, possibly associated with deep transfer fault zones. Active faulting at the time of deposition and compensation could have controlled the change in transport direction of the turbidite flows in the Laggan area towards the east/NE and parallel to the trend of the main Laggan faults (Figs 6 & 7). The Laggan sands correspond to turbiditic channelized lobes/lobes deposited at the base of slope as ponded turbidites, controlled by normal faults. The regional basin bathymetry also controlled the distribution of the turbidite lobes.

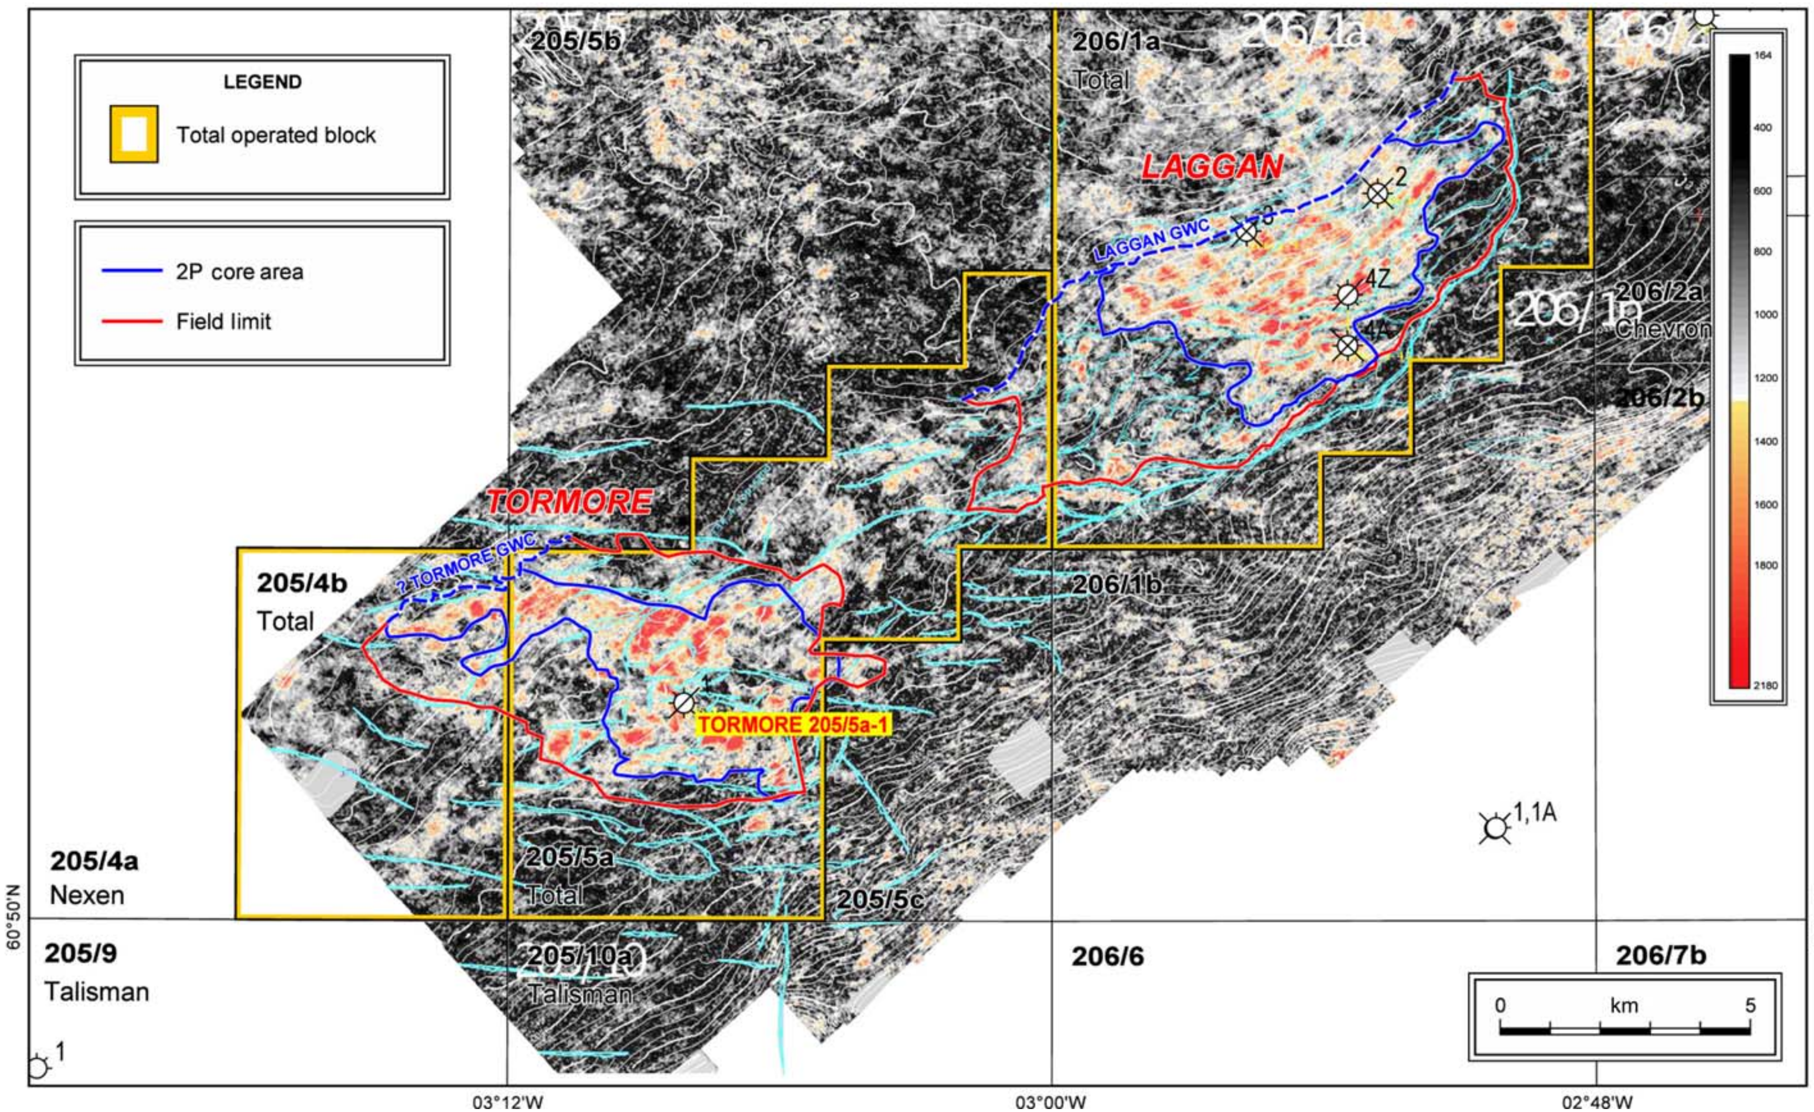

Fig. 4. Laggan, Tormore AVO and structural map. The Tormore exploration well is located 12 km to the SW of Laggan and was successful in finding a similar HC bearing reservoir as Laggan. The Laggan GWC corresponds to the AVO amplitude shut-off and it is assumed the same relationship applies for Tormore.

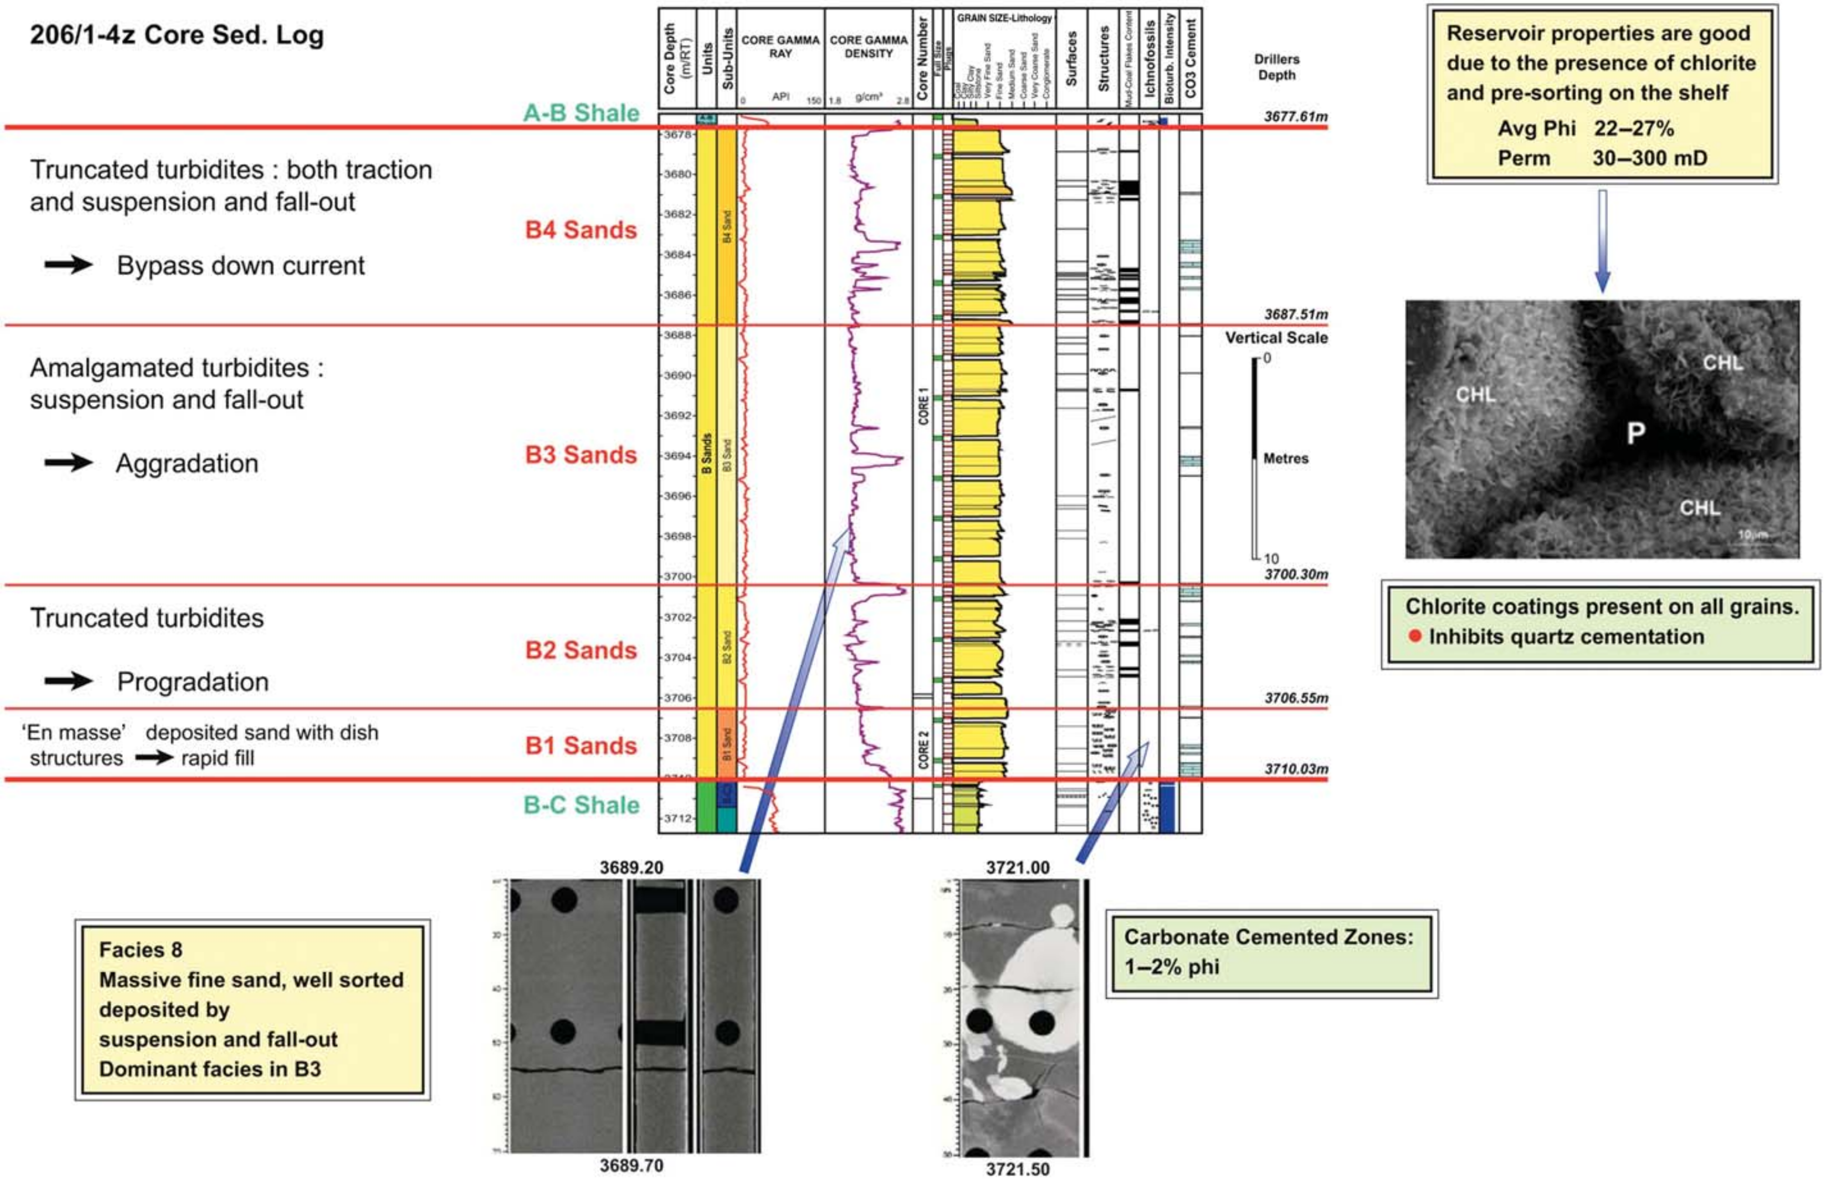

Fig. 5. Laggan reservoir characterization, with the interpretation of the 206/1a–4z cored interval shown. Reservoir properties are good due to pre-sorting on the shelf and the presence of chlorite.

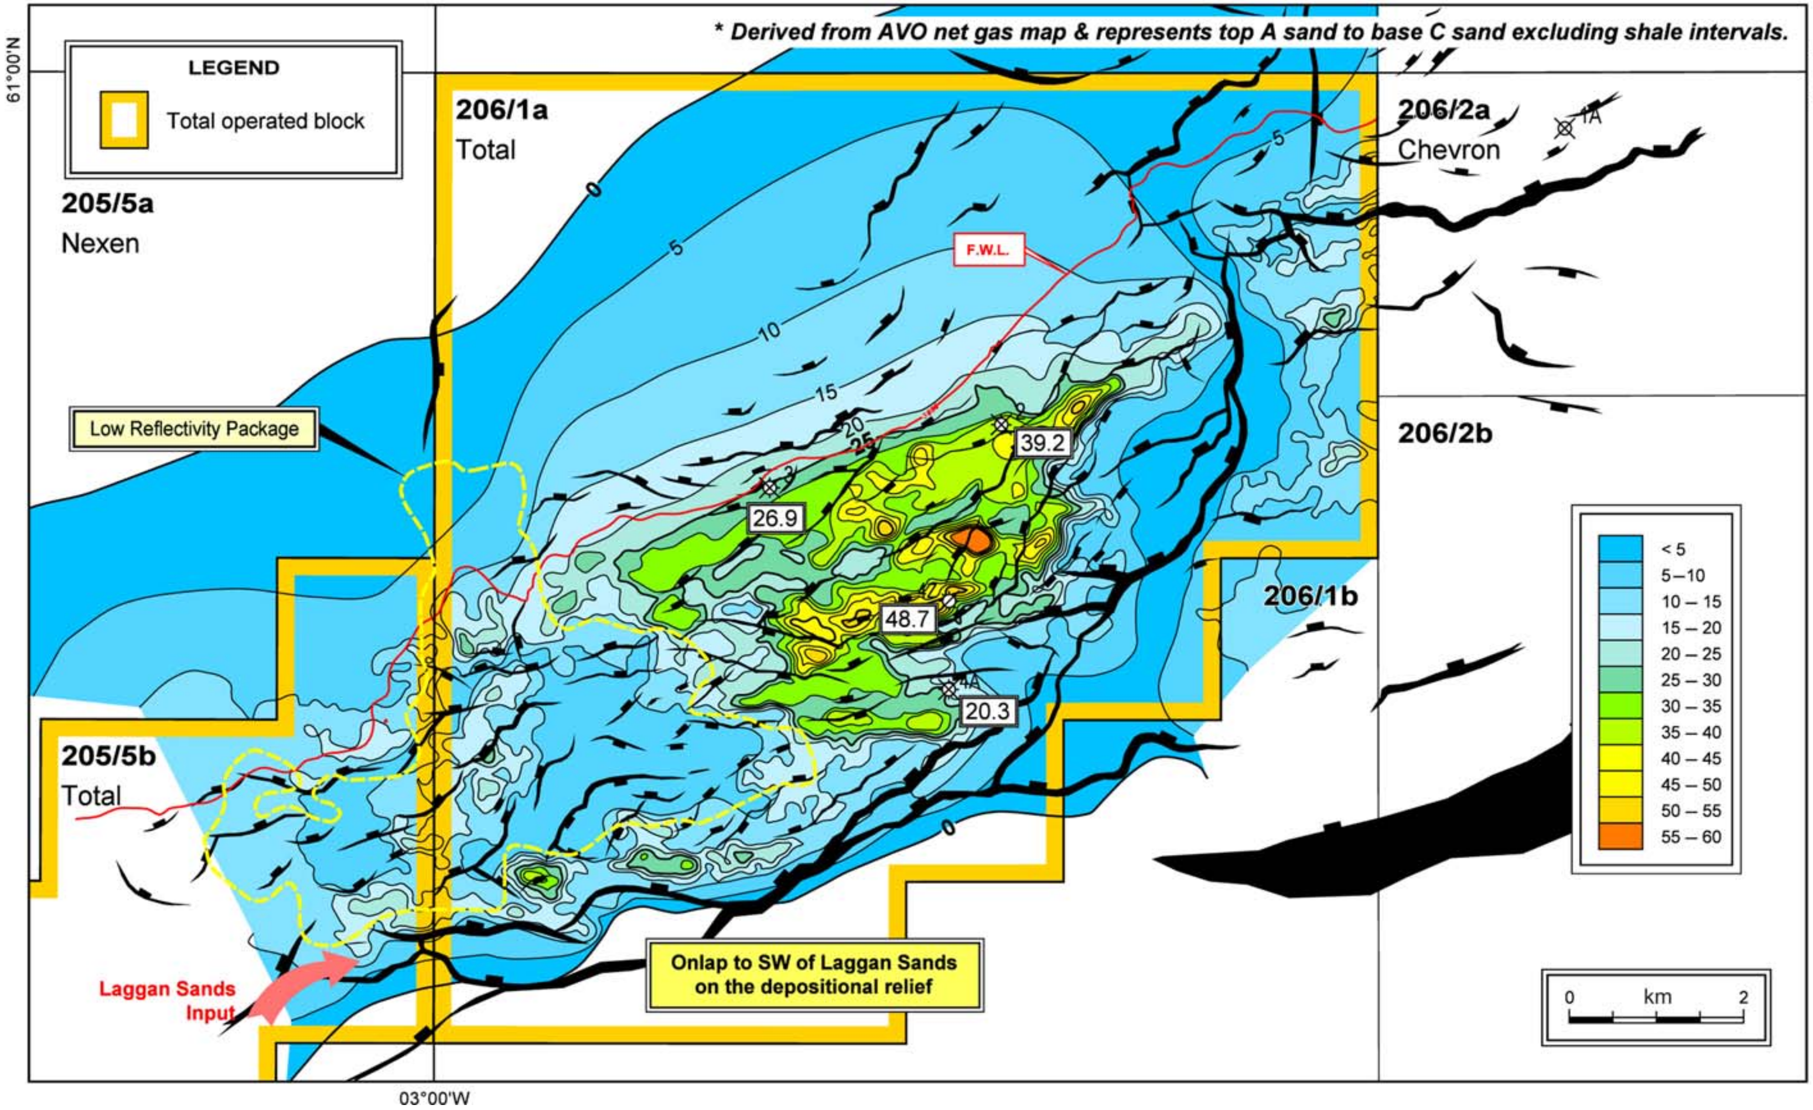

Fig. 6. Laggan sands, total gross sand isochore map. The map was derived from the Laggan AVO net gas sand map. The Laggan sands are interpreted to be more channelized/confined to the SW and more lobate/less confined in the main depocentre of Laggan, where the four wells have been drilled.

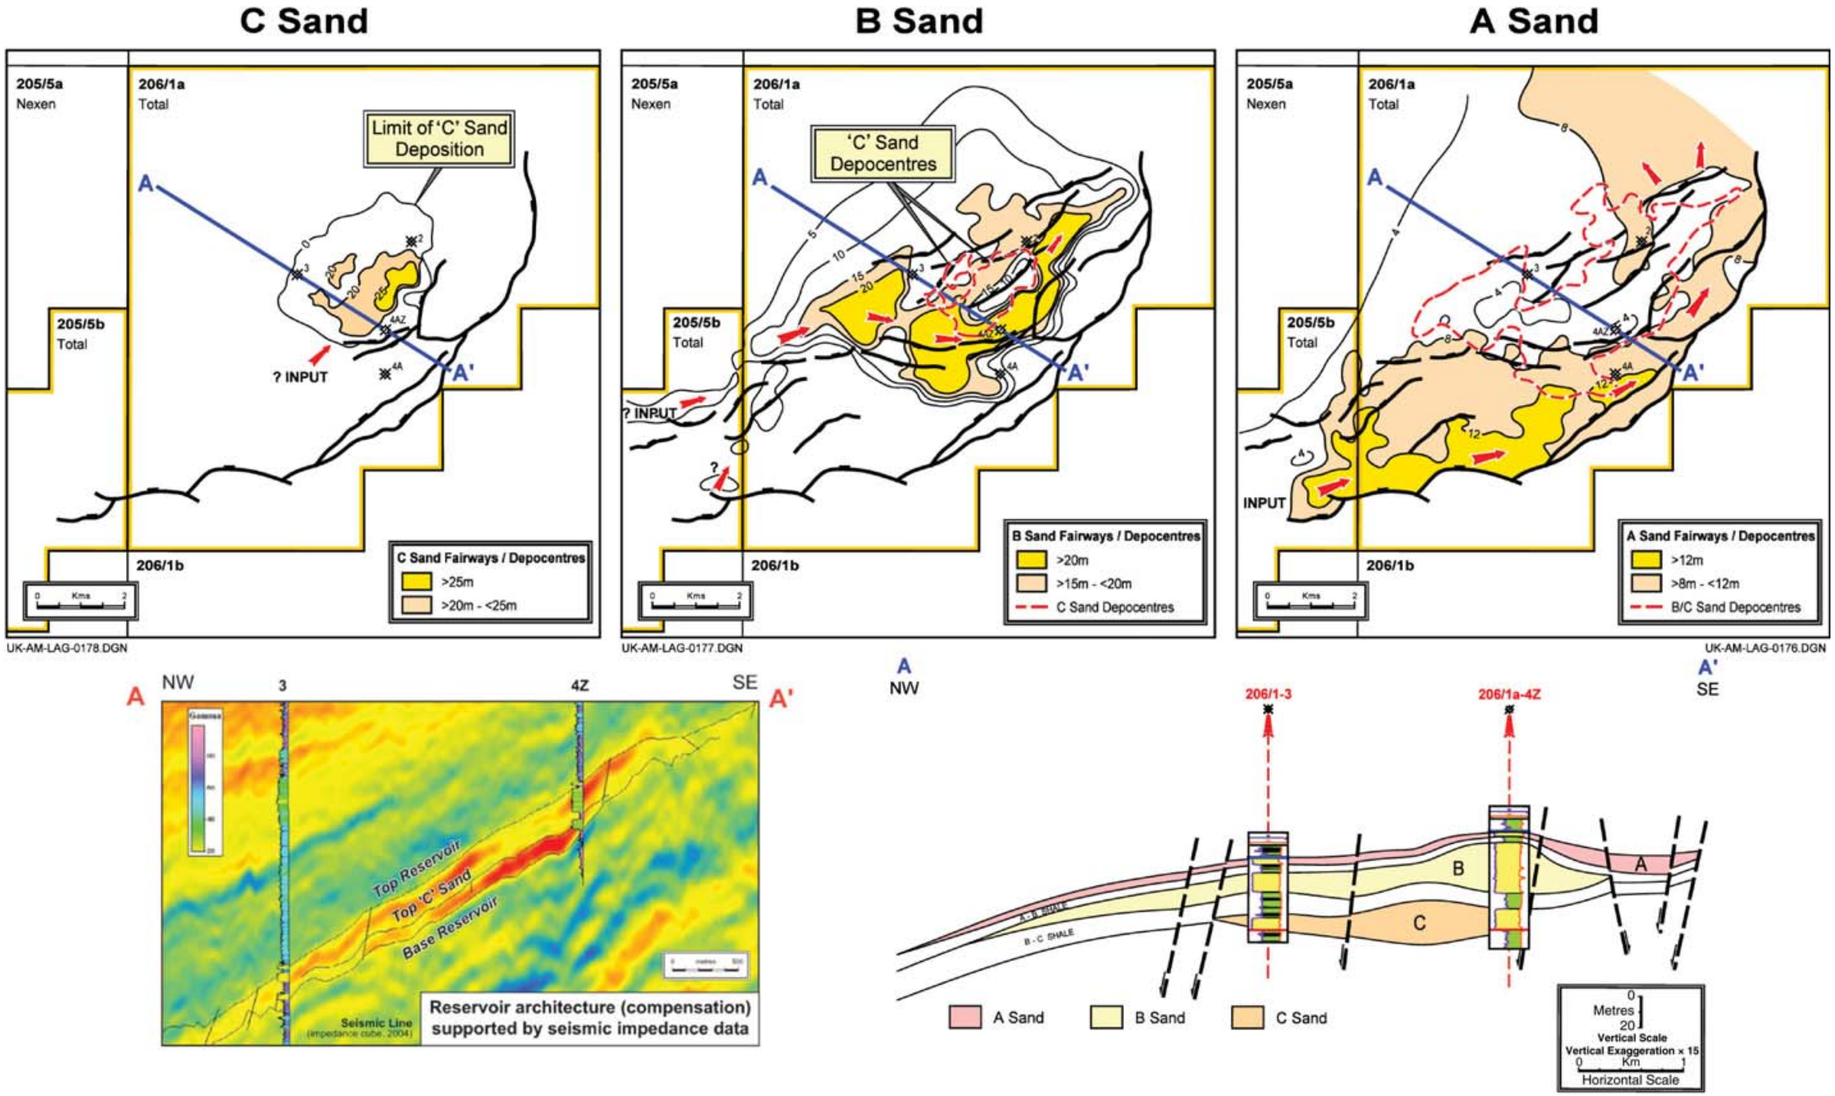

Fig. 7. Laggan depositional model for A, B and C sands. The role of compensation is inferred from seismic IP and well data. The B sand depocentres are located on the flank of the C sand depocentre. The A sand fairway is on the flank of the B sand fairway.

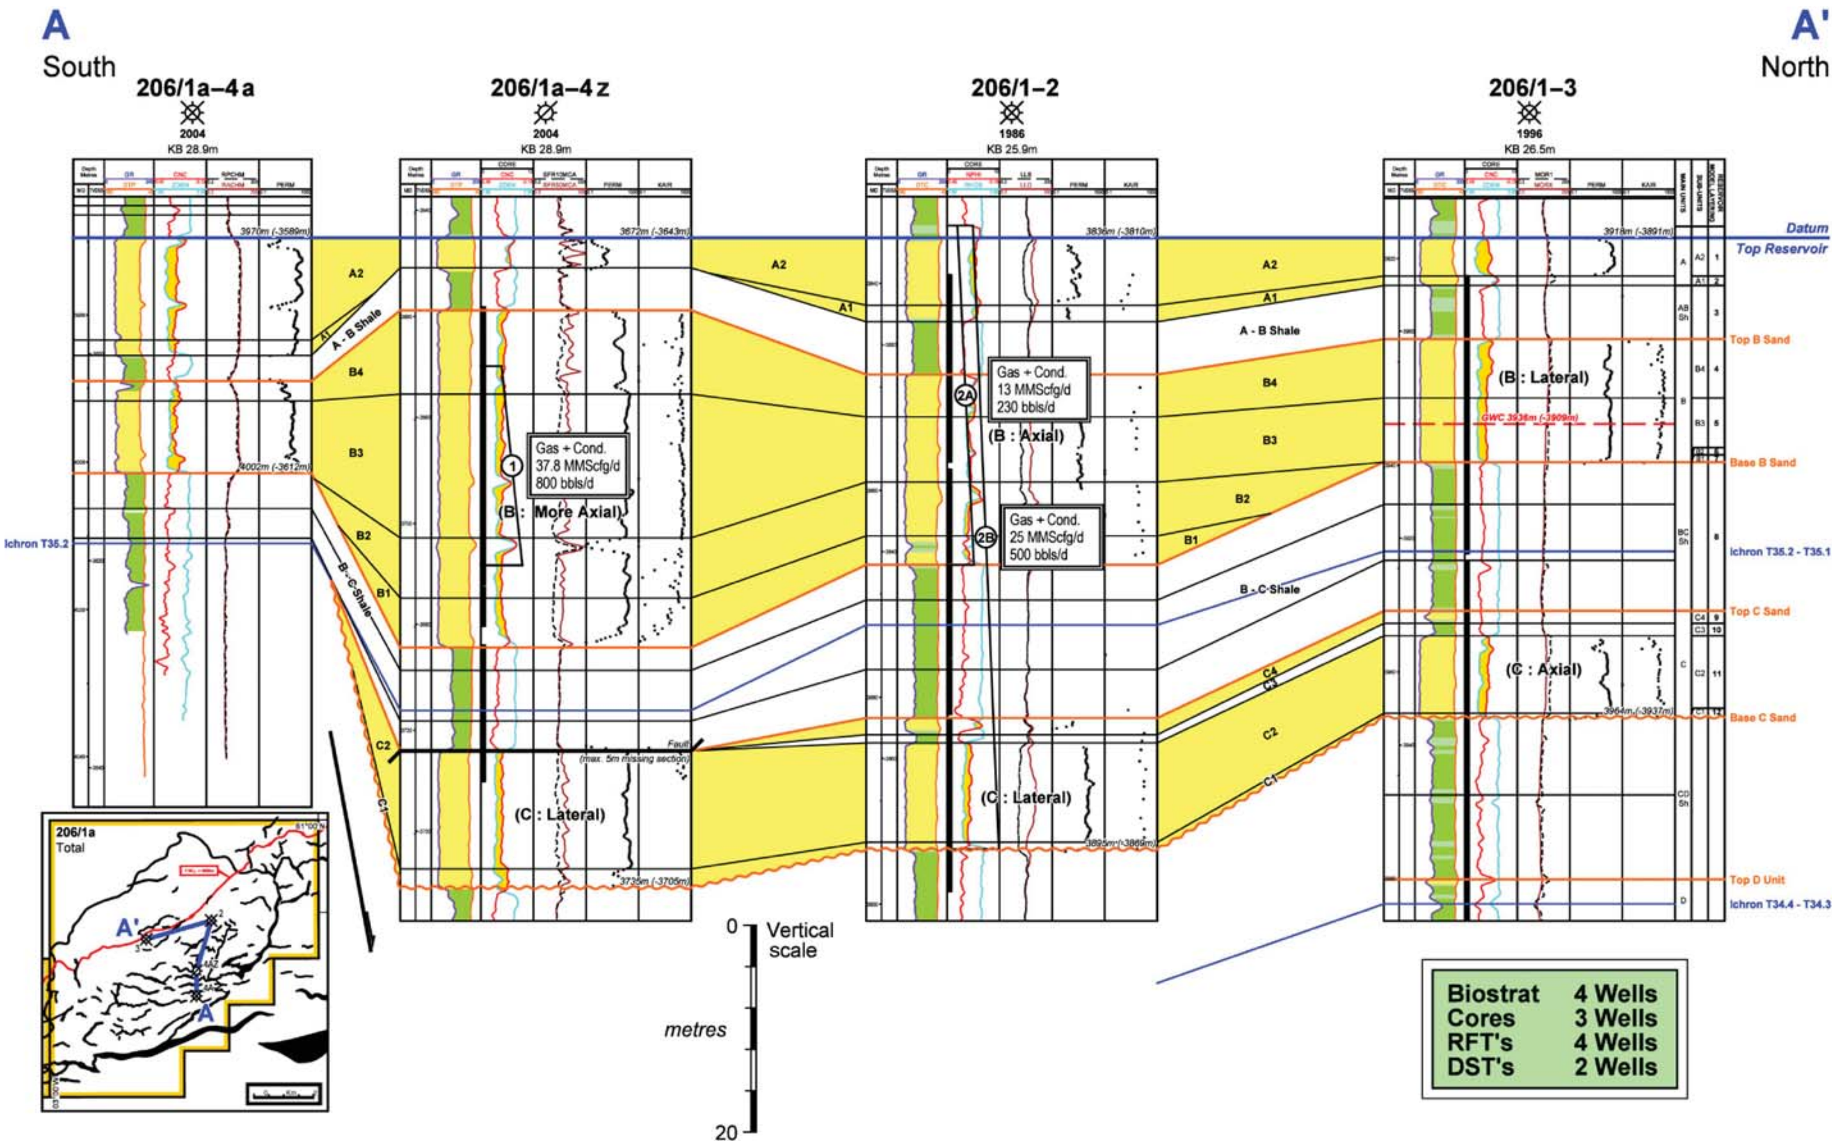

Fig. 8. Laggan Reservoir correlation. The sub-division of the reservoir into three main sand units (A, B, C sands), inter-bedded with two field-wide correlatable shales, is supported by biostratigraphic, seismic and sedimentological evidence.

Reservoir correlation

The sub-division of the reservoir into three main sand units (A, B and C sands), inter-bedded with two field-wide correlatable and predominantly hemi-pelagic shales is supported by the integrated geological scheme; in particular biostratigraphic, seismic and sedimentological evidence (Fig. 8).

A biostratigraphic study was completed by Ichron on the four Laggan wells. Correlatable biostratigraphic zones were identified and defined where possible on downhole occurrence, but influxes and base occurrences, along with trends in assemblage composition, were also used. The palynological and micropalaeontological zonations follow an internal Ichron scheme, which has been used widely in the West of Shetland Basin (Fig. 2 and Lamers & Carmichael 1999). Two key biostratigraphic markers have been identified which provide a framework for the reservoir correlation: first, Ichron T6 event (T35.2 to 35.1 sequence) within the B–C shales and notably absent in the 206/1a–4a well; and second, Ichron T5.4 event (T34.4 to 34.3 sequence) below the base reservoir (Figs 2 & 8).

The seismic interpretation also supports the model that the C sand is absent in the 206/1a–4a well, with the southern limit of the C sands controlled by a fault lying to the north of the 206/1a–4a well (Fig. 7). The more limited reservoir distribution of the C sands (present in only three of the four wells) in comparison with the overlying A and B sands (present in all four Laggan wells) is also compatible with the interpretation of the Laggan sands as ponded turbidites. C sand deposition comprised the initial infilling of the fault-controlled basin topography. It is therefore not surprising that the subsequent deposits of the A and B sands were more widespread.

Petrographic overview

In terms of the petrographic analysis of the three cored Laggan wells, the Laggan sands comprise arkosic sandstones with an average porosity from thin section analysis of 16% (10% primary, 6% secondary) for the calcite-free samples. Calcite cements occur in nodules, which make up about 10% of the thickness of the cored sands and have typically 1–2% porosity (Fig. 5). These nodules are not expected to form continuous layers. Non-calcite cemented samples have about 1–2% quartz cement and 3% clay cement (mainly illite and kaolinite). Although chlorite is a minor component (3–7 wt%), it occurs as a thin, continuous coat on all grains. Chlorite plays a key role in porosity and permeability preservation by inhibiting quartz cementation. Analysis of the chlorite indicates an Fe/Fe + Mg ratio of around 0.6 (Sullivan *et al.* 1999). This is a lower ratio than that found in chlorite from shallow marine sandstones (normally around 0.7–0.8, Hillier 1994). The current preferred mechanism for the origin of chlorite in the Laggan sands is related to the post-depositional infiltration of alteration products from tuffaceous material. Tuffs have been identified and analysed in cores in the interval below the Laggan sands and they contain trace elements, including rare earth elements similar to the chlorite analysed in the Laggan sands.

Petrophysical interpretation

Average porosity for the reservoir sands per Laggan well ranges between 19 and 23%. Net-to-gross values are between 90 and 100% for the reservoir sands. Wells 206/1a–4a and 206/1a–4z were drilled with the aim of confirming irreducible levels beyond the transition zones and both wells found irreducible water levels of around 16–18%.

A GWC of 3909 m TVDSS was encountered in the 206/1–3 well. This conclusion can be confidently drawn from reprocessed resistivity log data which supports the reservoir pressure data in defining the GWC.

Water salinity remains the single most important uncertainty for the Laggan petrophysical analysis. Well 206/1–3 sampled water with a salinity in the order of 6000 ppm in the aquifer. Derived water salinity values to match extensive core saturation height modelling and NMR log determined saturations indicate, however, that water salinity levels are of the order of 38 000 ppm NaCl equivalent in the updip 206/1a–4a and 4z wells. This implies a possible salinity gradient of approximately 150 ppm NaCl per metre, or a step change between the aquifer and the hydrocarbon leg. This uncertainty cannot be resolved with current data and requires additional sampling of the formation waters.

Extensive core-based capillary pressure experiments were conducted to evaluate the water saturation v. height in the Laggan sands. The reservoir material that was tested can, regardless of the sand interval, be seen as one coherent unit, as all capillary pressure experiments collapsed on one another after Leverett-*J* dynamic normalization. The resulting saturation height function by porosity classes is displayed in Figure 9 with the large transition zone effects of up to 200 m clearly seen.

As noted above, chlorite forms a ubiquitous grain coating within the fine to medium grained Laggan sands and has a fundamental effect on the petrophysical characteristics. Firstly, the chlorite at the reservoir depth preserves porosity as well as permeability by restricting potential quartz overgrowths. Secondly, the high surface area of the chlorite and its grain coating morphology result in high surface-bound water, which can provide an explanation for the extensive transition zone that is observed from capillary pressure experiments. The extensive transition zone is extraordinary given the fact that the reservoir is filled with lean gas condensate.

The current uncertainty on the Laggan water saturations determined from the integration of core and log measurements has been estimated as approximately $\pm 5\%$ saturation units.

Seismic interpretation

The 3D seismic dataset over Laggan comprises several different datasets acquired in 1995 and 1996. Unfortunately no single dataset covers Laggan. A marked improvement in data quality has been achieved through re-processing the data several times between 2002 and 2006. The current 3D seismic interpretation of Laggan was based on a combination of the 2005 PreSTM re-processed seismic dataset, which covers only the central part of the field and the 2002/2003 PreSTM reprocessed dataset for the rest of the field.

A semi-regional PreSTM seismic re-processing study was also performed in 2006 comprising six different surveys covering an area of 2044 km^2. The purpose of this study was to provide a regionally continuous dataset covering Laggan and surrounding blocks, and this was used to interpret Tormore.

A new 3D seismic acquisition campaign is planned in 2009 over Laggan and Tormore. The primary objective is to provide a modern, consistent 3D dataset to help optimize the location and often complex trajectories of the planned Laggan and Tormore development wells and provide a viable baseline for any future 4D project.

A seismic section through the Laggan wells is shown in Figure 10. The Laggan sands, being of lower IP than the overlying shales, correspond to a peak at the top of the reservoir, while the base corresponds to a trough (North Sea polarity). The black peak that can be observed between top and base reservoir in the 206/1–4z can be considered as near Top C sand. None of the individual sand layers (A, B and C sands with thickness variations from 3 to 33 m) is seismically resolved. The tuning thickness is estimated

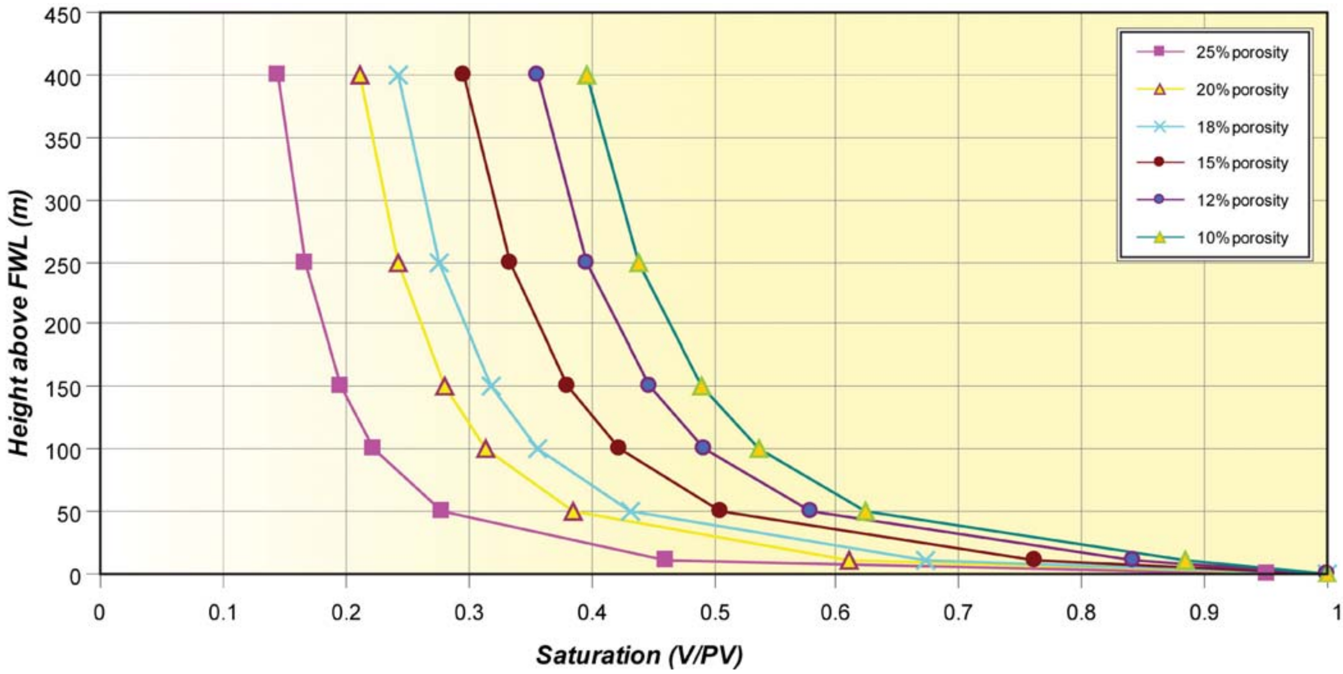

Fig. 9. Laggan *J*-function derived SW height relationship. Large transition zone effects of up to 200 m are clearly seen and are related to the presence of chlorite.

from the tuning curve to be between 16 and 20 ms, depending on which seismic dataset is considered. The Laggan sands gross reservoir thickness is below tuning thickness over the major part of Laggan.

Seismic inversion

A seismic acoustic inversion was completed in 2006. The resolution of the inversion dataset is, however, not enough to resolve the individual sand layers (Fig. 7). Furthermore, it is difficult to distinguish sand from shale layers using the inversion alone. The idea of using these inversion data to derive reservoir thickness was therefore quickly abandoned. The inversion data was mainly used for fine tuning the picking of the top and base of the reservoir, constraining the depositional model (reservoir architecture) and assessing aquifer size.

AVO analysis

The principle for Total's AVO analysis simply relates to the observation that Poisson's ratio (equivalent to V_p/V_s) contrast is the key driver for differences in the far angle reflectivities at identical near-angle reflectivities (Ostrander 1984).

In the west of Shetland, pre-stack data analysis needs to cope with imperfect data. The acquisition conditions are known to be harsh and the locally complex sedimentary overburden hampers seismic propagation. Seismic resolution and amplitude fidelity are therefore limited. Total's proprietary AVO analysis methodology is particularly suited for this challenging task (Paternoster *et al.* 2008). It relies first on a suite of seismic data quality assessments and is designed to robustly enhance AVO anomalies derived from the AVO 'Seismofacies' volume. Seismic data is taken into account as they are and not as they should be. Well data is not used to generate this AVO volume. It is used as an independent control and validation. The impact of frequency harmonization and data scaling on relative difference is a key factor in the analysis.

Net pay estimation

In the Laggan evaluation, AVO Seismofacies was used as a direct estimation of the cumulated (total) net pay of the Laggan sands. It should be noted that AVO enhances the contribution of Poisson's ratio to seismic attributes (Castagna & Swan 1997). Gas sands are enhanced relative to other lithological contrasts in the AVO volume. Filtering the higher frequency content of the seismic data increases the interference between the tops and bases of the various sand bodies. The resulting tuned AVO response can therefore be expected to be linearly related to the cumulated reservoir thickness. Interferences from internal contrasts simply discount the non-reservoir from the overall responses. These two characteristics are particularly suited to Laggan's blocky sand bodies and thickness ranges. As a result, the AVO Seismofacies response is found to be very well correlated with Net Pay thickness at the four Laggan well penetrations (Fig. 11). This crossplot gives a much improved correlation co-efficient relative to cross plotting net pay v. filtered amplitude data (0.96 v. 0.50).

Compartmentalization

The risk of compartmentalization is identified as the main dynamic uncertainty. This risk has been reduced through an improved definition of the fault configuration, by re-processing the 3D seismic and detailed seismic attribute analysis.

Pressure data (RFT and DST) from the 206/1–2 well indicates a possible disconnection within the reservoir (Fig. 12). The mapped faults from the seismic interpretation do not, however, form isolated panels within the reservoir. The possibility of field-wide compartments (potentially under seismic resolution) was therefore considered.

A DST was performed in the B sand in the 206/1a–4z well. The well was tested at a rate of 37.8 MMscfg/day and 800 bbls/day of condensate through a 1 inch choke. It is difficult to explain the transient depletion observed and mobility reduction seen on the pressure build up (PBU) derivative based on the depositional model. The Laggan sands are interpreted to have no significant lateral heterogeneity on the basis of the depositional model. A

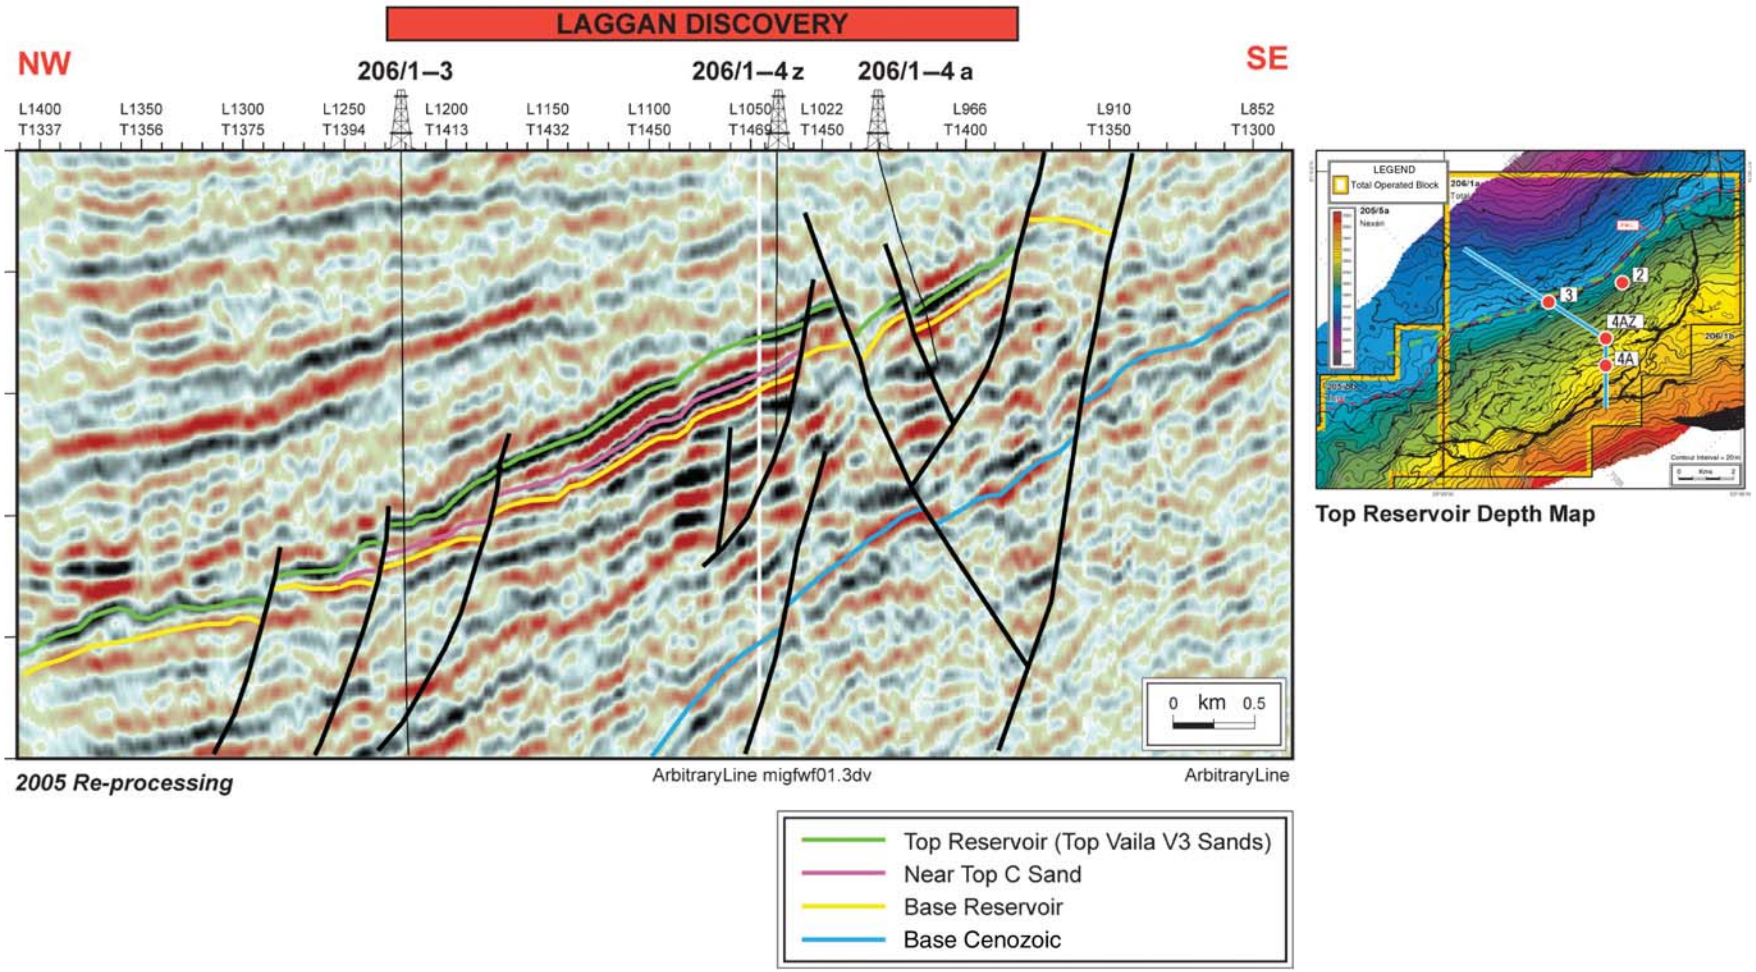

Fig. 10. Arbitrary seismic line through Laggan wells 206/1–3, 4a and 4z. The updip limit of the Laggan discovery is a significant fault downthrowing to the NW. None of the individual sands (A, B and C) are seismically resolved and the Laggan gross reservoir thickness is below tuning thickness over the major part of Laggan.

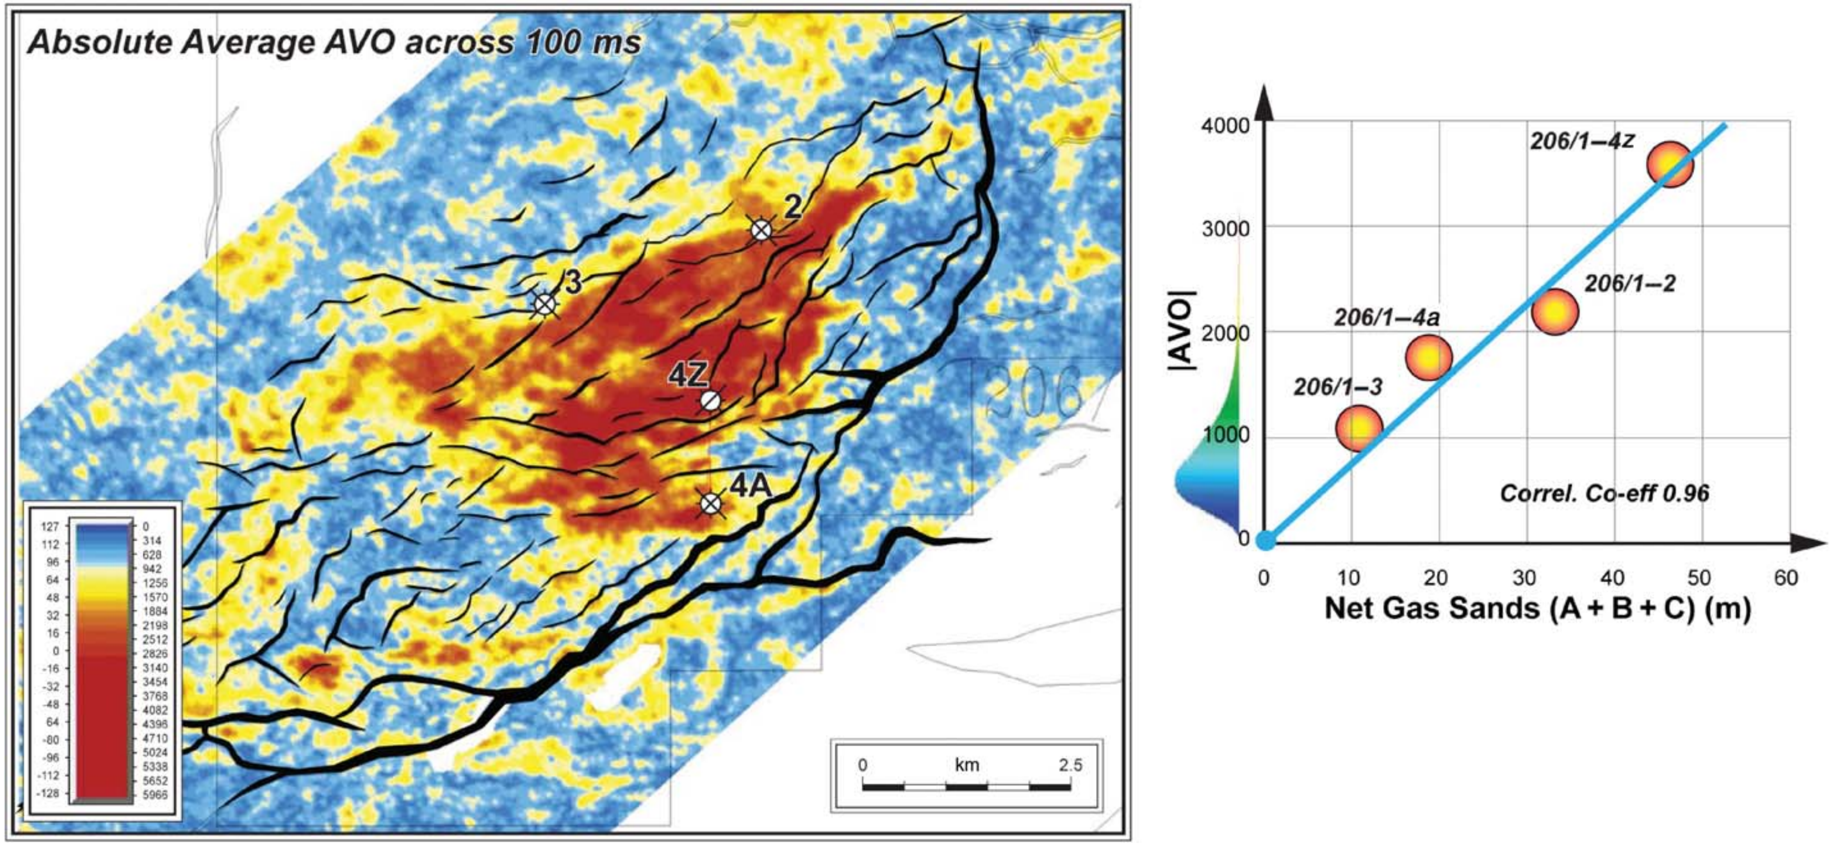

Fig. 11. Calculating net gas sand on Laggan using AVO. A very good correlation is observed between AVO and net gas sand. The relationship was applied to reduce the main static uncertainty, that is, predicting reservoir thickness away from well control.

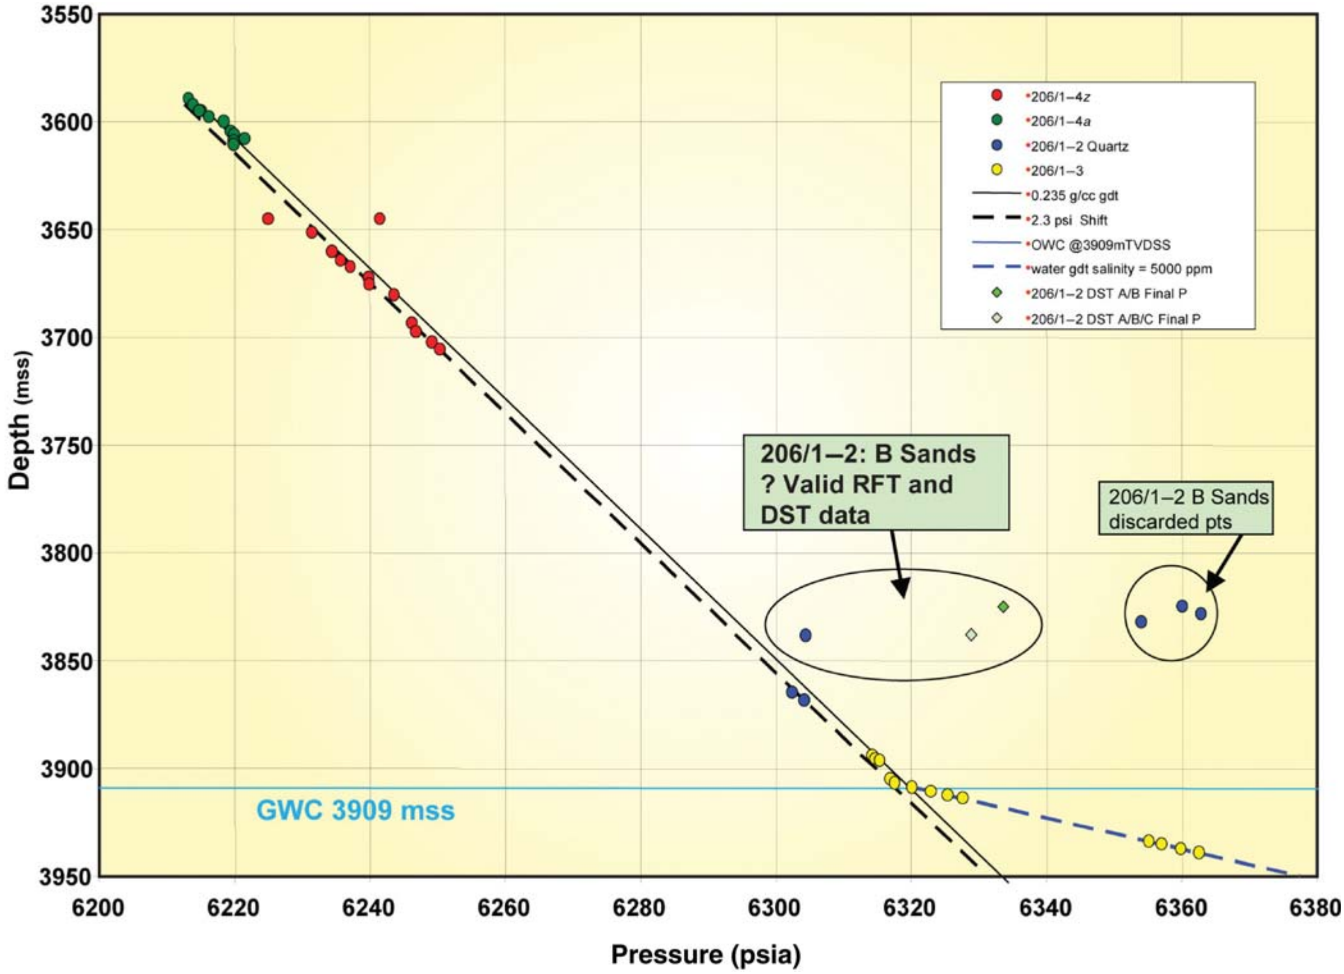

Fig. 12. Laggan pressure v. depth plot. Pressure data (RFT and DST) from the 206/1–2 well suggests a disconnection within the reservoir.

more likely concept is to explain the PBU characteristics based on sub-seismic faulting.

A complimentary fault seal evaluation study was performed involving the analysis of cores and fault juxtapositions (Fig. 13). The review of the Laggan cores indicated several cataclastic bands. These cataclastic bands have the potential to seal by the formation of finer particles by grain crushing with the destruction of chlorite coatings and consequently significant permeability reduction. The fault juxtaposition analysis using a 1D approach of Laggan well data indicated the potential to have both cataclasis and shale smearing with small throws (less than 25 m). No faults are evident from dipmeter logs, although it is recognized that cataclastic bands are below the resolution of the tool.

The analysis of seismic attribute data suggested a large number of relay zones. These zones could represent potential pathways for fluid flow, if they were not affected by cataclasis. The identification of potential compartments was based on the analysis of the following data with an iterative approach applied (Fig. 14). The mapped fault polygons were the starting point to define compartments and then it was assessed how far the faults could be realistically extended and whether they could realistically form compartments. Another consideration was the fault throw, with a simple concept applied; the larger the throw, the more likely the fault is to seal. Seismic attribute maps were analysed, with combined dip, azimuth and fault cubes proving to be particularly useful. The available dynamic data was also integrated in the study (pressure data from the four Laggan wells and DSTs performed in Laggan wells 206/1–2 and 4z).

An additional degree of complexity was, however, required to match the DST data with the introduction of segments, representing partially sealing panels. Segments are simply less well defined panels, with poor evidence of fault continuity relative to compartments, given the available data. The 206/1a–4z PBU was matched using first a 2D numerical model (in Saphir). A match was obtained using a variable transmissibility of the segments and by extending an existing fault. A second match was then performed using the Eclipse model, where the PBU was simulated (Fig. 15). A uniform reduction of transmissibility along the segments (transmissibility multiplier of 0.005) was used to match the transient depletion.

Finally, three different scenarios were defined to reflect the uncertainty and capture potential downside and upside cases, relative to the base case, as follows. Eight compartments were defined for the downside scenario within the main field area (Fig. 14). Two compartments were defined for the base case scenario within the main field area, compatible with a possible interpretation of the 206/1–2 RFT and DST data (Fig. 12). For the upside scenario, there were no compartments, reflecting the uncertainty with the 206/1–2 pressure data interpretation. For all three cases, partially sealing segments were defined with reduced transmissibility, in order to match the dynamic data.

Static uncertainty study

An uncertainty study (using ALEA/JACTA software) was completed to quantify the static uncertainties and in particular to

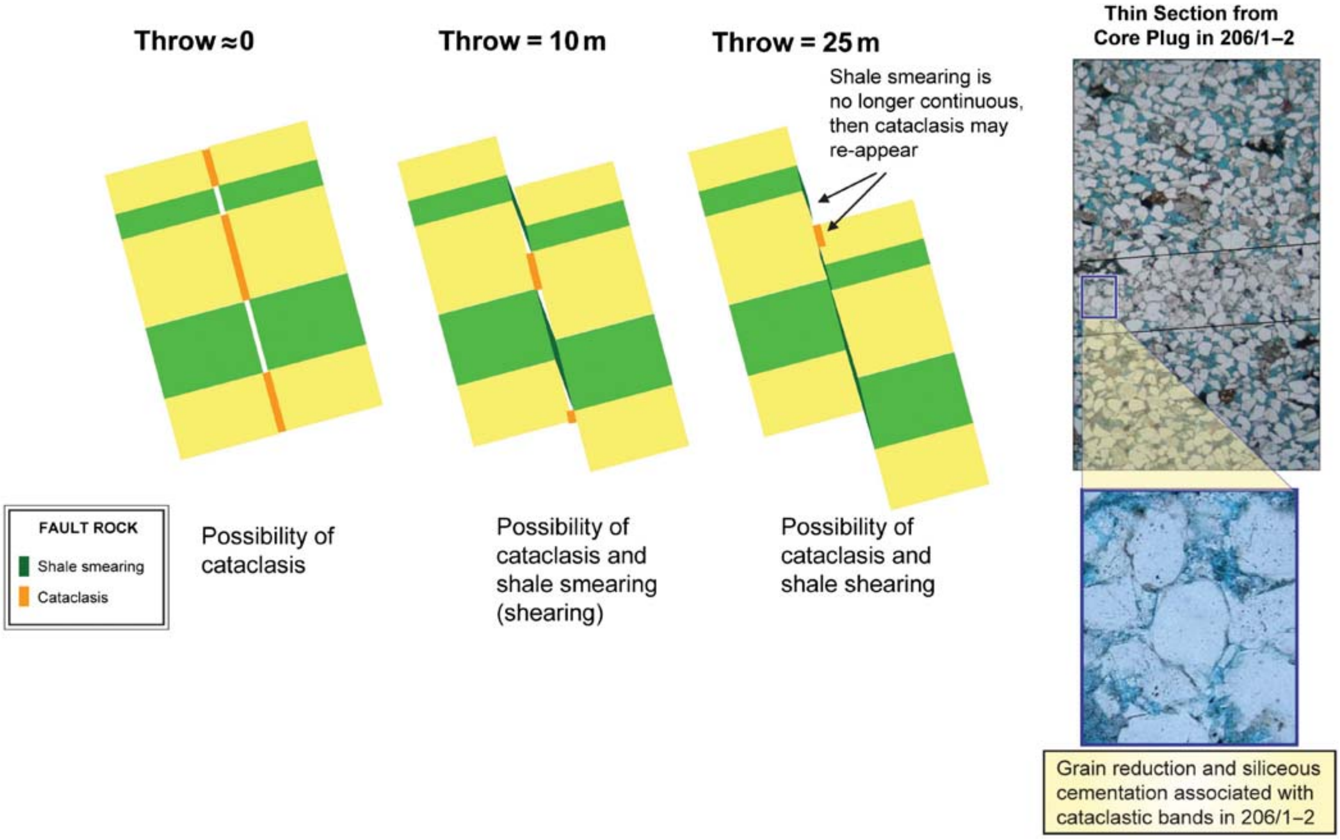

Fig. 13. Fault juxtaposition analysis and cataclastic bands in well 206/1–2. Fault juxtaposition analysis indicated the potential to have both cataclasis and shale smearing with faults with small throw (below seismic resolution).

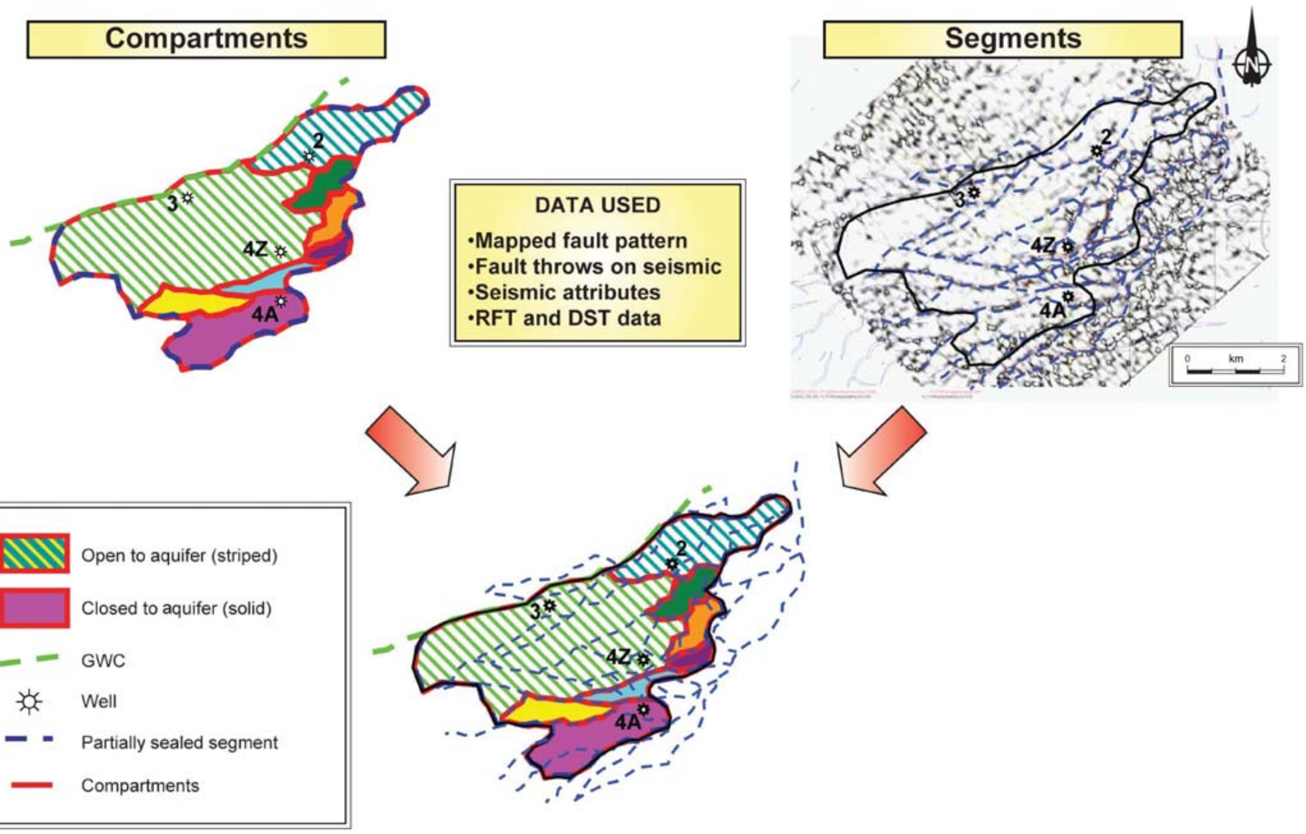

Fig. 14. Definition of compartments and segments. In order to match the dynamic data, a combination of isolated compartments and partially sealing segments was used in the reservoir simulation studies.

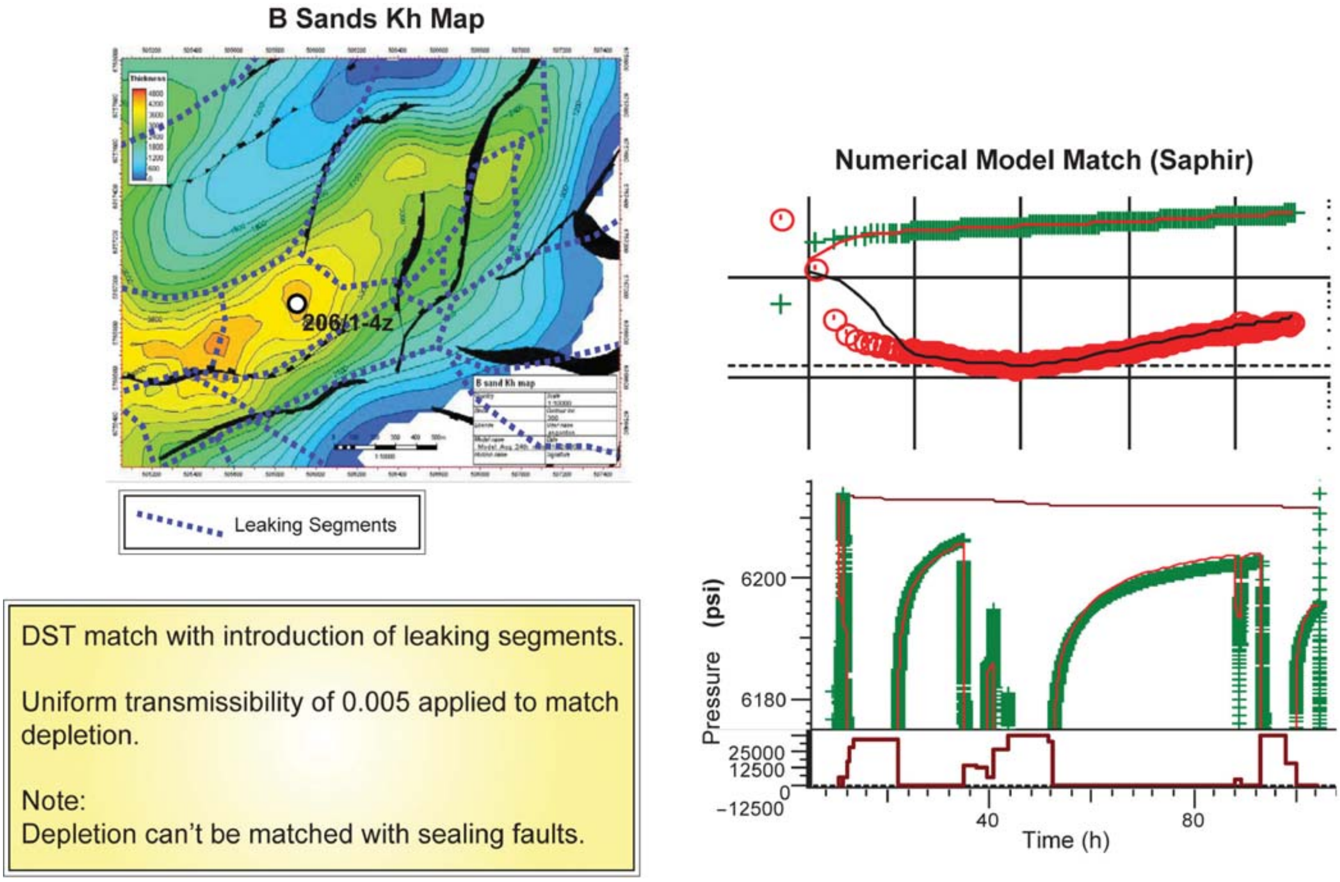

Fig. 15. 206/1a–4z match with leaking segments. The transient depletion and mobility reduction seen on the PBU was matched by partially sealing faults (in part sub-seismic).

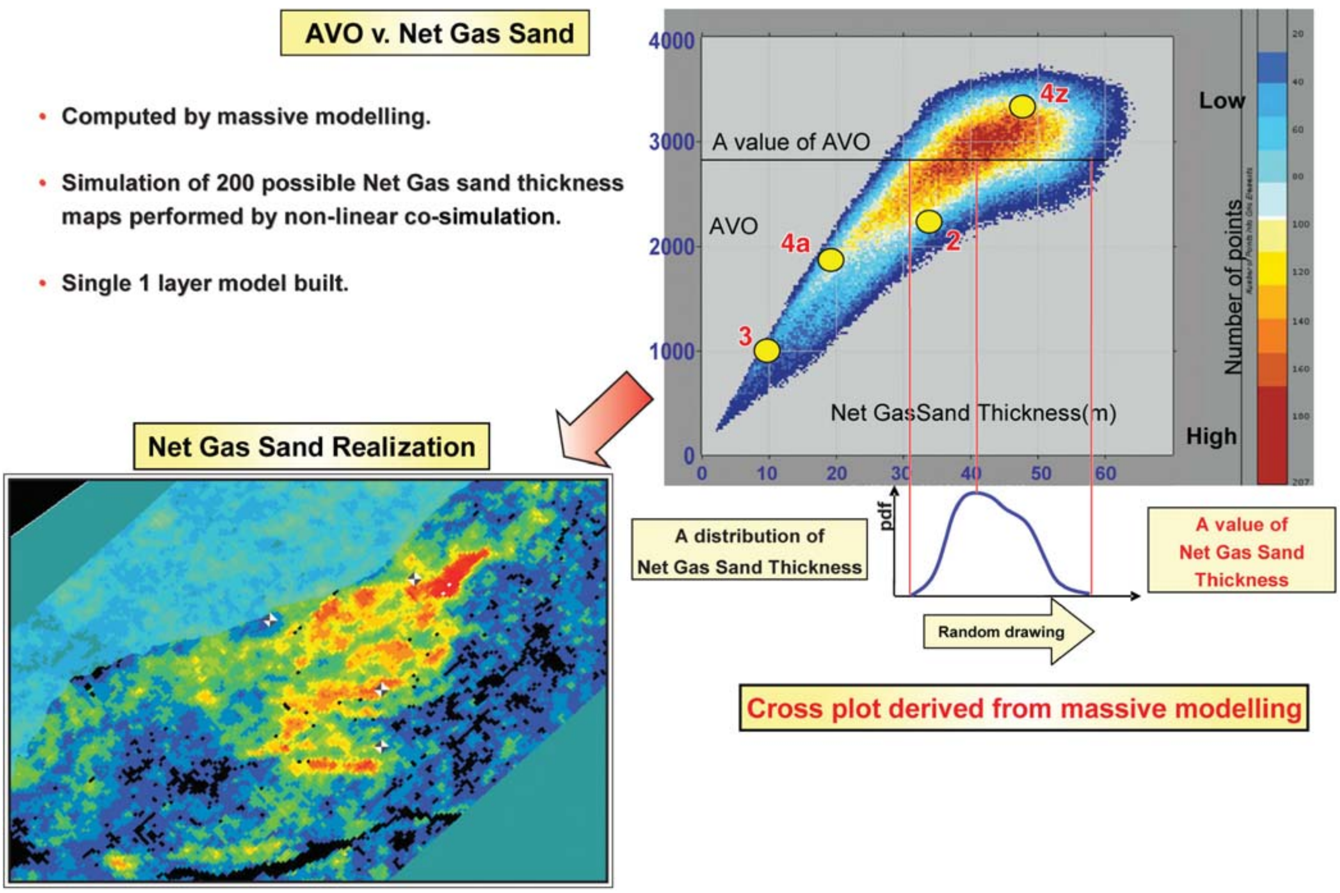

Fig. 16. Uncertainty on net gas sand thickness from AVO. The uncertainty was computed by massive modelling. Two hundred possible net gas sand thickness maps were generated by non-linear co-simulation.

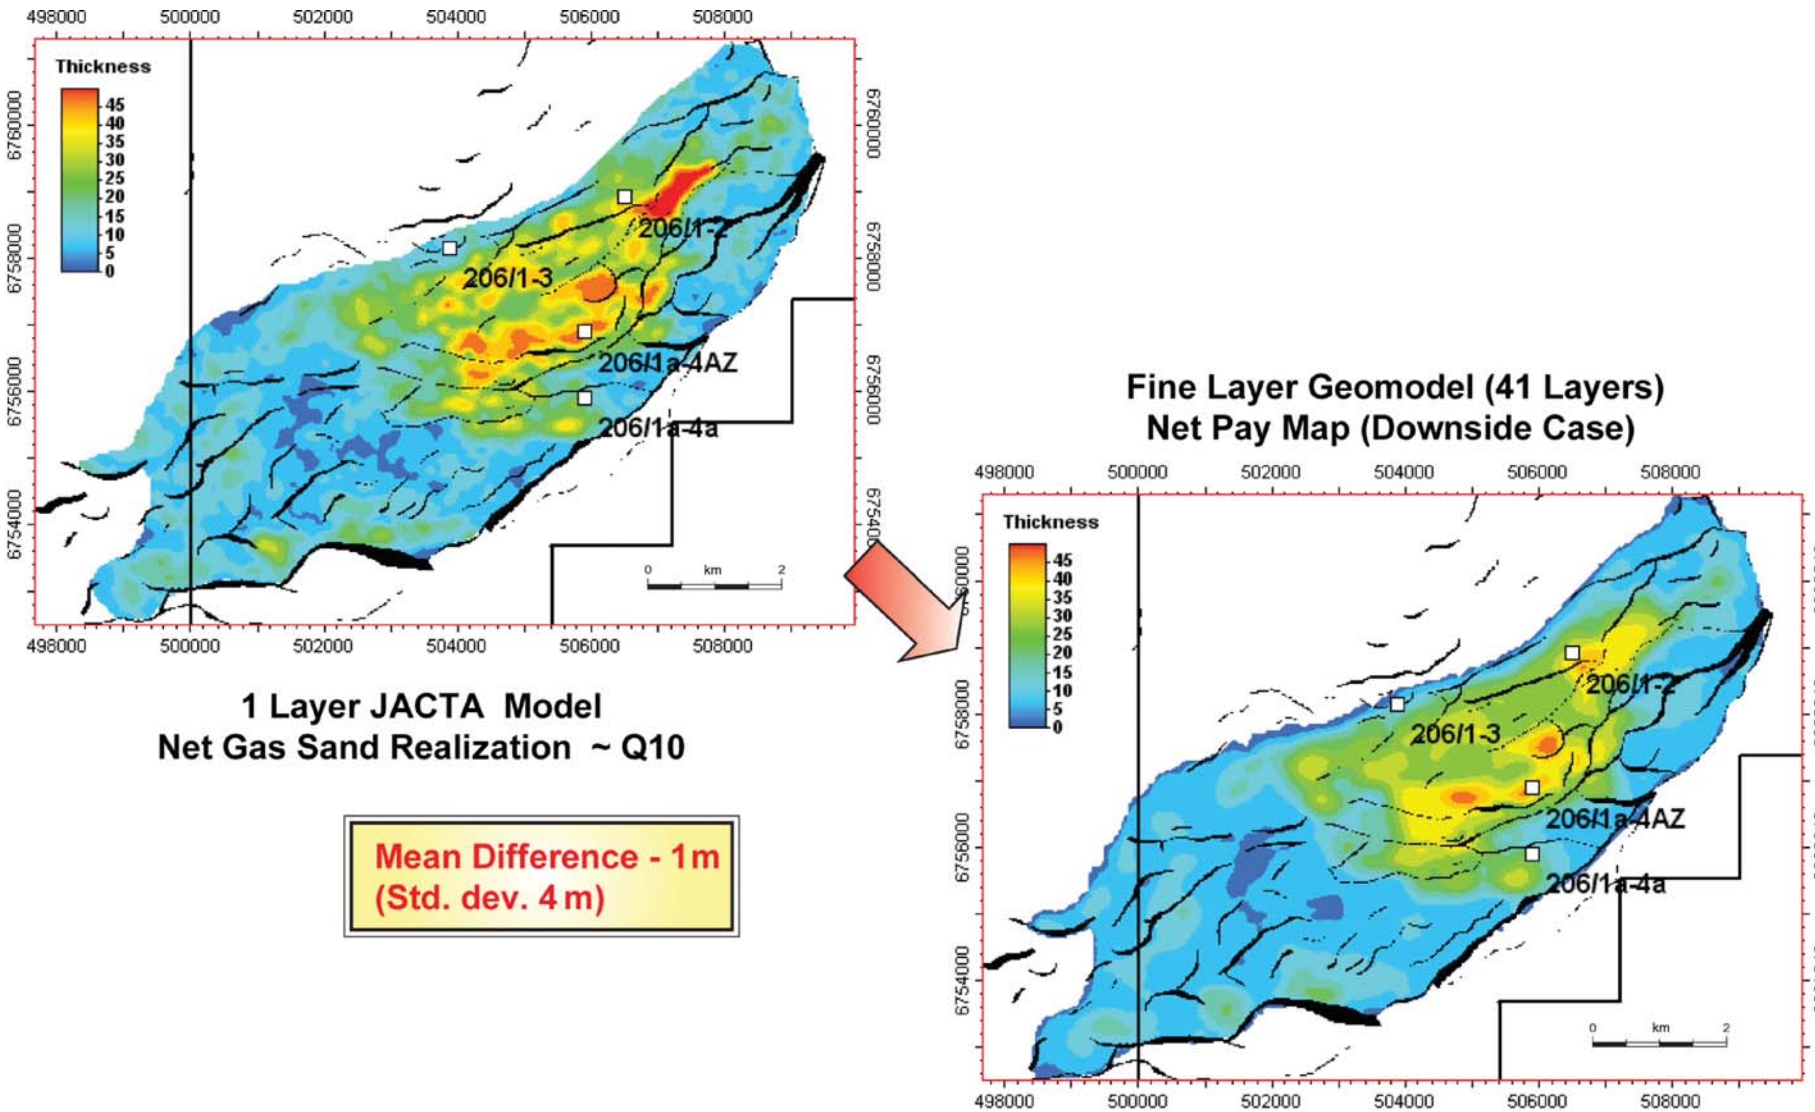

Fig. 17. Net pay v. net gas sand map (downside case). The challenge was to build fine-layer 3D geological models, which were broadly compatible with results of the one-layer JACTA models.

address the uncertainty on the relationship between AVO and net gas sand (Guemene *et al.* 2006). Static uncertainties evaluated in the study were:

(a) depth of top reservoir (from seismic picking) and depth conversion uncertainties;
(b) depth of the GWC;
(c) net gas sand derived from the AVO map;
(d) porosity modelling;
(e) water saturation evaluation.

The study was performed in three steps. First, an evaluation of the structural uncertainties was performed using ALEA software. The uncertainty in depth at top reservoir was assessed as ranging from 0 to 50 m, and 200 possible maps at top reservoir were simulated.

Second, the uncertainty on net sand from AVO was addressed. The dispersion was estimated using Massive Modelling, with the following workflow. Log elastic properties (Rho, V_p, V_s) were upscaled for each reservoir (A, B and C sands) to generate a distribution of parameter values at sand layer scale. Then millions of 1D models were generated, sampling the parameter distributions with sand and shale layer thicknesses representing the plausible variations across Laggan. Thereafter, massive seismic modelling of randomly sampled models (hundreds of thousands) was performed to generate AVO 'Seismofacies' traces. AVO attribute extraction was performed, as per real seismic data. The AVO v. net gas sand thickness (Net Gas column) was then cross plotted (Fig. 16).

The third step was the geological in-filling, using JACTA software. Two hundred possible net gas sand thickness maps were generated by non-linear co-simulation. A single 1 m-thick layer model was built. The porosity uncertainty was defined by the mean uncertainty affecting two average porosity maps derived from the Geomodel. The mean uncertainty was assessed as approximately 1 standard deviation corresponding to approximately ± 1 porosity unit.

The GWC was randomly sampled with the uncertainty range, based on the interpretation of the pressure data. The uncertainty was assessed as ranging from -3 to $+1$ m. The water saturation transition zone was defined by a J function and the associated uncertainty was modelled with an uncertainty range of approximately $\pm 5\%$.

Sensitivity analysis was performed to identify the key sources of uncertainty. The principal uncertainty was identified as the one related to the application of AVO to define net gas sand. Uncertainties relating to porosity and saturation are secondary. Structural uncertainties (top reservoir and GWC) are the least important, as expected with a significant hydrocarbon column of approximately 400 m and well-defined GWC from pressure and log data.

3D geological models

Three different 3D geological models were built to reflect the downside, base case and upside scenarios, which broadly reflected the results of the uncertainty study and the integrated geological scheme. As noted previously, the major static uncertainty is the sand thickness distribution and prediction, particularly in areas where the gross reservoir is below seismic tuning thickness.

In the 3D geological model for the base case scenario, the sand isochores were guided by the AVO total net gas sand map (primarily in the seismically tuned area), the seismic isochores (primarily in the non-tuned area) and the depositional model (e.g. Fig. 7). The fine layers in the base case geomodel were proportionally built, with the aim of having approximately 1–2 m-thick sand layers. The Net to Gross grids were generated by sequential Gaussian simulation (SGS) of upscaled well logs with azimuth trends compatible with the geological scheme. The porosity grids were also generated by SGS of upscaled well logs, with the seismic IP cube applied as external drift. A strong correlation between IP and porosity ($R = 0.95$) in the aquifer was demonstrated by a fluid substitution study using Gassmann modelling. The permeability grids were generated by permeability/porosity transforms for the individual sands, based on the Laggan core data. The water saturation grids were derived from the saturation height function, based on end face corrected capillary pressure data from the 206/1–3 and 4z wells. The free water level for Laggan was defined from RFT and log data in the 206/1–3 well at 3909 mss, as previously noted.

The construction of the downside and upside geomodels was broadly similar to the methodology applied in the base case scenario. The challenge was to build fine-layered 3D geological models, which were broadly compatible in terms of gas initially in place (GIIP) distribution with the corresponding 1 layer JACTA models (i.e. realizations which represented approximately Q10 and Q90 in terms of GIIP). The sand isochores in the downside and upside 3D geological models were based in particular on approximately Q10 and Q90 net gas sand realizations from JACTA (example Fig. 17). In the downside geomodel, a more pessimistic approach to porosity modelling was also applied relative to the most likely model, that is, SGS with no external trend applied and a more pessimistic saturation height function was also applied. In the upside geomodel, a more optimistic approach to porosity modelling was applied relative to the most likely model, that is, increased correlation coefficient applied with the seismic IP data as external drift, re-sampled in the geomodel. A more optimistic saturation height function was also applied.

The geomodels were then exported for reservoir simulation studies, including the optimization of the planned development wells for Laggan and reserves evaluations.

Tormore

The potential of Tormore was recognized, by applying the geoscience understanding of Laggan to help de-risk the prospect. In particular, it was recognized that Laggan could be used as an analogue for the Tormore trapping configuration and reservoir potential and that AVO could be used to help define the GWC. The exploration well was successful in finding a similar reservoir as was encountered in Laggan.

The Tormore discovery well, 205/5a-1 was drilled and tested in 2007 (Fig. 4). The well was tested at a rate of 28.3 MMscfg/day and 1975 bbls/day of condensate from the C sand. The condensate gas ratio (CGR) is approximately 70 stb/MMscf, that is, more than three times richer than Laggan.

The main static and dynamic uncertainties on Tormore are similar to Laggan, that is, sand thickness distribution and water saturation (long transition associated with chlorite) and the degree of compartmentalization.

Conclusions

The geoscience evaluation of Laggan has matured over the last four years, with the help of fully integrated studies using seismic and well data. The depositional model has been defined on the basis of an integrated study of cores, seismic and analogue studies. Seismic inversion studies have also helped constrain the reservoir architecture. Of particular value has been the application of AVO to quantify net gas sand, recognized as the principal static uncertainty. The main dynamic uncertainty is the risk of compartmentalization. This risk has been reduced through an improved definition of the fault configuration, by re-processing the seismic and detailed seismic attribute analysis.

Way forward

Development studies are now well advanced, with the discovery of Tormore in 2007 providing the potential for a combined development project. A new seismic acquisition campaign is planned in 2009 over Laggan and Tormore. The primary objective is to help optimize the location and often complex trajectories of the planned Laggan and Tormore development wells. An improved understanding of the Laggan and Tormore geological scheme should also hopefully arise, with an expected improvement in seismic imaging.

The authors would like to thank DONG, ENI and Chevron for their permission to publish this paper, as well as their invaluable contribution to the project. We would like also to acknowledge with many thanks the contributions of numerous colleagues who have also studied Laggan, including H. Declerck, H. van Dongen, J. Gerard, J. P. Gomez, J. M. Guemene, R. Rebut, S. Hillier and T. Whitbread.

Abstract: The Clair oilfield was discovered in 1977 and began production in 2005. It is a heterogeneous fractured sandstone reservoir with an estimated STOIIP of *c.* 1.5 billion barrels in the Phase 1 development area. An extended appraisal programme was required to assess reservoir deliverability, which is controlled by the distribution of natural fractures. Development drilling increased the understanding of the fracture system, through acquisition of conventional core, open-hole logging, drilling mud-loss recording, production logging and well test transient analysis. These data revealed a complex fracture system of conductive faults and background joints. Post-production formation pressure measurements showed greater lateral and vertical connectivity than would be expected from matrix and fluid properties alone. However, large pressure differences were encountered close to or across features mappable at a seismic scale. Closed fractures or sealing faults can form baffles between compartments, and conductive faults or fractures allow rapid pressure communication. In some cases the connection path or barrier can be identified with seismically mapped features. When the field was put onto water injection, one year after start-up, a key concern was the degree of imbibition of water from the fractures to the matrix. Despite the observed pressure connectivity, water breakthrough did not take place until 2007. Most producers have completions designed to permit zonal water shut-off. A successful intervention was carried out in early 2008, after a production logging run had demonstrated water entry at the toe of a high-angle well. The crestal Core segment of the development benefits from a permanent 4D seismic array of ocean-bottom cables. In 2007 the first permanent monitor survey was acquired and processing gave indications of a 4D response. These 4D data are improving the dynamic reservoir understanding and providing valuable spatial context to the well results.

Keywords: 4D seismic, Clair field, fractured reservoir, Old Red Sandstone, reservoir management

The Clair oilfield lies 75 km west of the Shetland Islands in UKCS blocks 206/7a (Production Licence P.168), 206/8 (P.165), 206/9a (P.170), 206/11a (P.168), 206/12a (P.169) and 206/13a (P.169), all awarded in the fourth licensing round of 1972. The current ownership is: BP 28.6015% (Operator), ConocoPhillips 24.0029%, Chevron 19.4225%, Shell 18.6831% and Hess 9.2900%. It was discovered in 1977 and in 1989 the field co-venturers entered into a 'Joint Appraisal Agreement' which resulted in the first 3D seismic survey being shot over the area, paving the way for the future appraisal campaign. After a successful extended well test the 'Clair Unitization and Field Operating Agreement' was approved in 1997. A field development plan was submitted and development consent was received in 2001. Production commenced in February 2005. From initial discovery to first oil the field was appraised by a total of 23 wells. Twelve development wells have subsequently been drilled from a fixed platform. Clair lies in a water depth of 140 m, and production is transported via the West of Shetland pipeline and on to the Sullom Voe terminal.

Pre-production modelling (Barr *et al.* 2007 and references therein) was designed to understand the range of uncertainty associated with production from the fracture network, and its interaction with the matrix where most of the oil is stored. As development continued the models were continually updated with new static and dynamic field data. This paper documents the first three years of field life, with reference to the original field development plan, and outline decisions that were taken as a response to the changing understanding of dynamic reservoir behaviour.

Structure and stratigraphy

The geology of the Clair oilfield has been described by Coney *et al.* (1993) and Barr *et al.* (2007). The hydrocarbon trap is a four-way dip closure, extending over *c.* 220 km^2. It is located in the extensional Faroe–Shetland Basin, which is of Devonian to Cretaceous age and has a predominantly NE–SW trending fault network (Fig. 1). The oilfield itself is situated on the crest and downflank terrace of the Rona Ridge, a basement high formed in the Devonian. The reservoir comprises late to mid Devonian Old Red Sandstone and contains an extensive natural fracture network. The whole Greater Clair closure is estimated to have a stock tank oil initially in place (STOIIP) in excess of 5 billion barrels.

Clair was discovered in 1977 when exploration well 206/8-1A penetrated 568 m of oil-bearing Devonian sandstones, which tested 25.2° API oil at 1502 BOPD from Unit V and 1415 BOPD from Unit VI (Ridd 1981). Appraisal continued with drill-out of the large structural blocks that comprise the closure, each demonstrating the lateral continuity of the Old Red Sandstone with similar reservoir properties.

The stratigraphy of the Clair Group (Fig. 2) was first described by Allen & Mange-Rajetzky (1992) and more recently by Nichols (2005). The Clair Group is a fluvial succession, with a thickness related to the amount of accommodation space preserved in the relict topography formed by Lewisian Gneiss basement. The Devonian Lower Clair Group forms the main hydrocarbon reservoir; the overlying Upper Clair Group (Carboniferous) contains abundant smectite and is not targeted by the current development. The Lower Clair Group is divided into six reservoir units; Unit VI, Unit V and Unit III have the highest reservoir quality. They are distinguished by correlation of conventional log suites (gamma-ray, resistivity, density); variation in heavy mineral assemblages (Morton *et al.* 2003) complements the log correlation. The Devonian–Carboniferous stratigraphy is unconformably overlain by the Upper Cretaceous Shetland Group, which forms the cap rock.

VINING, B. A. & PICKERING, S. C. (eds) *Petroleum Geology: From Mature Basins to New Frontiers – Proceedings of the 7th Petroleum Geology Conference*, 299–313. DOI: 10.1144/0070299

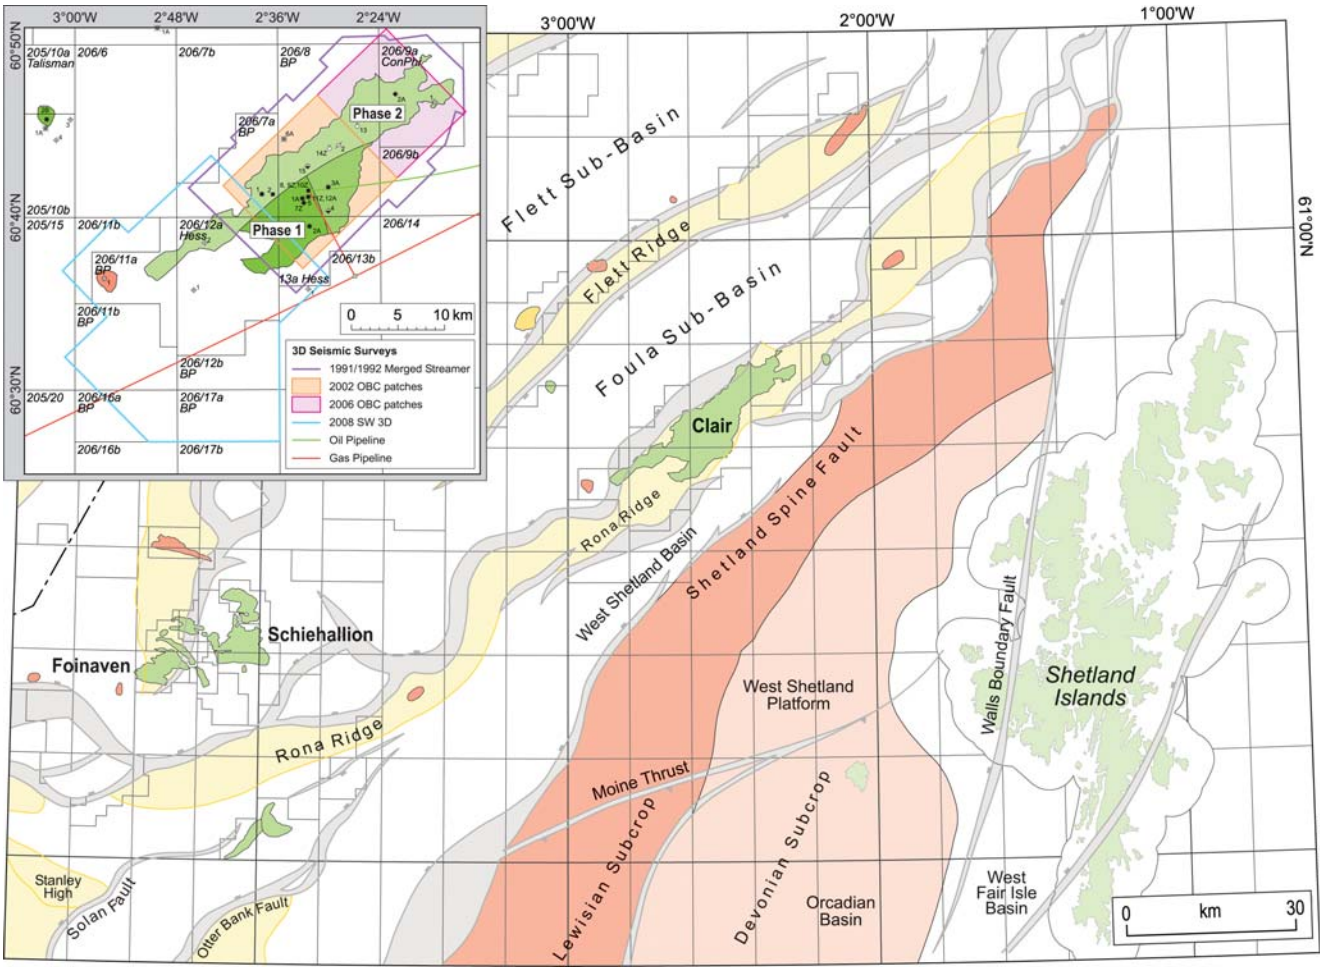

Fig. 1. Structural features of the Faroe–Shetland Basin, with Clair field location and seismic data coverage.

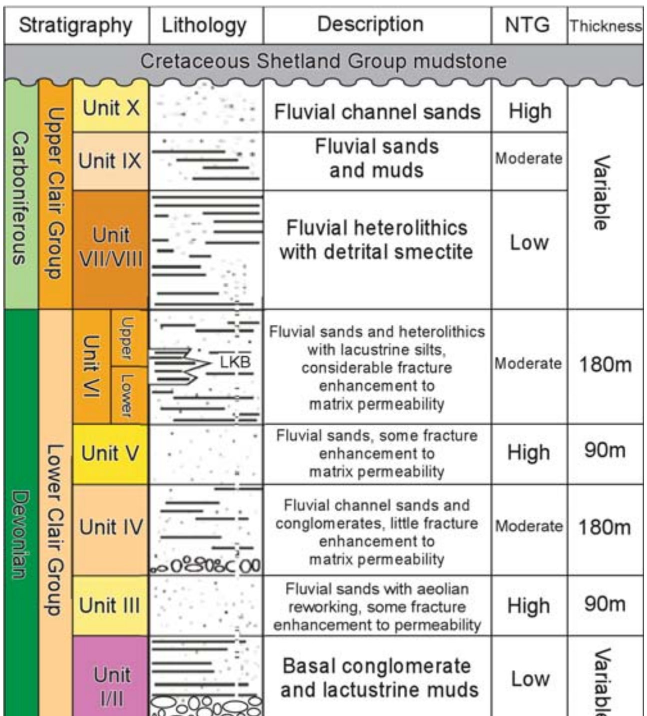

Fig. 2. Clair Group stratigraphy and matrix properties summary.

Development drilling to date has targeted two units of the Lower Clair Group, Unit V and Unit VI. Unit V (*c*. 90 m thick) is a homogeneous, high net-to-gross interval of fine- to medium-grained sandstone, representing the deposits of high energy fluvial channels and sheets. Reservoir quality is primarily controlled by grain size, with variable degradation caused by calcite cementation. Unit VI (*c*. 180 m thick) is a heterogeneous interval of fine grained sandstone and siltstone, representing the deposits of fluvial channels and channel abandonment facies. Unit VI is divided into upper and lower sub-units by the Lacustrine Key Bed (LKB), a pervasive mudstone present across much of the field. Typical reservoir matrix properties of the net sands are slightly poorer than in Unit V and the proportion of net sand is much lower. Within Unit VI the net to gross ratio varies widely across the field from non-net to good quality intervals in an unsystematic fashion. Unit III is similar to Unit V but with a higher proportion of aeolian facies. As in Unit V, the best matrix reservoir quality is found in the coarsest fluvial sands. Unit IV represents a more proximal, less well-sorted fluvial facies with a higher proportion of heterolithic and shaly sands, with poor reservoir properties.

Fractures are developed in all units to varying degrees (Barr *et al.* 2007, p. 209, Fig. 4b), controlled by mechanical stratigraphy, location within the field and proximity to faults. Brittle fractures dominate over granulation seams in the lower-porosity, fine-grained or cemented facies; however, many of these are occluded by calcite cement and do not contribute to fluid flow (Barr *et al.* 2007, p. 211, Fig. 6). Granulation seams are common in clean, high-permeability sands, but their baffling effect within the reservoir is diminished by a tendency for uncemented brittle fractures. Shaly sands and mudstones are weakly fractured and those which are present tend to be cemented. The net effect of these controls is that (in fractured parts of the field), fractures subtly enhance matrix permeability in Unit III and Unit V (but where dominant, granulation seams may degrade it), considerably enhance matrix permeability in Unit VI and make little or no contribution in Unit IV and in the LKB mudstone (Fig. 2). The Upper Clair Group is less well constrained but conductive fractures appear to be relatively unimportant.

Since early project planning the Greater Clair closure has been segmented into two areas: Phase 1 and Phase 2, named to reflect possible future phasing of the development (Fig. 1). The Phase 1 area consists of the Core, Graben and Horst segments, which have an estimated STOIIP of *c.* 1.5 billion barrels and are currently under development (Fig. 3). The Phase 2 area is the large SW–NE striking dip closure above the Rona Ridge, known locally as the Clair Ridge. The Ridge is currently under appraisal; recent well 206/8-13Z was abandoned with a downhole gauge that could transmit pressure data to the surface. The well is situated 8.5 km from the fixed production platform. Data from this gauge shows pressure decline over a time interval consistent with the overall pressure profile in the Core segment. This indicates that the Ridge Fault, dividing Phase 1 from Phase 2, could be transmissible or that pressure is being transmitted through conduits in the fractured basement. Closure of the Clair Ridge continues to the SW; this area was awarded in the 25th licensing round of 2008 as a traditional seaward licence (P.1570), comprising blocks 206/11b, 206/12b, 206/16a and 206/17a.

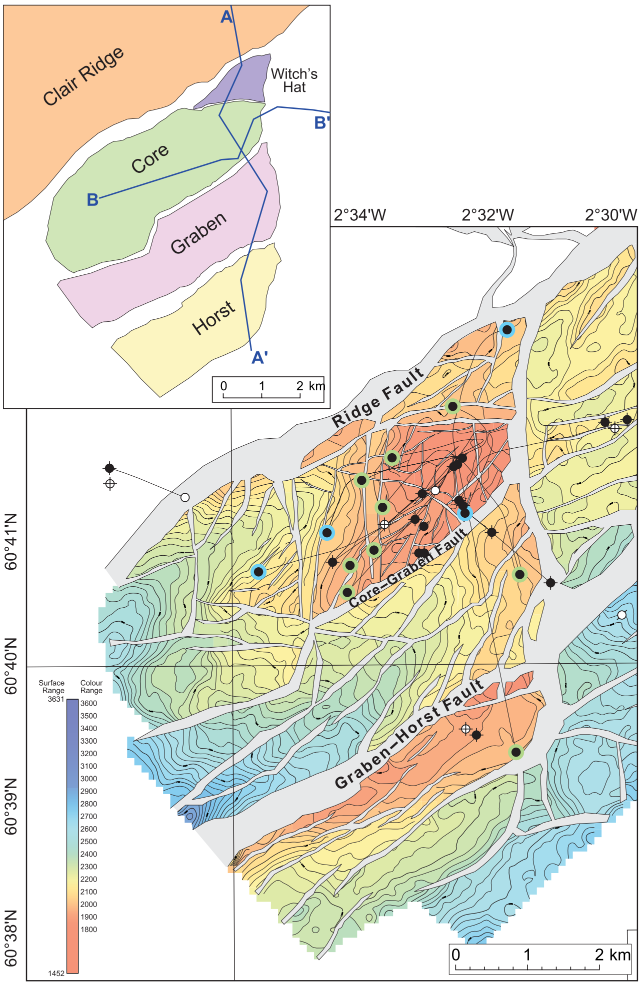

Fig. 3. Top Unit V map derived from OBC dataset, 2008. This map shows the field as developed in March 2009. Green circle represents a production well and blue circle represents a water injection well.

Within the Phase 1 area the Core, Graben and Horst segments (Fig. 4) are formed by significant NE–SW extensional faulting inherited from the Devonian–Carboniferous basin. Within the Core faults trend predominantly NE–SW, with some orientated north to south and east to west. The NE–SW trend is orthogonal to the main extension direction of the segment bounding Ridge Fault. The Core, Graben and Horst form a faulted roll-over structure in the hanging wall of the fault, with the Graben segment forming a crestal-collapse feature. Extension on the Graben-bounding faults primarily took place during deposition of Carboniferous Upper Clair Group sediments, indicated by significant thinning of the Upper Clair Group in the footwalls of the bounding faults. As a result of subsequent inversion, the Clair Group structural crest (the Base Cretaceous Unconformity) is located above the Graben.

Basement topography in the Core of the field is more irregular than in the Graben or on most of the Horst. The lowermost reservoir units thin significantly onto local basement highs. The thinner Lower Clair Group succession appears to be more intensely fractured than the thicker sections. Fault throws within the Core display displacements of the order of 25 m when mapped on seismic data. Larger faults within the area have throws in the range 50–75 m. Development drilling has demonstrated that mapped faults within the reservoir are generally transmissible, but some baffling occurs across larger faults, especially where different units are juxtaposed. Abundant faulting in the Core segment may be due to the proximity of the Ridge Fault.

The Graben contains fewer faults than the Core. The faults generally have a small throw in the up-dip area of the segment, increasing in throw to the SW. Two production wells have been drilled into the Graben, the second in 2009. Development drilling in the Graben has shown that the segment bounding Core–Graben Fault (Fig. 3) is partially transmissive, as depletion was observed in the Graben Lower Clair Group due to production from the Core. Maximum depletion was observed in Upper Unit VI (which is juxtaposed against Core segment Unit V); depletion decreases with distance from the fault.

As of 2008 the Horst was undeveloped. One production well was drilled and brought online in early 2009. In the up-dip area of the Horst there are relatively few faults compared with the Core. The SE edge of the structure is cut by a number of normal NE–SW trending faults which typically have displacements of 50–100 m. Displacement along the segment bounding Graben–Horst Fault is typically 200 m in the NE, but increases rapidly to the SW as the Graben deepens relative to the Horst.

This paper describes the most recent (2008) subsurface understanding of the Core segment of the Phase 1 development area only, where the majority of production and injection wells have been drilled.

Pre-development appraisal

After discovery by well 206/8-1A, the Core segment was appraised in 1980 with well 206/8-5 (Fig. 1). Upper Unit VI was tested at 1050 BOPD, following stimulation by hydraulic fracturing. In 1985 a further stimulation was planned in 206/8-7, but following mechanical problems the well was side-tracked and the programme was not completed. Allen & Mange-Rajetzky (1992) described the stratigraphy of the Clair Group with reference to the fully cored 206/8-7. Post-well heavy mineral analysis showed that the well penetrated the Core–Graben fault, resulting in a thinned and unrepresentative section.

Well 206/8-8 marked a turning point in the development of Clair. Drilled in 1991, facilitated by the 'Joint Appraisal

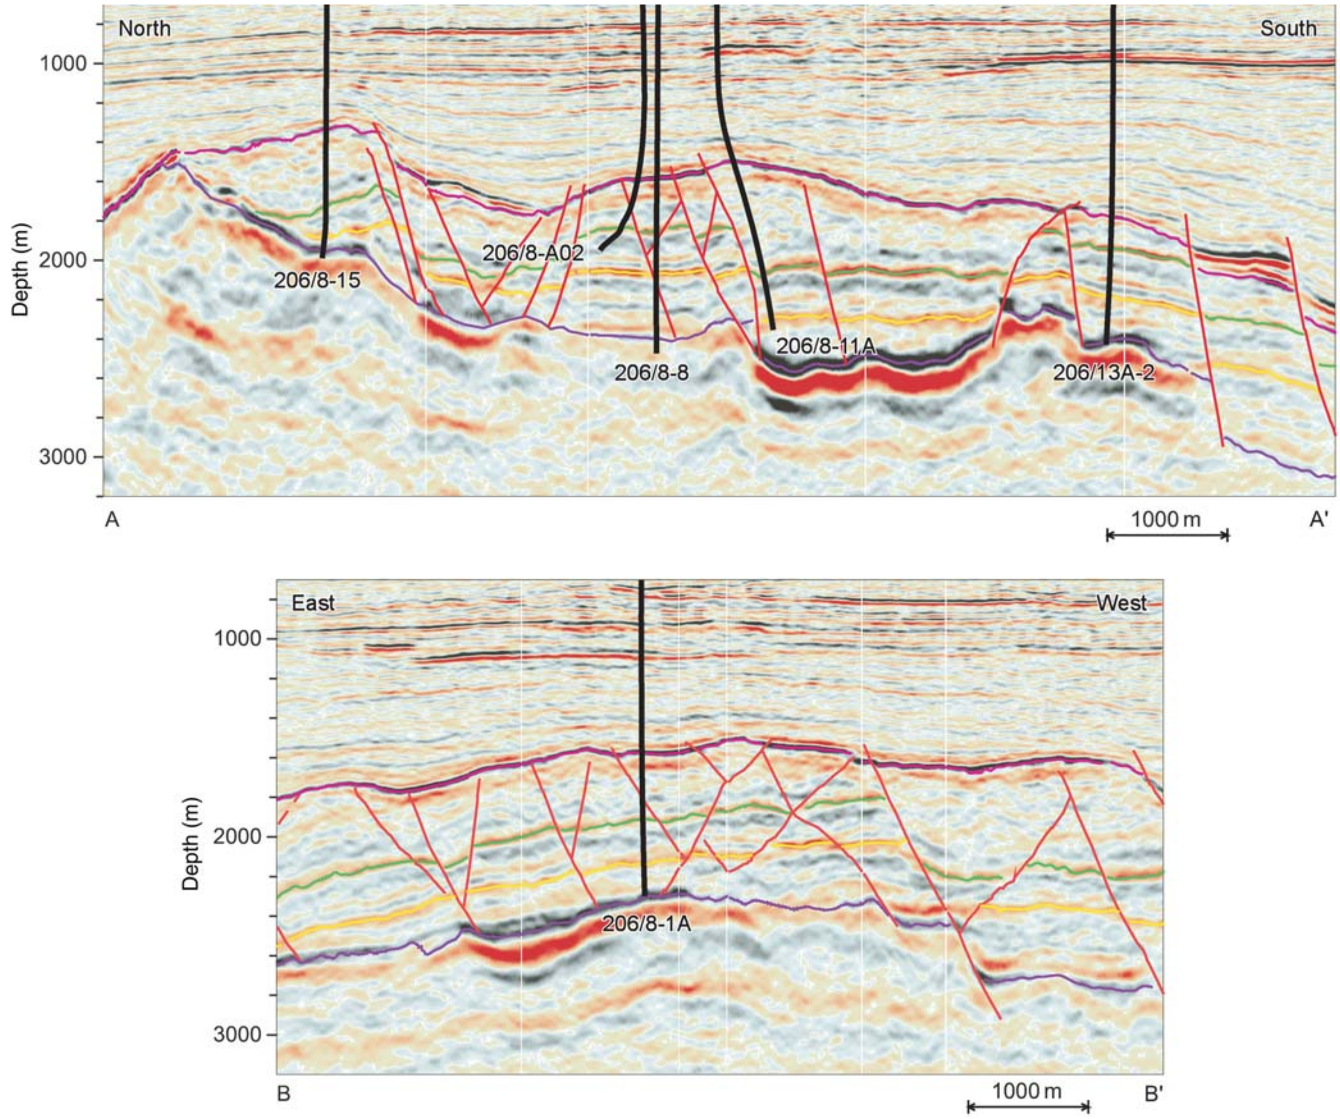

Fig. 4. Seismic line and cross-line through the Clair field from 2006 OBC data, line locations shown on Figure 3. Horizons are Base Cretaceous Unconformity (magenta), Top Unit V (green), Top Unit III (yellow) and Basement (purple).

Agreement', its aim was to demonstrate commercial flow rates from the Core, the central 'roll-over' area of Coney *et al.* (1993). The well was situated at the structural crest of the Core and penetrated a full succession. Fully cored and logged sedimentologically and structurally, it is now considered to be the Lower Clair Group reference section. Unit V tested at 3100 BOPD, which was maintained for the full six-day flow period. Unit VI was tested at 1850 BOPD, which increased to 3250 BOPD following hydraulic fracturing and was sustained for another six-day flow period. Permeability-height was an order of magnitude greater than that expected from the core plug data (Barr *et al.* 2007), clearly demonstrating the benefits of accessing the existing natural fracture network. The post-stimulation test also demonstrated that connection into the natural fracture network could be achieved with hydraulic fracturing. Well 206/8-8 was the last vertical appraisal well. Subsequent wells were deviated to target natural fractures, with increased length in specific reservoir units.

Well 206/8-9Z was drilled the following year with the objective of testing a high-angle section of Unit V, targeted to intersect the dominant open fracture orientation observed in 206/8-8 and to maximize reservoir length in Unit V. The high angle section in Unit V and Unit VI flowed at 7306 BOPD which was sustained for 9.5 hours. A large contribution to this flow was interpreted to be from the existing natural fracture network.

Well 206/8-10Z (1996) was the final appraisal well drilled in the Core segment; following the success of 206/8-9Z it targeted another naturally fractured section interpreted from seismic data. During a 50-day extended well test the horizontal section of Unit V and Unit VI produced at an average rate of 10,200 BOPD. This element of appraisal was instrumental in unlocking the commerciality of the development, demonstrating that a second well planned to intersect mapped fractured sections yielded another high production rate (Smith *et al.* 1995). This gave confidence that high production rate development wells could be planned by targeting similarly fractured areas (Smith & McGarrity 2001), providing a robust technical case from which further commercial and project planning could proceed. The sustained rate demonstrated the ability of natural fractures in the vicinity of the wellbore to link into the wider fracture network (Barr *et al.* 2007). Well 206/8-9Z was re-entered after the extended well test and side-tracked as observation well 206/8-9Y. It encountered depleted Lower Clair Group and material balance calculations indicated that a STOIIP of *c*. 500–600 MMBBL had been contacted by the extended well test. This volume was too large to be purely held in fracture aperture alone suggesting communication out into the wider matrix, reducing the uncertainty relating to segmentation and compartmentalization. Well 206/8-10Z was suspended for subsequent tie-back to the future development.

Original field development plan

After the successful appraisal campaign the Clair co-ventures sanctioned the project for development. Early on a decision was made to not pre-drill the field; this was intended to allow time for dynamic reservoir data from early wells to impact the later well sequence. The original development plan contained 23 wells (15 producers and eight water injectors), including the suspended 206/8-10Z (Fig. 5). The early producers were planned to target Unit V with a horizontal section; later wells had Unit VI targets. Early water injection was seen as critical as the aquifer was not expected to provide pressure support. Within the original field development plan the Core segment was to be the focus of the initial drilling sequence of 10 wells, including four water injectors. The field development plan concentrated on what were perceived to be the key uncertainties of the development at the time, specifically the dynamic response of the reservoir to production. These uncertainties were related to how the field would respond to water flood, controlled by the compartmentalization and connectivity of the fracture network and the degree of matrix imbibition. Development wells were expected to water out within 1–3 years, so the facilities were designed to handle large quantities of produced water.

Initial 3D seismic data over the development area was a streamer seismic survey, acquired in 1990. Data quality was poor despite reprocessing and, after a successful 2D ocean-bottom cable (OBC) trial in 2000, a 3D OBC was acquired in 2002, which led to a step change in data quality due to higher-fold, richer offset-azimuth distribution and improved multiple attenuation (Kommedal *et al.* 2005). This was subsequently reprocessed in 2006 along with additional OBC acquisition over the Clair Ridge, leading to further improvement and interpretation detail compared to the initial 3D streamer data (Fig. 6). The OBC data significantly helped well planning before start-up. The initial well sequence was planned, honouring the development plan strategy of maximizing

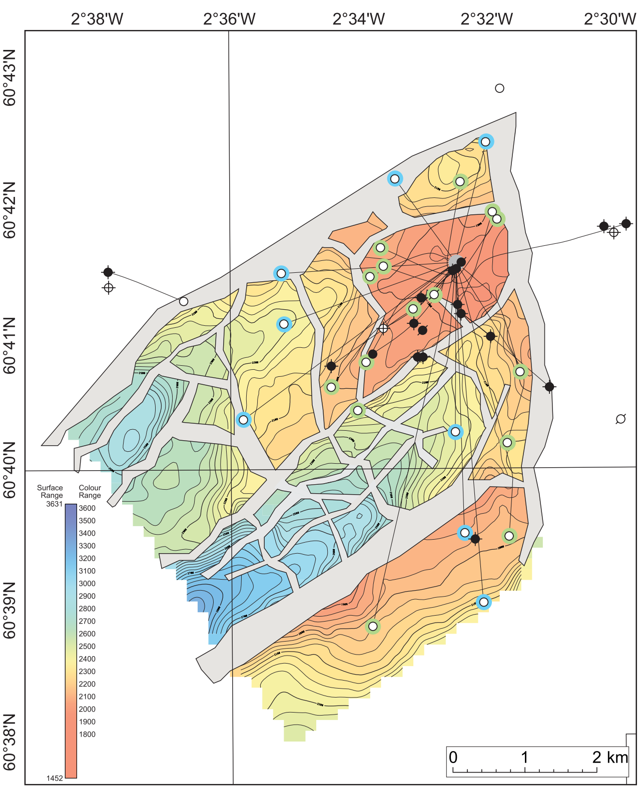

Fig. 5. Top Unit V map derived from streamer dataset, 2001. Green circle represents planned production well, blue circle represents planned water injection well and grey circle represents planned cutting re-injection well.

learning through careful phasing of the wells (the Plan–Do–Measure–Learn–Plan loop of Clifford *et al.* 2005).

Managing field start-up

The original field development plan called for early water injection wells to support offtake at 206/8-10Z. These injectors were planned to the SW of the Core segment, down the flank of the structure with the intention of initiating water drive up to the producing well stock at the crest (Fig. 5). The first new development well was planned to be a dedicated cuttings re-injector, with the second a downflank water injector. However, during the well design phase of the development well completions were changed to allow cuttings to be injected down the annulus and into the Cenozoic and Cretaceous overburden, removing the need for the dedicated well.

Producer-led start-up

As the project matured the well sequence evolved. There was an obvious desire for a fast production ramp-up, but this was at odds with the original field development plan of early water injection. Clair fluid produced from the 206/8-10Z extended well test was undersaturated, and at the end of the test reservoir pressure was 300–400 psi above bubble point. Therefore there was the possibility of safely producing for a period before water injection without inducing gas breakout. Clair had not been pre-drilled so dynamic reservoir data could be taken into account when planning future wells. The main uncertainties pertaining to well placement were related to how the reservoir would deplete and if mapped faults would be conductive or behave as baffles. A well sequence was developed to maximize depletion in the Core, through the placement of early producers. To manage offtake within the safety window above bubble point each well would be completed with a downhole pressure gauge, used to calculate reservoir pressure during regular pressure build-up tests. Formation pressure data acquired in the wells would address the main uncertainty of dynamic reservoir communication, establishing communication pathways across the field. Using this rationale a water injector could be optimally placed as understanding of the reservoir developed, giving flexibility to the future water flood pattern. This strategy also reduced the risk of directly connecting a producer and injector pair through a conductive fault, by only placing injectors in areas not deemed to be in direct communication with producers.

To ensure the delivery of high-rate early producers a similar well design to 206/8-10Z was adopted; horizontal Unit V sections targeting faults mapped on the OBC data. Production logging during the extended well test had demonstrated that the majority of the production was from Unit V, with most of the inflow occurring around the intersection with seismically mappable fault lineaments. The earlier horizontal well 206/8-9Z had demonstrated a similar pattern, but with a strong influx from a Unit VI interval which saw significant mud losses and is presumably fractured (Clifford *et al.* 2005, p. 8, Fig. 7). A suite of pre-production fracture models, built using conditioning maps based upon seismic edge-detection and other methods (Barr *et al.* 2007), had been used to model horizontal and vertical (Barr *et al.* 2007, p. 222, Fig. 15) well test production log profiles. Cored vertical wells provided constraints on small-scale joint conductivity, and horizontal wells crossing mappable faults or lineaments constrained fault-zone conductivity. The 206/8-10Z observations were consistent with a conductive-fault model, with a fault conductivity (fault aperture multiplied by permeability) of *c.* 7000 mDm. This proved to be a reasonable value for full-field history matching of the extended well test. However the pressure build-up and

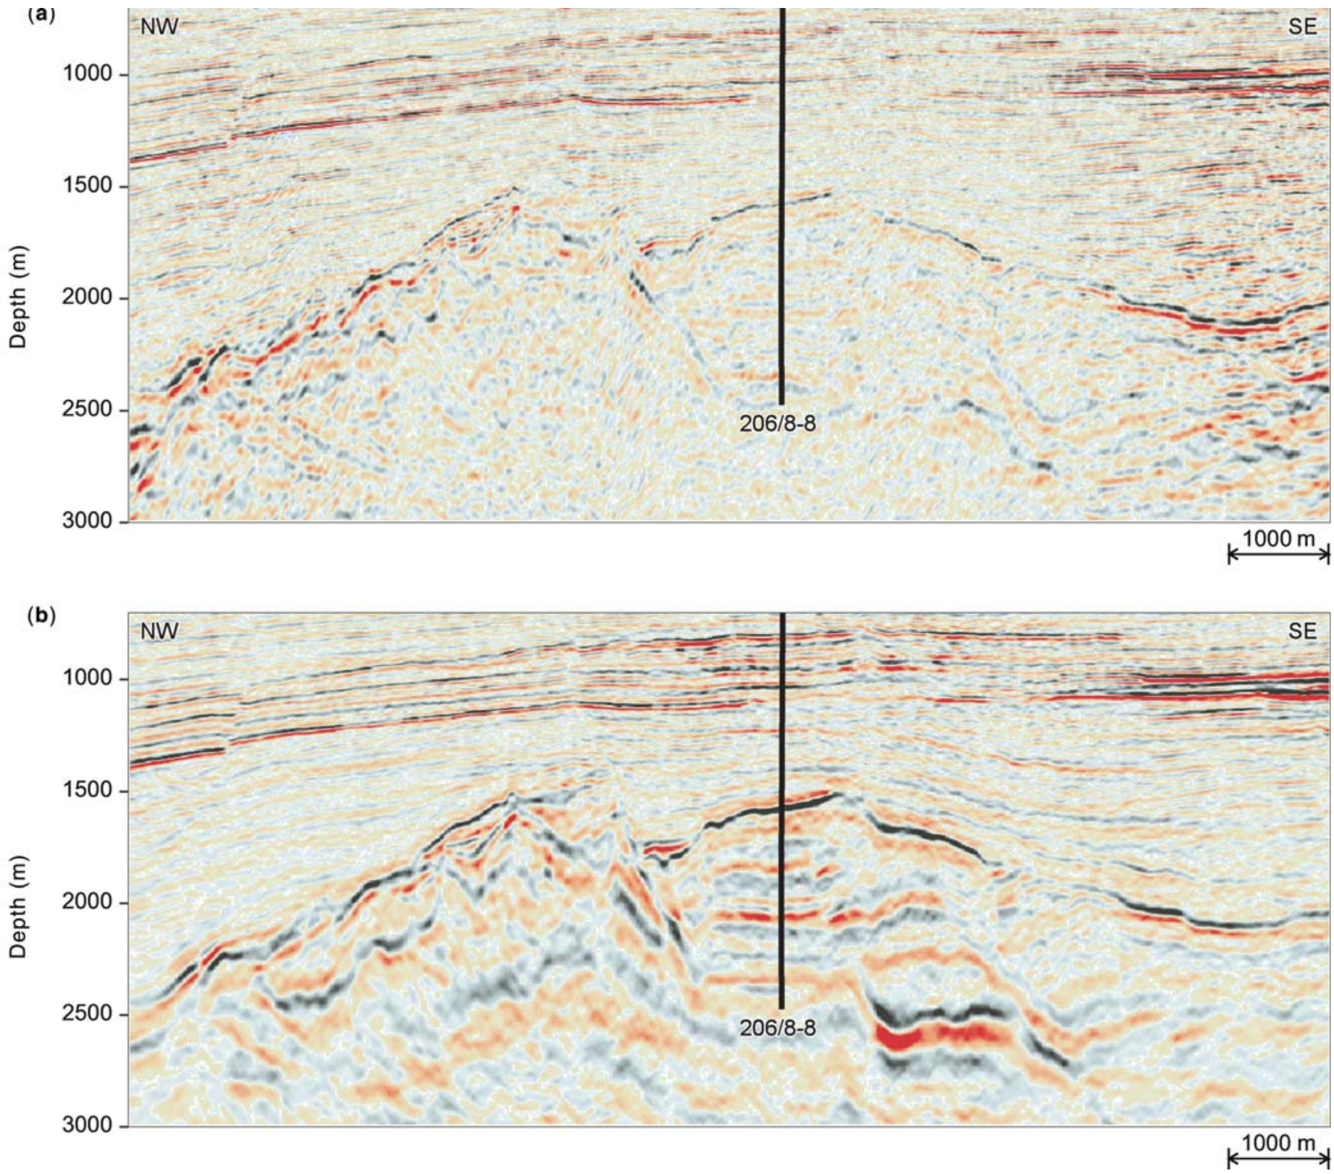

Fig. 6. Comparison of uninterpreted seismic data displayed in depth between (**a**) 1992 streamer data and (**b**) OBC data reprocessed in 2006. Well 206/8-8 is located approximately at the structural crest of the field. The Base Cretaceous Unconformity is visible at 1550 m at the well location and Top Unit V is at 1800 m.

material balance observations could also be matched by models with an intensely developed set of small-scale joints, all that was necessary was that contacted volume had the right overall permeability and oil in place. Production logging data supported the hypothesis that the well had produced from narrow, discrete fractured zones, or 'fracture clusters' related to the seismically mappable features. The averaging effect of a single, centrally placed well observation became apparent during subsequent development drilling, which found some wells much more fractured than 206/8-10Z and others less fractured. The observation of Barr *et al.* (2007) that most of the pre-production fracture models could be matched to the extended well test data is perhaps not surprising, given that the conductivity and spacing or frequency of their individual elements had been calibrated at or in the vicinity of the extended well test well. They anticipated that the percentage of models which matched would reduce as more wells were drilled, with most models failing by the second or third production well and all models failing to predict water breakthrough times from the fourth well (and first water injector).

Data acquisition strategy

An extensive static database had been built up over the years of appraisal, including over 5000 m of recovered core, conventional formation evaluation logs, image logs and mud loss data. The strategy for the early development wells was to have intensive data acquisition programmes to establish links between static data, dynamic data and reservoir performance. These data would be used to develop predictive models for matrix properties and fracture character, and help in understanding reservoir communication. Later infill wells had less intensive data acquisition as reservoir understanding developed. The first horizontal well of the development would provide a calibration point for future wells in the field. All planned wells crossed seismic features interpreted as faults, consistent with the successful horizontal appraisal wells. A core across one of these features was planned as a key reference dataset, to analyse fracture distribution and the lateral changes observed in the reservoir properties of the matrix.

To improve fracture characterization outside the cored interval, micro-resistivity and acoustic image logs were planned across the

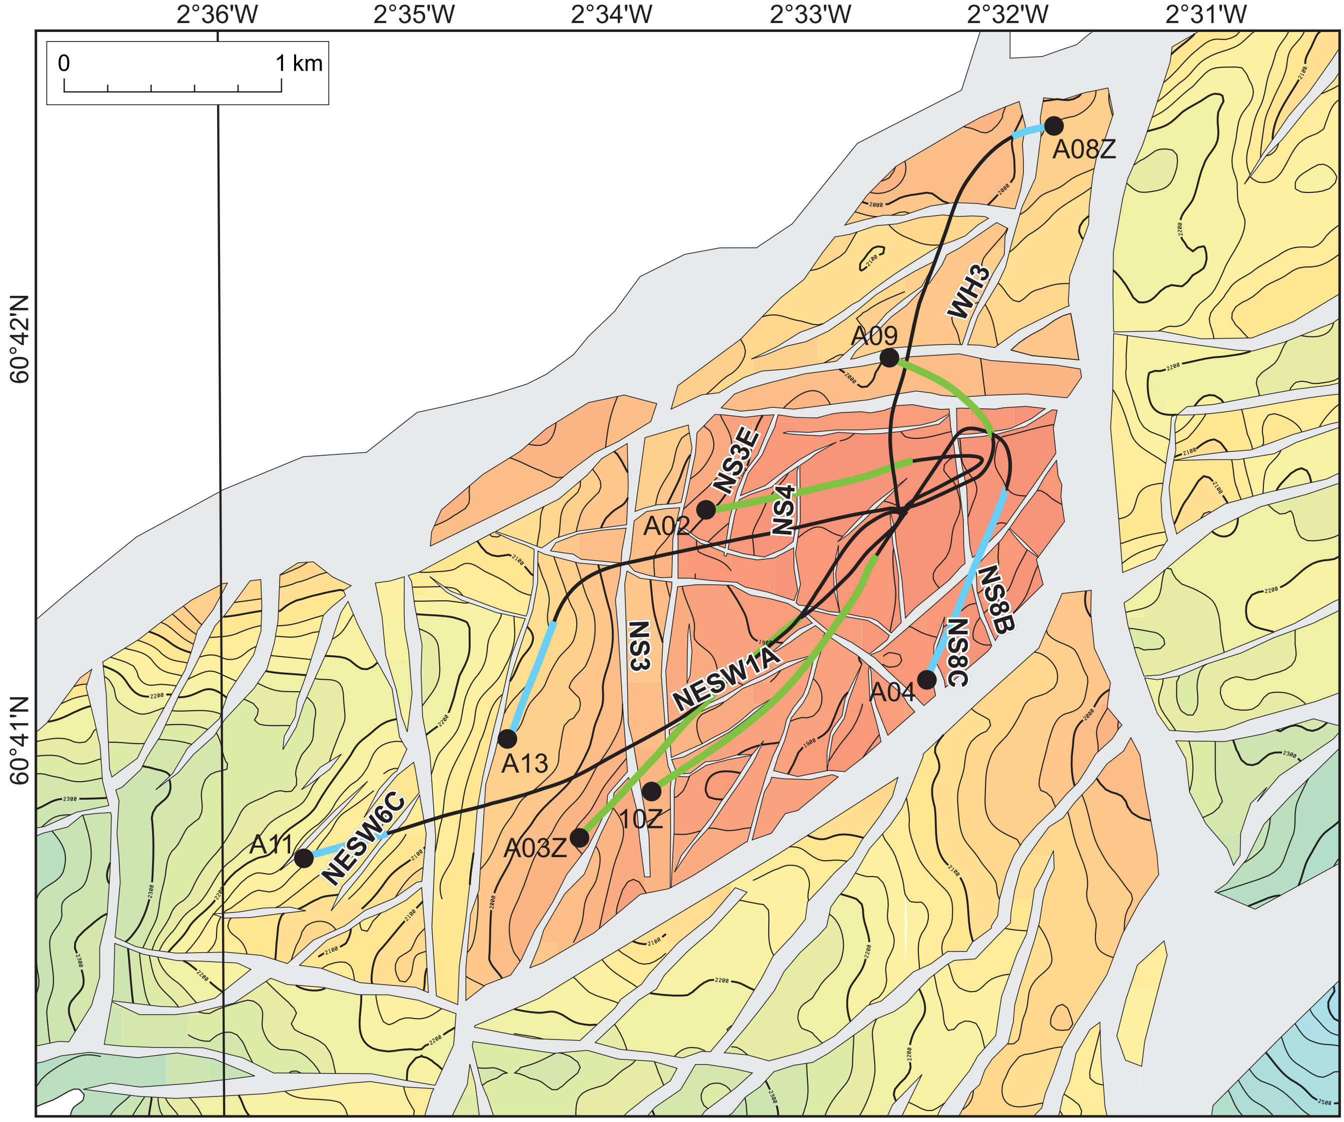

Fig. 7. Detailed map of the Top Unit V in Core segment. Producing and injecting completed sections are coloured green and blue respectively. Wells and faults referred to in the text are located.

whole reservoir section. This was the lynch-pin of the forward data acquisition plan: having confident calibration of the image logs to the core in the first well would enable interpretation of image logs in future uncored wells. For wells drilled with a water-based mud system, micro-resistivity tools can determine whether a fracture is open or closed at the wellbore: closed or cemented fractures will typically be resistive whereas open fractures filled with water-based mud will be conductive. Clay-plugged fractures also appear conductive but these were known from core observations to be relatively few in number. In an oil-based mud system an open fracture filled with oil will appear resistive. However, a calcite cemented fracture will also appear resistive. Acoustic image logs should in principle be best able to determine whether a fracture is open, with open fractures returning a low impedance signal, particularly if there has been some spalling of material at the wellbore. However, the acoustic logs have somewhat lower resolution and in Clair have proved to be more prone to acquisition-related problems such as stick-slip or (in the appraisal wells) baffling of the reflected signal by thick mud-cake. Azimuthal density and gamma logs have still lower resolution but can be recorded while drilling, giving them an advantage in making real-time drilling decisions. Although the density log can directly measure the porosity in an open fracture, only the largest fractures are detected because the response is dominated by the surrounding matrix.

Micro-resistivity and acoustic logs run over the same section identify different features, and fracture interpretation must consider both hole conditions and the strengths and weaknesses of each tool. Acoustic and density tools have full circumferential coverage; fractures cutting the wellbore at a low angle are readily interpreted. Micro-resistivity tools are pad-based, and the gaps created can complicate fracture identification. Running both tools in early wells established which method worked best within the Clair reservoir. To date, micro-resistivity tools in water-based mud have proven the best for both fracture and sedimentological characterization.

To establish the azimuth of fractures logged in core it is necessary to scribe upon acquisition. Scribing involves scouring a reference line of known orientation onto the core as it is acquired, but can lead to difficulties with recovery. Acquiring image logs over the cored section removes the need for scribing. Image logs are acquired with azimuthal data, providing a reference against which a core can be orientated. As fracture distribution was a key element of the core acquisition programme the core barrels were designed to be transported in large sections to minimize saw cuts to the fractured intervals. The barrels were opened onshore for description where matrix samples for special core analysis could be picked from unfractured sections of core. In past wells the usefulness of such samples had often been limited by the frequent occurrence of fractures and granulation seams, typically several per metre in 206/8-8 (Barr *et al.* 2007) in all but a few short, sparsely fractured sections.

Measurement of formation pressure enables an assessment of the degree of reservoir communication. The virgin pressure gradient of the reservoir had been established during appraisal. The near-vertical 206/8-9Y observation well recorded depletion from the top of Unit VI to near the base of Unit IV, despite extended well test offtake mainly from Unit V (Barr *et al.* 2007, p. 209; Fig. 4a), demonstrating vertical connectivity. In a fully homogeneous system uniform depletion would be expected, but the baffling and focussing nature of the fracture and matrix manifests as variable depletion along the well length. By measuring depletion at numerous points along a horizontal well it was hoped that direct comparisons could be made with fracture logs, building up the detailed picture of lateral connectivity within the reservoir desired for effective water injector placement.

All wells were planned to have a baseline production log run at time of start-up. This was to establish which units of the stratigraphy were producing and the relative contributions of fracture and matrix. To facilitate the production logging, and envisaging the need for continual production logs throughout field life, the platform facilities were designed with a dedicated intervention deck allowing simultaneous operations with drilling.

The data acquisition packages were designed to reduce over field life, so that just key data was subsequently collected, with confidence in the calibration having been previously established. For example, the core and image logs acquired in the original well would reduce to a single image log in later wells. The technology of logging while drilling (LWD) was used to move away from dedicated wireline or pipe-conveyed logging runs. As the development commenced and technology developed, all elements of the original package (with the exception of core) became available through the use of LWD technology. This does entail some loss of resolution in production wells drilled with oil-based mud, such that only the general proportion of fracturing along the well is determined, and relies on linkage to more sensitive core and wireline or pipe-conveyed logs in nearby wells.

Early well results

As originally planned the appraisal well 206/8-10Z was the first well to come into production, tied back as 206/8-A01. Well 206/8-A02 was the first well to be drilled from the fixed platform, a horizontal Unit V well crossing a fault of similar scale to that crossed by 206/8-10Z (Fig. 7). The well was cored across the targeted fault as planned. Core analysis demonstrated that the matrix properties of Unit V were consistent with those observed in other wells in the Core segment. The bed parallel core proved invaluable when assessing lateral heterogeneity of the fluvial channel systems and interpreting channel widths from cross-bedding dimensions. Palaeocurrent analysis suggests sand dispersal broadly towards the south. These interpretations are consistent with similar measurements made across the entire reservoir section from image log analysis, and with other wells support the gross depositional environment interpretation proposed by Nichols (2005) for the Clair field area and the wider basin. As planned, image log calibration with the cored section gave confidence that it was possible to resolve natural fractures in the logs.

Well 206/8-A02 (Fig. 8) crossed mapped fault NS4 at 2660 m measured depth (MD), and cores were acquired on both sides of the fault. A fault interpreted from wireline image logs corresponds to 2.4 m of unrecovered core between runs, representing the location of NS4. Fracture intensity is interpreted as the abundance of fractures per metre of logged core or image log, corrected for borehole orientation bias. Curves are calculated at a 1 and 20 m

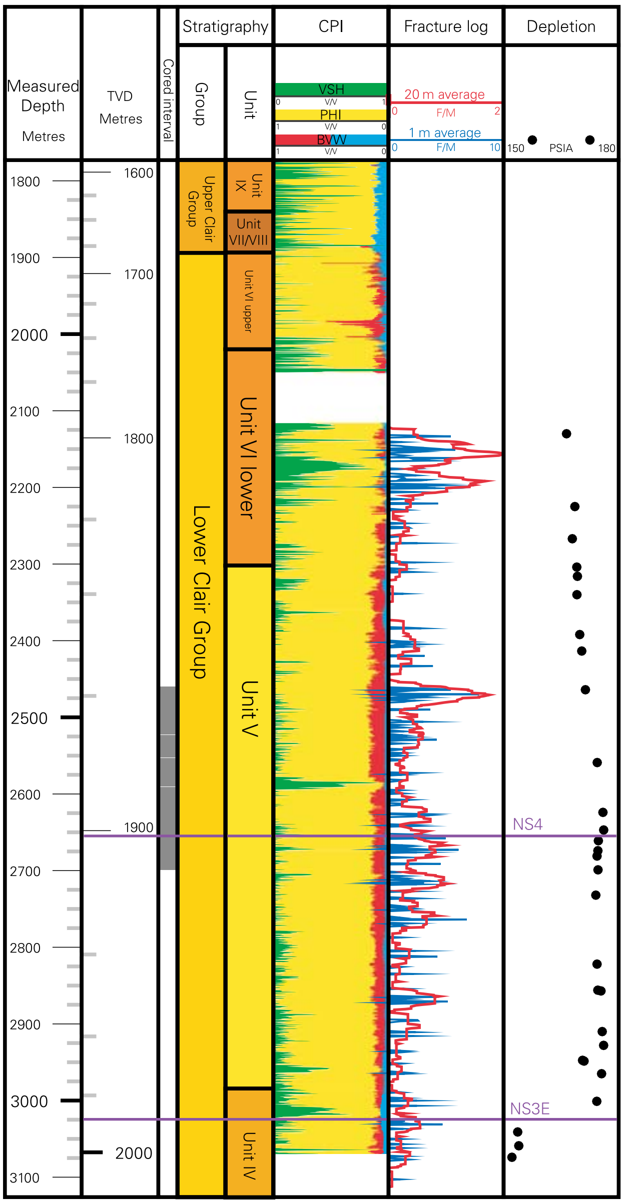

Fig. 8. Well data from 206/8-A02, displayed in measured depth. Fracture logs are derived from image log interpretation, corrected for borehole bias. Depletion is calculated from formation pressure measurements with respect to virgin pressure. Recovered core and interpreted faults are located.

moving average; the 20 m curve is commonly used within the Clair reservoir. Within the well fracture intensity was highest within the top of the logged section, within lower Unit VI, with intensities typically over one fracture per metre. In contrast to predrill expectations Unit V was relatively less fractured, with intensities typically under one fracture per metre, with no clear 'fracture cluster' visible around the fault. Depletion due to production from 206/8-10Z was observed along the length of 206/8-A02. A uniform depletion profile was observed throughout Unit VI and Unit V, indicating good vertical communication through fractures. Maximum depletion occurred as the well crossed fault NS4, but production logging showed that *c.* 80% of the inflow was occurring within Unit VI lower. The depleted Unit V contributed relatively little, although it was not possible to lift the drilling mud out of that section of the well so it is possible that the toe would have flowed had it been 'cleaned up'. The zone of high fracture density in Unit VI was interpreted to be related to a series of small mapped faults connecting down into Unit V. The zone of maximum depletion near fault NS4 did not correspond with the best matrix quality or with the highest fracture frequency observed on the image log. It perhaps reflects the presence of a narrow, conductive fault core as was seen on image logs in some subsequent wells. With pervasive fracturing over the whole of Unit V, uniform depletion except at the fault and no 'fracture cluster', the well is interpreted to be an example of joint-like behaviour in Unit V but fault-dominated in Unit VI. The toe of the well crosses NS3E and depletion significantly reduces by *c.* 30 psi. At the time of drilling it was thought that this could reflect the deterioration of matrix quality within Unit IV, although it seems equally likely that there could be reservoir quality degradation around the mapped fault (see below).

Well 206/8-A02 commenced production at a rate of 12 500 BOPD, consistent with estimates from pre-drill simulation. Measurements from permanent downhole gauges installed in the first two development wells showed that the pressure drop in the reservoir was slower than expected, possibly suggesting a larger contribution from the aquifer or a flux from outside the development area. Pressure support had also been indicated by repressurization of 206/8-10Z by the time it was re-entered, 8.5 years after the extended well test. In line with the producer-led start-up a third production well, 206/8-A03Z, was drilled. In order to maximize production in a known area, the well was drilled parallel to the 206/8-9Z well trajectory, crossing fault NESW1A that had contributed a significant amount of the inflow during the extended well test. The well path descends through Unit VI and becomes horizontal within Unit V (Fig. 7). It crosses from the footwall to the hanging wall of fault NESW1A (Fig. 9) at 2743 m MD, jumping up stratigraphy to the Unit VI/V boundary before repenetrating Unit V. Fracture analysis was complicated by acquisition issues but the fracture logs record relatively higher fracturing in Unit VI than Unit V. Within Unit V, high fracture counts correlate well to the crossing of fault NESW1A and NS3.

Formation pressure tests proved the most valuable data and recorded a much wider range of depletion than observed in 206/8-A02. The highest depletion was observed at fault NESW1A within Unit V. As in 206/8-A02, maximum depletion cannot be exactly matched to fracture-frequency maxima perhaps because the most conductive features are not clearly imaged. For example, in a highly-fractured zone or breccia it may be impossible to pick individual fractures, and the image may be degraded due to hole washout and enlargement. Alternatively depletion may be associated with a few long, well-connected fractures which present a similar aperture and hence image log appearance to the more abundant, shorter fractures. The decline rate in depletion away from the fault is similar in Units V and VI, despite the much better matrix quality in Unit V, indicating that more abundant or better connected fracture are present in Unit VI and serve to equalize the two units' overall permeability. It also indicates that fault NESW1A is unique in this well either in absolute conductivity or in connectedness to well 206/8-10Z, because the other fracture frequency peaks (some of which correspond to mapped faults or coherency lineaments) do not interrupt the uniform along-hole decline in depletion. Wells 206/8-10Z and 206/8-A03Z show some interference, suggesting that these wells are linked, but not directly by a single conductive fault. This favours the first interpretation, that it is the fault properties which are distinctive and not a fortuitous well-to-well connection. The well was brought on production at 8000 BOPD with no adverse affects to the existing two producing wells.

Injector positioning and timing

With three production wells in the Core segment and the reservoir undergoing primary depletion, no significant increase in gas–oil ratio (GOR) had been recorded but pressure data from the downhole

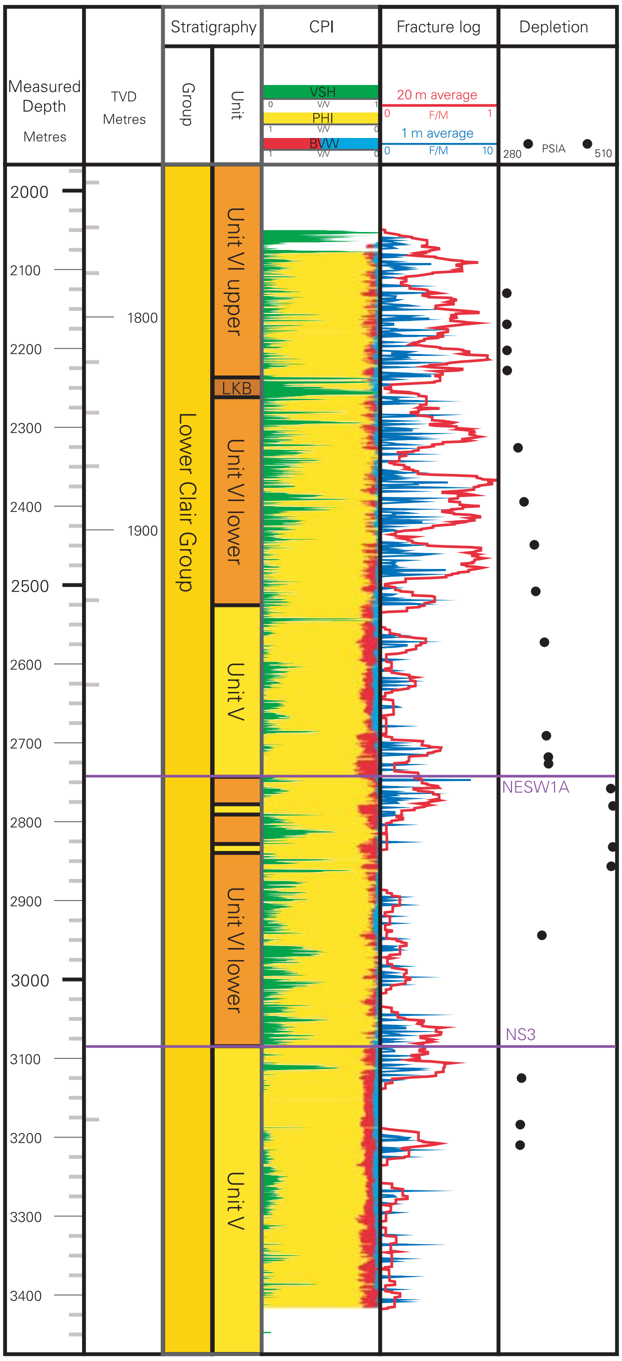

Fig. 9. Well data from 206/8-A03Z, displayed in measured depth. The well crosses fault NESW1A and cuts up stratigraphy along the Unit VI/Unit V boundary before crossing fault NS3 and re-entering Unit V.

gauges confirmed that pressure support would soon be required (Fig. 10). The goal of the producer-led start-up, to maximize depletion within the reservoir in order to optimally place water injecting wells, had been achieved. While the development drilling programme had continued, several water injector targets had been planned in parallel. The location of the first water injector was therefore not fixed at this stage (Clifford *et al.* 2005), and there were several attractive targets. Originally the first injector was planned to be located downflank. However, there was concern that the distance between that planned location and the pressure sink in the crestal Core (1.3 km) was too great to effectively support the producers. Pressure support could have taken too long to arrive. To mitigate this risk a crestal target was chosen, closer to the three producers (Fig. 7). As well as direct support to

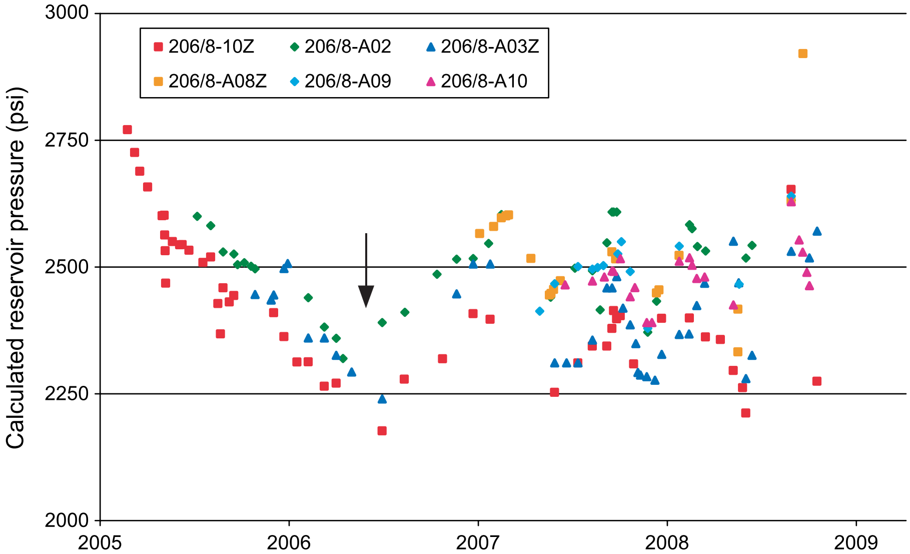

Fig. 10. Field pressure decline graph. Reservoir pressure is calculated from pressure measurements made at downhole gauges during pressure build-up tests. Arrow indicates start-up of water injection in June 2006.

the producers, the crestal injector also allowed for sweep of attic volume at the crest of the field.

The 206/8-A04 injector (Fig. 11) was drilled in the oil leg with water-based mud, which allowed for accurate fracture characterization using a micro-resistivity image log. In contrast to the previous two producers Unit VI is relatively less fractured than Unit V, with the greatest abundance of fractures being within the top of Unit V. The well crosses fault NS8B at 2605 m MD. Towards the toe of the well logged fractures become less abundant, presumably with distance away from the mapped fault. This behaviour is more akin to 206/8-A03Z with discrete fractured zones, and led to concern that injected water would preferentially flow into these fractures and not uniformly along the whole length of the well.

High depletion was observed throughout Unit V, demonstrating good communication with the producing wells. The highest depletion was observed at the toe of the well, just after fault NS8C was crossed. At this point the well was closest to the main producing interval logged in 206/8-10Z, further supporting a model of 'fracture clusters' around faults providing key communication pathways within the reservoir. After completion, an injection log was acquired over the reservoir. The temperature profile measured during a 12-hour shut-in pass yielded valuable insight into how the injector was performing. As cool sea water was injected the high reservoir temperature was cooled along the length of the wellbore; assuming that the degree of cooling was proportional to the amount of injection, interpretations can be made as to where the injection water is entering the formation. Temperature began to reduce in lower Unit VI and remained cool throughout the length of Unit V, over the highly fractured section, increasing marginally over the relatively less fractured toe section. This suggested good uniform injection across the whole of the completed length, not just the most fractured sections, which had been the original concern. This well has a very high total fracture count so it might be supposed that the uniform spread of injected water reflects a highly connected fracture set, such that even relatively unfractured sections are still above the percolation threshold and adding more fractures does not substantially increase the effective permeability. However, other aspects of the well behaviour contradict this interpretation: for example, well test pressure fall-off interpretation yields a relatively low *kh* (permeability multiplied by height), consistent with only moderate enhancement of matrix permeability. Together with evidence for matrix-like sweep of the water away from this well (see below), this suggests that the fractures, although frequent, are relatively poorly connected and most 'dead-end' in matrix. This data was the first evidence that water could imbibe into relatively unfractured matrix, increasing the sweep efficiency and ultimately leading to higher recovery.

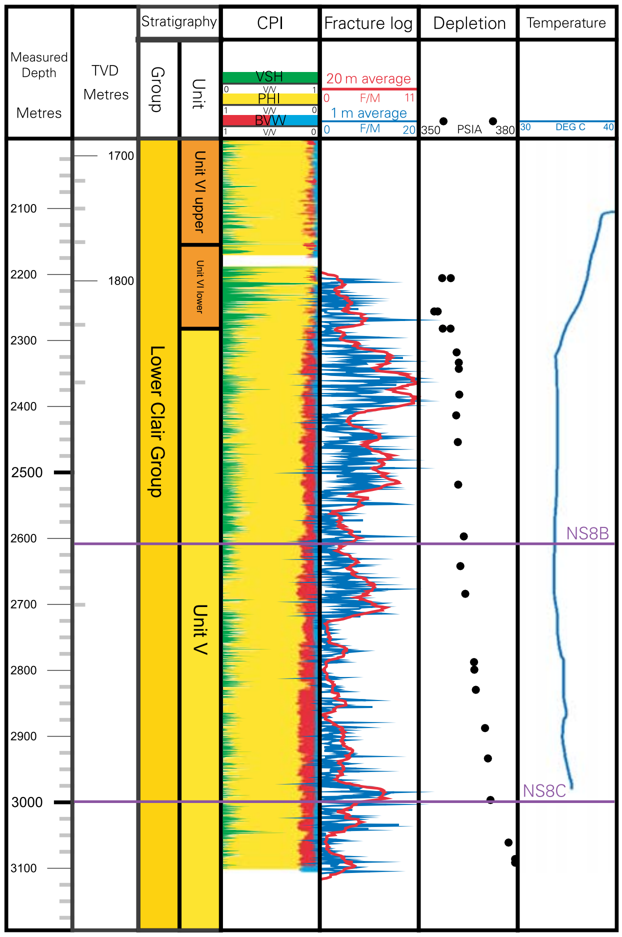

Fig. 11. Well data from first water injector 206/8-A04, displayed in measured depth. Note temperature profile from shut-in pass of production log; consistent cooling is observed, suggesting uniform injection.

The initial injection rate of 206/8-A04 was over 35 000 barrels of water per day (BWPD), consistent with pre-drill expectations, 18 months after first production from the field.

Well interference testing demonstrated that 206/8-A04 strongly supported 206/8-A02 (600 m away), and also provided pressure support to 206/8-10Z and 206/8-A03Z. Reservoir pressure rose in response to water injection (Fig. 10) but, despite their close proximity and pressure communication, 206/8-A02 did not experience early water breakthrough. Dry production was sustained for 20 months after the onset of water injection (Fig. 12). The volume of water injected by 206/8-A04 before water breakthrough occurred within 206/8-A02 was *c.* 6.5 million barrels. This indicates that the field does not consist solely of a fully connected network of conductive faults or ‘fracture clusters’. Some conductive elements must terminate in matrix so that flow is forced through both matrix and fractures. This enabled some of the more extreme models considered by Barr *et al.* (2007) to be ruled out. For example, those with all mapped faults conductive (Barr *et al.* 2007, p. 217; Fig. 10) or those with all the permeability enhancement provided by a dense, well-connected joint set (Barr *et al.* 2007, p. 220; Fig. 14) and points to the limitations of an extended well test in predicting water flood behaviour. Reasonable matches were obtained by combining disconnected subseismic fault models (Barr *et al.* 2007, p. 218; Fig. 12) with a scaled-down version of a relatively bland joint set model, just sufficient to explain the pressure equalization away from conductive faults and vertically in Unit VI. Matrix block size (which in the simulation model controls imbibition of water from fractures to matrix) was treated as a tuneable history-matching parameter and was best matched with values in the 5–10 m range. This is much larger than the tens of centimetres which would be inferred from conductive fracture spacing in 206/8-A04, supporting the view that most of those fractures are disconnected and only the larger ones link together to form a fracture network. Subsequent discrete fracture modelling used only the largest joints with along-hole spacings of several metres as conditioning input (fortuitously, this approximates to the detection limit of the medium resolution acoustic and micro-resistivity image logs).

Reservoir pressure was restored in the Core segment and successful surveillance had enabled learning to be maximized from three high-rate producers before the need for water injection. However, downflank injectors were required to assist in peripheral sweep and improve recovery. Well 206/8-A11 was drilled to the SW of the Core segment, as a high-angle well penetrating deep into the Lower Clair Group (Fig. 7). The well was drilled with a step out of *c.* 3 km from the fixed platform, outboard of major north–south trending faults, intersecting fault NESW6C at 4000 m MD. It was hoped that the fault would effectively diffuse the injection water along its length, providing the opportunity for uniform imbibition into the matrix and effective sweep up dip to the crest of the field. The well penetrated the standard Lower Clair Group succession (Fig. 13); fractures were most abundant in lower Unit VI (one to three fractures per metre), with counts dropping off to under 0.5 fractures per metre in Unit V. To date all previous wells had demonstrated a good degree of pressure communication throughout the reservoir. The well data demonstrated reasonable reservoir quality but no depletion within Unit V, implying no Unit V communication with the producers. This was probably the largest surprise since the field start-up, as until then only the segment bounding the Core–Graben Fault had proved to be a pressure baffle and even the fault separating the Core from the ‘Witch’s Hat’ segment, with over 100 m throw, had been open to flow. Also surprising was that Unit III, in the water leg, was depleted. All offtake in the development area is from Unit V and Unit VI so the observed depletion suggests that some faults are acting as vertical pressure conduits, allowing communication across low-permeability and relatively unfractured Unit IV to Unit III. This had actually been considered as an alternative interpretation of the 206/8-9Z production log data (Clifford *et al.* 2005, p. 8; Fig. 7). A strong Unit V matrix contribution was required to sustain flow from the toe of the well, where mud losses and open fractures were scarce. If no matrix contribution was assumed, the one conductive fault in that interval required pressure support from Unit III to match its inflow performance. This interpretation was considered less likely at the time, in light of the lack of Unit III depletion following the extended well test. In retrospect the well may have been connected into down-dip Unit III, which is poorly connected to updip Unit III at the observation well 206/8-9Y.

During injectivity testing 206/8-A11 quickly built pressure locally due to a lack of connection to the producers. The injection pressure was increased in an attempt to hydraulically fracture down into the undepleted Unit V. As sustainable injectivity rates of over 30 000 BWPD were achieved, the well clearly injected into a large

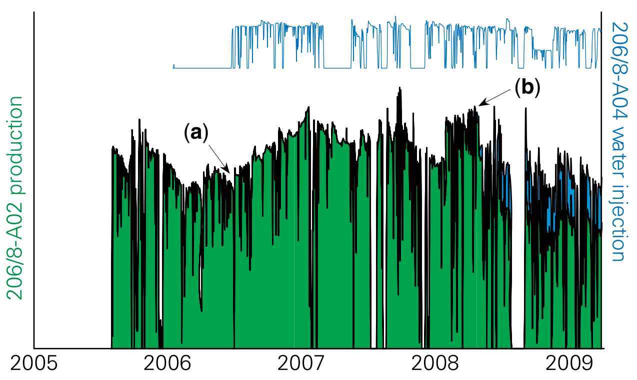

Fig. 12. Oil (green) and water (blue) production data from 206/8-A02 plotted with injection data from 206/8-A04 (upper blue line); distance between wells is *c.* 600 m. (**a**) Increase in production rate at time of injection start-up in June 2006; (**b**) water breakthrough in March 2008.

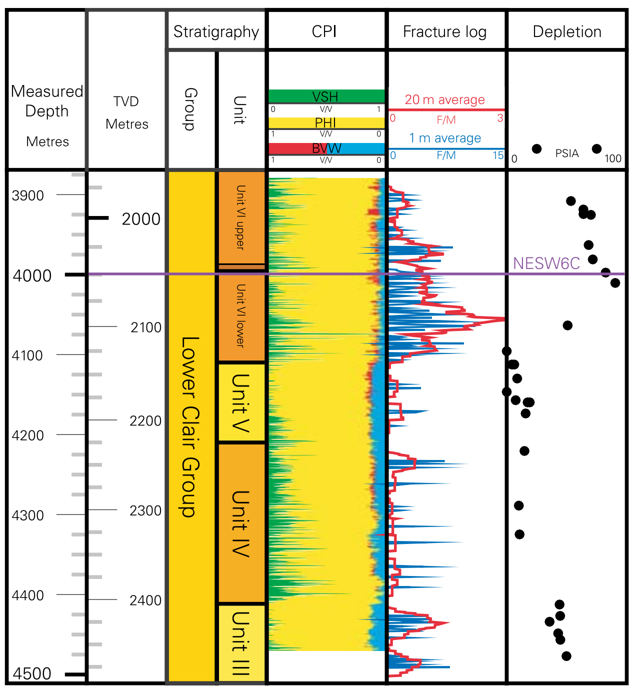

Fig. 13. Well data from water injector 206/8-A11, displayed in measured depth. Note lack of depletion within Unit V; Unit III appears depleted below.

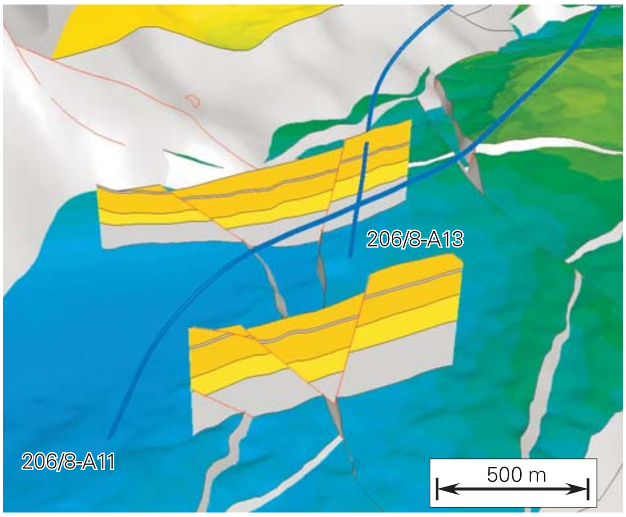

Fig. 14. North-facing perspective view of fault juxtaposition in the downdip Core segment; cross-sections are projected at both well locations. Orange stratigraphy represents Unit VI and yellow stratigraphy represents Unit V. At both locations fault offsets alone are not large enough to completely offset Unit V.

storage volume, it was concluded that it was better connected to the downflank aquifer (estimated at several billion barrels) than to the producing area. The well was completed as a Unit VI-only injector, with future plans to side-track up-dip.

The lack of depletion was difficult to explain by fault juxtaposition alone (Fig. 14) as the offsets are not great enough to completely isolate Unit V in this area, implying a degree of fault sealing. A second injector had been planned to the north of the 206/8-A11 well location, but as the previous well had demonstrated little or no communication to the crestal Core the target became much less attractive. The reason for the compartmentalization remains unclear, but there seemed significant risk that a second well in the same area may be prone to similar issues. As a direct result of these concerns the second downflank injector 206/8-A13 was moved east, closer to the producers to mitigate the risk of any baffling around the mapped fault. Reservoir quality in this well is significantly degraded in lower Unit V. A modest fault offset could juxtapose the good reservoir in the 206/8-A11 area against poor reservoir in 206/8-A13. This model could explain the undepleted pressure in 206/8-A11.

Across the field petrographic analysis of downhole samples of poor quality reservoir have indicated that the matrix has been pervasively cemented by calcite, and more rarely quartz, which occludes almost the entire pore network. Reservoir quality degradation could be related to local cementation around faults. Zones of cemented matrix had been observed during the appraisal programme, both within the Core and the other segments. Petrographic analysis of appraisal cores confirms the same pervasive calcite cementation seen in these development wells. The factors controlling the distribution of these cemented zones could relate to primary depositional fabric (with the proportion of calcrete varying across the field) and fluid movement through the fault system. At present it has not been possible to reliably map these cemented zones at a field scale, although they clearly can act as baffles within the reservoir.

It is also possible that the granulation seams which make up *c*. 50% of logged fractures also act as baffles, although it is unclear whether they form a connected network outside of fault damage zones. The calcite cemented fractures invariably show cavity-filling rather than crack-seal textures, and so are thought to represent filled open fractures rather than primary veins. As there is abundant dynamic evidence for a connected open fracture network, it is reasonable to assume that cementation of such a network would give rise to well connected barriers. One could take two extreme views of the impact of faults on Clair reservoir connectivity: on the one hand, granulation seams are pervasive, connected and therefore all faults are barriers except where breached by open fractures; alternatively, the primary fault and granulation seam fabric has been disrupted by multiple brittle reactivation events and all faults are open except where sealed by late cement. Either model would predict a patchwork of sealed, open and conductive faults, difficult to distinguish from dynamic data alone.

In light of these well results the production-led start-up is justified. If the original field development plan had been followed and downflank water injectors drilled at the start of the development (Fig. 5), there would have been no production offtake so lack of depletion in the downflank area would have been no indication of poor connectivity. This would have resulted in the completion of a well like 206/8-A11 across all reservoir units, and possibly other outboard injectors in similar positions. The strategy of maximizing depletion (within the safety window above bubble point) clearly showed that some downflank areas are not in pressure communication with the crestal Core, and as a result has helped to effectively place water injection wells.

As the development has progressed, production wells continue to target mapped faults. Two of the more recent producers in the Core segment have demonstrated particularly high production rates of up to 20 000 BOPD. Recent wells have marked a strategic shift as dedicated Unit VI-only producers, cutting a number of mapped faults. These wells access significantly poorer matrix but exploit the high fracture intensity seen in Unit VI in the early producing wells (Fig. 9).

Water breakthrough

A key uncertainty in the development was the timing of water breakthrough. This had been predicted to be relatively early in pre-development models, and this had greatly influenced the original field development plan. First water production occurred in September 2007 in the ‘Witch’s Hat’ fault block to the north of the main Core segment (Fig. 3). The ‘Witch’s Hat’ is a small downthrown segment directly to the south of the Ridge Fault, in a structurally complex area north of the fixed platform. The segment was developed in early 2007 with a producer–injector pair. The injector, 206/8-A08Z, was located in the northern corner of the segment, adjacent to the Ridge Fault, and was drilled first to provide additional support to the Core producers. It was drilled into a damage zone of what was later mapped as a north to south trending fault WH3 (Fig. 7). The well was initially planned based on a time migrated seismic dataset; there was significant improvement in the fault imaging with pre-stack depth migration that became available after the well was drilled. Reservoir quality was poorer than expected, but pressure data confirmed good connectivity to the rest of the Core. Despite the poor matrix properties the well achieved an injection rate of 35 000 BWPD and provided excellent pressure support to the Core. Dynamic data indicates that the poor matrix quality extends hundreds of metres from the fault (or at least that flow is confined within the fault, perhaps by a sealing damage zone), but reservoir pressure near the well has not increased dramatically so the fault must connect into a region of good-quality matrix (or more likely, matrix and fractures) which is being drained by the Core producers. This contrasts with 206/8-A04, where water was dispersed very close to the well in good quality matrix.

Well 206/8-A09 was drilled into the faulted terrace separating the Core segment from the ‘Witch’s Hat’ (Fig. 7). During drilling

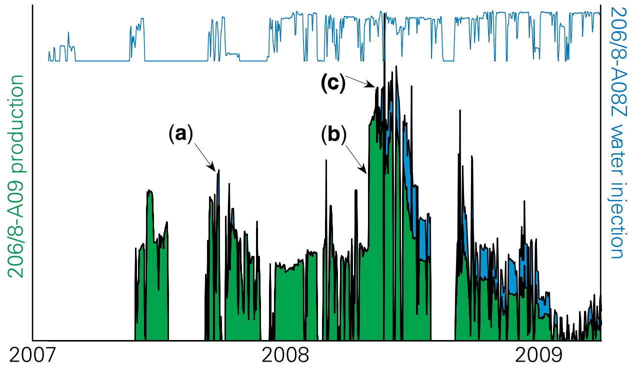

Fig. 15. Oil (green) and water (blue) production data from 206/8-A09 plotted with injection data from 206/8-A08Z (upper blue line), distance between wells is *c*. 1200 m. (**a**) Water breakthrough in September 2007; (**b**) rate increase in May 2008 after water shut-off; (**c**) continued water cut development.

of the reservoir section over 4500 barrels of drilling mud were lost, giving an early indication of large open fractures in this area. Subsequent image log interpretation confirmed a highly fractured section where individual fractures could not be distinguished due to the highly fractured nature of the reservoir. The well achieved an initial rate of over 5000 BOPD, with rapid interference (*c*. 1 hour) with its paired injector 206/8-A08Z, 1200 m to the north. At the time the well had the highest productivity index of any in the field, with its rate limited only by the platform's capacity to deal with the large amount of drilling solids (loss control material) which flowed back. At the time of completion in May 2007 there was no water production from the field, despite the beginning of water injection in June 2006. Shortly after 206/8-A09 was brought into production, water breakthrough occurred (Fig. 15). Testing the well showed that the water cut was strongly rate dependent (at 3000 barrels per day (BPD) the well produced dry, at 5000 BPD it produced at 30% water cut). The two wells within the 'Witch's Hat' segment appear to be in direct communication through the mapped conductive fault.

The risk of early water breakthrough had been recognized during the well design phase, and to mitigate against this the completion was designed to allowed for zonal isolation. A production log confirmed water entering at the toe section and the interval was successfully plugged back, restoring dry oil production. The well rate was successfully increased following the intervention but after two weeks the water-cut began to develop once again; the point of water entry had re-established at a shallower depth in response to the changed completion. The well was choked back to manage the increasing quantities of produced water and was listed as a candidate for a future side-track campaign. This experience demonstrated the risk of injector and producer directly connecting into the same fault system.

Water flood development

After the success of the permanent Life of Field Seismic (LoFS) system on Valhall (van Gestel *et al.* 2008) a small permanent system was installed in 2006 to monitor the 4D seismic response in the central Core segment (Foster *et al.* 2008). It had the objectives of monitoring the developing water flood front and identifying areas of gas breakout, enabling the optimization of development drilling locations and water injection management. As the 4D seismic response at Clair was predicted to be small (1–2% acoustic impedance change), the initial installation was a test to confirm if a response could be recognized. The plan was to acquire three surveys and then assess the results before deciding on future acquisition. Three annual surveys have now been acquired (2006, 2007 and 2008).

4D seismic data has helped in the understanding of water movement in the Core segment. Comparison of the first LoFS survey in 2006 to the original OBC data acquired before start-up has proved challenging due to high noise levels (low reproducibility between different receiver installations). Comparisons using the LoFS on LoFS surveys with the same permanently installed array have proved valuable in understanding the water flood pattern. For example the 4D difference map of 2006–2007 for the upper part of Unit V shows an acoustic hardening or dimming of the reservoir consistent with an increase of water saturation around the 206/8-A04 water injector (Fig. 16b). The area of inferred increased water saturation is concentrated at the heel section of the well with less pronounced changes at the toe. This correlates well to the temperature log (Fig. 11), which established that injection was occurring relatively uniformly across the completed section, but dropping off at the toe (also consistent with logged fracture distribution). Four-dimensional seismic data shows dimming is concentrated in the upper part of Unit V, which has the highest reservoir quality. Locally, where the water signature crosses a fault, there is a response in lower Unit V. Away from the fault the 4D change reverts back to upper Unit V. This could indicate vertical water movement along mapped fault planes.

The 4D difference map (Fig. 16a) shows that the area of dimming extends to the NW of the heel of 206/8-A04 towards the heel of 206/8-A02. The injector is drilled close to the intersection of two faults, and the 4D response to water is strongest at the intersection.

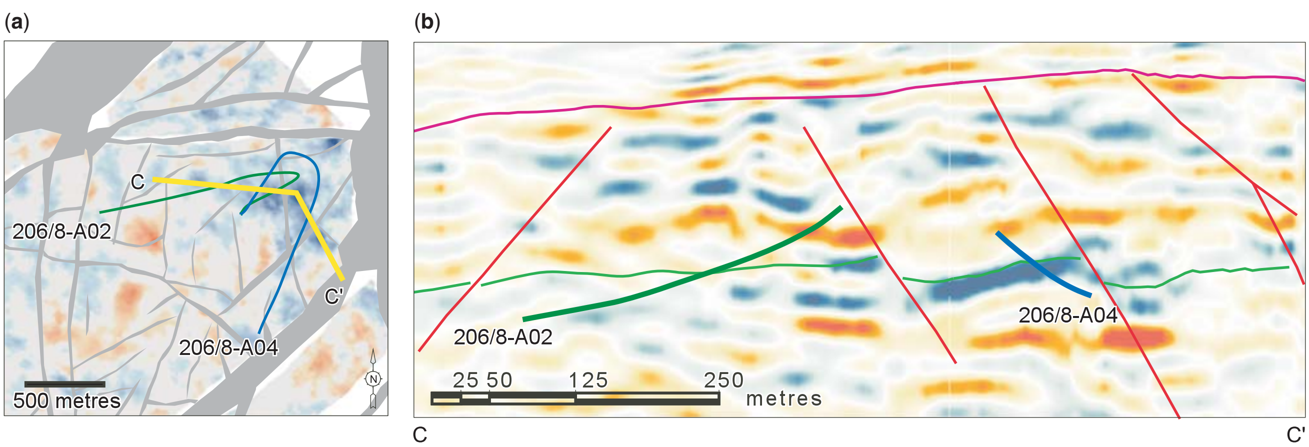

Fig. 16. (**a**) Core segment 2006–2007 4D difference map based upon Top Unit V; blue is inferred as water saturation increase. (**b**) Cross-section between injector 206/8-A04 and producer 206/8-A02. Horizons are Base Cretaceous Unconformity (magenta) and Top Unit V (green).

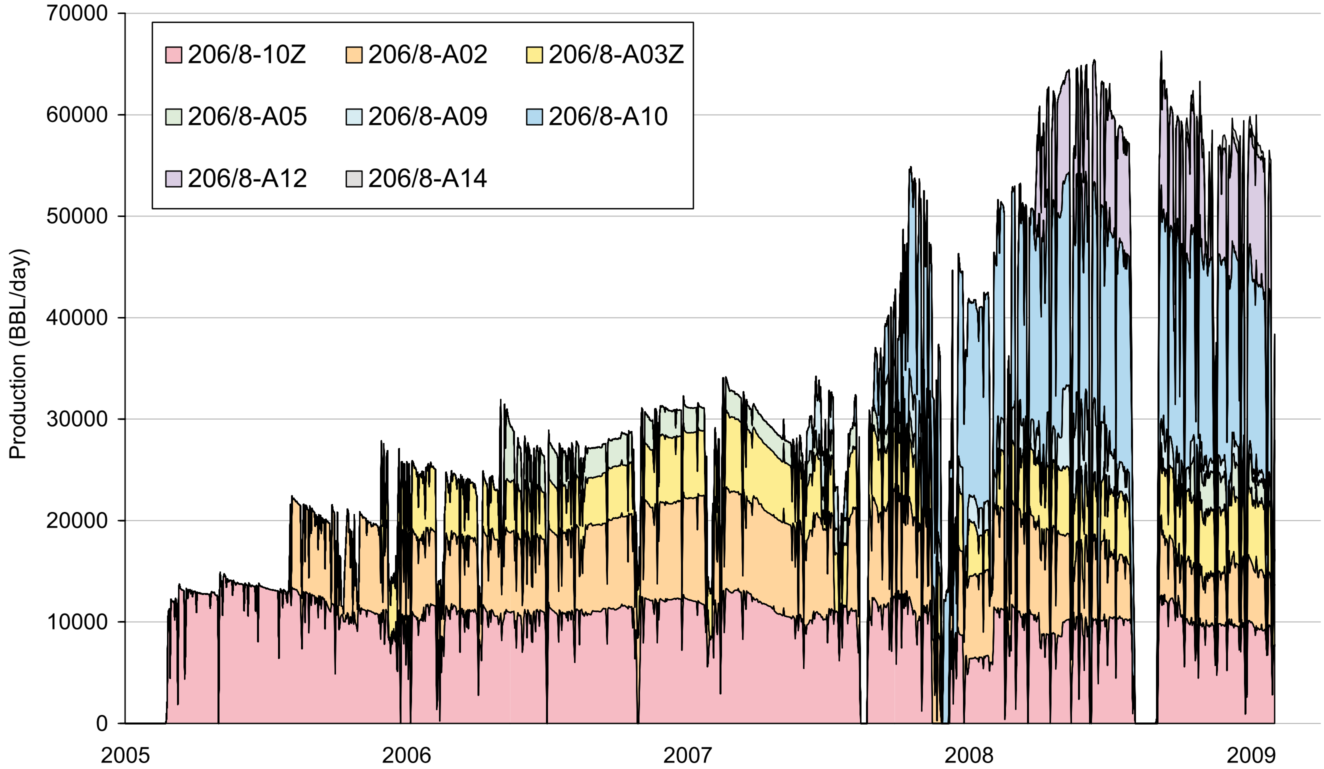

Fig. 17. Clair field start-up, oil production profile.

Well 206/8-A02 was the second well to see increased water production. Water breakthrough occurred 20 months after injection start-up in March 2008 (Fig. 12), suggesting that the two wells are not in direct communication. This is supported by the mapped area of dimming suggesting that the reservoir pressure in the area around the injector is much higher than the pressure around the producer.

Pressure support was provided to the all Core wells, with some seeing more direct support than others. This has created lateral and vertical differences in depletion, and probably small amounts of free gas in some areas when the reservoir pressure was near the bubble point. At low gas saturation the mobility of the gas is low or immobile, and no increased GOR has been seen in any of the production wells. At 206/8-A02 the 4D response is characterized by a brightening or acoustic softening, suggesting a small increase in gas saturation in the reservoir as a result of production. This can be tied to wells which have seen the highest pressure depletion. A similar brightening is also seen at other production wells in the Core segment and also in the Graben (Fig. 3), which is partly covered by LoFS 4D data and has been producing without pressure support since 2006.

The production capacity of the facilities was reached in mid-2008, three years after the first well was brought online (Fig. 17). In the Core segment the primary well targets have now been drilled or are currently being planned. Most future targets are likely to be accessed by side-tracking existing wells. In this complex reservoir, a detailed and integrated understanding is required to ensure that these side-track locations are successful. Four-dimensional seismic data will have a key role to play in identifying successful target areas, away from water and from areas of secondary gas development.

Conclusion

Early appraisal well data demonstrated the complex nature of the reservoir, which resulted in a 28 year gap between initial discovery and development start-up. During this period the appraisal campaign collected a wealth of static data, highlighting the main uncertainties and barriers to an earlier development. Initial vertical appraisal well rates were low; successive penetrations established the Clair Group stratigraphy and the influence of fractures. As seismic technology developed the natural fracture network was targeted, initially vertically with 206/8-8, demonstrating the potential of the reservoir to deliver increased rates from fractured intervals. With the ability to drill horizontal wells, and the developing knowledge of the fracture network, the appraisal campaign culminated in the successful drilling and testing of 206/8-10Z. The extensive appraisal well database allowed for a clear static description, highlighting the remaining dynamic uncertainties in the original field development plan.

Prior to production start-up the key decision was taken not to pre-drill, giving the opportunity to respond to dynamic changes within the reservoir with a flexible well sequence. A suite of fracture models attempted to capture the range of pre-production uncertainty. These models controlled the distribution of fractures within the reservoir, ranging from relatively densely fractured joints models to models with discrete ‘fracture clusters’ around mapped faults. This suite of models underpinned the future development, allowing data from subsequent wells to be analysed within an already established framework. At this time the degree of matrix imbibition was unknown and all planning included significant measures to handle large quantities of produced water.

To address the range of uncertainty, flexibility was seen as key to the development. Analysis of appraisal well data demonstrated that a producer-led start-up could be adopted, in a safety window above reservoir bubble point. This decision emphasized the importance of data acquisition in the early wells and all were completed with extensive datasets to fully characterize both fractures and matrix. Regular monitoring of pressure data allowed for the delay in water injection and an initial period to analyse the results from the first development wells. Early well results were in line with pre-drill simulation estimates. Key observations were made using reservoir pressure data, noting the contrasting styles of uniform depletion (206/8-A02) and depletion concentrated around interpreted 'fracture clusters' (206/8-A03Z). These observations allowed the pre-drill models to be refined while water injector targets were planned at multiple locations. The integration of all static and dynamic data underpinned the decision to drill the first water injector at a crestal position, in a change from the original field development plan.

The delay in the onset of water breakthrough after injection start-up was evidence that matrix imbibition was occurring and some downside pre-drill models could finally be eliminated. Core segment water breakthrough occurred 20 months after water injection start-up. Effective matrix imbibition has been inferred from the timing of water breakthrough and from the 4D seismic response. An injector inadvertently drilled within a fault damage zone in the 'Witch's Hat' segment is interpreted to have connected directly to a producer through the conductive fault system, highlighting one of the key pre-drill risks documented by the field development plan.

Data from later development wells continues to surprise, most notably with the lack of depletion observed downdip in the Core segment within well 206/8-A11. This reinforces the importance of the producer-led start-up, maximizing depletion in the Core to highlight communication pathways within the reservoir. As the development continues, 4D seismic data is improving the dynamic reservoir understanding and providing valuable spatial context to the well results. It may be possible to map these communication pathways and their associated barriers, and as the development continues, 4D seismic data will prove valuable in identifying future side-track targets.

The producer-led start-up created an opportunity to learn from the rapidly growing well stock and, crucially, influence the development based upon the observations made. The complex nature of the reservoir highlighted the need for the rapid, early data integration that defined the early years of the development of the Clair field.

This paper is published with kind permission of BP Exploration Operating Company Ltd and the Clair field co-venturers: ConocoPhillips (U.K.) Ltd, Chevron Upstream Europe, Shell UK Ltd and Hess Ltd. The development of the Clair field stands as a testament to the work of our predecessors throughout appraisal and pre-development, and more recently our colleagues within the Clair Reservoir Management Team. The authors would like to thank M. Kidd for cartography, and the manuscript has benefited significantly from reviews by W. Narr, R. Knipe and an anonymous reviewer.

Abstract: Twenty-three years after BP discovered the Chiswick Field in 1984, first gas production was achieved by Venture Production. During its long period of appraisal and development, this asset has passed between five different operators and a large number of co-venturers. Prior to development, the field represented one of the largest undeveloped gas volumes present in the UK Southern North Sea. Key uncertainties include reservoir compartmentalization, low net/gross ratios and poor reservoir permeability, uncertainties in structural mapping and gas–water contact depths, as well as a widely varying Carboniferous subcrop and significant lateral changes in fluviatile sandstone architecture. Drilling and completion during the first phase of development were a significant challenge, with ambitious long and deep fracture-stimulated horizontal wells. The installation comprised a five-slot minimum facilities well-head platform with production tied back via the Venture-operated Markham J6A Platform with gas landed in Den Helder, Holland. As part of Phase II development a further three wells are being planned to accelerate recovery and access the remaining undeveloped reserves in both the primary Carboniferous and secondary Rotliegend reservoirs in the Chiswick Field.

Keywords: Carboniferous, hydraulic fracturing

The Chiswick Field is located in block 49/4a, UK Southern North Sea (SNS), approximately 160 km NE of Great Yarmouth (Fig. 1). The reservoir is primarily of Upper Carboniferous Westphalian A and B age with Permian Rotliegend as a secondary reservoir target. The field is a slightly elongate faulted anticline lying on the same dominant Hercynian NW–SE trend as the Markham Field to the SE and the Ketch Field to the NW and covers an area of some 37 km^2. The field is subdivided into five main fault compartments named Alpha, Beta, Gamma, Delta and Epsilon (Fig. 2). Depth to the top reservoir is around 3300 m TVDss at the crest of the structure and the volume of gas-in-place is estimated to be in the region of 600 BCF. BP discovered the field in 1984 with the well 49/4-1, which encountered gas within the Carboniferous Westphalian A and B channel sandstones.

Chiswick remained one of the largest undeveloped gas accumulations in the SNS for more than 20 years predominantly as a consequence of the significant number of uncertainties associated with the field. Reservoir distribution is recognized as the primary uncertainty, particularly in undrilled fault blocks. The Carboniferous is erosionally truncated below the Hercynian unconformity; therefore, predicting whether Westphalian A or B reservoir is present at the subcrop away from well control is difficult and this is exacerbated by the channelized nature of the reservoir sands. The porosity and permeability of these sands is low and they are part of an overall low net to gross sequence. This introduces uncertainty with respect to the connectivity of individual channel sands and also in terms of production and the connection of sufficient quantities of sand to the wellbore to achieve economic flow rates. Further uncertainties exist in the form of potential reservoir compartmentalization and structural elevation as a result of depth conversion, which is made more challenging due to a complex overburden.

Field history

Block 49/4a has a complicated history beginning in 1965 when it was first awarded to Gulf Oil during the second licensing round. Since then, more than ten different licensees have been involved in 49/4a. Venture Production's involvement began in June 2006 when they acquired the entire share capital of CH4, giving a 95% interest in Chiswick. In March 2008 Venture purchased the remaining 5% equity from Wintershall. The number of equity swaps and licensees involved in the block has undoubtedly played a role in the length of time it has taken to develop the Chiswick Field.

Prior to Venture Production's involvement, four wells were drilled on the Chiswick structure. The first was in 1984 when BP drilled the discovery well 49/4-1, which encountered a 130 m gas column within the Westphalian A and B. Total net pay in this well is around 30 m with an average porosity of 8% and permeability of 2 mD. After a 10 000 lb mini fracture the well flowed at a maximum rate of 8.5 MMscf per day with a 690 psig flowing tubing head pressure (FTHP); the well was subsequently plugged and abandoned.

In 1986 BP drilled an appraisal well, 49/4-2A, in the fault block adjacent to the 49/4-1 well. The well was drilled in a down-dip location and, although a good quality interval of sands was encountered within the Westphalian A and B, much of it was in the water leg with only 5 m of net pay present. A DST failed to produce gas to surface.

BP's third well on the field, 49/4-3, was drilled in 1989 in the same fault block as 49/4-2A and encountered a 168 m gas column in the Westphalian A with net pay of around 30 m. After a 418 000 lb hydraulic fracture, the well flowed at 17.5 MMscf per day compared with a pre-stimulation flow rate of just 5.8 MMscf per day. Detailed analysis of the treatment suggested that the fracture design was not optimal and the well was not fully cleaned up prior to testing; nonetheless, the concept of hydraulically fracturing a vertical well was clearly a positive step towards a viable development strategy.

LASMO drilled well 49/4a-5 in 1999 in order to further appraise the reservoir in the 49/4-1 block. This sub-horizontal well was designed to penetrate multiple channel sands above the gas water contact. The well encountered 150 m of net pay within the Westphalian A and B, although true vertical thickness (TVT) was only 18 m, with porosity and permeability similar to that of the 49/4-1

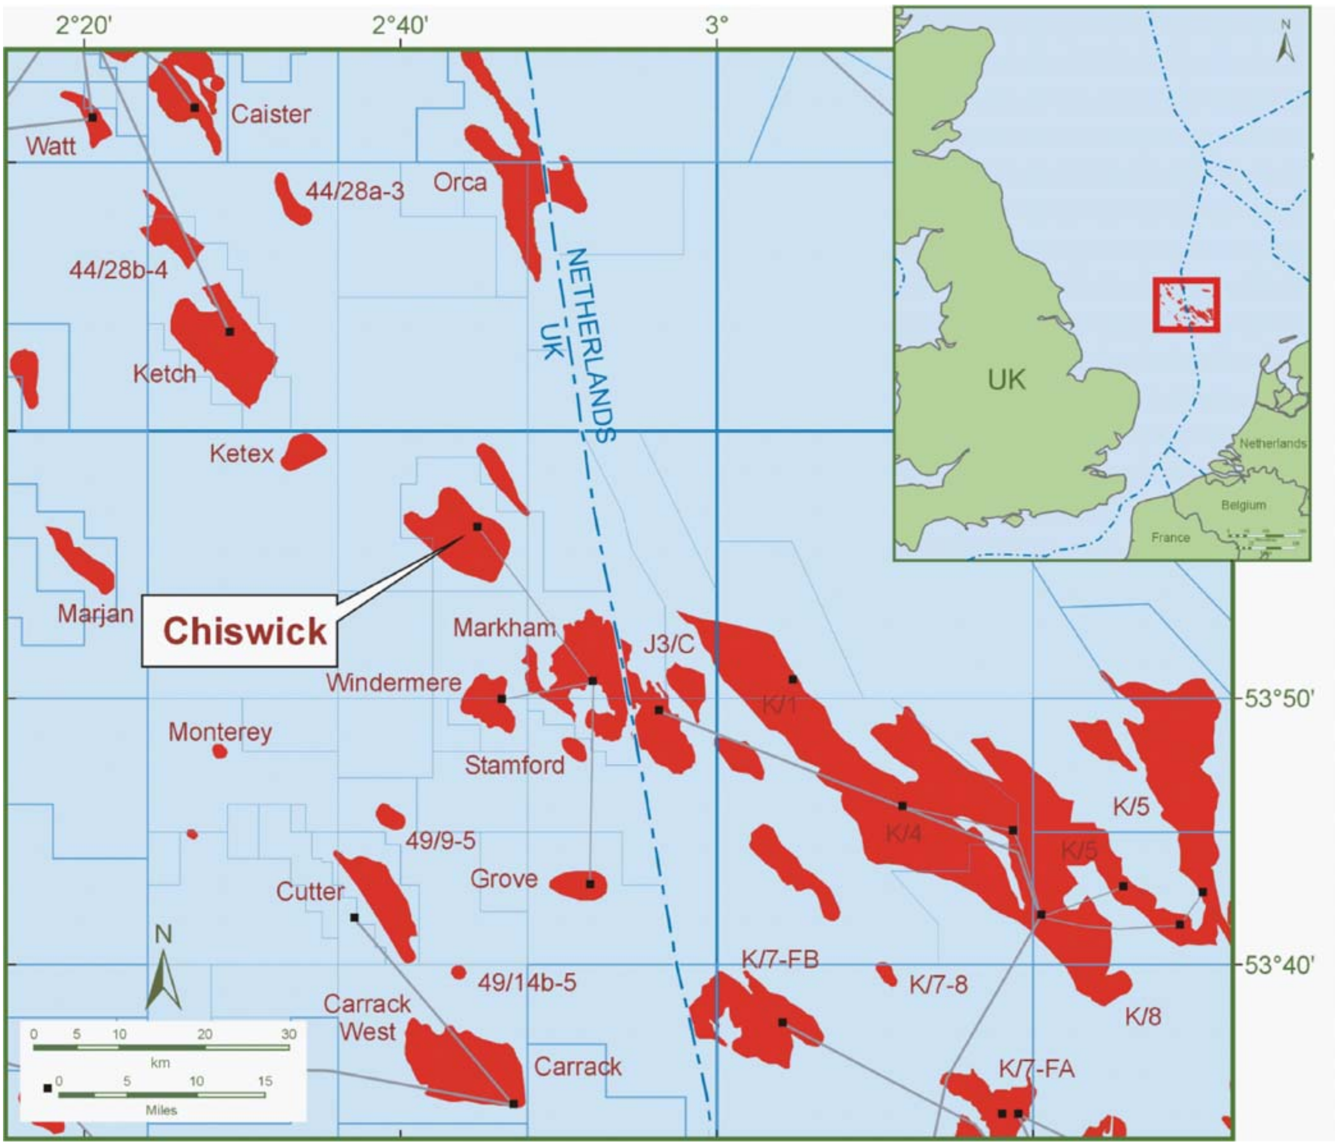

Fig. 1. Chiswick Field location map.

well. A drill stem test was performed which achieved a maximum flow rate of 13 MMscf per day through a slotted liner. Although this sub-horizontal well ultimately failed to produce a commercial flow rate, it was certainly more effective than the previous unstimulated vertical wells (Table 1).

Structural history and stratigraphy

Structure

This Chiswick Field lies in a region of structural complexity owing to multiple phases of tectonic activity which also controlled the preservation of the Carboniferous sediments. The area is dominated by a pre-Zechstein NW–SE structural grain which can be attributed to the Late Silurian Caledonian Orogeny. During the Early Carboniferous, north–south extension took place involving major normal and oblique slip reactivation of pre-existing faults trends forming tilted fault blocks. This episodic rifting allowed thick Lower Carboniferous packages to accumulate. In the late Carboniferous, the Variscan Orogeny resulted in transpressional fault reactivation and gentle folding of strata along the pre-existing NW–SE fault trend. Uplift and erosion followed, creating a major unconformity between the Carboniferous and overlying Permian sediments, commonly referred to as the Base Permian Unconformity (BPU). Further reactivation of Carboniferous faults occurred as a result of extensional episodes in the Jurassic (Cimmerian) and compressive inversional episodes in the Cretaceous and early Cenozoic (Glennie & Underhill 1998).

The Chiswick structure is defined at Top Carboniferous as a broad NW–SE-trending faulted anticline and was formed during the Variscan Orogeny. It is located on the southern edge of the Caister–Murdoch ridge which continues SE to the Markham Field. Pre-Permian NE–SW-trending faults with strike lengths much shorter than the major NW–SE faults cross-cut the structure, dividing it into three main sub-blocks, Alpha, Beta and Gamma.

Stratigraphy

The Carboniferous rocks present within the Chiswick Field are of Westphalian age and can be divided into two zones: the Westphalian A (Langsettian) and the younger Westphalian B (Duckmantian) (modified from Ritchie & Pratsides 1993). These two zones are divided by the *A. Vanderbeckei* marine band, which is a regionally extensive marker horizon (Fig. 3). The Carboniferous is erosionally truncated at the BPU and overlain by the Lower Permian Rotliegend. The Rotliegend contains thin Leman sands and silts overlain by thicker Silverpit shales/silts and sands. The Zechstein

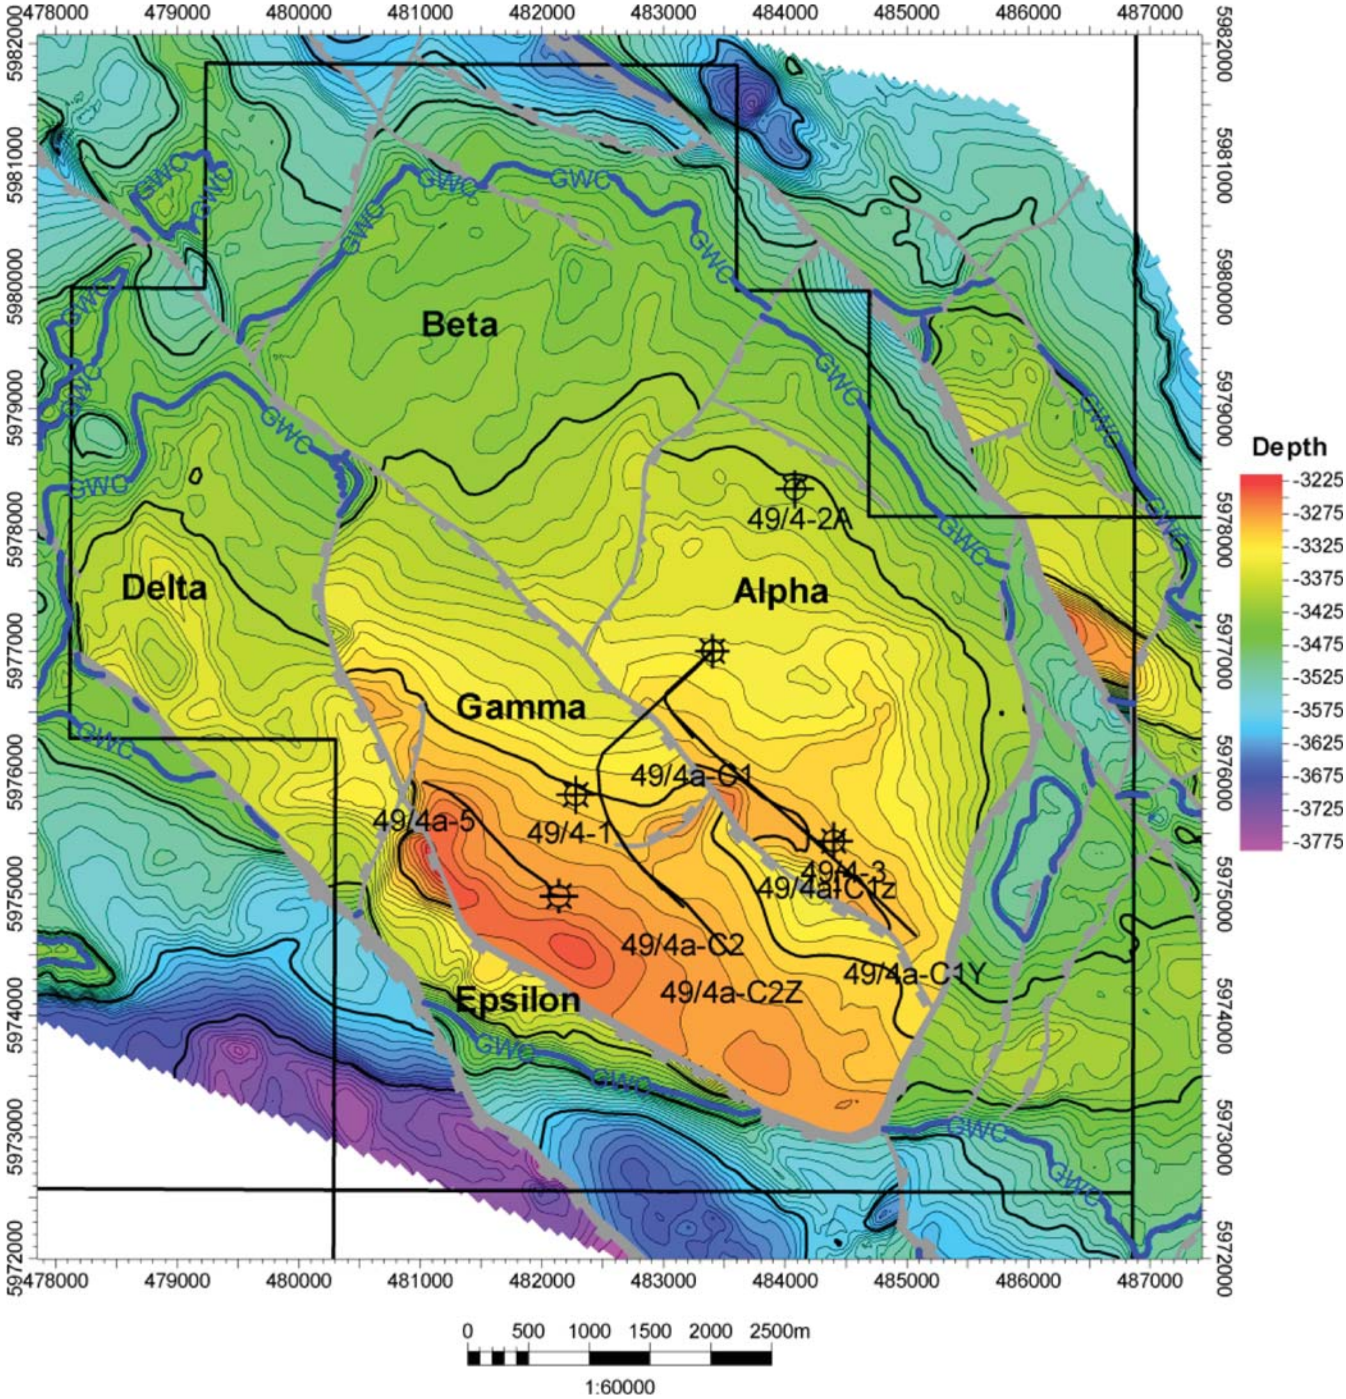

Fig. 2. Top Carboniferous depth structure map highlighting Chiswick Field sub-blocks.

Table 1. Chiswick appraisal well results

Well	Year	Operator	Maximum flow rate (MMSCF per day)		Comments
			Pre-fracture	Post-fracture	
49/4-1	1984	BP	0.2	8.5	10 000 lb mini fracture
49/4-2A	1986	BP	–	–	431 BWPD
49/4-3	1989	BP	5.8	17.7	418 000 lb fracture
49/4a-5	1999	Lasmo	13.0	–	Sub-horizontal well – slotted liner

evaporates act as a seal over the field. Overlying the Permian are the Triassic continental sandstones and shales with Jurassic sediments being absent in this area. The Early Cretaceous is dominated by mudstone facies and the Upper Cretaceous is represented by the Chalk group (Ritchie & Pratsides 1993). Clastic deposition resumed in the Early Cenozoic and is approximately 200 m thick over Chiswick.

Carboniferous reservoir

All Chiswick wells penetrate the Silverpit, Leman and the Westphalian A interval. Five out of the eight wells on the field encounter the Westphalian B depending on the extent of the truncation of the BPU in a given area. The Alpha block is predominantly eroded

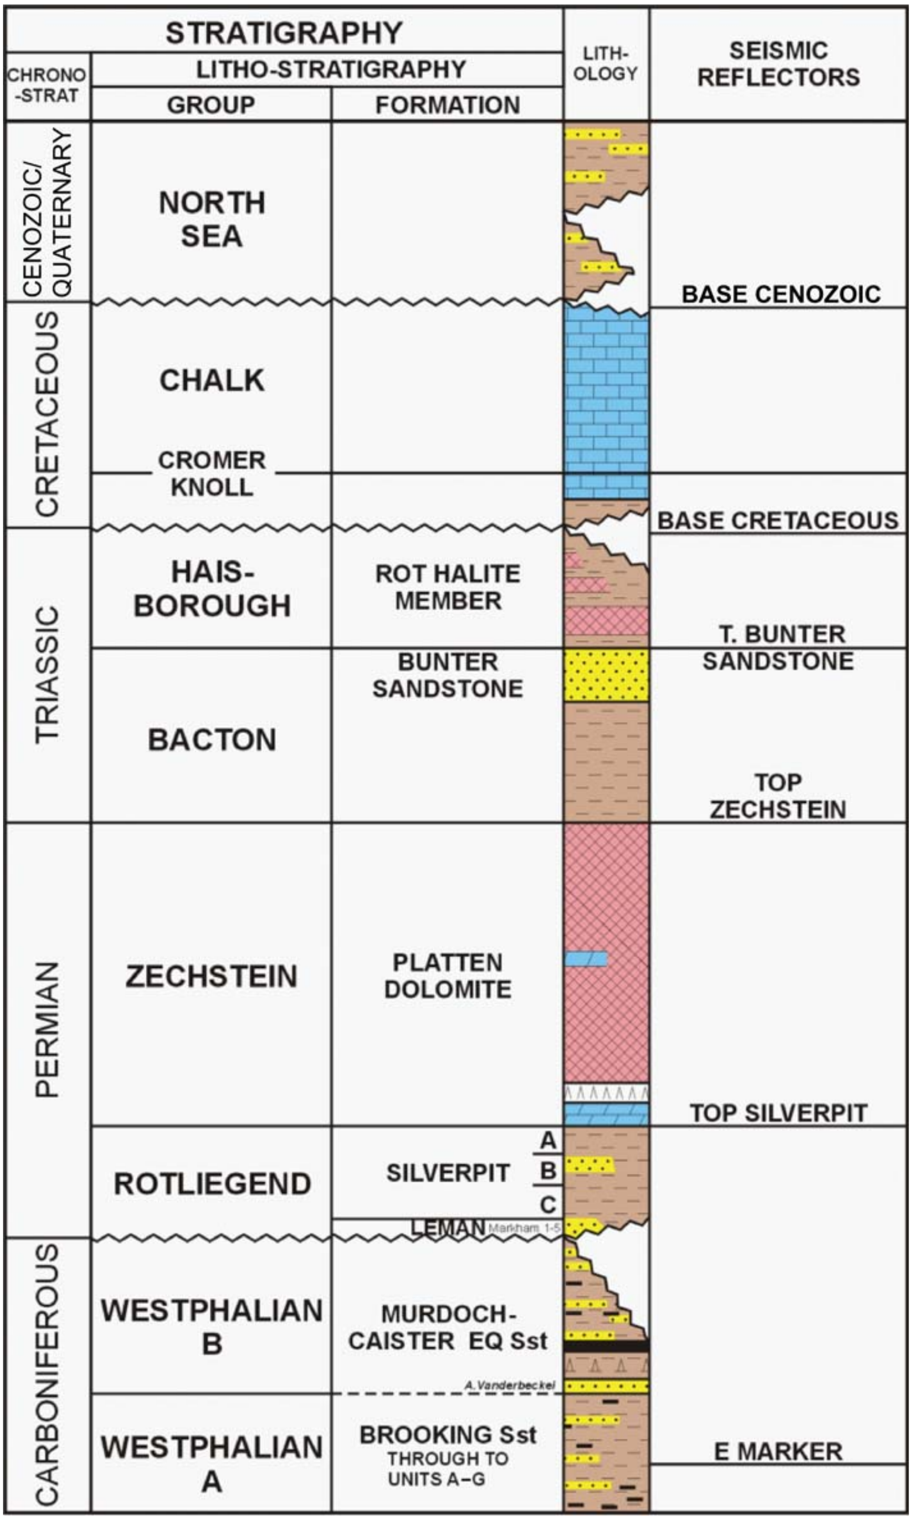

Fig. 3. Chiswick Field stratigraphic column.

down to Top Westphalian A, with the Gamma block preserving both the Westphalian A and part of the Westphalian B, which contains the Murdoch–Caister equivalent sands. The other three blocks, Beta, Delta and Epsilon Carboniferous subcrop, can be prognosed by interpreting on seismic the E coal marker of Westphalian A age, which is a laterally continuous coal horizon over the Chiswick Field and can be isopached to the unconformity (Fig. 3).

During the Carboniferous the Chiswick Field was situated within a low relief delta plain which contained fluvial, crevasse splays, flood plain and swamp deposits in an overall humid environment. The presence of organic matter resulted in the formation of coal seams within the field which represent marker beds that can be correlated and provide the basis of the nomenclature for the layers within the field. These coals also create barriers/baffles within the field and reduce vertical connectivity. One of these markers (E) was used for seismic interpretation as mentioned earlier. The Westphalian is highly variable both laterally and vertically and one of the main controls on deposition was sea level. A sea-level rise resulted in aggradation of the delta plain, leading to an overall poorly drained environment where marsh/lacustrine environments were present (Quirk 1993). This is compared with progradation of the delta plain associated with a sea-level drop. Within the Chiswick Field the channel sands are the main reservoir with the best reservoir quality within low sinuosity fluvial channels which are laterally extensive. The distribution, size and connectivity of these channel sands remain a major uncertainty within the field with regards to effective gas-in-place.

Westphalian A. The Westphalian A has been divided into units from Brooking through to A–G on the basis of a coal palynology correlation (Fig. 3). The net-to-gross of the Westphalian A is 38% with net porosities of 11% and net permeabilities of 32 mD from core and log analysis. The best reservoir quality lies within the E2 sands which have a net-to-gross of 43%, average net porosity of 12%. Interpretation of the core from wells 49/4-1, 49/4-2A and 49/4-3 shows the presence of low to moderate sinuosity fluvial channels sands with associated facies of crevasse splay, mouth bars and floodplain shales, silts and coals. The channel sands are upward-fining, vertically stacked and are thought to be laterally extensive based on well data and correlations. Interpretation of dipmeter data shows that most of the fluvial channel sands within the field originated from the north, which is consistent with the regional interpretation of Westphalian channel sands flowing from north to south from the Mid North Sea High (Bailey *et al.* 1993).

Westphalian B. The Westphalian B is separated from the Westphalian A by the *A. Vanderbeckei* marine band, which reflects the drowning of the coastal/delta plain. This marine band has been identified in 49/4-1, 49/4-2A, 49/4a-5 and the recent Gamma block well 49/4a-C2Z. At the base of Westphalian B and predominantly within the Gamma block lie the Murdoch–Caister equivalent channel sands. These sands are vertically stacked and represent low sinuosity, coarse-grained fluvial channels with an average net-to-gross of 55%, average net porosity of 13%. These sands were probably deposited during a relative drop in sea-level and sediment source rejuvenation from the Mid North Sea High where Devonian sediments were exposed (Bailey *et al.* 1993). They represent the best reservoir quality sands within the Chiswick Field and the porosity and permeability of these sands may have been enhanced by sub-BPU leaching of feldspars (Ritchie & Pratsides 1993).

Rotliegend reservoir

The Chiswick Field lies on the edge of the Silver Pit Lake where the Silverpit is represented by lacustrine claystone, siltstone and occasional sands (Fig. 3). Underlying the Silverpit and lying directly over the BPU are the Leman sands and siltstones which grade into aeolian facies towards the south as seen in the Venture-operated Markham Field, where this interval forms the main reservoir. The Silverpit and the Leman of the Rotliegend together have a relatively constant thickness of 220 m over Chiswick. The post-Hercynian topography influenced the distribution of sands, with aeolian sands being thin or absent over the structural highs and preserved downwind of these highs (Bailey *et al.* 1993). The low net-to-gross of 16% within the Leman sands in the Chiswick Field suggests that it was structurally higher than the Markham Field during the Lower Permian.

Over Chiswick the Leman thickness varies between 18 and 44 m with an average net porosity of 11%. The overlying Silverpit has a thickness between 185 and 200 m with a substantially lower net-to-gross of 8%, average net porosity of 11%.

Seismic interpretation

Database

Prior to the acquisition of 3D data, mapping had been based on 1700 km of 2D seismic from 14 different surveys. Interpretation was challenging owing to phase shifts, time shifts and differing migration velocities giving inconsistent imaging and variable data quality. In 1994 LASMO North Sea contracted Geco-Prakla to acquire and process 440 km^2 of 3D seismic data over block 49/4a covering the Chiswick Field and the surrounding area. The result was a high-quality pre-stack time-migrated volume on which key reflectors and faults could be mapped with confidence across the field, which undoubtedly reduced uncertainty in terms of structural and stratigraphic mapping. The data was reprocessed by Centrica in 2005 using a common reflection surface technique which resulted in improved signal-to-noise ratio, subtle enhancement of the intra-Carboniferous reflectors and sharpened fault definition. Improvements in the overburden can also be seen with superior imaging of steeply dipping chalk and intra-Zechstein events.

Interpretation

A number of key seismic horizons were picked in order to generate accurate depth structure maps of the field (Fig. 4):

(1) Top Chalk
(2) Top Red Chalk
(3) Top Zechstein
(4) Base Zechstein
(5) BPU
(6) Intra Carboniferous E Marker

The Top Chalk pick is generally unambiguous owing to a strong seismic event resulting from a large increase in acoustic impedance at the onset of the Cretaceous. Top Red Chalk is also quite consistent with a strong decrease in acoustic impedance going from the Upper Cretaceous Chalk into the clay rich Red Chalk of the Cromer Knoll group. Top Zechstein is another relatively clear seismic event with a positive impedance contrast going from the Bunter claystones into the Zechstein halite. Difficultly arises in areas where the salt is steeply dipping and the image is degraded. Mapping the Top Zechstein reveals pronounced NW–SE trending synclines and anticlines resulting from dramatic salt swells. Within the salt itself, very high amplitude discontinuous events can be seen. These represent high-velocity carbonate rafts which are abundant in the area and distort the image beneath, particularly when lying close to the base of the Zechstein. Top Rotliegend is a strong decrease in impedance going from Zechstein salt into Silverpit claystones and can be mapped with relative confidence in the area. This pick can be ambiguous when Zechstein carbonate rafts appear to touch down on the Top Rotliegend surface, causing interference. A marked difference in structure is noted at Top Rotliegend, where heavy faulting with a strong NW–SE trend is clearly visible. The interpretation of the BPU is quite problematic as the Carboniferous subcrop varies over the area, generating an inconsistent and often weak seismic response. The well data shows that the Rotliegend show little variation in thickness over the area. The thickness of the Rotliegend is quite consistent and shows a gradual change over the study area. Consequently a BPU surface was created using a Rotliegend isochore from the well data and adding this to the Top Rotliegend depth surface. The intra Carboniferous E Marker corresponds to the top of a Westphalian A coal band and was picked as it defines the structure of the Carboniferous below the unconformity. This horizon also defines the base of the main reservoir sands and is therefore important

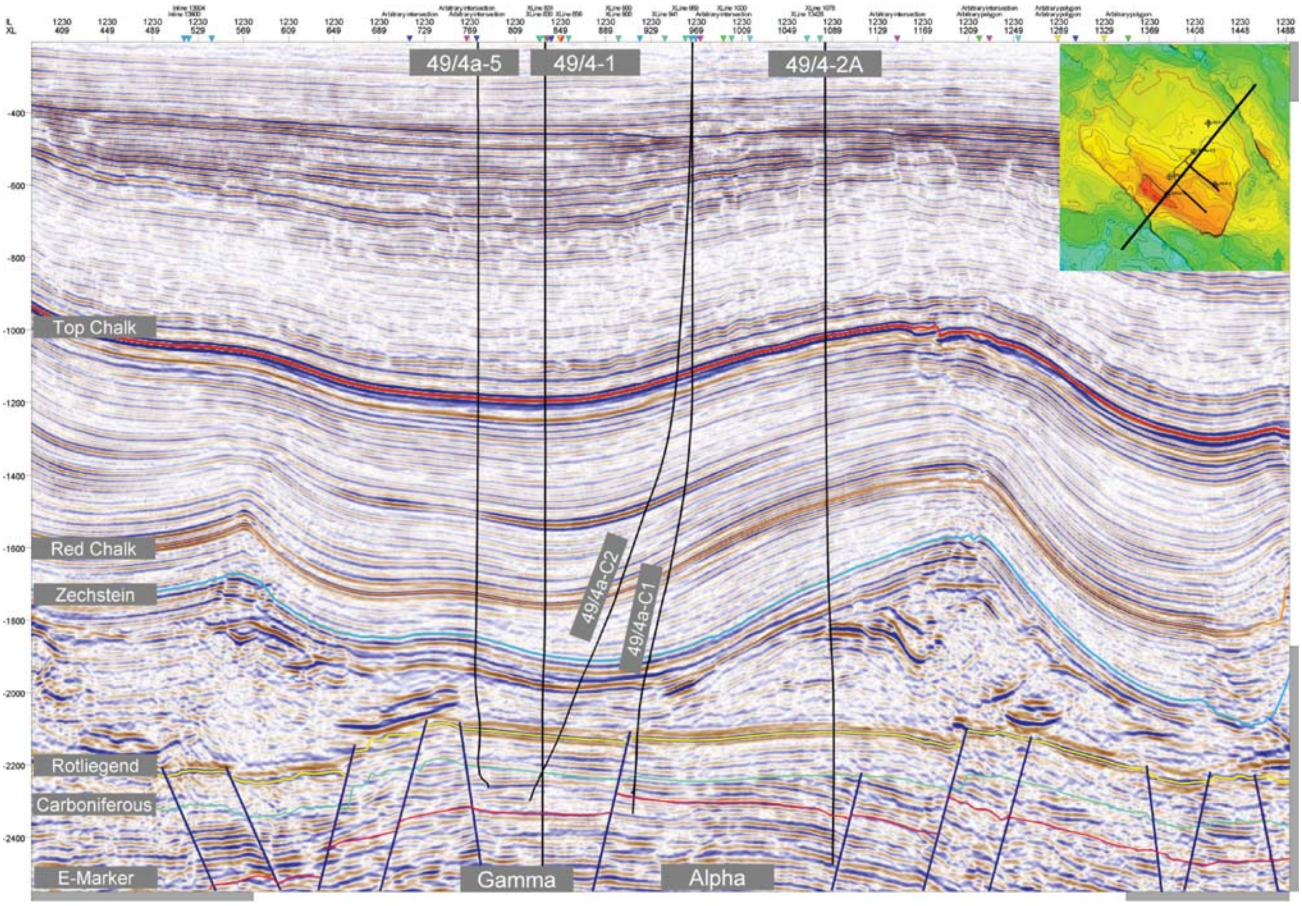

Fig. 4. Seismic section orientated SW–NE through the Chiswick Field.

for building the internal layering of the Carboniferous in the static reservoir model. Individual sands within the Carboniferous are not readily identifiable on seismic; they tend to have a similar acoustic impedance to the shales and thus show little seismic response. Much of the reflectivity within the Carboniferous is thought to be generated by coals. Seismic data gives only a generalized impression of the erosional character and subcrop at the Hercynian unconformity, which is highly dependent on data quality.

Depth conversion

The Chiswick Field shows considerable distortion in the time domain and this is primarily due to the variation in the thickness of the Zechstein salt; therefore accurate mapping and depth conversion are essential in understanding the configuration of the field (Fig. 5). Fortunately this is aided by comprehensive well coverage over the structure and surrounding area. Time grids were converted to depth using a vertical layer cake method with layers defined by the key seismic horizon already discussed. Instantaneous velocity v. depth functions were calculated for each of the layers down to Top Rotliegend using calibrated velocity logs from almost thirty wells. BPU was generated by using the Rotliegend well isochore added to the Top Rotliegend depth grid. E Marker was calculated using a constant velocity of 4250 m s^{-1} below the BPU. Residual depth errors at Top Rotliegend lie within the range of $\pm$10 m.

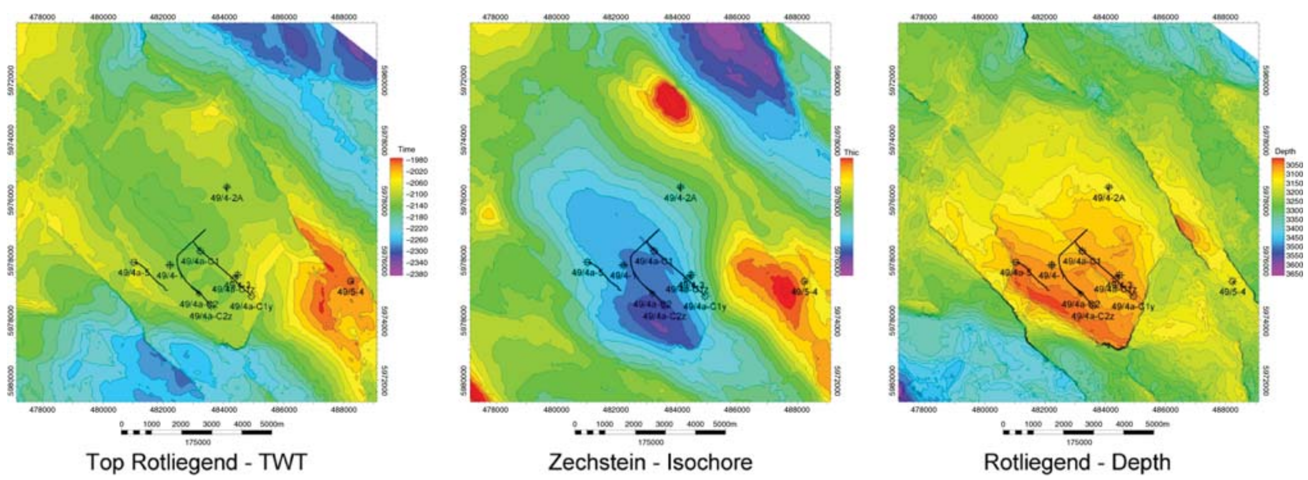

Fig. 5. Comparison of Top Rotliegend two-way time and depth maps with Zechstein isochore.

Phase I field development

Development plan

The Chiswick Field Development Plan and Environmental Statement were submitted to the DTI (Department of Trade and Industry) in April 2006 and approved in July that year. The proposed development plan was to drill two long reach horizontal wells, completed with conventional $5\frac{1}{2}$ inch cemented liners and stimulated with multiple propped hydraulic fractures. The development concept was based on reservoir engineering and hydraulic fracturing studies commissioned by CH4 and was designed to address the key concerns of reservoir connectivity and deliverability. With planned horizontal sections of more than 2000 m and up to five hydraulic fractures per well, the wells were designed to connect as many channel sands to the wellbore as possible and improve initial well productivity.

Hydraulic fracturing is a method of creating artificial fractures extending from the borehole into the reservoir formation, which provide a pathway for gas to flow more easily into the well. The fractures are formed by pumping fluid down the wellbore in order to increase downhole pressure to a level which exceeds the fracture gradient of the reservoir formation. The fluid is then forced into the fracture causing it to propagate further into the formation. A propping material is usually added to the fracture fluid in order to hold the fractures open once the operation has stopped and the fracturing fluid dissipated. Hydraulic fracturing has been an enabling technology in developing tight gas reservoirs around the world and has been used extensively in the North Sea to develop oil bearing Chalk reservoirs; however, Chiswick was the first UKCS gas field to be developed using this technique in horizontal wells.

Both wells were designed with the horizontal sections orientated such that they are in line with the regional maximum principle stress at reservoir level, thus encouraging the development of longitudinal fractures. The optimum fracture design was to place 400 000 lb of 12/18 resin-coated proppant with a borate cross-linked gel system, which according to fracture modelling studies would give a fracture half length of 200 m and a height of 75 m.

The first well was planned to target the reservoirs of the Alpha fault block and was to spud at the end of 2006, with a second well targeting the Gamma fault block in 2007. Both wells were drilled with the Noble Kolskaya jack-up rig and were operated by Wintershall, who had a 5% interest in the block at the time. Development of the field is through a normally unmanned five slot MFP (minimum facilities platform). This is tied back to the Markham J6A platform via a 17 km 10 inch pipeline where fluid processing was carried out before delivery onshore to the NAM-operated Den Helder gas terminal via the K13 extension and WGT (Westgastransport) pipeline.

Drilling results

Alpha well. The Chiswick Alpha well, 49/4a-C1, was spudded in December 2006 and presented a number of considerable technical challenges. Since the depths of individual sands cannot be accurately prognosed by geological or geophysical means, a pilot hole was drilled to allow accurate targeting of the reservoir sands. The pilot hole was then plugged back before kicking off the 49/4a-C1z horizontal reservoir section below the 9 5/8 inch casing shoe. Unfortunately, whilst drilling the horizontal section the hole began to pack off and, whilst attempting to work through the blockage, it was accidentally side-tracked. It was decided that drilling would continue and the new side-track became 49/4a-C1y. TD was reached in April 2007, having drilled 6073 mMD. The well had penetrated Westphalian A sands with a total gross thickness of 2415 m, of which 594 m was net pay with average porosities of 10–11%, and permeabilities in the order of 1–2 mD.

The well was suspended at this stage for just over 2 months until a stimulation vessel could be mobilized. Five separate zones within the C, D and E sands were subsequently fractured into which a total of 2 000 000 lb of proppant was pumped along with 600 000 gallons of fluid. Clean-up was performed over a period of 17 days, after which a maximum flow rate of approaching 50 MMscf per day was achieved. The well was brought on stream in September 2007 (Fig. 6).

Gamma well. The second Chiswick development, 49/4a-C2 well was spudded in June 2007. A pilot hole was not used in this instance owing to the proximity of the 49/4-1 well. Drilling again proved to be a challenge and, whilst attempting to drill through the Carboniferous at 4914 mMD, the well began to collapse. A number of days were spent reaming though coal layers, but eventually the well had to be side-tracked and became 49/4a-C2z. The side-track was kicked off at 4370 mMD in the Carboniferous Brooking B sandstone and was geosteered, using an azimuthal gamma log to stay within the main reservoir sands until TD. However, low rate of penetration (ROP) and multiple bottom hole assembly (BHA) failures slowed progress and, with the stimulation vessel timing in mind, TD was called in November 2007 having drilled 5485 mMD out of a planned 6000 mMD. The well had successfully penetrated a gross reservoir thickness of 1218 m, of which 353 m was net pay.

Hydraulic fractures were placed in four zones, one within the Caister Murdoch sands and three within the Brooking sandstones. In total, almost 1 000 000 lb of proppant was pumped along with around 420 000 gallons of fluid. Additionally, thin sands within the secondary Permian Silverpit and Leman reservoirs were perforated. Having spent 24 days cleaning up the well, a maximum flow rate of more than 62 MMscf per day was achieved with facilities constraints. The well then commenced production in March 2008 (Fig. 7).

Discussion

Despite considerable subsurface uncertainties, Phase I drilling on the Chiswick Field has resulted in two successful gas producers. Careful stratigraphic correlation based on palynological studies combined with detailed mapping has reduced the uncertainty in terms of reservoir distribution. This has greatly improved the understanding of the field and enabled better prediction of the Carboniferous subcrop across the Alpha and Gamma fault blocks, giving the ability to target specific reservoir units with improved accuracy. The two horizontal development wells were successfully geosteered using an azimuthal gamma ray (GR) tool to target specific reservoir units. These wells were hydraulically fractured to reduce some of the uncertainties surrounding sand-to-sand and sand-to-wellbore connectivity, the result of which has been excellent flow rates in both wells.

However, drilling the Phase I development wells on Chiswick has also highlighted a number of issues, particularly concerning optimum well design and fracture placement. Recent simulation work based on Phase I well results has attempted to understand well performance and the effectiveness of the hydraulic fractures, and in particular which zones are contributing to flow. The study shows that the two producing wells in the Alpha and Gamma blocks behave quite differently. The Alpha well exhibits a lower productivity than the Gamma well; however, the Alpha well is thought to be connected to a much larger reservoir volume which appears to drain most of the Chiswick Field. Conversely the Gamma well appears to drain a single highly permeable unit within the Gamma block.

Therefore the second phase of development will use sub-horizontal wells to improve vertical drainage of the field with a

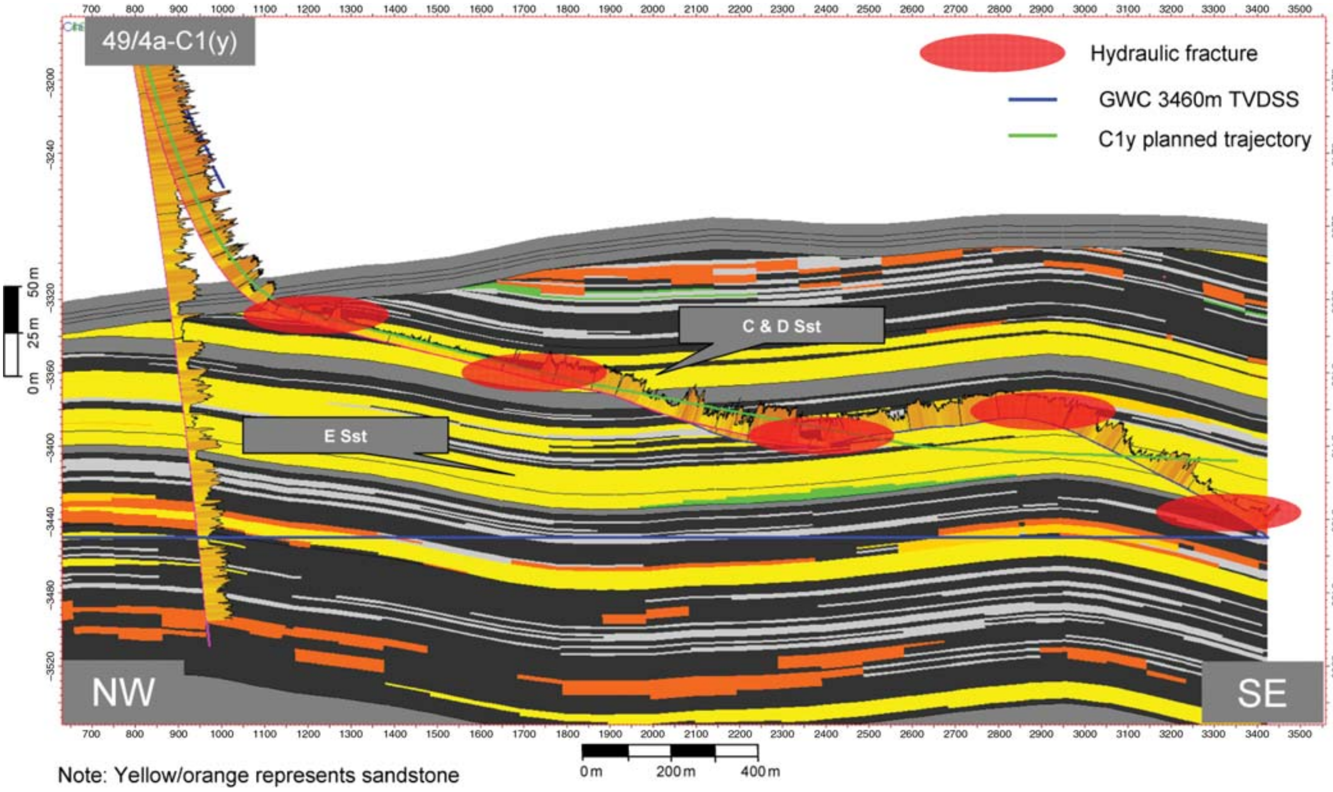

Fig. 6. Geological well section for 49/4a-C1 (Alpha) through pre-drill model showing hydraulic fracture locations.

single hydraulic fracture targeting each individual sand rather than multiple fractures within one sand unit. This approach is considered to be optimal, particularly in the case of the untested Beta block where uncertainty over Carboniferous subcrop and sand distribution remains the greatest.

Phase II field development

Venture plan to drill at least two additional wells on the Chiswick Field in the near future in order to add additional reserves and accelerate production. A new Chiswick geocellular model was created

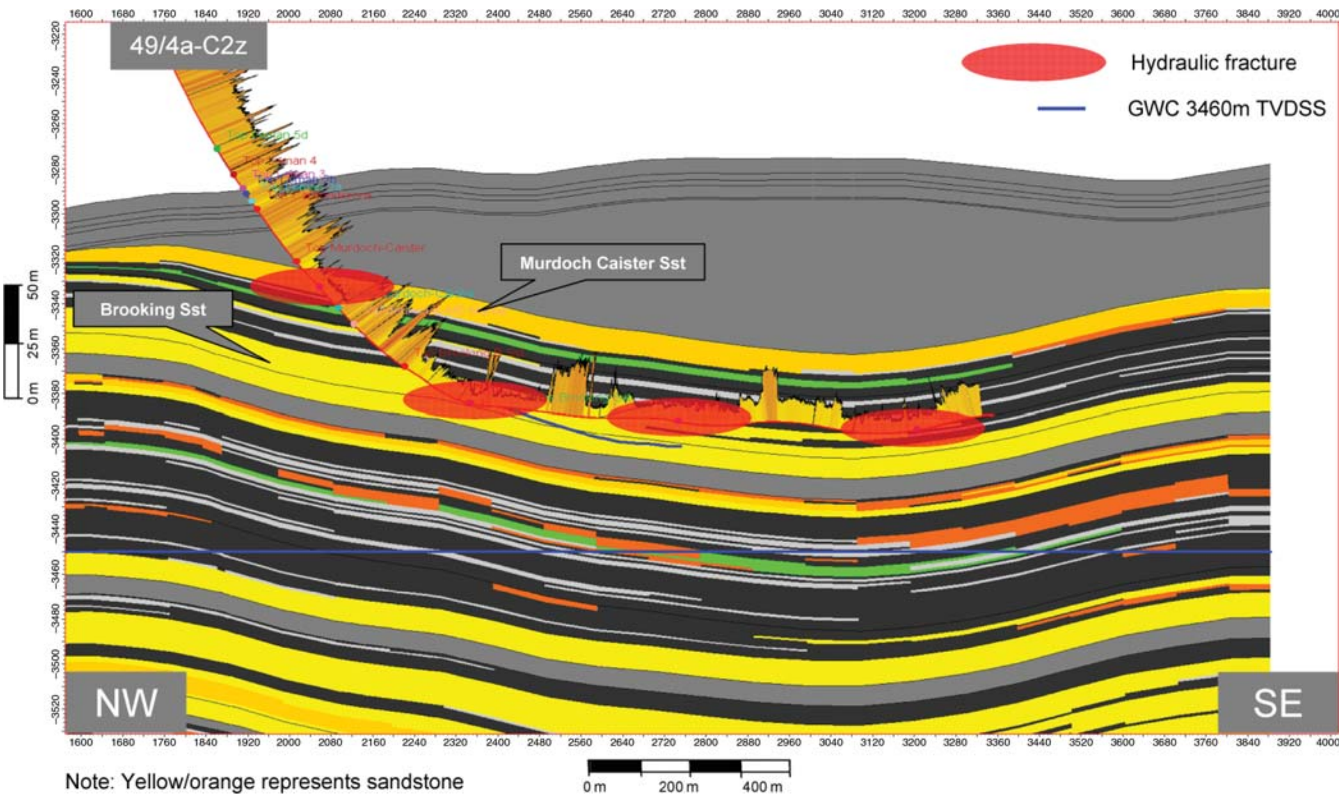

Fig. 7. Geological well section for 49/4a-C2 (Gamma) through pre-drill model showing hydraulic fracture locations.

based on the interpretation of the reprocessed seismic data and updated petrophysical analysis from Phase I drilling results.

This model was then simulated in an attempt to understand the performance of the two producing wells and to determine optimum areas for Phase II wells to be placed. Phase II development wells will incorporate the lessons learnt from Phase I in terms of well trajectory design, drilling practices and hydraulic fracturing strategy.

Conclusion

The Chiswick Field was brought on stream in September 2007 – 23 years after the discovery well was drilled with two wells producing at rates in excess of initial expectations. Subsurface uncertainties have been addressed with a comprehensive technical work programme and also through the use of appropriate technology in the form of hydraulically fractured long reach horizontal wells, a first for a North Sea gas development. Phase II of the Chiswick development is currently scheduled to commence late in 2009, when the first of at least two additional wells will be drilled.

Thanks are extended to M. Tringham for his significant contribution to the project and also to B. Stevens for his comprehensive reservoir engineering study. CH4 and Senergy (RML) are thanked for their work in progressing the project to development drilling phase, as are Wintershall's operations team for drilling the Alpha and Gamma wells. I. Bartholomew and K. Purvis are thanked for their helpful input as reviewers.

The Ensign enigma: improving well deliverability in a tight gas reservoir

K. PURVIS, K. E. OVERSHOTT, J. C. MADGETT and T. NIVEN

Venture Production plc, Kings Close, 62 Huntly Street, Aberdeen AB10 1RS, UK (e-mail: katie.overshott@centrica.com)

Abstract: The Ensign Gas Field is located in the Sole Pit basin in the Southern North Sea. The reservoir is the Rotliegend Group Leman Sandstone Formation of Lower Permian age and comprises sediments deposited in an arid continental environment. The main gas-bearing interval in the field consists of sabkha, waterlain and minor aeolian sands, reflecting deposition in an erg margin/lake margin setting. The poor primary reservoir quality of these sands has been severely reduced by extensive illite cementation resulting in average air permeabilities of <1 mD. Attempts to develop the field economically utilizing fracture-stimulated vertical wells has met with mixed results, with flow rates of 14 MMscf per day and lower being measured during testing. The most recent appraisal well drilled on the field was a long horizontal well that was stimulated with five hydraulic fractures resulting in an economic flow rate of 44 MMscf per day. Analysis of the core and log data acquired during the appraisal of the field has shown that the reservoir contains a heterogeneous distribution of fractures, faults and micro-faults. The fracture population is dominated by conductive north–south striking fractures, with subordinate NNW–SSE resistive fractures and NE–SW mixed fractures that are arranged in clusters, with zones of high and low fracture density. Well results to date suggest that the NE–SW open and partially open fractures observed in core do not improve reservoir productivity, but those orientated north–south that are conductive appear to improve well deliverability.

Keywords: Rotliegend, Leman Sandstone, illite cementation, fracture stimulation

The Ensign Field is located 90 km NE of the Norfolk coast in the Sole Pit area of the Southern North Sea (Fig. 1). The field is located 10 km east of the Shell-operated Barque Field and 15 km west of the Venture-operated Audrey Field. Ensign is an elongated NW–SE trending field 2 km wide and 8 km in length (Fig. 2). The water depth over the field is 90 ft, and the top reservoir is *c*. 8450 ft TVDSS at its crest.

The reservoir is the Leman Sandstone of the Lower Permian Rotliegend Group, and is *c*. 800 ft thick, but only partially gas-filled, owing to the depth of the spill point. The gas is very dry, containing 96% methane and small amounts of CO_2 (0.5%) and N_2 (1%). The gas in place volume for the Ensign field is *c*. 350 BCF.

The Ensign Field name was assigned while under the ownership of Shell and Esso, and reflects the practice of naming gas fields in the SNS after vessels and nautical terms from maritime history. The ensign is the flag or colour of a ship and came into use on the ships of Queen Elizabeth I in the 1570s, and imitated regimental flags, which at that time were called ensigns.

Field history

The Ensign Field is located in Blocks 48/14a and 48/15a that are covered by the P008 and P130 Licences respectively. The P008 licence was awarded to Shell and Esso in 1964 as part of the first licensing round, while P130 was a fourth round award to Conoco in 1972. Venture acquired 100% equity in the Ensign Field as a consequence of two separate transactions involving Shell UK Limited, Esso Exploration and Centrica Resources Limited in 2005.

The Ensign Field wells are listed in Table 1 along with information on well operator and well type. The field was discovered in 1986 by the Shell-operated 48/14-2 vertical well that encountered a 542 ft gas column in the poor quality Lower Permian Rotliegend sandstone reservoir (Fig. 2). Although the reservoir failed to flow during initial testing, after stimulation by hydraulic fracturing the well flowed at a sustained rate of *c*. 14 MMscf per day. This rate was not economic at the prevailing gas prices and consequently the field was not developed. In 1988 Conoco drilled a well 48/15a-6 in the eastern portion of the field, but the reservoir was encountered deep to prognosis predominantly in the water leg and was consequently not tested. The next appraisal well to be drilled was the Venture-operated well 48/14-5 that spudded in September 2006. This well was planned to appraise the reservoir and consequently had a full logging suite including borehole image logs and was cored. After fracture stimulation the well tested at rates of up to 20 MMscf per day, but this declined to 12 MMscf per day and the well was suspended as a potential future production well. The last well drilled in the field was spudded in September 2007 and was as a horizontal production well. The well encountered over 4500 ft of net sand, was stimulated by five hydraulic fractures and flowed at a facilities-constrained rate of 44 MMscf per day. The well has been suspended as a future production well.

Structure and tectonic setting

The Ensign Field is situated in the Southern Permian Basin in the NW–SE trending Sole Pit Basin (Fig. 1). The area has been subjected to a number of tectonic events, with the Hercynian orogeny in the Late Carboniferous resulting in the pervasive NW–SE structural grain (Glennie & Underhill 1998). The main phase of development of the Sole Pit Basin occurred in the Permian, when thermal subsidence occurred. During this period the Lower Permian Rotliegend continental sediments were deposited that form the reservoir of the Ensign Field. Basin subsidence continued from the Triassic to Late Cretaceous times by which time the reservoir of the Ensign Field would have been buried to a depth of $>13\,000$ ft TVDSS. The next stage of the structural history was successive periods of uplift during the early Cenozoic with a major phase of inversion in the Miocene related to the Alpine orogeny. The inversion in the Sole Pit during this period removed approximately 5000 ft of post-Liassic sediments and has resulted in the Ensign reservoir being at its current depth of *c*. 8500 ft TVDSS.

48/14a-6	2007	Venture	ADH	Multiple fracture	No

*Well type: E, exploration; A, appraisal; D, development; V, vertical; H, horizontal.

Stratigraphy

The stratigraphic sequence encountered in the Ensign Field is shown in Fig. 3. The oldest rocks penetrated by any of the Ensign Field wells are sands, silts and shales of Carboniferous age.

The Lower Permian Leman Sandstone rests unconformably on the Carboniferous and consists of a variety of facies associations, which have been interpreted as the products of deposition in fluvial (wadi), aeolian, sabkha and lacustrine environments (Glennie 1972). The Leman sandstones are overlain by a *c*. 550 ft thick Zechstein sequence comprising cyclic evaporites and carbonates that acts as the seal for the Ensign Field. The Zechstein deposits reflect the marine transgression into the Southern Permian Basin (Glennie & Buller 1983). Overlying the Zechstein are the three units of the Triassic Bacton Group: the Brockelschiefer, Bunter Shale and Bunter Sandstone that represent a return to continental sedimentation. In total the Bacton Group is *c*. 2000 ft thick over the Ensign Field. Subsequent deposition of the Middle and Upper Triassic Haisborough Group marks a return to marginal and fully marine environments with the occurrence of *c*. 2800 ft of evaporites and mudstones. Overlying the Triassic is a *c*. 2500 ft section of Lower Jurassic Lias shales with a thin veneer of Quaternary–Recent deposits beneath the sea bed. The absent Jurassic–Cenozoic section was removed during the Cenozoic inversion of the Sole Pit area.

Reservoir sedimentology

The Leman Sandstone reservoir of the Ensign Field was deposited in a continental desert environment (Glennie *et al.* 1978) and has

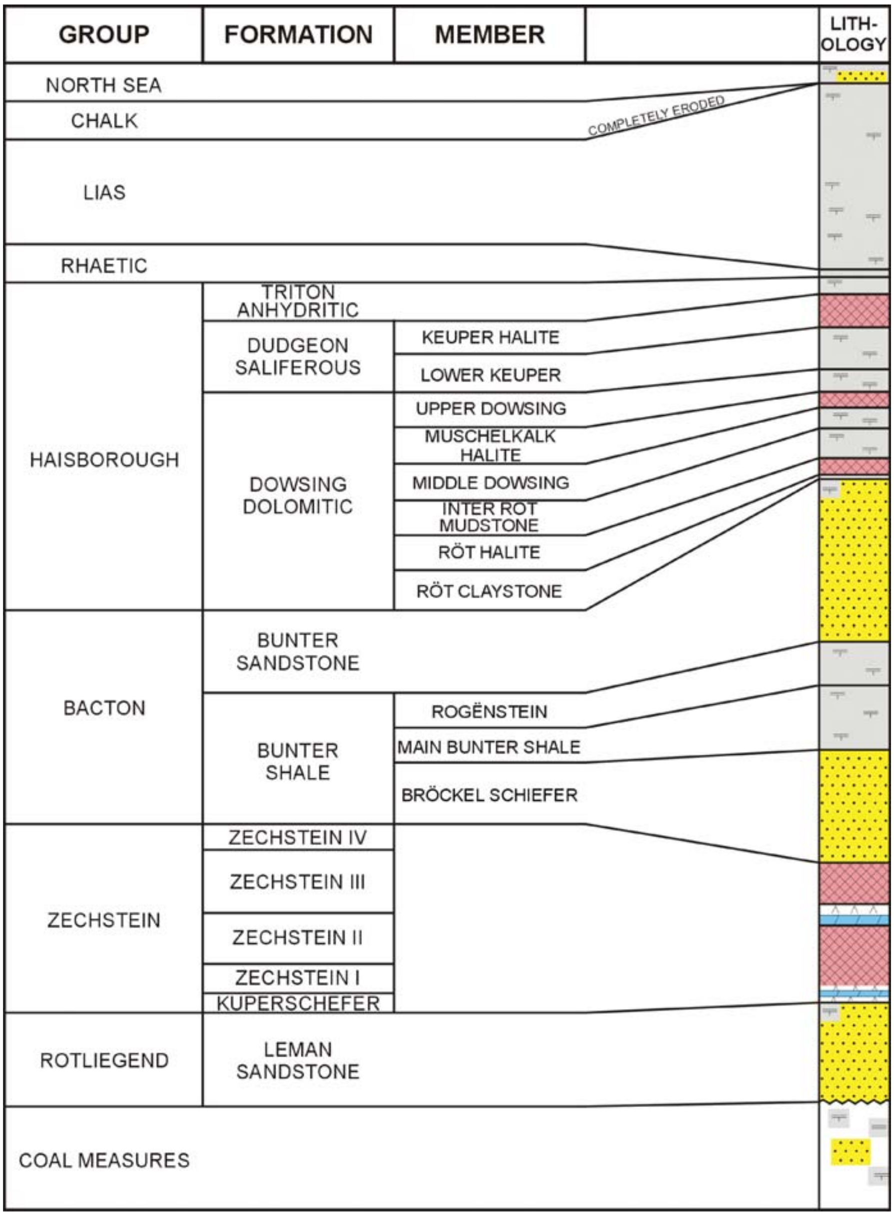

Fig. 3. Ensign Field stratigraphic sequence.

been divided by Venture into six reservoir zones (A–F) that can be correlated across the field.

The Upper A unit has been further subdivided into the A000 unit that corresponds to the Weissliegend at the very top of the Rotliegend. This unit comprises massive sands that were reworked as a result of the Zechstein marine transgression (Glennie & Buller 1983). In the Ensign Field this unit is extensively cemented and of very poor reservoir quality. The A100 lies below the Weissliegend and is dominated by sabkha, sandsheet and waterlain sandstones that were deposited in an erg margin–lake margin environment.

The B unit sandstones are of slightly better reservoir quality, reflecting the presence of more fluvial deposits, less sabkha sands and occasional aeolian units. The B unit sandstones represent the deposits of a less humid environment with less lacustrine influence.

The C unit underlies the B unit and is composed of 10–20 ft thick muddy sabkha sandstones and siltstones, and playa lake claystones. This unit is correlatable across the Ensign Field and over several kilometres in the Barque Field (Sarginson 2003). The C unit represents an expansion of the Silverpit lake, with the muddy sabkha deposits reflecting a more humid climate. The C unit is an important unit in the Ensign Field as it occurs just above the GWC in the central part of the field and acts as a natural barrier to the propagation of any hydraulic fractures owing to its high clay content.

The D and E units are characterized by large-scale cross-bedded aeolian sandstone units thought to have been deposited in a drier erg interior setting. These units have the best reservoir properties, with average porosities of 15–20%, although in the Ensign Field these units are predominantly located in the water leg.

The lowermost F unit comprises sandsheet, sabkha and waterlain sandstones deposited in an erg margin setting. This unit is entirely in the water leg.

Although the reservoir quality of the Leman Sandstone units can be related to their primary environment of deposition, with the aeolian units having higher porosities than the sabkha sands, extensive illite cementation has greatly reduced the permeability of the sandstones. In the A and B units, the main gas-bearing intervals in the Ensign Field, the average net pay core porosity is 9.8% and the average permeability is 0.15 mD.

Reservoir structure

The Ensign Field is situated at the crest of a NW–SE trending dip-closed anticline that is fault-bound to the SW (Fig. 2). The anticline was formed by transpressive tectonic stresses during the Cenozoic, which resulted in the widespread inversion of the basin (Glennie & Underhill 1998). The field is cross-cut by NNE–SSW trending lineaments that may be faults, but have not been cored and show no offsets on seismic data. These lineaments have been recognized in the nearby Barque Field (Sarginson 2003) and by analogy it is likely that cataclasis and mineralization may have resulted in these becoming permeability barriers, potentially compartmentalizing the reservoir.

Seismic interpretation

The original seismic volume used for the seismic interpretation of the Ensign Field area was the Galleon 3D that had been acquired by Shell in 1992. Analysis of the data revealed that the quality of this 3D data was not suitable for the planned appraisal and development of the field. It was therefore decided to undertake a PreSDM reprocessing exercise over the field and surrounding area utilizing the input from five different seismic volumes. The resulting 3D

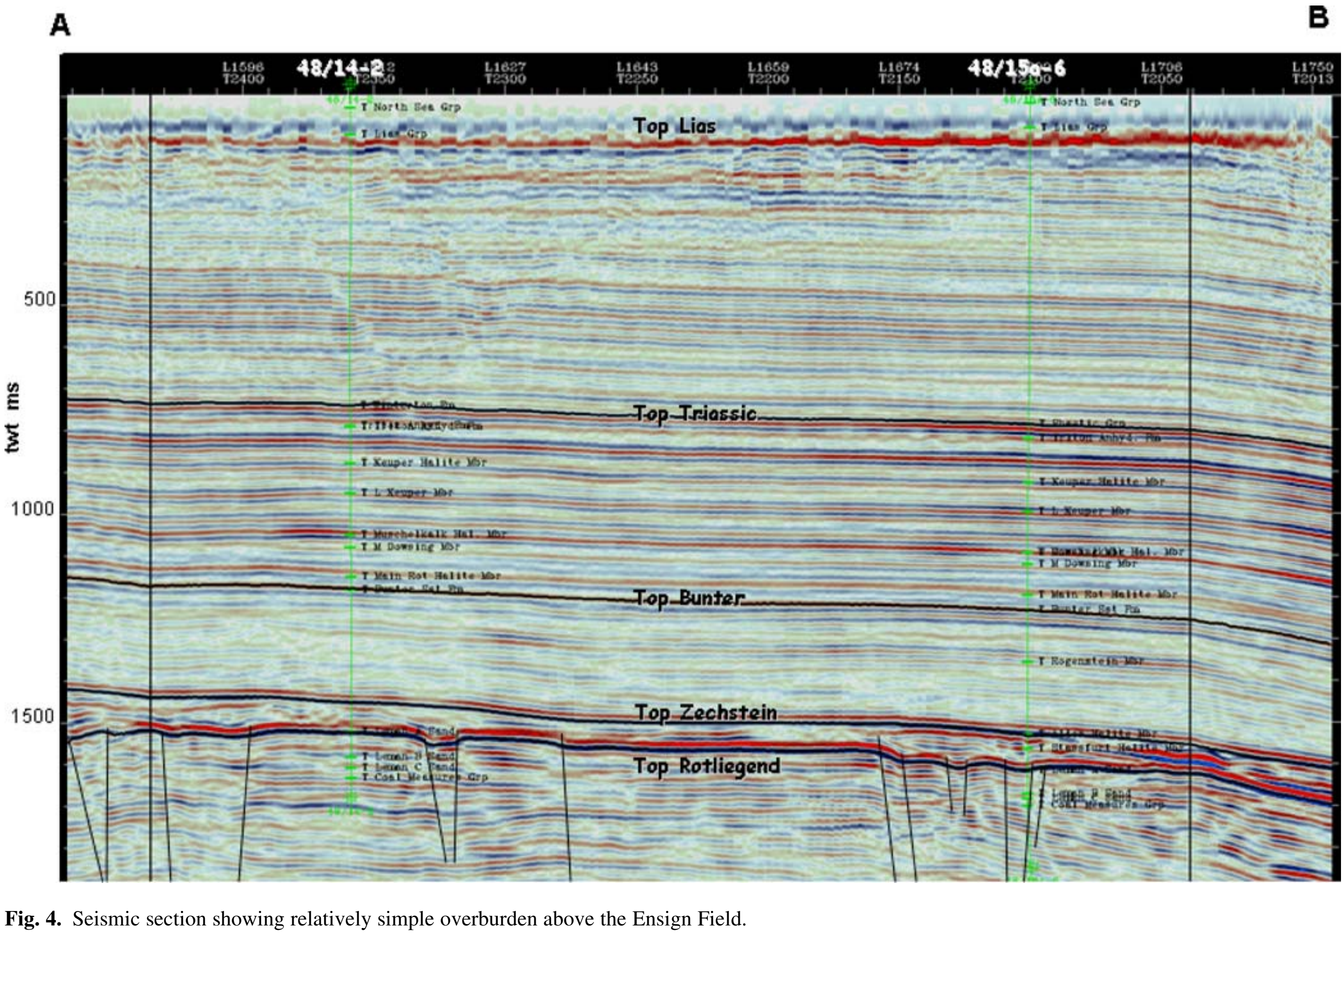

Fig. 4. Seismic section showing relatively simple overburden above the Ensign Field.

volume allowed a more detailed and coherent structural interpretation to be undertaken.

The overburden interval over the Ensign Field is relatively simple (Fig. 4). The Sole Pit inversion has removed the Cenozoic and Chalk units, resulting in the Lias being the first pre-Quaternary interval encountered below the sea bed. The Triassic section is very continuous and devoid of any large faults that occur in other parts of the Ensign–Audrey Field area to the NE. The Zechstein section is significantly thinner than the regional average which has been caused by halite withdrawal that fed the Audrey salt wall to the east. Consequently, the Zechstein over Ensign is dominated by a dolomite and anhydrite rich sequence that creates a higher than normal interval velocity.

Utilizing the initial discovery and appraisal wells to constrain the depth conversion, and the benign nature of the overburden, the subsequent appraisal wells have encountered the reservoir on prognosis.

Field appraisal Phase I

After acquiring the Ensign Field, Venture began an extensive data gathering and interpretation exercise in order to determine the best method of appraising and developing the field as quickly as possible. As mentioned above, part of this exercise involved the re-processing of the 3D seismic over the field that was part of a larger project that covered most of the acreage in the Venture-operated Audrey Field area. It was realized that the seismic reprocessing would take a significant amount of time and that this should not hold up the appraisal of the field. Consequently the results of the previous wells were reviewed in order to arrive at a better understanding of the controls on reservoir quality and deliverability. Key to unlocking the Ensign Field were the results of the Shell-operated discovery well 48/14-2 drilled 20 years previously. Although the well failed to flow when first tested, it flowed at a sustained rate of *c*. 14 MMscf per day after stimulation by a single hydraulic fracture. It was deemed that, with the prevailing gas price (2006), this type of well would form the basis of an economic development. In comparison it was felt that the Conoco well 48/15a-6 had less impact on the field appraisal as this well appeared to have been drilled into a complex fractured zone, was extensively fracture-cemented, and occurred in a portion of the field with a thinner gas column that would not form a part of the Ensign Field core development area.

48/14-2 well evaluation

The Ensign Discovery well encountered a 542 ft gas column predominantly in the upper A and B units of the Rotliegend sequence (Fig. 5). Unlike the neighbouring Shell-operated Barque gas field (Sarginson 2003), the lower units, which typically comprise

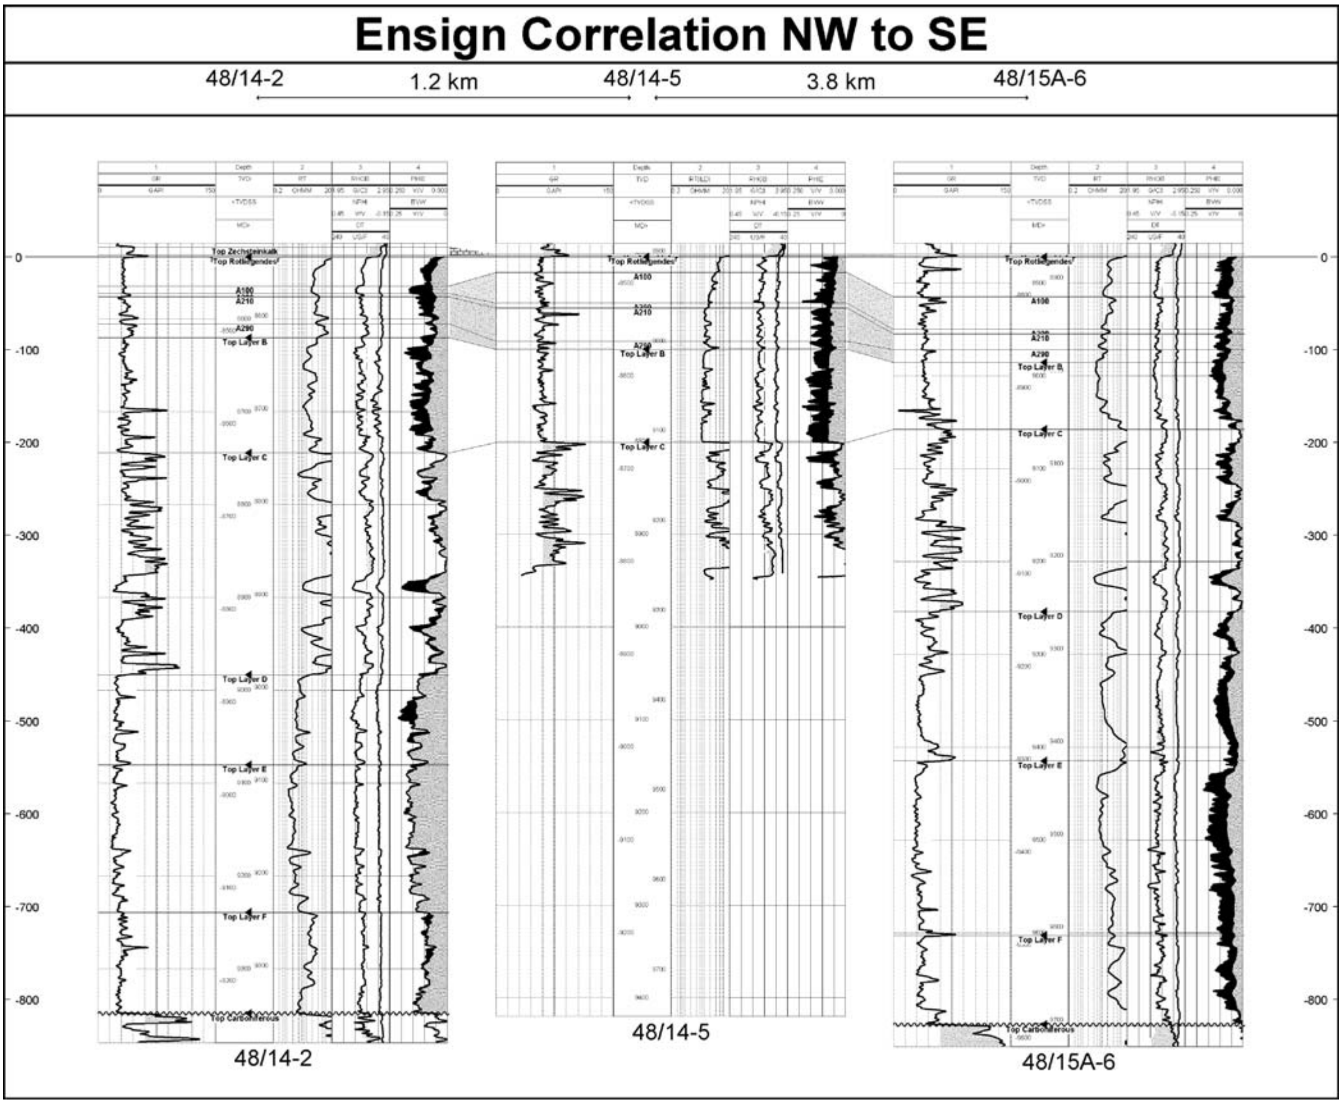

Fig. 5. Correlation panel of the Leman Sandstone in the discovery and appraisal wells of the Ensign Field.

better quality aeolian units, were below the GWC. The entire Rotliegend interval was cored (*c*. 800 ft), which provided a detailed facies and reservoir database.

Examination of the core acquired shows that the A–C units are dominated by sands interpreted as having been deposited in a damp sand flat (44%) and fluvial environment (23%) with very limited aeolian sands (5% dune facies and 2% dry sand flat). The core-derived porosity and permeability data (Fig. 6) show that these upper units of the reservoir are of very poor quality (<1 mD permeability) and scanning electron microscope (SEM) analysis confirms that this was primarily as a consequence of pore-lining illite that reduced the permeability (Fig. 7a). Although the aeolian units have slightly better reservoir quality, the average permeability of dune facies is 0.27 mD compared with the average damp sand flat permeability of 0.13 mD; it should be noted that the highest overall permeabilities were measured in the damp sand flat facies (0.82 mD). The low permeabilities measured in the aeolian sands, despite their larger grain size, better sorting and low detrital clay component, confirms the detrimental impact of the development of the authigenic fibrous illite on reservoir permeability.

Detailed examination of the core also showed that it was almost devoid of any fractures over its entire 800 ft. Analysis of the core photographs, core descriptions and the core itself revealed only four fractures in the *c*. 350 ft upper gas-bearing interval above the C unit. The fractures were either filled with anhydrite cement (2) or were small cataclastic shear fractures (2). Only one rubble zone was encountered at the base of one cored interval that appears not to be fracture-related. Core recovery of the A–C units was very good, with 100% recovery in five of the six cores and the one core with 97% recovery. The lack of any open or partially open fractures suggested that the productivity of the discovery well after fracture stimulation had not been enhanced by a naturally occurring fracture network.

The hydraulic fracture stimulation parameters for this well have been reviewed and interpreted in order to determine the size and

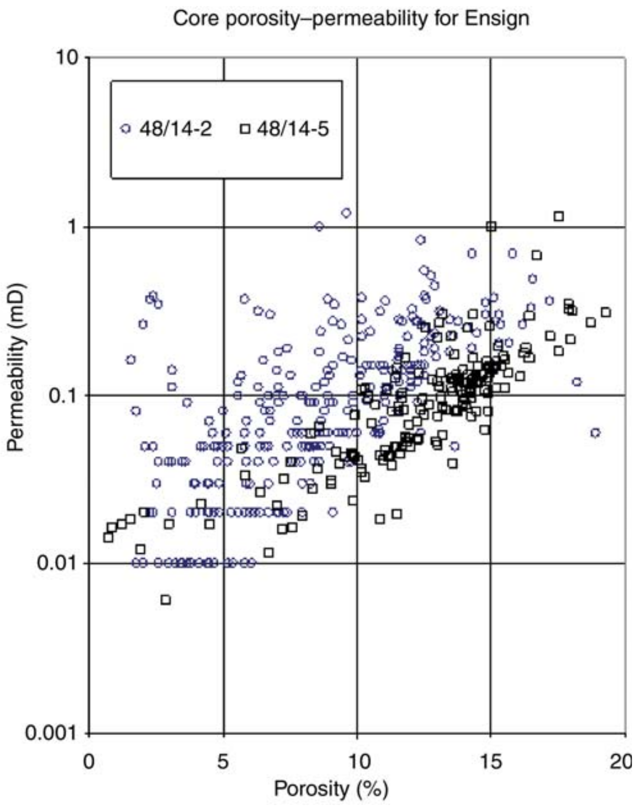

Fig. 6. Porosity–permeability cross plot of core recovered from the A–C units in wells 48/14-2 and 48/14-5.

effectiveness of the fracture induced. Table 2 shows the type and amount of proppant and fluids utilized. The initial fracture modelling results, whilst not unique, point to a fracture with a height of 160 ft, half length of 600 ft (i.e. the fracture extends 600 ft on either side of the well bore) and a width of *c*. 0.25 in. Utilizing these parameters and the resultant flow rates on test supports a productivity index (PI) of 11.5 Mscf day^{-1} psi^{-1} and a permeability height (Kh) of 51.2 mDft. It should be noted that the Kh of the perforated interval was significantly lower than this (*c*. 20 mDft), and consequently it would appear that the hydraulic fracture encountered a better quality reservoir away from the well bore.

Although it had previously been thought that the hydraulic fracture had connected into a naturally occurring open fracture network system, evaluation of the data acquired during and after the fracture stimulation did not support this view. Analysis of the well test data supported the view that there was only weak support for a fracture network connected to the well. The relatively low flow rates of *c*. 14 MMscf per day are in line with the overall poor quality reservoir.

Collation of all the available data (core, log, fracture stimulation, test results) supported the view that the Ensign Field could be developed utilizing fracture-stimulated sub-vertical wells. In order to test this theory and move the field towards development, an appraisal well (48/14a-5) was drilled into the fault block adjacent to the discovery well (Fig. 2). This well was designed with an extensive data acquisition program, including image log and core, as well as a fracture stimulation programme that was designed to create a larger, more effective fracture than that created in the discovery well 20 years previously.

The appraisal well was drilled in 2006 and targeted the upper reservoir intervals (units A and B) in order to minimize the risk of the planned hydraulic fracture extending into the water leg below the C unit. The well encountered the reservoir on prognosis and was successfully fracture-stimulated. In comparison to the 48/14-2 well, 730 000 lb of proppant were emplaced, 40% more than in the discovery well (Table 2). Despite the larger fracture developed, the well failed to flow at the sustained rates of the discovery well. The initial gas rates of 20 MMscf per day declined to below 12 MMscf per day, and failed to stabilize; that is, the gas rate was still falling when the well test was concluded. The poor well deliverability was unexpected and resulted in a detailed examination of the data acquired in the 48/14-5 well in order to understand the reason for the underperformance.

48/14a-5 well evaluation

Analysis of the core showed that the interval comprised similar facies to the 48/14-2 well, but with a higher proportion of waterlain sands. Aeolian dry sand flat deposits were more common than in the discovery well (14 v. 2%) but dune sands were less prevalent (1 v. 2%). However, the reservoir quality was very poor with low permeabilities (Fig. 6). Initially there were concerns that the permeabilities were lower than the discovery well, but this proved to be an analytical artefact as a consequence of the 48/14a-5 samples having been analysed at 800 psi confining pressure compared with the discovery well samples that were analysed at 230 psi confining pressure. It is believed that the lower measured permeabilities at the higher confining pressures are a consequence of the reduction in gas slippage and bypass during the permeability measurement. To confirm this to be the case, samples from the discovery well were re-analysed at 800 psi confining pressure, resulting in permeabilities similar to the 48/14a-5 well. SEM analysis confirmed that the cause of the very low permeabilities was extensive illite cementation (Fig. 7b) that was blocking the pore throats. Although no age dating was undertaken on the illites from this well, K–Ar dating of the illite fraction from the 48/14-2 and 48/15a-6

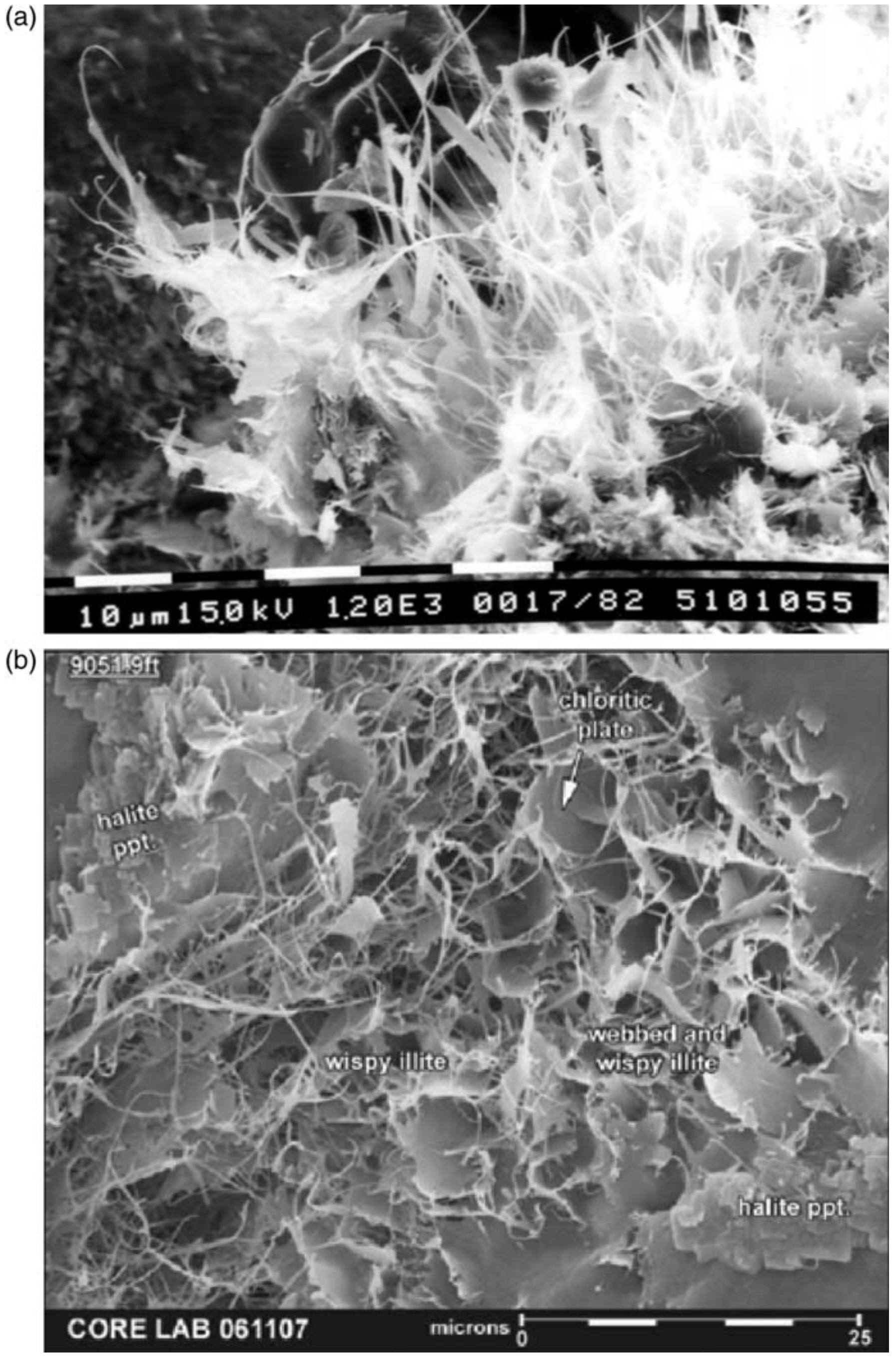

Fig. 7. (**a**) Scanning electron photomicrograph of fibrous illite from reservoir sample in well 48/14-2. (**b**) Scanning electron photomicrograph plate of fibrous illite from reservoir sample in well 48/14a-5.

Table 2. Hydraulic fracture proppant size and volumes utilized in the Ensign Field

Well	Proppant size*	Proppant type	Proppant volume
48/14-2	20/40	Ottawa Sand and Interprop	520 000 lb
48/14a-5	12/18	Resin-coated proppant	730 000 lb
48/14a-6 Fracture 1	12/18	Resin-coated proppant	380 000 lb
48/14a-6 Fracture 2			515 000 lb
48/14a-6 Fracture 3			500 000 lb
48/14a-6 Fracture 4			520 000 lb
48/14a-6 Fracture 5			500 000 lb

*Proppant size is measured in standard US sieve size.

wells produced a Late Jurassic age range of 147–167 Ma. This age of illite growth is comparable to other illite age dates in the Sole Pit Basin (Robinson *et al.* 1993).

In comparison to the core from well 48/14-2 that was almost devoid of fractures, the 48/14a-5 core contained a number of open and partially open fractures (Fig. 8), as well as a major drilling-induced axial tension fracture that ran for several metres along the core. The open and partially open fractures were observed in the core as high-angle features with minor amounts of vertical displacement, typically 4–5 mm, that were partially cemented by dolomite and anhydrite. Fracture widths were 0.5–6 mm, but predominantly 2–4 mm. No cataclastic shear zones were observed in the *c.* 193 ft of core recovered. In total, excluding drilling-induced fractures, 22 open, partially open and cemented fractures were observed in the *c.* 193 ft of core, that is, a fracture density of 8.7 ft per fracture, compared with the 48/14-2 fracture density of 87 ft per fracture. It was hoped that the open and partially open fractures could contribute to flow after fracture stimulation, but the well test results suggest that these fractures had no impact on well deliverability.

The acquisition of Schlumberger Full-bore Micro-Imager log data (FMI) over the reservoir interval allowed calibration of the fractures observed in core and the identification of additional fractures in the uncored intervals. It should be noted that, while fractures observed in the core can be described as open, partially open or closed and these fractures can be correlated directly with the FMI log, in the uncored intervals the fracture types can only be inferred from the FMI log data. It is assumed that as the FMI log produces resistivity images of the borehole, fractures that are electrically conductive are open, whilst those that are electrically resistive are closed or cemented (Serra 1989). The images showed the well to be extensively naturally fractured, with 83 fractures identified over an interval of 391 ft. The dominant orientation of the open and partially open fractures was NE–SW with dips of *c.* 65° towards the NW (Fig. 9), while the drilling-induced axial tension fractures were orientated NW–SE, reflecting the current stress environment in the SNS (World Stress Map 2008). It should be noted that any hydraulic fracture stimulation in the 48/14a-5 well would be perpendicular to the direction of minimum stress and hence be aligned parallel to the drilling-induced fractures. Consequently it is assumed that the hydraulic fracture in the 48/14a-5 well will have cross-cut the open and partially open fractures observed in the core and FMI. The poor performance of this well suggested that there was not a significant amount of flow from the naturally occurring fractures and that this orientation of fractures may not have any impact on reservoir deliverability. Owing to the poor and declining flow rates, no production logging was undertaken on this well, so it is not possible to determine where exactly in the perforated and hydraulically fractured interval any flow was coming from.

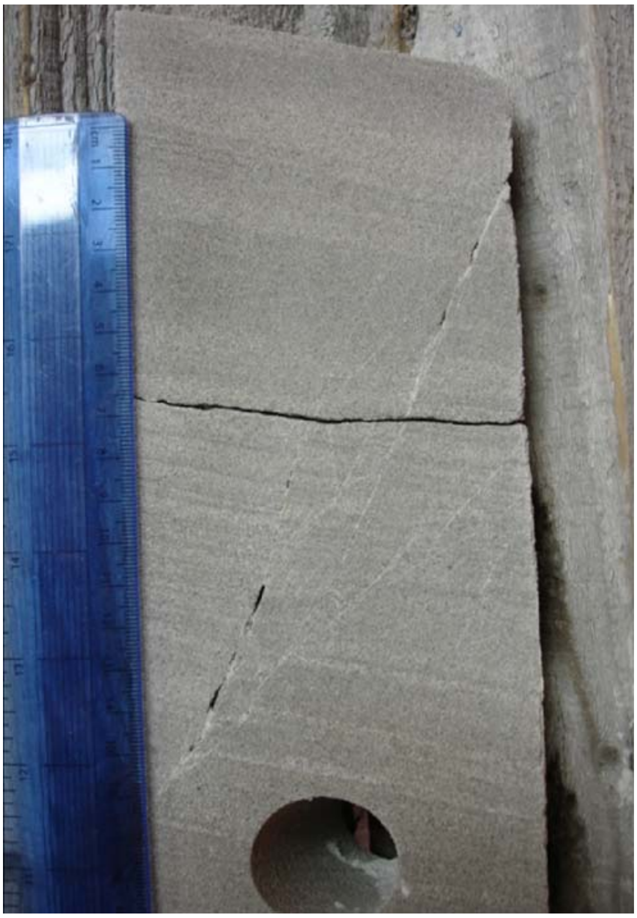

Fig. 8. Photograph of core taken from 48/14a-5 showing an open and partially open fracture network.

Appraisal Phase II

The results of the first appraisal well drilled by Venture suggested that the preferred option of developing the field utilizing fracture-stimulated near vertical wells would not be economic given the flow rates measured. Consequently the next appraisal well was planned as a long horizontal well that would be fracture stimulated with five hydraulic fractures. The successful development of the Venture-operated Chiswick Field utilizing multiple fractured horizontal wells proved this to be a viable approach to improving recovery in low productivity reservoirs (Nesbit & Overshott 2010).

The second Venture appraisal well (48/14a-6) targeted the NE portion of the field and had a trajectory such that it passed within 330 ft of the successfully fracture-stimulated discovery well (Fig. 2). The long horizontal length of the well (*c.* 5900 ft) was designed to allow the gas in several fault blocks to be accessed, as well as increasing the chance of encountering areas of better reservoir quality with the planned hydraulic fractures.

The well was successfully drilled in 2007 to a total measured depth of 15 275 ft, and encountered over 4800 ft of net sand (Fig. 10). The well was fracture stimulated over five intervals after the production liner was run. Each fracture was designed to emplace 500 000 lb of 12/18 proppant, that is, five times the volume of the original fracture stimulation of the 48/14-2 discovery well. When the well was tested it flowed at a rate of 44 MMscf per day that was limited by facilities constraints. The absolute open flow (AOF) of the well was calculated at 80 MMscf per day, at the high end of expectations. The well has been suspended and is planned for use as a production well.

48/14a-6 well evaluation

As the 48/14a-6 well was drilled within 330 ft of the fully cored discovery well 48/14-2, no core was taken. The reservoir interval was logged both using real-time MWD data and subsequent pipe-conveyed open hole logging, including an FMI. Analysis of the log data showed that the well penetrated the A100 and B units and had reservoir properties similar to the other wells drilled in the central portion of the field (Table 3). Analysis of the FMI data showed that the well had encountered a variable set of fractures that included faults, drilling-induced fractures as well as conductive, resistive and 'mixed' fractures with a distinct range of orientations. These findings were in marked contrast to previous observations that included the low number of fractures observed in the core from the discovery well 48/14-2, and the dominance of a single orientation of open and partially open fractures observed

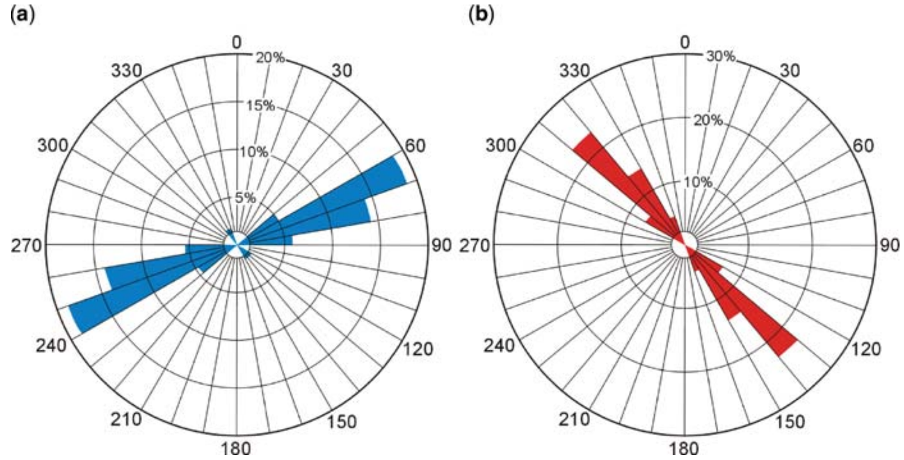

Fig. 9. Rose diagram showing strike orientation of (**a**) open and partially open fractures ($n = 53$) and (**b**) drilling-induced axial tension fractures ($n = 22$) in the FMI log acquired in well 48/14-5.

both in the core and FMI acquired in the 48/14a-5 appraisal well. It was hoped that, by studying the results of the FMI in the horizontal well, a unified theory could be derived to account for the well deliverability observed in the Ensign Field, which could aid the placement of future wells and optimize the field development.

Drilling induced fractures. Five drilling induced axial tension fractures were observed in the reservoir interval, with a NW–SE strike. These fractures are parallel to the direction of maximum horizontal stress, and are of the same orientation as the drilling-induced fractures observed in the 48/14-5 appraisal well.

Faults. 18 faults were observed in the FMI data, with the majority dipping to the east. A large conductive, north–south orientated fault was observed on the FMI with an associated conductive fracture network (Fig. 11).

Fractures. A total of 806 fractures were identified on the FMI log of which 665 were conductive, 115 resistive and 42 mixed, that is, partially conductive and partially resistive. By analogy to the 48/14a-5 well it is assumed that the electrically conductive fractures are open, and those that are resistive are closed or cemented. The different types of fracture also have a preferred orientation, with the conductive fractures striking north–south (dip east and west), the resistive fractures NNW–SSE (dip ENE and WSW), and the mixed fractures striking NE–SW (dip NW and SE) (Fig. 12). It was also noticed that the fractures are not spaced homogeneously along the well path, but appear in clusters, with zones of high fracture density and low fracture density. Given the well trajectory, the likely laterally extensive nature of the sand bodies and the lack of any obvious facies control on the fracture distribution observed in the 48/14a-5 core, it is unlikely that the zones of high fracture density observed in the 48/14a-6 well are related to variations in lithology.

It should be noted that a horizontal well provides a much denser sampling of rock heterogeneity than a vertical well, especially with respect to fractures that are typically high angle, and which may be undersampled by a vertical well. In addition, although an FMI image acquired in a vertical well may intersect fewer fractures, it does not impart any directional bias. In comparison, in a horizontal well the identification of fractures is strongly affected by borehole orientation and consequent sampling bias. The probability that a

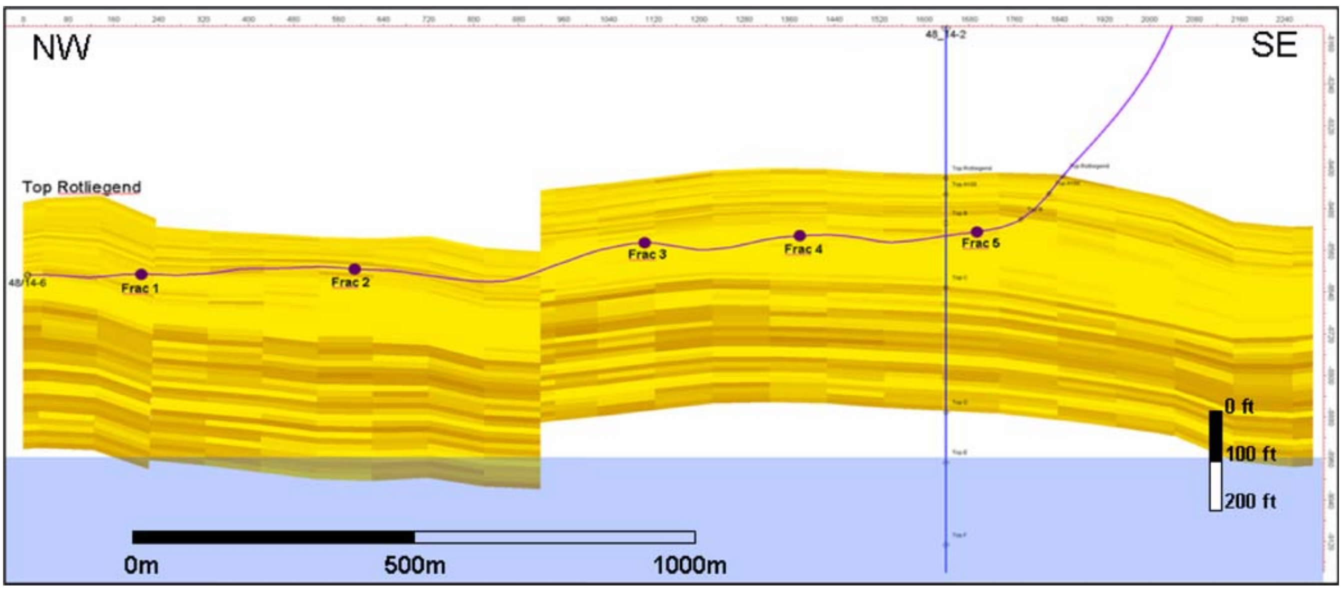

Fig. 10. Geological cross section showing the 48/14a-6 well path through the upper Leman Sandstone interval and the location of the hydraulic fracture-stimulated intervals.

Table 3. Average reservoir properties of the Upper Leman interval by unit

Well	Unit	Porosity (%)	Net/gross (%)	SW (%)
48/14-2	A000	10.9	90	56
	A100	11.3	90	61
	B	11.5	77	69
48/14a-5	A000	10.2	82	38
	A100	10.9	96	55
	B	13.4	99	55
48/14a-6*	A&B	11.4	75	48

*Owing to the well trajectory, it was not always possible to determine if the well was in the upper part of the B unit or the lower part of the A100 unit, hence for 48/14a-6 the reservoir quality has been averaged over all the units intersected. The low net/gross reflects the cemented fault zones that the well intersected.

fracture is identified on an FMI image in a horizontal well is dependent on the angle of intersection between the fracture and the well orientation. Fractures that are parallel to the well bore will be strongly undersampled, while those that are perpendicular to the well will be well sampled. This sampling bias can be corrected for and weighted fracture density distributions derived (Terzaghi 1965). The main impact with regards to the fracture distribution observed in the 48/14a-6 is that a Terzaghi weighted fracture distribution suggests that there are more resistive NNW–SSE fractures than imaged on the FMI log.

As well as the fracture type and orientation recorded in the FMI data, additional reservoir data was gathered after the well had been fracture stimulated. During the well flow testing a temperature log was acquired to observe whether the zones that had been fracture stimulated were actually contributing to flow. The observed temperature profile in the vicinity of the fracture-stimulated zones confirmed that they are contributing to flow, although it was not possible to quantify the relative flow contributions from each zone. Owing to operational constraints it was not possible to run

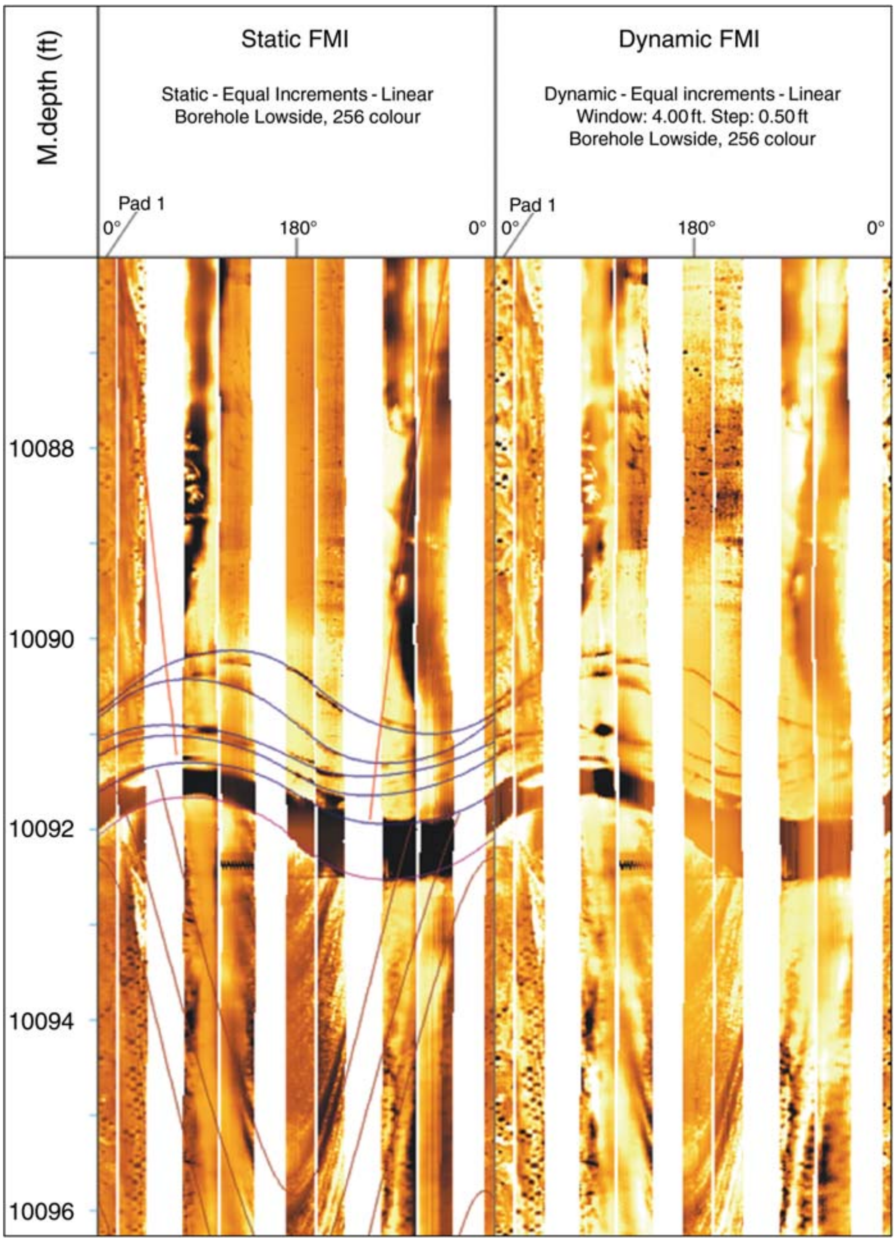

Fig. 11. FMI image of conductive fault and associated conductive fractures observed in the FMI log from well 48/14a-6. The fault is the dark (conductive) sinusoid at 10 092 ft on the FMI image.

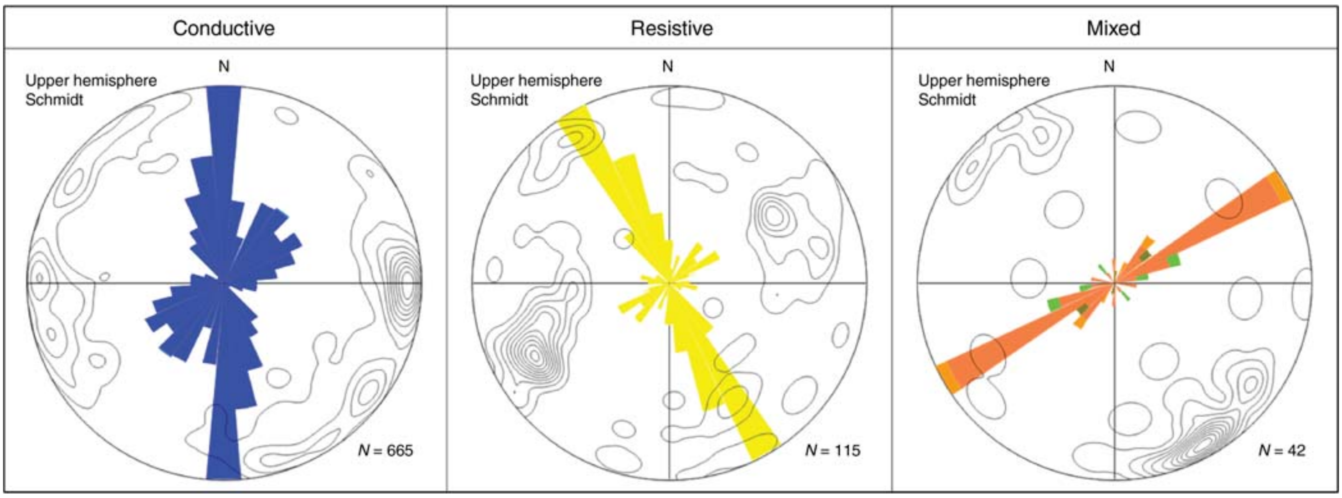

Fig. 12. Upper hemisphere Schmidt stereoplots showing the orientation of conductive, resistive and mixed fractures interpreted from the FMI acquired in the 48/14a-6 horizontal well.

a production log that may have quantified the contributions to flow from each zone.

Discussion: the potential role of naturally occurring fractures on productivity in tight gas reservoirs

The Ensign Field has proven more enigmatic than expected. The successful development of the central and northern portion of the field utilizing a multiple fracture-stimulated horizontal well has unlocked its potential, but a number of questions remain. For example: (1) why did the discovery well contain few fractures throughout its cored interval, although the FMI in this fault block shows a number of fractures and faults? (2) Why did the discovery well flow better than anticipated given its very poor reservoir quality? (3) Why did the 48/14a-5 well not flow better given that it encountered open and partially open fractures? Given the data acquired during Venture's appraisal campaign on Ensign, it is hoped that we can answer the critical question which is 'Is there an overriding control on reservoir deliverability that will help optimize the future development of the field?'

One conclusion that can be drawn from the observed fracture distribution is that different fracture types appear to have different effects on well deliverability. The open and partially open NE–SW striking fractures encountered in the 48/14a-5 appraisal well do not appear to have any impact on well deliverability. Although these fractures are observed to be open in core, they do not appear to enhance reservoir productivity, possibly because in the subsurface under the present stress regime they are closed, although partial mineralization of the fractures would tend to inhibit this. The only interval in the 48/14a-6 horizontal well that contained a significant proportion of these NE–SW striking mixed fractures was in the most northern fault block near the toe of the well. Unfortunately this interval was not accessed by the temperature log, and consequently may or may not be contributing to flow. It should be noted, however, that this interval also had the smallest induced fracture based upon the amount of proppant emplaced (Table 3).

Analysis of the fracture orientation in the fault block containing the discovery well shows a preponderance of the north–south striking conductive, potentially open, fractures. In addition, a large conductive north–south striking fault with associated conductive fractures was observed in the FMI log (Fig. 11) in the portion of the well that passed close to the discovery well. A plot of the 48/14a-6 well path showing the location and orientation of the fractures and the location of the 48/14-2 well bore at top reservoir (Fig. 13) suggests that the discovery well is located in a relatively fracture-free zone, between a series of fracture corridors. This may account for why the 48/14-2 well core contains few fractures and why on fracture stimulation the well performed better than expected given the very poor quality of the reservoir. It is likely that the induced hydraulic fracture would have extended across the north–south trending fracture corridors and 'tapped into' the natural fracture network. It should be noted, however, that the potential connection of the well bore with a network of natural fractures

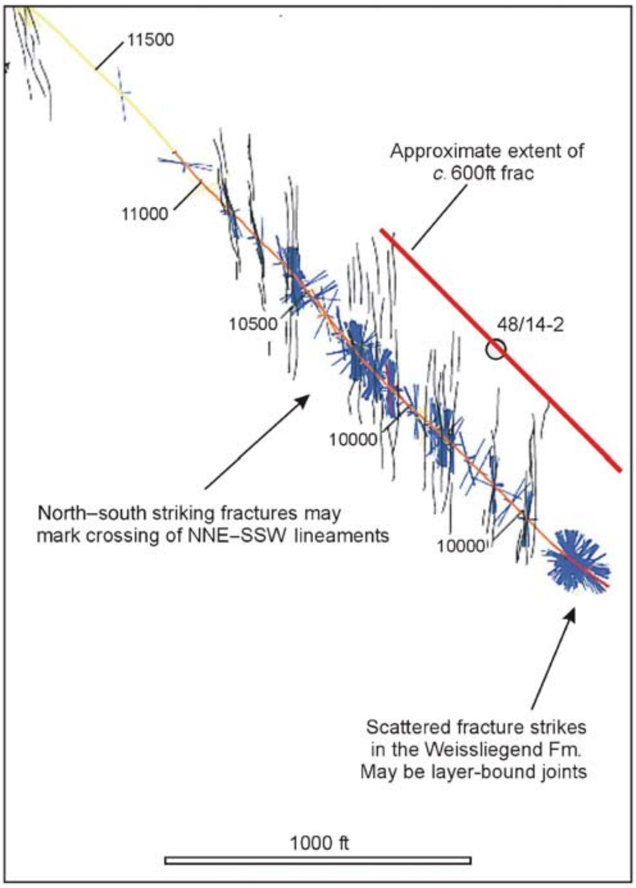

Fig. 13. Diagram showing the 48/14a-6 well path in the vicinity of the 48/14-2 discovery well annotated with the interpreted fractures and likely extent and orientation of the hydraulic fracture.

in both the 48/14-2 and 48/14a-6 wells does not appear to result in the response typical of a classic open fracture network. In both wells there does not appear to have been a sudden loss of fluids and proppant into the fracture system during the fracture stimulation process. It is more as if the natural fractures are acting as an improved matrix rather than a large-scale open fracture system.

Based on the observations and well results to date on Ensign it appears that: (1) the NE–SW striking open and partially open fractures do not appear to improve well deliverability; (2) the north–south striking conductive fractures appear to improve well deliverability; and (3) it is assumed that the resistive fractures that strike NW–SE have no impact upon well delivery.

The varying style and orientation of the fracture networks suggest that they may have formed under different stress and tectonic regimes during the structural development of the Ensign Field. At present the unifying theory of fracture formation, orientation and improvement in well deliverability has not been tested further in the Ensign Field. Ongoing technical work will hopefully improve our understanding on this matter. The model proposed for fracture style and orientation accounts for the well results to date and will be evaluated as the Ensign Field is developed further.

Conclusions

The Leman Sandstone reservoir of the Ensign Field comprises sabkha, fluvial and aeolian sandstones deposited in an arid continental environment. The sediments were deposited in a variety of erg margin–lake margin settings that have resulted in units that are correlatable across the field. In the Ensign Field the gas-bearing interval is dominated by sabkha and waterlain deposits with only minor aeolian sandstones.

Reservoir quality in the gas-bearing interval is universally very poor, in part owing to the poor primary depositional facies, but predominantly as a consequence of extensive illite cementation. The average core-derived permeability in the gas leg is <1 mD.

Core and FMI analysis shows that the Ensign Field has a heterogeneous distribution of fractures and faults. The fracture population is dominated by conductive (probably open) north–south striking fractures, with subordinate NNW–SSE resistive (probably closed) fractures and NE–SW mixed fractures. Analysis of the FMI data from the long horizontal well 48/14a-6 shows that the fractures are arranged in clusters, with zones of high and low fracture density.

Well results to date suggest that the NE–SW open and partially open fracture observed in core do not improve reservoir productivity, but those orientated north–south that are conductive appear to improve well deliverability.

The uncertainty in fracture type and distribution in the very tight gas reservoir of the Ensign Field has been overcome by utilizing a multiple fracture-stimulated long horizontal well. Although this technology has moved the field towards economic development, further technical work will be undertaken to reduce the uncertainty in the controls on well deliverability and optimize the field's future development.

The authors would like to thank the SNS gas asset team for their work that has resulted in the successful development of the Ensign Field. Sami Haidar at Fracture Technologies is thanked for early input into this work, and Schlumberger and Task Geoscience are acknowledged for the original FMI interpretations undertaken. The authors would also like to thank constructive reviews by Graham Goffey and Jon Gutmanis.

Delegate questions

Delegate: Ian Lisseter, Challenger Minerals Inc.

Question: Is there a density of FMI identified fracturing below which a multi-frac might not be attempted?

Answer: Owing to the uncertainty in the contribution of the fractures in the Ensign Field and the very low matrix permeability, horizontal wells that are stimulated by a number of hydraulic fractures is the base plan, irrespective of natural fracture density.

Question: What direction do the induced fractures have?

Answer: The induced fractures have the same orientation as the drilling-induced axial tension fractures that are parallel to S_{hmax}, and consequently are orientated approximately NW–SE.

Maximizing production and reserves from offshore heavy oil fields using seismic and drilling technology: Alba and Captain Fields, UKNS

J. M. HAMPSON, S. F. WALDEN and C. BELL

Chevron Upstream Europe, Chevron House, Hill of Rubislaw, Aberdeen AB15 6XL, UK (e-mail: johnhampson@chevron.com)

Abstract: Chevron North Sea Limited operates Alba and Captain, two large, mature, heavy oil fields in blocks 16/26 and 13/22a of the UK sector of the North Sea, respectively. Although the fields are structurally and stratigraphically different, their development schemes have been similar. Common components to both fields are that they are marine sandstone reservoirs; have one steel jacket, plus subsea templates; are under water injection for pressure support; utilize long horizontal development wells; use pilot holes and logging while drilling (LWD) geosteering tools to optimize well locations; and have seismic resolution issues. New technologies and techniques have been developed and adopted to maximize production and reserves from the fields. The benefits to both Alba and Captain of previous and new technologies are reviewed below.

Keywords: Alba, Captain, 4D seismic, fault, pilot hole, geosteering

Field history and background

Alba Field

The Alba Field is a mature (15 years on production), heavy oil (19° API) asset located in block 16/26 in the Outer Moray Firth, Central North Sea, 225 km NE of Aberdeen (Fig. 1). It was discovered in 1984 by a Britannia Field appraisal well (16/26-5), which encountered oil-bearing sands in the Eocene age Nauchlan and Brioc Sandstones and has been on stream since 1994. It is currently producing from 26 platforms and 10 subsea horizontal wells and has seven water injector wells (Fig. 2). Cumulative oil production reached 350×10^6 bbl in 2008 of a field STOIIP (stock tank oil initially in place) of 1000×10^6 bbl. Average daily oil production is currently 35 000 bopd with field water cut of 87% (Fig. 3).

The field overlies the Mesozoic Witch Ground Graben with the Fladen Ground Spur to the North and Renee Ridge to the South. The Alba reservoir is an elongate, Mid–Late Eocene, turbidite channel fill, deposited in a pre-existing erosional slope scar. The poorly consolidated sands were subjected to significant remobilization and injection shortly after deposition and burial. The reservoir facies is a quite simple, almost binary system of sand and intra-reservoir shale bodies; reservoir properties range from 30–35% porosity and 2–4 Da horizontal permeability.

The Alba reservoir level is affected by significant faulting (Lonergan & Cartwright 1999), which has strongly influenced reservoir architecture. Two fault families have been identified on various seismic datasets. Polygonal faults have developed in the surrounding shales as a result of de-watering and where they cut into the reservoir (laterally or into the top) seems to coincide with the location of major sand injectites. These faults only cut through the entire reservoir where it is relatively thin and have been mainly interpreted on compressional (P-wave or PP) seismic data. Sub-vertical faults are present mainly at reservoir level and form a dense network. These faults can be best observed on shear (S-wave or PS) seismic data and their generation mechanism is probably compaction-related.

Despite the importance of faulting, the poor imaging of the pre-production 1989 3D seismic data (P-wave streamer survey) did not permit detailed fault mapping. It was not until the acquisition of the 1998 4C (four component) OBC (Ocean Bottom Cable) survey and subsequent 2008 4D survey that interpretation of the faults improved (Fig. 4). Although these fault sets have been known in the past, their transmissibility character and impact on flow were previously unclear. A few early wells had shown evidence of possible fault baffling with oil- and water-filled sand found on either side of faulted shale breaks. However, elsewhere, faults may act as conduits, locally concentrating flow and causing point inflow in wells and significantly influencing fluid movement within the reservoir.

Alba Field development

Alba Field development has been driven by technology step-changes that have resulted in significant improvements in the understanding of static geology and dynamic reservoir conditions. Two key areas that have resulted in major changes are seismic and drilling.

Seismic technology. Prior to the first 3D survey, all that could be identified of what was subsequently to become Alba on 2D data was the oil–water contact (OWC) in the 12 Area of the field, a strong amplitude, flat seismic event. Alba now has had the benefit of five 3D seismic surveys, together with reprocessing of some datasets. These are shown in Table 1 (abbreviated name in parentheses).

The 1989 pre-production P-wave survey provided the first 3D seismic interpretation of the field. Early geological models suggested the field was a ‘tank of sand’ with discontinuous intra-reservoir shales, which were interpreted to have little or no impact on fluid movement and production (Fig. 5a). This interpretation was largely driven by the very poorly imaged top and base reservoir, but clearly identifiable OWC.

The first step-change in understanding of the field occurred following acquisition of the third seismic dataset in 1998 (MacLeod *et al.* 1999). This OBC survey recorded *S* (shear) wave energy, converted from P waves that provided the first image of top and base reservoir due to the large shear impedance contrast of the reservoir with the surrounding shale (Fig. 6). *PZ*, the recorded P-wave energy, was also acquired with the OBC and was used in the well planning process.

The shear impedance inversion of this dataset also provided the first image of sand/shale distribution within the reservoir. It was also following interpretation of these data that large-scale

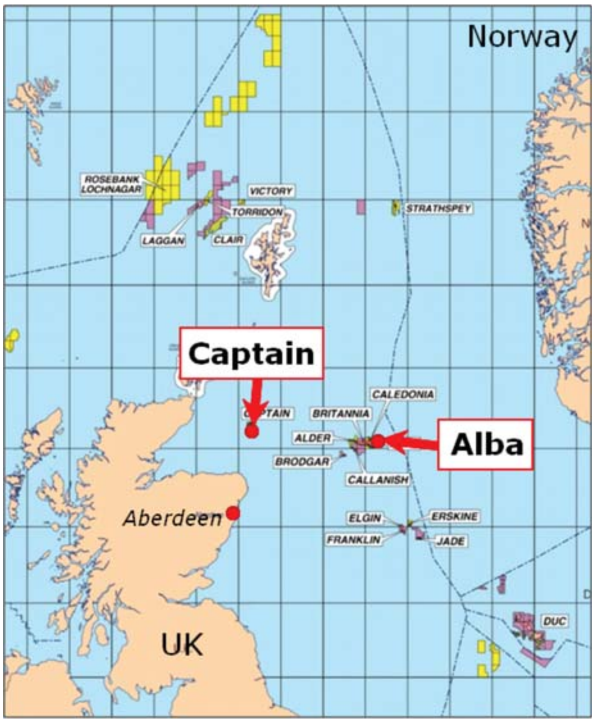

Fig. 1. Location map.

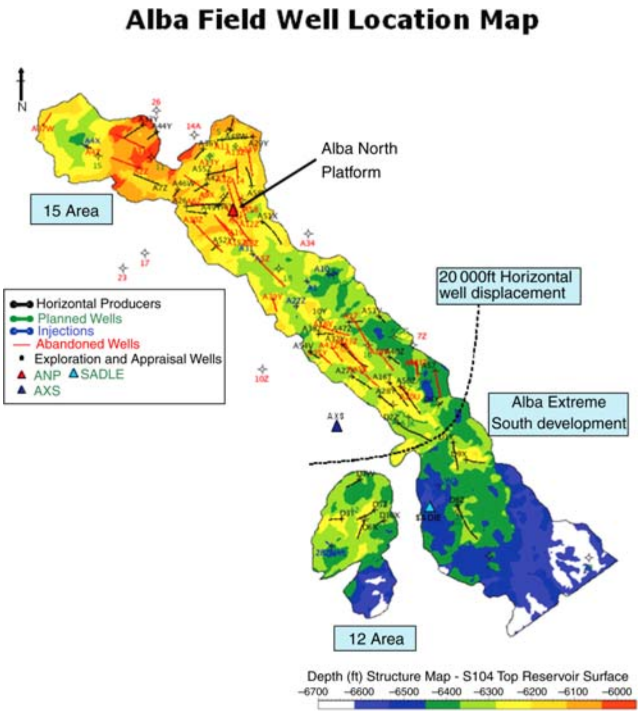

Fig. 2. Alba Field location map.

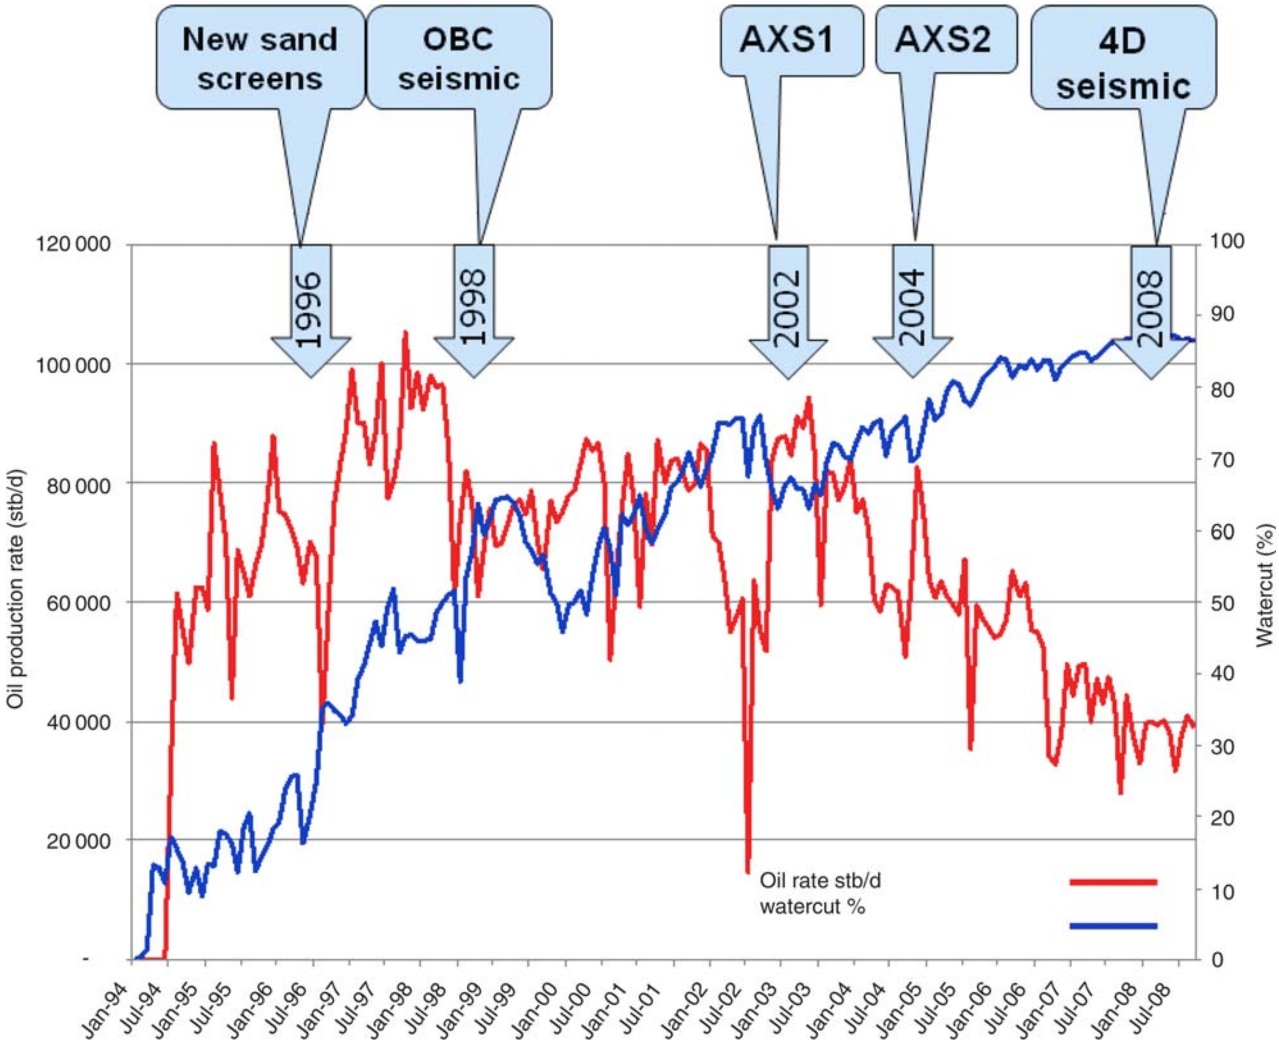

Fig. 3. Alba Field production.

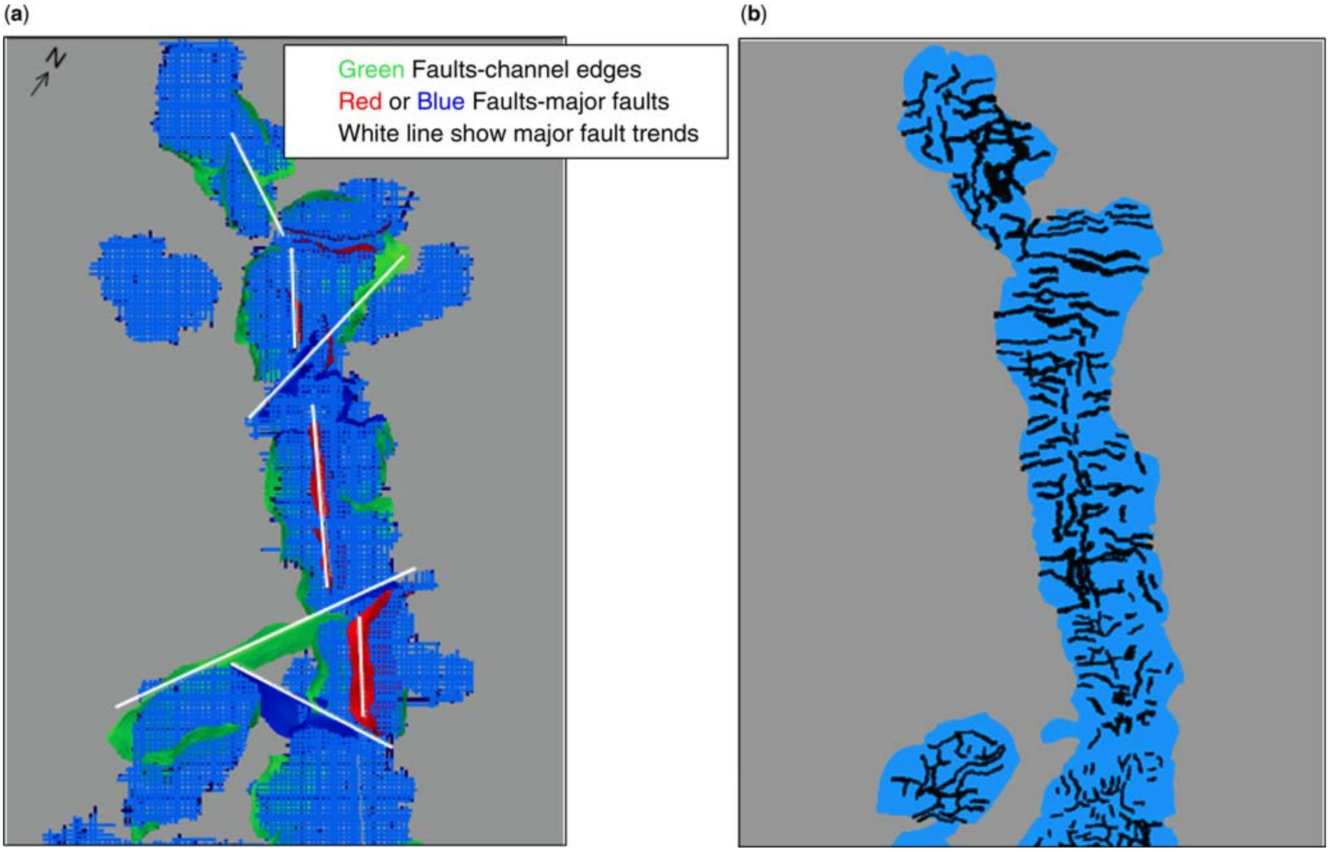

Fig. 4. Alba fault interpretations. (**a**) Early interpretation had few faults influencing fluid movement. (**b**) Current interpretation much more complex: enabled by joint interpretation of PP, PS & 4D; latest 3D interpretation application.

injected sands at the field margins ('wings') and above the main field were first recognized (Fig. 5b). They had previously been considered to be relatively small-scale features (Newton & Flanagan 1993), but the PS data quality enabled significant subsequent research.

In 2002 a non-proprietary P-wave seismic dataset was acquired primarily to image the deeper Britannia reservoir, not as a designed 4D dataset. The 2002 survey was recorded at a similar north–south azimuth to the 1991 survey. As a result, after some delay due to a feasibility study and other development priorities, the 2002 and 1991 datasets were co-processed together (PP05). This PP05 dataset has only been used qualitatively in target maturation due to the poor repeatability; comparing this dataset with the 2008 dedicated 4D acquisition highlights the fact that co-processing can only go so far in resolving acquisition-related 4D noise.

Table 1. Alba Field – seismic data history

1989	Alba streamer survey (not currently used because of poor imaging)
1991	Britannia streamer survey (Alba pre-production survey – PP91)
1998	Alba OBC 4C survey; PS and PZ recorded; not designed for 4D (PS99)
2002	Q15 streamer survey; not designed for 4D (PP02)
2004	Reprocessing of 1998 OBC survey (PS04)
2005	Parallel processing of Britannia and Q15 surveys (PP05)
2008	Alba streamer dedicated 4D (PP08)

Reprocessing of 1998 OBC that included a pre-stack, anisotropic migration (PS04) in 2004 provided an alternative image of the field. This dataset is somewhat lower frequency, but gives a useful alternative model when risking well targets.

Alba's viscous oil (19° API, 6–10 cP) properties together with the high poroperm sands result in a strong seismic fluid response, which makes it very suitable for 4D technology. Multiple feasibility studies have confirmed a very strong 4D signal on Alba due almost entirely to saturation changes because the field pressure has been maintained by full-voidage water injection over the field life. In order to locate the remaining oil after 14 years of production, a dedicated 4D survey was acquired in 2008 which provided the fourth time step after the 1991 Baseline, 1998 OBC PZ and 2002 Monitor surveys. Key components of the business case developed for a new 'dedicated' 4D were capturing incremental production, de-risking existing targets and reducing drilling costs by optimizing wellpath design. There were also several intangibles such as an improved reservoir model. The Alba drilling programme has been driven by the reservoir model built from the 1998 OBC seismic survey and the targets are now approaching the resolution of these reservoir models. The 2008 4D provides an independent constraint on reservoir history matching.

Alba is using new workflows to extract value from the survey. High noise levels in the previous 2002/1991 co-processed 4D data limited its use to a 'soft' constraint in prior history matching. However, with the data quality of the dedicated acquisition, interpreted oil–water contacts are being combined with traditional well-related history matching parameters as 'hard' data constraints in the simulation model history match (Fig. 7).

The re-interpretation of all three datasets, completed over the past 12 months, is providing new insights into the reservoir geology and, in particular, the way faults affect fluid flow. There

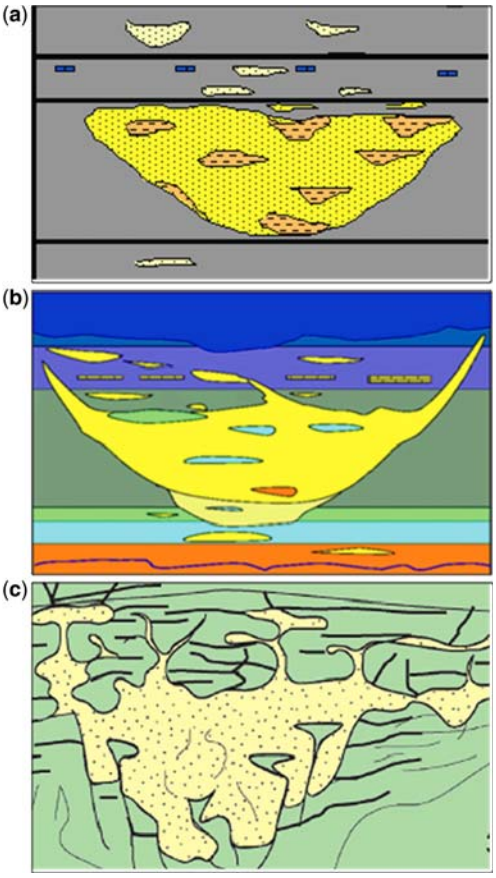

Fig. 5. Alba cartoon geological models. (**a**) At field development: simple, lensoid shape; PP seismic imaged OWC only. (**b**) After 1998 OBC seismic: imaged top/base; injected sands, wings and crest. (**c**) Probable complexity: multiple injectites, small- and large-scale faults (Surlyk *et al.* 2007).

are indications that water cones beneath producers are sharper than previously modelled, providing opportunities for inter-cone infill targets (Fig. 8). In addition, the impact of fault baffling on fluid movement has been noted in several areas of the field.

Injected sands and field edge. The presence of injected sands in Alba has been well documented (Duranti *et al.* 2002 and others). However the location, size and shape of the injectites was difficult to predict from seismic data and some early attempts to produce from them proved difficult as a result of early completion failures due to shale fines migration and sand screen hot-spotting. Work on seismic tuning (Fig. 9) showed a predictable relationship between amplitude decay and reservoir sand thickness. This changed the previous Alba edge of field 'cliff' model to the current more predictable thinning model and enabled more confident targeting of field edge drilling targets. Wells drilled on the eastern and western edges of the main field in 2005 confirmed the new thinning model predictions. The current view of likely field complexity is illustrated by the diagram in Figure 5c (Surlyk *et al.* 2007).

Alba drilling technology. Alba (and Captain) Field would not have been successfully developed without advances in horizontal drilling and completion technology that occurred during the 1990s because of the unconsolidated nature of the reservoir sand and the long (>500 ft) production intervals located close to the roof that are required to effectively capture the oil reserves.

Whilst rotary steerable systems (RSS) enabled long horizontal wells to be drilled, gravel-packed sand screens provided the necessary solids control required to prevent production of the fine-grained, poorly consolidated sand. The first of a new generation of sand screens was used in 1996 to combat early well failures and, together with gravel-packing, these have continued to provide effective sand control combined with long well life.

When field development was first sanctioned, two platforms had been planned. Only Alba Northern Platform (ANP) was ever commissioned. Before the second platform was built, advances in drilling technology meant that a significantly larger portion of the field could be reached by long horizontal wells. The first extended reach drilling (ERD) wells in 1997 hinted at difficulties to come in exploiting extreme southern reserves. Well lengths were originally 15 000 ft MD, but this limit was subsequently extended to the current 20 000 ft MD by the use of improved technology and drilling practices.

However, this still left significant reserves in the extreme south and 12 Area of the field. To produce this oil, the more cost-effective

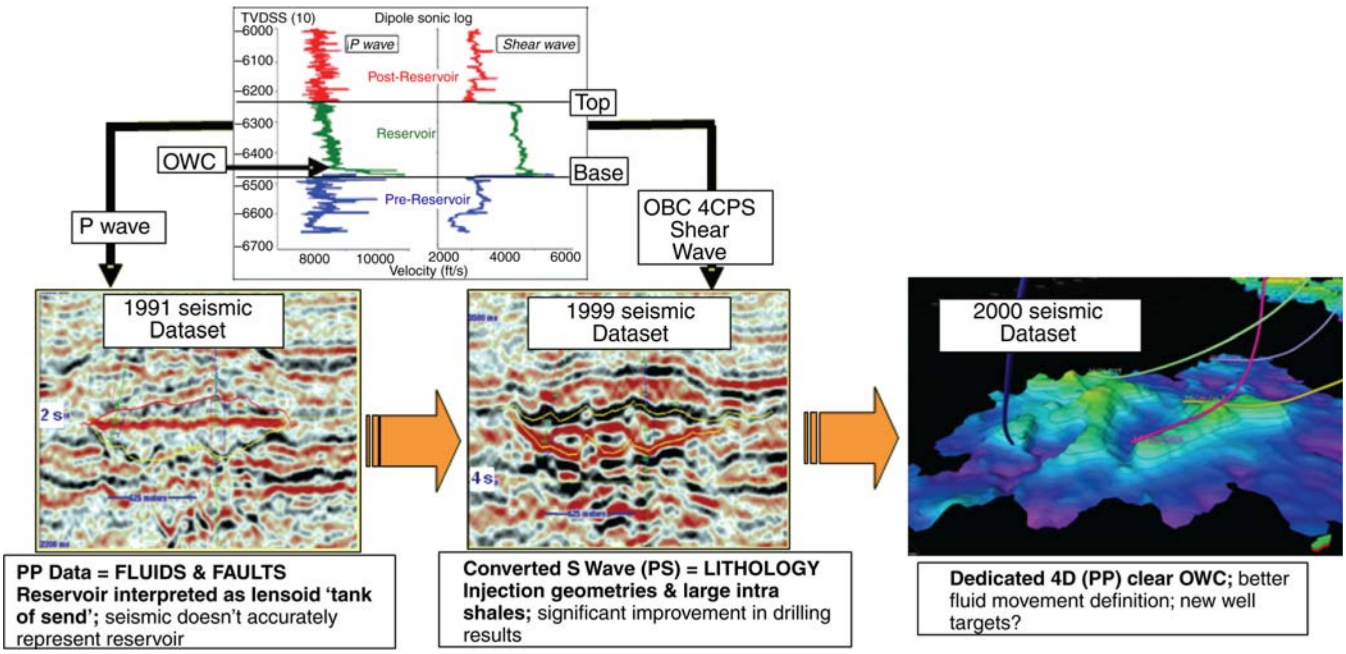

Fig. 6. Alba seismic datasets.

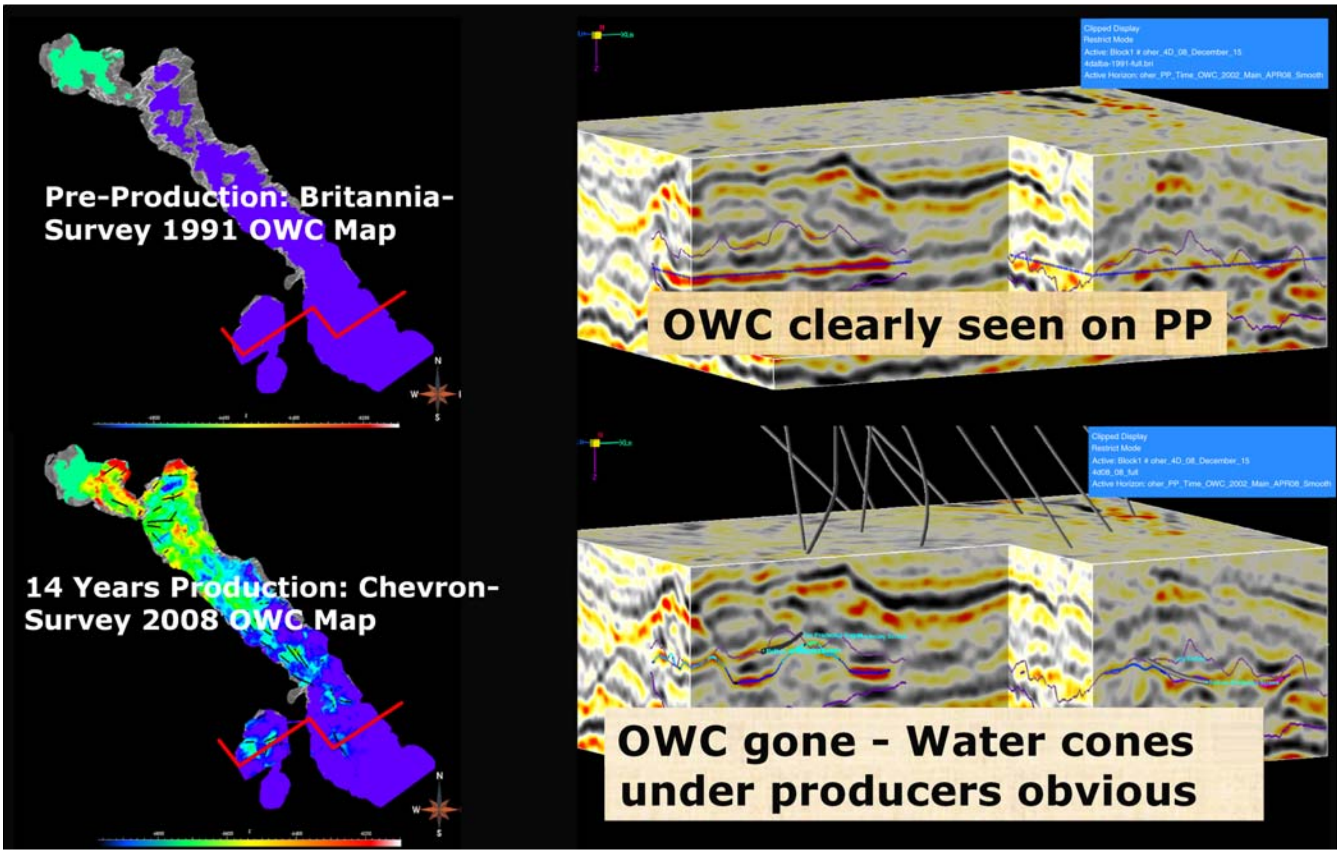

Fig. 7. Alba 4D seismic showing OWC movement.

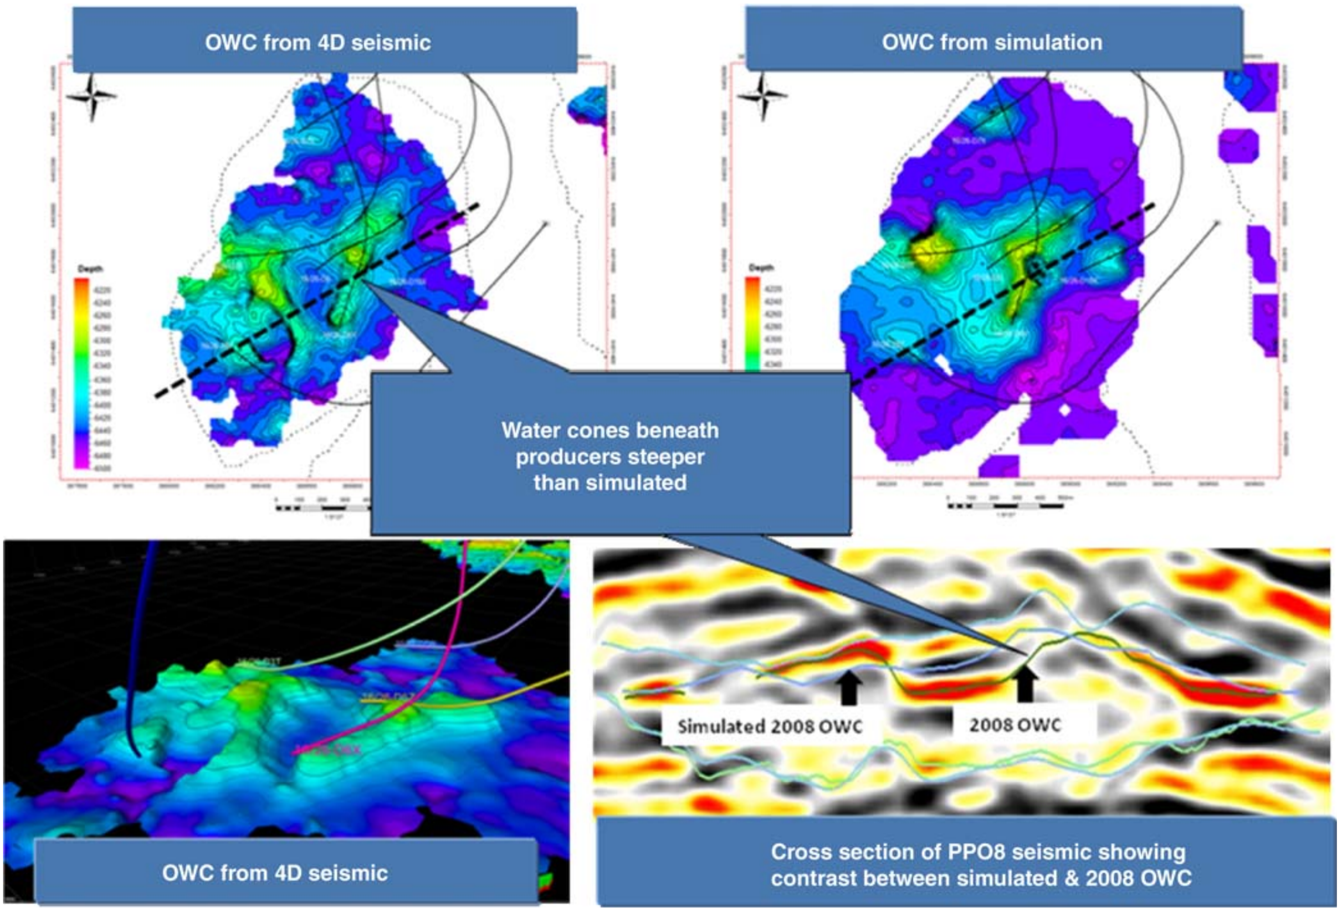

Fig. 8. Alba 4D data showing water cones beneath producers.

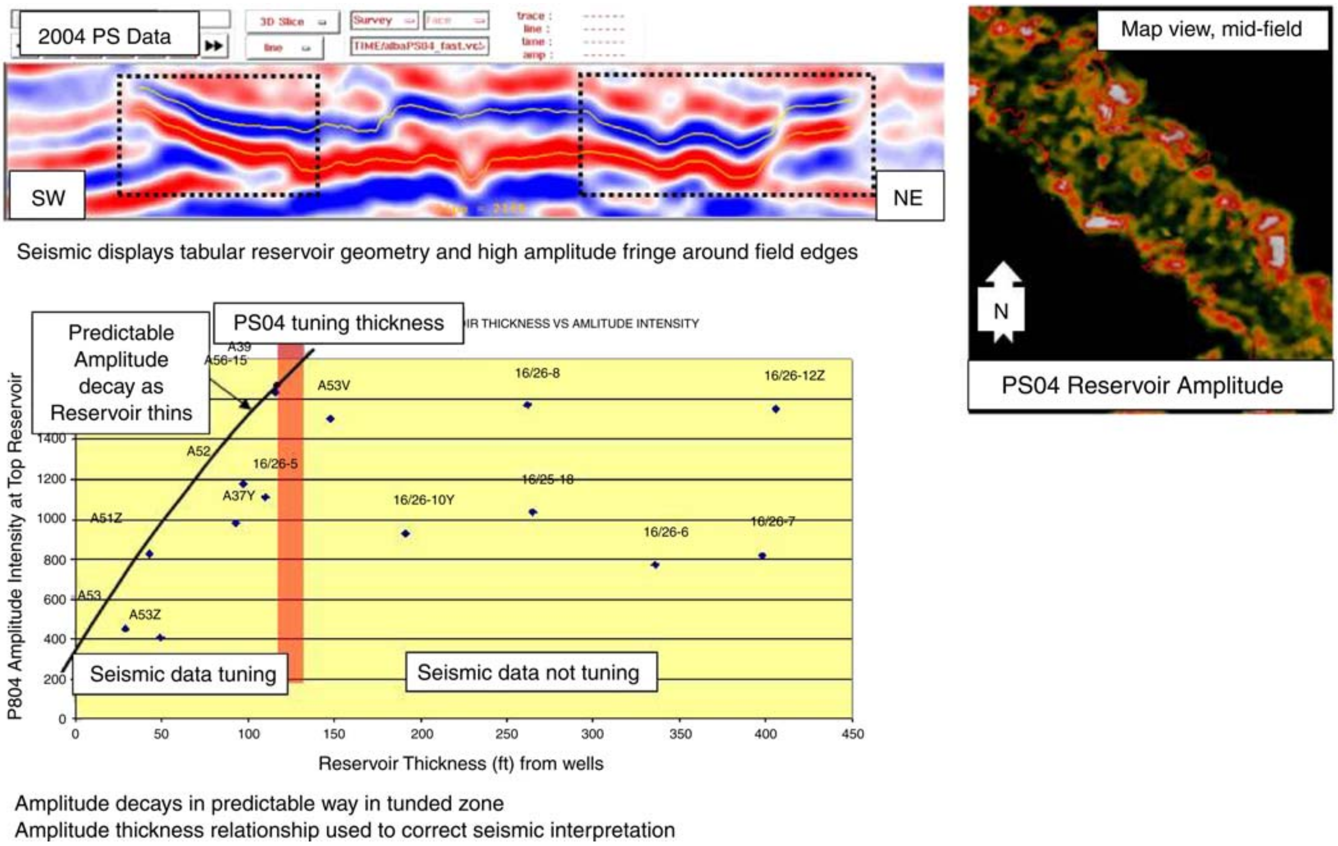

Fig. 9. Alba – field edge seismic tuning.

alternative of subsea manifolds and pipeline tie-back to ANP was utilized, starting in 2002 with AXS (Alba eXtreme South) phase 1 and continuing in 2004 and 2006 with additional producers.

ANP was built with 24 drilling slots, but currently has 31 wells. This was achieved by splitting seven slots in 2000. With 12 subsea wells, Alba has the capacity for 43 active wells. In fact the 59th platform well is being drilled in 2009 and this has been achieved by recovering failed well slots. A well failure rate of 5% per annum has meant that Alba has not been slot constrained.

In an attempt to reduce well costs, deep sidetrack slot recovery, where the production casing is exited in 8.5 ft hole size by means of a whipstock, instead of the previously used method of cutting and retrieving the 9.625 ft casing and drilling a new 12.25 ft hole, was successfully tested in 2006. This required the use of different well construction techniques in order to maintain minimum production hole size requirements. This is now the preferred well construction on Alba, wherever slot–target combinations are appropriate.

Alba pilot holes. The first pilot holes drilled on Alba were mostly sub-horizontal and were drilled to locate top reservoir and completion hole landout points. As a result, many early Alba wells were not located optimally in the reservoir and often left significant attic oil above the well. However, after acquiring the OBC data in 1998 (PS99), which completely changed the field understanding, sub-horizontal pilot holes were no longer required to locate the top reservoir. The very rugose top reservoir surface, resulting from sand remobilization and injection, necessitates horizontal pilot holes to be used to optimize completion hole locations, but the advent of geosteering LWD tools has reduced that need. The first geosteering using a deep-reading azimuthal resistivity LWD tool was tested in 2005, and quickly provided significant benefits in capturing attic oil by drilling close to top reservoir (Fig. 10). Geosteering using wellsite palaeontology and LWD had been used from well A2 onwards, but the dip direction of the shale was unknown and this technique was later abandoned. Drop trajectory pilot holes are drilled at key locations in order to calibrate the seismic data and reservoir models, by locating top and base reservoir and the producing OWC, which aids 4D seismic and reservoir model calibration.

Horizontal pilot holes have added $>1 \times 10^6$ stb oil by optimizing a single producer well location. Thus, seismic technology has been a key enabler to optimizing field development, increasing production and reserves. Improved imaging of reservoir geometry, lithology distribution and fault position has provided the means to locate additional production wells. Pilot holes have added significant additional recovery and are important for reservoir surveillance. Rotary steerable drilling systems and LWD geosteering tools have provided the mechanisms to optimally locate these wells and completion technology has enabled longer, higher, sand-free production rates and well life. Typical infill targets are $2-4 \times 10^6$ bbl recoverable, so the potential additional $0.5-1.5 \times 10^6$ bbl achieved using these technologies proves significant.

Captain Field

The Captain Field is a large (>1 Bbbl STOIIP) heavy oil accumulation located in block 13/22a of the Inner Moray Firth area of the UK sector of the North Sea, approximately 130 km NE of Aberdeen (Fig. 1).

The Captain Field was discovered in 1977 and developed in 1997 after a significant period of appraisal. It is a combined structural and stratigraphic closure that overlies the east–west trending Captain Ridge (Rose *et al.* 2000). Within this structure, relatively heavy (13–21° API) and extremely viscous oil (49–150 cP) and gas is trapped within largely unconsolidated sandstone reservoirs. The field is being developed with long horizontal wells (some

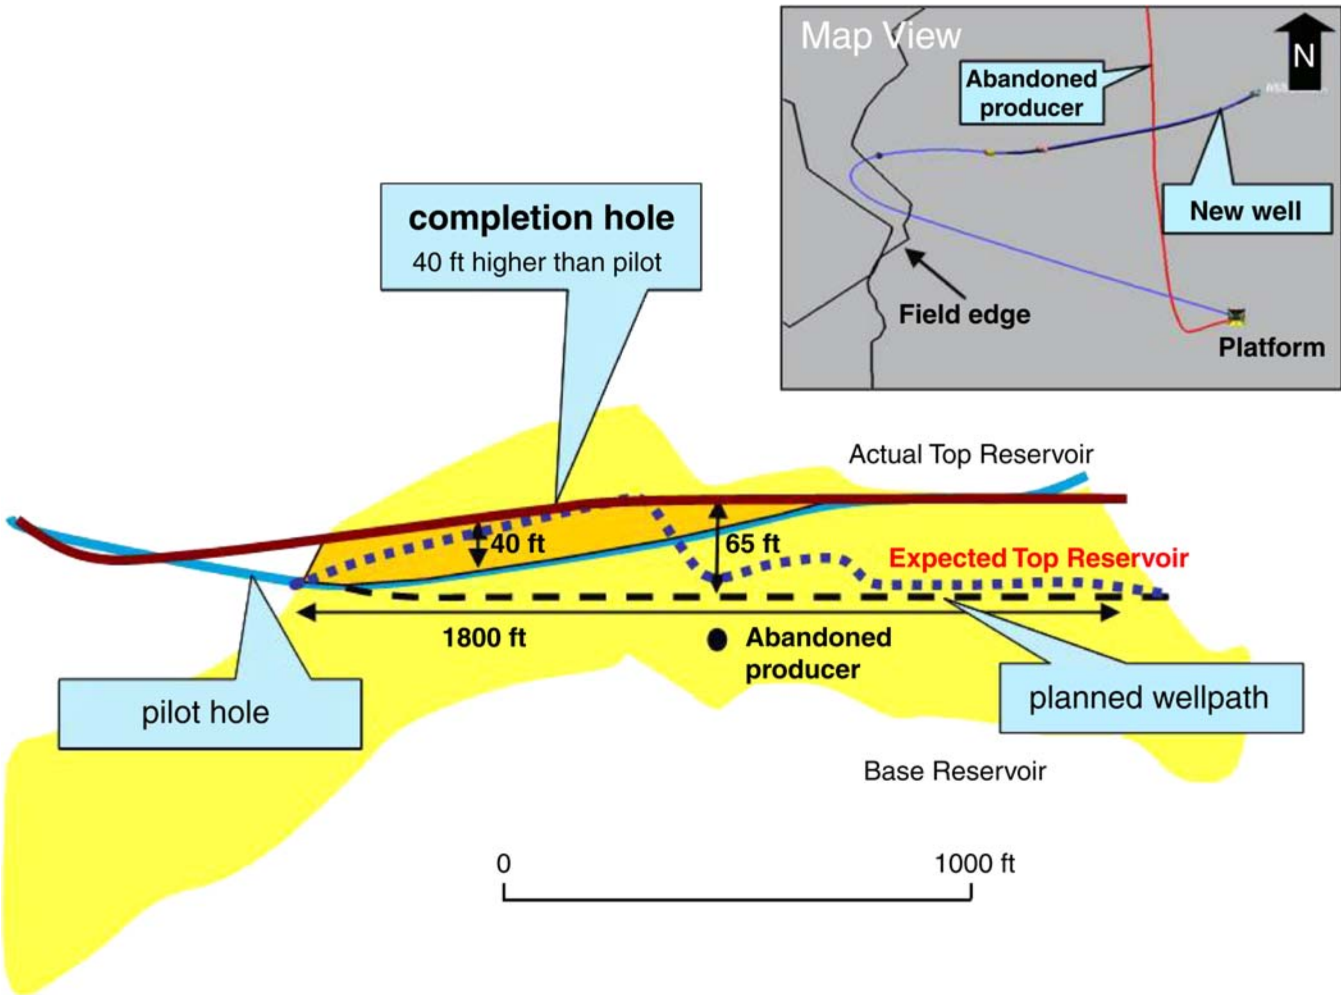

Fig. 10. Alba pilot hole – attic oil capture.

completions intervals greater than 8000 ft MD) at very shallow subsea depths (less than 3200 ft), is currently under water flood and has produced 240×10^6 bbl oil to date.

Captain reservoirs

The Captain Field has two main producing Lower Cretaceous reservoirs; the sheet-like deep-water Upper Captain Sandstone and the channelized Lower Captain Sandstone. In the eastern part of the Field, the Upper Jurassic, Heather Formation, faulted, marginal marine Ross Sand member is an important reservoir.

The Lower Cretaceous aged Upper Captain Sand (UCS) directly underlies 1300 ft of Cretaceous chalk (Figs 11 & 12) and contains the bulk of the reserves in the Field. The UCS lies between 0 and 50 ft below the base Chalk and the top reservoir is not resolvable on seismic. The reservoir is remarkably massive and lacks any internal architecture. Laterally, the reservoir is very continuous, as observed in horizontal wells, is highly porous (31% average) and permeable (5 Da average). The Upper Captain Sandstone hydrocarbon accumulation is a combined structural and stratigraphic trap. In general, the reservoir has the form of a gently northward dipping wedge of massive, sheet-like sandstone. An extensive aquifer lies along the northern margin of the accumulation and a large gas cap is present to the north central part of the field. Small, isolated gas caps are also present towards the updip pinchout and erosion edges.

The Lower Captain Sand (LCS) is interpreted to be a weakly confined, channelized reservoir with poorer reservoir quality (net-to-gross, porosity, permeability) than the UCS. The trapping mechanism is structural/stratigraphic in nature, the same as the UCS. There are a few production wells in the reservoir, but production performance is poorer than the UCS, and is not currently a focus of development. There can be erosion of the top reservoir surface, sometimes leading to 10–20 ft deep scours, which can make it difficult to drill close to the roof with horizontal wells.

The Jurassic (Oxfordian) age, Ross Sand member is between 60 and 120 ft thick, averaging 90 ft. It has fairly uniform thickness and good porosity (27% average) and permeability (2 Da average) in the eastern part of the Captain Field.

There are two vintages of 3D seismic data acquisition at Captain Field. The latest is a Q-Marine survey acquired in 2003 (Fig. 12). A test 2D 4C survey was acquired in 1997, but the results did not improve the imaging in the reservoir intervals.

The seismic imaging of the reservoirs is poor due to (1) the thick, relatively high velocity chalk interval that overlies the reservoirs, and (2) the close proximity of the strong base Chalk reflector to the main reservoir. This difficult imaging and low GOR preclude the use of 4D seismic monitoring. The Q-Marine survey is currently being reprocessed to improve overall imaging of the sub-chalk reservoirs.

Captain Field development

Drilling technology. Similarly to Alba Field, Captain Field would not have been successfully developed without advances in horizontal drilling technology that occurred during the 1990s.

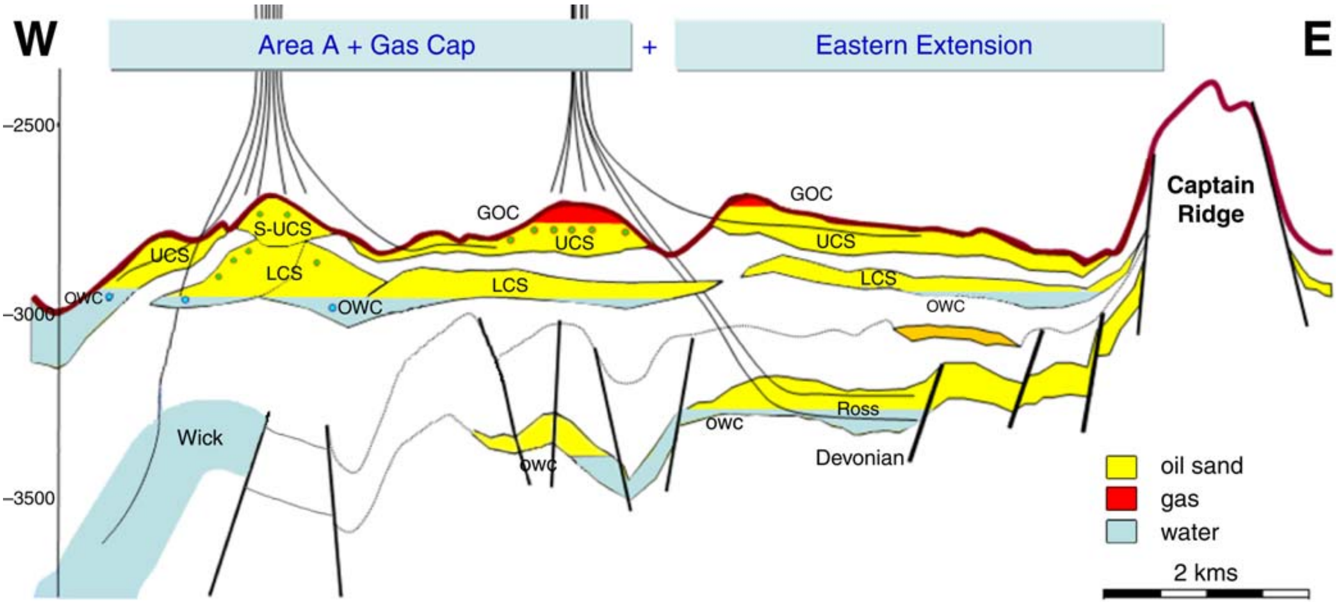

Fig. 11. Captain Field schematic cross section showing reservoirs.

This shallow reservoir with high viscosity oil cannot be produced at commercial rates from vertical wells. Early horizontal production wells were placed near the top third of the reservoir to minimize the chance of penetrating shales that are detrimental to gravel pack completions by risking the placement of the gravel along the entire wellbore as a result of washouts or blockage due to pack-offs. In 2005, Captain Field went exclusively with wire-wrapped screen completions that were more tolerant of shales. This allowed new wells to be placed near the top of the sand, producing the previously stranded attic oil.

Additional reserves are found out of reach of the platform (Fig. 13) and these are being produced via two subsea templates installed in 2000 and 2005. Technologies have been developed and employed to drill and complete long horizontal wells from these templates.

Captain pilot holes. To best capture attic oil, the elevation of the roof of the reservoir needs to be known. The top and base UCS reservoir is poorly imaged on seismic data. Since the top structure is poorly known away from well control, attic oil is left behind; since the base reservoir is also poorly known away from well control, water movement is very difficult to predict and model (Fig. 14). Thus, the best way to gather definitive information about the structure of the top and base UCS reservoir is to drill pilot holes that intersect both horizons. Pilot holes were first used on Captain in early 2004. Pilot holes are either horizontal S shaped – to penetrate top and base reservoir at multiple points along the well bore – or vertical drop pilots to gather information on deeper reservoirs. This appraisal method is clearly cost effective, as placing wells nearer the roof of the formation recovers significant incremental oil. The current estimate of the height of attic

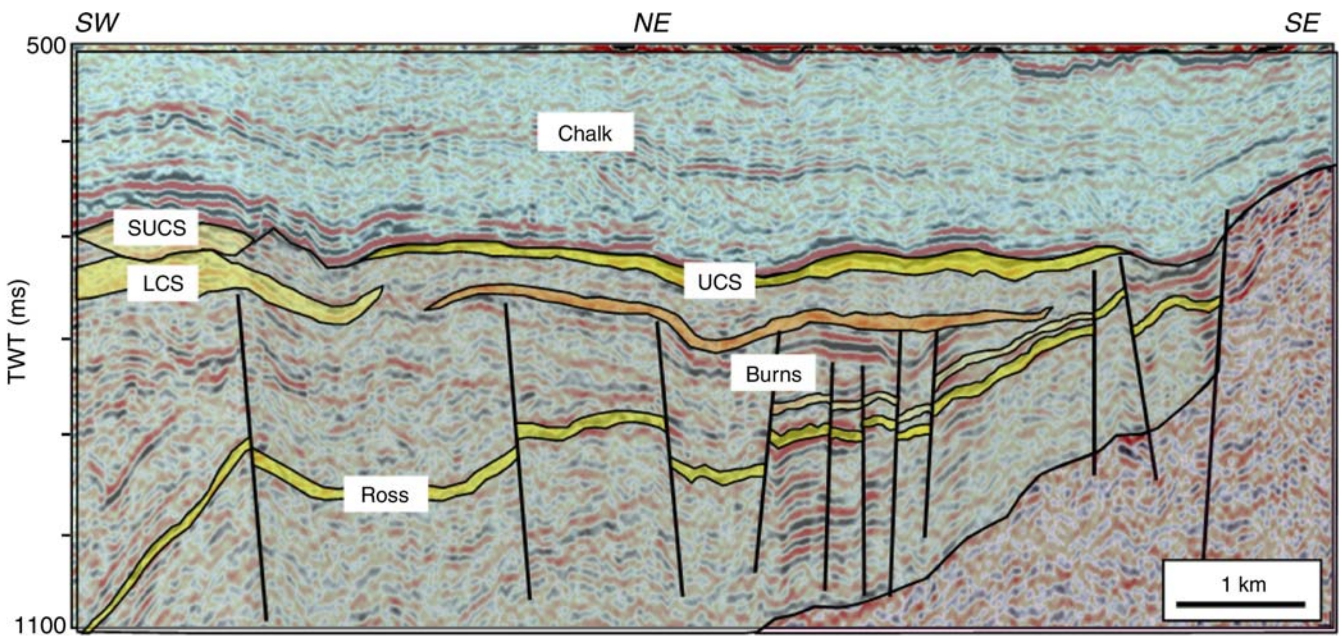

Fig. 12. Captain Field seismic, showing main reservoir intervals.

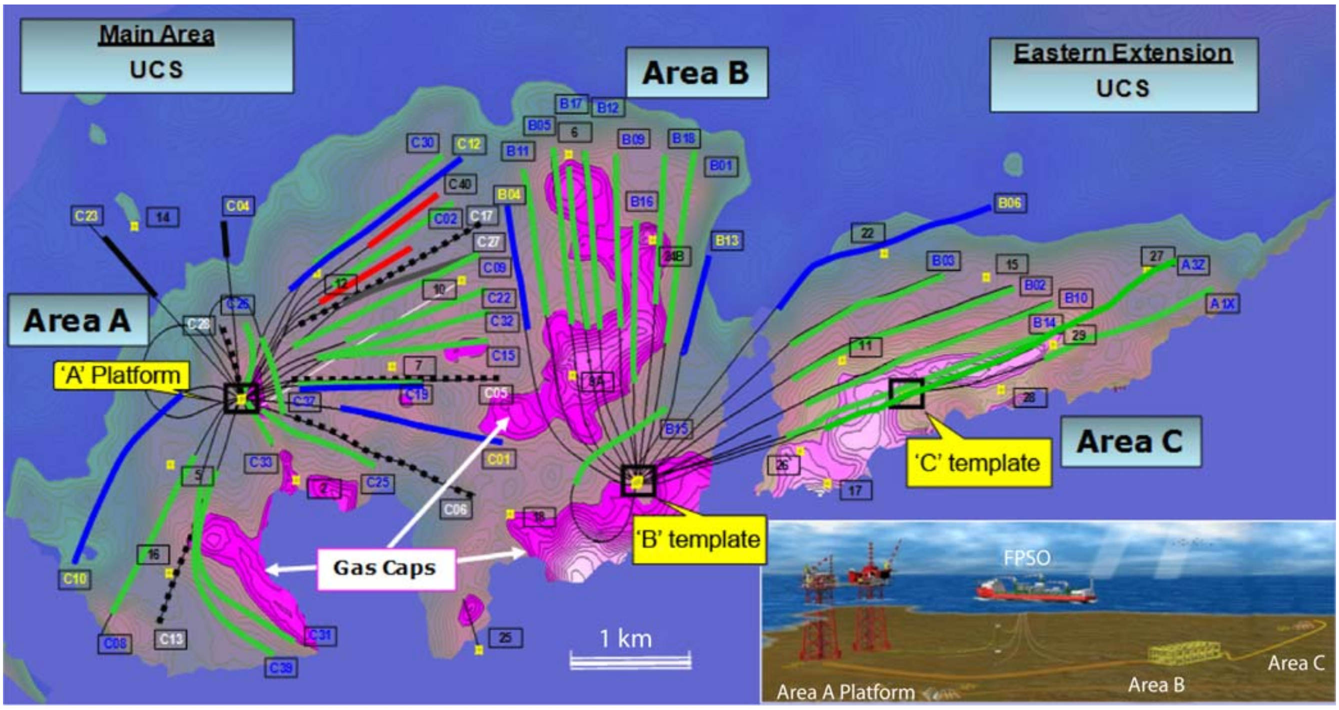

Fig. 13. Captain Field UCS map showing phased development areas.

oil above the producing intervals is shown in Figure 15. A key reason for the pilot holes is to reduce uncertainty and recognize upside in future well locations. This has been demonstrated in Area 'C' and the C39 well, southern lobe strategy that has accessed additional reserves to the south and west of the platform, previously thought to be too thin to develop. Horizontal and vertical pilot holes continue to be used on Captain to assess current targets and to appraise for future targets. As on Alba, the advent of azimuthal, deep reading resistivity geosteering LWD tools has reduced the need for drilling pilots to place wells at the top. The first true geosteering (deep-reading azimuthal resistivity) LWD tool used in 2005 provided significant benefits in capturing attic oil by drilling close to top reservoir. However, pilot holes are still required to assess reservoir thickness greater than 30 ft, and to gather information about deeper targets. Additionally, drop pilot holes are used at key locations to calibrate the seismic data and reservoir models.

Pilot well example. The A3 well was a subsea, horizontal well planned for the UCS in the eastern part of the field (Figs 13 & 16). This well was drilled because an earlier pilot hole had recognized upside in the area. The Ross/Burns reservoirs lie directly below the UCS and LCS. A drop pilot was planned for the Ross/Burns to test the OWC and reservoir continuity and communication between the Ross and minor Burns reservoir. The drop pilot was successfully completed. A new LKO (Lowest Known Oil) was found from the drop pilot, but no OWC. Pressure information proved that the LCS, Burns and Ross reservoirs were not in communication. After the drop pilot was completed, the horizontal well bore was drilled in the UCS. However, the dip in the top of the reservoir was not as expected and the pilot well dropped into a zone with higher water saturation. The well was steered up to find the top reservoir, which was encountered 40 ft higher than expected. A side track was then planned to follow the top reservoir and the final production well path was on average 25 ft higher in the reservoir than the original prognosed path. Reservoir simulation estimates indicate that an additional 1×10^6 bbl oil of reserves is expected from the final well path, a significant add to this target, since typical infill target size is approximately $2-3 \times 10^6$ bbl oil. It only took an extra day to drill the final well path and so the incremental cost was economically justified. Another key success of this well was the ability to generate a real-time rebuild of the reservoir model using distance to bed boundary calculation, enabling real-time simulation and informed decision making.

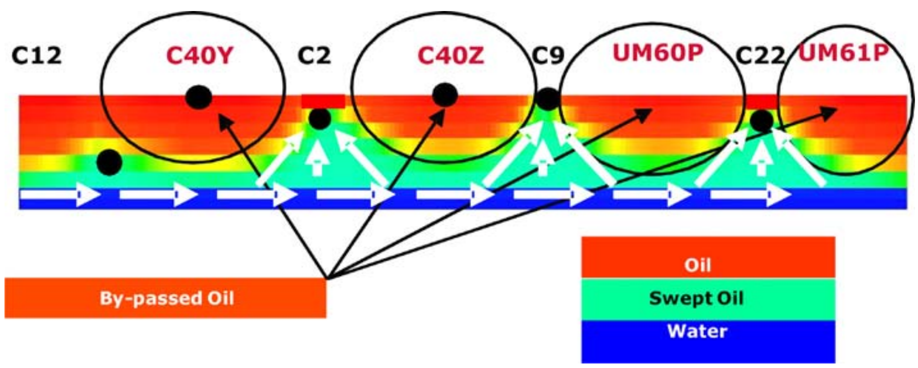

Fig. 14. Captain Field drainage schematic.

Future opportunities

Alba. The operator envisages that Alba Field has potential to produce 500×10^6 bbl oil (10% greater than currently estimated) through lower-cost drilling and target de-risking using the 4D seismic results. Although not currently slot constrained, due to a 5% annual well failure rate, Alba has many more, smaller targets than available slots. However, not all of them are currently economic, so alternative well construction techniques are under evaluation, including lower completions for increased shale tolerance and TTD (through tubing drilling). Additionally, multi-lateral wells, as recently drilled on Captain Field, are being investigated, allowing multiple targets to be drilled from one platform slot.

To allow targets further from the platform to be reached, managed pressure drilling (MPD) is planned. MPD is a method of regulating the bottom-hole drilling fluid pressure via a closed system of surface valves. This enables the 8.5 ft completion holes to be drilled with lower mud weights, overcoming the effective circulating density limitations currently experienced. This is because in smaller diameter ERD wells it is not possible to maintain sufficient overbalance to control reservoir pressure during connections, while also preventing fracturing of the overlying shale, without MPD.

Enhanced oil recovery (EOR) mechanisms are a potential alternative to the drill bit but are not currently attractive from a capital efficiency perspective. The most technically promising, polymer chemical flooding, works by wetting the reservoir sandstones to increase residual water saturation, thereby enabling additional oil to be produced. However, significant cost and logistical issues are associated with this technology.

Captain

The Captain Field vision is to recover 50% of the oil in place. Conventional field development options (close infill drilling and water flood) are forecast to recover 32% of the original oil in place. EOR mechanisms will be necessary to go beyond the expected recovery from conventional development and these are currently being investigated. High-resolution reservoir models are being used to predict polymer flood performance using different reservoir sensitivities. A pilot flood has been approved that will address flood performance, costs and logistical issues.

Two dual-lateral wells have been drilled on Captain Field and more are planned. Advantages are the ability to reach additional targets in areas of slot constraints, and economic advantages – dual lateral well costs have been 1.5 times those of a single well. Production challenges are being worked in long horizontal dual lateral wells in this highly viscous oil reservoir.

Both Alba and Captain continually evaluate new technology as appropriate. Seismic data is currently being reprocessed on Captain to better image the reservoirs and delineate future targets. Captain will test deep sidetrack well designs. Using existing trees, a sidetrack from the 9–5/8 ft casing will be attempted to replace a well with a lower completion failure and will optimally place the well higher to recover attic oil. Other improvements to

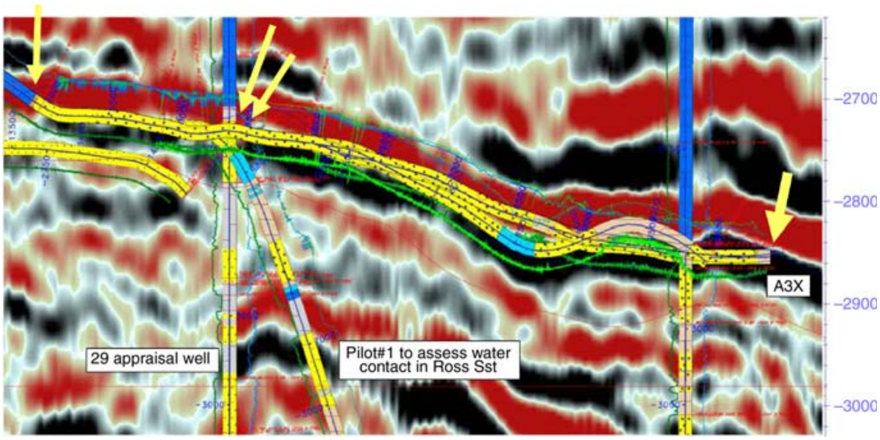

Fig. 16. Captain Field, Well A3 pilot holes, with seismic backdrop.

drilling and completion technology employed include placing cement in new wells higher to provide the option and flexibility to drill workover laterals.

Lessons learnt

Numerous lessons have been learnt during the ongoing development of Alba and Captain Fields. Their similarities have enabled these lessons to be shared to the mutual benefit of both assets and their owners. Some key lessons are listed below:

Seismic. Predicting water movement in a viscous oil system can prove challenging, particularly if the base reservoir and faults are poorly defined. Thus it is necessary to ensure that appropriate data acquisition and surveillance programmes are developed both before and during field development. Each new survey on Alba has improved reservoir understanding.

Maximum value must be extracted from seismic by processing and interpreting as quickly as possible. If reservoir image is a key uncertainty then reprocessing should be considered. Seismic processing techniques are continually being improved, so the value gained from reprocessed data will probably significantly outweigh the cost.

If the reservoir is suitable, it should be planned to acquire 4D data early in and throughout field life. The potential value of 4D data should not be underestimated and, if acquired early on, may change development plans and reduce Capex spend by optimally locating wells. Even the fast-track processed 4D Alba data has provided insights into fluid flow and water coning beneath producers.

Drilling/pilot holes. Early adoption of new drilling technology should always be considered. It can quickly add value. Rotary steerable systems and sand screen technology quickly opened up distant targets on both Alba and Captain.

Pilot holes, when appropriately used, can provide a cost-effective way to maximize value in a mature asset. As shown above, pilot holes can add significant oil volumes, establish current fluid contacts, minimize attic oil and lead to recognition of new target opportunities, thus increasing both production and reserves.

One should not always be driven by well costs, as a few extra days drilling can add significant value. Pilot holes on both Alba and Captain can be drilled in a few days, with costs being less than £0.5 mm.

Summary and conclusions

Alba and Captain Fields both have a number of subsurface similarities, including approximately 1 Bn barrels STOIIP; heavy oil (19° API), which is difficult to produce by conventional methods; very fine to medium grained, marine, mass flow sandstone reservoirs with good poroperm characteristics; and seismic resolution issues (but for differing reasons).

Development similarities include water flood for pressure support; one steel jacket, plus subsea templates; long horizontal development wells; pilot holes and LWD geosteering tools to optimize well locations; and production of more than original recoverable oil estimates.

Technology has provided three key enablers to help maximize production and reserves in these fields. These are 1) seismic technology – conventional and shear wave, streamer and OBC, 4D; 2) drilling technology – rotary steerable systems; long horizontal completion intervals; ERD; sand screens with gravel-packs; multilaterals; 3) pilot holes and geosteering technology – low cost, high benefit; LWD azimuthal geosteering tools.

Future technologies that may provide opportunities to further increase production and reserves include alternative well construction techniques, such as multi-lateral, slim-hole and managed pressure drilling, and enhanced oil recovery.

The benefits and business impact of these technologies include increased production and recovery potential, more wells from existing facilities, improved reservoir understanding and longer potential field life.

The authors would like to thank the Alba and Captain Subsurface teams for their valuable contributions and editorial advice. Thanks also to Chevron, the Alba co-owners (ConocoPhillips, StatoilHydro, BP, Total, Cieco and Endeavour) and Captain co-owner (KCCL) for their continued support and permission to publish this paper.

Locating the remaining oil in the Nelson Field

C. E. GILL and M. SHEPHERD

Shell UK Ltd, 1 Altens Farm Road, Nigg, Aberdeen AB24 5DG, UK (e-mail: Caroline.Gill@shell.com)

Abstract: The Nelson Field has been in production since 1994 and is at the mid-mature stage of field life. The current management strategy has focussed on identifying infill well locations with the aim of recovering bypassed oil. An increasingly detailed reservoir description is required in order to locate these opportunities and to help screen them for their economic viability. A systematic workflow has been followed through to localize those areas of the Nelson Field where the target oil volumes are most likely to be found. This workflow is given the name 'locate the remaining oil' within Shell. The aim of this workflow is to understand the relationship between sweep and the geological framework of the reservoir. On this basis, drainage cells are defined within the reservoir. Rather than behaving as a single 'tank' of oil with a common rising oil–water contact, the Nelson Field produces from nine discrete drainage volumes, each with separate producing oil–water contacts. The drainage cells have been defined on the basis of sedimentology, oil and water geochemistry in combination with quantitative volumetric analysis. Screening of the nine drainage cells in the reservoir has identified four cells that contain significant remaining volumes of mobile oil. These have then been investigated in further detail with a view to locating any stranded oil volumes that are unlikely to be produced by the existing well stock, and to determine if these are large enough to justify infill well drilling.

Keywords: bypassed oil, channelized turbidites, drainage cells, infill wells, Nelson Field

Many of the mature fields in the North Sea have been in production since the 1970s and the early 1980s. Nelson started production in 1994 and is one of the more recent of the large fields in the North Sea to come on stream. Yet by 2010, the Nelson Field has been producing for 16 years and is already at the mid-mature phase of its field life. At this stage, the reservoir is showing complex sweep patterns caused by the influx of both aquifer and injection water to replace the large volume of oil that has been produced. The result is a patchwork configuration of largely swept production fairways interspersed vertically and laterally with numerous bypassed oil pockets of various shapes and sizes.

A common theme in the management of offshore assets at this point in field life is the intent to maximize recovery by drilling new infill wells in order to target any bypassed oil volumes. In light of these difficulties, this paper describes pragmatic methods of predicting the location of remaining oil volumes in a mature producing offshore field. New offshore wells are deliberately targeted at locations where the high cost of drilling can be justified on the basis that the expected incremental oil reserves will be large enough to make the project economic. The task of defining new well opportunities can be challenging. As offshore fields age, it becomes increasingly difficult to establish with a high degree of certainty that any of the remaining oil pockets are big enough to justify drilling.

The basic difficulties involved in the practice of reservoir management of mature fields offshore can be summarized as follows:

(1) There are limits to the ability to map the detailed heterogeneity within a reservoir where there are so few well control points.
(2) It is not easy to detect the presence and location of the large target volumes, particularly in reservoirs with complex sedimentological-controlled heterogeneity.
(3) Locating the bypassed oil volumes is problematic in a reservoir with complex sweep patterns.
(4) It is hard to confidently estimate the range in target oil volumes given the uncertainty involved.
(5) Justifying the large expense of drilling wells is a challenge given an uncertain outcome.

The use of predictive models to plan infill wells

Predictive models of both the geology and sweep are required to plan infill wells. Given the sparseness of well control data offshore, these models tend to approximate to a first-order understanding of the reservoir character. Mapping at the macroscopic (inter-well) scale is used to establish both the main production fairways and those areas of the field where the geology is more complex. Cores and wireline logs in the wells will give a sense of the geological heterogeneity on a finer scale, and these provide an understanding of the detailed flow complexity, particularly with reference to sedimentological analogues at the outcrop scale. This level of analysis is usually sufficient to allow wells to be drilled with confidence in those areas of the field where they are likely to be in contact with large economic volumes of oil. These 'slam-dunk' wells tend to be identified and drilled early in field life. After field start-up, the intention is to keep a field on plateau for as long as possible and the drilling of low-risk targets will help to produce oil at sufficient rates to do this. This was the case with the Nelson Field, where the first production wells tended to be drilled in the thick sandy channel complexes rather than in the more heterogeneous areas of the reservoir. Once the more obvious targets have been drilled, then attention will be given to the medium- and high-risk volumes in the rest of the field. It is these types of targets that are commonly drilled in North Sea fields at the start of the 21st century.

There are three basic approaches that have been adopted by subsurface teams to define targets for drilling in mature fields offshore: (1) the reservoir engineering-led approach uses reservoir simulation models with the geological model at its core as the focus of defining remaining oil targets; (2) the geophysical-led approach uses 4D seismic data as the main basis for defining bypassed oil volumes in mature producing fields where the image quality is reasonable; and (3) the geology-led approach uses a predictive conceptual model which combines the reservoir geology framework and production data to help locate the remaining oil volumes. The task of locating the remaining oil, via a geologically led model, is the subject of this paper.

VINING, B. A. & PICKERING, S. C. (eds) *Petroleum Geology: From Mature Basins to New Frontiers – Proceedings of the 7th Petroleum Geology Conference*, 349–368. DOI: 10.1144/0070349

A workflow for locating the remaining oil

The workflow, which the geologist uses to evaluate infill potential in mature fields, has been called ‘Locate The Remaining Oil’ by Shell and ‘Target the Remaining Oil’ by Statoil (Wetzaeler *et al.* 1996; Hansen *et al.* 2002). It is based on techniques which were developed in the early days of production geology. Later, in the 1990s, the conceptual framework for locating the remaining oil volumes in mature fields was established when a number of important papers were published by staff from both the Bureau of Economic Geology at The University of Texas at Austin in the United States and Shell in Europe (e.g. Bryant & Livera 1991; Hamilton *et al.* 1998; Holtz & Hamilton 1998; Weber 1999).

The main steps in the workflow are as follows (Table 1):

Step 1: The reservoir geology is characterized within the context of a sequence stratigraphic subdivision. The sedimentological scheme is represented as lithofacies maps for each sequence and these show the major macroforms present. Macroforms are sediment bodies which are found at the macroscopic level of heterogeneity, that is, at a scale of hundreds of metres. The structural framework is also mapped and any faults delineated.

Step 2: The second stage involves understanding how the fluid flow within the reservoir is influenced by the geological framework. In a producing field, a basic analysis of reservoir performance will focus on determining the main production fairways accessed by the production wells, the location of volumes of ‘slow oil’ in low permeability rock and where oil is trapped in large dead-end volumes. There are two ways insights can be gained on how the reservoir geology influences fluid flow. The first involves the use of analogue data, either from producing fields with similar geology or from appropriate field outcrops. For example, if a nearby field producing from the same stratigraphic interval is known to show specific production patterns related to the reservoir architecture, then these are features that are worth looking for in the field under review. Outcrops with a similar environment of deposition to the reservoir in question can also be used to give insights as to how the geology may influence production behaviour. The second approach uses data integration techniques. Data integration is the main method for co-analysing geology and production data (Bryant & Livera 1991). The analysis focuses on understanding both the controls on vertical flow and the controls on areal flow within the reservoir. By combining production data with the geological interpretation, common patterns may be observed that show how the reservoir architecture is influencing the production pathways within the field. The method mainly involves graphical overlays of the two data types.

Step 3: Once the vertical and lateral controls on flow have been mapped out, these features are combined to define drainage cells (compartments) within the field. This is an important step, as it allows the production performance of the reservoir to be framed and localized within the field. Quantitative volumetric analysis of volumes in place v. the cumulative oil production at the drainage cell level will indicate those areas of the field where the larger volumes of remaining oil are more likely to be found.

Step 4: The next step involves looking for individual targets within each drainage cell, particularly those cells with significant remaining oil volumes. Specific trapping styles are looked for as a means of identifying target volumes.

Table 1. Workflow for locating the remaining oil in mature fields

1. The geological conceptual model is established for both the sedimentological and structural framework.
2. An analysis is made as to how the geological framework influences fluid flow.
   - 2.1 Analogue producing fields and outcrops are analysed to get insights into the producing characteristics of the review field.
   - 2.2 Data integration techniques are used to try to understand how the reservoir performs. This involves identifying the major permeability barriers to vertical and lateral flow.
3. Drainage cells (self-contained tanks) are defined within the reservoir. The remaining oil volumes are quantified for each drainage cell.
4. The trapping style within each drainage cell is established with view to defining target oil volumes for infill wells.

Background information on the Nelson Field

The Nelson Field is located in blocks 22/11, 22/6a and 22/12a in the UK Central North Sea. The field shows an elongate dip-closed structure and is one of several Paleocene-age oil fields located above the Forties Montrose High (Fig. 1).

The reservoir interval comprises sandstones of the Paleocene Forties Sandstone Member. The Forties Sandstone Member overlies the Lista Formation in a conformable relationship and is itself overlain by shales of the Sele Formation. The latter forms the seal for the field (Fig. 2).

The Nelson Field is developed with a 36-slot minimum facilities platform with a four-well subsea template to the south which is tied back to the platform (Fig. 3). The production facilities have a peak daily capacity of 160 000 barrels of oil and 65 million ft^3 of gas. Total liquid capacity is 250 000 barrels of fluid. The hydrocarbon type is a light 40° API oil with a gas–oil ratio of 555 scf/bbl. Live crude is exported by pipeline via the Forties Field to Cruden Bay on the east coast of Scotland. The oil originally in place is estimated at 790×10^6 bbl. Current cumulative oil production is approximately 430×10^6 bbl. Maximum production rates were approximately 160 000 barrels of oil per day in 1995 and the current rate is 20 000 barrels of oil per day.

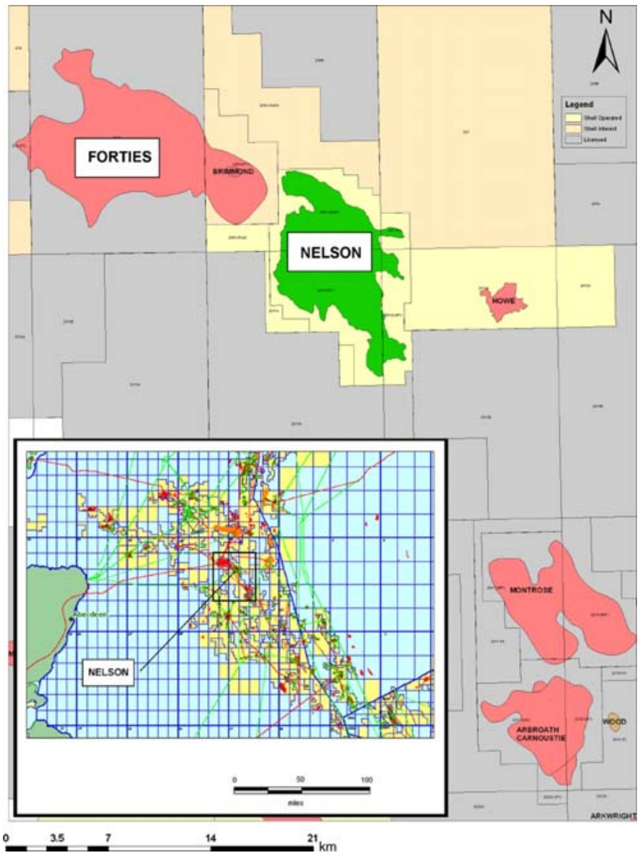

Fig. 1. Location of the Nelson Field in the Central North Sea.

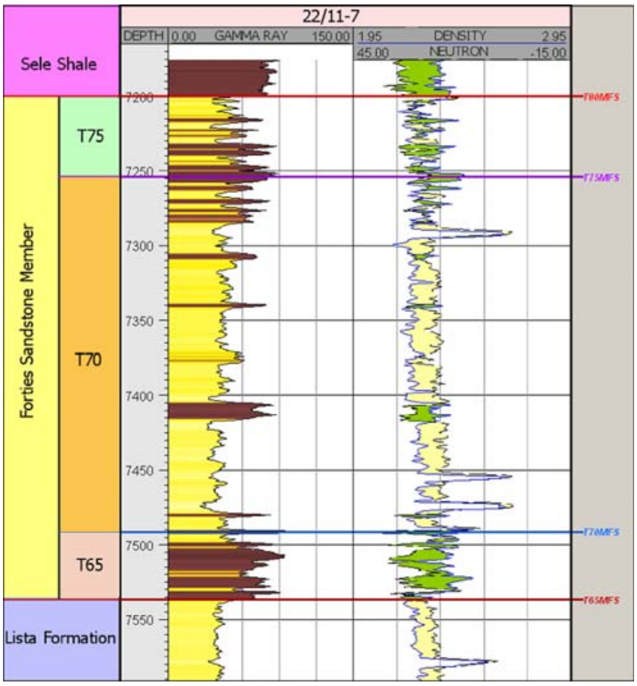

Fig. 2. Type well for the Nelson Field, well 22/11-7. The Paleocene Forties Sandstone Member comprises the reservoir interval for the Nelson Field. The T65, T70 and T75 sequences provide the stratigraphic framework for reservoir characterization.

Oil is produced from two main reservoir units in the Nelson Field; the stratigraphically younger unit is the T75 sequence, which is underlain by the T70 sequence. The principal areas of oil production are from three NW–SE trending sandstone-filled channel complexes, termed hereafter the western, central and eastern channels (Figs 4–6). The reservoir quality is excellent with overall net to gross in the main channel fairways averaging 70%, porosity averaging 23% and zonal average permeabilities ranging from 150 to 300 mD (Kunka *et al.* 2003).

The turbidite channel complexes are genetically linked to and flanked by channel margin deposits. These sediments comprise low net to gross (average 45%) interbedded shale and sandstone intervals. The turbidite channel complexes follow topographically low areas and show incision of the basal surface into underlying marine shales or pre-existing turbidite channels.

Pods of marine shales with thinner overbank/splay deposits lie in the areas between the channel complexes. These areas represent interchannel sediments.

The central channel complex (T70 sequence)

The central channel is in the older T70 sequence, which is separated from the younger T75 sequence by shales representing the T75 maximum flooding surface (MFS; Fig. 4). The overbank and splay deposits are thick and laterally extensive.

The western channel complex (T75 sequence)

The western channel complex is the stratigraphically youngest of the Nelson channel macroforms and was deposited to the west of the bathymetric high formed by the sediments of the older central channel complex (Fig. 4). The lower section shows an onlap relationship onto the basal surface, indicating that these sediments have ponded into a pre-existing channel feature. The upper portion is more tabular, and extends beyond the area of ponded channel fill sediments. It connects into a series of splay sands in the margin and interchannel area above the central channel complex (Fig. 7).

The eastern channel complex (T75 sequence)

The eastern channel complex was deposited on the margin of the topographic high left by the sediments of the central channel complex (Fig. 4). The eastern channel complex is more proximal than the western channel complex with higher energy deposits made up of multiple incised channels showing sharp channel boundaries. Only the western edge of the eastern channel is within the oil leg of the Nelson Field; the bulk of the channel complex extends to the east below the original oil–water contact (OWC).

Sea water injection is provided by four injection wells, situated peripherally around the field and located in the channel complex areas. These provide pressure and waterflood support to the production wells. The two seawater injectors in the north of the field are now used for produced water reinjection.

The use of analogue information to help understand remaining oil configurations in the Nelson Field

The Nelson Field produces from sediments that formed in a channelized turbidite setting. A review of technical papers on analogue producing fields and outcrops of channelized turbidite systems has been made with the aim of determining whether common patterns exist that can give an idea of how the geological characteristics of channelized turbidites control production behaviour and the location of bypassed oil volumes. A number of production patterns are known or have been inferred from analogue data and these are discussed below (Fig. 8).

Production patterns in channelized turbidite reservoirs

Amalgamation of sand complexes. Reservoir connectivity is controlled by the degree of lateral and vertical amalgamation of individual channel complexes. A spectrum of connectivity relationships can be seen in analogue reservoirs varying from total isolation of individual channels to widespread amalgamation of channel complexes to form a well-connected reservoir volume (e.g. Eubanks 1987).

Mud drapes. Sand-to-sand connectivity is sensitive to the amount of shale interbeds in the channel complexes (Weimer & Slatt 2004). Mud drapes are elements which act as baffles or barriers in these systems, forming as silty intervals overlying incised channel-form erosional surfaces (Beaubouef *et al.* 1999; Larue 2004).

Shale blankets. Thin but laterally extensive shale and debris flow horizons are known to act as vertical flow barriers in turbidite systems (Lowry *et al.* 1993; Hempton *et al.* 2005). They can act as surfaces to support water over-run and can also trap oil beneath them. An example of oil trapped below extensive shales is described from the Magnus Field (Fig. 8) (MacGregor *et al.* 2005).

Bypassed oil in channel margins. The channel complex fairways act as the main conduits for waterfloods, whereas channel margins commonly contain bypassed oil volumes. These volumes may be depositionally isolated as a result of flow barriers caused by complex channel–levee–overbank stratigraphic relationships (Cronin *et al.* 2000; Beaubouef 2004). Collapse structures are common on levee margins in channel–levee complexes and this may also contribute to poor connectivity. Alternatively, bypassed oil may occur even where there is good reservoir connectivity between the channels and the channel margins. The channel axes tend to be well swept in waterflooded reservoirs and there can be a tendency for oil to be bypassed or ‘banked’ in the channel margin areas. Subsequent sweep can isolate and immobilize large individual oil pockets in these areas as has been described for the Yowlumne Field in the United States (Clark *et al.* 1997).

Data integration

As a generalization, each producing field has a distinctive character in terms of its reservoir performance; certain dominant character traits tend to control the production behaviour. In order to understand the reservoir performance in this way, it is necessary to carry out a detailed analysis as to how the geological framework influences fluid flow.

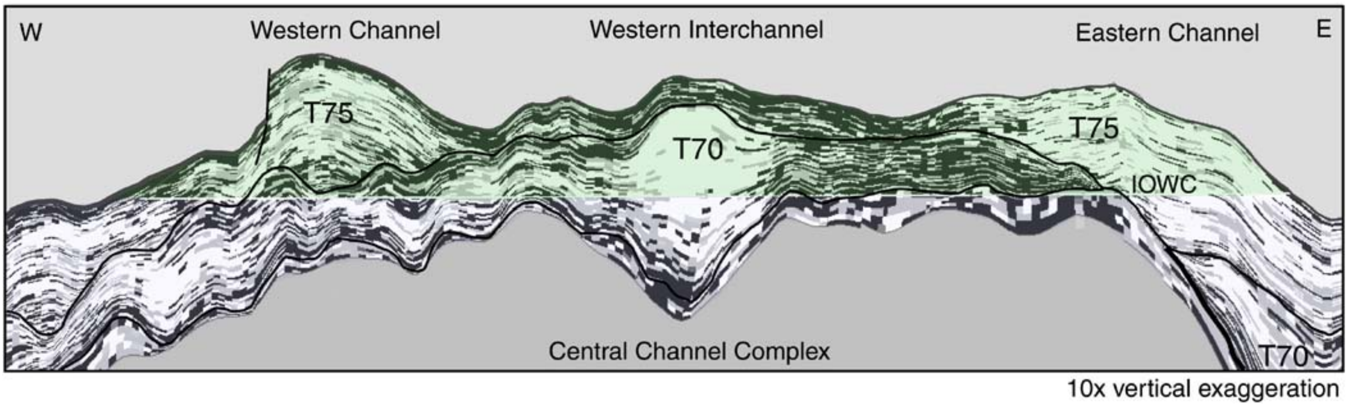

Fig. 4. Schematic net to gross cross-section west–east through Nelson Field showing the principal reservoir intervals. For the line of section see Figure 3. IOWC, initial oil–water contact.

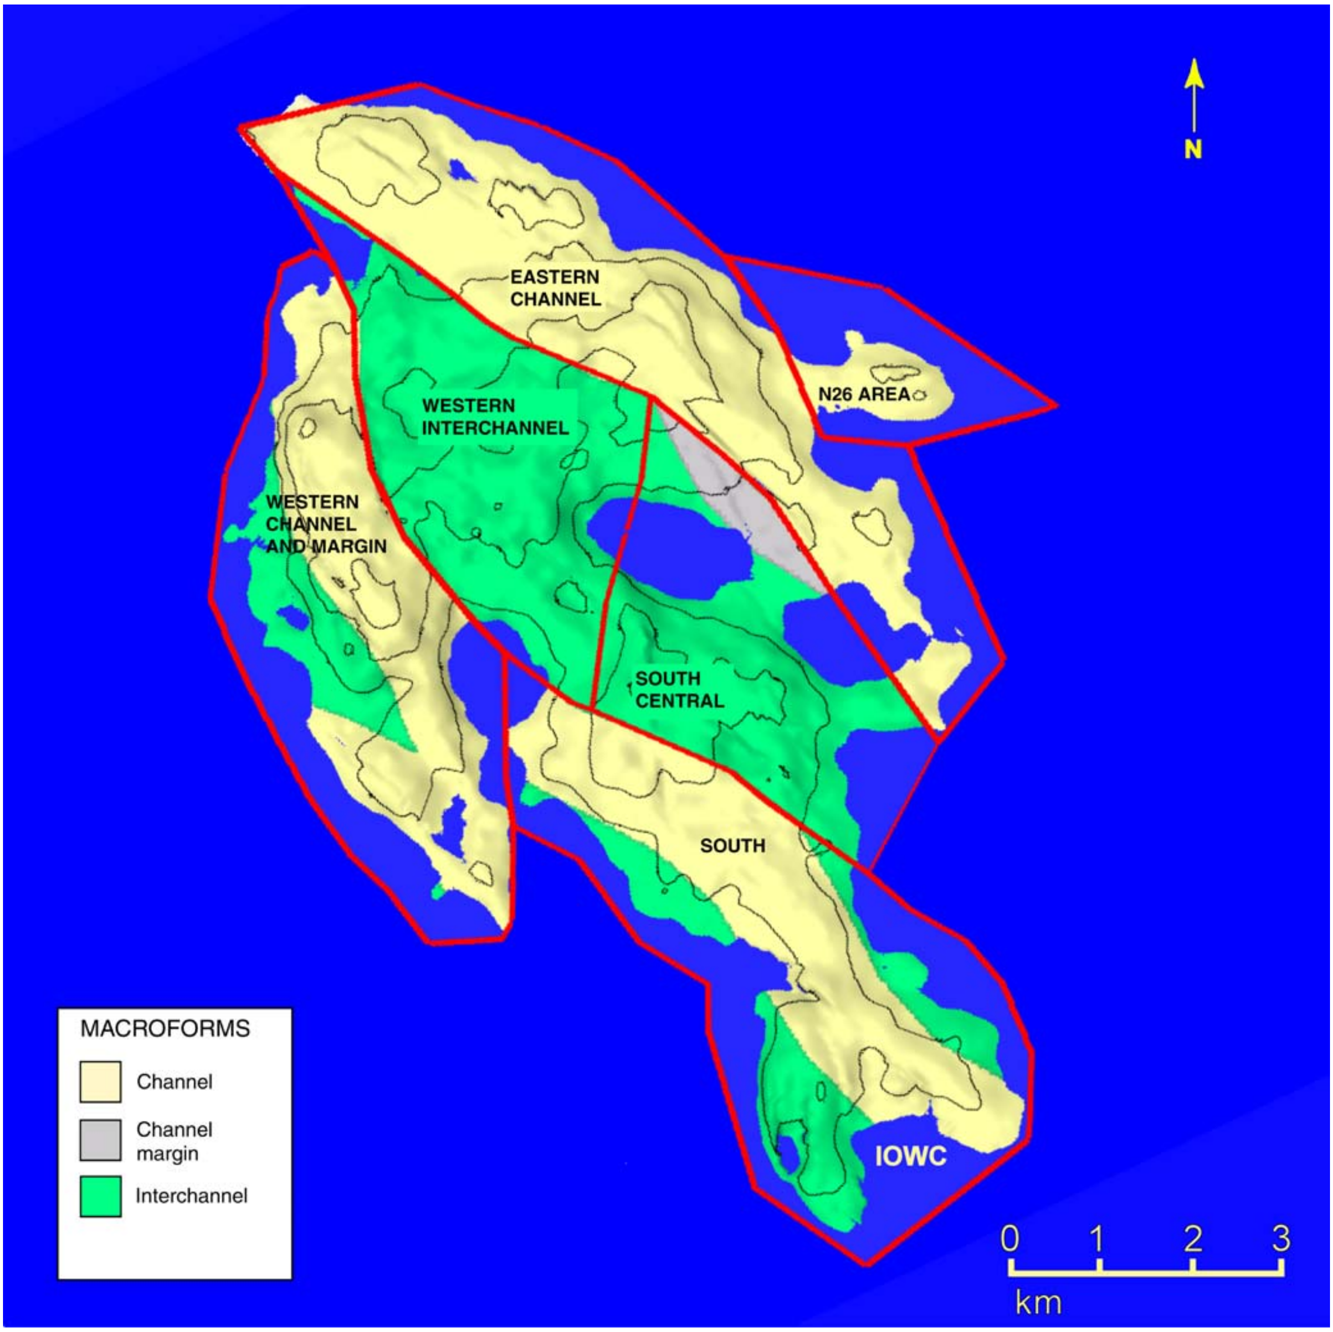

Fig. 5. Macroforms and drainage cells within the T75 reservoir unit. IOWC, initial oil–water contact.

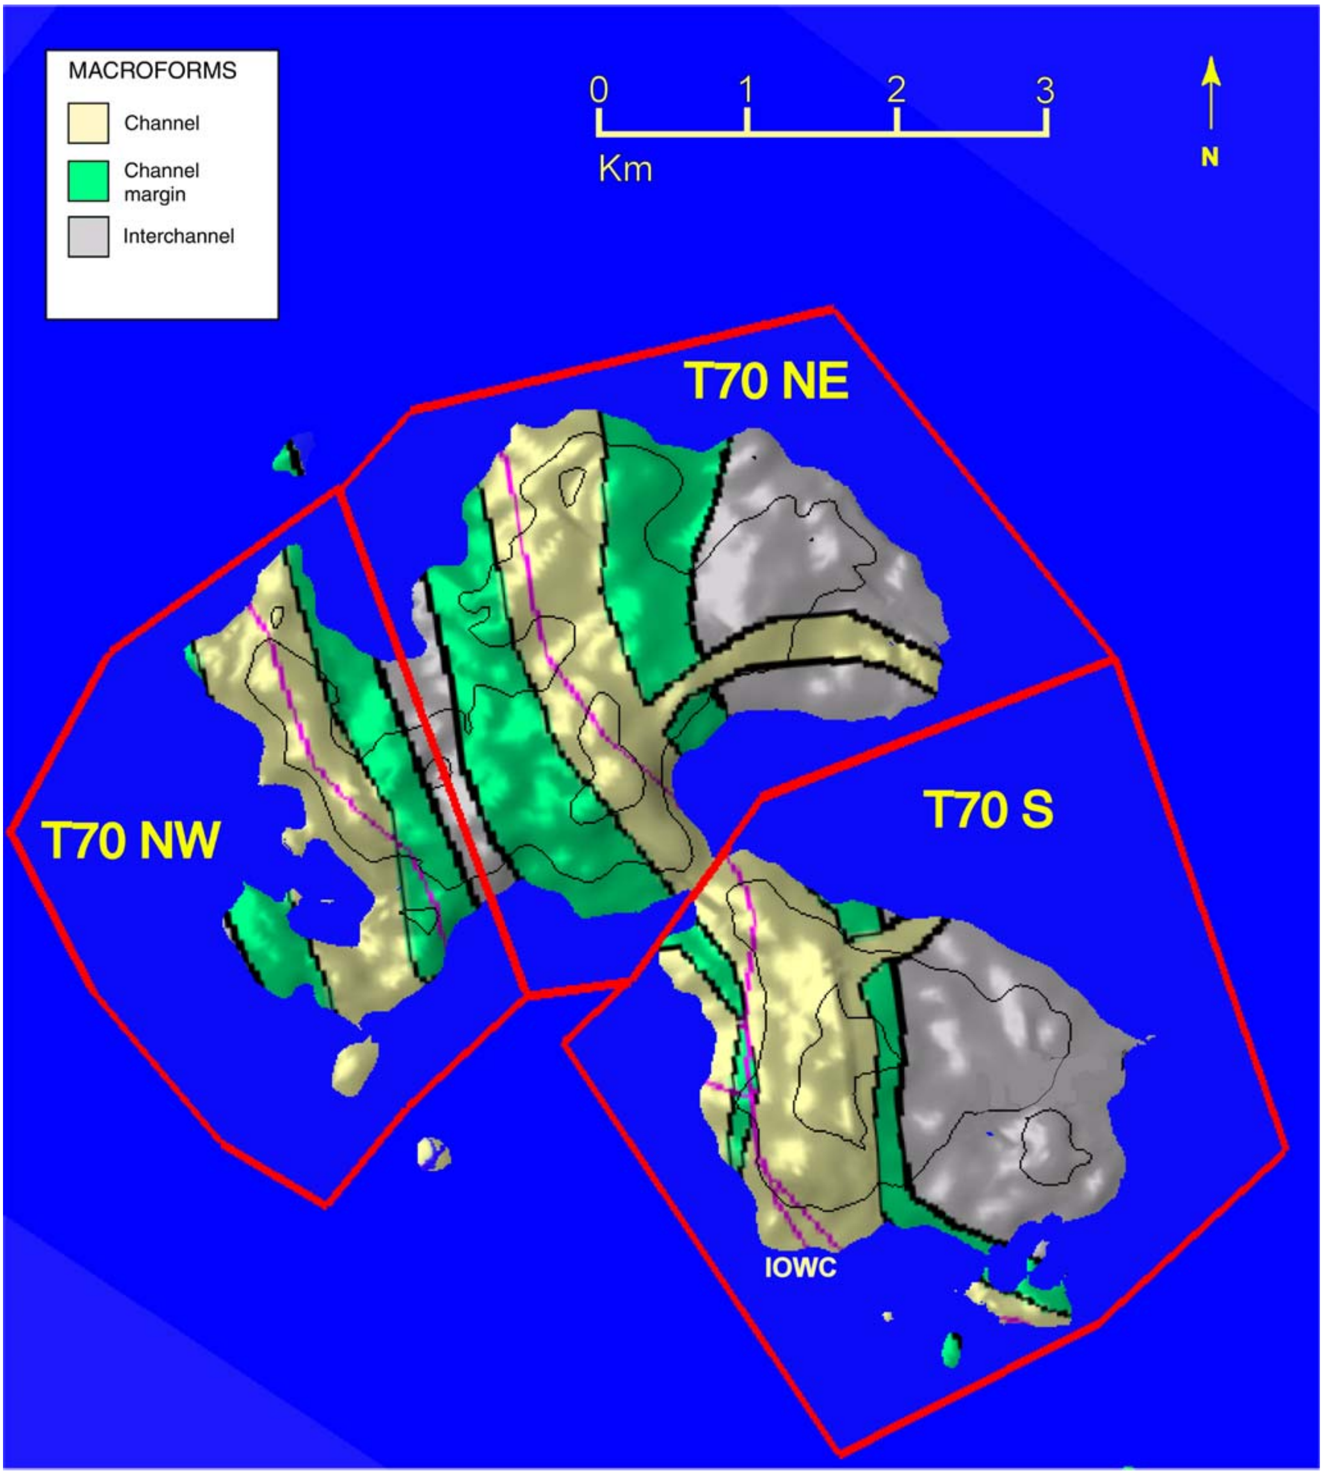

Fig. 6. Macroforms and drainage cells within the T70 reservoir unit. IOWC, initial oil–water contact.

Data integration involves compiling a dossier of individual observations relating sweep patterns to the geological framework. Over a hundred observations have been collected for the Nelson Field. Most of these have been made on a well-by-well basis. The observations are then linked together and illustrated by annotated maps and cross-sections showing both the geological framework and the sweep patterns. The aim is to produce a field-scale conceptual model to help explain the production behaviour of the reservoir. The process can be compared with using individual clues to help solve a giant 3D puzzle.

Data integration as applied to the Nelson Field

As applied to the Nelson Field, data integration methods tend to produce two types of 'clue'. Overlays of production data onto geological cross-sections provide clues on vertical flow controls; overlays of production data onto lithofacies maps give clues as to the controls on the horizontal flow component within the reservoir. To help with this analysis, the geological interpretation for Nelson was revised with the objective of providing lithofacies maps for each reservoir sequence (Figs 5 & 6).

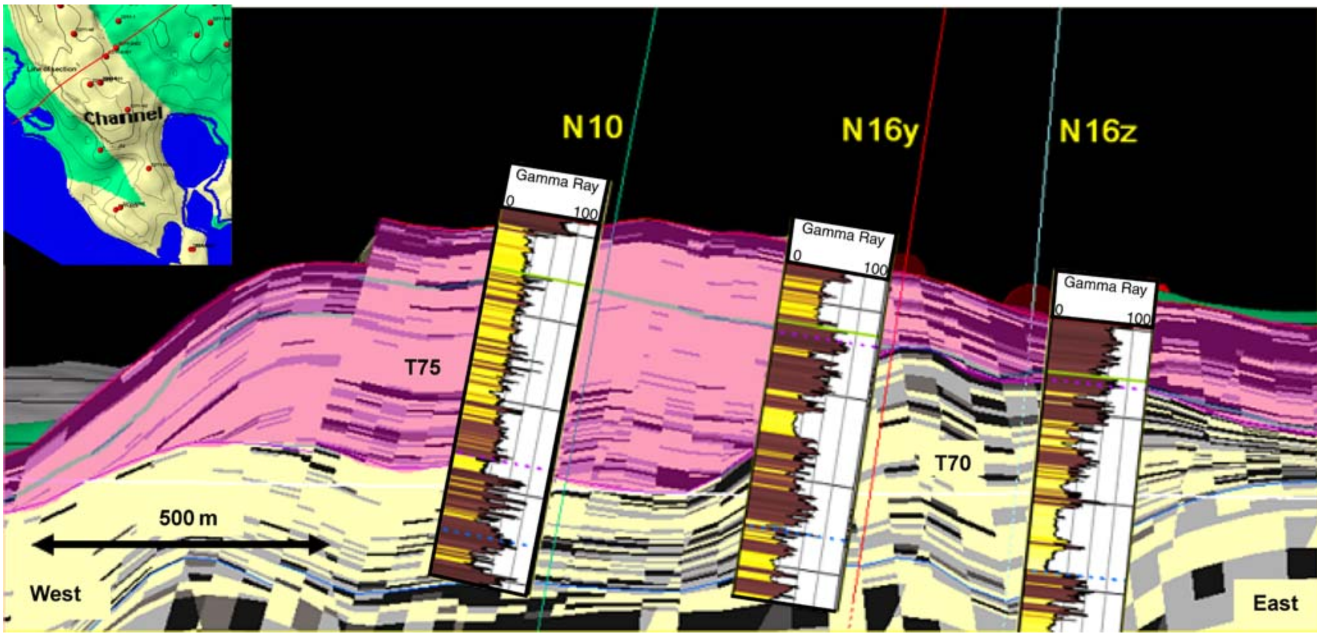

Fig. 7. West–east cross-section through the western channel showing the fill and spill geometry of the T75 unit; five times vertical exaggeration. The lower section onlaps onto the basal surface, with the sediments having ponded into a pre-existing channel feature. The upper portion is more tabular, and extends beyond the area of ponded channel fill sediments.

Methods of detecting geological influence on vertical flow

Methods used to detect geological influences on vertical flow have involved the investigation of patterns of OWC movement, water cut histories and documentation of pressure differences across shales and geochemistry. The aim is to subdivide the reservoir vertically into hydraulic units. The term hydraulic unit is used in the sense that these are reservoir intervals that show internal communication, but are bounded at the top and base by extensive permeability barriers to flow (Haldorsen & Lake 1984).

Oil–water contact movement. The OWC in a producing field will rise as a consequence of production. In the Nelson Field, the OWC rise can be measured by open hole logging in new infill wells or by production logging in existing wells. There have been several phases of infill drilling and open hole logs from these wells have provided good quality data to track OWC movement as a result of production (Fig. 9). Production logs, including pulsed neutron logs, have been run repeatedly in key oil producers in the field. Repeat production logs will give a history of how the OWC is rising over time. Various patterns may be seen such as a steady, continuous rise in the OWC, a static OWC or an OWC that rises for a few years and then becomes static, typically below a shale bed. These patterns can be used to infer the nature of aquifer influx. A continuously rising OWC indicates a bottom-water drive mechanism, whereas a static OWC is indicative of a baffled or edge-water drive operating. If a shale bed is observed to impede the rise in the OWC for a long period of time, then it is likely to be acting as a major baffle or a widespread permeability barrier to vertical flow.

The movement in the OWC is referenced to the initial oil–water contact (IOWC) as a datum level. In the Nelson Field the depth of the IOWC varies from 7449 to 7502 ft true vertical depth subsea (TVDSS) with a mean of 7470 ft TVDSS (Kunka *et al.* 2003).

Water shut-off performance. Water produced from the perforated interval of a production well can cause the fluids flowing up a well to be loaded with water, thus reducing the total flow rate. Once water cuts are in excess of 90–95%, the water-producing interval will be isolated by inserting a plug above them. The plug will be located opposite a shale interval in the wellbore. If the shale is laterally extensive then the water shut-off operation will prove successful in isolating or reducing the water production for some time. Both the plug and the shale in the reservoir behind the liner act together to isolate the open perforations in the well from a direct pathway for water influx from the swept zone. If the shale is not extensive, then water production will be unaffected in the well or will be reduced for only a short period. Water shut-off performance was used by Hamilton *et al.* (1998) to evaluate the status of permeability barriers within the Jackson Field in Australia. The result of each operation was recorded as a water shut-off table in terms of the reduction in water cut and for how long the plug was successful in doing this. This table gives a qualitative idea of the extent of individual flow barriers within the reservoir. Water shut-off events have been analysed for the Nelson Field. An example of successful water shut-off was seen in the N20z production well. A bridge plug was set opposite the T75 MFS in late 2004. This reduced the water cut from 80% to zero water production. Thus the T75 MFS appears to act as an effective barrier in this part of the field (Fig. 10).

Post-production formation tester logs. A vertical profile of formation pressures can be measured in infill wells using formation tester logs, for example, Schlumberger's RFT and MDT logs. The data are used to make a pressure–depth profile and this can show where differential depletion has resulted in a pressure difference across a barrier to vertical flow, a shale for instance. For example, the 22/11-A3 well was drilled in the south of the field in 1995. The formation tester logs run seven months after the start of field production showed a 210 psi pressure differential across the shale marking the T75 MFS (Fig. 11). This indicates that the shale is a significant permeability barrier to flow in the south of the field. In this area of the reservoir, production at the time was mainly from the T75 sand sequence, whereas the T70 sand sequence was effectively undepleted.

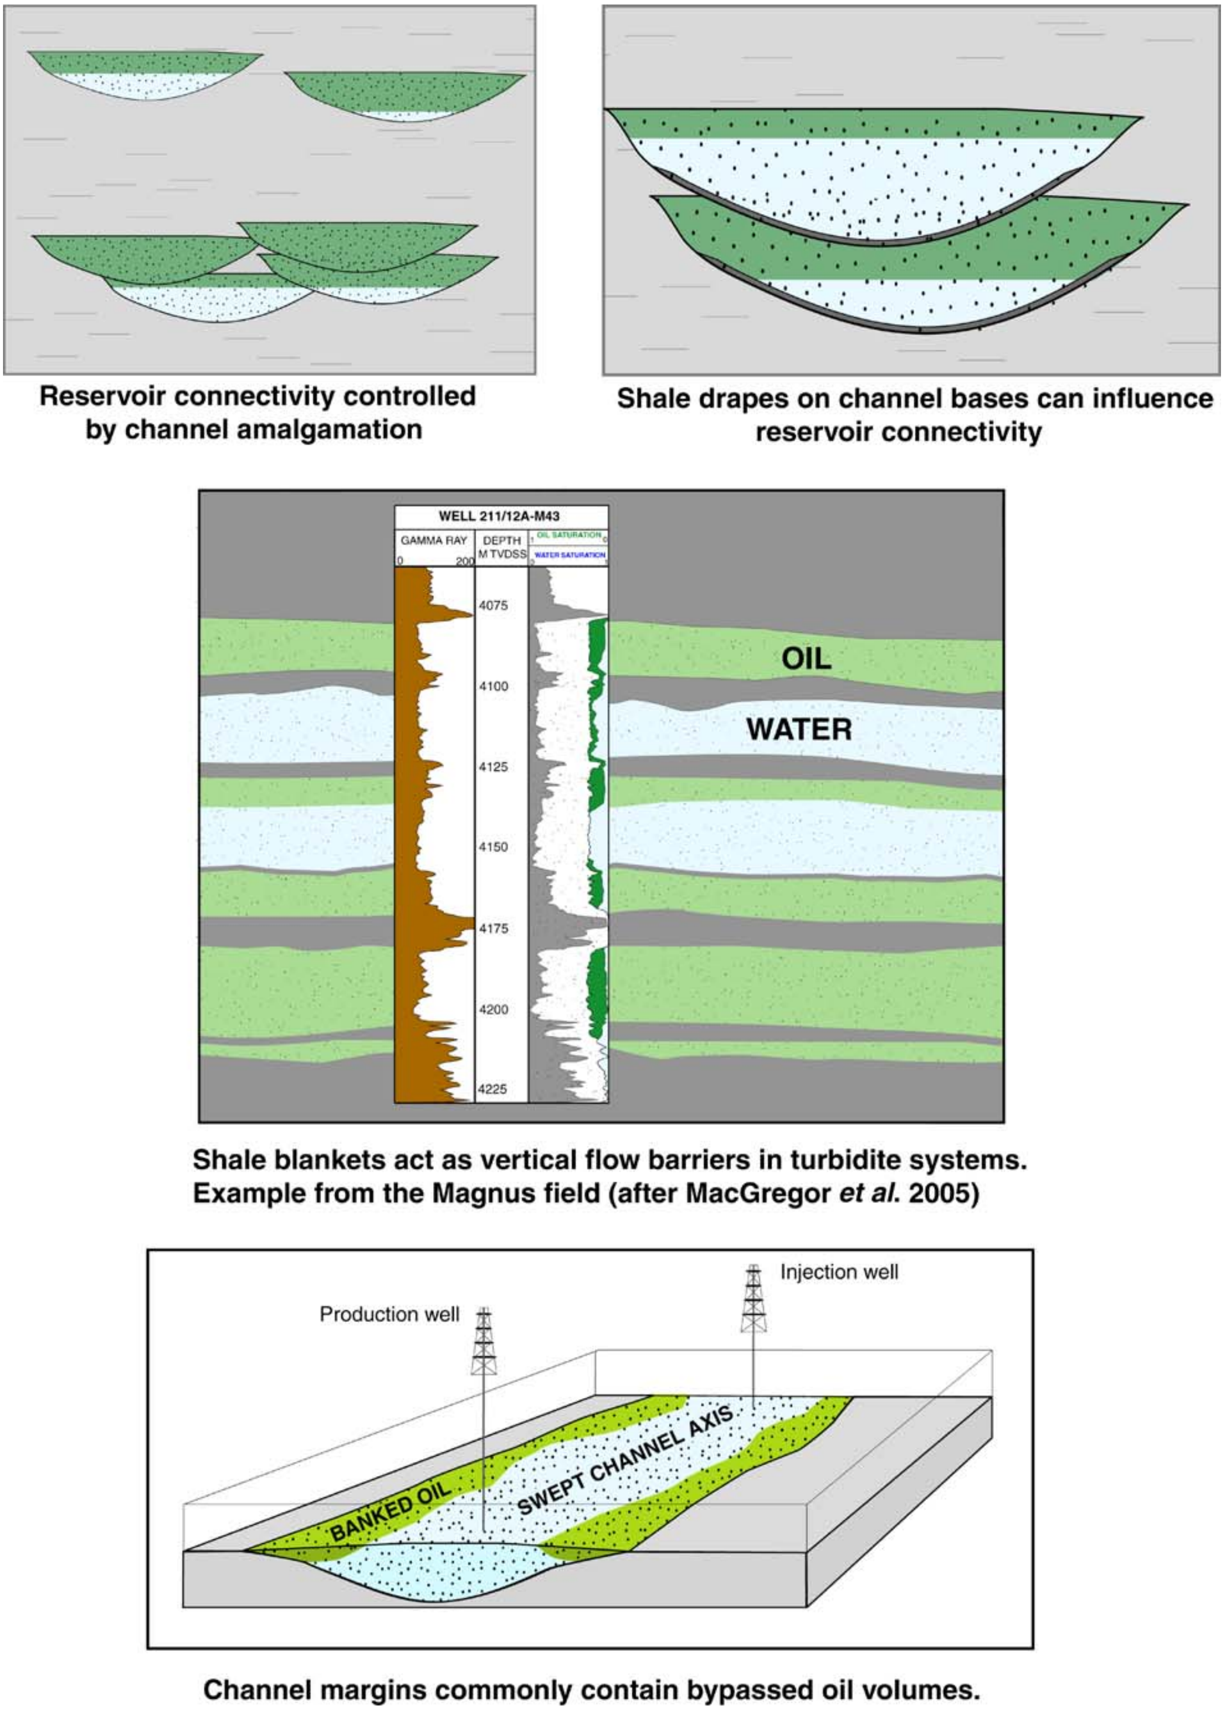

Fig. 8. Analogue information from fields with turbidite reservoirs has been used to help locate the remaining oil in the Nelson Field. Reservoir connectivity is controlled by the degree of channel amalgamation. Lateral connectivity is affected by shale drapes and shales blankets. Water over-run and bypassed oil is shown from the Magnus Field (MacGregor *et al.* 2005). Banked oil results from the preferential ingress of a waterflood along channel axes as in the Yowlumne Field, California (Clark *et al.* 1997).

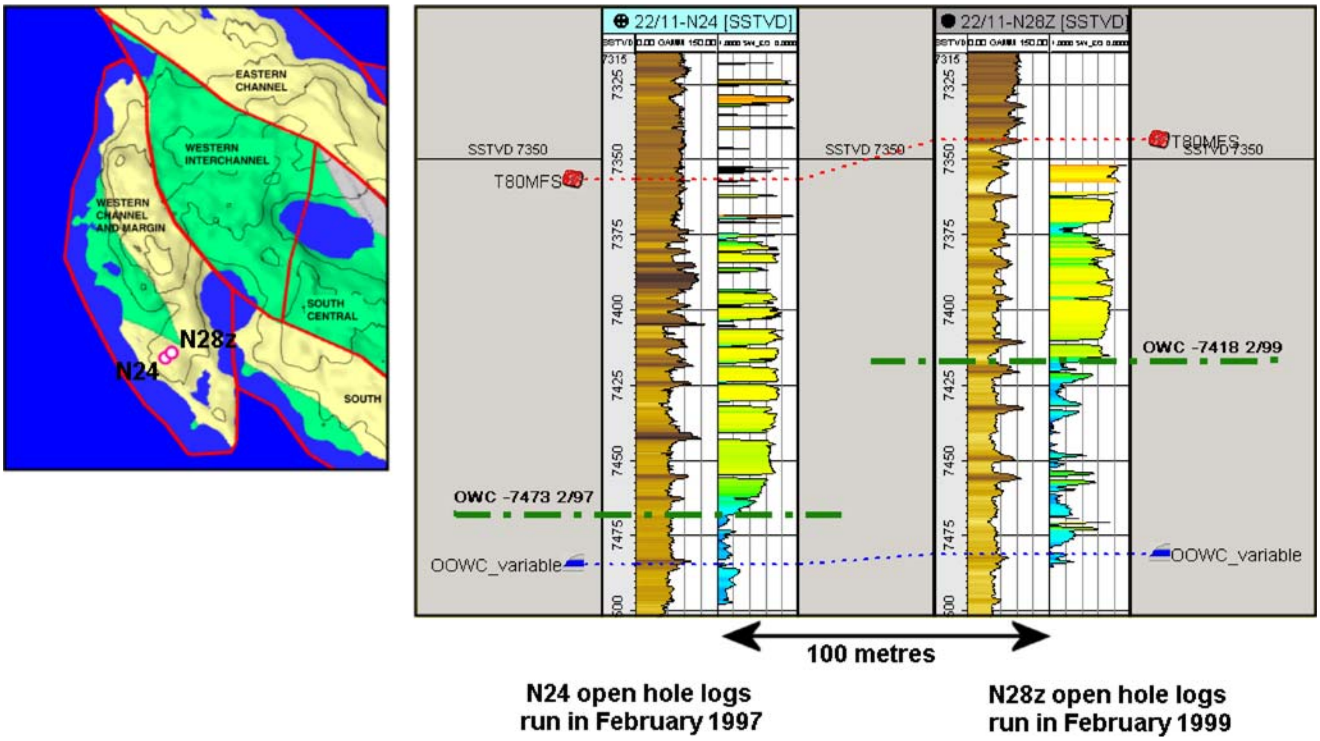

Fig. 9. Open hole gamma-ray and resistivity logs from two closely spaced (100 m apart) wells in the Western Channel (22/11-N24 and 22/11-N28Z). The OWC, shown as a green dashed line, had risen by 55 ft in two years. This is a fast-rising OWC which does not appear to have been impeded by shales. The resistivity log in 22/11-N28Z shows some thin zones, about 2–3 ft thick, showing some minor unswept oil left behind. The inset map shows the position of the wells.

Shut-in crossflow. It is common practice to record a shut-in flowmeter pass while running production logs in an oil producer. These will show where crossflow is taking place because of the presence of differentially pressured zones opposite the perforated interval of the well. The well is shut in so there is no flow to surface while logging. The log will show flow from a high pressure zone into a low pressure zone within the reservoir, if these exist. The permeability barrier separating the zones can often be picked on these logs. This marks the depth where flow out of the high-pressured interval flips over to flow entering the low-pressured interval. For example, shut-in flowmeter passes were used to establish the presence of a major shale baffle in well N15 in the western channel (Fig. 12). There is also evidence for a slow-moving OWC immediately beneath the shale.

Water geochemistry. The continuous sampling of produced water from each individual well throughout the lifetime of the Nelson Field means that it is possible to plot the variation in produced water compositions between wells across the field area and in individual wells with time. The ability to monitor variations in water major element chemistry with time can be considered as a time-lapse geochemistry method akin to similar methods that use oil geochemistry data (Milkov *et al.* 2007). In addition, the changing intervals open to production in the wells gives some sense as to the vertical variation in water composition.

For example, there is a systematic decrease in the produced water chloride ion concentration upwards through the reservoir. The uppermost unit in the reservoir produces water with the lowest chloride ion concentration. These low-salinity water samples are

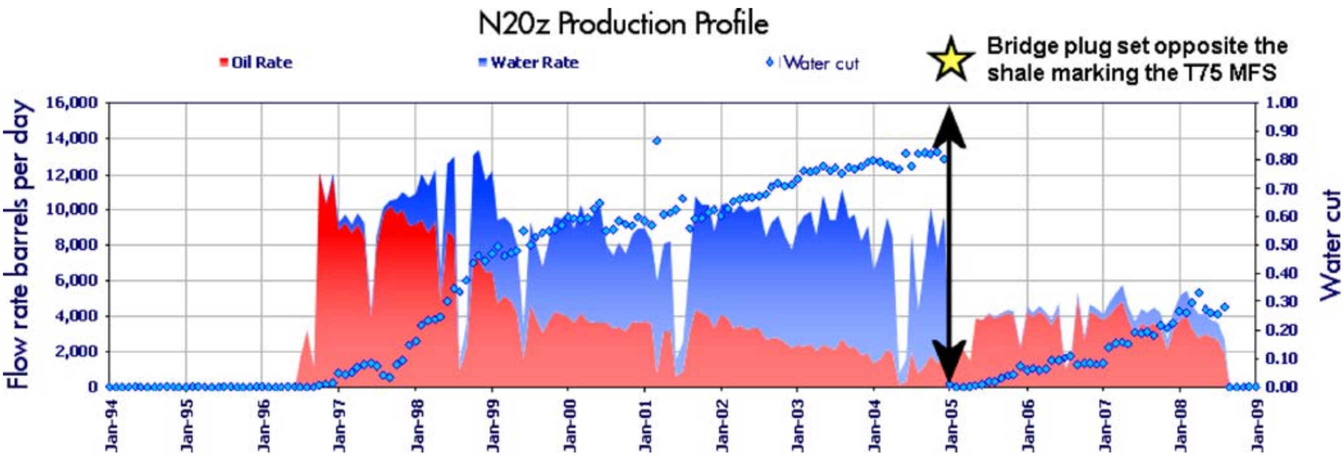

Fig. 10. A bridge plug set in late 2004 opposite the shale marking the T75 MFS was effective in reducing water production in well N20z. This indicates that the shale is laterally extensive and acts to impede the upward movement of water.

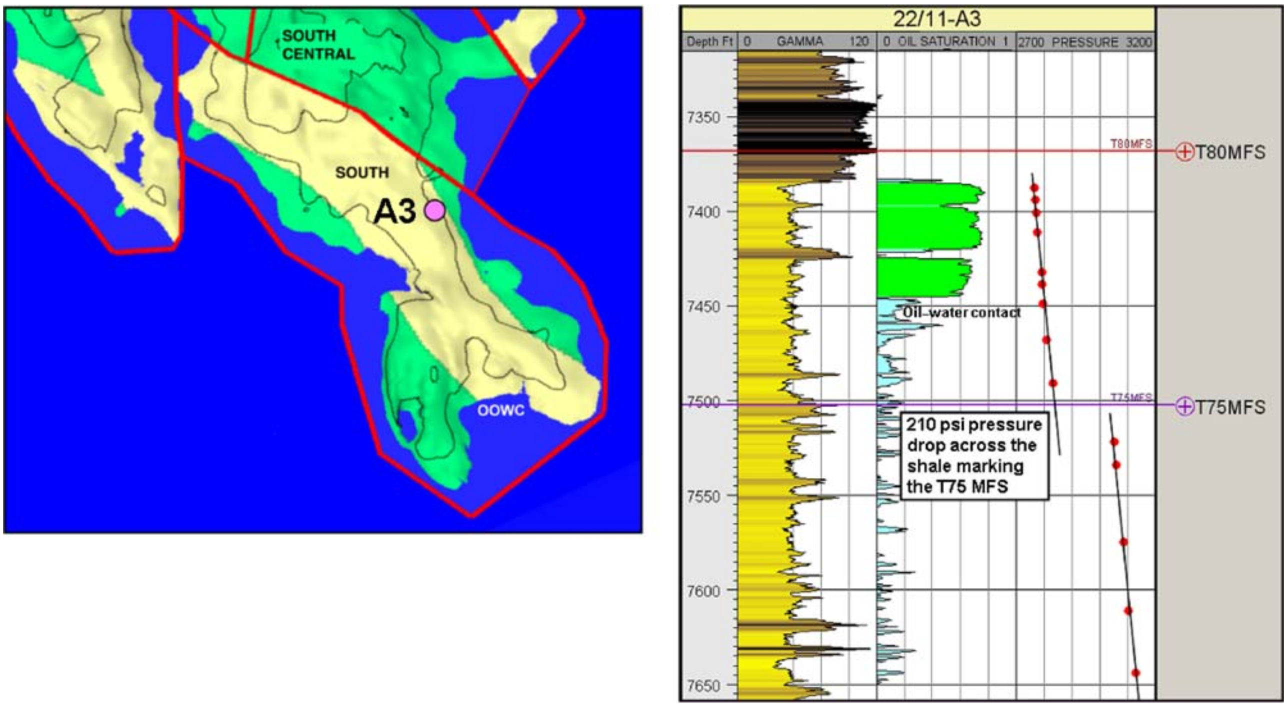

Fig. 11. Formation pressure-tester plot for well A3. The plot shows a 210 psi pressure drop across the shale marking the T75 MFS between the T75 and T70 reservoir units. The shale is extensive enough to separate reservoir zones at different pressures.

also typically sampled from producing intervals at a significant height above the initial OWC. The deepest samples (taken from the water leg in appraisal wells and from the lowermost perforated intervals in the oil leg) have the highest chloride ion concentration. For instance, the western channel shows an aquifer composition of about 60 800 mg l^{-1} chloride ion concentration, whereas produced water from the stratigraphically highest sand in the western channel area shows a mean chloride ion concentration of 57 949 mg l^{-1}.

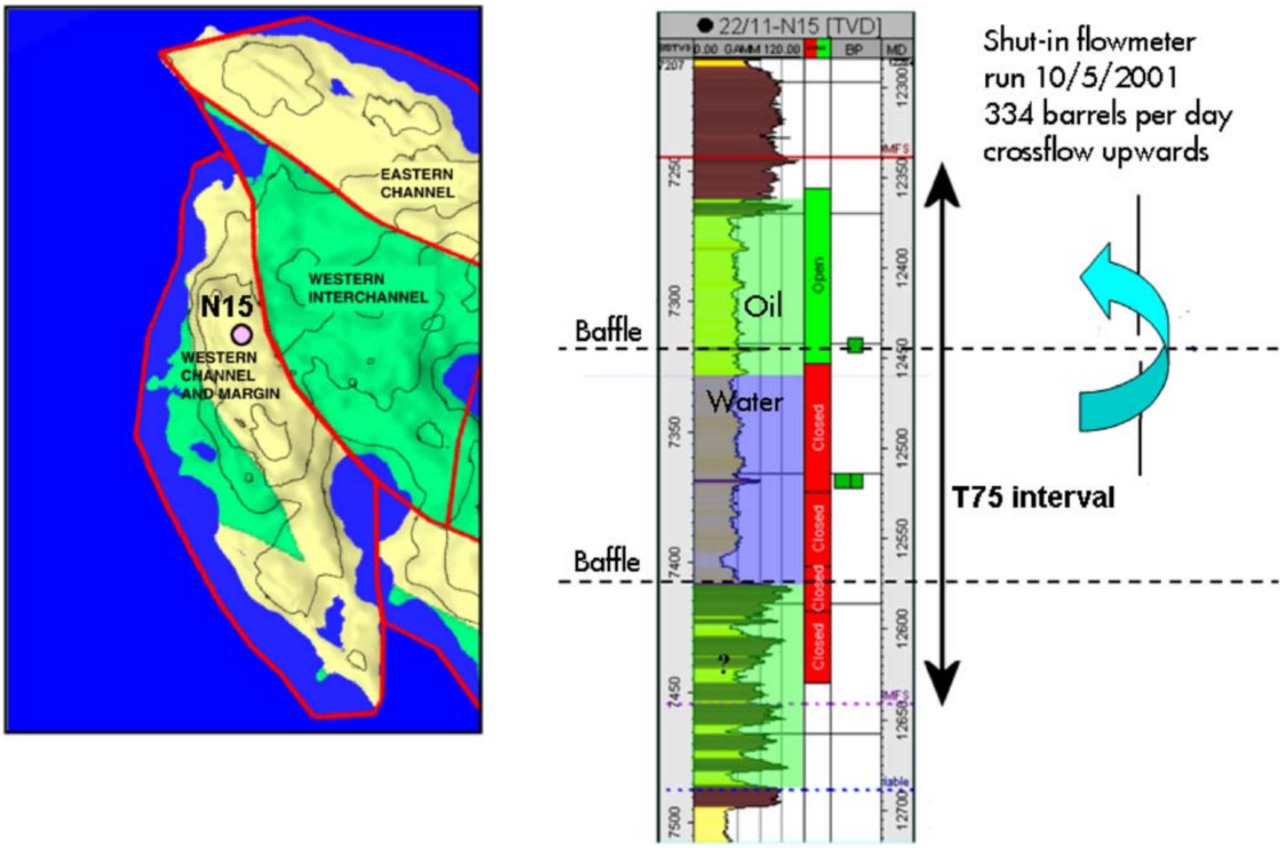

Fig. 12. A shut-in flowmeter pass shows crossflow from a high pressured reservoir unit to a low-pressure reservoir unit across the laterally extensive Last Chance Shale in the western channel well, N15. A bridge plug was set opposite the shale in order to isolate water influx from the lower perforations. SSTVD, subsea true vertical depth; BP, bridge plug setting depth; GAMM, gamma-ray log; MD, measured depth.

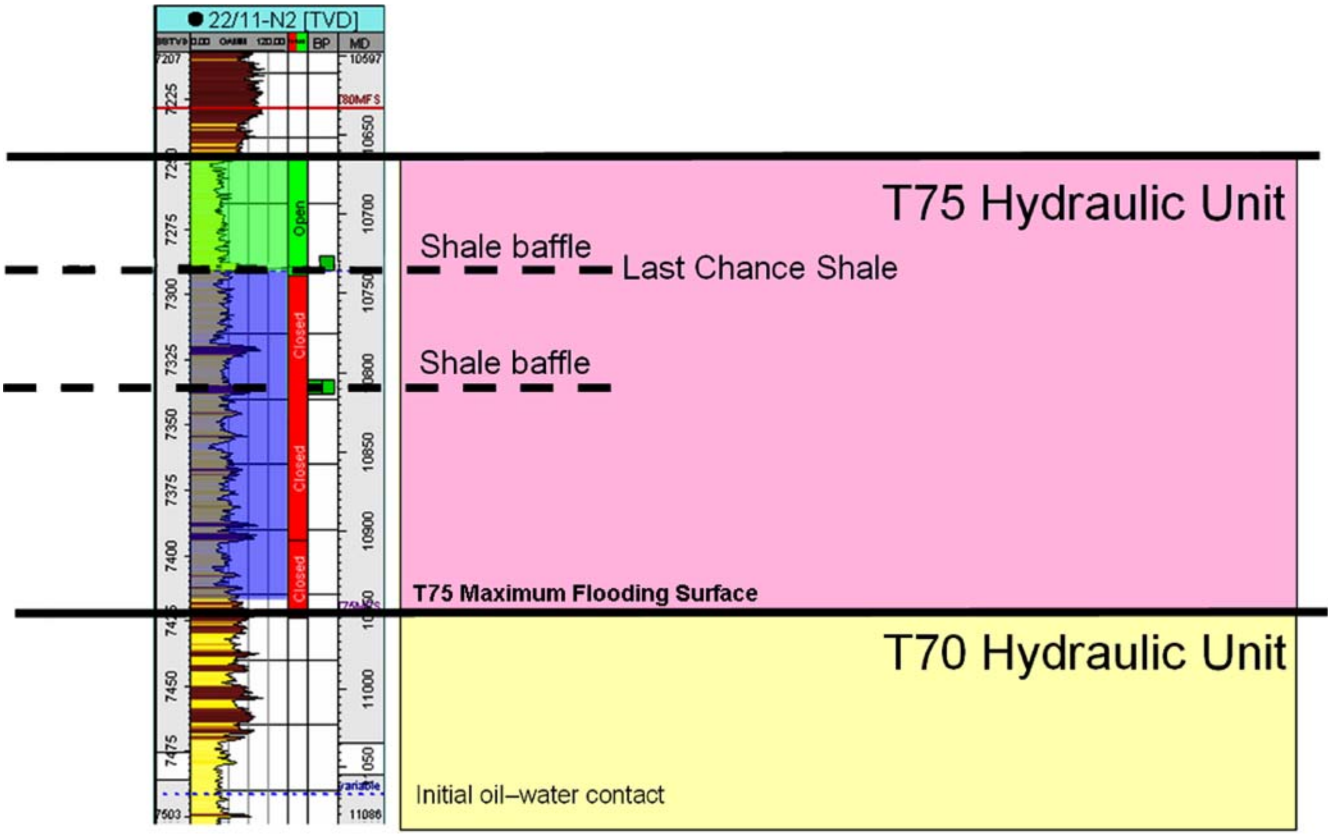

Fig. 13. The two main hydraulic units in the Nelson Field correspond to the T70 and T75 sequences, separated by the shale corresponding to the T75 maximum flooding surface. Two shale baffles are found within the T75 reservoir unit. The uppermost unit has been termed the 'Last Chance Shale'.

Lateral compartmentalization is shown by a correspondence between a specific produced water composition from wells and the macroform in which they are located. Laterally the eastern channel of the Nelson Field produces water with a lower chloride ion concentration than the western channel at all reservoir levels. The western interchannel region shows an intermediate composition to both flanking channel bodies.

Thus, the major element chemistry of produced water in individual wells is observed to change after successful water shut-off events, allowing shale barriers or major baffles to be detected (Gill *et al.* 2010).

Vertical flow barriers and baffles in the Nelson Field

The results of data integration indicate that there is one major flow barrier to vertical flow, a shale interval corresponding to the T75 MFS. This separates the Nelson reservoir into two hydraulic units corresponding to the T70 sequence (below) and the T75 sequence (above). Produced water geochemistry, water shut-off tables and formation tester log data are consistent with this interpretation (Fig. 13).

There are no obvious major baffles within the T70 central channel area, with the exception of some thin shales near the top of the interval in the south of the field. A rapid rise in the OWC was observed in the early years of production in the central channel complex.

There are two major baffles within the T75 western channel area, indicated by shut-in crossflow, punctuated OWC rises and water shut-off tables. The upper baffle is referred to informally as the 'Last Chance Shale'; so named because, in the more mature parts of the field, there are no more shales above this level where it is possible to set a bridge plug. The sandstone interval above is called the Last Chance Sand. In the eastern channel, the Last Chance Shale is the only shale interval that acts as a baffle. Pressure data suggests that it is leaky in both areas, more so in the west than the east. Nevertheless both baffles are extensive enough to separate high- and low-pressure sand intervals on the evidence of shut-in crossflow on flowmeter logs. There is evidence that the Last Chance Shale comprises a widespread series of low permeability debris flows (Fig. 14).

Geological significance of the vertical flow barriers and baffles

The main vertical flow barrier is the T75 MFS. There is a known correspondence between maximum flooding surfaces and in-field vertical flow barriers in the Jurassic deep-water sandstone reservoirs of the Northern North Sea (Partington *et al.* 1993). This is also potentially the case for the Cenozoic deep-water sandstone reservoirs.

The two major shale baffles in the T75 sequence cover large areas. Thin blanket mudstones are commonly extensive baffles and barriers in North Sea deep-water reservoirs (Hempton *et al.* 2005). For example, laterally extensive mudstones have been described as acting as permeability barriers or baffles in the Jurassic reservoirs of the Magnus Field (Shepherd *et al.* 1990) and the Miller Field (Garland *et al.* 1999); the Paleocene reservoirs of the Forties Field (Wills 1991) and the Balmoral Field (Gambaro & Currie 2003); and the Montrose and Arbroath Fields (Hogg 2003). Local erosion or minor faulting may be responsible for breaches in the shales, allowing a modicum of communication across them.

Methods of detecting controls on areal flow in the Nelson Field

The controls on areal flow are partly detected using data integration and partly inferred from the geological interpretation. For the Nelson Field, the assumption was made that compartmentalization

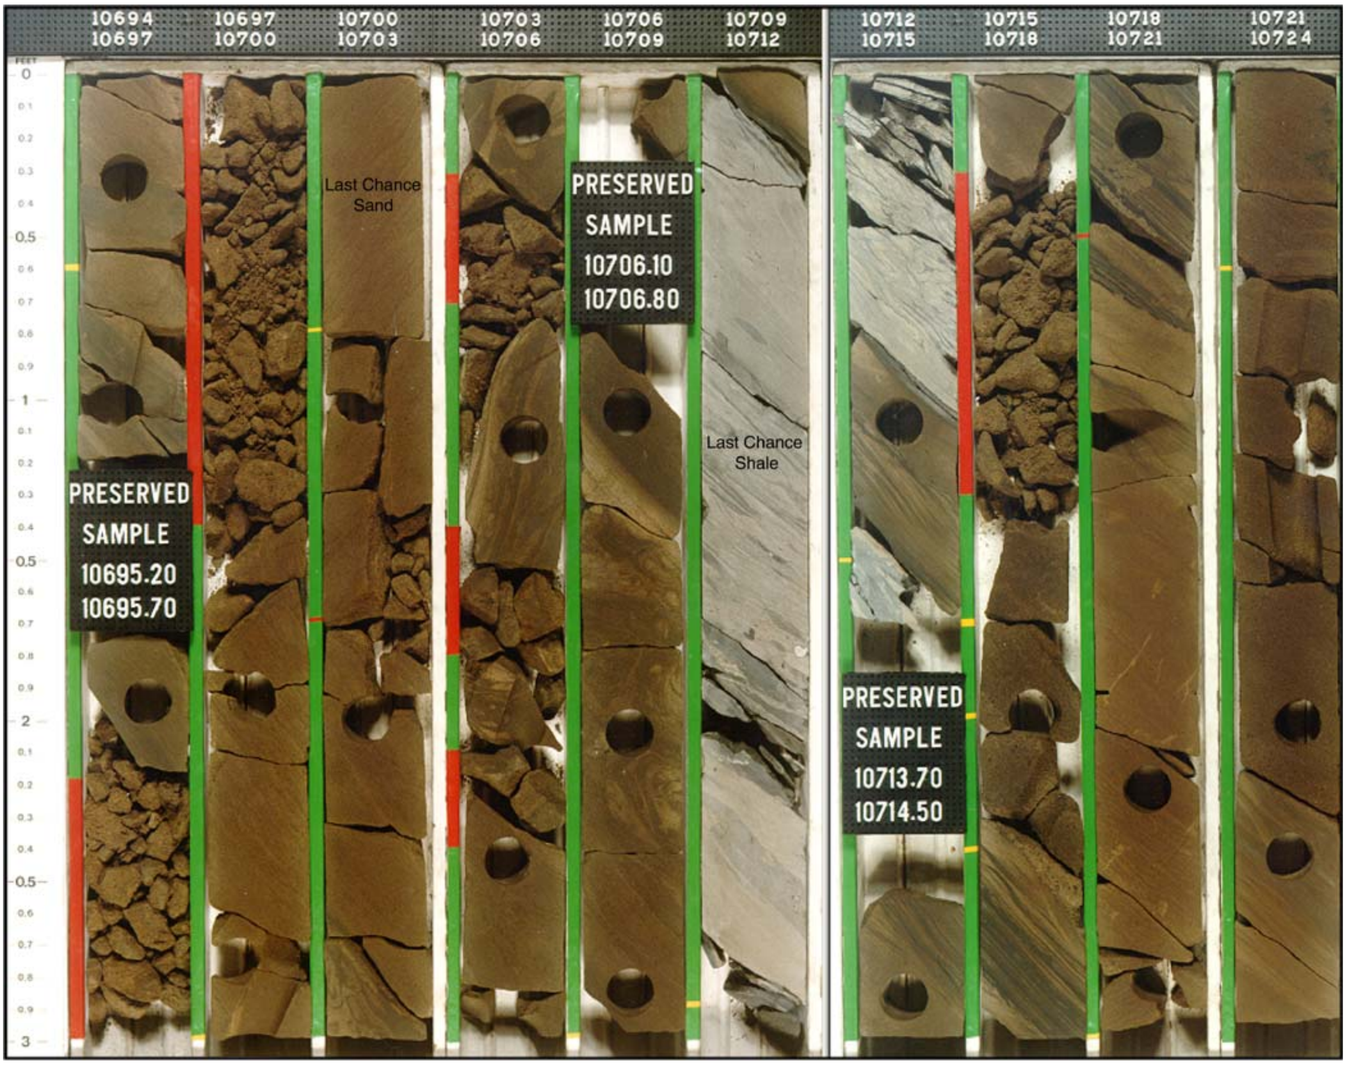

Fig. 14. Core photograph from well 22/11-N2 showing the debris flow at 10,709–10,716 ft cored depth, known to act as a baffle on a production timescale. This correlates to the unit known as the Last Chance Shale.

in the field results from poor to no connectivity through low net to gross areas defined by interchannel sediments in combination with structural cols that provide a significant degree of dip closure at or just above the level of the initial OWC. Data integration has not shown any features that would conflict with these initial assumptions.

The methods used to detect controls on areal flow include the recognition of OWC rise domains using water cut maps in conjunction with log facies maps, oil and water geochemistry and 4D seismic data.

Water cut maps used in conjunction with log facies maps

The comparison of water cut maps to log facies maps can be effective in establishing OWC rise domains, specifically areas where either bottom-water influx or edge-water influx is occurring. In the Nelson Field, areas of bottom-water influx are characterized by wells with high water cuts and log facies maps showing sand-prone reservoir intervals with only a small number of interbedded shales (Fig. 15). By contrast areas showing predominantly edge-water drive tend to show wells with low water cuts and numerous interbedded shales. Here, the lateral inflow of water has a longer path (along the shales) to reach the production wells and water cuts tend to be lower as a result. Figure 15 shows the contrast in log facies character between the western channel in the T75 interval (undergoing bottom-water drive) and the western interchannel area (undergoing edge-water drive). There is a marked dissimilarity in water cut behaviour between the two areas.

Water and oil geochemistry

Provincial variation in produced water geochemistry has been used to infer the location of compartments within the Nelson Field (Gill *et al.* 2010). Provincial variation in oil geochemistry is also seen. For example, the N26 area has markedly different oil compositions from the rest of the field.

4D seismic data

Nelson has a long history of the use of 4D seismic surveys, building on a 1990 pre-production 3D survey with one of the first dedicated marine 4D surveys in 1997 (Boyd-Gorst *et al.* 2001). Additional 4D monitor datasets were acquired in 2000 (McInally *et al.* 2003), 2003, 2006 and 2009. With each new survey, improved acquisition repeatability and combined reprocessing of vintage seismic data has led to successive improvements in time-lapse matching and differencing.

For the purposes of acquiring usable 4D seismic data, the Nelson fluid parameters can be considered to be relatively simple with a water sweep (fluid saturation) dominated signal and a strong aquifer. However, the interpretation of the 4D seismic signal is complicated by the labyrinthine reservoir geometry combined with areal and vertical variation in the net to gross. This creates

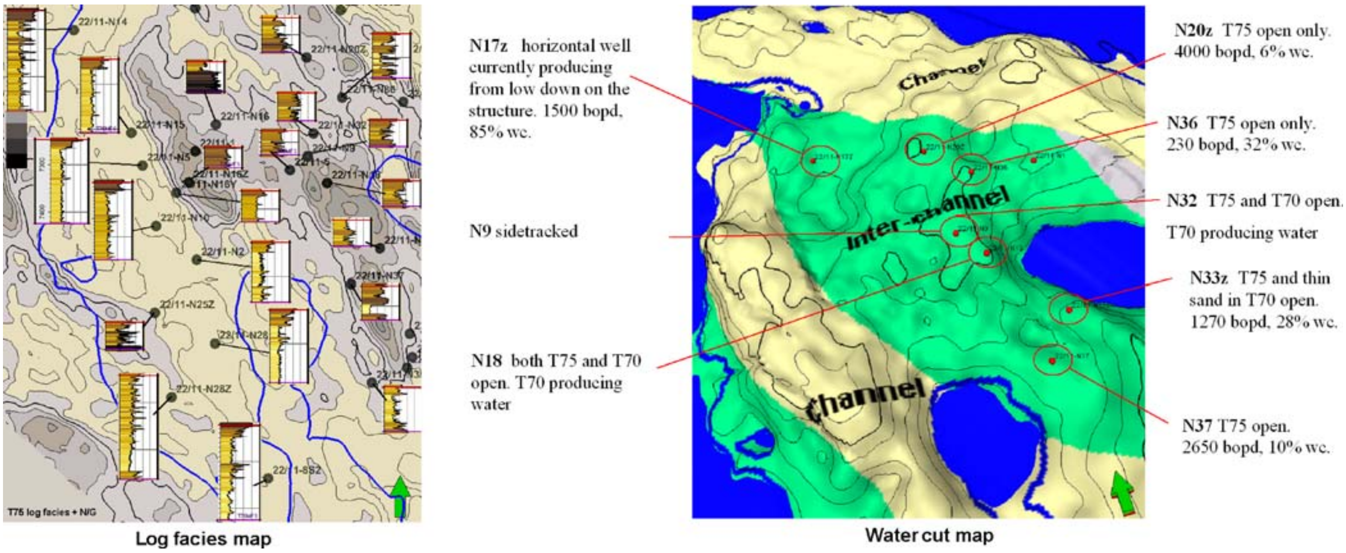

Fig. 15. Log facies map for the western channel complex and interchannel area showing the bedding style in both areas. The western channel shows few interbedded shales, bottom-water drive predominates and the water cuts are high in the wells located here. The interchannel area shows numerous interbedded shales, a predominantly edge-water drive with low water cuts. Bopd, barrels of oil per day; wc, water cut.

the situation where the existence of a 4D signal is a likely indication of sweep within a high net to gross sand body; however away from the main channel sands, the absence of a signal either could be due to an unswept sand, to poor quality reservoir within thin-bedded sands that are below seismic resolution or to the presence of non-reservoir rock.

Variable pressure-up signals (softening and slowdown causing a train of signal below top reservoir due to misalignment in the difference signal) are observed around the four water injectors; the extent of the response is an indication of each injector's connectivity to channel sands. As expected from a field with strong aquifer drive, no depletion signal has been detected in this relatively low-depletion (900 psi decrease from initial pressure) and pressure-connected reservoir.

Variability in the 4D signal is accounted for through an understanding of the stratigraphic geometry and the relative connectivity of reservoir sandstone units. Reservoir surveillance and the 4D seismic response can be considered consistent with a dominant bottom-water drive acting within the major channel complex fairways bodies. The 4D seismic response is much more ambiguous in the lower net to gross areas of the field where much of the remaining oil volumes are thought to reside (Fig. 16). Nevertheless, the main value of the information of the 4D seismic dataset in the Nelson Field is that it provides the means of screening out those areas of the reservoir that are probably swept.

Areal flow barriers and baffles in the Nelson Field

The main feature shown by data integration analysis is a distinction between the major eastern and western channel complex fairways and the central interchannel area in the T75 unit. The major channel areas show production wells with high water cuts and indications of a drive mechanism dominated by bottom-water influx. The interchannel area contains wells with low water cuts, showing interbedded sandstone–mudstone intervals with a dominant edge-water drive pattern.

Screening tools

Data integration allows the main geological controls on fluid flow to be established. The major elements are shales acting as barriers or baffles to vertical flow and combination stratigraphic/structural areal compartments. The net effect is to create drainage cells, which are self-contained volumes bounded by lateral and vertical permeability barriers (Shepherd 2009; Gill *et al.* 2010). The concept of a drainage cell is similar to what some geologists would refer to as a 'compartment'. For instance, Larue & Hovadik (2006) defined a compartment as a non-connected part of the reservoir. The phrase 'drainage cell' is used by preference to 'compartment' in the sense that it is an operational term for the purposes of screening reservoir volumes. A drainage cell may be slightly leaky, but if the rate of leakage is small compared to production rates then this will not be a matter of great importance to the reservoir management team.

Nine drainage cells have been defined in the Nelson Field as a result of data integration (Figs 5 & 6). It can be shown that the field does not drain as a single entity with a common OWC throughout. Instead, the field behaves in a multicellular manner, with each drainage cell having its own producing OWC. The drainage cells are more or less self-contained with minor to no connectivity between them on the producing time-scale of the field. In the T75 reservoir interval the drainage cells are defined by the macroforms present and are named after the location and the dominant macroform in the cell: these are the western channel and margin, western interchannel, eastern channel, south central, south and the N26 area drainage cells (Fig. 4). In the T70 reservoir interval the drainage cells are designated as the NW, NE and south drainage cells (Fig. 5).

The definition of drainage cells allows the subsurface team to localize areas of the field where there are significant remaining oil volumes. This has been done by compiling maturity tables which show for each drainage cells the total STOIIP, produced oil volume and an estimate of the remaining unrecovered mobile oil volume (Vining 1997). A maturity table can be illustrated as a fuel tank display showing the relative volumes of produced to remaining mobile oil. An example of such a display is shown for the T75 interval (Fig. 17). Maturity tables and fuel tank displays allow the remaining oil volumes to be localized and then screened for infill well potential. Drainage cells with low production rates and significant remaining mobile oil volumes are likely to be those areas of the field with large enough bypassed oil volumes to be worth targeting. Areas which are largely swept such as the main permeability fairways can also be identified. Maturity tables for the Nelson Field show that the genetically linked low-permeability macroforms may potentially contain significant volumes of remaining oil.

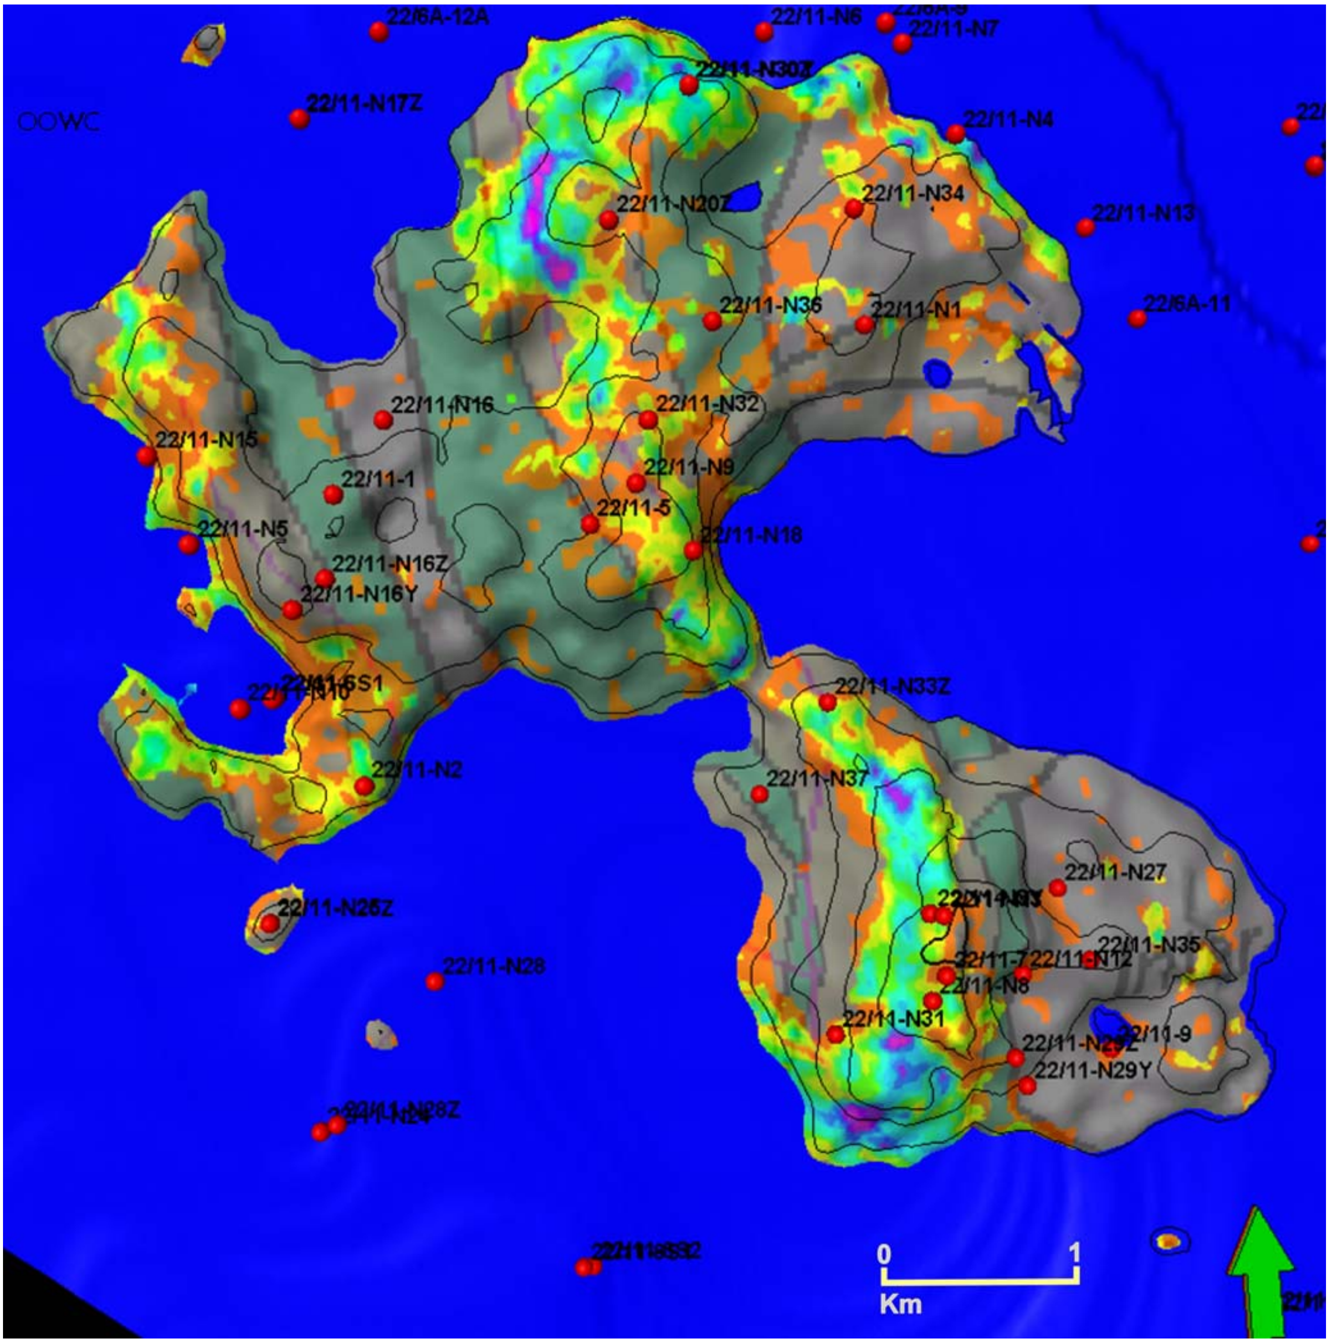

Fig. 16. Four-dimensional seismic response in the T70 sequence overlain on a map showing macroforms. A clear sweep signal is seen within the central channel complex (bright colours), whereas the channel margins show only a limited or no sweep response (grey tones). OOWC, original oil–water contact.

Four out of the nine drainage cells defined in the Nelson Field show significant remaining oil volumes; these are the western interchannel, the N26 area and the southern drainage cells in the T75 interval, together with the northeastern drainage cell in the T70 interval.

Having screened the more promising drainage cells for their remaining oil potential, the next stage is to determine the trapping style of the oil pockets within the identified drainage cells. The intent is to look for targets which may be of a large enough size to justify drilling with an infill well. In practice, these oil targets will either be found in dead-end structures with bypassed oil or will be held up in slow moving oil columns within low permeability rock. Trapped oil will also be found in smaller, uneconomic volumes.

Uneconomic oil volumes

For a typical North Sea platform well target to be economic, it should produce incremental reserves of at least $1–2 \times 10^6$ bbl. Data integration methods are able to identify bypassed oil volumes of this size, and these are discussed later. However, where sizable targets are not immediately obvious within a drainage cell that appears to have significant remaining oil volumes, there will be a concern that much of the unrecovered mobile oil is located in numerous small oil pockets which are unlikely to provide economic targets. At this stage, there is a need to judge from known observations, the use of outcrop analogues and general experience as to the likely level of the balance between the volume of uneconomic oil pockets v. the larger target volumes. Note though that there is

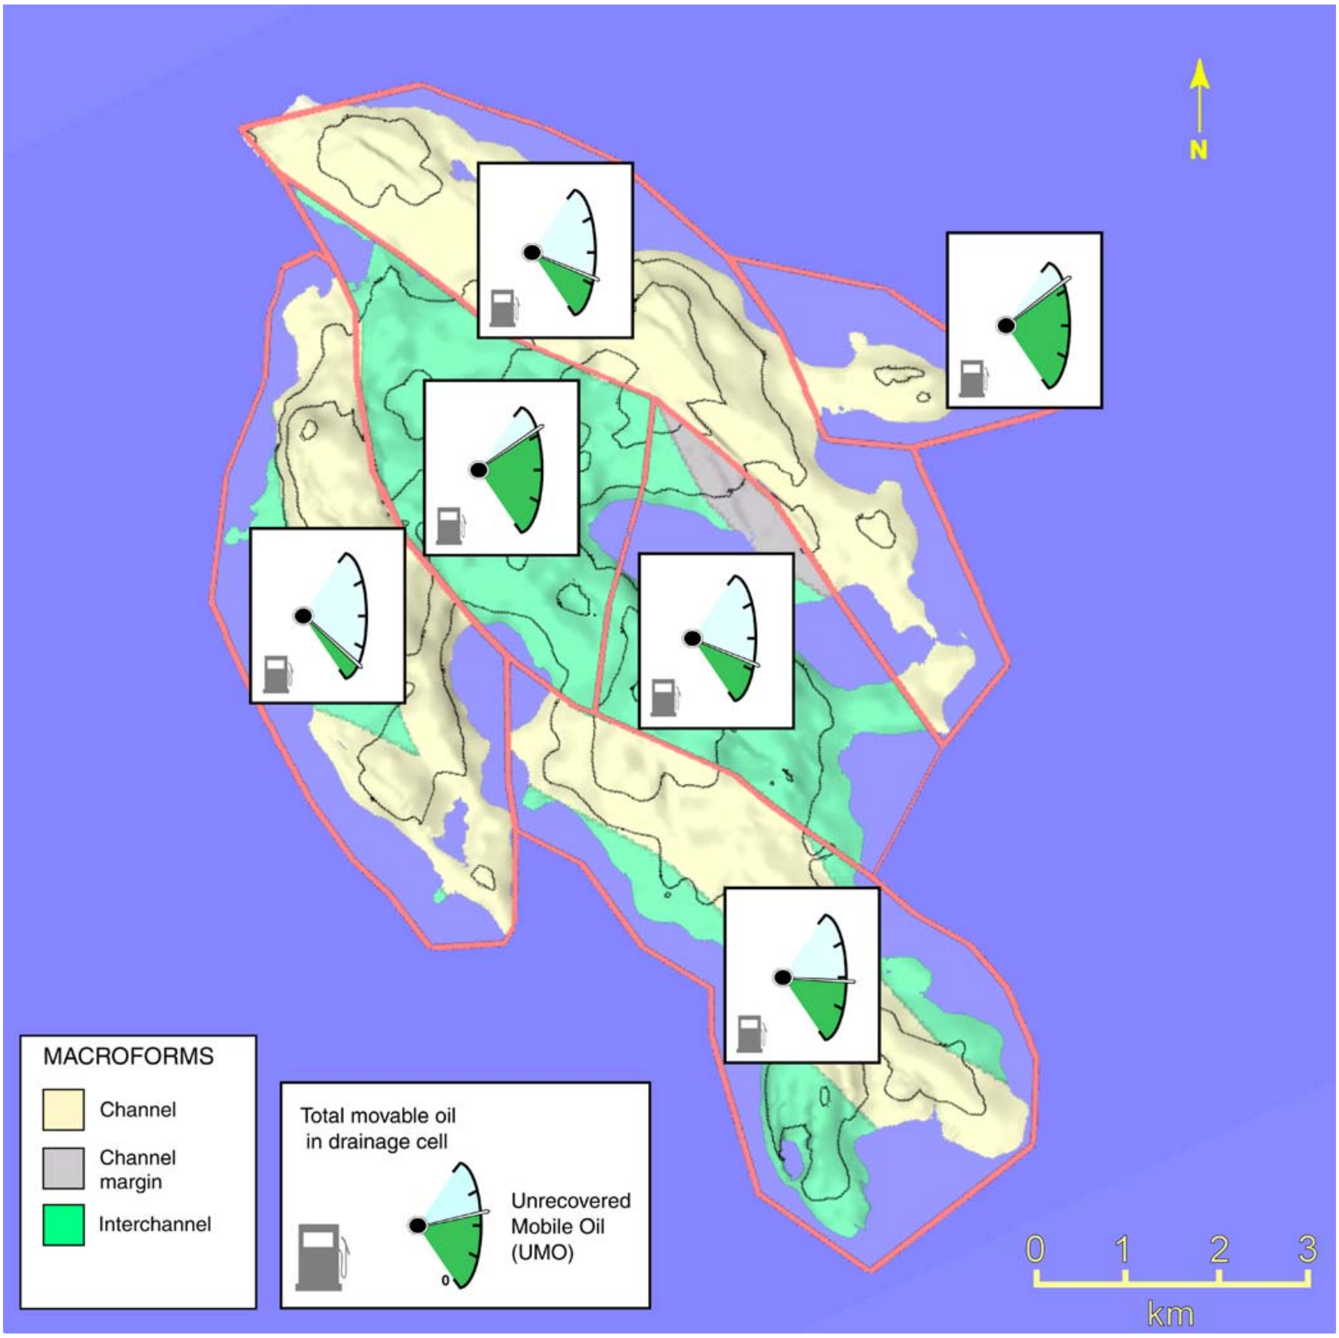

Fig. 17. Fuel tank display for the T75 unit. A full tank is equal to the total movable oil in the drainage cell. The fuel gauge shows the volume of remaining mobile oil left in each cell.

always an issue with small uneconomic volumes that they could be transformed into feasible targets under more favourable economic conditions or if the cost of infill drilling can be reduced.

The various associations for uneconomic oil volumes in the Nelson Field are thought to include thin beds, minor attic oil volumes, heterogeneous reservoir intervals, thin beds disconnected by faulting, local sand pinch-outs and volumes associated with channel margin complexities.

Thin beds

Poorly swept oil volumes occur in thin beds. It is noticeable that open hole logs in infill wells with swept oil columns show a small number of thin intervals 2–3 ft thick with oil saturations that are higher than residual saturations (i.e. greater than 20–25% oil). Some of these are capped by thin mudstone beds, although for others it is not clear from the log response as to why the oil is trapped. This observation is resonant of the comment by Wetzaeler *et al.* (1996) on remaining oil configurations in the Brent Field, that it can only take a subtle lithological change for oil to be trapped. It should be noted, however, that there is a possibility that some of these features may be artefacts of the log interpretation.

Minor attic oil volumes

An attic oil target occurs when oil is trapped in a structural culmination above the highest producing interval in an adjacent well (Shepherd 2009). Small unproducible attic oil volumes occur both at top reservoir level and underneath extensive blanket

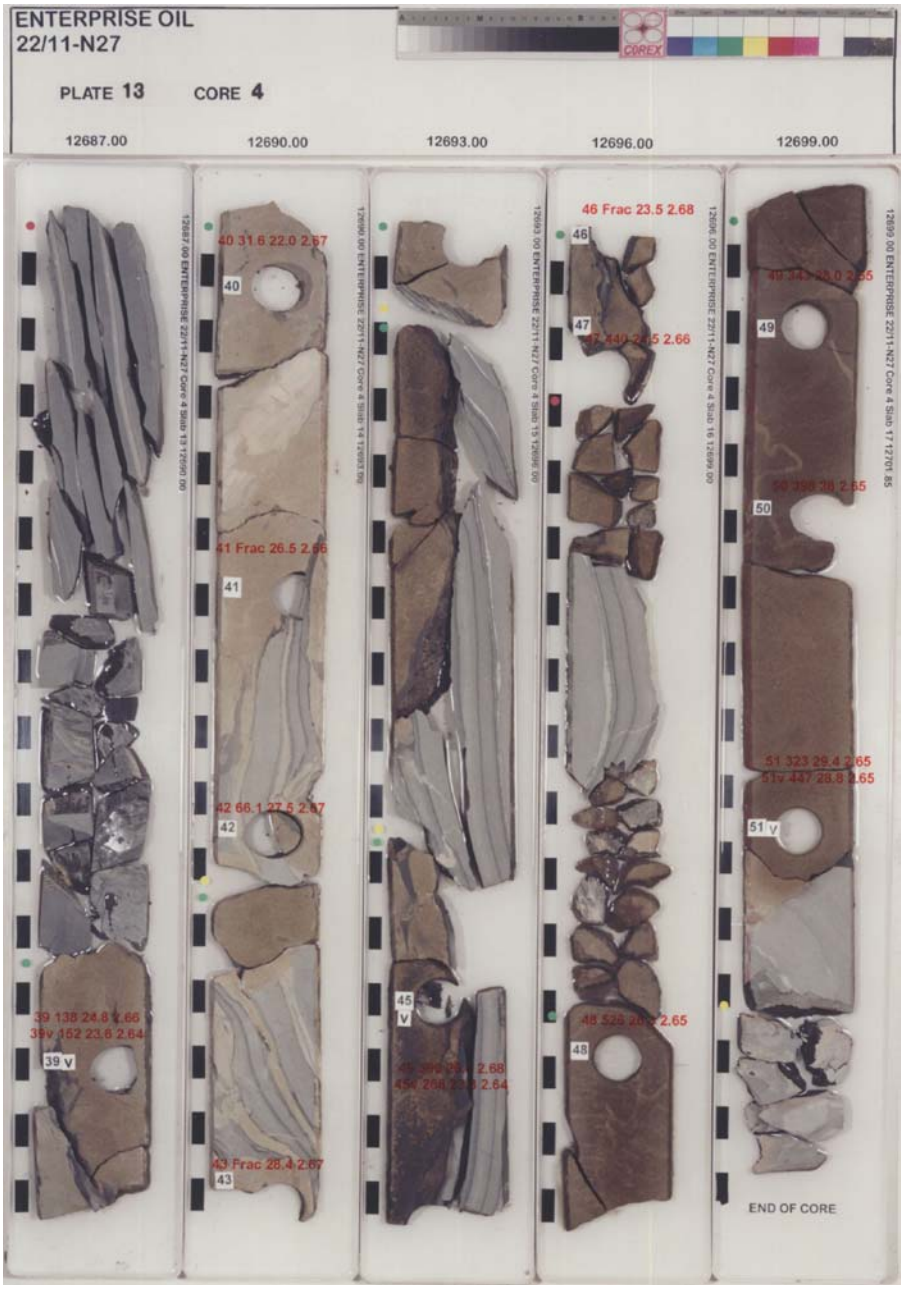

Fig. 18. Highly slumped and injected heterolithic sediments in well N27. The figures in red refer to the permeability, porosity and grain density values for each core plug. Frac, fracture.

mudstones. These are unproducible in the sense that the likely volumes will be too small to justify the expense of drilling them.

Heterogeneous reservoir intervals

Highly heterogeneous reservoir intervals may contain uneconomic oil volumes. For example, core in production well N27 shows an interval of highly slumped and injected turbidites (Fig. 18). This is the only example of extremely heterolithic sediments known to date in the Nelson Field. It is likely that the individual sandstone bodies in these features are small and tortuously connected with the potential for numerous small-scale dead ends and small isolated oil volumes.

Thin beds partially disconnected by faulting

Poor connectivity in thin-bedded intervals may be the result of minor faults. An observation has been made from modelling studies in the Westphalian succession in the Carboniferous East Pennine Coalfield that faults generally lead to a decrease in connectivity for reservoirs comprising thin, low net to gross channelized systems (Bailey *et al.* 2002). Although the observation is locality specific, the study highlights the potential effect of faults on reservoir connectivity in channelized sediments.

Local sand pinch-outs

Local sand pinch-outs may trap uneconomic oil volumes. Updip pinch-outs of thin interbedded sandstones may locally create reservoir dead-ends trapping oil.

Channel margin architecture

Complex channel margin relationships may contain small oil pockets that are uneconomic to produce. Channel margins in field exposures can show evidence for multiple incision, slumping

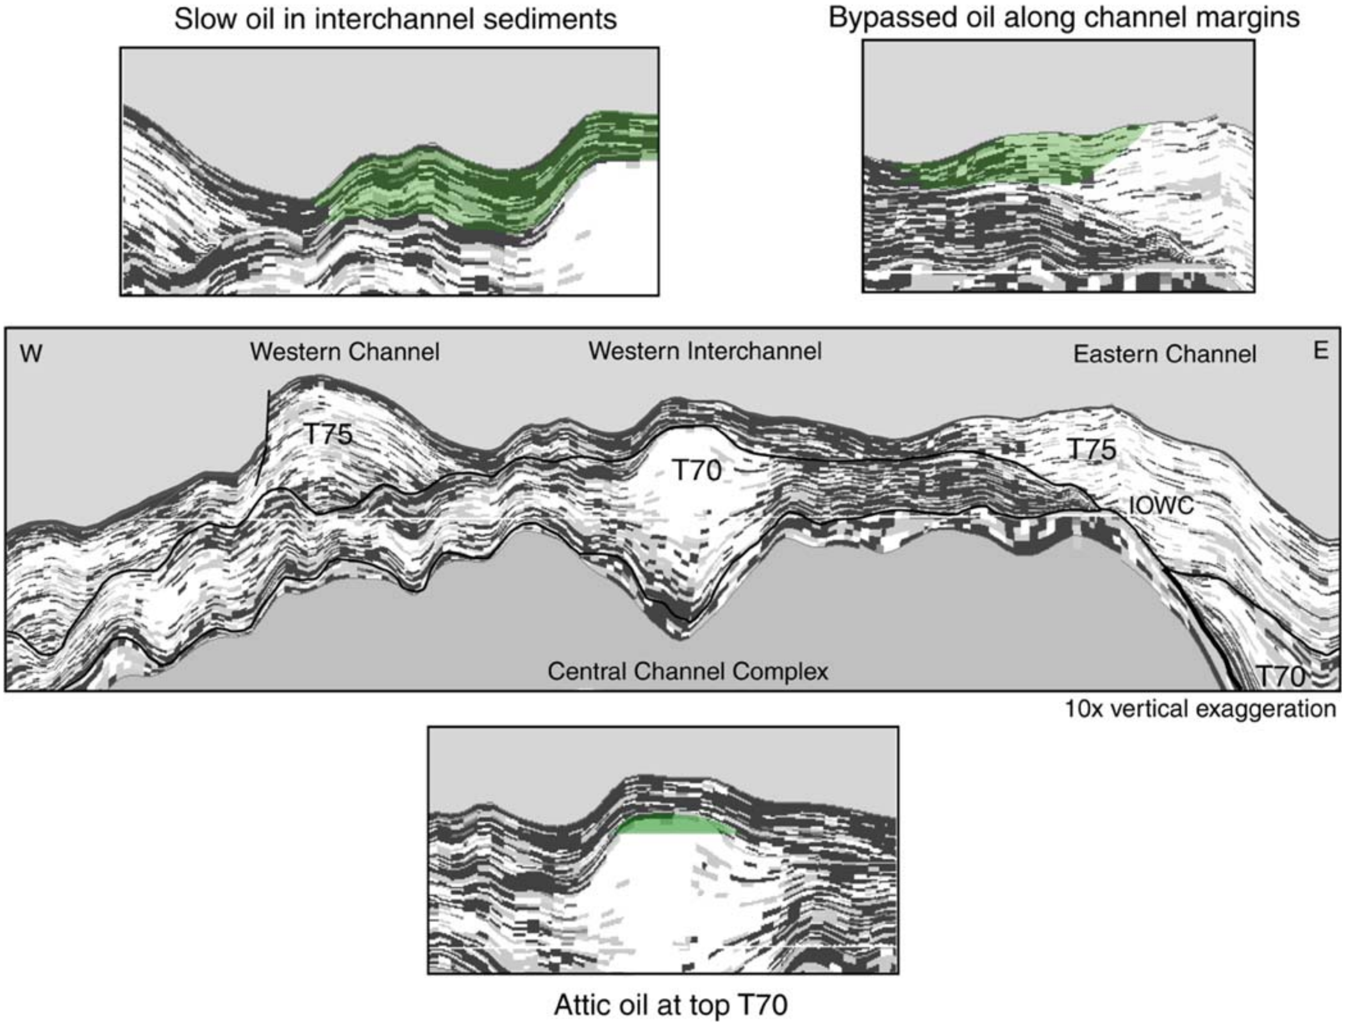

Fig. 19. Conceptual model showing different bypassed oil configurations in the Nelson Field. These include slow oil volumes in interchannel sediments, bypassed oil in the channel margins and attic oil configurations. IOWC, initial oil–water contact.

and localized shale drapes. There may be a significant volume of small dead-end volumes associated with these heterogeneities.

Target oil volumes

Target oil volumes are oil pockets that are likely to produce enough incremental oil to justify the cost of drilling the well and to provide an economic return on the money invested in the operation. Experience with producing fields suggests that it is possible to categorize specific type of target oil configurations (Wetzaeler *et al.* 1996). In the Nelson Field, there are three main types of target: These are attic oil, slow oil in the interchannel areas and channel margin oil. These are shown conceptually in Figure 19.

Significant attic oil volumes

The structural culmination defining attic oil volumes in the Nelson Field is typically a four-way dip closure beneath a permeability barrier (e.g. at the top of the reservoir), or a three-way dip closure bounded by a sealing fault. The attic oil configurations are generally low-relief dip closures updip from existing wells. Although these targets are easy to define, the volumes are generally small and are subject to depth conversion uncertainty. Attics are an important target in the Nelson Field as they are the simplest to identify.

Attic targets are not only recognized at the top of the T75 sequence (top reservoir) but are also identified at the top of the T70 sequence (with the T75 MFS as the top seal) and at top Lista level (with the T65 MFS as the top seal). In areas where there is an un-penetrated structural high at multiple reservoir levels and laterally continuous MFS shales at all levels it is also possible that stacked attic oil accumulations exist.

Fault bounded three-way dip closed attic volumes have also been recognized and can be identified on 4D seismic volumes.

Slow oil

This remaining oil type is specific to the large T75 interchannel area which lies between the two channel complexes. The area contains wells with low water cuts. In a mature field this can be a sign that there is a large volume of oil between the production wells and the source of water influx. There is a concern that there may not be enough producers to guarantee effective areal sweep and to ensure that the oil in this area will be produced by the end of field life.

Interchannel targets are defined within thinly developed overbank sands in two areas of low net to gross interbedded sandstone/shale sequences between the channel complexes. The initial Nelson exploration well 22/11-1 encountered such a low N/G shale-prone sequence in the inter-channel facies that the field was not properly evaluated as commercial until 18 years later. Currently producing sandstone intervals demonstrate the reservoir potential in these areas, but quality, rate, connectivity and volumes for infill wells are sensitive to localized variation in the interval net to gross.

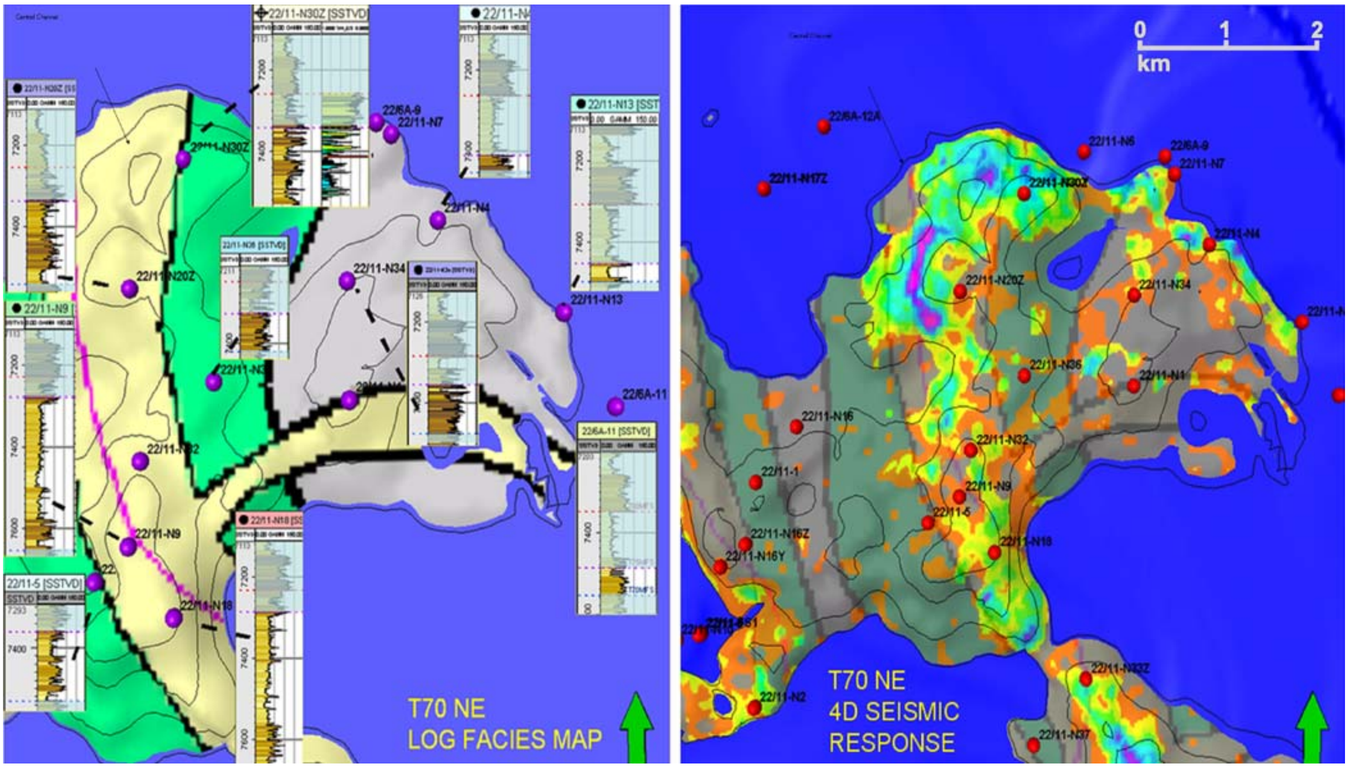

Fig. 20. Log facies map and the equivalent 4D seismic response for the NE sector of the T70 unit. The maps indicate that the channel margin areas potentially contain bypassed oil volumes.

Oil bypassed in channel margins

Maturity tables and 4D seismic data indicate that some of the channel axis drainage cells contain significant volumes of unrecovered mobile oil. Wells in the channels show indications of good sweep. The likelihood is that much of the remaining oil is located in the channel margin areas on the wings of the channels. This configuration is known to be a major bypassed oil target in the Forties Field (Vaughan *et al.* 2007). One possibility to explain bypassed oil in the channel margins is that the waterflood has occurred preferentially along the main channel axes and that oil has been banked along the channel margins. Viscous forces may be insufficient to displace oil in channel margin locations.

Channel margin opportunities represent bypassed oil in both channel margin sand pinch-outs in the main channel complexes and/or volumes trapped in thinner channel margin stacked sands (see Fig. 20). The 4D signal shows limited sweep in T75 and T70 sands along the margins of the central and western channels and this has driven the target identification process. The thin nature of channel margins (reducing sand thickness) is at the limit of seismic resolution. In order to more accurately identify the position of channel margins, inversion techniques were used.

The majority of the margin targets are located on both sides of the western channel complex in T75 sands. Reservoir surveillance suggests a relatively low offtake in this area as compared with other parts of the field and it is likely that significant remaining reserves exist here.

The southern end of the T70 central channel shows bypassed oil in the channel margins. The channel margins to the central channel complex extend eastward into a poorly understood low N/G area where a high level of heterogeneity has resulted in low recovery from the existing wells.

The western side of the eastern channel complex is predicted to show an erosive channel margin back-filled with sands and few intervening shales. The eastern margin of the eastern channel complex extends to the east beyond the field limit.

Discussion

The main theme of this paper is a discussion of the methods used to help locate the remaining oil in mature fields. The reservoir engineering-led approach commonly uses a reservoir simulation model as the main tool for reservoir management in offshore fields. These models are typically built with a coarse grid representation of the geological model as the framework for matching and predicting reservoir performance. Simulation models are ideal for solving reservoir management problems at the early stage of field development and in fields with relatively simple geology where high-confidence predictions of reservoir performance can be made throughout the field life. They may not work as well in fields with complex geology, particularly at the mature stage of development (Hansen *et al.* 2002). The reservoir simulation model is often too coarse to indicate the location of the subtler and smaller stranded oil volumes ($1-2 \times 10^6$ bbl). Paradoxically, these models can be considered to be reliable in predicting where not to drill in mature fields, that is in the largely swept, main production fairways. However, they do not have the detail to resolve the location of unswept oil volumes in the areas of more complex geology. In these areas, the simulation model will tend to show an abstract and diffuse range in oil saturations, generally above residual oil saturation; however, the more promising unswept areas will tend to be inadequately represented.

The geophysical-led approach works best in fields where there is good 4D seismic resolution and where there are no problems with survey repeatability. Although 4D seismic surveys are available for the Nelson Field, their main use to date has been less to locate the remaining oil than to provide information on where the reservoir is swept. In this way the 4D seismic method is performing a similar role to the reservoir simulation model as a screening tool to eliminate those areas of the reservoir where large remaining oil volumes are unlikely to be found.

The mature stage of field development is ideally suited to the geology-led approach, particularly if the other two approaches lack the resolution to help locate the remaining oil volumes in detail. A modified workflow for reservoir modelling is used compared with the conventional practice for fields at the appraisal or early production phase. The large amount of production data available for a mature oil field allows an evidence-based assessment of reservoir connectivity to be made in tandem with reservoir modelling studies, whereas a largely model-based approach is used to evaluate connectivity for reservoirs where there is much less production data.

The workflow given here focuses on those methods that have been used to help understand the reservoir performance in the Nelson Field. These are only part of the larger toolkit of techniques available to help determine the key geological features influencing fluid flow in reservoirs (Shepherd 2009). Whereas fluid flow in the Nelson Field is strongly controlled by stratigraphic compartmentalization and laterally extensive shales, other fields may show different features pertinent to the reservoir behaviour, for example, in a reservoir where the waterflood performance is dominated by major vertical permeability variation and where a flow unit characterization would be relevant. Nevertheless, the broad aspects of the workflow used in the Nelson Field is applicable to most producing reservoirs. These involve determining the main geological features controlling fluid flow in the field, establishing the number and location of drainage cells as a means to localizing and screening remaining oil volumes, and the analysis of trapping styles at the drainage cell level.

Conclusions

A 'Locate the Remaining Oil' analysis of the Nelson Field has resulted in the division of the Nelson Field into nine drainage cells which are defined by reservoir macroforms. Screening of these nine drainage cells has identified four cells that contain significant remaining volumes of mobile oil. These have then been investigated in order to locate any stranded oil volumes that are unlikely to be produced by the existing well stock, and to determine if these are large enough to justify infill well drilling. A number of opportunities have been identified which have led to a focussed drilling campaign in order to target these volumes.

The authors would like to thank the Nelson Field partners Shell UK Limited, Esso Exploration and Production UK Ltd, Total E & P UK plc, Petro Summit Investment UK Ltd and Premier Oil for publishing permission. The authors would like to thank all those who have worked on Nelson during the course of this study and G. Murray for assistance with drafting.

The Buzzard Field: anatomy of the reservoir from appraisal to production

F. M. RAY, S. J. PINNOCK, H. KATAMISH and J. B. TURNBULL

Nexen Petroleum UK Ltd., Charter Place, Vine Street, Uxbridge, Middlesex, UB8 1JG (e-mail: Francesca_Ray@nexeninc.com)

Abstract: The Buzzard oil field in the Outer Moray Firth, Central North Sea was discovered in 2001 and rapidly appraised during 2001–2002. Pre-production development drilling began in 2005 and the field was brought on stream in January 2007 by operator Nexen Petroleum UK Ltd. The Buzzard reservoir consists of Upper Jurassic deep marine turbidites within the Kimmeridge Clay Formation. Sands were derived from the shelf to the west and the resulting mass flow deposits were contained within a fault-bounded basin, whose margins were prone to mass wastage. The deposits pinchout to the west and thicken eastwards into the basin and hydrocarbon source kitchen. Following appraisal drilling, the high net-to-gross reservoir was interpreted as well connected. Interbedded shale layers were thought unlikely to control flow through the reservoir. However, a biostratigraphic review indicated that a consistent biostratigraphic event, indicative of reworking, could be identified field-wide. This shale layer is interpreted as a large-scale, muddy slump, extensive enough to form a significant vertical barrier to flow. Subsequent production data, modelling and chemostratigraphy studies suggest greater subdivision and vertical baffling within the main reservoir. Interpretation of these data has led to a move away from early models of Buzzard as a tank-like reservoir to a model dominated by compensationally stacked lobes, where hydraulic flow is influenced by sand body geometry and extensive shales. A comprehensive understanding of the Buzzard Field has only been possible through full integration of core, log and dynamic data, benefiting from a high density of well control, an extensive data acquisition programme and early reservoir monitoring. Ongoing reservoir management, involving continuous update of both the geological and dynamic models in response to new data, has enabled an evolving understanding of the Buzzard reservoirs, and placed the operator in an excellent position to proactively address future development challenges.

Keywords: turbidite, Upper Jurassic, integration, biostratigraphy, chemostratigraphy

The Buzzard Field development area is located across four blocks of the UK Central North Sea, 19/05, 19/10, 20/01 and 20/06, although the majority of the field occurs within part block 20/06a where the platform facilities are located. The field is situated approximately 50 km NE of the Scottish mainland in a water depth of 318 ft. The accumulation lies within the Outer Moray Firth region of the UK North Sea, at the western end of the Buchan Graben and at the southwestern limit of the Ettrick sub-basin (Fig. 1). To the west lies the Grampian Spur, an Upper Jurassic platform area, while the Peterhead Graben is located to the south. The Ettrick sub-basin is separated from the Peterhead Graben by a SW–NE trending Mesozoic structural high drilled by well 20/06-1 (Fig. 2). This structure constrains the southern limit of the Buzzard Field.

Structure and trap

Within the Buzzard Field development area, the main accumulation is offset by several west–east oriented normal faults (Fig. 3). These divide the field into three main regions referred to as the Southern, Central and Northern Panels, flanked by smaller structural terraces. The faults have a maximum offset of about 250 ft and are more or less continuous across the area of the accumulation. Both the Southern-Central and Central-Northern Panel bounding faults throw down to the north. The Northern Panel is limited on its northern margin by a down to the south, west–east oriented normal fault. Beyond this lies the Buzzard Northern Terrace into which the 20/01-5 appraisal well was drilled.

The trapping mechanism for the field is exclusively stratigraphic in nature as Buzzard sands are completely enclosed within sealing shales of the Kimmeridge Clay Formation. The sands were deposited by turbidite flows, from the west, into a structural low between the southerly Mesozoic high and the Buzzard Northern Terrace (Fig. 2). This gave rise to a thick sandy sequence in the centre of the low pinching-out onto the northern and southern flanks (the sands were not deposited in 20/06-1) and also westwards, towards the shelfal source area. Regional dip down to the east limits the oil accumulation with the field oil–water contact lying west and slightly updip of well 20/06-2 (Fig. 3).

Jurassic stratigraphy

Initial marine flooding of this part of the Buchan Graben can be dated to the Oxfordian and is recorded by the transgressive shallow marine Sgiath Sandstone (Fig. 4). Extension along SW–NE oriented fault systems resulted in rapid deepening of the graben in the Buzzard Field area. The Late Kimmeridgian to Early Volgian Buzzard Sandstone Member was deposited during this syn-rift phase into a relatively deep and anoxic basin. Extensional fault trends within the Late Volgian and Ryazanian were oriented west to east and lead to modification of the original SW–NE structural grain. It is this later trend that offsets the field, giving the present-day structural configuration.

The gross Jurassic interval in Buzzard wells is primarily subdivided on the basis of lithological variations and biostratigraphic markers which relate directly to the established Upper Jurassic chronostratigraphy of the North Sea (Fig. 4) (Partington *et al.* 1993). The total Jurassic package can be split into four formations (Kimmeridge Clay, Heather, Sgiath and Pentland) of which the Kimmeridge Clay is the thickest and contains the reservoir sands in the Buchan Graben area. Three major phases of turbidite sand deposition are informally recognized within the Kimmeridge Clay Formation: the Buzzard, Ettrick and Burns Sandstone Members, of which Buzzard is the oldest. In the Buzzard Field

area the Upper Jurassic interval is dominated by the Buzzard Sandstone Member, overlain by very thin, shale-prone Ettrick and Burns sections.

Field discovery and appraisal

Prospectivity in this part of the Buchan Graben was initiated by well 20/06-2, drilled in 1987 to test a relatively small four-way dip closure mapped within the Jurassic sequence (Fig. 3). The well is located eastward and downdip of the Buzzard Field but encountered a thick Buzzard Sandstone Member. An 11 ft oil column at the top of the Buzzard Sandstone Member in this well confirmed an active petroleum system in this part of the basin. However, the large potential prospectivity westward and updip of 20/06-2 was not tested for a further 14 years due to the perceived high-risk nature of the stratigraphic play.

The Buzzard discovery well, 20/06-3, was drilled in 2001. The well was sidetracked downdip as 20/06-3Z and together these wells proved a 753 ft oil column within the Buzzard Sandstone Member (Doré & Robbins 2005). During 2001 and 2002 six appraisal wells and two associated sidetracks were drilled (Fig. 3). Locations were based on the existing 3D seismic data, which was qualitatively interpreted to identify intra-reservoir packages defined by thickness, amplitude and morphology. These appraisal wells delineated most of the accumulation, confirming Buzzard as the biggest find in the North Sea since the discovery of the Nelson Field in 1988, and allowed an early commitment to field development. Since then, the field's structurally highest delineation well has proven an oil column height of over 1400 ft.

The Buzzard reservoir contains undersaturated 32° API oil at a reference pressure of 4628 psia and temperature of 195°F at a reservoir datum of 8735 ft TVDSS. The accumulation is some

Tracks, from left to right, are measured depth (MD); subsea true vertical depth (SSTVD); gamma ray (GR); density-neutron; resistivity (deep and shallow); sonic (DT) and Duxbury palynological zonation (Partington *et al.* 1993; Duxbury *et al.* 1999).

600 psia over-pressured relative to a normal hydrostatic gradient, suggesting the system is pressure isolated within the surrounding Kimmeridge Clay Formation shales.

Theme of the paper

The main focus of this paper is on the uppermost Buzzard Sandstone Member, the Buzzard 4 (B4) reservoir (Fig. 4), as it holds the majority of the STOIIP and reserves (approximately 90%). The format for the rest of the paper continues the timeline onwards from field appraisal through field development planning to the present day. The text is subdivided into four sections representing points in time (Mid 2003, End 2006, End 2007 and Mid 2009). In each, the critical data acquisition and interpretations of the time are discussed, illustrating the evolution in understanding of the Buzzard Field. This paper also demonstrates how development of the field has been adapted to account for revised subsurface interpretations in order to optimize field recovery, and exemplifies the benefits of early and continuous static and dynamic data acquisition and integration.

The Buzzard Field: mid 2003

The Buzzard Field Development Plan (FDP) was submitted during 2003 on the basis of 11 exploration and appraisal wells, together with the 3D seismic survey upon which the discovery was made. This survey was acquired in 1995 and reprocessed in 2000. Dynamic and fluid data was acquired from four drill stem tests (DSTs) carried out in the exploration and appraisal wells. Three of these were performed on discrete oil intervals, whilst the fourth was a production and injectivity test below the oil–water contact. At the time of the FDP, the base case estimate of oil-in-place and reserves was around 1000 and 500×10^6 stb, respectively.

Reservoir stratigraphy

The FDP reservoir subdivision, originally defined in the discovery well 20/06-3, was both lithostratigraphically and biostratigraphically driven. The reservoir sequence was subdivided into five chronostratigraphically constrained packages referred to, from top to bottom, as the Buzzard 4 (B4), Buzzard 3 (B3), Buzzard 2 (B2), Buzzard 1 (B1) and Buzzard 0 (B0) units (Fig. 4).

At this time, the uppermost reservoir unit, B4, was described as a laterally extensive, massive sand unit, dominated by high net-to-gross, high-density turbidites in the Central and Southern Panels (Fig. 5a). The extent of subordinate thin shales was uncertain. The B3 unit, underlying the B4, was interpreted as a laterally extensive hemipelagic shale unit. The B2 unit was described as a laterally extensive unit of variable reservoir quality, with high-quality B2 sands interpreted only in the Southern Panel. The

Note correlation into 20/06-3Z (discovery well sidetrack), where the thick, lower sand body is assigned to the B2 package. Tracks, from left to right, are GR infilled by stratigraphic unit and SSTVD. (**b**) Buzzard top structure map showing location of cross-section and postulated sediment input points.

oldest Buzzard units, B1 and B0, are laterally extensive, shale-dominated packages with very low to no reservoir potential.

Seismic interpretation

The FDP seismic interpretation characterized the Buzzard reservoir by three events: Top Buzzard, intra-Buzzard (referred to as the ‘Purple Pick’) and Base Buzzard. Top Buzzard corresponded to the top of the high net to gross, massive sand: the Buzzard 4 (B4) unit. The ‘Purple Pick’ was a conspicuous intra-reservoir event marking the base of the high net to gross package. The pick was apparently diachronous since the interpretation at that time was unable to reconcile the biostratigraphic and geophysical data. This resulted in the ‘Purple Pick’ coinciding with the base of the B4 unit in the Central Panel, but the base of the B2 in the Southern Panel (Fig. 5a). The Base Buzzard horizon was picked on an event close to the base of the B2 unit.

In general, the gross Buzzard reservoir envelope was considered to be well constrained within the core of the Southern, Central and Northern Panels. The areas with most uncertainty in reservoir pinchout definition were SE of well 19/10-1 in the Southern Panel, around 20/06-4Z in the Central Panel and west of 20/01-3 in the Northern Panel (Fig. 5b). Continuity of the Buzzard reservoir sands into the Northern Terrace was also uncertain, although there was strong evidence for thinning of the B4–B2 interval towards the north.

Geological model at field sanction

At FDP time, reservoir development and intra-reservoir stratigraphy were believed to be closely related to structural development. The depositional model was based on a concept whereby interactions between sediment supply and creation of accommodation space, through initiation and movement on half-graben faults, led to preferential deposition of sand rich flows. This seemed to explain the stratigraphic architecture of the sandy B4 unit in the Central and Southern Panels and the B2 in the Southern Panel (Fig. 5a). It was postulated that sand input kept pace with, or exceeded, the development of accommodation space via fault movement, resulting in thick sand accumulations. Other areas of the Buzzard Field, the Southern Terrace, Northern Panel and the Central Panel at the time of B2 unit deposition, were thought to have remained relatively ‘high’, with the resulting sedimentation being dominated by shale and limited sand.

It was postulated that the primary sediment supply to the area was via multiple input points, to the SW, west and NW (Fig. 5b). The major east–west faults which separated the field structural panels and terraces were mapped as having variable throw (up to a maximum of 250 ft), but were believed to be of sufficient magnitude along the majority of the fault to seal it as a result of clay smear. It was recognized that windows potentially existed along the fault plane, where throws were smaller, which might allow communication.

Using this geological model as a guide, seismic was used qualitatively to identify intra-reservoir packages defined by thickness, total absolute amplitude and morphology and correlated with well data to define areas of low, medium and high net to gross within the Buzzard Field. This approach had proved successful as a predictive model for appraisal drilling, and so formed the basis of the FDP Buzzard reservoir model used for initial development well planning. Gross reservoir packages, such as the B4, were defined deterministically as sandy units within which shales were stochastically populated, constrained by the seismically derived net to gross maps and honouring the well data. As per the conceptual model, this typically allowed full communication throughout the B4, as shales were modelled with very limited lateral extent.

A range of studies completed prior to the FDP, designed to further refine both vertical and lateral heterogeneity and compartmentalization in the field, proved difficult to integrate with the geological model at the time. These studies included chemostratigraphy, heavy mineral analysis, strontium residual salt analysis, core palaeomagnetic analysis and fault seal analysis. More recent follow-up studies, made with the benefit of twice as much well data plus dynamic data, have since proved the value of these alternative studies and contributed to the development of current geological models consistent with all the data.

Reservoir performance and fluids

The DSTs confirmed the presence and continuity of high permeability sands in the B4 and B2 units contributing to high well deliverability. Fluid analysis on bottom hole samples obtained from DSTs in 20/06-3 and 20/06-4 indicated the presence of H_2S. The highest values of H_2S in oil observed during the appraisal campaign were from a DST in 20/06-4 which tested the B4 sands in the Central Panel (Fig. 5b). This equated to well stream values of 42.1 ppm weight as H_2S. The 20/06-3 well DST tested the B4 interval in the Southern Panel and showed lower well stream values of 5 ppm weight as H_2S. The fluid composition from the 20/06-4 DST in the B4 unit was adopted for topsides design purposes, since it had showed the highest H_2S levels and was believed to represent approximately 40% of the oil in place.

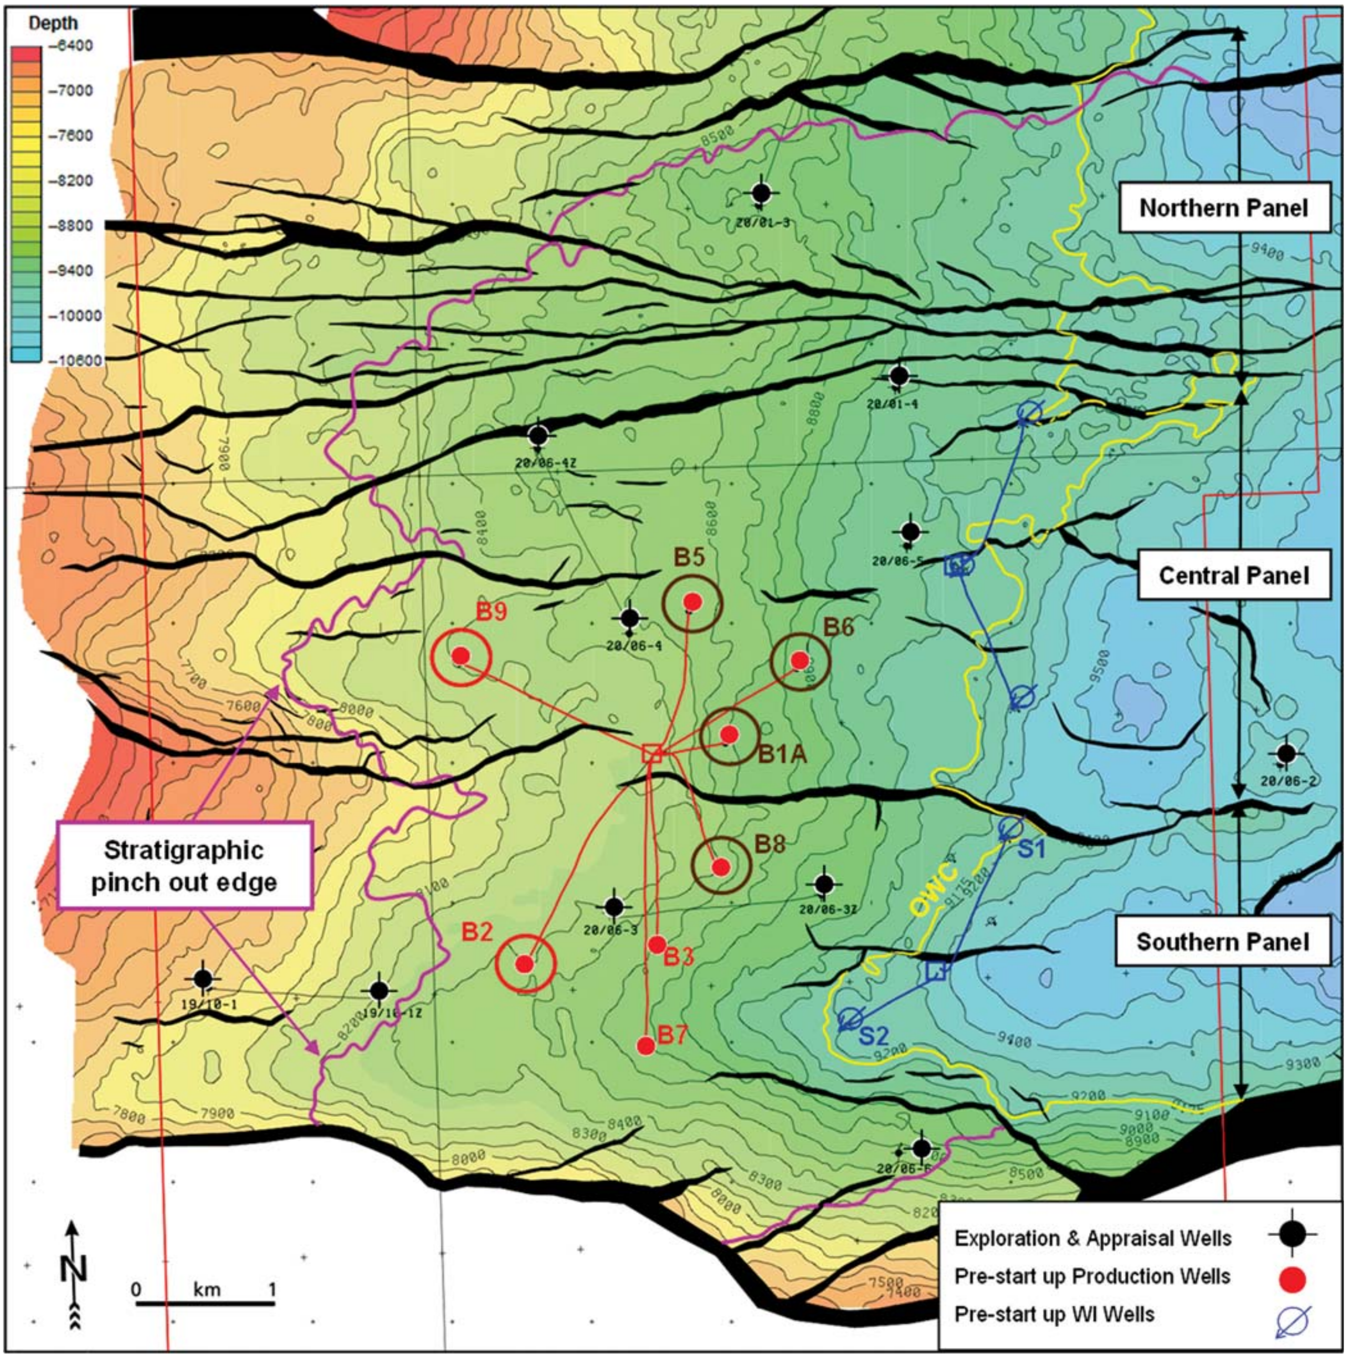

Fig. 6. Top structure map showing platform, subsea manifold locations and the 16 wells drilled prior to field start-up. Wells circled red are revised, updip production locations. Wells circled brown are perforated as pressure monitoring wells, rather than production wells as originally planned, due to higher than expected levels of H_2S.

The Buzzard Field: late 2005 to end 2006

In accordance with the FDP, a number of production and injection wells were drilled prior to the start of field production, between October 2005 and the end of 2006. Location of these pre-development wells was intended to provide a balance between the desire to produce the field at the design capacity from soon after start-up and the need to improve reservoir understanding prior to first oil. The strategy for pre-development production wells was to initially drill mid-flank wells covering a north to south span across the Southern and Central Panels. This was to mitigate against the risk of NW–SE trending compartmentalization through structural elements or stratigraphic pinchouts, which early studies had highlighted as a risk. Mid-flank producers were to be followed later in field life by updip production wells, with all wells completed progressively downwards from the B4 to the B2 unit, or converted to injectors in the B4 unit. Little scope was seen for water shut-off of individual sands within the B4 unit due to the perceived lack of laterally extensive sealing shales and the relatively high vertical permeabilities within the unit. Wells were to be drilled from a drilling platform located above the Central Panel (Fig. 6). This was installed, together with the production facility, in 2005–2006. Injection wells were to be drilled from two subsea manifolds located above the Southern and Central Panels.

Pre-development drilling results

Thirteen wells were drilled and completed between 2005 and first oil in 2007, eight producers and five injectors (Fig. 6). The strategy for the location of injection wells, which was to place them as close to the original oil–water contact (OOWC) as possible, did not change as a result of pre-development drilling. In contrast to the injection wells, production well planning changed dramatically as a consequence of pre-development drilling. The first well, 20/01-B1A, targeting the core of the field and 1–1.5 km from the nearest appraisal wells (Fig. 6), found H_2S levels three times greater than expected based on appraisal well predictions. Subsequent wells throughout the field demonstrated that the H_2S distribution varied significantly over short distances (Beilby *et al.* 2009). As a result, a solution for handling of higher H_2S levels later in field life was required and the decision to install a fourth platform to handle the fluids was made. This platform is due to be commissioned in 2010.

A more immediate consequence of the H_2S problem was a change in the pre-development drilling strategy. Mid-flank, potentially high H_2S, producer locations were revised to target updip areas believed to contain sweeter oil (Fig. 6, wells circled red). This change in strategy was successful and had the unforeseen benefit of leaving four mid-flank wells, which could not immediately come on stream due to high H_2S levels, available as pressure observation wells (Fig. 6, wells circled brown). These four wells in the Central and Southern Panels have subsequently provided invaluable information for understanding the performance of the B4 reservoir unit in the Buzzard Field.

Pre-development wells also clearly demonstrated the absence of any relationship between reservoir sand development and seismic amplitudes (or other properties), the FDP observations apparently being coincidental. While this did not significantly compromise

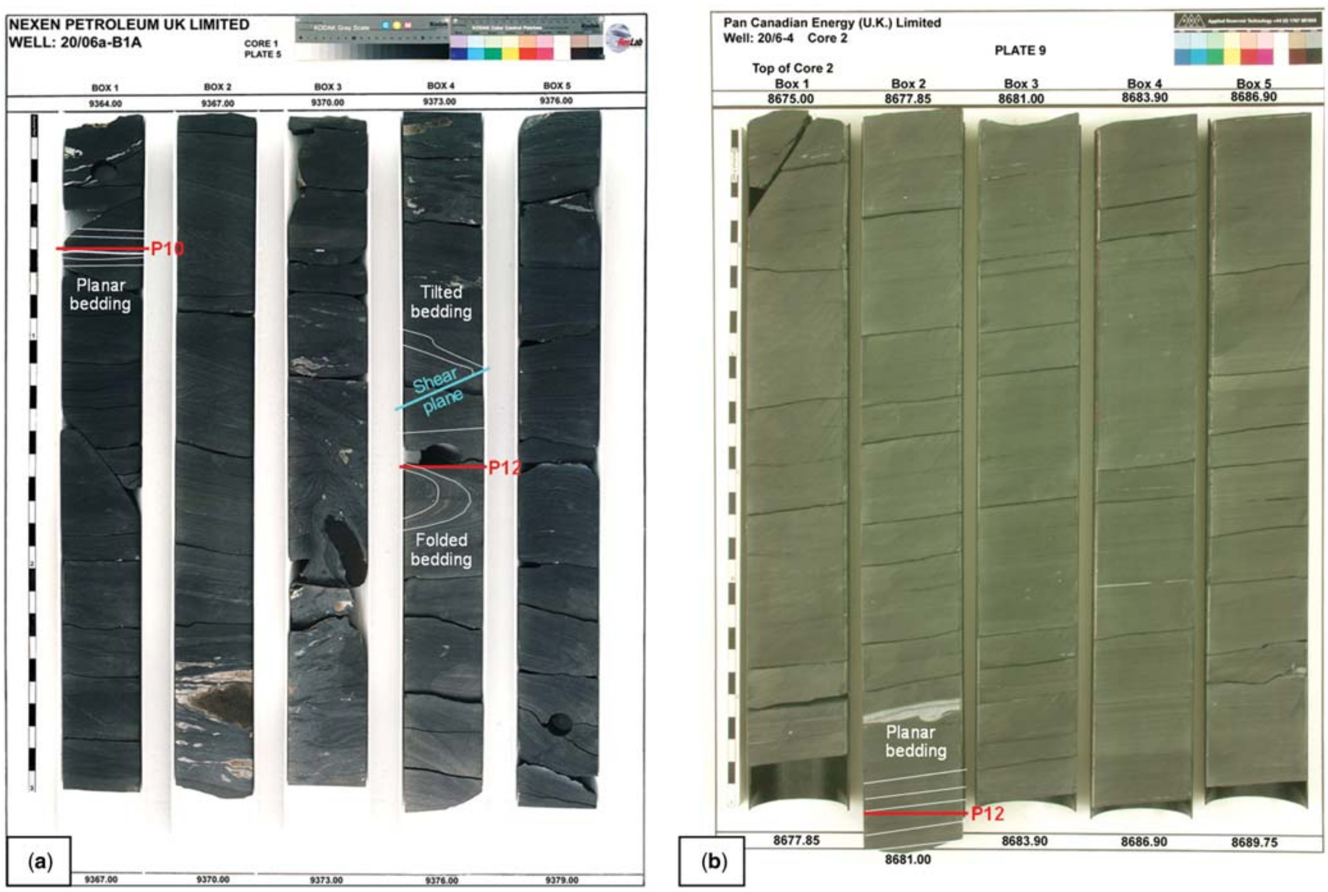

Fig. 7. Shales in core with field-wide consistent biostratigraphy markers P10 and P12. (**a**) P10 shale is planar laminated, whilst P12 shale is folded, tilted and sheared. (**b**) P12 event within a significant thickness of planar laminated shale. Assemblages of taxa in both P10 and P12 shales are consistent with an origin that includes reworked sediments, giving rise to the possibility that some of the planar laminated shales are not *in situ*, but are in fact large-scale slump blocks of partially lithified shale.

the results from these early development wells it did demonstrate both the caution that should be applied to such amplitude-based interpretations and the need for alternative methods of predicting reservoir quality and extent.

A consistent biostratigraphic interpretation

Wells drilled during the pre-development phase added to the considerable data acquisition programme begun by the appraisal wells. Full log suites were acquired in all wells, including pressure measurements, fluid samples, image logs and percussion sidewall cores. The additional conventional core taken at this stage doubled the total amount of core from the field to nearly 3000 ft.

Biostratigraphy had already been recognized as the most reliable aid to reservoir correlation, with palynological analysis providing by far the best stratigraphic resolution. Following a re-evaluation of the biostratigraphy in two appraisal wells in 2005, an intense programme of biostratigraphic analysis of conventional core, sidewall core and cuttings material was instigated covering a further five wells, with the aim of providing a robust biostratigraphic framework. This study confirmed the existence of consistent palynological events within the B4 unit, where previously the resolution had been limited to definition of only the gross B4–B0 packages.

Two particularly consistent events, recognized in all wells and referred to as the P10 and P12 events, displayed a range of palynoflora composed of B3 age markers together with younger taxa. At the time of the FDP, this assemblage was not recognized in all wells and, where it was observed, the shale containing it was assigned to the B3 unit. The constituent younger taxa were considered statistically insignificant. The new interpretation considered the younger taxa as more indicative of the age of deposition, implying that the B3 age taxa had been reworked and were incorporated as a result of slumping of older sediments. Sedimentological logging of these shales revealed a potentially confusing picture. Some of the P10 and P12 shales show clear evidence of remobilization, indicative of slump deposits (Fig. 7a), whereas others are planar laminated and appeared to be hemipelagic in origin (Fig. 7a, b). Correlation and mapping of the shale unit characterized by the P10 and P12 biostratigraphic events supported the interpretation of a laterally extensive intra-B4 shale, which was thickest in the Southern Panel and thinned towards the north (Fig. 8a). Evidence for slumping in core, in combination with reworked palynoflora, was the basis for suggesting that the Intra-B4 shale represented a kilometre-scale slump unit, probably derived through catastrophic failure of the southern basin margin. In places, the slump unit contains large-scale, partially lithified, blocks of shale.

Recognition of the Intra-B4 shale led to a redefinition of the B4 reservoir into an Upper and Lower unit and resulted in a notable revision to the correlation of the B4 and B2 units in the Southern Panel. In some wells, the shale originally picked as the B3 shale was re-defined as the Intra-B4 shale (Fig. 8b). In wells such as 20/06-3Z, sands originally designated as B2 became B4 units, giving rise to a Lower B4 unit up to 240 ft thick, but resulting in a thinner B2 package with considerably lower net to gross. This

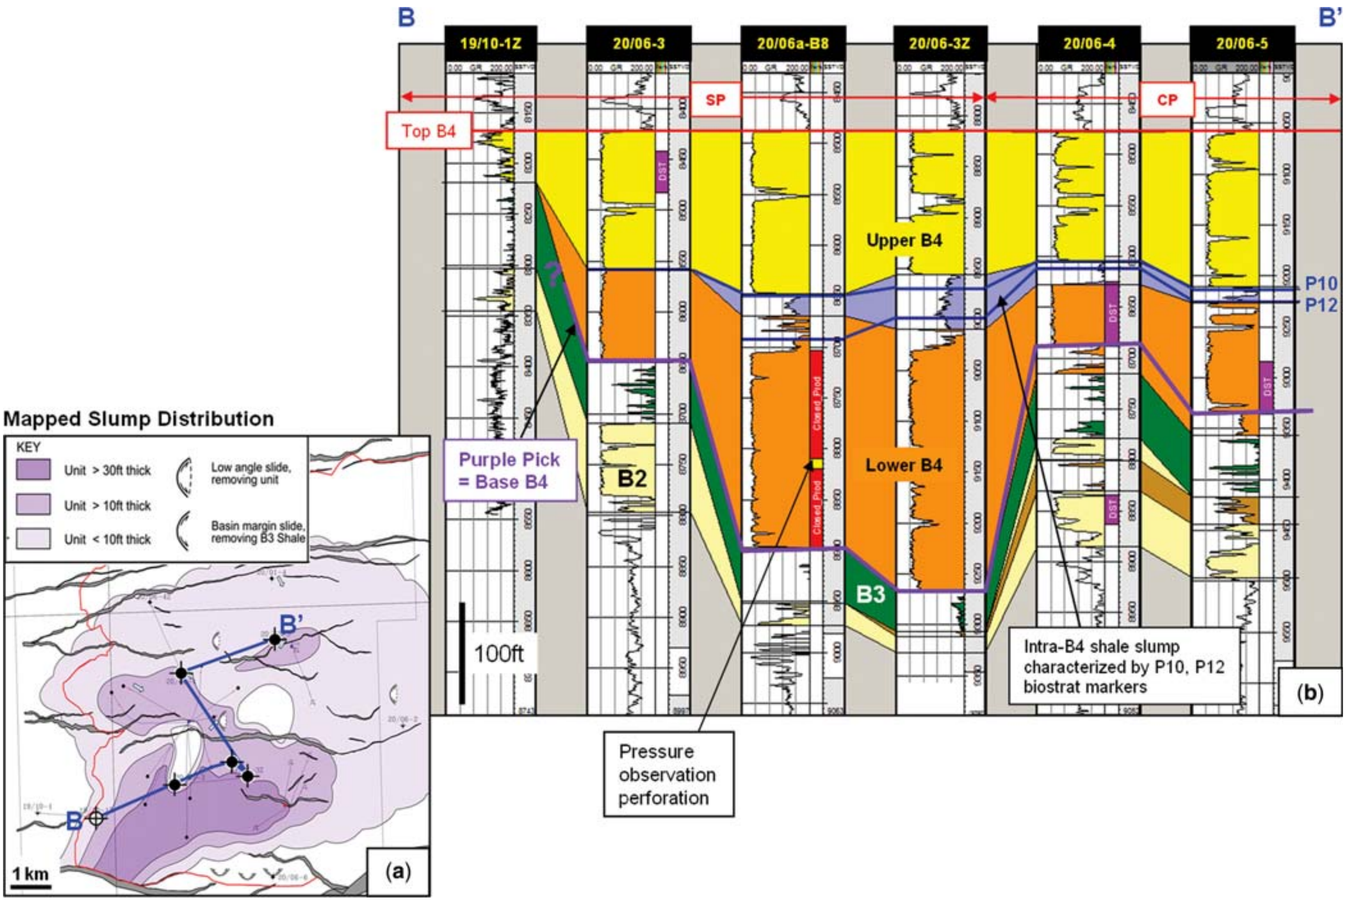

Fig. 8. Field-wide correlation and map of the Intra-B4 shale slump. Note the revised correlation in 20/06-3Z compared with Figure 5. The purple coloured shale unit has been re-interpreted from the B3 unit to the Intra-B4 shale and the underlying thick sand, coloured orange, formerly interpreted as the B2 unit, is now a Lower B4 unit. The Upper and Lower B4 are still considered to be laterally extensive sand-dominated units. Tracks, from left to right, are GR infilled by stratigraphic unit; perforation interval DST and SSTVD. SP, Southern Panel; CP, Central Panel.

alternative interpretation reconciled the seismic 'Purple Pick' with biostratigraphically driven correlations of wells field-wide and clarified the 'Purple Pick' as a base B4 marker. This allowed the gross B4 isochore package to be mapped directly on seismic.

Pre-development geological model

The revised correlation and seismic mapping no longer supported the tectonically controlled depositional model as proposed in the FDP. Thickest accumulations of sand were not confined to individual fault panels and hence there was little evidence to support the creation of accommodation space in associated half-grabens. Although it was supposed that the area remained tectonically active during deposition of the Buzzard sequence, this was confined to slight movements on the basin bounding faults, which triggered large-scale slumping as exemplified by the Intra-B4 shale unit. It became apparent that pre-existing basin topography must have played a significant role in controlling sand depositional geometries. In addition, mapping of the newly defined Upper and Lower B4 units indicated that a single source point, west of the Central Panel, rather than three separate source points, best fitted the new geometries. The modified correlation and mapping of the Upper and Lower B4 packages resulted in a radical change in the interpretation of sand connectivity and a shift in volumetric distribution within the Southern Panel, re-assigning more than 50×10^6 bbl from the B2 to the B4 unit. The development plan for the Southern Panel, which had expected to recomplete wells from the B4 to the B2 unit within the second year of field life, was revised to account for the new model, downgrading the importance of the B2 as a reservoir unit in the Buzzard Field and pushing its planned development further into the future.

Importantly, the geological model just prior to production start-up maintained the Upper and Lower B4 as discrete, field-wide hydraulic units, individually likely to behave in a tank-like manner. Shales within the body of each unit were considered to be small-scale features which would act as minor baffles only. The Upper and Lower B4 units were considered effectively isolated from each other, although it was thought that minor communication pathways could exist through fault juxtaposition. 'Holes' in the Intra-B4 shale, created by erosional downcutting of later, Upper B4-age flows, were also postulated to exist and to have the potential to provide leaky pathways between the Lower and Upper B4. This was based on evidence from the 20/06-3 well, where the Intra-B4 shale is absent, although the thick, sandy B4 unit present does contain large rip-up clasts with biomarkers commonly associated with the Intra-B4 shale (Fig. 8b).

The Buzzard Field: end 2007

Water injection began in December 2006, followed by first oil in January 2007. Prior to the field coming on stream, pressure data acquired in almost every pre-development well simply confirmed that all the wells lay on a common oil gradient, indicating that all sand units were potentially in hydraulic communication. Whether or not the Upper and Lower B4 units would communicate over a production time scale was a key question to be answered by post production start-up dynamic data.

By the end of 2007, an additional eight development wells had been drilled, bringing the total number of wells in the field to 35. Dynamic data, acquired after production start-up, provided an invaluable insight into the performance of the Buzzard Field. Key to this was downhole and tubing head pressure measurements acquired during interference testing.

Interference tests

At the time of field start-up, a set of interference tests were performed to gather information about lateral connectivity in the reservoir. Prior to production, pressure signals resulting from downdip injection were monitored in updip producers. The initial injection volume into the B4 was not large; only 300 000 barrels of water were injected into two Southern Panel injection wells, yet every single producer showed a pressure response, including wells located in the Central Panel. Even the most updip production well, 20/06a-B9, some 4 km away, saw a pressure response within 10 days (Fig. 9). These observations argued for a fairly open pressure system areally, even between the Central and Southern Panels. This was contrary to predictions based on the FDP model that the main structural panel bounding faults would be sealing.

Evidence for connectivity from pressure measurements

Prior to production start-up it was believed that the Intra-B4 shale, the biostratigraphically defined, laterally extensive shale between the Upper and Lower B4, would act as a vertical flow barrier. It was thought that only minimal connection between the two units existed, effectively resulting in segregated flow behaviour in the two B4 sands. However, post production start-up pressure profiles indicated that there was good communication across the Intra-B4 shale, indicative of highly effective Lower to Upper B4 connectivity, either through more widespread Upper to Lower B4 erosional contacts and/or fault juxtaposition of the two B4 units. The pressure profile in development well 20/06a-B14Z showed significant depletion both in the Upper and Lower B4, despite there being no off-take from the Lower B4 prior to drilling this well (Fig. 10a). The B2 unit was also depleted, to much the same level as the Lower B4. This was entirely unexpected, since the B2 unit was not under production and the field-wide B3 shale exists between the B4 and B2 packages. These data led to a review of the seismic in the area of the well and the identification of a small normal fault, south of the 20/06a-B14Z, which tips out rapidly to the east and west. At the point of maximum offset, where the throw is approximately 75 ft, the Upper and Lower B4 are juxtaposed and the Lower B4 and B2 are juxtaposed. Since the fault tips out, the pressure wave can easily travel around the ends of the fault to produce a localized system in which all the units communicate (Fig. 10b). Without the pressure data, this fault would not have been firmly identified on seismic since the amount of throw is close to seismic resolution. This example provided good evidence that faults of this magnitude exist and provide communication pathways between reservoir units in the Buzzard Field. More recent work has identified additional areas of fault juxtaposition which allow such cross-unit communication.

In contrast, pressure profiles from Southern Panel wells show a different story, in which only minor depletion in the B2 is observed, suggesting that the effects of such faulting may be localized.

Evidence for compartmentalization from pressure measurements

Whilst early monitoring of reservoir pressures has provided positive evidence of communication within the B4 and to the B2 unit, it has also, critically, enabled identification of isolated sand packages within the B4 reservoir. Mid flank, pre-production wells which could not come on stream due to H_2S levels were nevertheless perforated as pressure monitoring wells. Figure 11 shows the response of four pressure monitoring wells as a Southern Panel production well, 20/06a-B3, came on stream in January 2007.

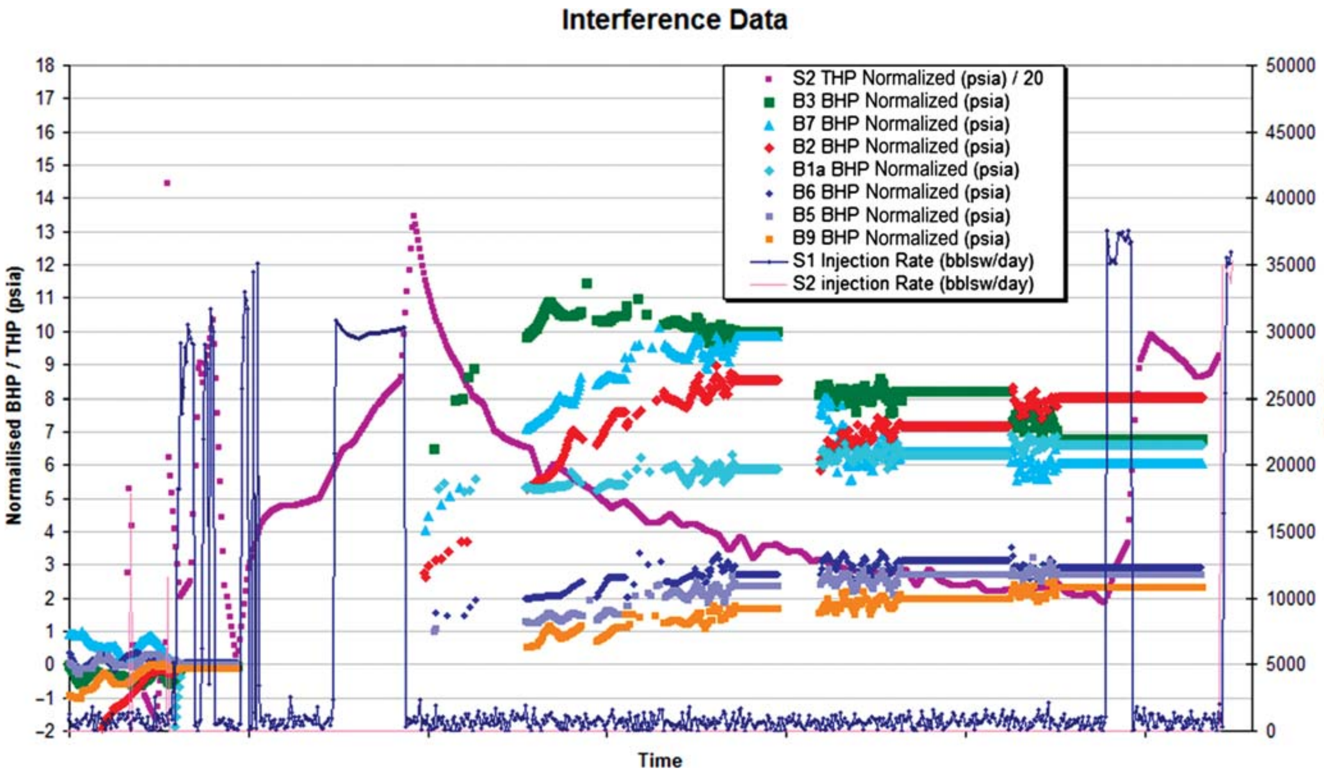

Fig. 9. Interference data plot showing production well bottom hole pressure (BHP) response in seven wells to initial water injection rate shown in barrels per day (Bbls/day) in Southern Panel injectors, 20/06a-S1 and 20/06a-S2. BHP shown as points and injection rate shown as lines. Tubing head pressure (THP) in the 20/06a-S2 injection well is also shown as points. All wells show a pressure response, including Central Panel pressure monitoring wells 20/06a-B1A, 20/06a-B6 and 20/06a-B5, and updip Central Panel producer 20/06a-B9. Refer to Figure 6 for well locations.

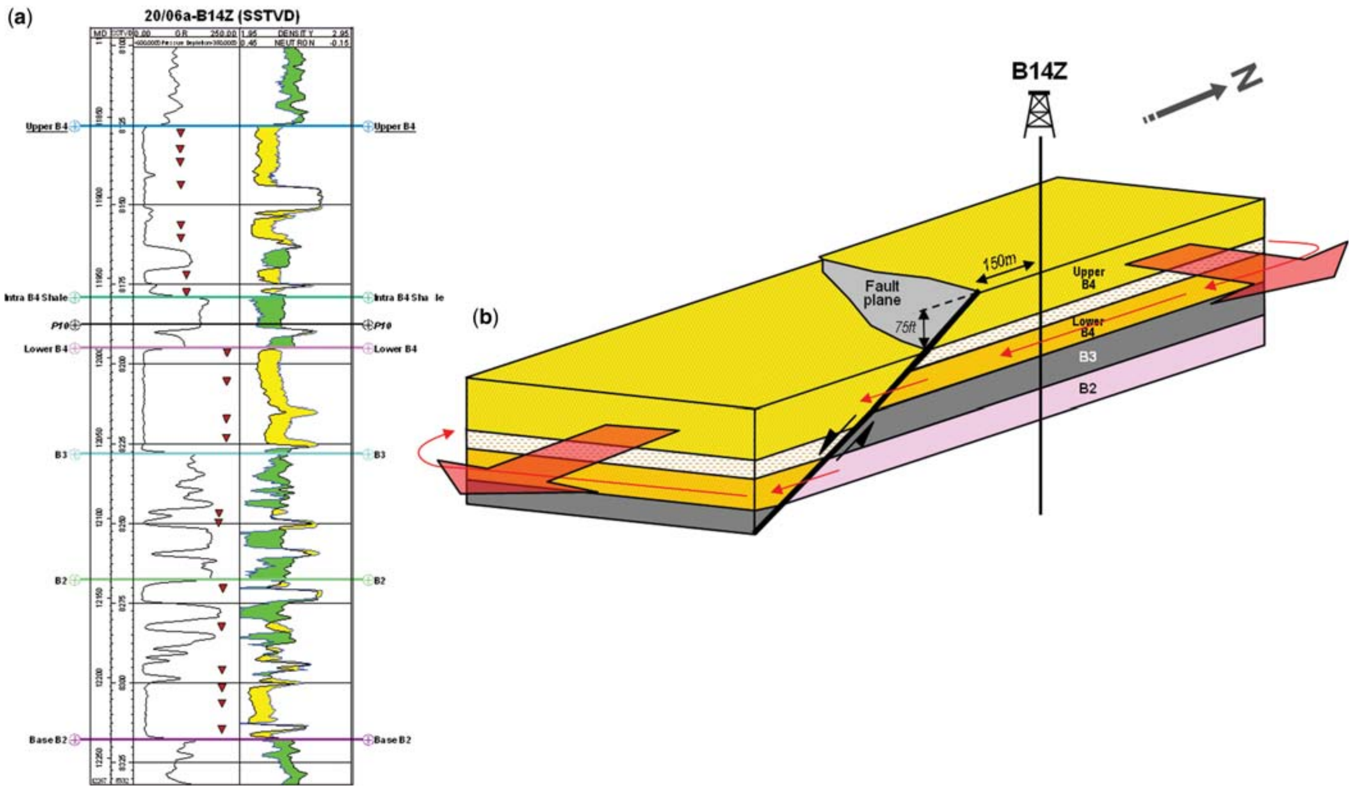

Fig. 10. (**a**) Central Panel updip production well 20/06a-B14Z drilled in 2007 showing pressure depletion as red triangles (track 3) relative to virgin reservoir conditions represented by the right hand side of the GR track. This illustrates depletion in Upper and Lower B4 units and the B2 unit, despite no offtake from the Lower B4 or B2 units. Tracks, from left to right, are MD; SSTVD; GR and density-neutron. (**b**) Cartoon block diagram showing how sand-to-sand juxtaposition across the tipping out fault near 20/06a-B14Z results in depletion of Upper and Lower B4 and B2 units. Inferred local flow pathways shown as small red arrows, with flow out of area to Upper B4 production wells as thick red arrows.

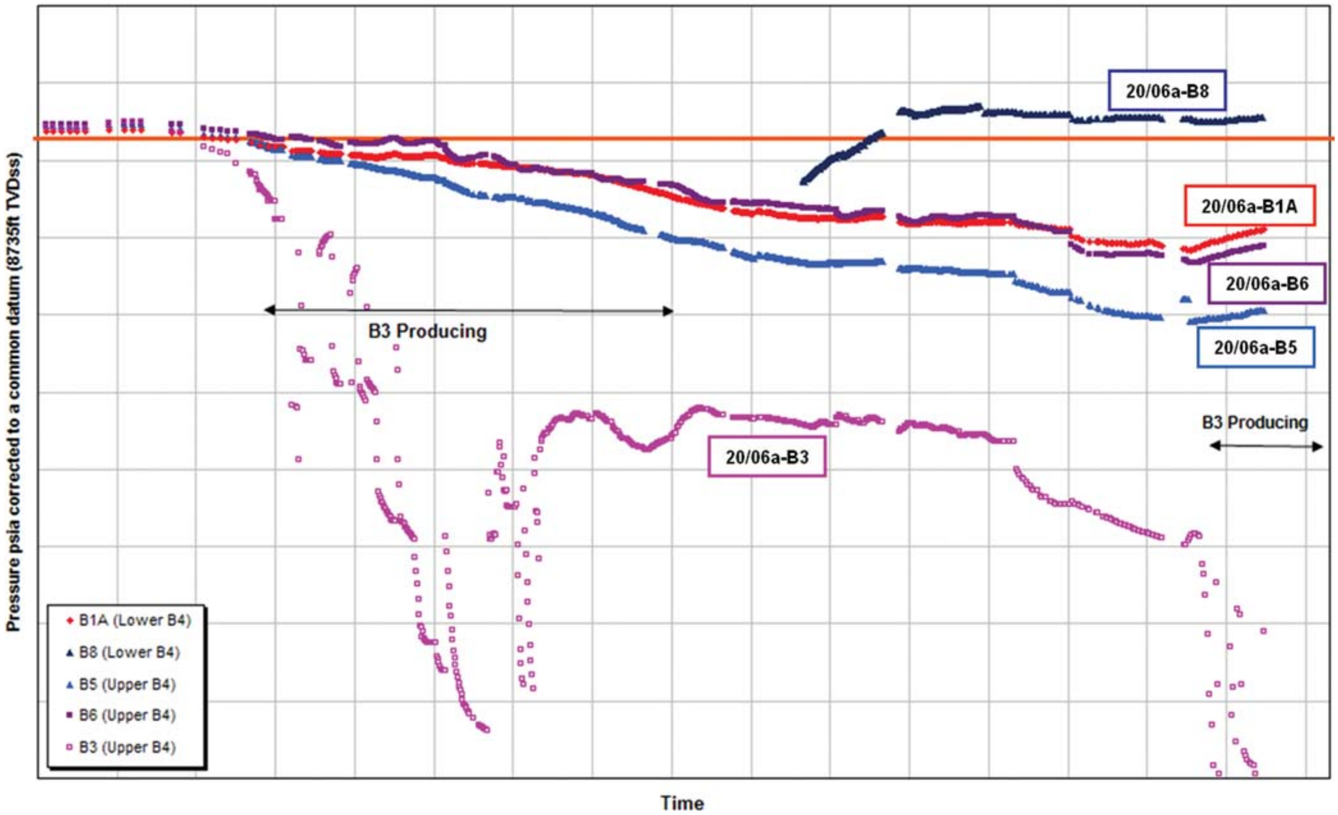

Fig. 11. Downhole gauge data (BHP) in mid flank pressure monitoring wells showing the response to Southern Panel well, 20/06a-B3, coming on stream. Orange line represents virgin reservoir pressure – all wells BHP slightly elevated initially due to injection as illustrated in Figure 9. Note pressure increase in Southern Panel well 20/06a-B8 in contrast to pressure decline seen in the Central Panel wells 20/06a-B1A, 20/06a-B5 and 20/06a-B6. Refer to Figure 6 for well locations.

Three of the wells (20/06a-B1A, -B5, -B6), located in the Central Panel, show consistent pressure decline, but the fourth well, 20/06a-B8, in the Southern Panel, continues to show pressure increase. Of these, the Southern Panel well, 20/06a-B8, and the closest Central Panel well, 20/06a-B1A, are completed in the same, Lower B4 interval. Early interference tests had indicated that all wells communicated with downdip injectors. The response in the Central Panel observation wells was interpreted as a balance between injection downdip and offtake updip. However, 20/06a-B8 in the Southern Panel, whilst responding to downdip injection, was clearly disconnected from any of the producing wells at the time, either in the Southern or Central Panel. In order to understand the dynamic information, seismic mapping and stratigraphic correlation of the B4 package in the Southern Panel were reassessed. Figure 12 shows the revised interpretation of the Lower B4 in the Southern Panel (Fig. 12a), which better honours all the data, and produces an excellent history match for the 20/06a-B8 well (Fig. 12b). Originally, the Lower B4 unit extended updip from 20/06a-B8 through the 20/06-3 well (Fig. 8). In this new model, still valid today, the thick sand package representing the Lower B4 in the Southern Panel pinches out rapidly updip of 20/06a-B8, allowing no communication with Southern Panel production wells.

History matching also indicated that the Lower B4 sand in the 20/06a-B8 does not fully communicate with the Upper B4, against which it is juxtaposed, across the Southern-Central Panel bounding fault. Optimum history matches were achieved by assigning low transmissibility to the western portion of the fault, whilst the eastern half was fully open. Whilst most of the early dynamic data were pointing towards a very open system, here was a clear indication that at least part of the Southern-Central bounding fault was not fully transmissible after all.

In this case, perhaps fortuitously, well 20/06a-B8 was in a good position to monitor reservoir pressure in this Lower B4 sand unit, without which early identification of stratigraphic compartmentalization would not have been possible. As a result, the extensive accumulation monitored by the 20/06a-B8 well, an estimated 70×10^6 bbl, can be targeted in the future to ensure fluids are efficiently recovered. The design of future infill well drilling strategies will have to take into account the possibility of similar stratigraphic compartmentalization, ensuring sufficient areal well coverage and extensive pressure sampling for all sand units. This data, and the revised geological model it led to, brought about a change in attitude to the Buzzard reservoirs, whereby the reservoir model containing simplistic, laterally extensive, 'tank-like' reservoir units was no longer considered viable.

The Buzzard Field today: mid 2009

During 2008, one appraisal, two production and two injection wells were drilled, bringing the total number of wells in the field development area to 40 (Fig. 13). As had been the strategy prior to first oil, and throughout the first year of production, the data acquisition programme continued with an emphasis on obtaining dynamic data. Cased hole production logs, saturation logs and reservoir pressures were acquired across the field to enhance understanding of production contribution from individual sand units and to determine whether there was evidence for any differential depletion between sands.

Efforts to dynamically model the field continued throughout, with model updates being made in order to capture the most recent information. One of the key results of simulation modelling was an indication that the B4 reservoir was more complex than the

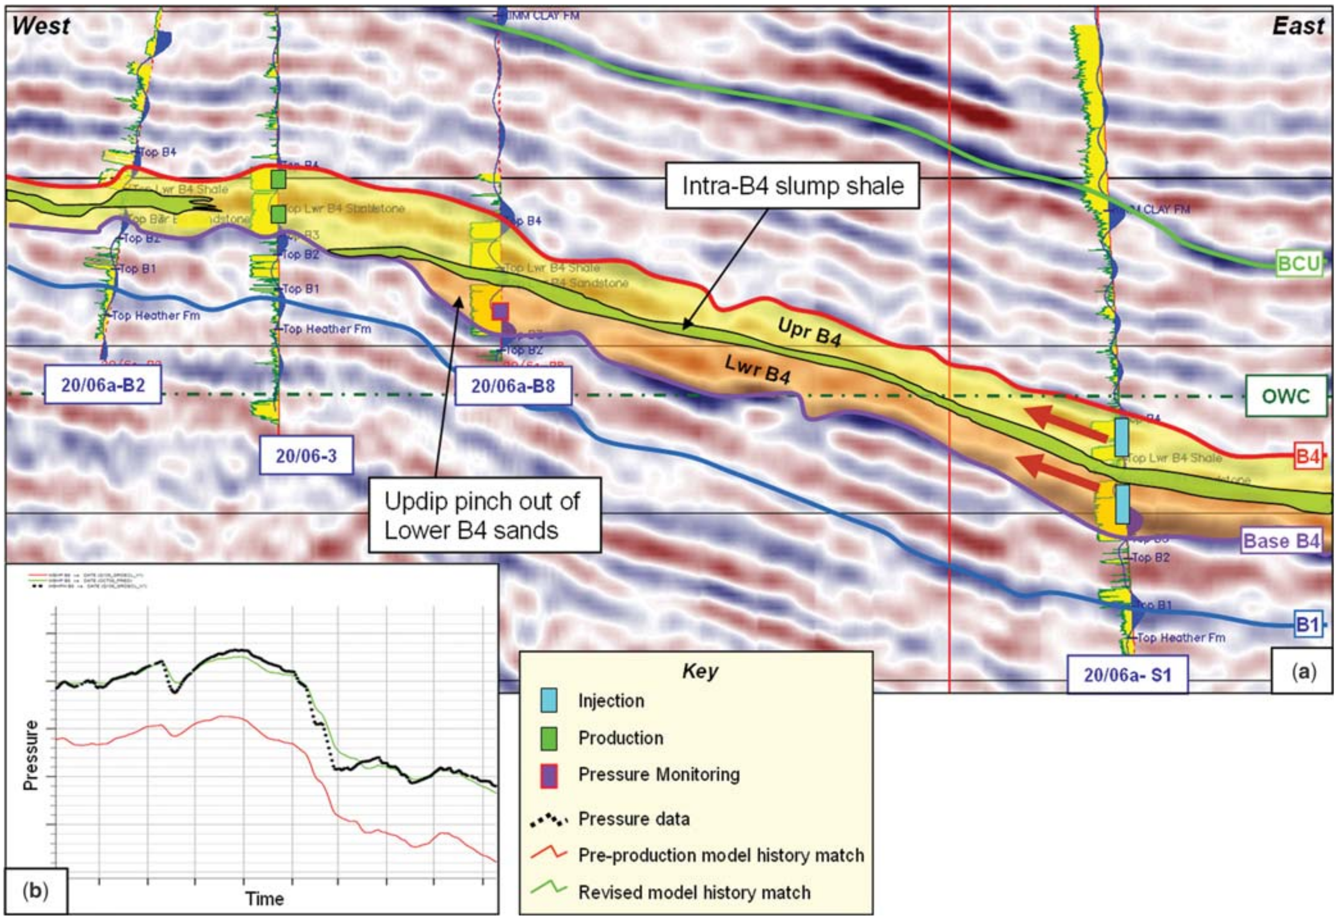

Fig. 12. (**a**) Revised interpretation of the Lower B4 unit in the Southern Panel (refer to Figure 6 for well locations). GR log displayed in wells together with perforation interval and type. (**b**) History match of the 20/06a-B8 well (actual data shown as black dots), before (red line) and after (green line) editing to capture the pinchout of the Lower B4 unit updip of the well.

simple Upper and Lower split built into the early production models of the field. Pressure surveys acquired in new wells typically indicated the presence of more than two hydraulic units (Fig. 14) and it became increasingly difficult to match field pressures in a simple two-layer model of the B4 reservoir. Matches were achieved by invoking an additional, extensive barrier to vertical flow within the Upper B4 and it became clear that a review of the field stratigraphy was required to determine whether a more complex vertical layering scheme, involving additional, laterally extensive shales, was supported by all the data.

In addition to the dynamic data incoming throughout this time, the results of a number of core-based studies also became available and, in conjunction with the continued biostratigraphic analysis of Buzzard wells, afforded a means to further subdivide the B4 reservoir. These studies were largely a continuation of work initiated at FDP time, but it was only through the addition of considerably more core material, some 2050 ft acquired in development wells, that useful patterns began to emerge, allowing improved integration of all the data towards a consistent Buzzard reservoir model. The most informative of these studies, outlined here, utilized chemostratigraphy.

Integration of Buzzard chemostratigraphy

Whilst a consistent approach to biostratigraphic analysis had provided a framework for correlation within the Buzzard Field, it is based solely on data from shale sections. The very sandy nature of the Buzzard reservoirs, together with their rapid mode of deposition as turbidites, precludes finding sufficient palynofloral material to be able to distinguish within sandy sections. Chemostratigraphy, on the other hand, characterizes sedimentary rock successions by using inorganic geochemical data and so is not limited by lithology. Rock geochemistry is sensitive to subtle changes in mineral abundance and composition. Apparently uniform sedimentary successions usually show primary differences in the geochemistry of their constituent minerals, or in the proportions of accessory minerals. The latter, which include heavy minerals and clay minerals, commonly have very distinctive trace element contents.

During 2007 and 2008, 355 sandstone and 292 claystone samples from core, cuttings and sidewall cores were analysed, providing data covering 34 different elements. This was used as the basis for defining sandstone and claystone chemostratigraphic packages within the Buzzard reservoir, with the most confident definition achieved through the B4 unit where the majority of samples came from.

Interpretation of the geochemical data allows the recognition of six sandstone and four claystone chemostratigraphic packages, although not all the packages are identified in all the wells (Fig. 15). The chemostratigraphic characterization of the sandstones (Fig. 15a) is largely based on changes related to potassium feldspar abundance and heavy mineral types, particularly zircon and rutile, which reflect variations in either provenance or the depositional pathways along which flows have travelled. The chemostratigraphic characterization of Buzzard claystones (Fig. 15b), on the other hand, may represent facies changes. Older claystones, with relatively higher calcium levels, appear to have been deposited in more oxic conditions, above the carbonate compensation depth (CCD). Younger claystones show decreased calcium levels,

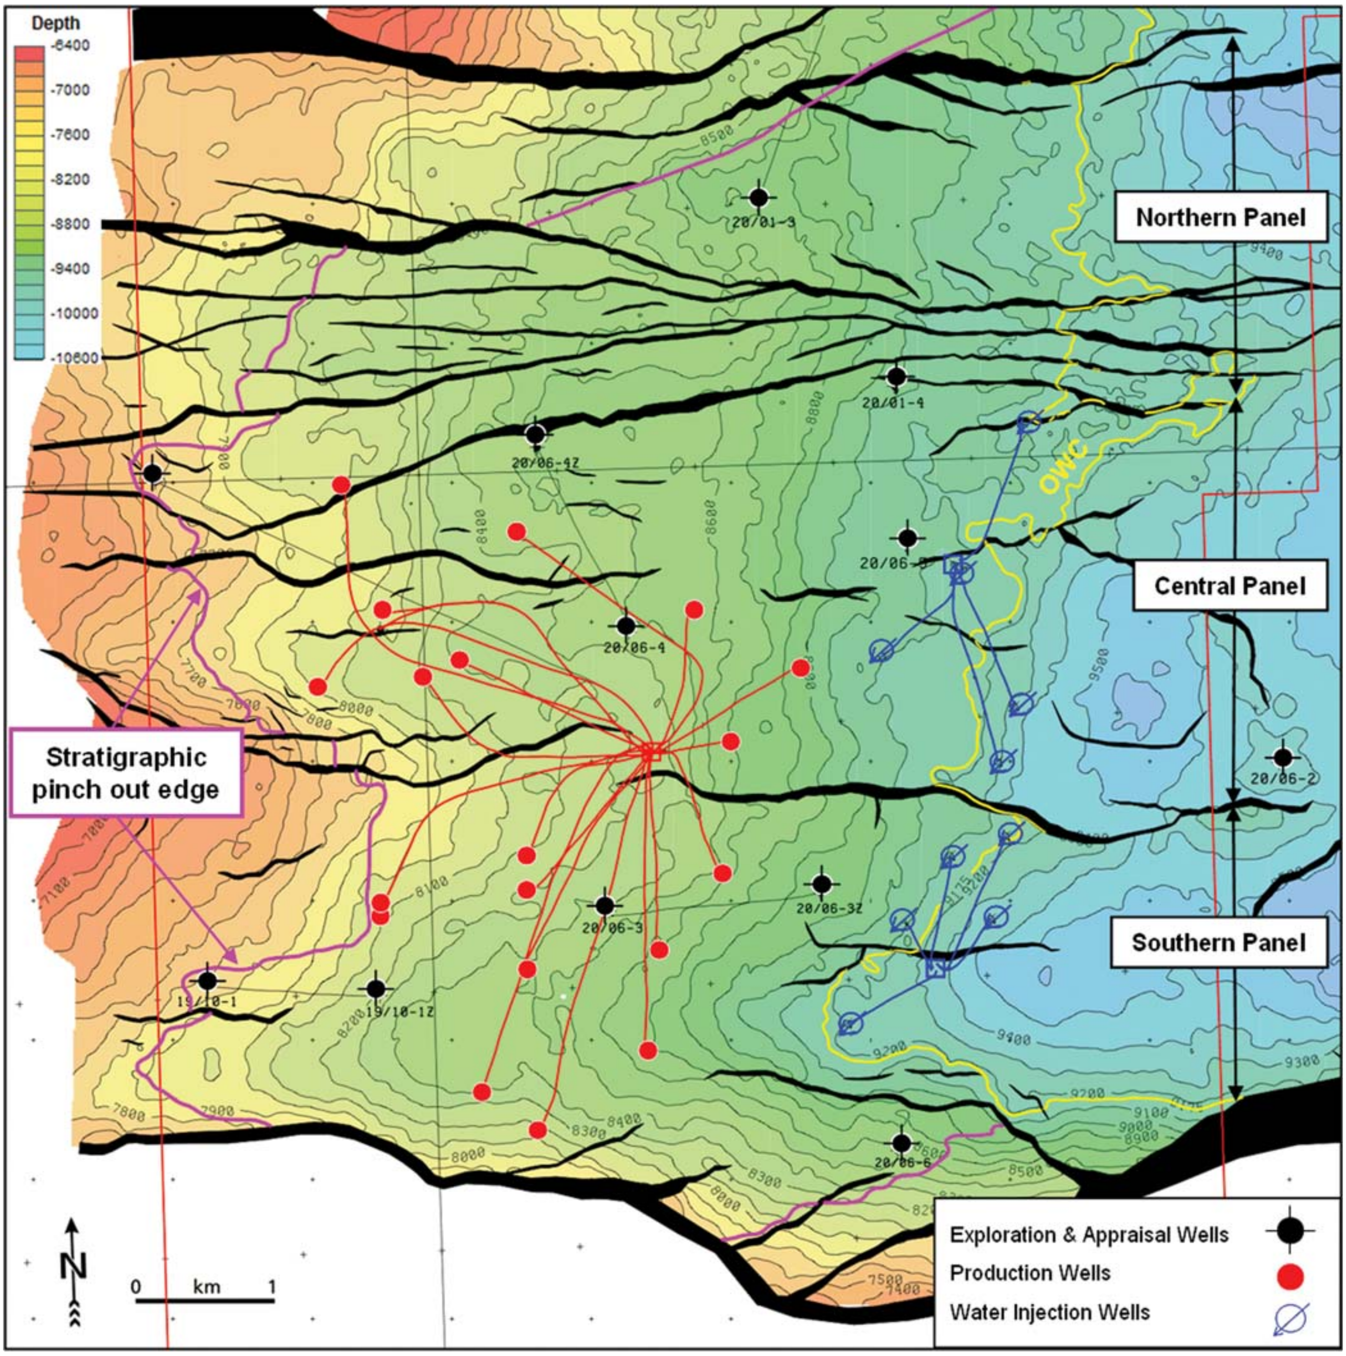

Fig. 13. Buzzard Field B4 reservoir top depth map showing present-day well coverage (as of March 2009), comprising 11 exploration and appraisal wells, 19 production wells and 10 water injection wells. Note the extension of the stratigraphic pinchout edge westwards due to new well results and revised geological interpretations.

indicating deposition below the CCD. Finer-scale geochemical variations may even help to distinguish within claystone packages, between hemipelagic and slump deposits.

When used in conjunction with the existing biostratigraphic framework, the large-scale chemostratigraphic packages help define four sandstone units in the Upper B4 and three in the Lower B4, interbedded with distinct shales (Fig. 16). The two most confidently defined claystone chemostratigraphic packages are consistent with the biostratigraphically defined Intra-B4 and B3 shales and have signatures relating to slumped or debritic, and hemipelagic type deposits, respectively. The resultant B4 reservoir zonation scheme, shown in Figure 16, has greater vertical heterogeneity than previously described but, when modelled, provides a better match to dynamic data.

Revised geological model

The integration of biostratigraphy and chemostratigraphy with feedback from dynamic data and modelling has enabled a more detailed subdivision of the Buzzard reservoir which is intrinsically linked to our understanding of how the reservoir is behaving under development conditions. Isopach mapping of individual Upper and Lower B4 units, defined by the new zonation scheme, supports the interpretation of each sandy unit as a separate turbidite lobe and demonstrates the topographic control of existing lobes and muddy slumps on subsequent depositional packages (Fig. 17). The maps illustrate how the B4 lobes were deposited through compensational stacking, whereby successive sandy flows fill the topographic lows adjacent to relative highs formed by previous deposits. These ‘highs’ may have been in the form of existing turbidite lobes or,

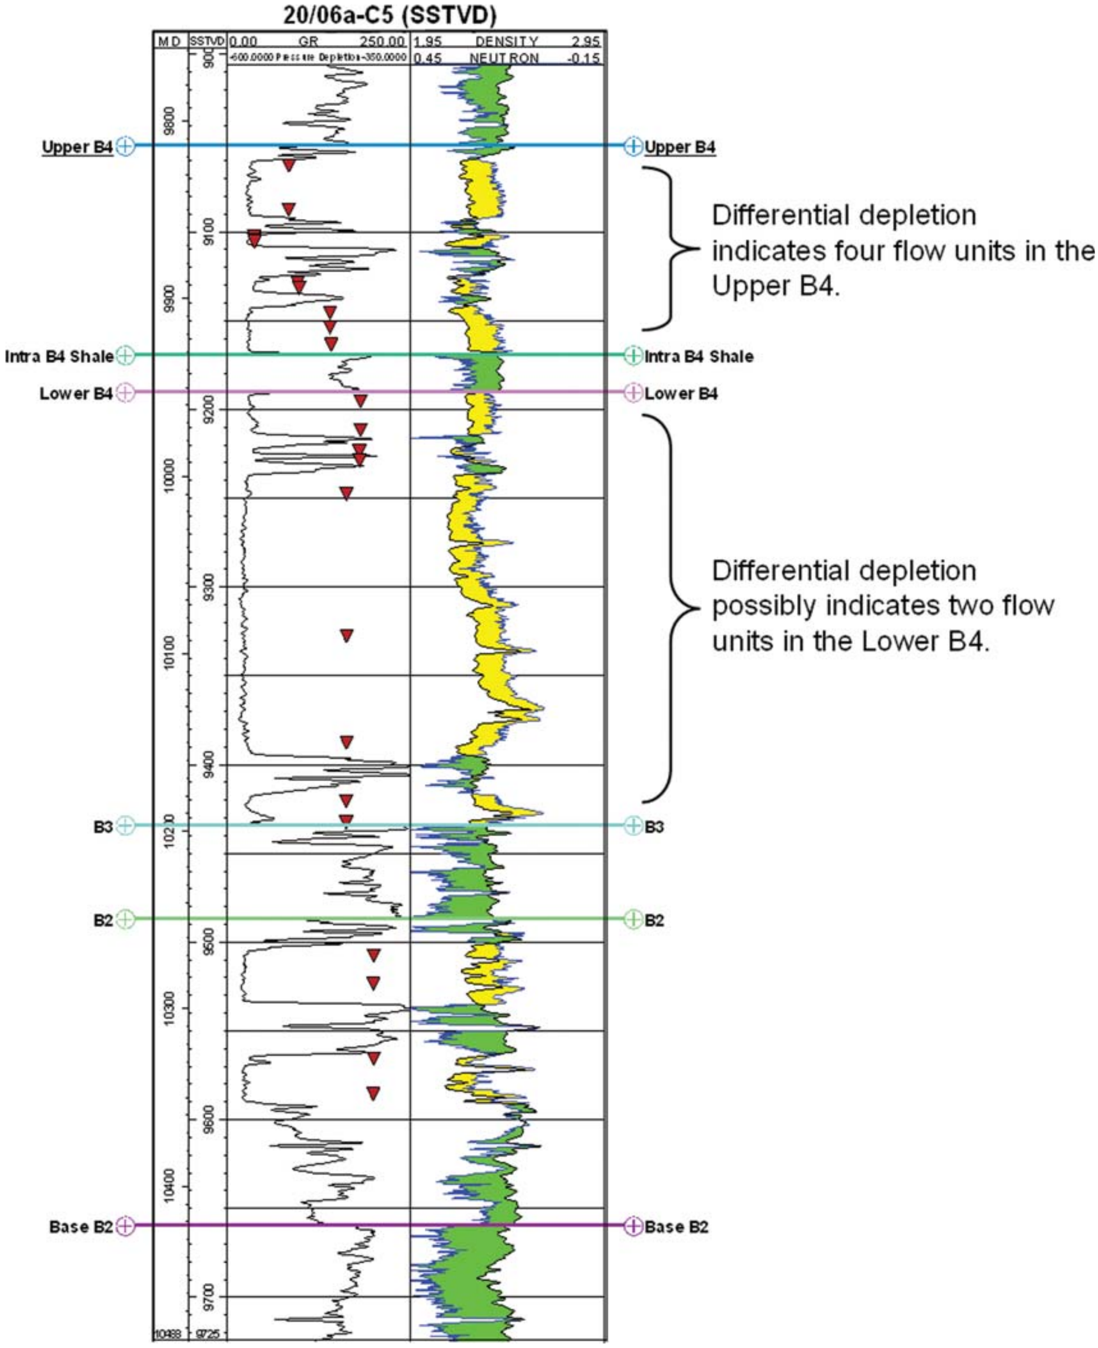

Fig. 14. Central Panel injection well drilled in 2008 showing pressure depletion as red triangles (track 3) relative to virgin reservoir conditions, represented by the right-hand side of the GR track, illustrating the potential for multiple flow units within the stratigraphic sequence already defined. Tracks, from left to right, are MD; SSTVD; GR and density-neutron.

as shown in Figure 17, the positive relief features created by periodic, catastrophic muddy slumps from the basin margins. Isopach maps of the individual reservoir units thicken eastwards, away from a westerly source point. Subtle changes in the maps over time suggest that the position of that source point may have shifted from a location in the Central Panel, during deposition of the Lower B4 units, to the Southern Panel during deposition of the Upper B4 units. Limited palaeoflow indicators from core and image log interpretations in Southern Panel wells are also supportive of a southerly source point during deposition of the Upper B4.

A similar model of deposition has been described by Gervais *et al.* (2004, 2006) for the Pleistocene age Golo turbidite system off the eastern margin of Corsica. This modern, sandy turbidite system is fed by a single river and canyon feeder and is confined by a structural ridge on one side and the continental shelf slope on the other, giving rise to a basin with similar dimensions and setting as the Buzzard Field. The processes for supplying sand into Buzzard may also have been similar to those proposed for some of these East Corsican fans, via turbidity currents generated through failure of pro-delta slopes where sediment was temporarily stored (Deptuck *et al.* 2008).

Current understanding of reservoir connectivity

The revised stratigraphy for the Buzzard Field has been used in recent modelling efforts and has proved successful in matching dynamic field data. The current model supports excellent field-wide communication despite the presence of laterally extensive shale layers within the B4 unit. The mechanism by which this communication is allowed is believed to be dominantly via sand

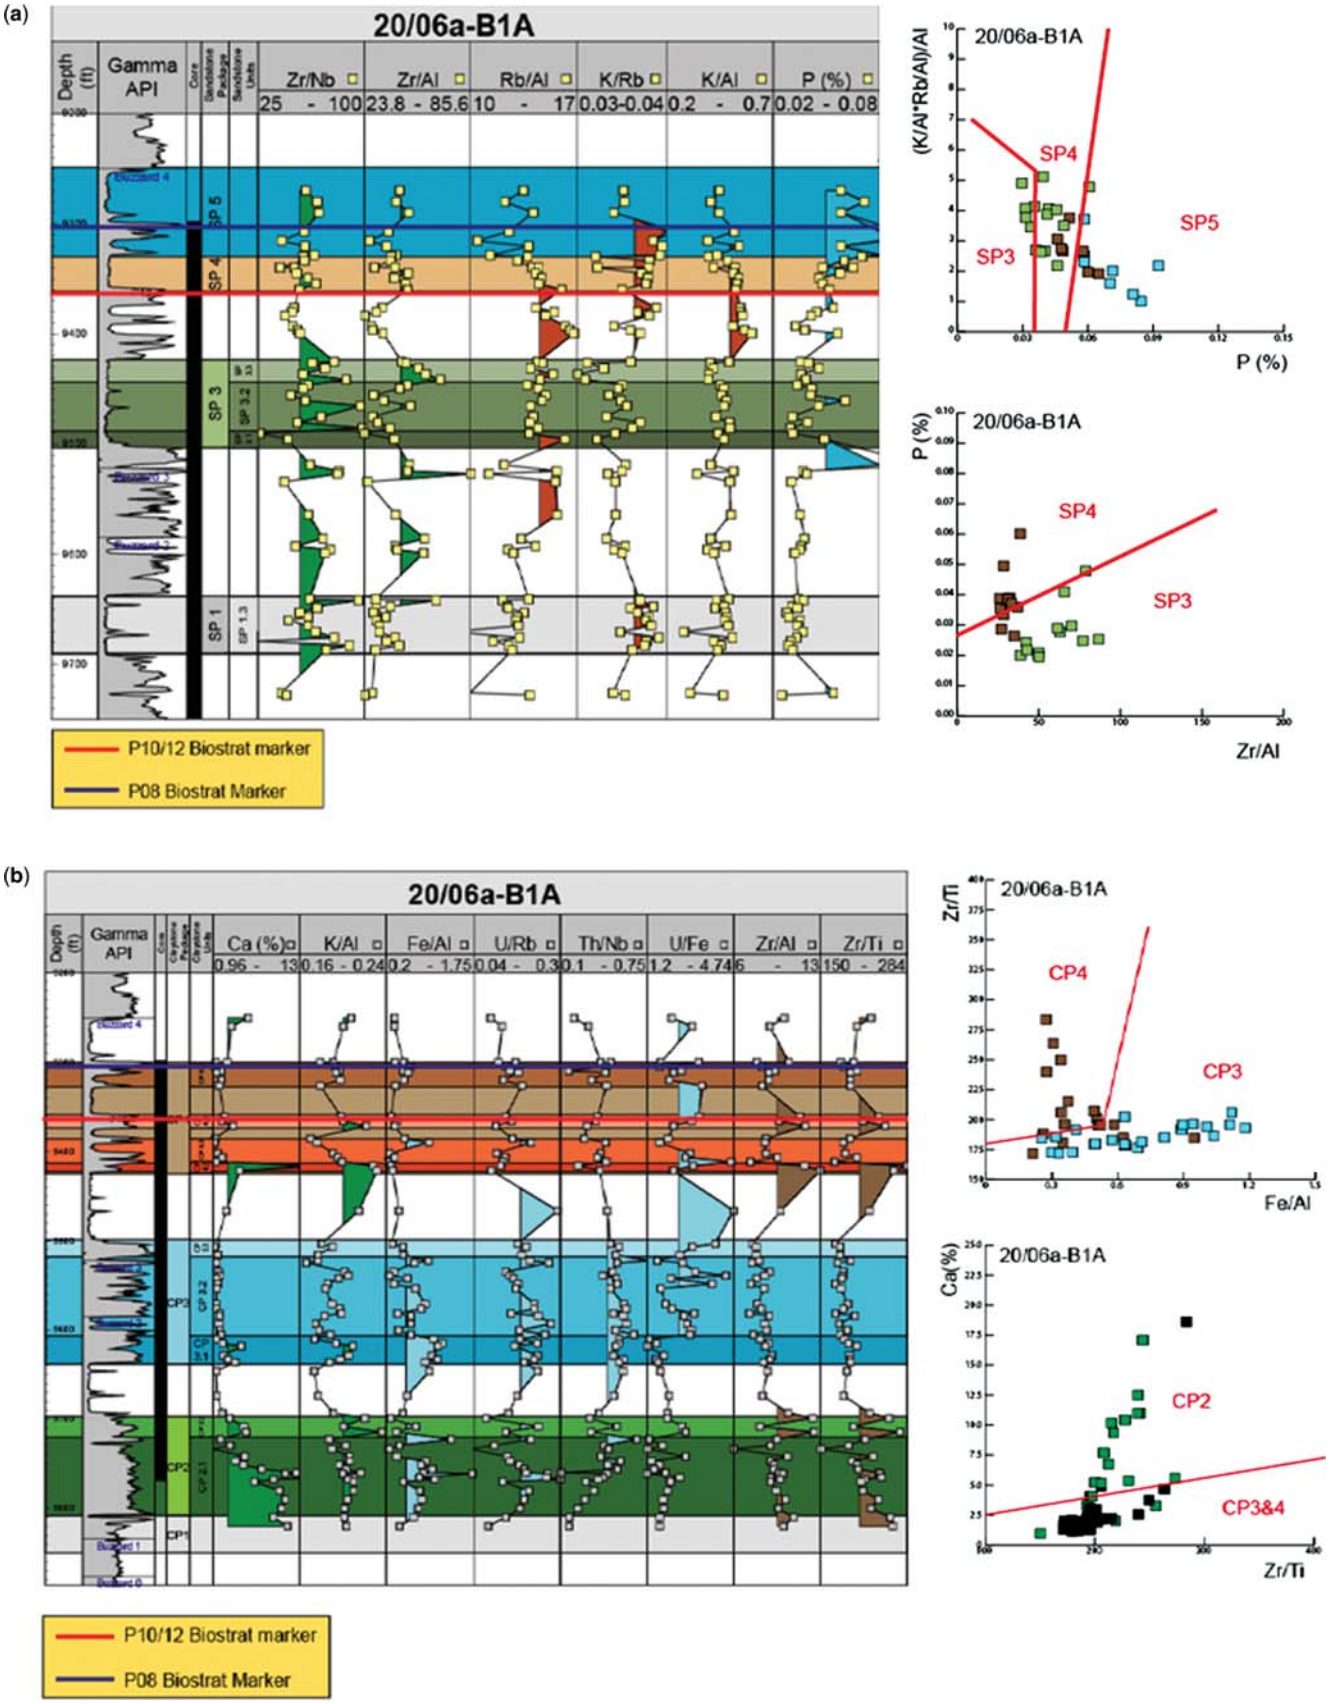

Fig. 15. Selected geochemical profiles and binary diagrams for well 20/06a-B1A, illustrating some of the (**a**) sand and (**b**) shale chemostratigraphic packages defined in the Buzzard wells. (a) Sandstone package SP5 is clearly characterized by high P levels, linked to abundance of biogenic apatite and carbonaceous debris. (b) Claystone package CP4 is characterized by high overall Zr–Al and Zr–Ti values, reflecting the abundance of silt-sized zircon grains as well as lower Fe–Al values related to lower abundance of pyrite.

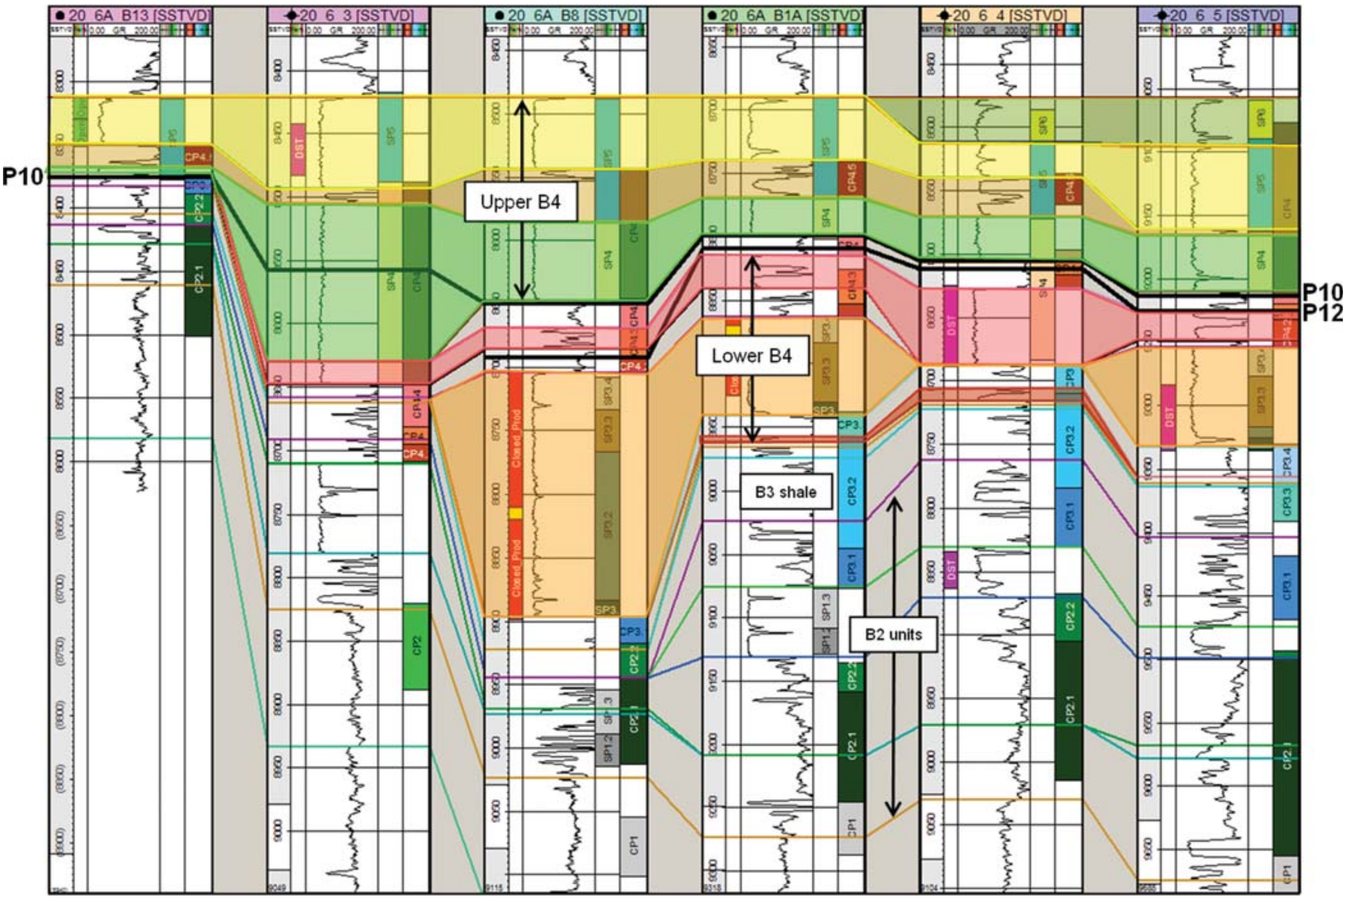

Fig. 16. South to north cross-section through Southern and Central Panel wells showing chemostratigraphic sand and claystone packages (tracks 4 and 5, respectively), relevant biostrat markers, P10 and P12 (black lines) and the current reservoir stratigraphy (coloured lines and shading). Tracks, from left to right, are subsea true vertical depth (SSTVD); perforated intervals [green, open; red, closed; yellow, pressure observation; purple, DST]; GR; chemostratigraphic sandstone packages and chemostratigraphic claystone packages.

to sand juxtaposition across non-sealing faults. There may also be a minor element of erosional sand on sand contact, but there is little evidence for significant erosion in Buzzard cores, with the exception of that observed and commented upon in well 20/06-3. The effect of the extensive shale layers is to promote strong flow layering within the B4, giving rise to the differential pressure depletion signals seen in recently drilled wells (Fig. 14).

The current model enhances understanding and prediction of production contribution, differential depletion and water breakthrough in the individual B4 reservoir sands. This will help to optimize future well planning and perforation strategy in production and injection wells to balance the water flood front advance and manage voidage within the field.

In addition, the improved reservoir zonation and sedimentological understanding provides a sound basis for more detailed investigation into variability in facies, grain size, porosity and permeability within the reservoir units. A greater appreciation of the controls on, and distribution of, these factors will further refine the reservoir model and hence its prediction capability.

Conclusions

The geological model for the Buzzard reservoir has changed over the last six years, in response to continuous data acquisition, integration and analysis through the pre- and post-startup phases of field life. The 'tank-like' reservoirs of FDP time have been superseded by a more complex model of compensationally stacked sand lobes. Shales, derived through intermittent, large-scale muddy slumps from the basin margins, are considerably more extensive than originally modelled, creating barriers to vertical flow within the gross reservoir package. These muddy slumps also create positive seafloor topography, influencing deposition of subsequent sandy flows. Conversely, sand lobes potentially have depositional limits within the main field area, such that prediction of sand presence and thickness across the field is far from straight forward. Understanding the geometry and distribution of sands and shale units is now seen as critical for successful reservoir management.

Evolution of the geological model has gone hand in hand with our understanding of connectivity within the B4 reservoir. The early FDP model of a highly connected B4 'tank' sand confined within fault panels by sealing faults was superseded by a model in which the FDP 'tank' was divided into an Upper and Lower unit. The expectation was of a high level of connectivity within each B4 unit, but a significant amount of vertical baffling between the units as faults were still considered sealing. Early development interference testing indicated faults were, on the whole, not sealing, but it also became apparent that stratigraphic compartmentalization, due to sand unit pinchout within the limits of the development area, could limit communication across the whole field. With the benefit of two and a half years of production data and continued data acquisition in newly drilled development wells, it is now evident that the B4 reservoir is divided into multiple hydraulic units, defined by individual sand lobes and laterally extensive shales acting as vertical baffles. Some of these lobes pinchout within the field development area. The effect of

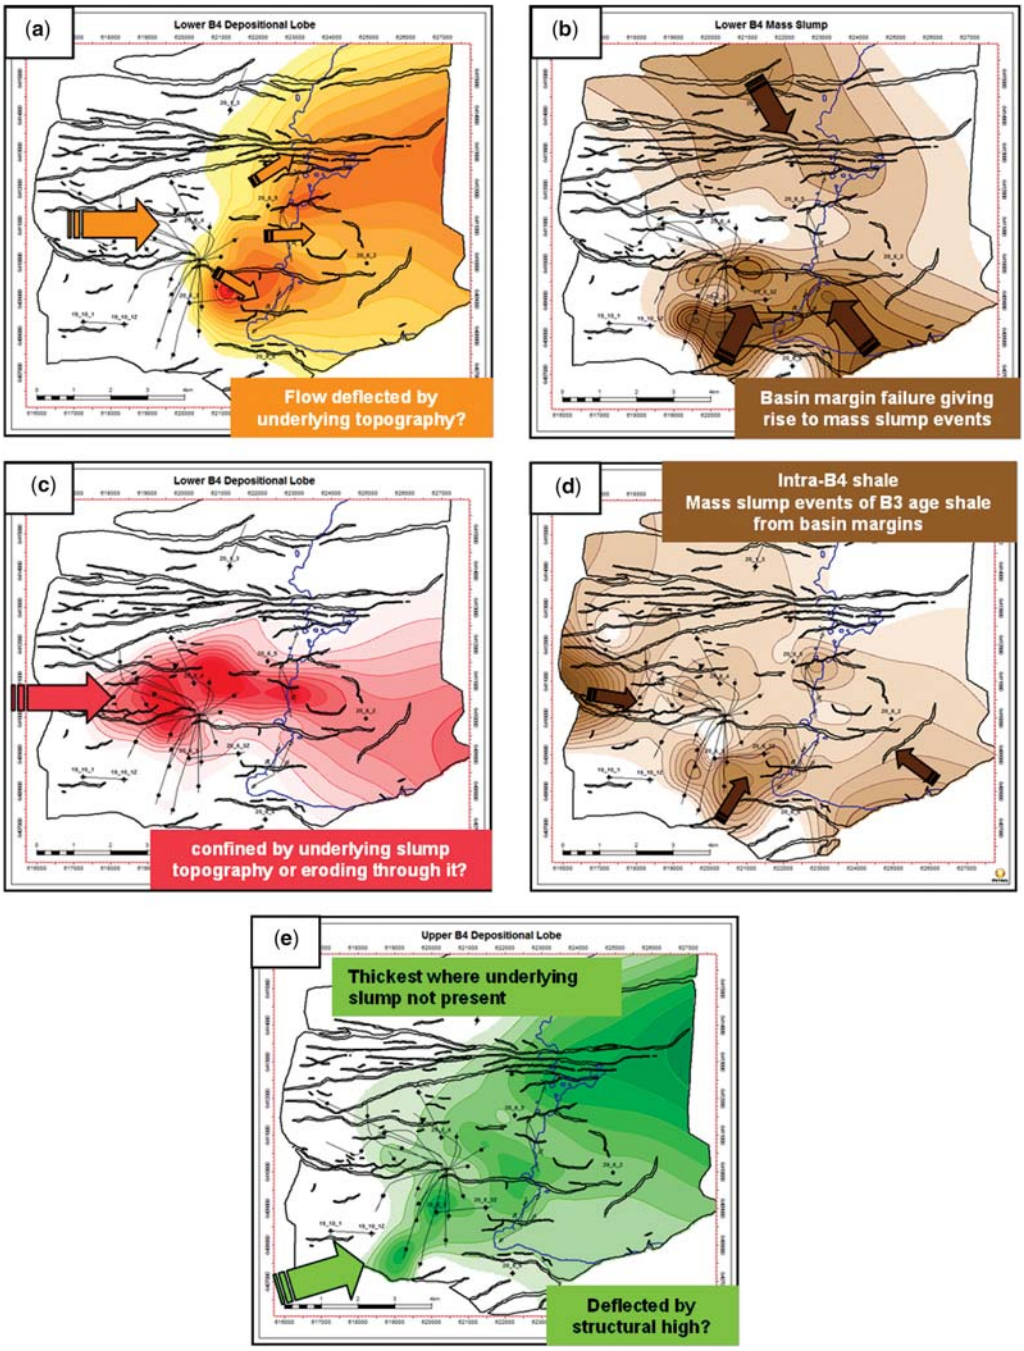

Fig. 17. Compensational stacking of the depositional sequence of some of the B4 units, from oldest, Lower B4 (**a–d**) to youngest, Upper B4 (**e**) illustrated with unit isochore maps; colours of units as per Figure 16. Lower B4 sands are derived from a westerly, Central Panel source point. Sand deposition is strongly influenced by existing topography as created by previous sands and mass slump deposits. Not all Upper B4 units are shown, but sand deposition post the Intra-B4 shale may be derived from a more southerly source point.

non-sealing faults within this vertically baffled reservoir is to maintain excellent lateral connectivity over the field as a whole.

Our present-day understanding of the Buzzard depositional system has been greatly assisted by the high density of well control, extensive data acquisition programmes, the use of wells for reservoir monitoring and full integration of static and dynamic reservoir data. This, in combination with an undeniably world class reservoir provided by mother nature, has enabled the operator to exceed FDP expectations, reaching plateau production levels of over 200 000 BOPD within six months of the field coming on stream. STOIIP and reserves expectations have increased by more than 40% since the FDP was written, which is partly attributable to improvements in the mapping of field net to gross in the geological model. Going forward, our improved understanding of the field will provide input into reservoir management and well planning strategies as well as supporting targeted data acquisition and studies programmes.

The Scott Field: revitalization of a mature field

G. R. BROOK, J. R. WARDELL, S. F. FLANAGAN and T. P. REGAN

Nexen Petroleum (UK) Ltd, Charter Place, Vine Street, Uxbridge, Middlesex UB8 1JG, UK (e-mail: glen_brook@nexeninc.com)

Abstract: The Scott Field, located in the UK Central North Sea, is in a mature stage of development. The Scott platform has been on production since 1993, when the Scott Field came on stream, followed in 1996 by the subsea tie-back of the Telford Field development, located to the south of Scott. By 2005 the Scott Field had produced 400×10^6 boe cumulative production. However, the field was producing at water cuts approaching 90% and the previously completed 2002–2004 infill drilling campaign had not met expectations. A change in strategy was undertaken in the subsequent 2005–2007 Scott drilling campaign, which yielded positive results, adding reserves and significantly increasing platform export rates. The focus moved from peripheral targets towards the edge of the field to lower risk targets closer to existing well control. Success was also attributed to focusing on the seismic interpretation of block bounding faults in poorly imaged areas of the field, allowing identification of small fault-bound targets. The recent drilling has demonstrated that significant value can be found in small and often complex accumulations within an extensively drilled mature field.

Keywords: mature asset, drilling, case study, North Sea, late field life development

The Scott Field lies in Blocks 15/21 and 15/22 of the UK sector of the North Sea (Fig. 1). It is operated by Nexen Petroleum (UK) Ltd. The field began production in September 1993 and reached plateau production of 200 000 bbl/day within several months, through seven pre-drilled production wells, with supporting injectors. The production potential of the field is currently around 20 000 bbl/day at a field watercut of 90%.

As the asset matures, it is getting more and more difficult to find reserve and production adding opportunities. Infill drilling targets have progressively decreased in size since the early field drilling. Additionally, the targets were of higher risk as infill opportunities at the margins of the field were being pursued.

Infill drilling on the field was paused in 2004 after a series of drilling results that were poorer than prognosed. A change in strategy was undertaken in the subsequent 2005–2007 campaign which yielded positive results, adding reserves and significantly increasing platform export rates. The focus moved from peripheral targets at the edge of the field towards lower risk targets closer to existing well control. In some instances the drilling targets were located just over 500 m from existing production wells in the same targeted reservoir interval. Success was also attributed to focusing on the seismic interpretation of block bounding faults in poorly imaged areas of the field. This increased the confidence on the interpretation of the reservoir adjacent to the bounding faults and also identified minor faulting that may have impacted on the sweep behaviour of the field, resulting in fault shadow accumulations. The recent drilling has demonstrated that significant value can be found in small and often complex accumulations within an extensively drilled mature field.

Geological description

The Scott Field is a structurally complex, Upper Jurassic sandstone reservoir located in the Outer Moray Firth, Scotland. The tectono-stratigraphic evolution of the Witch Ground Graben and the Scott and Telford fields have been documented by numerous workers (Boldy & Brealey 1990; O'Driscoll *et al.* 1990; Hibbert & Mackertich 1993; Jones *et al.* 1999; Guscott *et al.* 2003) and is only briefly summarized in this paper.

The Scott Field is highly compartmentalized with major faulting subdividing the field into a number of blocks (Fig. 2); two main fault trends are identified. The older of the fault trends forms part of the NE–SW trending Theta Graben fault system. This represents a mid Cimmerian extensional phase along a reactivated Caledonide trend. The principal expression of this fault is the Block I/Block II bounding fault and there is evidence for syn-depositional activity along this trend in the Scott Field. A later east–west orientated set of faults result from the Late Jurassic extension associated with the opening of the Witch Ground Graben. This episode of faulting postdates the deposition of the Scott and Piper reservoirs of the Scott Field and is responsible for the tilted fault block geometry of the field. Whilst the observed throw is greatest on the NE–SW trending fault separating Blocks I and II on the field, both orientations of faulting have sealing potential resulting in different fluid contacts in the main blocks of the field (Fig. 3).

Reservoir characterization has been performed from a combination of logging data, core data and production performance. There was an immense amount of core taken, particularly in the early days of Scott drilling with 62 wells wholly or partially cored, giving a total of about 19 000 feet of core (Thickpenny & Russell 2000). The abundance of data has led to the development of a robust depositional model for the Scott Field reservoirs.

The reservoir comprises four main sandstone units, the Upper and Lower Scott and the Upper and Lower Piper sandstones (Fig. 4). The reservoir sequence is defined by shales which separate the sandstones into flow units. The base of the reservoir sequence is the Skene Shale; the Upper and Lower Scott sandstones are divided by the G-Shale. The Mid-Shale, which represents a regionally correlatable flooding event, lies between the Scott and Piper and the Piper is partitioned by the Piper Shale. The entire sequence is overlain by the marine shales of the Kimmeridge Clay Formation (KCF). The KCF acts as both regional source rock and seal to the Scott Field.

Although the Scott sandstones are split into two distinct lobes, they are best considered as part of a single progradational coarsening and cleaning upwards shoreface system. The Lower Scott lobe is seen as a progradational shoreface overlain by two aggradational back barrier units which are separated by a correlatable coal.

VINING, B. A. & PICKERING, S. C. (eds) *Petroleum Geology: From Mature Basins to New Frontiers – Proceedings of the 7th Petroleum Geology Conference*, 387–403. DOI: 10.1144/0070387

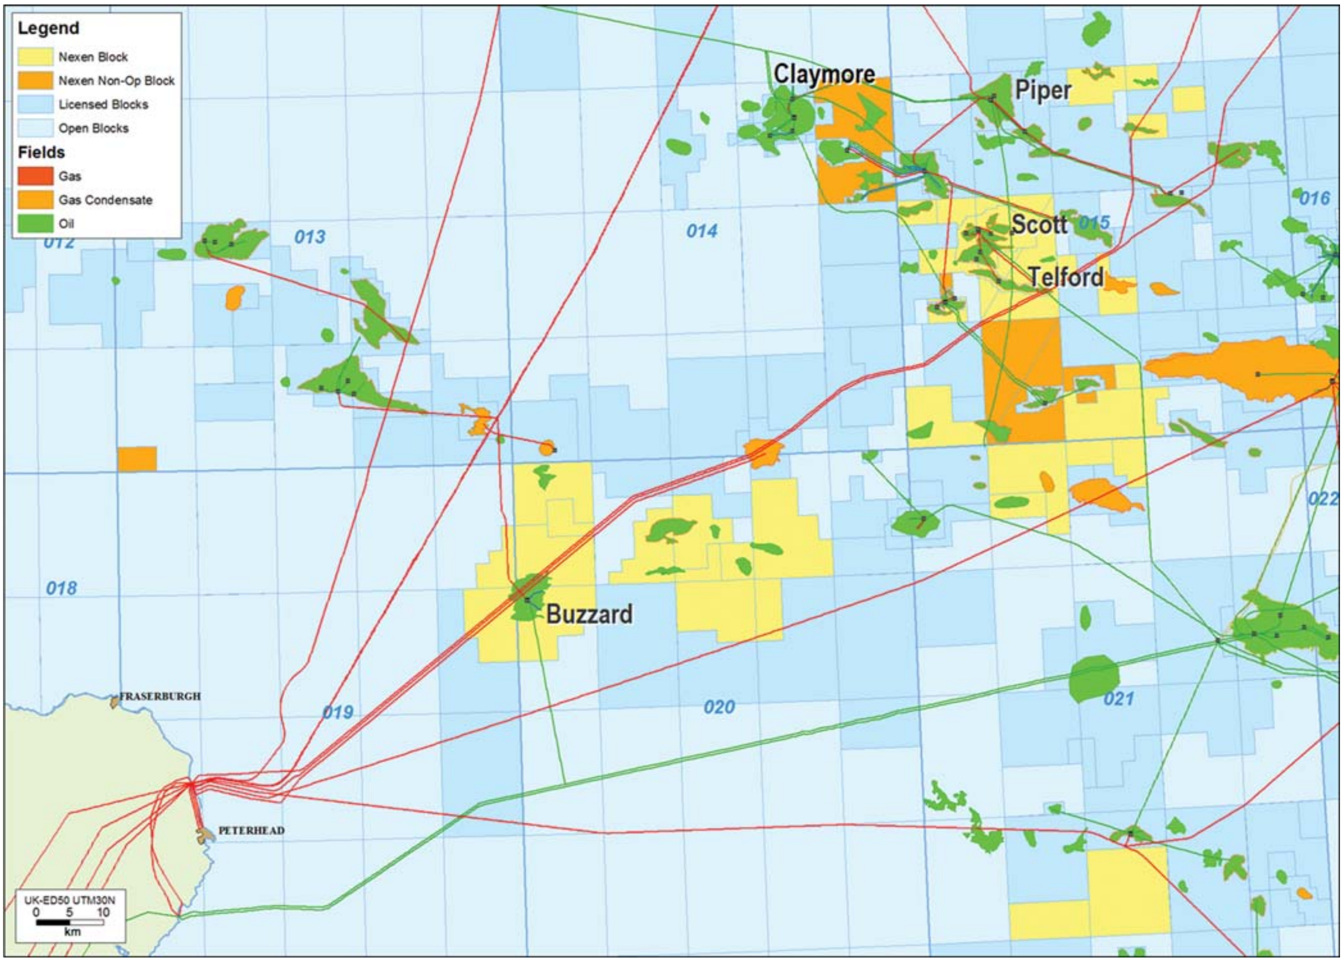

Fig. 1. Scott Field location map.

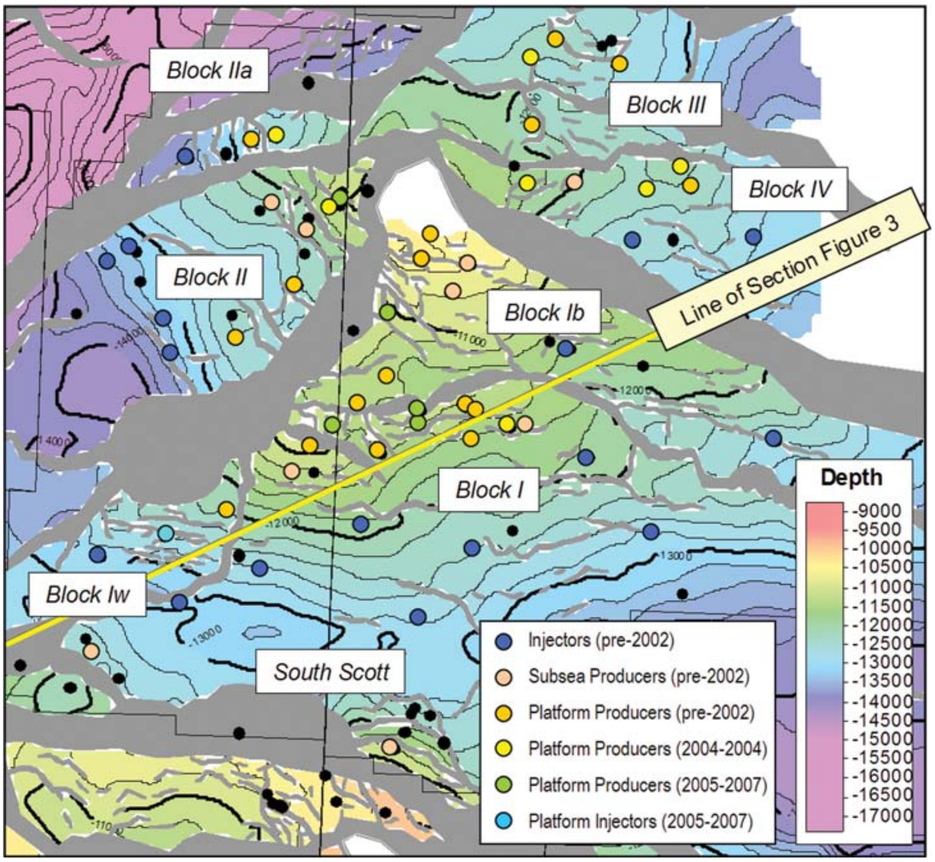

Fig. 2. Scott Field structure map.

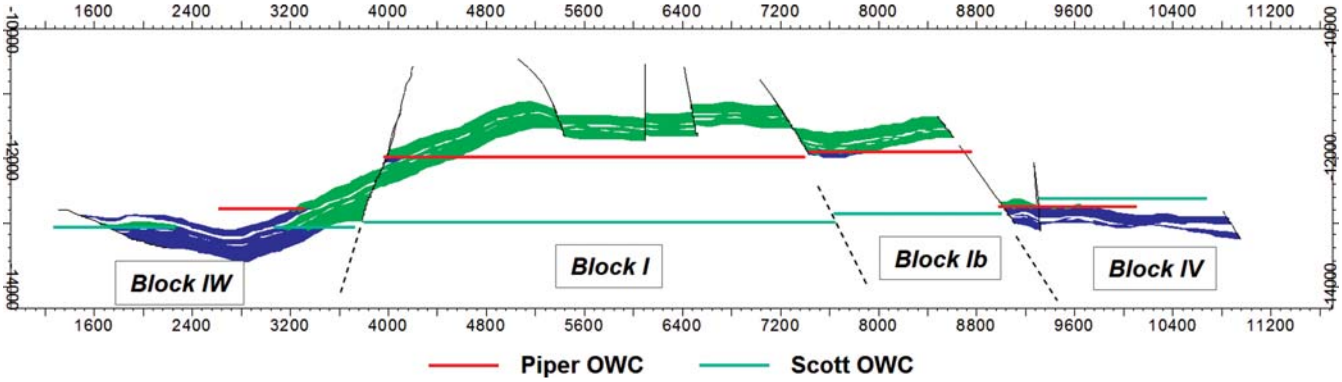

Fig. 3. Line of section shown in Figure 2, indicating structuration and variable OWC.

The shoreface sands and the lower back barrier units are of consistently good reservoir quality where found but the upper back barrier unit is of more variable quality. The Scott Formation sandstones thicken to the west in response to syn-sedimentary faulting, particularly across the Block I/Block II bounding fault and deposition towards a more basinal setting. The Scott Formation is thin to absent over much of Telford due to non-deposition.

The Piper sandstones are similarly split into two distinct units. The Lower Piper is further divided into two units, the 'ratty' Lower Piper below the 'blocky' Lower Piper. In both the 'ratty' and

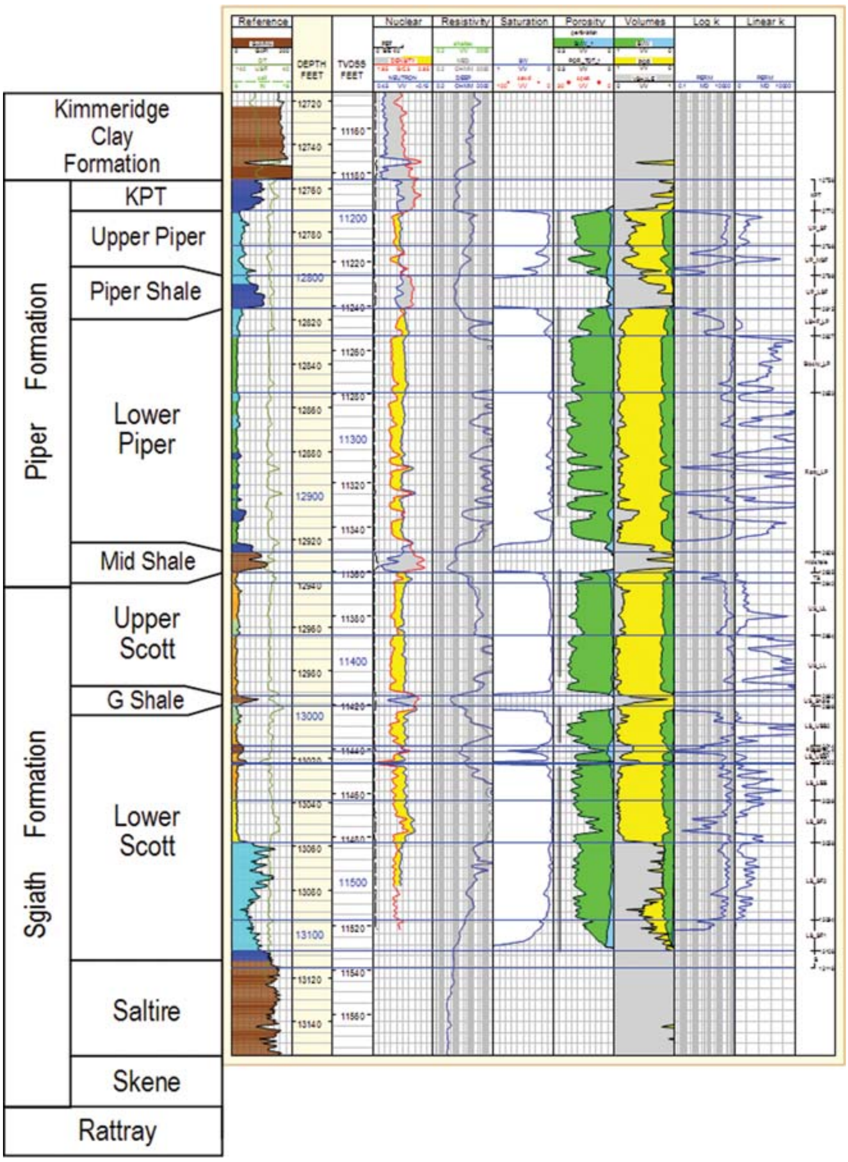

Fig. 4. Example log of a Scott well indicating zonation; track 1, GR/DT/CALI; track 2, PEF/DENS/NEUT; track 3, RES; track 4, SW; track 5, PERFS/PORO/BVW; track 6, VSH/PORO/BVW; tracks 7 and 8, PERM estimated.

'blocky' units, the better quality sands are submarine mass flow deposits. The 'ratty' and 'blocky' units are differentiated by the predominance of the background lower shoreface sediments into which the submarine mass flows were deposited; the more background lower shoreface sediments there are, the rattier the log signature. The Upper Piper sandstone is a progradational marine sequence capped by the Kimmeridge–Piper Transition unit (KPT), which comprises extensive back barrier deposits which grade upwards into the overlying KCF. The KPT unit is not of reservoir quality in the Scott Field. Both the Scott and the Piper formations display excellent reservoir quality with permeabilities in excess of 1 Da. The Piper Formation, in contrast to the Scott Formation, thickens to the east over the Scott Field toward the inferred palaeo-shoreline, and is the predominant reservoir unit in the Telford Field, with the KPT also being of reservoir quality at Telford.

The result of this tectonostratigraphic development of the field has resulted in the Scott Field comprising a number of complex tilted fault block traps (Fig. 2). Although depositional pinchouts are mapped, these are not thought to influence the trapping geometry. The structural style and the widespread Mid-Shale unit which separates the Scott and Piper formations has led to different fluid contacts within the individual blocks and between the two formations (Fig. 3).

Seismic database

The original 3D seismic survey over the Scott Field was acquired in 1992 and was used for the initial development drilling. Following several poor well results a new dataset was acquired in 1996. Ocean Bottom Cable (OBC) data were acquired in the centre of the field in order to avoid a two-boat undershoot of the Scott platform and conventional towed streamer data were acquired over the rest of the field. Although an improvement on the 1992 data, operational problems and poor weather conditions meant the data were very noisy with severe multiple problems. The dataset was reprocessed on several occasions and finally underwent Pre Stack Depth Migration (PreSDM) processing in 1999. This markedly improved the focussing of the data but did not improve the vertical resolution; nor did it remove the presence of the multiples. Reprocessing tests, primarily aimed at multiple attenuation, continued throughout 2000 without major success.

In 2001 the decision to shoot a new 3D survey over the Scott Field was made. A 4C/3D OBC survey was acquired primarily for the added advantages of the PZ multiple suppression, the improved spatial resolution and the improved coverage under the platform area. This was initially PSTM processed; however, an issue with the OBC survey was that the area covered was long and relatively narrow. As a consequence a large proportion of the data was in the migration aperture and suffered from mis-migration. It was decided therefore to merge the OBC data with the pre-existing 1996 streamer survey. In addition, the improvements seen from the 1999 PreSDM reprocessing justified a similar processing approach and PreSDM processing was also performed. This data was available in 2003 and showed significant improvements in the overall signal/noise, multiple suppression and fault definition (Fig. 5).

In 2006 post stack processing of the 2003 PreSDM data was carried. Noise cancellation and spectral whitening techniques were applied which increased the frequency content and vertical resolution at the reservoir level.

Seismic interpretation

In 2003 a seismic re-interpretation of the field was carried out using the new merged PreSDM 3D seismic data. The dramatic improvement in data quality resulting from the increase in the signal/noise ratio and the suppression of the worst of the multiples meant reflectors were more accurately positioned in the correct subsurface space. This allowed a more confident interpretation to be made over the highly faulted areas of the field where previously it was deemed impossible to site a well.

During 2003–2004 several wells were drilled in these more complex areas with varying levels of success. As a result a further seismic reinterpretation was carried out in 2005 which incorporated the results of these new wells. An extensive review of the faulting, together with a comprehensive 3D fault plane mapping exercise, was carried out. Well ties were also re-examined

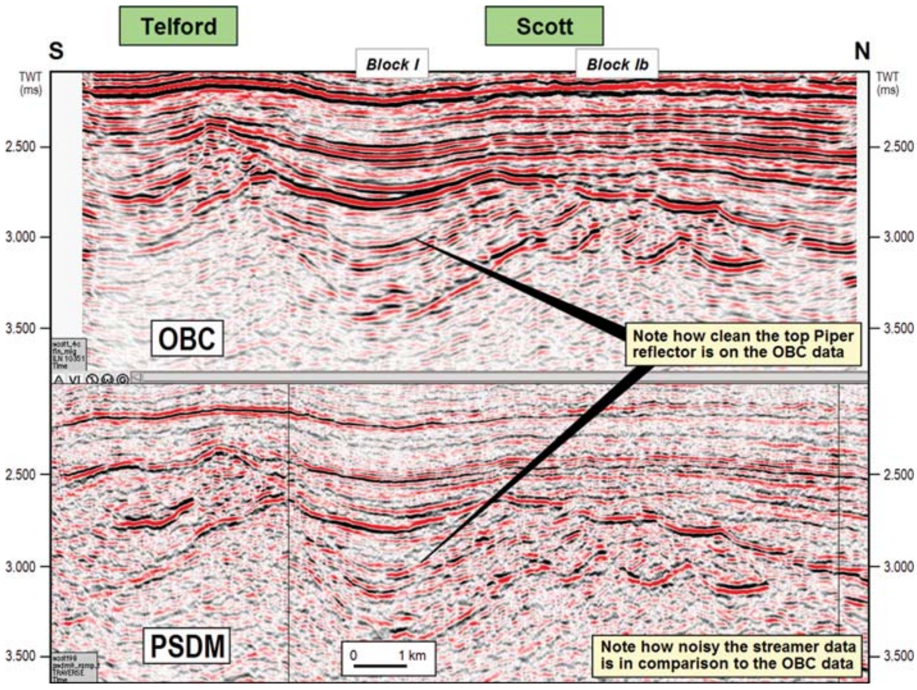

Fig. 5. Comparison of 2001 OBC data with 1999 PSDM data.

and two key markers, the BCU and a near Top Mid-Shale pick (located between the Piper and Scott reservoir units), were mapped in detail over the field. Previous mapping had attempted to pick a near Top Piper seismic event which the recent well ties suggested could not be accurately defined. Even though this seismic dataset was a marked improvement, the data quality was still of insufficient resolution to permit any further picking of intra-reservoir horizons.

The 2006 post–stack reprocessing improved the resolution at the reservoir level. Although it was still not possible to map intra-reservoir seismic events on this dataset, it did provide more reservoir detail and allowed mapping of smaller scale faults which had not been previously possible.

Production overview

From start-up to the end of 2008, the Scott Field has produced 400×10^6 bbl of oil, with peak rates in excess of 200 000 bbl/day, and cumulative gas production of 268 bcf. The current field oil production potential is around 20 000 bbl/day. Initially the field was produced through seven pre-drilled production wells, supported by water injection through seven injection wells that commenced injection a month after first oil. To date there have been a total of 34 production wells drilled of which 10 were sidetracks of previously drilled wells. There are 19 injection wells in the field providing pressure maintenance to the field continuously since start-up. The Scott platform has 350 000 bbl/day of injection capacity. The injection strategy has been to maintain voidage replacement in each of the identified fault blocks in the field. Voidage replacement has not always been maintained due to operational issues, which has resulted in fluctuations of the reservoir pressure at various times during the production life of the field. The majority of the production wells are located in the crestal regions of the major fault blocks. The injectors are located downdip, but still above the oil–water contact (OWC) due to deteriorating reservoir quality in the water leg that has been shown to severely impact injectivity. The typical spacing between the producers and the injectors is of the order of 1000 m.

Although plateau rates were achieved soon after start-up, production of water was earlier than anticipated and oil rates from several wells began to decline. The field water cut had climbed to 10% after just over one year of production. This compared unfavourably with other large developments in the area, which produced at minimal or low water cut for considerably longer. The Claymore Field did not reach a water cut of 10% until after two and a half years of production, whereas the Piper Field required four years of production to achieve a 10% water cut (DECC 2010). The overall production rate from the Scott Field was maintained by a continuous drilling programme, targeting areas of reservoir unswept by water flooding. Although generally successful, there were early indications of the difficulties in drilling at the margins of the major fault blocks. Drilling results during the producing life of the field have increased the interpreted complexity of the reservoir in terms of structure, facies and connectivity. The drilling campaign of 2003–2004 demonstrated that this complexity was still not fully understood, with wells generally underperforming prognosis.

2005–2007 infill campaign

Prior to the 2005 drilling campaign, a complete seismic re-interpretation and geological re-mapping of the field was performed. In addition, dynamic simulation models were built and history matched to aid the positioning of drilling targets.

There was a shift in strategy for the 2005 drilling campaign. Some of the well results from the previous drilling campaign had been disappointing. This was particularly the case with wells targeting the northern and southern edges of the field. There appeared to be greater than anticipated structural complexity at the tested edges of the field. As a result, these wells suffered from a number of issues including compartmentalization and lack of adequate pressure support. In addition, one of the wells encountered either a perched OWC or uncharged reservoir sands.

Owing to the lessons of the previous campaign, the 2005 drilling campaign focused on areas well within the defined area of the field and closer to well control. The targets identified included updip attic targets mainly identified from the seismic reinterpretation, areas of bypassed sweep as indicated by dynamic modelling as well as a downdip injection target identified through an extended well test. Examples of each type, comparing pre-drill expectations and post-drill results, are discussed below.

Updip attic targets

As a result of the presence of numerous independent tilted fault blocks, the potential for a number of updip attic targets was identified. Updip attic type targets formed the basis of the J33 and J35 wells in the drilling campaign.

The J35 well, drilled as the last well of the campaign in 2007, targeted the area updip of the J7 well in the NE area of Block I. Faulting out of the reservoir was viewed as the principal risk and a primary well location and a contingent fallback location were identified.

The location of the J35 target (Fig. 6) was originally mapped and identified on the 2003 PreSDM data and was chosen to access both the Piper and Scott reservoirs in Block I. The target is bounded to the north by the main Block I/Block Ib west–east striking fault and to the south and west by the NW–SE trending fault which was encountered by J4 (Fig. 7).

The interpretation of 2006 post-stack reprocessed volumes confirmed the presence of this target and identified an additional north–south trending fault to the east of the proposed J35 primary location. This fault downthrows to the east, has a maximum throw of *c.* 100 ft and appears to reduce to zero throw to the north. This created an upthrown fault terrace which formed the primary target for the well. Because of the close proximity of both the bounding faults, the area did carry a risk on reservoir presence. A downdip fall-back location (J35_FB) was therefore identified in the event that the well did not encounter any reservoir.

The size of the J35 target area fault terrace was controlled by the position and dip of the major bounding faults to the north and SW; shallow dipping faults would reduce the volume of reservoir under the fault plane, and potentially result in the reservoir being faulted out at the J35 location. Unfortunately, other than the seismic data there was little hard data, such as dipmeter logs in offset wells, to constrain the dip of these faults and as a consequence the dip of the faults remained uncertain.

A review of analogous faults in the vicinity of J35 was undertaken. Previously drilled wells in the campaign, J30 and J34, penetrated a fault which was believed to be a splay of the Block I/Block Ib boundary fault. Triangulation of the well–fault intersection points indicated that the fault plane, at this location, had a dip of approximately 60° to the north.

Seismic interpretation of the Block I/Block Ib bounding fault plane indicated that the J14 well to the NW should have intersected the Block I/Block Ib bounding fault. This well had a complete Piper and Scott section present. However, a detailed review of the underlying Skene and Rattray sections indicated that a portion of this section was missing, potentially due to faulting or non-deposition. The presence of a fault in the deeper section of the J14 well would support the interpretation of a steeply inclined

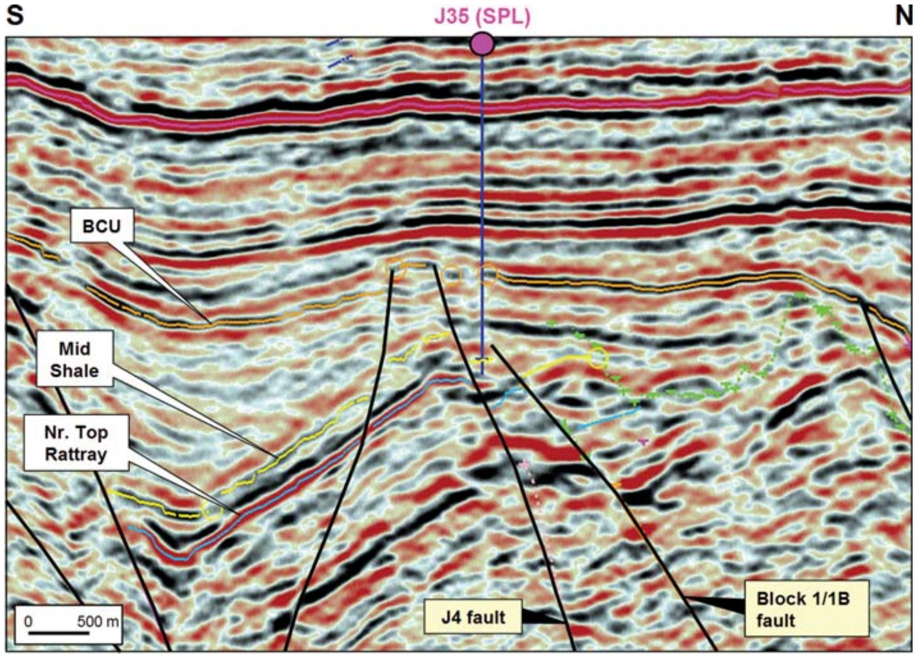

Fig. 7. Seismic line through J35 target.

Block I/Block Ib bounding fault plane, with dips similar to or greater than that seen in the J30, J34 wells.

Reservoir development from a depositional perspective was not an issue for the J35 location; offset wells clearly demonstrated that a thick sand sequence was deposited over the target location. All of the main reservoir units are present and show relatively uniform thickness and quality. There was no evidence in this region of the field that reservoir quality was reduced near faults. Wells J4, J30 and J34 all penetrate major faults, but showed no significant reservoir cementation or degradation as a result.

Dynamic modelling was used to confirm the presence of the unswept area since this target was a local fault bound high on the block. After history matching the model did indeed show the area not to have been fully swept, the principal risk being some partial oversweep updip of the J7 well. The model was also used to predict recovery of the fall-back target location. Recovery for the primary target was based on a volumetric uncertainty analysis.

The pre-drill volumetric recovery estimate for the primary target was $0.9–3.9 \times 10^6$ boe. The primary target was given a 50% chance of success, with absence of reservoir due to faulting identified as the primary risk. Compartmentalization and lack of pressure support were identified as risks, albeit minor, at the primary location due to the presence of the newly identified north–south trending fault to the east of the target. To aid any potential sidetrack decision, MDT logs were planned to identify any differences in pressure between the primary target and the rest of Block I that might indicate compartmentalization. In the event that the primary target was a failure due to the absence of reservoir sands through faulting, the recovery at the fallback target was estimated to be $0.7–1.8 \times 10^6$ boe with an 80% chance of success.

The well was drilled successfully at the primary location in the first quarter of 2007. The reservoir intervals came in between 30 and 80 feet shallow to prognosis. The well encountered full Upper and Lower Piper sections. Minor subseismic faulting, interpreted from image log interpretation, resulted in partial absence of the Lower Scott Sands (Fig. 8) leading to the shallow penetration of the base of the reservoir. Stratigraphic thinning was discounted due to the uniformity in Lower Scott thickness observed in offset wells. Some heavy minerals were believed to be present in the Lower Piper and Upper Scott sands, resulting in depressed resistivity along with elevated density, although there was no impact observed on the reservoir quality as exhibited by the gamma ray (GR) log (Fig. 9). This heavy mineral concentration is a feature commonly seen in the wells along the Block I/Block Ib fault and other block bounding faults, although the cause of this is not fully understood.

MDT logs were run prior to completing the well. The measured pressures indicated pressure depletion of at least 1000 psi from the assumed virgin reservoir pressure of *c.* 8000 psi. The Lower Piper was depleted by almost 2000 psi. The Upper and Lower Scott exhibited a common pressure gradient and were slightly less depleted than the Lower Piper. The Upper Piper was the least depleted but still had pressures 1000 psi below the estimated virgin reservoir pressure. These observations, along with some apparent partial sweep at the base of the Lower Scott, indicated that communication with the rest of Block I was very likely and that compartmentalization was not an issue.

The well was initially perforated in the Upper Scott sands which were believed to be unswept. However, the well initially produced at an oil rate of 8000 bbl/day with a water cut of 20%, potentially indicating communication with the partially swept Lower Scott sands. The water cut rose quickly to 40% before stabilizing. Despite the higher than expected early water cut, the performance of the well has been good, having produced 0.7×10^6 bbl of oil from the Upper Scott, with additional production potential remaining in the Piper sands.

The early water cut behaviour observed in well J35 is not unique. The other updip attic target, J33, had very good openhole results (Fig. 10), indicating unswept full sections of both Piper and Scott sands. Despite these results the well was producing at a water cut of 50% two weeks after initial perforation of the Lower Scott sands. The well has performed well, producing 1.8×10^6 bbl of oil with significant remaining unperforated production potential in the uphole zones.

Bypassed sweep targets

Because of the complex interplay of structure, depositional architecture and reservoir quality a number of bypassed or unswept

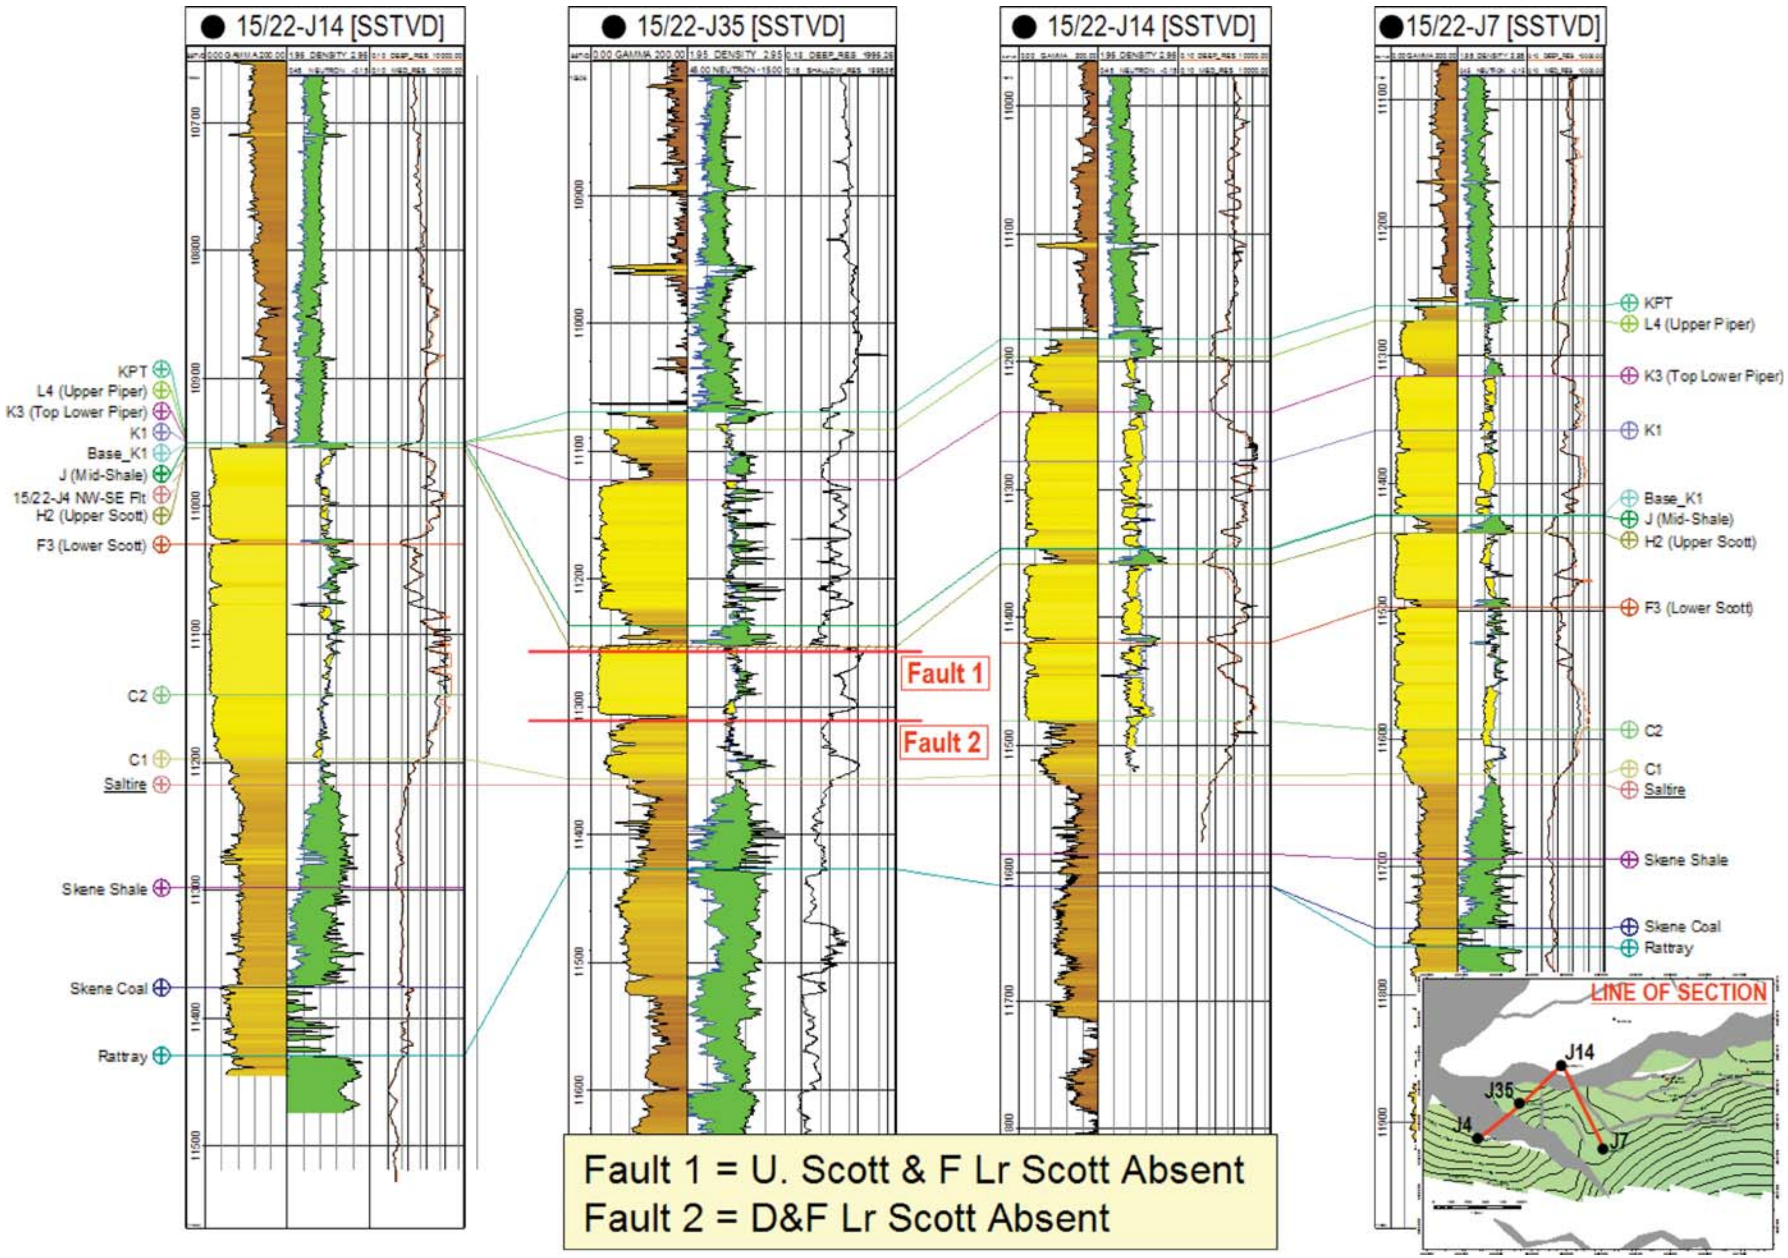

Fig. 8. J35 post-drill correlation, flattened on Saltire Fm., lLogs shown: track 1, GR; track 2, DENS/NEUT; track 3, RESISTIVITY.

targets were identified within the Scott Field. Such targets are often reliant on the sealing nature of intra-block faults with bypassed oil present in the shadow of sealing or baffling faults. Identification of such targets requires the integration of seismic interpretation, geological and simulation modelling studies to prove the validity of the target. The J32Z and J34 wells drilled in the campaign are representative of this type of target.

The J32Z location was chosen to access a mapped by-passed volume of hydrocarbon to the west of Block 1b (Fig. 11). The target is bounded to the north and south by two NW–SE striking faults which are both downthrown to the SW. The throw on the most northerly of these faults (fault '3' in Fig. 11) decreases to the SE from a maximum value of approximately 300 ft in the NW. This throw was deemed sufficient over some of its length

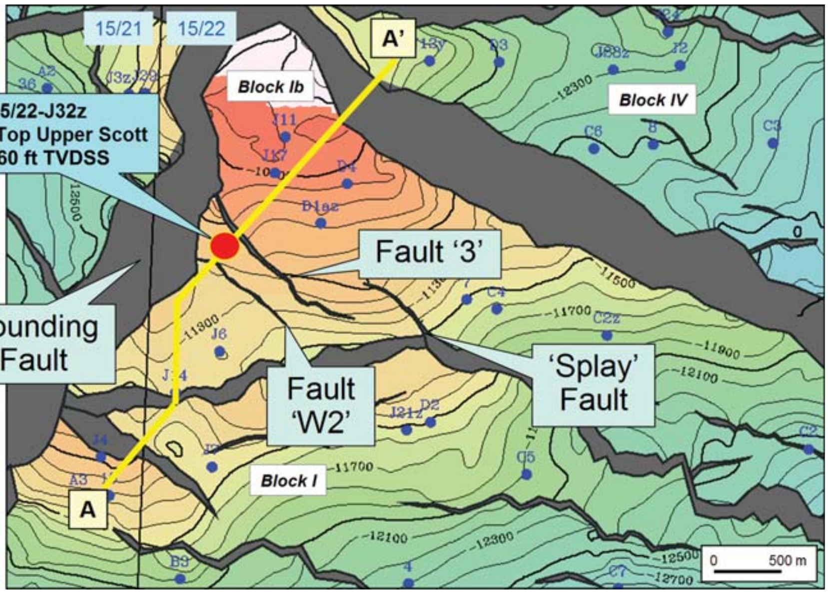

Fig. 11. Location of J32z target.

that it should offset the Scott Formation reservoir against older impermeable rocks of the Saltire Shale and Rattray Volcanics. Even where the throw was insufficient to completely offset reservoir against non-reservoir, the presence of clays and shales either side of the fault was thought to have generated sufficient shale gouge to seal the fault or at least significantly reduce permeability in the fault zone. The principal risk identified on the target was considered to be the sealing nature of the fault to the north of the proposed location with sweep likely if this fault was not sealing.

A dynamic modelling study was performed on Block Ib to assess the J32Z target area. Based on the 2004 geophysical fault interpretation, a number of modifications were made to the faulting pattern within the existing model to more accurately reflect the revised views on the faulting. The main changes were regarding the faulting between the main part of Block 1b and the J6/J14 area, namely faults '3' and 'W2', which were more pronounced than previously mapped (Figs 11 & 12). As a result of these changes, when the model was run through a history matching process, the J32Z target location became the most obvious remaining target within the block.

At the end of the history matching process, the target area was identified as having a significant volume of unswept oil associated with it, particularly in the Scott reservoir, which had been downthrown against non-reservoir at fault '3'. Given the non-unique nature of a history match solution in a large mature field, there was still an element of uncertainty associated with the model. As a result a risk factor was applied to all well production

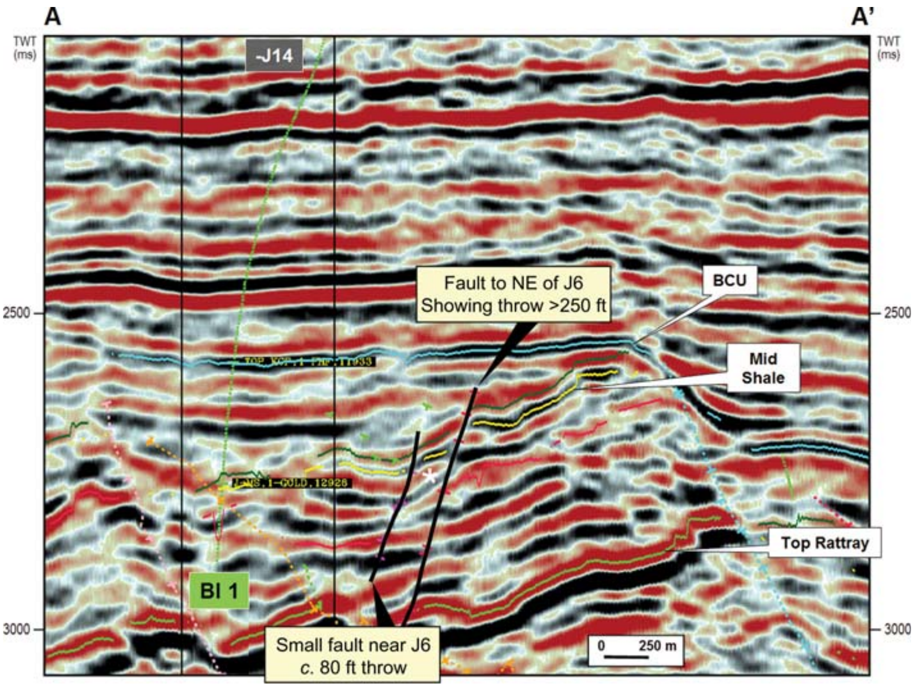

Fig. 12. Seismic line through J32z target.

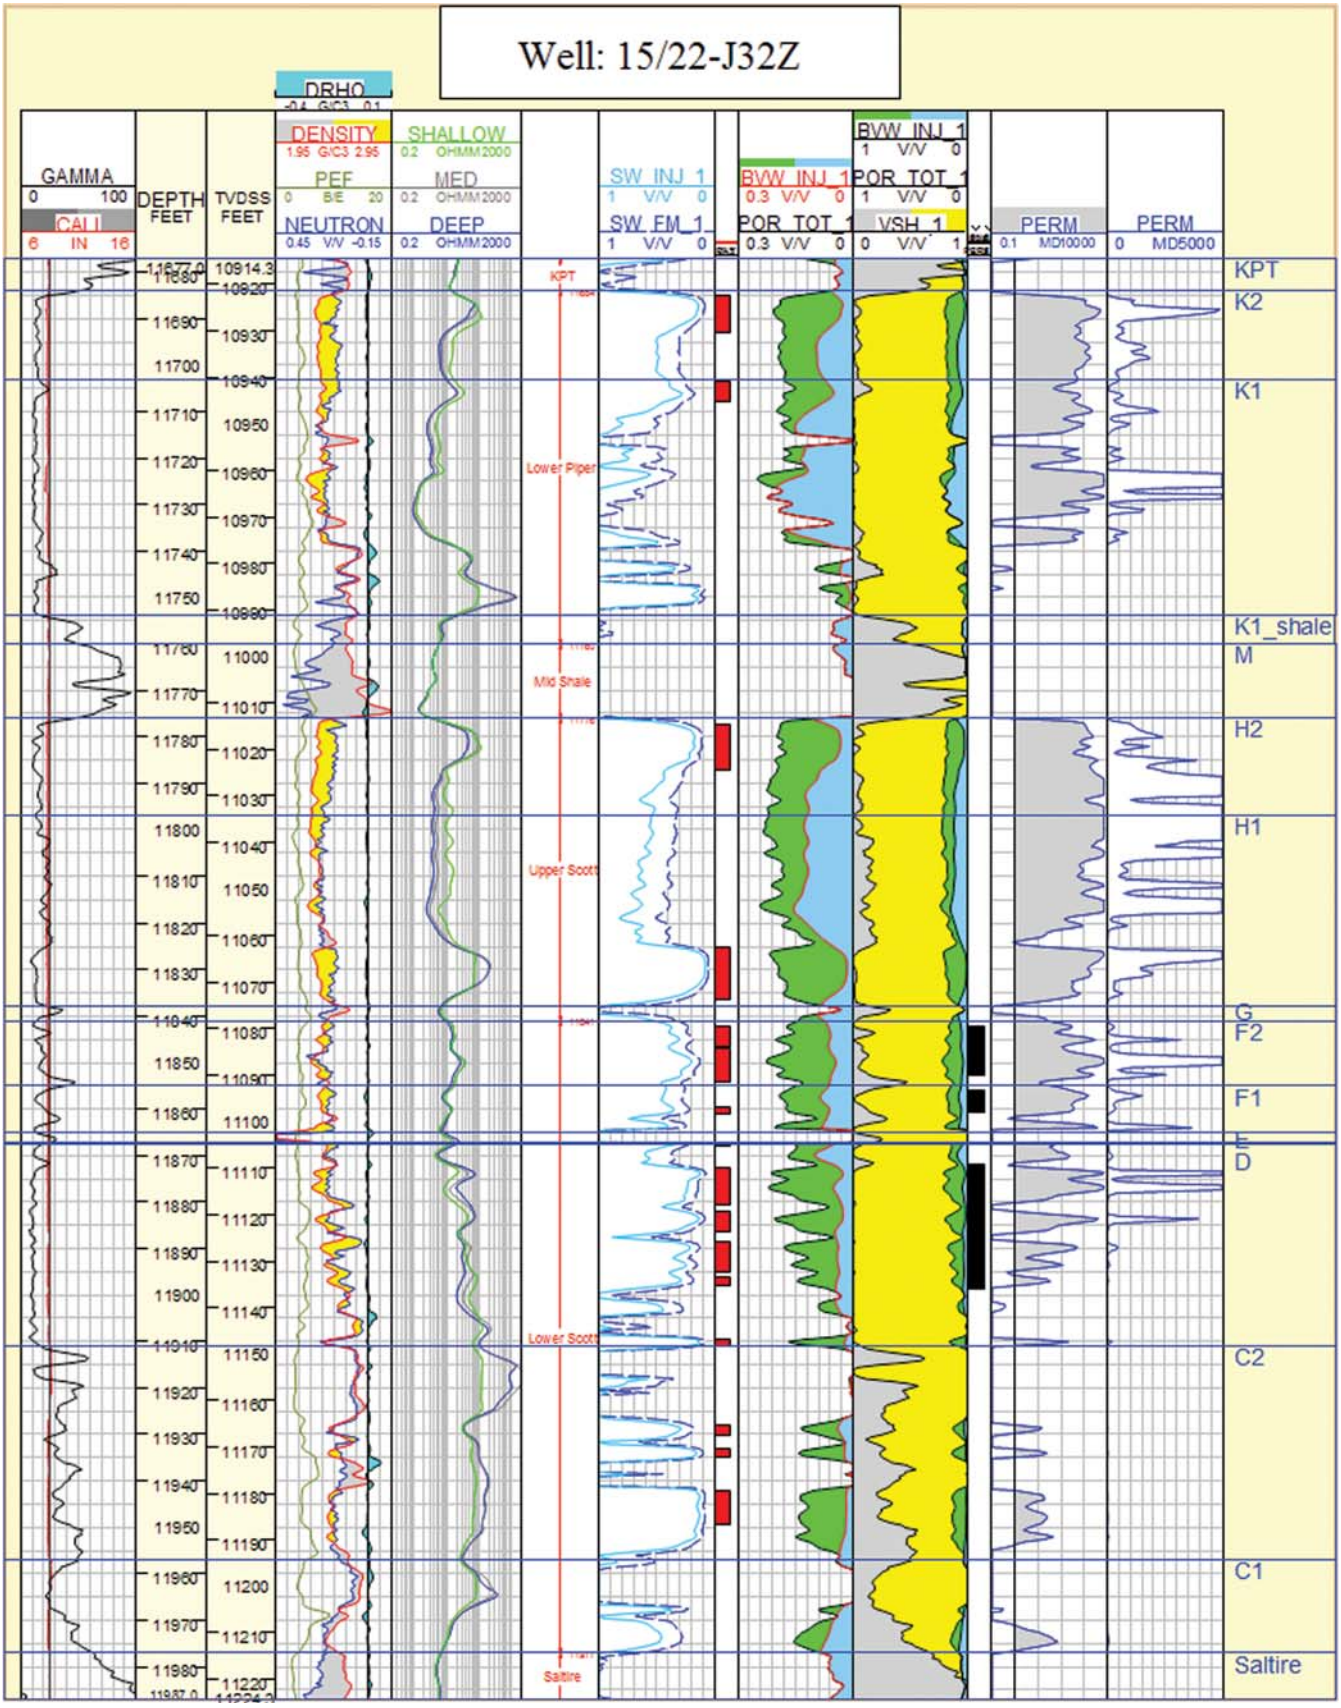

Fig. 13. J32z interpreted open hole results; tracks as in Figure 4.

rates coming from the model to give a more realistic expectation case. After running numerous prediction runs and sensitivities, J32Z had pre-drill estimated incremental recoveries of 1.1–2.7×10^6 bbl.

The well was drilled as the third well of the campaign as a sidetrack of the neighbouring J6 well. Geological results were as prognosed with thick Piper and Scott sands penetrated, although the Upper Piper sands were absent through faulting. Reservoir

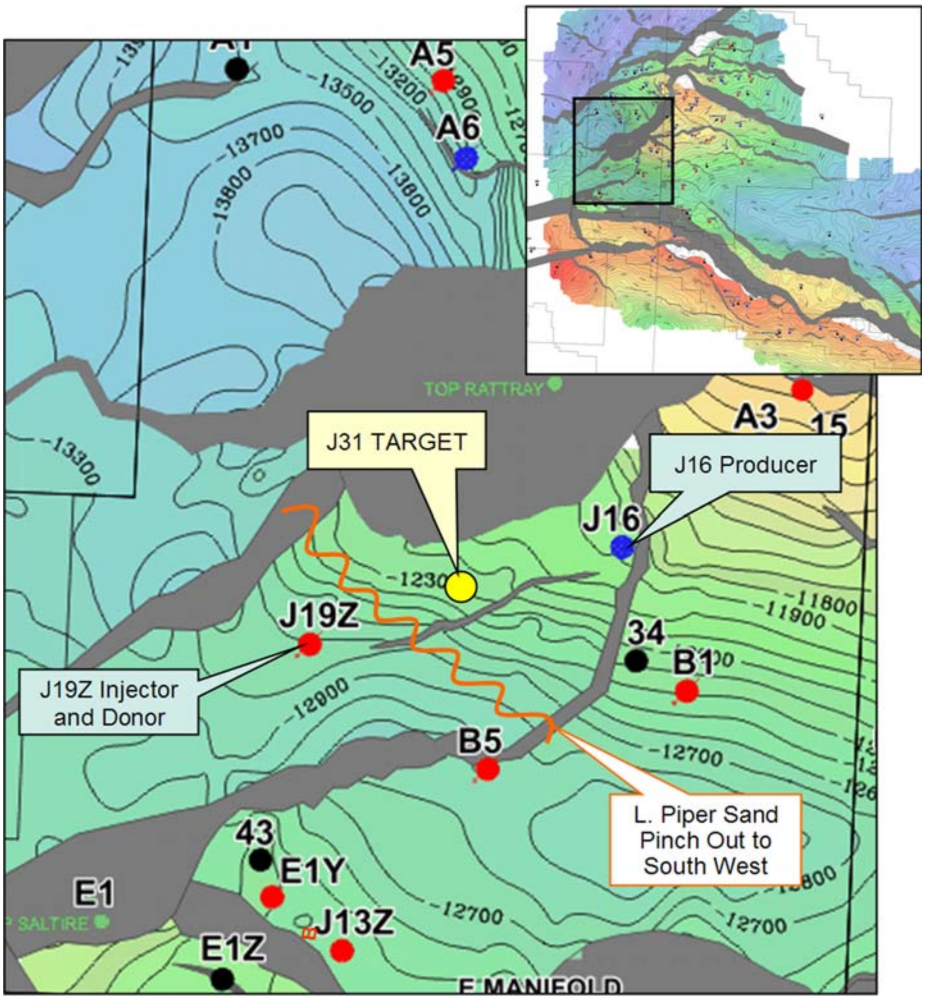

Fig. 14. Location of J31 target.

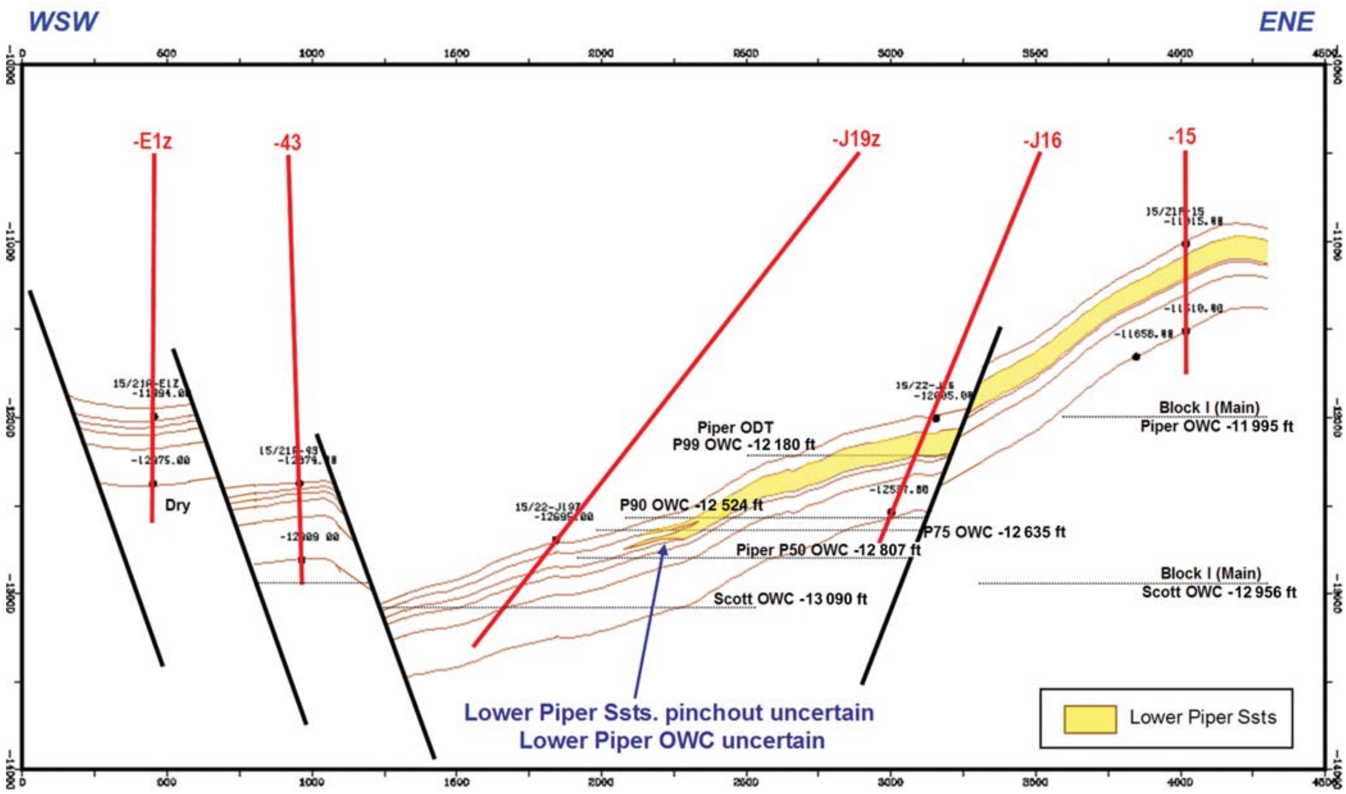

Fig. 15. Block IW, SW–NE cross section.

quality was good with high NTG, porosity and permeable sands, and generally reservoir quality was higher than anticipated (Fig. 13). Saturations were somewhat disappointing with evidence of sweep in both the Scott and Piper sands. The observed water saturation in the Upper Scott appeared to be higher in the lower quality sands, which would not normally be expected in a swept environment. This could possibly be a result of recharging or due to variable wettability in the Upper Scott sands.

The J32Z well initially produced at an oil rate of approximately 5000 bbl/day and a water cut of 80%. The water cut increased to 90% in about one month before levelling off. Although the water cut performance was poorer than had been anticipated, the well still added significant production rates. The ultimate recovery from the well is estimated at 1.4×10^6 bbl. The log interpreted sweep and the high water cut on initial production can be interpreted to indicate that the fault to the north of the well does not provide an adequate seal from updip producer wells. This is despite the significant throw and assumed shale gouge mapped along its length. Further production analysis and history matching including J32Z production data indicates that bypassed oil potential remains present in the block downdip of the fault identified to the south of the well.

Downdip injector

Block Iw, at the western end of Block I, had been recognized as an isolated compartment since the well J16 was put on production. The J16 well encountered both Scott and Piper reservoirs, at pressures below initial reservoir pressure. Despite this apparent depletion, initial production from the Scott Formation indicated that the interval was not receiving any significant pressure support from the injectors in the main area of Block I to the east.

As a consequence of the lack of pressure support, the J19Z injection well (the first Scott platform injection well) was drilled downdip to provide water injection to the Scott and Piper reservoirs penetrated in the updip J16 well (Fig. 14). However, the J19Z well did not encounter any Piper sands, interpreted to be due to a transition from stacked mass flow sands observed in the J16 well to shale prone lower shoreface in J19Z to the west (Fig. 15).

One of the opportunities identified for the drilling campaign was a downdip injector to intercept the Piper sands encountered in J16. The key uncertainty in the reserves potential for the well was the oil in place in the Lower Piper in Block Iw. A large range of oil in place, from 1.5 to 20×10^6 bbl, could be mapped in the Lower Piper due to the lack of well control on the pinchout edge of the sand, and the unknown OWC. Furthermore, the pinchout edge could not be readily inferred from the seismic data.

As part of the pre-drill ranking for the drilling campaign, it was critical to reduce the uncertainty on the oil in place in the Lower Piper of Block 1w. An intervention was planned and executed that isolated the producing Scott perforations in the J16 well (flowing at 90% water cut), and added a small perforation interval to the Piper sands. The well was produced on depletion for several weeks with several build-ups scheduled, all the time with pressure data recorded from the permanent downhole gauge.

Integrated analysis of the depletion trends and pressure buildup response indicated that the J16 Piper perforations were connected to $3-10 \times 10^6$ bbl of unsupported oil in place. Boundaries could be interpreted from pressure transient analysis consistent with the seismically mapped faults. Material balance analysis of the drawdown could establish only total compressibility of the connected system, but could not distinguish between aquifer and oil. The well data constrained the maximum total sand volume in Block Iw Lower Piper, thus placing a limit on the minimum oil leg/maximum aquifer scenario that would also match the calculated total compressibility of the system. Simulation models confirmed the material balance conclusions; multiple models could be constructed that matched the depletion and the pressure buildup derivative (Figs 16 & 17).

Simulation modelling indicated an incremental recovery of 10–40% from water injection (over depletion recovery) from the Piper sands. The value of a new dedicated Piper water injector, updip of the J19Z well, was compared with a sidetrack of the existing J19Z well – significant reserves remained to be recovered by the J19Z–J16 well pair from the Scott sands. Analysis indicated that the reserves potentially lost from the Scott sands were small compared with the value saving of a sidetrack over a new well.

The principal risk to the target was the presence of the Piper sands. Because of the uncertainty in the pinchout location the well was planned with contingent sidetracks. The J31 injection well was drilled as a sidetrack of the J19Z well as the second well of the campaign. The Piper sands encountered were thicker, but deeper than prognosed, and fully oil-bearing (Fig. 18). Reservoir quality was, however, lower than expected with an increased proportion of finer-grained, silty layers, probably reflecting the position of the Piper sands toward the edge of a depositional pinchout. The Scott sands were swept as prognosed. Post-drill estimates of the oil in place in the Lower Piper of Block Iw were revised towards the upper end of the pre-drill expectations.

A further complication arose during the time between execution of the J16 pressure data gathering, and the drilling of the well. The plug isolating the J16 Scott sands (overpressured due to injection) and the Piper sands (underpressured due to depletion) failed, resulting in cross-flow and causing apparent total loss of productivity from the Piper perforation. It was unclear if there would be total reservoir damage in the Piper sands in the vicinity of the J16 well bore (despite only a small interval having been perforated). In conjunction with putting the J31 well on injection, a remedial intervention was carried out in the J16 well to reinstate the bridge plug and add perforations over the whole J16 Piper interval.

Both wells were brought online. Injection rates in the J31 well were lower than pre-drill expectations, owing to the lower reservoir quality, but the damage to the J16 Piper was less than expected. The J16 well produced 3.1×10^6 bbl from the Piper interval before water breakthrough, ahead of expectations, and ultimate recovery from injection at the J31 well is expected to be 3.8×10^6 bbl.

Impact of drilling campaign on field production

The 2005–2007 drilling campaign had a significant positive impact on the production of the field. The addition of six successful wells saw Scott production increase from pre-campaign levels of 15 to greater than 35 kbbl/day at peak levels. Even though the high initial rates of Scott infill wells tend to decline quickly with

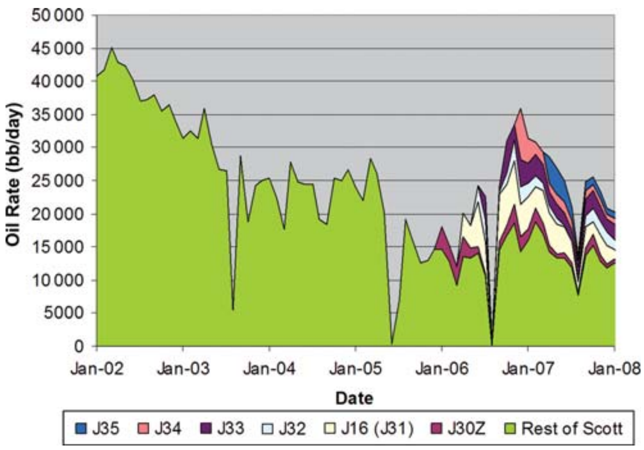

Fig. 19. Scott Field production illustrating impact of 2005–2007 drilling campaign.

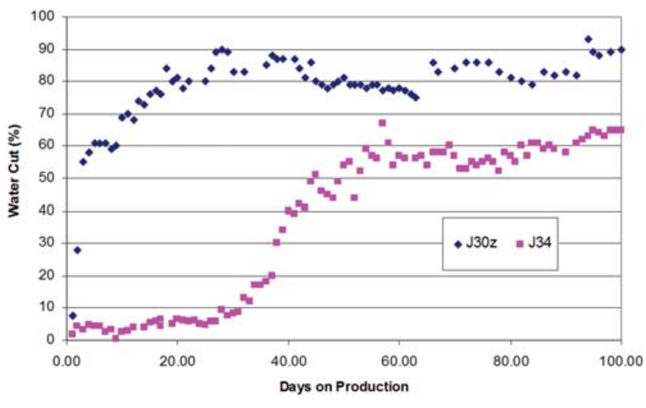

Fig. 20. Wellhead water cut measurements, wells J30Z and J34.

increasing water cut, the increase in field production rate was observed for about three years before returning to pre-campaign levels. When viewed in the context of the field historical production performance (Fig. 19), the benefit of the recent campaign is clearly demonstrated, showing a larger impact than previous infill campaigns.

Despite the considerable amount of production and drilling history on the Scott Field, the nature of the waterflood sweep is still not fully understood. The J32Z and J35 wells both encountered partially swept reservoir sections. The nature of the sweep in the J32Z well, with the higher quality sands showing sweep, cannot be fully explained. In general, the earlier wells in the campaign (J30Z, J32Z, J33), exhibited more rapid water cut evolution than had been anticipated. This led to more pessimistic pre-drill predictions of water cut for the later wells in the 2005–2007 drilling campaign (J34, J35). However, the production performance of these latter wells turned out to be much better than anticipated with more conventional and slower increases in water cut. A comparison of J30Z and J34 illustrates the variation in water cut performance of the infill targets (Fig. 20).

Conclusions

The overall impact of the 2005–2007 drilling campaign has been positive for the Scott Field, both in terms of increased production rates and reserves additions. The six successfully drilled infill wells have all contributed value to the asset.

A number of lessons have been learned from the results of the drilling campaign. Updip attic targets were very successful. The identified pre-drill risk of faulting out due to proximity of the major block bounding faults proved not to be an issue. The seismic interpretation based on the PreSDM volume has been shown to be reliable with respect to the major faults. However, minor faulting continues to be difficult to image and can result in partial absence of reservoir sands, as was experienced with the J35 well.

The downdip injector concept was successful with the J31 target and is easily justified for unsupported reservoir compartments. However, the scope for similar targets on the field is limited with most identified fault blocks currently receiving injection support.

The impact on field production of the campaign has been significant, particularly when compared with the previous drilling results. The strategy of drilling less risky targets, well within the field boundary, has been shown to be value adding even in a mature field that has already been extensively drilled.

The extensive drilling history on Scott has enabled the construction of robust depositional models for the Scott and Piper sands. However the results indicate that some uncertainty still exists in the seismic mapping (faults and horizons) and reservoir behaviour over the field. It is likely that future drilling campaigns will eventually have to target smaller higher risk areas as remaining targets closer to existing well control are drilled up. These are likely to be in areas of increased structural risk due to the poor imaging and complex nature of the faulting areas or where a detailed understanding of reservoir and fault characterization will be required to minimize risks.

The authors would like to thank Nexen Petroleum (UK) Ltd, Petro-Canada UK Ltd, Exxon Mobil Corp., Maersk Oil and Premier Oil plc for their kind permission to publish this paper.

Predicting production behaviour from deep HPHT Triassic reservoirs and the impact of sedimentary architecture on recovery

Abstract: The Triassic Skaggerak Formation is one of the main reservoirs in the high pressure–high temperature province of the North Sea. Production to date has come from fields located on the intra-basinal highs within the Central Graben, between 10 000 and 15 000 ft TVDss. Undrilled prospectivity has been recognized in structural traps in the deeper parts of the Central Graben up to 20 000 ft TVDss, yet reservoir effectiveness remains a key risk. Therefore, in order to optimize future exploration, appraisal and development programmes, it is necessary to consider the likely reservoir performance and production behaviour of these deeper Skaggerak prospects. The Skagerrak Formation comprises two main reservoir sandstones, the Judy Member and the overlying Joanne Member, separated by a thick shale interval, the Julius Member mudstone (Goldsmith *et al.* 2003). The two reservoirs show markedly different production behaviour despite their apparently similar character on wireline logs. Integration of the production behaviour from the Jade and Judy fields with the sedimentology has enabled the causes of this different production behaviour to be better understood, allowing the controls on reservoir flow to be modelled in both a static and dynamic environment. The understanding of the reservoir behaviour in the currently producing fields has been carried through to a predictive phase of simulation and modelling to determine the range of production behaviours expected for a deeper exploration portfolio. A clear porosity–depth trend exists within the Skagerrak Formation and this has been used to translate the robust history-matched reservoir models from the producing fields to the depth of the prospects. Sensitivity to fluid, porosity–depth trend and permeability of the deep reservoirs have been tested, and a range of likely production rates and behaviours established.

Keywords: Skagerrak Formation, Judy Member, Joanne Member, reservoir architecture, production performance, depth

The Skagerrak Formation of the UK and Norwegian high pressure–high temperature (HPHT) province has been on production since the mid 1990s. Judy (1996), Heron (1998), Egret (1999), Skua (2001) and Jade (2002) are well documented examples of Skagerrak Formation reservoirs (Jones *et al.* 2005; Keller *et al.* 2005; McKie & Audretsch 2005). The J Block area alone has produced over 240 mmboe to date from the Skaggerak Formation. With over 13 years of production performance from these fields, the understanding of the reservoir behaviour of the Skagerrak Formation is improving.

Increasingly, exploration in the HPHT province is targeting deep structural traps (often over 3000 ft deeper than the existing fields on production) within the Skagerrak Formation. Understanding the likely production behaviour of these reservoirs where porosity is known to degrade with depth has been key to defining the risks for exploration in this play. To this end, a reservoir modelling and simulation study has been undertaken to look at the interaction of degrading porosity (and hence permeability) with depth and its sensitivity to increasing reservoir pressure (improving recovery), for a range of fluids, for both the Joanne and Judy members. The study has been based on the history-matched modelling and simulation studies carried out on the Jade Field and the methodology used to generate the predictive history-matched model has been applied to generic models of the Judy and Joanne Member reservoirs at greater depths.

A difference in production behaviour can be seen between the Joanne and Judy Member sandstones over both the Jade and Judy Fields. The sedimentology has been integrated with the production behaviour and well test interpretation to determine the controls of the different sedimentary architectures on production performance. The different sedimentary architectures for the Joanne and Judy members have been incorporated into the reservoir model of the Jade Field, enabling a better simulation match to be obtained to the production.

Given the lack of well data at depth, the modelling is subject to a range of uncertainties; sensitivities have been carried out to test for different porosity–depth trends, different porosity–permeability relationships and sensitivity to hydrocarbon saturation. Fluid type is a key uncertainty when dealing with exploration; however, owing to the location of the prospects in the deep Central Graben, a lean gas condensate fluid was thought to be the most likely fluid present. This was modelled along with a richer gas condensate and a light volatile oil.

Models were run as simulation grids with a range of parameters (both geological and fluid) and recovery and well flow rates were analysed. The increased depth and pressure of the prospects was expected to result in an improved recovery (due to a large pressure drop between initial reservoir pressure and abandonment pressure); however, the effect of the fluid and the degradation of the porosity–permeability with depth was expected to counteract this. The study was designed to investigate the sensitivity of both the Joanne and the Judy members to these controls on production performance. Given the high costs and technical challenges of extreme HPHT exploration and developments, this understanding is critical to the future success and design of any appraisal/development activities as well as de-risking the exploration play.

Geology of the Skaggerak Formation

The geological setting has been well described in a series of regional background papers (Bartholomew *et al.* 1993; Helgeson 1999; Errat *et al.* 2005). The Triassic Skagerrak Formation was

Vining, B. A. & Pickering, S. C. (eds) *Petroleum Geology: From Mature Basins to New Frontiers – Proceedings of the 7th Petroleum Geology Conference*, 405–417. DOI: 10.1144/0070405

deposited in a series of salt and fault controlled mini-basins or 'pods' (Smith *et al.* 1993) within an overall rift basin. The Triassic is deposited immediately overlying a thick Zechstein salt section, which began to form pods (withdrawal basins) due to a combination of sediment loading and structural extension (Smith *et al.* 1993). In the Central Graben the salt section was relatively thick and the pods in general did not become grounded at this time on the underlying Rotliegend rifted basement. This allowed thick accumulations of sediment within the pods to be deposited. The basal part of the Triassic Heron Group (Goldsmith *et al.* 1995, 2003) is the Smith Bank Formation (shales, evaporites and thin sands), which forms the bulk of the fill of the pods. The overlying Skagerrak Formation (thickly interbedded units of sandstones and shales) is found in the upper parts of the pods, often being thinned but present between pods as the basin infilled. The pods represent localized depocentres but were not thought to have formed topographic lows (as they were largely maintained by sediment loading); they are responsible for the increased preservation of the sediments relative to the inter-pod areas. The Triassic is interpreted to have been deposited on a broad plain within the pre-existing Permo-Triassic rift basin.

The Skaggerak Formation is unconformably overlain by Mid and Late Jurassic, or Cretaceous sediments, which form a regional seal. The basin has become highly overpressured in the pre-Cretaceous section (Erratt *et al.* 1999, 2005; Haszeldine *et al.* 1999).

The Skagerrak Formation comprises three thick, continental sandstone sequences (Judy, Joanne and Josephine members), interbedded with predominantly mudstone units (Julius, Jonathan and Joshua members). The upper Josephine and Joshua members are only preserved in the deepest basinal areas and are not volumetrically significant in terms of production. The stratigraphic nomenclature used in this paper was first developed by Goldsmith *et al.* (1995, 2003) (Figs 1 & 2), and is still widely used in the UKCS Quad 30 (J Block) area to date. To the north, in the Heron and Marnock and ETAP area, a different stratigraphic naming convention is used (McKie & Audretsch 2005).

A thorough description of depositional facies found in the Skagerrak Formation is given by previous authors (Goldsmith *et al.* 2003; Jones *et al.* 2005; Keller *et al.* 2005; McKie & Audretsch 2005). Description of the Judy Field (Keller *et al.* 2005) splits the Skagerrak Formation sandstones into four main facies associations: channel sandstone, sheetflood sandstone, argillaceous sandstone and lacustrine mudstone. Palaeosols are also present within the Skaggerak and are found in all facies associations. The channel sandstones provide the best reservoir quality but the sheetflood sandstones also comprise net reservoir. The depositional environment for both the Joanne and the Judy sandstones is interpreted as 'deposition on the margins of an ephemeral lake to a relatively proximal alluvial plain or fluvial braidplain environment' (Keller *et al.* 2005). This covers quite a wide range of dryland depositional environments with potentially very different sedimentary architectures. Nichols & Fisher (2007) give a useful summary of a range of sedimentary architectures seen in an endorheic dryland system (Fig. 3). The Joanne Member of the

Fig. 1. Map of the Quad 30 area of the CNS showing locations of the producing Triassic Fields.

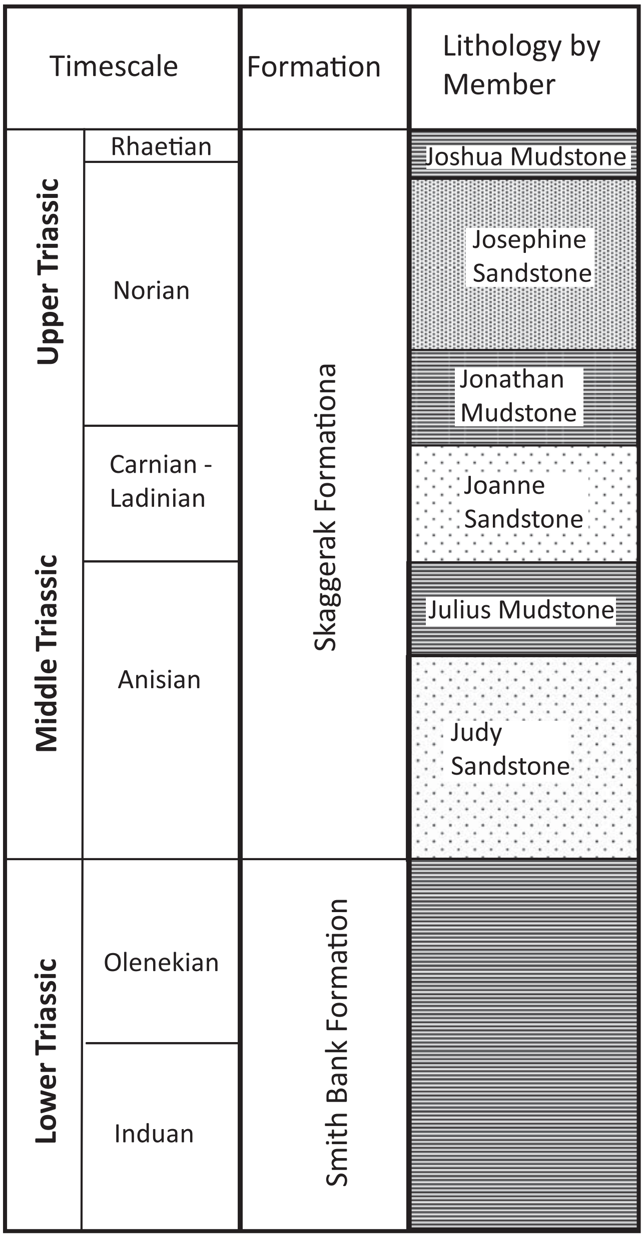

Fig. 2. Stratigraphic column of CNS Triassic (from Goldsmith *et al.* 2003) showing subdivision of the Skagerrak Formation.

Jade Field (Jones *et al.* 2005) is subdivided into an upper more channel-dominated interval and a lower more sheetflood-dominated section, based on a wireline log interpretation. The lower part of the Joanne Member and the Judy Member are not cored in Jade Field. The Judy Member is cored in offset well 30/7a-7 and is there described as finer grained with permeabilities an order of magnitude lower than those seen in the Joanne Member of the Jade Field. The depth difference between the Judy Member in these fields is *c.* 4000 ft true vertical depth subsea (TVDss) (Judy Field is the shallower).

Proprietary sedimentology and diagenesis studies carried out for the J Block partnership and BG Group by A. Melvin of PM Geos and AM Geos discriminate further between sedimentary environments in the Skagerrak (A. Melvin, pers. comm.). From the 30/7a-7 Judy Member core, the reservoir sandstones are described as being arkosic, very fine to fine grained, well sorted, laminated and of a fluvial (sheetflood) origin. These sandstones form the bulk of the reservoir facies although the core also comprises a cleaner, massive, fine grained sandstone, interpreted to be an ephemeral fluvial channel (A. Melvin, pers. comm.). The sandstones in the Judy core are interbedded with fine grained facies interpreted as flood basin and lacustrine and show a high degree of lamination. These facies are more thinly laminated and micaceous than in the core from the Joanne Member.

It is noted that the fluvial channel facies from the Joanne Member sandstones contrast with that seen in the Judy Member, in that it is commonly coarser grained with improved textural characteristics. The Joanne Member sandstones comprise fine to very fine arkosic sandstones but the sands are dominated by coarser-grained cleaner fluvial channel sandstones which show a low degree of compaction and cementation. Sheetflood facies are described as finer grained and better sorted than the channels but include micaceous laminae which serve to reduce porosity and permeability. The sheetflood facies are volumetrically less significant in the Joanne Member than the Judy Member (A. Melvin, pers. comm.). The variation in facies proportions between the Judy Member and the Joanne Member is interpreted to be the dominant control on the production behaviour as described in the following section.

Field production and well test behaviour

Over the 13 years of production from the Judy and Jade fields, the Skagerrak Formation reservoirs (Judy and Joanne members) have shown very different production and well test behaviour. The earlier fields (Judy, Heron, Egret) initially showed a disappointing production performance due to issues of fault compartmentalization and the misinterpretation of early well test data (Keller *et al.* 2005; McKie & Audretsch 2005).

The Joanne Member shows a characteristic decline on a P/Z plot (see Fig. 4) of an initial steep decline in pressure followed by a more gentle pressure decline. This behaviour is also seen in the Heron–Skua–Egret area and is interpreted by McKie & Audretsch (2005) as resulting from initial depletion from the high permeability channel systems followed by a later contribution from poorer quality splay sands (sheetfloods). This behaviour makes early analysis of connected volume (material balance) studies very misleading in the Joanne Member, as they show a far more limited connected volume than is eventually accessed by the well through time. McKie & Audretsch (2005) also note the presence from well test analysis of many localized boundaries which are not seen to affect longer term production performance. This behaviour is also seen on well tests from the Joanne Member in the J Block fields (Fig. 5a). A log–log analysis (pressure derivative) of the 30/7a-P03 well from (Joanne Member, Judy Field) is typical; all Joanne Member well tests from the J Block area show a similar pressure derivative analysis. The log–log plots show strong linear flow characteristics, indicating a linear body of width 80–200 ft. The linear bodies could also be fault constrained; however, the consistency of the well test character between Joanne Member wells indicates a sedimentological rather than a local fault control. The tests indicate initial high permeabilities (100–500 mD) followed by later background permeability of at least an order of magnitude lower (2–10 mD).

In contrast, Judy Member well tests (Fig. 5b) show a characteristic radial flow pattern and do not show barriers close to the wellbore (unless the well is located close to a known fault). The Judy Member well tests typically indicate permeabilities ranging in the tens of milliDarcy.

Both the Joanne and the Judy members show vertical pressure barriers in depleted pressure test datasets within the section. These support pressure differentials post production and are laterally persistent on a field scale. These vertical barriers are likely to correspond to very thin lacustrine and floodbasin shales seen in core. It is difficult to correlate these shales between wells; however, post-production pressure differentials supported across thin shales indicates their lateral continuity within the J Block

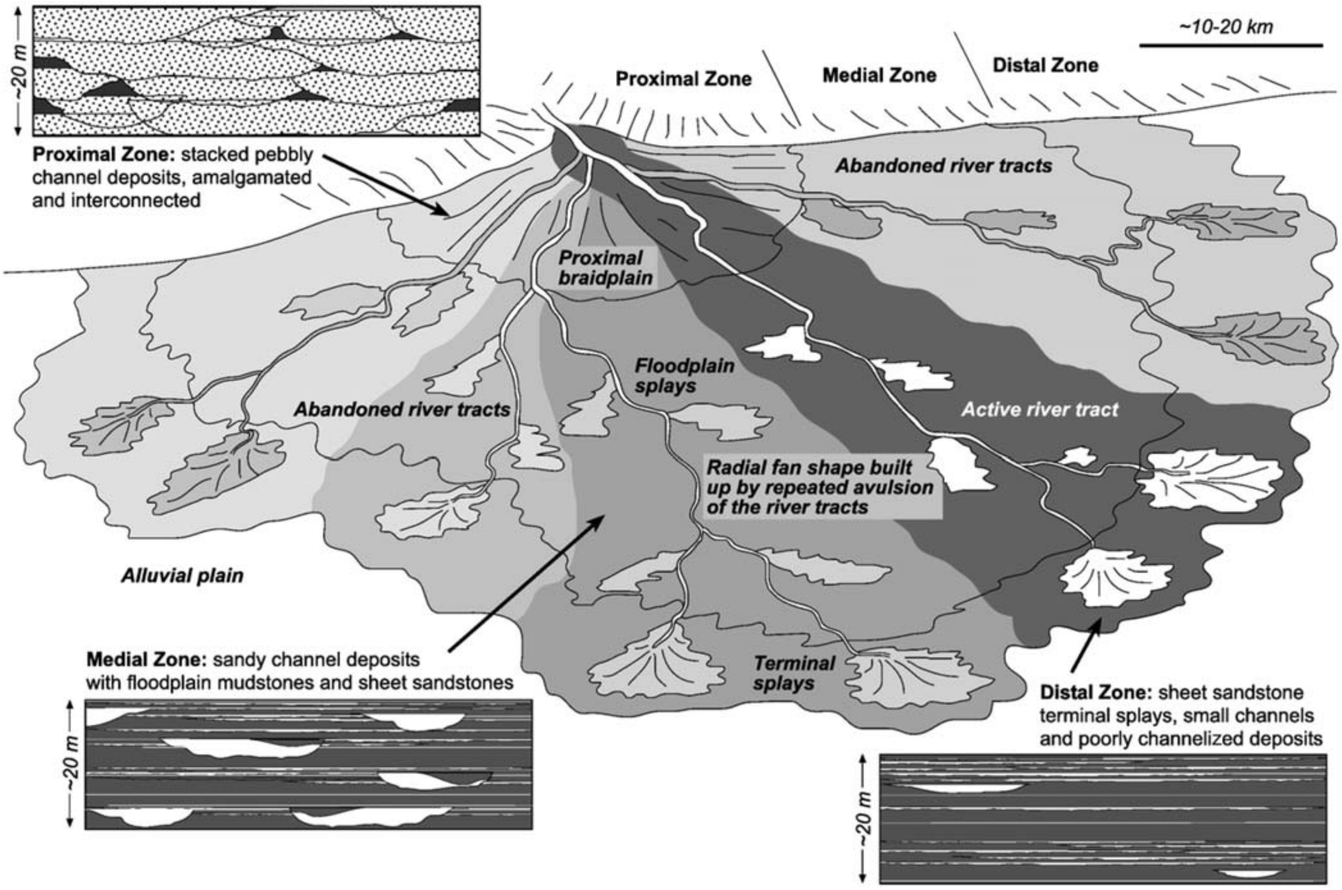

Fig. 3. Proximal to distal trends in channel and overbank processes across a fluvial distributary system. The Joanne Member is interpreted to be part of the medial zone of the system, and the Judy Member in the distal terminal splays (Nichols & Fisher 2007).

fields. Vertical barriers are also noted by McKie & Audretsch (2005) from the Heron cluster area to the north.

Implications of the reservoir behaviour for the sedimentological interpretation

This marked difference in production behaviour between the Judy Member and the Joanne Member is strongly indicative of different reservoir architecture and is seen consistently across both Jade and Judy Fields and offset satellites.

Although the dryland facies seen in the Joanne and Judy members originate in a similar environment, sedimentology studies (see above) point to differing proportions of these facies within the two reservoirs. This, coupled with the variation in production behaviour, suggests that the two reservoirs actually represent different dryland environments. The channel-dominated Joanne Member is more likely to represent a fluvial drainage system from a medial zone of a fluvial system (Nichols & Fisher 2007), where sandy, channelized, bedload-dominated and occasional meandering channels are interbedded with overbank splays and floodplain fines. The channel systems migrate through time

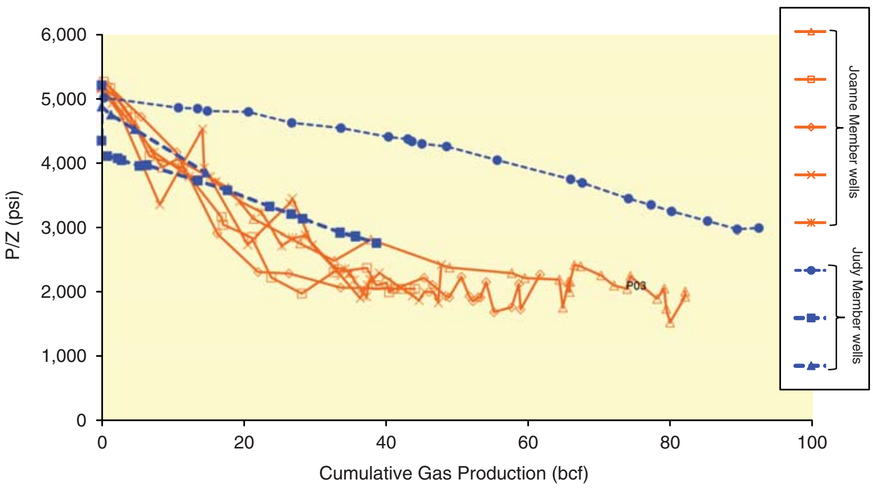

Fig. 4. Cumulative gas production plotted against pressure–time for the Judy Field. Judy Member wells show a steady decline in pressure through time, Joanne Member wells show a faster initial decline followed by a low later pressure decline.

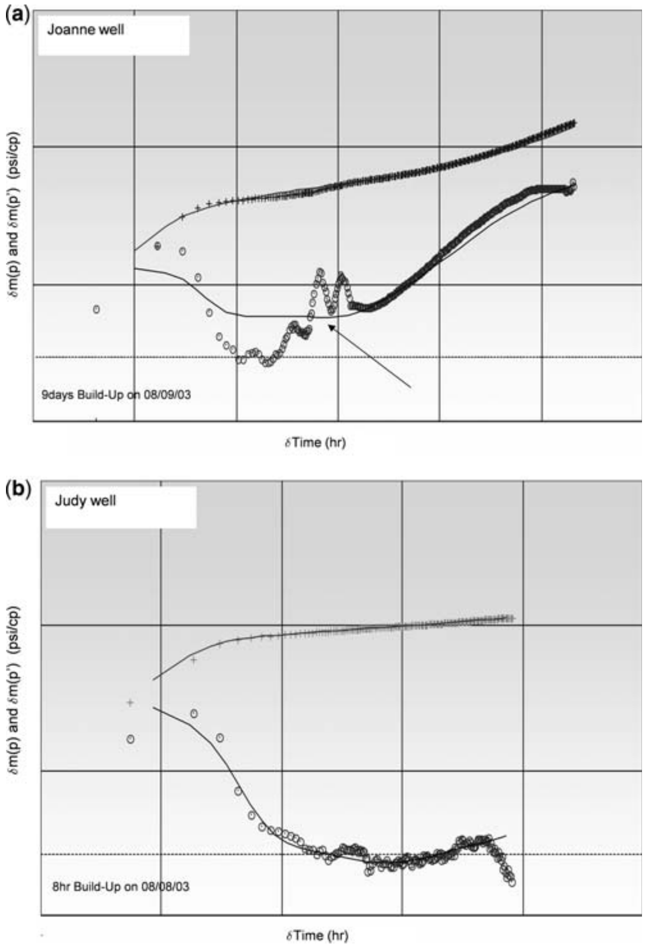

Fig. 5. (**a**) Log–log plot of 30/a-P03 well test. The plot shows the characteristic radial composite model of the Joanne Member well tests, with channels of high permeability seen initially and a lower permeability background seen later. (**b**) Log–log plot of 30/7a-P18 well test. This shows radial flow with no boundaries, indicating tank like pressure behaviour. This is characteristic of the Judy Member.

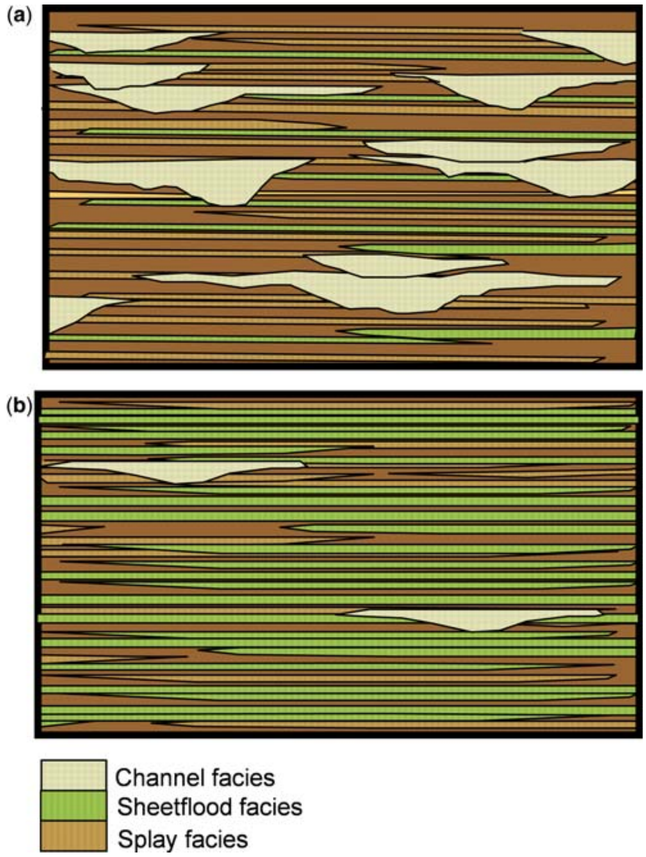

Fig. 6. (**a**) Conceptual stratigraphic architecture of the Joanne Member. (**b**) Conceptual stratigraphic architecture of the Judy Member.

across the pod area (and between pods), occasionally bypassing the pod entirely, allowing the establishment of thin lacustrine shales and palaeosols. The previous interpretation of the Joanne fluvial systems as 'unconfined' (Jones *et al.* 2005) is not compatible with the well test data where clear boundaries are seen on all tests. The fact that the channels are mostly bedload-dominated (braided) does not exclude deposition in a confined channel belt (Nichols & Fisher 2007). The linear flow behaviour seen on Joanne Member well tests is unlikely to be representing the margins of the pods, as the fields are generally located within the thickest part of the pods.

The sheetflood-dominated Judy Member may be interpreted as a sandy terminal splay system (Nichols & Fisher 2007), where sheetfloods are interbedded with thin, single-story ephemeral channels. The sheetfloods themselves are laterally more continuous and more homogenous in porosity–permeability characteristics. Vertical communication in this kind of reservoir architecture is poor, yet lateral connectivity is good, giving rise to the radial flow seen on the Judy Formation well tests and the steady homogenous depletion. The resultant architectures of these systems are likely to be very different (Fig. 6) and hence have been modelled separately in this study.

Previous studies on the J Block fields (Jones *et al.* 2005; Keller *et al.* 2005) have noted the range of sedimentary environments in the J Block Fields, but not the variation in architecture between the Joanne and Judy members, nor its control on the production behaviour.

Skagerrak diagenesis and relationship of porosity with depth

The depositional facies exerts the primary control on reservoir quality (A. Melvin, pers. comm.). The diagenetic history of the Skagerrak Formation sandstones shows episodes of both porosity loss (due to compaction and precipitation of cements), porosity gain (secondary dissolution) and porosity preservation (hydrocarbon emplacement, chlorite rims, overpressure). Much of the porosity loss is interpreted (A. Melvin, pers. comm.) as occurring from early burial to the Early Cretaceous accelerated by high heat flow, particularly in the deeper fault compartments. This resulted in silica and dolomite cementation and localized fault-related calcite cementation. Diagenesis was retarded during the Late Cretaceous–Recent burial, with the onset of overpressure and lower heat flow.

Secondary porosity preservation due to leaching from meteoric water below the Base Cretaceous Unconformity (BCU) is described as a porosity enhancing mechanism (A. Melvin, pers. comm.). Whilst this process is likely to have occurred on the very crestal parts of the upthrown fault blocks (J Block, Jade Field), it does not account for the significant preservation of porosity seen in deeper J Block wells (30/13-5, 30/8-3), where the Triassic reservoirs are overlain by a thick Jurassic section and are not directly bisected by the BCU. Likewise, retardation of quartz precipitation due to hydrocarbon charge is also not thought to be a significant factor in the preservation of porosity as good quality sandstones are seen in wells that have never been hydrocarbon charged or have only residual hydrocarbons (30/13-5, 30/13-3)

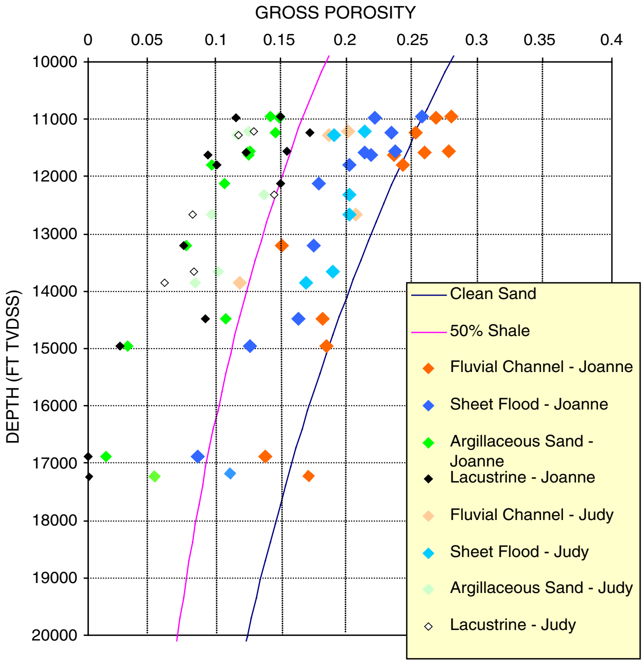

Fig. 7. Average gross porosity plotted with depth by facies for cored wells for the Joanne and Judy members. Sclater & Christie (1980) compaction curves are overlain.

(A. Melvin, pers. comm.). A strong relationship of porosity with depth can be derived from the existing well data (Fig. 7). What is not known is the impact of increasing overpressure with depth in the deep Triassic from 17 000 to 20 000 ft (TVDss) at top reservoir and its impact on retarding compaction (and cementation) related porosity loss.

Methods

The aim of the modelling was to determine the flow characteristics of deep Skaggerak Formation reservoirs from the known production behaviour from the Judy and Joanne Member reservoirs. The models were conditioned to ambient conditions at depth (pressure, temperature, etc.) with a range of fluids.

In order to model a range of possible production behaviour for deep Triassic reservoirs [17 000–20 000 ft (TVDss) at top reservoir], a range of porosity–depth relationships have been applied to the Jade well data to simulate a 'deep Joanne model' and a 'deep Judy model'. A single well (30/2c-J5) was chosen from the deepest offset producing field, Jade, with a Top reservoir depth of 14 340 ft TVDss. The well was translated to depth by applying a range of porosity–depth functions to obtain a high, mid and low case porosity log for the analogue model. A synthetic static and simulation model was built around the well to simulate reservoir behaviour at depth.

The 30/2c-J5 (Jade Field) well was chosen as an analogue for both the Joanne Member and Judy Member as it represents an 'average' Jade Field well and has a full coverage of basic log data (gamma ray, resistivity, density/neutron, sonic) to obtain the best estimation of wireline porosity. It also has a complete section of Joanne Member reservoir and is not eroded at the crest. Although the Skagerrak Formation varies in net to gross (NTG) character between Triassic pods and it is understood that a single well from a field will not accurately predict the NTG and porosity to be found in the exploration prospects, the 30/2c-J5 well was thought to represent a good 'average' well in both the Joanne and Judy members. The range in porosity–depth trends applied to the well to translate the porosity log to the synthetic model depths will go some way towards bracketing a NTG range for the Skagerrak Formation; however, a very low or very high NTG well would have a different production performance. The deep Judy and deep Joanne reservoirs were modelled separately as horizontal slabs, and translated to depth using a porosity–depth trend.

Porosity–depth trends

For the deep Judy model, a range of porosity–depth trends were chosen: 1.4 pu/1000 ft represented the regional porosity–depth trend taken from all the Judy Member well data in the area and was considered to be a good base case. By using core data taken from Judy Member sheetflood facies alone, a linear trend could be fitted through the data of 2.7 porosity units – %(pu)/1000 ft. This was considered a 'worst case' as there was little core control from deeper sections and it may reflect the effects of high porosities seen at shallow depths in the Judy Field, immediately below the BCU, thought to represent the effects of diagenetic leaching related to the unconformity. A trend of 1 pu/1000 ft enabled a match to the wireline porosities seen in the deepest Skagerrak Formation well to date (30/8-3) in the Judy Member (not cored from this well in the Judy Member) at around 18 100 ft, possibly showing some effect of porosity preservation due to overpressure (in addition to the diagenetic mechanisms mentioned previously). A 'high high' case was also run of 0.5 pu/1000 ft to capture a possible increase in the effect of increasing overpressure with depth and also to account for a higher NTG Judy Member section by proxy.

The J Block Joanne Member core data shows that different facies have different porosity decline trends with depth (fluvial channels decline at 2.2 pu/1000 ft, sheetfloods at 2.6 pu/1000 ft and the fine-grained argillaceous facies at 1.66 pu/1000 ft). Three alternative depth trends have been applied to the deep Joanne model, a high case of 1.4 pu/1000 ft, a low case of 3.0 pu/100 ft and a mid case of 2.2 pu/1000 ft. This reflects the fact that the Joanne Member channels are the main flowing zone in this unit and so the porosity–depth trend has been biased towards this. The high and low cases were designed to bracket the range of possible trends; in the high case this would account for a section with more sheetfloods or where overpressure had retarded compaction- and cementation-related porosity loss, and in the low case it would account for a lower NTG section. A sensitivity test was carried out whereby the log data were transformed by individual facies to the depths required; this was found to be very close to the base case porosity–depth trend (on account of the channels being the dominant facies in the Joanne Member).

Modelling parameters

A static geological grid was constructed for both the deep Judy and the deep Joanne reservoirs of 2 × 2 km. The workflow described in Figure 8 was used to generate the static and dynamic models. This workflow is consistent with that which had been used in the Jade Field to achieve a history-matched predictive simulation. The models were translated to a top reservoir depth to reflect possible well locations in offset deep Triassic prospects, such that the results of the simulation could be directly compared with well test esults.

Tables 1 and 2 show the parameter ranges applied to both the deep Judy and the deep Joanne models.

A facies based model was built for both the deep Joanne and deep Judy models. Table 3 details the modelling parameters applied to each grid. For the Joanne model a background facies conditioned by sequential indicator simulation (SIS) (a stochastic, variograms controlled distribution) was used to model the distribution of

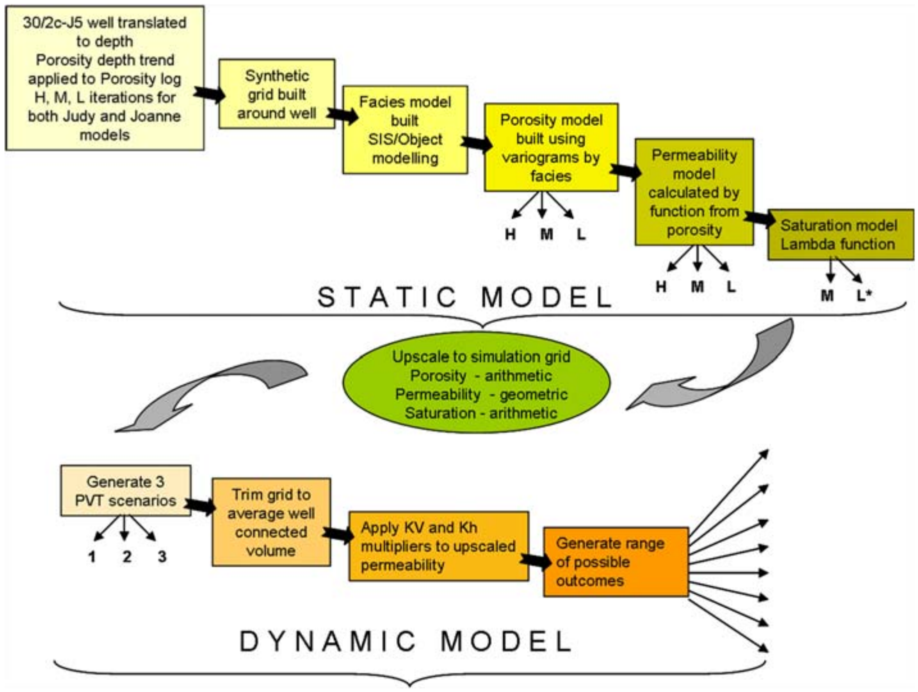

Fig. 8. Static and dynamic modelling workflow used in the construction of the deep Judy and deep Joanne models.

Table 1. Shows the range of parameter sensitivities tested for the deep Judy model

	Low	Base	High	High–high
Porosity–depth trend (pu/100 ft)	2.7	1.4	1	0.5
Porosity–permeability (applied by facies)	H, M, L	H, M, L	H, M, L	H, M, L
S_w (Lambda function)	Base, low	Base, low	Base, low	Base, low
Fluid – CGR (bbl/mmscf)	50/200/408	50/200/408	50/200/408	50/200/408

Table 2. The range of parameter sensitivities tested for the deep Joanne model

	Low	Base	High
Porosity–depth trend (pu/100 ft)	3	2.2	1.4
Porosity–permeability (applied by facies)	H, M, L	H, M, L	H, M, L
Fluid – CGR (bbl/mmscf)	50/200/408	50/200/408	50/200/408

argillaceous sandstones and sheetflood sandstones. An object-based channel distribution was then applied using the previously defined stochastic facies as a background. A ‘channel object’ was used to model the deposits of a confined braided channel and was thought to be representative as the main sand facies were likely to have been deposited in mid channel bars. The channel widths were based on the width of the boundaries determined by well test analysis and other dimensions from core data (thickness). Modern day analogues suggested a straight to sinuous form for these channels (Nichols & Fisher 2007). It should be noted that the channel bodies often represent a series of stacked amalgamated multi-storey channels. From the work of Larue & Hovadik (2006) for NTG over 35% the dimensions and shape of the bodies used becomes less important as connectivity in 3D increases. In the Skaggerak where vertical permeability is poor, the channel dimensions are important despite the relatively high NTG. Connectivity between the channels determines the initial high rate period of production in the Joanne Member. This model has been conditioned to the Jade Field production data through the production history match – and an iterative loop carried out with the facies modelling to condition the body sizes to match the production rates.

The Judy model uses a similar approach to the Joanne Member, with variogram-controlled SIS simulation. Owing to the connected nature of the sheetflood, larger variogram ranges were used of 1500 m. Smaller channel bodies were inserted into this background to represent the single-story nature of the channels seen in core and log.

Porosity distributions in the 3D grid were modelled by facies, using a sequential gaussian simulation and matched to well distributions and a 3% porosity net cutoff applied. No VClay cutoff was applied due to the difficulties of accurately determining a VClay log in the Skagerrak Formation due to the presence of heavy minerals. The 3% porosity cutoff is consistent with the offset Judy Field and Jade Field data, where production is seen from low porosity–permeability facies.

A core derived function between porosity and permeability was applied for each facies (Fig. 9) and sensitivities applied to this

Table 3. Model data for the deep Judy and the deep Joanne models

	Deep Judy model	Deep Joanne model
Top Reservoir depth (ft TVDss)	18 870	18 880
Depth translation from J5 (ΔD) (ft)	2657	4540
Reservoir thickness (ft)	1198	1436
Static grid cell size (W × L × T)	50 × 50 × 2 m	50 × 50 × 4.6 m
Upscaled grid cell size	75 × 75 × 2 m	60 × 60 × 4.6 m
OGIP final trimmed grid (variation due to PVT variation)	155–200 bcf	190–240 bcf
Initial model surface pressure (psia)	16 800	16 900
Vertical permeability (K_v) multiplier	0.01	0.01
Horizontal permeability (K_h) multiplier	1	0.1

to generate a high, low and base case permeability model for each porosity–depth realization. The same porosity–permeability functions were applied to both the deep Joanne and the deep Judy models.

Different saturation height models were applied to both models and were derived from Judy Member and Joanne Member well data. These used a lambda function (Brooks & Corey 1966). In the Judy Member much of the well data input to these models was derived from the transition zone (and the intention of the synthetic models was to generate a flow model from above the transition zone); a sensitivity was applied to this function to model the sensitivity low case saturations as the data were not thought to provide good constraint to the simulation model. The base case water saturations (S_w) ranged from 13 to 29%, for porosity values of 20–9% respectively at 1400 ft above the free water level (FWL). The sensitivity to the low side had a S_w range of 17–38% for the same porosity range, by varying the parameters *A* and *B* in the lambda function (Brooks & Corey 1966).

A FWL was set at the base of the deep Joanne model to coincide with the spill point seen on the prospect which the synthetic model was built to simulate. The Joanne Member showed a shorter transition zone than the Judy Member and the data used to derive a lambda saturation height function were primarily based on data considerably above the FWL; therefore a sensitivity to saturation function was not carried out on the deep Joanne model. The range of saturations seen at 1400 ft above the FWL was from 13 to 30% for 20–9% porosity.

Evaluation runs were generated on the upscaled grid, which had been trimmed to give an original gas in place (OGIP) comparable to that seen by wells in the offset J Block Fields. The grid was equilibrated with an initial pressure (Table 3) corresponding to the top reservoir depth. Unconstrained tubing was used and a minimum bottom-hole pressure of 5000 psi for both models. The simulation was run for a 20 year period. Both models were run with three alternate fluids, a light gas condensate of gas condensate ratio (CGR) of 50 (seen as the most likely case), a richer gas condensate (CGR = 200) and a volatile oil [gas oil ratio (GOR) = 2450]. Vertical (K_v) and horizontal (K_h) permeability multipliers were added to the deep Joanne and deep Judy models to achieve consistency with the history-matched Jade Field model. A K_v multiplier of 0.01 was applied to both models to reflect the poor vertical permeability seen in the offset fields. A K_h multiplier was applied to the deep Joanne model only of 0.1, which had been used to match the long-term production performance of the Joanne reservoir in the Jade Field. A match to the 30/2c-4 Joanne Member well test calculated permeability results in a K_h multiplier of 0.4. This decrease in effective flowing permeability through time is thought to reflect the increasing heterogeneity of the fluvial Joanne reservoir with distance from the wellbore.

Results

Deep Judy model results

The graphs in Figures 10 and 12 show the results of the low, base and high-high case porosity realizations (the high case was found to be close to the base case) for the synthetic Judy model, plotted by CGR.

Recovery Factor (RF) v. CGR/GOR (Fig. 10a, b). The RF for both gas and oil is significantly higher in the low CGR case than the volatile oil case. The gas RF shows an overlap between the porosity cases between the high and low permeability sensitivities. The oil RF plot shows less overlap between the porosity cases.

Initial gas rate v. CGR (Fig. 10c). This graph shows a decrease in initial gas production with increasing CGR/GOR (as would be expected). As with the RF, there is a good deal of overlap between the runs. The low porosity–low permeability case and the mid porosity–low permeability case both show significantly lower initial gas production rate than the other cases. All other cases produce an initial rate of around 45–57 mmscf/day in the low CGR = 50 (most likely) case. This mid porosity–permeability case with a CGR of 200 has an initial gas rate of around 30 mmscf/day, comparable with initial gas rates from Judy Fields of 50 mmscf/day for the P18 Judy Member well, around 7000 ft shallower (Jones *et al.* 2005; Keller *et al.* 2005).

Figure 10d shows gas RF plotted against mean net permeability. All three fluids follow a similar trend, showing a marked decrease in RF below 2 mD net permeability. However, for the light gas condensate case the RF remains above 50% even in the lowest porosity–permeability run. The sensitivity of the model to a low case saturation height function is shown in Figure 10e. There is relatively little sensitivity to CGR/GOR with a low case saturation model, and only in the lowest porosity–permeability case is a significant impact on gas RF seen (20–25%).

The expected ultimate recovery (EUR) recovery per model (Fig. 12a) over a 20 year time period shows little variation again between the CGR cases. The permeability sensitivities result in a few mmboe EUR difference for each porosity case. The cases plot in order of porosity–depth trend, with the lowest porosity cases producing less than 15 mmboe/well over 20 years.

Production profiles (Fig. 12b) for the mid porosity–permeability run show a steady rate decline through time with an initial rate of around 47 mmscf/day in the light gas condensate case. The volatile oil shows a drop off in gas recovery after four years, followed by a lower rate gas tail.

Deep Joanne model results

The graphs shown in Figure 11 show the results of the synthetic deep Joanne model.

The gas and oil recovery factors both show the low permeability sensitivities plotting at the low end of the range below the mid-case permeability realizations. Both the gas and oil RF are particularly poor for the high GOR (volatile oil) runs (Fig. 11a, b), with RFs at 10% or less for both gas and oil in the low permeability cases.

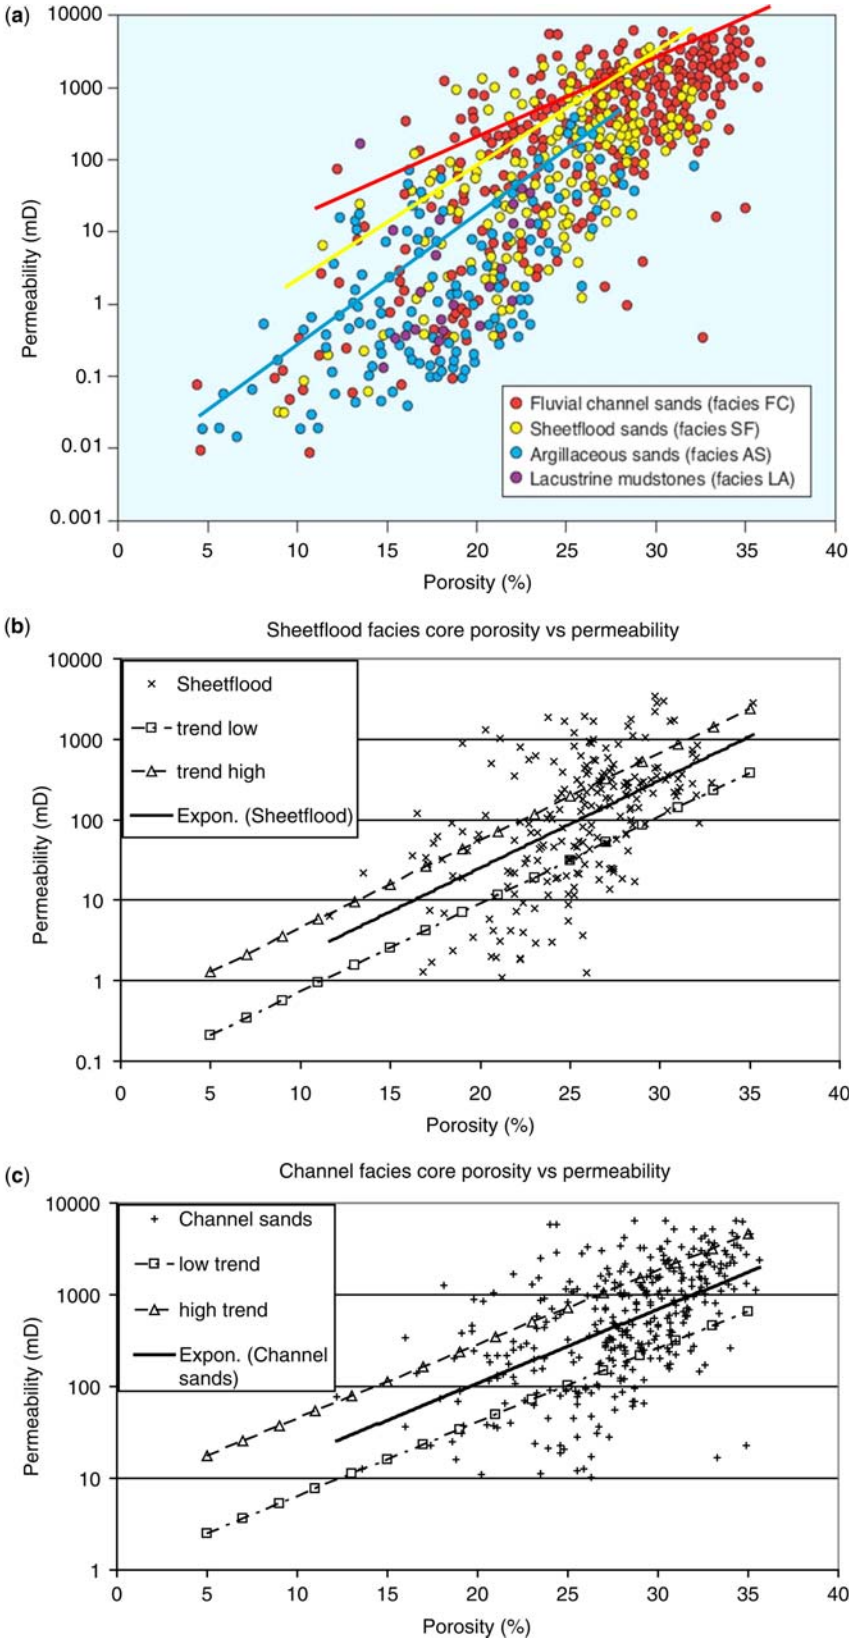

Fig. 9. Porosity v. permeability plot coloured by facies from the Joanne Formation of the UK Central North Sea (CNS) (Goldsmith *et al.* 2003). Data appear to be on one trend, yet split by facies it is composed of three trends. (**b**) Porosity v. permeability plot for the sheetflood facies only, showing the best fit exponential trend, plus a low and high case sensitivity. (**c**) Porosity v. permeability plot for the channel facies only, showing the best fit exponential trend, plus a low and high case sensitivity.

The gas RF when plotted against mean net permeability shows a significant reduction in RF below 10 mD net permeability (Fig. 11d) in all three cases of around 10–20%. For the volatile oil cases this reduction in RF seems to occur at round 20 mD.

Good RF and rates can be achieved in the low CGR case in all but the lowest permeability cases. For the richer gas condensate (CGR = 200) the RF and rates are more sensitive to permeability.

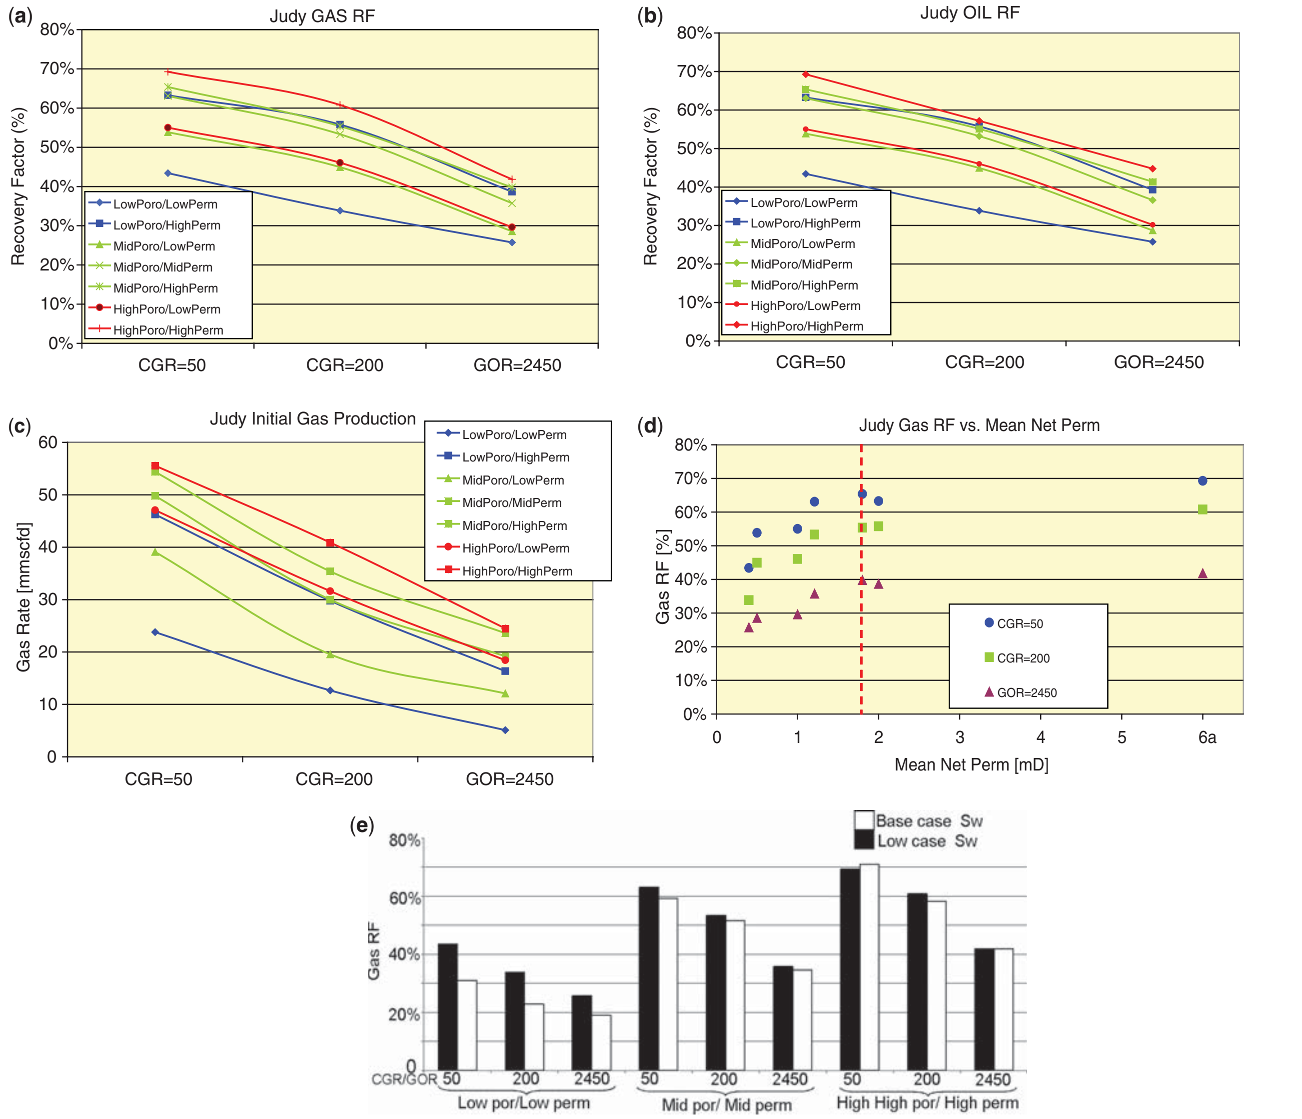

Fig. 10. (**a**) Judy Gas RF v. CGR/GOR. (**b**) Judy oil RF v. CGR/GOR. (**c**) Judy initial gas production rate v. CGR (**d**). Judy gas RF v. mean net model permeability. Red line shows permeability at which little incremental RF is achieved. (**e**) Sensitivity of deep Judy model mid case porosity run to a low case saturation height function.

The initial gas rate (Fig. 11c) is also strongly affected by CGR, with the volatile oil case producing at a rate of less than 5 mmscf/day. The low permeability cases for the lean and rich gas condensates are also less than 20 mmscf/day. The mid porosity–permeability case with a CGR of 200 has an initial gas rate of 28 mmscf/day. This is can be compared with published Jade Field rates at a similar CGR of 50–75 mmscf/day (Jones *et al.* 2006) from wells *c*. 2500 ft shallower.

The ultimate recoverable resources over the 20 year run life (Fig. 12a) show low recoveries in the high CGR case in all but the highest permeability sensitivities. For the gas condensate runs, the ultimate recoverable resources rank in order of porosity with no overlap between the permeability cases. The recovery is less than 15 mmboe in the low porosity–permeability run for all cases.

Discussion

The deep Judy model shows that gas recovery factor is controlled by both porosity and permeability, whereas oil RF is more strongly controlled by porosity. EUR resources through time are likely to be controlled by porosity rather than permeability. The model produces in a stable manner above 2 mD net permeability, with little incremental recovery above this value. Sensitivities to low case saturations also show a limited effect on recovery; the key controlling factor on recovery is porosity. The model is not sensitive to variations in CGR, suggesting that a volatile oil case would also be producible in the Judy Member reservoir under the extreme HPHT conditions expected. Initial gas rate is more sensitive to permeability and it is likely that the low permeability–low porosity cases may not prove to be effective reservoir.

The initial gas rates compare favourably with the P18 well on Judy Field (the 30/2c-J5 Judy Member producer on Jade Field is comingled with the Joanne Member), showing a third of the initial gas rate. The Judy Field is 7000 ft shallower than the deep models. In the deep models, the most likely fluid is predicted to be a light gas condensate – for which initial gas rates are comparable at 50 mmscf/day, suggesting that a lighter fluid may compensate for the decrease in reservoir properties with depth.

As the model initializes at a high pressure, it never falls below the dew point in the 20 year run time. This means that the sensitivity to the effects of condensate banking have not been studied but are likely to have an effect in the low permeability cases (due to lower flow rate) and high CGR cases. This effect would only be seen towards the end of the field life.

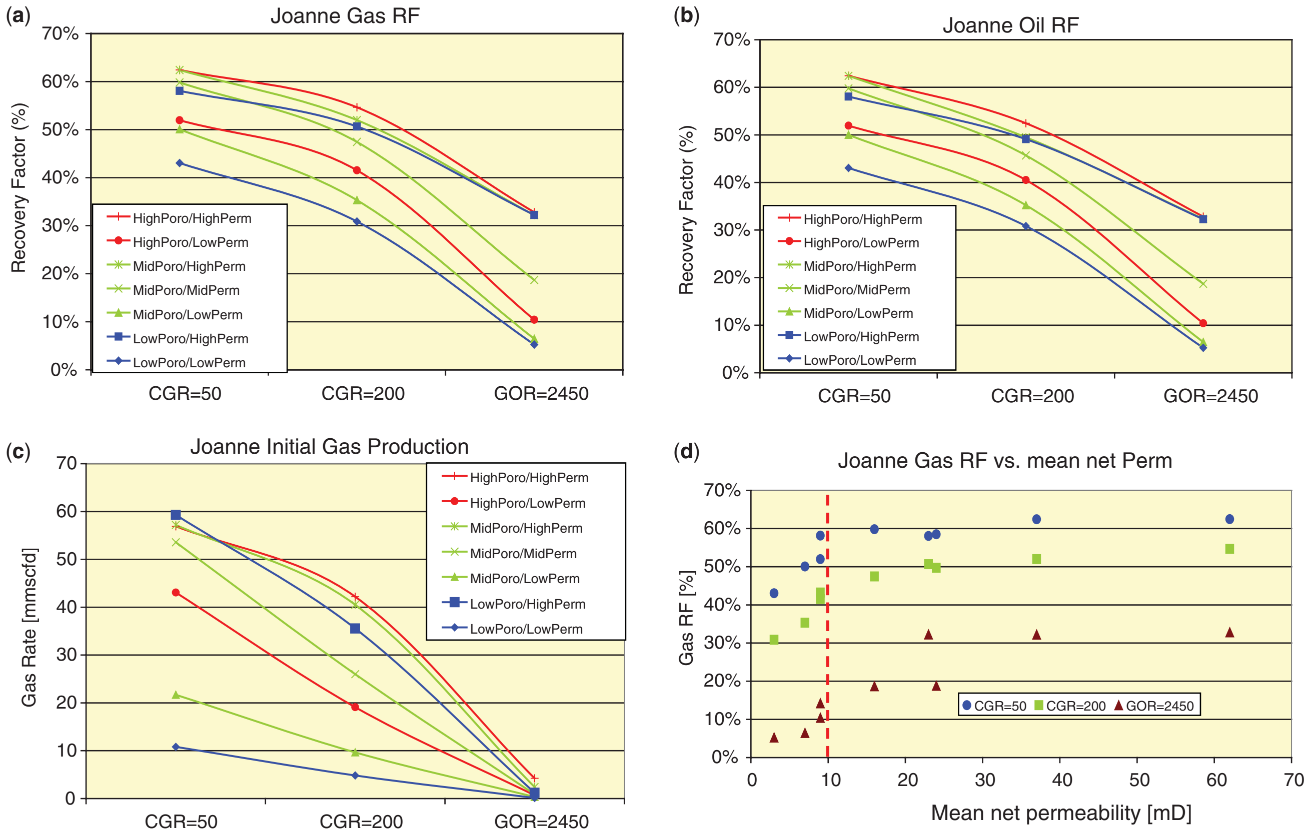

Fig. 11. (**a**) Joanne Gas RF v. CGR/GOR. (**b**) Joanne oil RF v. CGR/GOR. (**c**) Joanne initial gas production rate v. CGR (**d**) Joanne gas RF v. mean net model permeability. Red line shows permeability at which little incremental RF is achieved.

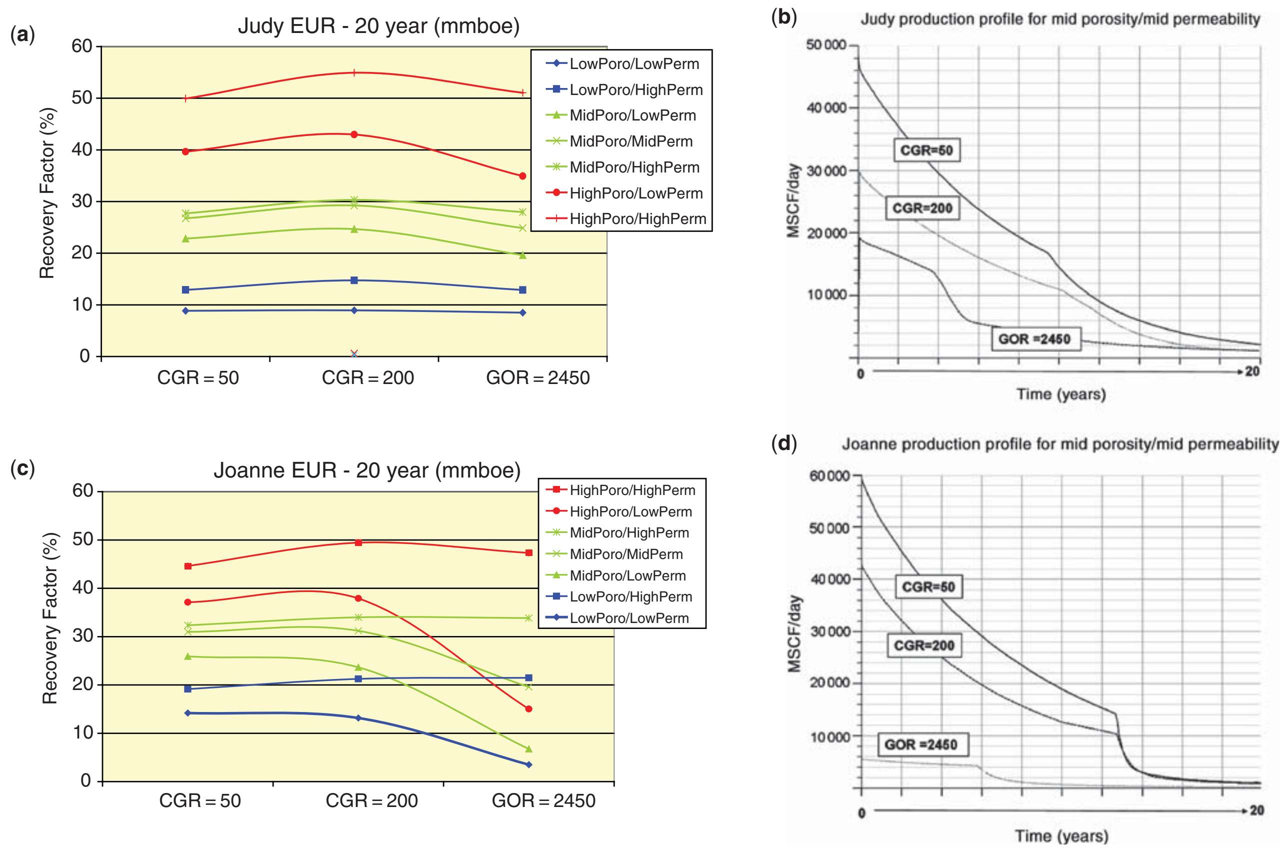

Fig. 12. (**a**) Judy EUR resources over 20 years. (**b**) Judy production profile v. CGR for mid porosity–permeability case. (**c**) Joanne EUR resources over 20 years. (**d**) Joanne production profile v. CGR for mid porosity–permeability case.

The Judy Member reservoir is interpreted as sheetflood-dominated. The production and well test behaviour show radial flow through a relatively homogenous system. Although the porosity–permeability characteristics of the Judy Member reservoir are poorer than the channel-dominated Joanne Member, this homogeneity allows a steady production decline and the good lateral connectivity results in much of the model volume being connected, increasing recovery. No K_h multiplier has been applied to the deep Judy model (consistent with the methodology used in the history-matched Jade Field model). The lack of K_h multipliers results from the laterally homogenous properties of sheetflood deposits, suggesting that the flowing permeability does not vary away from the well bore due to the lack of lateral baffles/barriers to flow.

The porosity–permeability transform used is based on core data that has not been corrected for reservoir pressure, temperature and fluids. This would imply that this dataset would be expected to be 'optimistic' in its prediction of permeability from porosity. As a best fit linear transform has been applied to this data set (by facies) and the permeability is plotted on a logarithmic scale, this will always lead to a low side estimation of the permeability in the model. It is acknowledged that the prediction of permeability from porosity remains a key uncertainty in this workflow as no core data from the depth of the prospects have yet been obtained to define this relationship at depth and that sensitivity of the Judy model to permeability may be greater than shown in this study. The behaviour of the deep Judy model contrasts with the deep Joanne model. The Joanne Member has consistently higher porosities and permeabilities in the channel sands in the Jade and Judy fields than the Judy Member, yet the deep production behaviour and RF show a much stronger control from permeability than that seen in the deep Judy model.

The deep Joanne model shows a strong control from both permeability and fluid type, both of which may significantly reduce gas rate. The deep Joanne model shows no incremental increase in gas RF above a 10 mD average net permeability cutoff (as compared with a 2 mD cutoff in the Judy model). The inherent production behaviour of the Joanne Member as a dual permeability system with the poorer quality sheetflood and overbank deposits serving to connect the higher permeability channels increases the dependency of the production on the lower permeability facies. When these are extrapolated to depth, the productivity of the entire Joanne reservoir declines. In the Joanne model, porosity controls the ultimate recoverable resources, yet permeability has a stronger control on liquid production and rate. The volatile oil cases are particularly adversely affected by the reduction in permeability and only the high porosity–permeability sensitivities recover more than 20 mmboe/well in the 20 year run time.

The gas production profiles for the mid case porosity–permeability realization for both the deep Joanne and Judy models (Fig. 11b, d) show that the deep Joanne model produces at higher rates (5000–10 000 mmscf/day more) for the gas condensate cases, but the volatile oil case is significantly poorer than for the deep Judy model.

The Joanne Member has had a K_h multiplier of 0.1 applied (consistent with that applied in the history-matched Jade Field model), which reflects the increasing sedimentological heterogeneity seen (baffles and barriers to flow) away from the well bore, consistent with its interpretation as a channel-dominated facies.

Porosity–depth trends remain a significant source of uncertainty in both the Joanne and Judy members. In both forward-modelled examples it is the low case porosity–depth trend that results in low recovery; this is 2.7 pu/1000 ft in the deep Judy model and 3 pu/1000 ft in the deep Joanne model. These results suggest that, in either reservoir, if the low case porosity–depth trend is coupled with poor permeability and/or low NTG, the reservoir is unlikely be effective. The deep Joanne model is more sensitive to permeability than the deep Judy model and there may be more reservoir risk associated with a deep Joanne prospect as a result.

As a single 'average Skagerrak Formation' well has been used as an analogue, the effect of significantly poorer or better NTG has not been explicitly modelled in this study. It is known that Skagerrak Formation stratigraphy changes between pods and that NTG varies also within pods, such that the applicability of a single 'representative well' must be questioned, and its applicability away from the Jade Field discussed. Although the stratigraphy may vary within the Judy Member, the overall homogeneous nature of the sheetflood sands means that the model will be likely to represent this type of facies within the region. The Heron–Marnock area to the north show a similar facies in the Lower Judy, with the upper Judy showing a fluvial dominated facies. In this area the deep Joanne model will better represent the production from the Upper Judy in the Heron–Marnock area. NTG variations within the Joanne and the Judy will significantly impact production and connectivity – particularly within the Joanne Member, which is very sensitive to variations in connectivity between the channels. This is seen in the offset fields and an NTG of $>25\%$ is likely to severely limit recovery. These results are consistent with plots of recovery v. NTG for heterogeneous reservoirs derived by Larue & Hovadik (2006), which show an 'S curve' decline in recovery below 35% NTG for most channelized reservoirs. The Judy Member reservoir may be less susceptible to low NTG scenarios as lateral connectivity is generally better than in the Joanne Member. However given that in a low NTG scenario the pore volume connected to the well bore will reduce and vertical permeability is poor, ultimate recovery per well may be severely reduced.

Given that the aim of this study is to study deep Skagerrak production behaviours, it can be seen that the mid and high porosity–depth trend cases all produced at viable rates. Structural complexity was not considered in this evaluation and production wells drilled into areas with significant faulting could be expected to have significantly poorer performance. Structural tilt will also impact production performance but has not been accounted for in this generic study.

Conclusions

The understanding of the Joanne and Judy reservoir production data from the currently producing J Block fields has allowed better understanding of the risks for deep Skagerrak Formation exploration targets, in that for the majority of cases the reservoir is able to flow over production timescales and at effective rates.

Recognition that the Joanne and Judy members have different characteristic reservoir production and well test behaviours has improved understanding of sedimentological architecture and connectivity. This can be related to different environments of deposition within an overall dryland setting for the Joanne and the Judy members of a medial fluvial system for the Joanne Member and a terminal splay for the Judy Member. Understanding of this fundamental difference in production style linked to sedimentary architecture has allowed facies-based models to be constructed that captured the fundamental heterogeneity of both the Joanne and the Judy reservoirs, resulting in a predictive history-matched model for the Jade Field. This tested methodology had been extrapolated to the deep Skagerrak Formation reservoirs to understand likely production behaviour with depth.

The deep Judy model flow rate and RF at depth are controlled mainly by porosity. The model is not as sensitive to CGR/GOR variations as the deep Joanne model and permeability is a secondary not a primary control on production. For net permeabilities of greater than 2 mD the recovery is stable.

The Joanne Member is more heterogeneous than the Judy Member and recovery from the deep Joanne model is more strongly controlled by permeability, particularly oil recovery. Increased CGR has a strongly detrimental effect on both recovery and rate. For net permeabilities of less than 10 mD there is a marked reduction in RF in all CGR cases. Either low permeability or a volatile oil may limit the effectiveness of a deep Joanne Member reservoir.

The behaviour of the two models has been used to understand the possible implications for production from deep Skagerrak Formation Reservoirs. In all but the lowest porosity–permeability and NTG cases the reservoir is predicted to be effective, due mainly to higher predicted overpressures and large differences between initial reservoir pressure and dew point.

The authors would like to thank BG Group for allowing publication of this material. The J Block and Jade partners are also thanked [Conoco Phillips UK Ltd, ENI (UK) Ltd, Chevron UK Ltd and OMV (UK) Ltd]. The opinions and interpretations expressed in this paper are the views of the authors and do not necessarily represent those of BG Group Ltd or its co-venturers. Proprietary sedimentology and diagenesis studies were carried out on the cored intervals in J Block and offset wells for the J Block partnership and BG Group by A. Melvin of PM Geos and AM Geos. The authors have also benefitted from discussion with other J Block workers: A. Gabb, R. Hiney, R. Charles, J. Hilton. M. Hardman and G. Cowan are also thanked for their comments and edits. Three anonymous reviewers are thanked for their time and helpful comments.

Sedimentology and unexpected pressure decline: the HP/HT Kristin Field

J. G. QUIN, P. ZWEIGEL, E. ELDHOLM, O. R. HANSEN, K. R. CHRISTOFFERSEN and A. ZAOSTROVSKI

Statoil, Strandveien 4, NO-7501 Stjørdal, Norway (e-mail: jqu@statoil.com)

Abstract: Since production began in the HP/HT Kristin Field off mid-Norway, reservoir pressure in each of the three mid to late Jurassic reservoir units (the Garn, Ile and Tofte formations) has declined significantly more rapidly than was initially predicted. In the Garn Formation, the Tofte Formation and to some extent also the Ile Formation, this has occurred at least partly because an unusual distribution of reservoir properties led to bias in the four-well appraisal dataset and this in turn resulted in an overestimation of reservoir properties. Of particular importance to this bias was the fact that very good but unrepresentative reservoir properties were encountered in all three reservoir zones in the discovery well located in the centre of the field. These, it is now realized, are not even typical of most of the central part of the field but are, instead, restricted within one, small, anomalous area. Study of cores and thin sections indicates that in each reservoir unit this directly reflects a concentration of more energetic depositional facies in the area while less energetic facies are present on three sides. This pattern was not predictable from the original dataset and seems to have arisen because there was structural control upon facies positioning during accumulation of the reservoir section. This influenced the distribution of cleaner, coarser grained, more proximal depositional facies and, ultimately, reservoir quality distribution and pressure development. What is interesting about Kristin Field is that the structural influence upon sedimentation is observed within the footwall stratigraphy of a major relay structure where the primary provenance direction was on the hanging-wall side. This pattern is the reverse of what is normally reported in tectono-stratigraphic studies.

Keywords: depletion, growth strata, shallow marine sandstone, tectono-stratigraphy, HP/HT

The high-pressure, high-temperature (HP/HT) Kristin Field lies 220 km off the mid-Norwegian coast (Fig. 1) in 350 m water depth and is a conventional structural trap comprising an elongate north–south oriented horst block (25 km long and 5 km across). The structure dips gently to the east and is partly eroded along the northern part of the western margin by the Base Cretaceous Unconformity (BCU). The field contains gas condensate in three Lower to Middle Jurassic paralic sandstone units buried at between 4600 and 4850 m ss and was discovered by Saga Petroleum in 1996. Three appraisal wells were subsequently drilled and a substantial discovery was proven with estimated original in-place volumes of around 100 MSm^3 of condensate and 100 GSm^3 of gas, a dew point of *c.* 400 bar and a gas–oil ratio of *c.* 1000 Sm^3/Sm^3 (Christoffersen *et al.* 2008). Statoil became the operator of Kristin Field in January 2000 and production began in November 2005. Since then, pressure in each of the three Kristin Field reservoir units has declined significantly more rapidly than was predicted at the appraisal stage. This has occurred at least partly because reservoir properties (mainly permeability) were initially overestimated as a result of a skewed appraisal well dataset. Of particular importance to this bias was the persistent presence of unrepresentatively high reservoir quality in the discovery well (well 2-3) which is located in the volumetrically important central part of the field. This manuscript examines what geological controls led to this phenomenon, how it skewed initial impressions of Kristin Field, and what impact it has had on field development.

Tectonics and burial history

From the early Carboniferous through to the opening of the north Atlantic in the early Eocene, the Norwegian continental margin underwent a prolonged episode of tectonic extension (Glennie & Underhill 1998; Doré *et al.* 1999; Brekke *et al.* 2001). This began with widespread active rifting between the Carboniferous and Permian, was followed by a phase of thermal relaxation between the Middle Triassic and the late Early Jurassic, and continued with intermittent tectonic activity from the Middle Jurassic through to the Cenozoic (Brekke *et al.* 2001). In the Halten Terrace area in which Kristin Field is located, the Middle Jurassic to Cenozoic rifting stage has traditionally been thought to have begun between deposition of the shallow marine Fangst Group and the overlying shelf mudrocks of the Upper Jurassic Viking Group (Dalland *et al.* 1988; Ehrenberg *et al.* 1992; Koch & Heum 1995; see Fig. 1). While this would place the reservoir section in Kristin Field (mainly Fangst Group) within the pre-rift section, some syn-depositional fault movement is nevertheless reported within the interval regionally (Corfield & Sharp 2000; Corfield *et al.* 2001; Marsh 2008) and is occasionally observed from growth across faults within the Kristin Field reservoir section. Deposition of the overlying Upper Jurassic Viking Group mudrocks coincided with much more intense tectonic activity (late Oxfordian/early Kimmeridgian and the Ryazanian/Valangian, e.g. Blystad *et al.* 1995; Underhill 1998) which is observed from major growth across faults within the interval. This pulse of tectonism also led to most of the structuration that is now associated with hydrocarbon accumulation in the Halten Terrace and in the area around Kristin Field this episode was characterized by thin-skinned gravitational sliding (Marsh 2008) towards the west. The faulted Jurassic section is capped by the BCU while the overlying succession is dominated by eastward onlapping marine shales with minor sandstone units derived from the Norwegian mainland.

Both hydrocarbon generation and the development of overpressure in the western part of the Halten Terrace seem to have been associated with a pulse of subsidence in the Pliocene (Skar *et al.* 1999). The overpressure is thought to have developed either in response to local mechanical compaction of shales (Borge 2002) or through transfer of pressure from the deep and highly

VINING, B. A. & PICKERING, S. C. (eds) *Petroleum Geology: From Mature Basins to New Frontiers – Proceedings of the 7th Petroleum Geology Conference*, 419–429. DOI: 10.1144/0070419

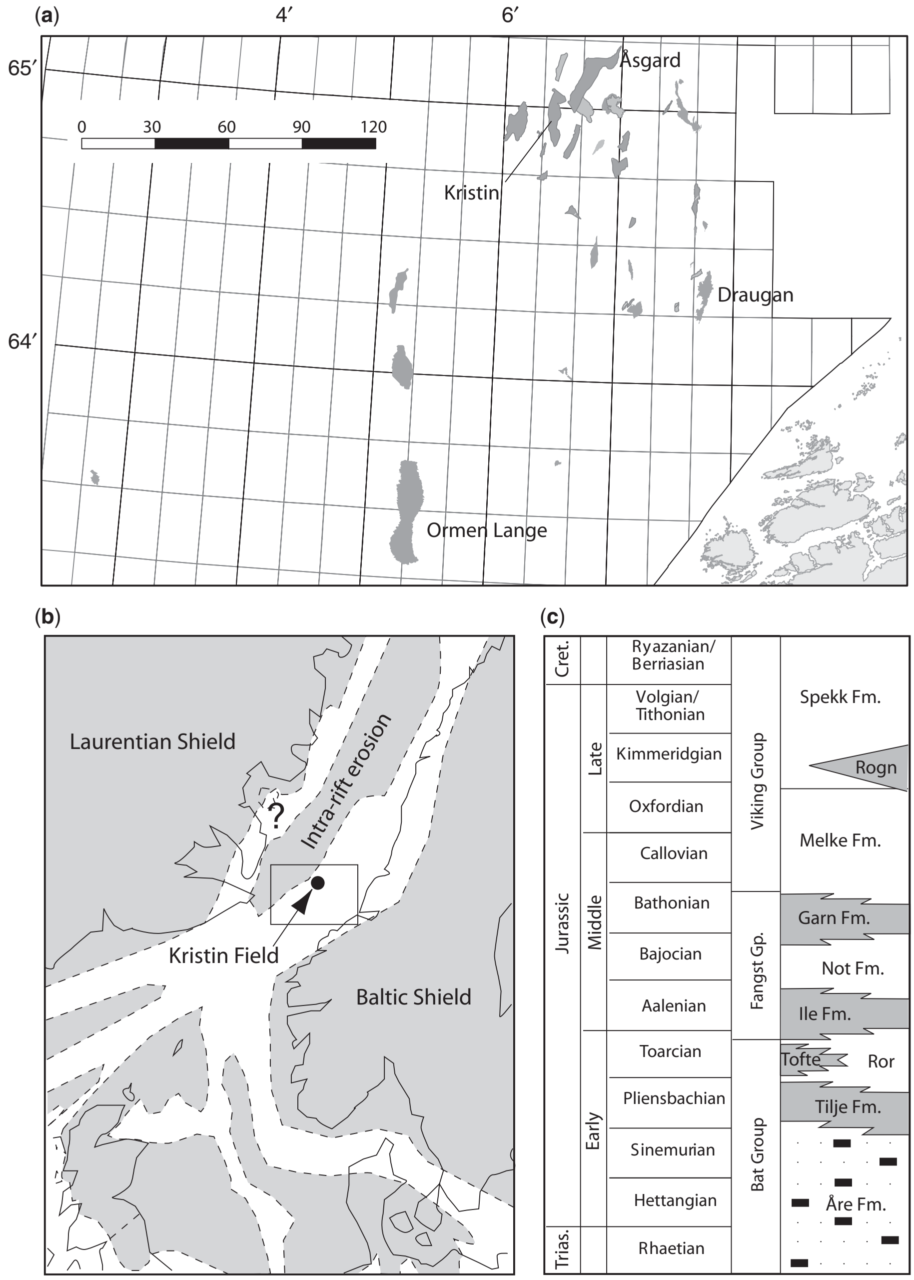

Fig. 1. (**a**) Kristin Field location map (NPD); (**b**) Middle Jurassic palaeogeography (modified from Doré 1992); and (**c**) Haltenbanken stratigraphic column (solid circles indicate producing reservoirs).

overpressured Rås Basin to the west (see Skar *et al.* 1999 for discussion). However, because overpressure developed late on in the burial history of the western Halten Terrace, it has a relatively minor impact upon both shale porosity calculated from logs (Hermanrud *et al.* 1998) and upon the reservoir quality of the sandstones.

Palaeogeography

Regional palaeogeographic reconstructions suggest that the Kristin Field reservoir section accumulated in the western part of the Halten-Trøndelag Basin – part of a long north to south oriented Jurassic seaway which is thought to have linked the Boreal and Tethys Oceans (Fig. 1). In the mid-Norway area (offshore), Gjelberg *et al.* (1987) and Jongepier *et al.* (1996) report sand influx from the west into this area, during accumulation of the Kristin Field reservoir section (i.e. Early to Middle Jurassic). This is supported both by well data and from outcrop studies (Dalland 1979) and has been taken to imply that the deep Cretaceous Møre and Vøring basins, to the west of the Halten Terrace, were areas of uplift sub-aerial exposure and sediment export (Doré 1992). In the Jameson Land area of East Greenland, Surlyk (1990) reports sediment influx from the north and east in time-equivalent strata. This implies that the proposed uplift extended to the western side of the present Norwegian Sea while the main north to south seaway lay to the east of the present day rift axis (Brekke *et al.* 2001). The palaeoaltitude of the Halten Terrace during the Jurassic was between 49 and 53° (Smith *et al.* 1994), while climatic conditions were probably warm with potential for strong seasonal differences in temperature and rainfall (Hallam *et al.* 1994).

Kristin Field

With an initial reservoir pressure of 911 bar and an initial temperature of 170°C, Kristin Field is the most extreme HP/HT field on the Norwegian shelf. The field is being produced by pure

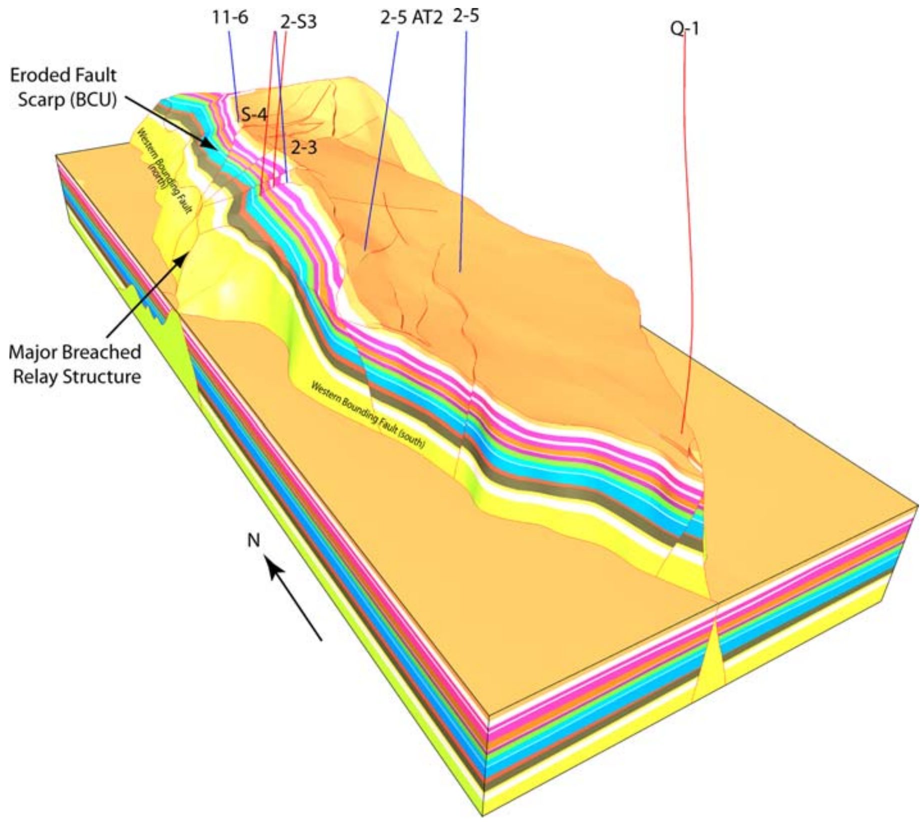

Fig. 2. Kristin Field structural model. Also shown are: the discovery well (2-3); the three appraisal wells (11-6, 2-5 and 2-5AT2) and three development wells (S-4H and S-3 HT3 adjacent to the discovery well and Q-1H in the south of the field).

depletion from 12 wells, almost all of which are located along the western structural crest (Fig. 2). The producing wells include: five dedicated Garn Formation producers; one dedicated Ile Formation producer; five co-mingled Garn and Ile formation producers; and one dedicated Tofte Formation producer. The dedicated producers are located in the central area, while comingled producers are situated towards the north and south. Although there is some uncertainty regarding the zonal production allocation in comingled wells (i.e. Garn and Ile formations), gas–oil ratios do give a reasonable indication of the relative flow contributions from the different reservoir units. There is also, in general, a good link between permeability calculated from logs (and calibrated to core) with flow tests and well productivity index (PI) and, consequently, log permeability is used directly in the simulation model without modification (see Fig. 3 for reservoir properties and porosity permeability plots). The field is covered by a variety of 3D and 4D seismic surveys which have allowed detailed mapping of the structure but have not provided robust insight into reservoir property distribution.

Diagenetic controls on reservoir quality

Despite major differences in the sedimentology of the three Kristin Field reservoir units, study of thin sections and core indicates that there is a strong link between primary depositional fabric and reservoir quality variation in all three units (i.e. depositional fabric drives diagenetic differences). The main depositional controls upon reservoir quality are: (1) the sorting and clay content of the sandstones which influences the degree of physical and chemical compaction (e.g. stylolites are abundant in mud-draped intervals but are almost absent in cleaner sandstones); (2) grain

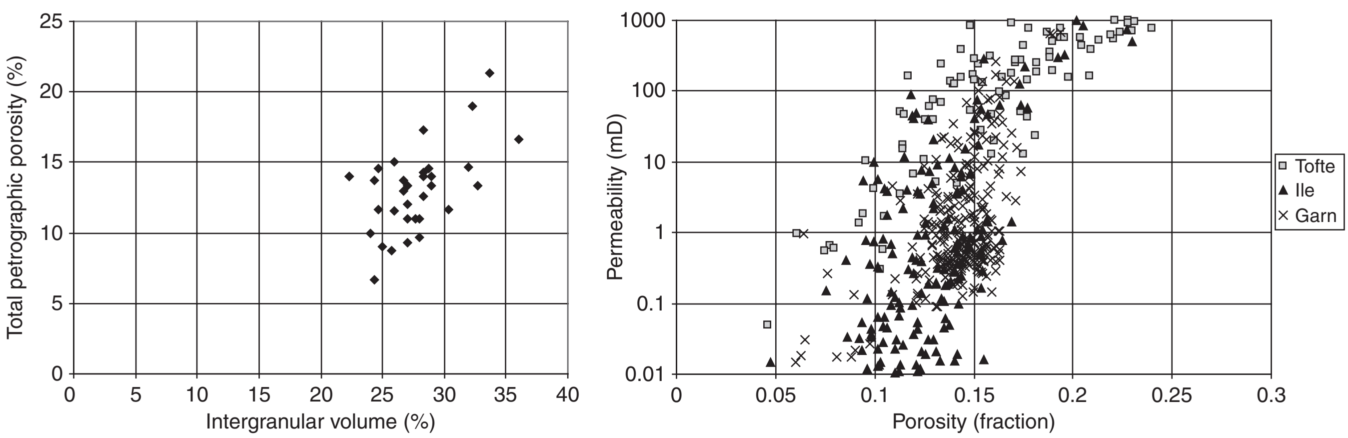

Fig. 3. Intergranular volume plotted against petrographic porosity for Garn Formation thin sections (left), and porosity to permeability plots for the discovery well (right).

size, which influences both the pore throat size and the quartz surface area available for growth of quartz cement; and (3) clay grain coats which also influence available quartz surface area. The most important grain coating mineral is chlorite, although illite and illite-chlorite mixtures are also reported in the Garn Formation (Storvoll *et al.* 2002). Grain coats typically exhibit an inner layer of concentrically laminated ooidal chlorite which probably formed by mechanical accretion of chlorite (or more probably an iron-rich precursor clay) as grains were rolled along the bottom. The actual source of iron is generally agreed to be river water, which carries a relatively rich load of colloidally suspended iron derived from weathering. Near the river mouth, increased salinity causes the iron to be flocculated and deposited in an amorphous reactive state (Ehrenberg 1993). The distribution of grain coats is poorly understood in Kristin Field, but they are more common in coarser cleaner intervals of sandstones and in facies interpreted to reflect deposition within tidal channels rather than the open shelf.

Although non-depositional controls upon reservoir quality distribution (i.e. variation) have been considered, they can be discounted as major controls upon reservoir quality distribution. For example, the structure is deep and relatively flat and depth trends are poor over the available dataset. Neither is there a good relationship between structural highs and enhanced reservoir quality, so evidence for an early hydrocarbon charge-preserving reservoir quality during burial is lacking. Nor is there a geographical association between the major bounding faults and better reservoir quality, so migration of porosity-enhancing corrosive fluids associated with the faults has not occurred. Indeed, the main bounding faults are not even in contact with the reservoir section in central and northern areas because of BCU erosion. There is also no evidence for a relationship between the distribution of enhanced reservoir quality and the proximity of the BCU, which indicates that porosity improvement due to leaching is not influential (nor is this phenomena observed in adjacent fields). Most importantly, however, there is a clear link between grain size, sorting and mud content with zones of enhanced reservoir quality.

Reservoir sedimentology

Given the strong link between reservoir quality distribution and primary depositional facies, the following section briefly describes the sedimentology of the three reservoir units and links this to Kristin Field pressure decline (e.g. Fig. 4).

Garn Formation

The *c.* 110 m thick Garn Formation is the uppermost of three formations that constitute the Fangst Group and the uppermost Kristin reservoir unit. The interval is contemporaneous with the Brent Group of the North Sea (Ehrenberg 1990) and is equivalent to the transgressive sandstones of the Pelion Formation in East Greenland (Doré 1992). The Garn Formation exhibits relatively constant thickness in both Kristin Field (where there are 18 well penetrations and 716 m of core) and where the unit is penetrated in wells further east across the Halten Terrace. However, the interval thins gradually both to the north and south along the axis of the Halten–Trøndelag Basin. The Garn Formation in Kristin Field exhibits fairly constant porosity (*c.* 13%), which compares favourably to the general depth trend for the unit. This is at least partly due to the presence of more grain coats, increased grain-size and fewer mud drapes. Permeability variation is more dramatic and strongly impacts production. Two broad permeability groups are observed from the current well dataset: (1) a low permeability background (typically <1 mD) which dominates the interval and is more common in the east of the field, and (2) higher permeability layers (typically up to tens of millidarcy) which are present (very) locally along the western flank of the field and which die out eastwards over short distances.

Description. The Garn Formation in Kristin Field is characterized by high net-to-gross ratios (>95%) and low gamma ray (GR) signatures and, in general, it is not normally possible to confidently correlate surfaces/units between wells. The base of the interval is defined by a rather abrupt upwards decrease in GR response which is the culmination of a cleaning upward succession within the upper part of the underlying Not Formation. The actual contact between the units corresponds to an upward step in grain size observed in core and an increase in reservoir properties. Nevertheless comparable facies are consistently observed either side of this surface and Si–Al ratios, measured across it, show that the clear cleaning upward profile which begins in the central part of the Not Formation continues into the basal part of the Garn Formation (Si–Al ratios from core-based chemostratigraphic analysis; Ichron). The Garn Formation itself is dominated by very fine to coarse grained subarkosic arenites (Ehrenberg 1990; Chuhan *et al.* 2001) which, while superficially homogeneous, can be divided into two main depositional facies in Kristin Field (for brevity, volumetrically minor facies are not described). Most important from a reservoir quality perspective are intervals of clean, typically cross-bedded sandstones which are usually several metres thick and which also include sections of parallel lamination or massive bedding and rare trace fossils (mainly *Trichichnus*, *Skolithos*, *Arenicolites*, *Ophiomorpha*, *Cylindrichnus*, bivalve burrows, resting traces and non-specific burrow mottles). Poorly developed coarsening and cleaning-upward trends are also occasionally observed. While permeability is not always

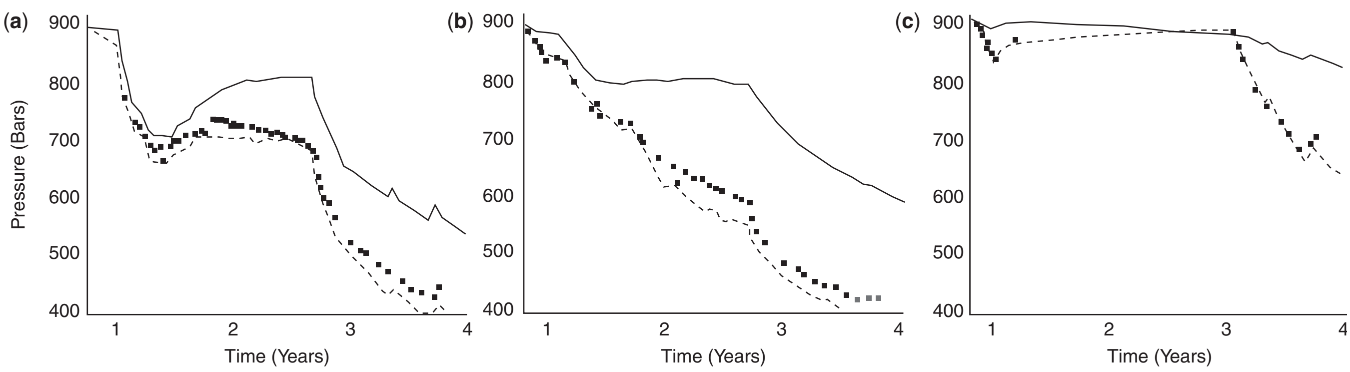

Fig. 4. Pressure profiles taken from: (**a**) a Garn Formation well; (**b**) an Ile Formation well; and (**c**) a Tofte Formation well. In each case the solid upper line refers to initial pressure prognoses, the lower solid line to the current history matched reservoir model, and the circles to calculated down-hole pressure measurements.

significantly higher in this facies, all intervals of high permeability within the Garn Formation occur within it. This facies dominates the Garn Formation in the west of the field (hence higher permeability in this area) and is also anomalously abundant in the central area where it is also notably coarser grained (mainly coarse sandstone). Intervals of this facies are normally thinner and less common in wells in the eastern part of the field (e.g. 30% in well 6406/2-5 compared with up to 80% on the western margin). The second and more volumetrically important depositional facies comprises cross-bedded very fine to medium grained sandstones with thin drapes rich in mudrock and mica which are prone to stylolite formation. Bioturbation is rare but can be prevalent and includes (*Ophiomorpha*, *Trichichnus*, *Skolithos*, bivalve burrows, resting traces, *Planolites*, *Palaeophycus* and *Chondrites*). This facies association is always associated with very poor reservoir quality and is common in the middle part of the Garn Formation and in the eastern part of the field.

Depositional synthesis. The depositional model for the Garn Formation implies accumulation within stacked, possibly tidally influenced shoreface successions. These accumulated during eastwards (and perhaps northeastwards) progradation through Kristin Field and are presumably separated by transgressive surfaces (generated during shoreface retreat) although these surfaces are seldom obvious. The general absence of either well-defined coarsening and cleaning upward trends (within shoreface packages) or well-developed shale-prone flooding intervals (between them) reflects a lack of accommodation in what was presumably a proximal part of the depositional system. In contrast, bioturbated shale-prone intervals and well-defined cleaning upward trends are present further east (e.g. Tyrihans Field). The clean cross-bedded facies is interpreted to represent upper shoreface environments while the draped cross-bedded facies is thought to reflect accumulation in lower shoreface settings. Given this depositional model, the observed reduction in the abundance of the clean cross-bedded facies over short distances from west to east across Kristin Field (over 2–3 km) is strange when one considers that coastlines almost certainly migrated some tens of kilometres to the east and NE of Kristin during regressive stages. A possible explanation for this pattern is that it results from shoreface stacking patterns (e.g. Fig. 5). One also has to question why intervals of higher permeability are encountered in some intervals of the clean cross-bedded facies but not in others. Here, it seems likely that these intervals reflect subtle intra-facies changes in mineralogy, sorting and grain size which are not readily observable in core. For example, chemostratigraphy suggests that these intervals reflect the mineralogically cleanest (most proximal?) parts of the shoreface (core-based chemostratigraphic analysis; Ichron). The fact that the coarsest grained sandstones (with better reservoir properties) are most prevalent in the central western area through several cycles of progradation and back-stepping potentially suggests that the distributary systems feeding sediment into the area and thus into the upper shoreface (or in another model perhaps ebb and flood tidal deltas) were structurally controlled.

Explanation for rapid pressure decline. The unusual distribution of reservoir facies within the Garn Formation of Kristin Field led to a highly biased appraisal well dataset which skewed initial understanding of the interval. Two unusual deposition/reservoir quality trends led to this bias. The first was the west to east decrease in the volume fraction of the clean cross-bedded facies and associated eastwards decrease in permeability. This biased (and continues to bias) the well dataset because most wells are located close to the western margin of the structure (Fig. 2). As a result, while mean (arithmetic) permeability calculated from the present total well dataset is *c*. 6 mD and was even higher in the PDO model, the mean permeability in the current reservoir model for the interval is only 0.4 mD. As the only appraisal well (well 2-5) intersecting the poorer quality reservoir (typical of the eastern part of Kristin) was located well to the south and only a little to the east of the other appraisal wells it did not, unfortunately, help define the orientation of this trend. The second misleading aspect of the appraisal well dataset was the presence of unusually coarse and clean sandstones with unrepresentatively good reservoir quality in the discovery well (well 2-3) in the centre of the field. This is still the best well drilled to date in the Garn Formation of Kristin Field with 18 other penetrations. The well particularly biased understanding of the volumetrically important central area of Kristin because, while appraisal well spacing is on an order of 5 km, the good properties encountered by the discovery well probably extend for just a few hundred metres to the east. Current reservoir models which include both a rapid west to east decrease in permeability and a concentration of better permeability in the central western area now provide a fairly accurate prediction of pressure development for the interval.

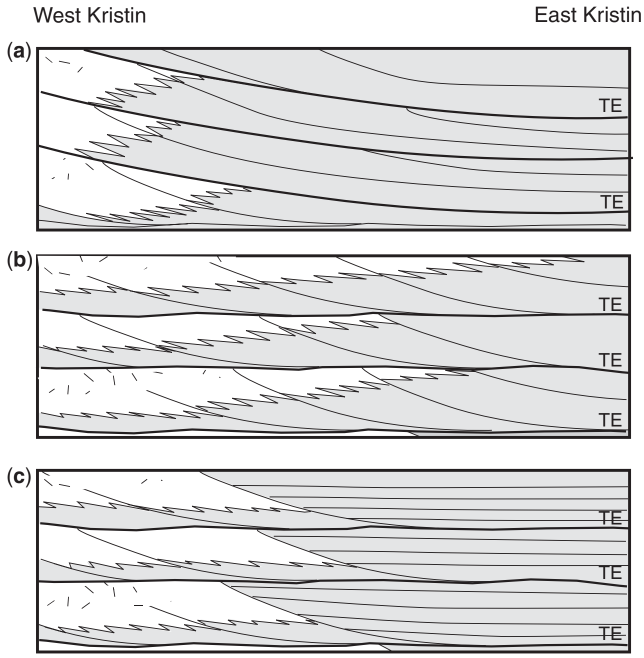

Fig. 5. Sketch models explaining why clean cross-bedded sandstones may be more common in the Garn Formation of western Kristin Field compared with the east. White shade, clean cross-bedded facies; grey shade, draped facies; stipple, high reservoir quality. (**a**) How this pattern might arise from a combination of changes in shoreface aggradation rate and later transgressive erosion; (**b**) how it might result from a progressive reduction in upper shoreface thickness due to a decrease in wave energy (as regression progressed eastwards); and (**c**) a scenario whereby there is a fundamental change in the style of the coastline and/or its orientation as regression proceeded eastwards (e.g. easterly regression from the basin margin is terminated by northerly axial regression).

Not Formation

Separating the Garn and Ile formations, the Not Formation is a regionally extensive mud-prone unit (45–55 m thick). The interval can be divided into two parts: a lower shale-prone section, which is characterized by high GR values, and an upper section which is more sand-prone and cleans upward. Core from both intervals includes a diverse trace fossil suite but traces become less common towards the top of the upper interval close to the transition with the Garn Formation. The lower shale-prone part of the Not Formation is interpreted to reflect accumulation in relatively distal shelf settings while the upper unit reflects accumulation in front of a prograding wave-dominated coast.

Ile Formation

The *c.* 85 m thick Ile Formation (penetrated by 12 wells and with 354 m of core) is the middle of the three Kristin reservoir units and is an important regional hydrocarbon-bearing interval (Koch & Heum 1995). The unit is sand-prone but is commonly heterolithic with flaser and wavy bedding present throughout and, in Kristin Field at least, the interval becomes increasingly heterolithic upwards. Accumulation of the unit (together with the Not Formation) is thought to have coincided with a significant hiatus (Aalenian–early Bajocian) in East Greenland (Doré 1992).

Description. The basal part of the unit (Ile 1: *c.* 5 m thick) comprises an upward-cleaning package of fine-grained sandstones in which the abundance of mud-drapes and bioturbation decreases up-section. The interval is intensely quartz cemented and is of minor reservoir significance. It is overlain, across an erosion surface, by a thick section (Ile 2: *c.* 20 m thick) dominated by two major facies (Fig. 6). The first and volumetrically more important comprises medium to coarse grained, predominantly trough cross-bedded sandstone with intercalated intervals containing climbing ripples, parallel lamination, intraclasts, vein quartz clasts, thin calcite cemented horizons and rare trace fossils (e.g. *Planolites*, *Palaeophycus*, *Skolithos*). Petrographic studies suggest that chlorite grain coats are common and reservoir quality is excellent (e.g. 19%, *c.* 300 mD). The second facies in this interval comprises decimetre to metre-scale intervals of flaser to wavy bedded, very-fine to medium grained heterolith which include abundant cross-bedding and asymmetric ripples, mud-drapes, fluid muds, mud clasts (some organic rich), thin calcite cemented horizons and a more diverse (although still limited) suite of trace fossils (*Planolites*, *Palaeophycus*, *Chondrites*, *Skolithos*, *Ophiomorpha*, *Asterosoma*, *Phycosiphon*). This facies is characterized by poor reservoir quality (e.g. 12%, <1 mD) due to high levels of quartz cementation and compaction which is in turn probably related to the finer grain size, higher clay content and rarity of grain-coating clay minerals. Two facies trends are observed in the interval. The first is that the heterolithic facies becomes more abundant up-section while the second is that the trough cross-bedded facies (with good properties) is more common in the central western part of the field near the discovery well. An intra-facies trend of increasing permeability towards this area is also observed. The overlying upper part of the Ile Formation (Ile 3: *c.* 53 m thick) begins with a 1–3 m thick, bioturbated, mud-prone interval which is present in all five cored Ile Formation wells and is considered a marker bed (*Planolites*, *Palaeophycus*, *Thalassinoides*, *Skolithos*, *Asterosoma*). Overlying this, the facies assemblage reverts to that observed in the lower Ile section (i.e. Ile 2) with the same two basic facies elements: (1) an excellent quality, predominantly trough cross-bedded sandstone facies; and (2) a heterolithic facies displaying very poor reservoir quality. Major facies trends also continue from the underlying, lower part of the Ile Formation with an up-section increase in the proportion of the heterolithic facies and a higher volume fraction of the trough cross-bedded sandstone facies within a small area in the central western part of the field.

Depositional synthesis. The thin, cleaning-upward, lower part of the Ile Formation (Ile 1) represents progradation (probably) from

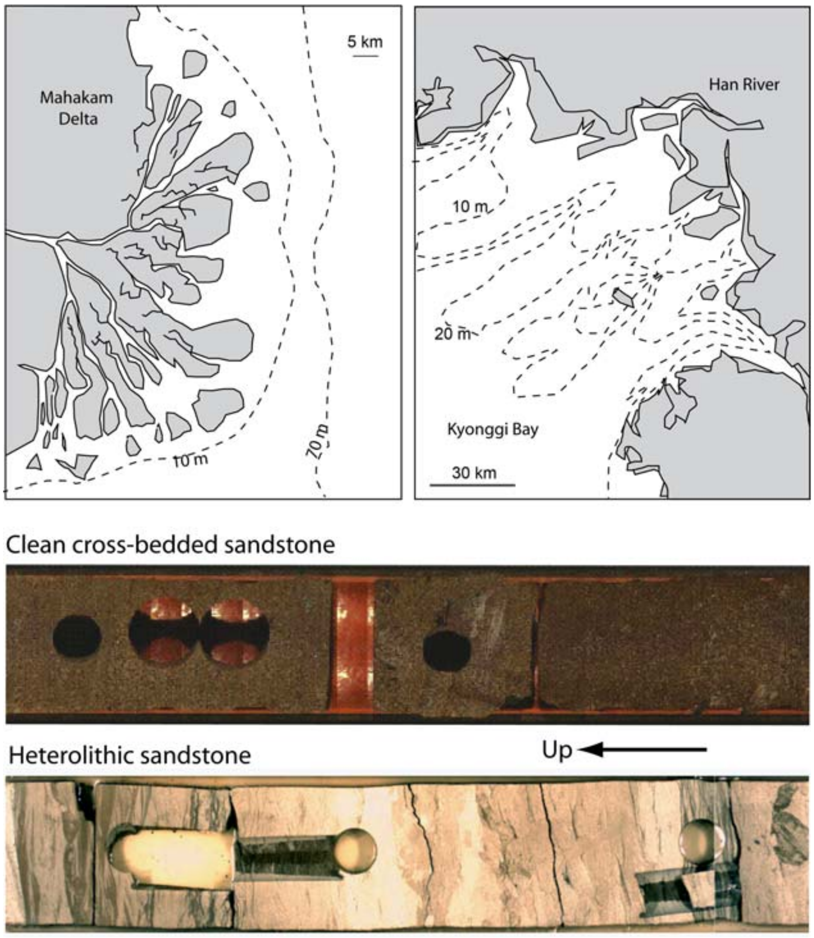

Fig. 6. Core photos illustrating the main facies components of the Ile Formation in Kristin Field. Above: possible modern analogues for the Ile Formation. (Left: Mahakem Delta, Indonesia. Right: Han River, Korea).

the west and shoaling of the succession from the shelf deposits of the Upper Ror Formation into proximal delta-front settings. Overlying this (across an erosion surface), a complicated stack of probable tide influenced bar and channel deposits (Ile 2) is generally interpreted to reflect deposition within a large tide influenced delta (McIlroy 2004) similar to that envisaged by Martinius *et al.* (2001) for the slightly older Tilje Formation. The trough cross-bedded facies is interpreted to reflect stronger fluvial influence while the heterolithic facies is thought to reflect stronger marine and tide influence. However fine-scale inter-bedding of both elements indicates that they clearly co-existed across much of the delta and, as a result, the observed facies assemblage is highly heterogeneous (Fig. 6). The bioturbated shale-prone interval at the base of Ile 3 is interpreted to represent an episode of marine transgression while the rest of Ile 3 (i.e. the upper part of the Ile Formation) reflects similar depositional environments to those interpreted for Ile 2. The fact that the heterolithic facies becomes more abundant up-section in both intervals is interpreted to reflect the predominance of transgression and back-stepping of the system westwards. The abundance of the coarser grained facies (with better reservoir properties) within a small area in the central western part of the field seems to indicate structural control on the location of the distributary system/tidal delta feeding through the area.

Explanation for rapid pressure decline. As in the Garn Formation, it is now clear that the Ile Formation properties in the central western area are unusually good with a higher volume fraction of the good-quality cross-bedded facies than elsewhere in the field. Unlike the Garn Formation, however, inclusion of this pattern in current reservoir models only improves, rather than resolves, the problem of overestimating pressure support. As a result, the current model can only be history-matched by including additional horizontal barriers and invoking considerable fault seal. Both host rock lithology (greater mud content) and faulting history (deeper deformation and thus more grain crushing and subsequent cementation) might explain why Ile Formation faults could be less permeable than those in the Garn Formation which are known to be relatively open. It remains questionable, however, whether the Ile Formation faults really can withhold the pressure differences implied by history-matched reservoir simulations (e.g. 400 bar) and it seems likely that understanding of the interval and the approach to modelling has some way to go.

Upper Ror Formation

Underlying the Ile Formation, the Upper Ror Formation is a mud-prone interval, *c.* 50–70 m thick. In Kristin Field it is less mud-prone than the Not Formation and may not form a perfect pressure seal to the Tofte Formation, an interpretation suggested by similar GWCs in the Tofte and Ile formations (fluid properties differ somewhat). The unit thickens and becomes more shale-prone eastward across the Kristin structure and is thinner to the SW in the Erlend Field (*c.* 5 km from Kristin Field). The Ror Formation contains a diverse trace fossil suite characteristic of accumulation in an open shelf setting.

Tofte Formation

The sand-prone Tofte Formation (*c.* 135 m thick) is the lowermost of the three Kristin Field reservoir units. It is only present along the western margin of the Halten Terrace because further to the east it shales out (over *c.* 15 km) as the Upper and Lower Ror Formation shales merge. As most of this eastward thinning is compensated by thickening of the Upper Ror Formation shale (rather than the Lower Ror Formation), it appears that maximum regression occurred near the base of the Tofte Formation. Following initial regression, the coastline then seems to have slowly back-stepped westwards such that the central and upper part of the Tofte Formation in the wells in the western part of Kristin Field accumulated contemporaneously with shelf mudrock in wells further east. The unit has been penetrated by six wells in Kristin Field, three of which (exploration wells) also penetrate the shaley Lower Ror Formation. Core has been taken in four wells (111 m) and comprises markedly different depositional facies both along depositional dip (east–west) and strike (north–south).

Description. In the northern part of Kristin Field in well 11–6 (Fig. 2), the cored interval (near the top of the Tofte Formation) is dominated by a thick section of lightly bioturbated, fine-grained sandstone comprising numerous draped cross-beds (trace fossils include bivalve burrows, *Rosselia* and *Siphonichnus*). Log signatures in both the cored and underlying uncored interval indicate subtle upwards cleaning patterns, 10–20 m thick, which in the cored section correspond to an upwards decrease in mud-drapes, mica content and bioturbation intensity, as well as an increase in maximum clast size. Permeability throughout the Tofte succession in this well is typically less than 1 mD. In well 2-5, located some 5 km SE of the central area, a similar succession with numerous stylolites, abundant organic rich clasts and bioturbation was encountered and, again, exhibits very poor reservoir properties.

In contrast to the successions encountered in both the northern and southern appraisal wells, three closely spaced, east–west aligned wells in the central area intersected markedly better reservoir properties (porosity of 19% compared to 9%). Core was taken from the upper part of the two easternmost of these wells. In well 2-S 3 (middle well), the lower and middle part of the cored section includes a thick interval dominated by red to brown massive sandstones which also contain rare low-angle cross-bedding. The interval displays excellent reservoir quality, lacks any bioturbation or mud-drapes and includes numerous floating sandstone intra-clasts, commonly up to pebble grade. In contrast, the cored section in the discovery well 2-3 (just 440 m to the east) is medium to coarse grained (i.e. slightly finer) and includes cross-beds throughout with some mud/mica drapes together with rare bioturbation (J-shaped burrows, *Trichichnus*, *Siphonichnus* resting traces, general burrow mottling). This change in depositional facies between the two wells seems to be associated with a rapid decrease in reservoir properties which is observed across all three wells, at least in the upper part of the Tofte Formation (e.g. 23% in S-4 to 19% in 2-S-3 to 12% well 2-3).

Depositional synthesis. The diverse trace fossil suite, abundance of mud drapes and presence of cleaning-upward cycles in the middle and upper parts of the Tofte Formation in the northern and southern parts of Kristin Field suggest a depositional environment dominated by prograding tide-influenced shelf deposits (with very poor reservoir quality). In contrast, in the central western part of the field, the unit comprises markedly coarser grained, commonly massive sandstones which display excellent reservoir properties. These are thought to reflect either rapid deposition within distributary channel bars or shallow sandy debris flows at the mouths of distributary channels which fed coarse sediment into the upper shoreface (Fig. 7). The persistent presence of coarser grained, less bioturbated facies (with better reservoir properties) in the central western area through several cycles of progradation and back-stepping (e.g. equivalent to several stacked cleaning upward cycles in northern and southern wells) seems to indicate that the distributary system feeding onto the Tofte shelf was somehow locked into this one fairly small area – at least during deposition of the middle and upper part of the unit.

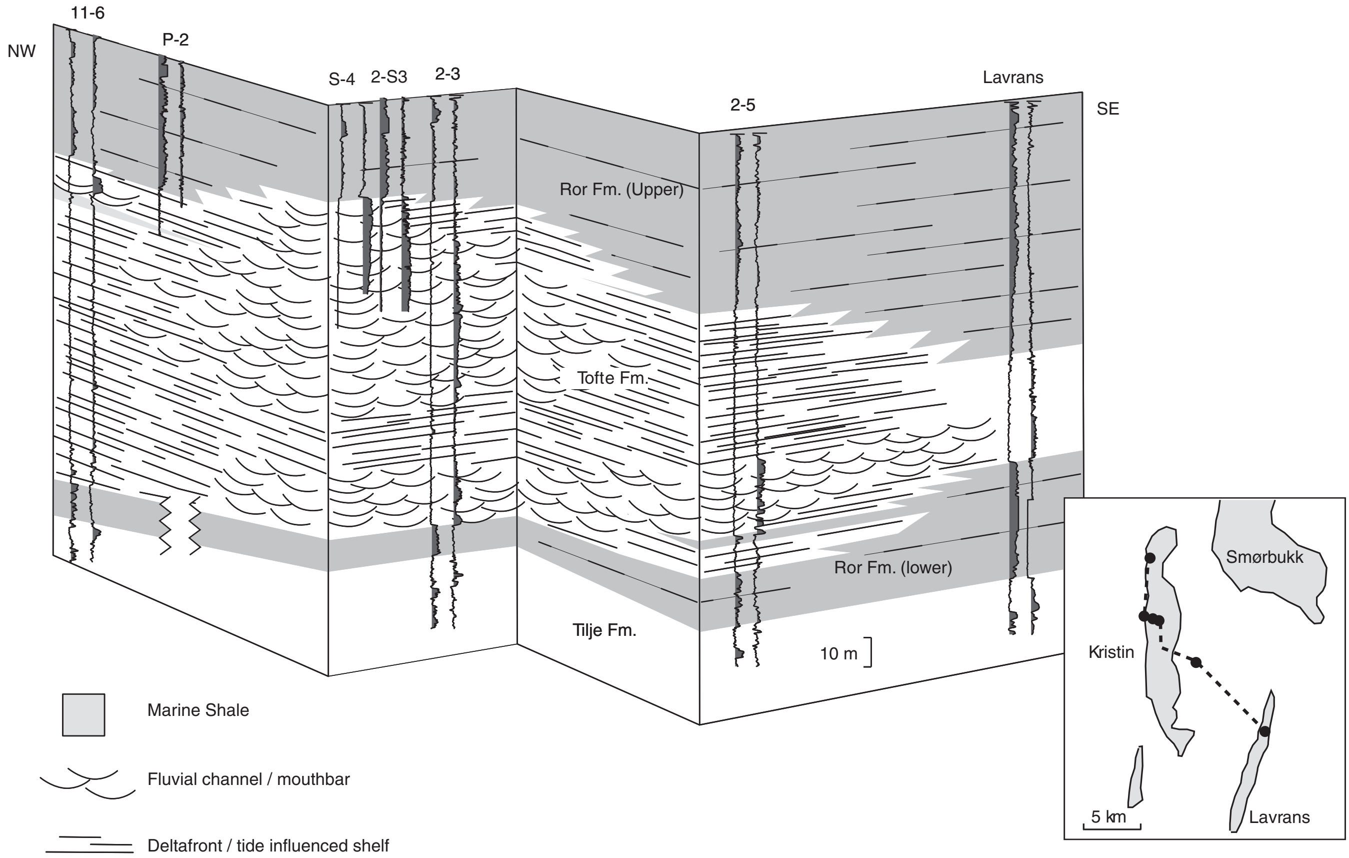

Fig. 7. Distribution of primary facies elements within the Tofte Formation of Kristin Field. Well logs, per well, are GR (left) and permeability (right).

Explanation for rapid pressure decline. The pressure observed from the one well which produces from the Tofte Formation (S-4) has declined significantly more rapidly than initially expected. This is thought to reflect a more rapid than predicted reduction in reservoir properties away from the central western area which probably occurs over just a few hundred metres to the east of the producing well. This pattern significantly reduces aquifer support but the intensity of this important trend towards poorer properties only became clear following the drilling of two closely spaced development wells immediately adjacent to the discovery well (Fig. 2).

Discussion

Since production began in 2005, reservoir pressure in each of the three Kristin Field reservoir sections has declined significantly more rapidly than was initially predicted. In the Garn Formation, the Tofte Formation and to some extent also the Ile Formation, this has occurred at least partly because the appraisal well dataset was biased and because this in turn led to an overprediction of reservoir properties. Although the appraisal well dataset was skewed in a number of ways, the most important bias resulted from the persistent presence of good but unrepresentative reservoir properties in the discovery well which is located in the volumetrically important central part of the field. It is now realized (with additional data) that these are in no way typical of the field as a whole or, indeed, even of most of the central area. This is illustrated in Figure 8, which shows that in eight of the 10 main Kristin Field reservoir sub-zones, mean (arithmetic) permeability is highest in just one of two closely spaced wells (both extensively cored) in the western central part of the field. The fact that reservoir properties seem to be repeatedly higher within this one small area suggests that the origin of the enhanced properties is the same in the different reservoir sub-zones and, based on study of thin sections and cores, is interpreted to reflect the persistent presence of more proximal depositional facies in the area (coarser grain-sizes, less bioturbation, fewer mud-drapes, better grain coats). The most likely explanation for this phenomenon is that the location of the fluvial or deltaic systems feeding sediment into the different reservoir units (or in another model perhaps, tidal inlets) was structurally influenced – presumably up-depositional-dip to the west. Further, given the smallness of the zone and the fact that reservoir properties seem to decrease rapidly as one moves eastwards across it, it seems likely that whatever exerted this control was in close geographic proximity. For this reason, the major breached relay structure located immediately west of the central part of the field is perhaps the most likely structural element to have exerted this control (Fig. 2). Although there are other possible explanations (see below), this model is interesting because it suggests that fault oversteps/relay ramps can influence the distribution of facies, not only within hanging-wall successions (e.g. Gawthorpe & Leeder 2000), but also within footwall successions in cases where the primary provenance direction is on the hanging-wall side (Fig. 9). Alternative models which could also explain the unusual facies/reservoir quality pattern observed across Kristin Field include: deflection of the fluvial system by only the northernmost of the two western bounding faults (which has larger displacement); the influence of other unidentified faults up-depositional-dip to the west; antecedent drainage; or salt movement. However regardless of what exactly caused this pattern, it is clear that it had an important and misleading influence on early understanding of the field. As a result, current reserve and pressure estimates are between base case and P90 estimates and problems related to condensate blockage will potentially be brought forward (to date, fluids seem to behave as expected). To bring the field back towards base case predictions, high-angle producers have been drilled where

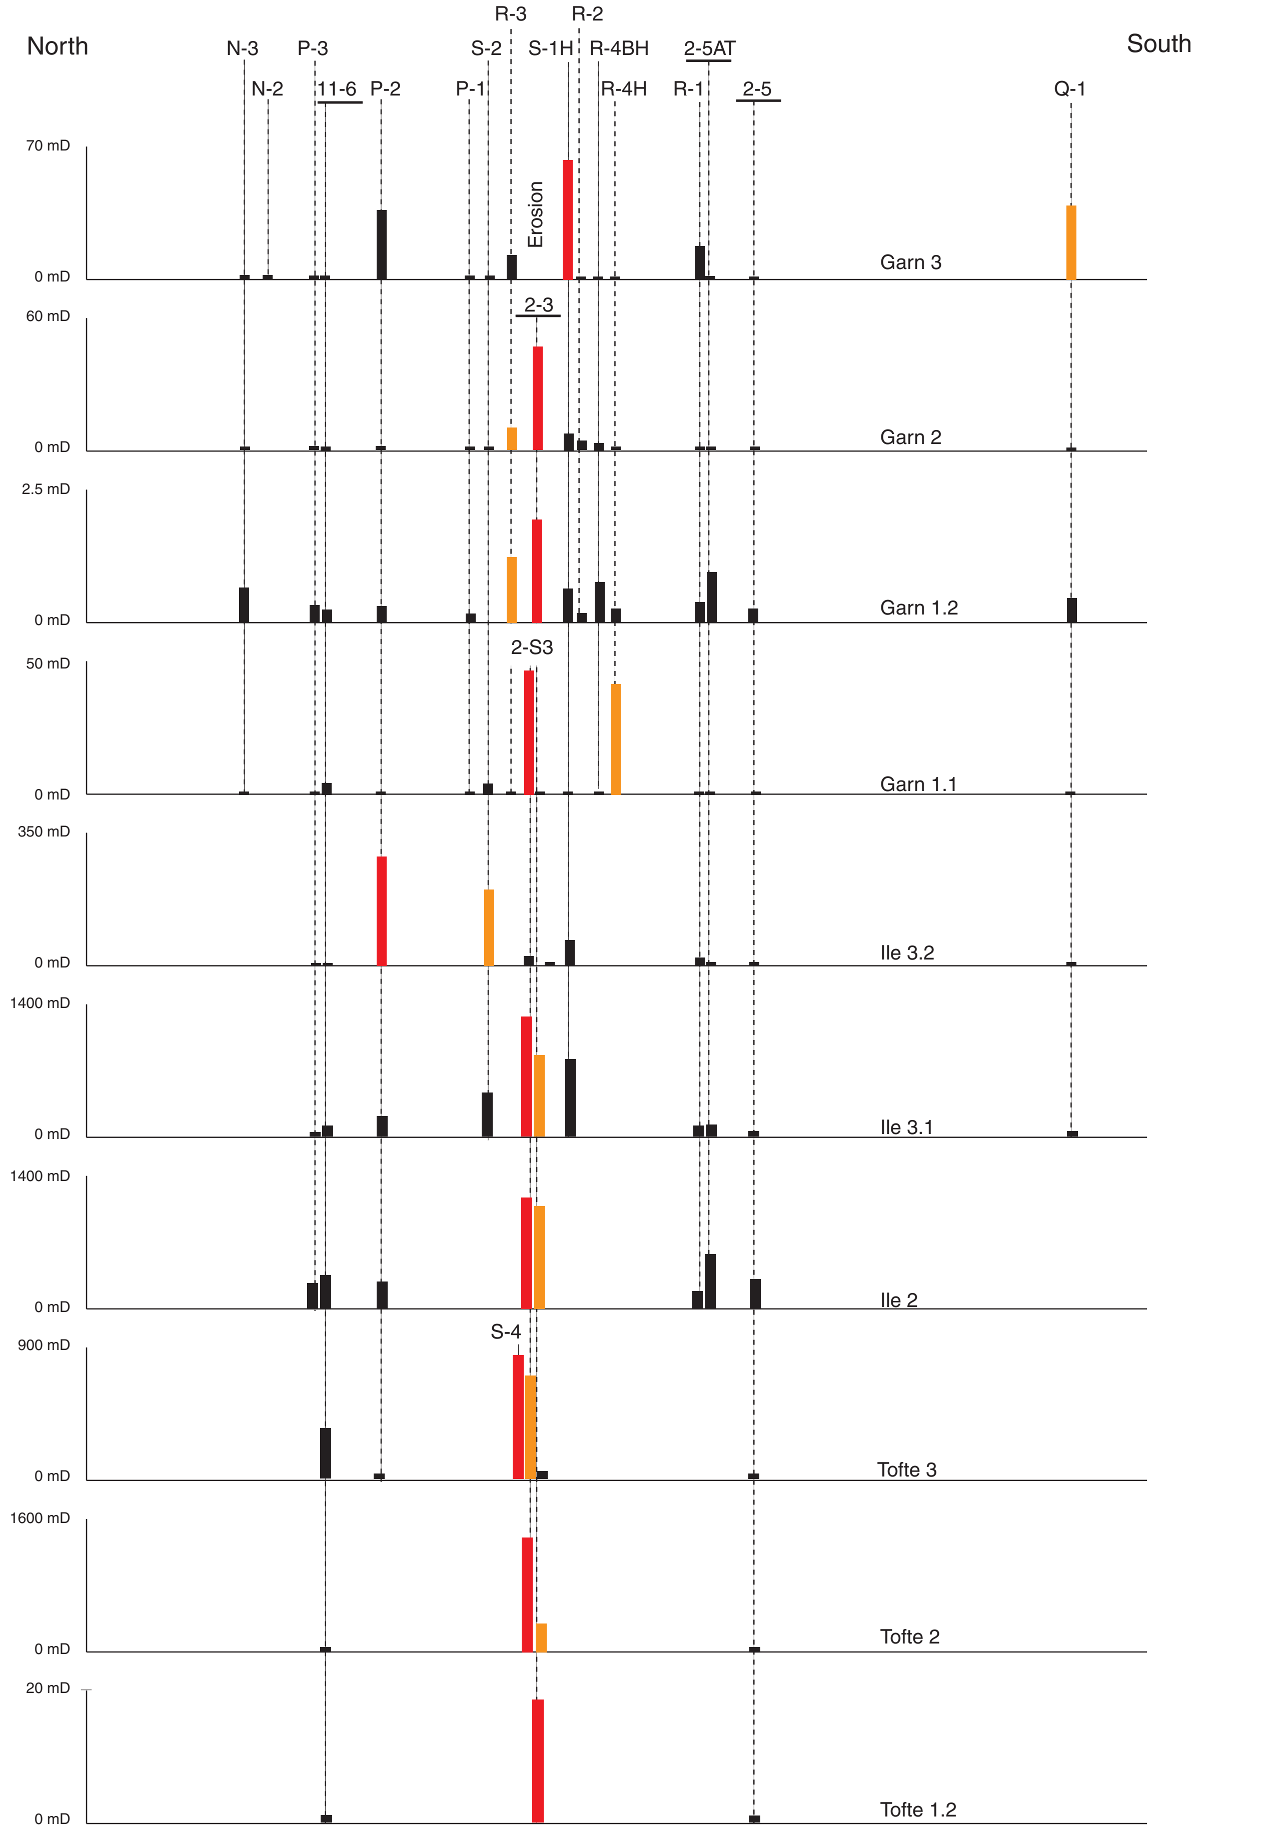

Fig. 8. North to south permeability distribution across Kristin Field with the highest and second highest permeability (per reservoir zone) highlighted (highest, red; second highest, orange). Appraisal wells are underlined. Note that in one of the two reservoir zones (Garn 3) where permeability is not highest in either of these wells the interval is not actually even present (it has been eroded out) yet production data still suggest anomalously good permeability immediately to the east.

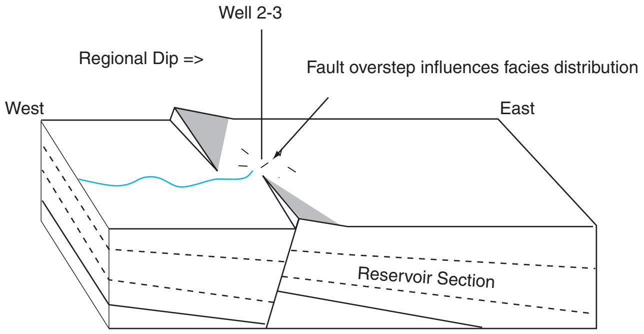

Fig. 9. The possible impact of a major fault overstep (on the western margin of Kristin Field) upon facies distribution and ultimately reservoir quality (view: looking north).

low-angle wells had originally been planned and a number of infill wells have been drilled.

Conclusions

Early impressions of the HP/HT Kristin Field were significantly skewed by the presence of very good but unrepresentative reservoir properties in the discovery well. This biased the appraisal well dataset which was itself significantly biased in some units. With the larger information dataset now available (wells, production data, etc.), it is clear that the good properties encountered by the discovery well are to a large extent limited to a very small anomalous area in the central western part of the field. This unusual pattern was not predictable from the original dataset and is thought to have arisen because of structural control upon the location of depositional facies. What is interesting about Kristin Field is that this structural influence is observed within the footwall stratigraphy of a major relay structure where the primary provenance direction was on the hanging-wall side. This pattern is the reverse of what is normally reported in tectono-stratigraphic studies.

The authors wish to thank Tony Peters and an anonymous reviewer for their comments which significantly improved the manuscript. We would also like to thank Rob Gawthorpe, Christian Brostrøm, Tanja Tora Blekastad, Peter McFadzean, Holger Rieke, Mari-Anne Hetle and Nicola Marsh. The study also draws from reports prepared by Ichron (particularly by Stuart Gowland) and from internal reports and studies including those by Olav Walderhaug, Carlo Messina and Carsten Elfenbein. The views expressed in this manuscript do not necessarily reflect those of the Kristin Unit partners and are not necessarily the only explanation for more rapid pressure decline than had been predicted. The partners, ExxonMobil, Total Norge, ENI Norge and Petoro, are thanked for granting permission to publish.

An old field in a new landscape: the renaissance of Donan

Abstract: The Donan Field was discovered in 1987 by BP well 15/20a-4. Oil is reservoired in Paleocene Lower Balmoral Sandstones of the Lista Formation. First oil was achieved from Donan on 28 April 1992 via two crestal producers to the Single Well Oil Production System (SWOPS) vessel *O.P.V. Seillean*. Peak production rates of 15 mstb/day were achieved before high well watercuts caused a significant drop in gross rates. Further attempts at development proved unsuccessful at the time. No further infill attempts were made as the field continued to be produced until it reached its economic limit in 1997. The field had produced 15.3×10^6 stb. Subsequently, block 15/20a was awarded to a partnership led by Kerr–McGee (North Sea) UK Ltd (now Maersk Oil North Sea UK Limited) in 2002 as part of the twentieth licensing round. Drilling results whilst testing the prospectivity on the block led to a focus towards Donan redevelopment. A combination of Rock Physics modelling and AVO, calibrated by appraisal drilling, and the integration of high-resolution biostratigraphy, played a significant role in the successful first phase of the 'Dumbarton Project', consisting of five horizontal producers and one produced water reinjection well. 'Second oil' from Donan was achieved on 19 January 2007 to the Global Producer III FPSO. Early production performance was in line with expectations with the field producing 20×10^6 stb within the first two years. In 2008 and 2009 further phases of development drilling took place on Donan with 2009 also expected to deliver two development wells in the Lochranza Field, a smaller, structurally distinct field to the east of Donan.

Keywords: Donan, Dumbarton, Paleocene, redevelopment, AVO, turbidite, Balmoral

The Donan Field has produced in excess of 20×10^6 bbl oil from its Paleocene reservoir since coming online in January 2007. At the time of writing, a second phase of infill development drilling is planned and due to commence in 2009. Thereafter, development drilling will commence on Lochranza, a satellite field located a short distance east of Donan. Whilst this introduction to Donan is not especially unusual, such a cursory assessment ignores the less-than-ordinary history of a field with a previous life, which was abandoned, and has subsequently been brought 'back from the dead'.

First discovered in 1987, the field was on production from 1992 to 1997 before being abandoned. This paper reviews the history of Donan. Using period reports it discusses the discovery of the field in the 1980s, first oil in 1992 and its eventual abandonment. It then documents the 2002 award of Block 15/20a in the twentieth licensing round for Jurassic prospectivity, the 're-discovery' of the Paleocene and the birth of the 'Dumbarton Project'. At a time when many are reflecting on the past four decades of North Sea Exploration and Production, the renaissance of Donan is an excellent example of how advances in technology coupled with a fresh insight can stimulate success.

A first life: Donan 1987–1997

Location and block history

The Donan field is located in blocks 15/20a and 15/20b, 27 km SW of Tiffany and 11 km NE of MacCulloch in the Central North Sea. Structurally, this places the field on the northern flank of the Witch Ground Graben to the SW of the Fladen Ground Spur (Fig. 1).

Block 15/20 was first awarded to BP in 1972 as part of the fourth licensing round. The part of the block covering Donan stayed in BP's operatorship through its various subdivisions until 1991, when block 15/20b was created for the twelfth licensing round. BP retained 100% of 15/20a with only 7.5% equity stake in 15/20b along with Conoco (60%), Croft Exploration (2.5%) and OMV (30%). In 1993 the Donan Field Area was unitized between BP (70%) and the Conoco Group (30%).

Block 15/20a was relinquished by BP in 2000 and awarded to Kerr–McGee (40%), EDC Europe [later to become Noble Energy (Europe) Ltd] (30%) and Enterprise Oil (30%) as part of the twentieth licensing round in 2002. In 2003, Enterprise Oil left the 15/20a block with their equity passing to Kerr–McGee. Meanwhile, 15/20b was acquired by Kerr–McGee (100%) for a cash consideration. In 2004 Noble Energy farmed into a 30% stake of 15/20b, unitizing the equity across the two blocks. Finally Maersk Oil bought Kerr–McGee's interest in both blocks in 2005 as part of a large Kerr–McGee UK asset sale.

Discovery and appraisal of Donan

Mapping of the 2D seismic data available at the time identified a structural closure at base Cretaceous and Paleocene levels in 15/20a. This structural closure was observed to become less pronounced between the lower Intra-Danian and the upper Early Eocene horizons that were used to define the Paleocene envelope. Towards the upper Early Eocene horizon, the structure was observed to be of lower relief (Fig. 2). Hence, the trapping mechanism was identified as the key risk associated with the Paleocene prospect. A secondary target at Jurassic level was also identified. Correlation from nearby wells suggested the presence of Upper Jurassic Piper reservoir sandstones and a closure. The key risk at this level was fault seal.

The 15/20a-3 well was drilled to test these prospects in 1986 and resulted in the discovery of a 75 ft oil column comprising light crude of 41° API in interbedded turbidites of the Andrew Formation (Deegan & Scull 1977) which were later re-classified as the Lower Balmoral Sandstone Unit (Knox & Holloway 1992). The well also

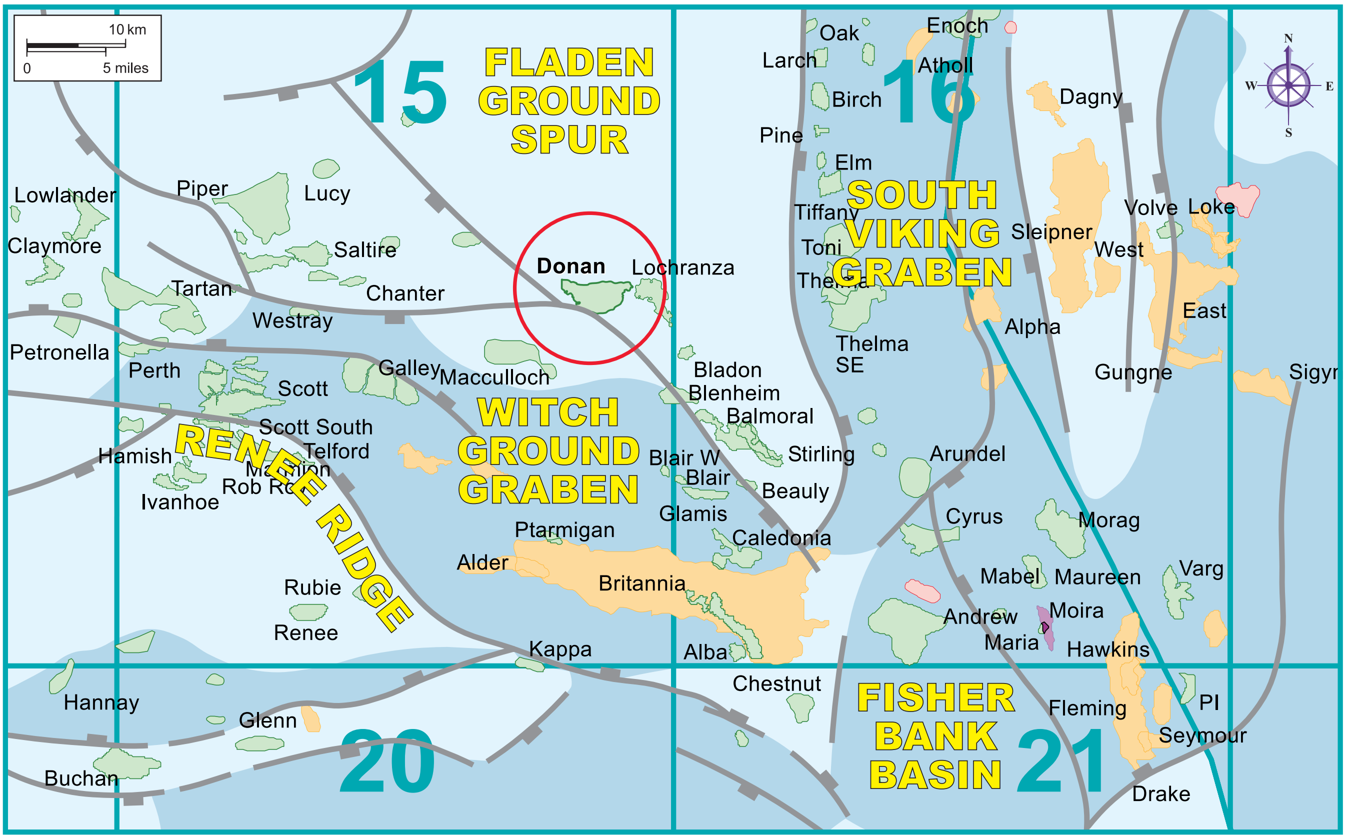

Fig. 1. Donan Field location map showing key structural elements.

successfully penetrated Jurassic Piper sandstones, although these were found to be water-wet. The well results are summarized in Table 1. Analysis of the discovery well results suggested that thicker Paleocene reservoir might be found further to the west.

This western culmination was appraised by the 15/20a-4 well in 1987 (Fig. 3). Identification of an oil column with a water-up-to (WUT) that was shallower than the contact observed in the eastern discovery well indicated that this accumulation was separate from the original discovery. The well was suspended upon completion of operations pending a development decision. A second appraisal well (15/20a-6) was drilled in 1990 from the same seabed location as 15/20a-4 to test the western part of the Donan structure and identify an original oil–water contact (OWC). This deviated well encountered thicker pay sands than the 15/20a-4 well and confirmed the contact at −6466 ft total vertical depth subsea (TVDss). This well was also suspended as a possible producer.

Further appraisal wells were drilled in the eastern accumulation, later called Pladda, in the early 1990s. Whilst these wells successfully identified hydrocarbons in the Paleocene, the volumes in place were assessed to be subeconomic for production.

At the end of the appraisal campaign, the Donan geological model was a simple layer-cake arrangement generated by the correlation of unconstrained wireline logs and the correlation of tuffs which are now believed to have been reworked and diachronous (Fig. 4). At this time, no field-specific biostratigraphy had been attempted to constrain any of the correlations and the existing biostratigraphic control was of too low resolution to be used in a meaningful way (Payne *et al.* 1999). The low net to gross reservoir sands were interpreted by BP as having been deposited during gradual and regional scale east-to-west retreat of the Andrew Fan. The layer-cake nature of the model, with laterally continuous shale layers separating the sands, led to the interpretation that production would be driven by aquifer influx along each sand layer. At this time the field had an estimated stock tank oil initially implace (STOIIP) of 82×10^6 stb with a range between 58 and 115×10^6 stb.

Donan field development

BP submitted an Annex B document for the development of the Donan Field to the Department of Energy in 1991 and first oil was achieved on 28 April 1992. The field was developed through the two existing wells via a detachable steel riser to the Single Well Oil Production System (SWOPS) vessel *O.P.V. Seillean*. The vessels name originates from the Gaelic for honey bee and had been used successfully on the Cyrus field prior to it being stationed on Donan. The SWOPS concept was part of BP's strategy for producing from its smaller fields in the North Sea with the vessel moving from field to field like a honey bee producing from the wells that would fill it to capacity in the shortest time. The *Seillean* was designed with the capability to process liquids onboard with a handling capacity of up to 15 mstb/d of oil from a maximum of two wells. However, the 300 mstb storage capacity meant that production was intermittent as the vessel had to disconnect to deliver its load to market. Using this development strategy, it was expected that the field would produce reserves of *c.* 16.5×10^6 stb of oil.

Other development schemes were considered for Donan, such as the deployment of a semi-submersible production system or tie-back to existing nearby facilities. The first year of production to the *O.P.V. Seillean* allowed well production performance to be monitored and integrated with subsurface studies before committing to a final development scheme. It was noted in the Annex B document that a further two wells may have been required to ensure effective development of reserves.

Early field performance

Upon production start-up on 28 April 1992, initial rates were good at around 13 000 bbl oil/day. The 15/20a-4 well saw early

Table 1. Donan discovery and appraisal well results

Well	Operator	Year	Objective	Lower Balmoral net pay thickness	Contact	Flow rate
15/20a-3, 3Z	BP	1986	Paleocene Lower Balmoral and Jurassic Piper Sands	11 ft TVD	OWC – 6509 ft tvdss	Not tested
15/20a-4	BP	1987	Lower Balmoral	46 ft TVD	ODT – 6455 ft tvdss	4170
15/20a-6	BP	1990	Lower Balmoral	62 ft TVD	OWC – 6466 ft tvdss	Not tested

water-breakthrough with well watercut increasing steadily over time, whilst the 15/20a-6 well had a year of dry production owing to its location high in the structure, the proximity of a shale baffle below and its limited completion length (Fig. 5). After unitization of the field, an Annex B Addendum for continued production was submitted and approved in 1993. Between 1993 and 1994, a programme of modifications was carried out to upgrade the vessel and flowlines to enhance gross liquid throughput from 16 to 23 mbpd. Production was also interrupted regularly when the SWOPS vessel reached capacity and had to sail to market.

Studies carried out during 1994, which included interpretation of a new 3D seismic volume acquired in 1993, revised the most likely STOIIP to 77.2×10^6 stb from 82×10^6 stb and indicated that the optimum development scheme was the continued use of the SWOPS vessel. Life of Field production consent for Donan was awarded to the partnership in early 1995. At this stage, gross rate and oil rate had started to decline since there was no operational gas lift system in the two producers to maintain liquid rates as the total watercut began to exceed 50% (Fig. 4).

Infill drilling

In order to improve the understanding of the reservoir architecture during these first years of production, a high-resolution dinocyst-based biostratigraphy study was initiated using core data (Payne *et al.* 1999). This led to a revision of the geological model from a simple layer-cake model with an upper sand deposited contemporaneously across the whole field, to a more heterogeneous system with sand bodies pinching out over relatively short distances (Fig. 6). Given the high watercut in the existing wells, the partnership initiated an infill drilling campaign in February 1995 designed to replace the original two wells with two new drier horizontal wells. These were drilled to the west of 15/20a-6 where the uppermost sand layer was expected to thicken based on the new geomodel (Targets A and B; Fig. 7). Inclined pilot holes were planned to test the reservoir model and oil column height prior to drilling the horizontal wells. Wellsite biostratigraphy was also employed to aid well placement.

The first pilot well drilled was 15/20b-12. This well encountered significant borehole instability in the Eocene section. Nevertheless

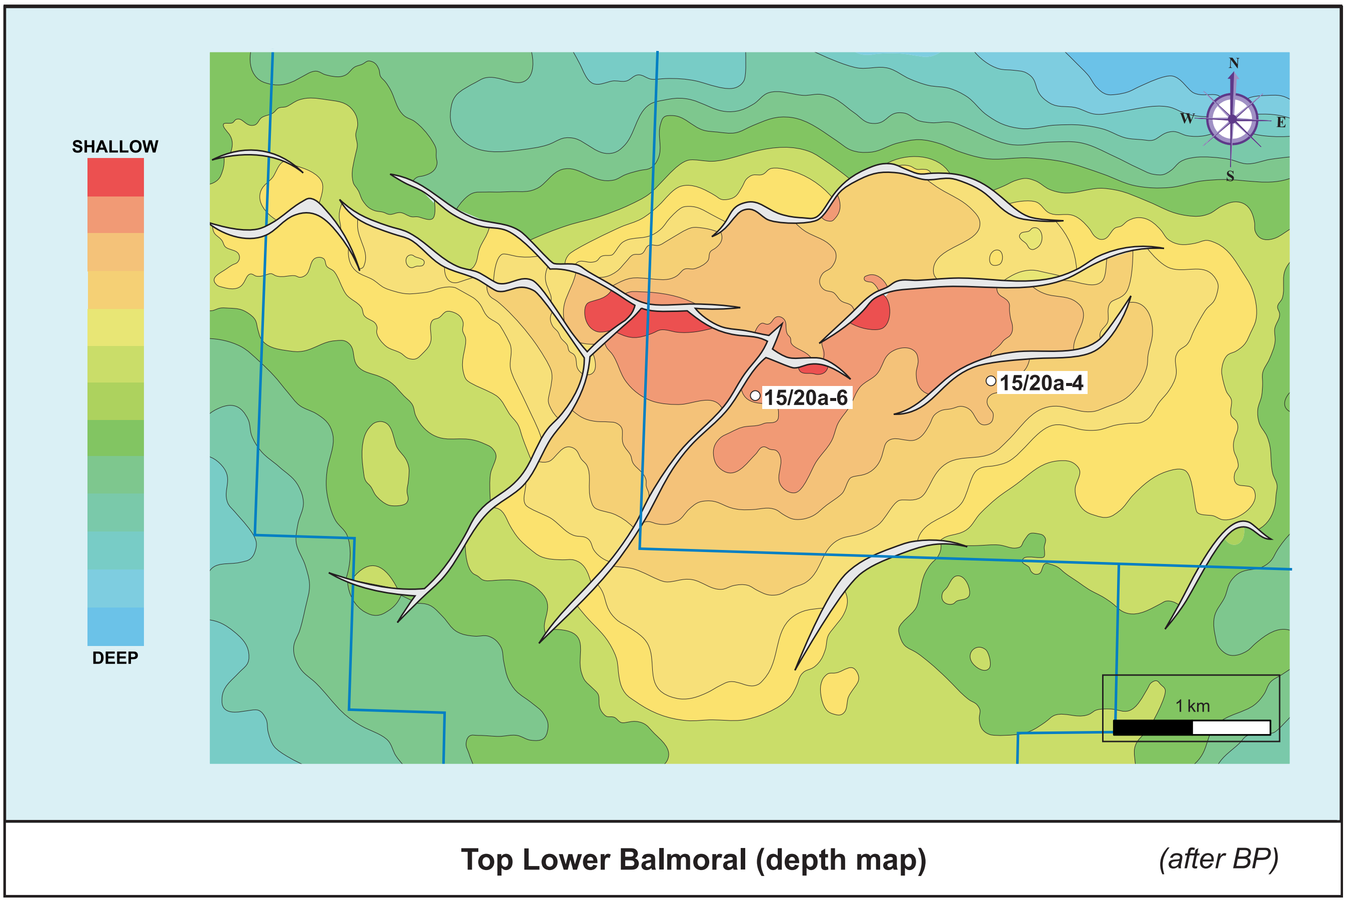

Fig. 3. Donan structure map showing appraisal well locations.

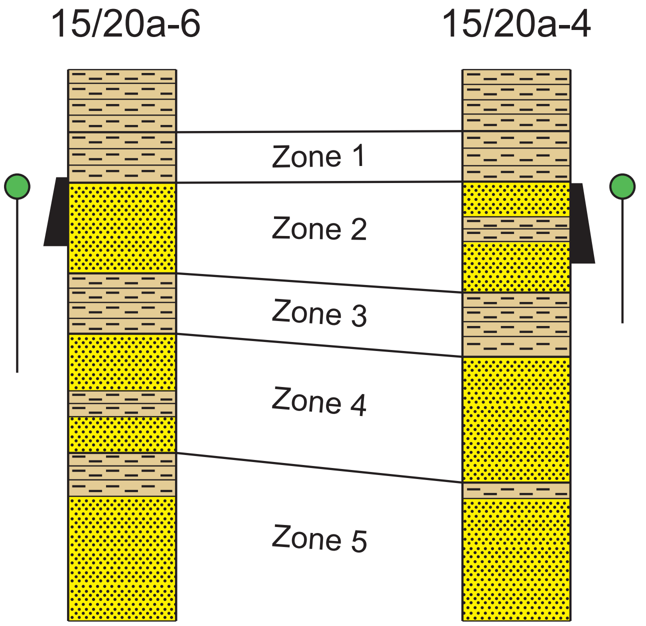

Fig. 4. Original layer-cake Donan model adapted from Payne *et al.* (1999).

the reservoir section was successfully penetrated on prognosis. On attempting to pull out of hole, the drilling assembly became stuck in the Eocene section and could not be recovered. Consequently, no wireline log data was acquired in the well. Despite the absence of log data, high gas readings in the reservoir section and high sand percentage in the drill-cuttings led to the decision to proceed with the main horizontal section (15/20b-12Z). The uppermost sand layer above the *Areoligera gippingensis* biomarker (Fig. 6) was expected to be of a similar thickness to that encountered in the pilot hole – *c*. 33 ft. The 15/20b-12Z well penetrated top reservoir and set a $9\frac{5}{8}$ ft casing only 100 m away from the original pilot wellbore. However, the upper sand layer encountered was only 7 ft thick in this location. This rapid change in layer thickness was attributed at the time to intra-reservoir faulting. Therefore a second sidetrack was planned to target the footwall of this fault where the upper sand layer was expected to be thicker. In the event, the *Areoligera gippingensis* marker came in prior to any sand being encountered, indicating that the upper sand layer was absent in this location. This led to the adoption of an alternative sedimentological model where rapid stratigraphic thinning was responsible for the variability of sand thickness, rather than faulting as previously proposed. Deepening the 15/20b-12Y well to test if the lower reservoir sands would be producible found them to be poorly developed and thin, with an apparent swept zone at the base of the reservoir section. This led to the abandonment of Target A as a viable infill option.

Despite poor results at Target A, Target B was still considered a robust option given its location between the 15/20a-6 well, where the upper sand layer above *Areoligera gippingensis* marker was of sufficient thickness, and the predicted source of the reservoir sands to the NW. Sidetrack 15/20b-12X was drilled as a pilot to test Target B (Fig. 7). Top sand was encountered 26 ft high to prognosis, was 7 ft thick and of poor quality. A 33 ft mud-prone layer was encountered before the quality of the sands began to improve. The best quality sands were identified some 82 ft below top sand but these were found to be in direct communication with the aquifer. A 16 ft swept zone was identified confirming the upward movement of the OWC caused by earlier field production from the 4 and 6 wells. The movement of the OWC indicated that the main mechanism of displacement was bottom-up drive by the aquifer, rather than lateral sweep of the individual sand layers. Analysis of this well data suggested that a reasonable producer could be drilled and completed subhorizontally (*c*. 86°) over the upper sand layers, which would be protected from the strong aquifer by the mud prone layer below. The 15/20b-12W well was drilled to the east of the pilot well as it was anticipated that the sand would thicken towards 15/20a-6. A gradational top sand was encountered high to prognosis. However, contrary to expectations, no well-developed sand was encountered in the upper section. Only thin sands were penetrated which were too close to the moved OWC identified in the 15/20b-12X well to be completed. These discouraging well results led to the abandonment of Target B as a viable infill location and to the suspension of infill drilling.

The changing geological view of Donan

The Donan geological model had changed significantly between 1992 and 1995. The validation of the high-resolution biostratigraphy study by the 15/20b-12 wells had shown that the nature of sand and shale distribution in the oil leg was far more complex than the original layer-cake model suggested. Rapid lateral facies changes of the upper reservoir observed during BP's infill campaign of 1995 was attributed to smaller, localized fans that

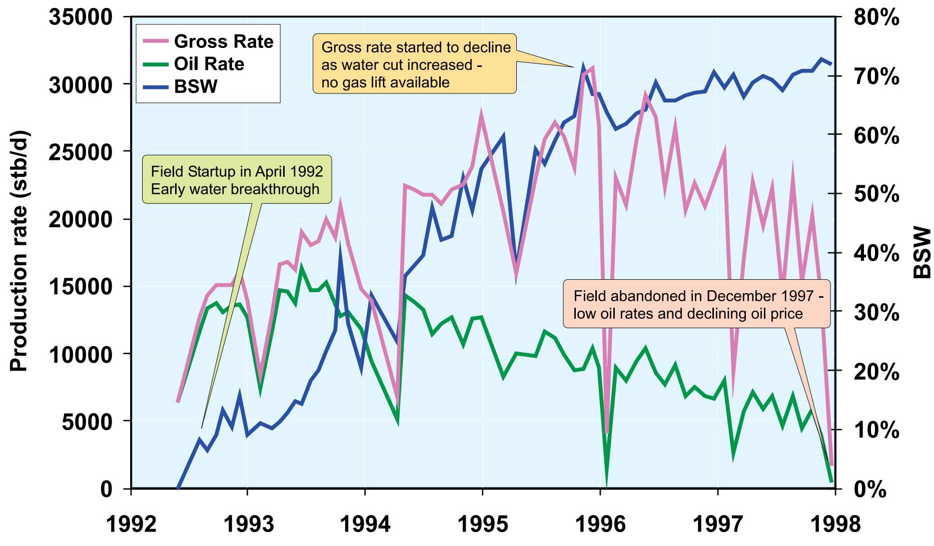

Fig. 5. Production plot showing Donan field performance between 1992 and 1997.

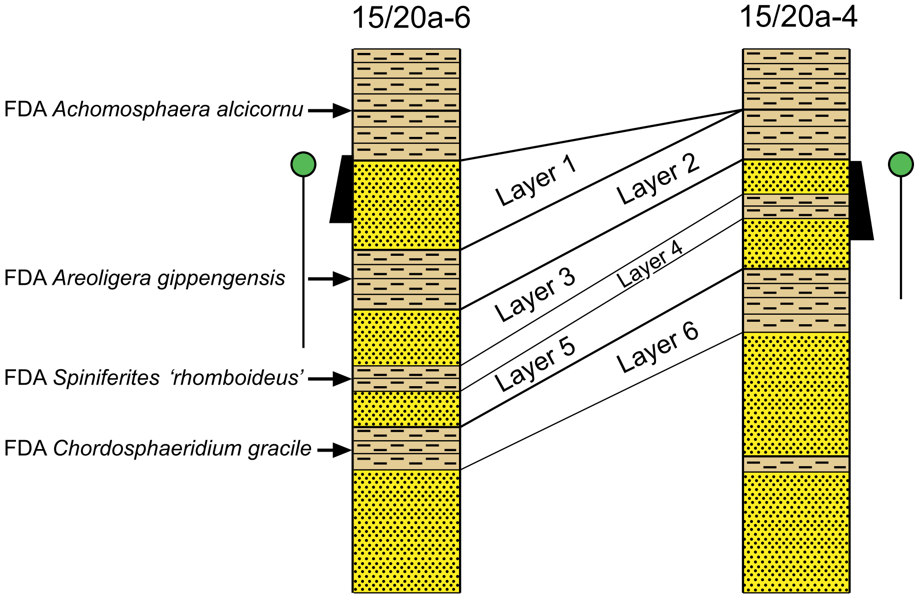

Fig. 6. Revised Donan model adapted from Payne *et al.* (1999) based on high-resolution biostratigraphy indicating a more heterogeneous system than previously modelled.

existed on the flanks of the major 'Andrew' fan axis that did not correspond to the more regional fan trends. Over Donan, a minor fan or splay may have been present with the unpredictable nature of sand distribution being related to splay or fan abandonment creating dilute sand events which were unevenly distributed around the field. Deeper, better quality reservoir sands were interpreted to reflect more stable conditions during the main phase of fan activity. However, these better quality reservoir elements were not accommodated to a great extent within the low relief Donan structure. The observation of raised OWCs in the 15/20b-12Y and -12X wells provided evidence for an aquifer-driven bottom drive mechanism indicating that whilst laterally extensive shales persisted

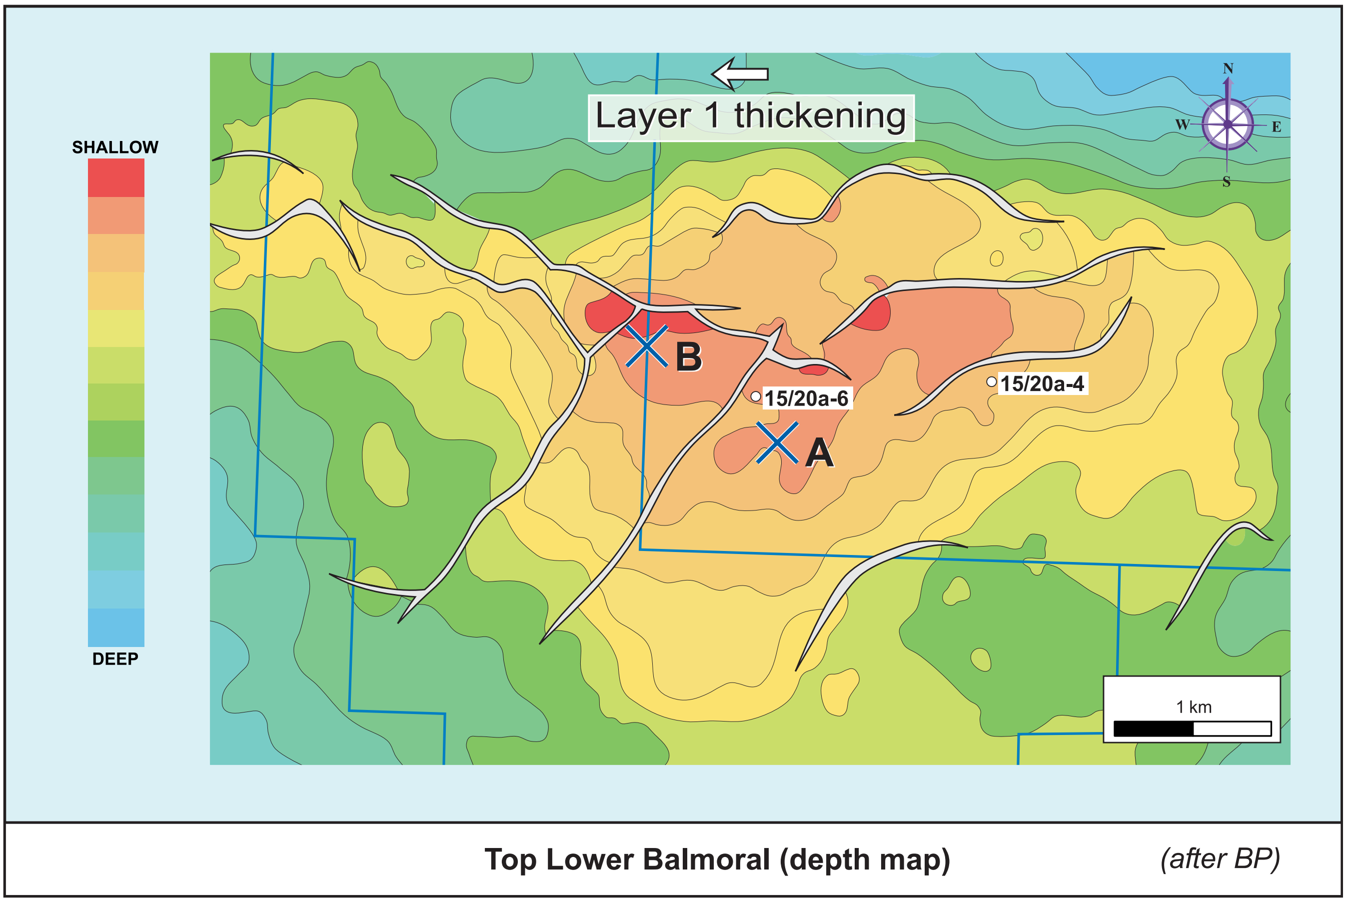

Fig. 7. Donan structure map showing infill locations (A), targeted by 15/20b-12, 12Z and 12Y, and (B), targeted by 15/20b-12X and 12W in 1995.

over much of the field, sufficient fluid pathways existed to allow vertical fluid flow.

Improved biostratigraphic data combined with modifications to the seismic pick made after infill drilling were used to create a new layering scheme for the reservoir. However, given the unpredictable nature of the sands encountered in the wells, it was deemed impossible to accurately represent the complete internal structure of the reservoir for simulation purposes.

Abandonment

In light of the disappointing infill well results and the increasingly complex picture of the reservoir, the STOIIP for the field was revised downwards from a most likely volume of 77.2 to 54×10^6 stb. The optimum development scheme for the field was to cease further development and continue production to the SWOPS vessel until this became uneconomic.

In the end, the *O.P.V Seillean* left the field on 24 December 1997 for the final time with the oil price on a downward trend that would see it reach the $10/bbl mark in 1999 (Fig. 8). The Donan field was abandoned by BP, having produced 15.3×10^6 stb.

Prospects of a new beginning: Donan 2001–2007

Following a screening study encompassing a number of blocks in the area, a partnership led by Kerr–McGee was awarded block 15/20a in 2002. The group recognized the potential of two discoveries in the block (Fig. 9). The first was the Jurassic age 'Jura' prospect that was discovered by the 15/20b-11Y well in 1992. Its closure was believed to lie somewhere to the NW beneath the abandoned Donan field. The second prospect was the Paleocene Pladda prospect penetrated by the 15/20a-3/3Z, 15/20a-9 and 15/20b-11Y wells. At the time, Pladda was considered too small to be economic unless developed after the success of Jura. In addition to the two prospects on the block, the group also saw significant potential for the redevelopment of Donan, which could, if successful, also facilitate the development of Pladda.

The twentieth licensing round award was based on a work programme that included a firm well to test the Jura prospect and a contingent well to test Pladda, the latter being dependent on the success of the firm well or success of a Donan redevelopment feasibility study. The firm well commitment was fulfilled by exploration well 15/20a-13, which was drilled in March 2003 to the east of the Donan structure. The primary objective of this well was to test the Piper Formation sandstone of the Jura prospect which had been discovered by 15/20b-11Y. This location was thought to lie *c.* 100 ft structurally updip of the 15/20b-11Y well with thicker development of the Upper Jurassic Sand. A secondary objective was to test the Paleocene sandstones of the

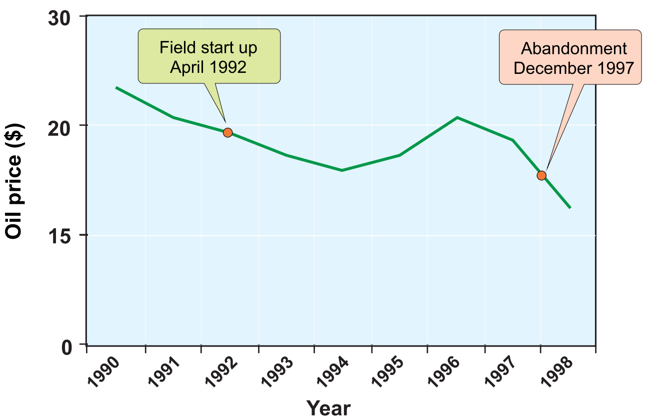

Fig. 8. Chart of oil price trends affecting the first life of Donan.

Pladda prospect. Mapping indicated that the well was targeting an area to the west of the structural closure of Pladda, therefore having a low chance of success. The well encountered a 40 ft oil column in the Paleocene Lower Balmoral sandstones whilst the Jurassic came in deeper than expected, was water-wet and well cemented. These well results, along with promising findings from initial Donan redevelopment study, prompted focus on the Paleocene and the implementation of a Donan appraisal campaign.

Key technologies influencing appraisal

Two key initiatives implemented by the partnership that had significant influence over the Donan appraisal and redevelopment were the application of detailed seismic analysis and high-resolution biostratigraphy.

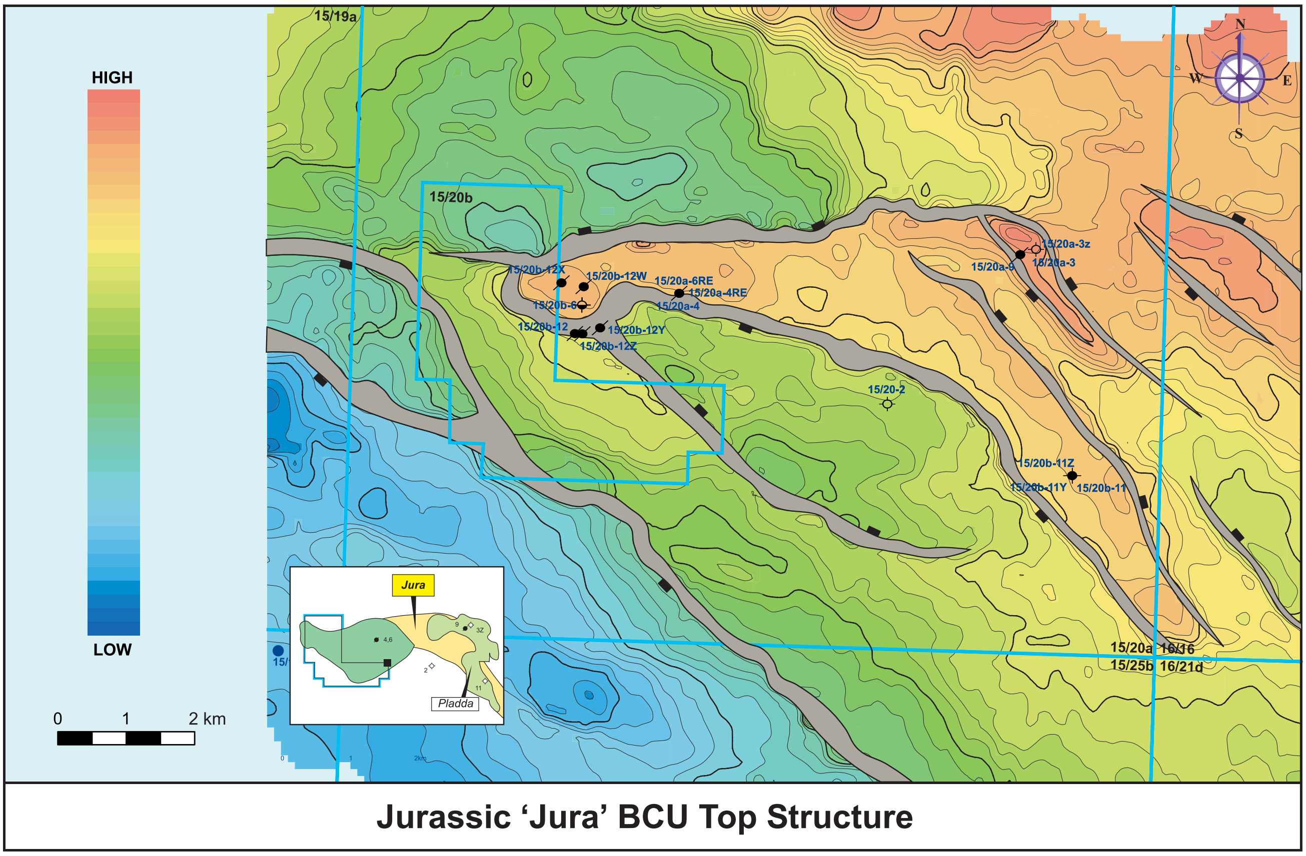
Following the 15/20a-13 well results, the migrated stacks for the complete 1993 survey were purchased through standard seismic data release procedures. These post-stack migrated volumes were observed to be of poor quality so the field tapes over blocks 15/20a and 15/20b were purchased to enable reprocessing. Reprocessed pre-stack time migrated (PSTM) data was delivered and loaded in November 2003. Whilst this dataset was a significant improvement, acquisition-related artefacts such as trace-to-trace amplitude and timing jitter, poor signal-to-noise and low frequency content at the reservoir interval remained. The tuning thickness of this new data was *c.* 76 ft.

Rock physics analysis carried out in-house using the 15/20a-4 well indicated that Class II amplitude variation with offset (AVO) (Rutherford & Williams 1989) should be observed in the seismic data at this location in the presence of oil. Synthetic well ties indicated that this AVO was characterized by the presence of a weak trough ('hard' – positive impedance change) on near traces with a bright peak ('soft' – negative impedance change) on fars (Fig. 10). At first, it was difficult to quantify the reliability of this AVO. There was some degree of uncertainty over the relationship between reflection amplitude and hydrocarbon pore thickness. Furthermore, there was the possibility that the presence of hydrocarbons could also be associated with dimming effects on both near and far angles. What was clear, however, was that the reprocessed PSTM data did demonstrate a clear AVO signature when far and near stacks were subtracted (Fig. 11). It was believed that this signature could be used to optimally place appraisal wells. The appraisal wells would acquire a full suite of sonic and shear sonic logs to calibrate the rock physics model and address the remaining uncertainties. It was expected that this calibration would have a major de-risking effect on development well placement.

Whilst a useful pay indicator, the AVO response made conventional seismic interpretation on full-stack reflection data difficult. Off the main structure, brine-filled reservoir sands could be picked on a hard trough event. On the crest of the field where the net-pay thickness was sufficient to generate AVO, the top reservoir could be picked on a soft peak (Fig. 12). Near and far angle stacks had to be used together to decide which was the most appropriate pick away from well control. The pick itself was considered to represent the 'top of the reservoir envelope' due to individual reservoir sands and oil column thickness in many areas being below seismic resolution.

In parallel with seismic re-processing and AVO analysis, a high-resolution biostratigraphy/sedimentology study was undertaken building on the earlier BP work. Five cored wells were used for interpretation along with several hundred cuttings samples. This study was used to develop an understanding of apparent stratigraphic heterogeneity, characterize claystones and to define the facies distribution so that this new biostratigraphic scheme could be used in a predictive manner. All of these were crucial to building

(a)



(b)

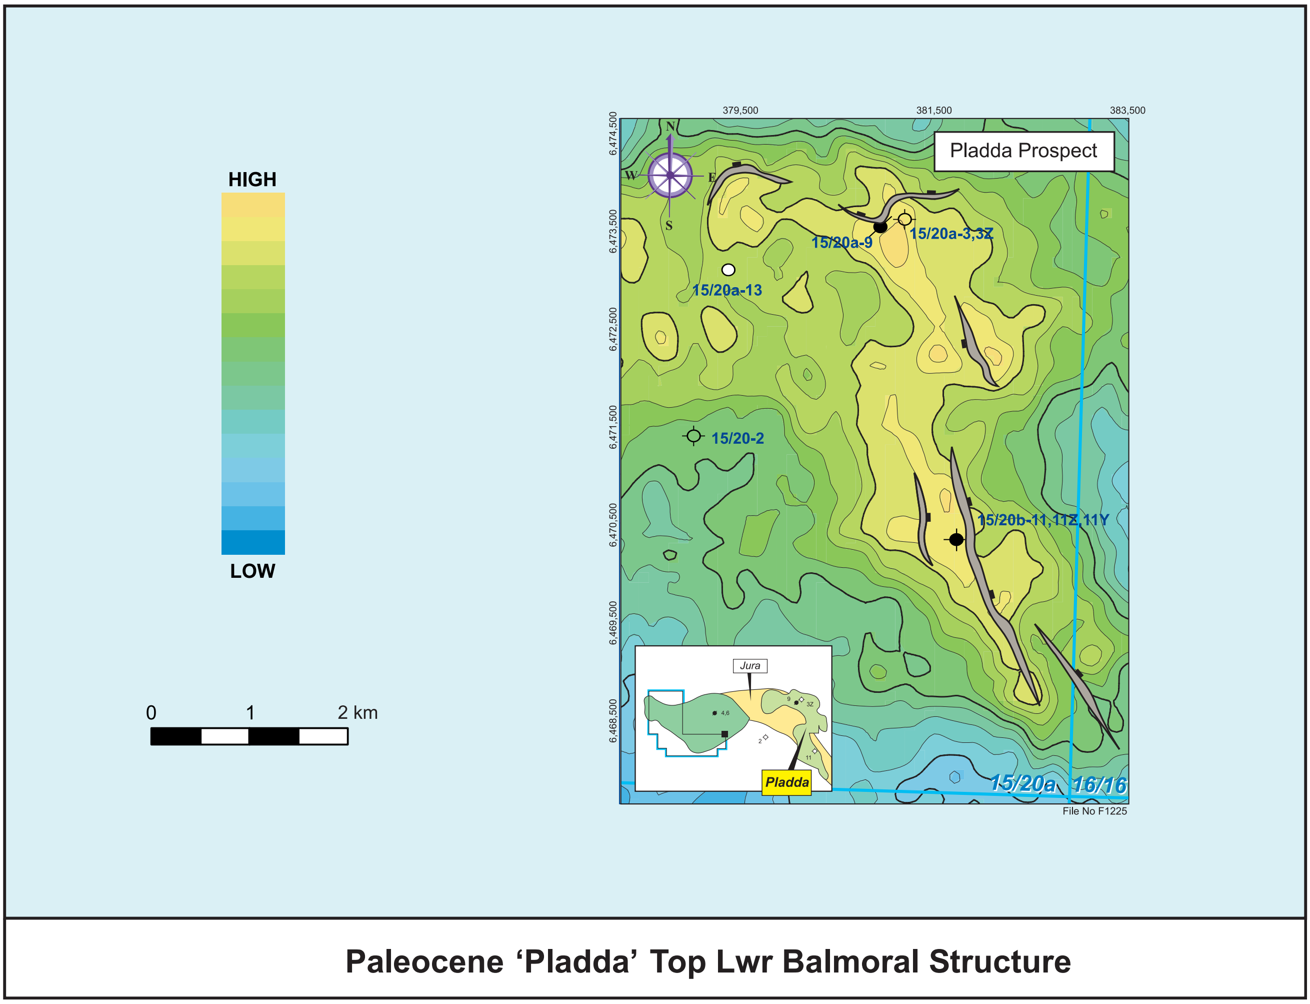


Fig. 9. (**a**) Jurassic 'Jura' and (**b**) Paleocene 'Pladda' prospects recognized by the partnership in the twentieth round in 2002.

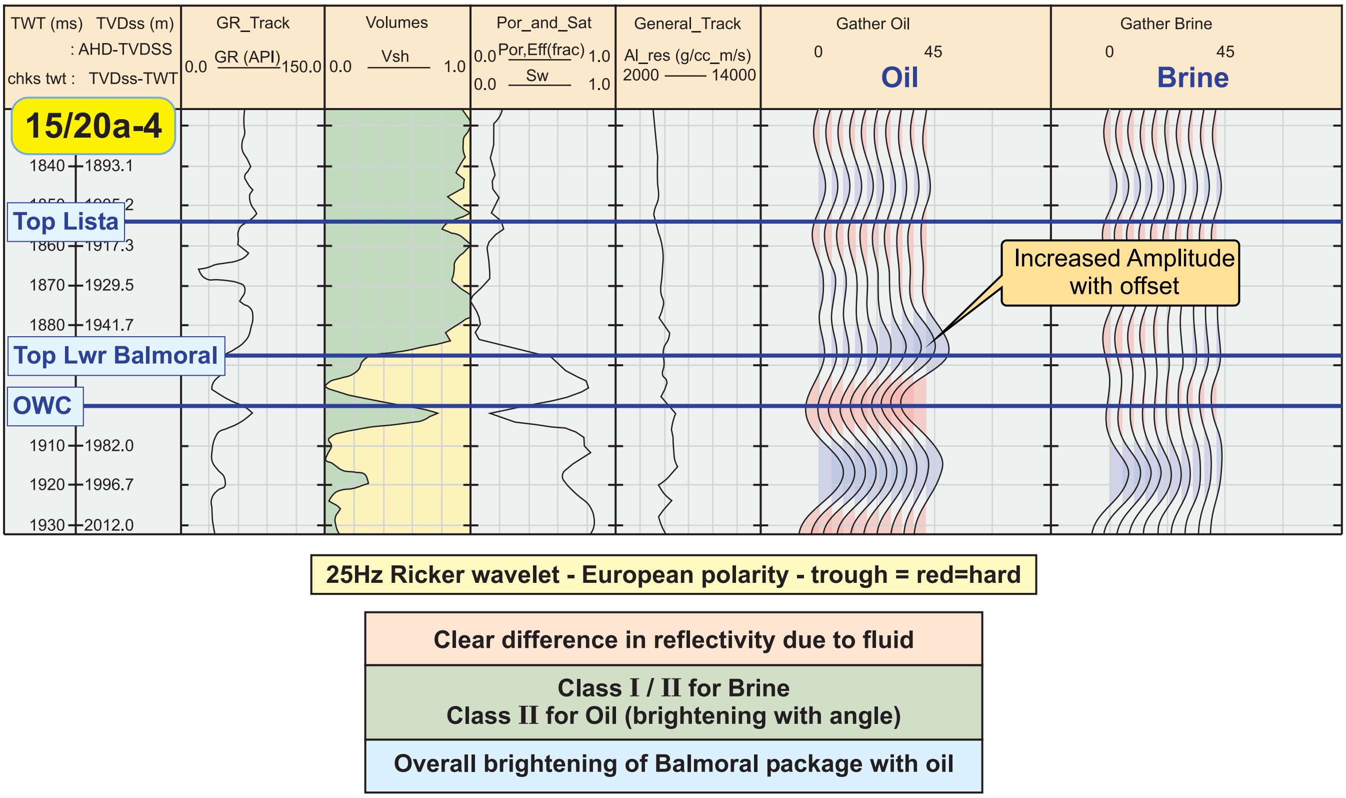

Fig. 10. Rock physics model for Donan showing AVO response in the presence of hydrocarbons in Lower Balmoral reservoir.

a working reservoir model that reflected the stratigraphic, depositional and facies relationships within and between the Donan and Pladda accumulations. Additionally, a framework of sufficient resolution was created to be used for geosteering future horizontal wells.

The new interpretation divided the reservoir into 10 units with six genetically linked sandstones deposited in a background of biostratigraphically correlated hemipelagic claystone intervals (Fig. 13). The sands themselves were interpreted as being deposited in sheet-like systems from high-density sand-rich gravity flows.

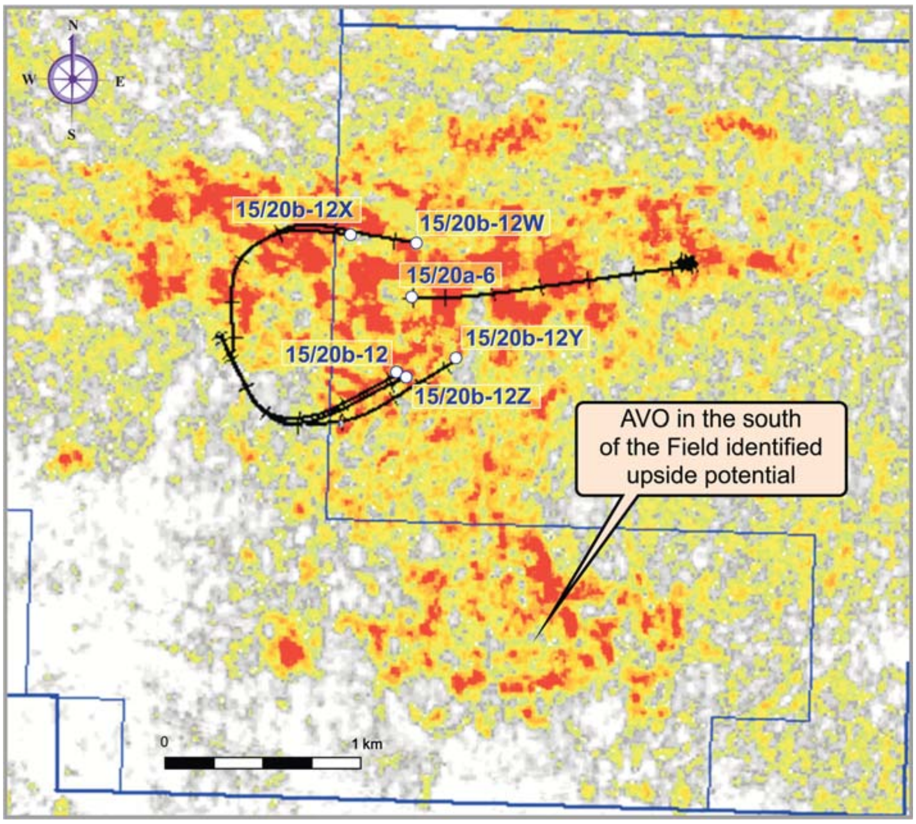

Fig. 11. Map of far minus near envelope over Donan showing clear AVO signature.

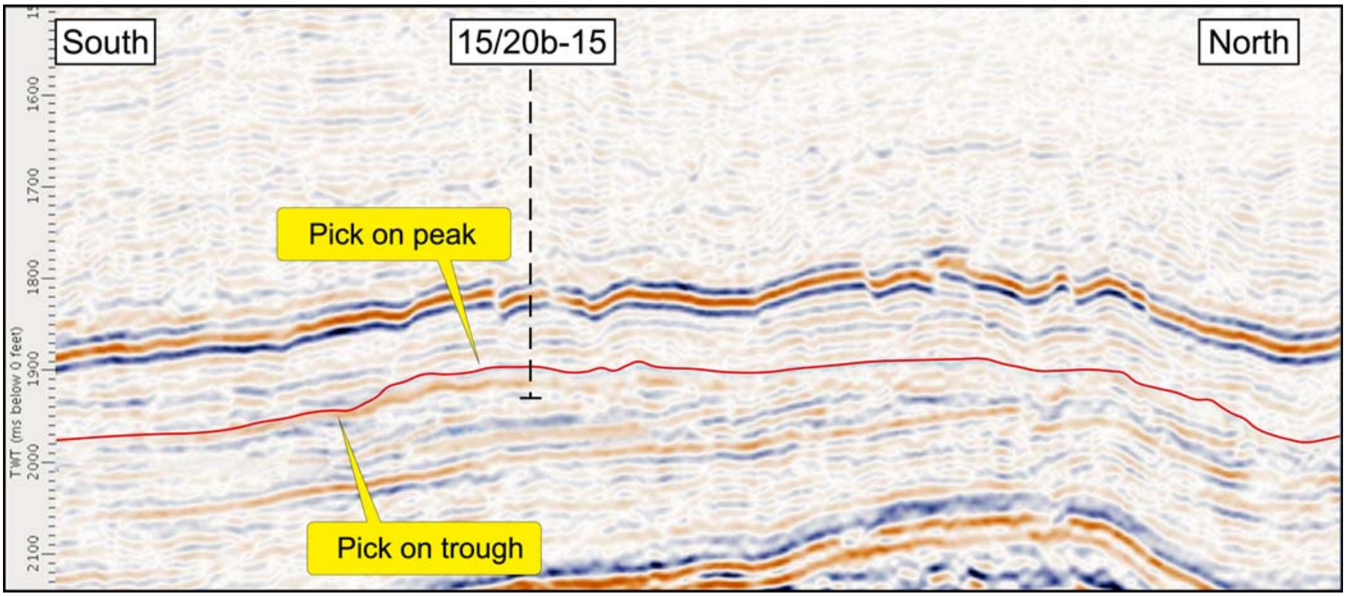

Fig. 12. Inline through full stack seismic data illustrating difficulty in picking on the flanks of the field where polarity flip occurs.

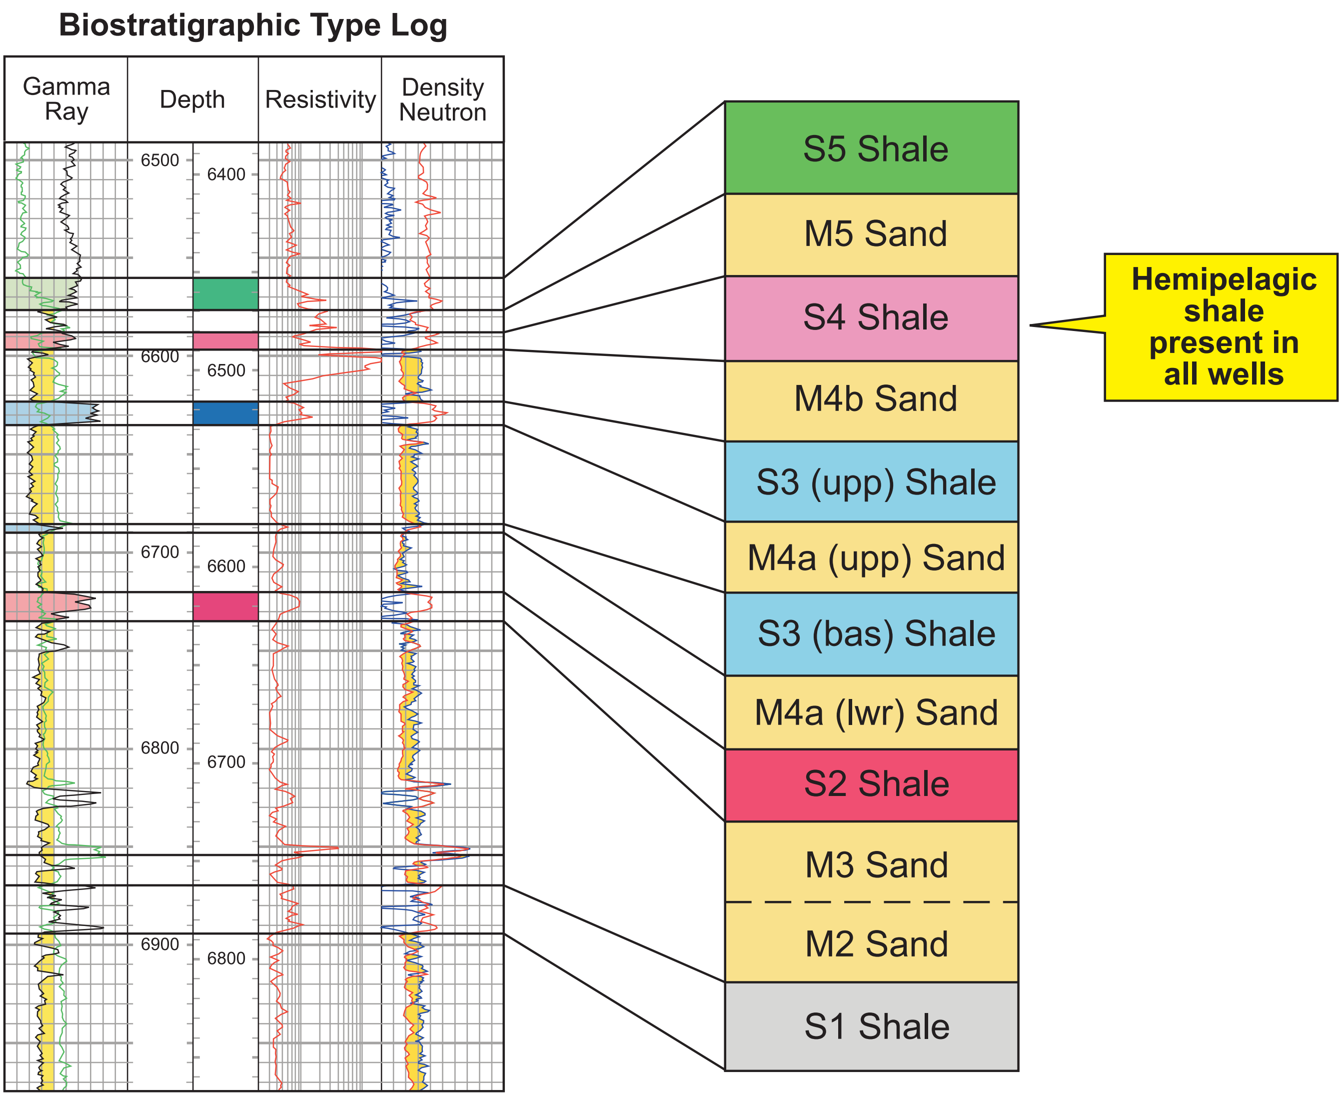

Fig. 13. Biostratigraphic subdivision Lower Balmoral sandstone reservoir units.

Only the youngest sandstone units were interpreted as showing any degree of flow-confinement, based on their lateral distribution. However, no overbank or channel margin deposits were recognized from core. A further level of complexity was added by the recognition of post-deposition remobilization and injection of sands during burial from core data. This injection is now believed to play a significant role in influencing vertical communication and water breakthrough.

Biostratigraphic data collected throughout the Donan appraisal campaign was integrated with a regional study to better understand the field's position in the larger Balmoral sandstone system.

Donan re-appraisal and the birth of the Dumbarton Project

The first appraisal well, 15/20a-14, was drilled in Q4 2003 to test a structural high that had been mapped to the east of the 15/20a-4 well (Fig. 14). The well was designed to calibrate the top reservoir pick, find sufficient net pay so that this well could act as a pilot for a future horizontal producer, confirm the field's moved OWC as predicted from dynamic modelling and verify possible remaining reserves.

The top sand was encountered some 91 ft TVD deep to prognosis at −6412 ft TVDss. However the well identified 17.5 ft net pay above a moved OWC, obtained from MDT pressures, of −6452 ft TVDss. The contact at this location had moved up 14 ft as a result of BP production.

Post-well analysis of the seismic data around the 15/20a-14 well indicated that the localized structural high may have been generated by a seismic artefact as well as the pick being made on the soft peak when the correct post-drill interpretation would have picked on the underlying hard trough below. This highlighted the difficulties in picking top reservoir. Indeed this target had primarily been driven by structure and not the AVO distribution.

Well 15/20b-15 was drilled in 2004 to test upside identified by a re-mapping of top Lower Balmoral on the re-processed seismic data and by the presence of a strong AVO anomaly at the structure's southern flank that extended outside BP's structure map (Fig. 14). The well was designed to calibrate the rock physics model, confirm reservoir presence and net pay and therefore determine likely reserves. At the time, the minimum economic field size for Donan redevelopment was assessed to be *c.* 16×10^6 stb and the field's recoverable range was believed to be around 10–53×10^6 stb (P90-P10). This wide range reflected the volumetric uncertainty associated with this untested area on the southern flank and areas to the North, away from the existing producers. Therefore, success in this upside location would justify further work and go a long way to confirming the viability of field redevelopment. The most likely redevelopment concept for Donan was considered to be a two-well scheme. However, pre-drill analysis suggested that, if a net pay thickness of 35 ft or greater were encountered in the southern area, then the likely reserves addition would justify a change of strategy to a three, or more, well development.

The 15/20b-15 well successfully encountered top sand close to prognosis and found 55 ft of net pay before identifying an OWC from well logs (Sw > 50%) of −6460 ft TVDss. This net pay thickness had considerable impact on the field development plan (FDP).

The final appraisal well drilled on Donan was 15/20b-16 which was spudded in June 2005. The success in the southern flank of the field had confirmed that the partnership would press ahead with an FDP. The objective of this final well was to characterize the likely additional reserves close to the northwestern structural closure of the field. The well was placed in an area of mapped structural elevation. However, the AVO signature was only patchy at this location (Fig. 14).

The well encountered top sand 44 ft TVD deep to prognosis and penetrated 18 ft of net pay before identifying an OWC from well logs of −6458 ft TVDss. Analysis of vertical seismic profile (VSP) data acquired during drilling indicated that once again the top Lower Balmoral had been picked on the wrong event in the seismic data and should have been tied to the trough instead of the upper peak event. This uncertainty over the seismic pick made it difficult to resolve field closure to the NW. Based on these well results, it was believed that the field closed just to the

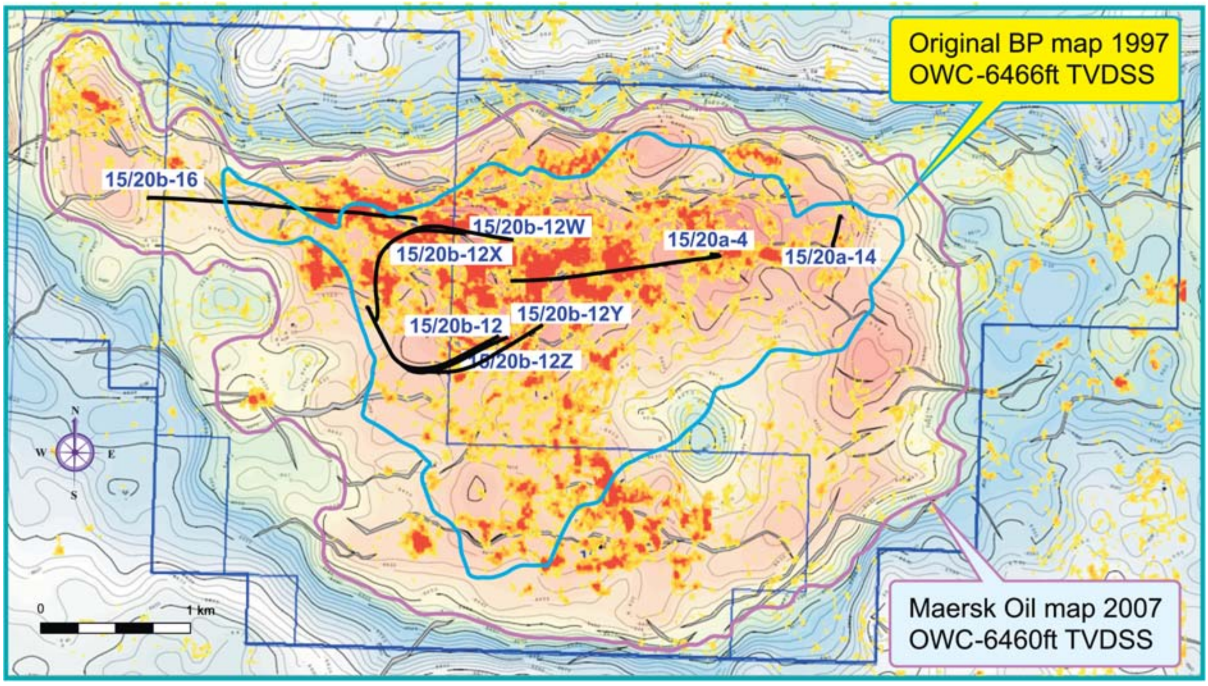

Fig. 14. Map showing appraisal well locations relative to AVO.

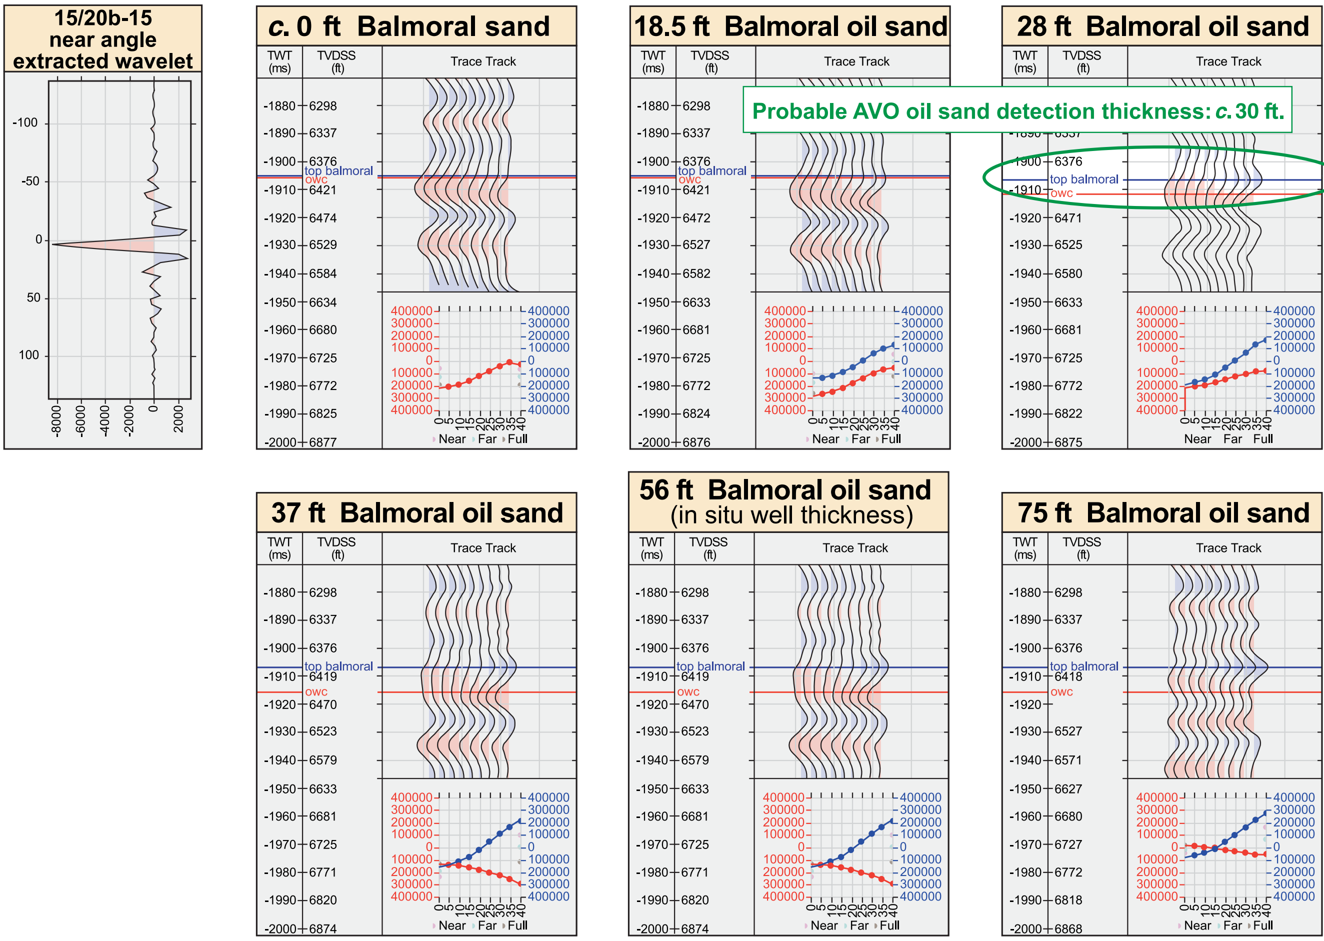

Fig. 15. Wedge modelling of reservoir sands indicating that the AVO response observed on Donan can be generated by net pay thicknesses of greater than 30 ft.

west of the well. However, this left a tempting area of AVO further to the NW, in a structurally higher position, just inside the block boundary, which would have to be further interrogated in the future.

By the end of the appraisal campaign, sufficient data had been gathered to suggest that the field would require a multi-well development plan to effectively realize reserves. The hypothesis that AVO could act as a net pay indicator had been validated and further wedge modelling using the well data indicated that areas where net pay was greater than 30 ft would exhibit Class II AVO (Fig. 15). Therefore, this could be used to aid development well placement using new seismic data which was acquired specifically for Donan by the partnership in 2005. Furthermore, the regional biostratigraphy study combined with the new appraisal data had allowed refinement of the geological model and given confidence that biosteering could be used to aid the placement of development wells in a particular sandbody.

The appraisal campaign had been a success and work began on the FDP. The partnership called the redevelopment the ‘Dumbarton Project’. Subsequent requests to change the field name to Dumbarton were turned down on the grounds that the 15/20b block had never been relinquished. However, in-house the field became known as Dumbarton.

Reservoir modelling

Following the successful appraisal campaign, a new geological model was constructed to reflect the current understanding of the field. Stratigraphic data collected from the wells was combined with the structural interpretation from seismic data to create a geocellular model which was then populated using rock property modelling. The consistency of reservoir sand properties across the field meant that constant values could be used with *J*-curves from a saturation-height model (applied to the original free water level) used to populate the variable oil saturations observed across the field. This model was input directly into simulation software for dynamic modelling.

Analysis of the historical behaviour of the field demonstrated that pressure was very well supported by the large aquifer. BP had concluded from surface pressure buildups during production shut-ins that there was no significant depletion in the field. A thorough review of regional formation pressure data, including the latest appraisal wells, suggested that *c.* 69 psi of depletion had in fact occurred since 1990 (Fig. 16). This depletion coincided with the extraction of fluids from Donan. However the trend appeared to have started two years before Donan came on stream, and continued afterwards. The effect of production from neighbouring fields (e.g. Balmoral and MacCulloch) was assessed to be the most likely explanation for this pressure depletion. In modelling the aquifer, compressibility calculations suggested an aquifer size of at least 50×10^9 bbl was present. The analysis of production and RFT data also demonstrated that depletion had occurred to the same extent across all sandstone units. This indicated that none of the hemipelagic shale units formed significant flow barriers. Flow across these hemipelagic shales could be explained by the presence of core scale sand injections and sub-seismic faulting. The main recovery mechanism was anticipated to be displacement of oil by aquifer influx from below. This was based on observation of sweep recorded in the 15/20a-12X well.

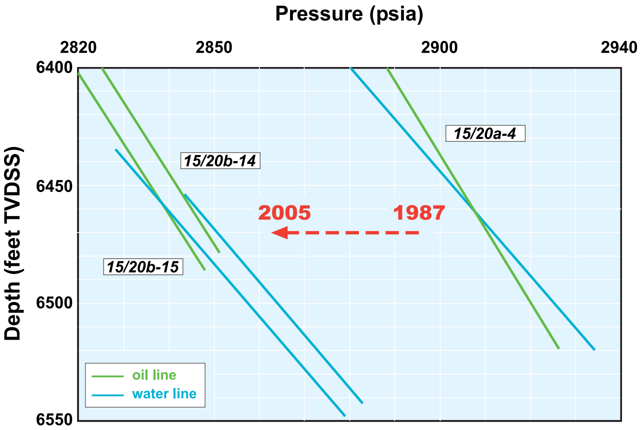

Fig. 16. Pressure plot showing depletion of Donan reservoir pre- and post-1992–1997 production.

Reservoir simulation of BP's five-year production history by Maersk demonstrated rapid local water coning at the two well locations. This left behind significant attic volumes which, at the time, were targeted by the 15/20b-12 wells. At the end of production, where field watercut was 70%, there were still significant reserves remaining. Simulation studies indicated that, in the 10 years of non-production, the water cones would have subsided somewhat (Fig. 17). Using BP's production as a constraint for history matching, further simulation was carried out to analyse the redevelopment potential. Simulation of new development wells indicated that water would rapidly encroach on horizontal producers with localized coning around the wellbore. Therefore, it was recognized that field development planning would have to optimize development well spacing to take this coning into account. With water cuts expected to be high, gas lift would be required to help lift the oil as water rates increased with production. A full suite of wellhead chokes, gauges and downhole gauges would allow the engineers to optimize gas lift distribution between the wells.

Field (re-)development plan

Reservoir modelling indicated that a phased development scheme would be optimal with five initial horizontal producers and one reinjection well for disposal of produced water (PWRI). Further phases of development drilling would depend on Phase I geological results and production performance. Data collected during development drilling would also address the remaining uncertainties of well performance (PI), the development of the water cones and the STOIIP. Given the number of development wells planned and detailed reviews of production facility options, it was decided that a stand-alone floating production storage and offloading (FPSO) facility would be used for the development. This would be owned jointly by Maersk Oil North Sea UK Limited (who had purchased Kerr–McGee's interests) and Noble Energy (Europe) Ltd. The Global Producer III (GPIII) FPSO was identified as a ready made candidate for Donan. At the time (2005) it was stationed at Maersk Oil's Leadon Field where production was close to the economic limit. The FPSO would provide processing systems for oil, gas, water production/treatment, water injection, oil and gas offload metering and have a storage capacity of 500 mbbl. Excess produced gas and condensate would be exported via pipeline. A project was initiated to carry out modifications on the FPSO's fluid handling capacities to suit the Donan fluids and handle the high volumes of produced water expected from the field.

The development wells themselves were designed to be drilled from a single drill centre cluster, batch set down to $12\frac{1}{4}$ inch hole before geosteering the horizontal sections and completing using a combination of excluder and equalizer screens.

Development drilling

Having completed the subsurface and facilities studies and with the FDP approved, detailed well planning commenced in the last quarter of 2005. This was carried out using the new 3D seismic dataset that was acquired by the partnership earlier in the year. Depth conversion was accomplished using a simple time–depth methodology utilizing the top reservoir time horizon mapped on seismic and well picks from wells in the area. The main cause of depth conversion uncertainty was interpretation uncertainty of the top reservoir horizon. This was due to changes in AVO character away from well control and at the flanks of the field where net pay thickness dropped below 25 ft. Overburden velocity anomalies created by Quaternary canyons and Eocene channels also proved problematic (Fig. 18).

The impact of overburden velocity anomalies on depth conversion has been examined by Armstrong *et al.* (2001). Their methodology of regional-residual separation was used on Donan to identify and correct time distortions of reflections at top reservoir level associated with shallow canyons and channels. This aided both well prognoses and the calculation of volumetrics in the areas where these distortions were greatest (Fig. 19). However, systematic errors in time interpretation created by picking on full-stack seismic data in the presence of AVO remained.

Development drilling commenced in January 2006 from the Noble Ton van Langeveld semisubmersible drilling rig. Each well was drilled down to $12\frac{1}{4}$ ft with the $9\frac{5}{8}$ ft casing set once reservoir sand was identified on landout by logging while drilling (LWD) gamma ray (GR), resistivity and neutron/density logs. Each $8\frac{1}{2}$ ft hole section was then drilled using an LWD logging suite of GR, resistivity and neutron/density logs as well as density and GR image logs, resistivity at bit and deep-reading azimuthal resistivity. These tools allowed the well to be geosteered as close to the roof as possible, maximizing standoff from the OWC at -6460 ft TVDss (Fig. 20). Wellsite biostratigraphy allowed both landouts and geosteered sections to be drilled within the pre-existing framework, ensuring that well positioning within the reservoir was understood. Following the drilling of each $8\frac{1}{2}$ ft section the well was completed, cleaned up and tested to the rig.

The drilling campaign lasted six months and successfully delivered five horizontal producers and one PWRI well (Fig. 21). Three sidetracks were required during drilling. Two of these sidetracks were geological, to locate/maximize reservoir, with one mechanical sidetrack required due to losses caused by drilling along a fault plane. The horizontal sections measured between 4000 and 6000 ft with pay lengths of 2000–3500 ft MD, giving an average net sand of around 65%. The wells achieved high productivities between 150 and 340 stb/d/psi.

Development drilling was followed by a further six months of subsea work and tie-in to the GPIII before production began in January of 2007.

Bringing Donan back: leveraging technology

The success of the Donan redevelopment (the Dumbarton Project) was influenced by a number of advances across the various technical disciplines:

- Rock physics modelling and seismic re-processing using pre-stack time migration allowed de-risking of wells and identification of significant upside that was previously unrecognized.

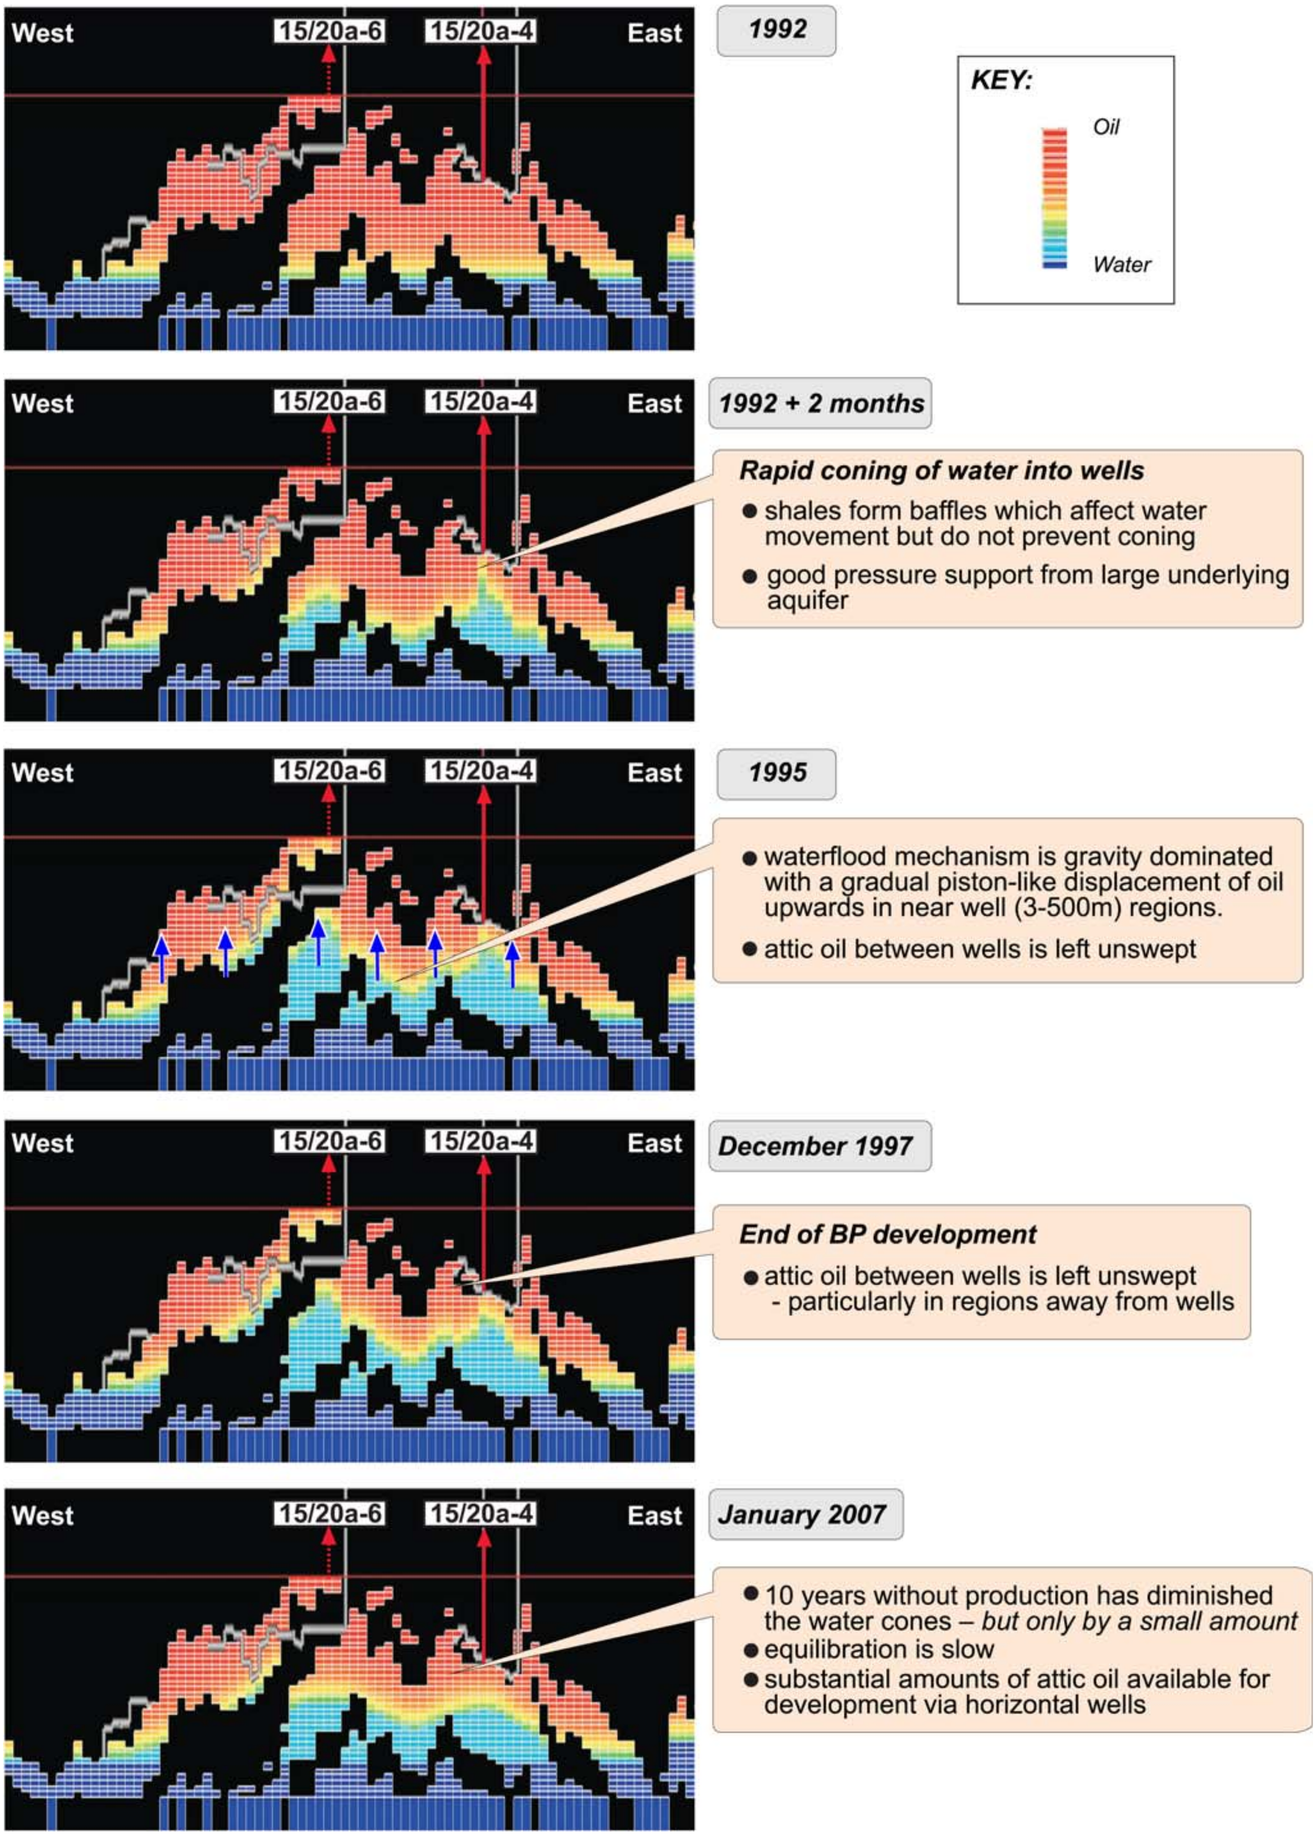

Fig. 17. Cross-sections through simulation model illustrating OWC behaviour during past production and the equilibration of cones since field abandonment.

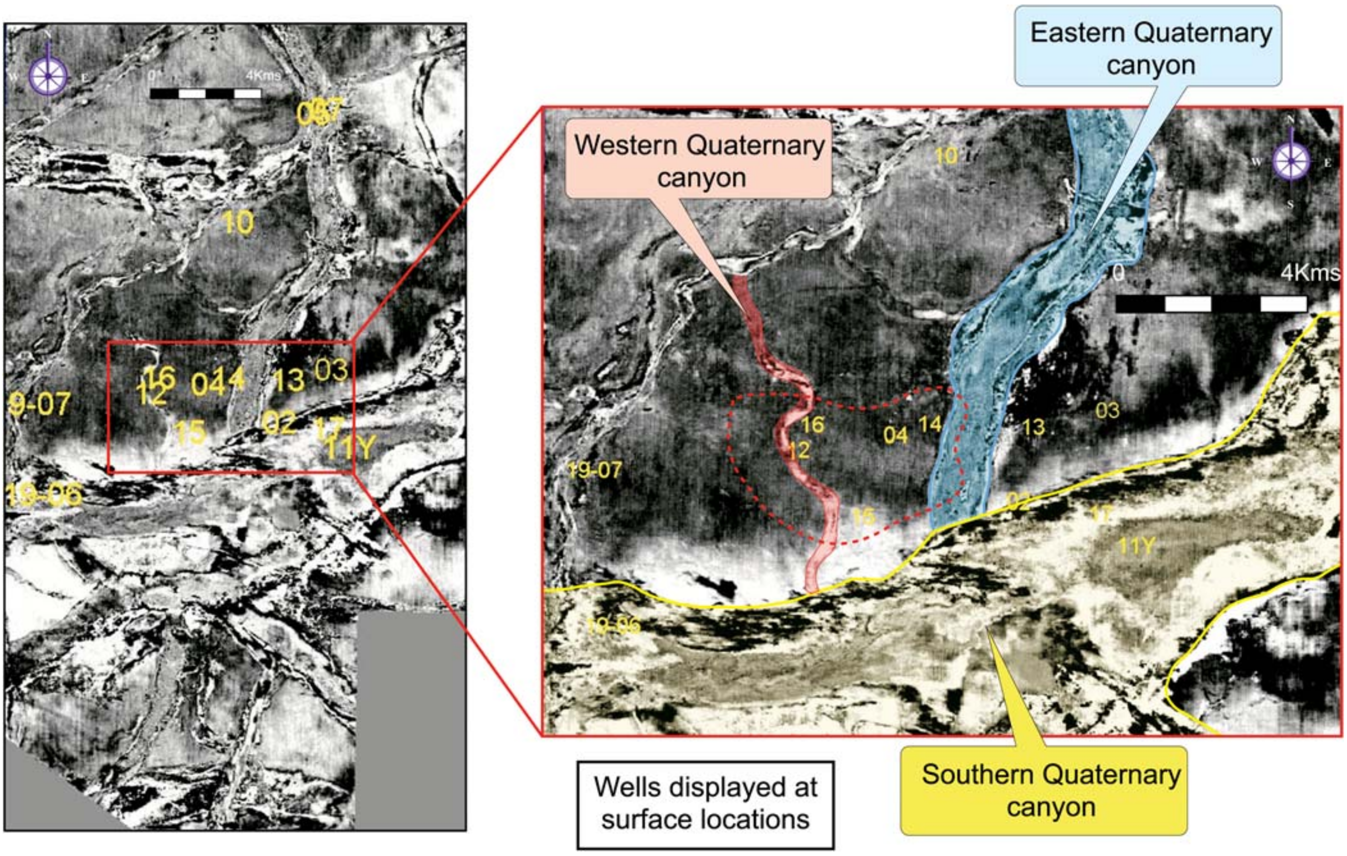

Fig. 18. Time slice showing overburden canyons that create depth uncertainties at Donan.

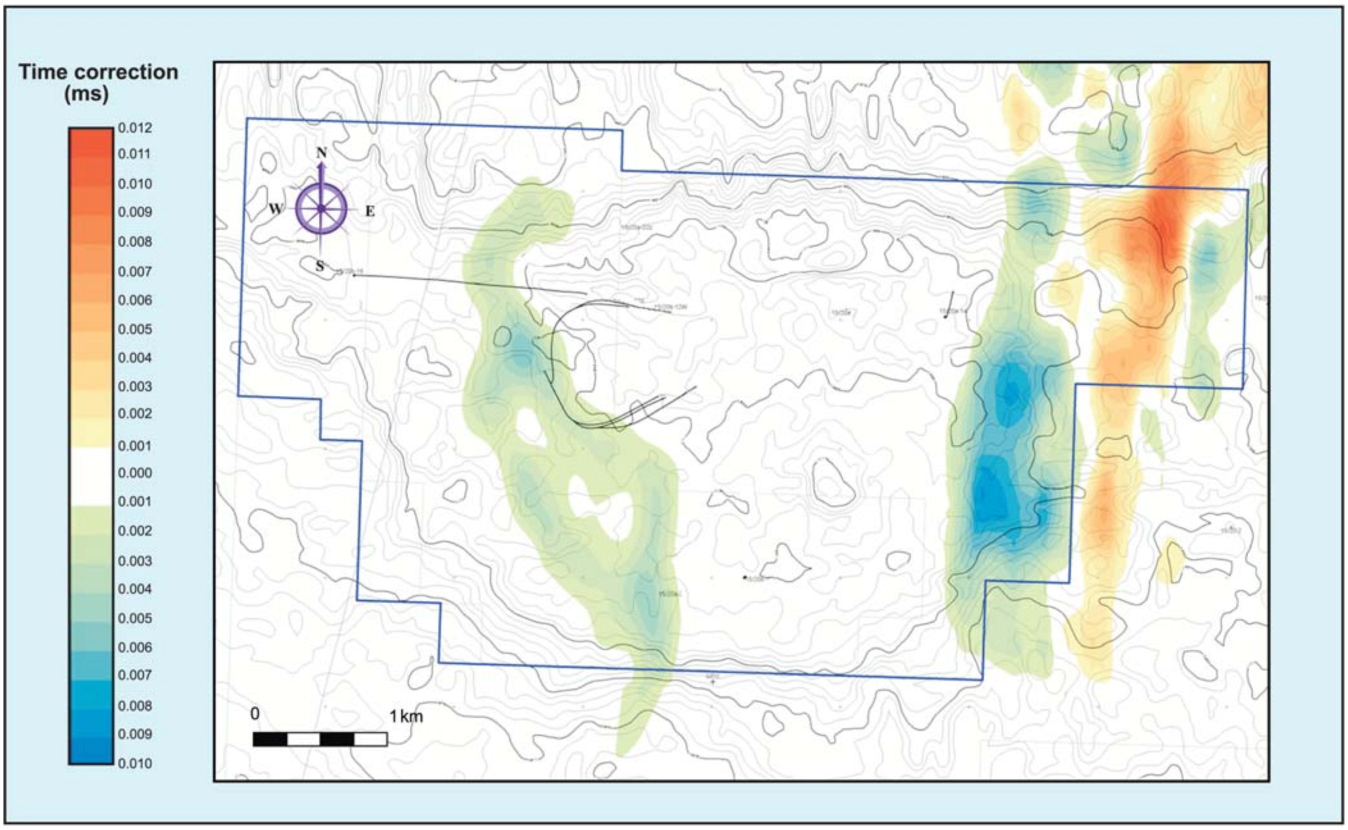

Fig. 19. Residuals map showing the time correction applied at top reservoir level to remove time distortion generated by overburden canyons.

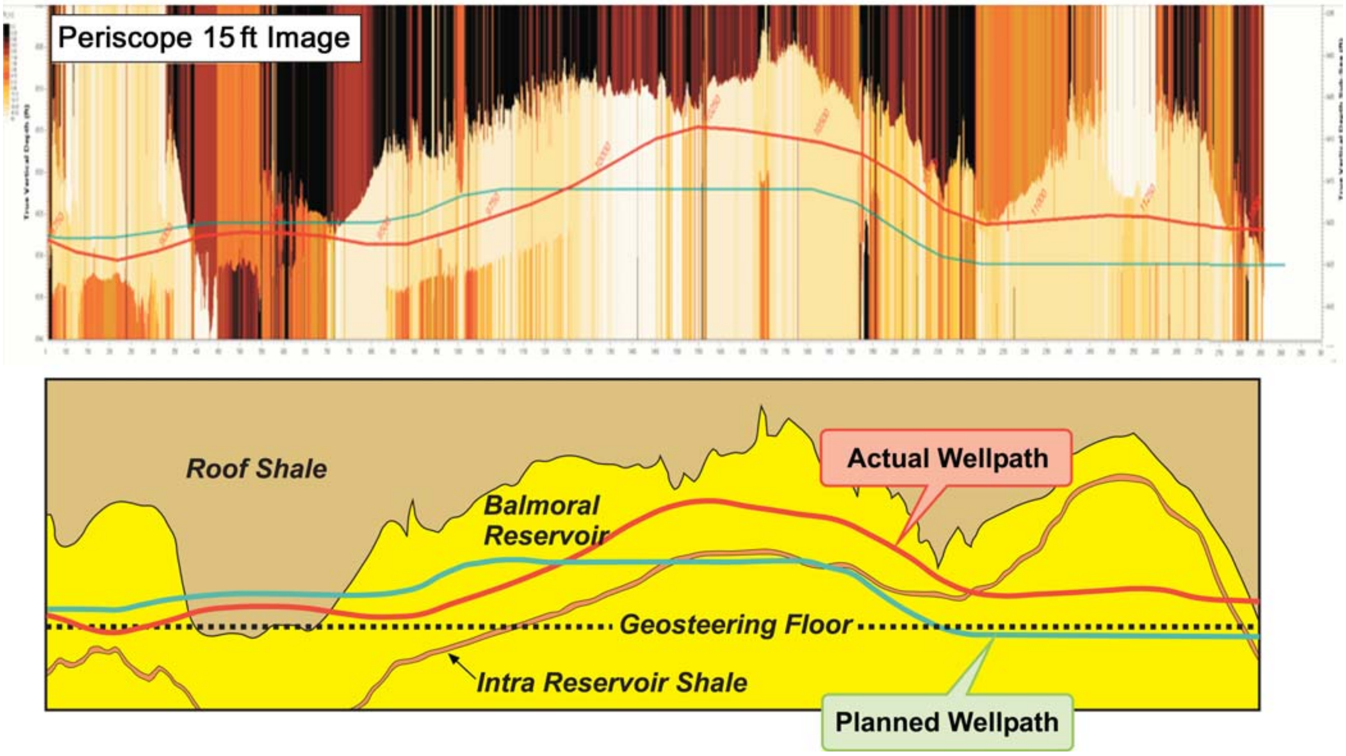

Fig. 20. Curtain plot from Periscope 15 (Schlumberger) showing planned v. actual geosteered wellpath.

- Advances in LWD technology, not least the advent of deep reading azimuthal resistivity tools, were crucial in ensuring accurate well placement and maximum standoff from the OWC. Well placement was also complemented by improvements in rotary steerable drilling assemblies with land-out accuracies significantly improved compared with what was achievable in the mid 1990s, with measurement while drilling (MWD) sensors located much closer to the drill-bit.
- The use of rotary steerable assemblies with improved hole cleaning made wellsite biostratigraphy more reliable than during the mid 1990s when inefficient hole cleaning by motor drilling meant that samples were commonly smeared. Detailed

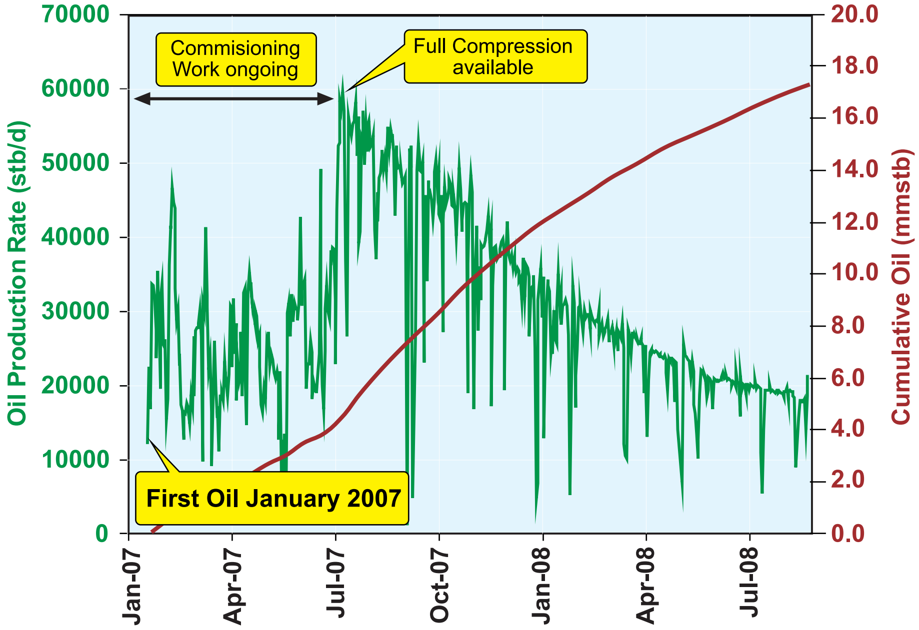

Fig. 22. Plot showing production performance from Phase I of the Dumbarton Project.

biostratigraphy and integration to a regional framework allowed correlation across the field and wells to be placed accurately.

- Improvements in wellbore stability management and drilling mud technology enabled the successful drilling of long horizontal sections.

Beyond 'second' oil: Donan 2007–?

Well performance

First oil from Phase 1 of the Dumbarton Project was produced on 19 January 2007. Early production was constrained due to commissioning activities (Fig. 22). However from mid July 2007, gross production rose and exceeded the expectation case as well rates increased to a range of 10–20 mstb/d/well. Well rates were, and are, ultimately constrained by a combination of facilities, ullage, flowline capacity and tubing performance. Water breakthrough occurred in well D2Z (Fig. 21) in April 2007 and in the other wells soon after. Gross rates fell through the latter half of 2007 as the watercut rose, and in November 2007 gas lift was employed to aid well performance. Since July 2007 excess gas has been injected back into the field using production well D2Z, due to the fact that gas export has not yet been fully commissioned. The watercut has risen in line with expectations.

The Dumbarton Project reached the milestone of 15.3×10^6 stb in May 2008, matching and then surpassing BP's five-year production total from Donan in a little over a year (Fig. 22).

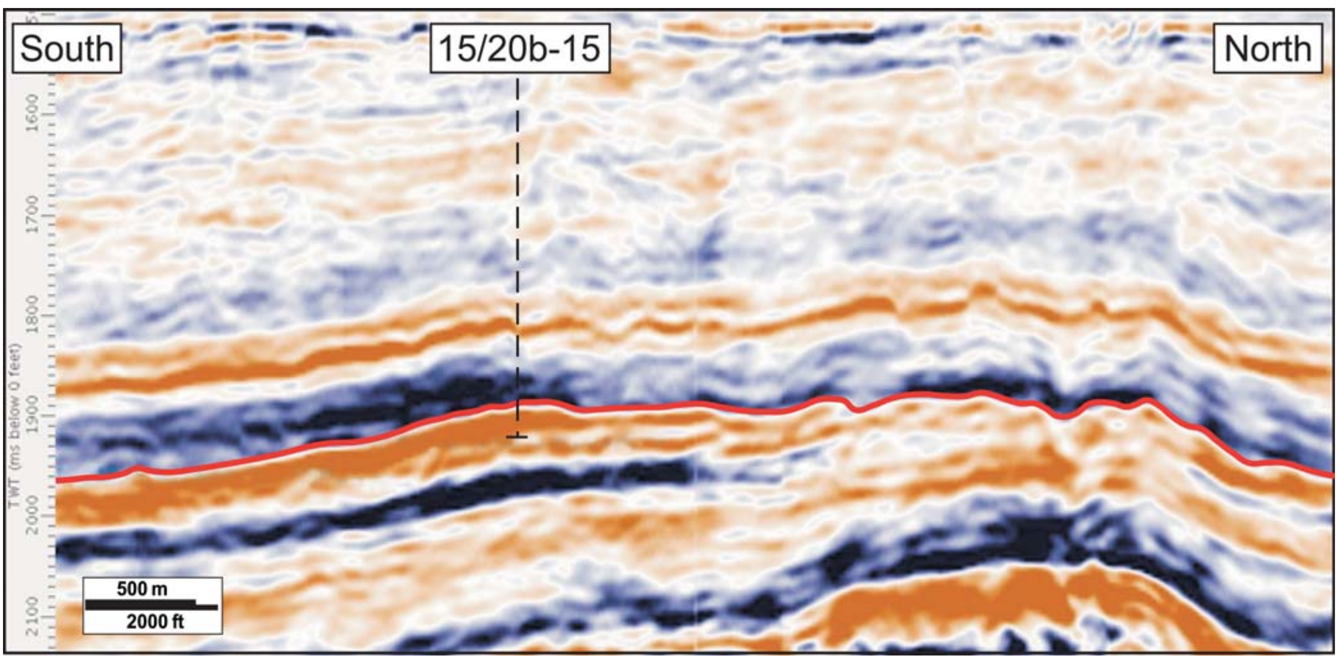

Fig. 23. Inline through lithology impedance volume showing more consistent pick on and off structure than previously achieved.

Preparing for infill drilling

In early 2008, well planning work commenced to place two additional horizontal producers and a further PWRI well on Donan. These new wells were covered by the original FDP and so became known as Phase Ib. A new top reservoir structure map was created using a reprocessed subset of the 2005 seismic data which had significantly improved signal-to-noise ratio. In order to make a consistent pick away from well control, the AI/GI cross-plot method (Whitcombe & Fletcher 2001) was used to create a lithology impedance volume. This separated the top Lower Balmoral unit from the overlying Lista roof shales and allowed a top reservoir pick to be made that was unaffected by fluid effects (Fig. 23). The geological model was then adjusted to honour this new depth structure map.

Re-mapping of the field showed a number of areas of structural relief with no associated AVO. As part of Phase Ib it was decided to test these areas for the presence of 'dim oil'. Given the success of AVO on Phase I, the D9 well was only given a 25% chance of success. Indeed, the new structure map placed top reservoir very close to the geosteering floor of −6430 ft TVDss, where 30 ft TVD was assessed to be the minimum acceptable standoff from the OWC. The well was designed such that if no reservoir was found at landout, the well would interrogate the structure before dropping inclination to find sand and log the OWC before sidetracking to a planned location that would intersect two AVO anomalies (Fig. 24). In order to further appraise the eastern side of the field, the PWRI (D8) well was designed to interrogate the highest structural point to the east of the field with no AVO to finally rule out the possibility of 'dim-oil'. The remaining infill development well in Phase Ib (D7) was planned to be the longest well to date on Donan, drilling on a north-westerly azimuth along a structural high marked by strong AVO (Fig. 24).

Since these would be the last wells covered by the original Donan FDP, an FDP addendum was submitted and approved that would allow a further phase of development to take place. Mapping had identified further potential targets that could be drilled as part of Phase II. These included a sidetrack of 15/20b-16 well to test a patchy AVO signature to the NW and apparently updip of the 15/20b-16 appraisal well and the 15/20a-D10 well which was planned to drill in a northwesterly azimuth very close to the 15/20b-12 well drilled by BP (Fig. 24).

2008 Drilling campaign

Infill drilling commenced in April 2008, once again from the Noble Ton van Langeveld drilling rig. The D7 well successfully found sand on prognosis. The D9 well, designed to appraise the area with no AVO to the SE of the field, found sand *c.* 5 ft deep to prognosis and below the geosteering floor. This confirmed the rock physics model that suggested that there was less than 25 ft net pay in this location. The well was then sidetracked to the D9Z location where it successfully entered top sand on prognosis corresponding to the observed AVO.

The D7 and D9Z (Fig. 24) wells had horizontal sections of 5899 and 1856 ft respectively and very high net to gross. Once again, the use of azimuthal resistivity and biostratigraphic control aided well

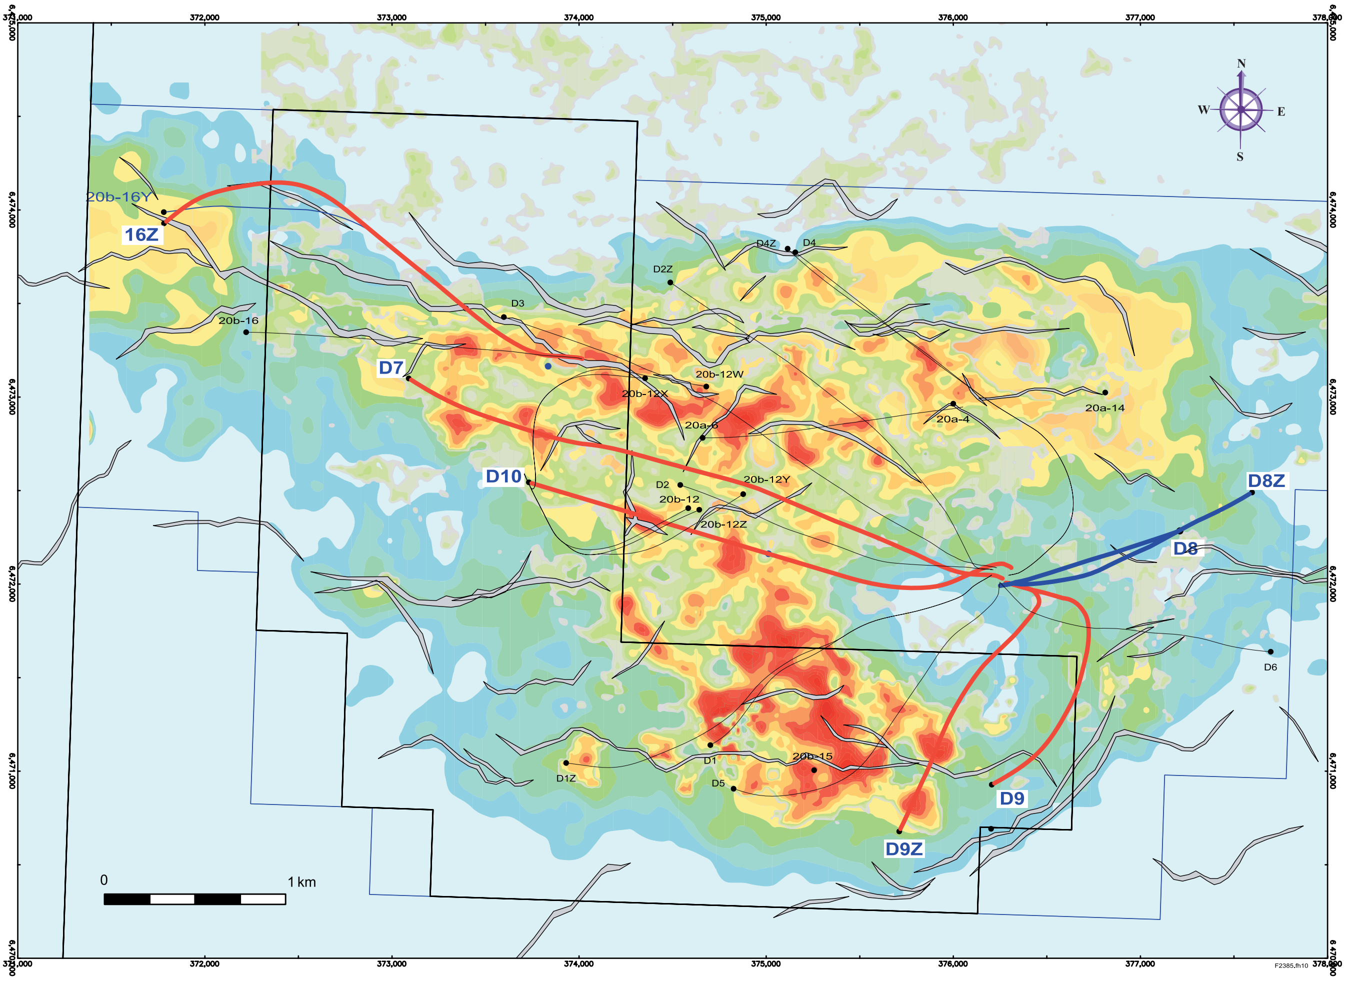

Fig. 24. Map showing Phase Ib, D7, D9 and D9Z infill well locations with AVO overlay and Phase II (D10 and 16Z) planned locations.

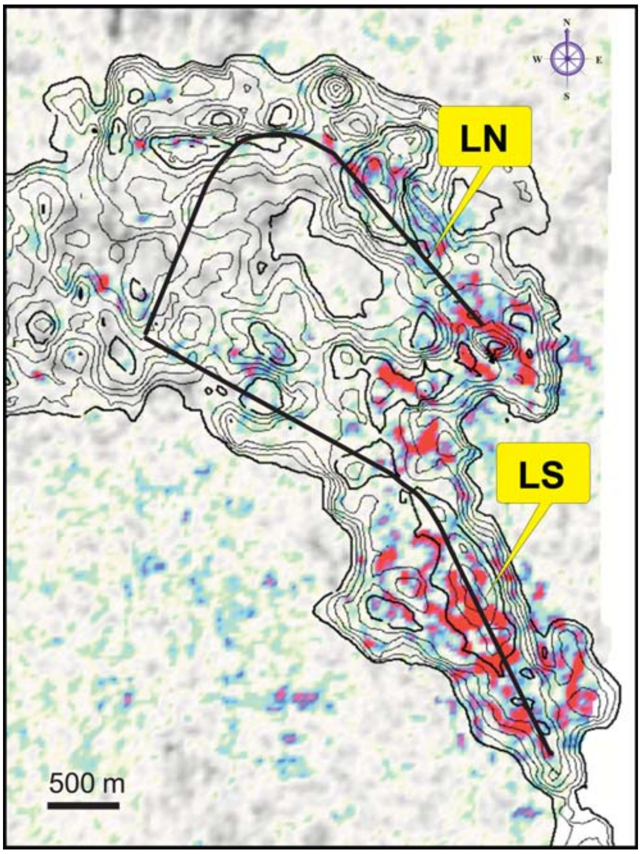

Fig. 25. Map showing AVO and structure along with planned development well locations for Lochranza field development.

placement. Both wells were completed using excluder screens and cleaned up to the rig, achieving very high productivities (PI) of 300–481 stb/d/psi. The D8 PWRI well drilled to test the structure to the east and encountered top Lower Balmoral on prognosis. However, the unit was shale prone with top sand being encountered at −6460 ft TVDss, below the OWC. This further confirmed the rock physics model and reliability of the AVO as a net pay indicator.

Exceptional drilling efficiencies meant that one of the Phase II wells could be accelerated. The suspended 15/20b-16 well was re-entered with a view to placing a development well in the AVO anomaly updip of the 18 ft oil column identified in the 15/20b-16 well. The 15/20b-16Z well encountered hydrocarbon-filled reservoir sand on prognosis. However, a WUT of −6415 ft TVDss was observed on logs, some 45 ft shallower than anticipated. The well was sidetracked and the 15/20b-16Y well was drilled to target the absolute crest of the local structure and confirmed the OWC at −6413 ft TVDss. This indicated that the Donan field must indeed close somewhere between 15/20b-16 and this location and that the original −6466 ft TVDss contact represents the structural spill to the NW. Whilst net pay thickness was sufficient to generate the AVO observed, the shallower contact and limited lateral extent of this local structure meant that the volumes were too small to be economic. The well was plugged and abandoned.

Infill well performance

In September 2008 the D7 and D9Z Phase Ib wells were brought on stream. These wells were given priority over the earlier wells for pipeline ullage, and high early gross production rates led to production being constrained by the surface equipment. These wells were brought back on stream after new subsea facilities were installed in October 2009 to accommodate further infill wells.

Future challenges

Next phase of development: the birth of Lochranza

At the time of writing, drilling of the remaining Phase II well on Donan is about to commence. This will place a further development well towards the west of the field, passing close to the 15/20b-12 well drilled by BP in 1995. Thereafter the drilling rig will move around 5 km east of Donan to commence development drilling on Lochranza, the renamed Pladda prospect.

Work to characterize Lochranza has continued in parallel to Donan development. Lochranza's small size would mean that, without the success of Donan and convenient subsea tieback, its reserves would never be realized economically. The development will comprise two horizontal producers that will be geosteered in the same manner as previous Donan wells (Fig. 25). It is expected that the field will be of lower net to gross than Donan with thinner sandstones providing a greater geosteering challenge than those drilled thus far.

Identifying remaining potential

As Donan matures, infill targets of sufficient size will become increasingly difficult to identify. The intensive well planning and operations of the last 2–3 years have limited the time available to carry out detailed subsurface studies to fully integrate the dynamic data with the reservoir model. At the end of the current drilling campaign, a full geological model re-build will take place to integrate new stratigraphic data with dynamic performance data. This study is expected to shed new light on the field, perhaps de-risking targets that currently seem marginal or identifying entirely new infill possibilities.

Conclusions

The Dumbarton Project has been a technical and commercial success for Maersk Oil North Sea Limited and partners Noble Energy (Europe) Limited. The renaissance of Donan has been achieved thanks to a number of technological advances since initial field abandonment in 1997. Advances in seismic technology and AVO processing have enabled the preservation of amplitudes in seismic data and the identification of the AVO expected from rock physics modelling. The development of more sophisticated drilling technology and LWD tools have allowed long, tortuous wellpaths to be drilled quickly and cheaply whilst optimizing well placement in the reservoir. These technological advances have been leveraged within an integrated and multidisciplinary framework by the many geoscientists and engineers who have worked on the project since its inception. Furthermore the realization at the corporate level that the abandoned Donan field represented a good opportunity worth pursuing illustrates the ambition of the partnership.

At a time when many are reflecting on the last four decades of exploration and production in the UKCS and assessing the current landscape, the renaissance of Donan and birth of Lochranza may represent the first of many opportunities to realize stranded value in this mature province.

The authors would like to thank the management of Maersk Oil North Sea UK Limited and Noble Energy (Europe) Ltd for permission to publish this paper. Thanks also to the reviewers of this paper for their constructive suggestions. Finally (and importantly) thanks are owed to all the geoscientists and engineers who have contributed to the Donan story over its 22-year history.

Appendix A: Donan Field data summary

Trap			
Type	Four-way dip closure – large basal aquifer	Gas–oil ratio (initial)	380 scf/stb
Depth to crest	−6340 ft tvss	Formation volume factor	1.21
Lowest closing contour	−6466 ft tvss	Bubble point (initial)	1408 psia
Oil–water contact	−6460 ft tvss	*Formation water*	
Oil column	Max 120 ft at crest	Salinity (average)	84550 mg l^{-1}
Pay zone			
Formation	Lower Balmoral Sandstone	Resistivity (average)	0.119 Ω m at 60 °F
Age	Thanetian (Late Paleocene)	*Reservoir conditions*	
Gross thickness	300 ft	Temperature	183°F
Lithology	Sandstone	Pressure (initial)	2830 psia (at −6460 ft TVDSS)
Porosity (average)	28%	*Production*	
Hydrocarbon saturation (average)	85%	Start-up	19 January 2007
Permeability	800 mD	Development	Five producers +1 PRWI, two infill wells drilled late 2008, one infill well drilled Q1 2009
Net to gross (average)	90%	Production rate	Gross rate 70 mbpd will increase to 150 mbpd
Hydrocarbons			
Density	38.7 API 0.83 g cm^3	Cumulative production	22 × 10^6 stb January 2007 to March 2009 plus 15.3 × 10^6 stb 1992–1997

Techniques in Exploration and Exploitation

A road map for the identification and recovery of by-passed pay

P. F. WORTHINGTON

Gaffney, Cline & Associates (Consultants) Pte Ltd, 80 Anson Road #31-01C, Fuji Xerox Towers, Singapore 079907 (e-mail: pworthington@gaffney-cline.com)

Abstract: By-passed pay can occur at or between wells. Either way, it constitutes a lower risk prospect than hydrocarbon accumulations in unappraised areas. Beyond this, there are three contemporary drivers for its exploitation. First, new technology in the form of sharper reservoir imaging allows insights that were not achievable previously. Second, an evolving understanding of how reservoirs work has led to improved procedures for maximizing the exploitation of even the most problematic accumulations. Third, market forces amid global post-peak production fears are giving the incremental development of by-passed pay an even greater commercial impetus today. An examination of case histories that illustrate the role of these drivers has led to a six-fold type classification of by-passed pay. Type 1 can be produced using an existing identified well. Type 2 requires a side track or a new well in order to capture the reserves. Each type is further subdivided into three classes. The classification scheme has provided the context for an emerging *modus operandi* to maximize commercially recoverable hydrocarbons in developed assets. Thus, the approach takes the form of a road map for practical application. By corollary, the type classification demonstrably accommodates a wide range of reported exploitations of by-passed pay from diverse reservoirs. Therefore, this classification constitutes a potential foundation for further systemic refinements to the identification and recovery of by-passed pay.

Keywords: net pay, by-passed pay, reserves, resources

Pay

Changing market conditions are encouraging operators to search out untapped hydrocarbon volumes within mature fields. The production of these volumes requires that they be incrementally economic. In conventional oil field parlance, this requirement becomes one of sufficient net hydrocarbon volumes to justify further development in terms of return on investment. This justification is partly based on an analysis of net pay as an input to the estimation of petroleum resources. In the following discussion, the use of terms such as 'Resources' and 'Reserves' tracks the Petroleum Resources Management System (PRMS) published by the Society of Petroleum Engineers *et al.* (2007).

Net pay

The literature contains various definitions of net pay as well as several different protocols for distinguishing net-pay from non-pay intervals. This paper adopts the scheme of Worthington & Cosentino (2005). Following this scheme, for a vertical well net pay is defined as the thickness of a reservoir or reservoir zone that contains significant quantities of movable hydrocarbons: in many cases it is the aggregated thickness of two or more subintervals. The product of reservoir area and net pay is the subsurface volume that expresses itself at a wellbore in terms of significant hydrocarbon production. This expression takes place through supracritical levels of porosity, permeability and hydrocarbon saturation, that is, those values that satisfy net-pay criteria, and how these properties vary over the net-pay interval(s).

Net pay can only be measured at a wellbore: elsewhere, it has to be interpolated or estimated. It is quantified from downhole logs using one or more petrophysical cut-offs and then propagated through a 3D reservoir model. There is no industry standard method for doing this, but one of the more common approaches is the conjunctive application of cut-offs for shale volume fraction, porosity, and water or hydrocarbon saturation (Worthington & Cosentino 2005). It is important that these cut-offs are dynamically conditioned, so that they take account of the requirement that net pay contains movable hydrocarbons (Worthington 2008).

By-passed pay

By-passed pay relates to significant movable hydrocarbons that cannot be drained by any existing well and will be left behind in the subsurface if nothing is done. In other words, by-passed pay satisfies the technical requirements for being classified as net pay but it has not been developed and might not even have been seen. This definition is set within the context of conventional reservoirs. It excludes residual hydrocarbons, which are immobile and therefore will stay in the reservoir. By-passed pay can occur at or between wells.

By-passed pay may or may not be a subset of the initial net pay. It depends on why the pay has been by-passed. There are four principal reasons.

- The accumulation was identified but was originally considered to be uneconomic.
- The pay was not seen either because downhole measurements did not identify it or because of inadequate perceptions on the part of the analyst.
- The degree of reservoir complexity was not fully evident at the time of formulating a field development plan. In other words, the field database and its interpretation were not adequate for a sufficiently detailed reservoir description, so that there was an oversimplified geoscience model at production start-up. This explanation has a widespread validity, because reservoir models tend to become more complex as more data are acquired.
- The recovery mechanism has been less efficient and effective than initial projections indicated, perhaps because of a preferential watering out or simply because discrete sand bodies were not intersected by a wellbore.

These are all common occurrences and therefore it follows that by-passed pay is potentially a common occurrence too. This is an

VINING, B. A. & PICKERING, S. C. (eds) *Petroleum Geology: From Mature Basins to New Frontiers – Proceedings of the 7th Petroleum Geology Conference*, 453–462. DOI: 10.1144/0070453

important contention because the exploitation of by-passed pay carries a lower risk and can be more cost effective than standard field operations. This paper considers different kinds of by-passed pay and identifies approaches for capturing them.

Types of by-passed pay

There are two types of by-passed pay. Type 1 is that which could be produced using an existing identified well, for example, where a hydrocarbon-bearing interval has never been perforated. Type 2 is that which requires a sidetrack or a new well in order to capture the reserves, for example, unswept hydrocarbon volumes in an inter-well region. On this basis alone, the term 'by-passed pay' is inappropriate, because pay is a thickness that can only be measured at a wellbore. The phrase 'by-passed hydrocarbons' would be more generally applicable. Types 1 and 2 can each be further subdivided in terms of three scenarios (Table 1).

Type 1: Scenario A

Hydrocarbons were seen but not developed at the time of well completion, for example, because there was no (gas) market at the time, the accumulation was not economically recoverable with the technology of the day (e.g. stimulation practices), there were safety concerns, or the recoverable volume was considered too small to be economically attractive (in terms of commodity prices, lifting costs and/or production sharing contractual terms). Once identified, the recoverable volumes should be classified as Contingent Resources until there is a plan to develop them. Another explanation is that the original net-pay cut-offs were too severe, so that the in-place volumes were considered to be unrecoverable and therefore could not be classified as Contingent Resources at the time. The ongoing requirement is to monitor continuously commodity prices vis-à-vis evolving technology, field/regional infrastructure and net storage/flow criteria, so that (incrementally economic) workover opportunities can be generated.

Type 1: Scenario B

Hydrocarbons were present but not seen at the time of well completion. At the most basic level, the hydrocarbons might simply have been outside the originally perceived evaluation interval, for example, shallow gas sands. The local perceptions of net pay might have been flawed, or the pay interval might literally have been overlooked. More profoundly, these Scenario B situations can arise because of deep invasion by drilling mud filtrate, laminated sedimentary sequences, fresh formation water or high capillarity of the reservoir rock caused by siltiness or microporosity. It is important to gather sufficient data so that departures from classical reservoir character can be identified. Fortunately, there are downhole technologies available to help deal with these situations. They include (through-casing) deep-sensing resistivity logs that see beyond the invaded zone, microresistivity imaging tools for identifying and demarcating thin beds, high-resolution multifrequency dielectric measurements to distinguish fresh water from oil, and magnetic resonance logs for identifying capillary-bound water. The deployment of these tools should be guided by special core analysis from a representative appraisal well. Such data have a potentially high value because, without them, hidden hydrocarbons can be lost forever.

A Scenario B situation might also arise because the concept of net pay evolves during the life of a field. For example, net pay is conditioned by the recovery mechanism, and that can change during field life (George & Stiles 1978). Another situation is that of late-onset gas production. This is most commonly found in an alternating sequence of tight and permeable gas-bearing sands. The permeable sands are identified as net pay: the tight sands are rightly excluded from net pay because they do not satisfy the cut-off criteria for flow. However, as pressure declines with depletion of the permeable sands, the induced pressure difference between the tight and permeable layers allows gas to flow into the permeable sands and thence be produced at the wellbore. The tight sands remain non-pay but the permeable sands can be assigned a recovery factor that is greater than 100%.

Table 1. Type classification of by-passed pay

Scenario	Description	Type 1: At wellbore	Type 2: Inter-well region
A	Recognizable at outset but not developed	1A	2A
B	Not recognized at outset but identified now	1B	2B
C	Developed at outset but unswept volumes evident	1C	2C

Type 1: Scenario C

Hydrocarbon intervals were seen and perforated at the time of well completion but post-production they have been identified as containing unswept volumes, for example, through formation damage, reservoir heterogeneity, premature well decline or early breakthrough of water fronts (either aquifer-sourced or injected). In other words, the in-place volumes might have been estimated meaningfully but there is no significant recovery along sections of the pay interval. Unswept volumes can be identified using through-casing resistivity logs, carbon–oxygen logs and/or pulsed neutron tools in time-lapse mode. Some of these situations might be obviated by utilizing more realistic models for predicting well performance. These models should be updated in response to evolving concepts of reservoir connectivity during production.

Type 2: Scenario A

Hydrocarbon occurrences were theoretically detectable through geoscience but either they were recognized but not drilled or they were recognized insufficiently. The former case might have arisen because of economic perceptions and/or drilling limitations. The latter case might be due to geoscience misinterpretation (especially in the presence of faulting), erroneous depth conversion placing the structure too low, or perhaps an uncalibrated attribute analysis. In many situations, this occurrence of by-passed pay is due to reservoir complexity or, more specifically, to the adoption of a field database that does not capture the geoscience complexity of the field. To some extent, this situation can be obviated by carrying out a commensurate reservoir appraisal, noting that a knowledge of hydrocarbon volumes on the flanks of the field does contribute to this process. There has been a tendency to short-cut appraisal by drilling only crestal or subcrestal wells: this strategy may appear financially beneficial in the short term, but over the life of a field it will almost certainly detract from the booking of Proved Reserves and in this regard alone it constitutes negligence. Further remedial action would be to integrate more effectively the benefits of enhanced workstation technology, better seismic-to-well ties, and advancing reservoir characterization concepts. In connection with this last point, note that stochastic methods of populating geoscience models may be limited in their added value. These methods generate realizations, which are intended to be analysed statistically. A realization does not constitute reality, because it is a member of a population that should be treated as a whole.

Type 2: Scenario B

Some inter-well hydrocarbon volumes were not indicated geologically or geophysically at the outset, for example, because of reservoir complexity, weak seismic imaging or inadequate (vertical) spatial resolution. Where the size of the field justifies it, the acquisition of sharper-imaging seismic data before the field has reached its mid-life stage, in conjunction with refined reservoir characterization, can help to extend plateau production considerably. The structural model and the encompassed geological architecture should be refined as more data become available. In this respect, contiguous field extensions that are identified in mid-life might also be regarded as by-passed pay. All things being equal, the potential upside associated with by-passed pay is likely to be greater for larger fields. At the same time, consider the conjunctive use of geophysical deliverables such as seismic attributes and inter-well products such as electromagnetic tomography, especially in complex reservoirs. Calibrated seismic attributes have a potential semiquantitative application to net reservoir and/or net pay mapping. Subject to the principles of geophysical equivalence and suppression, electromagnetic tomography can distinguish net pay from net reservoir.

Type 2: Scenario C

Untapped hydrocarbon accumulations are indicated during development, for example, through seismic time-lapse monitoring, early water production or exposed shortcomings in the geoscience model. The most important response is to revise one's geological concepts to conform to the realities of production data. This should lead to a refined geological architecture and most probably a more complex one, given that reservoirs become more complex as more data are acquired. It will also lead to a refined initialization of a reservoir simulator. In the light of this refined model, flood front(s) should be monitored with the object of ascertaining their effectiveness.

Application

The above classification scheme is illustrated through its application to some reported case histories from the past 15 years (Table 2).

Exploitation of by-passed pay

There are three overprints, two technical and one commercial. First, new technology in the form of sharper reservoir imaging, both downhole and in the inter-well region, allows insights that were not achievable previously. New production technologies lead to improved wellbore efficiencies. Today, the main technology drivers are the service companies, in contrast to 25 years ago when they were the (now diluted or sometimes even defunct) shared resource teams of the operators. Second, an evolving understanding of how reservoirs work has led to enhanced procedures for maximizing the exploitation of even the most problematic accumulations. These advances include better perceptions of reservoir connectivity and flow units as well as improved insights into how *in-situ* hydrocarbon volumes express themselves at the wellbore. Third, market forces amid global post-peak-production fears are imparting an even greater commercial impetus to the exploitation of by-passed pay. When commodity prices are high, the prize is greater. However, even in an economic downturn, there are opportunities in the form of acquisition targets (Sneider & Sneider 2001).

Identification

The first step is the recognition of by-passed pay. As implied above, this brings together input from sister disciplines that should be viewed conjunctively. The principal thrusts are itemized below:

- reservoir performance vis-à-vis a history-matched simulator;
- material balance studies in the light of estimated ultimate recovery;

Table 2. Type classification of some reported examples of by-passed pay

Investigator(s)	Formation/Field/Province	Type
Sibley & Mastoris (1994)	Eugene Island Block 338 Field, offshore Louisiana, USA	2C

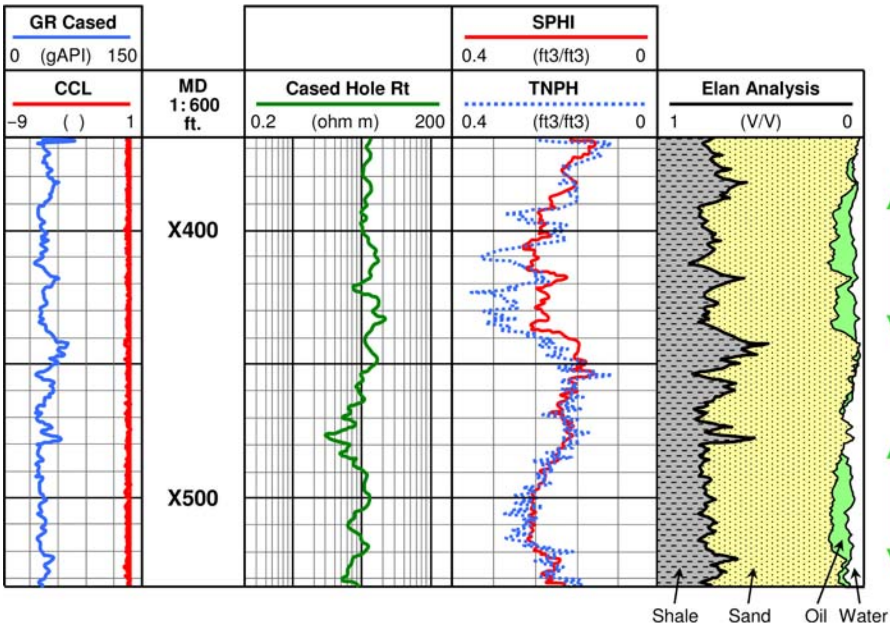

Fig. 1. Delaware Formation, west Permian Basin, USA: intervals previously missed because of large-scale invasion effects on the open-hole resistivity log now appear as by-passed pay when analysed using the deep-sensing cased-hole resistivity log. ELAN, elemental analysis (Schlumberger); GR, gamma ray log; MD, measured depth; Rt, true formation resistivity; SPHI, porosity from sonic log; TNPH, neutron porosity log response (Schlumberger); gAPI, gamma ray units as per American Petroleum Institute standard. (Redrawn from Bartenhagen *et al.* 2001.)

- (interwell) geophysics, principally 3D/4D seismic and electromagnetic imaging;
- improved structural modelling, especially faults and their transmissibilities;
- advanced reservoir characterization techniques, for example, high-resolution geological models, fracture modelling, analysis of reservoir connectivity, flow-unit identification;
- well performance relative to a 3D geoscience model;
- movement of fluid contacts – observed v. predicted;
- time-lapse well logging to expose undepleted intervals;
- re-evaluation of older wells in the light of new understanding to discover previously ‘hidden’ pay;
- retrospective identification of formation damage.

In pulling these matters together, reservoir analogues have an important reference role. Elements of the above have been used by many investigators (e.g. Montgomery 1998; Choon 2007; Von Pattay *et al.* 2007; Hustedt & Snippe 2008; Nishikiori 2008; Tioe *et al.* 2008).

Estimation of Resources

The second step is to estimate the additional Resources through the technical approaches listed above. By-passed pay will initially fall into the class of Contingent Resources (Society of Petroleum Engineers *et al.* 2007). This class refers to remaining hydrocarbon volumes that have been discovered, either directly at a wellbore or by interpolation of producing zones, so that the volumes are known to be present in significant quantities. The admitted volumes must also be recoverable in that the hydrocarbons will flow into a wellbore.

Commerciality

The third step encompasses an economic evaluation. This exercise benefits from the incremental nature of the hydrocarbon accumulations, which allows the evaluation to be more definitive. In general, larger by-passed volumes occur in larger fields: disappointments have usually related to smaller accumulations (e.g. Conner & Blesener 2005). To be classified as Reserves, the recovery must satisfy all the criteria for being classified as Contingent Resources and it must also be commercial, that is, it is not just economic, but there is also a commitment to develop the volumes and there is a plan to do so, for example, through recompletions or sidetrack drilling. Risk and uncertainty are lower, because the project is already advanced and knowledge of the reservoir is more detailed than it was at the time of production start-up.

Case histories

The above principles underpin the following case histories, which have been selected from Table 2.

Type 1: Scenario A

There are numerous cases of Type 1A by-passed pay. One example is the multilayer shallow gas sands of Western Canada, specifically the Medicine Hat Sandstone within southeast Alberta and southwest Saskatchewan, Canada (McConkey & Stromquist 2000).

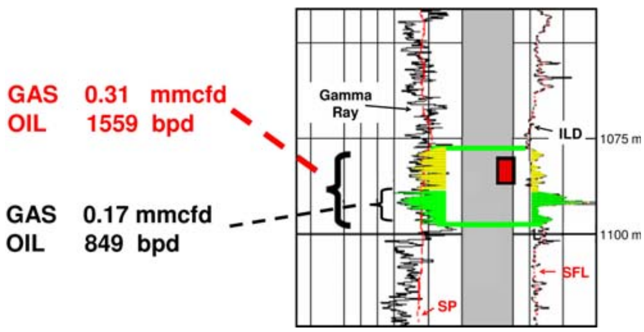

Fig. 2. Macuspana Basin, Gulf of Mexico: exploitation of by-passed hydrocarbons in a (yellow) layered sand/shale sequence leads to a doubling of production from the target zone. SP, self potential log; ILD, deep induction log; SFL, spherically focused log. (Adapted from Gómez *et al.* 2001.)

Of the 21 000 shallow gas wells that have been drilled in this region, many contain gas-bearing intervals that were never completed. The reasons lay in the earlier perceptions of uneconomic gas volumes within zones that were too thin to be completed with conventional limited-entry fracturing technology. As gas prices increased and conventional fracturing could be integrated with coiled tubing and retrievable downhole tool technology, these by-passed gas zones could be accessed economically. A similar situation has been reported in the Bowdoin Field in north-central Montana, USA (Thatcher *et al.* 2003).

Type 1: Scenario B

A Type 1B example of by-passed pay owing to deep invasion comes from the complex Delaware Formation in the western Permian Basin of Texas and New Mexico (Bartenhagen *et al.* 2001). A well drilled with a light water-base mud was completed around 1980. Resistivity logs saw aqueous filtrate and the recorded resistivity was therefore suppressed, so that the interpreted water saturations were excessively high. The original well completion was based on mud log shows and the neutron log together with resistivity logs in an offset well. The well was earmarked for abandonment in 2000. It was re-logged with cased-hole gamma ray (GR), neutron, sonic and resistivity logs. The cased-hole resistivity log is a deep-sensing measurement that sees beyond any remaining invasion: in contrast, the more traditional pulsed-neutron and carbon–oxygen tools have a shallow depth of investigation. The evaluation indicated several oil-bearing zones above the producing interval. Two of these are shown in Figure 1. Preliminary tests indicated that these additional zones would breathe new life into the well. Thus, the cased-hole survey found pay that previously had been hidden by drilling-induced formation damage.

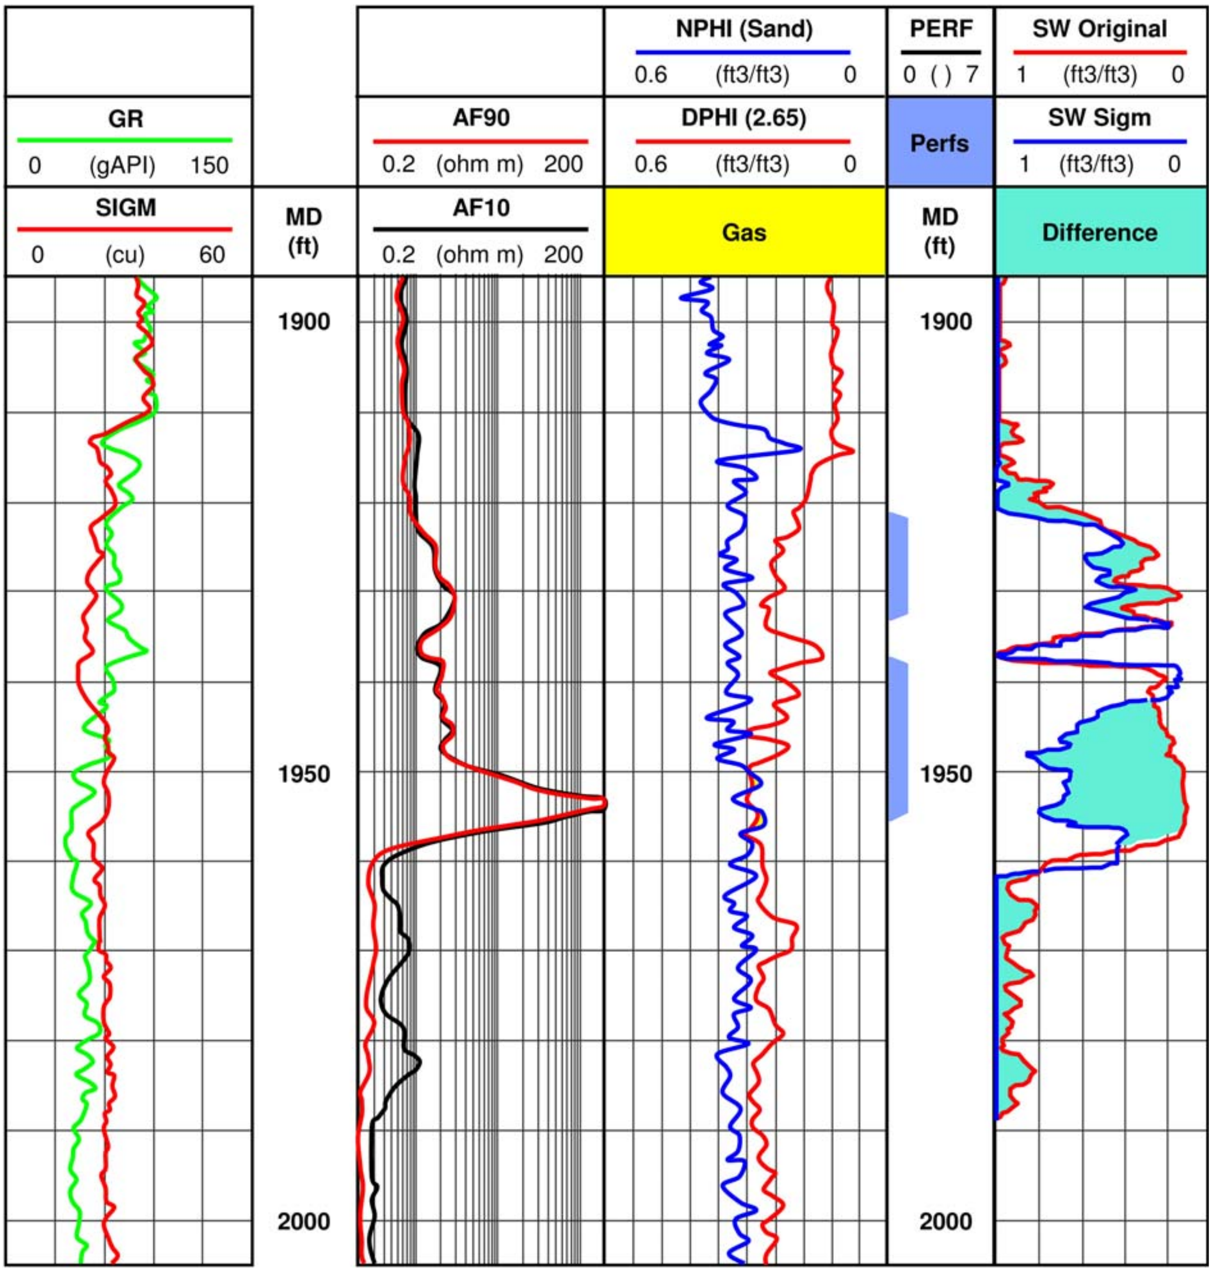

Fig. 3. Offshore Louisiana, USA: water saturation data derived from a (cased-hole) pulsed neutron log and compared with initial data (from open-hole logs) have exposed an unswept interval (around 1930 ft MD) above a swept zone. GR, gamma ray log; gAPI, gamma ray units as per American Petroleum Institute standard; SIGM, neutron capture cross-section; CU, capture units; AF90, array induction (deep) resistivity log (Schlumberger); AF10, array induction (shallow) resistivity log (Schlumberger); NPHI, porosity from neutron log; DPHI, porosity from density log; MD, measured depth; SW, water saturation. (Redrawn from Grant *et al.* 2008.)

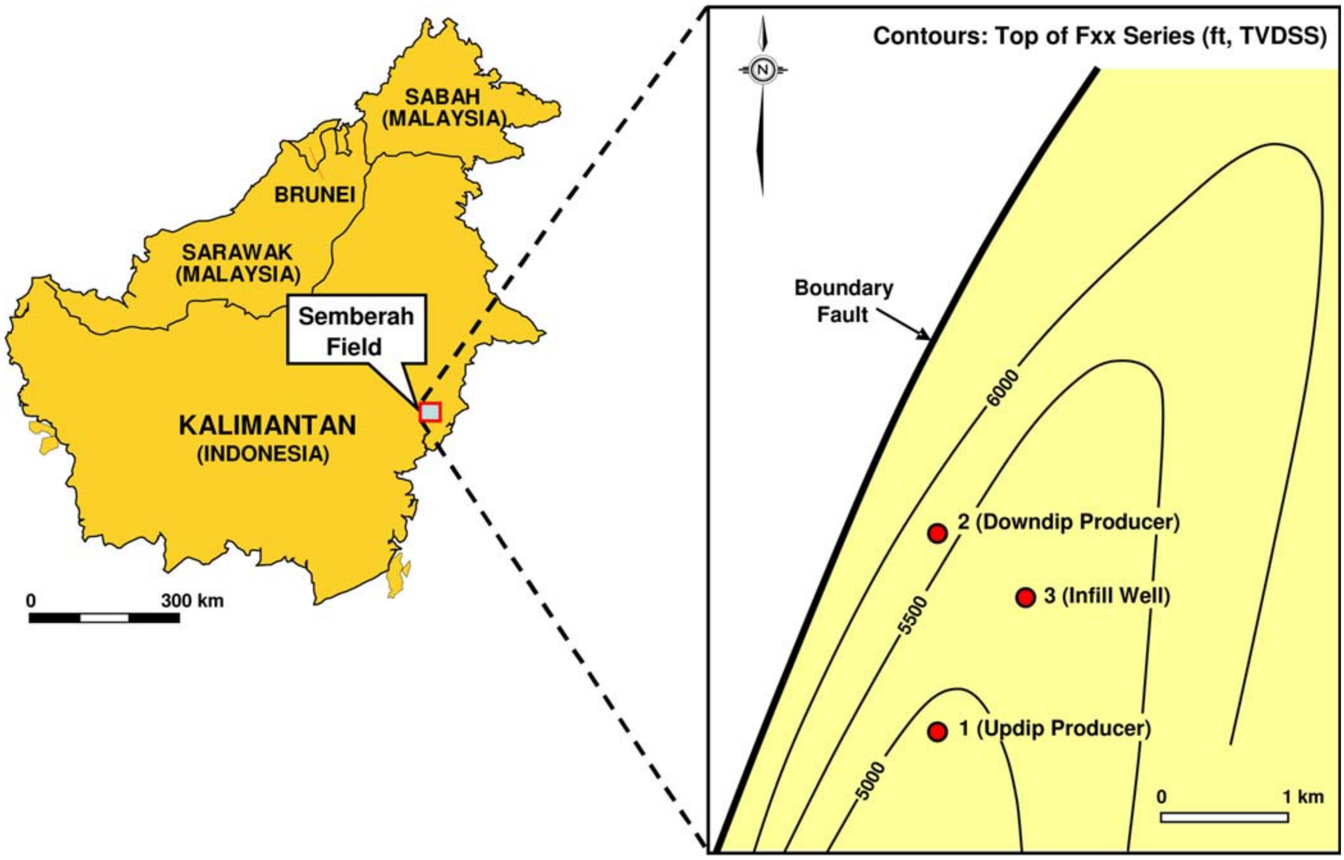

Fig. 4. Semberah Field, East Kalimantan, Indonesia: locations of updip producing Well 1, downdip producing Well 2, and infill Well 3. TVDSS, true vertical depth subsea. (Redrawn from Nikijuluw *et al.* 2005.)

A second example of hidden pay, this time owing to the nature of the rock itself, comes from the Vernet Field, Macuspana Basin, Gulf of Mexico (Gómez *et al.* 2001). The basin has been exploited since the early 1900s. The original interpretations of net pay are being re-visited in the light of contemporary understanding. The laminated sand-shale sequences (yellow in Fig. 2) were previously dismissed as water zones on the basis of a formation resistivity less than 2 Ω m. Yet, when perforated, they contributed to a doubling of production from the target interval.

Suppressed resistivity owing to laminated sand-shale sequences is the biggest cause of missed pay around the wellbore (Worthington 2000). It is a component of the low-resistivity (contrast) pay problem. It is encountered where the thicknesses of the laminations are below the spatial resolutions of conventional logging tools. The laminations act as resistors in parallel so that the average resistivity of the hydrocarbon-bearing sand (high resistivity) and the intraformational shale (low resistivity) is weighted towards the lower value. The best approach is to use key wells from the same geological province to set up an alert flag for the occurrence of laminated reservoirs. The approach draws upon core data and resistivity micro-imaging logs. Once the flag has been activated, well-log analysis should be customized.

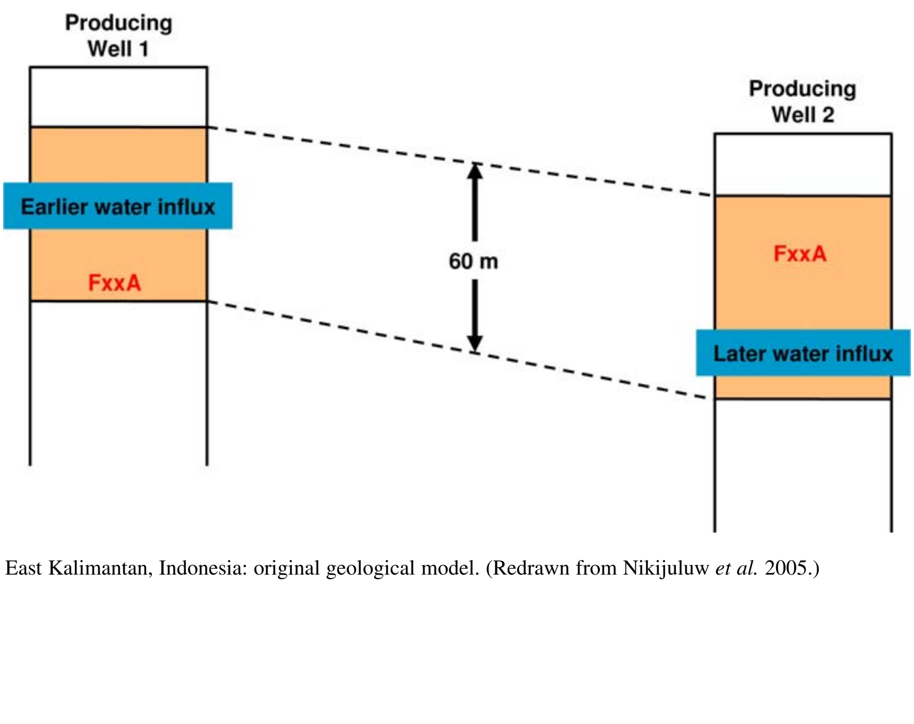

Fig. 5. Semberah Field, East Kalimantan, Indonesia: original geological model. (Redrawn from Nikijuluw *et al.* 2005.)

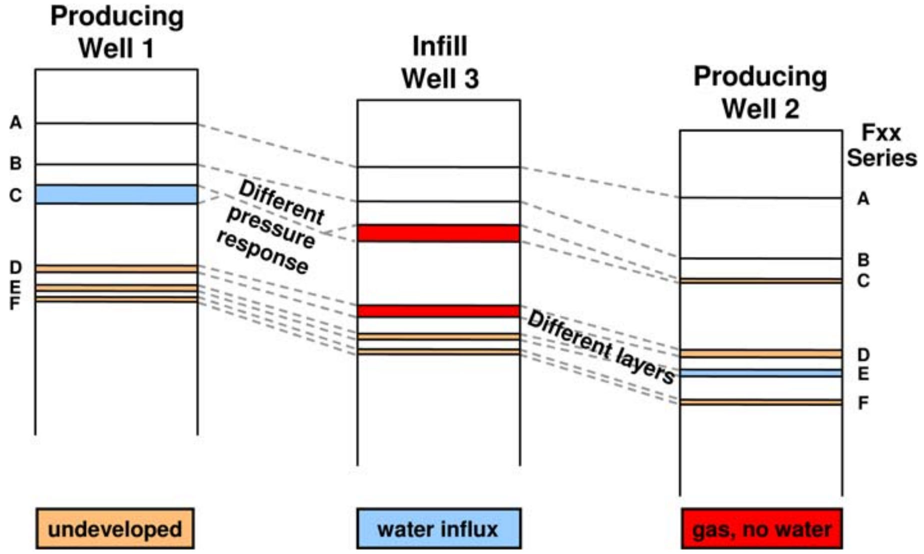

Fig. 6. Semberah Field, East Kalimantan, Indonesia: refined geological model. (Redrawn from Nikijuluw *et al.* 2005.)

These are important messages because the current drive to explore deep-water prospects on passive margins is impacted by the proliferation of turbidites, which invariably present a laminated-sand problem.

Type 1: Scenario C

Figure 3 shows a Type 1C example from an oil and gas field, offshore Louisiana (Grant *et al.* 2008). Pulsed neutron measurements were run through casing so that the neutron capture cross-section (sigma) could be used to infer water saturation (S_w), as a snapshot in time, for comparison with the S_w originally estimated from open-hole logs. Figure 3 shows two perforated intervals. The lower interval is being swept but the upper interval is not and therefore it is a candidate for recompletion to access the by-passed pay.

Type 2: Scenario A

A Type 2A example of an initially oversimplified geological model relates to the Semberah Field, East Kalimantan, Indonesia (Nikijuluw *et al.* 2005). The depositional setting is deltaic with channel/bar sands. The field contains both oil and gas. The geological model turned out to be at variance with water influx. Specifically, the updip producer (Well 1) showed earlier water influx than the downdip producer (Well 2) (Fig. 4). The model was initially that of a single reservoir unit (Fig. 5). This model was perceived to be inadequate. A campaign to locate by-passed pay in gas intervals led to a revised model based on an analysis of log and pressure data that included infill wells (e.g. Well 3, Fig. 4). The revised model comprised six reservoir zones, a distributary channel A and five delta front bars B–F (Fig. 6). It can be seen from Figure 6 that the (early) water influx in producing Well 1 occurred in a different layer from that in producing Well 2. The refined lithostratigraphy exposed undeveloped layers with potential for by-passed gas (Fig. 6).

This case history elucidates two key points. First, production data are the groundtruth for how the reservoir is working and, as such, they take precedence. All other data are spot samples or visualizations. However, note that the interpretation of production data can be ambiguous, for example, where there is comingling. Second, the greatest benefits can be secured through the integrated use of diverse data, in this case reservoir-pressure measurements and well logs within a stratigraphic framework.

Type 2: Scenario B

A Type 2B example of geological re-evaluation is taken from the West Lutong Field, offshore Sarawak (Pauzi *et al.* 1999). Most of

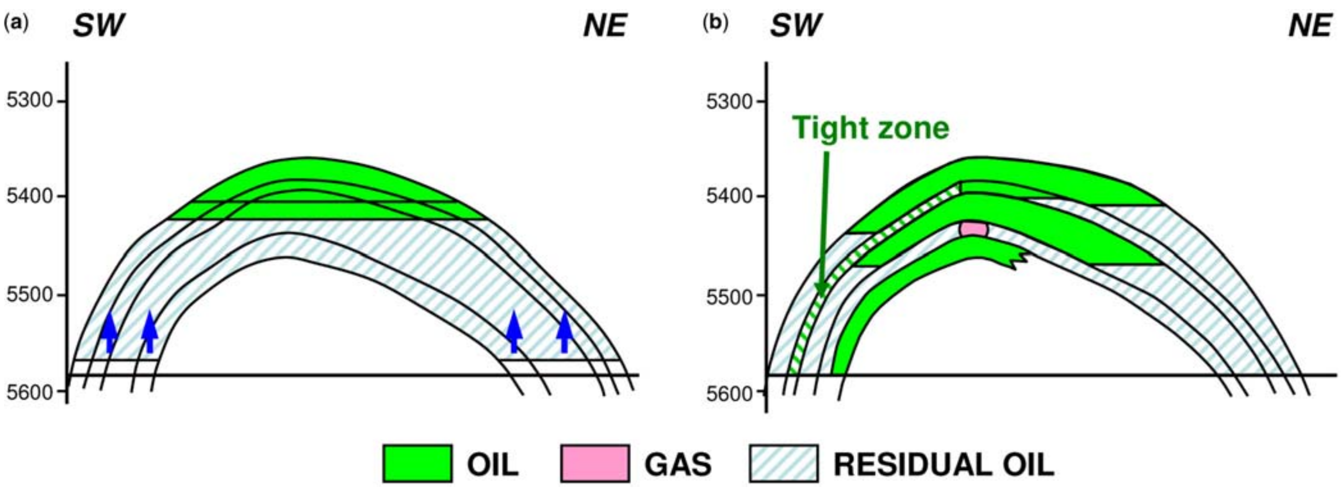

Fig. 7. West Lutong Field, offshore Sarawak, Malaysia: comparison of (**a**) initial and (**b**) reconstructed geological models. Depth units – ft. (After Pauzi *et al.* 1999.)

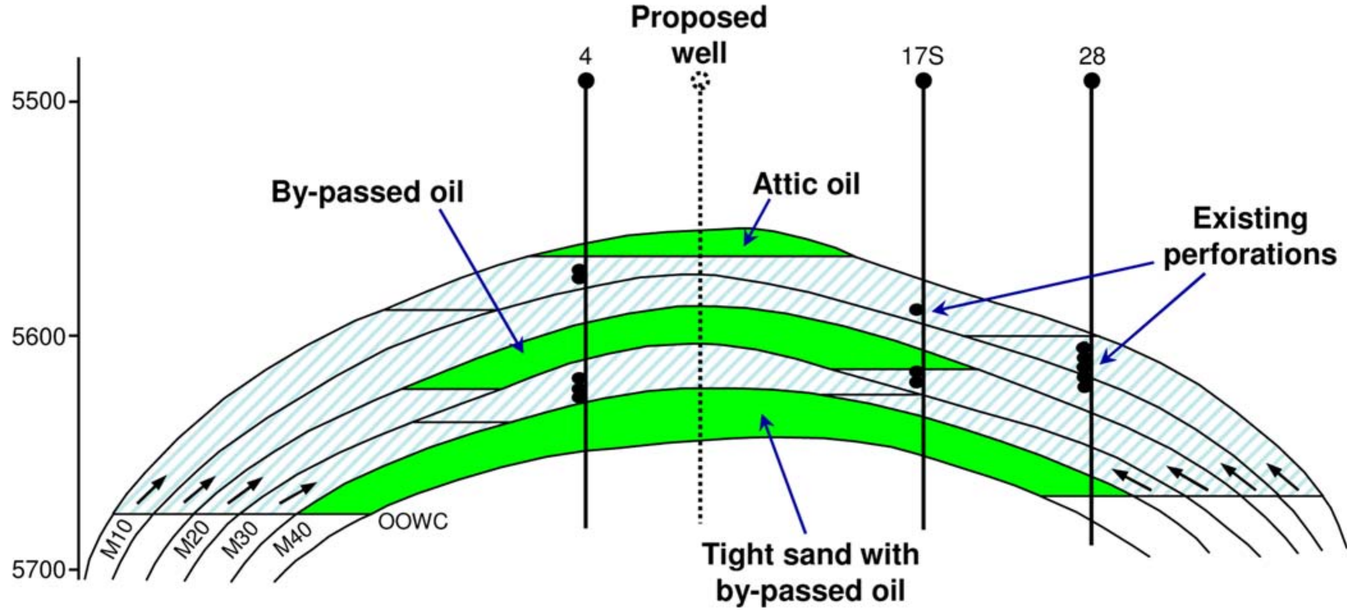

Fig. 8. West Lutong Field, offshore Sarawak, Malaysia: identification of by-passed hydrocarbons in the M-sand through the reconstruction of the field-wide geological model. Depth units – ft. (After Pauzi *et al.* 1999.)

the wells are clustered around the crest. The field was in decline despite several attempted rejuvenations. The original geological model was a homogeneous tank (Fig. 7a). A revised geological model comprised shale-separated sand layers of variable reservoir quality and possibly some inter-layer connectivity (Fig. 7b). The new model revealed opportunities for accessing by-passed pay in its various forms (Fig. 8).

Another Type 2B example with a more commercial emphasis is described in a press release put out by Energy Partners Ltd (EPL) on 31 March 2008. This announced the penetration of by-passed oil by an infill well in the heart of EPL's 100% owned East Bay Field, Gulf of Mexico, which was discovered 'nearly 60 years ago'. The press release alluded to further opportunities in undrilled fault blocks containing 'multiple oil-bearing sands'. It is typical of many others.

Type 2: Scenario C

A Type 2C example comes from the Eugene Island Block 338 oil field, offshore Louisiana (Sibley & Mastoris 1994). The field saw first production in 1972 with a water/pressure drive depletion mechanism. By 1982, production had declined to one-quarter of the peak in 1976 (Fig. 9). In 1988, the field became a candidate for sale during a time of low commodity prices because of its high operating costs. That same year 3D seismic was shot and subsequently interpreted to identify additional development potential. Data analysis revealed that high compressional wave velocity corresponded to high water saturation. This meant that a migrating water front could be resolved seismically provided that the residual oil saturation behind the front was no greater than 20% (Fig. 10). The analysis was supported by the fact that high seismic amplitudes

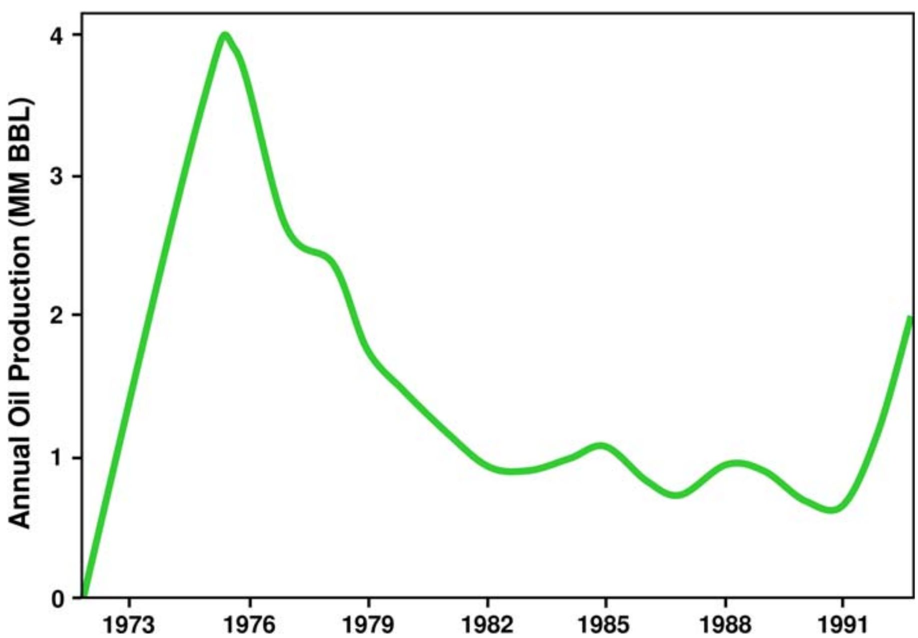

Fig. 9. Eugene Island Block 338 Field, offshore Louisiana: production profile 1972–1992. (Redrawn from Sibley & Mastoris 1994.)

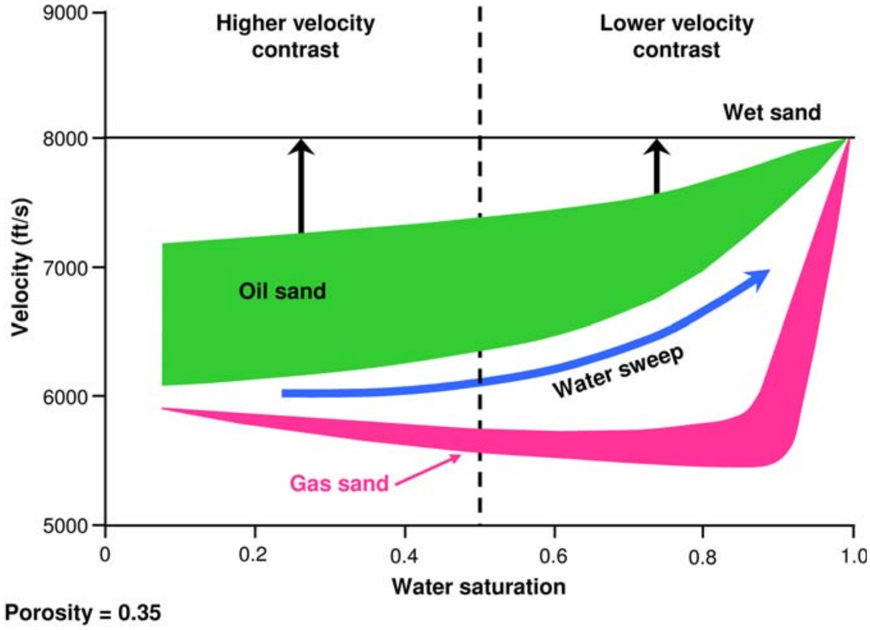

Fig. 10. Eugene Island Block 338 Field, offshore Louisiana: crossplot of seismic velocity and fluid saturation for oil and gas sands. (Redrawn from Sibley & Mastoris 1994.)

corresponded to hydrocarbon accumulations. Thus, unswept zones could be identified and targeted by drilling. The ensuing drilling campaign delivered a high success rate of commercial producers and this doubled field production after one year (Fig. 9).

Conclusions

A classification scheme has been proposed as the basis for a road map for the exploitation of by-passed pay. The recognition of Type 1 and Type 2 by-passed hydrocarbons draws strongly upon (through-casing) well logs and (3D/4D) seismic data, respectively. The exploitation of by-passed hydrocarbons is likely to be more economic for larger fields: reported disappointments usually relate to smaller accumulations. Current trends are directed towards the re-interpretation of existing field databases, cross-hole geophysics, time-lapse seismic with permanent sensors, and advancing the petrophysics of problematic reservoirs. The improvement of poorly performing waterfloods remains a highly pertinent objective. The fruits of these ongoing efforts are evident in contemporary press releases from operators who specifically report the discovery of (hitherto) by-passed hydrocarbons, with corresponding uplifts in reserves.

Tilting oil–water contact in the chalk of Tyra Field as interpreted from capillary pressure data

I. L. FABRICIUS[1] and M. A. RANA[2]

[1]*DTU Environment, Miljoevej 113, DK-2800 Kgs. Lyngby, Denmark (e-mail: ilf@env.dtu.dk)*
[2]*Talisman Energy (UK) Limited, 163 Holburn Street, Aberdeen AB10 6BZ, UK*

Abstract: The Tyra Field in the central North Sea is located in Palaeogene and Upper Cretaceous chalk. It contains a natural gas zone underlain by an oil leg. Based on analysis of logs and core data from ten wells drilled prior to the field being put into production, normalized water saturation depth-trends from logs were compared with normalized water saturation depth-trends predicted from capillary pressure core data. The ten wells lie close to a SW–NE cross section of the field. For the gas–oil contact, a free contact measured in one well corresponds to a practically horizontal contact interpreted from logging data in the remaining wells. A westerly dipping oil–water contact was found from logging data. Comparison of the depth-wise trends in normalized water saturation among the different wells indicates a regional pattern: in the western side of the field, the trends correspond to a situation of imbibition, where the free water level overlies an interval of residual oil, whereas in the eastern part of the field, the depth-wise trends in normalized water saturation correspond to a situation of drainage. The free water level apparently dips to the east due either to hydrodynamic action or to pressure inequilibrium in the aquifer following tectonic tilting.

Keywords: chalk, North Sea, capillary pressure, water saturation, fluid contacts

In the central North Sea, the Palaeogene and Upper Cretaceous Chalk Formations host accumulations of natural gas and oil (Andersen 1995). Several chalk fields had already been discovered by 1980, and in many cases operators of the fields found that oil–water contact (OWC) and free water level (FWL) tilt, and in some cases also the gas–oil contact (GOC) (Jacobsen *et al.* 1999). Figure 1 shows a cross section through a field with a horizontal GOC, a tilting OWC, and a tilting FWL. The presence of tilting contacts is a challenge in field delineation and in reservoir engineering. It also causes debate about the origin of the tilt. Regional subsidence or local tectonic action may cause lateral gradients in fluid pressure, which can cause tilt of the fluid contacts. Vejbæk *et al.* (2005) list three scenarios:

- Pressure equilibrium in hydrocarbon phases causes horizontal GOC, whereas a lateral pressure gradient in the water leg causes the FWL to dip in the direction of declining lateral pressure.
- Lateral pressure gradients in the same direction in hydrocarbon zone and in the water leg cause both GOC and FWL to dip in the same direction.
- Pressure equilibrium resides in the water leg, whereas a lateral pressure gradient in the oil zone alone causes GOC and FWL to tilt in opposing directions: GOC tilts in the direction of declining oil zone pressure, while FWL tilts in the direction of increasing oil zone pressure.

The question of interpreting fluid contacts is complicated by the high capillarity of the chalk, which causes free fluid contacts to differ from fluid contacts in the rock pores so that OWC differs from FWL (Figs 1 & 2; Engstrøm 1995). In the case of hydrocarbons flowing into the rock matrix from fractures, the drainage process may require an entry pressure, so that OWC is above the FWL. In the case of hydrocarbons seeping out of the seal at a higher rate than hydrocarbons entering the structure, the water imbibition process may cause OWC to be deeper than FWL. The present paper addresses FWL and fluid contacts in the chalk of the Tyra Field.

Tyra Field

The Tyra Field is a low-relief structure in the North Sea Central Graben (Fig. 3). It is situated in the Palaeogene and Upper Cretaceous Chalk Group (Fig. 4). It contains gas underlain by a rim of oil. Chalk porosity varies stratigraphically and regionally from 20 to 45%. Gas permeability also varies and is up to 20 mD. Natural fracturing is sparse. Core and logging data indicate that the OWC is not horizontal, but rather is relatively shallow in the northeastern part of the field, while it is relatively deep in the southwestern part of the field (Doyle & Conlin 1990; Nykjaer 1994).

Chalk is primarily composed of calcitic biogenic mud representing nannofossil remains. The mud is partly recrystallized through interaction with the pore water, so that the single mud particles tend to have surfaces representing calcitic rhombohedra. It also contains sand-size microfossils, which may be filled with calcitic cement or locally with silica cement. The Palaeogene chalk constitutes the Ekofisk Formation, which in addition to calcitic fossil remains contains clay and a relatively high and variable amount of microcrystalline quartz. The latter largely represents diagenetically mobilized biogenic opal as evidenced by the presence of

moulds after opaline fossils (Fig. 5a, Røgen & Fabricius 2002). Porosity in the Ekofisk Formation varies stratigraphically as a reflection of varying content of microfossils and microcrystalline quartz (Fig. 4). The Upper Cretaceous chalk is split into several formations. The uppermost, Tor Formation, is almost purely calcitic (Fig. 5b) and the porosity varies locally as a consequence of varying content of calcite-cemented microfossils. These local porosity variations scatter an overall depth-wise porosity decrease due to pore-filling cementation (Fig. 4; Fabricius *et al.* 2007). Because of the high and variable content of microcrystalline quartz, the chalk of Ekofisk Formation has higher and more variable specific surface than the chalk of the Tor Formation, and consequently, for a given porosity, chalk from Ekofisk Formation will have lower and less predictable permeability than chalk from Tor Formation (Mortensen *et al.* 1998; Røgen & Fabricius 2002).

Analysis of log- and core data

In order to evaluate how the tilting OWC relates to the FWL, we used conventional core analysis data, logging data, as well as data from Hg capillary pressure experiments including drainage as well as imbibition curves (Fig. 6). Data from ten wells (Table 1) were used in the study, including one well (TEB-8) where wireline formation tester data are available. TEB-8 is

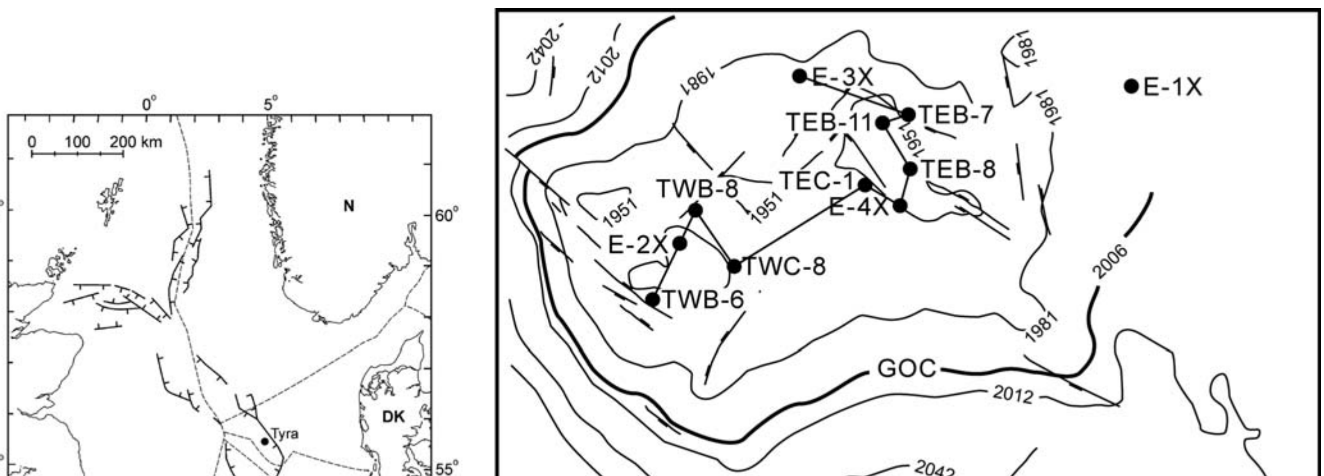

Fig. 3. Depth structure map of Tyra Field, modified after Halberg (2008). Interpreted GOC is shown. The original contour values in feet have been recalculated to metres.

located in the eastern part of the field. The ten wells comprise all wells drilled before the field was put into production in 1984 (Tables 1 & 2). The old exploration wells (E-2X, E-3X and E-4X) were drilled with water-based mud, whereas the remaining studied wells were drilled with oil-based mud. All wells were cored and conventional core analysis data are available. Top chalk, which is also the top of the gas zone, is accompanied by a distinct drop in natural gamma radiation, but it is also easy to define from the crossover of the neutron and density logs at the transition from shale to gas-bearing chalk (Fig. 4). In an interval with relatively low porosity in the Ekofisk Formation, the gas effect is small. The resistivity in this interval is also relatively small (Fig. 4). This indicates a high water saturation, probably due to high specific surface (i.e. 'small pore size') in the presumed water-wet chalk. The GOC is not always easy to define in intervals of high water saturation where the neutron-density gas effect is low. In some wells GOC interferes with the low-porosity interval in the Ekofisk Formation. In other wells the depth-wise increase in water-saturation in the transition zone causes low gas effect. The chosen GOC of 2006 m TVD msl is the value derived from the wireline formation tester data. This value is not in contradiction with the deeper limit of the neutron-density effect in any of the studied wells, bearing in mind that the error on depth determination from wirelines is probably larger than 1 per mil. The uncertainty also implies that a minor regional tilt in GOC cannot be excluded.

The OWC in each well was preliminarily picked from the resistivity log. Data from nine of the studied wells indicate practically the same reservoir temperature, but TWB-8 data indicate an anomalously high temperature (Table 2). The density of gas at reservoir conditions was derived from the pressure–depth gradient of the wireline formation tester data (Table 2). The density of the oil is less easy to define because of sparse wireline formation tester data points, but the noticeable hydrocarbon effect below the gas zone indicates relatively light oil (Fig. 4, Table 2).

The calculated water saturation from wireline logs depends on the interpreted water resistivity. If the water resistivity is calculated by Archie's method from the water leg in each well independently, we find apparent water resistivity to be relatively high in well TWB-8 in the western part of the field, where the OWC is low and difficult to define. This is not caused by a relatively high temperature in TWB-8, as this would rather cause a relatively low water resistivity for a given salinity. In our interpretation we for simplicity assume constant low water resistivity as derived from the remaining wells (Table 2). The water resistivity corresponds to a salinity of 35 700 ppm, which was used for calculating water density at reservoir pressure and temperature using Batzle and Wangs relations as cited in Mavko *et al.* (1998). This water density, ρ_w is consistent with wire-line formation tester data. The density of water-based mud filtrate, ρ_{mf}, was calculated by the same method from mud filtrate resistivity, R_{mf}.

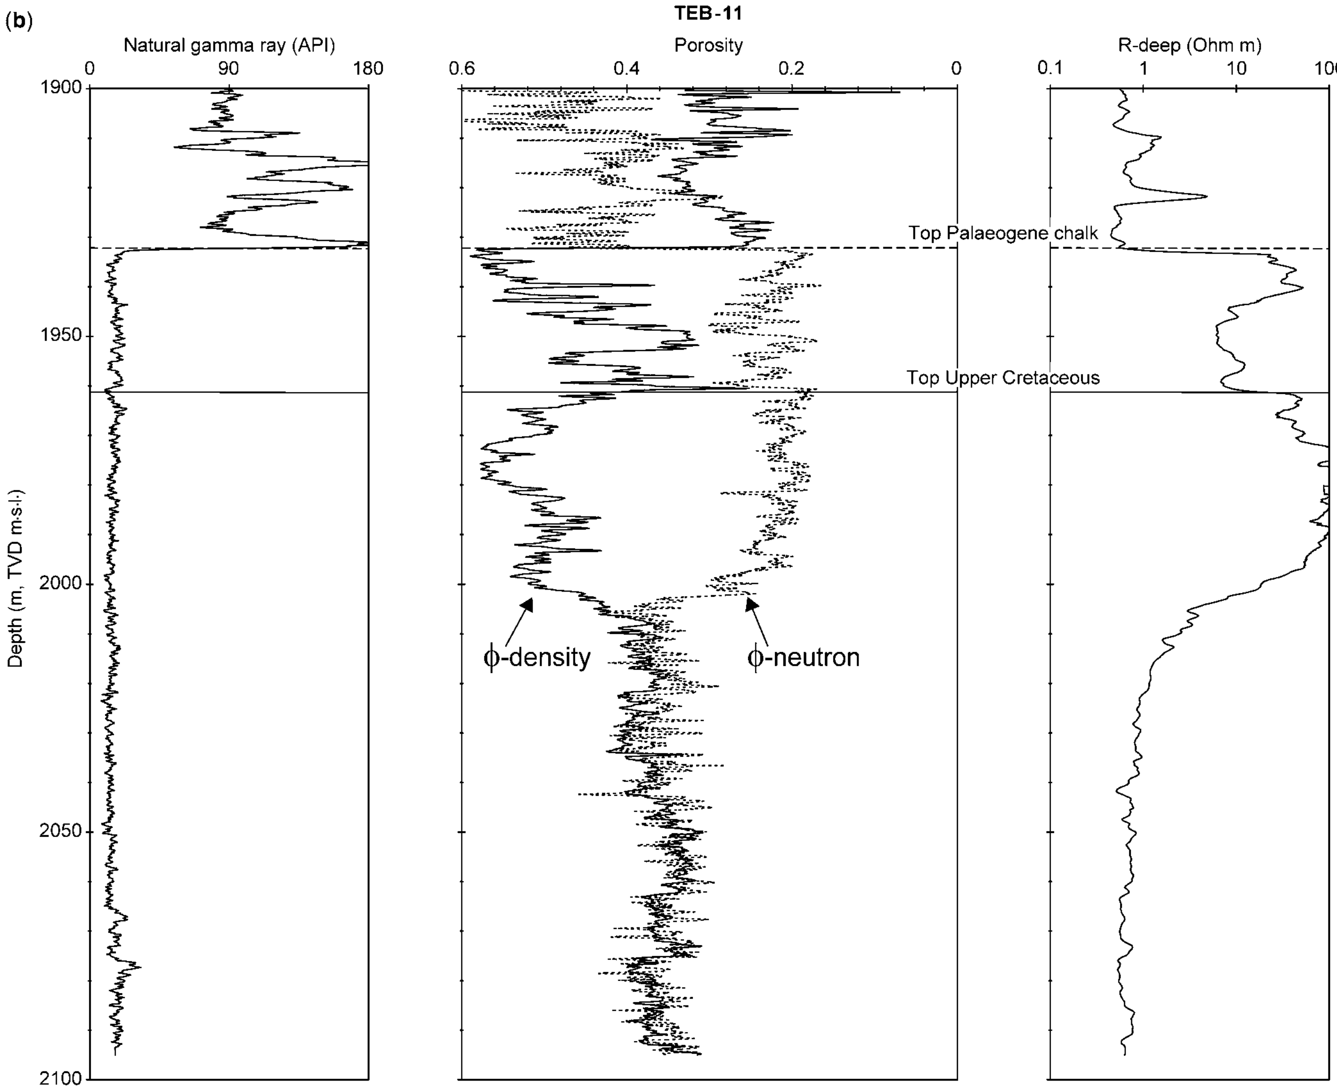

Fig. 4.

Porosity, ϕ, was calculated from bulk density, ρ_b and the shallowest resistivity log, R_{xo} in each well as checked by core porosity. In wells with water-based mud the resulting porosity log was matched to available core data by iteration, involving adjusting the resistivity R_{mfx} of mixed formation water and mud filtrate:

$$\rho_b = \rho_{calcite}(1-\phi) + \rho_{mfx}S_{xo}\phi + \rho_{hc}(1-S_{xo})\phi \tag{1}$$

$$S_{xo}^n = \frac{R_{mfx}}{(R_{xo}\phi^m)} \tag{2}$$

where $\rho_{calcite}$ is the density of calcite and ρ_{hc} is the density of either gas or oil depending on reservoir interval.

In wells drilled with oil-based mud, the resulting porosity log was fitted to available core data by iteration involving selection of a suitably high ρ_{hc} in the invaded zone, where the heavy mud filtrate is mixed with the formation hydrocarbons, and solving for bulk density and water saturation in the invaded zone, S_{xo}:

$$\rho_b = \rho_{calcite}(1-\phi) + \rho_w S_{xo}\phi + \rho_{hc}(1-S_{xo})\phi \tag{3}$$

$$S_{xo}^n = \frac{R_w}{(R_{xo}\phi^m)}. \tag{4}$$

Subsequently water saturation, S_w, was in both cases calculated from porosity and deep resistivity, R_t:

$$S_w^n = \frac{R_w}{(R_t\phi^m)}. \tag{5}$$

The cementation factor m was for simplicity assumed to be 2, although the higher specific surface of Ekofisk Formation would imply a slightly higher m (Olsen *et al.* 2008). The saturation exponent, n, was for simplicity assumed to be equal to m and thus set to 2. According to Van DeVerg *et al.* (1999), this is a sensible value for n where S_w is a result of imbibition; whereas when S_w is a result of drainage, they obtained values of n as low as 1.6. If the water saturation in a well is indeed a result of drainage rather than imbibition, the choice of $n = 2$ rather than $n = 1.6$ will cause too high water saturation, but will not influence the location of OWC. When comparing the resulting S_{xo} and S_w, in accordance with the procedure, we find that in wells drilled with water-based mud $S_w < S_{xo}$ in the upper part of the reservoir, whereas S_w and S_{xo} are similar in the transition zone. In wells drilled with oil-based mud we find S_w and S_{xo} to be similar in the upper part of the reservoir and $S_{xo} < S_w$ in the transition zone.

Direct comparison of OWC and FWL is only possible in TEB-8, where wireline formation tester data are available. In principle, in a homogeneous water-wet reservoir, the shape of

the water-saturation–depth curve should correspond directly to a capillary pressure curve. The Tyra Field is not homogeneous: porosity and specific surface vary stratigraphically. In order to overcome this problem, all water saturation data were normalized to the specific surface of pores, and expressed as pseudo water film thickness (PWFT, Larsen & Fabricius 2004). The specific surface of pores, S_p was estimated from conventional core analysis data on porosity and permeability, k, by use of Kozeny's equation:

$$k = c\frac{\phi^3}{S^2} = c\frac{\phi^3}{[(1-\phi)S_g]^2} = c\frac{\phi}{S_p^2} \tag{6}$$

where S is specific surface with respect to bulk volume, S_g is specific surface of solids and c, according to Mortensen *et al.* (1998), is a function of porosity which may be expressed by:

$$c = \left(4\cos\left(\frac{1}{3}\arccos\left(\phi\frac{8^2}{\pi^3}-1\right)+\frac{4}{3}\pi\right)+4\right)^{-1}. \tag{7}$$

Klinkenberg permeability, k, was estimated from air permeability by the empirical relation for chalk (Mortensen *et al.* 1998):

$$\begin{aligned} k &= 0.52k_a^{1.083} \quad (\text{where } k \text{ and } k_a \text{ are given in mD) or} \\ k &= 9.15k_a^{1.083} \quad (\text{where } k \text{ and } k_a \text{ are given in m}^2). \end{aligned} \tag{8}$$

From core analysis data we find a relatively constant S_g for each of the Formations, Ekofisk and Tor, although data from Ekofisk Formation scatter more than data from Tor Formation (Table 2, Fig. 7). $S_p = S_g\,(1-\phi)/\phi$ may then be calculated from the porosity log and PWFT calculated from:

$$\text{PWFT} = \frac{S_w}{S_p}. \tag{9}$$

Special core analysis data on air–mercury capillary pressure, P_c, for a number of core samples from Ekofisk and Tor formations were recalculated to PWFT v. height over FWL for the gas–water

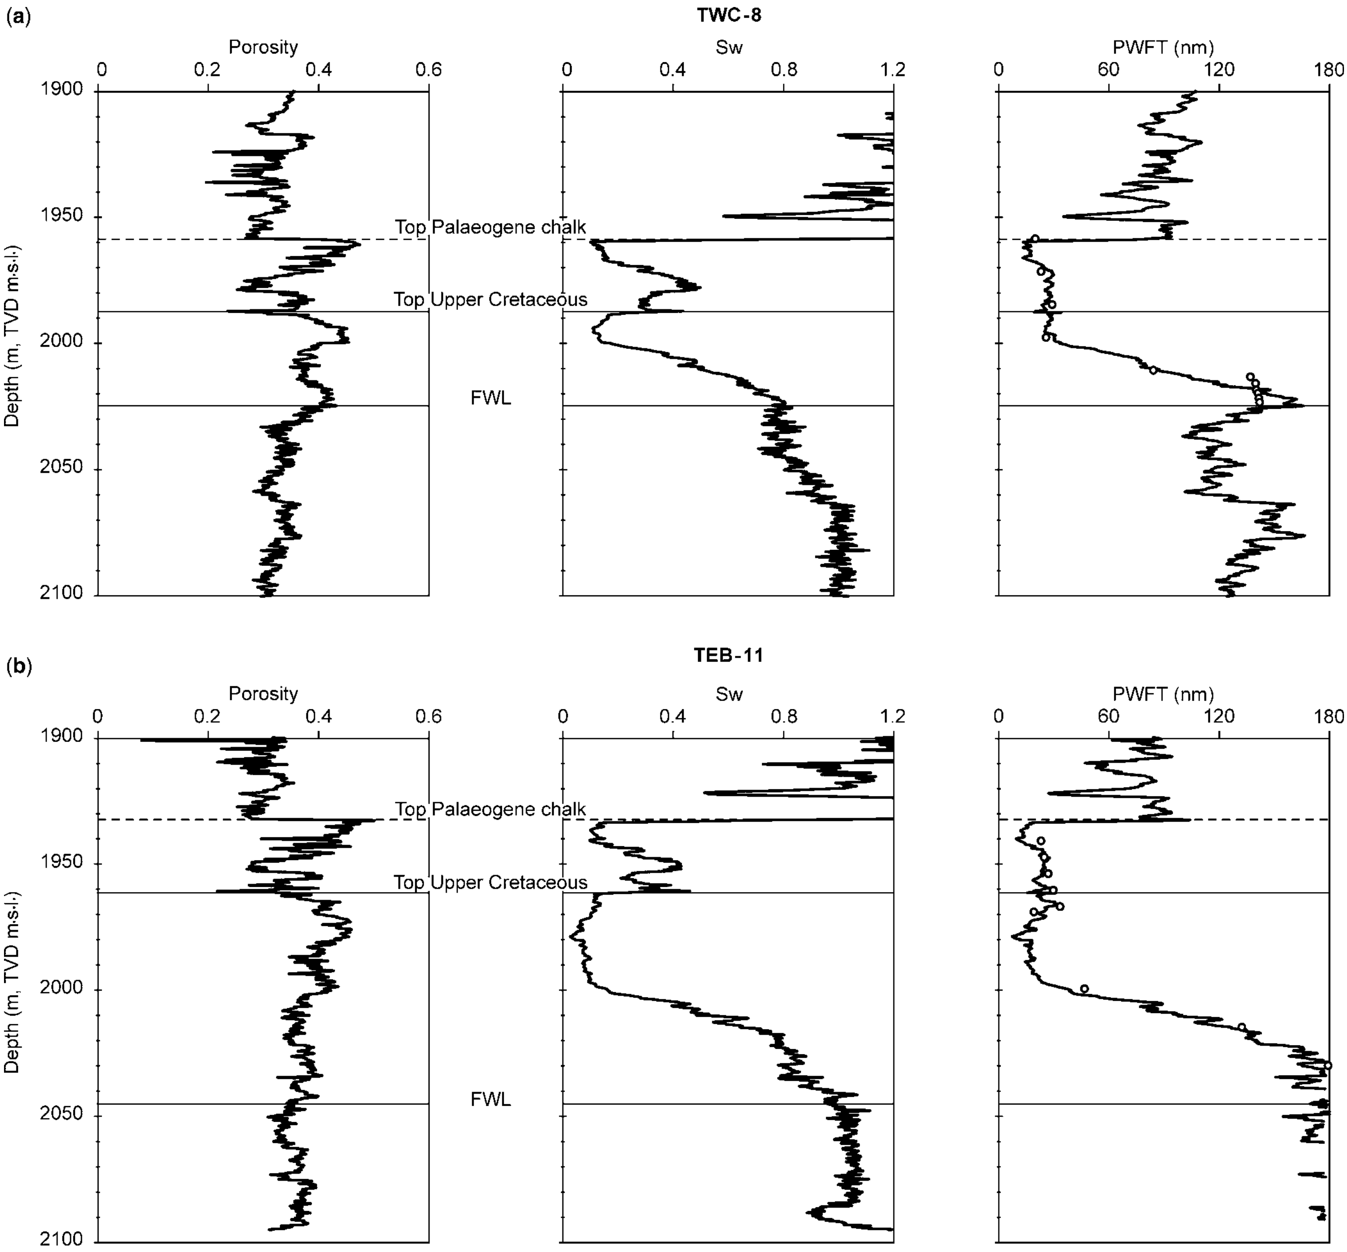

Fig. 8. Porosity, water saturation (S_w) and PWFT as calculated from logging data and core data. (**a**) Well TWC-8. system (Figs 6 & 8) and for the oil–water system using the Leverett J-function:

$$J(S_{we}) = \frac{P_c(S_{we})\sqrt{k/\phi}}{\sigma \cos\,\theta} \quad (10)$$

where S_{we} is the wetting phase saturation, σ is surface tension and θ is the contact angle. For the air–mercury system $\sigma \cos\theta = 372$ dyn/cm was chosen, for the water–oil system at reservoir conditions, $\sigma \cos\theta = 26$ dyn/cm was chosen, and for the water–gas system at reservoir conditions, $\sigma \cos\theta = 50$ dyn/cm was chosen.

Capillary pressure, P_c was recalculated to depth, D by:

$$P_c = (\mathrm{D} - \mathrm{FWL})g\rho_w - (\mathrm{D} - \mathrm{FWL})g\rho_{hc} \quad (11)$$

where g is the acceleration of gravity (in latitude of Tyra Field: 9.82 m s^{-2}) and ρ_{hc} is the density of gas in the gas zone and the density of oil in the oil zone. We thus assume the chalk to be water-wet and assume no capillary action between gas and oil. FWL for the gas and the oil zone was in the present case estimated to differ by less than a metre. From porosity and permeability, S_p was calculated from equations (6)–(8) and PWFT was calculated from equation (9).

Results

The depth trends of porosity, water saturation and PWFT vary among the studied wells along a roughly SW–NE trend (Figs 3 & 9). The two westernmost wells, TWB-6 and E-2X, are characterized by a relatively thin Ekofisk Formation, a relatively deep OWC, and shallower FWL. The PWFT-depth trends correspond to an imbibition curve with FWL at a depth of 2025 − 31 m, TVD m.s.l. (Table 1). The difference in mud type (water-based in E-2X and oil-based in TWB-6) does not seem to influence results. The next two wells, TWB-8 and TWC-8, have a thicker Ekofisk Formation and, based on the concept of imbibition, a FWL of 2023 m, TVD m.s.l. was found. OWC is deep although for TWC-8 not as deep as in the westernmost wells. For TWB-8, OWC is ambiguous. It may be below total depth or around the same level as in TWC-8 depending on the choice of pore water salinity in the water saturation calculation (Table 1). TEC-1 and E-4X are located further to the east (Figs 3 & 9). The Ekofisk Formation is relatively thick in these wells and OWC is relatively deep, so a drainage interpretation of the PWFT trend would require FWL to be slightly above OWC, and an imbibition interpretation may thus be more likely. This indicates an FWL of 2021–2024 m, TVD msl (Fig. 9, Table 1). TEB-8 and TEB-11 are located near the crest of the structure and hold thick gas columns (Figs 3 & 9). The hydrocarbon-bearing interval is relatively porous, and this may explain why FWL according to a drainage model falls close to the OWC (Fig. 9, Table 1). TEB-7 and E-3X are located where the structure is relatively deep and the hydrocarbon column relatively thin (Figs 3 & 9). The overall porosity in the hydrocarbon-bearing interval is lower than in the other wells. OWC is relatively shallow and distinctly shallower than the FWL, which according to the PWFT–depth trends represents a situation of drainage (Fig. 9, Table 1).

Discussion

The OWC of Tyra Field apparently dips to the SW whereas, from the studied wells, no significant tilt was observed on the GOC. This could be interpreted as a scenario of pressure equilibrium within and between the hydrocarbon phases, and towards the SW a declining pressure in the water phase. When taking into account the interpreted FWL, which dips to the NE, we rather expect a pressure declining towards the NE in the water phase. Apparently the OWC is then dipping in one direction and the FWL in another direction (Figs 1 & 9). At the same time hydrocarbons in the westerly wells seem to have been leaving the structure while water has been imbibed, whereas in the northeasternmost wells, hydrocarbons seem to have been entering the structure while water has drained out.

A way to account for the lateral pressure gradient in the water phase could be hydrodynamic action caused by easterly flow in the aquifer (Megson 1992). A situation of pressure compartments in the aquifer is also possible (Caillet *et al.* 1997), or rather a gradient in pore pressure caused by tilting of chalk with low lateral permeability in the aquifer. A simplified sequence of events could be: a structure at top chalk level forms; hydrocarbons are generated in a deeper source rock and migrate into the structure; in the underlying aquifer and the capillary transition zone porosity and permeability decrease due to partial cementation; the structure tilts to the SW; hydrocarbons consequently move to the NE leaving a residual oil leg in the SW; in the vertical direction pressure equilibrates between water and hydrocarbon phase; in the less permeable underlying aquifer pressure is not yet equilibrated, so that a lateral pressure gradient persists. The difference in perceived FWL in the northeastern and southwestern parts of the field corresponds to a minimum tectonic tilt corresponding to around 25 m in a vertical direction (Table 1).

Conclusions

Water saturation–depth trends through chalk of varying porosity and permeability may be related to capillary pressure curves when water saturations on log or capillary curves are normalized to PWFT on the pore walls. This procedure was applied to ten wells in the Tyra Field, and it indicates that water saturation in the easternmost part of the field matches a drainage capillary pressure curve, where the FWL corresponds to that derived from wireline formation testing. By contrast, in the western side of the field the water saturation matches an imbibition capillary pressure curve. These results would indicate that the Tyra structure has tilted to the west subsequent to the introduction of hydrocarbons, so that at the time just prior to production, hydrocarbons had been filling into the eastern part of the field, while hydrocarbons had been leaving the western side of the field.

A holostratigraphic approach to the chalk of the North Sea Eldfisk Field, Norway

M. J. HAMPTON,[1] H. W. BAILEY[1] and A. D. JONES[2]

[1]*Network Stratigraphic Consulting Ltd, Harvest House, Cranborne Road, Potters Bar, Herts, UK (e-mail: mj.hampton@btconnect.com)*
[2]*ConocoPhillips Norway, Postbox 3, 4064 Stavanger, Norway*

Abstract: A biostratigraphic review, conducted on 34 wells from the chalk of the Eldfisk Field, Norwegian Central Graben, has been integrated with petrophysical, geophysical and sedimentological information resulting in a revised lithostratigraphic framework for the chalk on this structure. Chalk of Danian to Turonian age is divided into five formations: the established Ekofisk Formation of Danian age and Tor Formation of Maastrichtian age, together with a new three-fold division of the Hod Formation, namely the Magne Formation of Campanian age, the Thud Formation of Santonian age and Narve Formation of Coniacian to Turonian age. This work demonstrates the application of this three-fold division of the Hod Formation. Internal field specific subdivisions of all formations are also presented for the Eldfisk Field. This lithostratigraphic framework is applied across the Eldfisk Field, together with the recognition of erosional features, unconformities, areas of non-deposition, reworking and lateral changes in biofacies. The results have also allowed recognition of the following regionally synchronous tectonic phases for the first time on a Norwegian chalk structure: Stille's Ilsede phase (Late Turonian–Coniacian) and Wernigerode phase (Late Santonian–'earliest' Campanian), Mittel–Santon phase (Middle Santonian) of Niebuhr *et al.* and Reidel's Peine phase ('latest' Early Campanian), together with un-named phases of 'latest' Campanian, intra Mid Maastrichtian and (previously unrecognized?) intra Danian age. Evidence for these tectonic phases is compared with work from Denmark, Germany and the Anglo-Paris Basin. An innovative approach to mapping lateral biofacies (principally water depth) variations has been applied using the microfaunal database. This enhances understanding of the timing of structural phases when integrated with time lines generated by nanoplankton data. Biofacies proxies for silica content in the sediment may also correlate with changes in reservoir quality. Biofacies interpretations have also facilitated the identification and mapping of allochthonous bioclastic rich debris flow deposits. The fully calibrated biostratigraphic, lithostratigraphic and tectonostratigraphic frameworks presented can be applied to chalk structures regionally.

Keywords: Eldfisk Field, chalk, North Sea, holostratigraphy, biostratigraphy

The Eldfisk Field, located in Block 2/7 in the Norwegian Sector of the North Sea (Fig. 1), has a total estimated in place volume of *c.* 3.0 BBoe (Brasher 1995). Production began in 1979 through a depletion drive mechanism and in 2001 a water injection programme was introduced to improve recovery. Compaction has led to well casing deformation problems and the need to constantly renew wells. Approximately 75 vertical wells were drilled during early field development; a subset of which provide the main stratigraphic input to this study. Since the mid 1990s over 50 geosteered horizontal wells have been drilled and it is likely that the any future drilling will be mainly horizontal in design.

The field, located on an inversion high called the Lindesnes Ridge in the Central Graben, consists of two domal structures (Alpha and Bravo) and a smaller low relief structure known as East Eldfisk. The Central Graben was tectonically active during chalk deposition, characterized by a complex and dynamic interplay between graben subsidence along major bounding faults, inversion and halokinetic tectonics. The chalk basinal areas surrounding Eldfisk exhibit chalk thicknesses of >2500 ft, whilst over the Eldfisk structure the chalk thins in places to *c.* 700 ft due to the interaction of erosion, unconformities, gravity flow deposition and structural history. This geological complexity, combined with the extremely poor seismic quality over the field due to shallow gas, means reservoir modelling is problematic. Detailed discussion on the tectonic history of Eldfisk can be found in Brewster & Dangerfield (1984), D'Heur (1984), Herrington *et al.* (1987), Michaud (1987) and Brasher (1995); a more regional summary can be found in Bramwell *et al.* (1999).

This holostratigraphic study was designed to improve the understanding of chalk deposition, stratigraphy, facies distribution and to link this to the tectonic history of the structure. All available geological data, including biostratigraphy, petrophysics, geophysics and lithofacies have been used to derive the study results.

Stratigraphic background

The lithostratigraphic nomenclature conventionally applied to Central Graben chalks, namely the Ekofisk, Tor, Hod and Hidra Formations, was initially published by Deegan & Scull (1977) and later updated by Isaksen & Tonstad (1989). A breakdown of Danish chalks has been published by Lieberkind *et al.* (1982) and in the UK by Johnson & Lott (1993). To integrate the wide variety of internal, informal chalk sub-divisions that were used by various operating companies, the Joint Chalk Research (JCR) project, Phase V, Fritsen (1999) was commissioned. This established a common stratigraphic nomenclature for the chalk in the Central Graben and divided the Hod Formation into the Magne, Thud and Narve Formations (Fig. 2). These formations are herein tied to a series of regionally synchronous tectonic phases recognized through the Late Cretaceous succession which can be geophysically mapped. Many of these events have been identified across NW Europe and the wider geographical implications of these events have been described by Mortimore & Pomerol (1997), Mortimore *et al.* (1998) and Niebuhr *et al.* (2000). These events were initially described by Stille (1924) and Reidel (1940, 1942) from the German Hartz Mountain region. Vejbaek & Andersen (2002) also recognized potentially synchronous regional phases of inversion from the Danish sector of the North Sea. Early Campanian to Maastrichtian inversion tectonics have also been described from Belgium, Netherlands and Germany by Bless *et al.* (1986).

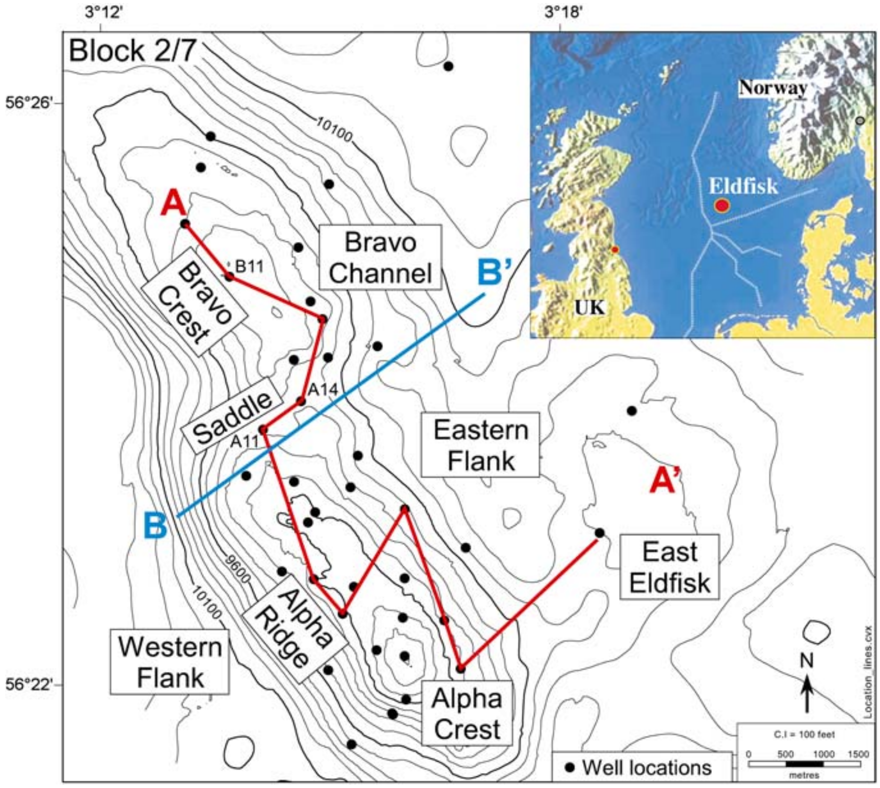

Fig. 1. Eldfisk Field location map (inset) and top Ekofisk Formation depth map (block 2/7). Map also shows wells used in the study and line of section A–A′ for Figure 4 and seismic line B–B′ in Figure 8. Informal geographical names used in the text are presented here.

Study objectives

Following a review of recent drilling activities and whilst planning for future development of the Eldfisk Field, it became apparent that the vast biostratigraphical database, gathered over 30 years of drilling, could be further integrated to improve the understanding of the field. Vertical wells hold a wealth of detailed stratigraphic information, are spread geographically across the field and are particularly well suited for the creation of 3D geological and reservoir models; however, many of these early wells were not analysed for biostratigraphy or were analysed approximately 30 years ago for microfauna only. As taxonomic concepts and biostratigraphic methods have improved significantly since these wells were first interpreted, it was decided to undertake a new, fully holostratigraphic study with the following objectives:

(1) to update the stratigraphic understanding of the chalk on Eldfisk to constrain the new 3D geological and simulation model and gain a better understanding of the growth of the structure and controls on chalk deposition;
(2) to improve understanding of stratigraphic layering, reworking events and the distribution of unconformities to aid horizontal geosteering;
(3) to enhance the geophysical interpretation, particularly in the large seismically obscured area that occurs across Eldfisk;
(4) to tie the biostratigraphy to the petrophysical interpretation and review anomalies in the database.

Methodology and integration of results

Detailed biostratigraphy was used as the foundation for the study as the chalk is well suited to biostratigraphic analysis due to the abundance of microfauna, nanoflora and macrofaunal remains that can be recovered. Results from cored wells were generated first in order to establish a correlation between biostratigraphy, lithofacies, petrophysics, lithostratigraphy and the geological model. Once calibrated, results were applied to wells containing ditch cuttings samples. Samples were analysed for microfaunal and nanofloral content and results were plotted against data from other geological disciplines. The nanofloral and microfaunal data were then used to build the stratigraphic framework; the microfaunal assemblages were also used to interpret biofacies changes along time lines generated by the nanofossil results.

Whilst the operator's 3D model is flow unit-based, it has been calibrated with the combined biostratigraphic scheme described here (Fig. 2). This scheme fully integrates all microfaunal and nanofloral events and has been developed following extensive biostratigraphic work on and around Eldfisk by Network Stratigraphic Consulting Ltd staff, building on previous published works on the region (King *et al.* 1989; Burnett *et al.* 1998; Fritsen 1999). This combined scheme has also been applied regionally to Central Graben chalks.

The complex depositional controls in the chalk have resulted in significant variations in lithofacies and a myriad unconformities that are manifested as significant vertical and lateral variations in petrophysical character. Therefore, without stratigraphic context various petrophysical correlations are possible. With time lines applied to the correlation panels it is possible to identify isochronous, widespread petrophysical features of correlative utility, punctuated by intervals of variable petrophysical character. In order to build and test the stratigraphic framework, the biostratigraphic interpretations were plotted alongside petrophysical CPI logs as stratigraphic summary logs for each well (Fig. 3). Integration of the biostratigraphy with the petrophysics (Fig. 4) allowed time lines to be drawn across correlation panels to identify:

(1) correlatable intervals with consistent and pervasive petrophysical characteristics;
(2) intervals that display variable petrophysical characteristics but are of the same age.

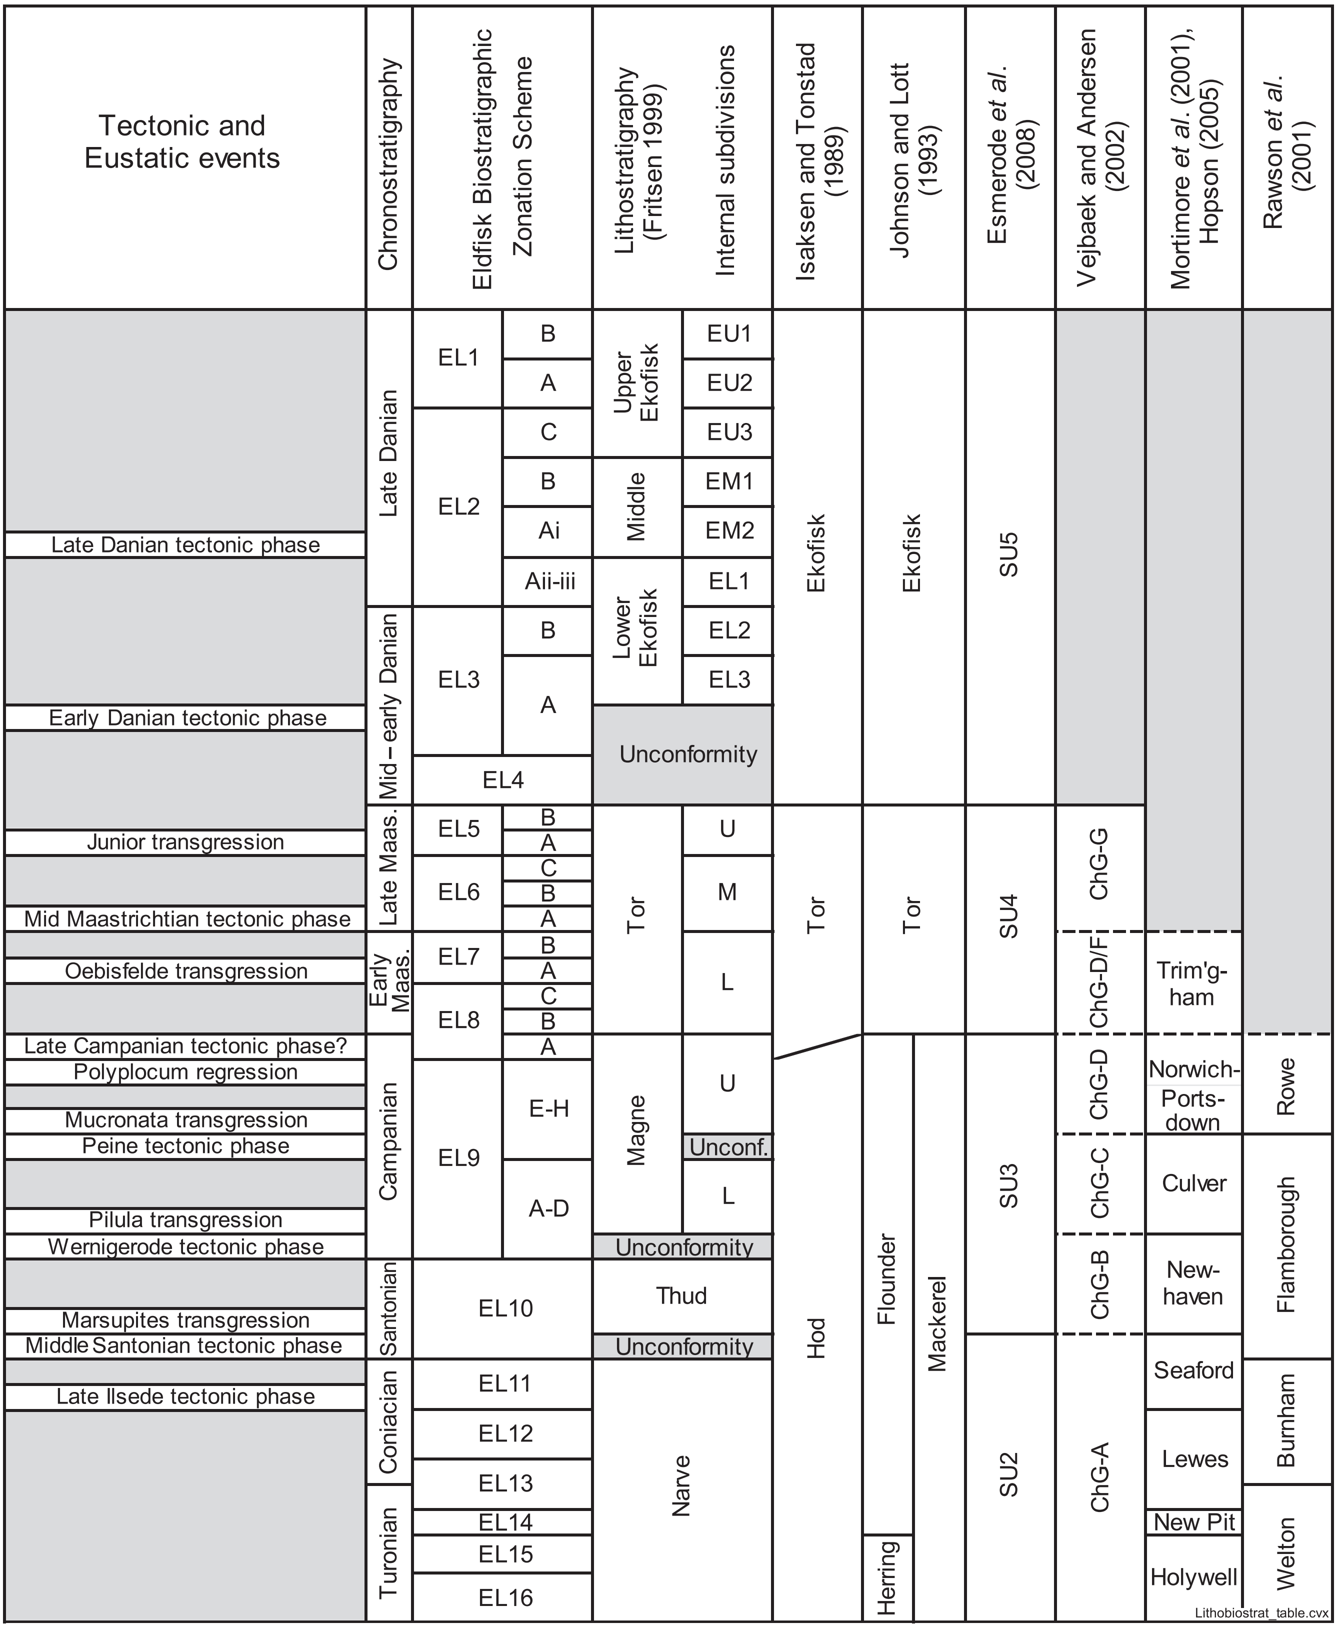

Fig. 2. Biozonation, chronostratigraphy and lithostratigraphy of the chalk on Eldfisk correlated with regional lithostratigraphic nomenclature, eustatic and tectonic events.

Examples of consistent correlative features include:

(a) Upper Ekofisk (EU) – this regionally pervasive unit is characterized at its base by high-porosity, low-density, clean hydrocarbon saturated chalks which display increasing gamma ray, decreasing porosity and increasing density trends up. Biostratigraphy dates this hemipelagic, autochthonous sequence as 'latest' Danian Subzones EL2C–EL1A. Lithofacies grade from massive, homogeneous chalks at the base to argillaceous, bioturbated periodites at the top.

(b) Lower Ekofisk (EL) – a widespread unit displaying higher gamma ray, higher density values and lower porosity characteristics than immediately adjacent sediments. The lithofacies are

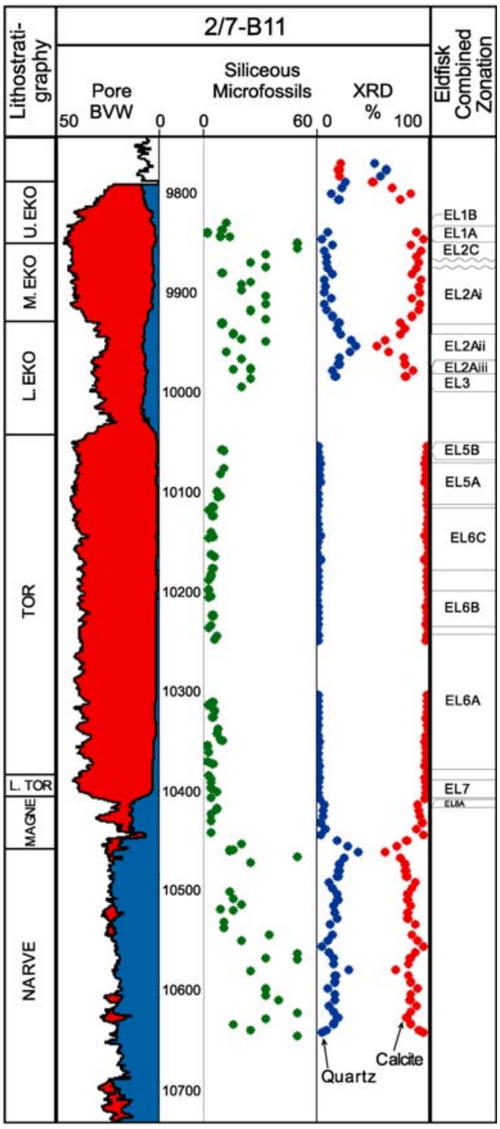

Fig. 3. Example stratigraphic summary log, from well 2/7-B-11, displaying the biostratigraphic interpretation alongside selected petrophysical data. This example also plots siliceous microfossil abundance (radiolarian) abundance against silica (quartz) content illustrating the relationship between high radiolarian abundance and high silica content in the sediment and its subsequent detrimental effect on porosity.

characterized by argillaceous hemipelagic periodites, dated as ‘early’ Danian subzones EL2Aii to Zone EL4.

Therefore, sequences displaying isochronously consistent petrophysical and lithological character were identified which in turn are punctuated by intervals of variable petrophysical and lithological character, for example:

(c) Middle Ekofisk (EM). Once the time lines are applied and the consistent character of the EU and EL is identified, it is apparent that there is considerable variation within the intervening EM unit; logs display laterally and vertically variable porosity and thickness in this unit. The biostratigraphic data reveals that these variations are influenced by differences in the geographical extent and temporal source of the reworking. The top of the Middle Ekofisk Formation is characterized by a phase of intra Ekofisk Formation (‘early’ Danian) derived reworking and is assigned to Subzone EL2B. This unit is characterized by higher gamma ray, higher density and lower porosity values than adjacent sediments (Fig. 4) and yields high proportions of chert.

The lower part of the Middle Ekofisk Formation is assigned to Subzone EL2Ai and yields dominantly *in situ*, ‘late’ Danian assemblages. This clean, low-gamma ray, high-porosity, low-density chalk is an important reservoir horizon. Within Subzone EL2Ai a phase of Late Cretaceous reworking can be recognized. This is focused in the ‘saddle area’, which acted as a depocentre for the remobilized Tor Formation derived sediments. These reworking levels clearly have a detrimental effect on the porosity which contrasts with the neighbouring Ekofisk trough where large-scale reworking equates with high-porosity reservoir horizons. However, the relationships between allochthonous and autochthonous levels within the EM are complex (Fig. 5). The Late Cretaceous reworking is concentrated in the saddle area (attaining up to 20% of assemblages) where it lies within otherwise autochthonous EM sediments which are in turn overlain by reworked intra Danian sediments. Further on to the structure these reworking events converge with little evidence for autochthonous sedimentation in between. Finally, in crestal locations the intra Danian and Late Cretaceous reworking is absent, resulting in high-porosity EU sediment lying contiguously upon high-porosity EM sediments. Therefore, these reworked horizons appear to act as permeability barriers or aquicludes in certain locations. The Middle Ekofisk Formation is characterized by a variety of lithofacies including conglomeratic and brecciated chalks, evidence for soft sediment deformation, including slump structures, convoluted bedding, overturned folds and homogenous massive chalks, together with evidence for hemipelagic rhythmic chalk and marl couplets, illustrating the mixture of autochthonous and allochthonous deposits.

(d) Tor Formation (EL6) – the integration of petrophysics and biostratigraphic results has improved the understanding of the distribution and generation of Tor Formation sediments. Late Maastrichtian Tor Formation Zone EL6 is characterized by high-porosity clean chalks which vary in thickness across the region. This interval comprises abundant, distinctive inoceramid debris in excess of 40% of the microfaunal recovery and often as high as 75–80%; the coarse bioclastic nature of these sediments may account for the high porosities. Given that inoceramid numbers were diminishing during the Maastrichtian, reaching extinction at the Cretaceous–Cenozoic boundary (inoceramids that occurred at this time were small and unlikely to be present in the numbers required to generate the high recovery of prismatic fragments recorded), the most likely explanation for deposition of this bioclast-dominated carbonate is by hydrodynamic sorting as part of an allochthonous process of sedimentation. This is a well established feature of Late Cretaceous carbonate turbidites (Neuweiler 1989) in which prismatic fragments of inoceramid shells act as coarse detrital elements in what is otherwise a normal Bouma turbidite sequence (Fig. 6). The faunal associations displayed on this figure are typical of the Tor Formation.

This zone appears to achieve maximum thickness on East Eldfisk and on the SW, southern and SE margins of the Alpha structure and in the Bravo channel on the Bravo structure. It is thin to absent on ‘crestal’ areas of Eldfisk Alpha and Bravo as defined during the Early Maastrichtian, suggesting the gravity flows were not deposited on structural highs. Overall depositional trends mirror those of the Early Maastrichtian, suggesting the palaeotopography developed at this time-controlled deposition of the Zone EL6 gravity flows. Hatton (1986) and Kennedy (1987) suggest penecontemporaneous allochthonous sediments were derived from the graben margin towards the NE. Conversely, derivation of these sediments could potentially be from a southerly source area, at least in part, as the area to the south was a more positive structure at this time and debris flows were being generated in this area during the ‘mid’ Maastrichtian (Sikora *et al.* 1999). Therefore knowledge of where these high-porosity gravity flows have been deposited helps in the selection of Tor Formation well locations. The presence of reworked nanofossil taxa and intraclasts supports the gravity flow

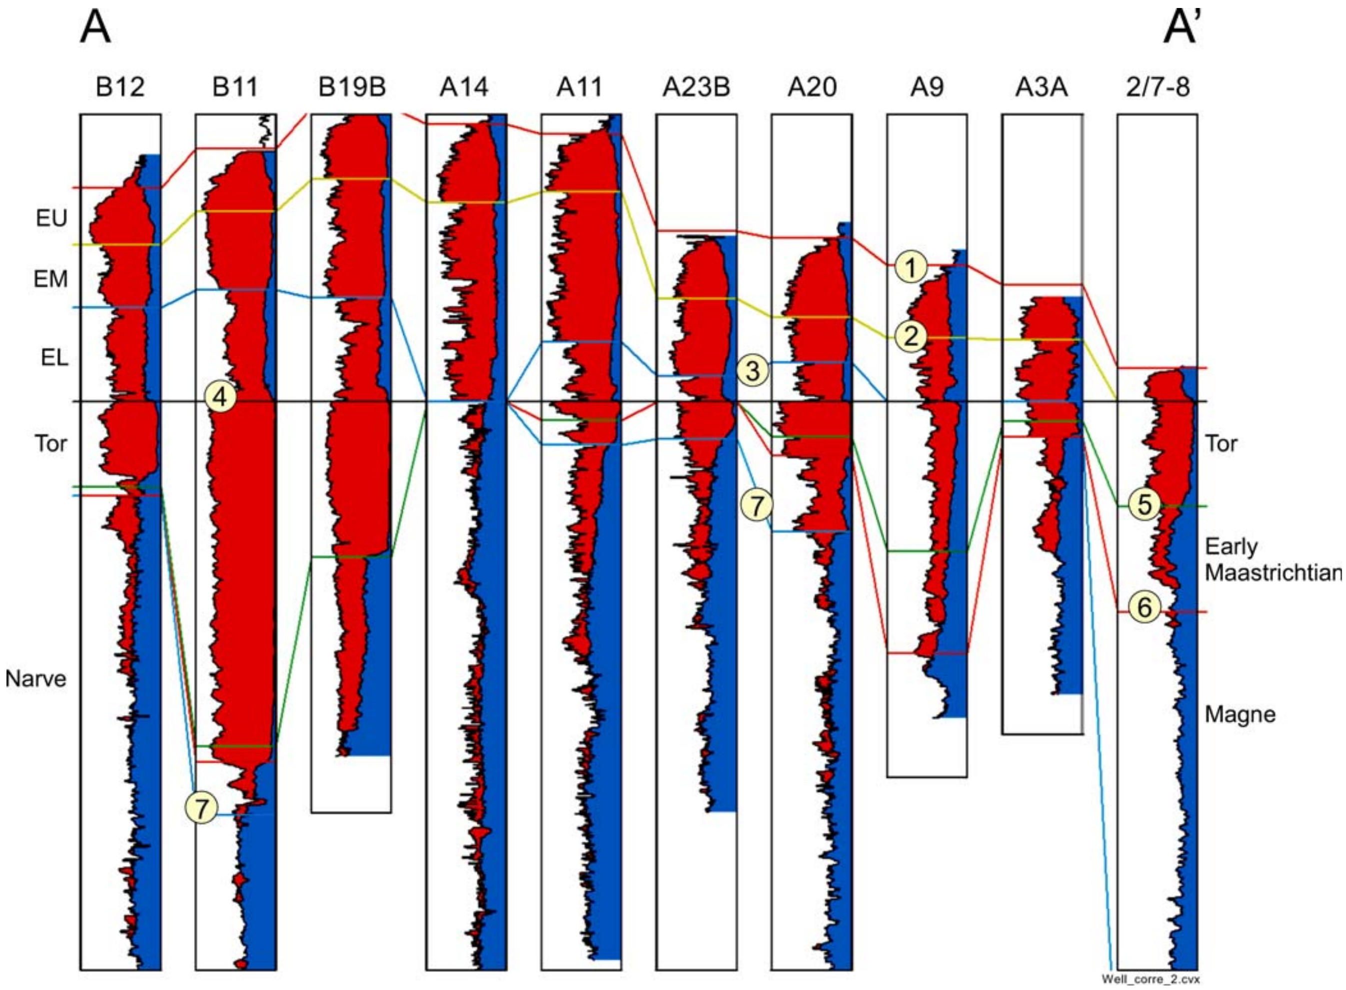

Fig. 4. Key well correlation (section A–A′ in Fig. 1) flattened on top Cretaceous. Lines represent the following horizon tops: (1) Ekofisk, (2) Middle Ekofisk, (3) Lower Ekofisk, (4) Tor, (5) Early Maastrichtian, (6) Magne, (7) Narve. Porosity (red) and Bulk Volume Water (blue) 50–0%.

origin for these sediments. The Tor Formation is also generally devoid of siliceous microfossils such as radiolaria. There appears to be a good relationship between the abundance of siliceous microfossils, the proportion of quartz determined by XRD analyses and porosity (Fig. 3); therefore the potential exists for radiolarian abundance to act as an inverse proxy for porosity.

(e) Magne Formation. Sediments that display Tor Formation petrophysical properties (high porosity with good separation between the porosity and BVW on CPI logs, e.g. Well 2/7-A-23B on Fig. 4), are present across the northern part of the Alpha ridge and NW flank of the Alpha structure. Prior to biostratigraphic analyses these sediments have previously been assigned to the Tor Formation, based principally on petrophysical character (clean, low gamma ray and high porosity). The presence of an allochthonous debris flow, including small chalk clasts, recorded in core from the western flank may well have contributed to the assignment of this unit to the Tor Formation. However, biostratigraphic results reveal these sediments to be Late Campanian Magne Formation. Porosity and permeability plots from the Magne Formation in well 2/7-A-23B (Fig. 7) illustrate that the Magne Formation follows Hod Formation poroperm trends rather than Tor Formation trends when plotted against data from across Eldfisk Alpha and is therefore genetically unrelated to the Tor Formation. Subtle poroperm differences suggest this unit may not act as a single flow unit when in contact with the Tor Formation.

When the geological data is integrated, it is apparent that there are autochthonous, hemipelagic, undisturbed, often rhythmic, isochronous intervals characterized by widespread, consistent characteristics. These intervals are punctuated by intervals of variable petrophysical character, yielding evidence for allochthonous sedimentation. Therefore, chalk deposition on Eldfisk is characterized by periods of eustatically controlled, tectonically quiescent sedimentation, interrupted by synchronous episodes of tectonically controlled sedimentation.

Improved understanding of the timing and differential growth of various parts of the structure can be determined by integration of the biostratigraphy with geophysical and biofacies data. The importance of mapping the variations in reworking and facies distribution is not only important from a reservoir modelling perspective but is also critical when geosteering horizontal wells in any particular reservoir layer.

Geophysical data

The presence of shallow gas in the overburden of Eldfisk means that approximately 60% of the wells drilled on Eldfisk are located in a seismically obscured zone. A four-component 3D Ocean Bottom Cable acquisition programme was acquired and processed in 2001, with the primary purpose of undershooting the Alpha and Bravo complexes and attempting to obtain a better image through the gas affected overburden. In 2007 a P-wave prestack depth migration project was instigated to further improve the image. The resultant PZ imaged data volume reduced this obscured area by 20% and improved the overall imaging on the flanks of the

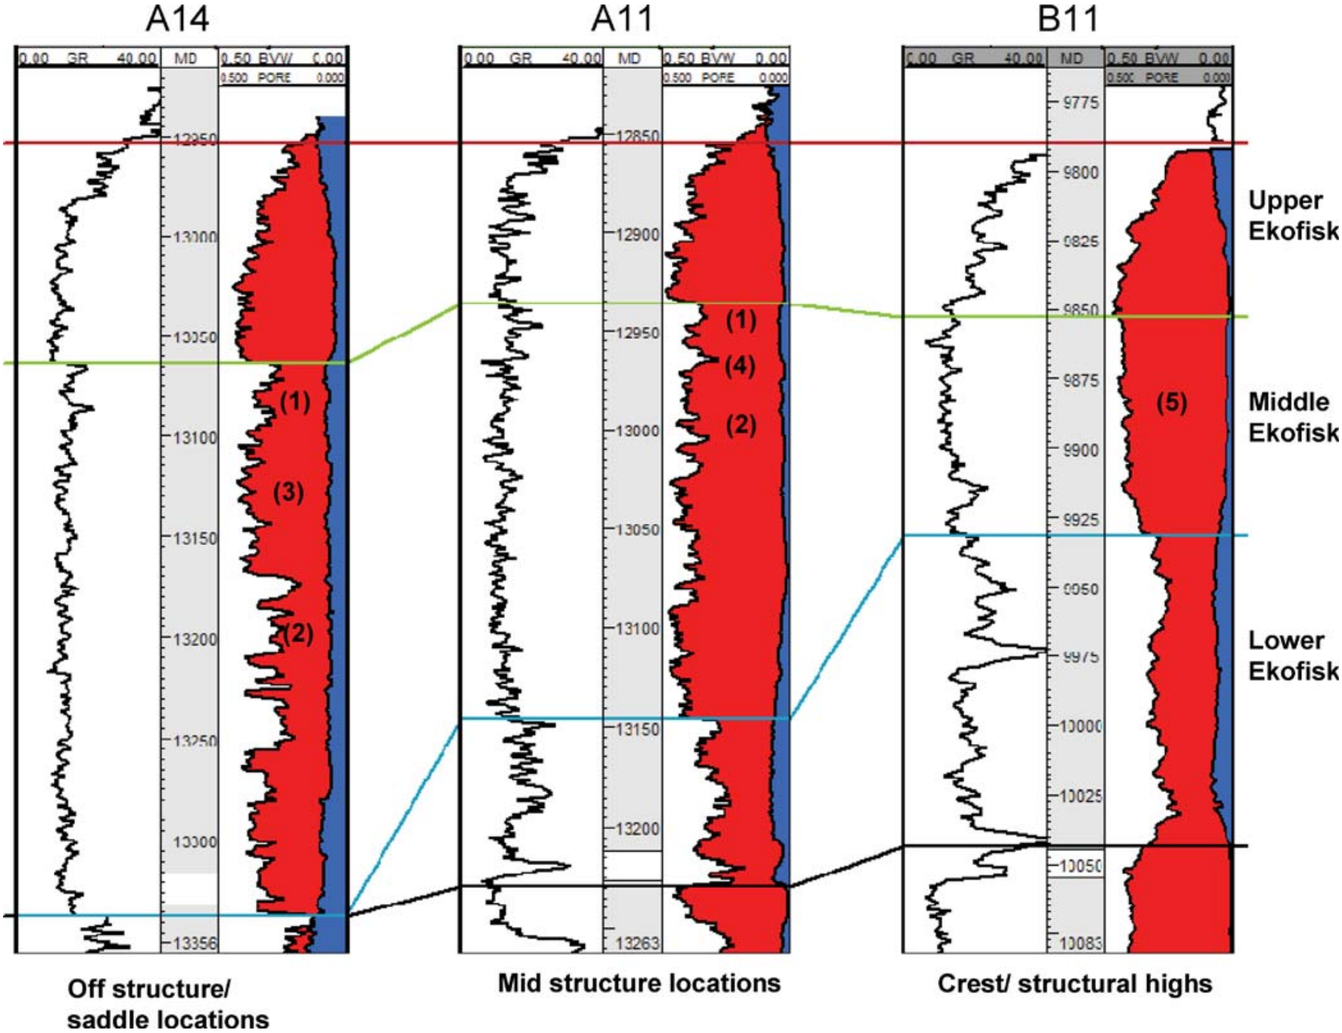

Fig. 5. Intra Danian reworking (1) and Cretaceous reworking (2) levels are characterized by reduced porosity. In the saddle area reworked horizons (3) are separated by autochthonous, high-porosity sediments. These reworked horizons converge towards structural highs and are not separated by high-porosity autochthonous beds (4). However no low-porosity reworked horizons (5) are present on the crest. Traditional log correlation could lead to ambiguous results, however, when tied to the biostratigraphy mappable patterns of reworking emerge and these maps are presented in this paper. This in turn leads to improved 3D modelling and is extremely important when geo-steering horizontal wells. Track 1, gamma ray 0–50 API; track 2, porosity (red) and bulk volume water (blue) 50–0%.

field. The new seismic volume was then integrated with the biostratigraphic analyses to produce a meaningful interpretation of the Alpha and Bravo crests (Fig. 8). The following chalk horizons were calibrated with the petrophysics and biostratigraphy in the interpretation:

(1) Narve Formation – the top of the Narve Formation is picked at a weak reflector overlying a generally ‘washed out’ seismic character that can be tracked regionally.
(2) Thud Formation – this is generally thin or absent in the study area and therefore beyond seismic resolution. The lower boundary is described geophysically in Fritsen (1999) as an onlap surface, suggesting a phase of structural growth between deposition of the Narve and Thud Formations.
(3) Magne Formation – Fritsen (1999) defines the seismic criterion for the boundary between the Magne and Thud Formation as an onlap surface, again suggesting a phase of structural growth between deposition of these formations. Regionally, the seismic criterion for picking the boundary between the Magne and Tor Formation in Fritsen (1999) is a well defined reflector separating a lower amplitude interval below from a higher amplitude interval above and is also locally an onlap surface. The presence of a stronger geophysical signature supports differentiation of this (former Hod Formation) unit from the Narve Formation
(4) Tor Formation – the top of this formation can be difficult to pick without well ties due to lack of contrast attributed to the presence of an unconformity and the absence of the basal ‘Ekofisk tight zone’ in the study area. The presence of a more continuous reflector pattern in the upper part may reflect the hemipelagic Zone EL5, while the discontinuous pattern observed within the Tor Formation may represent the remobilized deposits assigned to Zone EL6, where seismic resolution allows.
(5) Ekofisk Formation – in Fritsen (1999) the top of the Ekofisk Formation is evident as a clear seismic event, the result of an increase in acoustic impedance. Poor seismic resolution prohibits internal subdivision, although the chaotic internal seismic character may be related to allochthonous deposition.

The seismic interpretation of the flanks of the structure is reasonably straight forward as the stratigraphy is relatively thick and not restricted by the tuning thickness of the seismic (horizontal resolution limits). However, as the interpretation is pushed towards the crest the combination of thinning and the obscured seismic zones means that the picks become increasingly more driven by

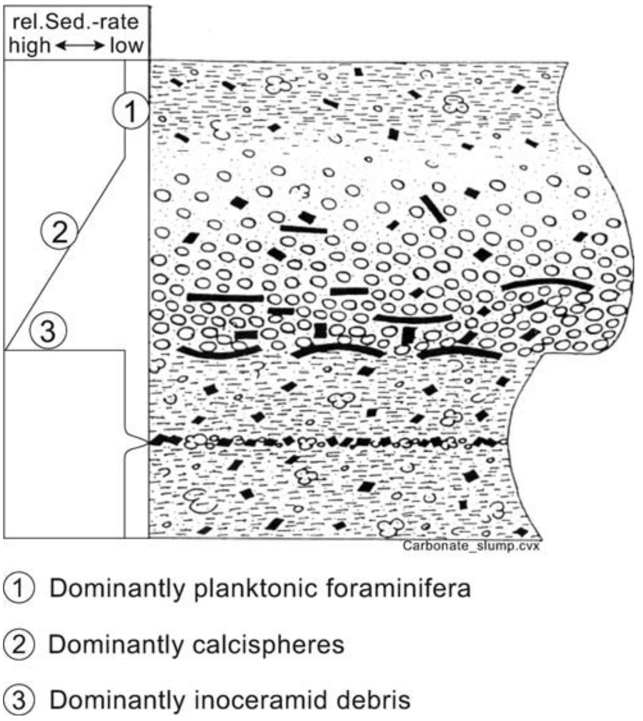

Fig. 6. Typical carbonate slump with concentrations of inoceramid debris, planktonic foraminifera and calcispheres, after Neuweiler (1989). This hydrodynamic sorting pattern is particularly common in the Tor Formation regionally.

the biostratigraphic and structural controls. The final interpretation consists of hand-contoured maps and relies on the extensive and consistent biostratigraphic input outlined in this paper. The integration of seismic and biostratigraphy on the flanks has brought more confidence in the mapping of the field and this is particularly apparent where the seismic image degrades and more reliance is placed on the integrated petrophysical and biostratigraphic

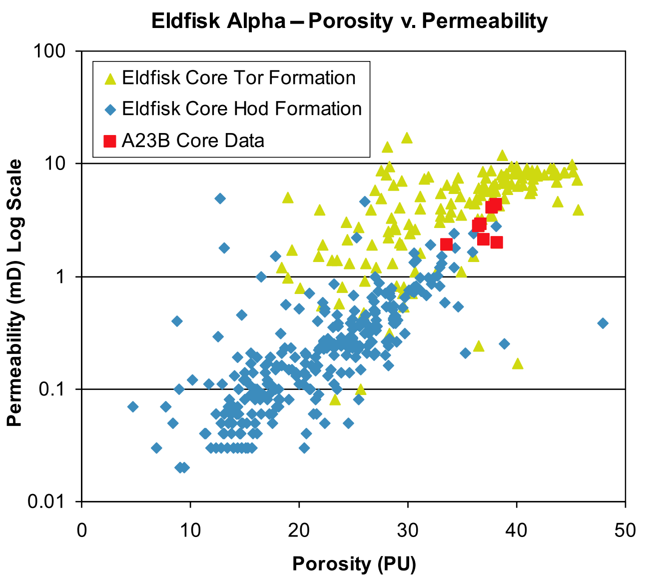

Fig. 7. Porosity v. permeability plots from the Magne Formation from well 2/7A-23B, illustrating that the Magne Formation follows Hod Formation porosity permeability trends rather than Tor Formation trends when plotted against core data from Eldfisk Alpha. These sediments, which display good reservoir characteristics, had previously been assigned to the Tor Formation.

derived tops. The flow units used in the 3D model are below seismic resolution and mapping of these is reliant on the isopachs derived from this study.

Biofacies methodology

The biofacies component of this study is targeted at determining the relative palaeobathymetry of chalk deposition over the Eldfisk region to aid facies mapping, improve understanding of the structural growth of the field and identify possible future drilling targets. To achieve this, the palaeoslope biofacies model defined by Olsson & Nyong (1984), Nyong & Olsson (1984) and Sikora & Olsson (1991) has been used. Following their defining criteria, all benthic foraminifera are ascribed to either a biofacies group or range of groups. Their model is applicable to the North Sea area as it was initially developed within the North Atlantic region and many species are common to both areas. The original statistical definition of their depth/biofacies groups has been accepted here. However, additional work has been undertaken identifying the palaeobathymetric groups to which foraminifera recorded in this study, but not utilized by Nyong & Olsson (1984) and Sikora & Olsson (1991), belong. While other environmental factors such as temperature, current circulation, nutrient and oxygen supply also have an effect, the distribution of benthic taxa is interpreted largely as a response to bathymetric controls and is consequently used to assess changing palaeobathymetric trends. Six main biofacies groups have been recognized during this study, using the Nyong & Olsson (1984) model as an initial basis. However, additional factors will have had an effect, particularly the development of dysaerobic conditions at the seafloor, resulting in apparent deeper biofacies signals. Therefore, while elements of the microfauna are consistent with lower bathyal to abyssal biofacies as defined by Nyong & Olsson (1984), it is unlikely that such depths were present in North Sea chalk seas. To reflect depth trends rather than absolute values the terms Upper Slope, Middle Slope, Lower Slope and Basinal have been applied to represent the Upper, Middle, Lower Bathyal and Abyssal biofacies of Nyong & Olsson (1984) but not necessarily the absolute palaeodepths (Fig. 9). In addition, information derived from the planktonic foraminifera, radiolaria, calcispheres, ostracods and other bioclastic debris has also been used to assess changing trends in the depositional environment.

In the present study planktonic morphotypes, as identified by Hart & Bailey (1979) have been formalized and divided into component groups according to life cycle water depth preference. This technique in establishing trends in water depth changes has never previously been applied to North Sea Late Cretaceous chalks. It is strictly an experimental approach that, when compared with the benthic foraminiferal analysis outlined above, shows a similarity of trends sufficiently strong to support the value of using this method, particularly when used in conjunction with other biofacies data. This is also summarized in Figure 9; however, this correlation remains tentative given that other environmental factors mentioned above (notably palaeotemperature) can influence the distribution of planktonic foraminifera. Planktonic/benthic (P/B) ratios have not been used to imply palaeobathymetry in the chalk in this study. There is evidence to show that planktonic recovery from onshore chalk outcrop sections is approximately 10% of that seen in adjacent flint meals (Bailey & Clayton 2010). This suggests there must be a post-diagenetic factor and questions the use of P/B ratios as a palaeobathymetric tool in the chalk.

Radiolaria exhibit levels of increased abundance and diversity during periods of chalk deposition in the North Sea basin. They are useful stratigraphically and also indicate changes in original water mass movement. Their abundance at levels in the Narve, Thud and Ekofisk Formations coincide with deeper water,

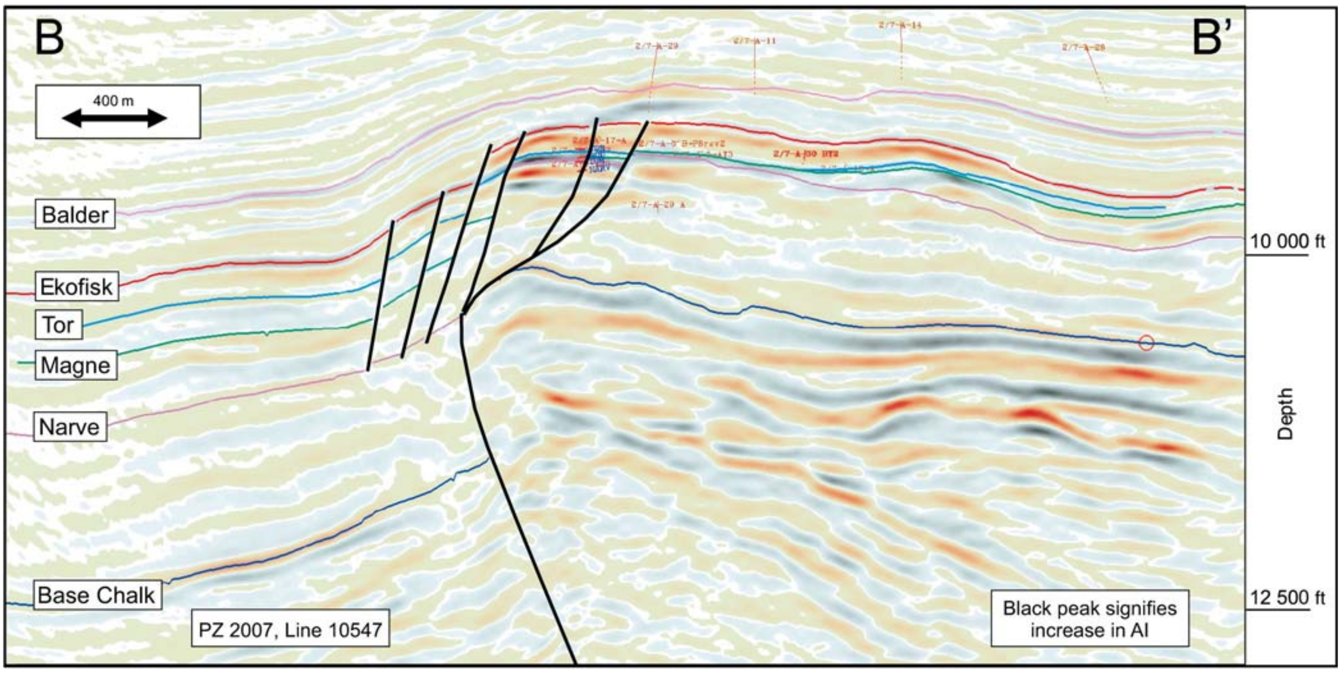

Fig. 8. The depth seismic line B–B′ across the Eldfisk Field saddle area (see Fig. 1 for location) demonstrates the array of unconformities in the chalk sequences.

hemipelagic, autochthonous depositional conditions with reduced levels of reworking. Results from this study agree with Brasher & Vagle (1996) and suggest that radiolarian abundance may act as a proxy for the silica content and therefore chalk porosity (Fig. 3).

Inoceramid bivalves occur frequently in Late Cretaceous chalks and there is evidence they were associated with dysaerobic seafloor conditions (Harries *et al.* 1996). Individual complete specimens range in size from *c.* 2 cm to 2 m and originally comprised a two-layered structure of aragonitic and prismatic calcite. The former is unstable and easily destroyed during early diagenesis, leaving a resistant prismatic layer. These shells often disaggregate and, at certain stratigraphic levels, the disaggregated prisms can form a significant constituent of the sediment. This characteristic is important during deposition of the Tor Formation, where considerable thicknesses of high-porosity chalks, associated with mass flows and comprising dominantly inoceramid debris (often 70% of microfaunal recovery), were deposited to the south and

Biofacies Groups	Sea floor environment	Planktonic Foram Groups	Descriptors	Examples
1	Inner Neritic (Shelf)	Unkeeled forms	Simple spherical - subspherical chambers, no major ext. ornam't e.g. keels	*Rugoglobigerina Whiteinella Hedbergella Heterohelix Globigerinelloides*
2	Middle Neritic (Shelf)	Keeled Group 1	Flat, biconvex morphotypes, 1 or 2 keels	*Globotruncanella, Arch. cretacea, Marg. marginata*
3	Outer Neritic (Shelf)	Keeled Group 2	Planoconvex - part trochospiral, 1 or 2 keels	*Hel'globotruncana praehelvetica, Praeglobotruncana stephani, Dicarinella primitiva, Rosita fornicata*
4	Upper Slope	Keeled Group 3		
5	Lower Slope	NB: Planktonic groups do not imply a precise depth range. Other environmental factors e.g. temperature, current circulation, oxygen supply may affect their distribution	Strongly planoconvex - high trochospiral, 1 or 2 keels	*Hel'globotruncana helvetica Praeglobotruncana gibba, Dicarinella concavata, Rosita contusa*
6	Basinal

east of the region (see 'Allochthonous biofacies' section below). Echinoderm debris, bryozoan debris and ostracods also form significant elements of the coarser calcitic component and concentrations may also occur at levels interpreted as being part of mass flow deposits.

Calcispheres (the encystment stage of calcareous dinoflagellate algae) are most abundantly found in shelf margin to upper slope sediments (Adams *et al.* 1967); their occurrence in deeper settings may be due to subsequent reworking downslope as part of the sediment load (Neuweiler 1989).

Allochthonous biofacies

It is important to improve understanding of the distribution of different reworking events and the variable impact of these events on porosity across the structure. Chalk reworking is well established in Norwegian Central Graben chalk fields (e.g. Perch-Nielsen *et al.* 1979), with subsequent discussion of the variable sedimentology by Hatton (1986) and Kennedy (1987). Because of the derived nature of the microfaunal components, remobilized sequences are not suited to palaeobathymetric biofacies interpretations. Late Cretaceous chalk turbidite sequences are described from onshore Germany (Neuweiler 1989), where different bioclastic elements form discrete size-sorted levels, comparable with grain size units in normal Bouma sequences (Fig. 6); comparable sequences are recorded repeatedly through the succession in Central Graben chalks. When unlithified chalk is redeposited as a gravity flow it creates turbidites/mass flows analogous with those in siliciclastic sediments. Consequently, coarser fragments (e.g. inoceramid and echinoderm debris) are deposited in more proximal, higher energy locations, whereas the finer fragmented nanoplankton-dominated fraction is deposited as distal mud cloud deposits or at lower energy levels. Other common bioclastic elements, principally foraminifera, radiolaria and calcispheres, are size sorted, with larger foraminifera in more proximal or higher energy deposits and small, lighter forms occurring with calcispheres in more intermediate locations or at intermediate energy levels within mass flows. The impact of grain size on porosity distribution in the chalk was also discussed by Brasher & Vagle (1996).

Of the fine-grained nanofossil component, robust morphotypes of calcareous nanoplankton appear to preferentially survive transportation and re-deposition within allochthonous chalks; examples include the genera *Micula*, *Lucianorhabdus*, *Prediscosphaera* and *Arkhangelskiella*. The recognition of assemblages dominated by these forms (in the absence of a diverse nanoflora also yielding delicate forms) therefore assists the identification of such sediments.

Whilst the interpretation of individual biofacies in a well can be problematic, for the reasons outlined above, the combination of petrophysics, geophysical interpretation and the collective interpretation of many wells along confirmed time lines gives confidence in a field-wide model based on many wells. The position of the changes in facies and water depth interpreted and mapped conforms to reasonable geological pattern and strengthens the confidence in the technique. The biofacies maps produced cite palaeobathymetries deeper than commonly quoted for onshore chalks. Although dysaerobic conditions at the seafloor may give an apparently deeper biofacies signal, the chalk in the Central Graben appears to have been deposited at significantly greater depths than previously appreciated. Regardless of the specific depth of deposition, the relative patterns and trends still hold.

Results (discussed in lithostratigraphic order)

The lithostratigraphic definitions of the Ekofisk and Tor formations follow Isaksen & Tonstad (1989); the definitions of the Narve, Thud and Magne formations follow Fritsen (1999), but are referred to in an informal sense pending formal validation. Regional biostratigraphic and seismic evidence suggests that the Thud Formation is best developed in basinal lows (Fritsen 1999), and this is supported by evidence for the Thud Formation off-structure on East Eldfisk. The first record of cored Thud Formation, as identified in this study (well 2/7-A-23B), allows better calibration with petrophysical and geophysical data. This also permits better definition of this formation than the original description by Fritsen (1999). The Magne Formation can be subdivided into two distinct sequences: a Late Campanian, Upper Magne Formation sequence which is relatively widespread and an Early Campanian, Lower Magne Formation sequence which is only rarely preserved and identified in the study area. The Tor Formation is restricted to the Maastrichtian on Eldfisk; the top of the Late Maastrichtian defines the upper boundary (Zone EL5), and the lower boundary equates with the base of the Early Maastrichtian (Subzone EL8B). The boundary between the Magne and Tor Formations broadly coincides with the boundary between the Campanian and Maastrichtian stages. The results of this study allow the Tor Formation to be subdivided into three distinct (allostratigraphic) sequences. Similarly, the Ekofisk Formation can be subdivided into three distinct (allostratigraphic) sequences which correlate well with the ConocoPhillips geological model subdivisions. These unit breakdowns are below seismic resolution and based on the biostratigraphic and petrophysical interpretations.

Narve Formation

Age. Turonian to Coniacian, Zones EL16–EL11. The top of the Narve Formation represents a variable unconformity surface on Eldfisk, the top of which ranges from Subzone EL11B at its youngest on Alpha; to Zone EL13 in the 'saddle', an area which also displays maximum section loss at this unconformity (overlain by 'late' Danian Ekofisk sediments, a time gap of 23 Ma).

Lithology/petrophysics. Generally deposited as 'deep' water, hemipelagic, rhythmically bedded, alternating dark grey and light grey–off-white argillaceous periodites which vary in thickness from tens of centimetres up to a metre. The relatively high argillaceous content is reflected in the relatively high gamma ray values seen in the Narve Formation on Eldfisk. Petrophysical logs typically display low-porosity, poor reservoir characteristics.

Biofacies. Described by Kennedy (1987) as a time of quiet, pelagic deposition with potentially anoxic bottom waters in bathyal settings with little evidence for strong structural relief. The poor recovery of benthic foraminifera at this time suggests probable dysaerobic conditions.

Tectonostratigraphy. The main Ilsede phase tectonics occurred in rocks older than those studied as analyses ceased on confirmation of top Narve Formation. However, inversion during this tectonic phase resulted in the early growth of the Eldfisk structure, upon which evidence for subsequent tectonic phases is expressed.

Regional correlation. Equates with the Middle Hod Member of Isaksen & Tonstad (1989), the Seaford (*pars.*), Lewes Nodular, New Pit and Holywell Formations in the UK and seismic unit SU2 of Esmerode *et al.* (2008) and seismic sequence ChG-A of Vejbaek & Andersen (2002) in Denmark.

Thud Formation

Age. Constrained to Zone EL10 of Santonian age on Eldfisk.

Lithology/petrophysics. Fritsen (1999) described alternating argillaceous and clean chalks (periodites), the higher gamma values observed therein suggest clay content higher than in the overlying Magne Formation. Cored Thud Formation sediments from this study, in which argillaceous chalk and clean chalk periodite couplets display variable but generally high gamma and low-porosity values, confirm this description.

Biofacies. Deepwater, transgressive benthic foraminifera such as *Stensioeina*, together with lithofacies data implies a deeper water (bathyal) environment and ubiquitous deposition in the area before subsequent erosion.

Tectonostratigraphy. The lower boundary of the Thud Formation on the western flank of Eldfisk Alpha is of Middle Santonian, Subzone EL10B age, and the boundary between the Thud Formation and intra Coniacian Narve Formation unconformable. These age constraints suggest the influence of 'Mittel Santon puls' tectonics. The lower boundary and therefore Thud Formation deposition on Alpha are associated with the Middle Santonian *Marsupites* transgression (as described in German outcrop sections, Niebuhr *et al.* 2000). Cored Thud Formation sediments yield a zone of irregularly shaped inoceramid bivalve shell fragments (Fig. 10a), representing soft sediment, slumped, fragmentation of a specimen of the genus *Sphenoceramus* (C. J. Wood, pers. comm. 2007). Initial pulses of the Wernigerode tectonic phase are expressed by an interval of slumping in many German and southern England outcrop sections and dated as Santonian. A phase of inversion tectonics has also been described from the Aachen–Antwerp area by Bless *et al.* (1986) close to the Santonian–Campanian boundary. The cumulative effect of these tectonic and eustatic events, together with the subsequent intra Campanian Peine tectonic event, accounts for the absence of Thud Formation sediments on structural highs. The occurrence of slumping and intraclasts within the upper part of the Thud Formation on the western margin of the Eldfisk Alpha structure appears to be an expression of the Wernigerode tectonic event. (Fig. 10b).

Correlation. Lithostratigraphic comparison of age equivalent sections in onshore northern Germany confirms the presence of argillaceous chalks in the mid Santonian to basal Early Campanian sequences and broadly equates with the marl-rich Newhaven Chalk Formation in the UK, proving the widespread geographical extent of this distinctive unit. In the Danish sector the Thud Formation equates with ChG-B of Vejbaek & Andersen (2002) and seismic unit SU3 (*pars.*) of Esmerode *et al.* (2008).

Lower Magne Formation

Sediments assigned to the Lower Magne Formation are present in flank/off structure locations on Eldfisk where they generally overlie Thud Formation sediments. However, the presence of Early Campanian age sediments resting directly on Narve Formation on the NE flank of Alpha suggests that this sequence is genetically separable from the Thud Formation.

Age. Lower Magne Formation sediments range in age from Early Campanian, Subzones EL9A–EL9E.

Lithology/petrophysics. A distinctive petrophysical log signature (characterized by 'bow-shaped' density and porosity profiles) attributable to the Early Campanian Magne Formation can be seen in off-structure locations, particularly East Eldfisk. The presence of relatively expanded sequences off structure suggests preservation of these sediments in basinal settings despite removal from structural highs.

Biofacies. Biofacies data indicates deepening from middle to lower slope/basinal water depths towards East Eldfisk and the presence of a palaeotopographic high towards Alpha.

Tectonostratigraphy. The presence of Lower Magne Formation directly overlying the Narve Formation on the NE flank suggests

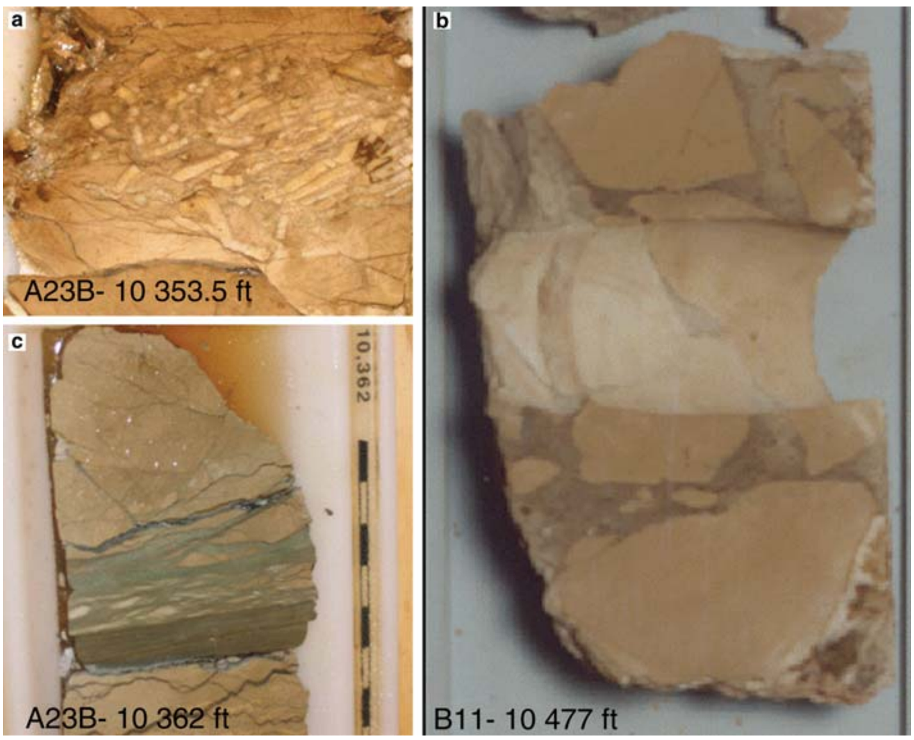

Fig. 10. (**a**) Example of Wernigerode Phase tectonics; small scale slumping recognized in the deformation of inoceramid (*Sphenoceramus*) bivalves in 2/7-A-23B. Core section represents approximately 4 inches. (**b**) Example of Wernigerode Phase tectonics; clasts in Santonian Thud Formation sediments in 2/7-A-23B. (**c**) Example of Peine Phase tectonics: clasts in Campanian age sediments in cored 2/7-B-11. Core section represents approximately 4 inches.

that the Thud Formation may have been removed during the Wernigerode tectonic event and associated eustatic lowstand, prior to the onset of Magne Formation deposition during the subsequent *pilula* and *mucronata* transgressions. Elsewhere, the scarcity of Early Campanian Lower Magne Formation relative to the Late Campanian Upper Magne Formation may suggest that its absence is a function of the 'latest' Early Campanian Peine tectonic phase, possibly combined with the effects of a coincident eustatic fall.

Correlation. The Lower Magne Formation equates with the Culver Formation, onshore UK. In the Danish sector this unit equates with seismic sequence ChG-C (Vejbaek & Andersen 2002) and seismic unit SU3 (*pars.*) (Esmerode *et al.* 2008).

Upper Magne Formation

Age. Late Campanian Subzone EL9E–EL8A.

Lithology/petrophysics. A range of lithofacies (including hemipelagic periodites, homogenous chalk and brecciated chalk) have been assigned to the Magne Formation, reflecting different depositional environments as the structure grew through the Campanian. These variations are supported herein by lateral variations in the petrophysical log curves; for example, reservoir quality Magne Formation described in well 2/7-A-23B on the Alpha structure contrasts with the low-porosity, tighter, deeper water biofacies in 'basinal' well 2/7-8 (Fig. 4). Late Campanian sediments occur in many wells across the study area, but principally across the northern part and eastern flank of the Eldfisk Alpha structure and across the East Eldfisk structure. The Magne Formation is notably absent across the highest points on the crest and southwestern parts of the Alpha structure. The distribution across the Bravo structure is less clear due to a lack of data points. The top of the Magne Formation displays higher gamma ray values than the overlying Tor Formation, which equates with red/pink chalk facies in off-structure or basinal settings.

Biofacies. Biofacies data implies a shallowing environment of deposition towards a crestal feature on the south of the Alpha structure, with a similar pattern observed on parts of the Bravo structure (Fig. 11). This indicates growth of significantly positive structures by the Late Campanian, characterized by non-deposition, condensation and hard-ground development on structural crests. This has also been reported from the adjacent Valhall structure (Sikora *et al.* 1999). The presence of reworked Narve Formation within the Magne Formation on the eastern flank of Alpha indicates that areas of Narve Formation were exposed during the Late Campanian. Surrounding areas are characterized by middle to lower slope environments giving an overall impression of a gentle dip slope to the east during the Late Campanian.

Tectonostratigraphy. Late Campanian Upper Magne Formation sediments post-date Peine phase tectonics and their deposition is associated with the subsequent *mucronata* transgression, the local European equivalent to global maximum sea levels recorded during the Late Campanian.

Correlation. In the Danish sector this unit equates with seismic sequence ChG-D (*pars.*) of Vejbaek & Andersen (2002) and seismic unit SU3 (*pars.*) of Esmerode *et al.* (2008). Sedimentological features such as intraclasts and hard-grounds in the upper part of the Magne Formation, together with an eastwards shift in the location of the structural high in the 'earliest' Maastrichtian, suggest a phase of inversion near the Campanian–Maastrichtian boundary, coincident with inversion in the Aachen–Antwerp area (Bless *et al.* 1986). Results indicate that crestal reservoir facies are genetically unrelated to the reservoir sediments within the Tor Formation. Intra Magne Formation brecciated debris flows,

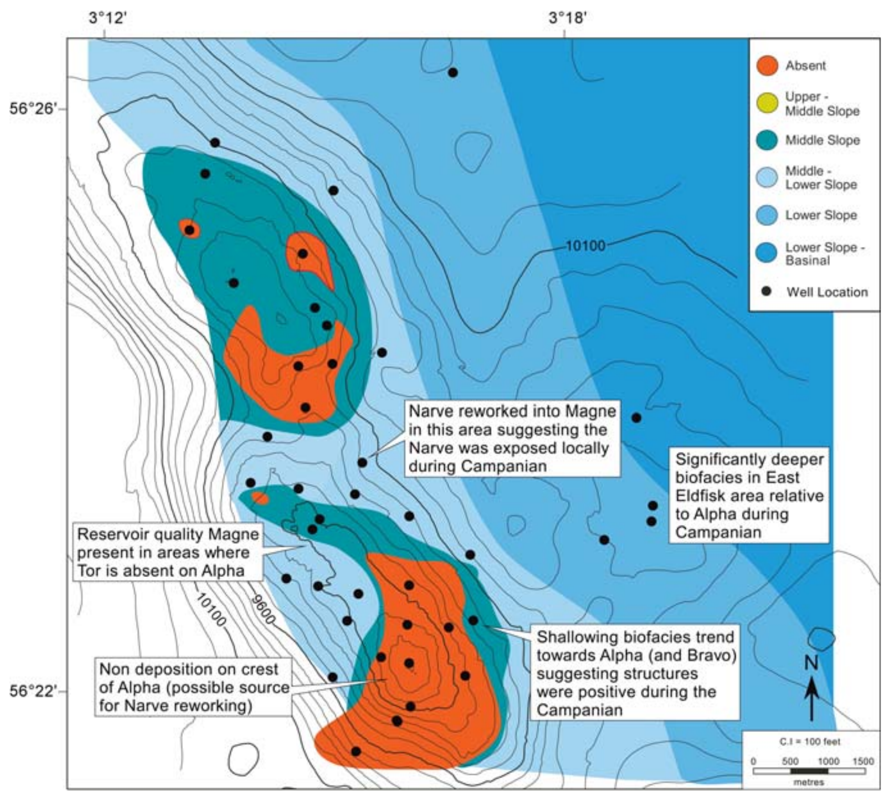

Fig. 11. Biofacies map for the Late Campanian Magne Formation showing a shallowing pattern towards, and non-deposition on structurally higher areas. P/B groups do not imply precise depth ranges but do give an impression of shallowing and deepening depth trends.

interpreted as expressions of Peine phase tectonics, can be seen in core from the Alpha and Bravo structures (Fig. 10c).

Lower Tor Formation

Age. Early Maastrichtian Subzone EL8B to Zone EL7.

Lithology/petrophysics. Petrophysical variations may be a function of biofacies and lithofacies variations reflecting the continuation of the palaeotopography established in the Late Campanian.

Biofacies. Early Maastrichtian hemipelagic sediments display onlap and infill distribution patterns, controlled by the existing palaeotopography. Distinct depocentres occur within the 'Bravo channel', along the eastern and southern flank of the Alpha structure and extending out towards the East Eldfisk structure. These depocentres exhibit middle–lower slope biofacies signatures (Fig. 12). There are areas of absence along the crest of the Alpha structure, a continuation of the pattern of non-deposition on structural highs recognized during the Campanian, combined with erosion during subsequent tectonic phases. The relatively shallower crestal 'Alpha ridge' appears to have shifted NW to encompass the whole of the present day 'saddle' area. On Bravo there is evidence of a positive crestal area NW of the 'Bravo channel' (non-deposition), surrounded by upper–middle slope deposits. To the south and east of the 'Alpha ridge', upper–middle slope depths are recorded. During this period there is biofacies evidence for progressive shallowing across the study area.

Tectonostratigraphy. Any deposition over the 'Alpha ridge' during this time was subsequently eroded. There is little evidence for tectonism during deposition of the Lower Tor Formation, although a tectonic phase is close to the Campanian–Maastrichtian (Magne–Tor Formation) boundary.

Middle Tor Formation

Age. Late Maastrichtian, Zone EL6.

Lithology/petrophysics. Sediments are rich in coarse bioclastic debris, particularly inoceramid bivalve fragments, providing high-porosity reservoir in depocentres around the Alpha structure and in the Bravo channel (Fig. 13).

Biofacies. Given the allochthonous, derived nature of sediments of this age, it is not possible to conduct palaeobathymetric biofacies interpretations.

Tectonostratigraphy. An intra Maastrichtian tectonic phase may be the mechanism for triggering this re-deposition and may correlate on a regional scale with intra Maastrichtian inversion events from the Aachen–Antwerp area onshore (Bless *et al.* 1986) and northern Europe (Ernst & Wood 2000).

Upper Tor Formation

Age. Late Maastrichtian Zone EL5.

Lithology/petrophysics. Deposition and distribution of Late Maastrichtian Zone EL5 chalks appear relatively widespread, with the exception of an area along the 'crestal ridge' area of the Alpha structure, extending into the 'saddle area' between Alpha and Bravo and locally on the northern part of East Eldfisk. Zone EL5 is characterized by clean, porous chalks at the base, becoming slightly less porous up section, reflecting the change from allochthonous to autochthonous sedimentation.

Biofacies. This zone is interpreted as a hemipelagic 'drape' across the Eldfisk structures following the cessation of the Combined Zone EL6 reworking episodes. Its absence from the areas illustrated in

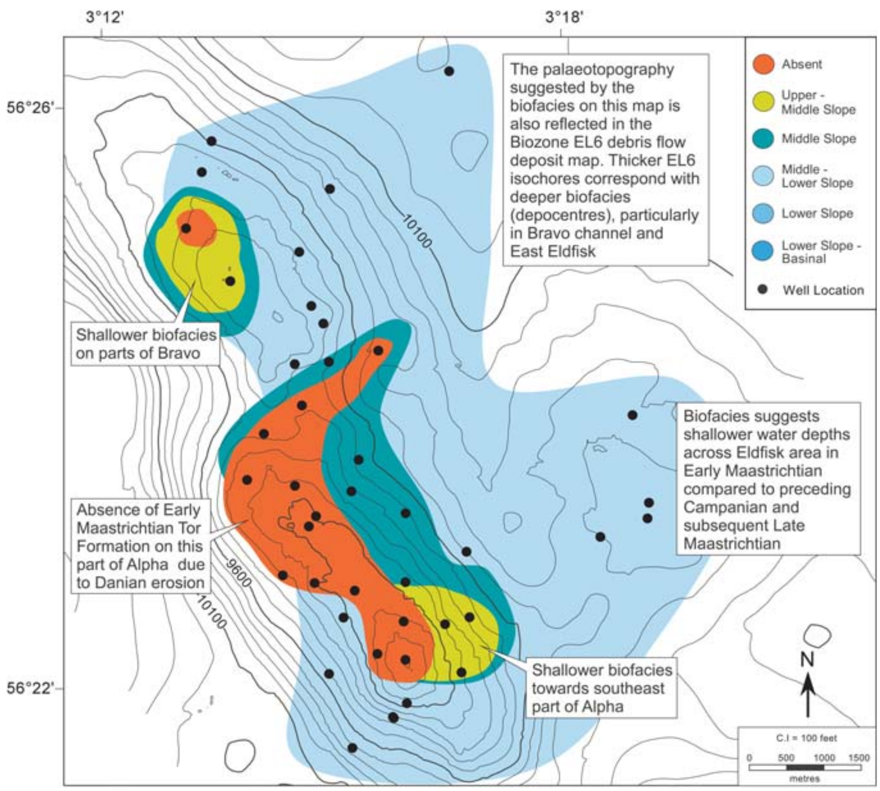

Fig. 12. Biofacies map for the Early Maastrichtian Tor Formation, showing a shallowing pattern towards, and non-deposition on structurally higher areas.

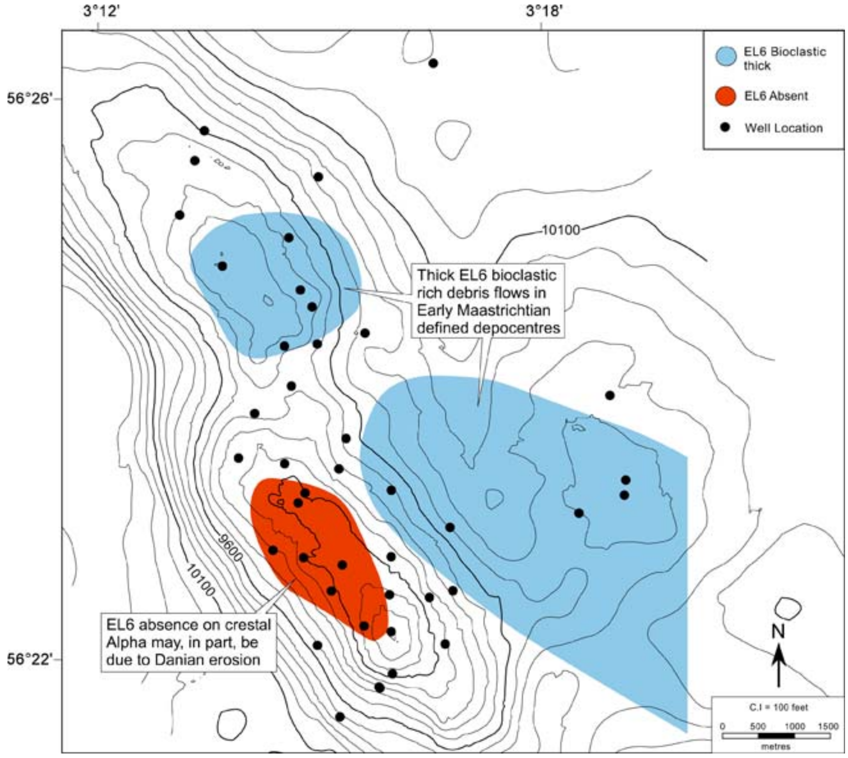

Fig. 13. Map illustrating main depocentres and areas of absence for bioclastic-rich debris flows (possibly eroded) assigned to Zone EL6.

Figures 14 and 15 is attributed to subsequent erosion during the 'early' Danian.

Late Maastrichtian Subzone EL5A represents the initial phase of a period of pervasive hemipelagic sedimentation, relatively rich in planktonic foraminifera. Subzone EL5A was deposited in middle–lower slope water depths over Alpha, increasing to lower slope towards the SW of Alpha. Structural relief is less pronounced due to backfilling of depocentres during the 'mid' Maastrichtian. An absence of Late Maastrichtian Subzone EL5A chalks on a well-defined 'ridge' along the length of the Alpha structure is attributed to subsequent erosion during the Danian. This is indicated by the absence of a pronounced biofacies shallowing trend towards this 'ridge' and by the fact that the area of absence also cuts across biofacies contours.

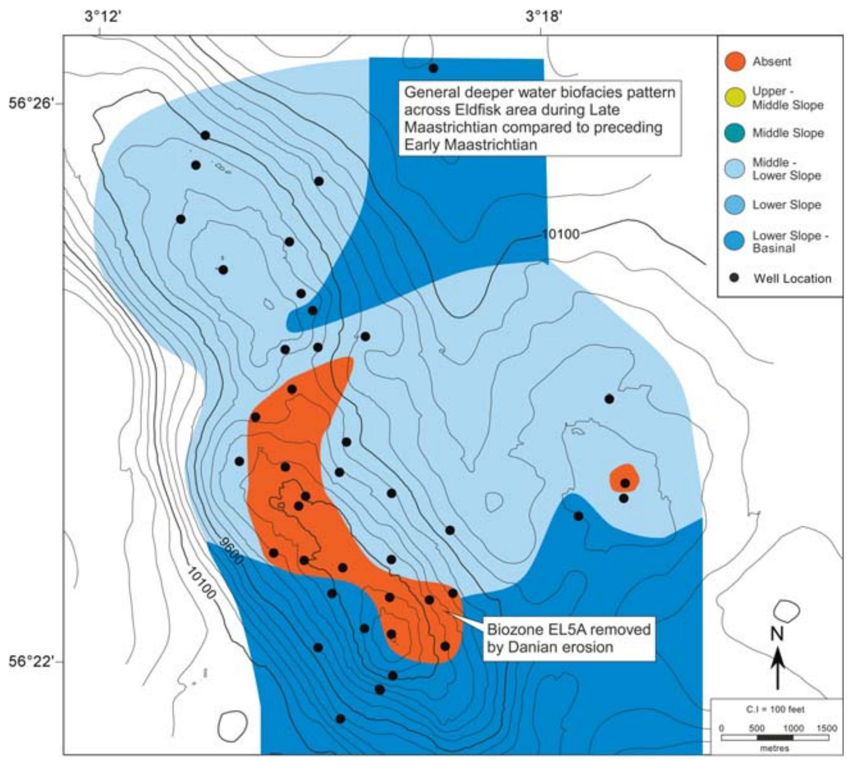

Fig. 14. Biofacies map for Late Maastrichtian Tor Formation Subzone EL5A, representing a hemipelagic drape across the structures.

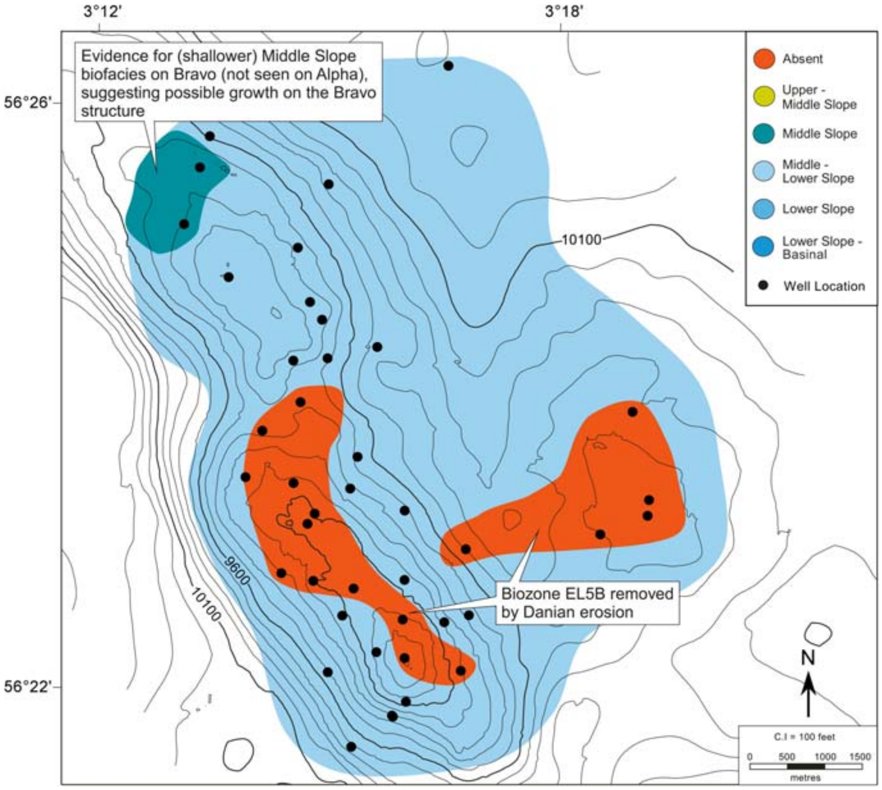

Fig. 15. Biofacies map for Late Maastrichtian Tor Formation Subzone EL5B. The areas of absence are attributable to a subsequent erosion event.

Top Tor Formation, Late Maastrichtian Subzone EL5B also represents a hemipelagic, plankton-rich drape over the Eldfisk structure deposited in middle to lower slope water depths. A shallower (middle slope) biofacies is also recorded at this time over the northern part of Eldfisk Bravo, indicating some structural relief in this area. The planktonic foraminifera which characterize this interval are generally regarded as being of relatively warm water (Tethyan) origin. There is evidence suggesting their ubiquitous record throughout the North Sea and northern Europe is due to the establishment of an Atlantic proto-Gulf Stream during the Late Cretaceous which swept southwards through the North Sea Basin towards the end Cretaceous carrying this distinctive planktonic association through the region and onto the European continental shelf (Hart 2007), where it is recorded in onshore Denmark (Troelsen 1955) and northern Germany (Koch 1977; Schulz & Schmid 1983). The hemipelagic origins of this unit imply deposition across the Eldfisk structure. Where absent, it is probably due to (uplift and) erosion at the end Cretaceous or during the earliest Danian.

Tectonostratigraphy. Time equivalent sediments from the adjacent Ekofisk trough continue to yield evidence for intra Tor Formation reworking, suggesting tectonically induced gravity flow deposition continued in that area, possibly correlatable with Late Maastrichtian inversion episodes described by Bless *et al.* (1986) from the Aachen–Antwerp area, while largely hemipelagic deposition occurred on Eldfisk.

Lower Ekofisk Formation

Age. 'Early' Danian Zone EL4 to 'late' Danian Subzone EL2Aii. Sediments of 'earliest' Danian, Zone EL4 are not routinely observed on the Eldfisk structures. It is difficult to definitively determine whether this is due to erosion or non-deposition. The occurrence of a thin Zone EL4 in core high on the western flank confirms that sediments of this age may have been deposited on (at least part of) the structure, with subsequent erosion downcutting into the Tor. Nevertheless, the thin occurrence of this zone renders it difficult to identify in ditch cuttings sample material. In contrast, Zone EL4 is well developed as the 'Ekofisk tight zone' in the adjacent Ekofisk trough. Zones EL3–EL2Aii are present on Eldfisk.

Lithology/petrophysics. Core facies interpretations reveal these sediments are characterized by argillaceous periodites, suggesting *in situ*, deep water, hemipelagic deposition. The argillaceous periodites are reflected in the petrophysical logs, displaying higher gamma ray and density values than adjacent sediments.

Biofacies. Lower Ekofisk Formation sediments assigned to Zone EL3 are more widespread in their distribution and were deposited at middle–lower slope depths (Fig. 16), with a lower slope signal along the western flank of Alpha, implying the presence of a steeper scarp structure. In contrast to Alpha, much of Bravo is characterized by a deeper lower slope microfaunal biofacies, although lower–middle slope biofacies depths interpreted towards the north suggest some structural relief.

Tectonostratigraphy. Thick sequences of Lower Ekofisk Formation (essentially Zone EL3) are developed on the Bravo structure where this unit generally caps the Tor Formation. This implies that this area acted as a depocentre at this time. The pervasive occurrence of Zone EL3 suggests any removal of Zone EL4 occurred prior to EL3 deposition, possibly associated with an unnamed 'early' Danian tectonic event. Thinner sequences of Lower Ekofisk Formation sediments are developed along the western margin of the Alpha structure; they are largely absent on the eastern margin of the Alpha structure and on the East Eldfisk structure. Subsequent erosion or non-deposition from these areas suggests they may have been structurally higher than the Bravo structure during or just after deposition of the EL. When compared with the Tor Formation (Subzone EL5B), these areas of absence

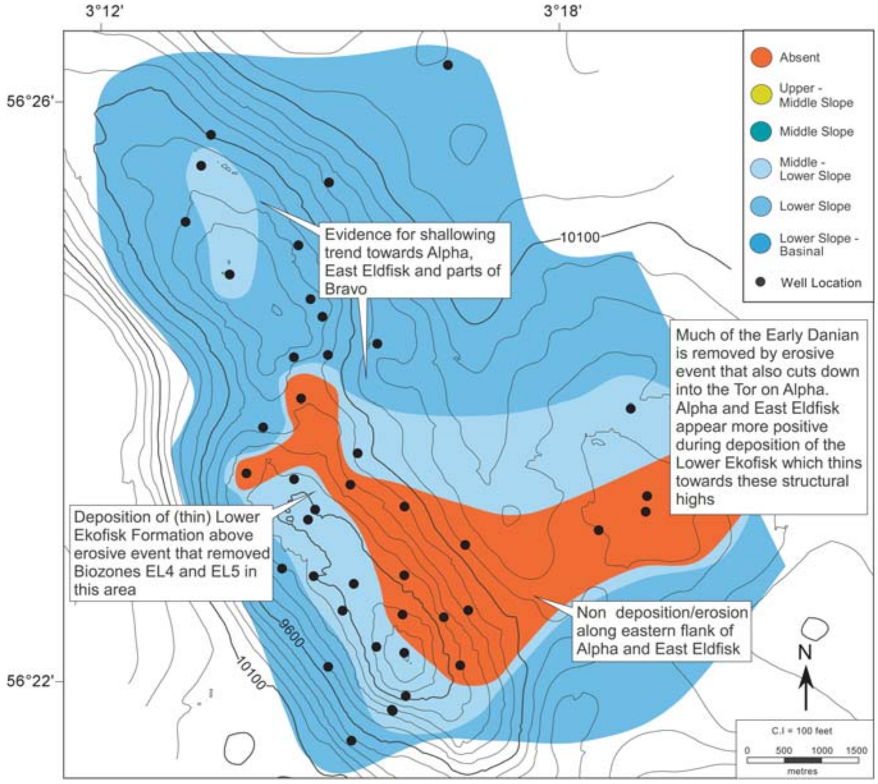

Fig. 16. Biofacies map for the 'mid-early' Danian Lower Ekofisk Formation. The areas of absence have shifted relative to the Late Maastrichtian, suggesting different erosional phases from the Late Maastrichtian.

suggest eastward migration of the crestal line of the 'Alpha ridge' due to movement on the underlying Skrubbe fault. The absence of these sediments on East Eldfisk, following backfilling and structural growth of East Eldfisk during the Maastrichtian, resulted in the presence of an eastern structurally positive area during the 'early' Danian.

Middle Ekofisk Formation

Age. 'Late' Danian, comprising Subzones EL2Ai–EL2B.

Lithology/petrophysics. Middle Ekofisk Formation sediments are the primary hydrocarbon-producing sediments in the Ekofisk Formation on Eldfisk. This ubiquitous unit across Alpha and Bravo displays considerable thickness variations. Thicker sequences are developed in the 'saddle area' between the Alpha and Bravo structure, whilst EM sediments are absent on the East Eldfisk structure. Lateral variations in thickness are attributed to variations in the proportion of *in situ* 'late' Danian material, reworked Late Cretaceous derived sediments and reworked intra Danian sediments. The reworking has a detrimental effect on the porosity in this unit.

Biofacies. The structural relief is supported by biofacies data which implies a shallower middle slope environment of deposition along the 'Alpha ridge', the southern part of crestal Alpha representing the shallowest environment (and structurally higher). No biofacies data exist for the East Eldfisk structure as no sediments of this age are preserved over this area and extending onto the SE flank of Alpha, suggesting that this area was also a structural high at this time. Around the 'Alpha ridge', middle–lower slope water depths are recognized in virtually every well; deeper water lower slope facies existed towards the SW flank (Fig. 17).

Tectonostratigraphy. An undescribed intra Danian tectonic phase may provide a mechanism for the reworking observed; such a phase has been intimated by Mackertich & Goulding (1999) on the South Arne Field. Presumably, comparable local tectonism can be invoked to account for the active reworking of both Late Cretaceous and Danian sediments during the deposition of the Middle Ekofisk Formation described here. Certainly inversion pulses along the Lindesnes Ridge, most active during the Late Cretaceous, are considered to continue through the Cenozoic by Wride (1995), who also recognizes continued reversal movements along the Skrubbe Fault during this time.

Upper Ekofisk Formation

Age. 'Late' Danian Subzones EL2C–EL1B.

Lithology/petrophysics. This unit is pervasive across Eldfisk and grades from clean, porous hydrocarbon saturated chalks in Subzone EL2C to marls transitional with the overlying Våle Formation in Subzone EL1B. This reflects progressive submergence of the region during the transitional phase from chalk deposition during the Danian to dominantly argillaceous deposits in the Selandian Våle Formation. *Zoophycos* trace fossils become conspicuous and increase in abundance in the EU, perhaps suggesting decreasing oxygen levels in the bottom waters as water depth increases. The Upper Ekofisk Formation is relatively uniformly developed across the Bravo and Alpha structures and interpreted as a largely autochthonous, hemipelagic drape which can be recognized regionally. Some variation in thickness is seen towards East Eldfisk, where this unit appears to thin, inferring the continued presence of the structural high towards East Eldfisk as recognized during deposition of the Middle Ekofisk Formation.

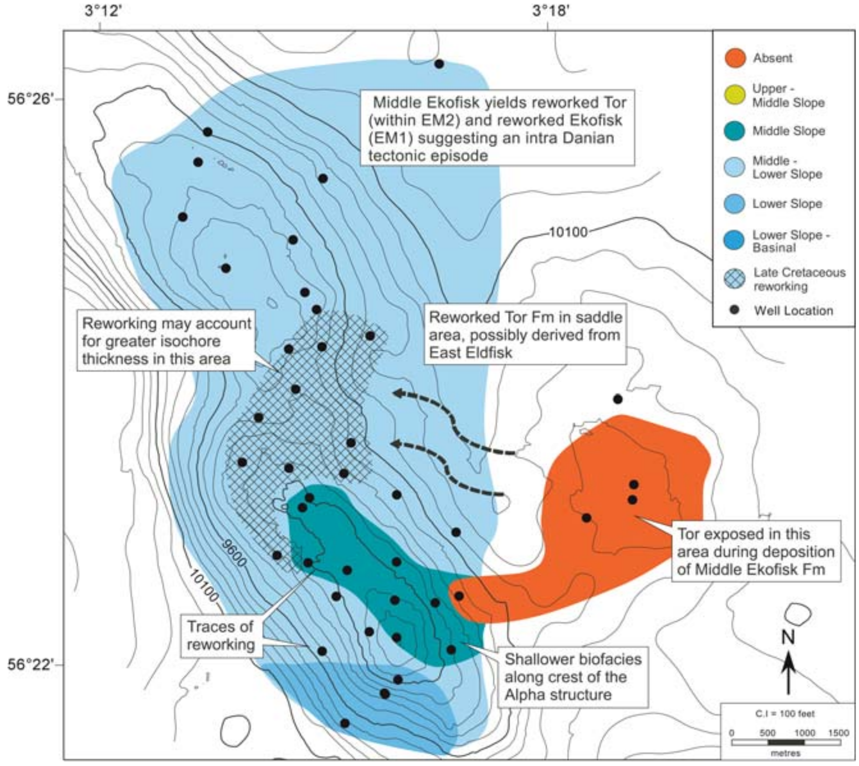

Fig. 17. Biofacies map for the 'late' Danian Middle Ekofisk Formation suggesting structural relief and growth of East Eldfisk. An area of Late Cretaceous reworking, concentrated in the saddle area, was mapped and this proved to be an important marker for geo-steering a horizontal well in the area.

Biofacies. Results imply a gradual increase in water depth from the crestal area northeastwards into East Eldfisk. Structural relief is still evident with lower slope to basinal water depths interpreted around the margins of the Eldfisk structures, shallowing slightly through lower slope on the flanks to middle-lower slope depths across crestal Alpha (Fig. 18).

Conclusions

The tectonic and eustatic events that have controlled chalk deposition on the Eldfisk structure as recognized in this study are summarized in Figures 19 and 20. They have been used in interpreting the structural history of Eldfisk, their impact on the deposition and

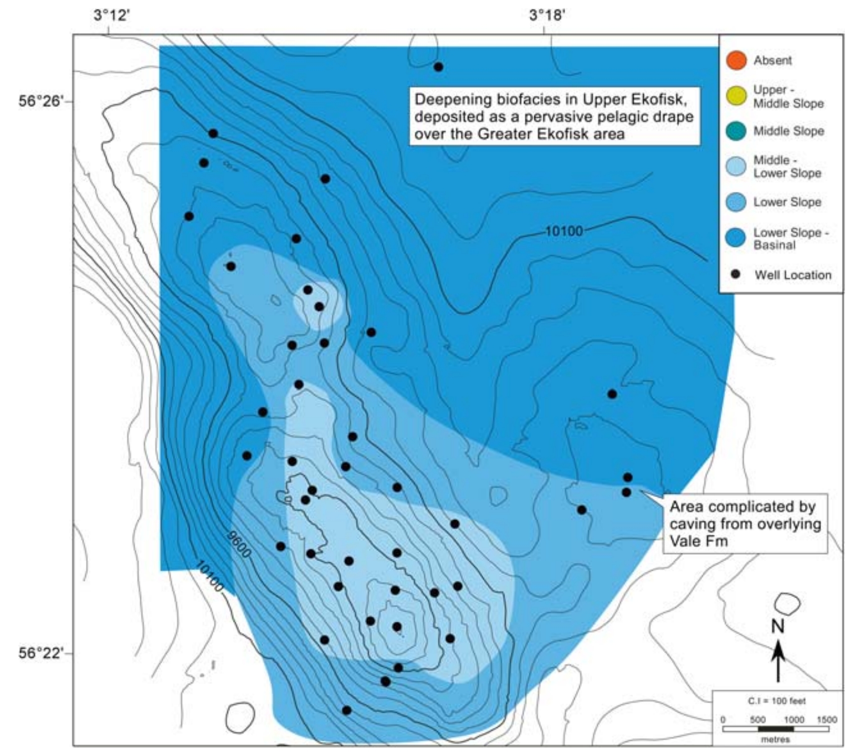

Fig. 18. Biofacies map for the 'late' Danian Upper Ekofisk Formation, suggesting deepening water trend throughout the 'latest' Danian. The deepening trend continues into the marls of the Våle Formation.

Event	Age	Formation	Comments	Reference
Unnamed mid–late (EM) Danian event	Mid–Late Danian	Mid Ekofisk	Erosion on East Eldfisk, reworking of Late Cretaceous sediments into local depocentres on Eldfisk, large scale re-deposition in the Ekofisk trough. Regionally pervasive re-deposition of 'early' Danian sediments. Growth faulting on Eldfisk? Penecontemporaneous re-mobilization of Zone EL2Ai (soft sediment overfolds seen in Ekofisk trough).	Mudge and Jones 2004
'Laramide' Tectonic event	End Cretaceous–earliest Danian structural phase	Tor	Early Danian erosive event removing Zone EL4 over Eldfisk. Erosion of Tor Formation Zone EL5 from the 'Alpha ridge'.	Hart 2007
Junior transgression	Late Maastrichtian	Tor	Brings warm water planktonics into N. Sea and deposits Zone EL5 as hemipelagic drape.	
'Mid' Maastrichtian Tectonic event	'Mid' Maastrichtian, Zone EL6	Tor	A series of minor structural events recognized across Northern Germany which may equate to generation of bioclastic rich debris flows on Eldfisk. Growth faulting resulting in eastwards shift of 'Alpha ridge'. Growth of East Eldfisk structure.	Bless *et al.* 1986; Niebuhr *et al.* 2000
Oebisfelde transgression	Early Maastrichtian	Tor	Responsible for deposition of 'lower' Tor Formation, nondeposition on structural highs.	Niebuhr *et al.* 2000
Polyplocum Regression/Late Campanian tectonic phase	Latest Campanian	Magne	Onset of sealevel fall and the onset of hardground formation on structural highs, possibly coincident with a Late Campanian tectonic phase; possibly responsible for formation of Bravo channel (crestal collapse or slope failure feature?), intraclasts in upper Magne Formation.	Bless *et al.* 1996; Niebuhr *et al.* 2000
Mucronata Transgression	Late Campanian	Magne	Widespread flooding phase - initiates high sealevels recognized globally. Magne deposited in variety of lithofacies due to presence of structure formed during earlier Peine phase. Nondeposition on crestal areas where Narve is exposed and reworked into surrounding Magne.	Niebuhr *et al.* 2000
Peine Tectonic event	Lower/Upper Campanian boundary	Magne	Major, widely recognized, structural event over Northern Europe which resulted in significant unconformities and removed the Early Campanian (and older) sediments from Eldfisk.	Riedel 1940,1942; Bless *et al.* 1986; Mortimore & Pomerol 1991, 1997, 1998
Pilula Transgression	Early Campanian transgressive phase	Magne	Recognized across northern Germany and the UK. Sediments probably deposited over the structure but only preserved in East Eldfisk and flanks of the Eldfisk structure. Base Magne shows onlap relationship (on Thud) and overstep (on Narve) reflecting previous structural growth phases.	Niebuhr *et al.* 2000
Wernigerode Tectonic event	End Santonian event	Thud	Recognized across much of Europe and into North & West Africa. Major inter-regional structural re-alignment, structural growth and erosion possibly responsible for removal of Thud over much of Eldfisk.	Stille 1924; Guiraud & Bosworth 1997; Mortimore & Pomerol 1991,1997; Mortimore *et al.* 1998;
Marsupites Transgression:	Late Santonian flooding event	Thud	Probably deposits Thud over entire area (deep water biofacies when preserved). Base Thud displays onlap relationship due to presence of structurally created topography. Thud preserved in off structure settings.	
Mittel Santon Pulse	Middle Santonian	Narve	Minor tectonic event recognized in northern Germany, London Basin and probably in the Central Graben area. Erodes Early Santonian sediments and erodes down into the Narve Formation.	Niebuhr *et al.* 2000
Undulatoplicatus Transgression	Base Santonian flooding event	Narve	Recognized across Northern Europe but evidence on Eldfisk has currently not been recognized due to subsequent erosional events.	Niebuhr *et al.* 2000
Ilsede	Early (mid Turonian) and late (Late Turonian–Early Coniacian) phases	Narve	Major phase of structural movements recognized across Europe. Initial stages of inversion during 'mid' Turonian led to growth of the Eldfisk structure upon which subsequent tectonic phases are expressed.	Stille 1924; Mortimore & Pomelro 1991, 1997; Mortimore *et al.* 1998

Fig. 19. Summary of the tectonic and eustatic events discussed in this study.

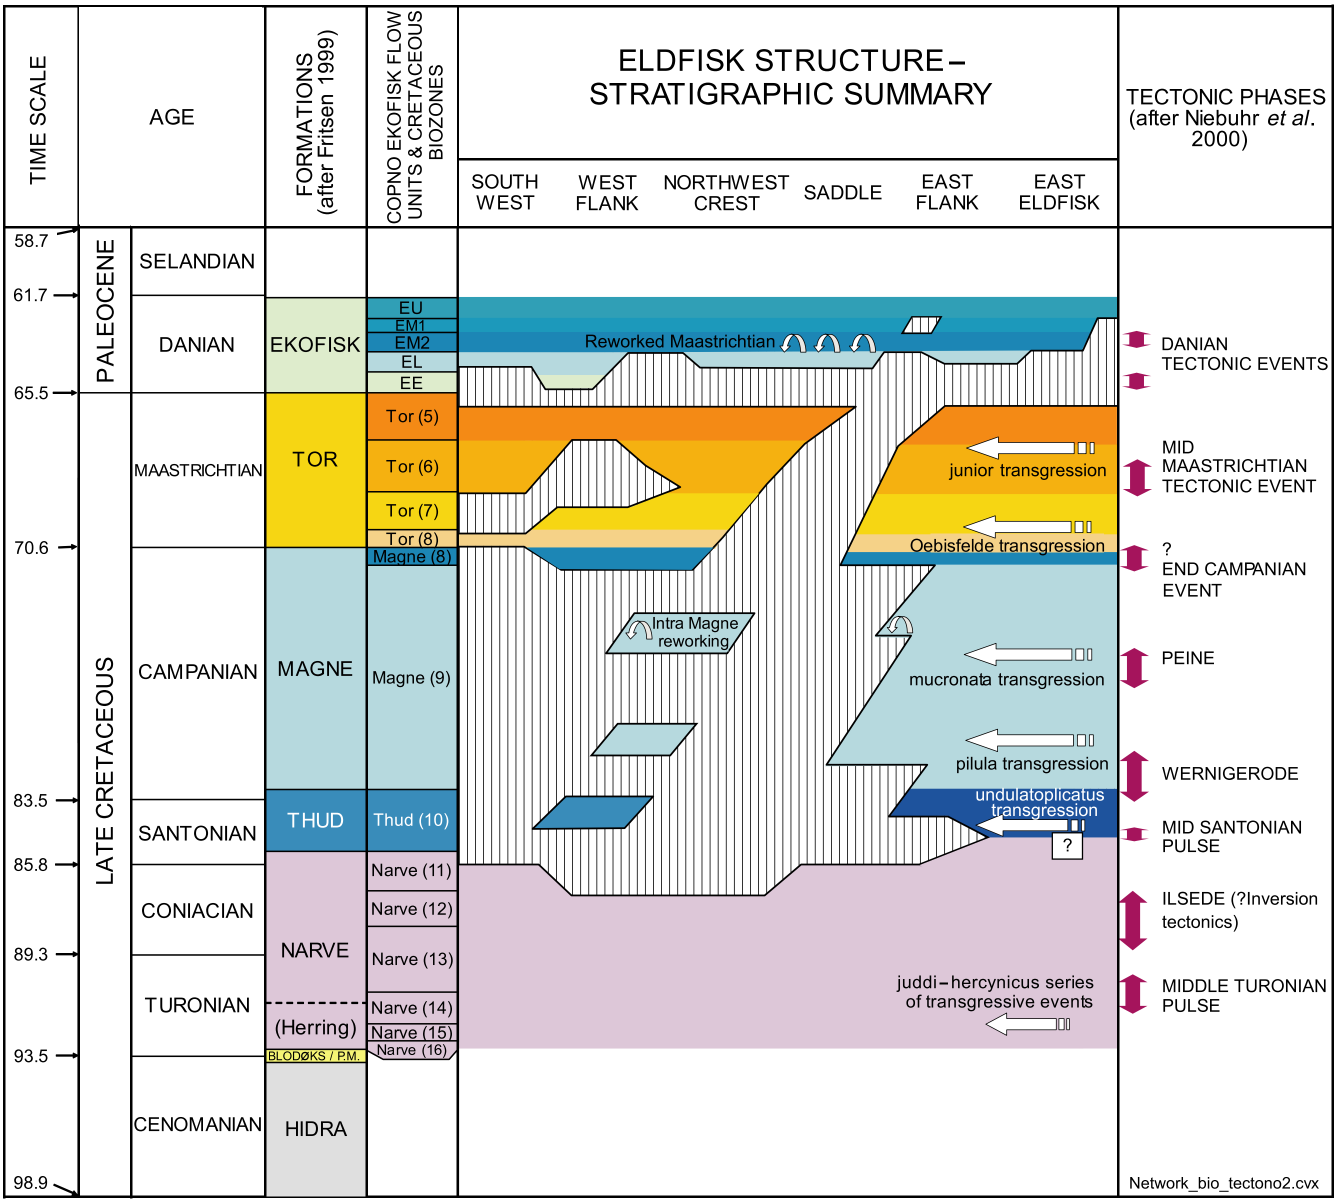

Fig. 20. Eldfisk Field biostratigraphic and tectonostratigraphic summary showing depositional variations across the structure, including a near-complete sequence on the gentle sloping eastern flank of Alpha (dominantly eustatic control) v. the punctuated (tectonic/fault control) pattern on the steeper, western flank and crestal areas.

preservation of discrete sediment packages and the various hiatuses and unconformities that bound them. Having defined this sequence of events it proved possible to create a geological model based on a tightly constrained stratigraphy, which has been shown to hold in all the wells in the study area. Tectonically controlled sedimentation in the Central Graben is well known; however, this study confirms the pulsed, punctuated nature of the tectonics. This study implies that the timing of these phases correlates with tectonic phases described from Germany, the Low Countries and the Anglo-Paris basin, thus extending the area influenced by Sub-Hercynian tectonics. Previously undescribed tectonic phases are also described from the Danian. The subdivision of the reservoir has also proven useful in the following ways:

(1) predicting where and why reservoir facies are developed on the structures;
(2) greater appreciation of the geographical and temporal extent of reworking in the EM and its effect on porosity on this structure;
(3) a new three-fold division of the Tor Formation with recognition and appreciation of the distribution of an allochthonous, bioclastic debris rich, porous Middle Tor Formation unit;
(4) recognition of variable lithofacies and petrofacies in the Magne Formation, including a crestal high-porosity reservoir facies comparable to the Tor Formation but with subtle poroperm differences.

Despite the complex inter-relationships between eustatic sea level changes, tectonic events and halokinetic movements which are acknowledged to exist, stratigraphical studies on numerous wells in this region have given rise to a stratigraphic framework in which the same sequence of events can be recognized over a large area with remarkable regularity, punctuated by unconformities and hiatuses at predictable stratigraphic levels. The holostratigraphic approach outlined here has greatly enhanced the geological appreciation of the Eldfisk Field by creating a unified geological model that ties with current regional understanding. This in turn has impacted on the geophysical interpretation and will guide the new 3D geological and simulation models that are currently under construction. The study had an immediate impact on the ongoing drilling programme, where the improved understanding has helped geo-steer horizontal wells. The biostratigraphic and lithostratigraphic framework has since been successfully applied to other chalk fields across the North Sea Basin for geosteering, geostopping and multiwell correlation studies; however, no wide-scale regional study has yet been undertaken to understand the utility of the technique on the basin scale.

Often the biggest hurdle to studies such as these is the gathering and compilation of a vast array of data that has been archived over a long period of time. However, the effort is rewarded as these types of studies become increasingly important in attempts to exploit the remaining resources on a field and prove that, even after 30 years of production and drilling, there is still a lot to be learnt on these old production assets.

The authors would like to thank the Eldfisk Group for permission to publish this paper: ConocoPhillips Skandinavia AS (Operator), Total E&P Norge AS, ENI Norge AS, StatoilHydro Petroleum AS and Petoro AS. Thanks to P. McQuillan for providing geophysical background and interpretations and L. Gallagher, R. Mortimore and F. Gradstein are thanked for advice and constructive comments throughout this project and for reading early drafts of this text. S. Balke is thanked for his continued support and enthusiasm throughout this project. The many reviewers of this paper are also thanked for their time and helpful comments. The interpretations expressed in this paper are the opinions and responsibilities of the authors and do not necessarily reflect those of ConocoPhillips or its co-venturers.

Abstract: A high magnitude of overpressure is a characteristic of the deep, sub-Chalk reservoirs of the Central North Sea. The Upper Cretaceous chalk there comprises both reservoir and non-reservoir intervals, the former volumetrically minor but most commonly identified near the top of the Tor Formation. The majority of non-reservoir chalk has been extensively cemented with average fractional gross porosity of 0.08, and permeability in the nano- to microDarcy range (10^{-18}–10^{-21} m^2), and sealing properties comparable to shale. Hence deeply buried chalk is comparable to shale in preventing dewatering and allowing overpressure to develop. Direct pressure measurements in the Chalk are restricted to the reservoir intervals, plus in rare fractured chalk, but reveal that Chalk pressures lie on a pressure gradient which links to the Lower Cenozoic reservoir above the Chalk and the Jurassic/Triassic reservoir pressures below. Hence a pore pressure profile of constantly increasing overpressure with increasing depth is indicated. Mud weight profiles through the Chalk, by contrast, show many borehole pressures lower than those indicated by these direct measurements, implying wells are routinely drilled underbalanced. The Chalk is therefore considered the main pressure transition zone to high pressures in sub-Chalk reservoirs. In addition to its role as a regional seal for overpressure, the Base Chalk can be shown to be highly significant to trap integrity. Analysis of dry holes and hydrocarbon discoveries relative to their aquifer seal capacity (the difference between water pressure and minimum stress) shows that the best empirical relationship exists at Base Chalk, rather than Base Seal/Top Reservoir, where the relationship is traditionally examined. Using a database of 65 wells from the HP/HT area of the Central North Sea, and extending the known aquifer gradients from the Fulmar reservoirs via Base Cretaceous to Base Chalk, leads to a risking threshold at 5.2 MPa (750 psi) aquifer seal capacity. Discoveries constitute 88% of the wells above the threshold and 36% below, with 100% dry holes where the aquifer seal capacity is zero (i.e. predicted breached trap). This relationship at Base Chalk can be used to identify leak points which control vertical hydrocarbon migration as well as assessing the risk associated with drilling high-pressure prospects in the Central North Sea.

Keywords: overpressure, Central North Sea, seal breach

A high magnitude of overpressure is a characteristic of the deep, sub-Chalk reservoirs of the Central North Sea (Gaarenstroom *et al.* 1993). The excess pressure is distributed mainly in Jurassic and Triassic pressure cells with overpressure increasing with depth. The origin of the overpressure is considered to be a function of rapid loading during late Cenozoic burial as well as contributions from thermal processes (e.g. gas generation) during deep, high-temperature burial (Swarbrick *et al.* 2002, 2005*a*, *b*). Some valid high-pressure trap structures have been drilled and have found hydrocarbons; others have been found to be water-wet (dry holes), and some of these show evidence of leakage of earlier trapped hydrocarbons.

Hydrocarbon leakage occurs either when the hydrocarbon buoyancy pressures exceed the capillary entry pressure (membrane failure) or when pore pressures exceed the fracture strength of the seal (hydraulic failure). Jurassic and Cretaceous sealing units in the Central North Sea have high capillary entry pressures which favour hydraulic failure as the main leakage process (Ingram & Urai 1999). Data in the Central North Sea show that many deep reservoirs have pore pressure close to the estimated fracture strength of the seal. The seal above these high-pressure reservoirs consists of variable thicknesses of Jurassic and Lower Cretaceous shales (with minor sandstone and limestone units in some locations) and the Upper Cretaceous Chalk. There are few direct pore pressure measurements to validate pressure profiles in these dominantly fine-grained sediments within the seal. Many published pressure profiles are based on drilling data, especially mud pressures coupled with the presence of gas. These interpretations feature a rapid increase of overpressure at the base of the Chalk and through the Lower Cretaceous and Upper Jurassic shales, where present (Holm 1998*a*, *b*). We re-assess the data in light of new permeability for the Chalk (Mallon *et al.* 2005; Mallon & Swarbrick 2008) from rare direct pressure measurements plus gas data. A high-quality database of 1248 wells was made available by IHS. The study location area is displayed in Figure 1. These data included direct pressure measurements such as Repeat Formation Tester (RFT), Drill Stem Tests (DST) and Kicks, as well as ancillary data such as stratigraphic tops and mud weights. Drilling reports were utilized where possible to provide evidence of pressures encountered during drilling such as connection gas build-ups and other drilling data.

Pressure transition zone through the Chalk

The Upper Cretaceous Chalk of the Central North Sea varies in thickness between 850 and 1500 m (2800 and 5000 ft) at burial depths of 2000–4000 m (6600–13 100 ft). The chalk comprises both reservoir and non-reservoir intervals, the former most commonly identified near the top of the Tor Formation (although porous units are present also in the Herring Formation). Reservoir chalk is interpreted as a re-deposited chalk, rapidly buried and removed from the sediment–water interface, thereby reducing cementation (Brasher & Vagle 1996).

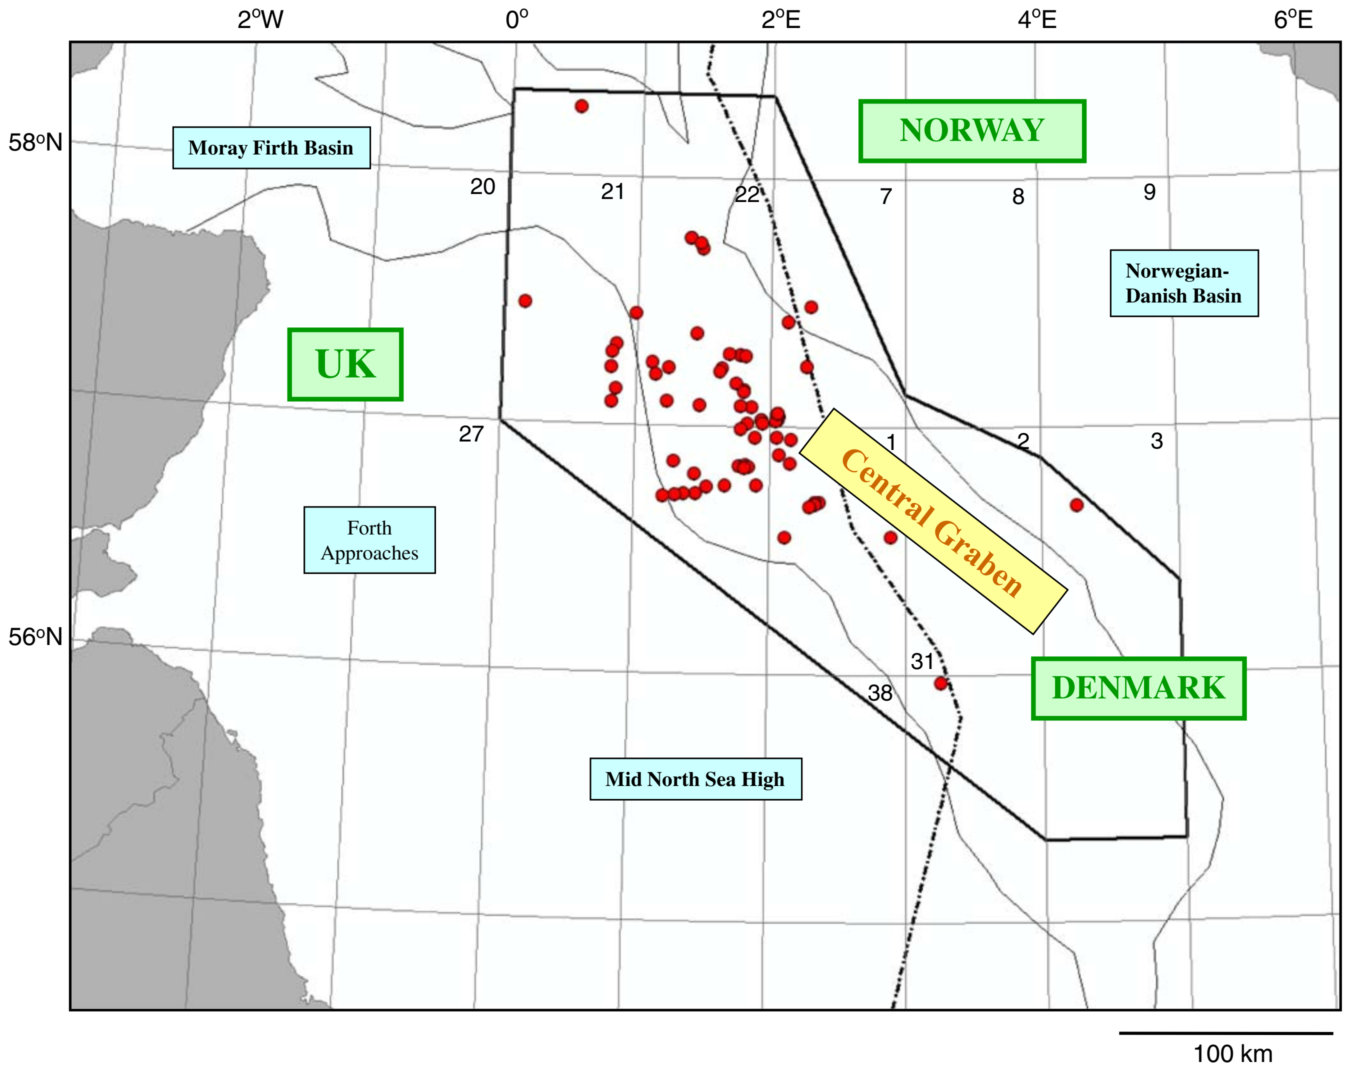

Fig. 1. Location of the North Sea Central Graben. Red dots represent the location of the 65 wells used in the analysis of hydraulic top-seal failure (see text).

Characteristics of non-reservoir chalk

The non-reservoir chalk is dominantly pelagic with varied lithofacies: (a) massive, clean chalk comprising coccolith fragments with early contact cements; (b) massive, clean chalk with localized stylolites; and (c) burrowed, laminated argillaceous chalk containing dissolution seams (Fig. 2). Mallon *et al.* (2005, 2008) describe the deeply buried non-reservoir chalk as extensively cemented with fractional gross porosity from 0.04 to 0.18 (average 0.08), compared with 0.20–0.40 in the reservoir intervals at similar depths. The permeability of the reservoir chalk is in the milliDarcy to microDarcy range (10^{-15}–10^{-18} m^2), compared with non-reservoir chalk permeability in the nano- to microDarcy range (10^{-18}–10^{-21} m^2) depending on depth of burial. Low values in non-reservoir chalk are comparable to shale permeability (Mallon *et al.* 2005). Hence deeply buried chalk has equal ability as shale to seal overpressure in underlying highly pressured reservoirs. Moreover, core reveals the chalk to be predominantly massive and cemented and unlike the highly layered fabric of the underlying Cretaceous (Cromer Knoll) and Upper Jurassic (Kimmeridge and Heather) shales.

Pressures in the Upper Cretaceous Chalk

Direct pressure measurements in the chalk are restricted to the reservoir intervals, plus rare measurements in fractured chalk. It is not possible to independently assess the pore fluid pressures in non-reservoir chalk due to a lack of relationship between porosity and effective stress (Lubanzadio *et al.* 2002). When plotted on a pressure–depth plot, Chalk fluid pressures recorded in reservoir units such as the Tor and Herring Formations normally lie on a pressure gradient linking pressures found in Lower Cenozoic reservoir above the Chalk with Jurassic/Triassic reservoir pressures below (Fig. 3). The resulting profiles show pressure transition zones of constantly increasing overpressure with increasing depth.

Mud pressure profiles through Chalk succession

Mud pressures represent an upper limit to pore pressures where the rocks are sufficiently permeable to allow fluid flow into the borehole during drilling operations. In the non-reservoir chalk we believe the permeability is low enough for mud weights to be below the actual pore fluid pressures. Sediments can only be drilled underbalanced (pore pressures are higher than mud weight) when they have extremely low permeability. This situation applies to non-reservoir chalk. We calculate that for a 1000 m (3300 ft), non-reservoir chalk section of $12\frac{1}{4}$ in diameter borehole with formation water 6.9 MPa (1000 psi) higher pressure than the borehole pressure, and assuming 50 nD permeability Chalk, the fluid influx approximates only 0.5 barrels per day, that is, below influx detection levels.

The low permeability and potential to drill underbalanced helps explain the mud weight profiles observed through the Chalk. In UK well 22/30a-2 (Heron Discovery) (Fig. 4), the mud weight was

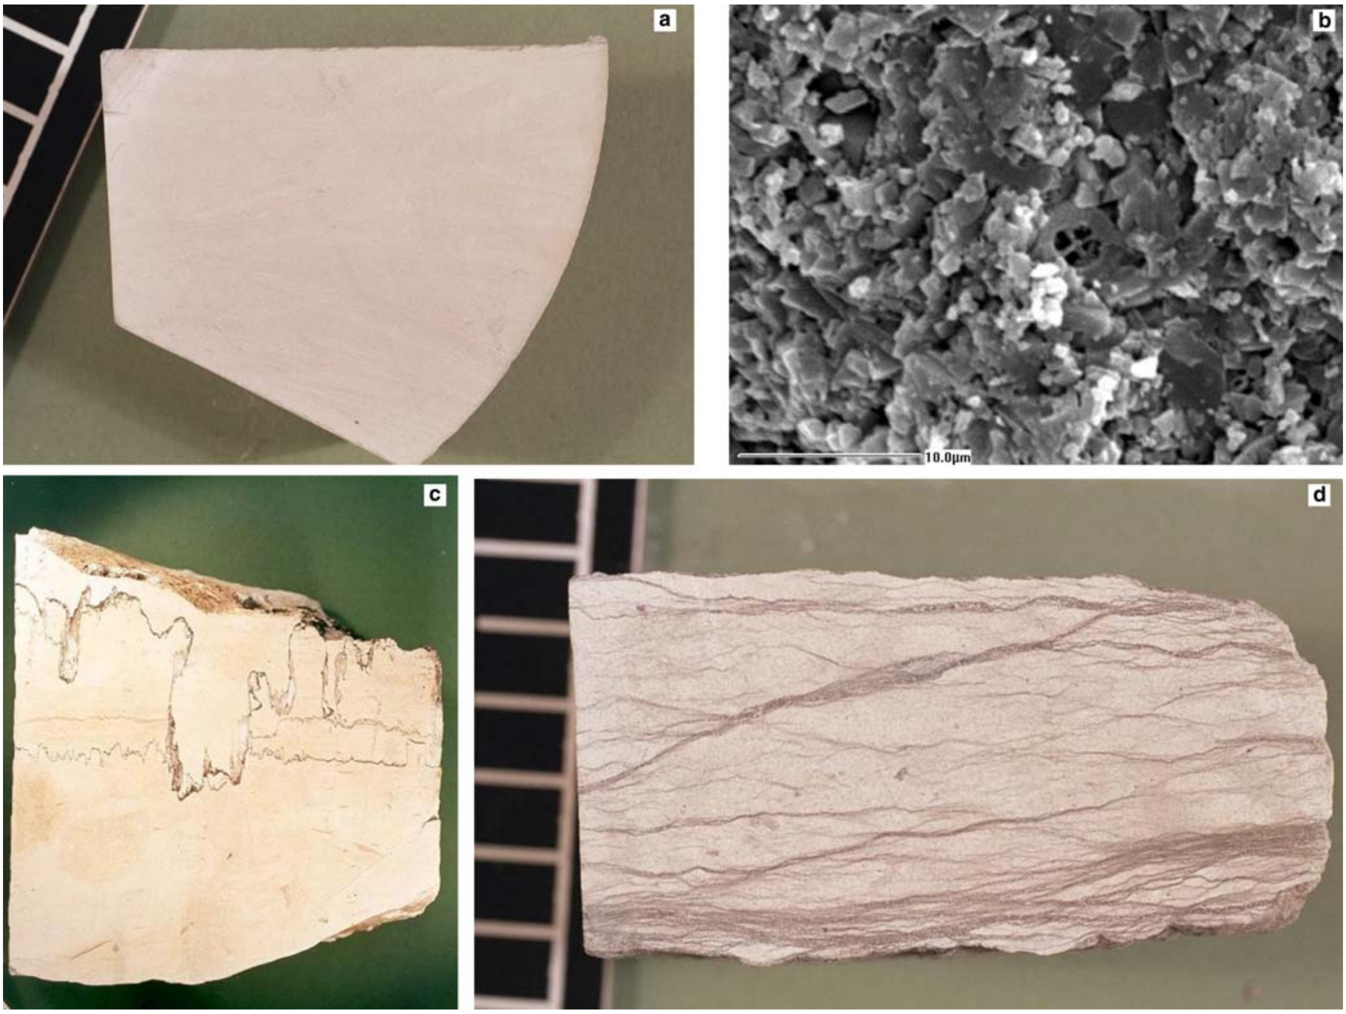

Fig. 2. Reservoir and non-reservoir chalk facies: (**a**) massive, clean chalk comprising coccolith fragments with early contact cements; (**b**) SEM view of the same; (**c**) massive, clean chalk with localized stylolites; and (**d**) burrowed, laminated, argillaceous chalk containing dissolution seams.

maintained at 12.3 ppg through the Cromer Knoll to a deep casing point. After setting casing, the mud weight was increased to 17.5 ppg, prior to drilling into the Fulmar reservoir with 47.7 MPa (6920 psi) overpressure. In our model for Chalk pressures the pore pressure was much higher through the Chalk than represented by the mud weight profile, but no measureable influx occurred because of the low permeability. Other wells, such as UK well 22/30c-10 (Elgin Appraisal; Fig. 4), show mud weight increased several times through the Hod and Hidra Formations to control increases in gas. Influx of gas is consistent with higher formation pressures than balanced by the mud weight (Holm *et al.* 2008).

Furthermore, the relevance of thick sub-Chalk shales above the high-pressure Fulmar reservoir for sealing of high pressure reservoirs is also challenged. In Figure 5, four UK wells situated in the deeper parts of the Central North Sea have variable thicknesses of sub-Chalk mudrocks above highly overpressured Fulmar reservoir beneath. The mud weight profiles in UK wells 22/29-2 and 22/30b-4 are lower than the corresponding pressure transition zones associated with these wells. In well 22/29-2, the thickness of the Base Chalk to Top Fulmar reservoir is only 34 m (109 ft), yet there is 39 MPa (5700 psi) overpressure in the Fulmar. Since the Chalk and sub-Chalk mudrocks/shales have similar permeability the Chalk is acting as part of the pressure seal in this example.

The role of the Chalk as a regional seal

The Chalk is considered the main pressure transition zone to high pressures in sub-chalk reservoirs, rather than the sharp transition zone starting near Base Chalk and continuing through the Cromer Knoll/Kimmeridge Clay favoured by other authors (e.g. Holm 1998*a*, *b*; Daniel 2001; Winefield *et al.* 2005). We believe the evidence for the actual pore pressure profile, based on available but rare pressure measurements in the more permeable units, points to a steady-state pressure profile controlled by low overpressure, Cenozoic reservoirs above, and reservoir and sub-Chalk mudrock pressures below the Chalk.

The evidence presented above implies that the North Sea Chalk must play a significant role in the development of the high overpressures found in deeper reservoirs, especially in the Central North Sea area. Earlier emphasis on the rock properties of the volumetrically minor reservoir chalk may have led to the belief that the chalk did not contribute to trapping of overpressure beneath. The results revealed in this paper, coupled with permeability data from non-reservoir chalk, dispel that assessment. We now explore the evidence for the Base Chalk as a significant barrier to upwards hydrocarbon migration and hence a major influence on the preservation of hydrocarbons in Jurassic/Triassic traps, located deeper in the section.

Seal breach analysis

Seals leak, or breach, and hydrocarbons are re-migrated to younger reservoirs by either hydraulic failure (either by shear, i.e. faulting or reactivation of an existing fault, or by opening of tensile fractures) or membrane leakage (when the hydrocarbon buoyancy pressure

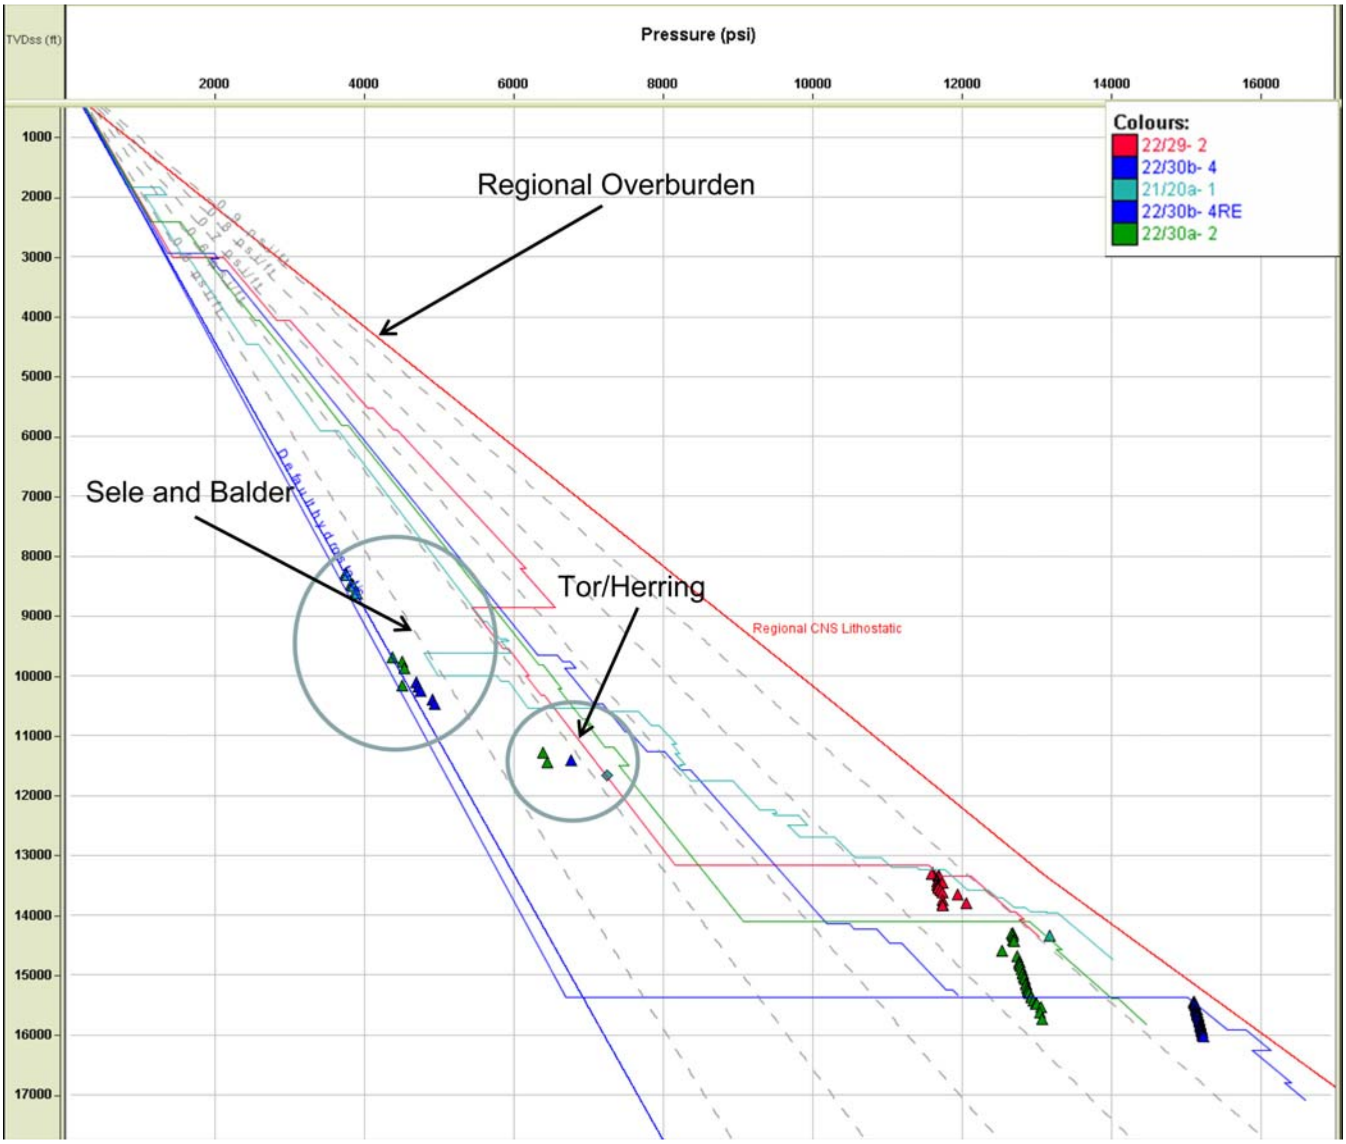

Fig. 3. Pressure–depth plot showing data from UK wells 22/29-2 (Seagull discovery), 22/30b-4 (Shearwater discovery) and RE, 21/20a-1 and 22/30a-2 (Heron Discovery) displaying profiles of increasing overpressures with increasing depth of burial. Coloured lines represent mud weights used to drill these wells.

exceeds the capillary entry pressures of the seal). As Jurassic and Cretaceous sealing units in the Central North Sea have high capillary entry pressures (due to their fine-grained lithology), hydraulic failure is the main leakage process. Gaarenstroom *et al.* (1993) assessed the risk of seal breach in the Central North Sea by calculating the 'retention capacity' (their term) of the top seal in relation to hydraulic failure and concluded that when the difference between pore fluid pressures and minimum horizontal stress at Top Reservoir is less than approximately 7.0 MPa (1000 psi) there is a high risk of seal breach into the overlying seal. Similar conclusions were reached by Holm (1998*a*, *b*) and Winefield *et al.* (2005), who also emphasized the role of the overlying shales (i.e. Jurassic Kimmeridge/Heather Formations and the Lower Cretaceous Cromer Knoll Group) in sealing the deep high-pressure reservoirs beneath.

Aquifer seal capacity

We have re-examined the analysis of Gaarenstroom *et al.* (1993), using a larger database of high pressure wells over a wider geographical region of the Central North Sea (Fig. 1). For each well the **aquifer seal capacity**, here defined as the difference between water pressure, extrapolated from the reservoir pressure data, and minimum compressive stress at the reservoir/field crest, have been estimated (Fig. 6) using all available data. The influence of hydrocarbon buoyancy has been examined later in relation to the data using hydrocarbon seal capacity in discovery wells. Measured pore fluid pressure can be used to determine both aquifer and hydrocarbon gradients. Fracture strength was estimated using a relationship built from rock stress relationships coupled with borehole Leak Off Test and incorporating a fluid pressure–stress coupling terms to capture the poroelastic fluid–stress interaction (see Engelder & Fischer 1994). Lithostatic stress was determined from five wells with almost complete density log coverage, to depths of nearly 5500 m (18 000 ft). Analysis of top seal failure (seal breach) ideally compares aquifer pressure with minimum stress at the crestal location of a structure (Fig. 6), and we have assumed that each well penetrated the reservoir within 150 m (492 ft) of the crest.

Assuming a water-wet reservoir, the buoyancy pressure in the hydrocarbon phase is considered to have a minor influence on rock behaviour, and hydraulic failure is most closely linked to aquifer pressure. Given that in a petroleum accumulation, the pores in the trap are filled with a two-phase fluid system, and the

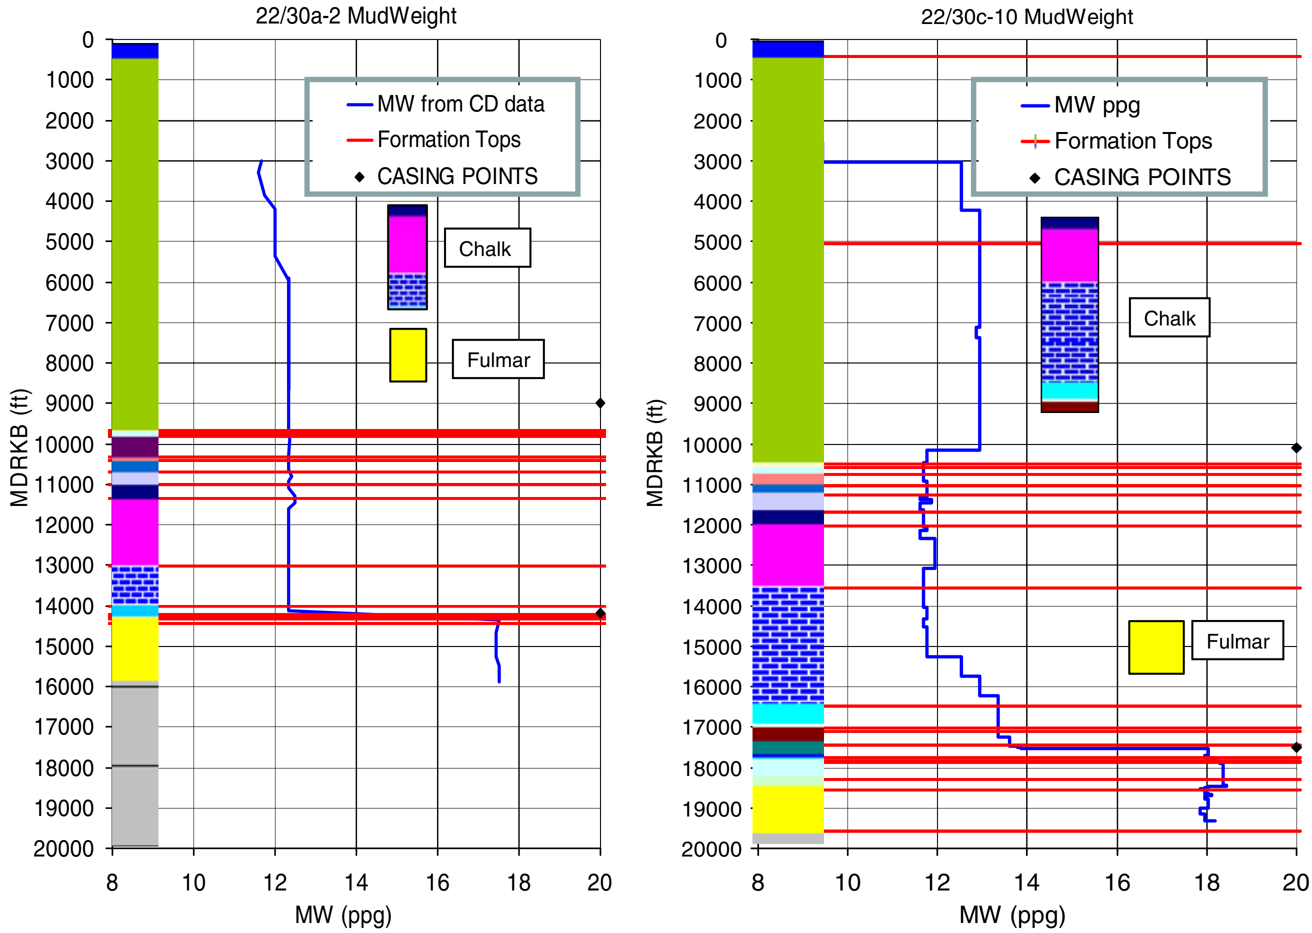

Fig. 4. A typical UK well 22/30a-2 has been drilled with a low mud weight to near Base Chalk. In contrast, in some wells, such as 22/30c-10, mud weight increases several times over the same stratigraphic intervals, to subdue high gas readings interpreted as high pressure. The absence of indications of high fluid pressures in the chalk in many wells is on account of the low porosity and low permeability of deeply buried Central North Sea chalk.

petroleum and water are immiscible, then in such a water-wet reservoir (i.e. one in which water coats the rock grains in a continuous phase or film, as it does in the overlying seal lithology), the overpressure in the hydrocarbon phase relative to the water phase does not increase the risk of hydrofracturing the reservoir's seal. Bjørkum *et al.* (1998) reason that the interfacial tension (elastic forces at the fluid interface and an influence on capillary entry pressure of the seal) balances the hydrocarbon buoyancy. This assumption appears to be reasonable for the typical hydrocarbon column heights found in the Central North Sea, that is, 160 m (500 ft), and is supported by data in Hermanrud *et al.* (2005) where pressure differences between the oil and water phases in a water-wet, oil-saturated core were equivalent to these column lengths. Gaarenstroom *et al.* (1993), along with a list of others referred to by Bjørkum *et al.* (1998), consider that buoyancy pressure in the hydrocarbon column contributes to hydrofracturing of the reservoir cap rock seal.

Comparison of methods

Differences between the results for sealing at Top Reservoir presented here and other studies in the same area arise from two main factors: (a) our reliance on aquifer seal capacity (this study) v. hydrocarbon pressure in hydrocarbon discoveries and aquifer pressure for dry holes (e.g. Gaarenstroom *et al.* 1993) and (b) our use of the lower of either (i) fracture gradient based on an algorithm incorporating a fluid pressure–horizontal stress term or (ii) lithostatic stress v. use of a minimum bound for Leak Off Test (Gaarenstroom *et al.* 1993; Winefield *et al.* 2005).

Using all available aquifer pressures, a lithostatic stress relationship was generated from density data in selected wells (rather than utilizing a default 1.0 psi/ft). A fracture strength model, based on a regional dataset of Leak Off Tests incorporating a fluid pressure–horizontal stress coupling term, was also generated. The minimum stress in the North Sea Central Graben is then assumed to be the smaller of the fracture strength or the lithostatic stress. We observe that at depths of >4300 m (approximately 14 000 ft) the Leak Off Tests can exceed the lithostatic stress. This apparent stress reversal most likely results from the high pore pressures at depth, as well as the reliance on data from vertical or near-vertical boreholes. Leak Off Tests in vertical boreholes, conducted where the vertical stress is the minimum stress, create vertical fractures initially near the borehole wall, due to the reordering of the stress magnitudes by the Hoop stresses. As these fractures controlled by the horizontal stress magnitude lengthen outside the region of Hoop stresses, they rotate to horizontal in the far field area, responding to the vertical stress field. In these circumstances leak-off pressures are higher than lithostatic result. Other explanations for leak-off pressures higher than the vertical stress are (1) high tensile strength of the rock and (2) increase in lateral compressive stress in the basin (as suggested for many deep basins by Grauls 1998).

Comparison of dry holes and discoveries

Dry hole v. hydrocarbon discovery assignment of well-bores in this study of 65 wells (Fig. 1) are based on (a) published data sources such as Gaarenstroom *et al.* (1993) and Winefield *et al.* (2005) and (b) examination of well logs in other wells. Dry holes were

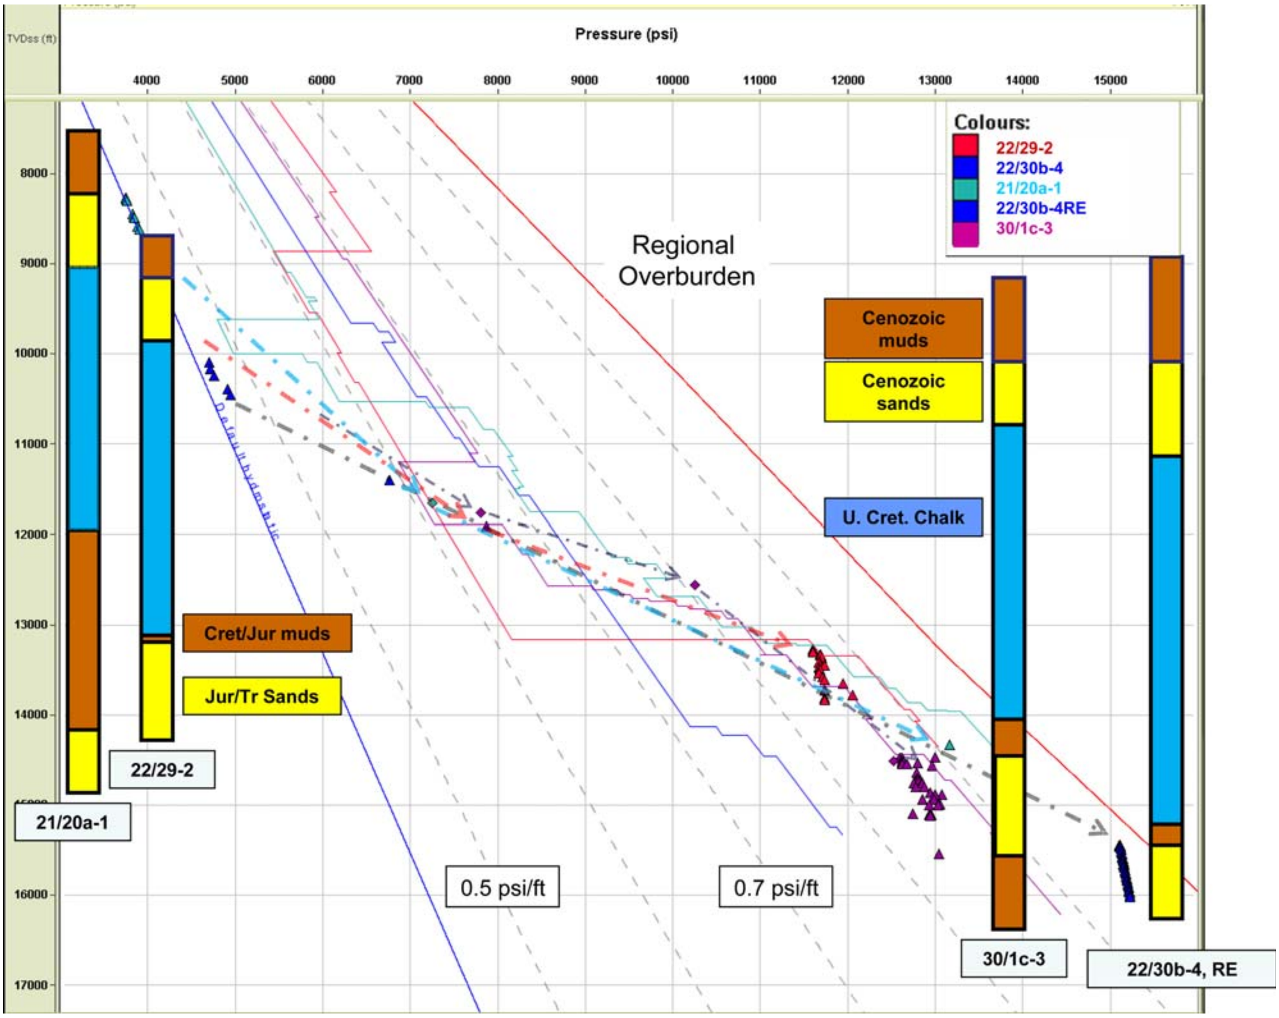

Fig. 5. Direct pressures in the chalk are relatively rare. Several UK wells with these pressure tests are shown, and each indicates increasing overpressure through the chalk, supporting a pressure transition zone of steady increase in overpressure into the underlying Cretaceous/Jurassic shale and reservoir beneath. Mud weights in UK wells 22/29-2 and 22/30b-4 are lower than the corresponding pressure transition zones inferred for these wells. In UK well 22/29-2, the shale thickness between chalk and Fulmar Reservoir is only 109 ft, with a measured overpressure of 39.3 MPa (5700 psi).

assumed to have leaked due to seal failure. Those dry wells where published sources showed the well was drilled off-structure were eliminated from the analysis (e.g. 21/16-3). Only one well per structure was included, so as to remove field-bias. Only wells with an aquifer seal capacity <17.2 MPa (2500 psi) at Top Reservoir are included, leaving a total of 65 wells in the final study set. All data used in the analysis are displayed in Table 1.

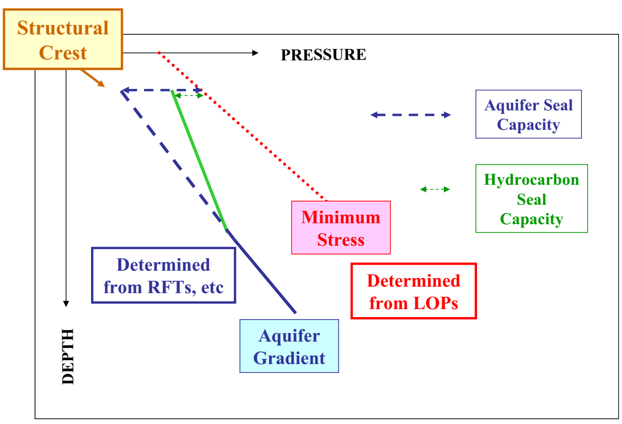

Fig. 6. Aquifer seal capacity is determined where the aquifer overpressure is established and compared with the minimum stress at the structural crest. In a discovery hydrocarbon seal capacity is the difference between hydrocarbon-phase pressure and minimum stress. Minimum stress refers to either fracture or lithostatic pressure.

Top reservoir/base seal

The initial evaluation of aquifer seal capacity relative to distribution of dry holes and hydrocarbon discoveries was completed at Top Fulmar reservoir (the traditional stratigraphic level for analysis of top-seal failure; Fig. 7). There is a marked difference in statistics for discoveries above and below a threshold of 9.7 MPa (1400 psi): 83% discoveries when aquifer seal capacity is above and only 43% discoveries when it is below the threshold. The results compare with a threshold at 7.0 MPa (1000 psi) in Gaarenstroom *et al.* (1993). We note, however, that some dry holes known (from analysis of core) to be ‘leaking’ (hydrocarbon-stained vertical fractures), such as UK wells 21/20a-1 and 22/8a-3, have a higher aquifer seal capacity than UK well 22/30a-4, which has one of the smallest aquifer seal capacities, yet with a 460 m (1510 ft) hydrocarbon column. Whilst we believe the analysis of aquifer seal capacity is appropriate for assessing seal risk, for comparison we have also completed the analysis using hydrocarbon seal capacity at Top Reservoir for discoveries (Fig. 8). Since the hydrocarbon column heights are generally less than 150 m (480 ft) in the Central

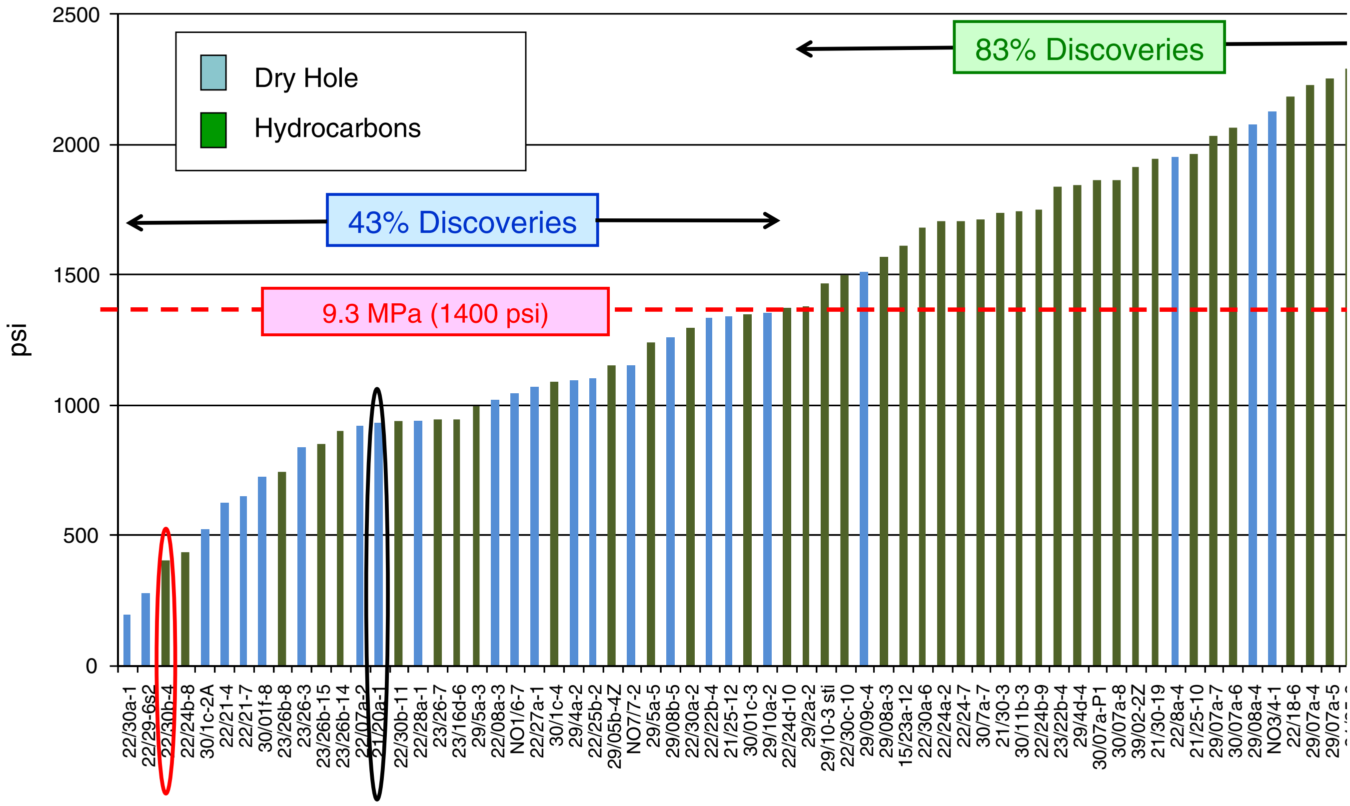

Fig. 7. Histogram of dry hole and hydrocarbon discoveries v. aquifer seal capacity at Top Reservoir. Out of 65 wells 83% are discoveries and 43% are dry holes when an aquifer seal capacity of 9.3 MPa (1400 psi) is used as threshold. However the analysis does not adequately explain UK well 21/20a-1 (black oval), a dry hole with 929 psi aquifer seal capacity but hydrocarbon shows in vertical fractures through the chalk, and UK well 22/30b-4 (red oval), with its long gas column but only 402 psi aquifer seal capacity.

North Sea there is little change in overall results, with the same threshold of 9.7 MPa (1400 psi) between discovery statistics of 82% above and 46% below the threshold. Plotting hydrocarbon or aquifer seal capacity v. hydrocarbon column height shows no relationship since all wells, except UK well 22/30a-4, have an aquifer seal capacity which exceeds the hydrocarbon buoyancy created by the hydrocarbon column height in the Fulmar reservoir.

Base Cretaceous Unconformity

Analysis of direct pressure measurements from turbidite sandstone within both the Heather and Kimmeridge Clay Formations shows that these thin reservoirs generally share the same aquifer gradient as the underlying Fulmar reservoir within any one pressure compartment (Fig. 9). We have therefore re-examined the relationship between aquifer seal capacity and dry hole/discovery at Base Cretaceous Unconformity. To calculate aquifer seal capacity the aquifer gradient in each of the wells was projected to the Base Cretaceous Unconformity, a stratigraphic marker identified in all study wells. Extrapolating the aquifer gradient to Base Cretaceous Unconformity results in smaller aquifer seal capacity estimates in all wells, the reduction dependent on the stratigraphic thickness of the Jurassic section above Top Reservoir (Fig. 10). For example in UK well 22/30a-4 the Top Fulmar to Base Cretaceous Unconformity interval is 61 m (200 ft) leading to a reduction of aquifer seal capacity of just 0.9 MPa (131 psi), whereas the same interval in UK well 21/20a-1 is 398 m (1305 ft) with reduction of aquifer seal capacity of 5.9 MPa (854 psi).

The relative position of the study wells is changed at Base Cretaceous Unconformity (Fig. 11). The threshold based on high frequency of hydrocarbon discoveries has now moved to 8.3 MPa (1200 psi) with 84% discoveries above and 41% discoveries beneath this threshold. There are three wells with ‘negative’ aquifer seal capacity, each therefore predicted to be breached, and each is a dry hole.

Base Chalk

There are no direct indications of fluid pressures in the Cromer Knoll except in the Greater Britannia area in the north of the study area. Hence over much of the study area the fluid pressures between Base Cretaceous Unconformity and Base Chalk are unknown. In order to examine the potential of the Chalk as a key horizon controlling hydrocarbon retention we have extended the aquifer gradients for each pressure cell to Base Chalk in each of the wells. The analysis at Base Chalk (Fig. 12) reveals a threshold aquifer seal capacity of 5.2 MPa (750 psi), with 88% discoveries above and 36% discoveries below. Further there are six wells with zero or negative seal capacity, all of them dry holes. We note that UK well 22/30a-4, with its long hydrocarbon column, remains with a positive aquifer seal capacity of 1.2 MPa (173 psi) at Base Chalk, reflecting the thin stratigraphic thickness between Top Fulmar and Base Chalk. Care was taken to avoid the Britannia Field area that has been affected by lateral drainage of pressures in Lower Cretaceous Britannia Sandstone since these reservoir pressures are not representative of the Cromer Knoll shales (O’Connor & Swarbrick 2008).

Discussion

Analysis of dry holes and hydrocarbon discoveries relative to their aquifer seal capacity shows the best empirical relationship at Base Chalk, as opposed to Top Reservoir, where the relationship is traditionally examined. At both Base Cretaceous Unconformity and Base Chalk, 100% dry holes are observed where the aquifer seal

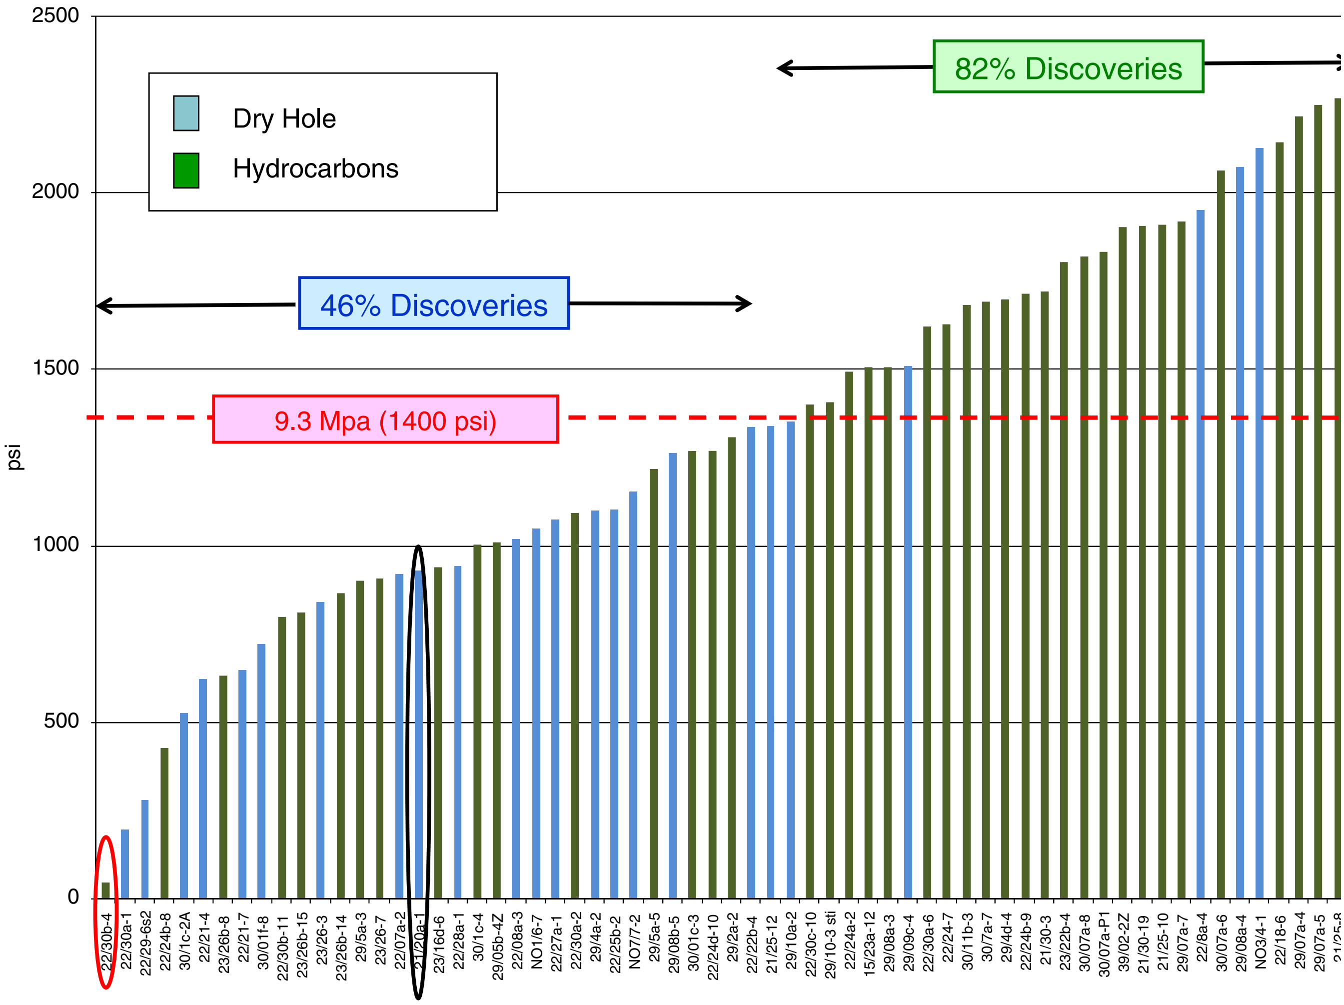

Fig. 8. Analysis of dry holes and discoveries at Top Reservoir using hydrocarbon seal capacity (in psi) for discoveries and the same values of aquifer seal capacity as shown in Figure 7 for dry holes.

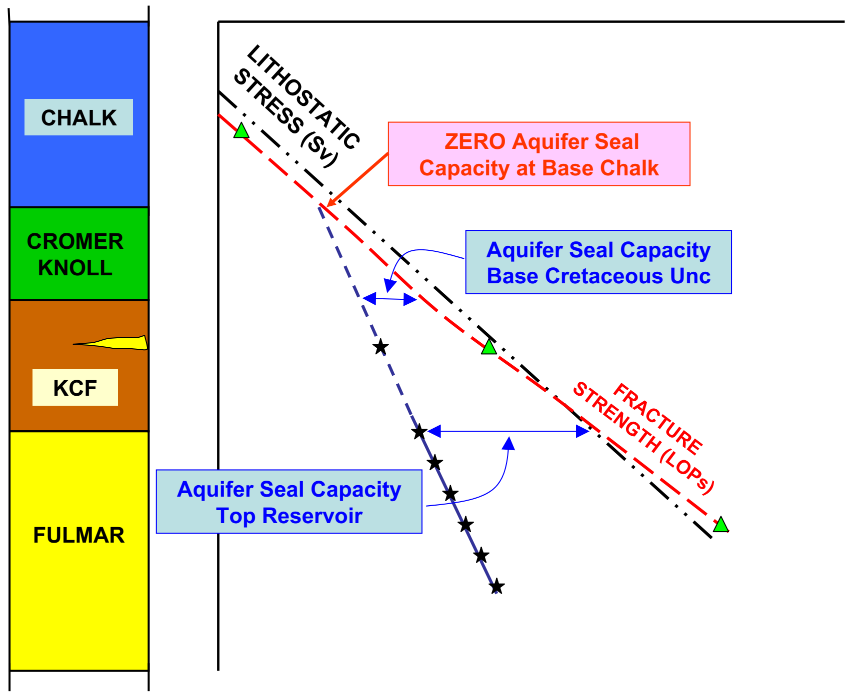

Fig. 9. Evidence from pressures in turbidite sands in the Kimmeridge Clay Formation (KCF) indicates pressure continuity between Fulmar and KCF sandstone reservoirs. The same aquifer gradient can be projected to shallower stratigraphic levels (e.g. Base Cretaceous Unconformity, Base Chalk), reducing the aquifer seal capacity reduces. Pressures in the Cromer Knoll Group are not known but have been extended to Base Chalk in order to examine the sealing/trapping relationship there.

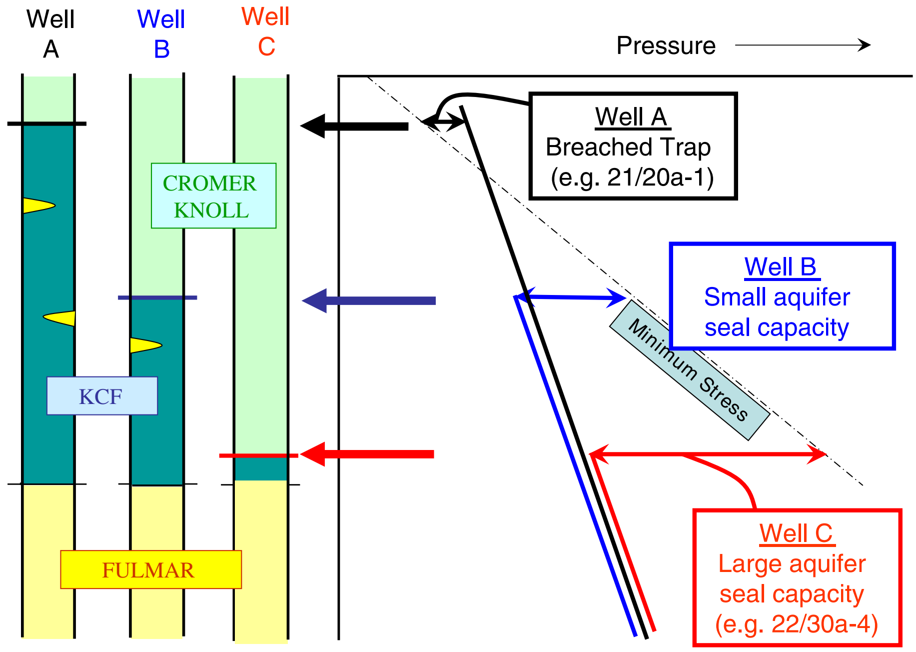

Fig. 10. Schematic diagram to illustrate how stratigraphic thicknesses control changes in aquifer seal capacity when an aquifer gradient is extended up-section. As an illustration well 22/30a-4 has very thin KCF and hence a similar aquifer seal capacity as at Top Fulmar. Where the stratigraphic thickness of KCF is large the aquifer pressure can reach the pressure of the minimum stress, implying seal breach conditions.

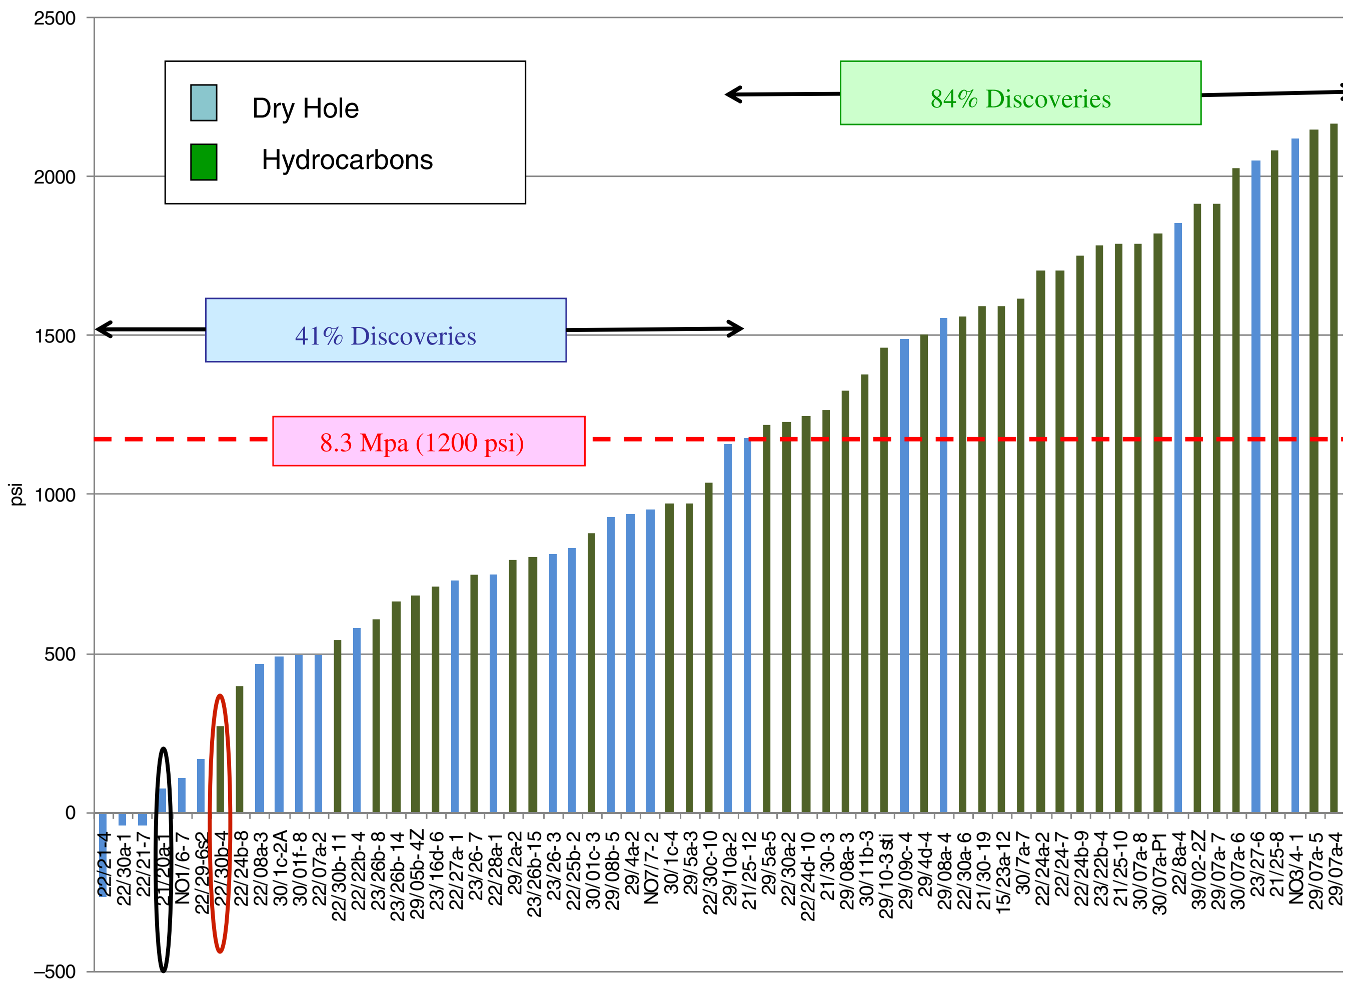

Fig. 11. Histogram of dry hole and hydrocarbon discoveries v. aquifer seal capacity at Base Cretaceous Unconformity. Out of 65 wells 84% are discoveries and 41% are dry holes when an aquifer seal capacity of 8.3 MPa (1200 psi) is used as threshold.

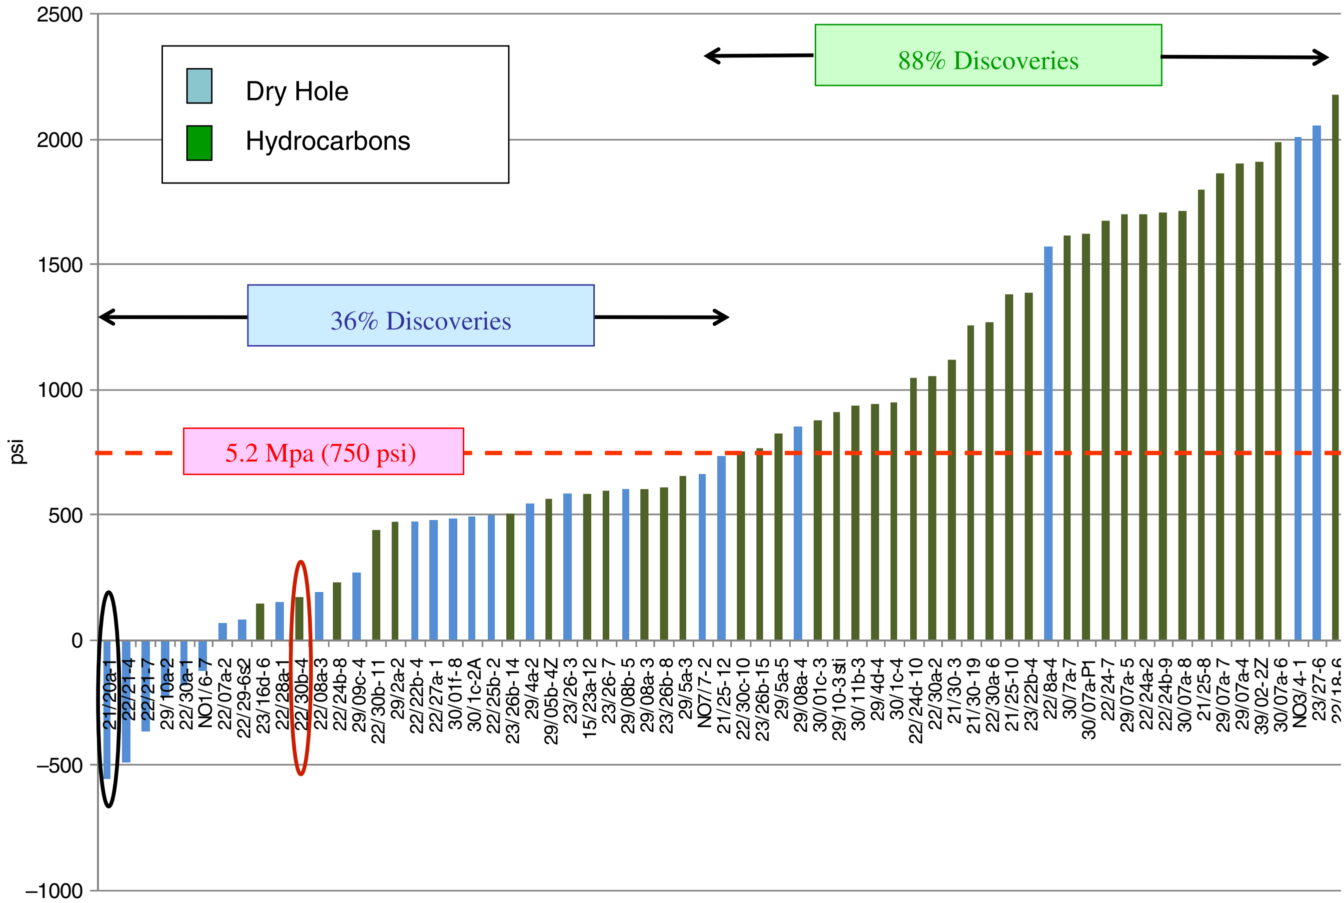

Fig. 12. Histogram of dry hole and hydrocarbon discoveries v. aquifer seal capacity at Base Chalk. Out of 65 wells 88% are discoveries and 36% are dry holes when an aquifer seal capacity of 5.2 MPa (750 psi) is used as threshold. Of those wells with negative aquifer seal capacity values, and hence predicted to be breached traps, all are dry holes.

capacity is zero or negative (i.e. predicted breached trap). At aquifer seal capacity magnitudes of >5.2 MPa (750 psi), 88% of wells drilled in the HP/HT area of the Central Graben are discoveries. We suggest, therefore, that Base Chalk may exert a controlling influence on hydrocarbon retention in this area.

There are leaking/leaked traps with positive values of aquifer seal capacity up to 750 psi (Fig. 12), such as UK well 22/8a-3 with core-based evidence for active petroleum leakage along vertical fractures in the Chalk. There are also wells with negative aquifer seal capacity values down to approximately −3.8 MPa (−556 psi), such as UK well 21/20a-1, with the same core-based evidence for active leakage. Whilst accepting the challenge of what the negative values of aquifer seal capacity may mean in terms of hydraulic failure and pressure retention, we believe that the data are not so precise that we can expect zero to be the breach value for all wells in that condition. We are therefore suggesting that the technique has an uncertainty of ±3.4 MPa (500 psi) around the zero value. It would be an over-interpretation of the data and processes to try to explain how a value of –3.4 MPa (−500 psi) for well 21/20a-1 might be created.

A field analogue from the Catskill Mountains, Upstate New York (Fig. 13) shows gas-generated hydraulic fractures extending only as far as the cemented sandstone, beyond which these fractures are unable to propagate. We suggest that the same concept may apply in the Central North Sea, that is, the cemented, and often massive, Chalk has higher fracture strength than the underlying stratified shales, which are more susceptible to hydraulic failure. The photograph also shows a later fracture set with different orientation (marked by arrow), which extends upwards through the entire section, but dated as much later, during uplift.

The Chalk is the hydrocarbon seal in several fields in the Central North Sea where chalk immediately overlies the Fulmar (e.g. 30/16-6) or Triassic reservoirs, for example, 22/24-2 Marnoch. We have demonstrated above that the pressure transition zones through the chalk indicated by rare direct pressure measurements also demonstrate that the Chalk is a pressure seal. Analysis of aquifer seal capacity in relation to hydrocarbon trapping also points to the Chalk as a potential control on hydrocarbon retention in these high-pressure areas, where hydraulic failure can lead to breached traps. The continuity of an aquifer gradient from Top Fulmar reservoir at least to Base Cretaceous Unconformity helps to explain the improved relationship between trapping and aquifer seal capacity estimates for our current dataset. However, the mechanism by which the pressures in thin multiple turbidites approximately equilibrate with the underlying Fulmar reservoir remains uncertain. Since the area where most of these wells are located coincides with areas where the Kimmeridge Clay Formation source rock is gas-generative (Cayley 1987), it is tempting to suggest that excess pressure due to gas generation has generated hydraulic fractures which have propagated downwards, thereby linking the reservoirs. Simultaneous upwards propagation may also help explain how aquifer gradients may also extend to Base Chalk, although this remains unproven. The common occurrence of gas influxes and reported issues relating to borehole instability when drilling the sub-Chalk section in many wells we examined suggests not only high pore pressure in the late Jurassic and Cromer Knoll mudrocks but also a high concentration of fractures.

We have highlighted that there is a major lithological distinction between the late Jurassic and Cromer Knoll Group mudrocks, and the fine-grained carbonates of the Chalk. The massive nature of the

Fig. 13. Field analogue from the Catskill Mountains, Upstate New York. Fractures believed to be created by gas at depth, which are arrested by a thin cemented clastic unit. We suggest comparison to the chalk arresting hydraulic fractures extending from Top Reservoir to Base Chalk. The photograph also shows a late fracture set (marked by an arrow), which extends upwards through the entire section, but related to stress release during uplift.

Chalk carbonates, compared with the more lithologically varied shales, may be significant in terms of how stresses are accommodated in the basin-fill, that is, brittle or ductile failure. Alternatively the fracture strength of the Chalk may be superior to the deeper strata.

In terms of implications for the risking of deep, high pressure traps in the Central North Sea, the above analysis allows for a pre-drill risk strategy. Specifically where the fluid pressure prediction has been predicted for the Top Fulmar reservoir, an aquifer gradient can be projected to Base Cretaceous Unconformity and Base Chalk. Using the predictions of fracture gradient and lithostatic at these depths, if the aquifer seal capacity is less than 5.2 MPa at Base Chalk or 8.3 MPa at Base Cretaceous Unconformity, there is a higher probability of dry hole than discovery. If a negative or zero value is predicted at either stratigraphic level a dry hole is predicted.

Conclusions

(1) Deeply buried Upper Cretaceous Chalk in the North Sea Central Graben is as effective as shale at creating a pressure seal.
(2) The pressure transition zone through the chalk in this area can be best described by a steady-state pressure profile.
(3) The chalk appears to have been drilled underbalanced in most wells in the study area.
(4) The low permeability of the non-reservoir chalks precludes influx during drilling, except where locally higher permeability (by several orders of magnitude) or fractures/faults exist.
(5) Analysis of aquifer seal capacity based on aquifer gradients extended from Fulmar Reservoir through Base Cretaceous Unconformity to Base Chalk indicates the most robust relationship between dry holes and discoveries is at Base Chalk.
(6) Further research is needed to understand more fully how fluid pressures equilibrate between Top Reservoir and Base Chalk through the Heather, Kimmeridge Clay and Cromer Knoll mudrock units, and why the Base Chalk may be a preferred stratigraphic unit relative to hydrocarbon entrapment.

The authors would like to thank IHS for provision of data and permission to use the data as part of the study. Thanks also to Patricia Kelly for generation of the well location map. An earlier version of the manuscript was helpfully improved by comments from John Smallwood and an anonymous referee.

Abstract: Accurate fault interpretation is key to building a robust and reliable reservoir model, and is essential for further study of fault-seal behaviour and reservoir compartmentalization. Conventional fault interpretation defines faults as planar features. Although the concept of fault damage zones (FDZ) is well established, manual delineation of FDZ from subsurface imaging data is difficult and rarely attempted. In this work we are using the concept of a seismic fault distortion zone (SFDZ). The SFDZ differs from the geological FDZ and is the 3D extent of the regions where the presence of a fault has perturbed the seismic image. The SFDZ represents an area of significant uncertainty within the seismic volume where the signal is distorted either by changes in geology associated with faulting or by imaging problems due to the presence of the fault. Delineation of the SFDZ is a key step in further analysing 3D seismic data to provide information regarding variations in seismic attributes across a fault that can be used to indicate how juxtaposition of strata influences a potential sealing fault. The SFDZ is delineated using an adaptive region growing algorithm and produces a set of detailed 3D SFDZ geobodies. The delineated SFDZ is then used as the input to a set of analysis techniques that examine 3D volumetric juxtaposition of seismic attributes, and properties relative to the fault. The techniques involve automated statistical measurement along seismic structure relative to the fault itself. The workflow has been applied and its utility assessed on an underground gas storage dataset. Initial results suggest that by taking account of the 3D geometry of the SFDZ and subsequently analysing 3D frequency and acoustic impedance volumes relative to these structures, an improved understanding of the juxtaposition of layers across the fault and the lateral variability, juxtaposition can be determined at seismic resolution, and subsequently used to assess the potential for fault seal and fluid migration.

Keywords: fault network, juxtaposition, inner distortion zones, outer distortion zone

When faults are picked during interpretation of seismic data, they are commonly picked as a single plane running through the centre of a faulted zone. A fault's expression in seismic data is rarely a sharp discontinuity and both manual and automated methods for picking faults must address the problem of precise placement of the fault surface. There is uncertainty in the fault's 'true' position at seismic scale, whichever method is used.

However, both outcrop and well data studies show that complex and often asymmetric zones of disturbance, such as fracturing, grain crushing and bending of rock layers, exist around fault surfaces that can typically range from several centimetres up to 200 m on a single side. The reader is directed to Berg & Skar (2005) for an illustration of the disturbance surrounding the Moab Fault, Utah. Although the character of these zones varies to a great degree, they can generally be classified into a fault core and more extensive fault damage zones (FDZ). Typically, the fault core is characterized by fault gouge, internal fault rock, slip surfaces, clay smear and alteration, and will have accommodated the majority of displacement. The FDZ is characterized by subsidiary faults, folds, deformation bands, veins and joints, which reduce in frequency away from the fault core. Subsidiary faulting is dominantly parallel to the main fault, but can also occur in vertical or antithetic planes to the main fault (Kim *et al.* 2004; Berg & Skar 2005). Towards the extent of the FDZ there are often significant regions of drag in the surrounding strata, which may or may not be characterized as damage.

On a seismic scale, the fault core is not resolvable. In standard seismic acquisition, the typical bin spacing of 12.5–25 m is well above the width of the fault core for the majority of faults on a reservoir scale. Therefore the focus of this research is solely on a wider seismic fault distortion zone (SFDZ) that is generally resolvable on high-quality 3D PSTM or PSDM seismic data. We further classify this into an inner seismic distortion zone and an outer seismic distortion zone where these are defined through appropriate use of seismic attributes.

- **The inner zone** is generally expressed by a disruption to the reflectors and reduction in seismic amplitudes (shown schematically in Fig. 1). The inner zone represents the limits to the zone of uncertainty associated with the positioning of the fault core within the seismic volume. The seismic response here is likely to be unreliable, as the fault itself will have introduced distortion during the imaging process. Traditional fault attributes such as semblance-based measurements are used in characterizing the inner zone.
- **The outer zone** is a wider zone within which reflector drag, folding and distortion related to faulting is present and resolvable (shown schematically in Fig. 1). This type of expression can be defined through the use of curvature- and flexure-type seismic attributes.

Note, this classification is similar to that adopted by Jones & Knipe (1996) in their interpretation of 'fault damage zones' across a range of scales using seismic attribute maps, although here we work consistently with 3D seismic data-based measurements.

Defining the fault network

Prior to analysing the fault network, structurally oriented, adaptive and edge-preserving noise cancellation algorithms are applied.

VINING, B. A. & PICKERING, S. C. (eds) *Petroleum Geology: From Mature Basins to New Frontiers – Proceedings of the 7th Petroleum Geology Conference*, 509–515. DOI: 10.1144/0070509

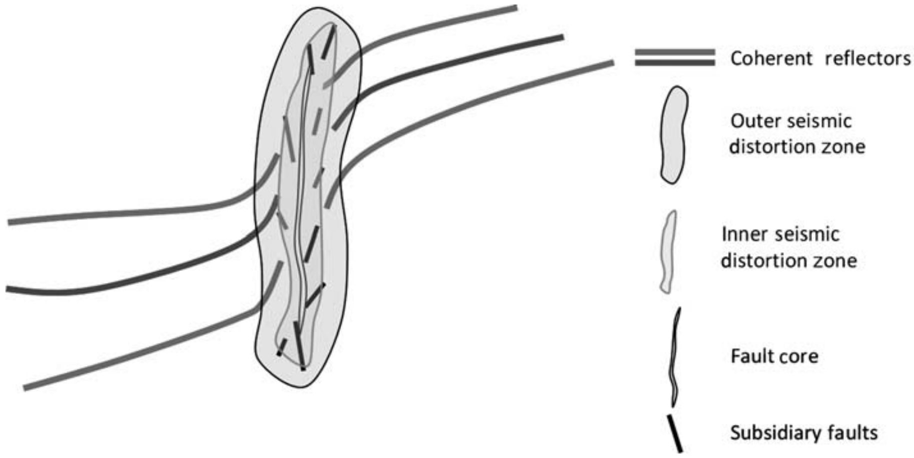

Fig. 1. Schematic demonstrating the inner and outer seismic distortion zones associated with faulting.

By increasing the signal-to-noise ratio whilst preserving edges, a clearer definition of fault v. non-fault can be obtained.

A 3D seismic processing workflow has been defined and implemented in order to allow fault systems to be analysed by drawing on the information available within noise-cancelled 3D seismic reflectivity, derived seismic attribute and inverted seismic property volumes. This workflow builds on existing post-stack fault imaging and fault network skeleton extraction methods (Fig. 2a, b) to provide a starting point for the fault relative seismic analysis workflow that we discuss here. The process of fault imaging provides us with a number of fault attributes, typically computed through trace-to-trace correlation and/or discontinuity detection algorithms, which are used to extract a skeleton of single-voxel-thick surfaces across the whole dataset.

This fault skeleton represents potential faults as exhibited in the chosen seismic fault attribute response and is a data-driven approach to positioning a 3D fault surface within the zones of uncertainty around faults in the seismic.

Defining the damage zone

In order to define the limits of the SFDZ across the volume of interest, an automatic region-growing algorithm is utilized. The fault skeleton is used as a starting seed for a region-growing process. Used in combination with a selected seismic attribute which highlights the extent of SFDZ in the data, fault structures within the fault skeleton are extended in three dimensions so that they cover the corresponding SFDZ regions. The algorithm analyses all adjoining voxels to the seed and those that meet interpreter-defined growth criteria are accepted as part of the SFDZ geobody (Fig. 2c).

The nature and thickness of the SFDZ geobodies that are extracted vary according to the attribute used in the calculation. This in turn responds to different SFDZ expressions within the seismic data (i.e. flexures in reflectors, dimming of amplitude, phase change, apparent reflector termination). Seismic expression of the faults can vary significantly within a single seismic dataset. As a result, faults are rarely completely captured by individual attributes across a dataset and optimum results often come from using a number of attributes in combination.

Figure 3 shows a selection of attributes and how they image the SFDZs of two faults. The inner zone is well defined by attributes such as deformation distance (a vector-based measurement of disruption), semblance, dip and tensor (a measurement of disruption based on eigenvalues of the gradient structural tensor). The outer zone is well defined by measurements of curvature, including the measure of structurally oriented curvature shown here.

Fault relative analysis associated with damage zones

Once an SFDZ has been defined (either the inner or outer zone depending on user focus), both its lateral thickness and changes in a selected seismic attribute response across the SFDZ can be evaluated. The thickness of the damage zone is mapped directly onto the fault network and enables the user to rapidly see variations in the extent of fault-related distortion. The outer surface of the SFDZ geobody is also extracted (Fig. 2d) and this ‘skin’ is used to constrain statistical analysis of seismic attributes. By studying the juxtaposition across the damage zones of the defined SFDZ and calculating the difference in these attribute values on either side of the SFDZ, areas of significant contrast and areas of no contrast are readily highlighted. This is achieved via the application of structurally oriented filters that initially sample then juxtapose data from either side of the damage zone onto the central fault plane. Steering volumes are used to align the structurally oriented filter footprints along dominant reflectors and thus maintain structural variations. By taking the local mean of an attribute, a noise-free representation of it is provided, whilst the variance gives a measure of its distribution. Results are initially stored on the skin of the damage zone (Fig. 2f), then horizontally juxtaposed from both sides onto the central plane in a direction perpendicular to the trend of the central fault. With the variance and mean attribute value on either side of the fault now stored co-incident to the fault plane, a difference volume can be generated and the contrast in properties across the fault visualized in a single volume, which is named the juxtaposition difference (Fig. 2g). The result of this process is a data-derived juxtaposition map being produced, at seismic resolution, on the 3D fault surface representation itself.

Attributes proposed for this workflow include acoustic impedance (AI), porosity or frequency. However juxtaposition difference maps for any seismic attribute or inverted volume could be applied during this process. Through the use of appropriate seismic attributes and inversion data, the juxtaposition difference can aid in the overall process of assessing fault seal by allowing detailed examination of subsurface properties around faults via seismic resolution attribute maps as opposed to interpretation-based juxtaposition diagrams.

In the case of AI, we see the following behaviour: where there is shale-to-sandstone contact at the SFDZ, the juxtaposition difference will yield high values and where there is either a sandstone-to-sandstone or shale-to-shale contact at the damage zone, the FSC index will yield low values. By restricting the evaluation zone of interest to centre on the reservoir interval and calibrating with known lithologies at well locations, low juxtaposition difference regions corresponding to sandstone-to-sandstone

contacts can be identified, and thus potential non-sealing regions are highlighted and spatially defined for further analysis within an overall fault seal analysis workflow.

In the case of a sandstone-to-sandstone contact, a juxtaposition difference value of zero implies that the AI on either side of the fault is identical and a small value implies that there are differences in AI of the sandstone on either side of the fault. The 3D nature of the analysis enables the lateral and vertical variation of these contrasts to be viewed along the length of a single fault or across a fault network.

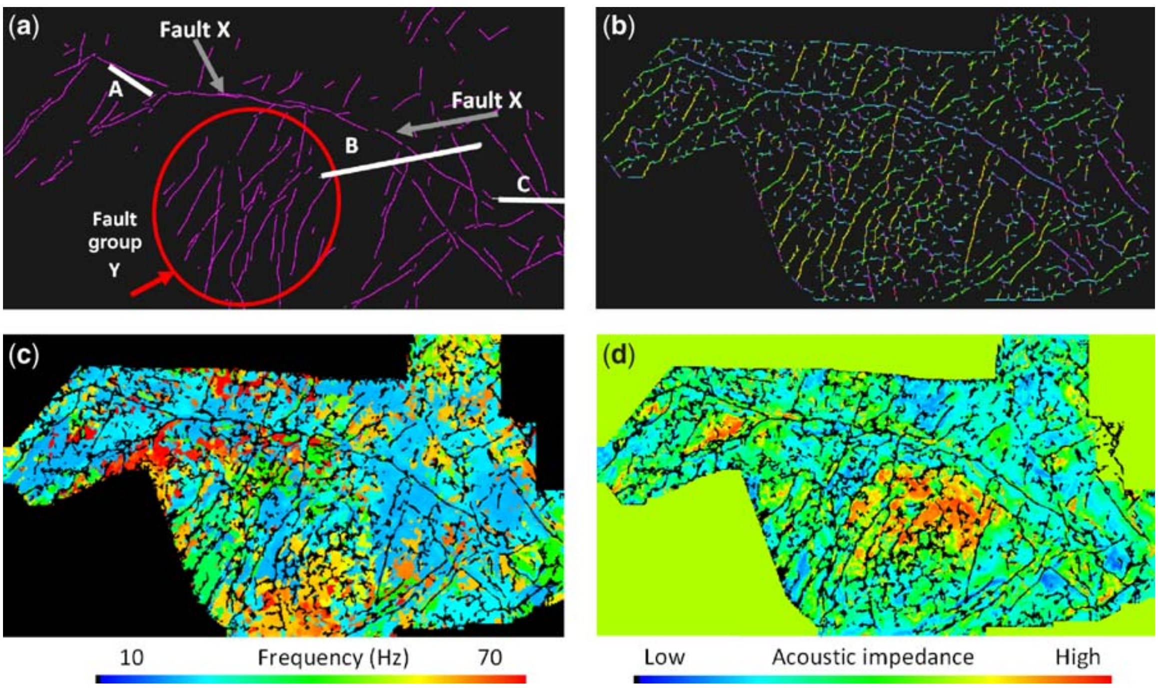

Fig. 4. Fault imaging: (**a**) manual interpretation of fault network with key wells marked A–C; (**b**) automatically detected fault network mapped with 2D trend; (**c**) SFDZ (black) mapped on to frequency; and (**d**) SFDZ (black) mapped on to AI. This analysis can be seen in time-slices or in a horizon-consistent manner.

In the juxtaposition analysis described above, the data-derived SFDZ is used to ensure that only data samples outside of the SFDZ are included in the measurement. In an additional step within the workflow, the statistics of the selected seismic property volume can also be assessed within the SFDZ. Within the SFDZ the analysis is performed relative to the seismic sampling grid, as (by definition) there are no conformable reflectors present here, and larger sample neighbourhoods are typically adopted. The calculation of the bulk mean and variance within the SFDZ is used to produce a further attribute map of the fault surface (Fig. 2e). This can be used to examine the apparent continuity of seismic properties within the SFDZ.

Case study

The workflow described above has been applied to approximately 100 km^2 of 3D seismic data acquired over an onshore underground gas storage area (UGS). The data is a merge of three different vintages that have been processed to produce a single seismic reflectivity volume. The seismic data is of fair to very good quality with bin spacing of 20×20 m and elevated noise in some areas as a result of varying fold due to the presence of surface facilities.

The target level contains three reservoir intervals, with an approximate total thickness of 70–160 m. This interval is contaminated by noise, remaining internal multiples and intrinsic complexity (three reservoir levels, themselves divided into four levels). However, the current interpretation of the entire sequence has good well control, with more than 100 wells present in the area.

Within this data, several fault studies have been performed, focusing at different levels: above the top reservoir, adjacent to top reservoir, and inside the reservoir itself. The decoupling of fault studies into depth ranges is a direct consequence of tectonic decoupling that can be observed on seismic reflectivity.

Initial mapping and manual interpretation of faults provides a good but simple understanding of the faulting present in each of

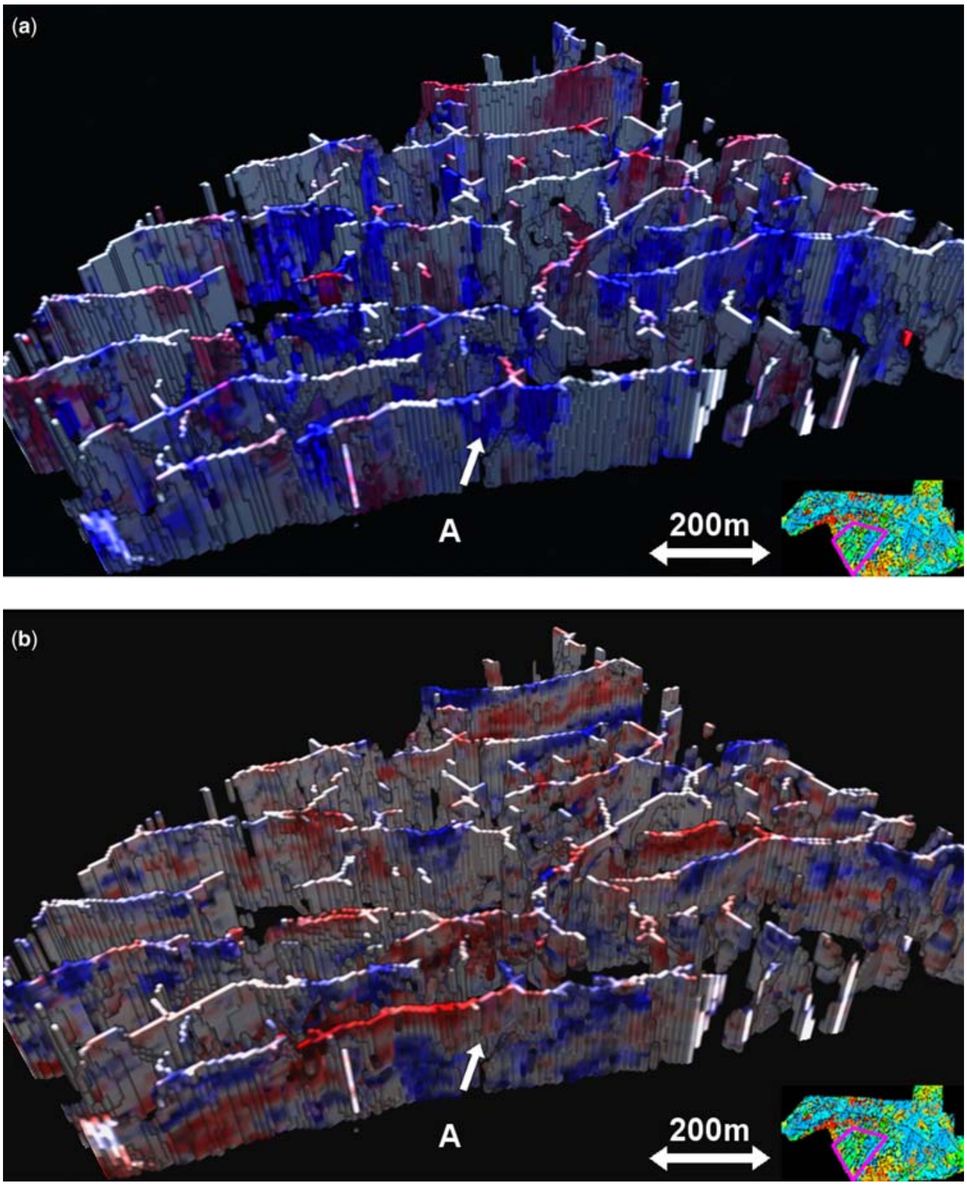

Fig. 5. (**a**) Frequency and (**b**) AI volume-rendered view of the fault network skeleton mapped with the juxtaposition difference values. (a) FDZ index volumes for frequency. Blue shows an increase in frequency to the top of the 3D image, red shows a decrease in frequency to the top of the 3D image and white shows no contrast in frequency. The small base map in the right-hand corner shows the position of the sub volume on the images seen in Figure 4. (b) FDZ index volumes for AI. Blue shows an increase in A1 to the top of the 3D image, red shows a decrease in A1 to the top of the 3D image and white shows no contrast in A1. The small base map in the right-hand corner shows the position of the sub-volume on the images seen in Figure 4.

the levels (Fig. 4a), but does not provide information about the interplay between faults and fluid movement, although different pressure regimes have been discovered between some specific pairs of wells (well pairs A–B and B–C in Fig. 4a).

In order to optimize results, structurally oriented edge-preserving and adaptive noise-cancellation filters were applied to remove the coherent and random noise within the seismic reflectivity data whilst maintaining the structure of subtle faults and discontinuities. By utilizing automated fault detection and extraction workflows, a more detailed map of faulting than previously interpreted has been defined (Fig. 4b), enabling interpreters to distinguish and study internal fractured zones in addition to major and en-echelon faults seen in the area. By mapping the volumetrically calculated SFDZ onto a horizon of interest or viewing simply along a time slice, we can see the variation in thickness between and along faults (Fig. 4c, d). Varying damage zone thickness can relate to different fault mechanisms as well as the lithology in which faulting has occurred and is of interest as it can influence fluid flow across a fault. Damage zones along both fault X and fault group Y have similar widths, which range from 80 to 120 m.

SFDZ analysis has been applied to both frequency and AI volumes. Seismic frequency can be affected and attenuated by depth, lithology, bed thickness, porosity and fluid fill. In particular, the presence of gas is often seen to reduce frequency. It can be clearly seen in Figure 4c that dominant faults (such as those in fault group Y) and their associated damage zones are often sharply bounding areas of high and low frequency.

The juxtaposition difference (Fig. 5a) for this volume provides increased detail of how the contrast in frequency changes spatially along the length of faults within fault group Y. Reds and blues both indicate zones of high frequency contrast (up to 60 Hz). Blue shows an increase in frequency across the fault towards the top of the 3D image, red shows a decrease in frequency across the fault towards the top of the 3D image and white shows no contrast in frequency. The juxtaposition difference volume implies that the sealing potential based on frequency juxtaposition alone is much more variable

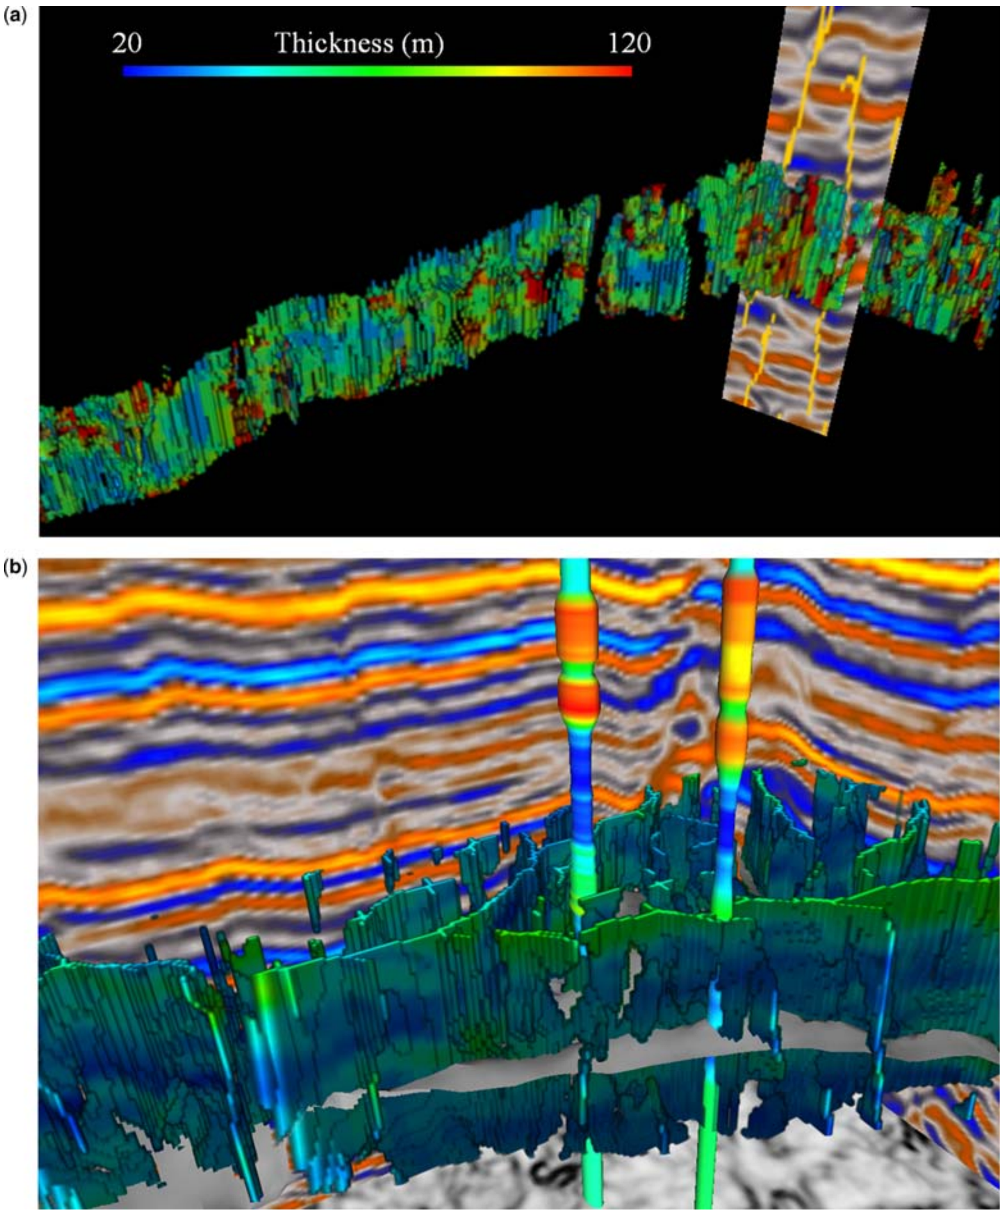

Fig. 6. (**a**) Volume render of a single fault cropped to the reservoir level alone and mapped with SFDZ thickness. Variations from low (blue) to high (red) thickness can be observed. Rapid lateral and vertical changes suggest possible areas of fluid transmissibility are localized. (**b**) Well information. The AI within the inner damage zone (mapped onto fault network) is seen to correlate with *P* wave velocity (Vp) logs, bringing thus the first step in the well calibration procedure (using the porosity logs and pressure measurements).

along the length of these faults than the horizon slice initially suggests. Analysing the AI yields similar results. By embedding the SFDZ into the AI volume, zones where faults are bounding large contrasts in AI can easily be seen (Fig. 4d). FSC index volumes for both frequency and AI reveal high contrasts and thus high potential for juxtaposition-based sealing at many locations, such as that marked A on Figure 5a, b. However, it is apparent that these regions of potential sealing are all localized and there are many (white) regions of no contrast that have the potential to provide pathways for fluid migration.

Focusing on a particular fault at the reservoir zone enables detailed juxtaposition difference and thickness variations (Fig. 6a) to be mapped. Rapid lateral and vertical changes in thickness as well as juxtaposition difference suggest possible areas of fluid transmissibility are localized.

Visualization and correlation of well logs as displayed in Figure 6b demonstrates that the information borne by fault analysis (local sample mean of inverted AI within the damage zone) is supported by existing well data. The incorporation of additional and more advanced well information could thus be used for further extrapolation and calibration.

Caveats and discussion

- The analysis of seismic-scale FDZ and contrast in attributes/properties across them can provide additional information and a greater degree of detail regarding the juxtaposition-based sealing potential of a fault, or fault network. It must be noted that this is just one of several mechanisms for sealing as a result of faulting.
- The technique relies on seismic reflectivity data and seismic attributes with a high lateral resolution and yields more accurate results when data has been acquired with a small bin spacing (i.e. 12.5 m).
- The fault imaging and fault network skeleton can be used to highlight significantly more detail at and around existing fault interpretations as well as highlighting new unconsidered candidate faults that may positively impact on the overall understanding of reservoir sealing behaviour.
- Although the seismic data under observation is highly perturbed (faulted and even acting as wave propagation barriers), much information can be directly inferred from fault and SFDZ studies. Nevertheless, it is believed that seismic data is statistically sufficient to derive accurate information on sealing/non-sealing capacities (varying within one fault), provided some calibrating additional data (pressure from wells) is given.
- Future work includes applying this new workflow to other datasets, particularly those with interpreted fault, FDZ geometries and including parallel fault sealing studies.
- As a data-driven workflow to examine subsurface properties around faults, it is highly dependent upon the use of robust attributes and inverted data, and upon the availability of well data in order to calibrate the results.
- As far as UGS projects are concerned, a dynamic/historic view of the fault-sealing behaviour should also be sought, as there are likely to be significant variations in seismic response with time.

Conclusions

We have an established workflow that has been applied to a number of case studies. The techniques for extracting a damage zone around the fault are well defined. More work is required in order to understand the best combination of information, from both seismic and wells, needed to demonstrate the behaviour of fluid across an identified damage zone.

For the UGS study presented here, damage zone thickness and symmetry measures, contrast in AI response across the damaged zone, AI variability and spectral decomposition techniques have been used in combination to produce indicators of potential fault-sealing behaviour.

Prior to this study, the structural system was simplified in order to fit with current models, but the detailed interpretation of the complete fault network, including small faults subsets, and the behaviour provided by FDZ analysis, is delivering a better understanding of the fault network and will have an impact on the forecast of production profiles.

One may highlight that the varying behaviour vertically and horizontally of what were previously considered to be simple single faults brings a clear call for more integration between reservoir models and detailed geological (horizons and faults behaviour included) models derived from seismic data.

The authors are grateful for Storengy (formerly GdF/DGI) for making this data available. The seismic acquisition was partly funded by TEN-E Network from the European Community. Elements of the workflow presented have been developed as part of the following R&D Collaborations: FSC (Fault Seal Capacity) Workflow Stage I – ffA, GDFSUEZ; FSC Workflow Stage II Joint Industry Project – ffA, GDFSUEZ, StatoilHydro.

4D acquisition and processing: a North Sea case study on the relative contributions to improved 4D repeatability

E. C. RUSHMERE, M. DYCE, S. CAMPBELL and A. J. HILL

BP, Dyce Complex, 1–4 Wellheads Avenue, Stoneywood Park, Dyce, Aberdeen AB21 7DF, UK (e-mail: ed.rushmere@uk.bp.com)

Abstract: Using a case study from the Mungo Field in the Central North Sea, we investigate the relative impact of acquisition and processing improvements on 4D seismic repeatability. The results show that, while advancements in both have helped to reduce 4D noise, significant noise reduction can be attributed to processing alone. 4D noise can be thought of as any non-production-related amplitudes that are observable on a 4D difference section, and has both random and coherent components. Both are undesirable as they can mask any real 4D signal. A great deal of effort is employed to reduce noise levels by optimizing acquisition and processing between the 3D surveys, which are differenced to highlight the 4D signal. This paper studies the changes introduced by acquisition and processing improvements using the calibrated difference in reflectivity measure.

Keywords: 4D, repeatability, North Sea, acquisition, processing

4D noise levels were calculated between three acquisition vintages, upon which two processing flows were applied. An additional application of 'STAR', a 4D post-stack noise reduction process was tested (Zamorouev *et al.* 2006). Comparisons of repeatability were made using calibrated difference reflectivity (CDR) to highlight improvements through processing, acquisition and combinations of both. For each result a CDR value, map and amplitude spectrum were calculated to represent the 4D noise in that 4D difference volume.

For the Mungo 4D Noise Case Study, the total contribution of all improvement is to drive down the 4D noise level by a factor of 3. Acquisition efforts to better match source and receiver locations between baseline and monitor surveys account for approximately one-third of this uplift. The application of STAR accounts for approximately one-third of the total noise reduction, while improvements to the 4D processing flow provide the remaining uplift.

A typical method for the analysis of 4D anomalies is the study of 3D seismic difference volumes. The energy in a difference volume is a sum of the 4D signal, random noise which does not match between datasets, and coherent noise caused by the imperfect matching of events. Both forms of noise are undesirable as they can mask any 4D signal that would otherwise be interpretable, as shown in Figure 1. A great deal of effort is employed to reduce 4D noise levels and improve repeatability by optimizing acquisition and processing parameters between 3D surveys, the final objective being to remove both coherent and random noise from the difference volume and improve our ability to interpret the 4D signal. This paper studies the changes introduced by each acquisition and processing step of a typical flow, and attempts to identify where the greatest reduction in 4D noise is achieved.

Repeatability measurements

It is common to use an attribute to measure the level of noise in a 4D difference volume. This can be recalculated as new processing or acquisition is introduced to determine the improvement in the seismic difference, or reduction in the noise level. One measure is the CDR (Dyce *et al.* 2004).

This attribute computes the RMS amplitudes in a 4D difference volume between two 3D seismic surveys. However, CDR is different from many industry standard repeatability measures, for example normalized root mean square (NRMS), in that it also calibrates the seismic amplitudes to the well reflectivity by matching the spectra of the data and the well over the seismic bandwidth through an application of blueing. Blueing the seismic difference volume ensures the CDR measure can be directly compared with predictions of 4D signal from rock properties modelling, both in terms of reflectivity and predicted change of acoustic impedance. The definition of CDR, the windowed RMS amplitude from the difference of two blued seismic volumes A and B, is shown in equation (1):

$$\mathrm{CDR} = \mathrm{RMS}(A - B). \tag{1}$$

The definition of NRMS is given in equation (2):

$$\mathrm{NRMS} = \frac{\mathrm{RMS}(A - B)}{\left(\frac{\mathrm{RMS}(A) + \mathrm{RMS}(B)}{2}\right)}. \tag{2}$$

The simple relationship between the two attributes can be seen as the reciprocal of the average of the RMS amplitude of the two seismic volumes.

Improvements in acquisition or processing should reduce random noise and better align primaries between surveys, lowering the amplitudes in the difference and reducing the CDR. From this we can determine which aspect of the flow provides the most improvement, and whether poor acquisition repeatability can be compensated for in later processing.

The intention of CDR is to measure 4D noise; therefore the repeatability analysis should take place over a window of seismic difference data in the region of the reservoir, but not in an area where a 4D signal is expected. This could be just above the top reservoir (assuming there are no 4D geo-mechanical changes in the overburden), or at the reservoir level but away from any production/injection effects.

Case study details

In many 4D projects, a CDR value is only calculated on the baseline and monitor surveys following the final processing. This only

VINING, B. A. & PICKERING, S. C. (eds) *Petroleum Geology: From Mature Basins to New Frontiers – Proceedings of the 7th Petroleum Geology Conference*, 517–522. DOI: 10.1144/0070517

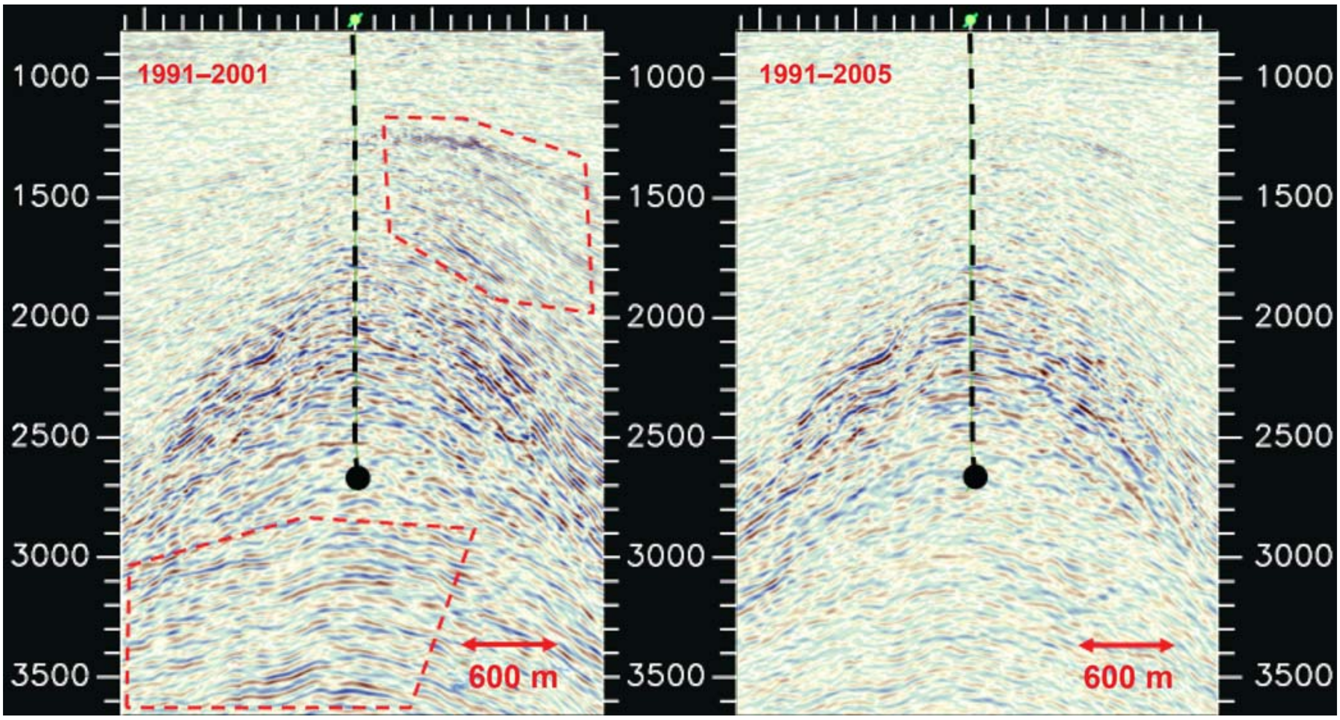

Fig. 1. Seismic time difference volumes over the Mungo Central North Sea (CNS) field comparing 1991, 2001 and 2005 vintages. Areas of 4D noise reduction are highlighted in the dashed boxes. Vertical magnification is *c.* 1.5×.

provides information on the combined result of all acquisition and processing improvements. In this study, I intend to show the improvements from each aspect of an acquisition and processing flow, including which steps are most important for improving 4D repeatability. The study area is the Mungo field as shown in Figure 2. It is a diapir flank structure in the Eastern Trough of the Central North Sea (CNS), located mainly in Paleocene turbidite sandstones (Sele formation) sealed beneath Eocene mudstones with an updip termination against Zechstein salt. The flanks dip at up to 50° with 1500 m of vertical relief. These steep dips introduce significant challenges when trying to image the 4D response within the 100–400 m thick reservoir oil leg (Pooler & Amory 1999).

In addition, the updip event terminations reduce the interpretable area of many of the horizons of interest. The CDR calculations are taken from a 300 ms window extracted over the flanks of the structure, ending 100 ms above the section predicted to show 4D signal.

CDR calculation

The CDR attribute can be presented in three ways: a single value representative of the entire analysis area, a map of local variability, or an amplitude spectrum showing the CDR relationship with frequency. Figure 3 shows two of these methods, a map of local

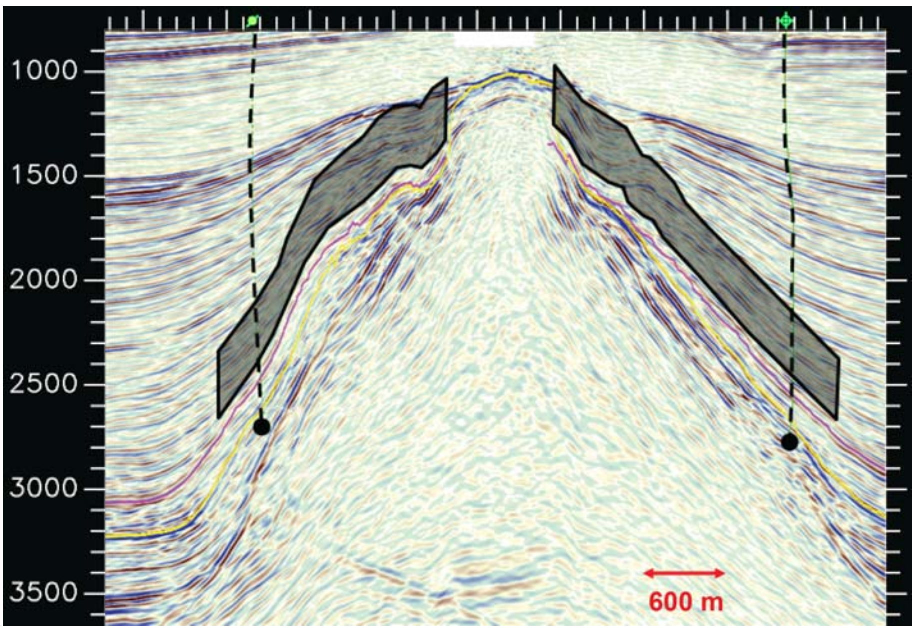

Fig. 2. Seismic time section through the Mungo diapir showing two projected well paths and two key horizons (top chalk (lower) and top Sele formation (upper)). Highlighted in dashed boxes are the windows of interest used to calculate 4D repeatability. Vertical magnification is *c.* 1.5×.

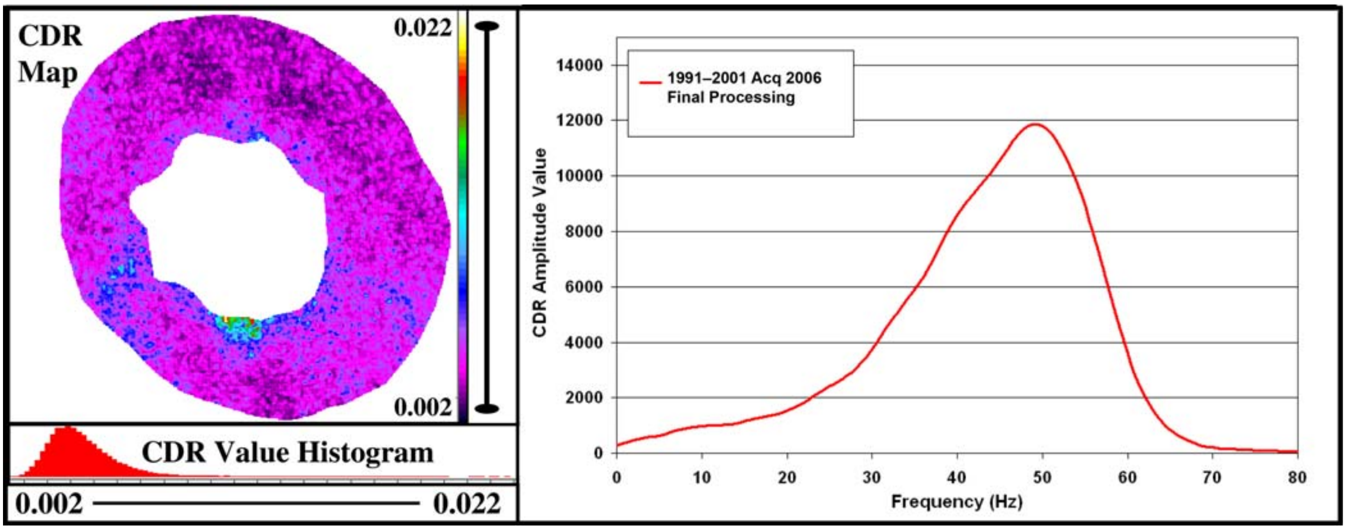

Fig. 3. Map of local CDR variations (left) and CDR frequency spectrum (right) for Mungo CNS field, 2001 monitor v. 1991 baseline acquisition and 2006 full processing flow. The CDR drops above 50 Hz due to the limit in the frequency content of the data.

variations of CDR and an amplitude variation with frequency. The light grey areas on the map indicate high CDR values relating to a platform undershoot where the acquisition repeatability deteriorates. The spectrum shows an average frequency content of the difference volume for the seismic area covered by the map. The difficulty in interpreting regions of interest based on incomplete horizons can be observed here, with the updip terminations leading to a ‘donut’-shaped horizon.

The CDR calculations were taken from surveys acquired in 1991, 2001 and 2005. The acquisition parameters for the three surveys are presented in Table 1, showing the similarities and differences in the acquisition methods which may result in variability in the final seismic volumes. 4D processing was carried out in 2001 and 2006, and included a series of fast-track products where a subset of the final processing steps were applied. An additional application of STAR (Zamorouev *et al.* 2006), a 4D post-stack noise reduction process, was also tested. This utilizes the higher signal-to-noise properties of a sum of multiple seismic vintages to help clean up each individual vintage through the application of a local scalar to each sample. This scalar is defined as the value that will move the sample amplitude onto a best fit linear trend calculated from a cross plot of the average amplitudes of the two vintages against the individual vintage, extracted over a window centred on the sample, as shown in Figure 4. It is a process that reduces noise in

Table 1. Acquisition parameters for the three seismic survey vintages

	Survey vintage 1991	Survey vintage 2001	Survey vintage 2005
Total volume of source	2 × 5012 cubic inches	2 × 3397 cubic inches (source x) 2 × 3000 cubic inches (source y)	2 × 3490 cubic inches
Type of energy source	Bolt Airguns	Bolt LongLife Airguns (source x) Sleeve guns (source y)	Airgun − G-gun + sleeve
Source depth	5 m	5 m	5 m
Shot point interval	50 m (25 m flip-flop)	50 m (25 m flip-flop)	50 m (25 m flip-flop)
Sail line direction	0°/180°	0°/180°	Repeat 1991 source positioning
Number of cables	3	6	7
Nominal xline streamer separation	100 m	100 m	75 m
Cable length	3.0 km	4.0 km	4.0 km
Cable depth	8 m	8 m	8 m
Number of channels	240	320	324
Group interval	12.5 m	12.5 m	12.5 m
Total no. of channels	720	1920	2268
Cable direction	0°/180°	0°/180°	Repeat 1991 receiver positioning
Inline near offset (centre source a near receiver)	136 m	189 m	130 m
Nominal stacking fold	30	40	40

the 4D difference volume, but if applied carelessly can deteriorate time shifts which could be due to real 4D changes.

For each combination of acquisition and processing a CDR value, map and spectrum were calculated. The individual CDR value was recorded for each acquisition and processing combination, whilst the frequency spectrum and map were only used in the study of regional and frequency variability. The full suite of individual CDR measures is presented in Figure 5, indicating the CDR drops from 0.0105 to 0.0038 following the implementation of all processing and acquisition improvements. This is interpreted as an approximate three-fold reduction in 4D noise. The CDR measure was recorded over a 10–45 Hz bandwidth for all cases to ensure consistency, and the parameterization and velocity models used in a given processing flows were not varied between the three seismic volumes.

The three most significant comparisons are:

(1) *Processing flow improvements* – the 2006 processing flow included improved regularization and enhanced pre-stack noise attenuation compared with the 2001 flow. By calculating the repeatability following each flow for the 1991 and 2001 acquisition vintage difference, we can assess the impact of processing improvements.
(2) *Improved acquisition repeatability* – in both the 2001 and 2005 monitor surveys the seismic acquisition was designed to repeat the line orientation of the 1991 baseline survey. However, in

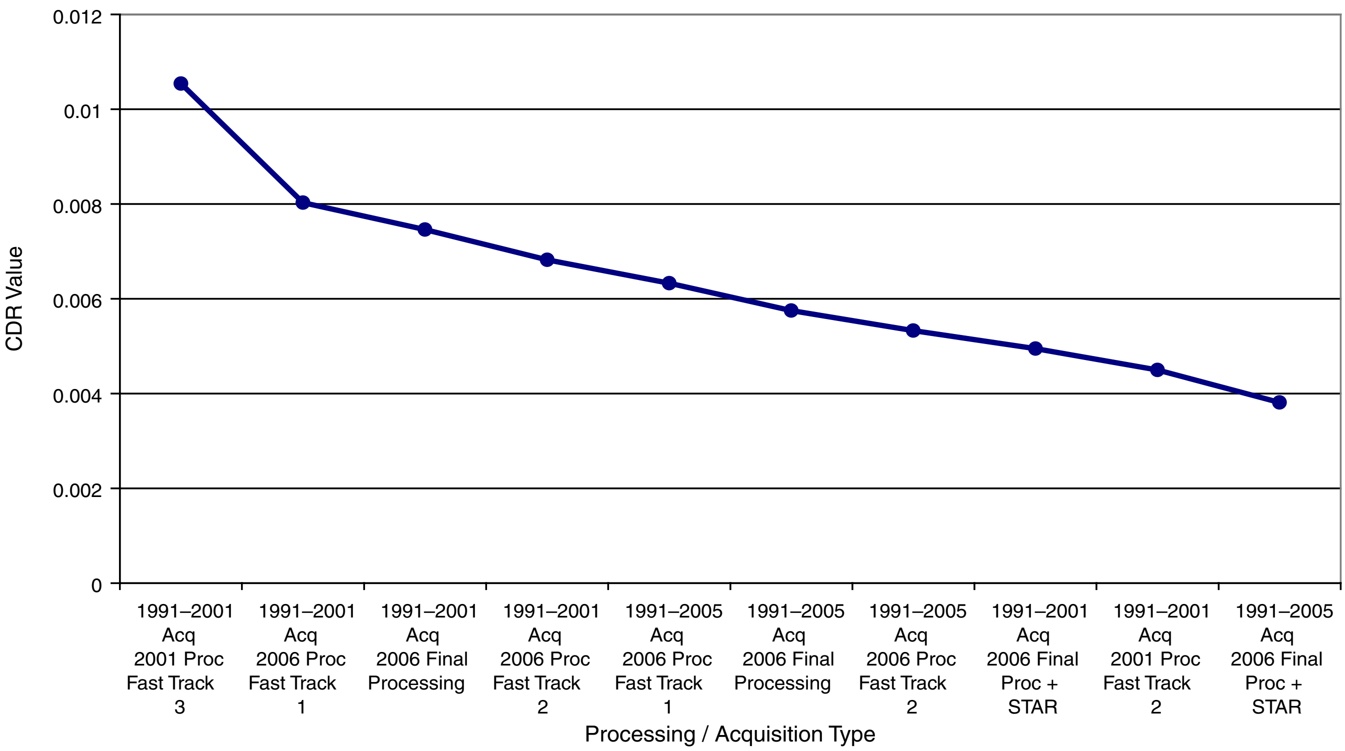

Fig. 5. The reductions in CDR from improved repeatability for different acquisition vintages and processing runs.

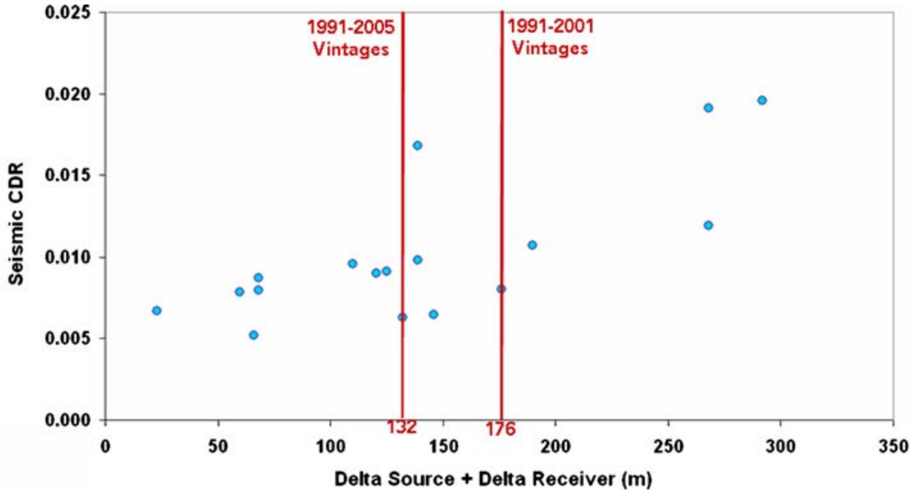

Fig. 6. Relationship between acquisition repeatability (delta source + delta receiver) and seismic CDR for a series of 4D surveys. The vertical lines show the DS + DR for the Mungo monitor surveys, annotated with the relevant vintages.

2005 particular care was taken to match the original source and receiver locations as far as surface currents and the positioning systems of the acquisition would allow. A simple measure used to assess the acquisition repeatability is the average of the variation in source and receiver locations between each monitor and the baseline survey at a reference offset, in this case 1000 m. This measure is referred to as delta source plus delta receiver, or DS + DR. By comparing the 1991–2001 and 1991–2005 acquisition repeatability for the 2006 processing flow, we can assess the impact of the increased effort to improve acquisition repeatability. We can observe the relationship between acquisition and seismic repeatability for a series of field examples in Figure 6, all taken for a 1000 m offset but with different acquisition parameters and conditions. The 2005 monitor survey shows a lower values of DS + DR when compared with the 2001 acquisition, and assuming the 1000 m offset positioning is indicative of the full offset range, it more closely matched the original acquisition repeatability. The CDR value decreases as the DS + DR is minimized, indicating the enhanced repeatability of the 2005 monitor due to the acquisition improvements.

(3) *Additional 4D noise reduction* – the repeatability calculation pre and post the application of STAR provides an assessment of the improvement in repeatability achieved by including specific 4D noise reduction techniques. We can observe these significant comparisons in Figure 7.

The relative percentage improvements are detailed in Table 2. The results show a decrease in CDR, and hence a reduction in the 4D noise, for both processing and acquisition enhancement. For this case study the largest relative improvement comes from the application of STAR compared with both 2001 and 2005 monitor surveys with final 2006 processing. This is a simple post-stack specific 4D noise reduction processing step. The acquisition changes in this study offer the lowest overall relative repeatability improvement. However, all results are comparable, including what can be achieved from additional steps during the processing flow to better reduce 3D noise and align data.

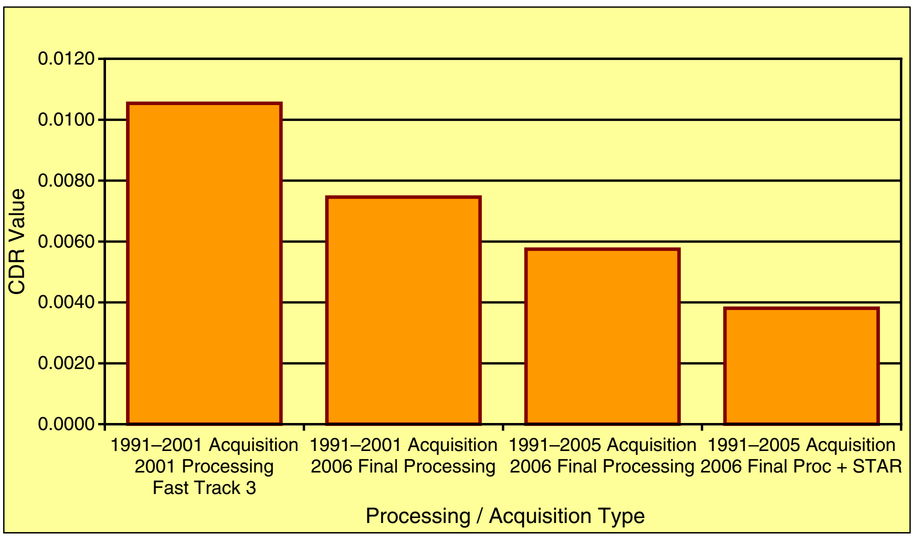

Fig. 7. CDR variations with improving processing and acquisition. Processing improvements are highlighted in columns 1 and 2, acquisition improvement in columns 2 and 3 and STAR improvements in column 3 and 4.

Table 2. CDR improvements. The last column shows percentage improvements in repeatability for different processing and acquisition. The fifth row is an additional test on the percentage improvement from the STAR process compared with row 2

	Processing and acquisition	CDR value	CDR incremental improvement
1	1991–2001 acquisition 2001 processing Fast_Track_3	0.0105	
2	1991–2001 acquisition 2006 final processing	0.0075	29% (v. row 1)
3	1991–2005 acquisition 2006 final processing	0.0058	23% (v. row 2)
4	1991–2005 acquisition 2006 Final Proc + STAR	0.0038	34% (v. row 3)
5	1991–2001 acquisition 2006 final proc + STAR	0.0050	34% (v. row 2)

Conclusions

This case study indicates that repeatability can be improved using the following methods in the order of significance:

(1) specific post-stack 4D noise attenuation;
(2) more extensive and tailored 4D processing flows;
(3) higher acquisition repeatability.

The results suggest that, in terms of the level of 4D noise, the most significant improvements can be achieved by the application of STAR. However, it is evident that no single aspect of the flow enhances the data dramatically enough to be considered in isolation; it is the combination of all efforts which leads to the three-fold improvement. Furthermore, it should be noted that, although it appears that the acquisition refinements produce the least significant reduction in 4D noise, this is likely to be due to the high level of acquisition repeatability achieved in the original monitor survey in 2001. Further improvements would be difficult to achieve, as opposed to a base case of two 3D surveys acquired and processed individually with no attempt made to match source–receiver locations or processing flow.

Whilst good acquisition repeatability helps align primary energy between acquisition vintages and therefore low 4D noise levels, it is clear that substantial reductions in 4D noise can also be achieved through 4D processing improvements. Finally, it should be highlighted that the value gained by investing in the methods described in this study is that 4D noise can be significantly reduced, leading to an improvement in the interpretability of the 4D signal, and thus a greater understanding of the dynamics of a reservoir during its development.

The authors would like to thank BP management and the Mungo field partners, Murphy Petroleum, Total E&P UK and NOEX Co. for providing feedback and allowing permission to publish information on the study area.

Abstract: At South Arne a highly repeatable time-lapse seismic survey (normalized root-mean-square error or NRMS of less than 0.1) allowed us to reliably monitor reservoir production processes during five years of reservoir depletion. Time-lapse AVO (amplitude v. offset) inversion and rock-physics analysis enables accurate monitoring of fluid pathways. On the crest of the field, water injection results in a heterogeneous sweep of the reservoir, whereby the majority of the injected water intrudes into a highly porous body. This is in contrast to a pre-existing reservoir simulation model predicting a homogeneous sweep. On the SW flank, time-lapse AVO inversion to changes in water saturation ΔS_w reveals that the drainage pattern is fault controlled. Time-lapse seismic data furthermore explain the lack of production from the far end of a horizontal producer (as observed by production logging), by showing that the injected water does not result in the expected pressure support. On the highly porous crest of the reservoir compaction occurs. Time-lapse time shifts in the overburden are used as a measure for compaction and are compared with predictions of reservoir compaction from reservoir geomechanical modelling. In areas where compaction observations and predictions disagree, time-lapse seismic data give the necessary insight to validate, calibrate and update the reservoir geomechanical model. The information contained in time-lapse seismic data can only be fully extracted and used when the reservoir simulation model, the reservoir geomechanical model and the time-lapse seismic inversion models are co-visualized and available in the same software application with one set of coordinates. This allows for easy and reliable investigation of reservoir depletion and gives deeper insight than using reservoir simulation or time-lapse seismic individually.

Petroleum geology and reservoir production of South Arne

The South Arne field is situated in the Danish sector of the North Sea. It is a chalk field extending 12.5 by 4 km with the long axis of the double-dipping anticline trending in a NNW–SSE direction. Production started in July 1999 predominantly from horizontal wells oriented along the axis of the reservoir in a NNW–SSE direction (Fig. 1). Cumulative production to date (March 2008) is 116 MMstb of 34.2 API oil and 166 Bscf of gas. For comparison, at Valhall a total of 500 MMstb of oil have been produced in the first 20 years (Barkved *et al.* 2003). On the north shoulder of the anticline, post-depositional faults create a graben-like structure at the crest of the reservoir (Mackertich & Goulding 1999). The graben strikes in a NNW–SSE direction, the same direction as the anticline. A second set of WNW–ESE trending faults can be interpreted from 3D seismic data over the entire field, except in an area obscured by a gas cloud. The second set of faults contributes significantly to reservoir depletion. The oil-bearing intervals are the Late Cretaceous Tor (referred to as lower reservoir in this paper) and overlying early Cretaceous Ekofisk (upper reservoir) formations. Reservoir quality is variable and the best reservoir quality is found on the crest of the north flank with a total reservoir thickness up to 65 m, split between Tor (approximately 40 m) and the overlying Ekofisk (approximately 25 m) formations (Fig. 2). The Ekofisk and Tor formations are separated by the Ekofisk tight zone. Porosity values on the north flank in the Tor range from 25 to 46%, with an average porosity of 37%. Matrix permeability in the Tor ranges of 1–10 mD, with fractures and faults adding significantly to permeability. On the western and eastern flank of the reservoir the chalk sequence thickens with distance from the axis of the anticline (Fig. 2), increasing the thickness of the reservoir interval. At the same time porosity and permeability drop significantly (Mackertich & Goulding 1999; Megson & Hardman 2001). Because of the low permeability in the distal part of the chalk sequence, pressure support by the water table is minimal and water injection is necessary to provide the necessary drive energy for hydrocarbon production. In the high-porosity region on the crest of the reservoir, compaction adds additional drive energy, estimated at 20% of total drive energy. Source rock is provided by the underlying Late Jurassic shale sequences.

The reservoir produces from horizontal wells, interleaved with horizontal water injection wells (Figs 1 & 2). Production is enhanced by induced vertical fractures and further supported by water injection. Both producers and injectors are stimulated by acid frac or hydro-facing using a proppant. The induced fractures are vertical and aligned with the direction of the horizontal wells, drilled in the direction of minimal horizontal stress, to enable a

VINING, B. A. & PICKERING, S. C. (eds) *Petroleum Geology: From Mature Basins to New Frontiers – Proceedings of the 7th Petroleum Geology Conference*, 523–535. DOI: 10.1144/0070523

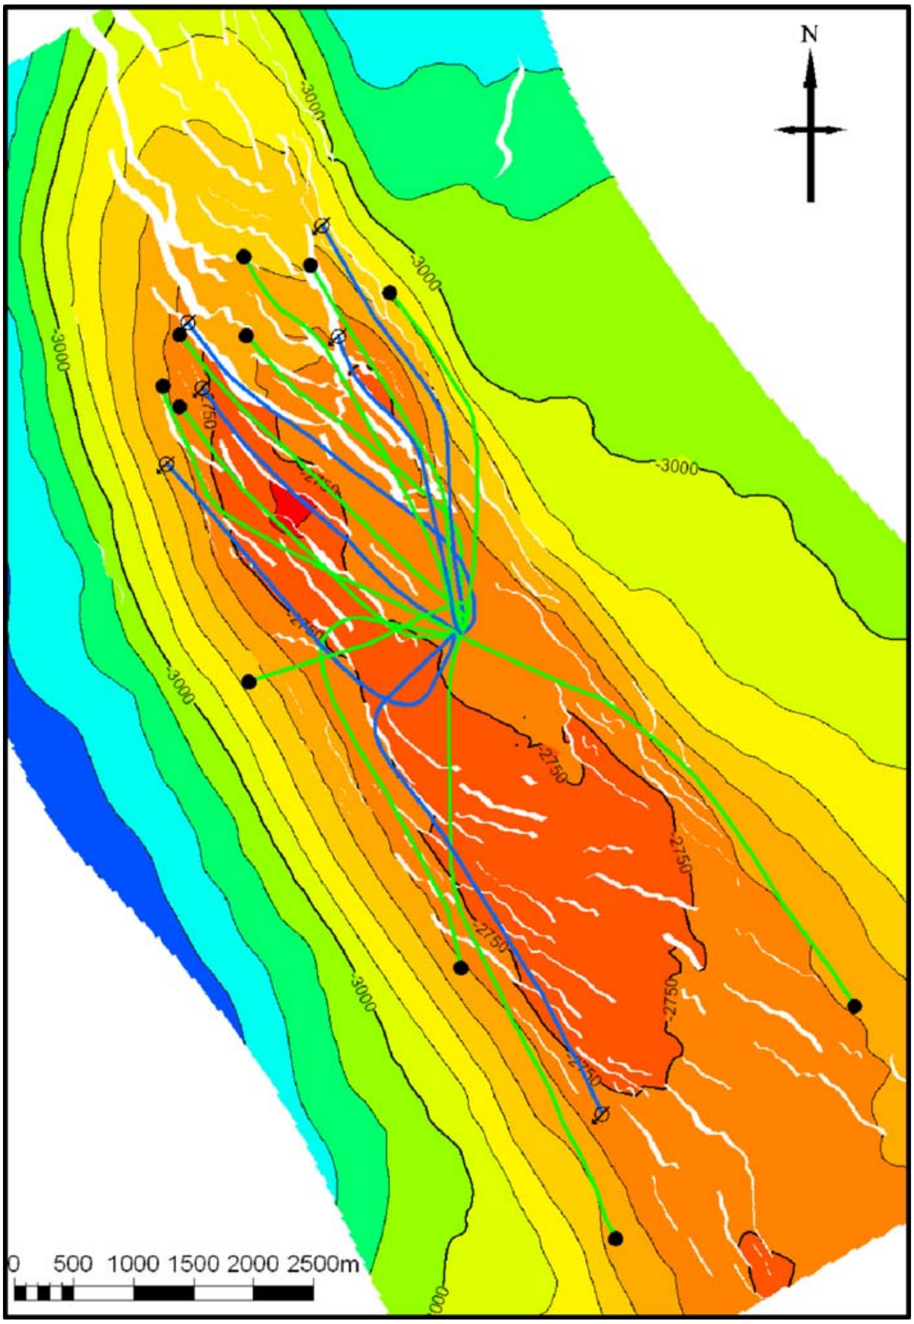

Fig. 1. Top-reservoir structure shows an elongated anticline. The northern crest exhibits a graben structure on the crest of the reservoir. The reservoir is produced by interleaved horizontal producers (in green, with solid black dot at toe of well) and water injectors (in blue, with black circle and arrow).

homogenous sweep across the reservoir interval. For an in-depth discussion of the petroleum geology of South Arne and field history, the reader is referred to the excellent paper of Mackertich & Goulding (1999).

Time-lapse seismic data: acquisition, processing and inversion

In recent years, time-lapse seismic data are increasingly used as a reservoir management tool and to assist in field development planning. The use of time-lapse seismic data in conjunction with reservoir simulation models and production data allows the creation of an internally consistent subsurface model. Published field examples of such integrated case studies include Lena, Gulf of Mexico (Johnston *et al.* 2000), Gullfaks, North Sea (Najjar *et al.* 2003), Jotun, North Sea (Gouveia *et al.* 2004), Girassol and Jasmin, West Africa (Gonzalez-Carballo *et al.* 2006), Gannet C (Staples *et al.* 2006) and Marlim (Thedy *et al.* 2007). More recently, the impact of reservoir compaction on time-lapse seismic data has been studied in more detail (Guilbot & Smith 2002; Hatchell *et al.* 2003) and reservoir geomechanical models are included into workflows that integrate time-lapse seismic data with subsurface flow and geomechanical models (Barkved & Kristiansen 2005; Staples *et al.* 2006; De Gennaro *et al.* 2008). In this paper we demonstrate that high quality time-lapse seismic data, in conjunction with careful time-lapse seismic processing and application of advanced reservoir seismic inversion methods, yields detailed insight into reservoir fluid flow and geomechanical processes. By co-visualizing the subsurface models derived from time-lapse seismic data, the reservoir simulation model and the reservoir geomechanical model, we generate an understanding of reservoir production processes that could not be achieved when using each model individually.

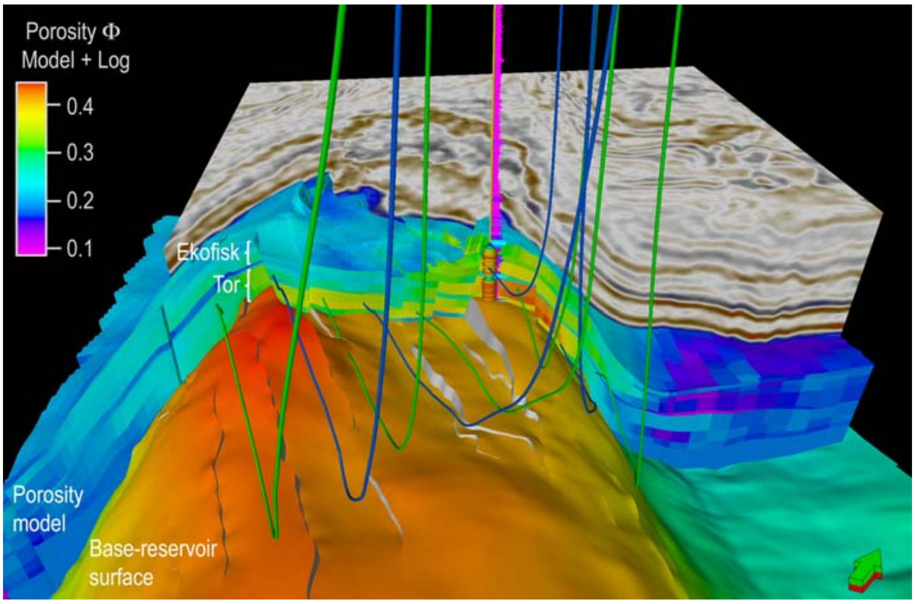

Fig. 2. Three-dimensional view of northern crest. The base reservoir surface clearly shows the graben structure. The simulator porosity model shows the highest porosities (in excess of 40%) on the crest of the reservoir, with a clear division between the upper (Ekofisk) and lower (Tor) reservoir. The porosity log at the appraisal well also clearly shows the low porosity tight zone separating the two reservoirs. Also note the excellent anti-correlation between the porosity log (displayed as barrel) and the velocity log (displayed as a vane). Finally note the strong top-reservoir reflector visible in the seismic data, facilitating the interpretation of reservoir geometry.

Acquisition and processing

Two 3D seismic surveys are available for a time-lapse seismic study. A pre-production baseline survey was acquired in 1995, using 4×4600 m streamers at 100 m streamer separation and a 50 m source interval. The monitor survey was shot during five weeks in September and October 2005 after five years of reservoir production. This acquisition time includes downtime due to bad weather (about one-third of the time) at the end of the North Sea seismic season. The monitor survey was shot using 8×4600 m streamers at 50 m separation and a source interval of 25 m. The survey design for the monitor survey aimed to repeat the acquisition geometry of the base survey as closely as possible, and using steerable streamers helped to closely match the baseline geometry during acquisition. This resulted in a good repeatability of seismic data in areas where no time-lapse changes occur and consequently provided good visibility and high signal-to-noise ratio of the time-lapse seismic signal. At South Arne, the repeatability (Kragh & Christie 2002), using normalized root-mean-square error (NRMS) between traces of base and monitor survey as a metric, was 0.15 at reservoir level after fast-track processing, which was available three weeks after the end of data acquisition (Schiøtt & King 2006). After careful time-lapse processing and 4D matching, an NRMS value of less than 0.10 was measured across the reservoir interval. In comparison with other time-lapse surveys (e.g. Smit *et al.* 2005 report values between 7 and 37%) the NRMS value of the South Arne survey is low, showing that a high repeatability was achieved. The final processing sequence included the application of tidal static corrections, swell noise attenuation, tau-p deconvolution and Kirchoff pre-stack time-migration. Both base and monitor surveys were co-processed using a deterministic processing sequence, carefully maintaining amplitude preserved time-lapse signal.

Time-lapse time shifts and amplitude changes

Seismic data observations include the amplitude and the arrival time of a wavelet reflected from an interface in the subsurface. At South Arne the interfaces between the reservoir and the overburden, as well as the reservoir and the underburden, are strong reflectors (Figs 2 & 3). Figure 3a, b displays vertical sections of the baseline survey and the monitor survey, respectively. The top- and base-reservoir reflector interpretations are indicated by black lines. Additionally, the interface between the upper (Ekofisk) reservoir and the lower (Tor) reservoir is marked. The displayed section contains the vertical well displayed in Figure 2 and the well location is indicated by a vertical line. For further analysis, traces from the 1995 baseline survey and the 2005 monitor survey are extracted and displayed in Figure 3c, d. The trace from the baseline survey is displayed in green and the monitor survey trace is displayed in blue. Amplitude changes ΔA and time-lapse time shifts Δt are readily visible. At reservoir level, the arrival times of the baseline survey t_1 (in green) are consistently earlier than the corresponding arrival times of the equivalent reflections in the monitor survey t_2 (in blue). The observed time-lapse time shifts $\Delta t = t_1 - t_2$ are negative, with a maximum observed value of approximately -7 ms. The measurement of time-lapse time shifts can be automated (Nickel *et al.* 2003) and the results can be used to time-align corresponding traces of base and monitor survey (Fig. 4a, b). The time-aligned traces can then be subtracted and the amplitude differences plotted (Fig. 4c), giving a first qualitative indication of reservoir production processes. The amplitude changes ΔA show a clear fault control of the time-lapse seismic response and therefore fault control of the reservoir depletion process. The location of the largest amplitude change furthermore corresponds with the location of an injector well.

Time-lapse time shifts can be used to time-align different vintages of time-lapse seismic surveys. On the other hand, time-lapse time shifts also have a diagnostic value in monitoring reservoir compaction (Guilbot & Smith 2002; Hatchell *et al.* 2003; Nickel *et al.* 2003). The time shifts in the overburden can be explained by a combination of geomechanical modelling (predicting reservoir compaction as pore-pressure in the reservoir is reduced) and associated overburden stretching. Overburden stretching affects seismic time-lapse data in two ways. Firstly, the path length of the monitor survey increases as the overburden elongates and secondly, the vertical velocity decreases as the overburden stretches and

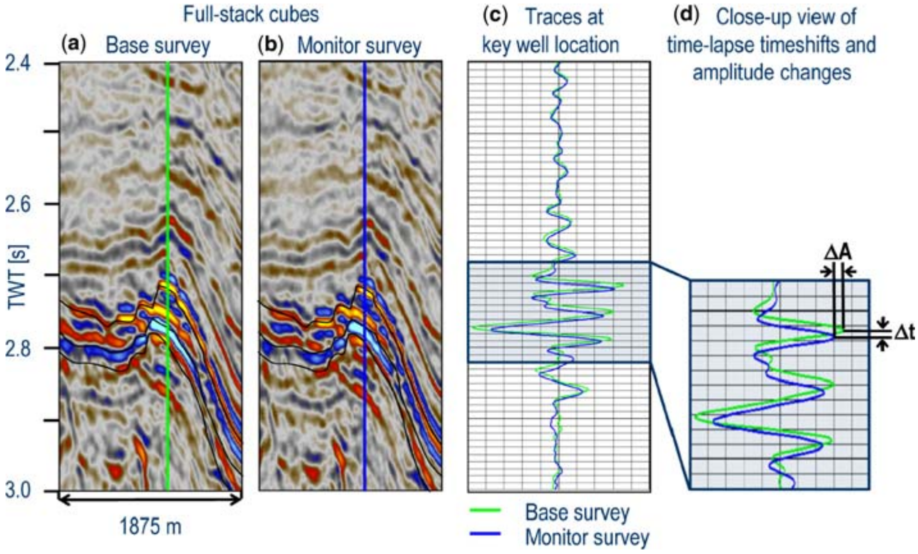

Fig. 3. Vertical sections of full-stack seismic cubes after pre-stack Kirchhoff time migration for (**a**) base survey and (**b**) monitor survey. The location of the appraisal well (see Fig. 2) is indicated by the vertical lines. (**c**) Extracting a single trace at the location of the appraisal well allows investigation of time-lapse signal changes at this location. (**d**) A close-up look shows an increase in travel-time Δt (time-lapse time shift caused by reservoir compaction) and a dimming in amplitude ΔA between the base and monitor surveys.

vertical effective stress decreases (Hatchell & Bourne 2005; Herwanger & Horne 2005). Both effects cause an increase in travel time for the monitor survey compared with the base survey in compacting reservoirs. In Figure 4d we plot the measured time shifts in a vertical section along a profile containing the appraisal well (for well location see Fig. 2). Note that the time shifts are clearly fault-bounded. This will become even more apparent when we investigate the time shifts extracted along the top-reservoir horizon later in this paper.

Time-lapse AVO inversion

In time-lapse AVO inversion, we use the fact that the amplitude of a reflected wave depends on the change of elastic properties across the interface. The reflection coefficients as a function of the incidence angle are given by the Zoeppritz equations (e.g. Mavko *et al.* 1998). A variety of approximations exist that allow for a deeper insight which parameters govern the AVO response. For vertical incidence, the reflection amplitude of a reflected P-wave is determined by the contrast in acoustic impedance (AI) above and below the interface:

$$R(0^\circ) = \frac{(AI_2 - AI_1)}{(AI_2 + AI_1)}$$

where AI_2 and AI_1 are the acoustic impedances (i.e. the product of seismic P-wave velocity V_p and bulk density ρ) in the lower and upper layer, respectively. At intermediate angles of incidence Θ

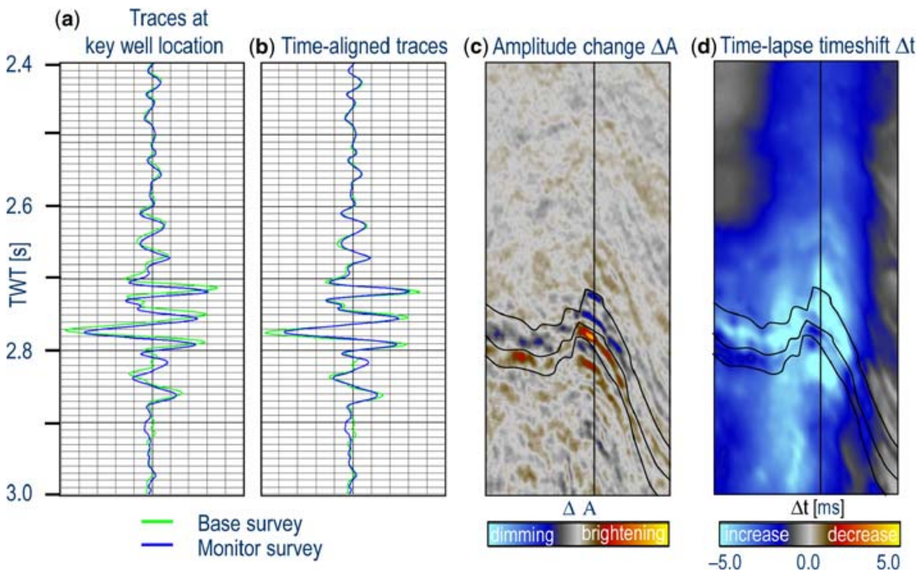

Fig. 4. (**a**) Single trace of the base and monitor surveys at the location of the appraisal well. (**b**) Same traces as (a) with time-lapse time shift removed. (**c**) After removing time-lapse time shifts, a difference cube can be generated. Note the fault control of the amplitude changes, giving a first indication of fault control of depletion processes. (**d**) Time-lapse time shifts at each sample location can be plotted and used as a diagnostic tool. Note that the time shifts are fault controlled and that the largest shifts occur above the region of the reservoir that shows the largest amplitude changes. This region, not surprisingly, also correlates with the location of the best producer.

of the seismic wave on an interface, the contrast in shear-wave velocities or Poisson's ratio v becomes influential (Shuey 1985):

$$R(\Theta) = R(0^\circ) + \left(A_0 R(0^\circ) + \frac{\Delta v}{(1-v)^2}\right) \sin^2 \Theta.$$

Here $R(0^\circ)$ is the normal incidence reflection coefficient, governed by the acoustic impedance contrast, A_0 specifies a normal, gradual decrease of amplitude with offset (full expression given in Shuey 1985), and finally Δv and v specify the Poisson's ratio difference $\Delta v = v_2 - v_1$ across the interface and the average $v = 0.5(v_2 + v_1)$ of Poisson's ratio below and above the interface.

The variation of reflection coefficient with incidence angle, recorded in seismic data, can be used to estimate 3D volumes of acoustic impedance and Poisson's ratio using 3D AVO inversions. Here we use seven cubes of seismic angle-band stacks as input, with incidence angles ranging from 0 to 35°. The seven angle-band stacks are inverted simultaneously using an angle-band stack specific wavelet (Rasmussen *et al.* 2004). The outputs of the 3D AVO inversions are 3D models of acoustic impedance and Poisson's ratio at each sample of a seismic cube, in this case a regularly sampled grid of 12.5 × 25 m in horizontal directions and 2 ms in the vertical direction. In Figure 5a, b, we display cross-sections through the acoustic impedance and Poisson's ratio model, respectively. The location of the appraisal well is indicated by the black line. Note that the low acoustic impedance in the AVO inversion model corresponds with the high porosity observed in the log (Fig. 2).

For time-lapse AVO inversion, we use angle-band stacks for both base and monitor surveys as input and simultaneously invert for acoustic impedance (AI_{Baseline}), Poisson's ratio (v_{Baseline}) and additionally for the ratio changes $AI_{\text{Monitor}}/AI_{\text{Baseline}}$ and $v_{\text{Monitor}}/v_{\text{Baseline}}$ of these parameters (see Fig. 5c, d). The time-lapse AVO inversion is described in more detail in Schiøtt *et al.* (2008). For reservoir management purposes, it is desirable to understand the change in reservoir properties, such as changes in water saturation ΔS_w, reservoir pressure ΔP and porosity $\Delta\Phi$. The inverted changes in acoustic impedance AI or Poisson's ratio ν are an intermediate step to seismically monitor changes in reservoir engineering parameters. To determine reservoir engineering parameters, it is necessary to first derive a calibrated rock physics model that allows translation of the observed changes in AI and v to changes in reservoir properties. At South Arne, acoustic impedance AI is closely correlated with porosity Φ in the chalk sequences and Poisson's ratio v is a sensitive fluid indicator. Note that other factors, such as depositional environment and compaction history, will also influence the seismic behaviour of the chalks comprising the reservoir (Vejbæk *et al.* 2005). Therefore, the rock physics model needs to be calibrated for each reservoir unit. The calibration is done using log data and, where available, laboratory measurements. In Gommesen *et al.* (2004), three different rock physics models are each fitted to observations of acoustic impedance and Poisson's ratio as functions of porosity and water saturation. All models agree that, for the South Arne chalks, acoustic impedance is a good porosity indicator, whereas Poisson's ratio is a good fluid indicator.

The rock physics model employed for the lower reservoir (Tor) in this study is displayed in Figure 6. Each dot in the figure represents a prediction of Poisson's ratio (on the abscissa) and acoustic impedance (on the ordinate) for a given porosity Φ (colour coded) and water saturation S_w using a rock physics model at virgin reservoir pressure. Note again the predominant dependence of acoustic impedance on porosity and of Poisson's ratio on water saturation. Application of the rock physics model allows the effective translation of changes in acoustic impedance ΔAI and Poisson's ratio $\Delta\nu$ to changes in water saturation ΔS_w and porosity $\Delta\Phi$, and vice versa. The resulting rock physics time-lapse AVO inversion images of porosity change $\Delta\Phi$, water saturation change ΔS_w and gas saturation change ΔS_g are displayed in Figure 7a–c, respectively. The estimation of three quantities ($\Delta\Phi$, ΔS_w, ΔS_g) from two independent quantities (ΔAI, Δv) is essentially underdetermined. However it is made possible by the fact that an extreme decrease in Poisson's ratio cannot be explained by water saturation changes alone, whereas an increase in gas saturation can explain this effect. Note also that for the shale sequences outside the reservoir, no calibrated rock physics model is available. Therefore the overburden and underburden are masked out for the rock physics inversion. It would be of interest, however, to relate inverted changes in elastic properties in the overburden and underburden to changes in strain or porosity for geomechanical applications such as seal-integrity studies.

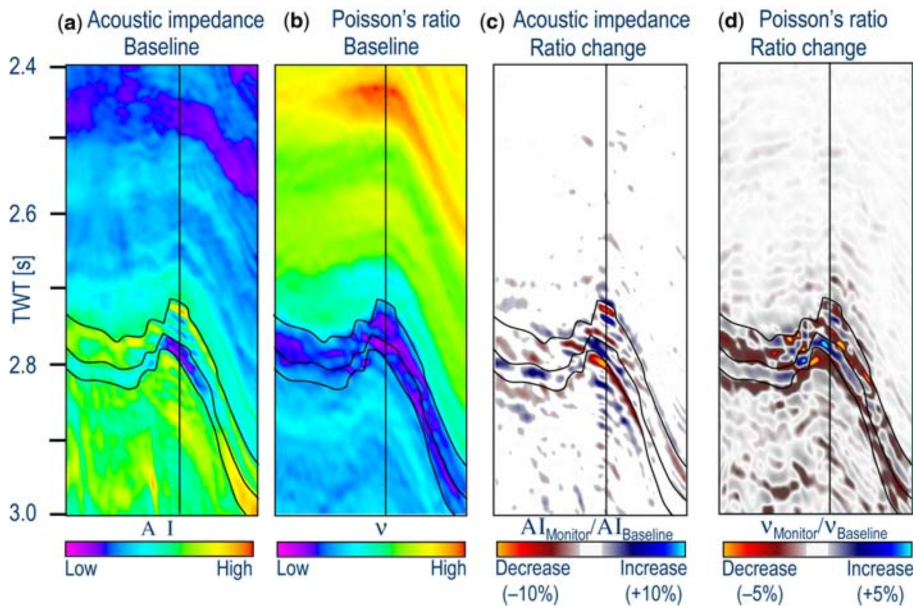

Fig. 5. (**a**) Acoustic impedance and (**b**) Poisson's ratio can be derived from 3D AVO inversion. Time-lapse AVO inversion additionally allows computation of (**c**) change in acoustic impedance and (**d**) change in Poisson's ratio. See text for detail.

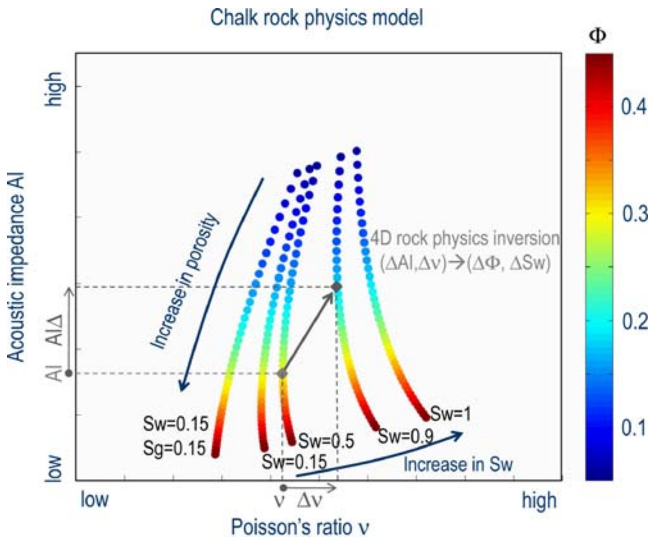

Fig. 6. Acoustic impedance and Poisson's ratio are closely related to porosity and water saturation in South Arne chalks. An increase in porosity causes a decrease in acoustic impedance, with hardly any influence on Poisson's ratio. Increasing water saturation (at constant porosity) causes a strong increase in Poisson's ratio, with hardly any imprint on acoustic impedance. A rock physics model allows translation of elastic properties observed from AVO inversion to reservoir properties.

Application of time-lapse rock physics AVO inversion and time-lapse time shift observations

Applied time-lapse seismic interpretation helps to address questions about reservoir production dynamics. The challenge for the reservoir engineers and the asset team is to determine an interpretative mental image of the production process and create a subsurface model that can be reconciled with all available information. In this section, we co-visualize the production-induced time-lapse seismic results with corresponding properties from reservoir simulation models. This allows a direct comparison of reservoir depletion as seen by time-lapse seismic and as predicted from either a reservoir simulation model or a reservoir geomechanical model.

Reservoir depletion of the northern crest

In a first example, we study the depletion pattern on the northern crest of the reservoir. To this end, we compare water saturation changes derived by time-lapse seismic rock physics AVO inversion (seismic ΔS_w) and water saturation changes predicted from the reservoir simulation model (simulation ΔS_w). The key findings are that (i) water pathways are more heterogeneous than the simulation model predicts, (ii) the reservoir drains mainly from a high porosity body and (iii) the injected water spreads predominantly in the lateral updip direction, whereas the simulation model had predicted more of a vertical movement.

In Figure 8 the seismic ΔS_w (Fig. 8a) and simulation ΔS_w (Fig. 8b) are displayed along a vertical profile. The location of the profile is indicated on the map inset in Figure 8a. Both figures use the same colour scale: areas with the strongest increase in water saturation are displayed by the deep shades of blue and areas with marginal or no change of water saturation are displayed by light hues and in white. The intersections of the horizontal wells with the displayed vertical section through the reservoir are indicated by solid black dots for oil producers and circles with tilted arrows for water injectors. The seismic ΔS_w shows strong lateral continuity and is concentrated in the lower (Tor) reservoir. The only change in seismic ΔS_w in the upper reservoir occurs around the injection well I2. The water injected at I1 appears to be moving updip and remains in the lower reservoir. This observation is in contrast to the simulation model prediction that the injected water would spread vertically into the upper reservoir.

To investigate the lateral spread of the injected water, we compute a map of average change in water saturation for the

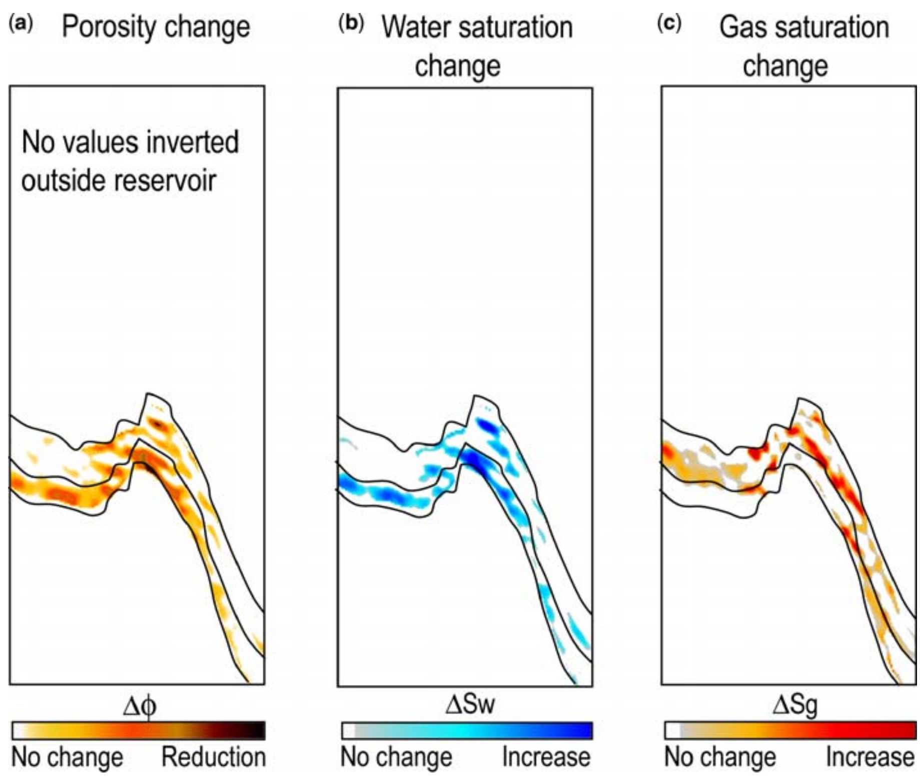

Fig. 7. Application of the South Arne rock physics model allows estimates of (**a**) change in porosity Φ, (**b**) change in water saturation ΔS_w and (**c**) change in gas saturation ΔS_g. No calibrated rock physics model existed for the over- and underburden and therefore these zones are masked for the inversion procedure.

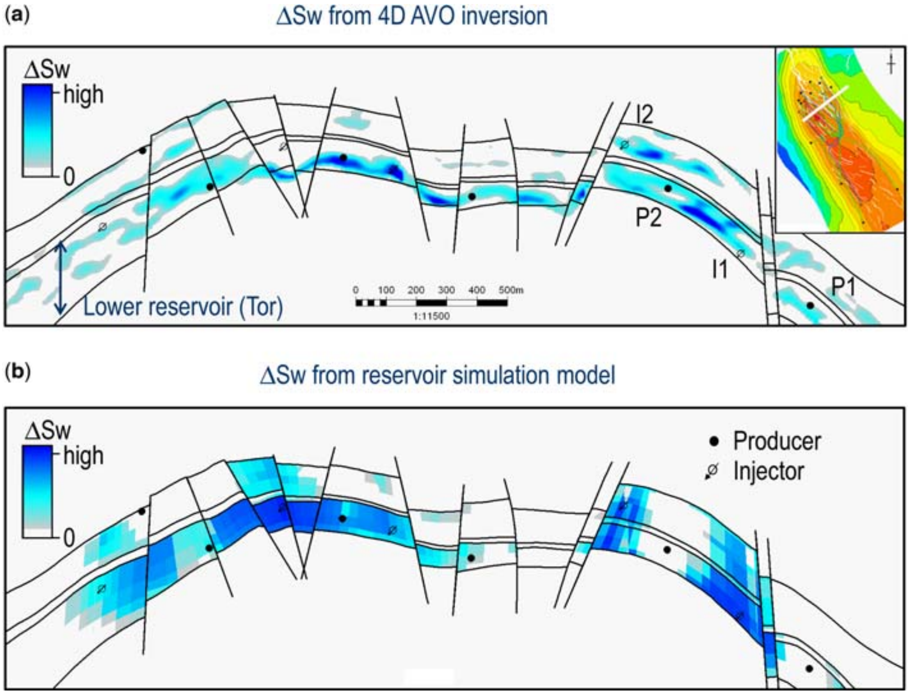

Fig. 8. (**a**) ΔS_w derived from time-lapse rock physics inversion and (**b**) ΔS_w predicted by the reservoir simulation model. Profile length is approximately 3 km and vertical exaggeration is by a factor of 3. Change in water saturation is colour coded with large increases in water saturation indicated by dark blue colours. The locations of producing wells are indicated by the solid black dots and the locations of injector wells are indicated by circles with arrows. Producer and injector wells discussed in the text are labelled P1, P2, I1 and I2.

lower reservoir by vertically averaging ΔS_w in the lower (Tor) reservoir for both seismic ΔS_w and simulator ΔS_w. The average Tor ΔS_w is then plotted on the bottom reservoir surface (Fig. 9a, b). Simulation ΔS_w shows three fingers of increased water saturation. The two left fingers are centred on injector wells I1 and I2, and the third finger originates from an abandoned injector well (not displayed in this map). Seismic ΔS_w, on the other hand, shows a heterogeneous water front moving updip from injector I1 along most of the well, with a strong change in water saturation at the centre of the well. Based on the seismic ΔS_w map the water injected into the I2 injector well seems to gather in an elongated zigzag shaped feature of about 700 m length and a width varying between 200 and 300 m, whereas the simulation ΔS_w predicts a uniform injection pattern centred along the I2 injector.

To investigate the observed heterogeneous nature of change in ΔS_w further, we display the seismic and simulator ΔS_w in a 3D plot together with the porosity from the reservoir simulation model (Fig. 10a, b). The simulation model shows a homogeneous

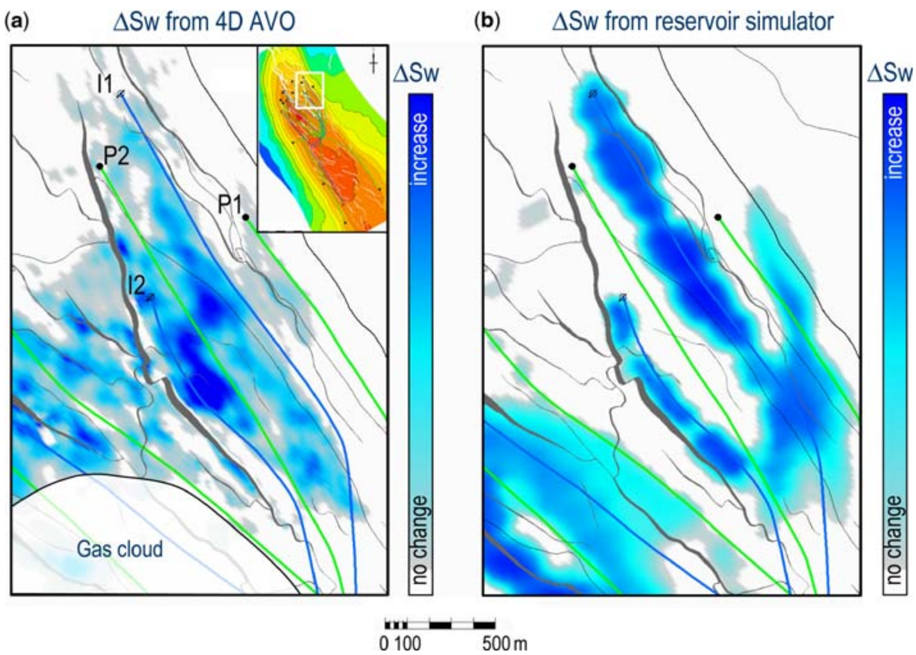

Fig. 9. (**a**) Map of ΔS_w derived from time-lapse rock physics inversion and (**b**) map of ΔS_w predicted by the reservoir simulation model. The average water saturation in the lower reservoir (Tor) is vertically averaged and the average ΔS_w is displayed on the base reservoir surface. Note the zigzag shaped pattern for increased seismic ΔS_w and the three-fingered pattern in simulator ΔS_w. See text for a detailed discussion.

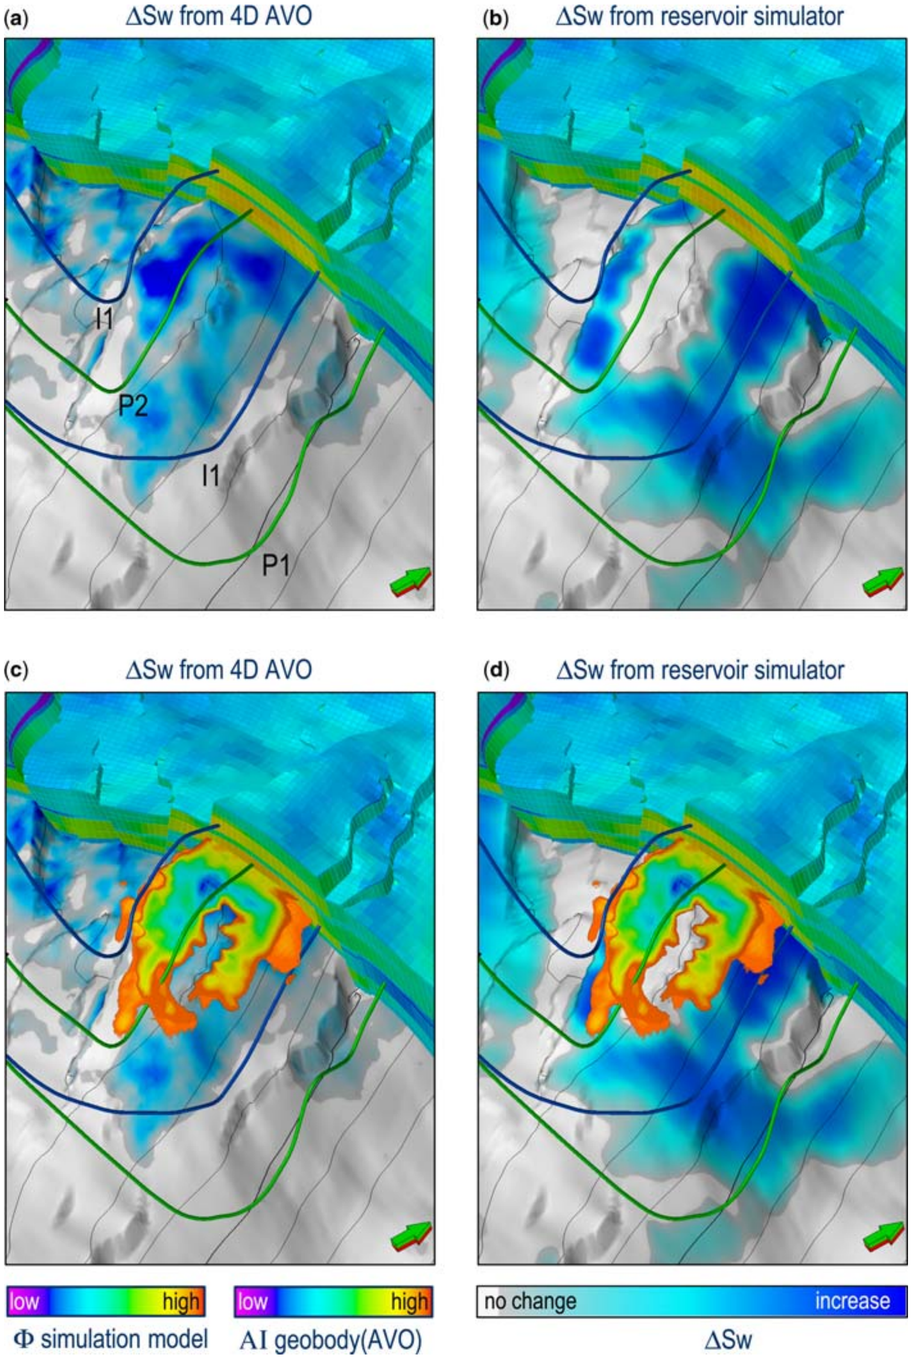

Fig. 10. Three-dimensional view of (**a**) seismic ΔS_w and (**b**) simulator ΔS_w co-visualized with the simulator porosity and the producer (green) and injector (blue) well locations on the northern crest. The ΔS_w maps are the same as in Figure 9. When adding a seismically derived geobody of acoustic impedance (**c** and **d**), it becomes apparent that the water saturation changes in (a) follow the high porosity/high permeability zone outlined by the geobody, whereas the water saturation changes in (b) follow a simplistic porosity/permeability model. See text for discussion.

porosity (and thus homogeneous permeability) distribution in the lower (Tor) reservoir. This explains the symmetric spread of the injected water around the injector wells. New insight is gained when additionally displaying a geobody of seismic-derived acoustic impedance (Fig. 10c, d) in the 3D image. The geobody is extracted in such a way that it represents a volume of low acoustic impedance; that is, a volume of high porosity (Fig. 6). The top of the geobody is sliced off such that the distribution of values inside the geobody can also be seen. In Figure 10c it becomes immediately clear that the changes in regions of high water saturation mirror the regions of high porosity and permeability. The injected water is simply intruding a permeable zone, creating a heterogeneous water saturation pattern.

The information gained from seismic ΔS_w gives a clear picture of a heterogeneous reservoir sweep within a body of high porosity and permeability. This additional knowledge can potentially be used to selectively sweep the lesser drained areas by fracturing these areas to increase permeability.

Fault control of injected water on the SW flank

Faults can act as flow barriers or fluid conduits. For accurate production forecasts from reservoir simulation models, faults and fractures need to be included in the reservoir model. However, including faults in a reservoir model adds additional complexity, since their location and physical properties need to be determined – information that is not always readily available. On the other hand, a huge number of minor faults can often be extracted from 3D seismic data – the question of which of these faults contribute to fluid flow (and therefore need to be included into a flow model) still needs to be addressed. In this section, we show that time-lapse seismic observations can assist in finding the locations of transmissive faults. We can clearly demonstrate that fluid flow on the SW flank is fault dominated. The joint use of time-lapse seismic observations and production logging data creates a clearer and consistent picture of drainage of the SW flank.

In Figure 11, we compare changes in water saturation ΔS_w observed from time-lapse seismic AVO inversion (Fig. 11a), and predicted from the reservoir simulation model (Fig. 11b). The location of the displayed area and the view direction for the 3D plot are indicated in the inset in Figure 11a. Again, we compute the vertically averaged ΔS_w and display the averaged ΔS_w as a map attached to the bottom reservoir surface. Additionally, we display the injector well I3 and two producers P4 and P5, and a vertical seismic section. The seismic ΔS_w shows several streaks of increased water saturation emanating downdip from injector well I3, whereas the simulation ΔS_w shows a homogeneous spread of injected water around well I3. The locations of the streaks of increased water saturation coincide with the locations of minor faults (marked by red arrows) that are visible in the seismic data. The seismic data suggest that the injected water has found a conductive pathway from injector I3 to producer P4 along three conductive zones and the majority of the water seems to be injected into the first half of I3. In a similar manner, production logging data has shown that the P5 well produces predominantly from the first half of the well, indicating a lack of pressure support in the toe-half of P5. The time-lapse seismic data show only minor changes in ΔS_w towards the toe of producer P5, indicating that only a negligible amount of water is injected into this region. This is consistent with the lack of production towards the toe of the well, indicating a lack of pressure support and is consistent with the production logging data. This additional insight may be used for a workover campaign to re-fracture the toe end of injector I3 and producer P5, in order to increase production from this low permeability zone.

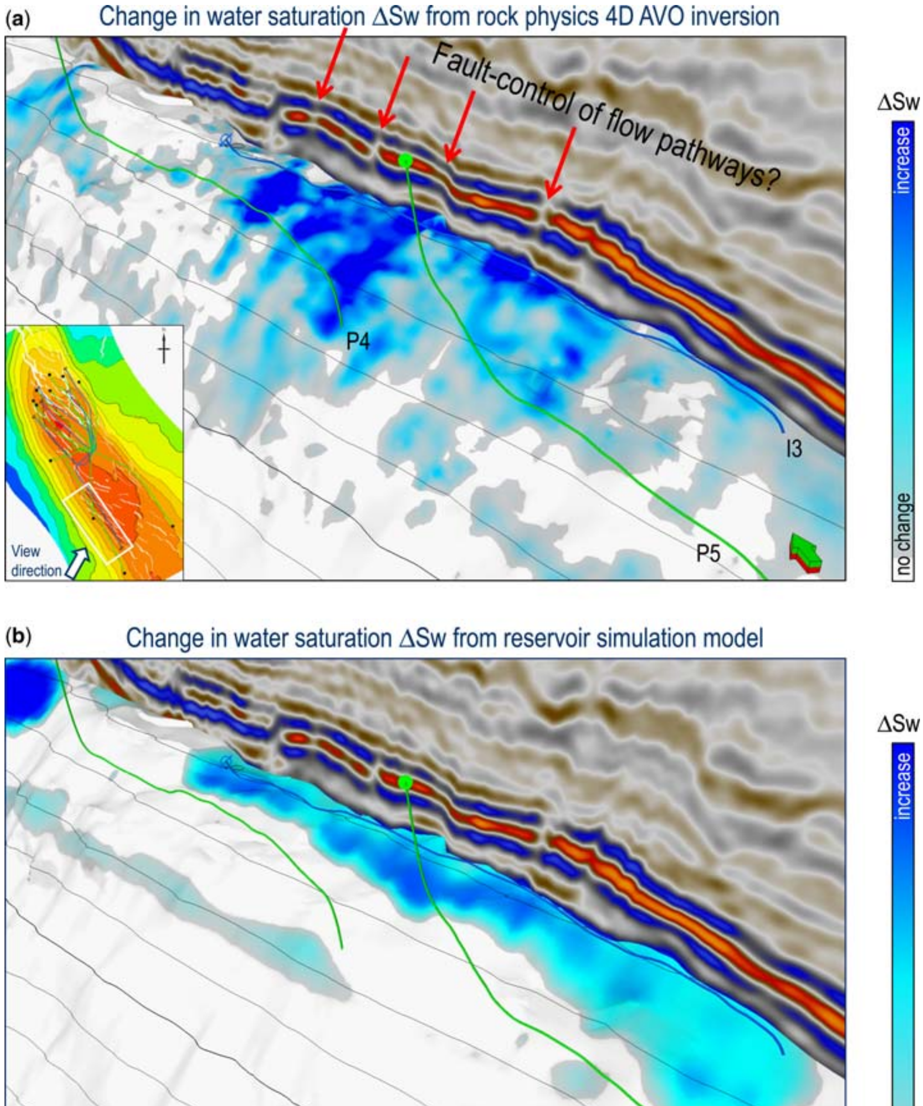

Fig. 11. Changes in water saturation ΔS_w (**a**) observed from time-lapse rock physics inversion and (**b**) predicted from reservoir simulation. Injector well I3 is marked in blue and two producers P4 and P5 are marked in green. The seismic derived ΔS_w shows a series of blue streaks indicating conductive pathways. Their locations coincide with minor faults (marked by red arrows) observed in seismic data.

The observations of fault control on reservoir depletion have also had implications for the field development of an extension of South Arne to the north of the currently producing region. Three new appraisal wells were drilled – an appraisal well to the north and NE tested the reservoir at virgin pressure, whereas an appraisal well to the NW tested at substantially lower pressure. Fault control along radial faults offers a suitable explanation as to why the well towards the NW is already partially pressure depleted. The faults are observed in seismic data (Mackertich & Goulding 1999) and the time-lapse seismic data have given a strong indication of the faults acting as fluid conduits. Hess has therefore built several reservoir models of the northern extension, simulating different depletion scenarios, including fault-controlled reservoir depletion, causing a skewed map of pressure depletion.

Compaction monitoring on the northern crest

The high porosity chalk comprising the reservoir on the northern crest makes production-induced reservoir compaction a distinct possibility, and reservoir compaction at the nearby Ekofisk (e.g. Boade *et al.* 1989; Chin & Nagel 2004) and Valhall (Cook & Jewell 1996; Barkved *et al.* 2003) chalk fields is well published. Laboratory experiments from the upper (Ekofisk) and lower (Tor) reservoir show the typical chalk compaction behaviour (Fig. 12a, b): as pore-pressure is reduced and mean effective stress increases, the chalk initially shows a slow (but reversible) decline in porosity. At a critical effective stress, irreversible compaction occurs as the weakly cemented grain-to-grain bonds fail and porosity drops sharply. High porosity in chalks causes a lower critical stress at which porosity collapse starts to occur. In the lower reservoir, the critical stress can be as low as 12 MPa at an initial porosity of 45%. Replacing oil by water in the pore space additionally lowers the critical stress, as water weakens the grain contacts.

In order to predict reservoir compaction and associated porosity and permeability changes, a full-field reservoir geomechanical model was built and coupled to the reservoir simulation model. A calibrated reservoir geomechanical model will assist in reliably assessing the amount of compaction drive energy. This allows for a better production forecast by including stress-dependent permeability and allows the operator to assess the risk of well failure by differential compaction. Geomechanical simulations also need to be calibrated (i.e. matched) with data observations in the same way that reservoir simulation models can be history matched using produced water and hydrocarbon volume and observed reservoir pressure. For compaction simulations, time-lapse seismic can produce the necessary calibration tool. In Figure 13, we compare time-lapse time shifts Δt on the top-reservoir horizon with displacement Δz of the same horizon predicted from reservoir geomechanical modelling. The time-lapse time shifts are taken as a proxy for the predicted vertical displacement. This seems a reasonable assumption, since the time shifts are caused by the compaction-induced stretching of the overburden and an associated velocity slowdown. However, the exact nature and means of calibrating the relationship between overburden stretching, velocity slowdown and observed time shifts is still a field of active research and debate (Hatchell & Bourne 2005; Staples *et al.* 2007; De Gennaro *et al.* 2008).

The observed time-lapse time shift Δt map (Fig. 13a) and computed vertical displacement Δz map (Fig. 13b) broadly agree. Maximum Δt is 6 ms and the maximum Δz is 1.5 m. This relationship between time-lapse time shifts and vertical displacement is in broad agreement with observations at Valhall (Hatchell & Bourne 2005) and Ekofisk (Janssen *et al.* 2006). Both maps show fault control of reservoir compaction, where faults clearly act as flow barriers. However, more interesting than the similarities are the subtle differences between the two maps. Areas where the observed compaction is stronger than predicted are indicated by yellow ellipses, and vice versa, areas where observed compaction is less than predicted are marked by red ellipses in Figure 13a, b. This can be seen especially clearly for the area drained by producer P1, where compaction of up to 75cm is predicted, but no time-lapse time shifts are observed.

These observations can be used to adjust the material properties of the reservoir geomechanical model. In areas that are seen to be compacting from seismic, but where the simulation model does not predict compaction, either the porosity may be increased or the critical stress at which irreversible deformation occurs can be lowered. For producer P3 it would be reasonable to increase porosity in the central area marked by the yellow ellipse and decrease porosity in the area marked by the red ellipse. The net result on production for the entire producer P3 may then be left unchanged and the history matching of production for the entire well would not be affected. The inversion results for acoustic impedance *AI* or rock physics inversion to porosity Φ can additionally assist in determining whether the simulator porosity model should be updated.

A quantitative comparison between compaction estimates from time-lapse seismic AVO inversions and reservoir geomechanical modelling gives a similar picture of compaction as given by time-lapse time shifts and vertical strain images. In

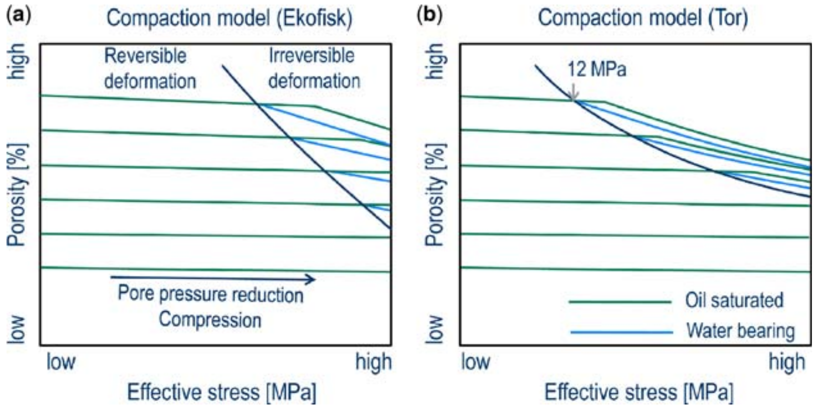

Fig. 12. Porosity as a function of effective stress for the (**a**) Ekofisk formation and (**b**) Tor formation. Each curve shows the porosity–effective stress relationship for a different initial porosity. Blue curves show the behaviour for water-bearing chalk and green curves show the behaviour for hydrocarbon-bearing chalk. For small effective stress, the porosity reduction is reversible (elastic deformation). At a critical stress, irreversible deformation occurs. Water in the pore space reduces the critical stress to as low as 12 MPa for chalk with 45% porosity in the Tor interval.

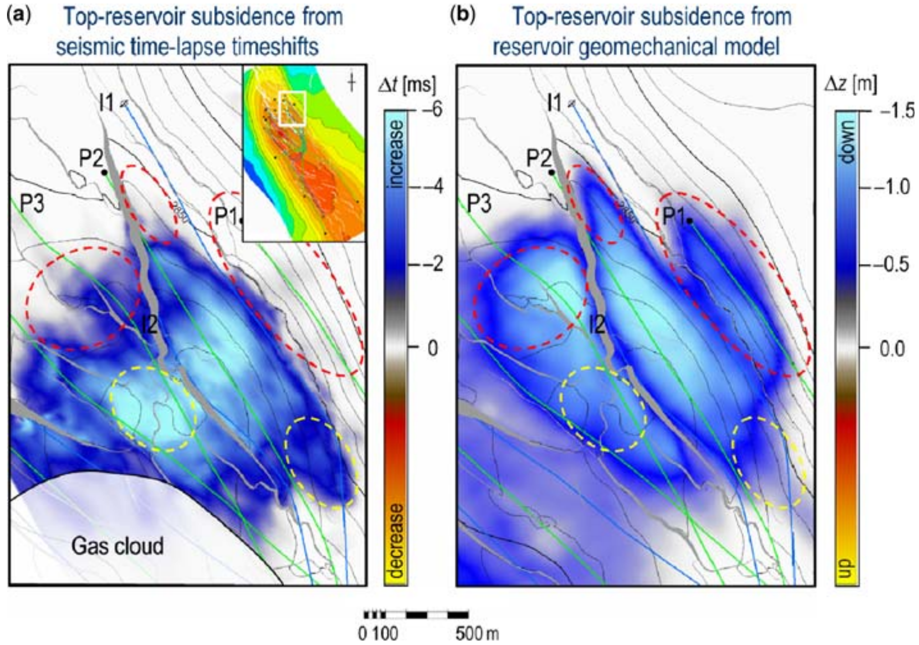

Fig. 13. Observed and predicted reservoir compaction. (**a**) Compaction-induced travel time changes to the top-reservoir reflector (time-lapse time shifts Δt) as a measure for top-reservoir subsidence. (**b**) Predicted vertical displacement Δz of the top-reservoir surface. A 6 ms increase in travel time corresponds roughly to 1.5 m top-reservoir subsidence. Areas where observed subsidence is larger than predicted subsidence are marked by yellow ellipses, and vice versa, areas where observed subsidence is less than predicted subsidence are marked by red ellipses. Note the clear fault control in both observed and predicted subsidence.

Figure 14, we compare porosity changes $\Delta\Phi$, inferred from time-lapse AVO inversion and volumetric strain ε_V from the reservoir geomechanical model. Assuming that a negative volumetric strain (i.e. a decrease in volume) is caused by reduction in porosity, the two quantities describe the same process. Porosity reduction of approximately -2.5% is measured by time-lapse seismic data across the lower (Tor) reservoir across most of the crestal area, with predicted volumetric strain of *c.* -3%. Discrepancies are again observed around producer P1, where time-lapse seismic observations detect only negligible porosity reduction and the reservoir geomechanical model predicts volumetric strains of -1.5%.

Discussion

The aim of time-lapse seismic interpretation should be to identify differences between a current understanding of reservoir dynamics and the reservoir dynamics inferred from time-lapse seismic data. Only then does time-lapse seismic add value by creating a new

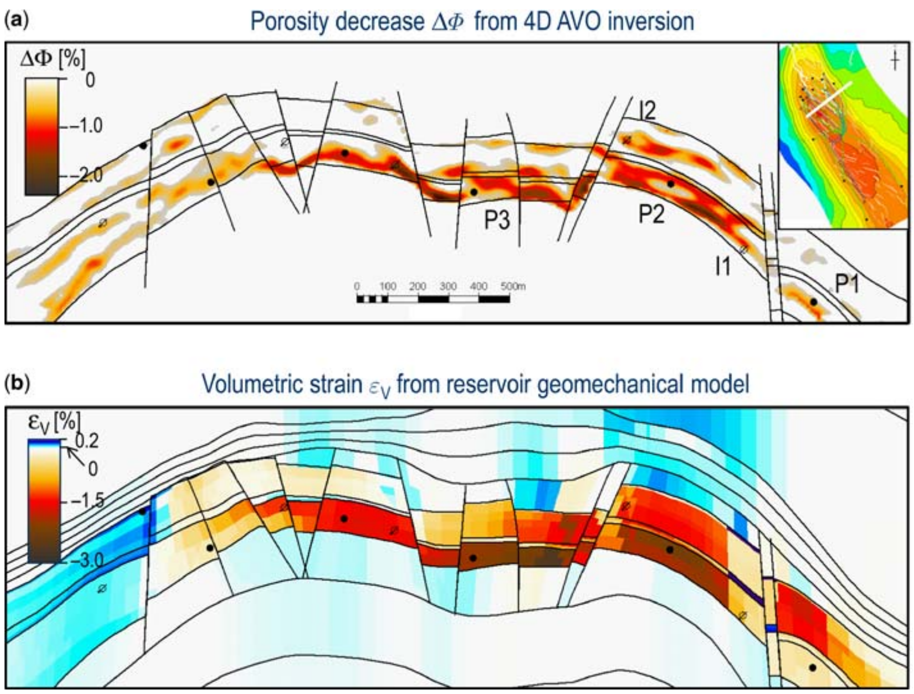

Fig. 14. (**a**) Porosity reduction $\Delta\Phi$ derived from time-lapse rock physics AVO inversion. (**b**) Volumetric strain change ε_V predicted from reservoir geomechanical modelling. Under the assumption that porosity decrease is the primary reason for volumetric strain change, the two images are directly comparable. See text for discussion.

understanding of the field. If time-lapse seismic confirms what we already know, its application simply adds peace of mind.

At South Arne, we have identified a high-porosity, high-permeability zone on the northern crest of the reservoir that may be responsible for a heterogeneous sweep, whereas the simulation model predicts a homogeneous sweep. Nevertheless, the seismically derived ΔS_w and $\Delta\Phi$ needs to be investigated with a critical eye: the employed rock physics model accurately describes the effect of changes in water saturation in intact rock. However, we also know that the rock on the crest of the reservoir experiences approximately -3% of volumetric strain and undergoes irreversible compaction with grain-to-grain bonds failing and a possible occurrence of grain-crushing. We are currently striving for a deeper understanding how irreversible compaction influences the acoustic impedance and Poisson's ratio as determined by seismic observations. This lack of understanding adds some uncertainty to our interpretations.

Time-lapse seismic has given a clear indication of faults adding additional hydraulic permeability at South Arne, and we have shown a particularly clear example from the SW flank of the field. It must be noted that, in this part of the field, the strike-direction of the faults and the sail direction during seismic acquisition are aligned, and some of the fault-related time-lapse changes may be related to acquisition artefacts. We do not believe that this is the case. Firstly the fault-related time-lapse differences do not extend into the overburden above the reservoir whereas an acquisition footprint on the time-lapse differences would. Secondly, there is no correlation between any 'striping' in repeatability plots and the location of the interpreted conductive pathways. If the interpreted conductive pathways were spurious, other minor faults would also show up with time-lapse differences. Thirdly, the time-lapse observations confirm and explain reservoir dynamics from production logging adding to a consistent picture of reservoir drainage.

Besides adding hydraulic permeability along fault strike direction, faults clearly cause compartmentalization of the field. We gave an example of fault-controlled reservoir compartmentalization on the north flank, where time shift maps clearly show an imprint from fault locations. Faults therefore clearly cause macroscopic permeability anisotropy, with flow enabled along the strike direction and impaired across the fault. This behaviour has been included in a reservoir simulation model for a planned field extension to the north of the currently productive area. Including permeability anisotropy by introducing hydraulically conductive faults causes skewed maps of pressure depletion, which are in accordance to the reservoir pressure encountered when drilling appraisal wells for the extension.

In order to extract the full information contained in time-lapse seismic data, it is necessary to use time-lapse seismic data and inversion models in conjunction with all other data available on the dynamic behaviour of the field. In this paper we showed that co-visualization and joint interpretation of reservoir dynamics from time-lapse seismic data and reservoir simulation models creates deeper insight than could be gained from either tool individually.

Conclusion

We have presented a case study applying time-lapse seismic to obtain a clearer understanding of reservoir depletion patterns, production dynamics, the influence of faults on fluid flow and reservoir compaction. Using time-lapse seismic data in conjunction with a reservoir simulation model in the same software environment, using common colour tables and common scales for maps and cross-sections, allows for rapid scanning of differences and similarities between the depletion patterns derived from time-lapse seismic and reservoir simulation. Reconciliation of the reservoir simulation model and the reservoir geomechanical model with time-lapse seismic data and inversion models results in a well calibrated simulation model. The calibrated models, in turn, have a higher probability of accurately predicting future reservoir production and therefore allow for more efficient day-to-day reservoir management and for optimization of future field development.

The authors wish to thank the South Arne partnership Hess, DONG Energy, Noreco and Danoil for permission to publish this paper. We also would like to acknowledge the work of Frédéric Bourgeois and James Minton in building and running the South Arne reservoir geomechanical model; the work of Valerie Biran and Kjetil Westeng on rock physics modelling and low frequency model building for rock physics AVO inversion; and the work of Paul Groombridge and Paul Ramsden on time-lapse data processing of the South Arne dataset.

3D seismic mapping and porosity variation of intra-chalk units in the southern Danish North Sea

T. ABRAMOVITZ, C. ANDERSEN, F. C. JAKOBSEN, L. KRISTENSEN and E. SHELDON

Geological Survey of Denmark and Greenland (GEUS), Øster Voldgade 10, DK-1350 Copenhagen K, Denmark (e-mail: tab@geus.dk)

Abstract: Deposition of the Upper Cretaceous–Danian Chalk Group in the Salt Dome Province of the southern Danish Central Graben took place during a tectonic period dominated by post-rift subsidence, halokinesis and structural inversion. This resulted in highly variable chalk distribution with >1300 m of chalk located in synclines and <200 m preserved on inversion highs and salt structures. The area is mature with respect to exploration with most of the chalk fields located in structural traps discovered in the 1970s. However, the Halfdan discovery in 1999 illustrates the existence of off-structural traps, leading to renewed exploration interest. To locate additional off-structural traps, a detailed geological model is necessary for prediction of chalk intervals with reservoir potential. To unravel basin development, we combine 3D seismic interpretation, well log correlation and 2D seismic inversion to estimate acoustic impedance along selected profiles. The 2D acoustic impedance profiles are converted to total porosity and used to identify areas with potential untargeted reservoirs. A prominent high-amplitude reflection is interpreted as a regional unconformity separating two distinctly different chalk deposition patterns. Nannofossil biostratigraphy suggests a latest Campanian to early Maastrichtian age for the unconformity. It corresponds to an increase in acoustic impedance and decrease in porosity in wells. The Tor Formation contains porous intervals while the underlying Hod Formation contains less porous chalk. The Hod Formation has a maximum porosity of <20% based on well log and inversion data. In contrast, inversion data indicate that the Tor Formation comprises reservoir-grade porosity at several locations on downflank structures. In several areas, the inversion-based maximum porosity is predicted to be higher than expected, compared with porosity/depth trends derived from well data. Therefore, the spatial porosity variation in chalk is complex and controlled by factors other than burial depth.

Keywords: Chalk Group, Danish North Sea, GR/DT well log correlation, 3D seismic interpretation, seismic inversion, porosity anomalies, chalk reservoir potential

The majority of present-day oil and gas production in the Danish part of the North Sea is from fields with chalk reservoirs of Late Cretaceous (Maastrichtian) and Early Paleocene (Danian) ages (Fig. 1). The application of seismic data inverted for acoustic impedance (AI) has been a rewarding technology for porosity prediction in chalk exploration (Mackertich & Goulding 1999; Albrechtsen *et al.* 2001; Megson & Tygesen 2005). The predominantly mono-mineralic nature of chalk enables a robust empirical correlation between AI derived from the inversion of seismic data and total porosity (PHIT) (Anderson 1999; Jacobsen *et al.* 1999). The Halfdan discovery in 1999 was largely due to seismic inversion results that revealed low AI corresponding to high porosity values in the Maastrichtian chalk. This was later proven to contain non-structurally trapped oil.

In this paper, we use 3D seismic interpretation, well log correlation and 2D seismic inversion to estimate AI, and thus porosity, along key profiles in the Southern Salt Dome Province of the Danish Central Graben. The 2D AI profiles are converted to total porosity using an AI-PHIT transform for the entire Chalk Group based on 14 wells located in the study area. Our aim is to unravel the basin development and to distinguish between areas with potential untargeted reservoirs and areas acting as baffles to flow. We argue that the Maastrichtian Tor Formation has reservoir-grade porosity at several locations on downflank structures. These locations are situated where the inversion-based porosity is higher than expected when compared with porosity/depth trends derived from well data.

Database

The study area comprises parts of the Southern Salt Dome Province in the Danish Central Graben. It is covered by a 3D seismic data set, the Kraka Extension survey, which was acquired by Mærsk Olie and Gas AS in 2000. The survey has inline and crossline intervals of 12.5 m and covers an area of 1150 km^2. The data were time-migrated and converted to zero phase. Post-stack seismic processing included spectral balancing with a subsequent scaling to improve the resolution of the original seismic data. The main frequency content is 10–60 Hz after reprocessing and the vertical seismic resolution is 12–15 m for the upper part of the Chalk Group.

The survey covers the basin extending from the Coffee Soil Fault in the east to the Rolf Field near the Danish/German border in the west. The northwestern limit of the seismic survey reaches the flank of the Tyra Gas Field. Most of the Danish hydrocarbon reserves are located in chalk fields in the study area. These reserves include the large Dan, Halfdan, Gorm and Skjold Fields and the small Kraka, Rolf, Dagmar and Regnar Fields (Fig. 2). The latter three plus Skjold are located on shallow salt-piercement structures with a thin chalk section, typically less than 200 m thick. The combined ultimate recoverable reserves in the eight fields are estimated to be 370×10^6 m^3 of oil and 80×10^9 Nm^3 of gas (Danish Energy Agency 2008).

Six key wells, all of which penetrate the entire chalk section, have been selected for detailed seismic well ties and as input for

VINING, B. A. & PICKERING, S. C. (eds) *Petroleum Geology: From Mature Basins to New Frontiers – Proceedings of the 7th Petroleum Geology Conference*, 537–548. DOI: 10.1144/0070537

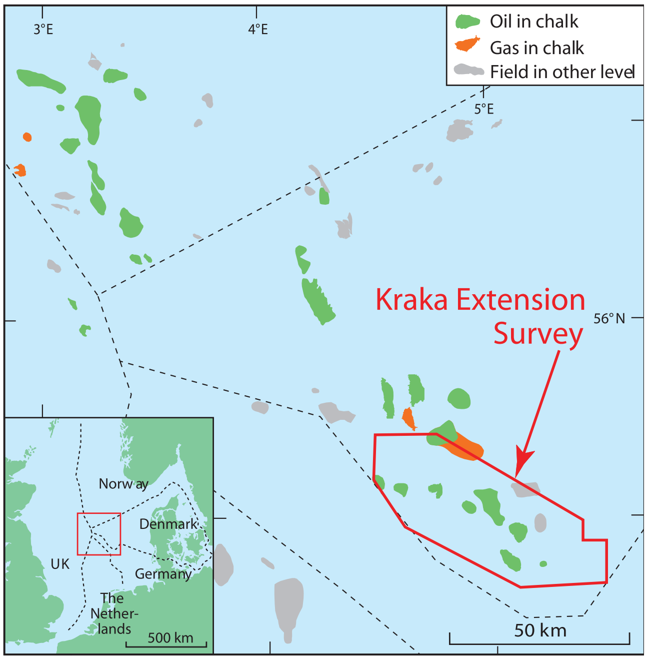

Fig. 1. Location map of the study area in the Danish North Sea.

wavelet extraction for seismic inversion. These wells are Olga-1X and Anne-3 on the Kraka structure, M-8X on the Dan structure, Nana-1XP, which is the vertical discovery well on the non-structural Halfdan accumulation, and finally U-1X and Skjold Flank-1, the latter situated in a basinal setting. Four 2D profiles crossing the well locations have been extracted from the 3D volume and inverted for AI. The profiles have been selected in such a way that they represent a range of structural settings and chalk burial depths (Fig. 2).

Geological setting

Deposition of the Late Cretaceous–Danian Chalk Group in the southern part of the Danish Central Graben took place during a phase of regional subsidence following Late Jurassic rifting. This period was marked by high sea-level, high sea-surface temperature and a peak in production of organic matter. The Late Cretaceous regional subsidence pattern was modified by halokinesis of the Zechstein salt and was punctuated by widespread structural inversion in the form of compression along old extensional fault trends, flexuring and folding of basin infill (e.g. Cartwright 1989; Vejbæk & Andersen 2002). This resulted in the development of areas with bathymetric elevations and the formation of local depocentres in the intervening lows. The structural movements gave rise to a

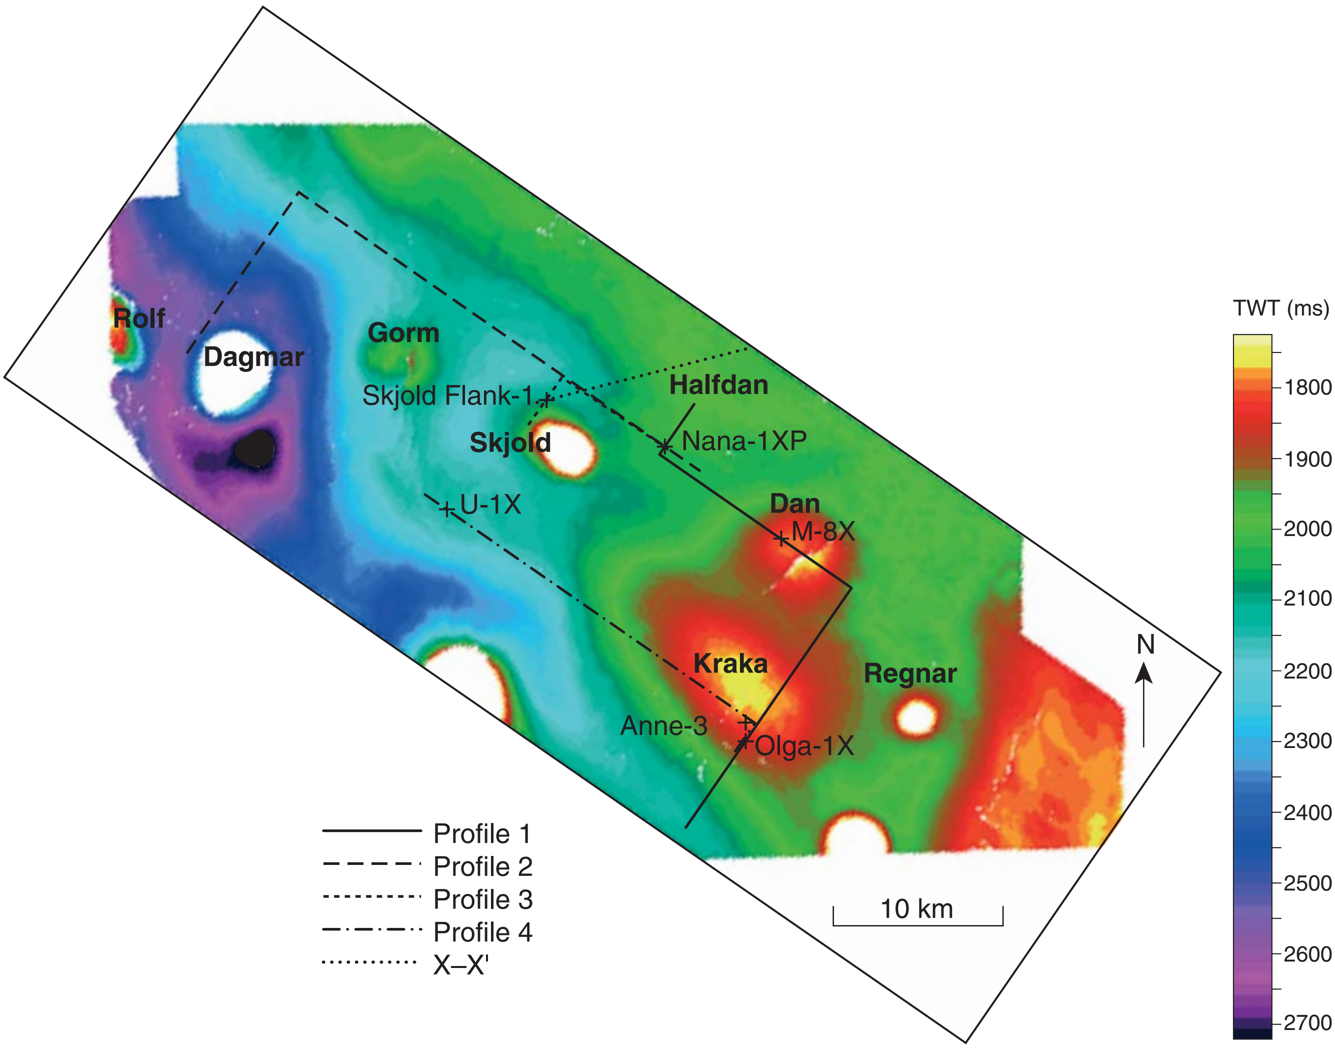

Fig. 2. Top Chalk Group time–structure map with location of 2D profiles, key wells and producing fields. Note: contours on the shallow salt diapirs with thin Chalk not shown.

number of unconformities that are easily recognized as truncation and onlap surfaces on seismic profiles and to stratigraphic hiatuses recorded in wells.

Chalk represents a unique, very fine-grained reservoir rock, characterized by high porosity and low matrix permeability. It is a pelagic carbonate sediment formed by settling of calcareous nannoplankton remains (i.e. coccoliths) from suspension in the water column (Hancock 1975). The North Sea chalk is a mono-mineralic carbonate rock that consists of 96–99% calcite ($CaCO_3$), non-carbonate biogenic particles (radiolarian, diatoms and sponge spicules) and small amounts of clay minerals due to influx of erosional detritus (Håkansson *et al.* 1974; Kennedy 1987). After pelagic deposition, the chalk deposits were subjected to redistribution by various processes. These include downslope mass flow movements from slope instability caused by syn-depositional tectonics as well as alongslope bottom currents that caused seafloor geometry modifications in the form of incised valleys, channels, drifts, ridges and mounds (Evans *et al.* 2003; Lykke-Andersen & Surlyk 2004; Surlyk *et al.* 2008). In the lower part of the chalk section, the interaction of downslope and alongslope processes has been demonstrated by Esmerode *et al.* (2008) in an area immediately north of the present study area.

The structural style in the Kraka Extension survey area is illustrated by the time isochore of the Chalk Group (Fig. 3). This shows very large thickness variations from less than 100 ms on top of the salt diapirs and up to 650 ms (*c*. 1300 m; Britze *et al.* 1995) in the rim-syncline east of the Dagmar Field. The chalk is reduced in thickness over the Dan and Kraka structures, which are caused by growth of underlying salt pillows. Similarly, the chalk time isochores are less than 200 ms on the flanks of a NW–SE trending inversion ridge east of the Nana-1XP location ('Igor-Tyra Ridge' by Britze *et al.* 1995) and on a north–south oriented ridge extending from the U-1X well northwards to the Gorm Field. The latter, termed the 'Gorm-Lola Ridge', is caused by a combination of structural inversion and halokinesis.

Stratigraphic subdivision of the chalk and reservoir properties

The lithology and stratigraphic subdivision of the chalk section in five of the key study wells are illustrated in the well correlation diagram (Fig. 4) together with seismic ties of the mapped horizons. In addition, the log-derived hydrocarbon saturation profiles in the field wells are shown.

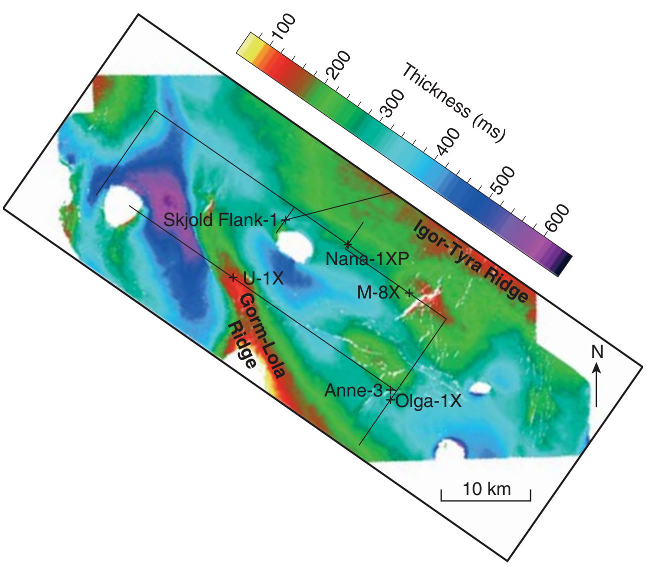

Fig. 3. Time isochore map of the total Chalk Group with location of key wells and major inversion ridges. Note: isochores on the salt diapirs not shown.

The lithology is illustrated by the gamma ray (GR) and sonic (DT) log curves. A distinction is made between 'high' GR argillaceous chalk and 'low' GR clean chalk. The DT log response serves as a porosity indicator in the clean chalk, which has been divided into four porosity classes to highlight the porosity variations.

We have used the standard lithostratigraphic nomenclature for the Central North Sea (Surlyk *et al.* 2003) and subdivided the chalk section into the Hod, Tor and Ekofisk Formations. The Cenomanian and lowermost Turonian Hidra and Blodøks Formations are thin in the area and are usually below seismic resolution.

The boundary in the wells between the Tor and Hod Formations is generally marked by a sharp decrease in porosity and can be traced seismically as an unconformity (prominent high amplitude reflection) over most of the study area. New biostratigraphic studies carried out on cuttings samples from the Olga-1X well suggest that the unconformity is Late Campanian to Early Maastrichtian in age. Using the 'UC^{BP}' (Late Cretaceous boreal province) nannofossil biozonation scheme of Burnett (1998), the unconformity separates chalk dated as $UC16^{BP}$ (Campanian/Maastrichtian boundary interval) from the overlying chalk unit dated as $UC19^{BP}$ ('Middle' Maastrichtian). A distinct intra-Hod unconformity is picked as a continuous peak and is identified by a relatively strong negative reflection coefficient. It is locally truncated and merges with the overlying near-top Hod unconformity. In most well sections, it corresponds to the top of an argillaceous interval. The age is biostratigraphically unconstrained, but a Santonian age has been suggested by Vejbæk & Andersen (2002).

The Maastrichtian Tor Formation is divided into an upper and lower unit separated by an intra-Tor seismic marker. In the Anne-3 well on the Kraka structure, the lower unit is missing and the upper part of the Tor Formation directly overlies the near-top Hod unconformity. The top of the Tor Formation is marked by a ubiquitous hardground, separating it from the overlying Ekofisk Formation of Danian age. The uppermost part of the Tor Formation is the main reservoir in the Dan and Halfdan Fields. It is a pelagic chalk that exhibits a characteristic cyclic pattern of high and low porosity over a 1–3 m scale that is regionally correlatable (Scholle *et al.* 1998). In the high-porosity intervals, the porosity may reach 35–37%. On a reservoir scale, the average porosity is 25–30%.

The Danian Ekofisk Formation is the main reservoir in the underfilled Kraka Field (Klinkby *et al.* 2005). The formation is divided into an upper unit characterized by relatively clean chalk and a lower unit characterized by impure argillaceous and siliceous chalk, which may form a barrier to vertical flow during production.

The effective porosity (PHIE) v. depth trends for each of the mapped chalk units in 14 vertical exploration wells have been analysed and compared with the classical model of Scholle (1977) (Fig. 5). This model predicts porosity as a function of burial depth and is based on empirical data of normally compacted chalk without overpressure and hydrocarbons. The recorded trends deviate considerably from the Scholle curve with more than 20% excess porosity in the shallow parts and rapid porosity deterioration with depth in the basal part, where the porosity trend approaches the model. The excess porosity in the uppermost chalk units is mostly caused by the porosity preserving effects related to overpressure, early hydrocarbon emplacement and possibly also reworking. In the southern part of Danish Central Graben, the chalk reservoirs are overpressured 6–10 MPa, which reduces the effective stress (Brasher & Vagle 1996; Japsen *et al.* 2005) – the magnitude of the overpressure is, however, only half the overpressure observed in the Norwegian chalk fields like Valhall and Ekofisk. Despite the modest overpressure in the study area, the abnormal pressure conditions restrict fluid removal, resulting in undercompacted

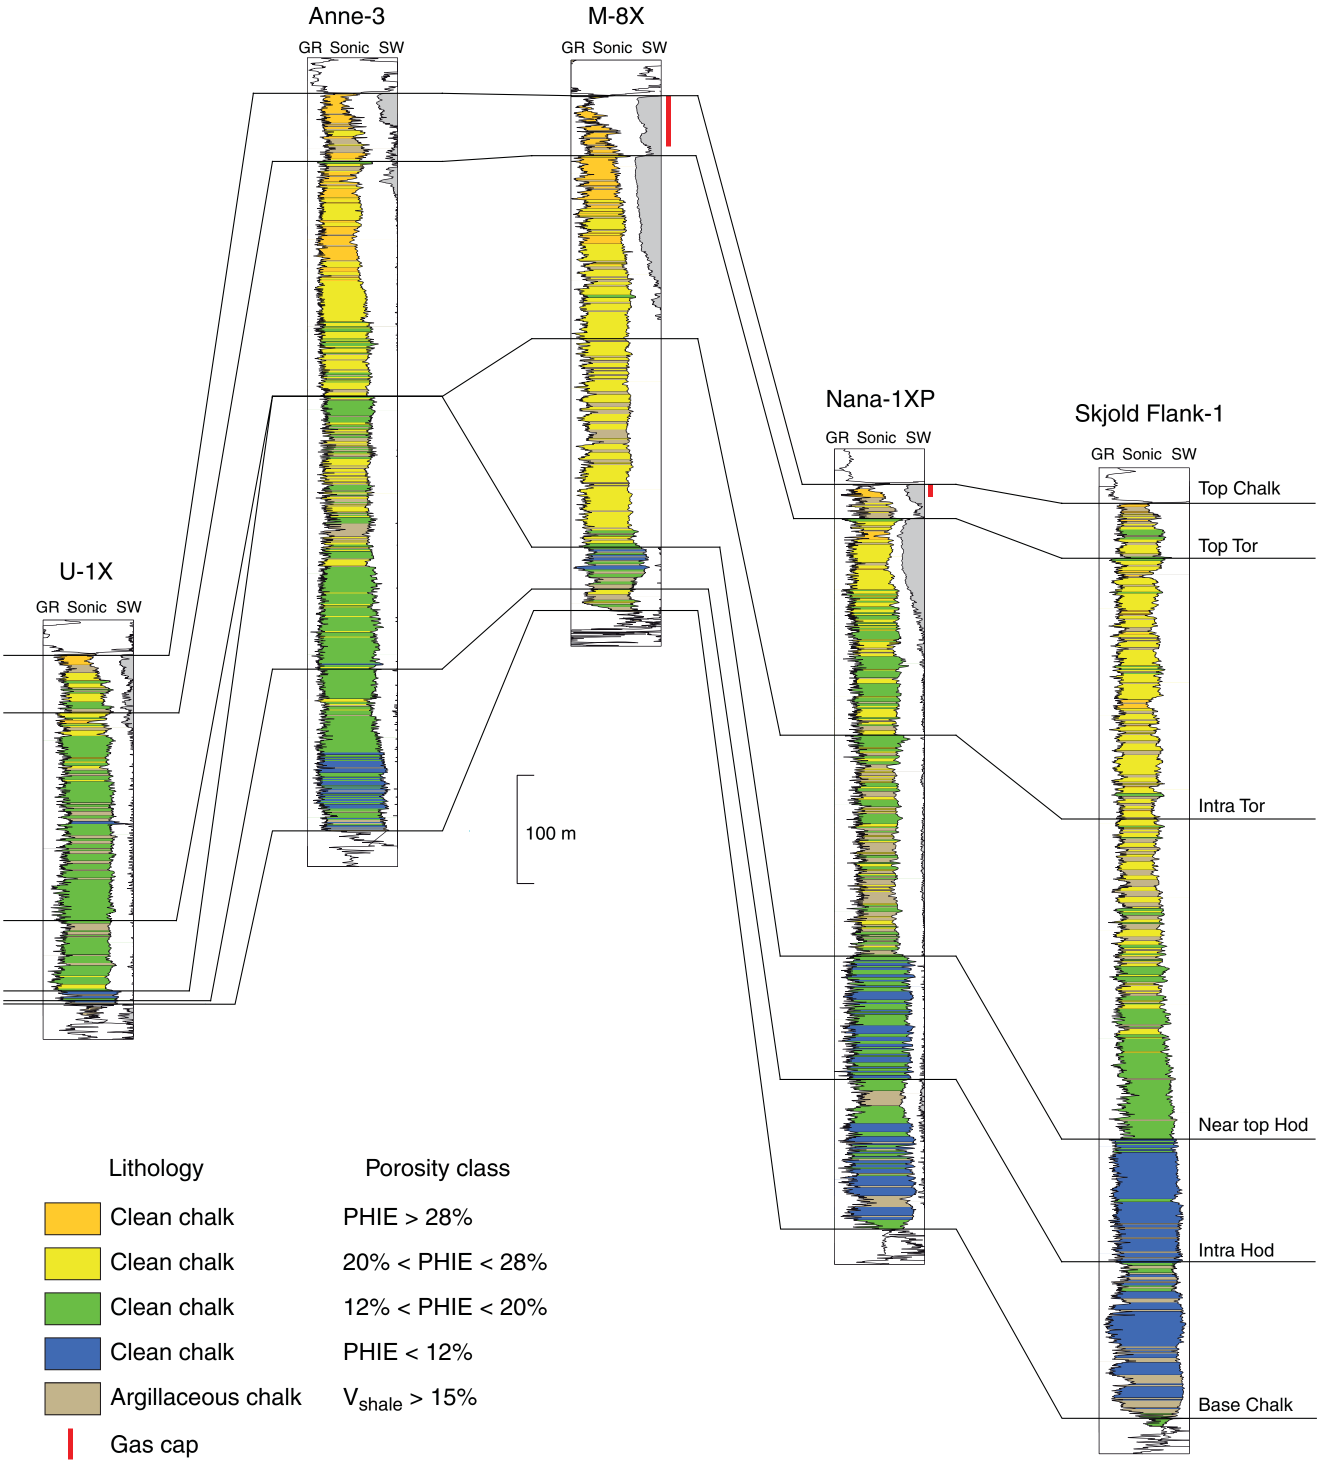

Fig. 4. Well correlation diagram through five key wells showing the lithology, hydrocarbon saturation and seismic tie of mapped horizons. The DT-log response is used as porosity indicator in clean chalk, which has been subdivided into four porosity classes.

chalk sections and higher than normal porosities. In many Danish chalk fields the porosity deterioration gradient is steeper than expected in the light of a normal porosity/depth trend, suggesting that hydrocarbon migration into the formation is a secondary source of porosity preservation. Furthermore, porosity above 40% is recorded in wells with high hydrocarbon saturations, illustrating that the presence of oil and gas also influences porosity preservation by impeding chemical compaction. Moreover, it is commonly accepted that re-sedimented chalk may *in general* exhibit a higher porosity level than pelagic chalk at the same depth known from the Norwegian greater Ekofisk area (Hatton 1986) and the northern part of the Danish Central Graben area (Nygaard *et al.* 1983).

The marked drop in porosity in the deep well sections shows that the effectiveness of overpressure in preserving high porosity is lost. Hence, the drilled pre-Tor Formation chalks in the Southern Salt Dome Province are generally tight (<20% PHIE) and without reservoir properties unless heavily fractured.

Basin development

The Late Cretaceous–Danian basin development in the survey area is illustrated in a series of time-isochore maps (Fig. 6a–f). The pre-Maastrichtian interval, which includes the Hod Formation and the thin Blodøks and Hidra Formations, shows large thickness

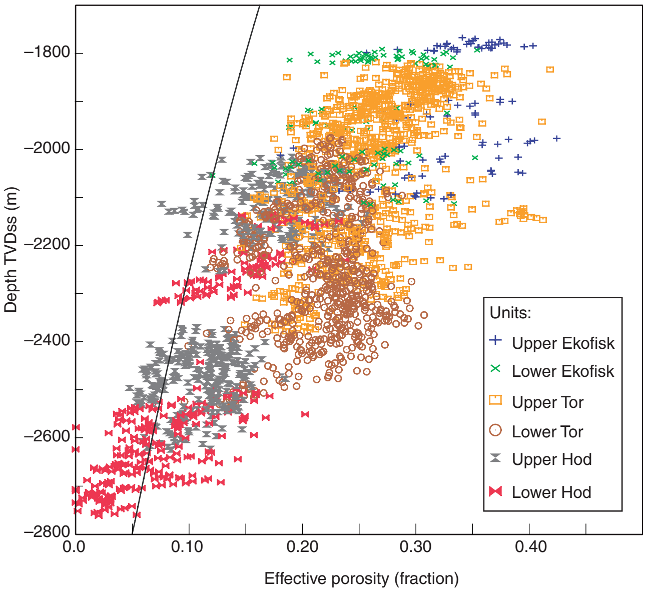

Fig. 5. Effective porosity (PHIE) v. true vertical depth colour coded with respect to stratigraphic unit. The plot is based on interpreted well log data from 14 selected wells located in the study area. The black solid line represents the model by Scholle (1977), which predicts the porosity as function of burial depth for normally compacted chalks.

variations (Fig. 6a). The main depocentre, which is up to 300 ms thick, is found in the rim-syncline north and east of the Dagmar salt diapir. The Gorm–Lola Ridge separates it from a NW–SE oriented depocentre that covers the southern flank of the Kraka structure. The Hod interval is also thin over the Dan Field area, indicating structural growth caused by underlying salt. The marked unconformity at near-top Hod level is clearly imaged on a composite seismic section through three key wells (Fig. 7). Clear truncations of underlying reflections are observed in the synclinal area between the present day Kraka and Dan structures.

The early basin development can be further illustrated by the time isochore of the lower Hod interval, which lies between the intra-Hod unconformity and the Base Chalk reflector (Fig. 6b). The interval shows basal onlap and is absent on the Gorm–Lola Ridge and the Dan and Kraka structures. A conspicuous NW–SE trending ridge system is mapped north of the Nana-1XP location parallel to the Tyra–Igor inversion ridge. The ridge system is a result of the effects of low-angle listric faults caused by slides and channel cuts developed on the flank of a rising inversion structure (Fig. 8). We suggest that these features are derived from an interaction of downslope mass movements and alongslope currents as described by Esmerode *et al.* (2008) in the adjacent area to the north.

The time isochore of the Maastrichtian Tor Formation (Fig. 6c) shows a shift in depocentre locations compared with Hod Formation depocentres. Most notable is a northeastward shift of the NW–SE oriented depocentre mapped in the central part of the area that contains up to 200 ms of Tor Formation chalk. The basin development during the Maastrichtian can be differentiated further when considering the time-isochores of the lower and upper part of the interval (Fig. 6d, e). The lower part of the Tor Formation, between the near-top Hod and the intra-Tor seismic markers, onlaps the near-top Hod unconformity towards the SW in the Kraka area (Fig. 7) and towards the NE in the direction of the Tyra–Igor inversion ridge. This is in contrast to the upper part of the Tor Formation, which has a more uniform thickness distribution across the area. Only minor thickness variations are observed in the central Kraka and Dan areas, suggesting quiet depositional conditions with little or no structural growth during the Late Maastrichtian (Kristensen *et al.* 1995; Klinkby *et al.* 2005).

The Danian Ekofisk Formation is generally thin, with time isochores greater than 50 ms mapped only in the areas on the northeastern flank of the Dan structure and the southern flank of Kraka (Fig. 6f). Here, local thickness minima and maxima are attributed to early post-Danian sliding of poorly consolidated chalk sediments (Surlyk *et al.* 2003; Klinkby *et al.* 2005).

Seismic inversion

Application of seismic inversion techniques for predicting porosity in North Sea chalk is a standard geophysical tool as there is a robust relationship between AI and porosity in clean chalk without gas-bearing zones. Excluding gas-zones and using a V_{shale} cut-off of 2%, a cross-plot of log-derived AI and PHIT of 14 wells in the study area shows a well-defined correlation with only minor scatter around a second-order polynomial regression line. This is expressed as: PHIT $= 0.729 - 7.08 \times 10^{-5}\text{AI} + 1.55 \times 10^{-9}\ \text{AI}^2$, where porosity is given as a fraction and AI is in $\text{g cm}^{-3} \times \text{m s}^{-1}$ (Fig. 9). The total (or apparent) porosity was calculated using the density log only, which may introduce a minor error in the estimate since no correction is made for hydrocarbon and shale content. The use of PHIT instead of PHIE for correlation with seismically derived porosity estimates is considered the most applicable, since porosity derived from the seismic data is 'bulk' porosity that includes any porosity bound in clay (e.g. clay-bound water) and other minerals. Furthermore, our analysis has shown that use of the above equation will locally overestimate total porosity by up to 5 p.u. in chalk with shale content above 10%. A similar overestimate of porosity is demonstrated in gas-bearing intervals.

In the present study, seismic inversion along four selected 2D key profiles was performed using the commercial ISIS software package developed for the petroleum industry. The inversion algorithm is a deterministic approach based on a simulated annealing algorithm (Maver & Rasmussen 1995; Rasmussen & Maver 1996).

The 2D seismic inversion work flow

The general 2D workflow is an iterative process carried out in loops as illustrated in Figure 10. It involves loading and conditioning the input data, performing a log to seismic calibration, wavelet estimation, low-frequency (i.e. background impedance) model generation and seismic inversion defined by four inversion parameters: signal-to-noise ratio, horizontal continuity, relative deviation of the low-frequency model and a threshold for reflection coefficients (Maver & Rasmussen 1995; Rasmussen & Maver 1996). The input data consists of 2D seismic profiles extracted from the 3D Kraka extension survey and the well log data (sonic, density and time-depth data) from the relevant wells.

The well-to-seismic tie is the most crucial step in the inversion procedure. The available check-shots (time–depth data) are used to create a reflectivity series with the same sampling rate (4 ms) as the input seismic data and to convert the log data from the depth domain into the two-way travel time (TWT) domain. The AI is calculated by multiplying the calibrated density log and the velocity log derived from the calibrated sonic log. The reflectivity series is computed by differentiating the AI series. After the initial log calibration, a preliminary wavelet is estimated by deriving the convolution operator between the reflectivity log and the seismic trace at the well location using a least squares wavelet estimation method. If necessary, visual ties are added to shift, stretch or squeeze the logs. The best-fit wavelet models as much of the coherent seismic data as possible and as little of the noise as possible, and is derived using the Akaike's final prediction error (FPE) criterion

in combination with visual inspection of the wavelet and synthetic seismic trace (Maver & Rasmussen 1995). For each well location, the log calibration and wavelet estimation experiments are repeated until no further improvements are needed. The optimum wavelet used for the inversion is the one with the smallest relative misfit and the highest cross-correlation factor at the different well locations.

The low-frequency components of the AI variations are not present in the seismic data and have to be taken into account in the seismic inversion process. A low-frequency model (*a priori* model) introduces the sub-seismic frequencies into the seismic inversion result. The 2D low-frequency model is constructed by laterally extrapolating the final calibrated impedance logs from the wells along interpreted seismic horizons extracted from the 3D seismic data to guide and yield the absolute level of AIs along the seismic profile.

The four 2D profiles selected for this study (for location see Fig. 2) all have well ties to at least one of the five wells displayed in the well correlation profile (Fig. 4). The Nana-1XP well serves as a type well used for wavelet estimation for three of the 2D key profiles (Fig. 10). The absolute acoustic impedance (AAI) inversion results that include the low frequency model are based on the final calibrated impedance logs from the wells along each profile. Hence, no blind tests are used. The 2D AI inversion results are converted to total porosity using the AI–PHIT transform obtained from the second-order polynomial regression line shown in Figure 9 and are imaged as 2D PHIT profiles (s TWT) (Figs 12 & 13).

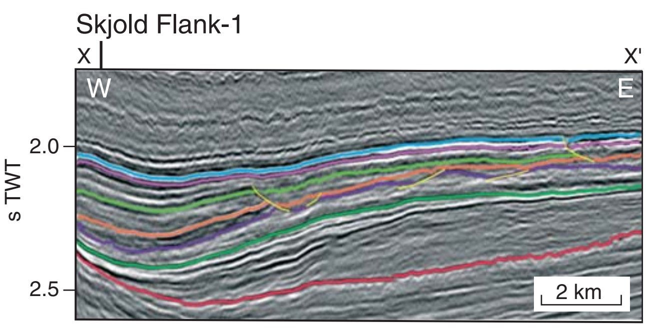

Fig. 8. Low-angle, listric faults and channel cuts in Hod Formation on the flank of the Tyra–Igor inversion ridge. Location is shown as profile X–X′ on Figure 2.

Inversion results along key profiles

Key profile 1. This profile is a composite, 30 km-long cross-section that strikes SSW–NNE across the Kraka Field (Olga-1X and Anne-3) and the Dan Field (M-8X) and then strikes ESE–WNW through the Nana-1XP well (Figs 2, 7 & 12). The Olga-1X, M-8X and Nana-1XP are all vertical wells and have suitable sonic, density and time–depth log curves covering the entire Chalk Group. The deviated Anne-3 well is located 1 km NE of profile 1 and was not used for wavelet estimation. The optimum wavelet is a least squares wavelet estimation obtained from Nana-1XP (Fig. 11).

A 2D low-frequency model was constructed by laterally guiding and extrapolating the calibrated impedance log from the four wells along the top Chalk, top Tor, near-top Hod and base Chalk reflectors, and then low-pass filtering the model (Fig. 12a). Between the Kraka and Dan Fields, the absolute level of AI reveals intermediate values (7–8.1 $\times$ 10^6 kg ms^{-2}) in the Tor interval and high values (>8.5 $\times$ 10^6 10^6 kg ms^{-2}) below the near-top Hod reflector as defined by the impedance logs from the Olga-1X and M-8X

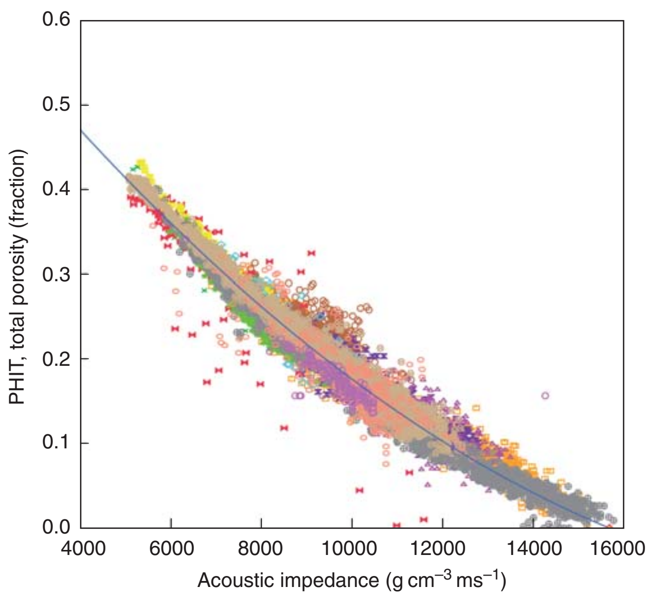

Fig. 9. Acoustic impedance v. total porosity (PHIT) in clean chalk from 14 chalk wells in the study area. A V-shale cut-off of 2% is applied. Gas-bearing zones are omitted.

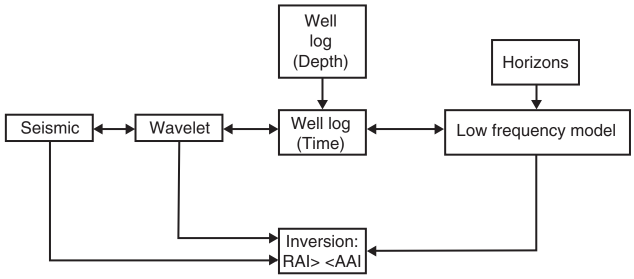

Fig. 10. Diagram for the ISIS 2D inversion workflow.

wells. Further to the NE near the Nana-1XP well, the Tor interval is dominated by a higher AI level and significantly higher values ($>10 \times 10^6$ kg ms^{-2}) below the near-top Hod reflector.

The inversion result as seen in the 2D AAI profile (Fig. 12b) clearly illustrates the fine-scale impedance variations within the Chalk Group. This implies the presence of alternating high and low AI layers onlapping onto the near-top Hod reflector in the deeper part of the Tor interval in the syncline between the Kraka and Dan Fields. These alternating high and low AI layers have a total porosity in the range of 20–25 and 29–32%, respectively (Fig. 12c). A maximum total porosity (above 30%) is found in the upper Ekofisk Formation and the topmost part of the Tor Formation. In the pre-Tor interval, the calculated PHIT values are mostly below 20%.

Key profile 2. Profile 2 is an arbitrary, 40 km long cross-section that extends from the NE flank of the Dagmar Field, covers the basin north of the Gorm and Skjold Fields, and continues past the Nana-1XP to the SE (Figs 2 & 13*a*). For the 2D low-frequency model, the calibrated impedance log from the Nana-1XP well and three interpreted horizons (top chalk, near-top Hod and the base Chalk) were used. A least squares wavelet estimated in the Nana-1XP well was used for the inversion.

The thickness of the Tor interval is fairly constant, but increases slightly in the rim-syncline north of the Dagmar Field. The uppermost part of this unit is characterized by a high porosity (>28%)

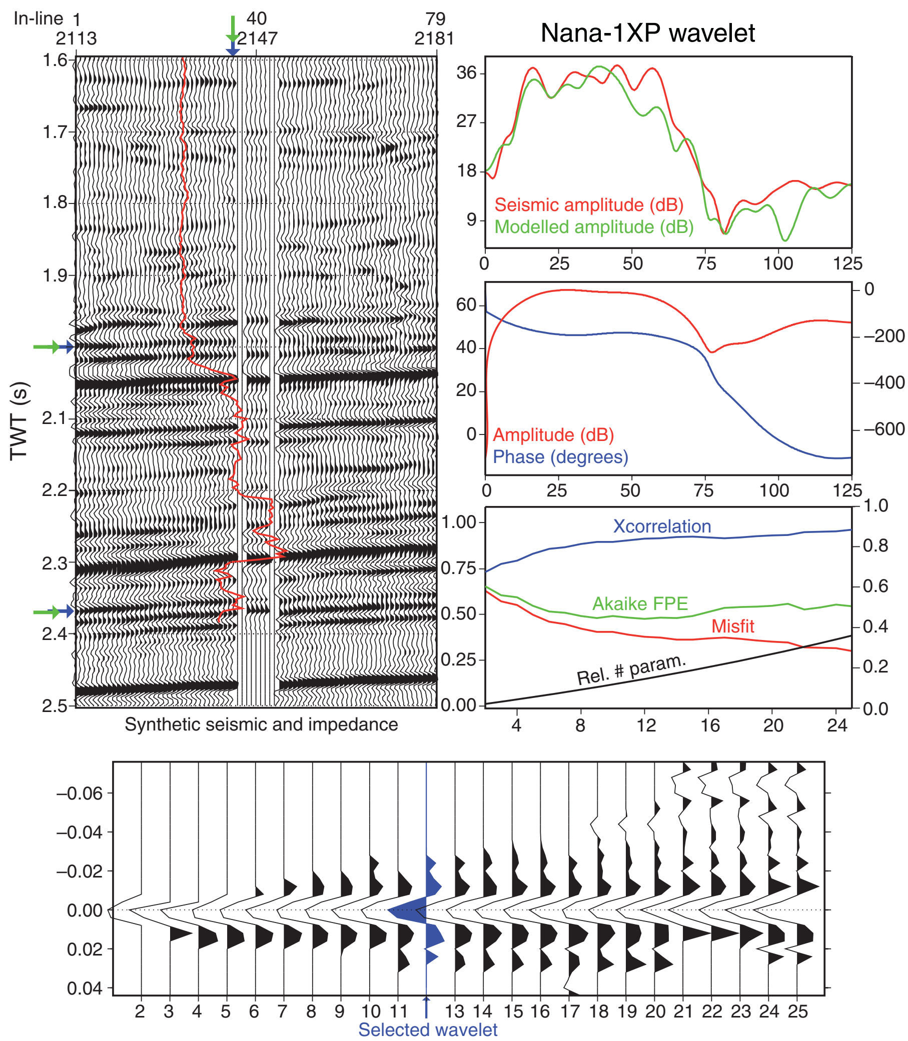

Fig. 11. Quality-control plot of the least squares wavelet estimation in the Nana-1XP well. *Bottom panel*: the stable wavelet suite with wavelet lengths ranging between 2 and 25 samples (8–100 ms) on the horizontal axis. *Left panel*: the synthetic trace derived by convolution of the optimum wavelet with the reflectivity log from the well is inserted into the seismic data. The AI log is shown in red. *Top right panel*: amplitude spectra of the seismic trace at the well location and the modelled synthetic trace in the wavelet estimation window by blue arrows on the left panel. *Middle right panel*: phase and amplitude spectra of the optimum wavelet (estimated between the green arrows on left panel). *Bottom right panel*: the relative misfit energy, Akaike's FPE cross-correlation and relative number of parameters. Akaike's FPE is a function of the misfit, which decreases as a function of the wavelet length, and the relative number of parameters, which increases as a function of the wavelet length. The relative number of parameters is equal to the length of the estimation window within which the misfit between the synthetic trace and the seismic data is calculated. The wavelet with the minimum value of Akaike's FPE, that is, the optimum wavelet, models as much of the coherent seismic signal as possible without modelling a significant amount of local noise.

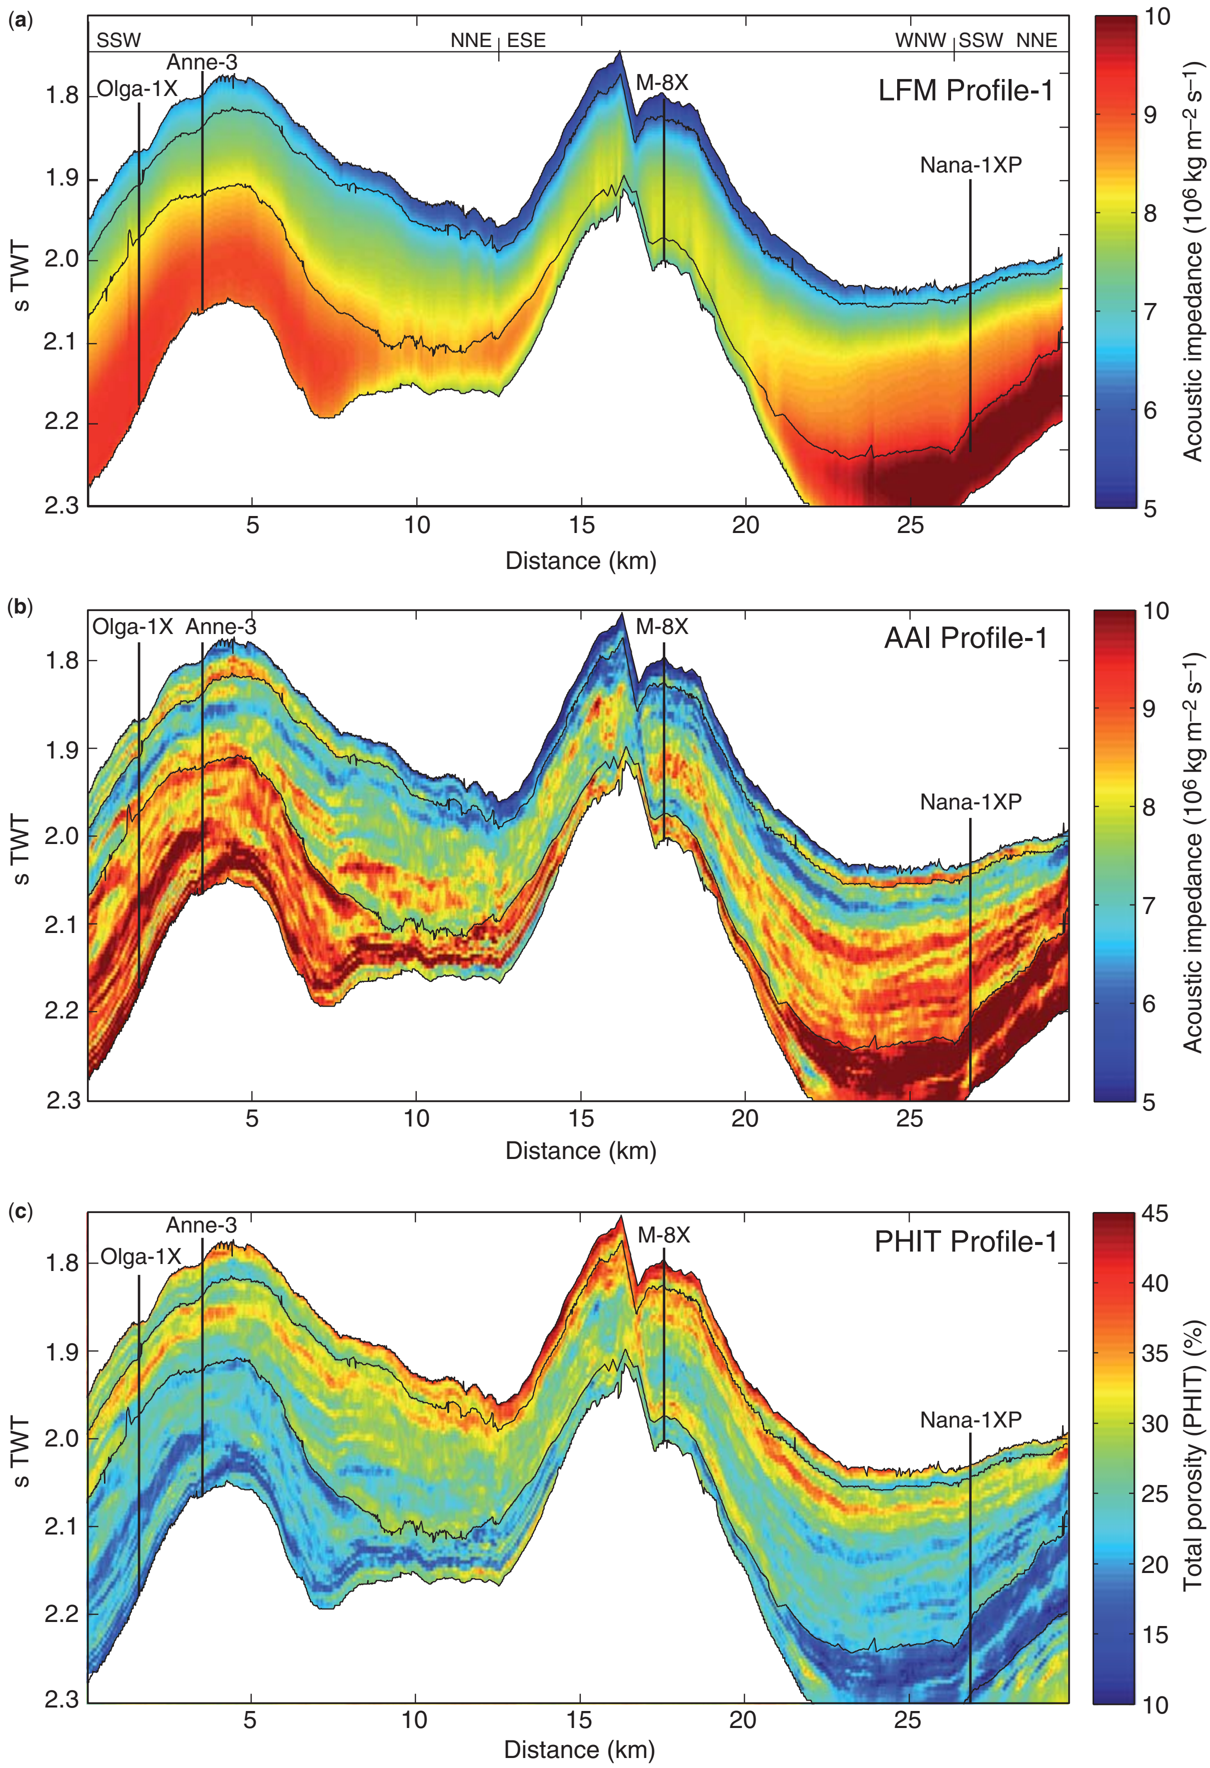

Fig. 12. Inversion results of key profile 1 corresponding to the seismic section shown in Figure 7. The profile location is indicated in Figure 2. (**a**) The 2D low-frequency model; (**b**) the 2D AAI section; (**c**) the calculated total porosity (PHIT) as a percentage.

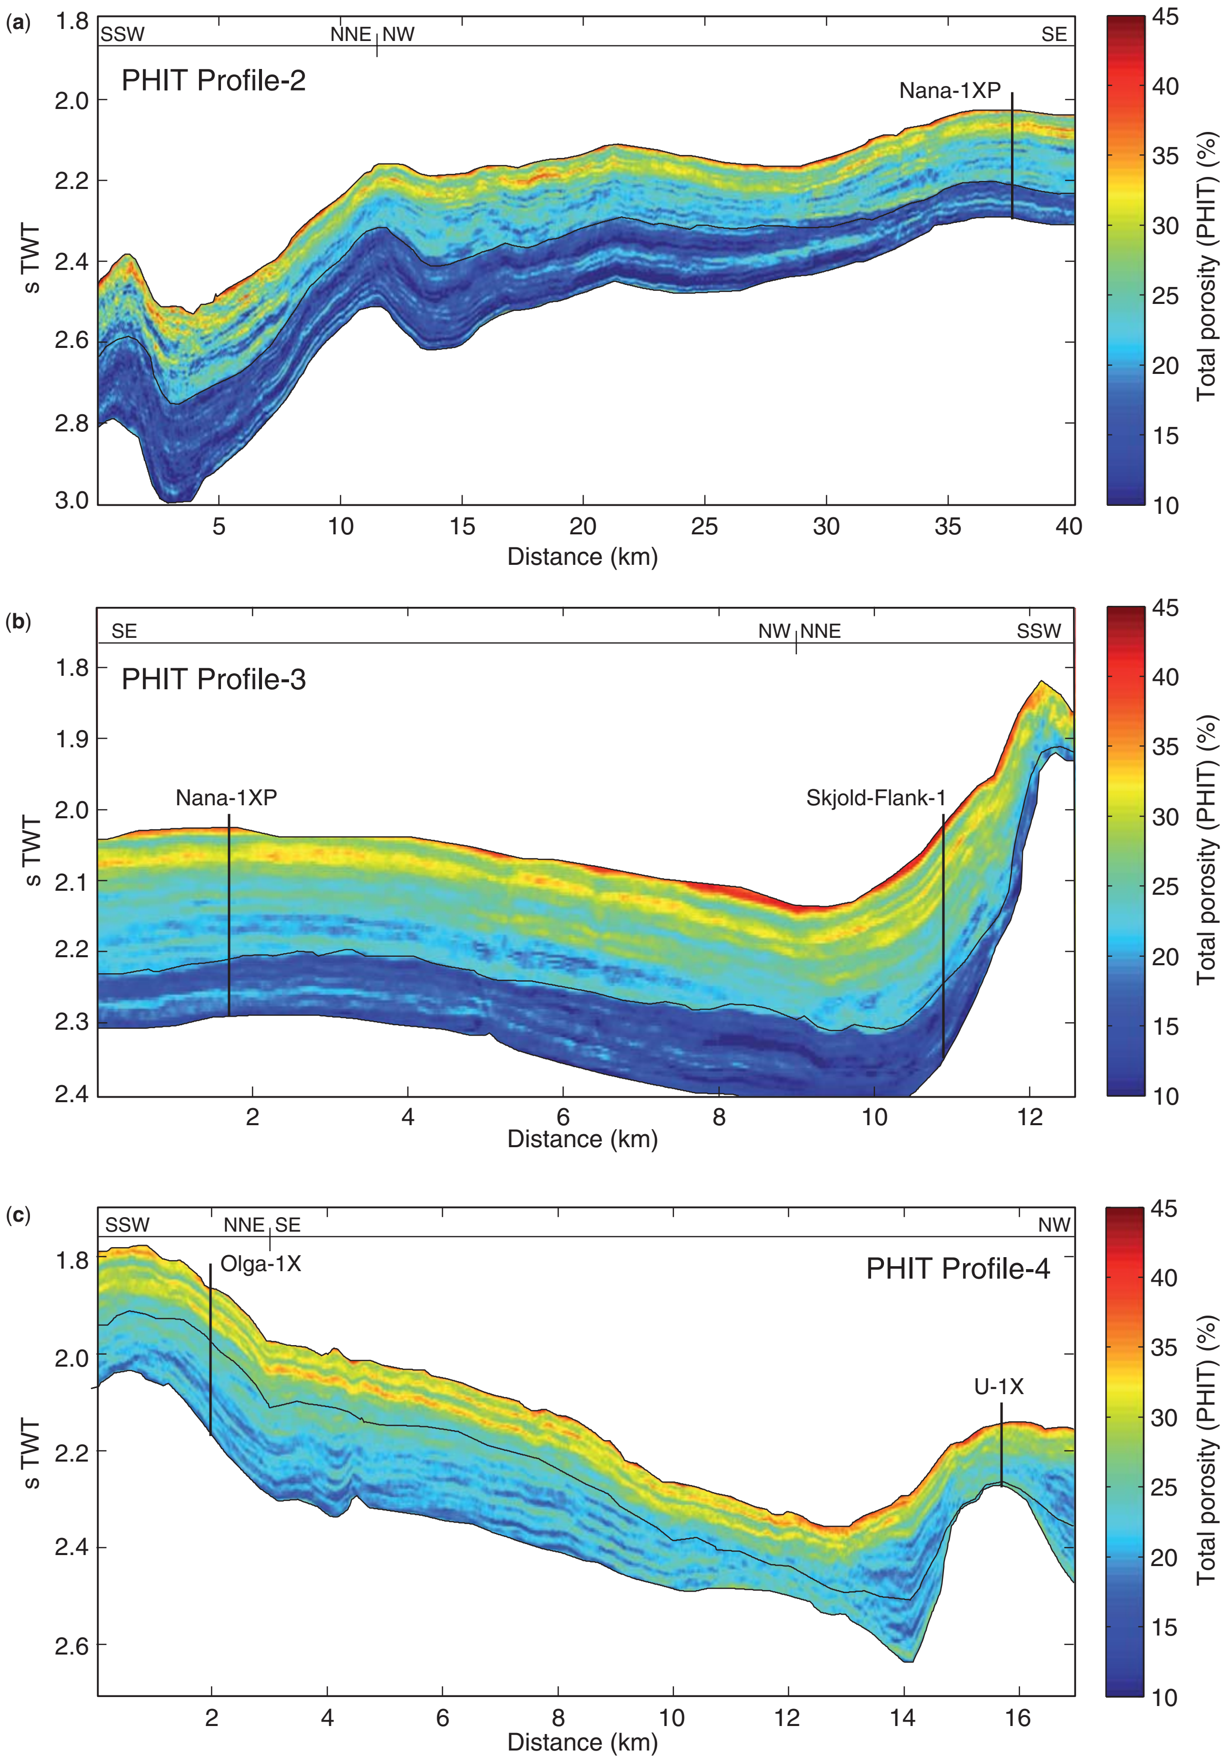

Fig. 13. Selected total porosity (PHIT) 2D sections discussed in the text: (**a**) profile 2; (**b**) profile 3; (**c**) profile 4.

along the profile. In some parts, the PHIT values are as high as 30–40%, mainly concentrated in the Dagmar rim-syncline. Similar high values are found in a zone in the central part of the profile (at distance 20 km) and close to the Nana-1XP well. The deeper part of the Tor Formation is characterized by alternating high- and low-porosity layers in the rim syncline of the Dagmar high. The thin, high-porosity layers have PHIT values in the range of 30–40% and are found in a deeper time window between 2.5 and 2.8 s TWT. In general, the Hod Formation is rather tight, with PHIT values of less than 20%. However, the impedance-derived porosity indicates the existence of a thin layer with a total porosity of approximately 25% extending from the Nana-1XP well and further to the NW. This may partly be an artefact, since this layer ties to the section immediately below the intra-Hod unconformity and is characterized by argillaceous chalk that gives rise to a slight overestimation of the effective porosity.

Key profile 3. Profile 3 is a 12 km long composite cross-section extending from the Nana-1XP well in the Haldan Field area to the Skjold Flank-1 well that was drilled on the flank of the Skjold diapir (Figs 2 & 13b). The 2D low-frequency model was constructed using the calibrated impedance logs from the Nana-1XP and Skjold Flank-1 wells and three interpreted horizons (top Chalk, near top Hod and the base Chalk). The least squares wavelet estimated in the Nana-1XP well was used for the inversion.

A continuous high-porosity (PHIT $>$ 30%) layer is observed in the upper part of the Tor Formation along the entire profile. The lower part of the Tor Formation is characterized by lower porosity (generally PHIT $<$ 25%), apart from a region in the central part of the profile north of the Skjold Field, where PHIT values are as high as 30–32%. The pre-Tor interval is tight with a total porosity below 20%.

Key profile 4. Profile 4 is a 16 km long cross-section extending from the Olga-1X well on the SE flank of the Kraka structure to the U-1X well on the Gorm-Lola Ridge (Figs 2 & 13c). The 2D low-frequency model was constructed using the calibrated impedance logs from the Olga-1X and U-1X wells and three interpreted horizons (top Chalk, near-top Hod and the base Chalk). For this profile, a least squares wavelet estimated in the Olga-1X well was used for the inversion. The profile covers the basin south of the Kraka Field, where the Chalk Group is as thick as 400 ms (Fig. 3). Two separate high-porosity layers with a total porosity in the range of 32–37% are found in the upper part of the chalk section along the entire length of the profile and are independent of the present day burial depth.

Fine-scaled impedance variations are observed in the pre-Tor section. Here, the maximum total porosity appears slightly higher (20–25%) compared with the other key profiles. This difference is caused by inverting with the Olga-1X wavelet compared with the other profiles where Nana-1XP was used. The Olga-1X well log has lower AI values in the Hod Formation than Nana-1XP.

Discussion and conclusion

A multi-disciplinary approach consisting of detailed 3D seismic mapping, well log correlation, petrophysical log analysis and seismic inversion enables a consistent division and mapping of individual depositional units within the Chalk Group. The 2D seismic inversion data allow estimation of the distribution of porosity variations in each unit and are used to distinguish between areas with potential untargeted reservoirs and areas acting as baffles to flow.

An AI-PHIT relationship is established for the entire Chalk Group in the study area and 2D AI profiles are converted to total porosity. The 2D profiles from the seismic inversion (Figs 12 & 13) clearly illustrate highly porous units in the uppermost Ekofisk Formation and the uppermost Tor Formation. The porosity bodies in the upper Tor appear as continuous layers and are found throughout the entire study area, including both structural highs and basinal settings. The study also demonstrates the existence of high-porosity layers at deeper levels in the Maastrichtian Tor Formation, where discrete high-porosity layers onlap the near-top Hod unconformity. Below the unconformity, the Hod Formation appears as a generally tight unit with porosity $<$20%.

Significant tectonic inversion transformed former basin areas into morphological highs. Isochore maps of the various chalk units (Fig. 6) illustrate the basin development in the study area. The Chalk Group is thickest in the western basin between the Dagmar and Gorm Fields; the latter are located at the northern end of a NNW–SSE striking ridge with a reduced thickness. The isochore maps for the Hod Formation (Fig. 6a) and the Tor Formation (Fig. 6c) indicate a change in the tectonic regime and the location of depocentres. In fact, the formations are an inverse of each other like a mould and a cast: the Hod Formation is thick where Tor Formation is thin and vice versa. The deposition of the Hod Formation is assumed to take place in a basinal setting with relatively high clay content.

The Maastrichtian Tor Formation is divided into an upper and lower unit separated by an intra-Tor seismic marker. The lower Tor Formation is found in local basins associated with syn-depositional uplift and the generation of rim synclines. The syn-depositional uplift and the associated development of a pronounced high relief morphology triggered slope instability that resulted in intra-Chalk sediment mass-movement. Alternating high and low AI layers that onlap the near–top Hod unconformity have a total porosity of between 20–25 and 29–32% and thus demonstrate the presence of high-porosity units in the deeper part of the Maastrichtian interval (Fig. 12c). The porosity distribution in the lower Tor Formation determined from the inversion is most likely related to the reworked chalk units as identified in the section. A highly discontinuous reflection pattern in the lower Tor Formation may be interpreted to be related to strong bottom currents that lead to the development of intra-Chalk channels, drifts and mounds (e.g. Lykke-Andersen & Surlyk 2004; Esmerode *et al.* 2008; Surlyk *et al.* 2008). An alternative explanation for the formation of many of the significant deep intra-Chalk seismic and stratal discontinuities is suggested by interpreting these as being caused by gravity-driven erosion and sedimentary processes that developed in response to the intense syn-depositional tectonics.

The uppermost part of the Tor Formation is the main reservoir in the Dan, Halfdan and Gorm Fields. It is a pelagic chalk that exhibits a characteristic cyclic pattern of high and low porosity over a 1–3 m scale that is regionally correlatable (Scholle *et al.* 1998). In the high-porosity intervals, the porosity may reach 35–37% and on a reservoir scale the average porosity is 25–30%.

The excess porosity in the uppermost part of the Chalk Group is mostly caused by porosity preserving effects related to overpressure (6–10 MPa in the study area), which reduces the effective stress (Brasher & Vagle 1996; Japsen *et al.* 2005). However, porosity above 40% is locally recorded in wells with high hydrocarbon saturations, illustrating that the presence of oil and gas also influences porosity preservation by impeding chemical compaction. The drop in porosity in the Hod Formation shows that the effectiveness of overpressure in preserving high porosity appears to decrease with depth.

The inverted AI data and derived total porosity values along selected 2D key profiles show good agreement with the values observed in wells. The uppermost part of the Tor Formation has the highest porosity ($>$28%). In some parts, PHIT values are as high as 30–40%. In the rim syncline of the Dagmar salt diapir, the lower part of the Tor Formation is characterized by alternating high- and low-porosity layers. The thin, high-porosity layers have PHIT values of 30–40% in a time window between 2.5 and 2.8 s TWT.

The inversion-based maximum porosity is predicted to be higher than expected based on the porosity/depth trends from well data only. This indicates that the spatial porosity variation of the chalk is complex and is controlled by more than burial depth. The inversion results show that porous chalk is not restricted to shallow features only, but reservoir-grade chalk of the Tor Formation is regionally widespread and may be found at exceptional depths.

We would like to thank J. A. Cartwright for the very constructive review of the paper. Jette Halskov (GEUS) is acknowledged for preparing the figures, and John Hopper (GEUS) is thanked for critical reading of the first draft.

Abstract: Natural variation in sound speed within ocean water can degrade sub-seabed images from 2D, 3D and 4D seismic reflection datasets. Degrading effects include vertical offset of reflections between adjacent or intersecting sail lines and difficulties in suppressing multiples from water layer reverberations. Here we investigate water layer variability in Rockall Trough, offshore Ireland, in water depths ranging from 200 m to 3.5 km. A compilation of vertical sound speed profiles, calculated from temperature and salinity profiles obtained by probes lowered from ships, shows that the mean sound speed in the water layer mostly varies between 1490 and 1500 m s^{-1}. Vertical offsets of up to about 15 ms two-way travel time are predicted at seismic line intersections. A significant amount of the total observed sound speed variability can occur along a single seismic sail line. These effects result mainly from spatial and temporal fluctuations in the thicknesses of, and vertical sound speed gradients within, an upper layer of North Atlantic Central Water and a mid-depth layer of Mediterranean Outflow Water. Seismic sections across Rockall Trough commonly show lateral variability in reflectivity within these same two water layers. Some reflective packages contain lens-shaped structures consisting of reflective rims and transparent cores and with diameters between 10 and 50 km. Other reflective packages have abrupt, almost vertical boundaries and no distinct transparent core. We infer that the lateral boundaries of the reflective packages are likely to be associated with significant variations in average water layer sound speed. When processing 2D, 3D and 4D seismic surveys of regions of high oceanic variability, such as Rockall Trough, it is necessary to employ techniques that can solve for and then remove the effect of significant fluctuations in water layer sound speed over time periods as short as a few hours and distances as short as a kilometre.

Keywords: seismic reflection imaging, seismic oceanography, seismic data processing, oceanic circulation, mixing, Rockall Trough

Variation in sound speed within ocean water can cause problems in sub-seabed seismic reflection imaging (Wombell 1997; Barley 1999; Bertrand & Macbeth 2003; Mackay *et al.* 2003; Xu & Pham 2003; Lacombe *et al.* 2006, 2009). Water layer sound speed variations arise from natural variations in temperature and salinity associated with oceanic currents. In 2D and 3D seismic surveying, water layer sound speed variations cause travel time offsets and amplitude variations between adjacent and intersecting sail lines. Water layer variability also complicates the suppression of multiples from water layer reverberations (Jakubowicz 2006; Hatchell *et al.* 2008; Hardy & Jones 2009). Four-dimensional seismic surveying compounds these problems (Bertrand & Macbeth 2003; Lacombe *et al.* 2009). Other risks related to oceanic variability affect prospect evaluation and production (Vogel & Symonds 2002). Riser design must account for shear from the water currents that are associated with sound speed variability. Water temperature variability over time affects oil viscosity within the riser. All of these risks are expected to increase as hydrocarbon exploration steps out into deeper water, partly because a thicker water layer accentuates mistakes in assigning water layer sound speeds during processing, and also because oceanic mixing, and consequent high sound speed variability, is often concentrated at steep seabed slopes along continental edges (Barley 1999; Egbert & Ray 2001).

Several important questions arise when planning acquisition and processing of seismic reflection datasets for hydrocarbon exploration or field management. How might water layer sound speed vary during acquisition of a single sail line? How might sound speed vary between acquisitions of adjacent or crossing sail lines? How might sound speed vary between repeated 3D survey acquisitions in a 4D programme? What acquisition and processing strategies are required to cope with the expected water layer variability, in order to minimize subsurface image degradation and hence reduce risk in exploration or production?

The recent realization that oceanic sound speed variations can be directly imaged using standard seismic reflection data and processing techniques provides a new method to investigate these questions (Holbrook *et al.* 2003; Jones *et al.* 2008). The deepwater basins offshore west of the UK and Ireland are good locations to study the effect of water layer variability in water depths between 200 m and 3.5 km (Fig. 1). Sound speed variation within the water column can be imaged directly using seismic reflection data (Figs 2–4). Long seismic profiles show considerable variation in water column sound speed structure from place to place within Rockall Trough (Fig. 2). Lines adjacent to the Rockall Trough margin suggest that sound speed structure is influenced by interaction between oceanic currents with the steep seabed topography (Fig. 3). Short overlapping sections of 2D lines, collected following air-gun failure and repair, show that the water layer sound structure can vary significantly over only a few hours (Fig. 4).

In this paper, we first examine legacy oceanographic observations in order to illustrate the cause of the sound speed fluctuations, and to define the scale of the problem facing sub-seabed seismic imaging. We then interpret the seismic images in order to

begin to address some of the questions raised above. Finally, we discuss the implications for the planning, acquisition and processing of seismic surveys in deep water regions.

Oceanic variability from legacy oceanographic data

The North Atlantic is an important hub in the global oceanic thermohaline circulation. Irish offshore territory is situated just south of the sea between Norway and Greenland where warm surface water arrives from the south, sinks to form cold deep water and returns southward along the Atlantic seabed (Sherwin & Turrell 2005). In Rockall Trough, this oceanic stratification is easily visible in vertical temperature and salinity profiles obtained by lowering conductivity–temperature–depth (CTD) probes from research vessels, and in sound speed profiles calculated from these (Fig. 5). Four water layers can be distinguished and each layer has a distinctive pattern of sound speed variability (New & Smythe-Wright 2001). In the surface layer, down to a depth of about 100 m, sound speed varies by >20 m s^{-1} and can either increase or decrease with depth. The next layer down, termed North Atlantic Central Water by oceanographers, has increasing sound speed with depth. In the third layer, composed of a mixture of Mediterranean Outflow Water and Labrador Sea Water, sound speed decreases with depth. The deepest layer, cold North Atlantic Deep Water, has increasing sound speed with depth.

Several different modes of variability can be seen in this compilation of oceanographic data (Fig. 5). At a given depth, sound speed can vary by more than 20 m s^{-1} in layer 1 and by 10 m s^{-1} in layers 2 and 3. The vertical sound speed gradient across the layer can vary significantly in layers 1–3 and can even change sign in layer 1. These variations in sound speed magnitude and gradient mean that the depth to the boundary between layers 2 and 3 can vary by more than a kilometre. Smaller scale variability with a vertical wavelength of 100 to <10 m often occurs within layers 2 and 3. This type of variation, termed fine structure by oceanographers, is important because its wavelength is similar to the seismic wavelength. Fine structure is responsible for the reflective packages observed within the water layer of seismic sections (Figs 2–4). The amplitude and vertical wavelength of fine structure in layers 2 and 3 is very variable. The sound speed compilation in

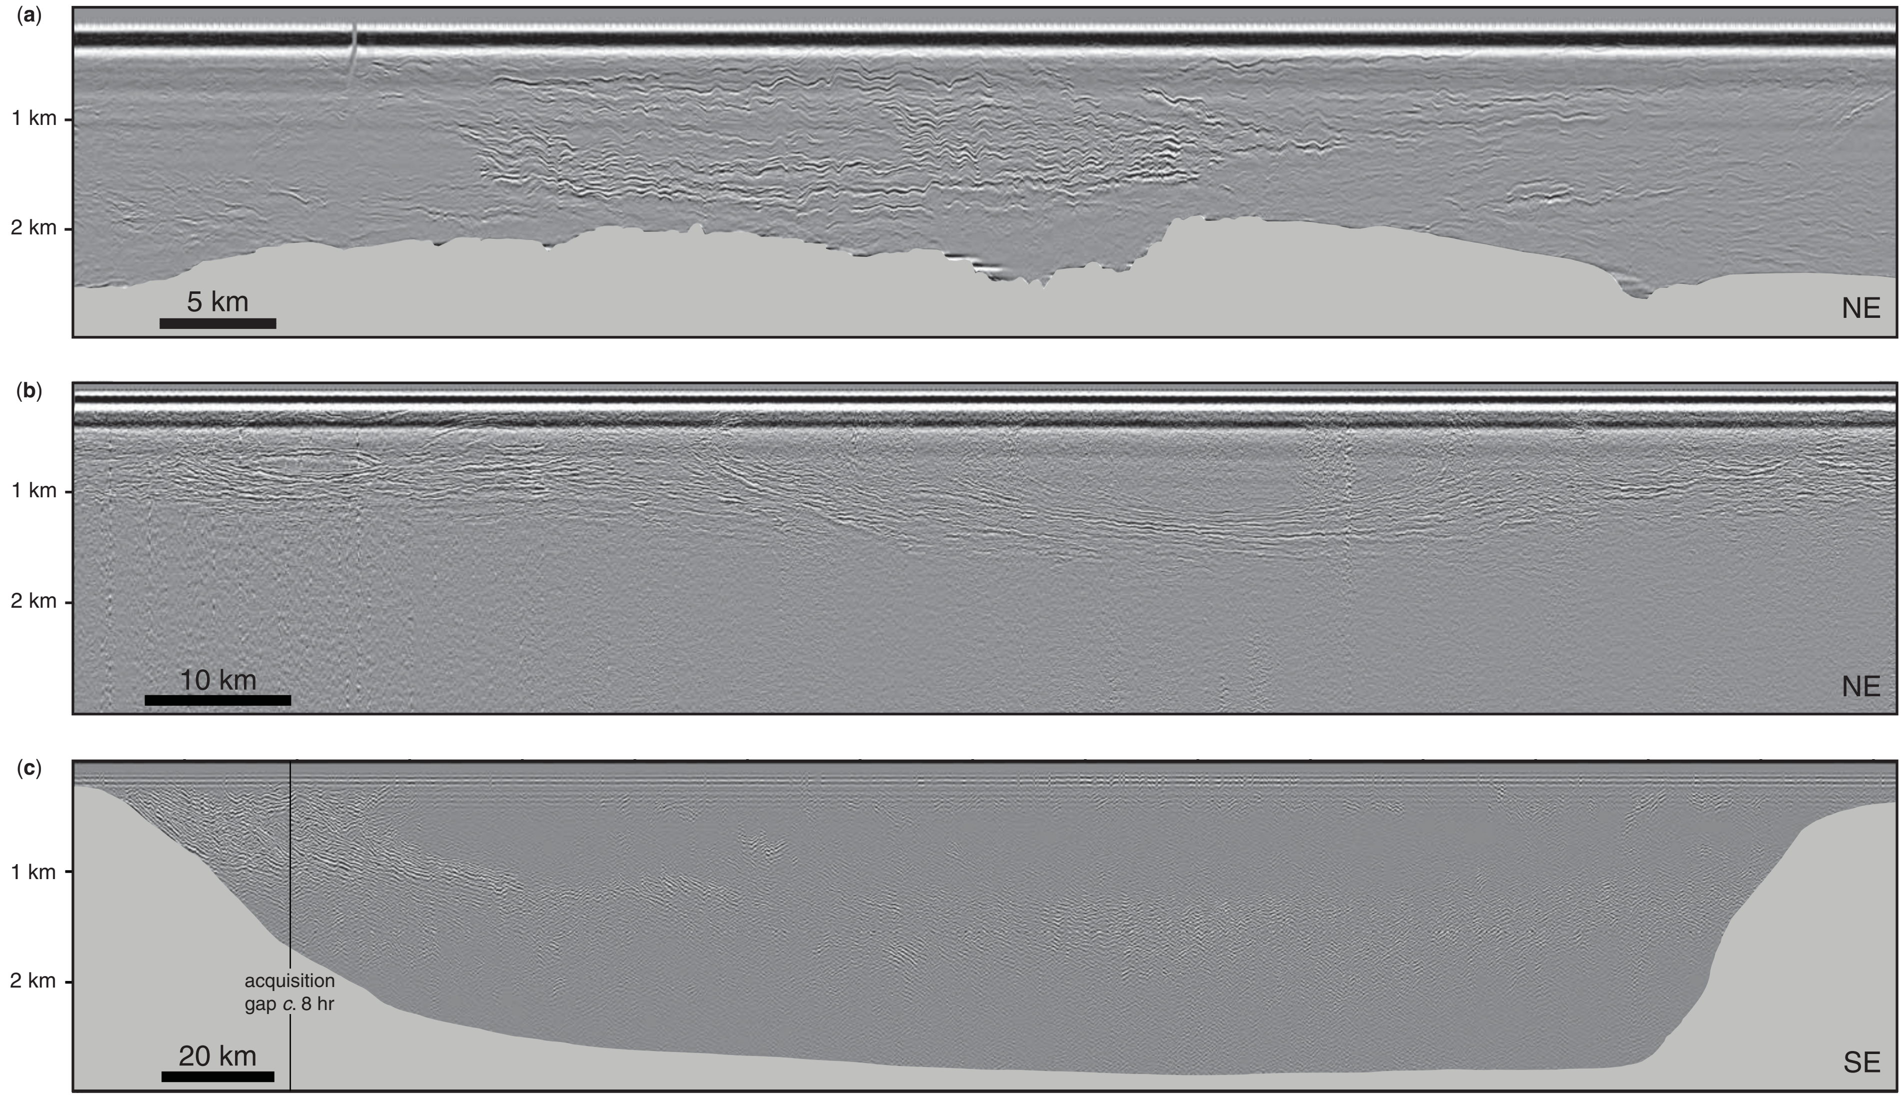

Fig. 2. Regional seismic profiles showing water layer reflectivity: (**a**) ISROCK-96-09; (**b**) PAD-95-11; (**c**) WESTLINE. Line locations marked on Figure 1. Processing sequence given in Jones *et al.* (2008), where a typical shot gather is illustrated. Normal move-out (NMO) correction was done at a constant velocity of 1500 m s^{-1} to produce the stacked sections in Figures 2–4. Move-out on water layer reflections contains both a normal hyperbolic component and a component related to water motion, so applying standard velocity analysis does not necessarily provide a physically meaningful velocity field (Jones *et al.* 2008). There is no difference in gross reflectivity structure, which is the main focus of this paper, between sections stacked after constant-velocity NMO and variable-velocity NMO, although the curvature of individual reflections on scales of a few hundred metres can vary. Figures 2–4 have not been migrated because of these difficulties arising from water motion.

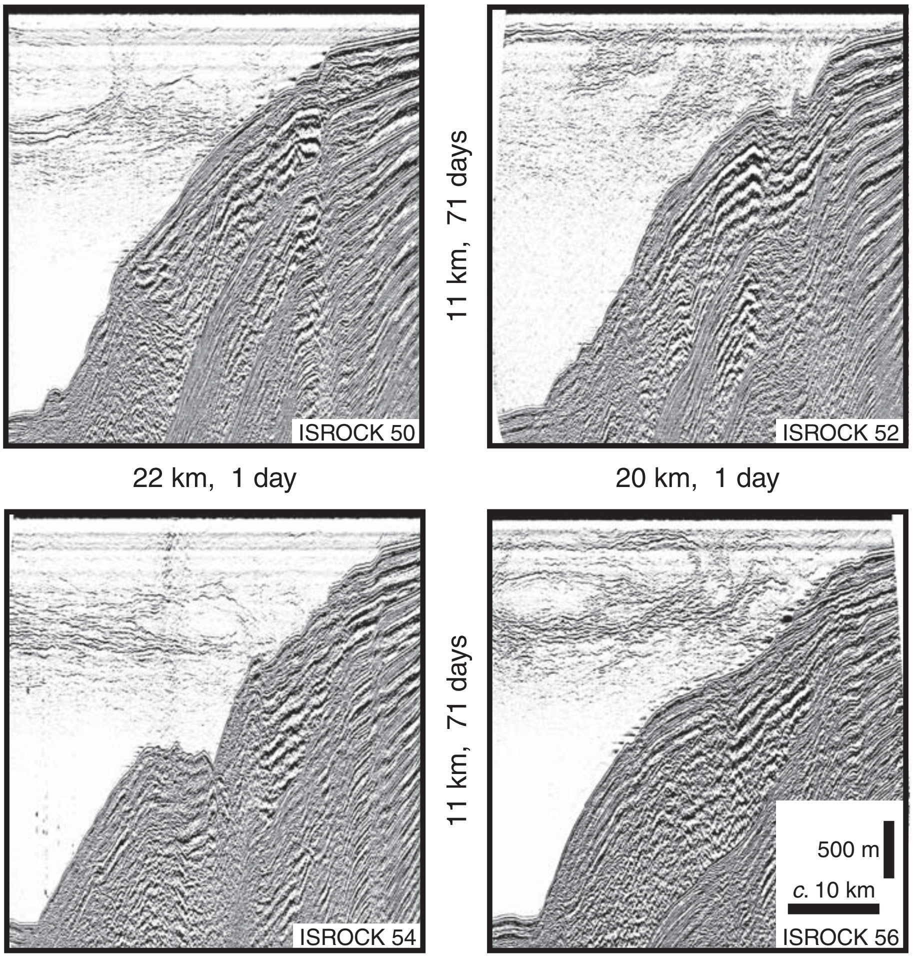

Fig. 3. Four adjacent lines perpendicular to the seabed slope on the western margin of Porcupine Bank (line locations on Fig. 8). Lines 50 and 54 were shot 22 km apart on consecutive days in late June 1996; lines 52 and 56 were shot 20 km apart on consecutive days in early September, 71 days later. The scale on bottom right panel applies to all panels; the vertical scale applies to the water layer only. See caption to Figure 1 for processing sequence.

Figure 5c covers the whole of Rockall Trough but significant variability can still occur within limited geographical regions (Fig. 5d).

Several water layer sound speed sections across Rockall Trough are plotted in Figure 6. Each sound speed section is reconstructed from a series of CTD probe casts along a straight transect obtained over a period of several days, similar to the time periods taken to acquire the regional seismic sections in Figure 2. An important observation is that layers 2 and 3 are each composed of strings of lens-shaped features. The lateral positions and the differences in sound speed from edge to centre of each lens vary from section to section. Annual variation along a single transect is demonstrated by comparing the November 1996 and 1997 sections. Seasonal variation between nearby transects is demonstrated by comparing the May and November 1997 sections. Satellite monitoring of sea-surface height anomalies shows that the Rockall Trough is covered by a set of swells and depressions that have similar diameters to the sound speed lenses within the water column, and which change significantly on a time-scale of weeks. It is tempting to link these sea-surface height anomalies with the sound speed lenses observed on the sound speed sections, thereby indicating a time-scale of weeks for variation of the sound speed lenses, but the detailed work required to test this hypothesis has not yet been carried out.

The implications of all this variability for seismic imaging are summarized in Figure 7. The risk of vertical two-way travel time offsets is mainly controlled by uncertainty over the average sound speed of the water column. Mean water layer sound speed in Rockall Trough mostly varies between 1490 and 1500 m s^{-1} (Fig. 7a). Variability is greater in winter and less, though still significant, during the summer seismic acquisition season. Large uncertainty in mean sound speed occurs above 2 km and uncertainty decreases somewhat in deeper water (Fig. 7b). The decrease in uncertainty in the deepest water occurs because the strong sound speed variability in layers 2 and 3 is progressively offset by the uniform gradient of layer 4 (Fig. 5). The right-hand column of Figure 7 estimates the vertical offset in two-way travel time at the seabed that is expected to result if the water layer is assigned a constant sound speed. Vertical offsets of over 15 ms are expected when the water layer is assigned the modal mean sound speed of 1496.5 m s^{-1} (Fig. 7c, d). Worse choices for mean water layer sound speed will lead to larger offsets. Large offsets are more likely in deeper water if the modal value is chosen to represent the water layer sound speed.

Oceanic variability from seismic data

The sound speed cross-sections in Figure 6 suggest that a significant component of the total oceanic variability summarized in Figure 7 can occur on the space–time scale of a single seismic line. However, horizontal resolution of the sound speed sections is limited by the sparse cast spacing. The ability to image sound speed variability on seismic data itself offers the opportunity to resolve the true spatial and temporal scales over which variability occurs.

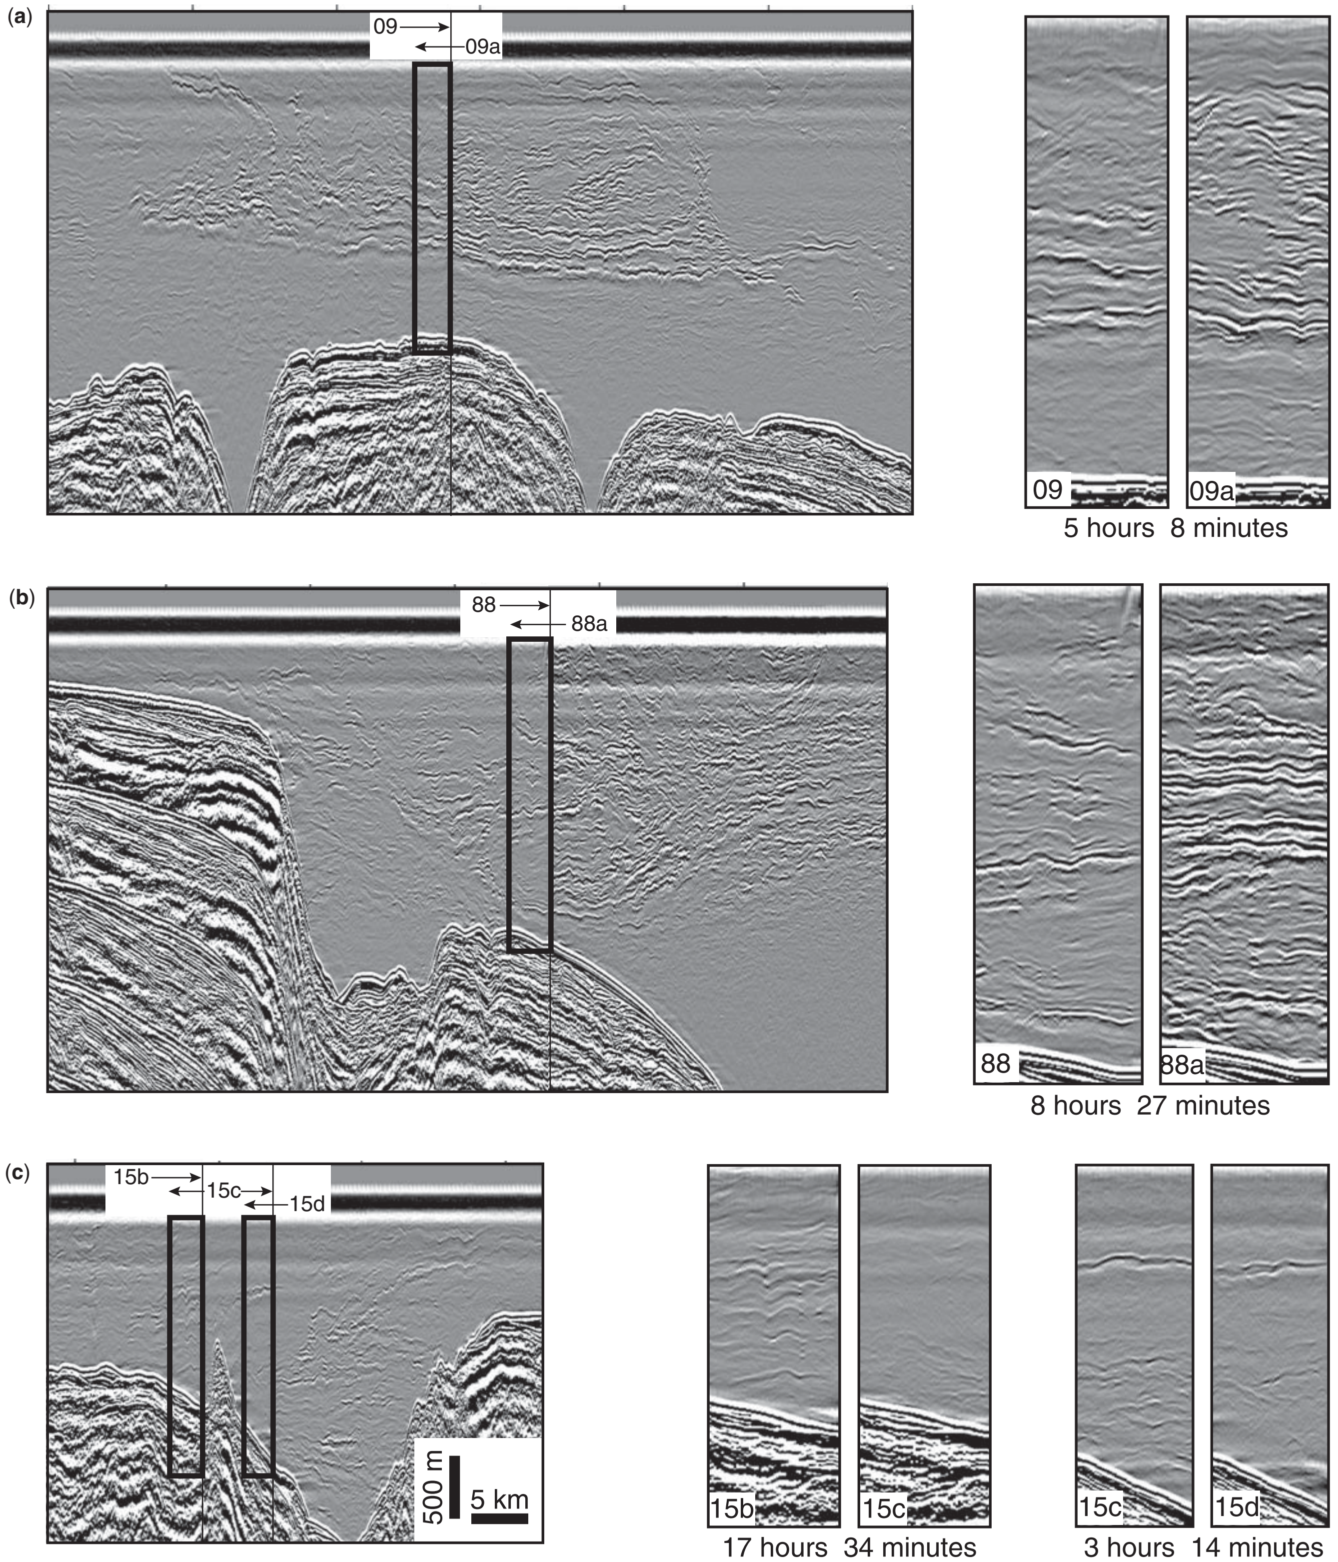

Fig. 4. Overlapping seismic sections to illustrate variability in water layer structure over a few hours: (**a**) ISROCK line 09; (**b**) line 88; (**c**) line 15. Line locations marked on Figure 8. Locations of overlapping sections are marked with bold boxes on the left-hand panels; re-started lines are named by adding a, b etc. to the line number. Both overlapping sections in each pair are expanded to the right and the separation in time is indicated beneath. The scale on left-hand panel (c) applies to all three left-hand panels; the vertical scale applies to the water layer only. See caption to Figure 1 for processing sequence.

Spatial variation

In Rockall Trough, oceanic sound speed structure commonly appears on seismic sections as a strongly reflective layer at depths above 1.5 km (Figs 2–4). Comparison with sound speed profiles from CTD probe data (Fig. 5) suggests that the seismic energy is reflected by the fine-structure (that is the variations with a vertical wavelength of 100 to <10 m, similar to the seismic wavelength) observed over the same depth range. We cannot test this idea directly in Rockall Trough since we do not have direct measurements of water layer sound speed coincident with the seismic sections. However, the relationship between

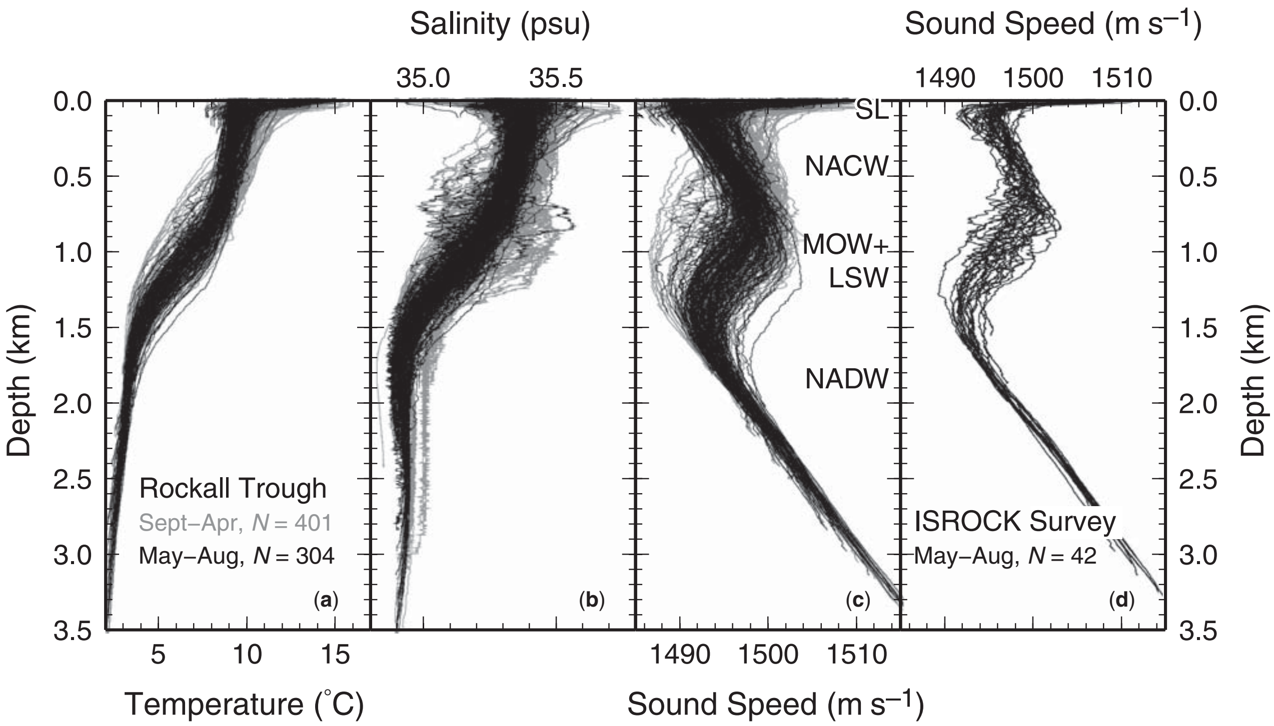

Fig. 5. Water layer stratigraphy in Rockall Trough. Profiles on panels (a–c) cover the entire area of Rockall Trough (all blue squares on Fig. 1). (**d**) Sound speed profiles in the region of the ISROCK seismic survey (white-filled blue squares on Fig. 1). Abbreviations: SL, surface layer; NACW, North Atlantic Central Water; MOW + LSW, Mediterranean Outflow Water and Labrador Sea Water; NADW, North Atlantic Deep Water.

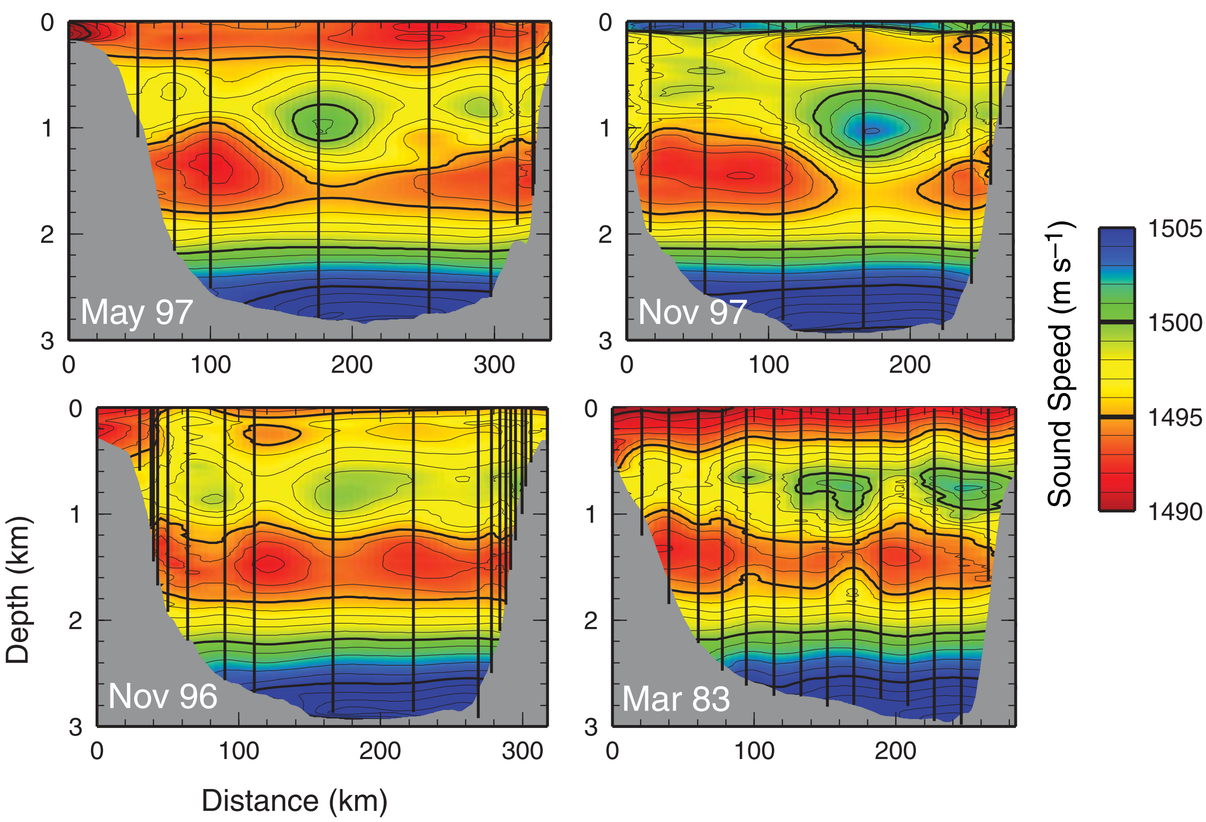

Fig. 6. Regional cross-sections of sound speed from CTD probe casts (locations on Fig. 1). The temperature and salinity profiles were converted to sound speed using the 1980 Equation of State of Seawater (EOS-80; Fofonoff & Millard 1983). Cast locations were projected onto straight lines; locations of measured profiles on each projected section are denoted by vertical black lines. Where unconstrained by data, the edges of each sound speed section were set to the average sound speed profile for Rockall Trough, obtained by averaging the dataset in Figure 5c. The sections were gridded using a using the minimum curvature scheme from the Generic Mapping Tools (GMT) with a mesh size of 5 km by 20 m. Finally, the seabed along each section was interpolated from the GEBCO database.

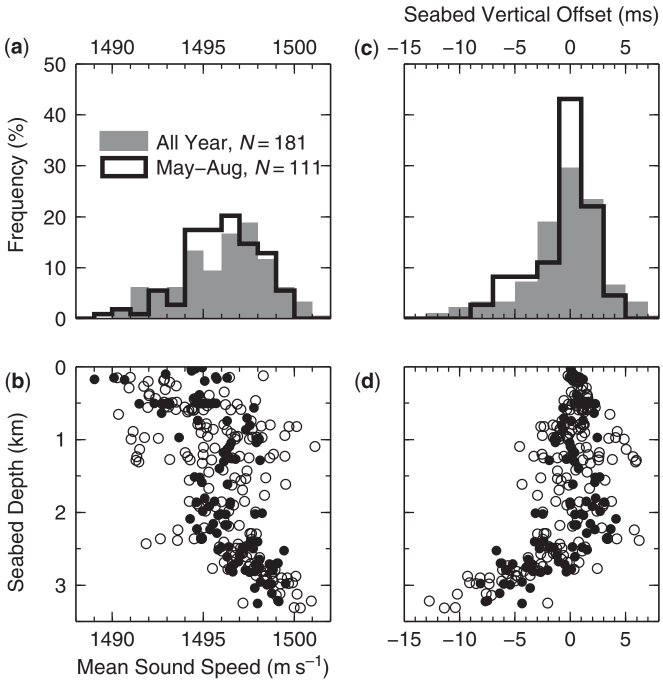

Fig. 7. Statistical variation in mean water layer sound speed and resulting vertical offset in two-way travel time at the seabed, calculated using the Rockall Trough sound speed profiles in Figure 5a–c.

individual seismic reflections and vertical sound speed gradients has been confirmed in joint seismic/oceanographic experiments offshore Norway and in the Gulf of Cadiz (Nandi *et al.* 2004; Biescas *et al.* 2008).

There is strong lateral variation in the reflection strength and internal structure of the reflective regions in Rockall Trough. Figure 2a shows an example of a discrete package of reflective water about 30 km wide and surrounded by seismically transparent water. This seismic section lies adjacent to the Porcupine Bank, parallel to the margin of Rockall Trough. The base of the reflective package is defined by a series of high-amplitude, fairly continuous reflections. The reflection strength is more variable within the upper part of the package. The southern boundary is defined by abrupt terminations of reflections over a horizontal distance of <1 km. The northern boundary is shaped more like the edge of a lens and covers a lateral distance of about 5 km. Another type of lateral variation is illustrated in Figure 2b, which crosses deep water where the Rockall Trough opens southward into the Atlantic oceanic basin. Undulations in the reflections define two lens-shaped features, the smaller with a diameter of 10 km and the larger with a diameter of 40 km. Each lens consists of a marginal zone of continuous high-amplitude reflections enclosing a seismically transparent interior. Such lenticular features are common within our Rockall Trough seismic database.

Seismic reflectivity is generated by vertical sound speed gradients on the scale of the seismic wavelength (<100 m; Ruddick *et al.* 2009), whereas the variability in water layer travel time summarized in Figure 7 is mainly controlled by the larger scale (100 m to 1 km) structure of the water layers. Do the packages of reflective and transparent water visible on seismic sections correspond to spatial changes in sound speed? It is hard to answer this question in the absence of oceanic probe measurements coincident with the seismic sections. However, two pieces of evidence suggest that packages of different reflectivity structure do have significantly different average sound speed. First, the reflective packages commonly have similar dimensions and occur at the same levels in the water column as the sound speed variations in Figure 6. Secondly, the lens-shaped reflective features resemble eddies recognized on a coincident seismic and oceanographic dataset in the Gulf of Cadiz (Biescas *et al.* 2008). Following this interpretation, the Rockall lenticular features might consist of a core of relatively warm, salty Mediterranean Outflow Water, probably mixed to some degree with Labrador Sea Water (New & Smythe-Wright 2001), and surrounded by fresher, cooler water. These variations in temperature and salinity are expected to be associated with sound speed variations. Furthermore, the sharp edges of some of the reflective packages imply that significant sound speed variations can occur over horizontal distances of a kilometre.

Temporal variation

Sea water is in constant motion, and all seismic reflection surveys contain information on how the water layer changes through time. Individual shots records effectively provide snapshots of oceanic reflectivity structure because the distances that water can move over the few seconds of the record are too small to be resolved by industry seismic data. Common Mid Point gathers typically contain traces collected over more than 15 min and it appears possible to detect movement in the reflectivity structure over such periods (Jones *et al.* 2008). Seismic sail lines take many hours or even a few days to acquire, during which time significant amounts of water motion can occur. In this section we provide a few examples of evidence for hourly to monthly variability in reflectivity structure that can be obtained from the typical 2D speculative survey ISROCK, acquired over the western margin of Porcupine Bank, adjacent to Rockall Trough, in 1996 (Fig. 8).

Short-term (hourly) variability. Changes in the water layer over a few hours to a day can be demonstrated by comparing overlapping line segments. There are 22 overlapping sections in the ISROCK survey and four are shown in Figure 4. In each case acquisition was suspended following an air-gun fault, repairs were made (always well within a day), and the line was resumed with an overlapping segment in order to build up a full fold of coverage. Figure 4a shows an overlapping pair that image the package of highly reflective water in Figure 2a. Although, the bottom of the reflective package remained at roughly the same

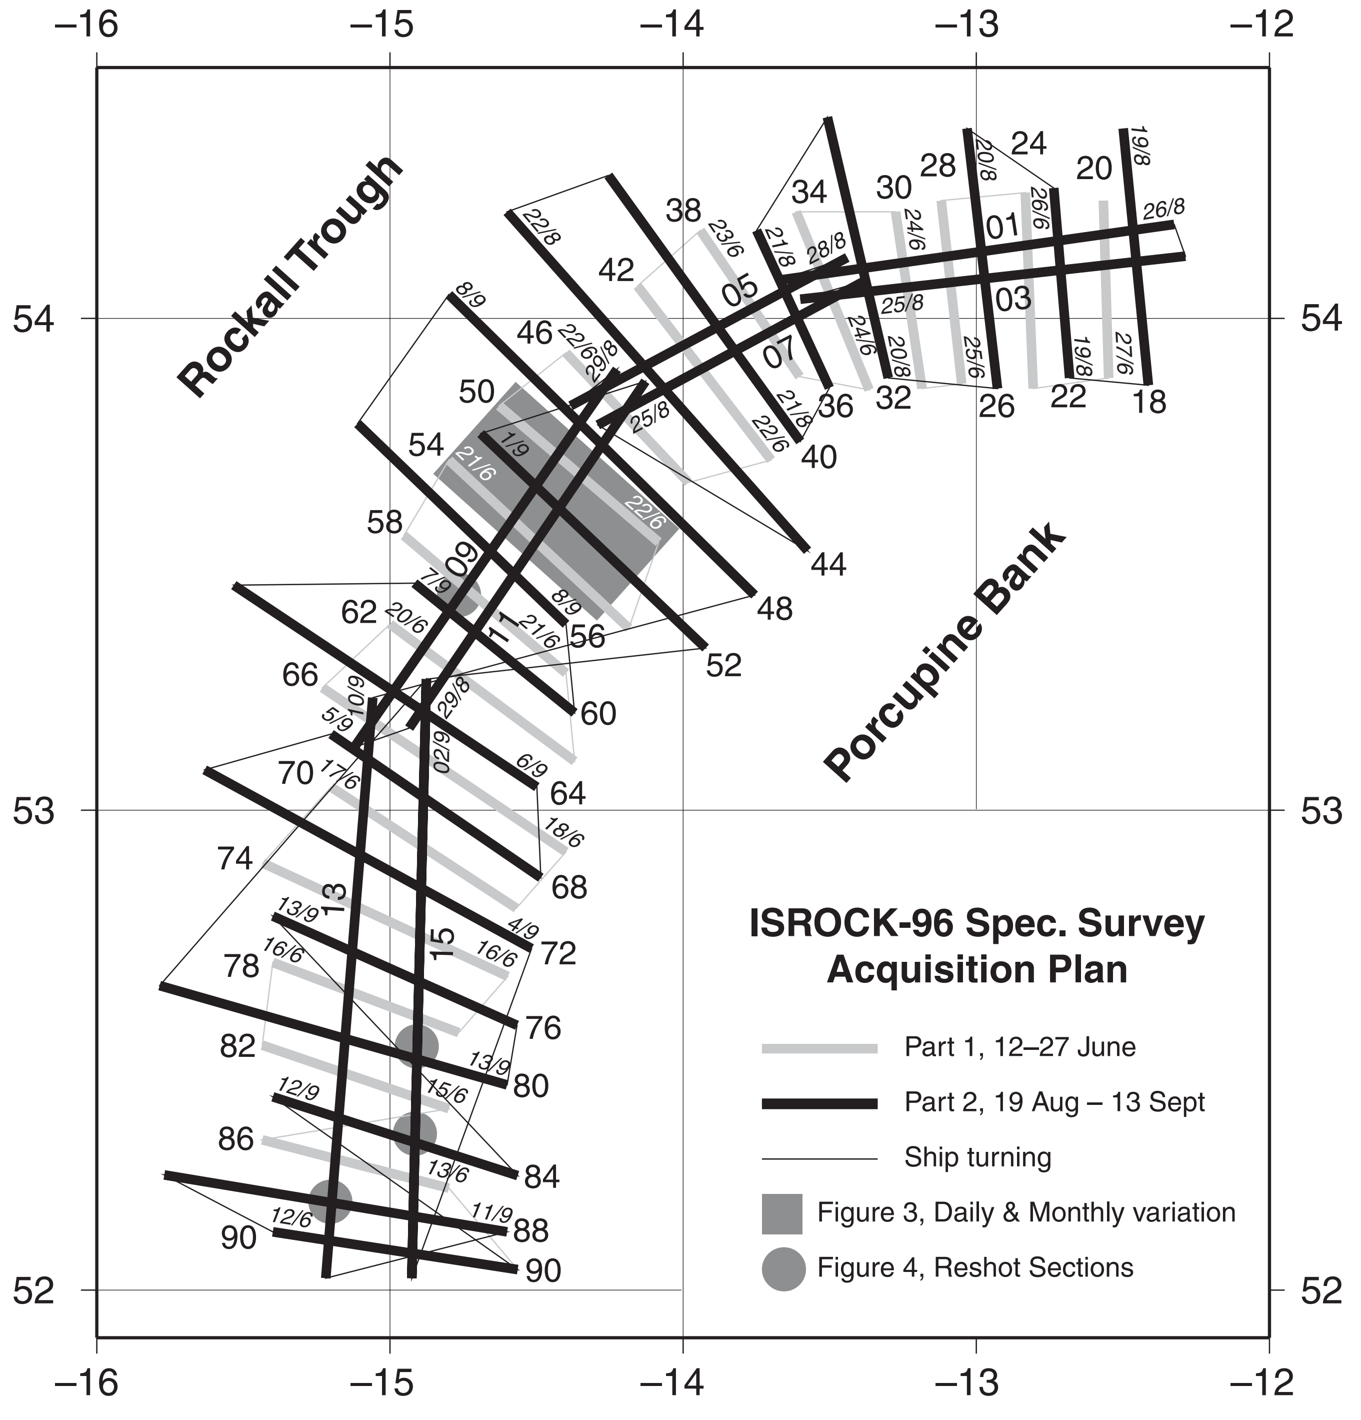

Fig. 8. Acquisition plan for the ISROCK-96 seismic survey. Roman numbers next to each line are line numbers and italicized numbers show day and month of acquisition.

depth, the internal reflectivity structure near the base of the package changed somewhat and the internal structure near the top of the package altered significantly over a period of just over 5 h. Figure 4c shows two pairs of overlapping sections: in the first (15b/c) the water changes from moderately reflective to almost transparent over a period of 17.5 h; in the second (15c/d) a single prominent reflection is visible in the middle of the water column for more than 3 h.

These examples clearly show that the reflectivity structure of the water column overlying a particular point on the seabed can either remain similar or change radically over a period of a few hours. From the industrial point of view, it would be useful to know the changes in average sound speed that accompany these changes in reflectivity structure. The arguments in the previous sections suggest that changes in the order of several metres per second might occur. This question might be answered in future by careful velocity analysis of the water layer. From the point of view of oceanographic research, this observation method gives the rate of change of reflectivity in a reference frame fixed to the seabed; that is, the Eulerian derivative of the reflectivity structure. It would be interesting to separate the effects of fluid motion over the observation point and change within a particular parcel of water; that is, to measure both components of the Lagrangian derivative. This question cannot be easily answered using overlapping sections of 2D seismic data, although it could be addressed in future using 3D data.

Longer term (daily to monthly) variability. ISROCK consists of 45 lines, with 68 ties between two lines and six ties between three lines. The line ties range in time gap from several days to several months (Fig. 8). This survey was shot in two halves, with a set of lines at about 20 km spacing shot in late June (coloured grey in Fig. 8) and an interleaving set shot in late August to early September (coloured black). Figure 3 exploits this acquisition pattern to illustrate water layer variability. Lines 50 and 54 (shot 1 day and 20 km apart) both show a reflective package at moderate depth that impinges on the continental slope and relatively transparent shallow water. Lines 52 and 56 show the same area more than 2 months later, when reflectivity at shallower levels is observed. There are distinct changes in water structure over months to years, and these are the variations that cause difficulty in 4D seismic surveying.

Implications for seismic surveying

When planning a seismic survey in deep water, we have shown above that freely available legacy oceanographic data can be used to assess the likely extent of oceanic variability. Legacy seismic data can also be used to estimate how rapidly and by how much the water layer sound speed is likely to vary at a given location. Significant variability in water layer sound speed is to be expected in areas where water masses that differ in temperature and salinity come into contact and also near to steep seabed topography (Egbert & Ray 2001; Biescas *et al.* 2008).

When processing 2D, 3D and 4D seismic surveys of regions of high oceanic variability, such as Rockall Trough, it may be necessary to employ techniques that can solve for and then remove the effect of significant fluctuations in water layer sound speed over time periods as short as a few hours and distances as short as a kilometre. The current industry standard solution is known as 'cold-water statics' (Wombell 1997; Xu & Pham 2003). This approach corrects for variation in the average sound speed in the water layer using a layer replacement method borrowed from land-based seismic processing. However, the standard implementations do not account for the sort of rapid lateral and temporal variability in water layer sound speed observed in Rockall Trough. Processing schemes that account for strong spatial and temporal water layer variations do exist; for example, Mackay *et al.* (2003) discussed the possibility of measuring seismic water layer sound speeds directly using semblance analysis and inversion of direct arrivals.

During seismic acquisition, it may be helpful to measure oceanic sound speed directly using CTD or sound speed probes if legacy seismic and oceanographic data indicate that strong variability might occur. Expendable probes are designed to be deployed from an underway vessel and need not interfere with seismic acquisition, especially if deployed from a chase boat. Two useful types are the expendable sound speed probe (XSP) and the expendable conductivity–temperature–depth (XCTD) probe. Portable, re-usable probes are available that can be deployed from a chase boat using nothing more than a small winch and a suitable length of line. We have successfully operated both expendable and re-usable oceanic probes to augment industrial and academic 2D and 3D seismic surveys. It is neither practical nor necessary to make closely spaced probe casts and produce sound speed sections comparable to those in Figure 6. Instead the aim should be to analyse probe data collected across the entire footprint and time-span of the survey, as in Figure 7, to ascertain whether the survey was affected by significant water layer sound speed variation. This analysis should be completed by the end of seismic acquisition and used to decide whether to invest in processing steps that can account for strong spatial and temporal water layer sound speed variations.

Implications for oceanography

Seismic reflection surveying provides a remote sensing tool that can rapidly image large volumes of the oceanic interior at a lateral resolution of tens of metres. For comparison, the spacing between the traditional oceanographic probe casts used to build the sound speed cross-sections in Figure 7 ranges from a few kilometres to tens of kilometres. Seismic reflection data is therefore providing new opportunities to investigate the detailed structure of oceanic features, such as fronts between water masses and eddies, and to observe how these features evolve and how they interact with seabed topography. The seismic data presented here show strong spatial and temporal variability. Whilst this variability represents a risk to the hydrocarbon industry, it represents an opportunity to oceanographers. The variations in sound speed that generate seismic reflectivity arise from mixing between water masses of distinctive physical properties, so that measurements of the variability can potentially constrain oceanic mixing rates. An accurate description of oceanic mixing is an integral part of ocean circulation models, which are an in turn part of global climate models. We therefore recommend that the hydrocarbon industry makes the water layer part of seismic reflection data available for academic research.

Conclusions

(1) Natural variation in sound speed occurs within the water layer of some deepwater oceanic regions such as Rockall Trough, offshore west of Ireland. This variation is likely to degrade sub-seabed reflection images. Degrading effects include vertical offset of reflections between adjacent sail lines and line intersections, and difficulties in suppressing multiples from water layer reverberations.

(2) Risk assessment for water layer sound speed variation is an essential part of planning 2D, 3D and 4D seismic surveying in deep water. An initial assessment of water layer risk can be made from legacy oceanographic probe data. Legacy seismic data can be used to refine the risk assessment by showing how rapidly and by how much the water layer sound speed is likely to vary at a given location.

(3) In areas of vigorous oceanic mixing, such as offshore west of the UK and Ireland, expect strong water layer variability along individual sail lines. In Rockall Trough, the mean water layer sound speed mostly varies between 1490 and 1500 m s^{-1}, and vertical offsets of up to about 15 ms travel time at line intersections are predicted.

(4) Currently standard processing techniques for removing the effect of water layer variability are not designed to cope with the variability observed in Rockall Trough. Instead, it is necessary to employ techniques that can solve for and then remove the effect of fluctuations in water layer sound speed over time periods as short as a few hours and distances as short as a kilometre.

We are grateful to the Irish Petroleum Affairs Division (in particular to Peter Croker) and to Spectrum Geo Ltd for providing the seismic data illustrated here. We also acknowledge the support of the Irish Marine Institute, both by providing access to oceanographic datasets and by granting use of the R/V *Celtic Explorer* to SMJ under the SSTI (Strategy for Science, Technology and Innovation) Ship-Time Programme 2007, funded under the Irish Government's National Development Plan (Marine Research Sub-Programme). We thank the Irish Petroleum Infrastructure Project for supporting the seismic processing facility at Trinity College Dublin. Other supporters of our oceanography work are Providence Resources, Statoil Ireland, ExxonMobil and BG Group. C. Sutton is supported by a studentship from Trinity College Dublin. All seismic processing was performed using the Seismic Unix system. We thank Richard Hobbs, John Smallwood and an anonymous reviewer for their comments on the original version of this manuscript.

Abstract: The Geological Survey of Norway (NGU) has produced new aeromagnetic and gravity maps from Norway and adjacent areas, compiled from ground, airborne and satellite data. Petrophysical measurements on core samples, hand specimens and on *in situ* bedrock exposures are essential for the interpretation of these maps. Onshore, the most prominent gravity and magnetic anomalies are attributed to lower crustal rocks that have been brought closer to the surface. The asymmetry of the gravity anomalies along the Lapland Granulite Belt and Kongsberg–Bamble Complex, combined with the steep gradient, points to the overthrusted high-density granulites as being the main source of the observed anomalies. The Kongsberg–Bamble anomaly can be traced southwards through the Kattegat to southern Sweden. This concept of gravity field modelling can also be applied to the Mid-Norwegian continental shelf and could partially explain the observed high-density rocks occurring below the Møre and Vøring basins and in the Lofoten area. Extrapolations of Late-Caledonian detachment structures occurring on the mainland can be traced on aeromagnetic and gravimetric images towards the NW across the continental margin. Subcropping Late Palaeozoic to Cenozoic sedimentary units along the mid-Norwegian coast produce a conspicuous magnetic anomaly pattern. The asymmetry of the low-amplitude anomalies, with a steep gradient and a negative anomaly to the east and a gentler gradient to the west, relates the anomalies to gently westward dipping strata. Recent aeromagnetic surveys in the Barents Sea have revealed negative magnetic anomalies associated with shallow salt diapirs. Buried Quaternary channels partly filled with gravel and boulders of crystalline rocks generate magnetic anomalies in the North Sea. The new maps also show that the opening of the Norwegian–Greenland Sea occurred along stable continental margins without offsets across minor fracture zones, or involving jumps in the spreading axis. A triple junction formed at 48 Ma between the Lofoten and Norway Basins.

Keywords: aeromagnetic data, gravity data, petrophysical data, Norway, North Sea, Norwegian Sea, Barents Sea

The Geological Survey of Norway (NGU) has acquired aeromagnetic and gravity data over the last 50 and 40 years, respectively, and has recently decided to release new aeromagnetic and gravity maps of Norway and adjacent areas. In addition to managing the datasets, we actively utilize the data to improve our understanding of the structure and evolution of the Norwegian mainland and adjacent continental margin and oceanic domains.

NGU has national responsibility for operating and maintaining the potential field databases in Norway. The survey acquired aeromagnetic data from the Norwegian mainland and continental shelf during the period 1959–1976. A second programme of high-resolution aeromagnetic mapping was initiated in offshore areas in 1993.

Gravity data have been systematically measured on mainland Norway by NGU over the last 40 years. In conjunction with marine data, which are often obtained in connection with seismic data acquisition, the gravity coverage is extensive enough to study both local and regional features.

Over the last 30 years, NGU has also carried out a petrophysical sampling programme on hand specimens from the Norwegian mainland, as well as on offshore drillcores. The petrophysical data on hand specimens can be utilized to estimate the magnetic properties of basement rocks in the offshore areas.

The new aeromagnetic and gravity maps contain many features ascribed to major tectonic elements, and portray their regional distribution. Aeromagnetic data reflect rock distributions at any depths from the surface to depths where the magnetic rocks reach the Curie temperature. The first-generation, offshore gravity and magnetic datasets were used mainly for interpretation of basement topography and detection of intra-sedimentary volcanic units and intrusions. The high quality of the data acquired in recent years provides the possibility of mapping high-frequency anomalies caused by sources located within the sedimentary successions. The improved quality is due to the use of (1) state-of-the-art instrumentation, (2) real-time, differential GPS navigation equipment, (3) a denser line spacing and (4) advanced micro-levelling software. Magnetic data are also utilized to reduce the well-bore positional uncertainty in offshore wells (Russell *et al.* 1995).

This review paper summarizes the results of recent studies carried out by NGU and collaborators and is intended to illustrate various scientific and petroleum implications of our recent high-quality aeromagnetic and gravity surveys.

Datasets

Bathymetric and topographic data

A combined bathymetry–topography compilation is particularly useful for (1) terrain corrections of the mainland gravity data, (2) Bouguer corrections of the offshore data and (3) Airy isostatic

VINING, B. A. & PICKERING, S. C. (eds) *Petroleum Geology: From Mature Basins to New Frontiers – Proceedings of the 7th Petroleum Geology Conference*, 559–586. DOI: 10.1144/0070559

correction of the final Bouguer grid. Bathymetric data includes (1) modern multi-beam echo sounder data, (2) digitized naval maps in areas adjacent to the coast and (3) depth data collected during seismic surveys. Dataset 1 has the highest quality whilst dataset 3 is the poorest. Norwegian Hydrographic Service supplied data in shallow Norwegian waters. A revised version of the International Bathymetric Chart of the Arctic Ocean, IBCAO v. 2.23 (Jakobsson *et al.* 2008), was included for the remaining area of the Norwegian–Greenland Sea and the eastern Barents Sea. This DEM is available in polar stereographic projection, with 2 km cell size. We further inserted data from the arc-minute grid of the General Bathymetric Chart of the Oceans (GEBCO) in the North Sea area (http://www.gebco.net/data_and_products/gridded_bathymetry_data/).

High-resolution topography grids for mainland Norway (100×100 m) and Svalbard (1×1 km) were supplied by the Norwegian Mapping Authority. Topography for Fennoscandia, Iceland, Faroe Islands, Scotland and eastern Greenland was downloaded from the GTOPO30 dataset (http://edcwww.cr.usgs.gov/landdaac/gtopo30/gtopo30.html). The final grid shown in Figure 1 was displayed using the shaded-relief technique with illumination from the NE. The cell size of the combined grid is 250×250 m.

Aeromagnetic data

As noted above, the whole of Norway (including the largest continental shelf in western Europe) was covered with aeromagnetic surveys from 1959 to 1975. In 1957, NGU acquired the first fluxgate magnetometer from the US Geological Survey in exchange for an electromagnetic Turam system. The first onshore survey was flown in 1959 in the Løkken and Kautokeino regions, and the first offshore survey was completed in 1962 in the Skagerrak region.

Aeromagnetic data collected on the Norwegian mainland prior to 1976 are provided in the form of a matrix digitized from manually drawn contour maps (Norges geologiske undersøkelse 1992; Smethurst *et al.* 1994). Flight altitudes and directions, and line-spacings of the aeromagnetic surveys, varied widely. The areas of low flight altitude of mainland Norway (150–300 m) were covered between 1959 and 1968 using a stinger-mounted fluxgate magnetometer. From 1969 to 1976, a stinger-mounted proton magnetometer was used, covering western Norway and most of northern Norway with measurements made at flight altitudes ranging from 800 to 1500 m a.s.l. (Table 1). The cell size of the grid is 500×500 m. The magnetic total field is reduced to anomaly values using the Definite Geomagnetic Reference Field 1965.0 (DGRF 1965.0). NGU and Amarok (now TGS-NOPEC Geophysical Company) launched a programme for remapping the Norwegian continental shelf in 1993, applying a line spacing of 2 km.

Both vintage and new surveys were levelled applying the standard Geosoft (2006) statistical method to the tie-lines, followed by a statistical levelling of the profiles utilizing the levelled tie-lines. The IGRF field was calculated and subtracted from the levelled survey lines to produce the magnetic anomalies of the survey areas. We applied the more sophisticated, moving median filtering method (Mauring & Kihle 2006) in areas where levelling errors still existed subsequent to the standard statistical levelling. This was often the case for the vintage surveys where the number of tie-lines was inadequate for a thorough levelling (Fig. 2a). The median method can also be applied to profiles with varying orientation, such as the 1970–1975 surveys that were acquired along parabolic Decca lanes. The median method was also successfully applied in areas with subtle low-frequency anomalies in reflown areas on the shallow continental shelf. The moving median levelling technique showed its advantages, and errors down to less than one nanoTesla (nT) have been removed. Specifications for the different subareas are given in Table 1. The individual datasets have been interpolated to square grids of 500×500 m using the minimum curvature method (Briggs 1974; Geosoft 2005). The grids were trimmed to a *c.* 10 km overlap and merged using a minimum curvature algorithm, GridKnit, developed by Geosoft (2008).

The coverage has been extended into the oceanic domain outside the continental margin with the line/tie-line spacing of 5/20 km. A total of 240 000 km was acquired by NGU covering an area of *c.* 500 000 km^2. NGU and TGS have both acquired their surveys with cesium vapour magnetometers installed in a towed bird located 70 m below the aeroplane and in a tail stinger, respectively. During the last 15 years, the two systems have been flown with Piper PA-31 aeroplanes. They were tested in a joint flight in 1996 and the performances of the two systems were almost identical. The noise envelope of the magnetometers is usually less than 0.2 nT and most of the data are within limits of ± 0.04 nT. Real-time differential GPS navigation with a minimum of four satellites was used throughout the surveys, resulting in a navigation accuracy better than ± 3 m.

The final aeromagnetic map (Fig. 3) also includes aeromagnetic data from Great Britain and mainland Greenland from the 5×5 km GAMMAA5 grid (Verhoef *et al.* 1996). This grid was regridded to 500×500 m cells before being merged into the final compilation.

The southwestern part of the Barents Sea was remapped in 1997–2009. The more recent NGU datasets (SNAS-06, BAS-06, BASAR-08, BARSAR-09; Løvaas *et al.* 2006; Gernigon *et al.* 2007; Brönner *et al.* 2009) are not included in the present compilation since they are not yet released. The resolution of these modern aeromagnetic data is 0.1–0.2 nT.

Long-wavelength magnetic anomalies are not reliably represented in regional aeromagnetic compilations. We have therefore applied a high-pass filter on the compiled grid using a 330 km Gaussian filter, and added the spherical harmonic degrees ≤ 120 (i.e. ≥ 330 km wavelength) of the CHAMP satellite magnetic anomaly model MF6 (Maus *et al.* 2008). The removed 330 km low-pass filtered component of the aeromagnetic compilation is shown in Figure 2c, while Figure 2d shows the substituted 330 km low-pass version of the MF6 model. The final corrected map is presented in Figure 3.

Gravity data

The gravity compilation represents an update of the 1:3 million scale gravity map published by Skilbrei *et al.* (2000). We have added substantially more data on the Mid-Norwegian continental shelf and on the mainland of southern Norway. We have also carried out a more detailed terrain correction and removed the bathymetric effects of the fjords in the mainland gravity data. The terrain correction of the up to 1400 m-deep fjords amounts to 15×10^{-5} m s^{-2} (mGal). The marine gravity database consists of 554 000 km of ship profiles collected by the Norwegian Petroleum Directorate (NPD), TGS-NOPEC Geophysical Company (TGS), the Norwegian Mapping Authority (SK) and various commercial companies. We have included *c.* 68 000 land gravity stations measured by NGU, SK and several Norwegian and foreign universities from mainland Norway and *c.* 1000 stations measured by SK on Svalbard. The mainland data are stored in the national gravity database at NGU (Gellein *et al.* 1993). Bouguer gravity data from mainland Greenland (Strykowski & Forsberg 1998), Iceland (Thorbergsson *et al.* 1990) and Scotland (British Geological Survey 1997) are also included in the compilation.

The profile data offshore Norway have been levelled using the median levelling technique (Mauring & Kihle 2006). The compiled free-air dataset has been interpolated to a square grid of 2×2 km

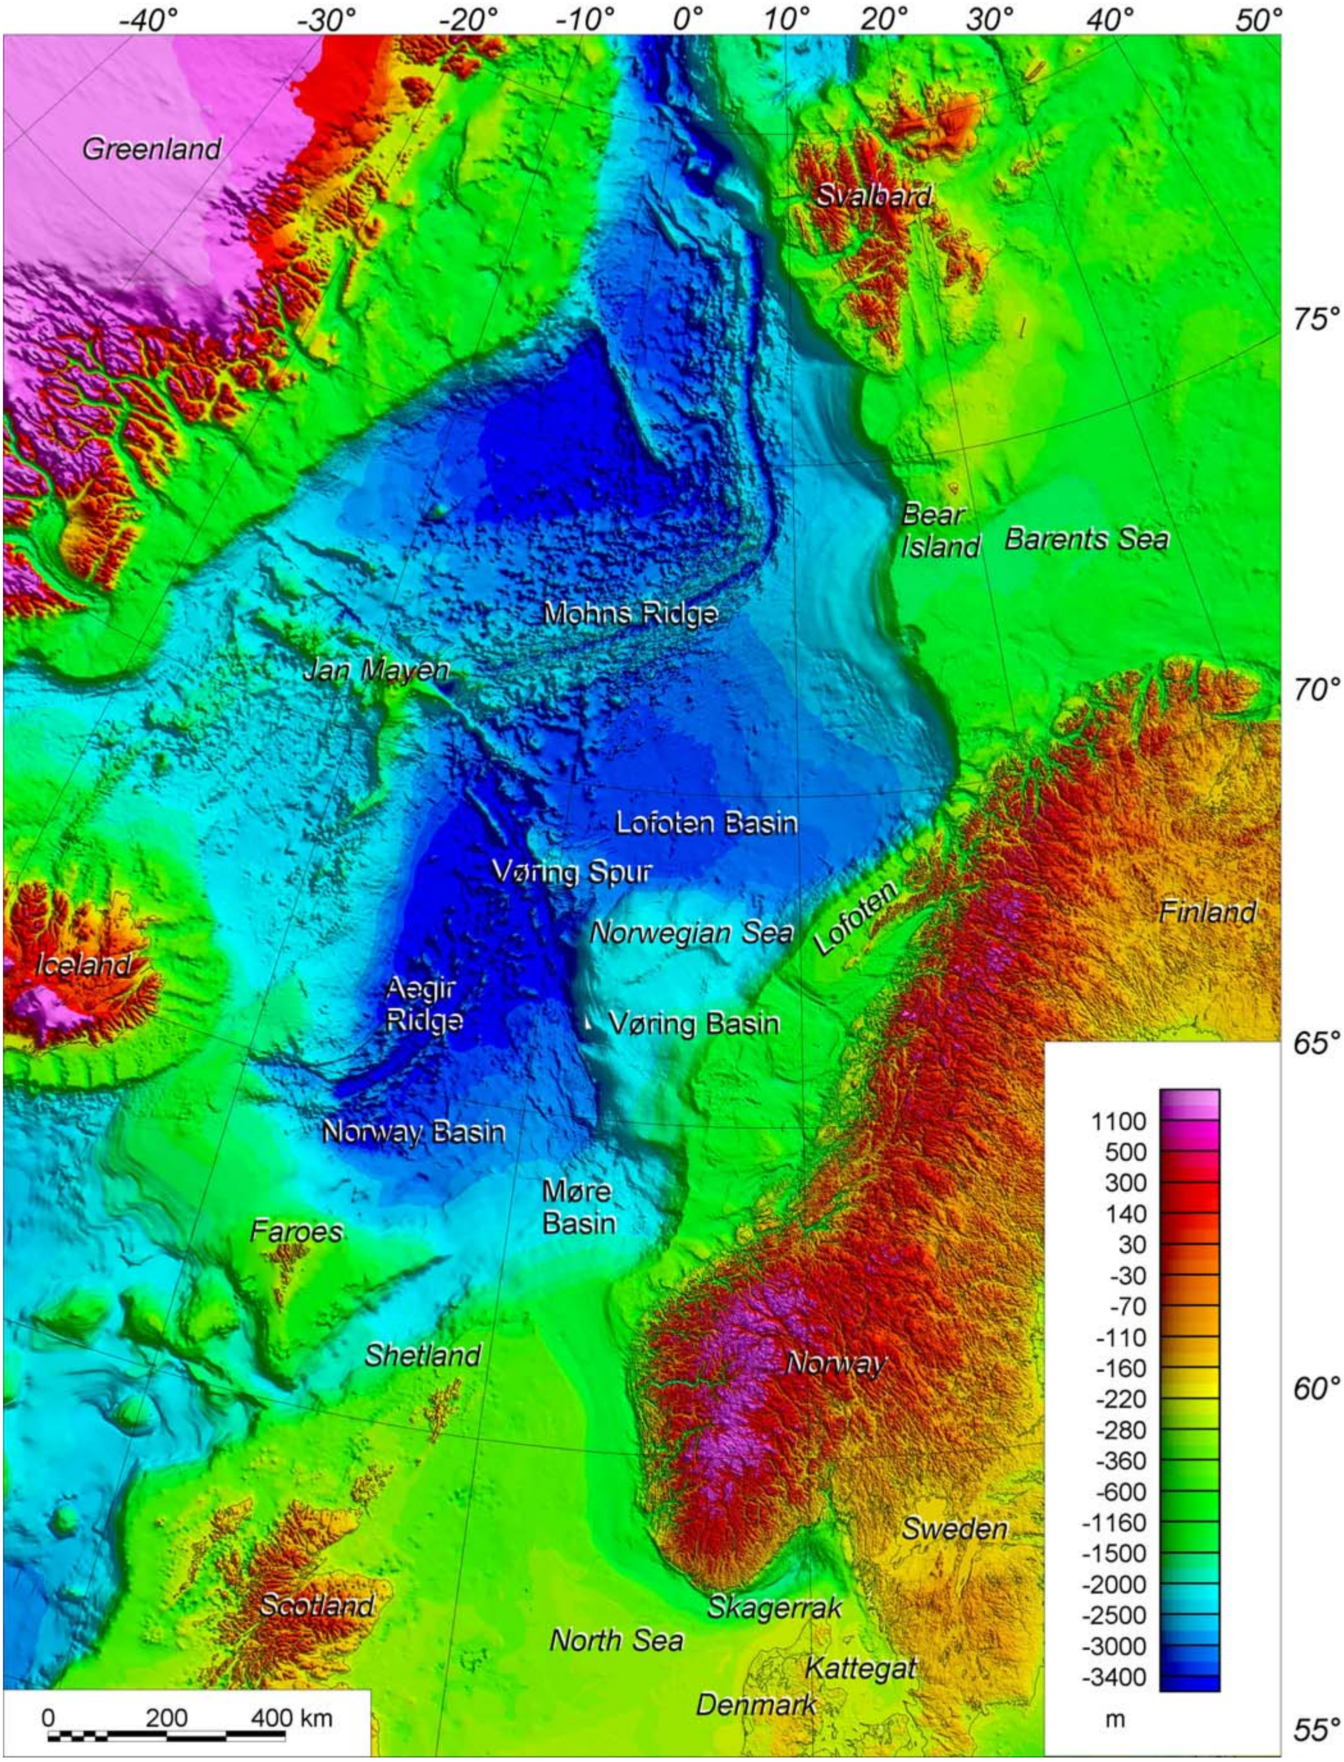

Fig. 1. Bathymetry and topography map of the NE Atlantic. The 250 × 250 m grid represents an updated version of the Dehls *et al.* (2000) compilation using new releases of bathymetric data from the Arctic Ocean, IBCAO v. 2.23 (Jakobsson *et al.* 2008) and the world oceans (GEBCO). High-resolution topography data (100 × 100 m) for Norway and the adjacent land areas were supplied by the Norwegian Mapping Authority and the US Geological Survey, respectively.

Table 1. Offshore aeromagnetic surveys compiled for the present study (Figs 2, 3 & 6a)

Year	Area	Operator, reference	Survey name	Sensor elevation (m)	Line spacing (km)	Length (km)

The individual datasets are stored in NGUs Dragon database (DiRect Access to Geophysics On the Net, Smethurst & Lauritsen 2003).

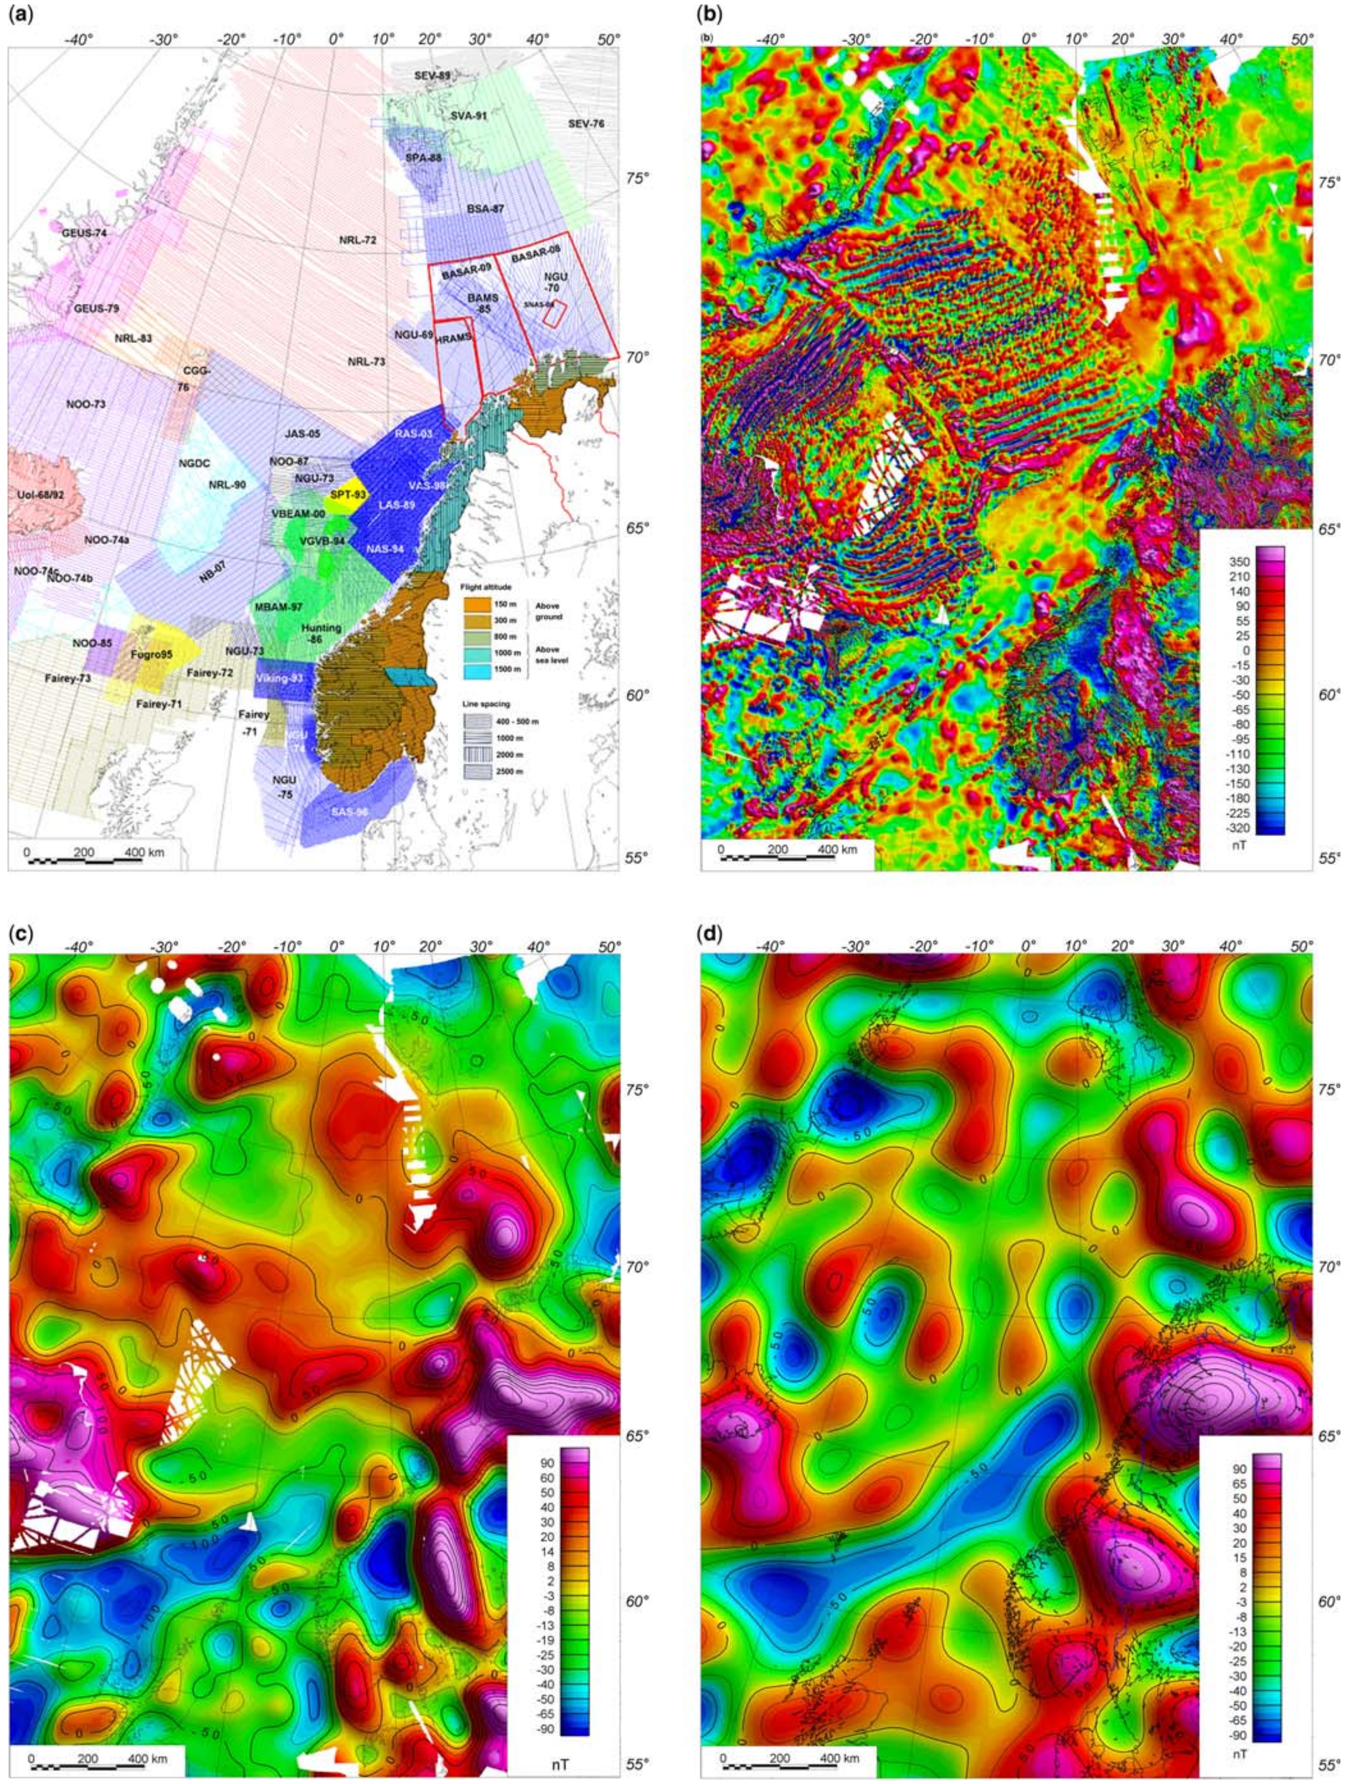

Fig. 2. (**a**) Compilation of magnetic surveys in the NE Atlantic area. The subgrids from the 40 aeromagnetic surveys and two marine magnetic datasets listed in Table 1 are produced from original profile data and added to the mainland Norway compilation. The red frames in the Barents Sea show three high-resolution surveys that are not included in the compilation for confidentiality reasons. (**b**) Grid compilation of the surveys. The total magnetic field is referred to the IGRF. We have filled in data from Scotland and East Greenland from the North Atlantic aeromagnetic compilation by Verhoef *et al.* (1996) and in Denmark, Sweden and Finland from the Fennoscandia aeromagnetic compilation by Korhonen *et al.* (2002*a*). (**c**) A 330 km long-wavelength component has been removed from the magnetic dataset and replaced by (**d**) the 330 km long-wavelength component of the MF6 magnetic model by Maus *et al.* (2008) based on the CHAMP satellite data. The final magnetic grid is shown in Figure 3.

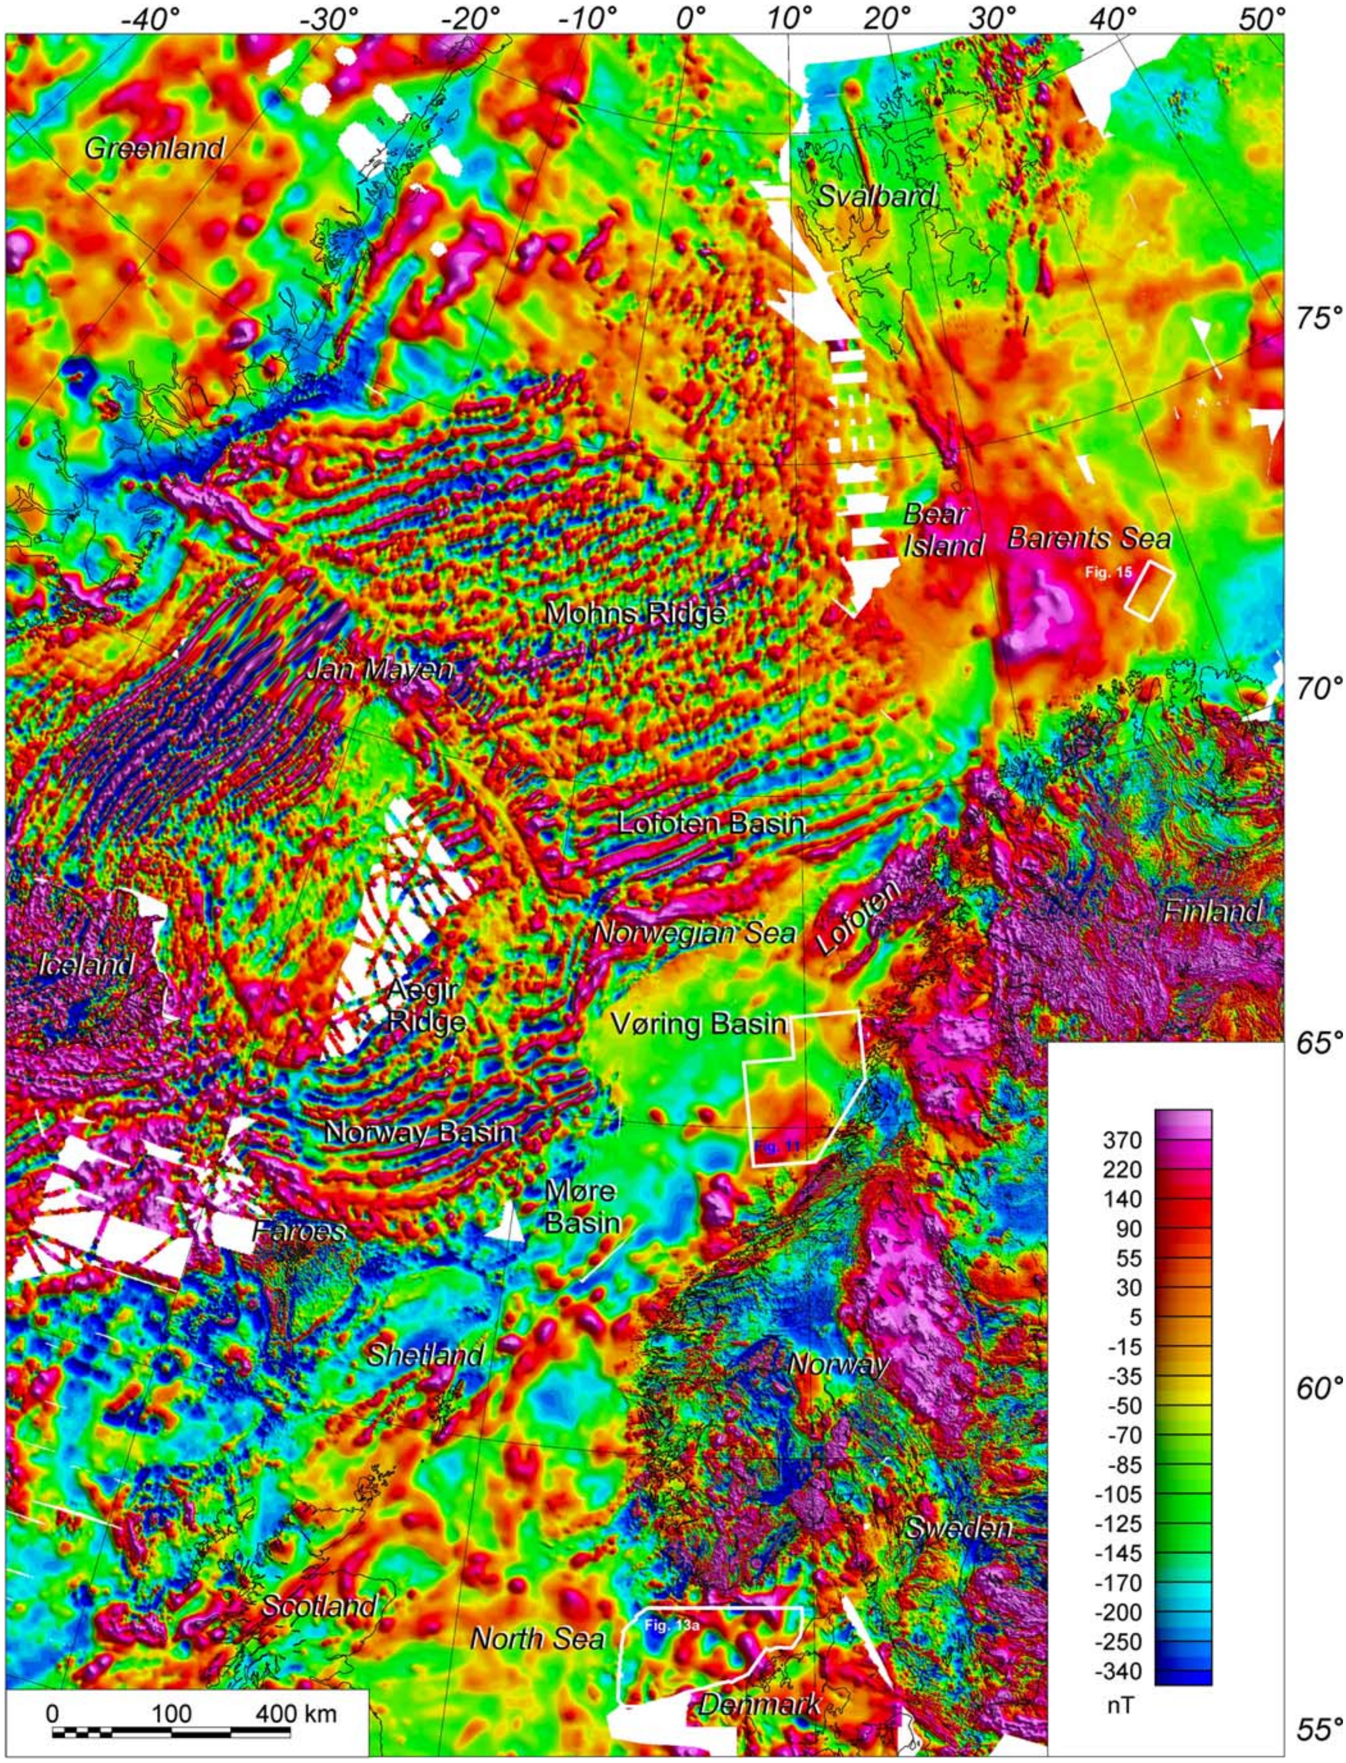

Fig. 3. Magnetic compilation of the NE Atlantic. Total magnetic field referred to IGRF. The map is displayed using the shaded-relief technique with illumination from the SE. The long-wavelength component ($\geq$330 km) of the grid was replaced with the spherical harmonic degrees $\leq$120 (i.e. $\geq$330 km wavelength) of the CHAMP satellite magnetic anomaly model MF6 (Maus *et al.* 2008). The white frames in the Norwegian Sea and the North Sea show the location maps of the analytic signal of the total magnetic field shown in Figures 11 & 13a, respectively. The white frame in the Barents Sea shows the outline of the southern Nordkapp Basin Aeromagnetic Survey 2006 (SNAS-06) where the salt diapir in Figure 15 is located. A 1 : 3 million scale version of the map can be downloaded from http://www.ngu.no/upload/Kart%20og%20data/Geofysikkart%20stort%20format/Mag_3_mill.pdf.

using the minimum curvature method (Briggs 1974; Geosoft 2005). The simple Bouguer correction at sea (Mathisen 1976) was carried out using a density of 2200 kg m^{-3}. The International Standardization Net 1971 (IGSN 71) and the Gravity Formula 1980 for normal gravity have been used to level the surveys. The compiled dataset was merged with the gravity data from the 2.5×2.5 km Fennoscandian grid to the east and south (Denmark, Finland and Sweden; Korhonen *et al.* 2002*b*), and the DNSC08 satellite altimetry gravity data from the National Space Institute, Technical University of Denmark, in the deepwater areas of the Norwegian Sea and the eastern Barents Sea (Andersen *et al.* 2008). The Fennoscandian grid had to be shifted by a constant of -16.3×10^{-5} m s^{-2} to make it fit to our IGSN 71 data. Figure 4a shows the locations of the individual datasets. Figure 4b shows the free-air gravity field at sea and Bouguer gravity on the mainland while Figure 4c displays the Bouguer gravity on the mainland as well as in the offshore areas.

The Airy–Heiskanen 'root' (Heiskanen & Moritz 1967) was calculated from a smoothed version of the compiled topographic and bathymetric dataset in Figure 1. The gravitational attraction (Fig. 4d) from the 'root' was calculated using the AIRYROOT algorithm (Simpson *et al.* 1983). The isostatic residual (Fig. 5) was achieved by subtracting the gravity response of the Airy–Heiskanen 'root' from the calculated Bouguer gravity data in Figure 4c. The Airy isostatic residual map enhances crustal anomalies better than traditional free-air and Bouguer gravity maps.

Petrophysical data

Some of the pronounced magnetic and gravity anomalies present along the coast of Norway are continuous from the mainland onto the continental shelf. Consequently, it is important to know the magnetic properties of the rocks on land when assessing the 3D structure of the basement. NGU has therefore carried out petrophysical sampling programmes (including susceptibility and remanence measurements) to assist the bedrock mapping and mineral exploration programmes on mainland Norway (Åm & Oftedahl 1977; Sindre 1977; Olesen *et al.* 1990, 1991, 1997*b*, 2002; Skilbrei *et al.* 1991; McEnroe *et al.* 2001). In addition, density measurements have been carried out on bedrock samples in conjunction with gravity campaigns (Svela 1971; Chroston 1974; Lønne & Sellevoll 1975; Ramberg 1976).

Approximately 28 000 rock samples (Fig. 6), collected during geological mapping and geophysical studies, have been measured with respect to density, susceptibility and remanence (Torsvik & Olesen 1988). The data are stored in NGUs petrophysical database (Olesen *et al.* 1993).

We have produced maps of susceptibility and density by calculating the average values within each geological unit represented on the Norwegian part of the northern Europe bedrock map (Sigmond 2002) (Fig. 7). Non-representative samples (e.g. sulphide mineralizations, hydrothermal alterations, mylonites, diabase and eclogite) were removed from the dataset before map production. The applied colour scale for the susceptibility map is logarithmic in order to depict the several magnitude-wide distributions within each rock unit.
